
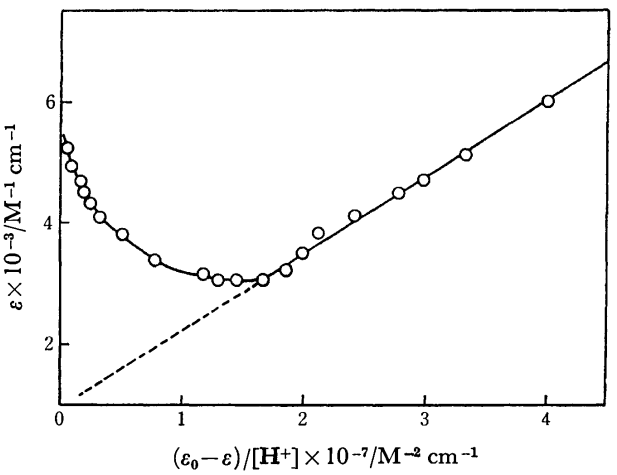

Fig. 3. Relationship between ε and $(\varepsilon_0-\varepsilon)/[H^+]$ at $[Co(II)salen]_0=5.50\times10^{-4}$ M, 360 nm, and $\mu=0.25$ M.

Therefore, a plot of ε against $(\varepsilon_0-\varepsilon)/[H^+]$ gives a straight line at sufficiently low hydrogen ion concentration as shown in Fig. 3, from whose slope and intercept, K_1 and ε_1 are obtained. At higher hydrogen ion concentration, however, the plot deviates from the linearity, caused by occurrence of the considerable amount of diprotonated species. At this range of hydrogen ion concentration, another linearity between ε and $\Delta\varepsilon(1+K_1[H^+])/K_1[H^+]^2$ must hold from the modification of Eq. (4), as follows:

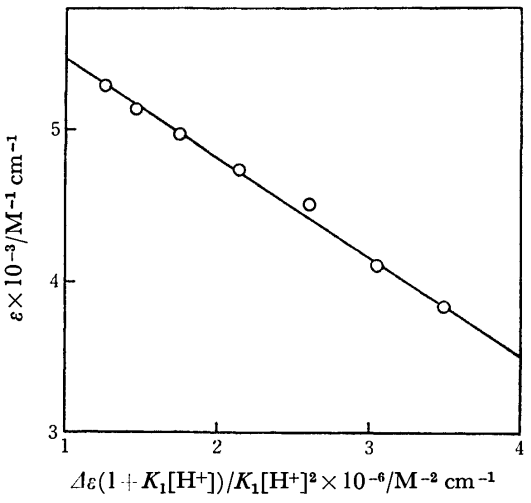

Fig. 4. Linear relationship between ε and $\Delta\varepsilon(1+K_1[H^+])/K_1[H^+]^2$ at $[Co(II)salen]_0=5.50\times10^{-4}$ M, 360 nm, and $\mu=0.25$ M.

$$\varepsilon = \varepsilon_2 - \frac{1}{K_2}\frac{\Delta\varepsilon(1+K_1[H^+])}{K_1[H^+]^2} \tag{7}$$

where $\Delta\varepsilon$ stands for the increment of ε caused by the occurrence of Co(II)salenH_2^{2+}. The linearity of Eq. (7) is shown in Fig. 4, from whose slope and intercept, K_2 and ε_2 are obtained. The values of K_1, K_2, ε_1, and ε_2 thus obtained are also listed in Table 1. The K_1 values from the two different methods agree with each other within experimental error.

Oxygen Uptake by Co(II)salen and Protonation of Oxygenated Complexes. The oxygen uptake by Co(II)-salen in the absence of acid in DMSO is very slow, the spectral change during the oxygenation being shown in Fig. 5. In the figure, it is seen that an absorption peak at 340 nm due to Co(II)salen gradually diminishes in the course of the oxygenation, while an alternative peak at 390 nm grows up due to the oxygenated species with an isosbestic point between the unoxygenated and oxygenated complexes at 325 nm. The mole ratio of

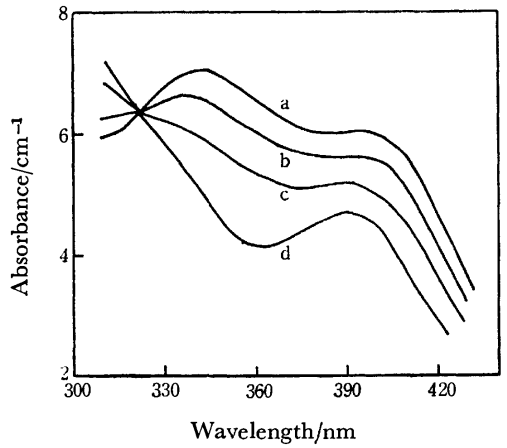

Fig. 5. Spectral change during the oxygenation of Co(II)salen at $[Co(II)salen]_0=8.20\times10^{-4}$ M in an atmospheric air at room temperature. Time after initiation of the reaction, (a) 11 min, (b) 87 min, (c) 300 min, (d) ∞

Table 2. Mole ratio n of O_2-uptake to the total Co-(II)salen under an atmospheric air at 25 °C

$[Co(II)salen]_0$ M	$[O_2$-uptake] M	n
5.16×10^{-3}	2.60×10^{-3}	0.50
1.00×10^{-2}	4.88×10^{-3}	0.48
1.28×10^{-2}	6.50×10^{-3}	0.51
1.42×10^{-2}	7.04×10^{-3}	0.50

oxygen uptake to the total Co(II)salen, n=[Absorbed O_2]/$[Co(II)salen]_0$ at infinite time is approximately 0.5 as listed in Table 2, which indicates the formation of a 2:1 complex as represented by $(Co(III)salen)_2O_2$ at room temperature. Thus, a chemical equilibrium is established as follows:

$$2Co(II)\ salen + O_2 \rightleftarrows (Co(III)\ salen)_2O_2 \tag{8}$$

$$K_3 = \frac{[(Co(III)\ salen)_2O_2]}{[Co(II)\ salen]^2[O_2]} \tag{9}$$

The equilibrium constant K_3 must be immeasurably large under the present condition, so large that the reaction could be regarded to be irreversible.[7,8]

When perchloric acid was added to binuclear oxygenated complex, a slight spectral change but no release of oxygen was observed. Therefore, it is deduced that the protonation of $(Co(III)salen)_2O_2$ must have occurred and quickly attained to an equilibrium.

$$(Co(III)\ salen)_2O_2 + H^+ \rightleftarrows (Co(III)\ salen)_2O_2H^+ \tag{10}$$

$$K_4 = \frac{[(Co(III)\ salen)_2O_2H^+]}{[(Co(III)\ salen)_2O_2][H^+]} \tag{11}$$

The equilibrium constant K_4 can be obtained by the method similar to the case of K_1 with ε_3, ε_4, and K_4 in place of ε_0, ε_1, and K_1 respectively and with ignoring the third term of the right-hand side in Eq. (4). The linearity of ε *vs.* $(\varepsilon_3-\varepsilon)/[H^+]$ is shown in Fig. 6 and the calculated data associated with the equilibrium 10 at 25 °C are as follows:

$$\left.\begin{aligned} K_4 &= 3.3\times10^5\ M^{-1} \\ \varepsilon_3 &= 1.11\times10^4\ M^{-1}\cdot cm^{-1} \\ \varepsilon_4 &= 9.80\times10^3\ M^{-1}\cdot cm^{-1} \end{aligned}\right\}\ \text{at 390 nm}$$

When Co(II)salen is oxygenated in the presence of perchloric acid, Reactions 1, 5, 8, and 10 might take

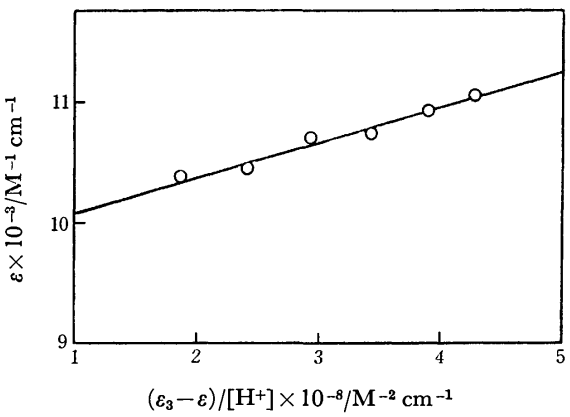

Fig. 6. Linear relationship between ε and $(\varepsilon_3-\varepsilon)/[H^+]$ at $[(Co(III)salen)_2O_2]_0=3.12\times10^{-4}$ M, 390 nm, and $\mu=0.25$ M.

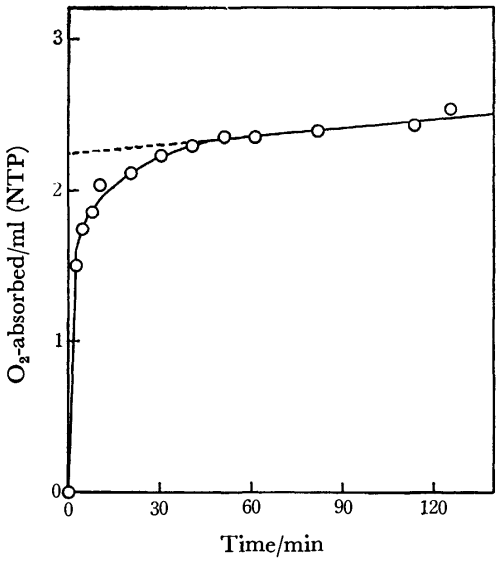

Fig. 7. Rate of oxygen uptake by Co(II)salen in the presence of perchloric acid under an atmospheric air at $[Co(II)salen]_0 = 1.00 \times 10^{-2}$ M, $[HClO_4]_0 = 2.19 \times 10^{-2}$ M, $\mu = 0.25$ M, and 25 °C.

place altogether, among which only Reaction 8 proceeds very slowly. The rate of oxygen uptake in the presence of acid is drawn in Fig. 7. The curve consists of two parts with a rapid uptake at earlier stage of the reaction, followed by a very slow uptake at later one. This means that the primary and the secondary protonation reactions of Co(II)salen (Reactions 1 and 5) quickly reach their equilibria without regard to the presence of oxygen and then, on the gradual progress of Reaction 8, the deprotonation reactions (backward reactions of 1 and 5) produce again Co(II)salen to be oxygenated. The protonated species themselves, Co(II)salenH$^+$ and Co(II)salenH_2^{2+}, are inert to oxygenation. The observed apparent oxygen uptake ratio n at earlier stage

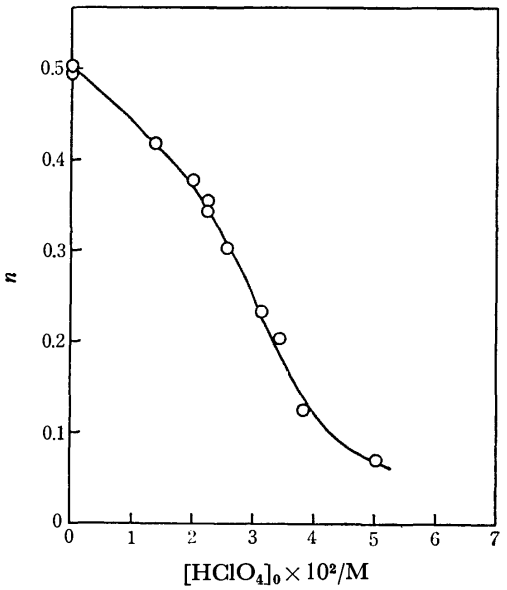

Fig. 8. Oxygen uptake ratio n, dependent upon acid concentration at $[Co(II)salen]_0 = 1.00 \times 10^{-2}$ M, $\mu = 0.25$ M, and 25 °C.

at various acid concentrations is represented in Fig. 8, in which n decreases with increasing acid concentration, being approximately expressed by a following equation, derived on the basis that the protonated species can not be oxygenated.

$$n = \frac{1}{2}\left(1 - \frac{K_1(1+K_2[H^+])[H^+][Co(II)\,salen]}{[Co(II)\,salen]_0}\right) \quad (12)$$

Discussion

The mono- and di-protonated Co(II)salen are produced according to the acid concentration. The protonation may take place at lone electron-pairs on oxygen atoms of Co(II)salen, resulting in weakening the electron donating ability of oxygen atom to Co(II) and consequently of Co(II) which might have reduced O_2 to O_2^-. Therefore, the protonated species must be inert to oxygenation as observed above.

The reducing ability of Co(II) is known to be affected by the basic nature of X at low temperature as expressed in the reaction,

$$\text{Co(II) salen}\cdot X + O_2 \rightleftarrows (O_2\text{Co(II) salen}\cdot X)^* \rightleftarrows O_2^-\cdot\text{Co(III) salen}\cdot X \quad (13)$$

the enthalpy of the reaction being in parallel with basicity of X in the order,[7] pyridine>DMSO>NCS^-> tetrahydrofuran > *N*, *N*-dimethylacetamide > CH_2Cl_2, where X coordinates with Co(II) at the site perpendicular to the salen plane. Thus, the basic nature of X assists Co(II)salen in reducing O_2 to O_2^-. Therefore, the inertness of the protonated species to the oxygenation is easily convinced by the fact that the proton is, say, of the least basic nature, although the attaching positions of X and H^+ are different to each other.

According to Ochiai,[8] the formation of 1 : 1 superoxo or 2 : 1 μ-peroxo complex by oxygen uptake depends upon the nature of solvent, ligand, and temperature. In our present case, the latter complex seems to be far more favored than the former in DMSO at room temperature, because of a considerably large negative free energy.[8]

The protonation of 2 : 1 μ-peroxo complex, (Co(III)-salen)$_2O_2$ (Reaction 10), occurs at the bridging O_2^{2-} on producing hydroperoxo ion, HO_2^-. The formation constants of protonated μ-peroxo binuclear cobalt complexes are compared as follows. The ammine, ethylenediamine, and cyano complexes in aqueous solutions maintain chemical equilibria with respective equilibrium constants,[12,13]

$$(NH_3)_5Co\text{-}O_2\text{-}Co(NH_3)_5^{4+} + H^+ \rightleftarrows (NH_3)_5Co\text{-}(O_2H)\text{-}Co(NH_3)_5^{5+} \quad (14)$$

$$\log K_{NH_3} = -1.2 \pm 0.2$$

$$(en)_2Co(NH_2)(O_2)Co(en)_2^{3+} + H^+ \rightleftarrows (en)_2Co(NH_2)(O_2H)Co(en)_2^{4+} \quad (15)$$

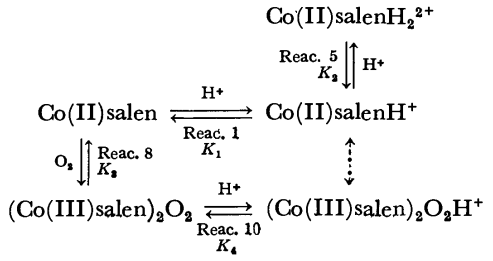
$$\log K_{en} = 0.8$$

$$(CN)_5Co\text{-}O_2\text{-}Co(CN)_5^{6-} + H^+ \rightleftharpoons (CN)_5Co\text{-}O_2(H)\text{-}Co(CN)_5^{5-} \quad (16)$$

$$\log K_{CN} = 10.5$$

while $\log K_{salen}$ for Co(II)salen in DMSO ($=\log K_4$ in Eq. (11)) has been found to be 5.5. Although the solvent used only for Co(II)salen was different from others, the order of K's, $K_{NH_3}<K_{en}<K_{salen}<K_{CN}$, agrees with the reverse order of electric charges on Co-complexes, $4+_{NH_3}>3+_{en}>0_{salen}>6-_{CN}$, indicating that the reactions are largely retarded or favored by Coulombic repulsive or attractive force between the Co-complex and H^+, respectively. The dielectric constant of DMSO is 46.7, being small as compared to that of water 78, but the effect of the smallness of dielectric constant of DMSO might be minute because the oxygenated Co(II)salen complex is chargeless. Consequently, the magnitude of K_4 for Reaction 10 seems to be reasonable.

In conclusion, the reactions considered in the present study are summarized below.



Since the protonating site differs from each other among Reactions 1, 5, and 10, all reactions lie in a line with the protonated species being inhibited for direct oxygenation or deoxygenation, as shown by a dotted arrow. Only Reaction 8 is very slow with an apparent decrease in oxygenation ratio in acid DMSO.

The Photochemical Reaction of Benzofuran Derivatives with Benzophenone or Benzaldehyde

Yoshiyuki KAWASE, Seiji YAMAGUCHI, Hirokazu OCHIAI, and Hisanori HORITA

Department of Chemistry, Faculty of Literature and Science, Toyama University, Gofuku, Toyama 930

(Received February 15, 1974)

The photochemical reaction of 2-methyl-, 2,3-dimethyl-, 2,3-butano-, and 2-hydroxymethyl-benzofuran with benzophenone gave the corresponding oxetanes in yields higher than, or comparable to, those in the case of unsubstituted benzofuran, but in lower yields than in the cases of 3-methyl- and 2-isopropyl-benzofuran. The oxetanes were also produced by the reaction of 2-methyl-, 2,3-dimethyl-, and 2,3-butano-benzofuran with benzaldehyde, but these yields were not so high because of their instability. The reaction of 2-methoxycarbonyl- and 2-cyano-benzofuran with benzophenone or benzaldehyde gave dimers of the benzofurans, as in the case of 2-phenylbenzofuran.

It has been reported that the photochemical reaction of furan derivatives with carbonyl compounds furnished the oxetanes;[1] also, a similar reaction of benzofuran with benzophenone or benzaldehyde furnished the oxetane, while benzofuran with acetone or acetophenone as well as 2-phenylbenzofuran with benzophenone or benzaldehyde furnished the cyclo-dimer of the benzofuran.[2] Now in the present experiments, the reaction of 2-, 3-, and 2,3-substituted benzofurans (**1**) with benzophenone (**2**) or benzaldehyde (**3**) was studied in order to investigate the effect of the substituents.

j	CN	H
k	CO2H	H

A benzene solution of a benzofuran derivative (**1a—j**) and benzophenone (**2**) or benzaldehyde (**3**) was irradiated for several hours by means of a 100 W high-pressure mercury lamp in a nitrogen atmosphere, the solvent was removed *in vacuo*, and the residual product was crystallized. In several cases, the reaction rate was checked by NMR spectroscopy. It was found that the reaction mixture contained only one kind of product and the starting materials, and that the yield of the product reached a maximum at about 20 hr irradiation in the case of **1a**, **b**, and **d** with **2**, while it reached a maximum at about 8 hr irradiation in the case of **1a**, **b**, and **d** with **3**. Therefore, the reaction was stopped at those times. The reaction of **1b**, **d**, **e**, and **f** with **2** furnished the corresponding oxetanes (**4b**, **d**, **e**, and **f**) in yields higher than, or comparable to, those in the case of benzofuran[2] (**1a**), but **1c** and **1g** furnished the oxetanes (**4c** and **4g**) in low yields only. In the case of the reaction of **1a—e** with **3**, a fairly large amount (about a 60% yield) of the oxetane (**5a—e**) was detected in the reaction mixture. However, not much of the pure product was isolated because of the instability of the oxetane; particularly the pure **5c** could not be isolated.

The structures of the oxetanes (**4** and **5**) were determined by elemental analyses and by spectroscopy (IR, NMR, and Mass), particularly by comparing their NMR data with those[2] of **4a** and **5a**. That is, the structures of **4b**, **4f**, **4g**, and **5b** were determined by means of the fact that the chemical shifts of 2a-H of **4b**, **4f**, **4g** (δ=4.56, 5.02, 4.82) and of **5b** (δ=3.83) were comparable with those of **4a** (δ=4.97) and **5a** (δ=4.12) respectively. Also, the structure of **4c** was determined by means of the chemical shift of 7a-H (δ=6.21) being comparable with that of **4a** (δ=6.50). Upon the basis of these data, the structure of **4d** was determined by means of the fact that the chemical shifts of 2a- and 7a-methyl hydrogen (δ=1.65 and 1.64) were comparable with those of **4c** and **4b** (δ= 1.40 and 1.61) respectively, while the structure of **5d** was determined by means of the fact that the shift of 7a-methyl hydrogen (δ=1.64) was comparable with that of **5b** (δ=1.75). Further, **4e** and **5e** were considered to have the structures shown in the chart by analogy to the cases of **4d** and **5d**. The configuration of the oxetanes (**5**) at the C_2-position has not yet been determined, but it seemed that the C_2-phenyl groups of **5a** and **5b** might be *cis* to the 2a-H, by analogy to the case of the oxetane produced from furan and benzaldehyde.[1g]

In the present reaction, the intermediate biradical, **6** or **7**, may be formed by the electrophilic attack of the oxygen radical of the excited triplet state of the carbonyl group, and the oxetane may be formed by the intra-molecular coupling of the biradical, as in the case of the reaction of furan derivatives with carbonyl compounds.[1] The alkyl groups (R and R') on the furan ring may facilitate the attack of the oxygen radical and increase the stability of the intermediate biradical; they may thus favor the formation of the oxetane. Indeed, in the reaction of the benzofuran derivative with benzophenone, the yields of the oxetane formation in the case of **4b**, **d**, and **e** are much higher than those of unsubstituted benzofuran. However, it seems necessary to consider the steric hindrance in order to explain the low yields of **4g** and **4c** and the yield of **4d** being lower than that of **4b**. In the reaction of the benzofuran derivative with benzaldehyde, the yield of the oxetane is not very high, and the oxetane is unstable on standing. It seems that these facts are

i) Ac=acetone, Cl=chloroform, Me=methanol, and Pe=petroleum ether. ii) *Cf.* Ref. 2. Lit, mp 132 °C. iii) *Cf.* Ref. 2. Lit, mp 95—96 °C. iv) This was not detectable. v) *Cf.* Ref. 2. Lit, mp 279—280 °C.

due to the formation of the not-very-much-stabilized intermediate biradical, **7**; the stabilizing effect of the R and R′ groups is not great enough to improve the stability of **7**.

The reaction of 2-methoxycarbonyl- and 2-cyanobenzofuran (**1i** and **1j**) with **2** or **3** gave dimers (**8i** and **8j**) of the benzofurans in low yields, much as in the case of 2-phenylbenzofuran[2] (**1h**). The hydrolysis of **8i** as well as **8j** gave the same carboxylic acid, **8k** (**8**(R=CO_2H)). The structures of **8h**—**k** have not yet been established. In the reaction of **1i** and **1j** with **2** or **3**, it seems that the energy level of the excited benzofuran derivative is lowered by conjugation with the substituent, and **1i** and **1j** receive energy from the excited carbonyl compound to react with another molecule of **1i** and **1j**, the carbonyl compound having been used as a sensitizer.

Experimental

The melting points were not corrected; the IR spectra were measured on a Hitachi EPI-S spectrophotometer, the NMR spectra, on a JEOL JNM-C-60H (60 MHz) spectrometer, and the mass spectra, on a JEOL JMS-OIS spectrometer. The data are summarized in the tables.

Materials. The benzofuran[3] (**1a**), 2-methylbenzofuran[4] (**1b**), 3-methylbenzofuran[5] (**1c**), 2,3-dimethylbenzofuran[6] (**1d**), 2,3-butanobenzofuran[7] (**1e**), 2-benzofuranylmethyl alcohol[8] (**1f**), 2-phenylbenzofuran[9] (**1h**), methyl 2-benzofurancarboxylate[8] (**1i**), and 2-benzofurancarbonitrile[10] (**1j**) were prepared by the literature procedures. The 2-isopropylbenzofuran (**1g**) was prepared by the action of diethyl isopropylmalonate on salicylaldehyde, as will be reported later.

The Photochemical Reaction of the Benzofuran Derivative (1) with Benzophenone (2) or Benzaldehyde (3). A benzene solution of **1** and **2** or **3** (each 0.02 mol in 200 ml of benzene) was irradiated by means of a 100 W high-pressure mercury lamp through a Pyrex jacket (Rikosangyo Co.) in a nitrogen atmosphere at 20—25 °C for several hours, as is shown in the table. The solvent was then removed *in vacuo*, and the residual product was crystallized from the solvent shown in the table.

Table 2. Elemental analyses of the new compounds

The Hydrolysis of 8i. A mixture of **8i** (0.2 g), 50% aqueous potassium hydroxide (2 g), and methanol (2 ml) was refluxed for 3 hr. The reaction mixture was then treated as usual, and the product was crystallized from acetone to give 0.1 g (50%) of an acid, **8k**; mp 332 °C (decomp.), ν_{max}^{KBr} cm^{-1}: 3450—2510 (OH), 1712 (CO).

The Hydrolysis of 8j. A mixture of **8j** (0.5 g), 50% aqueous potassium hydroxide (6 g), and ethylene glycohol (5 ml) was heated at 100 °C for 8 hr. The reaction mixture was then diluted with water and acidified. The precipitates thus obtained were crystallized from acetone to give 0.15 g (26%) of **8k**, identical with the other sample.

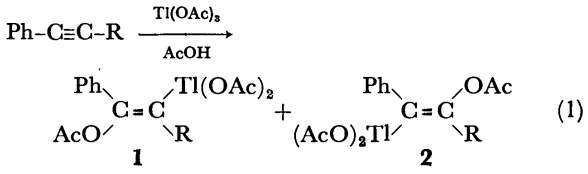
(Received March 29, 1974)

The *trans* acetoxythallation of alkylphenylacetylene with $Tl(OAc)_3$ proceeds in acetic acid at 50—75 °C for 1—3 hr to give a mixture of two isomeric vinylthallium(III) compounds in 54—79% yields, 2-acetoxy-1-alkyl-2-phenyl- and 2-acetoxy-2-alkyl-1-phenylvinylthallium(III) diacetates [$C_6H_5C(OAc)=C(R)-Tl(OAc)_2$ (**1**) and $C_6H_5C(Tl(OAc)_2)=C(OAc)R$ (**2**), where R=Me, Et, *n*-Pr, and *n*-Bu]. Protodethallation of **1** and **2** in refluxing acetic acid occurs with retention of configuration to afford $C_6H_5C(OAc)=C(R)H$ (**3**) and $C_6H_5CH=C(OAc)R$ (**4**), respectively. The reaction of **1** and **2** with $NaBH_4$ in protic solvents at pH 6—7 also gives **3** and **4** with retention of configuration, where the hydrogen for replacement of thallium group comes almost completely (>98%) from the solvent. **1** and **2** are relatively stable to water and dilute HCl, while they readily give ketones in alkaline condition. Halogeno-, cyano-, and thiocyanodethallations of **1** is conducted by reactions with the corresponding copper(II) or (I) salts in acetonitrile to give $C_6H_5C(OAc)=C(R)X$ (X=I, Br, Cl, CN, and SCN) with retention of configuration. Bromodethallation of **1**(R=CH_3) by bromine gives $C_6H_5C(OAc)=C(CH_3)Br$ stereospecifically in pyridine (retention), while α,α-dibromopropiophenone is obtained in CS_2 and acetonitrile.

Oxymercuration and oxythallation of olefins give stable β-alkoxyalkylmercury and β-alkoxyalkylthallium compounds, respectively.[1,2] Oxymercuration of acetylenes affords the β-alkoxyvinylmercury compounds.[3] Although the reaction pathways through oxythallation of acetylenes were postulated in the hydration[4] and oxidation[5] reactions of acetylenes with thallium(III) salts, there has been no report on the successful isolation of oxythallated compounds (the oxythallates) of acetylenes by direct reaction between acetylenes and thallium (III) salts. Recently, Uemura *et al.*[6] and Sharma and Fellers[7] succeeded independently in isolating the oxythallates from alkylphenylacetylenes and dialkylacetylenes, respectively. The thallium group of oxythallates of olefins was replaced by halogens and pseudohalogens by use of the corresponding copper salts[8] and by hydrogen in the reduction with $NaBH_4$ in protic solvents.[9] Arylthallium compounds reacted similarly with such reagents to give aryl halides[10] and pseudohalides.[11] It seems worthwhile examining how the vinylic C–Tl bond of the oxythallates of acetylenes acts towards these reagents in order to compare the nature of the various kinds of C–Tl bonds. We report herewith on the preparation of the oxythallates of alkylphenylacetylenes and also the results of some reactions of the isolated vinylthallium compounds with acetic acid, $NaBH_4$, alkali, halogens, and copper halides, cyanide and thiocyanate.

Results and Discussion

Preparation of Acetoxythallated Compounds of Alkylphenylacetylenes, 1 and 2. Methyl-, ethyl-, *n*-propyl-, and *n*-butyl-phenylacetylenes reacted with $Tl(OAc)_3$ in acetic acid at 50—75 °C for 1—3 hr to give an isomeric mixture of 2-acetoxy-1-alkyl-2-phenylvinylthallium diacetate (**1**) and 2-acetoxy-2-alkyl-1-phenylvinylthallium diacetate (**2**) in 54—79% yield as in the following. The yield of products decreased with an increase in the bulkiness of the alkyl group. The isomer ratios (**1**:**2**) determined by treatment with $NaBH_4$ were 2.8—



(1)

2.5 for Me, 1.9—1.8 for Et, *n*-Pr, and *n*-Bu. A mixture of **1** and **2** was isolated as white amorphous solids, stable in air and soluble in polar solvents, which were recrystallized from alcohols, acetone, CCl_4, 1,2-dichloroethane and benzene. Separation of each isomer was achieved by careful recrystallization from suitable solvents such as methanol, ethanol or diethyl ether. Each of the isomers **1** (R=Me), **1** (R=Et), and **2** (R=Et) was separated in a pure form, but it was not possible to separate either of **1** or **2** having the *n*-propyl or *n*-butyl group. The reaction conditions for the preparation of **1** and **2**, isolated yields, isomer ratios of **1** to **2**, melting points, and analytical data are summarized in Table 1.

The IR spectra (paraffin and hexachlorobutadiene mulls) of **1** and **2** showed strong absorption bands at 1760 and 1640 cm^{-1} due to vinyl ester group, $\nu_{C=O}$ and $\nu_{C=C}$ respectively, together with many bands in the acetate region [1600 (sh), 1560 (s), 1515 (s), 1420 (s, broad), and 1365 (m) cm^{-1}] which can be assigned to both the bridging and non-bridging acetate groups as has been discussed in the cases of aryl- and alkylthallium diacetates.[8,12]

Assignment of the structures of **1** and **2** was best carried out by NMR spectra (in CD_3OD). Coupling constants between Tl and the protons of the methyl or methylene group at allylic position in **1** were 976—1316 Hz, while those in **2** were 116—142 Hz. The values are quite reasonable considering the results reported by Maher and Evans in various organothallium compounds.[13] The aromatic ring protons were coupled with Tl in **2**, J_{Tl-o-H} and J_{Tl-m-H} being 126 and 64 Hz respectively, in contrast to the nearly singlet peak in **1**, showing that Tl was attached to the carbon α and β to phenyl group in **2** and **1**

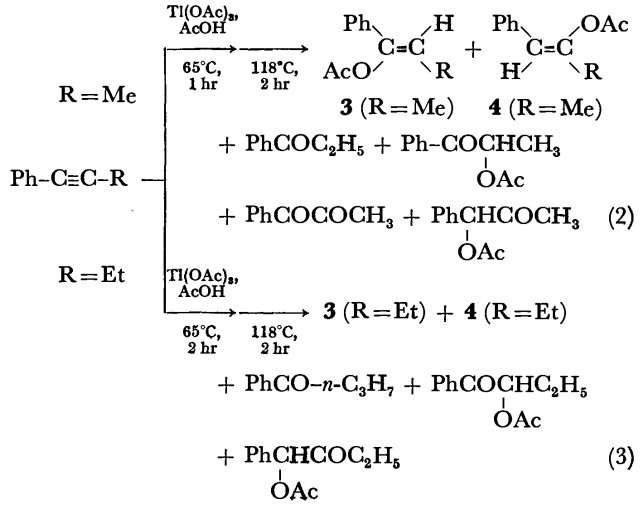
a) Based on $Tl(OAc)_3$ charged. Yields in parentheses were based on $Tl(OAc)_3$ consumed. b) Determined by hydrogenolysis with $NaBH_4$ in methanol.

respectively. The methyl protons of acetoxy group appeared as a doublet (J=13 Hz). This can be attributed to long-range coupling with Tl ($^6J_{Tl-H}$= 3.0 Hz was reported[14]) or through-space coupling with Tl. Since the coupling constant of 142 Hz (J_{Tl-CH_3}) in **2** (R=Me) agrees with that of 144 Hz between Tl on C_3 and methyl protons on C_2 in the 2-acetoxy-3-diacetoxythallium-*trans*-2-butene[7] where acetoxy (on C_2) and thallium (on C_3) are in *trans* position, we may assign the structure of **2** to the *trans*-acetoxythallate. From the NMR data and the structure of **2**, it seems reasonable to assign the structure of **1** as another *trans*-acetoxythallate. We also confirmed this configuration by protolysis and hydrogenolysis of **1**. Structures of **1** and **2** suggest that acetoxythallation proceeded completely in a *trans* fashion at least in the case of alkylphenylacetylenes. In contrast, Sharma and Fellers[7] obtained a mixture of *trans*- and *cis*-acetoxythallates from dimethylacetylene, but they observed at the same time the formation of only the *trans*-isomer from diethylacetylene. The bulkiness of substituent on acetylenes seems to affect the mode of addition of thallium-(III) salt to triple bond.

When the reaction mixture was refluxed for 2 hr in acetic acid after being kept at 65 °C for 1 hr, none of **1** and **2** was isolated, various organic products being obtained instead. Thus, from methylphenylacetylene, a mixture of 1-acetoxy-*trans*-1-phenylpropene [**3**(R=Me)], 2-acetoxy-*trans*-1-phenylpropene [**4**(R=Me)],



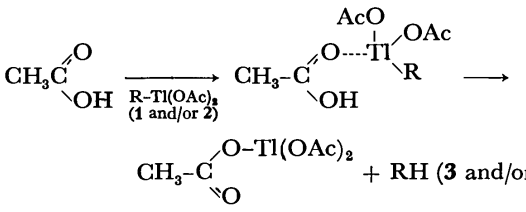
propiophenone, α-acetoxypropiophenone, 1-phenyl-1,2-propanedione, and 1-acetoxy-1-phenylacetone was obtained as shown below, **3** and **4** being the main products. Similarly, 1-acetoxy-*trans*-1-phenylbutene [**3**(R=Et)], 2-acetoxy-*trans*-1-phenylbutene [**4**(R=Et)], butyrophenone, acetoxybutyrophenone and 1-acetoxy-1-phenyl-2-butanone were the identified products from the reaction of ethylphenylacetylene. Here, **3** and **4** may be formed by protolysis of the intermediate acetoxythallates **1** and **2** by the solvent, while products other than **3** and **4** were found to be formed by the subsequent oxidation reaction of **3** and **4** with $Tl(OAc)_3$. In these reactions all of $Tl(OAc)_3$ was reduced to the thallium(I) salt, due partly to the oxidation of **3** and **4** and partly because of that of acetic acid solvent.[15]

From *t*-butylphenylacetylene (R=*t*-Bu) and diphenylacetylene (R=Ph), none of **1** and **2** was isolated by being stirred at 65 °C for 1—3 hr, and even under more drastic reaction conditions (at refluxing temperature for 4—24 hr) acetylenes were recovered almost quantitatively together with small amounts of the oxidation products. Several attempts to isolate **1** and **2** (or the methoxythallates) from the reaction of methylphenyl- or ethylphenylacetylenes with $Tl(OAc)_3$ in methanol solvent were unsuccessful under stirring at 25 °C for 5 hr, acetylenes being recovered in all cases. At refluxing temperature for 4 hr only the oxidation product, methyl 2-phenylpropionate,[16] was obtained in 50% yield from methylphenylacetylene as in the case of the reaction with $Tl(NO_3)_3$.[5]

Protodethallation of 1 and 2 by Acetic Acid. In order to confirm the possibility that various organic products (Eqs. (2) and (3)) were formed *via* the acetoxythallates of acetylenes, **1** or a mixture of **1** and **2** was heated in refluxing acetic acid for 2 hr. It was found that **1**(R=Me) gave **3**(R=Me) as the main product together with propiophenone, α-acetoxypropiophenone, and 1-phenyl-1,2-propanedione, while a mixture of **1**(R=Me) and **2**(R=Me) afforded **4**(R=Me) and 1-acetoxy-1-phenylacetone in addition to the four products. All the products were the same as those obtained directly from methylphenylacetylene. Similarly, a mixture of **1**(R=Et) and **2**(R=Et) gave the same products as those in Eq. (3), **3**(R=Et) and **4**(R=Et) being the main products. All the products other than **3** and **4** were formed by oxidation of **3** and **4** with $Tl(OAc)_3$; for example, **3**(R=Me) gave α-acetoxypropiophenone

as the main product together with small amounts of propiophenone and 1-phenyl-1,2-propanedione. A mixture of **3**(R=Me) and **4**(R=Me) afforded the above three compounds and 1-acetoxy-1-phenylacetone. A report was given on the α-acetoxylation and α,α-diacetoxylation (sometimes isolated as α-diketone) of ketones with $Tl(OAc)_3$ in acetic acid.[17] It was confirmed that propiophenone, butyrophenone, and phenylacetone reacted with $Tl(OAc)_3$ to give α-acetoxylated compounds and α-diketones (see Experimental). We might conclude that protolysis of **1** and **2** with acetic acid gives **3** and **4** followed by their subsequent oxidation with regenerated $Tl(OAc)_3$, and consequently that all the various products shown in Eqs. (2) and (3) were formed *via* acetoxythallation of acetylenes. The fact that *trans*-acetoxythallates gave exclusively **3** and **4** (where phenyl and alkyl are in *trans*-position) without formation of the *cis*-isomers indicates protodethallation to be completely stereospecific. In addition to the fact that proto- or halodemetallation and metal-metal exchange reaction of vinyl metal compounds (such metals as Hg, Sb, Sn, Li, and B) proceed electrophilically with retention of configuration,[18] deuteriodeboronation of vinylboron compounds by deuterioacetic acid[19] and also protolysis of vinylcopper compounds[20] proceed with complete retention of configuration. The results of protodethallation support the conclusion that acetoxythallation of alkylphenylacetylenes to form **1** and **2** proceeds completely in a *trans* fashion.

In contrast to facile protodethallation in acetic acid, **1** and **2** are stable in water and in aqueous HCl. For example, **1**(R=Me) gave **3**(R=Me) (5% yield), propiophenone (2%), α-acetoxypropiophenone (3%) together with methylphenylacetylene (4%) as the products only after refluxing for 3 hr. When **1**(R=Me) was treated with aqueous ethanol containing HCl (*ca.* 0.5 M) at 20 °C for 3 hr, hardly any reaction occurred. The almost quantitative protodethallation in acetic acid and the stability toward water and aqueous HCl seem to be a characteristic feature of the acetoxythallates of acetylenes. The alkoxythallates of olefins were solvolyzed with acetic acid and water to give oxidation products of olefins and no protodethallated compounds, while deoxythallation affording starting olefins occurred easily with aqueous ethanolic HCl.[8] It should be noted[21] that protolysis of various organoboranes proceeded smoothly by carboxylic acids with retention of configuration, but not by strong mineral acids, and that the unique effectiveness of carboxylic acids is attributed to the capability of boron of coordinating at the oxygen of the carbonyl group. We might assume that protolysis of vinylthallium compounds proceeds similarly to give **3** and/or **4** with



(4)

retention of configuration according to the following scheme, namely through coordination of thallium with the oxygen of the carbonyl group, and regenerated $Tl(OAc)_3$.

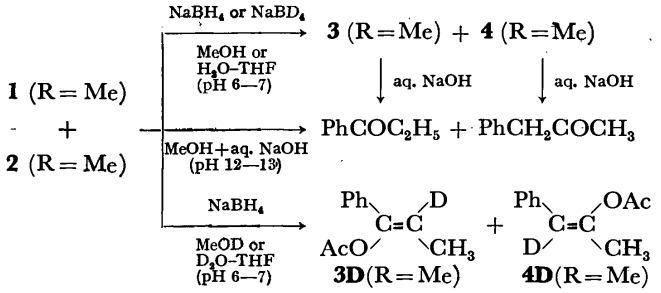
a) Based on Tl compounds charged. b) Determined by NMR. c) 1-Phenylpropanol was obtained in 5% yield. d) React. Temp., 5 °C.

Hydrogenolysis of 1 and 2 by the Reaction with $NaBH_4$ in Protic Solvents. Hydrodemercuration of the oxymercurials of olefins by alkaline $NaBH_4$ reduction affording alcohols, ethers and amines *etc.* has been a current topic in the field of oxymetallation (solvomercuration-demercuration).[22,23] Oxymercuration of acetylenes and subsequent demercuration (*in situ*) by $NaBH_4$ gave ketones in an alkaline condition,[24] and enol acetates, enol ethers, and amines in a neutral condition.[25] The alkoxythallates of styrene were reduced by methanolic $NaBH_4$ especially in an alkaline condition to give styrene, α-alkoxyethylbenzenes and dialkylthallium salts, where styrene (the deoxythallation product) was the main product.[9] The hydrogen for replacement of thallium came from the solvent in contrast to the reduction of the oxymercurials of olefins where the hydrogen of $NaBH_4$ was used for hydrodemercuration.[23] In order to see how the thallium group of the oxythallates of acetylenes is replaced by hydrogen in the reaction with $NaBH_4$, **1** or a mixture of **1** and **2** was treated with $NaBH_4$ in various solvents such as methanol, aqueous methanol and aqueous THF at 0 °C for 1 hr. Some typical results are summarized in Table 2. In a neutral or slightly acidic condition (pH 6—7), **3**(R=Me) was obtained from **1**(R=Me) in a good yield together with a small amount of methylphenylacetylene (the deoxythallation product). Similarly a mixture of **1**(R=Me) and **2**(R=Me) was reduced to a mixture of **3**(R=Me) and **4**(R=Me) in methanol in more than 90% yield as shown in the following.

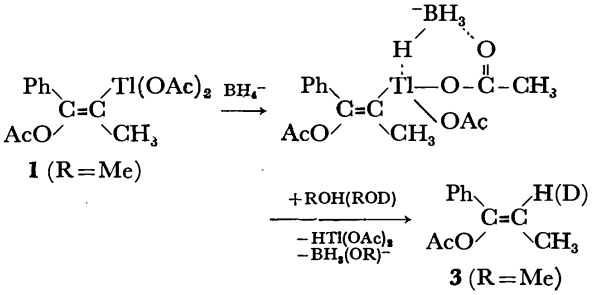


(5)

Since an isomer ratio of the products **3**(R=Me) and **4**(R=Me) was nearly the same as that of **1**(R=Me)/**2**(R=Me) determined by NMR, this reduction method was used for determining the ratios of **1** to **2** in the mixtures of the crude acetoxythallates of acetylenes (Table 1). In an alkaline condition (pH 12—13), **1**(R=Me) and a mixture of **1**(R=Me) and **2**(R=Me) afforded propiophenone and a mixture of propiophenone and phenylacetone, respectively, almost quantitatively. It was confirmed that **3**(R=Me) and **4**(R=Me) were readily hydrolyzed in this alkaline condition to propiophenone and phenylacetone respectively. It was also revealed that both **1**(R=Me) and **2**(R=Me) reacted with aqueous alkali to give the corresponding ketone even in the absence of $NaBH_4$ (Eq. (5)), the only difference being that the yield of **4** was lower in the absence of $NaBH_4$ than that in its presence. It is conceivable that **1** and **2** were solvolyzed in the reaction without $NaBH_4$ to the corresponding α-thallated ketones followed by hydrodethallation to give propiophenone and phenylacetone. Thus in the alkaline $NaBH_4$ reduction of **1** and **2**, both reaction routes would be operative.

When the reaction was carried out with $NaBD_4$ in methanol, hardly any deuterium incorporation was observed in the products, while the reaction with $NaBH_4$ in deuterated solvent such as MeOD or D_2O nearly completely gave the deuterated products, 1-acetoxy-2-deuterio-*trans*-1-phenylpropene (**3D**) and 2-acetoxy-1-deuterio-*trans*-1-phenylpropene (**4D**) (Eq. (5)). This shows that the hydrogen for replacement of thallium group came almost completely from the solvent and not from $NaBH_4$ as in the case of the reduction of the alkoxythallates of styrene.[9] In the reduction of arylthallium bis(trifluoroacetates) with $NaBH_4$ in ethanol, Herbert[26] pointed out that 2—8% of the hydrogen for replacement of thallium group to afford aromatic hydrocarbons came from $NaBH_4$. In the case of the reduction of the oxythallates of olefins and acetylenes, however, we could obtain only a small amount (at most 2% by NMR) of the deuterated products from the reaction with $NaBD_4$ in methanol.

The following facts should be noted when considering the reaction scheme of the reduction in a neutral condition: The reaction proceeded completely stereospecifically with retention of configuration. The reaction with the use of $BF_3(MeOH)_2$ or $B(OCH_3)_3$ instead of $NaBH_4$ gave none of **3** and **4**. Although the hydrogen for replacement of the thallium group came from the solvent, $NaBH_4$ was necessary as a reactant and not as a catalyst. The alkaline $NaBH_4$ reduction of oxymercurials of olefins proceeds *via* formation of an organomercuric hydride (RHgH) which undergoes homolytic dissociation to produce R· and ·HgH radicals, and the hydrogen for replacement of mercury arises from $NaBH_4$ and not from the solvent.[23] If a similar reaction scheme is operative in the reduction of the acetoxythallates of acetylenes and the intermediate organothallium hydride gives the vinyl radicals, they should give a mixture of *cis*- and *trans*-isomers since the vinyl radicals interconvert rapidly and give the isomeric mixtures.[27] For example, the reaction of *trans*-chlorovinylmercury (II) chloride with iodine in DMSO gave completely *trans*-1-chloro-2-iodoethylene by S_E1 mechanism, while a similar reaction gave a mixture of *trans*- and *cis*-isomers (50:50) in CCl_4 or benzene under an irradiation of light by a free-radical



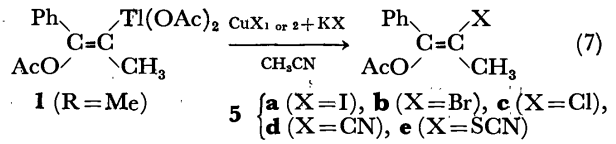
$$HTl(OAc)_2 \longrightarrow HOAc + TlOAc$$

$$1 + BH_3(OR)^- \xrightarrow{-HTl(OAc)_2} 3 + BH_2(OR)_2^-$$

$$\xrightarrow{1} 3 + BH(OR)_3^- \qquad (6)$$

mechanism.[28] Thus the radical reaction scheme may be excluded in our case. Considering the stereochemistry of the product we could assume that the reduction proceeds *via* an electrophilic substitution of thallium in vinylthallium compound by hydrogen or deuterium of the solvent, since the electrophilic substitution of metal in vinylmetal compounds by halogens, proton and metals proceed in almost all cases with retention of configuration, as shown in the scheme (6). This scheme shows why deuterium came from the solvent and not from $NaBD_4$. The borohydride might turn to oxyborohydride such as $B(OR)_4^-$ or $BH(OR)_3^-$. There is a possibility that $BH(OR)_3^-$ species becomes unreactive since the yields of **3** and/or **4** did not exceed 75% (based on $NaBH_4$ charged) in the reactions using a quarter or less mole of $NaBH_4$ and 1 mol of **1** and/or **2**. For example, the reaction of **1** (3 mmol) with $NaBH_4$ (0.75 mmol, 3 mmol equivalent H) gave 2.07 mmol of **3**, and the reaction with **1**+**2** (3.5 mmol) and $NaBH_4$ (0.35 mmol, 1.5 mmol equivalent H) gave 0.91 mmol of a mixture of **3** and **4** (Table 2). The result can be explained by assuming that three out of four hydrogens of BH_4^- were effective for reduction. We have observed similar phenomena in the $NaBH_4$ reduction of the alkoxythallates of styrene.[29]

Reaction of 1(R=Me) with Copper Salts and Halogens. Halogeno-, cyano-, and thiocyanodethallations proceed in the reactions of the arylthallium compounds[10,11] or the alkoxythallates of styrene[8] with copper halides, cyanides, and thiocyanates and in some case with iodine, bromine and potassium salts. In order to investigate whether a similar reaction occurs with the acetoxythallate of acetylene which has vinyl carbon–thallium bond, **1**(R=Me) was treated with copper(II) and (I) salts in various organic solvents. As shown in the following scheme thallium was replaced by iodide, bromide, chloride, cyanide and thiocyanate to give **5**, acetonitrile being chosen as the solvent.



(7)

1 (R=Me) **5** {**a** (X=I), **b** (X=Br), **c** (X=Cl), **d** (X=CN), **e** (X=SCN)

Typical results are summarized in Table 3. Each of the products **5a**—**e** was found by glc and NMR to be uncontaminated with its geometrical isomer. **5a** and **5b** were identical with the products obtained by the reaction of **1** with molecular iodine (in CH_3OH) and bromine (in pyridine), where electrophilic substitution with retention of the configuration is the most plausible reaction scheme if we take into consideration the results of iodination[28] of vinylmercury compound in polar solvent and those of bromination of vinylmercuric bromide in pyridine.[30] We might thus conclude that all the products **5a**—**e** have the same configuration as that of the starting acetoxythallates of alkylphenylacetylenes.

Iododethallation proceeded with copper(I) iodide. Other reactions occurred with copper(II) salts in contrast to the case of the alkoxythallates of styrene having an alkyl carbon–thallium bond, where copper(I) salts were more effective for halogeno- and pseudohalogenodethallations. Although the reaction of **1**(R=Me) with KI afforded **5a** in a good yield, none of **5** was obtained by the use of other potassium salts. Satisfactory results were obtained for bromodethallation by copper salt by the reaction with $CuBr_2$ in the presence of KBr in acetonitrile. Other solvents such as dioxane, DMF, and methanol were also used for bromodethallation, but the yields of **5b** were low. There is a possibility that bromodethallation occurs with free bromine liberated by autodecomposition of $CuBr_2$ into Cu_2Br_2.[31] The result of the separate reaction of **1**(R=Me) with bromine in acetonitrile which gave α,α-dibromopropiophenone (**6**) and none of **5b**, however, excluded the above possibility and showed that $CuBr_2$ itself was

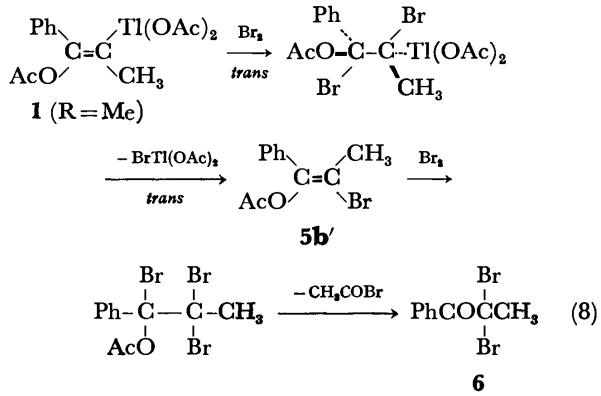
a) Based on **1** (R=Me) charged. b) 50 ml.

a reactant in the reaction with **1**. When a mixture of **1**(R=Me) and **2**(R=Me) was treated with $CuBr_2$, a mixture of **5b** and 2-acetoxy-1-bromo-*trans*-1-phenylpropene was obtained as expected. Other reactions such as chloro-, cyano-, and thiocyanodethallations proceeded with the corresponding copper(II) salts, but the yields of the products **5c—e** were low under the reaction conditions shown in Table 3.

In order to prepare an authentic sample of **5**, **1**(R=Me) was treated with iodine and bromine in suitable solvents. **1**(R=Me) reacted with iodine in methanol to give **5a**, while a mixture of **5b**, **6**, and another product (**5b'**, the isomer of **5b**; see Experimental) was obtained by the reaction with bromine. Only **5b** was obtained in pyridine in a good yield, while only **6** was obtained in carbon disulfide just as in the case of acetonitrile. The results of the reaction of **1** with halogens are summarized in Table 4. Since the alkoxythallates of styrene did not react with iodine and bromine,[8] the results show another example of the difference of reactivity between alkyl C–Tl and vinyl C–Tl bonds. The product in the reaction of **1**(R=Me) with bromine depends on the solvent which is in line with the reaction of vinylmercuric bromide.[30] In carbon disulfide, acetonitrile and methanol, the *trans*-addition of bromine to the double bond followed by *trans*-debromothallation may be operative in giving **5b'** which then reacts with another mole of bromine to afford **6**, as shown in the following.



In pyridine, the coordination of pyridine to thallium may activate the C–Tl bond towards the electrophilic attack by bromine. We confirmed that **5b** reacts very easily with bromine in carbon disulfide and acetonitrile to give **6**, while in pyridine the reaction does not proceed under the reaction conditions where halodethallation by halogen was carried out.

Experimental

The IR spectra were taken with Hitachi EPI-S2 and JASCO IR-S spectrometers in paraffin and hexachlorobutadiene mulls. The NMR spectra were recorded with a Varian A-60 spectrometer in $CDCl_3$, CCl_4, or CD_3OD as solvents, using TMS as an internal standard. Glc analyses were carried out on Shimadzu 5APTF and 4BMPF apparatus, using PEG 6000(25%)-Chromosorb W (3m), Apiezon L (30%)-Celite (1m), DEGS(25%)-Shimalite (1m), and EGSS-X(30%)-Chromosorb W (1m) columns (N_2 as carrier gas).

Materials. The following alkylphenylacetylenes were prepared from sodium phenylacetylide and *p*-toluenesulfonic acid alkyl ester:[32] methylphenylacetylene, bp 76—77 °C/18 mmHg (lit,[33] bp 185 °C); ethylphenylacetylene, bp 88—89 °C/16 mmHg (lit,[33] bp 201—203 °C); *n*-propylphenylacetylene, bp 97—104 °C/17 mmHg (lit,[33] bp 102—103 °C/18.5 mmHg); *n*-butylphenylacetylene, bp 82—86 °C/2.5 mmHg (lit,[33] bp 119—121 °C/18 mmHg). *t*-Butylphenylacetylene was prepared from phenylacetylene, ethyl magnesium bromide, and *t*-butyl bromide,[34] bp 92—97 °C/19 mmHg (bp 94—95 °C/18 mmHg). Diphenylacetylene was prepared by the alkaline dehydrobromination of stilbene dibromide;[35] mp 60—61 °C (lit,[35] mp 60—61 °C). Other organic materials were purified before use by distillation. Commercial inorganic materials were used without further purification. $Cu(NCS)_2$ was prepared from $CuSO_4 \cdot 5H_2O$ and KSCN.[36] $Tl(OAc)_3$ was prepared by stirring Tl_2O_3 in acetic acid at 65 °C for 24 hr. All the deuterium compounds, $NaBD_4$ (98%, Merck), CH_3OD (99%, CEA) and D_2O (99.8%, CEA) were used without purification.

Preparation of Acetoxythallates of Acetylenes, 1 and 2. The following preparation of **1**(R=Me) and **2**(R=Me) shows a typical procedure. To a slightly heterogeneous solution of $Tl(OAc)_3$ (3.81 g, 10 mmol) in acetic acid (10 ml) was added methylphenylacetylene (2.3 g, 20 mmol) drop by drop at 65 °C under stirring to give a pale-green solution. When the mixture was kept at 65 °C for 1 hr the color of the solution turned dark green. The solution was cooled down and acetic acid was evaporated off at room temperature with a rotary evaporator. The white solids obtained were purified by dissolution into $CHCl_3$ to remove the insoluble unreacted $Tl(OAc)_3$ (0.63 g), and then by washing with *n*-hexane after evaporation of $CHCl_3$ to remove the unreacted methylphenylacetylene and small amounts of the oxidation products to give a crude mixture of **1**(R=Me) and **2**(R=Me) (3.7 g; 75 and 89% yields based on $Tl(OAc)_3$ charged and consumed respectively); **1**/**2**=2.5 (by NMR), mp 135—

145 °C. The mixture was recrystallized from ethanol-*n*-hexane (1 : 1) mixed solvent and analyzed. **1**(R=Me) (1.0 g) was separated by recrystallization twice from ethanol, several attempts to isolate **2**(R=Me) being unsuccessful. NMR (CD_3OD) of **1**(R=Me) δ 1.85 [s, 6H, $Tl(OCOCH_3)_2$], 2.15 (d, 3H, $\equiv C-CH_3$, $J_{^{205}Tl-H}$=986 Hz, $J_{^{203}Tl-H}$=976 Hz), 2.18 (d, 3H, acetoxy, J_{Tl-H}=13 Hz), 7.40 (s, 5H, phenyl). NMR (CD_3OD) of **2**(R=Me) determined from a mixture of **1** and **2** is as follows: δ 1.83 (d, 3H, acetoxy, J_{Tl-H}=13 Hz), 1.85 [s, 6H, $Tl(OCOCH_3)_2$], 2.30 (d, 3H, J_{Tl-H}=142 Hz), 7.2—7.3 (m, 5H, phenyl, J_{Tl-o-H}=125.5 Hz, J_{Tl-m-H}=64 Hz).

The reaction with ethylphenylacetylene gave an oily product on evaporation of acetic acid. After unreacted $Tl(OAc)_3$ was removed with $CHCl_3$, it was solidified by being left to stand in *n*-hexane for two days or by decantation with *n*-hexane several times to give 3.6 g of a mixture of **1**(R=Et) and **2**(R=Et). This was recrystallized from either CCl_4, benzene, acetone or ethanol-*n*-hexane. Extraction with ether afforded 0.4 g of pure **1**(R=Et). NMR (CD_3OD) of **1**(R=Et) δ 1.15 (m, 3H, $C\underline{H}_3CH_2$-, J_{H-H}=7 Hz, J_{Tl-H}=20 Hz), 1.87 [s, 6H, $Tl(OCOCH_3)_2$], 2.17 (d, 3H, acetoxy, J_{Tl-H}=13 Hz), 2.66 (m, 2H, $CH_3C\underline{H}_2$-, J_{H-H}=7 Hz, J_{Tl-H}=1299 Hz), 7.40 (s, 5H, phenyl). Recrystallization from methanol gave 0.24 g of pure **2**(R=Et) as white needles. NMR (CD_3OD) of **2**(R=Et) δ 1.34 (t, 3H, $C\underline{H}_3CH_2$-, J_{H-H}=7 Hz), 1.85 (d, 3H, acetoxy, J_{Tl-H}=13 Hz), 1.90 [s, 6H, $Tl(OCOCH_3)_2$], 2.68 (m, 2H, $CH_3C\underline{H}_2$-, J_{H-H}=7 Hz, J_{Tl-H}=116 Hz), 7.2—7.3 [m, 5H, phenyl, J_{Tl-o-H}=126 Hz, J_{Tl-m-H}=64 Hz).

3.5 g and 2.9 g of a mixture of **1** and **2** were similarly obtained from *n*-propylphenylacetylene and *n*-butylphenylacetylene, respectively. The products from *n*-butylphenylacetylene, also oily at first, were treated as in the case of ethylphenylacetylene in order to solidify the products. They were recrystallized from either acetone or 1,2-dichloroethane and analyzed. Several attempts to separate each product were unsuccessful. NMR (CD_3OD) spectra of the mixture could be analyzed. $J_{Tl-H(-CH_2-C\equiv)}$ was 1311 and 1316 Hz in **1**(R=*n*-Pr) and **1**(R=*n*-Bu) respectively, couplings of *o*- and *m*-hydrogen of phenyl group with thallium being also observed in **2**(R=*n*-Pr) and **2**(R=*n*-Bu).

All the reactions could be carried out at 50—75 °C without affecting either the ratio or the yield of **1** and **2**. A larger scale reaction (about 10 times) also gave satisfactory results.

Reaction of Methyl- and Ethylphenylacetylenes with $Tl(OAc)_3$. To an acetic acid (10 ml) solution of $Tl(OAc)_3$ (1.9 g, 5 mmol) was added methylphenylacetylene (1.16 g, 10 mmol) at 65 °C and the resulting pale-green solution was kept for 1 hr and then refluxed for 2 hr when the color of the homogeneous solution turned to orange and then to red. After being cooled down to room temperature, aqueous NaCl was added to the solution and the precipitated TlCl was filtered off. The filtrate was extracted with benzene and the extract was washed with aqueous $NaHCO_3$ and dried over Na_2SO_4. The extract was concentrated to *ca.* 5 ml with a rotary evaporator and analyzed by glc with ethyl cinnamate as an internal standard. The products were propiophenone (7%), 1-phenyl-1,2-propanedione (13%), **3**(R=Me) (78%), **4**(R=Me) (29%), α-acetoxypropiophenone (7%), and 1-acetoxy-1-phenylacetone (6%). The last two compounds were not separated by glc, their yields being determined by NMR. The yields were calculated on the basis of $Tl(OAc)_3$ charged. The yields of the above products in another experiment were 5, 12, 67, 25, 7, and 6%, respectively.

A similar treatment of ethylphenylacetylene gave a mixture of the following products; butyrophenone (6%), **3**(R=Et) (44%), **4**(R=Et) (24%), α-acetoxybutyrophenone (4%), 1-acetoxy-1-phenyl-2-butanone (**3**) and an unidentified compound (<3%).

*Reaction of **3**(R=Me) and **4**(R=Me) with $Tl(OAc)_3$.* A mixture of **3**(R=Me) (0.53 g, 3 mmol), $Tl(OAc)_3$ (1.91 g, 5 mmol), and acetic acid (20 ml) was refluxed for 2 hr, 75% of Tl^{3+} salt being consumed (iodometrically). The reaction mixture was treated as described above. Glc analysis showed the presence of unreacted **3**(R=Me) (0.26 mmol), 1-phenyl-1,2-propanedione [0.08 mmol, 3% yield based on **3**(R=Me) charged], propiophenone (0.13 mmol, 4%) and α-acetoxypropiophenone (1.84 mmol, 61%). A similar reaction of a mixture of **3**(R=Me) and **4**(R=Me) (0.53 g, 3 mmol, **3**/**4**=3.0) with $Tl(OAc)_3$ (1.15 g, 3 mmol) in acetic acid (20 ml) gave propiophenone (0.18 mmol, 6%), 1-phenyl-1,2-propanedione (0.21 mmol, 7%), α-acetoxypropiophenone (0.66 mmol, 22%), 1-acetoxy-1-phenylacetone (0.51 mmol, 17%) together with unreacted 1.08 mmol of **3**(R=Me) and 0.09 mmol of **4**(R=Me).

Reaction of Propiophenone, Butyrophenone, and Phenylacetone with $Tl(OAc)_3$. The reaction of propiophenone (1.34 g, 10 mmol) with $Tl(OAc)_3$ (3.81 g, 10 mmol) in acetic acid (30 ml) under reflux for 2 hr gave 1-phenyl-1,2-propanedione (3% yield) and α-acetoxypropiophenone[17] (50% yield, bp 140—145 °C/16 mmHg) as products. A similar reaction using butyrophenone afforded α-acetoxybutyrophenone (23%) and small amounts of unidentified products. Distillation gave pure α-acetoxybutyrophenone; bp 110—115 °C/3 mmHg, IR 1738 and 1695 ($\nu_{C=O}$) cm^{-1}. NMR ($CDCl_3$) δ 1.00 (t, 3H, J_{H-H}=7 Hz, CH_3-), 1.6—2.2 (m, 2H, $-CH_2-$), 2.13 (s, 3H, acetoxy), 5.82 (m, 1H, -CH-), 7.2—7.7 (m, 3H, phenyl), 7.8—8.2 (m, 2H, phenyl). Similarly, 1-acetoxy-1-phenylacetone (74%) and 1-phenyl-1,2-propanedione (4%) were obtained from the reaction of phenylacetone. Distillation gave pure 1-acetoxy-1-phenylacetone; bp 140—147 °C/17 mmHg. IR 1740 ($\nu_{C=O}$), 1228 (ν_{C-O}) cm^{-1}. NMR (CCl_4) δ 2.02 (s, 3H, CH_3-), 2.10 (s, 3H, acetoxy), 5.85 (s, 1H, methine), 7.35 (s, 5H, phenyl). Found: C, 69.28; H, 6.45%. Calcd for $C_{11}H_{12}O_3$: C, 68.73; H, 6.29%.

*Protodethallation of a Mixture of **1** and **2** by Acetic Acid.* A mixture of **1**(R=Me) and **2**(R=Me) (1.5 g, 3 mmol, **1**/**2**=2.6) was dissolved in 20 ml acetic acid and the resulting slightly yellow homogeneous solution was refluxed for 2 hr to give a red solution. After being cooled down to room temperature, the reaction mixture was treated as described above and analyzed by glc. The products were methylphenylacetylene (1% yield), propiophenone (8%), 1-phenyl-1,2-propanedione (7%), **3**(R=Me) (46%), **4**(R=Me) (6%), α-acetoxypropiophenone (13%), and 1-acetoxy-1-phenylacetone (12%). A similar treatment of a mixture of **1**(R=Et) and **2**(R=Et) (**1**/**2**=1.6) gave the following products; ethylphenylacetylene (1%), butyrophenone (12%), **3**(R=Et) (39%), **4**(R=Et) (17%), α-acetoxybutyrophenone (6%), and 1-acetoxy-1-phenyl-2-butanone (5%).

*Reaction of **1** and **2** with $NaBH_4$ in Protic Solvents.* To a methanol (20 ml) solution containing 1.50 g (3.0 mmol) of **1**(R=Me) was added solid $NaBH_4$ (0.06 g, 1.5 mmol) in several portions, the temperature being kept at 0—4 °C. The mixture was then stirred for 1 hr at 0 °C. After the addition of aqueous NaCl and filtration of the resulting TlCl, the filtrate was extracted with benzene, and the extract was treated as described above. Glc analysis showed the presence of 0.09 mmol of methylphenylacetylene and 2.55 mmol (85%) of **3**(R=Me). The retention time of glc and the NMR spectrum of **3**(R=Me) were consistent with those of the sample prepared by the method reported by Fahey and Lee[37] but different from those of its isomer, 1-acetoxy-*cis*-1-phenylpropene.[37] NMR (CCl_4) δ 1.65 (d, 3H, CH_3-C=,

J_{H-H}=7 Hz), 2.16 (s, 3H, acetoxy), 5.75 (q, 1H, =CH, J_{H-H}=7 Hz), 7.0—7.4 (m, 5H, phenyl). A mixture of **1**(R=Me) and **2**(R=Me) (3.7 g, 7.5 mmol) gave a mixture of methylphenylacetylene (0.22 mmol), **3**(R=Me) (4.95 mmol), and **4**(R=Me) (1.80 mmol) by a similar treatment. Distillation gave 0.91 g (5.2 mmol) of a mixture of **3**(R=Me) and **4**(R=Me) (**3**/**4**=3.0), bp 122—130 °C/19.5 mmHg. NMR (CCl_4) of **4**(R=Me) was consistent with that reported by House *et al.*,[38] δ 2.03 (d, 3H, CH_3-C=, J_{H-H}=1 Hz), 2.06 (s, 3H, acetoxy), 5.83 (q, 1H, H-C=, J_{H-H}=1 Hz). 7.0—7.4 (m, 5H, phenyl). Analysis of a mixture of **3** and **4**. Found: C, 75.09; H, 7.02%. Calcd for $C_{11}H_{12}O_2$: C, 74.97; H, 6.86%.

The reaction of **1** (R=Me) with $NaBH_4$ in CH_3OD solvent gave 1-acetoxy-2-deuterio-*trans*-1-phenylpropene; bp 125—129 °C/22 mmHg. NMR (CCl_4) δ 1.64 (s, 3H, CH_3-C=), 2.17 (s, 3H, acetoxy), 7.1—7.4 (m, 5H, phenyl). Found: C, 74.65; H, 6.98%. Calcd for $C_{11}H_{13}O_2$: C, 74.55; H, 7.39%. A mixture of **1** (R=Me) and **2** (R=Me) was reduced by $NaBH_4$ in THF-D_2O (1: 1) solvent at 5 °C for 1 hr to give 1-acetoxy-2-deuterio-*trans*-1-phenylpropene and 2-acetoxy-1-deuterio-*trans*-1-phenylpropene as the products. NMR (CCl_4) of the latter compound, δ 2.04 (s, 3H, CH_3-C=), 2.06 (s, 3H, acetoxy), 7.1—7.4 (m, 5H, phenyl).

The products obtained by a similar treatment in methanol with other oxythallates are as follows. A mixture of **3** (R=Et) and **4** (R=Et) (84% yield by glc, **3**/**4**=1.8); 63% yield by distillation, bp 132—135 °C/19.5 mmHg. **3** (R=Et) was prepared by refluxing butyrophenone in acetic anhydride in the presence of *p*-toluenesulfonic acid, bp 107—108 °C/5 mm Hg. NMR (CCl_4) δ 1.05 (t, 3H, $C\underline{H}_3CH_2$-, J_{H-H}=7 Hz), 1.8—2.3 (m, 2H, $CH_3C\underline{H}_2$-), 2.15 (s, 3H, acetoxy), 5.67 (t, 1H, =CH, J_{H-H}=7 Hz), 7.1—7.4 (m, 5H, phenyl). NMR (CCl_4) of **4** (R=Et) determined from a mixture of **3** (R=Et) and **4** (R=Et) is as follows: δ 1.13 (t, 3H, $C\underline{H}_3CH_2$-, J_{H-H}=7 Hz), 2.07 (s, 3H, acetoxy), 2.27 (q, 2H, $CH_3C\underline{H}_2$-, J_{H-H}=7 Hz), 5.85 (t, 1H, =CH, J_{H-H}=1 Hz), 7.1—7.4 (m, 5H, phenyl). A mixture of **3** (R=*n*-Pr) and **4** (R=*n*-Pr): 67% yield by distillation, bp 142—146 °C/19.5 mmHg. Found: C, 76.28; H, 8.17%. Calcd for $C_{13}H_{16}O_2$: C, 76.44; H, 7.90% A mixture of **3** (R=*n*-Bu) and **4** (R=*n*-Bu): 59% yield by distillation, bp 153—156 °C/17.5 mmHg. Found: C, 77.42; H, 8.67%. Calcd for $C_{14}H_{18}O_2$: C, 77.03; H, 8.31%.

Reaction of 1(R=Me) and 2(R=Me) with NaOH. To a methanol (15 ml) solution of **1** (R=Me) (2 mmol) was added aqueous 3M-NaOH (5 ml) drop by drop, the temperature being kept at 0 °C. After the mixture was stirred for 1 hr at 0 °C, the precipitated Tl_2O_3 was filtered off and the filtrate was treated as usual. Glc analysis showed the formation of a trace amount of methylphenylacetylene and 2 mmol (100% yield) of propiophenone. A similar treatment of a mixture of **1**(R=Me) and **2**(R=Me) (2 mmol, **1**/**2**=0.8) gave methylphenylacetylene (0.05 mmol), propiophenone (0.82 mmol), and phenylacetone (0.23 mmol) as the products.

Reaction of 1(R=Me) with Copper Salts. The following shows a typical procedure. A yellowish green heterogeneous mixture of **1**(R=Me) (1.0 g, 2 mmol), CuI (0.76 g, 4 mmol), and KI (1.3 g, 8 mmol) in acetonitrile (20 ml) was stirred for 2 hr under refluxing temperature. After the reaction mixture had been cooled the dark-yellow precipitates were filtered. The filtrate was added to water and extracted with diethyl ether. Glc analysis of the ether extract using cumene and benzophenone as internal standards showed the presence of 0.1 mmol of methylphenylacetylene and 1.16 mmol (58% yield) of **5a**. Bp 114—116 °C/4 mmHg. NMR (CCl_4) δ 2.04 (s, 3H, acetoxy), 2.47 (s, 3H, CH_3-C=), 7.1—7.6 (m, 5H, phenyl). Found: C, 43.41; H, 3.60%. Calcd for $C_{11}H_{11}O_2I$: C, 43.73; H, 3.67%.

Characterization of other products is as follows. **5b**: bp 97—103 °C/3 mmHg. IR 1768 ($\nu_{C=O}$), 1200 (ν_{C-O}) cm^{-1}. NMR (CCl_4) δ 2.04 (s, 3H, acetoxy), 2.30 (s, 3H, CH_3C=), 7.2—7.6 (m, 5H, phenyl). Found: C, 52.07; H, 4.33%. Calcd for $C_{11}H_{11}O_2Br$: C, 51.79; H, 4.35%. It was revealed by NMR that there was an unidentified compound together with **5b** and **6** in the products obtained by the reaction of **1**(R=Me) with bromine in methanol at 20 °C for 2 hr. We may assign this compound as a geometrical isomer of **5b** [**5b′** (phenyl and methyl groups are on the same side)]; NMR (CCl_4) δ 2.09 (s, 3H, acetoxy), 2.33 (s, 3H, CH_3C=). 2-Acetoxy-1-bromo-*trans*-1-phenylpropene (**5b″**): The reaction of a mixture of **1**(R=Me) and **2**(R=Me) (5.0 g, 10 mmol, **1**/**2**=0.8) with $CuBr_2$ (4.5 g, 20 mmol) and KBr (4.8 g, 40 mmol) in acetonitrile (50 ml) under reflux for 2 hr gave **5b** and **5b″** as products (**5b**/**5b″**=1.13). Distillation gave a mixture of **5b** and **5b″**; 0.91 g (36% yield, **5b**/**5b″**=0.93), bp 95—105 °C/3 mmHg. NMR (CCl_4) of **5b″**, δ 1.81 (s, 3H, CH_3C=), 2.20 (s, 3H, acetoxy), 7.1—7.6 (m, 5H, phenyl). Analysis of a mixture of **5b** and **5b″**. Found: C, 52.22; H, 4.34%. **5c**: IR 1765 ($\nu_{C=O}$), 1200 (ν_{C-O}) cm^{-1}. NMR (CCl_4) δ 2.08 (s, 3H), 2.12 (s, 3H), 7.1—7.6 (m, 5H). Mass spectrum (*m/e*) 210 (M^+). **5d**: IR 2020 (ν_{CN}), 1775 ($\nu_{C=O}$), 1185 (ν_{C-O}) cm^{-1}. Mass spectrum (*m/e*) 201 (M^+). NMR (CCl_4) δ 1.93 (s, 3H, acetoxy), 2.19 (s, 3H, CH_3C=), 7.2—7.8 (m, 5H, phenyl). **5e**: IR 2150 (ν_{SCN}), 1765 ($\nu_{C=O}$), 1192 (ν_{C-O}) cm^{-1}. Mass spectrum (*m/e*) 233 (M^+). NMR (CCl_4) δ 2.11 (s, 3H, acetoxy), 2.22 (s, 3H, CH_3C=), 7.3 (s, 5H, phenyl). **6**: To a solution of **1**(R=Me) (1.0 g, 2 mmol) in CS_2 (15 ml) was added bromine (0.64 g, 4 mmol) in CS_2 (5 ml) drop by drop at 20 °C and the resulting red solution was stirred for 2 hr when the color turned pale orange. Glc analysis revealed the presence of a small amount of methylphenylacetylene and 1.98 mmol (99% yield) of **6**. Distillation gave 0.2 g (34% yield) of pure **6**; bp 100—104 °C/3.5 mmHg. IR 1682 ($\nu_{C=O}$) cm^{-1}. Mass spectrum (*m/e*) 290 (M^+), 292 (M^++2), 294 (M^++4). NMR (CCl_4) δ 2.72 (s, 3H, CH_3-), 7.2—7.6 [m, 3H, phenyl (*m*- and *p*-H)], 8.2—8.5 [m, 2H, phenyl (*o*-H)].

Synthesis of N^{ε}-Hydroxy-L-lysine

Yoshikazu Isowa and Muneki Ohmori

Sagami Chemical Research Center, Nishi-Ohnuma, Sagamihara, Kanagawa 229

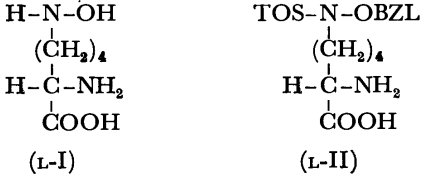
(Received April 22, 1974)

Optically active N^{ε}-hydroxy-L-lysine monohydrochloride (L-I·HCl) was synthesized from N^{ε}-tosyl-$N^{\prime}$-benzyloxy-L-lysine (L-II) obtained by the procedure employed for the preparation of N^{δ}-tosyl-N^{δ}-benzyloxy-L-ornithine. Removal of the protecting groups of L-II was carried out by the following two methods: a) treatment of L-II with boron tris(trifluoroacetate) in trifluoroacetic acid gave L-I in one step, which was isolated as 2-nitroindane-1,3-dione salt; b) deprotection of L-II *via* N^{ε}-benzyloxy-L-lysine (L-VIII), detosylation with hydrogen bromide in acetic acid and phenol, followed by debenzylation with hydrogenolysis, gave L-I·HCl having properties identical with those of the natural product obtained from mycobactine.

$N^{\prime}$-Hydroxy-L-lysine (L-I) is an important intermediate in the synthesis of mycobactines, sexadentate chelating agents for ferric iron, which occur naturally and stimulate the growth of mycobacteria.

Snow reviewed the isolation and structual elucidation of L-I.[1] Its synthesis by various methods gave only the racemic form. Rogers and Neilands[2] prepared the $N^{\prime}$-hydroxy-DL-lysine (DL-I) in the form of its 2-nitroindane-1,3-dione salt from the 5-(4-bromobutyl)-hydantoin *via* the corresponding nitro- and hydroxyamino-hydantoin. Lancini, Lazzari, and Diena[3] obtained DL-I by the reaction of hydroxyamine with 5-(4-bromobutyl) hydantoin and the following hydrolysis with hydrochloric acid. Black, Brown, and Wade[4] suggested the preparation of DL-I·2 HCl by reacting diethyl 5-bromo-1-phthalimidopentane-1,1-dicarboxylate with benzaldoxime, followed by the transformation of the nitrone to the corresponding hydroxyamine hydrochloride, the final product being characterized only in solution. It was found that $N^{\prime}$-hydroxy-DL-lysine (DL-I) was obtained from N^{α}-phthalyl-DL-lysine *via* the corresponding nitrone derivative.[5]

L-Isomer of I is a key compound for providing a route to the mycobactine. We wish to report on the synthesis of N^{ε}-hydroxy-L-lysine with the use of N^{ε}-tosyl-$N^{\prime}$-benzyloxy-L-lysine (L-II), obtained by the procedure employed for the preparation of N^{δ}-tosyl-N^{δ}-benzyloxy-L-ornithine.[6] L-II is suitably protected at N^{ε}-position and therefore can be converted into N^{ε}-hydroxy-L-lysine (L-I) by removing the protecting groups under mild conditions without loss of optical purity.



(L-I) (L-II)

The sequence of reactions employed in the preparation of DL-II is given in Fig. 1.

O-Benzyl-*N*-tosylhydroxyamine (III)[6] was first haloalkylated with 1,4-dibromobutane to 4-(*N*-tosyl-*N*-benzyloxy)aminobutyl bromide (IV). This was allowed to react with diethyl sodio-acetamidomalonate, and the product (V) was refluxed with concentrated hydrochloric acid–acetic acid to yield the racemic $N^{\prime}$-tosyl-N^{ε}-benzyloxy-DL-lysine (DL-II).

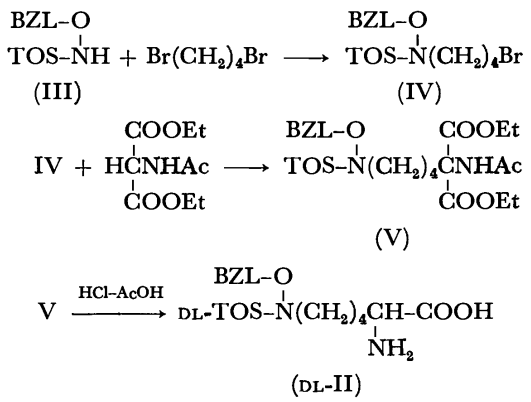


Fig. 1. Synthesis of $N^{\prime}$-tosyl-N^{ε}-benzyloxy-DL-lysine (DL-II): BZL, benzyl; TOS, *p*-toluenesulfonyl; Ac, acetyl.

Optically active N^{ε}-tosyl-$N^{\prime}$-benzyloxy-L-lysine(L-II) was obtained by the enzymatic resolution of N^{α}-acetyl-N^{ε}-tosyl-$N^{\prime}$-benzyloxy-DL-lysine (DL-VI) *via* its anilide (L-VII) with aniline in the presence of papain (Fig. 2).

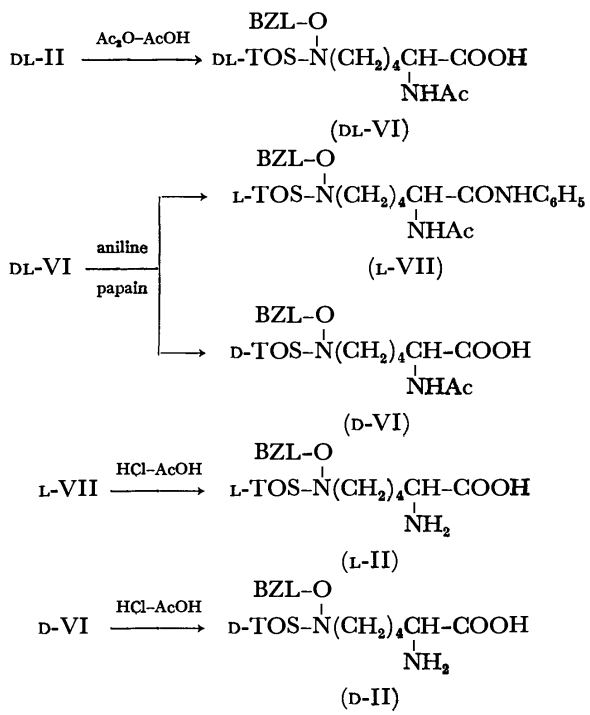

Fig. 2. Optical resolution of N^{α}-acetyl-N^{ε}-tosyl-N^{ε}-benzyloxy-DL-lysine (DL-VI).

The resulting N^{α}-acetyl-N'-tosyl-N'-benzyloxy-L-lysine anilide (L-VII) and N^{α}-acetyl-N^{ϵ}-tosyl-N^{ϵ}-benzyloxy-D-lysine (D-VI) showed optical rotations of $[\alpha]_D^{24}$ −48.6° and $[\alpha]_D^{22}$ −13.3° in chloroform solution. N^{ϵ}-Tosyl-N'-benzyloxy-L-lysine (L-II) and its D-isomer (D-II) prepared by acid hydrolysis of L-VII and D-VI showed optical rotations of $[\alpha]_D^{24}$ +18.4° and $[\alpha]_D^{22}$ −17.9° in acetic acid solution, respectively.

The optically active N^{ϵ}-protected hydroxylysine (L-II) thus obtained was deprotected *via* two different routes, a and b (Fig. 3), to N'-hydroxy-L-lysine (L-I) under mild conditions without racemization.

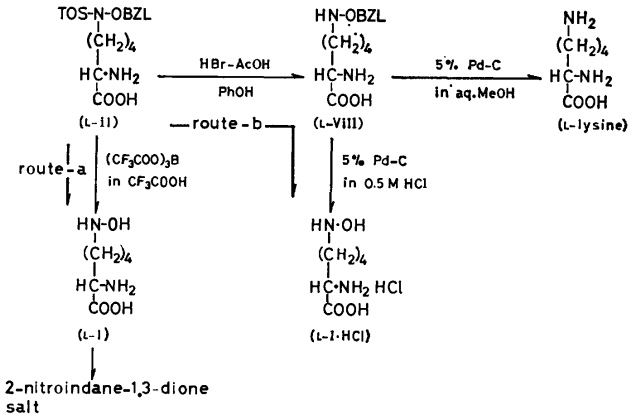

Fig. 3. Deprotection of N^{ϵ}-tosyl-N^{ϵ}-benzyloxy-L-lysine (L-II).

In route-a, the treatment of L-II with boron tris-(trifluoroacetate)[7] followed by neutralization of the product with aqueous ammonia afforded L-I as a colorless solid, mp 223—226 °C (decomp.) and $[\alpha]_D^{24}$ +24.2° (*c* 0.5, M hydrochloric acid) (lit,[8] mp 223—225 °C (decomp.) and $[\alpha]_D^{18}$ +23.9° (*c* 5.1, M hydrochloric acid)), in 58% yield. The N'-hydroxy-L-lysine (L-I) thus obtained was immediately transformed into 2-nitroindane-1,3-dione salt, because of the difficulty of preparing the L-I (HCl-free) in a state of reasonable purity; L-I was relatively unstable in the neutral and alkaline solution. The salt was obtained as pale brown crystals with melting point and the results of elemental analysis agreeing with those of the natural product reported by Snow.[8]

In route-b, the N'-protected hydroxylysine (L-II) was first detosylated with 36% hydrogen bomide in acetic acid in the presence of phenol and the resulting product (L-VIII) was hydrogenolyzed over 5% palladium on carbon in 0.5 M hydrochloric acid to afford the monohydrochloride (L-I·HCl) in 89% yield. In contrast, when the reduction procedure was carried out in a neutral solution *i.e.* in aqueous methanol, L-lysine was obtained in 51% yield. The monohydrochloride (L-I·HCl) could be precipitated from aqueous solution by addition of ethanol, because of the low solubility of L-I·HCl in aqueous ethanolic solution. The hydrochloride (L-I·HCl) thus obtained had mp 192—194 °C (decomp.) and $[\alpha]_D^{24}$ +25.5° in M hydrochloric acid. The hydroxyamine group was detected by the strong red coloration caused by treatment of the product with an alkaline solution of triphenyltetrazolium chloride. The structure of the synthetic L-I·HCl was confirmed by NMR and IR spectroscopy and elemental analysis. In particular, significant NMR-spectral features of L-I·HCl in trifluoroacetic acid corresponded with those of N^{δ}-hydroxy-L-ornithine monohydrochloride.[9]

The optical purity of L-II should be maintained in the reaction sequence, since L-lysine obtained by the hydrogenolysis of L-VIII in a neutral solution showed the same specific rotation as that of an authentic sample[10] and the synthetic specimens of L-I and L-I·HCl exhibited specific rotations identical with the corresponding data for the natural product.[8]

In view of the stability and yield of the desired product, we suggest that route-b (Fig. 3) is preferable for the preparation of N'-hydroxy-L-lysine (L-I).

Experimental

All melting points were determined with a Yanagimoto electric micromelting point apparatus and are uncorrected. Optical rotations were measured with a Yanagimoto automatic polarimeter OR-50. The nuclear magnetic resonance spectra were run on a Varian HA-100 High Resolution NMR spectrometer, using tetramethylsilane as an internal standard. Infrared spectra were recorded on a Hitachi EPI-G3 spectrophotometer as KBr disk.

O-Benzyl-N-tosylhydroxyamine (III). This compound was prepared by the procedure reported.[6]

4-(N-Tosyl-N-benzyloxy)aminobutyl Bromide (IV). To a solution of sodium (20.8 g, 0.902 mol) in ethanol (1.2 l) was added III (250 g, 0.902 mol) with vigorous stirring at 70 °C. After a clear solution was obtained, 1,4-dibromobutane (583 g, 2.70 mol) was added at once. The mixture was refluxed for 6 hr, and evaporated *in vacuo* to give oily material, which was extracted with ethyl acetate (1.4 l), the organic layer being thoroughly washed with water and dried over sodium sulfate. Evaporation of the solvent afforded IV as oily material, which was crystallized from ethyl acetate–*n*-hexane; yield 320 g (86%), mp 56—59 °C.

Found: C, 52.29; H, 5.45; N, 3.21%. Calcd for $C_{18}H_{22}NO_3SBr$: C, 52.43; H, 5.38; N, 3.40%.

Diethyl 5-(N-Tosyl-N-benzyloxy)amino-1-acetamidopentane-1,1-dicarboxylate (V). To a solution of sodium (15.1 g, 0.657 mol) in ethanol (1.0 l) was added diethyl acetamidomalonate (143 g, 0.657 mol) with stirring. After 5 min, IV (271 g, 0.657 mol) was added and refluxed for 8 hr. The solvent was then removed *in vacuo* and the residue was extracted with chloroform (1.2 l). The chloroform layer was successively washed with water, diluted hydrochloric acid and water, dried over sodium sulfate, and evaporated to yield a pale yellow syrup which gave a negative Beilstein test; yield 302 g (84%). Attempts to crystallize the syrup were unsuccessful and it was used for the next step without analysis or purification.

N'-Tosyl-N'-benzyloxy-DL-lysine (DL-II). A solution of V (275 g, 0.502 mol) in a mixture of acetic acid (2.4 l) and concentrated hydrochloric acid (800 ml) was heated under gentle reflux for 8 hr. The solution was evaporated *in vacuo* and 14% aqueous ammonia was added to the residue with ice-cooling. The resulting solid was collected by filtration, washed with water, and recrystallized from aqueous acetic acid; yield 147 g (72%) and mp 178—185 °C (decomp.).

Found: C, 58.87; H, 6.21; N, 6.96%. Calcd for $C_{20}H_{26}N_2O_5S$: C, 59.09; H, 6.45; N, 6.89%.

The product showed blue coloration on heating with an

aqueous solution of ninhydrin.

N^{α}-*Acetyl*-N^{ε}-*tosyl*-N^{ε}-*benzyloxy*-DL-*lysine* (DL-*VI*). Acetic anhydride (40 g, 0.392 mol) was slowly added to a stirred solution of DL-II (121 g, 0.297 mol) in acetic acid (600 ml). After being stirred for 12 hr at room temperature, the solvent was evaporated *in vacuo*. Water was added to decompose excess acetic anhydride and the resulting mixture was extracted with ethyl acetate (600 ml). The organic layer was washed with water and dried over sodium sulfate. The residue obtained on evaporation of the solvent was crystallized from ethyl acetate–petroleum ether to give DL-VI as an amorphous powder; yield 119 g, (89%) and mp 139—141 °C. Recrystallization from ethyl acetate caused no rise in melting point.

Found: C, 58.95; H, 6.47; N, 6.01%. Calcd for $C_{22}H_{28}N_2O_6S$: C, 58.91; H, 6.29; N, 6.25%.

Resolution of N^{α}-*Acetyl*-N^{ε}-*tosyl*-N^{ε}-*benzyloxy*-DL-*lysine* (DL-*VI*); N^{α}-*Acetyl*-N^{ε}-*tosyl*-N^{ε}-*benzyloxy*-L-*lysine Anilide* (L-*VII*). DL-Acetylamino acid (DL-VI) (44.8 g, 0.10 mol) was dissolved in 0.75 M sodium hydroxide (350 ml) and the solution was adjusted to pH 6.20 with 0.5 M citric acid. Papain (15 g) was added to the solution together with freshly distilled aniline (12 ml) and cysteine hydrochloride monohydrate (5.5 g). The mixture was incubated for 36 hr at 38 °C and the anilide deposited was collected by suction and washed with water, 7% aqueous ammonia and water. Recrystallization from methanol–water (3:1) gave clorless crystals; yield 23 g (88%), mp 137—139 °C and $[\alpha]_D^{24}$ −48.6° (*c* 1.0, chloroform).

Found: C, 64.27; H, 6.47; N, 7.84%. Calcd for $C_{28}H_{33}N_3O_5S$: C, 64.22; H, 6.35; N, 8.02%.

N^{α}-*Acetyl*-N^{ε}-*tosyl*-N^{ε}-*benzyloxy*-D-*lysine* (D-*VI*). The above filtrate combined with the washings adjusted to pH 2 with 5 M hydrochloric acid. The precipitate was then collected by suction, washed with water and dried. Recrystallization from ethyl acetate gave colorless crystals; yield 16 g (71%), mp 155—157 °C and $[\alpha]_D^{22}$ −13.3° (*c* 1.0, chloroform).

Found: C, 58.74; H, 6.31; N, 6.10%. Calcd for $C_{22}H_{28}N_2O_6S$: C, 58.91; H, 6.29; N, 6.25%.

N^{ε}-*Tosyl*-N^{ε}-*benzyloxy*-L-*lysine* (L-*II*). L-VII (17.0 g, 32.5 mmol) was dissolved in a mixture of acetic acid (130 ml) and concentrated hydrochloric acid (50 ml). After being refluxed for 6 hr, the solution was evaporated *in vacuo* and aqueous ammonia was added to the residue with ice-cooling. The deposits were collected by suction, washed with water and dried. Recrystallization from dilute acetic acid and treatment with hot methanol gave an amorphous powder; yield 11.4 g (86%), mp 204—207 °C (decomp.) and $[\alpha]_D^{24}$ +18.4° (*c* 1.0, acetic acid).

Found: C, 58.88; H, 6.46; N, 6.66%. Calcd for $C_{20}H_{26}N_2O_5S$: C, 59.09; H, 6.45; N, 6.89%.

N^{ε}-*Tosyl*-N^{ε}-*benzyloxy*-D-*lysine* (D-*II*). This was obtained from D-VI by the method employed for the preparation of L-II; yield 80%, mp 199—204 °C (decomp.) and $[\alpha]_D^{22}$ −17.9° (*c* 1.0, acetic acid).

Found: C, 58.80; H, 6.36; N, 6.87%. Calcd for $C_{20}H_{26}N_2O_5S$: C, 59.09; H, 6.45; N, 6.89%.

N^{ε}-*Hydroxy*-L-*lysine* (L-*I*) (*prepared in route-a*). L-II (10 g, 24.6 mmol) was added at 5 °C to a solution of boron tris(trifluoroacetate) prepared from boron tribromide (66 g, 263 mmol) in trifluoroacetic acid (150 ml). The reaction mixture was then stirred for 48 hr at room temperature and evaporated *in vacuo* below 30 °C. Methanol was added to the residue to decompose excess boron tris(trifluoroacetate) and the mixture was evaporated *in vacuo*. To the oily residue was added 6 M hydrochloric acid (250 ml) and the mixture was refluxed for 1 hr. Insoluble brown material was filtered off and the filtrate was concentrated *in vacuo*. Colorless crystals further precipitated were removed by suction and the filtrate was evaporated to dryness. The semi solid thus obtained was dissolved in ethanol (20 ml) and the solution was adjusted to pH 6—7 with 14% aqueous ammonia to yield a crude solid. The substance was reprecipitated from aqueous solution by adding ethanol and collected by suction. Procedures of neutralization with aqueous ammonia, reprecipitation, and collection by suction should be carried out as quickly as possible to avoid decomposition of hydroxyamine. L-I was obtained as an amorphous solid; yield 2.3 g (58%), mp 223—226 °C (decomp.) and $[\alpha]_D^{24}$ +24.2° (*c* 0.5, M hydrochloric acid).

Found: C, 45.38; H, 8.29; N, 17.19%. Calcd for $C_6H_{14}N_2O_3$: C, 44.43; H, 8.70; N, 17.27%.

The product showed a deep red coloration with alkaline triphenyltetrazolium chloride and an intense blue coloration with ninhydrin, and was negative to the Beilstein test. Successive purification caused the decomposition of hydroxyamine.

Preparation of 2-Nitroindane-1,3-dione Salt of L-*I*. The crystalline 2-nitroindane-1,3-dione salt was prepared by dissolution of L-I (100 mg) in hot water (7 ml) containing 2-nitroindane-1,3-dione (100 mg), followed by slow cooling of the resulting solution. The product (85 mg) was recrystallized twice from water to yield the salt as pale brown crystals; mp 217—218 °C (decomp.) (lit,[8] mp 217.0—217.5 °C (decomp.)).

Found: C, 50.91; H, 5.32; N, 11.75%. Calcd for $C_{15}H_{19}N_3O_7$: C, 50.98; H, 5.42; N, 11.89%.

N^{ε}-*Benzyloxy*-L-*lysine* (L-*VIII*). L-II (4.06 g, 10 mmol) was added at room temperature to a 20 ml solution of 36% hydrogen bromide in acetic acid and phenol (4 g) in a glass-stoppered bottle. After being stirred for 48 hr, the solution was evaporated *in vacuo* at a temperature below 35 °C. The residual syrup was extracted with water and the aqueous layer was washed repeatedly with ether, treated with activated carbon and evaporated *in vacuo* at a temperature below 35 °C. The residue was dissolved in water (5 ml) and adjusted to pH 7—8 with aqueous ammonia to yield a crude solid. Recrystallization from hot water gave L-VIII as a leaflet; yield 1.8 g (73%), mp 238—241 °C (decomp.) and $[\alpha]_D^{23}$ +18.1° (*c* 1.0, M hydrochloric acid).

Found: C, 61.83; H, 7.98; N, 11.21%. Calcd for $C_{13}H_{20}N_2O_3$: C, 61.88; H, 7.99; N, 11.11%.

The NMR spectrum in trifluoroacetic acid showed a multiplet at δ 1.90 (4H; β,γ-CH_2), a multiplet at δ 2.18 (2H; δ-CH_2), a multiplet at δ 3.51 (2H; ε-CH_2), a multiplet at δ 4.36 (1H; α-CH), a singlet at δ 5.19 (2H; BZL-CH_2), a sharp signal at δ 7.46 (8H; α-NH_3^+ and BZL-C_6H_5), and a broad signal at δ 9.57 (2H; ε-NH_2^+).

N^{ε}-*Hydroxy*-L-*lysine Monohydrochloride* (L-*I*·*HCl*) (*prepared in route-b*). A solution of L-VIII (500 mg, 1.98 mmol) in 0.5 M hydrochloric acid (20 ml) was hydrogenolyzed over 5% palladium on carbon (500 mg) at room temperature and atmospheric pressure for 24 hr. After the catalyst was removed by suction, the solution was evaporated to dryness. The residue was dissolved in water and again evaporated to dryness to eliminate excess hydrochloric acid and then dissolved in water (2 ml). The pH of this solution was brought to 4—5 by addition of pyridine. Addition of ethanol (4 ml) to the resulting solution gave a colorless solid, which was reprecipitated from aqueous solution by adding ethanol to afford L-I·HCl as an amorphous powder; yield 350 mg (89%), mp 192—194 °C (decomp.) and $[\alpha]_D^{24}$ +25.5° (*c* 0.22, M hydrochloric acid).

Found: C, 36.41; H, 7.61; N, 14.13%. Calcd for $C_6H_{15}N_2O_3Cl$: C, 36.27; H, 7.61; N, 14.10%.

The product showed a deep red coloration with alkaline triphenyltetrazolium chloride and a blue coloration with ninhydrin, and was positive to the Beilstein test.

Figure 4 shows the NMR spectrum of the synthesized L-I·HCl in trifluoroacetic acid with tetramethylsilane as an internal standard; δ 1.98 (4H; β,γ-CH_2), 2.27 (2H; δ-CH_2), 3.58 (2H; ε-CH_2), 4.44 (1H; α-CH), 7.53 (3H; α-NH_3^+), and 9.95 (2H; ε-NH_2^+).

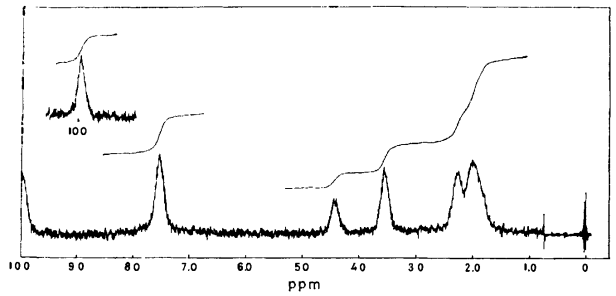

Fig. 4. NMR spectrum of N^{ε}-hydroxy-L-lysine monohydrochloride (L-I·HCl).

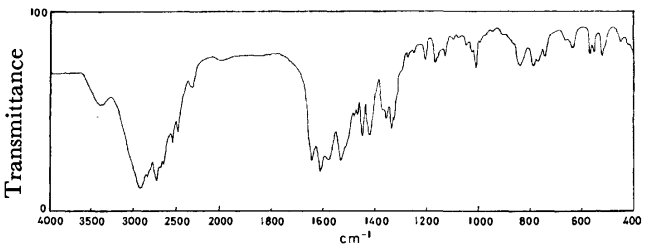

Fig. 5. Infrared spectrum of N^{ε}-hydroxy-L-lysine monohydrochloride (L-I·HCl).

A very close similarity to N^{δ}-hydroxy-L-ornithine monohydrochloride was observed in the IR spectrum (Fig. 5).

Hydrogenation of N^{ε}*-Benzyloxy-L-lysine (L-VIII) in a Neutral Solution.* A solution of L-VIII (200 mg, 0.79 mmol) in a mixture of methanol (10 ml) and water (5 ml) was hydrogenolyzed over 5% palladium on carbon (100 mg) at room temperature under atmospheric pressure for 48 hr. To the mixture was added M hydrochloric acid (5 ml) and the catalyst was filtered off. The filtrate was evaporated, adjusted to pH 5—6 by addition of pyridine and further evaporated. The residue solidified by addition of ethanol was reprecipitated from its aqueous solution by addition of ethanol to yield L-lysine monohydrochloride; yield 74 mg (51%), mp 259—263 °C (decomp., undepressed by admixture with an authentic sample[10]) and $[\alpha]_D^{22}$ +21.4° (*c* 0.38, M hydrochloric acid) (the authentic sample, $[\alpha]_D^{22}$ +20.7° (*c* 0.34, M hydrochloric acid)).

Studies of Acyl and Thioacyl Isocyanates. XIV.[1] The Reactions of Benzoyl and Thiobenzoyl Isocyanates with Hydrazones

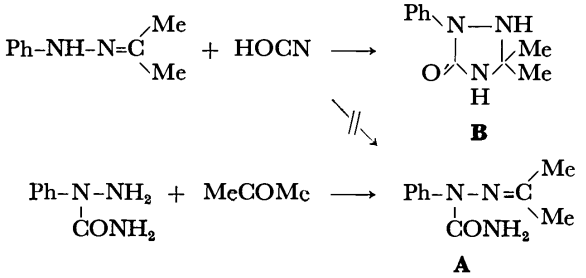
Otohiko TSUGE* and Shuji KANEMASA

Research Institute of Industrial Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received April 30, 1974)

Benzoyl (**1**) and thiobenzoyl isocyanates (**2**) reacted with benzaldehyde arylhydrazones and methylhydrazone to give the corresponding semicarbazones as isolated products respectively. In the reactions with acetone arylhydrazones and methylhydrazone, however, the *s*-triazolidin-5-ones whose structures corresponded to the ring tautomers of semicarbazones, were isolated as sole products from the reaction of **1**, and **2** afforded the (4+2) cycloadducts of **2** to the C=N bond of hydrazones and *s*-triazolidin-5-ones. It has been found that in some cases, the semicarbazones isomerize into their ring tautomers, and the isomerization obeys good first-order kinetics taking into account the equilibrium. Although **1** did not react with *p*-tosyl- and benzoylhydrazones, **2** easily added to both hydrazones to yield the corresponding (4+2) cycloadducts.

In a previous paper[2] dealing with the reactions of benzoyl (**1**) and thiobenzoyl isocyanates (**2**) with hydrazines, we reported that **1** reacted with phenylhydrazine to give 1-phenyl-4-benzoylsemicarbazide, while the reaction of **2** with the same hydrazine gave 1,3-diphenyl-Δ^3-triazolin-5-one under the elimination of hydrogen sulfide. It has been also described that the Δ^3-triazolin-5-one was identical with the hydrolytic product of adducts of **1** to benzaldehyde phenylhydrazone (**3a**) and acetone phenylhydrazone (**4a**), and the adducts would be the corresponding 4-benzoyl-2-phenylsemicarbazones, respectively. It has been clarified by Schildknecht and Hatzmann,[3] however, that an adduct[4,5] of cyanic acid to **4a** is not acetone 2-phenylsemicarbazone (**A**) but its ring tautomer, 3,3-dimethyl-1-phenyl-*s*-triazolidin-5-one (**B**), while a product[6] obtained from 2-phenylsemicarbazide and acetone is the semicarbazone (**A**).

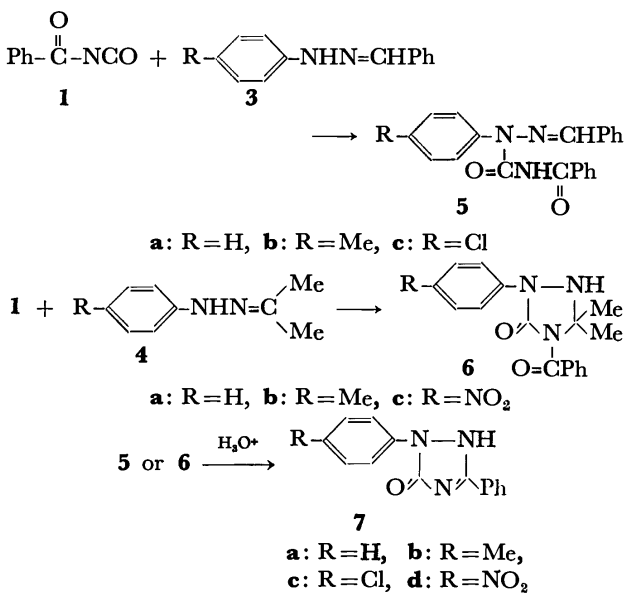


Consequently, we were obliged to reinvestigate whether the products obtained by the reaction of **1** with **3a** and **4a** would be really the corresponding 4-benzoyl-2-phenylsemicarbazones. It has been now proved that the adduct to **4a** is not the semicarbazone but its ring tautomer, although the adduct to **3a** is the semicarbazone. This fact seems to indicate that **1** might react with hydrazone to afford either the semicarbazone or its ring tautomer depending on the nature of carbonyl component of hydrazone. On the other hand, little attention has been paid to the reaction of **2** with hydrazones. Since the reactivity of **2** in 1,4-cycloaddition to C=N bonds is greater than that of **1**,[7-10] the reaction of **2** with hydrazone might be expected to give a (4+2) cycloadduct, besides the semicarbazone and its ring tautomer.

This paper deals with the reactions of **1** and **2** with aryl- and methylhydrazones of benzaldehyde and acetone. In this context, the reactions with *p*-tosyl- and benzoylhydrazones are also described.

Results and Discussion

Reactions with Benzaldehyde and Acetone Arylhydrazones. Benzoyl isocyanate (**1**) reacted with benzaldehyde phenylhydrazone (**3a**) and with acetone phenylhydrazone (**4a**) to give the corresponding 1 : 1 adducts, **5a** and **6a**, in excellent yields, respectively. The IR spectrum of **5a** showed well-defined absorption bands at 3460 (NH), 1760 (C=O), 1510 and 1490 cm^{-1} (Amide II), and the NMR spectrum in deuteriochloroform ($CDCl_3$) exhibited signals at δ 7.1—8.1 (16H, m, aromatic protons and N=C**H**) and 10.55 ppm (1H, broad, N**H**). On the other hand, the IR spectrum of **6a** showed no bands assignable to Amide II absorptions, but displayed characteristic bands at 3190 (NH), 1740, 1640 (C=O), 1330, and 1310 cm^{-1}. In the NMR spectrum in $CDCl_3$ signals appeared at δ 1.70 (6H, s, C**H**$_3$), 4.6 (1H, broad, N**H**), and 6.9—7.8 ppm (10H, m, aromatic protons). These spectral data indicate that **5a** is an adduct of different type from **6a**, although



Scheme 1.

* To whom correspondence should be addressed.

hydrolyses of both **5a** and **6a** gave the same product, 1,3-diphenyl-Δ^3-*s*-triazolin-5-one (**7a**), whose structure was established by the identification with an authentic sample.[2]

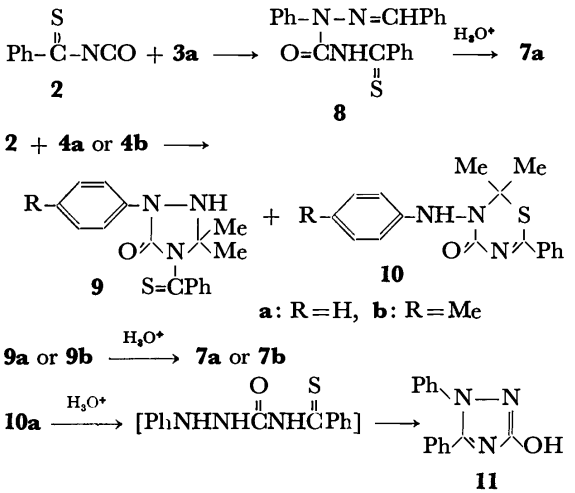
Schildknecht and Hatzmann[3] reported that in the NMR spectra in $CDCl_3$ acetone 2-phenylsemicarbazone (**A**) showed two singlets (each 3H) assignable to two methyls-protons at δ 1.63 and 2.1 ppm, while two methyls-protons of 3,3-dimethyl-1-phenyl-*s*-triazolidin-5-one (**B**) appeared as a singlet (6H) at δ 1.46 ppm. As mentioned above, **6a** exhibited a singlet (6H) due to two methyls-protons in the spectrum.

On the basis of the spectral data and of the results of hydrolysis, the structures of **5a** and **6a** were deduced as benzaldehyde 4-benzoyl-2-phenylsemicarbazone and 4-benzoyl-3,3-dimethyl-1-phenyl-*s*-triazolidin-5-one, respectively.

Similarly, the reaction of **1** with benzaldehyde *p*-tolyl- (**3b**) and *p*-chlorophenylhydrazones (**3c**) gave the corresponding semicarbazones, **5b** and **5c**, while the *s*-triazolidin-5-ones, **6b** and **6c**, were obtained in the reaction with acetone *p*-tolyl- (**4b**) and *p*-nitrophenylhydrazones (**4c**). On treatment with hydrochloric acid, all **5** and **6** were converted into the corresponding Δ^3-*s*-triazolin-5-ones, **7b**—**7d**, in good yields respectively (Scheme 1).

The reaction of thiobenzoyl isocyanate (**2**) with **3a** afforded benzaldehyde 2-phenyl-4-thiobenzoylsemicarbazone (**8**), whose structure was confirmed on the basis of its spectral data. Hydrolysis of **8** gave Δ^3-*s*-triazolin-5-one **7a**. In the reaction with **4a**, however, two 1:1 adducts, **9a** and **10a**, were obtained in 19 and 60% yields, respectively.

The minor product **9a** was deduced to be 3,3-dimethyl-1-phenyl-4-thiobenzoyl-*s*-triazolidin-5-one on the basis of the following evidence. The IR spectrum of **9a** was quite similar to that of **6a**, and in its NMR spectrum two methyls-protons and NH-proton appeared at δ 1.89 (6H, s) and 4.95 ppm (1H, broad), besides aromatic protons. Treatment of **9a** with hydrochloric acid gave Δ^3-*s*-triazolin-5-one **7a**. On the other hand, the IR spectrum of major product **10a** exhibited characteristic bands at 3310 (NH), 1650 (C=O), and 1530 cm^{-1}, and the NMR spectrum showed signals at



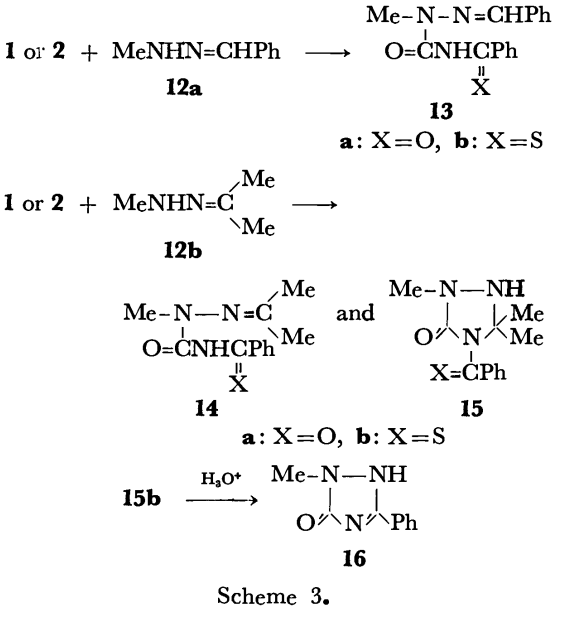
Scheme 2.

δ 1.80 (6H, s, CH_3) and 6.5 ppm (1H, broad, NH), besides aromatic protons. Hydrolysis of **10a** afforded 3-hydroxy-1,5-diphenyltriazole (**11**), whose structure corresponds to that of the compound derived from 1-phenyl-4-thiobenzoylsemicarbazide with the elimination of hydrogen sulfide. The structure of **11** was confirmed by the identification with an authentic sample.[2] On the basis of the above observations, the structure of **10a** was deduced as 3-anilino-2,2-dimethyl-6-phenyl-2,3-dihydro-4H-1,3,5-thiadiazin-4-one, which corresponds to the (4+2) cycloadduct of **2** to the C=N bond of **4a**.

Similarly, **2** reacted with **4b** to give the corresponding *s*-triazolidin-5-one **9b** and 2,3-dihydro-4*H*-1,3,5-thiadiazin-4-one **10b** in 32 and 29% yields, respectively.

Reactions with Benzaldehyde and Acetone Methylhydrazones. The reactions of both isocyanates **1** and **2** with benzaldehyde methylhydrazone (**12a**) afforded the corresponding semicarbazones **13a** and **13b**, whose structures were confirmed on the basis of their spectral data, in good yields respectively.

By the IR and NMR spectroscopic studies it was found that the crystals obtained from the reaction of **1** with acetone methylhydrazone (**12b**) were a mixture of the corresponding semicarbazone **14a** and its ring tautomer **15a**, but no **14a** could be isolated and **15a** was obtained as the sole pure compound from the mixture. Furthermore, the relative amount of **15a** was increased with an increase in the reaction time. Similar phenomena were observed in the reaction of **2** with **12b**, and *s*-triazolidin-5-one **15b**, which on hydrolysis gave 1-methyl-3-phenyl-Δ^3-*s*-triazolin-5-one (**16**), was only isolated (Scheme 3).



Scheme 3.

The above observations indicate that semicarbazones **14a** and **14b** isomerize into the corresponding ring tautomers **15a** and **15b**, respectively. Consequently, the isomerization was followed by the NMR spectroscopy.

Isocyanate **1** was mixed with **12b** in chloroform at −70 °C, and the NMR spectrum of the reaction mix-

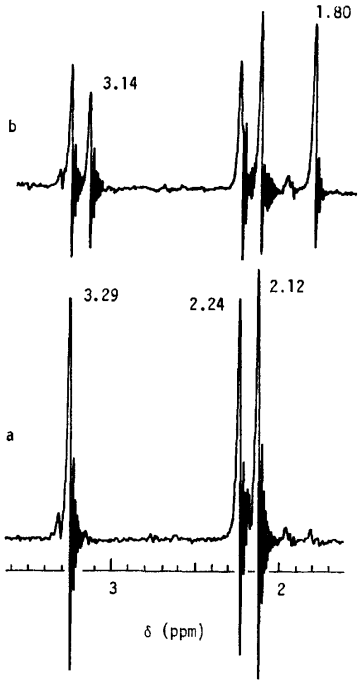


Fig. 1. NMR spectra of the reaction system **1**—**12b** in chloroform at 36.0 °C. a: Pure **14a**. b: A mixture of **14a** and **15a** (44%) after 2.5 hr.

ture was immediately measured at a constant temperature. For example, the NMR spectrum at 36.0 °C is illustrated in Fig. 1-a: three singlets appear at δ 2.12, 2.24, and 3.29 ppm in the same intensity. The singlets at δ 2.12 and 2.24 ppm can be assigned as two methyls-protons of isopropylidene group and that at δ 3.29 is ascribable to the *N*-methyl-protons in the semicarbazone **14a**.[11] The spectrum changes with time. As shown in Fig. 1-b, the initial three singlets decrease in intensity in the same ratio, and new two singlets with the relative intensity of 2: 1 show up at δ 1.80 and 3.14. These new two singlets can be assigned as the 3,3-dimethyls- and *N*-methyl-protons in the *s*-triazolidin-5-one **15a**, respectively. Furthermore, it was found by the IR spectrum that the crude product obtained from the reaction of **1** with **12b** at 0 °C was composed of **14a** and **15a**, and the microanalysis of the product agreed with that of a 1: 1 adduct of **1** to **12b**. These facts indicate clearly that the initial semicarbazone **14a** isomerizes into its ring tautomer **15a**. It was also established that both the isomerizations at 36.0 and 54.0 °C give the equilibrium composition composed of 40% of **14a** and 60% of **15a** after some time.

The first-order rate of the isomerization of **14a** taking into account the equilibrium may be expressed as follows:

$$dx/dt = k(a-x) - k'x \quad (1)$$

where a is the initial concentration of **14a**, x is the concentration of **14a** consumed after t s, and k and k' are the rate constants of the consumption and the formation of **14a** respectively.

If the concentration of **15a** at the equilibrium is x_e,

$$k(a-x_e) - k'x_e = 0 \quad (2)$$

From Eqs. (1) and (2), the rate of the consumption of **14a** may be given by:

$$dx/dt = ka(x_e-x)/x_e \quad (3)$$

Equation (3) then gives:

$$\ln [x_e/(x_e-x)] = kat/x_e$$

As illustrated in Fig. 2, the plots of $\ln[x_e/(x_e-x)]$ *vs.* the reaction times at various temperatures show straight lines. The rate constants k at 30.5, 36.0, 45.5, and 54.0 °C were 4.2×10^{-5}, 9.3×10^{-5}, 2.2×10^{-4}, and 4.0×10^{-4} s^{-1}, respectively. The plots of the logarithm of the rate constants against reciprocal absolute temperatures showed the straight line. The rate of isomerization of **14a** in benzene at 36.0 °C was measured, and the rate constant k was found to be 1.1×10^{-4} s^{-1}: little solvent effect was observed.

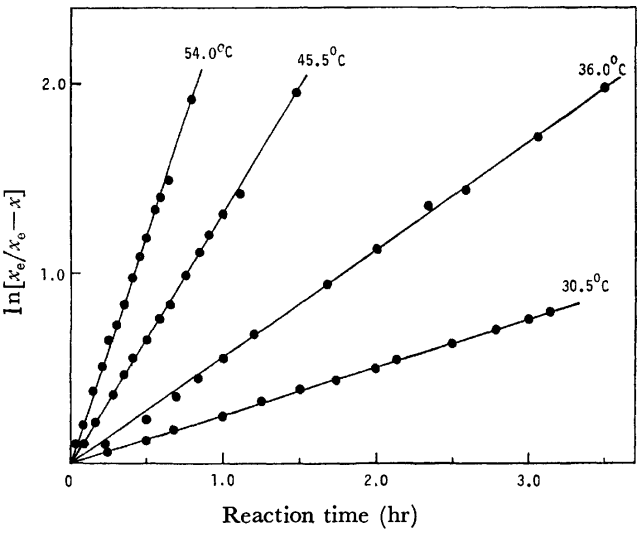

Fig. 2. Plots of the first-order function *vs.* reaction time at various temperatures in the reaction system **1**—**12b**.

The energy parameters calculated on the basis of the above observations are given in Table 1.

It was also clarified by the NMR spectroscopic study that acetone 4-benzoyl-2-phenylsemicarbazone is initially formed in the reaction of **1** with acetone phenylhydrazone (**4a**), and isomerizes into its ring tautomer **6a** with reaction time. The isomerization obeys good first-order kinetics, and the energy parameters and the concentration of **6a** at the equilibrium are also summarized in Table 1.

Table 1. Energy parameters

Parameter[a]	Reaction system	
	1—**12b**	**1**—**4a**
E_a(kcal/mol)	19.2	18.6
A(s^{-1})	3.39×10^9	2.14×10^9
$\Delta H^{\ddagger}_{25}$(kcal/mol)	18.6	18.0
$\Delta S^{\ddagger}_{25}$(cal/mol·deg)	−17.0	−17.7
$\Delta F^{\ddagger}_{25}$(kcal/mol)	23.67	23.27
x_e (%) in $CHCl_3$	60	*ca.* 100

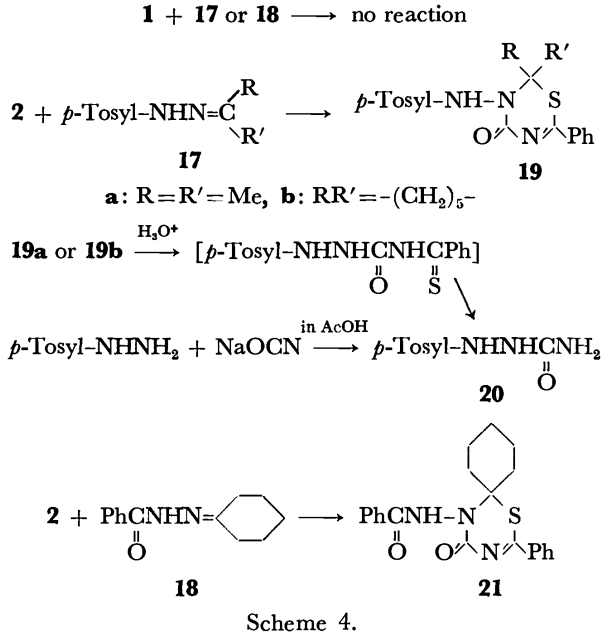
a) E_a: Activation energy; A: Frequency factor; $\Delta H^{\ddagger}_{25}$: Enthalpy of activation at 25 °C; $\Delta S^{\ddagger}_{25}$: Entropy of activation at 25 °C; $\Delta F^{\ddagger}_{25}$: Free energy of activation at 25 °C; x_e: Concentration of *s*-triazolidin-5-one **15a** or **6a** at the equilibrium.

However, semicarbazones **13a** and **13b** did not isomerize into their ring tautomers and were recovered quantitatively even at 80 °C.

Reactions with p-*Tosyl- and Benzoylhydrazones.* On the basis of the results mentioned above, it could be viewed that **1** attacks exclusively the more basic nitrogen atom, and **2** reacts with the more and/or the less basic nitrogen atom of hydrazone. It is then expected that both **1** and **2** would give the (4+2) cycloadducts as predominant products in the reaction with hydrazones having electronwithdrawing groups such as *p*-tosyl and benzoyl.

However, **1** did not react with *p*-tosylhydrazones, **17a** and **17b**, and cyclohexanone benzoylhydrazone (**18**) even when the reaction was carried out under reflux in benzene.

The reaction of **2** with *p*-tosylhydrazones, **17a** and **17b**, afforded the corresponding (4+2) cycloadducts, **19a** and **19b**, whose structures were confirmed on the basis of their spectral data and of the result of hydrolysis.



Scheme 4.

Hydrolyses of both **19a** and **19b** afforded 1-*p*-tosylsemicarbazide (**20**), which was identical with an authentic sample prepared from *p*-tosylhydrazine and cyanic acid.

Similarly, **2** reacted with benzoylhydrazone **18** to give the corresponding (4+2) cycloadduct **21** (Scheme 4).

Experimental

All melting and boiling points are uncorrected. The IR spectra were measured as KBr disks, and NMR spectra were determined at 60 MHz with a Hitachi R-20 NMR spectrometer with TMS as an internal reference.

Materials. Benzoyl isocyanate (**1**) was prepared by the reported method.[12] Thiobenzoyl isocyanate (**2**): a solution of 1.0 g of 2-phenylthiazoline-4,5-dione in 10 ml of xylene was heated at 120 °C, giving a reddish violet solution of **2** which was used *in situ*.[13] This solution is referred to as the standard solution of **2**.

Hydrazones were prepared by the reaction of the corresponding hydrazine with carbonyl coumpounds. Benzaldehyde phenyl- (**3a**), mp 152 °C [lit,[14] mp 152.5 °C]; *p*-tolyl- (**3b**), mp 125 °C [lit,[15] mp 125 °C]; *p*-chlorophenylhydrazone (**3c**), mp 129—130 °C [lit,[16] mp 127 °C]; acetone phenyl- (**4a**)- mp 32 °C [lit,[17] mp 21 °C]; *p*-tolyl- (**4b**), mp 51—52 °C [lit,[18] mp 50—52 °C]; *p*-nitrophenylhydrazone (**4c**), mp 149 °C [lit,[19] mp 148—148.5 °C]; benzaldehyde methylhydrazone (**12a**), viscous liquid, NMR ($CDCl_3$) δ: 2.76 (3H, s, N-C**H**$_3$), 5.61 (1H, s, =C**H**), 7.1—7.6 (6H, m, aromatic and N**H**); acetone methylhydrazone (**12b**), bp 115—117 °C, NMR ($CDCl_3$) δ: 1.73, 1.89 (each 3H, s, C**H**$_3$), 2.85 (3H, s, N-C**H**$_3$), 4.32 (1H, broad, N**H**); acetone *p*-tosyl- (**17a**), mp 150 °C [lit,[20] mp 153 °C]; cyclohexanone *p*-tosylhydrazone (**17b**), mp 158 °C [lit,[20] mp 156 °C]; cyclohexanone benzoylhydrazone (**18**), mp 158—159 °C [lit,[21] mp 158—159 °C].

Reaction of 1 with 3a. To a solution of 2.0 g of **3a** in 20 ml of benzene was added 1.5 g of **1** at 0 °C, and then the reaction mixture was stirred at room temperature for 30 min: during which time crystals precipitated. Filtration gave 1.4 g of crystals. The filtrate was evaporated *in vacuo* to leave 2.0 g of crystals. Recrystallization of the combined crystals (3.5 g, 97%) from ethanol afforded 4-benzoyl-2-phenylsemicarbazone (**5a**), mp 164 °C, as colorless needles.

Found: C, 73.32; H, 5.01; N, 12.33%. Calcd for $C_{21}H_{17}N_3O_2$: C, 73.45; H, 4.99; N, 12.24%.

Similarly, **1** reacted with **3b** and **3c** under the same conditions, giving the corresponding semicarbazones quantitatively.

4-Benzoyl-2-*p*-tolylsemicarbazone (**5b**): mp 175—176 °C, colorless needles.

Found: C, 74.21; H, 5.20; N, 11.75%. Calcd for $C_{22}H_{19}N_3O_2$: C, 73.93; H, 5.36; N, 11.75%.

IR: 3380 (NH), 1755 (C=O), 1500 and 1480 cm^{-1} (Amide II).

4-Benzoyl-2-*p*-chlorophenylsemicarbazone (**5c**): mp 177—178 °C, colorless needles.

Found: C, 67.02; H, 4.12; N, 11.14%. Calcd for $C_{21}H_{16}N_3O_2Cl$: C, 66.75; H, 4.24; N, 11.13%.

IR: 3380 (NH), 1750 (C=O), 1500 and 1480 (Amide II).

Reaction of 1 with 4b. To a solution of 4.0 g of **4b** in 20 ml of benzene was added 3.6 g of **1** at 0 °C, and the reaction mixture was stirred at room temperature for 30 min. The mixture was concentrated *in vacuo* to give resinous material, which on trituration with petroleum ether (bp 35—50 °C) crystallized. Recrystallization from ethanol gave 6.8 g (90%) of 4-benzoyl-3,3-dimethyl-1-*p*-tolyl-*s*-triazolidin-5-one (**6b**), mp 161—162 °C (decomp.), as colorless prisms.

Found: C, 70.17; H, 6.22; N, 13.55%. Calcd for $C_{18}H_{19}N_3O_2$: C, 69.88; H, 6.19; N, 13.58%.

IR: 3250 (NH), 1750, 1655 (C=O) and 1320 cm^{-1}. NMR ($CDCl_3$) δ: 1.70 (6H, s, C**H**$_3$), 2.28 (3H, s, -C_6H_4C**H**$_3$), 4.1 (1H, broad, N**H**), 7.0—7.7 (9H, m, aromatic protons).

Similarly, the reaction of **1** with **4a** and **4c** under the same conditions gave the corresponding *s*-triazolidin-5-ones in almost quantitative yields, respectively.

4-Benzoyl-3,3-dimethyl-1-phenyl-*s*-triazolidin-5-one (**6a**): mp 140.5—141 °C (decomp.), colorless prisms.

Found: C, 69.31; H, 6.02; N, 14.12%. Calcd for $C_{17}H_{17}N_3O_2$: C, 69.13; H, 5.80; N, 14.23%.

4-Benzoyl-3,3-dimethyl-1-*p*-nitrophenyl-*s*-triazolidin-5-one (**6c**): mp 203.5 °C (decomp.), pale yellow prisms.

Found: C, 59.95; H, 4.52; N, 16.52%. Calcd for $C_{17}H_{16}N_4O_4$: C, 59.99; H, 4.74; N, 16.46%.

IR: 3230 (NH), 1750, 1660 (C=O) and 1320 cm^{-1}.

Hydrolysis of 5a. A solution of 0.3 g of **5a** in 10 ml of 15% hydrochloric acid was heated at 100 °C for 1 hr. After cooling, filtration gave crystals. Recrystallization from

ethanol afforded 0.24 g (100%) of 1,3-diphenyl-Δ^3-*s*-triazolin-5-one (**7a**), mp 230—231 °C, which was identical with an authentic sample.[2]

Similarly, hydrolysis of **5b**, **5c**, and **6a**—**6c** with hydrochloric acid afforded the corresponding Δ^3-*s*-triazolin-5-ones in good yields, respectively. 1-*p*-Tolyl- (**7b**), mp 232.5 °C [lit,[2] mp 232.5 °C], 1-*p*-chlorophenyl- (**7c**), mp 273 °C [lit,[2] mp 273 °C], and 1-*p*-nitrophenyl-3-phenyl-Δ^3-*s*-triazolin-5-one (**7d**), mp 329—330 °C [lit,[2] mp 329—330 °C], were identified with the respective authentic samples.[2]

Reaction of 2 with 3a. To a standard solution of **2** was added 1.0 g of **3a** at 0 °C: crystals precipitated immediately. Filtration gave pale yellow crystals, which on recrystallization from ethanol afforded 1.5 g (79% yield based on 2-phenylthiazoline-4,5-dione used) of 2-phenyl-4-thiobenzoylsemicarbazone (**8**), mp 163—163.5 °C (decomp.), as pale yellow prisms.

Found: C, 70.38; H, 4.62; N, 11.48%. Calcd for $C_{21}H_{17}N_3OS$: C, 70.18; H, 4.77; N, 11.69%.

IR: 3400 (NH), 1720 (C=O) and 1460 cm^{-1} (Amide II). NMR ($CDCl_3$) δ: 7.1—7.9 (16H, m, aromatic and N=C**H**), 11.5 (1H, broad, N**H**).

Reaction of 2 with 4a. To a standard solution of **2** was added 0.78 g of **4a** at 0 °C, and the reaction mixture was stirred at room temperature for 1 hr: during which time crystals appeared. Filtration gave crystals, which on recrystallization from acetone afforded 0.97 g (60%) of 3-anilino-2,2-dimethyl-6-phenyl-2,3-dihydro-4*H*-1,3,5-thiadiazin-4-one (**10a**), mp 124—125 °C (decomp.), as yellow prisms.

Found: C, 65.54; H, 5.40; N, 13.72%. Calcd for $C_{17}H_{17}N_3OS$: C, 65.58; H, 5.50; N, 13.50%.

The filtrate was concentrated *in vacuo* below 15 °C to leave a residue, which on trituration with diethyl ether gave crystals. Recrystallization from ethanol afforded 0.31 g (19%) of 3,3-dimethyl-1-phenyl-4-thiobenzoyl-*s*-triazolin-5-one (**9a**), mp 141 °C (decomp.), as yellow needles.

Found: C, 65.64; H, 5.26; N, 13.77%. Calcd for $C_{17}H_{17}N_3OS$: C, 65.58; H, 5.50; N, 13.50%.

IR: 3270 (NH), 1720 (C=O) and 1350 cm^{-1}.

Similarly, the reaction of **2** with **4b** afforded the corresponding 1:1 adducts, **9b** and **10b**, in 32 and 29% yields, respectively.

3,3-Dimethyl-4-thiobenzoyl-1-*p*-tolyl-*s*-triazolidin-5-one (**9b**): mp 151.5—152 °C (decomp.), yellow needles.

Found: C, 66.69; H, 5.90; N, 13.00%. Calcd for $C_{18}H_{19}N_3OS$: C, 66.44; H, 5.89; N, 12.92%.

IR: 3260 (NH), 1720 (C=O), 1340 and 1330 cm^{-1}. NMR ($CDCl_3$) δ: 1.90 (6H, s, C**H**$_3$), 2.30 (3H, s, -C_6H_4C**H**$_3$), 5.05 (1H, broad, N**H**), 7.0—7.8 (9H, m, aromatic protons).

2,2-Dimethyl-3-*p*-methylanilino-6-phenyl-2,3-dihydro-4*H*-1,3,5-thiadiazin-4-one (**10b**): mp 115—116 °C (decomp.), yellow prisms.

Found: C, 66.58; H, 5.93; N, 12.89%. Calcd for $C_{18}H_{19}N_3OS$: C, 66.44; H, 5.89; N, 12.92%.

IR: 3310 (NH), 1660 (C=O), 1550 and 1520 cm^{-1}. NMR ($CDCl_3$) δ: 1.80 (6H, s, C**H**$_3$), 2.26 (3H, s, -C_6H_4C**H**$_3$), 6.4 (1H, broad, N**H**), 6.8—7.6 (7H, m, aromatic protons), 8.0—8.3 (2H, m, *o*-protons of 6-phenyl).

Hydrolysis of 10a. A solution of 1.5 g of **10a** in 20 ml of methanol was refluxed with concentrated hydrochloric acid (5 ml) for 30 min. The mixture was concentrated *in vacuo* to leave a residue, which on trituration with aqueous ethanol gave crystals. Recrystallization from ethanol afforded 0.79 g (69%) of 3-hydroxy-1,5-diphenyl-*s*-triazole (**11**), mp 290 °C [lit,[2] mp 290 °C], as colorless needles.

Reaction of 1 with 12a. To a solution of 1.34 g of **12a** in 10 ml of benzene was added 1.47 g of **1** at 0 °C, and then the reaction mixture was stirred at room temperature for 30 min. The mixture was concentrated *in vacuo* to leave a residue, which on trituration with petroleum ether (bp 40—60 °C) gave crystals. Recrystallization from a mixture of benzene and petroleum ether (bp 60—80 °C) afforded 2.4 g (86%) of benzaldehyde 4-benzoyl-2-methylsemicarbazone (**13a**), mp 137—138 °C (decomp.), as colorless needles.

Found: C, 68.54; H, 5.23; N, 14.90%. Calcd for $C_{16}H_{15}N_3O_2$: C, 68.31; H, 5.38; N, 14.94%.

IR: 3450 (NH), 1745 (C=O), 1510 and 1490 cm^{-1} (Amide II). NMR ($CDCl_3$) δ: 3.43 (3H, s, N-C**H**$_3$), 7.3—8.0 (11H, m, aromatic and N=C**H**), 10.45 (1H, broad, N**H**).

Similarly, the reaction of a standard solution of **2** with **12a** gave the 2-methyl-4-thiobenzoylsemicarbazone **13b**, mp 146—147 °C (decomp.), in 74% yield.

Found: C, 64.61; H, 4.95; N, 13.94%. Calcd for $C_{16}H_{15}N_3OS$: C, 64.63; H, 5.09; N, 14.14%.

IR: 3370 (NH), 1735 (C=O) and 1505 cm^{-1} (Amide II). NMR ($CDCl_3$) δ: 3.41 (3H, s, N-C**H**$_3$), 7.3—7.9 (11H, m, aromatic and N=C**H**), 11.4 (1H, broad, N**H**).

Reaction of 1 with 12b. To a solution of 0.86 g of **12b** in 15 ml of benzene was added 1.47 g of **1**, and then the reaction mixture was stirred at room temperature for 10 hr. The mixture was concentrated *in vacuo* to leave a residue, which on trituration with petroleum ether (bp 40—60 °C) gave crystals. The crystals were washed with benzene and then diethyl ether to afford 1.65 g (71%) of 4-benzoyl-1,3,3-trimethyl-*s*-triazolidin-5-one (**15a**), mp 105.5—107 °C (decomp.).

Found: C, 61.78; H, 6.33; N, 18.27%. Calcd for $C_{12}H_{15}N_3O_2$: C, 61.78; H, 6.48; N, 18.02%.

IR: 3230 (NH), 1735 and 1645 cm^{-1} (C=O). NMR ($CDCl_3$) δ: 1.80 (6H, s, C**H**$_3$), 3.14 (3H, s, N-C**H**$_3$), 4.5 (1H, broad, N**H**), 7.3—7.9 (5H, m, aromatic protons).

Similarly, the reaction of a standard solution of **2** with **12b** at 0 °C for 10 min afforded 67% yield of the corresponding *s*-triazolidin-5-one **15b**, mp 106.5—107.5 °C (decomp.), as yellow needles.

Found: C, 57.97; H, 5.89; N, 17.09%. Calcd for $C_{12}H_{15}N_3OS$: C, 57.82; H, 6.07; N, 16.86%.

IR: 3240 (NH) and 1735 cm^{-1} (C=O).

Hydrolysis of 15b. A solution of 0.2 g of **15b** in 10 ml of methanol was stirred with concentrated hydrochloric acid (1 ml) at room temperature for 1 hr: during which time hydrogen sulfide evolved and the mixture turned into a colorless solution. The solution was concentrated *in vacuo* to leave crystals, which on recrystallization from ethanol afforded 0.13 g (93%) of 1-methyl-3-phenyl-Δ^3-*s*-triazolin-5-one (**16**), mp 216.5—217.5 °C, as colorless needles.

Found: C, 61.89; H, 4.96; N, 24.19%. Calcd for $C_9H_9N_3O$: C, 61.70; H, 5.18; N, 23.99%.

IR: 2800—3140 (NH) and 1690 cm^{-1} (C=O). NMR ($CDCl_3$) δ: 3.56 (3H, s, N-C**H**$_3$), 7.4—8.0 (5H, m, aromatic protons), 11.1 (1H, broad, N**H**).

General Kinetic Method. After a solution of **1** in benzene or chloroform was mixed with equimolar amount of **12b** or **4a** at −70 °C, a part of the solution was quickly transferred into a NMR-measurement tube and then the variation in the semicarbazone/*s*-triazolidin-5-one ratio was followed by the NMR spectrum at a constant temperature.

Reaction of 2 with 17a. A standard solution of **2** was heated with 1.09 g of **17a** at 50—70 °C for 5 min, and then the mixture was stirred at room temperature for 1 hr: during which time crystals precipitated. Recrystallization from a mixture of benzene and petroleum ether (bp 60—80 °C) afforded 1.38 g (73%) of 2,2-dimethyl-6-phenyl-3-*p*-tosylamino-2,3-dihydro-4*H*-1,3,5-thiadiazin-4-one (**19a**), mp 149

°C (decomp.), as colorless needles.

Found: C, 55.76; H, 4.91; N, 10.67%. Calcd for $C_{18}H_{19}N_3O_3S_2$: C, 55.52; H, 4.92; N, 10.79%.

IR: 3220 (NH) and 1685 cm^{-1} (C=O). NMR ($CDCl_3$) δ: 1.74, 2.01 (each 3H, s, CH_3), 2.42 (3H, s, $-C_6H_4CH_3$), 7.2—8.1 (10H, m, aromatic and NH).

Similarly, **2** reacted with **17b** to give 63% yield of the corresponding 2,3-dihydro-4*H*-1,3,5-thiadiazin-4-one **19b**, mp 151.5—152 °C (decomp.), as colrless prisms.

Found: C, 59.01; H, 5.36; N, 9.80%. Calcd for $C_{21}H_{23}N_3O_3S_2$: C, 58.73; H, 5.40; N, 9.79%.

IR: 3250 (NH) and 1685 cm^{-1} (C=O). NMR ($CDCl_3$) δ: 2.40 (3H, s, $-C_6H_4CH_3$), 1.5—2.7 (10H, m, CH_2), 7.0—8.1 (10H, m, aromatic and NH).

1-p-Tosylsemicarbazide (20). i) A solution of 0.5 g of **19a** in 10 ml of methanol was refluxed with concentrated hydrochloric acid (5 ml) for 30 min. The mixture was concentrated *in vacuo* to leave crystals, which on recrystallization from ethanol gave 0.21 g (72%) of **20** as colorless prisms, mp 243 °C (decomp.).

Found: C, 41.72; H, 4.73; N, 18.63%. Calcd for $C_8H_{11}N_3O_3S$: C, 41.92; H, 4.84; N, 18.34%.

IR: 3480, 3390, 3060 (NH), 1650 (C=O) and 1170 cm^{-1} (SO_2).

Similarly, hydrolysis of **19b** (0.8 g) with concentrated hydrochloric acid (10 ml) at 100 °C for 5 hr gave 0.43 g (100%) of **20**.

ii) To a suspension of 0.8 g of *p*-tosylhydrazine in 10 ml of acetic acid was slowly added 2.0 g of sodium cyanate at room temperature. The mixture was heated at 70—80 °C for 10 min, and then stirred at room temperature for 1 hr. After it was poured into ice-water, filtration gave crystals, which on recrystallization from ethanol afforded 0.75 g (76.5 %) of **20**, mp 243 °C (decomp.).

Reaction of 2 with 18. To a standard solution of **2** was added 1.13 g of **18** at 0 °C, and the mixture was then stirred at room temperature for 1 hr: during which time crystals precipitated. Recrystallization from benzene afforded 1.5 g (76%) of the 2,3-dihydro-4*H*-1,3,5-thiadiazin-4-one **21**, mp 158.5—159 °C (decomp.), as yellow needles.

Found: C, 66.55; H, 5.75; N, 10.86%. Calcd for $C_{21}H_{21}N_3O_2S$: C, 66.48; H, 5.58; N, 11.08%.

IR: 3320 (NH), 1695 and 1665 cm^{-1} (C=O). NMR ($CDCl_3$) δ: 1.2—1.9 (6H, m, CH_2), 1.9—2.5 (4H, m, CH_2), 7.0—8.2 (10H, m, aromatic protons), 9.91 (1H, s, NH).

This work was supported in part by a Grant-in-Aid of Industrial Scientific Research from the Asahi Glass Co., Ltd. for which the authors' thanks are due.

The Crystal and Molecular Structure of Tyramine Hydrochloride

Kyoko TAMURA, Akio WAKAHARA, Takaji FUJIWARA, and Ken-ichi TOMITA
Faculty of Pharmaceutical Sciences, Osaka University, Toneyama, Toyonaka, Osaka 560
(Received May 2, 1974)

The structure of tyramine hydrochloride has been determined by X-ray diffraction method using the data collected by counter diffractometer techniques. Crystals are orthorhombic, with space group *Pbcn*, $Z=8$, $a=19.961$, $b=10.756$, and $c=8.243$ Å. The structure was solved by the direct method with the symbolic addition procedure, and refined by least-squares method. The atoms constituting the tyramine cation lie on the two planes, that is, that of the phenol ring and that of the extended side chain. The dihedral angle between these two planes is 71°. The extended conformation about the C–C bond of aminoethyl group is such that the NH_3^+ group is *trans* with respect to the phenol ring. Half-weighted two independent chlorine ions are found on the two-fold axis with distance of 4.5 Å, having some different modes of hydrogen-bonding system for these two ions.

Tyramine, the decarboxylated amine of tyrosine, is a precursor of *p*-hydroxyphenylacetate in the metabolic pathway of L-tyrosine. It is of particular interest to investigate systematically the structure-activity relationship among tyrosine metabolites, in view of some very important findings about the correlation between the molecular structures and metabolic pathway of tryptophan which were already reported by us.[1-4] This work is undertaken as a part of the programme of studying the crystal structures of the aromatic amino acid metabolites.

Experimental

Commercially obtained tyramine hydrochloride was dissolved in methanol. By slow evaporation, very thin colorless plate-like crystals were grown at room temperature. Oscillation and Weissenberg photographs around the *b*- and *c*-axes showed the crystal to be orthorhombic. From the systematic extinctions, the space group was uniquely determined as *Pbcn*. Unit cell parameters were determined with a Rigaku Denki four circle diffractometer. Density was measured by the flotation method in a mixture of benzene and carbon tetrachloride. The crystal data are listed in Table 1. Three-

Space group; *Pbcn*

dimensional intensity data were recorded on a computer-controlled four circle diffractometer with Ni-filtered Cu-$K\alpha$ radiation using a crystal mounted about the *b*-axis. The ω-2θ scanning mode was employed at a rate of 2° per minute through the scanning range of $2\theta-0.6°$ for $K\alpha_1$ and $2\theta+0.6°$ for $K\alpha_2$. Background countings were taken for 10 seconds at both sides of each peak. In order to correct the intensities for coincidence loss, the counting rate was kept less than 8000 counts per second with an automatic attenuator mechanism. The intensities of three standard reflections measured for every 25 reflections of the data set showed no decrease in intensity during the run.

The intensities were measured for the 1168 independent reflections with $\sin\theta/\lambda$ less than 0.54. Of these, 576 had the net intensity exceeded three times of its estimated standard deviation; the rest was regarded as unobserved reflections. The data were then adjusted to the absolute scale and normalized structure factor, E, and a list of $\sum_2$ relationships with proper probabilities were calculated.

Determination and Refinement of Structure

The structure of tyramine hydrochloride was solved by direct phase determination using the symbolic addition procedure.[5] Reflections with $|E|>1.2$ were selected, five of them being given a sign or a letter symbol as follows;

h	k	l	phase	$\|E\|$
1	10	1	+	3.035
13	5	2	+	3.185
15	5	1	+	2.567
18	2	2	A	2.989
15	7	2	B	3.140

The phases of 137 reflections were determined in terms of starting signs and letters, and three-dimensional E-maps were computed for the possible four cases. Of these E-maps, one (A=−, B=+) clearly revealed two independent high peaks corresponding to two chlorine atoms, with a distance of 4.5 Å lying on the two-fold axis. Furthermore, the benzene ring plane enables us to distinguish the peaks of tyramine cation from other spurious ones on this map. The positional coordinates of the twelve atoms as selected from the E-map were refined by successive Fourier syntheses.

Further refinement was carried out by the full-matrix least-squares method with unit weight. Four cycles of refinement with the isotropic temperature factor reduced an R index ($R=\sum||F_o|-|F_c||/\sum|F_o|$) to 0.157. More five cycles with anisotropic temperature factors for all non-hydrogen atoms decreased an R value to 0.129. At this stage, a difference Fourier synthesis was calculated to determine the locations of hydrogen atoms. Nine of twelve hydrogen atoms were satisfactorily located with reasonable peak heights. However, three peaks corresponding to ammonium hydrogen atoms were obscure. The positional parameters of these hydrogen atoms were estimated as follows. The amino nitrogen atom has three chlorine neighbors at reasonable

TABLE 2. OBSERVED AND CALCULATED STRUCTURE FACTORS FOR TYRAMINE HYDROCHLORIDE

The columns in each group headed by the values of h and l give k, $2|F_o|$, and $2|F_c|$.

distances of hydrogen-bonding, and then three hydrogen atoms were placed at proper positions on the N–H···Cl$^-$ line, assuming the N–H distance to be 1.01 Å. The final cycles of refinement, involving the hydrogen atoms with isotropic temperature factors, by the block-diagonal least-squares method dropped R to 0.114. It was thought that unfavorable outer shape of the crystal caused a rather high R factor. Observed and calculated structure factors from the last cycle are given in Table 2, and the final atomic coordinates and thermal parameters with their estimated standard deviations in Table 3 and 4. The atomic scattering factors used throughout the refinement were taken from *International Tables for X-ray Crystallography* (1962). All the numerical calculations were done on an NEAC 2200—700 computer in the computing center of this University using the programs of UNICS system.

Description and Discussion of the Structure

The interatomic distances and valency angles are shown in Fig. 1. In the phenol ring part, the mean C–C distance of 1.388 Å and the C(4)–O distance of 1.361 Å are not significantly different from those values found in L-tyrosine (1.390 and 1.369 Å),[6] L-tyrosine hydrochloride (1.391 and 1.374 Å)[7] and DL-tyrosine (1.393 and 1.371 Å).[8] The small distortions of the

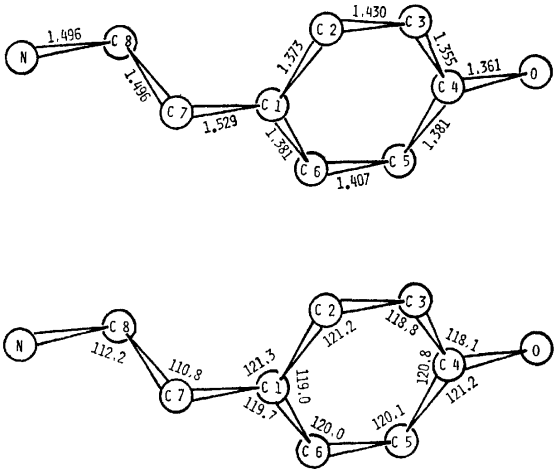

Fig. 1. Bond lengths and angles of tyramine cation. The standard deviations are 0.02 Å in bond lengths and 1.0° in bond angles between non-hydrogen atoms.

external C–C–O angles from 120° at the C(4) atom are frequently observed in phenol derivatives. The larger one always occurs at the angle C–C–O where the C–C bond is *cis* with respect to the O–H bond as suggested by Andersen *et al.*[9] The bond lengths and angles in the ethylamine side chain are very similar to the corresponding values found in other decarboxylated metabolites (amines); phenylethylamine hydrochloride,[10] dopamine hydrochloride,[11] 6-hydroxydopamine hydrochloride,[12] noradrenaline hydrochloride[13] and adrenaline hydrogen tartrate.[14]

Tyramine molecule consists of two planes; phenol ring and the fully extended ethylamine side chain. The dihedral angle between the plane of six-membered ring and the one defined by C(1)–C(7)–C(8)–N is 70.6°. The best plane through the six ring atoms was calculated by the least-squares method. The perpendicular displacements of the non-hydrogen atoms from this plane satisfying the equation: $0.2705X+0.5509Y+0.7895Z=9.8559$, are given in Table 5. The molecular conformation can be described as maximally extended form, *i.e.* the N–C(8) bond is nearly parallel to the C(7)–C(1) bond. The orientation of NH_3^+

Table 5. Deviations of atoms from the least-squares plane through the benzene ring (in Å)

Atom	Distance	Atom[a)]	Distance
C (1)	0.002	C (7)	0.013
C (2)	−0.013	C (8)	1.336
C (3)	0.003	N	1.386
C (4)	0.018	O	0.087
C (5)	−0.029	Cl (1)	4.497
C (6)	0.019	Cl (2)	2.026

a) Excluded from calculation of the plane.

group about the C(7)–C(8) bond is *trans* with respect to the C(1) atom, which is involved in the phenol ring, and the torsion angles as defined by Klyne and Prelog[15] are 179.4° (*anti-periplanar*) and 71.2° (*synclinal*) for C(1)–C(7)–C(8)–N and C(2)–C(1)–C(7)–C(8), respectively. Similar extended conformations were also reported in the crystal structures of phenylethylamine (188.9 and 72.6°),[10] dopamine (174.2 and 79.2°),[11] 6-hydroxydopamine (185.0 and 83.4°)[12] and noradrenaline (176.1 and 81.5°).[13] It is of particular interest to note that the *gauche* conformation about the C(7)–C(8) bond (the folded form) is not yet found in any crystal structure of the decarboxylated metabolite of phenylalanine and tyrosine.

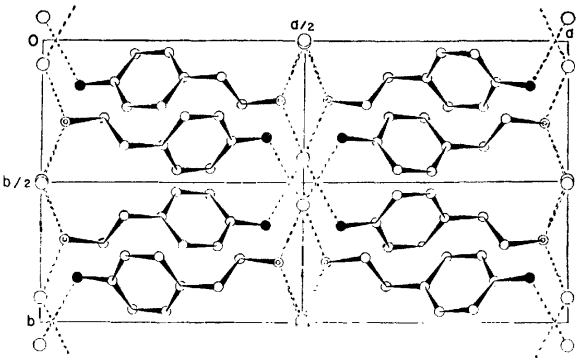

Fig. 2. The crystal structure of tyramine hydrochloride projected along the *c*-axis. The broken lines indicate the hydrogen bonds.

The packing of the molecules in this crystal is illustrated in Fig. 2, which apparently shows the network of hydrogen bonds stabilizing the structure. The crystal structure is describable as consisting of infinite chlorine layers parallel to the *bc*-plane, between which tyramine cations are arranged. The hydroxyl and ammonium hydrogen atoms are all engaged in hydrogen bonds with adjacent chlorine ions. The amino nitrogen atom has three chlorine neighbors at the distances of 3.177, 3.191, and 3.205 Å. The phenol oxygen atom acts as a donor in hydrogen bond to chlorine ion with the length of 3.028 Å. One of the interesting features of this crystal structure is the fact that two independent chlorine ions exist on the two-fold axis with distance of 4.484 Å. There is, therefore, some difference in hydrogen bonding for the two crystallographically independent chlorine ions. The Cl(2) atom is an acceptor in four N–H···Cl⁻ type hydrogen bonds, whereas Cl(1) acts as an acceptor of two N–H···Cl⁻ and two O–H···Cl⁻ hydrogen bonds.

This investigation was partly supported by the research grant from the Ministry of Education, Japan. We wish to express our sincere thanks for this support.

An Inversion of Configuration of Threonine and Allothreonine in the *N,O*-Acyl Migration Reaction with Concentrated Sulfuric Acid[1)]

Tateaki WAKAMIYA, Yuzo TARUMI, and Tetsuo SHIBA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received May 2, 1974)

On the *N,O*-acyl migration reaction of β-hydroxy-α-amino acids with concentrated sulfuric acid, a configuration of the carbon atom carrying hydroxyl group was found to be inverted through the reaction. Thus, threonine residue in peptide was converted to allothreonine residue and *vice versa* in the selective chemical cleavage of threonine peptide employing the *N,O*-migration with concentrated sulfuric acid. The reaction mechanism involving S_Ni elimination of *O*-sulfate formed as an intermediate was suggested. The inversion did not occur in the *N,O*-acyl migration reaction with other mineral acids than sulfuric acid.

For the selective chemical cleavage of peptide bonds at β-hydroxy-α-amino acid residue, the *N,O*-acyl migration reaction in strong acids has been studied by many workers.[2)] Although the mechanism of the rearrangement had been discussed by Bergmann *et al.*[3)] and Elliott *et al.*,[2b,4)] a stereochemistry of the reaction has never been clarified yet. In our structural study on the antibiotics tuberactinomycins, we noticed that *threo*-γ-hydroxy-β-lysine was converted to *erythro* form in the *N,O*-migration reaction with concentrated sulfuric acid.[5)] The similar inversion may occur in the chemical cleavage reaction of threonine peptides with concentrated sulfuric acid. In this study, we investigated the *N,O*-acyl migration reaction in threonine peptides with concentrated sulfuric acid from the view point of the configurational change. Consequently, it was found in this reaction that threonine residue was converted to allothreonine residue, and reversely, allothreonine residue changed to threonine residue both in good yields. This fact has been overlooked hitherto in the sequential analysis of peptide using *N,O*-migration reaction with concentrated sulfuric acid. Furthermore, it was proved that this inversion took place certainly at β-carbon atom and not at α-carbon atom of threonine from results of ORD spectra of allothreonines which were obtained from the migration products of several acyl-L-threonine derivatives or L-threonine peptides.

In addition, the migration reaction of acyl derivatives of threonine or allothreonine was also examined, attempting to exploit a novel method for epimerization of threonine or allothreonine. Of the acyl derivatives tested, such as acetyl, benzoyl, benzyloxycarbonyl-threonine and so on, some of them participated to the migration reaction, though the yields were not satisfactory.

Experimental

Materials. The threonine peptides, *i.e.*, DL-alanyl-DL-threonine, benzyloxycarbonylglycyl-DL-threonine, and glycyl-L-threonyl-L-phenylalanine were prepared either by saponification or hydrogenolytic debenzyloxycarbonylation of the corresponding derivatives which had been early synthesized in our laboratory.[6)] The peptides involving DL-amino acids are actually mixtures of diastereoisomers. However, use of such compounds does not disturb the estimation of the epimerization on β-carbon atom of threonine or allothreonine. Benzyloxycarbonylglycyl-L-threonine and benzyloxycarbonyl-L-alanyl-L-threonine were prepared through the active ester method and isolated as dicyclohexylammonium salts. The corresponding allothreonine peptides were also synthesized by the active ester or by the dicyclohexylcarbodiimide method as mentioned below.

Benzyloxycarbonylglycyl-DL-allothreonine. To a solution of DL-allothreonine (1.19 g, 0.01 mol) and sodium hydrogencarbonate (1.85 g, 0.022 mol) in 15 ml of water, a solution of *p*-nitrophenyl benzyloxycarbonylglycinate (3.16 g, 0.01 mol) in 20 ml of dioxane was added. After stirring at room temperature for 50 hr, the reaction mixture was evaporated *in vacuo*. The residue was dissolved in water and insoluble material was filtered off. The filtrate was acidified with 6 M HCl and extracted with ethyl acetate. Ethyl acetate layer was washed with water and dried over anhydrous sodium sulfate. After evaporation of ethyl acetate, the oily residue was crystallized by treatment with petroleum ether. It was recrystallized from ethyl acetate, yield 1.90 g (61.5%), mp 130 °C.

Found: C, 54.35; H, 5.89; N, 8.96%. Calcd for $C_{14}H_{18}O_6N_2$: C, 54.19; H, 5.85; N, 9.03%.

Benzyloxycarbonyl-L-alanyl-DL-allothreonine. This compound was prepared from *p*-nitrophenyl benzyloxycarbonyl-L-alaninate (3.34 g, 0.01 mol) and DL-allothreonine (1.19 g, 0.01 mol) in the same procedure as mentioned above. The product was isolated as a dicyclohexylammonium salt which was recrystallized from ethanol and ether, yield 2.79 g (55.2%).

Found: C, 63.70; H, 8.50; N, 8.35%. Calcd for $C_{27}H_{43}O_6N_3$: C, 64.13; H, 8.57; N, 8.31%.

Benzyloxycarbonyl-DL-allothreonine. DL-Allothreonine (3.00 g, 0.025 mol) was benzyloxycarbonylated according to the synthesis of benzyloxycarbonyl-L-threonine.[7)] The oily product was crystallized as a dicyclohexylammonium salt, yield 9.80 g (89.3%). It was recrystallized from ethanol–ether–petroleum ether, mp 147—149 °C.

Found: C, 66.14; H, 8.83; N, 6.40%. Calcd for $C_{24}H_{33}O_5N_2$: C, 66.33; H, 8.81; N, 6.45%.

Benzyloxycarbonyl-DL-allothreonyl-L-phenylalanine Methyl Ester. Benzyloxycarbonyl-DL-allothreonine dicyclohexylammonium salt (4.50 g, 1.04 mmol) was coupled with methyl L-phenylalaninate hydrochloride (2.24 g, 1.04 mmol) by the dicyclohexylcarbodiimide method in dimethylformamide. The product was recrystallized from ethyl acetate and petroleum ether, yield 4.05 g (94.0%).

Found: C, 63.63; H, 6.38; N, 6.84%. Calcd for $C_{22}H_{26}O_6N_2$: C, 63.75; H, 6.32; N, 6.74%.

DL-Allothreonyl-L-phenylalanine Methyl Ester Hydrobromide. Benzyloxycarbonyl-DL-allothreonyl-L-phenylalanine methyl ester (1.70 g, 0.41 mmol) was dissolved in 5 ml of 30% hydrogen bromide in glacial acetic acid, and anhydrous ether

was added after one hour. The oily product was triturated with anhydrous ether several times and dried over sodium hydroxide *in vacuo*, yield 1.45 g (oil, almost quantitatively).

Benzyloxycarbonyl-L-alanyl-DL-allothreonyl-L-phenylalanine Methyl Ester. Benzyloxycarbonyl-L-alanine (0.60 g, 0.27 mmol) was condensed with DL-allothreonyl-L-phenylalanine methyl ester prepared from its hydrobromide (0.75 g, 0.21 mmol) through the dicyclohexylcarbodiimide method in tetrahydrofuran. The product was recrystallized from ethyl acetate and petroleum ether, yield 0.71 g (73.3%).

Found: C, 61.73; H, 6.71; N, 8.74%. Calcd for $C_{25}H_{31}O_7N_3$: C, 61.84; H, 6.44; N, 8.66%.

Benzyloxycarbonylglycyl-DL-allothreonyl-L-phenylalanine Methyl Ester. Benzyloxycarbonylglycine (0.52 g, 0.25 mmol) was condensed with DL-allothreonyl-L-phenylalanine methyl ester prepared from its hydrobromide (0.70 g, 0.19 mmol) in the similar manner to that mentioned above. The product was recrystallized from ethyl acetate and petroleum ether, yield 0.70 g (76.5%).

Found: C, 59.91; H, 6.29; N, 8.69%. Calcd for $C_{24}H_{29}O_7N_3 \cdot 1/2\,H_2O$: C, 59.99; H, 6.29; N, 8.75%.

Acyl Threonine and Acyl Allothreonine. Acyl derivatives of threonine and allothreonine were synthesized according to the convenient procedure. The melting points of the products are summarized in Table 1.

Table 1. Melting points of acylthreonine and acylallothreonine

Acyl group	Mp (°C)	
	Threonine[a)]	Allothreonine[a)]
CH_3CO	132—133	136—137
	131—132[b)]

$C_6H_5CH_2OCO$	103—104[b)]	147—149[c)]

a) DL-Forms were used except b). b) L-Forms were used. c) Isolated as a dicyclohexylammonium salt.

Preparation of O-Sulfate of Threonine and Allothreonine. L-Threonine (1.00 g) was dissolved in 20 ml of concentrated sulfuric acid and allowed to stand for 10 days in a sealed tube. The solution was poured into cold ether. Precipitate was washed with ether several times by decantation and finally filtered off. The crude product was powdered and dissolved in water. The solution was passed through a Dowex 50 W×8 (H^+ form) column. Acidic eluate was concentrated *in vacuo* and the residue was recrystallized from water and acetone to give monohydrate as fine prisms, yield 1.40 g (85%), mp 149—150 °C.

Found: C, 22.00; H, 5.07; N, 6.33; S, 14.71%. Calcd for $C_4H_9O_6NS \cdot H_2O$: C, 22.12; H, 5.10; N, 6.45; S, 14.76%.

DL-Allothreonine (1.00 g) gave fine prisms of *O*-sulfate by the similar procedure, yield 1.35 g (82%), mp 220—230 °C (decomp.).

Found: C, 23.99; H, 4.66; N, 7.03; S, 15.98%. Calcd for $C_4H_9O_6NS$: C, 24.12; H, 4.55; N, 7.03; S, 16.10%.

Ninhydrin Reagent. Ninhydrin reagent was prepared by addition of stannous chloride dihydrate (20 mg) and 0.5 M citrate buffer (5 ml) to a solution of ninhydrin (380 mg) in methylcellosolve (95 ml).

N,O-Migration Reaction. Sample of each 100—200 mg of peptide or acyl derivative of threonine or allothreonine was dissolved in 5—6 ml of concentrated sulfuric acid. The solution was allowed to stand at 20—25 °C for 10—30 days in a sealed tube. The reaction was stopped by pouring the reaction mixture into a plenty of cold ether in the case of peptide or into 25—30 ml of 2 M hydrochloric acid in the case of the acyl derivative.

Paper Chromatographic Separation of Threonine and Allothreonine. Precipitate from the migration product of peptide obtained as mentioned above was hydrolyzed with 6 M hydrochloric acid at 110 °C for 8 hr. Each hydrolyzate was spotted on Toyo Roshi No. 51 filter paper (10×40 cm) on a line of 7 cm length after thorough removal of hydrochloric acid by evaporation. On the other hand, the aqueous acidic solution of the migration product of acyl derivative was heated at 110 °C for 8 hr. Each hydrolyzate was passed through a column of Amberlite IR-45 (OH^- form) and a neutral eluate containing threonine and allothreonine was concentrated *in vacuo*. The residue was dissolved in a small amount of water and spotted on filter paper as mentioned above. Three sheets of the papers for each one sample were developed by use of R-solvent, *i.e.*, supernatant of *n*-butanol–water–acetone–28% ammonium hydroxide (40:30:5:5 v/v). For satisfactory separation of threonine, allothreonine, and alanine, it was necessary to repeat the development a few times.

Estimation of Inversion Rate.[8)] Ninhydrin reagent was sprayed to the developed paper, and then the colored parts of threonine and allothreonine were cut off separately. The combined pieces of paper taken were sufficiently wetted with 0.1 M sodium hydroxide solution in a test tube (13×150 mm) and the tube was placed in a vacuum desiccator overnight on concentrated sulfuric acid. The pH was then brought to 5 with 0.2 M citric acid solution. Ninhydrin reagent (1.0 ml) was added to each tube which was shaken for 5—10 min and kept in a boiling water bath for 25 min. After cooling, distilled water (3 ml) was added, and the extract was poured into volumetric flask of 10 ml. Complete extraction of the colored material from the paper was carried out by treatment with acetone (3 ml). Finally the volume in the flask was adjusted to 10 ml with distilled water. The color strength was estimated using a Hitachi 124 Spectrophotometer at 570 nm. As reference in the colorimetry, a blank part of the same paper of an equal area was treated in the similar manner.

Measurement of ORD Spectra. Each hydrolyzate of migration products of acetyl-L-threonine, ethyloxycarbonyl-L-threonine, benzyloxycarbonylglycyl-L-threonine, benzyloxycarbonyl-L-alanyl-L-threonine, and benzyloxycarbonylglycyl-L-threonyl-L-phenylalanine was chromatographed on Toyo Roshi No. 51 filter paper (40×40 cm, eight sheets). The development was repeated three times each after drying and a part of allothreonine was cut off. Allothreonine was extracted with water from the paper and recrystallized from water and ethanol. ORD spectra were obtained with a JASCO Model ORD/UV-5 in water.

Results and Discussion

The results in the migration reactions of threonine and allothreonine peptides were listed in Table 2, in which the degrees of inversion were summarized as relative ratios of threonine to allothreonine.

As can be seen in Table 2, the configuration on β-carbon atom of both threonine and allothreonine

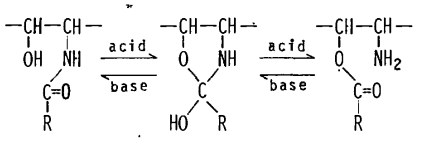
a) Amino acids used are of DL-forms in peptides b) and of L-forms in peptides c). In peptides d), alanine and phenylalanine are of L-forms and allothreonine (Ath) is of DL-form.



(I)

Fig. 1. Reaction mechanism of rearrangement *via* hydroxyoxazolidine (I).

peptides was inverted in a fairly good yield through the migration reaction in concentrated sulfuric acid. This newly found fact is very important not only stereochemically, but also for a reaction mechanism of *N,O*-acyl migration. Bergmann had first suggested a plausible way *via* hydroxyoxazolidine intermediate (I) for the *N,O*-acyl migration reaction in strong acids (Fig. 1).[3a)] According to this mechanism, the configuration on β-carbon atom carrying hydroxyl group should be retained. There has never been reported that the inversion occurred through the acyl migration reaction of peptides and proteins hitherto investigated and the above mechanism seemed to be accepted in many studies of protein chemistry. On the other hand, there are known some examples in which an inversion of the configuration actually took place in acyl migration reaction. Thus *N*-acyl-(−)-ephedrine was converted to *O*-acyl-(+)-ψ-ephedrine by treatment with hydrochloric acid.[9)] However, this is a special case where the so-called neighboring group effect between methyl and phenyl groups is participated. Such a steric effect cannot be operated at threonine or allothreonine peptides.

In other examples, Elliott pointed out a possibility that an inversion of configuration may occur on an asymmetric carbon atom carrying the hydroxyl group in a reaction of acyl amino alcohol with thionyl chloride through oxazoline ring formation (Fig. 2).[4)] Furthermore, Elliott attempted to reveal a mechanism of acyl migration reaction in concentrated sulfuric acid, however he could not manifest the real reaction mechanism so far.[2b)]

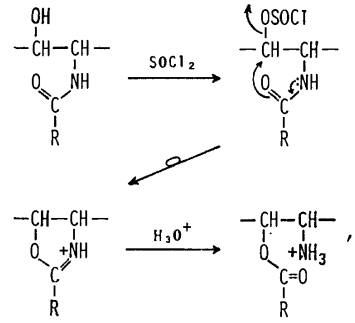


Fig. 2. Reaction mechanism of rearrangement by thionyl chloride accompanied with inversion.

From our experimental results in this study, a configurational change of β-carbon atom of threonine or allothreonine in peptide chain on the acyl migration reaction with concentrated sulfuric acid was demonstrated at the first time. There are suggested two important facts to support the inversion mechanism. First, *O*-sulfate of serine or threonine was readily isolated on simple treatment of these amino acids with concentrated sulfuric acid.[10)] Secondly, Fasman also observed the formation of *O*-sulfate before ester formation in the acyl migration reaction of poly-DL-serine in concentrated sulfuric acid.[11)] Taking these facts into consideration, we now propose the most plausible reaction mechanism as follows (Fig. 3).

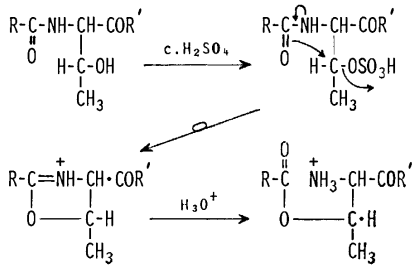

Fig. 3. Proposed mechanism of acyl migration reaction in concentrated sulfuric acid.

According to this mechanism, the *N,O*-acyl migration reaction in concentrated sulfuric acid is initiated by a formation of *O*-sulfate which is known as a strong electron-withdrawing group. A synchronous reaction of S_Ni type by an elimination of *O*-sulfate and an attack of oxygen of carbonyl group resulted in a formation of an oxazoline intermediate which is finally hydrolyzed to *O*-acyl derivative.

We have to examine a possibility that an acyl amino acids may be converted in concentrated sulfuric acid to an oxazolone derivative which causes a racemization at α-carbon atom according to the well-known mechanism. Actually, benzoyl and *p*-chlorobenzoyl derivatives of threonine and allothreonine gave 4-ethylidene-2-phenyloxazolone and 2-*p*-chlorophenyl-4-ethylidene-oxazolone respectively, under the condition employed in the migration reaction, while the formation of such oxazolone compound was never recognized in another

acyl derivatives, *e.g.*, acetyl, ethyloxycarbonyl or benzyloxycarbonylthreonine. If the apparent configurational changes in the latter cases should be due to the racemization at α-carbon atom through the oxazolone formation, allothreonine produced from L-threonine residue must be of D-form. However, measurements of ORD spectra of allothreonine obtained from the migration products of acetyl-L-threonine, ethyloxycarbonyl-L-threonine, benzyloxycarbonylglycyl-L-threonine, benzyloxycarbonyl-L-alanyl-L-threonine, and benzyloxycarbonylglycyl-L-threonyl-L-phenylalanine ascertained the complete retention of the configuration of α-carbon atom in threonine in all cases. The possibility of the inversion through racemization of oxazolone derivatives can also be excluded by the fact that threonine or allothreonine was not obtained by the hydrolysis of the unsaturated oxazolones mentioned above.

Table 3. Inversion rates of acyl derivatives of threonine and allothreonine

Acyl groups	Yields (%) of inversion from	
	Acylthreonine	Acylallothreonine
CH_3CO	16	11
$ClCH_2CO$	22	18
CF_3CO	1	13
$C_6H_5OCH_2CO$	9	18
C_2H_5OCO	39	30
$C_6H_5CH_2OCO$	3	7

Contrary to the peptide migration, an inversion of simple acyl derivatives of threonine and allothreonine occurred only in a low yield (Table 3). The reaction rate of the acyl migration reaction is known to be very slow even in the threonine peptides.[2m,12] Therefore, it may be considered that either the reaction of the acyl derivative proceeded in an extreme slow rate or a simple hydrolysis preceded to the slow migration reaction.

It can be now concluded that the acyl migration reaction with concentrated sulfuric acid leads to a complete inversion of the configuration on β-carbon atom of β-hydroxy-α-amino acids in peptides as far as the migration reaction takes place. In addition, it was confirmed that the inversion occurs only in concentrated sulfuric acid but not in another mineral acids, *e.g.*, hydrochloric acid, hydrobromic acid, and anhydrous hydrogen fluoride.

In view of wide applications of *N,O*-acyl migration reaction of threonine residue with concentrated sulfuric acid for determination of primary structures of peptides or proteins, the stereochemistry of β-carbon atom in threonine must be taken into consideration hereafter based on the new findings in this study.

The authors wish to express their appreciations to Ajinomoto Co. Ltd., for supply of allothreonine.

Synthesis of Streptolidine (Roseonine, Geamine)[1]

Shoichi KUSUMOTO, Shinichi TSUJI, and Tetsuo SHIBA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received August 2, 1974)

Streptolidine (roseonine, geamine) (**1**), a guanidino amino acid component of the streptothricin group antibiotics, was synthesized starting from D-ribose (**8**). The epimino compound (**11b**) was prepared from **8** in five synthetic steps. Azidolysis of **11b** gave the arabino-type compound (**12b**), which in turn was converted to the key intermediate tribenzyloxycarbamido lactone (**23b**) by oxidation of *C*-1. The lactone **23b** was rearranged to the free lactam (**4**) after deprotection, and then guanidinated with cyanogen bromide. The identity of the hydrolysis product of this guanidino lactam with natural streptolidine in all respects certified the proposed structure involving the steric configurations.

Streptolidine is a guanidino amino acid which widely distributes as a constituent of a number of *Streptomyces* antibiotics. It was first isolated from the hydrolyzate of streptothricin and streptolin.[2] The two amino acids thereafter reported, *i.e.*, roseonine from roseothricin[3] and geamine from geomycin,[4] were identified as the same substance. In 1961 Carter *et al.*[5] deduced the chemical structure of this amino acid by means of degradation studies. Its absolute configuration was recently established by X-ray crystallography as **1**.[6] As reported in our preliminary communication,[1] we synthesized streptolidine of the natural configuration from D-ribose.

Results and Discussion

Streptolidine has a unique structure in which a 2-amino-2-imidazoline ring and three asymmetric centers are involved. This peculiar feature in the structure seems to be the reason for delay in the chemical synthesis of the rather small molecule so far. The key intermediate of the synthesis is desired to be (2*S*,3*S*,4*R*)-2,3,5-triamino-4-hydroxypentanoic acid (**2**) or its equivalent, *e.g.*, its lactone (**3**) or lactam form (**4**). In this study, natural pentoses of the corresponding stereochemistry were chosen as the starting materials. Thus, attempts were made to convert three hydroxy groups on *C*-2, 3 and 5 of furanoside molecules stereoselectively into amino groups. In this way, the trouble in separation of stereoisomeric mixture otherwise synthesized can be avoided.

Many procedures have been presented to introduce an amino group into a sugar moiety. Among them the S_N2-type displacement of *O*-sulfonate with azide anion seems to be the most promissing one in our case. A synthetic pathway for preparation of **3** from D-xylose (**5**) was first investigated. When methyl 2,3,5-tri-*O*-mesyl-β-D-xylofuranoside (**6**) was treated with sodium azide under various conditions, however, 2,3,5-triazide (**7**) could not be obtained in an appreciable yield. Thus, the approach to **3** by this way was abandoned. The details on this experiment will be presented elsewhere.

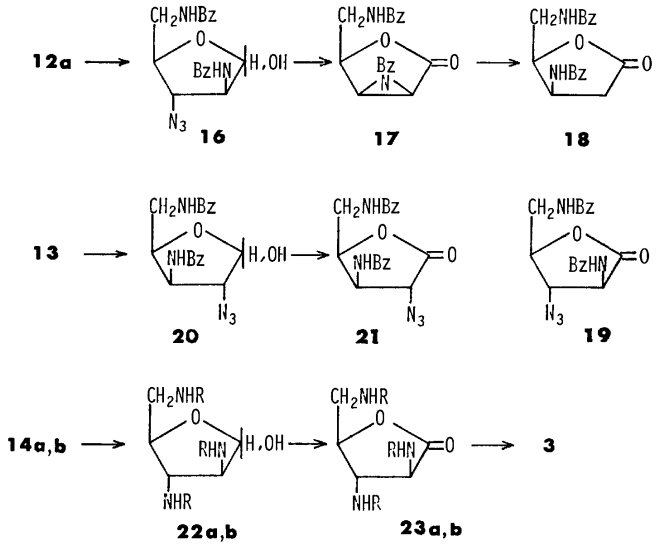
Recently, Hildesheim *et al.*[7] prepared two isomers of monoazido dibenzamido trideoxypentose (**12a** and **13**) through azidolysis of an epimino compound (**11a**) derived from D-ribose (**8**). They assigned tentatively one isomer with a smaller $J_{1,2}$-value of 1 Hz to xylo-type (**13**) and the other with a larger value to arabino-type (**12a**) structure respectively. Each compound could be reduced and benzoylated to give methyl tribenzamido trideoxy xylofuranoside (**15**) and arabinofuranoside (**14a**). Since the compounds **12a** and **14a** have the same steric fashion as in **3**, oxidation of **12a** or **14a** at *C*-1 would be expected to lead to the desired intermediate **3** after several steps of further transformations. Thus, the methyl glycoside of **12a** was hydrolyzed with hydrochloric acid without ap-

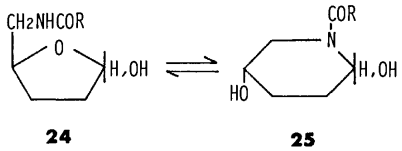
preciable cleavage of benzoyl group. However, oxidation of the resulting compound **16** with chromium trioxide in pyridine afforded a mixture of two products. Although the main product showed two carbonyl bands due to amides (1680 and 1645 cm^{-1}) in its IR spectrum, the azide band disappeared, and no signal of an olefin proton in its NMR spectrum was observed. These results together with its molecular formula ($C_{19}H_{16}N_2O_4$) suggest an epimino structure (**17**) for this compound. This assignment was confirmed by the following transformation. Catalytic hydrogenation of **17** afforded a product of a molecular formula $C_{19}H_{18}N_2O_4$, whose NMR spectrum showed signals at δ 2.50 (1H, d, J=10 Hz) and 2.82[8] (1H, q, J=10, 5 Hz). These signals could be attributed to the two hydrogens on *C*-2 of the structure shown in **18**. The epimino ring in **17** obviously resulted from an elimination of the azido group with a participation of the neighboring benzamido group. As a minor product in the oxidation reaction of **16**, a small amount of **19** of the desired azido lactone structure was isolated. This structure was supported from its IR spectrum (2140, 1770 cm^{-1}). Further progress of the synthesis using this azido lactone had to be given up, because of a small amount available.

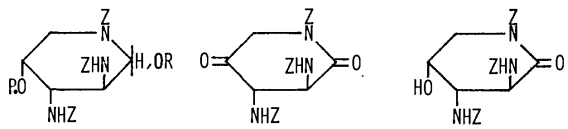


In a parallel experiment, **13** was hydrolyzed to **20**, which was oxidized with chromium trioxide-pyridine to afford an azido lactone (**21**) (ν_{max} 2130, 1790 cm^{-1}) without elimination of the azido group successfully. Decoupling experiments on this lactone (**21**) showed that a doublet signal at δ 4.12 (1H, J=10 Hz) changed to a singlet when the signal at δ 5.25 (1H, quartet-like) coupling further with an NH proton at δ 9.07 (1H, d, J=9 Hz) was irradiated. This result indicates clearly that the signal at δ 4.12 should be due to the proton on *C*-2 and the structure of this lactone must be represented as α-azido structure of xylo-type as shown in **21**. Consequently, it was unequivocally established that both **13** and **20** have the xylo-type configuration in accordance with Hildesheim's assignment. Comparison of the behaviors of **16** and **20** in oxidation reaction indicates that the facile elimination of an azido group occurs particularly at β-position but not α-position to a carbonyl function.

This finding leads to a strategy that the azido group on *C*-3 of **12a** should be reduced prior to the oxidation of *C*-1 in the synthetic approach towards **3**. Thus, the azido glycoside **12a** was first converted to tribenzamido derivative (**14a**) of arabino-type, which was then oxidized to tribenzamido lactone (**23a**) with chromium trioxide in pyridine through a hydrolysis product **22a**. However, the benzoyl groups of **23a** resisted against removal by acid hydrolysis. Thus, on refluxing in 6 M hydrochloric acid, **23a** gave a complex mixture of several products. Methanolysis with dry hydrogen chloride could not give an improved result.

Therefore, the benzoyl group was replaced with benzyloxycarbonyl group for the amino protection. In a simillar manner as in the benzoyl derivative (**11a**), the dibenzyloxycarbonyl epimino compound (**11b**) was prepared from D-ribose. Treatment of **11b** with sodium azide in dimethylformamide (DMF) gave a single product of the arabino-type azido derivative (**12b**). Catalytic hydrogenation of **12b** afforded triamino compound **14c** as trihydrochloride. Both compounds **12b** and **14c** certainly maintain the arabino-type configuration, since benzoylation of **14c** afforded **14a** of the determined structure. After the exhausted benzyloxycarbonylation of **14c** to **14b**, the glycoside linkage was hydrolyzed by refluxing with *p*-toluenesulfonic acid in dioxane to give **22b** in about 35% yield accompanied with 40% of unchanged **14b**. A longer refluxing as far as the starting material disappeared, or use of hydrochloric acid for the hydrolysis gave rather worse results presumably because of the acid-lability of the benzyloxycarbonyl group. The hydrolysis product was isolated through silica gel chromatography and recrystallized from chloroform. Although a compound with a 5-acylaminopentose structure is known to exist often as an equilibrium mixture of the corresponding furanose (**24**) and piperidine (**25**) form,[9] this product seemed to remain mainly in the furanose form (**22b**) during the isolation procedure since a γ-lactone was formed by oxidation of **22b** and no change was observed in the IR spectrum in repeated recrystallization. However, when **22b** was treated with acetic anhydride in pyridine, a diacetate (**26**) was obtained as a sole





product. This fact might be well elucidated by assuming that the piperidine form (**27**) is preferred in pyridine solution.[10] Similar preferences of piperidine form in *N*-benzyloxycarbonyl derivatives were also reported in some pentoses[11] and in idose series,[12] though it is not a case in the corresponding *N*-acetyl or benzoyl derivatives.[13]

Oxidation of **22b**[14] was effected with chromium trioxide in acetic acid, and the product was isolated by silica gel chromatography. This product could not be obtained in a crystalline state, although its IR spectrum showed, in accordance with the expected γ-lactone structure (**23b**), a carbonyl band at 1800 cm^{-1} together with a broad band at around 1710 cm^{-1} due to benzyloxycarbonyl groups. Removal of the benzyloxycarbonyl groups from this oxidation product with hydrogen bromide in acetic acid afforded an extremely hygroscopic hydrobromide as white powder, whose IR spectrum showed a weak absorption band at 1650 cm^{-1} besides an intensive one at 1800 cm^{-1} due to γ-lactone. The former band should be attributed to an amide carbonyl group of δ-lactam structure (**4**). The elemental analysis of this hydrobromide, in one experimental run, showed the composition of a 7: 3 mixture of lactone (**3**) trihydrobromide and lactam (**4**) dihydrobromide. Since it is improbable that the conversion of **3** into **4** occurred during the deprotection stage or thereafter when no basic condition was employed, the above observation suggests that the oxidation product **23b** might have already contained a small amount of lactam form **29** which arised from **27**. When an aqueous solution of a mixture of the hydrobromide of **3** and **4** was passed through a column of Amberlite IR-45 (OH^- form) and the eluate evaporated *in vacuo*, the residue showed only a carbonyl band due to lactam (**4**) and no other compound was eluted at all. This indicates the easy transformation of **3** trihydrobromide into **4** on neutralization.

The final stage of streptolidine synthesis was carried out as follows. An aqueous solution of a mixture of the hydrobromide of **3** and **4** was brought to pH 11 with 1 M sodium hydroxide. The preferred formation of **4** in this solution was proved by isolation of its bis-4-hydroxyazobenzene-4'-sulfonic acid (HABS) salt. The solution was then treated directly with cyanogen bromide. In this reaction, the amino group on *C*-5 in the lactam form was protected against an action of cyanogen bromide and a selective formation of the 2-amino-2-imidazoline ring between *C*-2 and *C*-3 was expected. The reaction mixture was refluxed with hydrochloric acid to hydrolyze the lactam ring and then subjected to a column of Dowex 50×8 (NH_4^+ form). Elution with 0.2 M ammonia afforded a fraction which showed a single ninhydrin positive spot identical with natural streptolidine on both paper chromatography (PPC) and paper electrophoresis (PEP).

Table 1. Comparison of synthetic and natural streptolidine

	Synthetic	Natural
R_f value on PPC[a]	0.29	0.29
Mobility on PEP[b]	11.0 cm	11.0 cm
Elution time on amino acid analysis	47.0 min	47.0 min
Bis-HABS salt		
mp	250—254°C (dec.)	250—254°C (dec.)
$[\alpha]_D$ in MeOH	+20.5° (*c* 0.29)	+22.1° (*c* 0.29)
Dihydrochloride		
mp	239 °C (dec.)	241 °C (dec.)
$[\alpha]_D^{20}$ in H_2O	+52.2° (*c* 0.16)	+54.2° (*c* 0.15)

a) Isopropanol–HCOOH–H_2O (4:1:1) b) Pyridine–AcOH–H_2O (30:4:966)

This product was isolated as crystalline bis-HABS salt, mp 250—254 °C (decomp.), $[\alpha]_D^{21}$ +20.5° (methanol), which was identical with the same salt of the natural amino acid, mp 250—254 °C (decomp.), $[\alpha]_D^{19}$ +22.1° (methanol). Identity was further confirmed by comparison of mp and IR spectrum of dihydrochloride, mobility on PEP, R_f value on PPC as well as the elution time on amino acid analysis with those of the natural specimen. Consequently, the structure and the stereochemistry of streptolidine were unequivocally established as **1** by the present chemical synthesis.

Experimental

All melting points are uncorrected. The NMR spectra were taken on a Varian T-60 spectrometer in deuteriochloroform unless otherwise stated, using tetramethylsilane as an internal standard. Chemical shifts and coupling constants were recorded in δ values and Hz, and frequencies in cm^{-1}. Optical rotations were measured with Perkin-Elmer polarimeter model 141. Paper electrophoresis (PEP) was carried out in a pyridine–acetic acid–water (30: 4: 966) buffer solution.

*3-Azido-2,5-dibenzamido-2,3,5-trideoxy-*D*-arabinofuranose (**16**).* To a solution of methyl 3-azido-2,5-dibenzamido-2,3,5-trideoxy-β-D-arabinofuranoside (**12a**)[7] (200 mg) in dioxane (60 ml) was added 2 M HCl (40 ml), and the mixture was heated under reflux for 2.5 hr. After cooling, the solution was extracted with CH_2Cl_2. The extract was washed with water, dried over $MgSO_4$ and evaporated to give **16** (155 mg, 80%). Recrystallization was effected from ethyl acetate; mp 187—188 °C.

Found: C, 59.65; H, 5.05; N, 18.53%. Calcd for $C_{19}H_{19}N_5O_4$: C, 59.83; H, 5.02; N, 18.36%.

*Oxidation of **16** with Chromium Trioxide in Pyridine.* To an ice-cooled solution of CrO_3 (240 mg, 2.4 mmol) in dry pyridine (15 ml) was added a solution of **16** (155 mg, 0.41 mmol) in dry pyridine (3 ml). The mixture was stirred at 0 °C for 2 hr, then at room temperature overnight, and extracted with CH_2Cl_2. The extract was treated as usual and evaporated *in vacuo* to leave a brown residue, which was chromatographed on silica gel column. Ethyl acetate–*n*-hexane (2: 1) eluted **17** (100 mg, 73%), which was recrystallized from ethyl acetate–*n*-hexane; mp 196—197 °C; ν_{max} (Nujol) 1680, 1645; $[\alpha]_D^{28}$ +55.6° (*c* 1.87, ethyl acetate).

Found: C, 67.76; H, 4.82; N, 8.48%. Calcd for $C_{19}H_{16}N_2O_4$: C, 67.85; H, 4.80; N, 8.33%.

Further elution with the same solvent afforded a small amount of **19**; mp 167—169 °C; ν_{max} (Nujol) 2140, 1770.

*3,5-Dibenzamido-2,3,5-trideoxy-*D*-xylono-1,4-lactone (**18**).* Hydrogen was passed through a stirred solution of **17** (400 mg, 1.06 mmol) in methanol (20 ml) and concentrated hydrochloric acid (0.13 ml) in the presence of palladium black. After 20 hr, the catalyst was removed by filtration and the solvent evaporated *in vacuo*. The residue was dissolved in

CH_2Cl_2, washed with water, dried over $MgSO_4$ and evaporated to give **18** (216 mg, 52%), which was recrystallized from ethyl acetate–*n*-hexane; mp 212—213 °C; $[\alpha]_D^{28}$ +32.0° (*c* 1.78, ethyl acetate–DMF (3:1)). NMR (in pyridine): 2.50 (1H, d, $J=10$), 2.82 (1H, q, $J=5$, 10).

Found: C, 67.33; H, 5.36; N, 8.28%. Calcd for $C_{19}H_{18}N_2O_4$: C, 67.44; H, 5.36; N, 8.28%.

*2-Azido-3,5-dibenzamido-2,3,5-trideoxy-*D*-xylofuranose (20).* To a solution of methyl 2-azido-3,5-dibenzamido-2,3,5-trideoxy-β-D-xylofuranoside (**13**)[7] (2.75 g, 6.96 mmol) in dioxane (200 ml) was added 1 M HCl (40 ml), and the mixture was heated under reflux for 1.5 hr. After cooling, a reaction mixture was extracted with CH_2Cl_2 and the extract was treated as usual. The residue obtained by evaporation was chromatographed on silica gel column. Elution with CH_2Cl_2–ethyl acetate (4:1) gave unchanged **13** (1.20 g, 44%) and then **20** (0.315 g, 12%). The latter was recrystallized from $CHCl_3$–*n*-hexane; mp 177—179 °C (decomp.).

Found: C, 59.68; H, 5.07; N, 18.48%. Calcd for $C_{19}H_{19}N_5O_4$: C, 59.83; H, 5.02; N, 18.36%.

*2-Azido-3,5-dibenzamido-2,3,5-trideoxy-*D*-xylono-1,4-lactone (21).* To an ice-cooled solution of CrO_3 (420 mg, 4.2 mmol) in dry pyridine (15 ml) was added a solution of **20** (240 mg, 0.63 mmol) in dry pyridine (5 ml). The mixture was stirred at 0° for 20 hr, and extracted with CH_2Cl_2. Working up in the usual manner and evaporation of the solvent *in vacuo* afforded a brown residue, which was chromatographed on silica gel column. Elution with ethyl acetate–*n*-hexane gave **21** (160 mg, 67%), which was recrystallized from ethyl acetate–*n*-hexane; mp 164—166 °C (decomp.); ν_{max} ($CHCl_3$) 2130, 1790. NMR ($CDCl_3$, 100 MHz): around 3.6 and 4.2 (each 1H, m; 2H-5), 4.12 (1H, d, $J=10$; H-2), 4.85 (1H, broad; H-4), 5.25 (1H, q; H-3), 7.3—8.2 (11H; aromatic H and NH-5), 9.07 (1H, d, $J=9$; NH-3).

Found: C, 59.74; H, 4.59; N, 18.03%. Calcd for $C_{19}H_{17}N_5O_4$: C, 60.15; H, 4.52; N, 18.46%.

*2,3,5-Tribenzamido-2,3,5-trideoxy-*D*-arabinofuranose (22a).* A mixture of methyl 2,3,5-tribenzamido-2,3,5-trideoxy-β-D-arabinofuranoside (**14a**)[7] (1.80 g, 3.80 mmol), $CuCl_2 \cdot 2H_2O$ (2.1 g), dioxane (20 ml) and 0.5 M HCl (40 ml) was heated under reflux for 2 hr. After cooling, the mixture was evaporated *in vacuo* to dryness. To the residue was added water (50 ml) and $CHCl_3$ (150 ml), and the mixture was heated under reflux for 30 min. The organic layer was separated, treated as usual and evaporated *in vacuo* to leave a residue, which was recrystallized from $CHCl_3$ to afford **22a** (0.46 g, 26%); ν_{max} (Nujol) 3450, 3340, 1700—1670 (broad).

From the mother liquor was recovered the unchanged **14a** (1.20 g, 67%).

*2,3,5-Tribenzamido-2,3,5-trideoxy-*D*-arabono-1,4-lactone (23a).* To an ice-cooled solution of CrO_3 (0.70 g, 7 mmol) in dry pyridine (30 ml) was added **22a** (600 mg, 1.31 mmol) in dry pyridine (20 ml). The mixture was stirred at 0°C for 4 hr, then at room temperature for 20 hr, and worked up as usual. After evaporation of the solvent *in vacuo*, the residue was chromatographed on silica gel column. Elution with $CHCl_3$–ethyl acetate (1:2) afforded **23a** (470 mg, 78%), which was recrystallized from dioxane–water; mp 217—218 °C; $[\alpha]_D^{28}$ −102.4° (*c* 1.45, DMF).

Found: C, 67.85; H, 5.32; N, 8.87%. Calcd for $C_{26}H_{23}N_3O_5 \cdot 1/5C_4H_8O_2$: C, 67.75; H, 5.22; N, 8.85%.

Attempts for Removal of Benzoyl Groups of **23a**. *1) Hydrolysis with HCl*: Compound **23a** (20 mg) was heated under reflux in 6 M HCl (9 ml) and the progress of the reaction was followed by means of PEP. Even after 5 hr, the reaction was not finished, though there appeared three main spots and the reaction mixture turned into deep brown. Heating for a longer time caused considerable decomposition of the products. Use of acetic acid or dioxane as co-solvent or use of more dilute HCl did not improve the result.

2) Methanolysis: A 15% solution of dry HCl in absolute methanol (10 ml) was added to **23a** (400 mg) and the mixture was heated under reflux for 17 hr. PEP showed the presence of several ninhydrin-positive spots in the mixture, from which **3** could not be isolated.

*Methyl 5-Benzyloxycarbamido-2,3-benzyloxycarbonylepimino-2,3,5-trideoxy-β-*D*-lyxofuranoside (11b).* Benzyloxycarbonyl chloride (18.1 g, 105 mmol) was added portionwise to an ice-cooled solution of methyl 5-amino-2,3-epimino-2,3,5-trideoxy-β-D-lyxofuranoside (**11c**)[7] (5.6 g, 44 mmol) and triethylamine (14.6 ml, 105 mmol) in ethanol (250 ml) during 20 min with stirring. The reaction mixture was stirred at 0 °C for 30 min and at room temperature for 2.5 hr. Then water (400 ml) was added and crystals of **11b** were filtered off (13.5 g, 75%). Recrystallization was effected from ethyl acetate–*n*-hexane; mp 115.5—116.5 °C, $[\alpha]_D^{24}$ −35.7° (*c* 2.02, ethyl acetate).

Found: C, 64.18; H, 5.85; N, 6.79%. Calcd for $C_{22}H_{24}N_2O_6$: C, 64.06; H, 5.87; N, 6.79%.

*Methyl 3-Azido-2,5-dibenzyloxycarbamido-2,3,5-trideoxy-β-*D*-arabinofuranoside (12b).* Sodium azide (10.0 g, 155 mmol) was added to a solution of **11b** (12.8 g, 31.0 mmol) in dry DMF (200 ml), and the mixture was heated at 90 °C for 1 hr with stirring. After cooling, the mixture was filtered through Celite and evaporated to dryness *in vacuo*. Water and CH_2Cl_2 were added to the residue. The organic layer was separated, washed with water, dried over $MgSO_4$ and concentrated *in vacuo*. The remaining syrup was passed through a column of silica gel. Elution with benzene–ethyl acetate (4:1) afforded **12b** (6.5 g, 46%), which was recrystallized from ethyl acetate–*n*-hexane; mp 103.5—105 °C; $[\alpha]_D^{24}$ −27.3° (*c* 2.20, ethyl acetate). NMR: 3.39 (3H, s; CH_3O , 4.77 (1H, d, $J=5$; H-1), 5.16 and 5.19 (each 2H, s; $2C_6H_5C\underline{H}_2O$) and near 7.3 (10H; aromatic).

Found: C, 58.15; H, 5.52; N, 15.30%. Calcd for $C_{22}H_{25}N_5O_6$: C, 58.01; H, 5.53; N, 15.38%.

*Methyl 2,3,5-Triamino-2,3,5-trideoxy-β-*D*-arabinofuranoside (14c) Trihydrochloride.* A solution of **12b** (3.8 g, 8.35 mmol) and concentrated hydrochloric acid (2.5 ml) in methanol (60 ml) was added with 5% palladium on carbon (0.4 g). A slow stream of hydrogen was passed through this mixture with stirring at room temperature overnight. The catalyst was filtered off and ether was added to the filtrate. Trihydrochloride of **14c** was crystallized out as needles; 1.85 g (82%). It was recrystallized from water–methanol–ether; mp 240 °C (decomp.); $[\alpha]_D^{19}$ −57.1° (*c* 1.81, water).

Found: C, 26.71; H, 6.77; N, 15.37; Cl, 39.14%. Calcd for $C_6H_{18}N_3O_2Cl_3$: C, 26.63; H, 6.71; N, 15.53; Cl, 39.31%.

*Methyl 2,3,5-Tribenzyloxycarbamido-2,3,5-trideoxy-β-*D*-arabinofuranoside (14b).* To an ice-cooled solution of **14c** (3.7 g, 14 mmol) and triethylamine (7.5 ml, 54 mmol) in ethanol (120 ml) was added benzyloxycarbonyl chloride (9.1 g, 54 mmol) portionwise during 20 min with stirring. After stirring in an ice-bath for 30 min, triethylamine (5.5 ml, 39 mmol) and benzyloxycarbonyl chloride (3.0 g, 18 mmol) were added and stirring was continued at room temperature for another 1 hr. The product (**14b**) crystallized out was filtered off and recrystallized from $CHCl_3$–*n*-hexane (6.9 g, 90%). An analytical sample was obtained by recrystallization from dioxane–water; mp 202—203 °C, $[\alpha]_D^{19}$ −17.0° (*c* 1.98, $CHCl_3$).

Found: C, 63.43; H, 6.12; N, 7.02%. Calcd for $C_{30}H_{33}N_3O_8 \cdot 1/2C_4H_8O_2$: C, 63.25; H, 6.14; N, 6.92%.

*2,3,5-Tribenzyloxycarbamido-2,3,5-trideoxy-*D*-arabinofuranose*

(22b). To a solution of **14b** (4.28 g) in dioxane (200 ml) was added 2 M aqueous solution of *p*-toluenesulfonic acid (200 ml). The mixture was heated under reflux for 2 hr, then concentrated to half of its volume *in vacuo*, and extracted with $CHCl_3$. The extract was washed with aqueous $NaHCO_3$ and water, dried over $MgSO_4$ and evaporated *in vacuo*. The resulting residue was chromatographed on silica gel column. Elution with $CHCl_3$–ethyl acetate (2: 1) first afforded the unchanged **14b** (1.80 g, 42%) and then **22b** (1.45 g, 35%). The latter was recrystallized from $CHCl_3$; mp 211—212 °C.

Found: C, 63.00; H, 5.71; N, 7.67%. Calcd for $C_{29}H_{31}N_3O_8$: C, 63.38; H, 5.69; N, 7.65%.

*2,3,5-Tribenzyloxycarbamido-2,3,5-trideoxy-*D*-arabono-1,4-lactone (23b).* To a solution of **22b** (2.0 g, 3.6 mmol) in acetic acid (240 ml) was added CrO_3 (0.36 g, 3.6 mmol) in acetic acid–water (4: 1, 3.6 ml). The mixture was stirred at room temperature for 1.5 hr, then added with water, and extracted with $CHCl_3$. The residue obtained by the usual working up was chromatographed on silica gel column. Elution with $CHCl_3$–ethyl acetate (2: 1) afforded unchanged **22b** (0.62 g, 31%) and further elution with the same solvent gave **23b** (0.52 g, 26%) as sticky syrup; ν_{max} ($CHCl_3$) 1800, 1730—1690 (broad).

*1,4-Di-*O*-acetyl-2,3,5-tribenzyloxycarbamido-2,3,5-trideoxy-*D*-arabinopyranose (26).* Acetic anhydride (0.05 ml) was added to a stirred solution of **22b** (29.0 mg) in pyridine (0.3 ml) under ice-cooling. The mixture was set aside at room temperature for 48 hr and then evaporated *in vacuo*. The residue was dissolved in $CHCl_3$ and added with *n*-hexane to afford **26** (23.9 mg, 71%), which was recrystallized from $CHCl_3$–*n*-hexane; mp 186—186.5 °C. NMR: 1.89 and 2.09 (each 3H, s; $2CH_3CO$).

Found: C, 62.40; H, 5.53; N, 6.58%. Calcd for $C_{33}H_{35}N_3O_{10}$: C, 62.55; H, 5.57; N, 6.63%.

*2,3,5-Triamino-2,3,5-trideoxy-*D*-arabono-1,4-lactone (3) Trihydrobromide and 2,3,5-Triamino-2,3,5-trideoxy-*D*-arabono-1,5-lactam (4) Dihydrobromide.* Anisole (0.3 ml) and **23b** (455 mg), containing a small amount of **29** (see text), was dissolved in acetic acid (10 ml) which was previously saturated with dry hydrogen bromide. The mixture was allowed to stand at room temperature for 1.5 hr. Addition of anhydrous ether afforded very hygroscopic white powder (300 mg); ν_{max} (Nujol): 1800, 1650 (weak).

Found: C, 16.62; H, 3.92; N, 11.20; Br, 59.69%. Calcd for a 7: 3-mixture of **3** trihydrobromide ($C_5H_{14}N_3O_2Br_3$) and **4** dihydrobromide ($C_5H_{13}N_3O_2Br_2$): C, 16.51; H, 3.80; N, 11.56; Br, 59.33%.

Transformation of Trihydrobromide of 3 into 4. 1) On Ion Exchange Resin: A mixture of hydrobromide of **3** and **4**, obtained from **23b** (290 mg) was dissolved in water, subjected to a column of Amberlite IR-45 (OH^- form) and eluted with water. The eluate was evaporated *in vacuo* to afford **4** solely as hygroscopic amorphous solid: ν_{max} (Nujol) 1640.

2) With NaOH: The hydrobromide (40 mg) mentioned above was dissolved in water (8 ml). This solution was brought to pH 11 by addition of 1 M NaOH and left stand at room temperature for 2 hr. To this solution was added 4-hydroxyazobenzene-4′-sulfonic acid (HABS) to afford bis-HABS salt of **4**, which was recrystallized from water; mp 190 °C (decomp.); ν_{max} (Nujol) 1640.

Found: C, 46.34; H, 4.92%. Calcd for $C_5H_{11}N_3O_2 \cdot 2(C_{12}H_{10}N_2O_4S) \cdot 3H_2O$: C, 46.08; H, 4.94%.

Streptolidine (1). To an aqueous solution (90 ml) of **4**, prepared from **23b** (0.74 g, 1.35 mmol) using NaOH as mentioned above, was added a solution of BrCN (0.32 g, 3.0 mmol) in water (6.5 ml) portionwise over a period of 2.5 hr with stirring. During this time the pH of the reaction mixture fell to 6.9. The mixture was stirred at room temperature for additional 30 min and then evaporated *in vacuo* to dryness. The residue was heated in 6 M HCl (150 ml) under reflux for 2 hr and then evaporated *in vacuo*. The residue was dissolved in a little water and subjected to a column of Dowex 50×8 (NH_4^+ form, 1.5×36 cm). The column was first washed with water (500 ml) and eluted with 0.2 M NH_4OH. Eluate of each 2 ml was collected and each fraction was tested by means of PEP and PPC (2-propanol–formic acid–water 4:1:1). Fractions 21—31 showed a single ninhydrin-positive spot, which was identical with that of natural streptolidine. Fractions 18—20 and 32—41, containing the same substance overlapped with some other impurities, were combined and again chromatographed as above, affording fractions which showed also a single spot identical with streptolidine. These and the fractions 21—31 in the first chromatography were combined, concentrated *in vacuo* to a small volume, added with 4-hydroxyazobenzene-4′-sulfonic acid (HABS, 150 mg) and heated on a boiling water bath to obtain a clear solution. On cooling, crystals (95 mg) of bis-HABS salt of streptolidine were obtained. From the mother liquor was obtained more amount (37 mg) of them; total 132 mg (12.5% from **23b**). Recrystallization was effected from hot water; mp 250—254 °C (decomp.); $[\alpha]_D^{21}$ +20.5° (*c* 0.29, methanol).

Found: C, 46.23; H, 4.63; N, 14.22; S, 8.08%. Calcd for $C_6H_{12}N_4O_3 \cdot 2(C_{12}H_{10}N_2O_4S) \cdot 2H_2O$; C, 46.15; H, 4.65; N, 14.35; S, 8.21%.

Bis-HABS salt (81 mg) was subjected to PEP using TOYO No. 50 paper (4 pieces of 40 cm length×16 cm width; 1.3 mA/cm, 1.5 hr). The ninhydrin-positive substance was extracted from the paper with 2 M HCl and the extract concentrated *in vacuo* to afford streptolidine dihydrochloride (25.5 mg) as crystalline residue, which was recrystallized from water–ethanol; mp 239 °C (decomp.); $[\alpha]_D^{20}$ +52.2° (*c* 0.115, H_2O).

The IR spectra of bis-HABS salt and dihydrochloride of synthetic streptolidine were fully identical with those of natural specimen. R_f-values on PPC, mobilities on PEP and elution times on amino acid analysis of the synthetic and natural product were all identical (see Table 1).

The authors wish to express their appreciations to Ajinomoto Co., Inc. and Takeda Chemical Industries Ltd., for their kind supplies of the starting materials, and Shionogi Co., Ltd., for gift of the natural specimen.

Enthalpies of Hydrogen Bond Formation between Diphenylamines and Dimethyl Sulfoxide

Minoru HIROTA, Kazumasa SHINOZUKA, and Yoshiki HAMADA*

Department of Applied Chemistry, Faculty of Engineering, Yokohama National University, Minami-ku, Yokohama 233

(Received May 21, 1974)

Enthalpies of hydrogen bond formation for the diphenylamine–dimethyl sulfoxide systems were determined by infrared spectroscopic method. The ΔH values for 4-methoxy, 4-methyl, unsubstituted, 3-methoxy, 3-chloro, 3-nitro, and 4-nitro-diphenylamines are −9.6, −10.1, −11.1, −11.2, −12.8, −13.9, and −13.9 kJ mol^{-1}, respectively. The substituent effects are discussed in relation with those on N–H stretching frequencies.

N–H stretching absorptions of amines and amides have been investigated extensively, and a large number of reports were published by many authors.[1-10] The substituent effects on the N–H stretching frequencies were also investigated and were correlated with the Hammett's σ-constants. The N–H frequencies of the substituted anilines and *N*-methylanilines increase as the σ-constants increase.[2] However, the trend of the N–H frequency shift in these amines is reversed when the N–H groups are in substituted amides.[6] The reversed gradients of the Hammett plots in the substituted aniline and the amide series could be interpreted by taking into accounts the change in hybridization of the nitrogen atoms in these series of compounds.[10] Anilines were proved to exist as a non-planar conformation from the dipole moment measurement,[11] and this provides an evidence for the sp^3-like hybridization of the nitrogen atom. On the other hand, the planar sp^2 hybridization is evident for the amide nitrogen atom. Thus, it is of interest to investigate whether the nitrogen atom takes a planar (sp^2) or a non-planar (sp^3-like) hybridization in diphenylamines. The recent investigations of the present authors have provided an evidence for the fact that the diphenylamines with electron-donating substituents are still non-planar but those with electron-withdrawing substituents, such as the nitro group, take planar conformations at the nitrogen atoms.[10,12] On the contrary, the proton chemical shifts of the diphenylamines exhibit a normal σ-constant *vs.* chemical shift plot and this means that the electron density on the imino hydrogen atom decreases linearly with the substituent constant. This, in turn, implies that the hydrogen donating power of the imino group increases linearly with the increase in σ-values when the imino group participates in a hydrogen bond. Thus, in spite of the anomalous ν_{N-H} *vs.* σ plot, the hydrogen bond shift ($\Delta\nu$) and the enthalpy of hydrogen bond formation might increase linearly with increasing σ-value.

To examine the above conclusions experimentally, the intermolecular hydrogen bonding between the diphenylamines and dimethyl sulfoxide was investigated by the infrared spectroscopic method. Since diphenylamines are rather weak proton donor, a strong proton acceptor is chosen so as to keep an enough amount of the associated species to determine the formation constant of the hydrogen-bonded complex at an enough low concentration to prevent the effect of the self-association of the amine.

Experimental

The infrared N–H stretching spectra were recorded with a Hitachi Model 225 grating infrared spectrophotometer, and the absorption frequencies were calibrated by the absorption bands of water vapor at 3447.09 and 3442.41 cm^{-1} in order to keep the accuracy of the wavenumber within 0.5 cm^{-1}. The measurements were carried out on the ternary diphenylamine–dimethyl sulfoxide–carbon tetrachloride system at the temperatures ranging from 280 to 330 K. Throughout each measurement, the temperature of the solution was kept sufficiently constant. (The temperature variation was kept within 0.5 K). The enthalpy of hydrogen bond formation was calculated by plotting logarithms of the intensity ratios of the N–H stretching bands arisen from the free and the hydrogen-bonded species of diphenylamine ($\varepsilon_b/\varepsilon_f$) against the reciprocals of the temperatures ($1/T$).

The diphenylamines were prepared by the known methods[13-16] and carefully purified either by distillation or by recrystallization.

Results and Discussion

After several preliminary experiments on the association between diphenylamine and some hydrogen acceptors (namely acetone, dimethylformamide, diethyl ether, and dimethyl sulfoxide), dimethyl sulfoxide was chosen as an appropriate hydrogen acceptor to investigate, the substituent effect on the hydrogen-donating power of diphenylamines. In diphenylamine (0.005 mol l^{-1})–dimethyl sulfoxide (0.1 mol l^{-1})–carbon tetrachloride systems, the N–H stretching absorptions of the

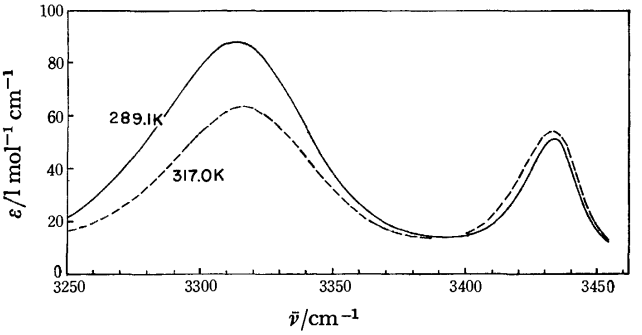

Fig. 1. N–H Stretching absorptions of diphenylamine measured at two temperatures (289.1 K and 317.0 K). The band at 3436 cm^{-1} is assigned to the free species of the amine, and the one at 3314 cm^{-1} to the species associated with dimethyl sulfoxide.

free and the hydrogen-bonded species of diphenylamine are fortunately located separately in the spectra as shown in Fig. 1.

This allows us to use the absorbance to evaluate the amounts of the free and the hydrogen-bonded species without tedious process to separate the two overlapping bands to obtain the integrated intensities. The ratio of the absorbances of the free and the hydrogen-bonded species ($\varepsilon_b/\varepsilon_f$) was determined at various temperatures ranging from 280 to 330 K, and the enthalpy of the hydrogen-bond formation was estimated from the temperature dependence of the equilibrium constant which is assumed to be proportional to $\varepsilon_b/\varepsilon_f$. An example of $\log(\varepsilon_b/\varepsilon_f)$ *vs.* T^{-1} plots is shown in Fig. 2. As the plot can be approximated by a straight line, the enthalpy is estimated from its slope. The results are shown in Table 1 together with the hydrogen bond shifts $\Delta\nu$ which are defined by the equation $\Delta\nu=\nu_f-\nu_b$, where ν_f and ν_b are the NH stretching frequencies of the free and the hydrogen-bonded species of diphenylamines.

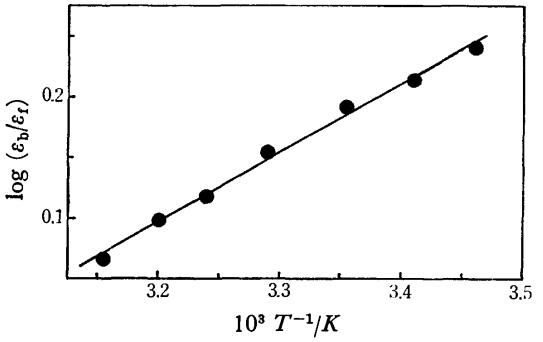

Fig. 2. The temperature dependence of the N-H band intensities of the free and the hydrogen-bonded species of diphenylamine presented as the log ($\varepsilon_b/\varepsilon_f$) *vs.* T^{-1} plot.

Table 1. Hydrogen bond shifts and enthalpies of hydrogen bond formation for diphenylamine–dimethyl sulfoxide–CCl_4 systems

Diphenylamine	ν_{NH}		$\Delta\nu$/cm^{-1}	$-\Delta H$/kJ·mol^{-1}
	ν_f/cm^{-1}	ν_b/cm^{-1}		
4-Methoxy	3432	3320	112	9.6±0.6
4-Methyl	3433	3317	116	10.1±0.6
Unsubstituted	3436	3314	122	11.1±0.6
3-Methoxy	3435	3314	121	11.2±0.8
3-Chloro	3433	3308	125	12.8±1.0
3-Nitro	3433	3301	132	13.9±0.6
4-Nitro	3430	3286	144	13.9±0.6

In order to examine the substituent effect, the enthalpies and the hydrogen bond shifts were plotted against σ values and shown in Figs. 3 and 4, respectively. As expected, the linear relations were observed for both $\Delta\nu$ *vs.* σ and ΔH *vs.* σ plots. This shows that the hydrogen-donating abilities of the diphenylamines increase with the increase in σ values. The result agrees with the substituent effect observed in the series of phenols.

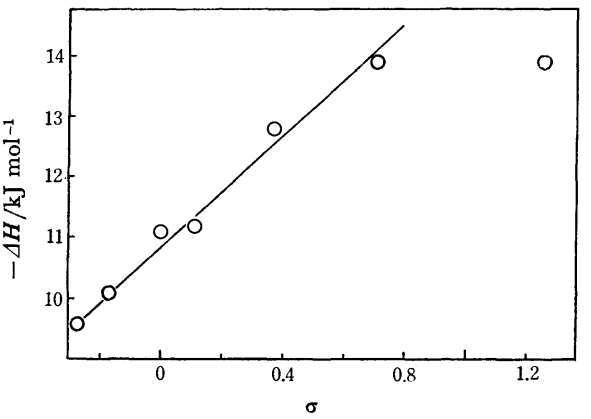

Fig. 3. The ΔH *vs.* σ plot.

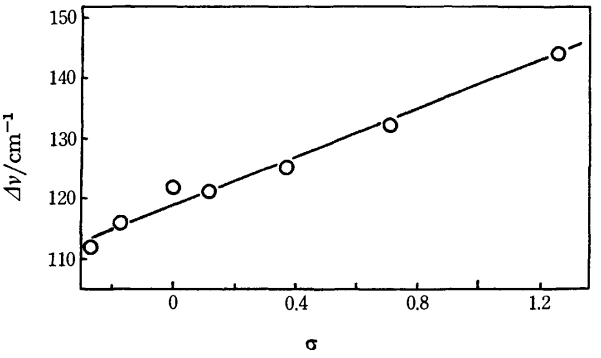

Fig. 4. The $\Delta\nu$ *vs.* σ plot.

The substituent effect on the enthalpies results from the change in acidities of the diphenylamines. In general, a stronger acid forms a stronger hydrogen bond when other conditions are similar. From the electrostatic point of view, this phenomenon is explained that the larger N–H dipole of a diphenylamine carrying an electron-withdrawing substituent attracts more intensely the S–O dipole of dimethyl sulfoxide. By the concept of the charge transfer interaction, the results are interpreted as follows. Lower electron density on the N–H group stablizes its anti-bonding σ*-orbital, and then the unshared electrons of the proton acceptor can interact more easily with the σ*-orbital. Hence, the stronger hydrogen bond is formed when the substituent on the diphenylamine is more electron attracting.[19]

The hybridization of the imino nitrogen atom changes so as to increase the s-character of the nitrogen orbital when the substituent becomes more electronegative. As the s-character of the N atomic orbital increases, the resulting N–H molecular orbitals tend to be lower in energy. This again favors for the hydrogen bond formation. Somewhat convex curvatures of the plots may be caused by the reinforced effect of the electronegativity and the hybridization in the negative σ region. However, further investigation is necessary to estimate their effect separately. A considerable deviation from the line is observed with 4-nitrodiphenylamine, and this may be attributed to the strong conjugation between the nitrophenyl and the imino groups which enforces the both groups planar.

Enthalpies of hydrogen bond formation of the unsubstituted diphenylamine have been measured by several authors employing various hydrogen acceptors. Among the hydrogen acceptors investigated, triethylamine forms the strongest hydrogen bond of which enthalpy is estimated to be $-18.8\,\mathrm{kJ\,mol^{-1}}$. The N–H···O hydrogen bond of diphenylamine is by far weaker. The enthalpies of formation were reported to be -10.0, -10.5, and $-11.7\,\mathrm{kJ\,mol^{-1}}$, respectively, when the acceptors are dioxane, acetone, and methyl acetate.[17,18] Thus, the results of the present authors seem to be consistent with the previous reports. The hydrogen bonding of substituted diphenylamines has never been reported.

The present investigation was partly supported by a Scientific Research Grant from the Ministry of Education of Japan for which the authors are grateful.

Superacids and Their Derivatives. V.[1] Kinetics and Mechanism of the Cationic Polymerization of 3,3-Bis(chloromethyl)oxacyclobutane Initiated by Ethyl Trifluoromethanesulfonate. Evidence for Ester Type Propagating Species

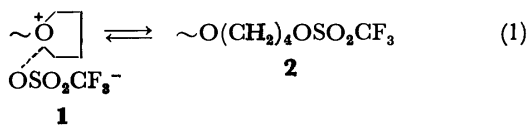
Shiro KOBAYASHI, Hidenori DANDA, and Takeo SAEGUSA

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606

(Received April 18, 1974)

Kinetic analysis of the cationic ring-opening polymerization of 3,3-bis(chloromethyl)oxacyclobutane (BCMO) initiated by ethyl trifluoromethanesulfonate ($EtOSO_2CF_3$) was carried out by direct determination of the instantaneous concentrations of monomer, initiator, and propagating species by means of ^1H and ^{19}F NMR spectroscopy. It was established that the polymerization of BCMO proceeds *via* an ester type propagating species (**4**). The propagating species of the first (P_1^*) and subsequent propagations (P_n^*, $n \geqq 2$) were directly observed. The rate constants of initiation (k_i) and propagations of the first (k_{p1}), second (k_{p2}) and subsequent steps (k_{pn}, $n \geqq 3$) were determined. Activation parameters as well as the solvent effect supported the proposed mechanism, in which the rate-determining step is a dipole-dipole reaction between monomer and propagating ester species to form the intermediate cyclic oxonium ions (**7**, **8**, and **10**) as unstable transient species.

In a series of our studies on the reaction of superacid derivatives with cyclic ethers, we have reported kinetic studies on the cationic ring-opening polymerization of tetrahydrofuran (THF) initiated by superacid esters[1,2] and by pyrosulfuryl chloride,[3] and on the oxonium formation from superacid esters and tetrahydropyran.[4] Generally, the cationic ring-opening polymerization of THF by Lewis acid catalysts proceeds *via* cyclic trialkyl oxonium propagating species.[5] In the THF polymerization by superacid ester initiators, however, an equilibrium between cyclic oxonium **1** and ester **2** species of the propagating end is involved during the course of polymerization.[2,6,7]

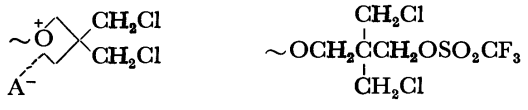


$$\sim\overset{+}{O}\!\square \rightleftharpoons \sim O(CH_2)_4OSO_2CF_3 \quad (1)$$

$OSO_2CF_3^-$ (**1**) (**2**)

It was confirmed by means of ^{19}F NMR spectroscopy that equilibrium (1) takes place in the propagating species of the THF polymerization initiated by ethyl trifluoromethanesulfonate ($EtOSO_2CF_3$).[1]

In the cationic polymerization of four-membered cyclic ethers by acid catalysts, a mechanism involving a cyclic oxonium propagating species **3** is generally accepted.[5,8] As an extension of studies on the cationic polymerization of cyclic ethers initiated by superacid



3 **4**

esters, we examined the polymerization of 3,3-bis(chloromethyl)oxacyclobutane (BCMO) by $EtOSO_2CF_3$ initiator. Kinetics of the BCMO polymerization has been carried out by means of ^1H NMR spectroscopy. It was found that an ester type **4** is a propagating species. In the present paper we wish to give clear-out evidence for an ester type propagating species in the polymerization of cyclic ethers.

Results and Discussion

^1H NMR Studies. The polymerization reaction was monitored directly by ^1H NMR spectroscopy. Figure 1 shows examples of ^1H NMR spectra of the reaction system, in which the molar feed ratio of BCMO to $EtOSO_2CF_3$ is 6: 1. In the ^1H NMR spectrum after 5 min at 63 °C (Fig. 1(a)), 55% of the initial $EtOSO_2CF_3$ underwent reaction. A quartet at δ 4.82 (peak H) and a triplet at δ 1.60 (peak I) are due to methylene (2H) and methyl protons (3H) of $EtOSO_2CF_3$, respectively. Peaks H and I diminished with progress of the reaction, peaks A_1, D, E, F, and G increasing. $EtOSO_2CF_3$ was completely consumed at 63 °C within 15 min.

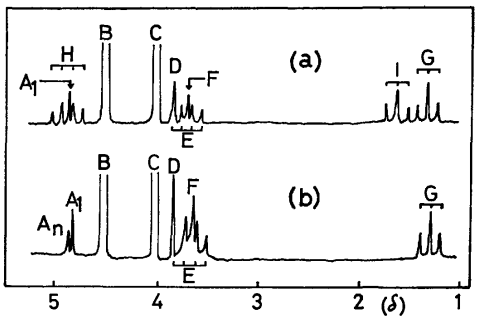


Fig. 1. ^1H NMR spectra of BCMO polymerization mixture by $EtOSO_2CF_3$ in nitrobenzene at 63 °C; (a) after 5 min and (b) after 180 min.

A new peak A_n appears in the ^1H NMR spectrum at a reaction time of 180 min at 63 °C (Fig. 1(b)). Singlet peaks, A_1 at δ 4.80 and A_n at δ 4.83, are assigned respectively to α-methylene protons (2H) of $-OSO_2CF_3$ group in ester type species **5** and **6** (*vide infra*). A signal of the open-chain chloromethyl protons (4H) appears at δ 3.82 (peak D). A peak due to α-methylene protons (2H) of open-chain ether group is observed at δ 3.64 (peak F). A quartet peak E at δ 3.67 and triplet peak G at δ 1.33 are ascribed respectively to methylene protons (2H) and methyl protons (3H) of

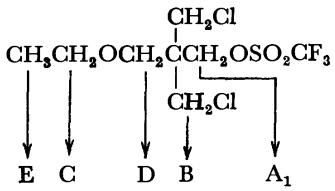
6, $n \geqq 2$

ethoxy group at the polymer end. Large singlets, B and C, are due to α-methylene protons (4H) and chloromethyl protons (4H) of BCMO monomer. Signal assignments given in Fig. 1(a) and (b) are summarized in Table 1.

For the sake of confirmation, a model compound of 3-ethoxy-2,2-bis(chloromethyl)propyl trifluoromethanesulfonate **5** was prepared by the reaction of $EtOSO_2CF_3$ and BCMO (see Experimental). **5** was isolated by distillation *in vacuo*, bp 45—46 °C (0.04mmHg). The NMR spectrum of **5** in nitrobenzene is shown in Fig. 2(a). Chemical shifts of **5** in $CDCl_3$ and in nitrobenzene are given in Table 2. It should be noted that the chemical shift of signal A_1 of **5** in nitrobenzene coincides with that of the polymerization system (Table 1). This provides a strong evidence that signal A_1 of the reaction system is due to α-methylene protons of ester type species ~~~$CH_2OSO_2CF_3$ of **4**. Chemical shifts of other signals in nitrobenzene (Table 2) are almost the same as those of corresponding peaks (Table 1).

An oligomer of **6** was prepared in order to confirm the assignment of peak A_n. The oligomer obtained did not contain **5** at all, and showed no signal at δ 4.80 (peak A_1 region). The average degree of polymerization of **6** was found to be n=2.30 (see Experimental). The signal due to α-methylene protons of ~~~$CH_2OSO_2CF_3$ in **6** appears at δ 4.83 (Fig. 2(b)), which is identical with the chemical shift of peak A_n of the

TABLE 2. SIGNAL ASSIGNMENTS OF THE MODEL COMPOUND **5**



Signal	Chemical shift in ppm[a] (from Me_4Si)	
	in $CDCl_3$	in nitrobenzene
A_1	4.56 (s)	4.80 (s)
B	3.63 (s)	3.84 (s)
C	3.48 (q)	3.67 (q)
D	3.45 (s)	3.65 (s)
E	1.15 (t)	1.34 (t)

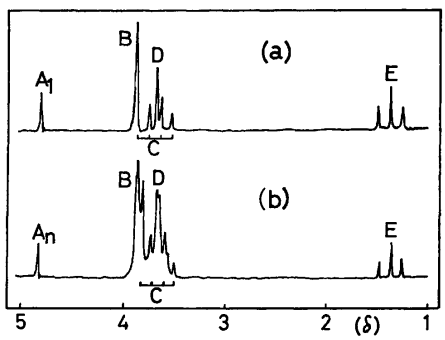

Fig. 2. ^1H NMR spectra in nitrobenzene at 35 °C of (a) **5** and (b) oligomer.

polymerization system. It is reasonable that the methylene proton signal due to ~~~$CH_2OSO_2CF_3$ of **6** appears at a field 0.03 ppm lower than that of **5**, since $Et\{OCH_2C(CH_2Cl)_2CH_2\}_{n-1}$ group in **6** is a little more electron-withdrawing than Et-group in **5**.

In coincidence with the observations of ^1H NMR spectroscopy, a signal due to the CF_3 group of **6** appeared at a lower field than that of **5** in ^{19}F NMR spectroscopy. The fluorine-19 chemical shift of a sharp singlet due to **6** was −3.58 ppm from the external standard of CF_3CO_2H capillary, whereas that due to **5** was −3.44 ppm in nitrobenzene.

Kinetics. The following scheme of reactions explains the course of BCMO polymerization.

Initiation

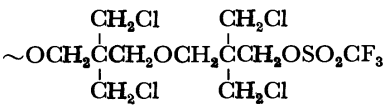
10



(4)

11 (P^*_{n+1})

Oxonium species **7**, **8**, and **10** might be involved as intermediates. However, these intermediates are not stable under the reaction conditions, undergoing rearrangement quickly to the ester type species **5**, **9**, and **11**, respectively.

The rate of initiation is given by

$$-\frac{d[I]}{dt} = k_i[I][M] \tag{5}$$

where k_i is the rate constant of initiation, and [I] and [M] are the concentrations of $EtOSO_2CF_3$ and BCMO, respectively. Integration of Eq. (5) gives

$$\ln\frac{[I]_0}{[I]_t} = k_i\int_0^t [M]dt \tag{6}$$

where $[I]_0$ is the initial feed concentration of $EtOSO_2CF_3$. The ratio $[I]_0/[I]_t$ was calculated from the integration values of peaks I and G in Fig. 1(a). The integrated value of [M] was obtained by graphical integration on the [M]-time curve. A linear plot of Eq. (6) is shown in Fig. 3, with a slope $k_i=1.4\times10^{-3}$ l/mol·s at 70 °C.

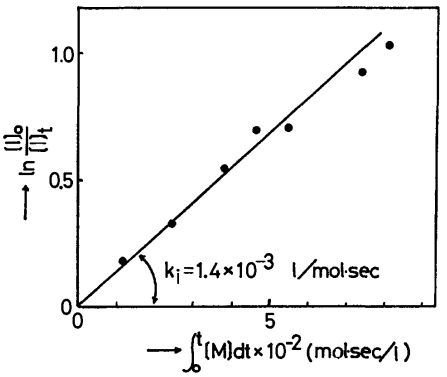


Fig. 3. Plots of Eq. (6) in BCMO polymerization by $EtOSO_2CF_3$ in nitrobenzene at 70 °C: $[I]_0=0.56$ mol/l, $[M]_0=3.90$ mol/l.

After the complete reaction of initiator, the consumption rate of the first propagating species P_1* is given by

$$-\frac{d[P_1^*]}{dt} = k_{p1}[P_1^*][M] \tag{7}$$

where k_{P1} is the rate constant of the first propagation. Integration of Eq. (7) with respect to time gives

$$\ln\frac{[P_1^*]_{t_1}}{[P_1^*]_{t_2}} = k_{p1}\int_{t_1}^{t_2}[M]dt \tag{8}$$

where t_1 and t_2 are reaction times longer than the time required for the complete reaction of initiator. The ratio $[P_1^*]_{t_1}/[P_1^*]_{t_2}$ was obtained by the integration values of peaks A_1 and A_n in Fig. 1(b). Figure 4 shows a linear plot of Eq. (8), with a slope $k_{p1}=1.4\times10^{-5}$ l/mol·s at 70 °C.

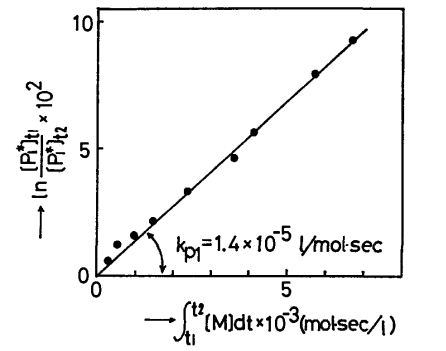

Fig. 4. Plots of Eq. (8) in BCMO polymerization by $EtOSO_2CF_3$ in nitrobenzene at 70 °C: $[I]_0=0.56$ mol/l, $[M]_0=3.90$ mol/l.

Kinetic runs of the BCMO polymerization by $EtOSO_2CF_3$ were similarly carried out at three other temperatures. At lower temperatures between 63—85 °C the reaction rate was small, and the polymerization was followed until P_1^* disappeared. Arrhenius plots of k_i and k_{p1} values were linear, and activation parameters were calculated (Table 3). For higher conversions, the polymerizations were carried out at higher temperatures (*vide infra*).

TABLE 3. RATE CONSTANTS AND ACTIVATION PARAMETERS OF INITIATION (k_i) AND THE FIRST PROPAGATION (k_{p1}) IN THE BCMO POLYMERIZATION BY $EtOSO_2CF_3$ IN NITROBENZENE SOLVENT[a)]

$\Delta S^{\ddagger}$ (e. u.)	−36	−46

a) Reaction conditions; $[M]_0=3.90$ mol/l, $[I]_0=0.56$ mol/l.

Polymerization by $EtOCH_2C(CH_2Cl)_2CH_2OSO_2CF_3$ (5). According to the scheme of the $EtOSO_2CF_3$-initiated polymerization of BCMO (reaction mechanism (2)—(4)), **5** corresponds to the smallest species of propagation (P_1^*). Thus, the kinetics of polymerization by **5** was studied at higher temperatures. In this case, polymerization starts directly from the first propagating step (reaction mechanism (3)). Figure 5 shows the time-conversion cur e of BCMO monomer at 128 °C.

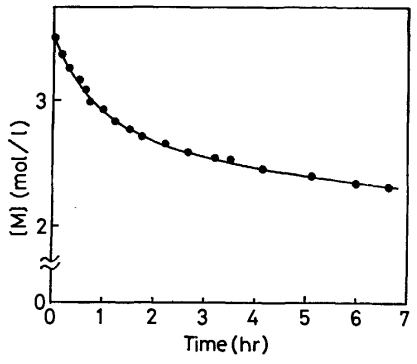

Fig. 5. Relationships between time and monomer conversion in BCMO polymerization initiated with **5** in nitrobenzene at 128 °C: $[5]_0=0.45$ mol/l, $[M]_0=3.50$ mol/l.

The rate of polymerization by **5** is given by

$$-\frac{d[M]}{dt} = k_{p1}[P_1^*][M] + [M]\sum_{n=2} k_{pn}[P_n^*] \qquad (9)$$

The combined value of $[P_1^*]$ and $[P_n^*]$ was found by integration of peaks A_1 and A_n to be constant throughout the kinetic run. This supports the view that the system is of living character under the kinetic reaction conditions. The stoichiometry between the combined value of peaks A_1 and A_n (total 2H) and peak G (3H) was found to hold, *i.e.*, $[P_1^*]+\sum_{n=2}[P_n^*]=[5]_0$. On the assumption that $k_{p2}=k_{p3}=\cdots\cdots=k_{pn}$, integration of Eq. (9) with respect to time from t_1 to t_2 gives

$$\ln\frac{[M]_{t_1}}{[M]_{t_2}} = k_{p1}\int_{t_1}^{t_2}[P_1^*]dt + k_{pn}\int_{t_1}^{t_2}[P_n^*]dt \qquad (10)$$

The $[P_1^*]$-time relationships were obtained by monitoring the reaction with ^1H NMR spectroscopy (peaks A_1 and A_n). Since peaks A_1 and A_n partly overlap with each other, the reaction was also followed by ^{19}F NMR spectroscopy. Signals due to the CF_3 group of **5** and **6** appeared as sharp singlets at −3.91 and −4.08 ppm, respectively, from an external standard of CF_3CO_2H capillary under the polymerization conditions. Results by both methods were in good agreement with each other (Fig. 6). A linear plot of Eq. (8) was made (Fig. 7), whose slope gave $k_{p1}=1.8\times10^{-4}$ l/mol·s at 128 °C.

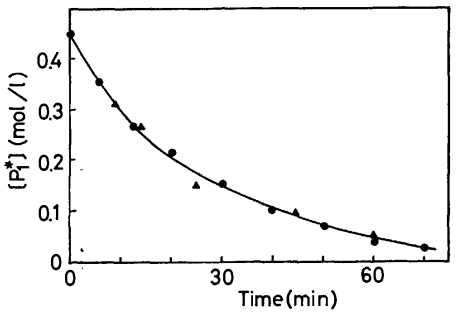

Fig. 6. $[P_1^*]$-time relationships in BCMO polymerization initiated with **5** in nitrobenzene at 128 °C monitored by ^1H NMR (-●-) and ^{19}F NMR (-▲-) spectroscopy: $[5]_0=0.45$ ml/l, $[M]_0=3.50$ mol/l.

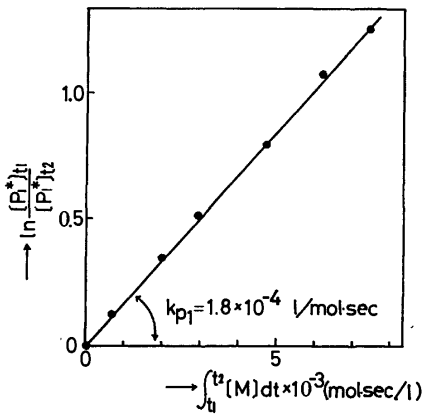

Fig. 7. Plots of Eq. (8) in BCMO polymerization initiated with **5** in nitrobenzene at 128 °C: $[5]_0=0.45$ mol/l, $[M]_0=3.50$ mol/l.

Equation (10) is converted into

$$\ln\frac{[M]_{t_1}}{[M]_{t_2}} - k_{p1}\int_{t_1}^{t_2}[P_1^*]dt = k_{pn}\int_{t_1}^{t_2}[P_n^*]dt \qquad (11)$$

Figure 8 shows a plot of Eq. (11), consisting of two straight lines A and B of different slopes. The plot indicates $k_{p2}>k_{p3}\simeq k_{p4}$. Line A was utilized to calculate k_{p2}, since the monomer consumption in its period corresponded to the stage of the second to third propagation step. Thus, $k_{p2}=5.7\times10^{-5}$ l/mol·s at 128

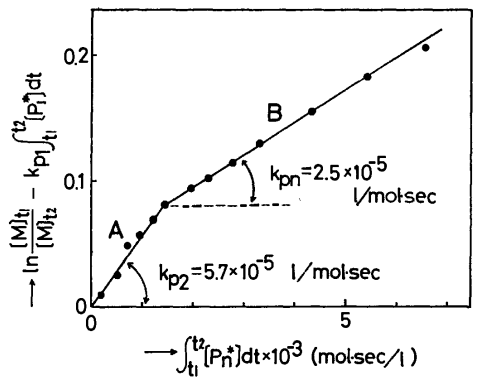

Fig. 8. Plots of Eq. (11) in BCMO polymerization initiated with **5** in nitrobenzene at 128 °C: $[\mathbf{5}]_0=0.45$ mol/l, $[M]_0=3.50$ mol/l.

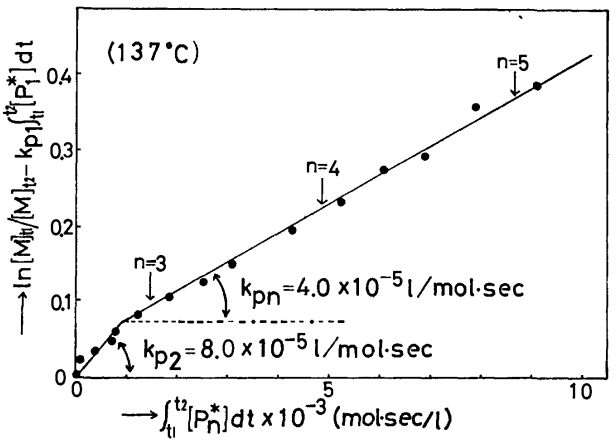

Fig. 9. Plots of Eq. (11) in BCMO polymerization initiated with **5** in nitrobenzene at 137 °C: $[\mathbf{5}]_0=0.37$ mol/l, $[M]_0=3.80$ mol/l.

°C was obtained from the slope of line A. After the reaction stage of line A, the rate constant was calculated to be $k_{p3}=k_{p4}=k_{pn}=2.5\times10^{-5}$ l/mol·s at 128 °C from the slope of line B. It became clear in the polymerization at higher reaction temperature of 137 °C that k_{pn} does not change any more after the third propagation step (Fig. 9), *i.e.*, k_{pn} was constant from $n=3$ to at least $n=5$.

Similar results were obtained with $EtOSO_2CF_3$ initiator instead of **5** initiator at 128 °C. These data along with activation parameters are given in Table 4.

Table 4. Rate constants of propagation and activation parameters in the BCMO polymerization initiated by the compound (**5**) in nitrobenzene solvent

Temp. (°C)	$k_{p1}\times10^5$ (l/mol·s)	$k_{p2}\times10^5$ (l/mol·s)	$k_{pn}\times10^5$ (l/mol·s)

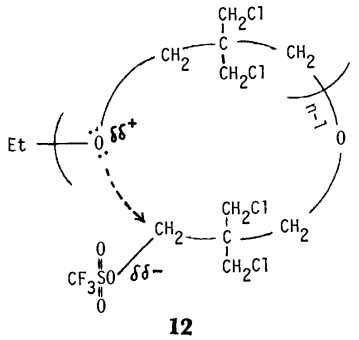
a) Reaction conditions; $[M]_0=3.50$ mol/l, $[\mathbf{5}]_0=0.45$ mol/l. b) $EtOSO_2CF_3$ initiator. c) Reaction conditions; $[M]_0=3.80$ mol/l, $[\mathbf{5}]_0=0.37$ mol/l.

Reaction Mechanism. All the results are in line with the reaction mechanisms (2)—(4). In fact, the propagating species of ester type were observed directly by both ^1H and ^{19}F NMR spectroscopy during the kinetic run. The first propagating species **5** was isolated by vacuum distillation and the **5**-initiated BCMO polymerization commenced directly from the first propagation.

The rate of propagation varied during the course of polymerization *i.e.*, $k_{p1}>k_{p2}>k_{p3}=k_{pn}$ ($n\geqq3$) (Table 4). These values could be determined since P_1^* and P_n^* ($n\geqq2$) were directly observed by both ^1H and ^{19}F NMR spectroscopy. The difference in k_p is due to the difference in electrophilic reactivity of alkyl groups toward BCMO monomer for $n=1$, 2 and $\geqq3$ in **6**. The larger the alkyl chain ($n\geqq3$), the less the reactivity. This might be partly due to the increase of bulkiness of alkyl groups. It could be assumed that **6** is stabilized (deactivated) through an intramolecular coordination as given by **12**, *i.e.*, such cyclization probably becomes more profound for $n\geqq3$ whereas it is not possible for $n=1$.



12

Examination of activation parameters (Tables 3 and 4) also supports the mechanisms (2)—(4). They are characterized by a general feature of activation parameters of S_N2 reaction between two neutral molecules producing an ionic species as a final product or a transient intermediate, the combination of low activation enthalpy (favorable for rate) and low activation entropy (unfavorable) taking place in each process.[4] The following reaction is reversible,

$$ROSO_2X + \text{O}\!\!\bigcirc \underset{}{\overset{k_{ox}}{\rightleftharpoons}} R\text{-}\overset{+}{\text{O}}\!\!\bigcirc \qquad (12)$$

R=Me, Et, *n*-Pr; X=CF_3, F, Cl; OSO_2X^-

the process of oxonium formation (k_{ox}) having a relatively low ΔH^* (favorable for k_{ox}) and a low ΔS^* (unfavorable for k_{ox}).[4] A similar phenomenon is often observed in the Menschutkin reaction in which an ammonium ion is formed from alkyl iodide and amine (Eq. (13)).[9]

$$RI + R_3'N \longrightarrow RR_3'\overset{+}{N}I^- \qquad (13)$$

The magnitudes of k_{p1} are about one-hundredth of those of k_i (Table 3). The small k_{p1} value is ascribed to the lower ΔS^* value; ΔH^* values being the same in both cases. The difference in rate of initiation and the first propagation is due to that of the electrophilic reactivity

of alkyl groups attached to OSO_2CF_3 toward the BCMO nucleophile, *e.g.*, CH_3CH_2-group for the former and $EtOCH_2C(CH_2Cl)_2CH_2$-group for the latter. A similar result was reported by Buncel and Millington[10] for the hydrolysis of primary alkyl chlorosulfates (**13**) in 85.3% aqueous dioxane, in which the reactivity of the ethyl group (**13a**) was 4.2×10^2 times as high as that of the

$ROSO_2Cl$

13a $R=CH_3CH_2$-
13b $R=(CH_3)_3CCH_2$-

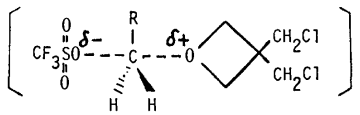
neopentyl group (**13b**). The alkyl group of propagating species is bulkier (unfavorable) than the neopentyl group of **13b**, whereas α-carbon atom of the former should be more positive due to electron-withdrawing chloromethyl groups (favorable) than that of the latter group. The combination of steric and electronic factors brings forth the reactivity difference of $k_i/k_{p1}\fallingdotseq100$.

TABLE 5. RATE CONSTANTS OF INITIATION (k_i) AND THE FIRST PROPAGATION (k_{p1}) IN THE BCMO POLYMERIZATION BY $EtOSO_2CF_3$ IN THREE DIFFERENT SOLVENTS AT 63 °C[a]

Solvent	$k_i\times10^3$ (l/mol·s)	$k_{p1}\times10^5$ (l/mol·s)
Nitrobenzene	0.87	0.90
Chlorobenzene	0.20	0.17
Methylcyclohexane	——[b]	0.10

a) Reaction conditions; $[M]_0=3.90$ mol/l, $[I]_0=0.56$ mol/l. b) The k_i value could not be determined since the solvent signals overlapped with methyl signals of peaks G and I.

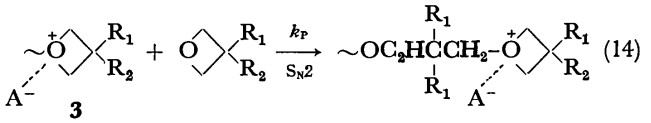
Solvent Effect. In order to obtain information on the mechanistic features, solvent effect was examined. Values of k_i and k_{p1} in the BCMO polymerization by $EtOSO_2CF_3$ initiator in three different solvents at 63 °C are given in Table 5. Both k_i and k_{p1} values increase in polar solvents, *e.g.*, k_{p1} is 5.3 times higher in nitrobenzene than in chlorobenzene. The results also provide evidence for the mechanisms (2)—(4). In the reaction between two neutral molecules of ester type species (electrophile) and BCMO monomer (nucleophile) the ionic transition state **14** will be



14 R = CH_3- or $\sim CH_2C(CH_2Cl)_2CH_2Cl$

more stabilized by solvation in a polar solvent as compared with the initial state of two neutral molecules. Similarly the oxonium formation (Eq. (12)) was favored in polar solvents, *e.g.*, k_{ox} in nitrobenzene was 2.65 times larger than that in chlorobenzene for R=Et and X=Cl in Eq. (12).[4]

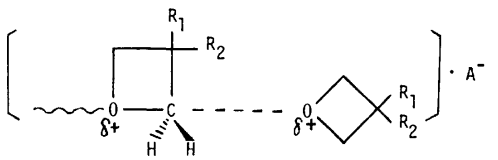
The solvent effect (Table 5) is in sharp contrast to that observed in the cationic polymerization of four-membered cyclic ethers by typical Lewis acids such as BF_3, *i.e.*, k_p values of both unsubstituted and 3-methyloxacyclobutanes by BF_3 initiator were about 9 times higher in a nonpolar solvent of methylcyclohexane than in a polar one of CH_2Cl_2.[8] It is generally accepted that the polymerization of oxacyclobutanes initiated by typical Lewis acids proceeds *via* an S_N2 reaction between the propagating cyclic oxonium **3** (electrophile) and monomer (nucleophile):[5,8]



(14)

3

where A^- represents the counter anion derived from initiator. In this case the transition state given by **15** is less solvated than the initial state, since the positive charge is more dispersed in **15** than in the initial state of oxonium. Thus, k_p decreases in a polar solvent with BF_3 catalyst.[8]

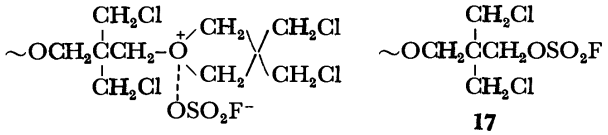


15

In the BCMO polymerization by BF_3, solvent effects were examined by Penczek and Penczek,[11] who found that the polymerization proceed through the oxonium propagating species and that the apparent overall rate of polymerization is greater in more polar solvents. The increase of the overall rate was ascribed to the increase in the rate of initiation, *i.e.*, concentration of the propagating species increased but the propagation rate did not.

In contrast to the present results it has been found that polymerization of oxacyclobutane and of 3-methyloxacyclobutane initiated by $EtOSO_2CF_3$ proceeds *via* oxonium propagating species.[12] The difference is due to two chloromethyl groups of BCMO, which brings about not only a destabilization of intermediate oxonium ions (**7**, **8**, and **10**) but also a decrease in the nucleophilic reactivity of BCMO monomer.

Recently, Pruckmayr and Wu[13] reported on a ^1H NMR study of BCMO polymerization initiated by superacid of fluorosulfuric acid ($HOSO_2F$). However, the rate constants were not determined since the system was complicated owing to the presence of "acidic" proton derived from $HOSO_2F$. Unlike their system the present polymerization with $EtOSO_2CF_3$ was clean, since no such acidic proton is involved. Thus, kinetic analysis was successfully made. Concerning ^1H NMR spectral assignments they ascribed peaks at δ 4.56 and 4.31 in CH_2Cl_2 (peaks A and C in Fig. 7[13]) respectively to the open-chain methylene and the ring methylene protons adjacent to the propagating oxonium **16**. However, it is unlikely that a trialkyl four-membered cyclic



16

17

oxonium such as **16** is observed as a long-lived species under their ^1H NMR measurement conditions. It is also very unlikely that ring methylene protons of **16** appear at higher chemical shift (δ 4.31) than those of BCMO (δ 4.41).[13] We propose here with that a peak at δ 4.56[13] is assigned to α-methylene protons of OSO_2F group of **17**. To support this assignment a signal due to α-methylene protons of OSO_2CF_3 of **5** appears at nearly the same chemical shift of δ 4.60 in CH_2Cl_2,[12] since the chemical shift of α-methylene protons of OSO_2X is not affected by X=F, Cl, and CF_3.[14] Thus, we believe that ester type **17** is involved as a stable propagating species also in the BCMO polymerization by $HOSO_2F$ initiator.

Experimental

Materials. BCMO and all solvents were purified as previously reported.[1,4,15] $EtOSO_2CF_3$ was prepared by the reaction of diethyl sulfate with CF_3SO_3H.[2]

3-Ethoxy-2,2-bis(chloromethyl)propyl trifluoromethanesulfonate **5** was prepared as follows. A mixture of 8.36 mmol of BCMO and 10.0 mmol of $EtOSO_2CF_3$ in 2.0 ml of CH_2Cl_2 was allowed to react for 10 days at 35 °C, in which BCMO was completely consumed. CH_2Cl_2 and excess $EtOSO_2CF_3$ were then removed, and **5** was isolated in 90% yield by vacuum distillation, bp 45—46 °C/0.04 mmHg. The data of the ^1H NMR spectrum are given in Table 2. ^{19}F NMR (nitrobenzene): −3.44 ppm (~~~OSO_2CF_3) (from the external standard of CF_3CO_2H capillary). IR (neat): ν_{max} 1420, 1210, and 1150 cm^{-1} ($-SO_2-$).[16]

Found: C, 28.95; H, 3.94%. Calcd for $C_8H_{13}F_3O_4SCl_2$: C, 28.84; H, 3.90%.

Preparation of Oligomer. A mixture of BCMO (8.30 mmol) and $EtOSO_2CF_3$ (1.20 mmol) in 1.0 ml of nitrobenzene was allowed to react at 100 °C. After 10 hr, signal A_1 disappeared completely, and only signal A_n was observed in the ^1H NMR spectrum. Unchanged BCMO and nitrobenzene were removed *in vacuo*. The residue was an oligomer of oily material (0.60 g). The average degree of oligomerization was determined by ^1H NMR to be n=2.30 from the integration ratio of peaks B, C, and D to peak A_n of the ^1H NMR spectrum (Fig. 2 (b)). ^{19}F NMR (nitrobenzene): −3.58 ppm (~~~OSO_2CF_3) (from the external standard of CF_3CO_2H capillary). IR (neat): ν_{max} 1420, 1210, and 1145 cm^{-1} ($-SO_2-$).[16] The molecular weight of oligomer was determined to be 510 by vapor pressure osmometry, which is close to the calculated value of 535 with n=2.30 in **6**. Thus, the 0.60 g oligomer obtained corresponds to 1.12 mmol, which does not differ much from the concentration of the initiator of $EtOSO_2CF_3$. This indicates that each initiator produces 1 mol of oligomer.

Found: C, 32.56; H, 4.26; F, 10.68; S, 6.45; Cl, 30.60%. Calcd for $C_{14.50}H_{23.40}F_3O_{5.30}SCl_{4.60}$ (n=2.30 in **6**): C, 32.58; H, 4.41; F, 10.66; S, 6.00; Cl, 30.50%.

NMR Measurement. A typical example is as follows. Into an NMR sample tube were introduced 1.67 mmol of BCMO, 0.24 mmol of $EtOSO_2CF_3$ and 0.20 ml of nitrobenzene at −78 °C under nitrogen. The tube was sealed and stirred at the same temperature. The extent of the reaction was negligible at this point. The tube was then inserted into the NMR probe which was kept at a constant temperature. The reaction was then monitored. A Hitachi R-20B NMR spectrometer equipped with radio frequency counters of ^1H (60 MHz) and ^{19}F (56.456 MHz) nuclei was used. The reaction temperature was kept constant within ±1 °C and the experimental error of the NMR analysis was within ±2%.

Molecular Weight Determination. The molecular weight of the oligomer was determined by a vapor pressure osmometer (Hitachi Perkin-Elmer model 115) in dimethylformamide at 55 °C.

Superacids and Their Derivatives. VI.[1] Kinetics of the Cationic Ring-Opening Polymerization of Tetrahydrofuran Initiated by Ethyl 2,4,6-Trinitrobenzenesulfonate

Shiro KOBAYASHI, Tamotsu NAKAGAWA, Hidenori DANDA, and Takeo SAEGUSA

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606

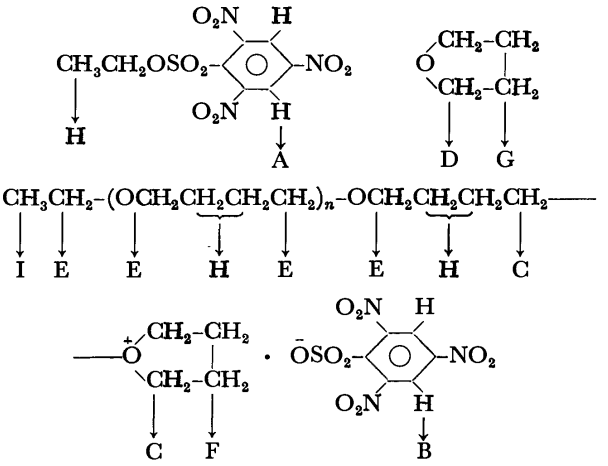
(Received July 11, 1974)

Ethyl 2,4,6-trinitrobenzenesulfonate ("trinitate", EtOTn) was found to induce the ring-opening polymerization of tetrahydrofuran (THF). Kinetic studies of the THF polymerization by EtOTn initiator were carried out in CH_2Cl_2 solution by NMR spectroscopy. The instantaneous concentrations of the counteranion of the propagating oxonium species (**1**) and monomer were directly determined at the same time by the NMR measurement. The rate constants of initiation (k_i) and propagation ($k_{p(i)}$) due to **1** were obtained. Upon the view of $k_{p(i)}$ values with various initiators, it was concluded that the $k_{p(i)}$ values are changed significantly depending on the nature of the counteranion.

In recent several studies on the cationic ring-opening polymerization of tetrahydrofuran (THF) superacids and their ester or anhydride derivatives have been employed as initiator.[2-7] In these studies trifluoromethanesulfonic (TfOH),[2,3,5-7] fluorosulfuric (FSO_3H),[2,7] and chlorosulfuric acids ($ClSO_3H$)[2,4] were used as the superacid component. Primary alkyl esters of these acids are known to form oxonium ions with tetrahydropyran.[8] Generally, initiators are effective for the cationic ring-opening polymerization of THF, when they can form stable trialkyl oxonium ions. 2,4,6-Trinitrobenzenesulfonic acid (TnOH) is well known to be an only acid among organic acids except for TfOH to produce a stable trialkyl oxonium ion in the reaction with ether.[9,10] As an extension of our studies on the superacids and their derivatives, therefore, we examined the THF polymerization initiated by ethyl 2,4,6-trinitrobenzenesulfonate which we wish to abbreviate as "ethyl trinitate" (EtOTn). It was found that EtOTn induced the THF polymerization. Now, we wish to report kinetic results of this system. Kinetic analysis was performed by NMR spestroscopy.

Results and Discussion

NMR Spectroscopy. Figure 1 shows an example of NMR spectrum of the THF polymerization with EtOTn initiator after 60 min at 20 °C in CH_2Cl_2. The initial concentrations of monomer $[M]_0$ and of initiator $[I]_0$ were 6.78 and 0.167 mol/l, respectively. Among the signals in Fig. 1 peaks A at δ 8.84 and B at δ 8.56 should be noted. They are assigned respectively to aromatic protons (2H) of EtOTn (peak A) and of trinitate anion (peak B). The assignment of peak B is supported by the fact that the aromatic protons of triethyloxonium trinitate appears at the same chemical shift of peak B (See Experimental). The pattern of signals C–I is very similar to that of the polymerization mixture by EtOTf initiator, whose signal assignments were already performed.[2] Therefore, only the result of the assignment is shown here as follows;



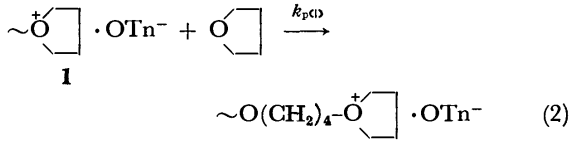
A quartet signal due to methylene protons of EtOTn should appear around at δ 4.8—4.3. However, it is not detected clearly in Fig. 1 because of the low concentration of EtOTn.

Kinetics. The course of the THF polymerization by EtOTn is given by the following reactions (Eqs. (1) and (2)).

Initiation

(1)

Propagation



(2)

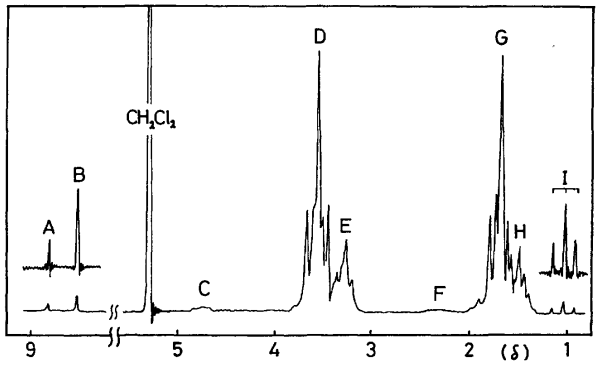


Fig. 1. NMR spectrum of the THF polymerization system initiated by ethyl 2,4,6-trinitrobenzenesulfonate in CH_2Cl_2 after 60 min at 20 °C.

Based on the above reactions of a bimolecular mechanism, the integrated rate equations of initiation and propagation are given by Eqs. (3) and (4), respectively[2,3]

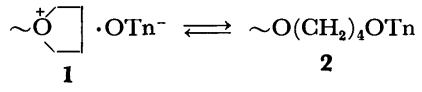
$$\ln \frac{[I]_{t_1}}{[I]_{t_2}} = k_i \int_{t_1}^{t_2} [M]dt \quad (3)$$

and

$$\ln \frac{[M]_{t_1}-[M]_e}{[M]_{t_2}-[M]_e} = k_{p(i)} \int_{t_1}^{t_2} [O^+]dt \quad (4)$$

where k_i and $k_{p(i)}$ denote the rate constants of initiation and of propagation due to the oxonium ion species **1**, $[O^+]$ is the concentration of the oxonium propagating species, and [I], [M], and $[M]_e$ are respectively the initiator, monomer, and equilibrium monomer concentrations.[2]

The peak area of B was equal to two-third of that of triplet peak I throughout the kinetic run, *i.e.*, the molar ratio between the counteranion (OTn^-) of the propagating polymer end **1** and ethyl group at the other polymer end was held unity, *i.e.*, $[O^+]=[I]_0-[I]$. This indicates that the polymerization system was of living character without termination and in addition that the propagating end was mainly the oxonium ion type of **1** in CH_2Cl_2 solution, although the ester type **2** of the propagating end might be involved, as observed in the case of the EtOTf-initiated system.[3] However, the characteristic signal due to α-methylene protons of ~~~CH_2OTn **2** at δ 4.2 region[2] was not detected. It was difficult to determine precisely the concentration of the propagating species **1** directly from the oxonium proton peaks C and F, since both of them were very broad due to the low concentration of **1**.



1 **2**

The instantaneous concentrations of EtOTn and **1** were determined by monitoring peaks A and B, respectively. The variation of the monomer concentration was obtained from peaks D and E. It should be noted that both the concentrations of the counteranion of the propagating species **1** and of monomer could directly be determined at the same time by the NMR measurement alone. Figures 2 and 3 show plots of Eqs. (3) and (4), respectively, the slopes of which gave the values of k_i and $k_{p(i)}$. Similarly, the kinetics were carried out also at 0 and 10 °C in CH_2Cl_2. These

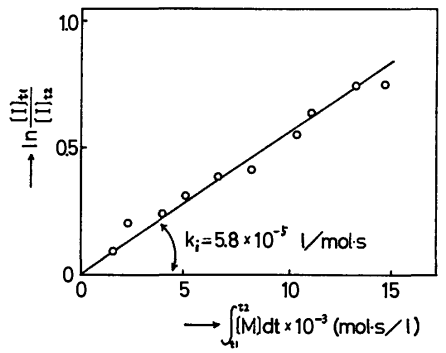


Fig. 2. Plot of Eq. (3) in the THF polymerization at 20 °C in CH_2Cl_2.

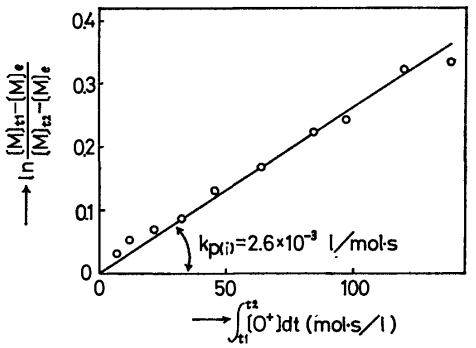

Fig. 3. Plot of Eq. (4) in the THF polymerization at 20 °C in CH_2Cl_2.

results and activation parameters of initiation and propagation are shown in Table 1. The data scattered considerably because $[I]_0$ was low due to the reduced solubility of EtOTn in the system. $[I]_0$ was six times less than that of the previous kinetics of the EtOTf-initiated system.[2,3] The $k_{p(i)}$ value (0.70×10^{-3} l/mol·s at 0 °C) of EtOTn initiator is smaller than that of EtOTf (2.0×10^{-3} l/mol·s at 0 °C).[3] The values of ΔH^* and ΔS^* are also very low in both initiation and propagation. This finding may be related to the bulkiness of OTn group; in both reactions of (1) and (2) the bulky OTn group causing an unfavorable geometry at the transition state (lower ΔS^* value).

Table 1. Rate constants of initiation (k_i) and of propagation ($k_{p(i)}$) and activation parameters in the THF polymerization by EtOTn initiator in CH_2Cl_2 solution[a]

Temp (°C)	$10^3\cdot k_{p(i)}$ (1/mol·s)	$10^5\cdot k_i$ (1/mol·s)

As to the effect of the counteranion on the rate of the THF polymerization there are several data available. Table 2 lists the rate constants of propagation by various initiators, all of which were determined recently in our laboratory.[11-13] All the rate constants of propagation in Table 2 represent those due to the oxonium ion propagating species ($k_{p(i)}$). It has been presented that the value of $k_{p(i)}$ was not changed depending on the nature of the counteranion.[6,14] However, the $k_{p(i)}$ values in Table 2 vary from 0.70×10^{-3} to 7.8×10^{-3} l/mol·s at 0 °C. Our view is, therefore, that the $k_{p(i)}$ value changes significantly depending on the counteranion derived from the initiator.

Experimental

Reagents. THF and CH_2Cl_2 were purified as previously reported.[2,3] EtOTn was prepared according to Pettitt and Helmkamp[6,10] as follows. A commercial reagent of TnONa·$2H_2O$ was converted by concd HCl solution to the free acid of TnOH, mp 172—174 °C (lit,[10] 174—177 °C). A solution of 2.0 g (6.8 mmol) of TnOH dissolved in hot 15 ml of ethyl acetate was then kept at 5—10 °C. To this solution was added 1.2 g (6.3 mmol) of triethyloxonium tetrafluoroborate[15] in 2 ml of nitromethane and cooled in an ice-bath for 5 min with stirring. The mixture was poured into 25 ml of anhydrous ether. White precipitate was collected by filtration. The precipitate was washed with 5 ml of ether, finally with 3 ml of petroleum ether, and dried *in vacuo* to give 1.6 g of Et_3O^+ OTn^-, mp 88—90 °C (lit,[9] 88—89 °C). NMR (CH_3NO_2); δ 8.55 (sharp s, 2,4,6-$(NO_2)_3C_6H_2$-, 2H), 4.83 (q, $(-CH_2-)_3$ O^+ overlapping partly with CH_3NO_2), and 1.66 (t, $(CH_3-)_3$, 9H). EtOTn was obtained by the thermal decomposition of Et_3O^+ OTn^- at 40—50 °C under the reduced pressure (~0.5 mmHg) for 80 hr, mp 140—141 °C (lit,[9] 142—144 °C). NMR (CH_3NO_2); δ 8.85 (sharp S, 2,4,6-$(NO_2)_3C_6H_2$-, 2H) and 1.46 (t, CH_3-, 3H). The methylene proton signal overlapped with that of CH_3NO_2.

Kinetic Procedures. All operations were carried out under nitrogen. In an NMR sample tube were placed at −78 °C 24.2 mg (0.754 mmol) of EtOTn, 0.250 ml of THF, and 0.200 ml of CH_2Cl_2. The tube was sealed at the same temperature and shaked vigorously at room temperature until EtOTn was completely dissolved to give homogenous solution. The tube was then put into the NMR probe insert which was kept constant at the reaction temperature. Up to this step the reaction proceeded to a small extent. Therefore, this moment was taken to be t_1 when carrying out the kinetic analyses according to Eqs. (3) and (4). Then, the reaction was monitored by recording the spectrum several times on a Hitachi R-20B NMR spectrometer (60 MHz). The reaction temperature was kept constant within ±1 °C and the experimental error of the integration was within ±5%.

Preparation of Diethylaluminium Chelates, $R_2P(S)$-X-$AlEt_2$ (X=NMe, S) and Some Reactions with Carbonyl Compounds

Kouichi URATA, Toshinobu YOGO, Kenji ITOH, and Yoshio ISHII*

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

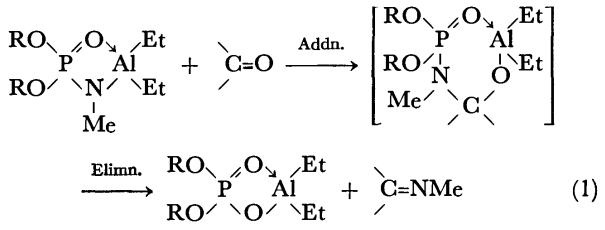
(Received July 22, 1974)

New monomeric organoaluminium chelate compounds; *N*-diethylaluminium *N*-methyl dialkylthiophosphinic amide and dialkyldithiophosphinate; $R_2P(S)$-X-$AlEt_2$ (X=NMe, S), were prepared. Spectroscopic results of these compounds indicate an intramolecular coordination of sulfur atom of P=S bond to the organoaluminium moiety. Addition reactions of $Me_2P(S)$-NMe-$AlEt_2$ and $Et_2P(S)$-S-$AlEt_2$ with phenyl isocyanate gave the corresponding 1/1 adducts and only small amount of elimination product was obtained. A reaction of $Me_2P(S)$-NMe-$AlEt_2$ with benzaldehyde gave $Me_2P(S)$-NMe-CH(Et)Ph and PhCH=NMe (by two ways of addition-elimination).

Group III organometallic chelate compounds of dialkyl (or diaryl) dithiophosphinic acid; $R_2P(S)$-S-MR_2' (M=Al, Ga, and In), have been confirmed to exhibit a strong intramolecular interaction between the metal atom and the thiophosphoryl group.[1,2] For instance, Coates prepared two dimethylaluminium derivatives of dimethyl(or diphenyl)dithiophosphinic acid; $R_2P(S)$-S-$AlMe_2$ (R=Me, Ph) and claimed an intramolecular coordination based on their infrared spectra.

The corresponding *N*-alkyl dialkylthiophosphinic organoaluminium amides; $R_2P(S)$-NR'-AlR_2'', have not been reported,[3] and the chemical behavior of these class of organoaluminium chelate compounds; $R_2P(S)$-X-$AlEt_2$ (X=NMe, S), has been unexplored.

In our former paper,[4] diethylaluminium dialkyl *N*-methylphosphoramidates; $(RO)_2P(O)$-NMe-$AlEt_2$ (R=Me, Et), were found to react with carbonyl compounds giving the corresponding imino compounds by way of an addition and subsequent elimination reactions as Eq. (1).



(1)

Therefore, *N*-diethylaluminium *N*-methyl dialkylthiophosphinic amide; $R_2P(S)NMeAlEt_2$, and dialkyldithiophosphinate; $R_2P(S)SAlEt_2$, are expected to react with carbonyl compounds analogously affording the corresponding >C=NMe or >C=S compounds.

We describe here the preparation of chelate compounds of type $R_2P(S)$-X-$AlEt_2$ (X=NMe, S) and their reactions with carbonyl compounds.

Results and Discussion

Preparation of $R_2P(S)$-X-$AlEt_2$ Compounds. *N*-Diethylaluminium *N*-methyl dialkylthiophosphinic amides; $R_2P(S)$-NMe-$AlEt_2$ (Ia—d) were prepared from the reactions between $R_2P(S)NHMe$ (IIIa—d) and Et_3Al in refluxing benzene in 60—80% yields (Eq. (2)).

$$\underset{\text{(IIIa—d)}}{R_2P(S)NHMe} + Et_3Al \xrightarrow[80°C]{\text{benzene}} \underset{\text{(Ia—d)}}{R_2P(S)NMeAlEt_2} + C_2H_6 \quad (2)$$

(R; a=Me, b=Et, c=*i*-Pr, d=*t*-Bu)

The corresponding three dithiophosphinic acid derivatives; $R_2P(S)$-S-$AlEt_2$ (IIa—c) were prepared analogously from the reactions of $R_2P(S)SH$ (IVa—c) with Et_3Al. These new compounds are distillable and their physical, analytical results are summarized in Table 1.

The cryoscopic molecular weight determination in benzene shows that these compounds have monomeric structure in consistent with an intramolecular coordination.

Infrared and NMR Spectra. In Table 2 $\nu_{P=S}$ absorptions of (Ia—d, IIa—c) were compared with those of the parent organophosphorus compounds (IIIa—d, IVa—c) (in the range of 650—550 cm^{-1}).[5] The lower frequency shift of the $\nu_{P=S}$ absorptions in

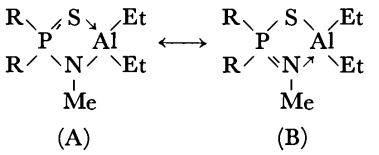
a) In 2% benzene solution. b) vs, very strong; m, medium; w, weak.

organoaluminium chelates (−20——60 cm^{-1}) may be explained in terms of the intramolecular coordination of the sulfur atom of thiophosphoryl group to organoaluminium moiety. The appearance of new absorption bands around 1190—1200 cm^{-1} (assignable to $\nu_{P=N}$[6,7]) indicates the contribution of a resonance form (B), in which (p—d)π interaction between phosphorus and nitrogen atom is involved.

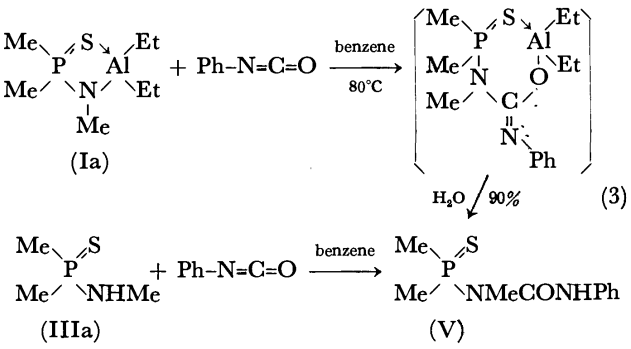


(A) (B)

NMR results are summarized in Table 3. The internal chemical shifts in NMR spectra; $\Delta=\delta AlCH_2-\delta AlCH_2CH_3$ (ppm); are larger ($\Delta=-0.90$——-1.10 ppm) than that of Et_3Al ($\Delta=-0.75$ ppm). Narashimhan[8,9] correlated the electronegativity of the metal (x_M) with internal chemical shifts (Δ) of the ethyl group of ethylmetalloids as $x_M=0.62\Delta+2.07$. The apparent electronegativity values of the aluminium atom (x_{Alapp}) in Ia—d and IIa—c are calculated as 1.39—1.49 (Table 3). This means the aluminium atom in the chelate compounds has more negative charge than that in Et_3Al ($x_{Al}=1.60$, $\Delta=-0.75$ ppm).

The J_{PNCH} values of $R_2P(S)NMeAlEt_2$ (Ia—d) are 17—20 Hz, whereas those of parent compounds $R_2P(S)NHMe$ (IIIa—d) are apparently smaller (11—15 Hz). This indicates the significant contribution of a (p—d)π overlap between phosphorus and nitrogen atoms in (Ia—d) (*cf.* P^{V}=N-CH; J_{PNCH}=20—30 Hz[10,11]). An increase of (p—d)π bonding between phosphorus and nitrogen atoms by diethylaluminium moiety was reported in the case of $Y_2P(O)NMe$-$AlEt_2$ (Y=RO, NR_2).[4]

Reactions of (Ia) and (IIb) with Carbonyl Compounds. The reaction of (Ia) with phenyl isocyanate at 80 °C for 15 hr and subsequent hydrolysis gave only the 1/1 insertion product (V) in 90% yield as Eq. (3). No elimination product (Ph-N=C=N-Me) was obtained.



(3)

A reaction of Ia with benzaldehyde gave both *N*-benzylidenemethylamine (30%) and *N*-dimethylthiophosphinyl-*N*-phenylethylcarbinylmethylamine; $(CH_3)_2P(S)$-NCH_3-$CH(C_2H_5)C_6H_5$ (VI) (40%).

(Ia) PhCH=NMe + $Me_2P(S)NMeCH(Et)Ph$
(30%) (VI) (40%)

Evidence for the structure of (VI) are as follows; (i) the NMR spectrum (Fig. 1) and analyses were consistent with (VI). (ii) The reaction of an analogous dimethylaluminium compound; $Me_2P(S)$–NMe–$AlMe_2$ (VII), affords $Me_2P(S)$–NMe–CH(Me)Ph (VIII, 40%) along with 30% of PhCH=NMe. The NMR spectrum of (VIII) showed a similar spectrum pattern with an analogous known phosphorus compound; Ph_2P–NCH_3–$CH(CH_3)C_6H_5$.[12]

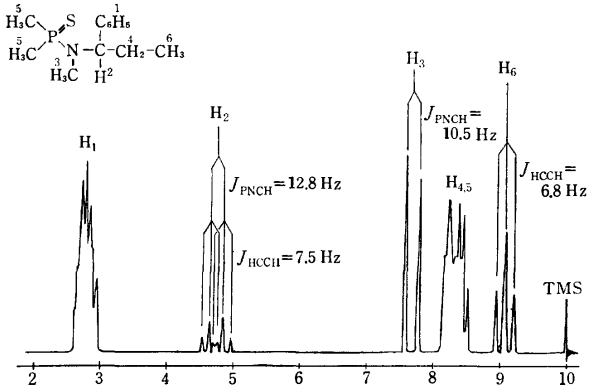

Fig. 1. NMR spectrum of $Me_2P(S)$–NMe–CH(Et)Ph (VI) (in CCl_4).

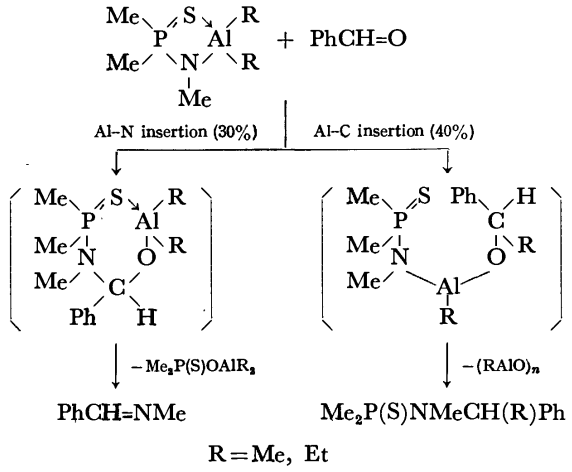
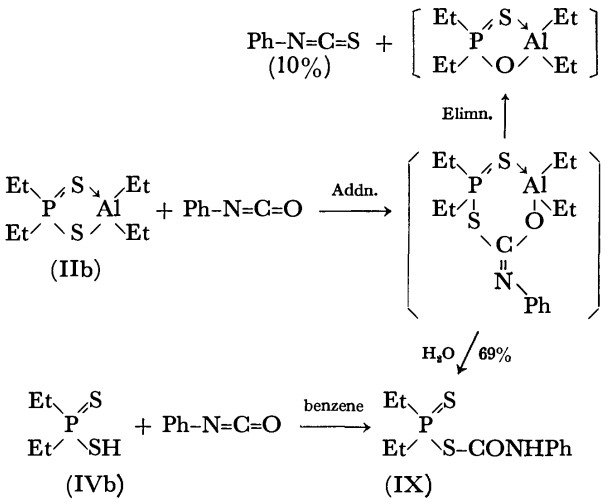
The formation of $Me_2P(S)$–NMe–CH(R)Ph (VIII for R=Me and VI for R=Et) is explained in terms of an insertion of benzaldehyde into the Al–C bond of (Ia) followed by an elimination of the R–Al–O unit. Plausible mechanism was shown as follows.



R=Me, Et

The reaction of IIb with Ph–N=C=O at 80 °C for 12 hr and subsequent distillation gave Ph–N=C=S (in only 10% yield). Major product was a 1/1 insertion product, $Et_2P(S)$–S–CONHPh (IX) in 69%, which was obtained by hydrolytic demetallation of the residue.



In conclusion, the insertion reactions of carbonyl compounds into an Al–N or an Al–S bond in Ia or IIb take place readily, whereas the subsequent elimination process proceeded to a less extent than the case of $(RO)_2P(O)NMeAlEt_2$ which induced exclusively iminocarbonylation reactions by an addition-elimination process.[4] This difference in reactivity of the elimination process may be due to the acidity of the phosphorus atom.

Experimental

Elemental analyses of organoaluminium compounds were carried out by Alfred Bernhardt Microanal. Lab. in West Germany. Aluminium content was analysed gravimetrically. Molecular weight determination and spectral measurement were carried out under dry nitrogen or argon atomosphere. Molecular weights in benzene solution were determined cryoscopically. Infrared and NMR spectra were recorded with a JASCO IR-S, DG-403G, and JEOL C-60HL spectrometers, respectively.

Commercial Et_3Al and Me_3Al (Ethyl. Corp.) were used without further purification. Organic solvents were thoroughly dried over sodium wire or molecular sieve. Starting phosphorus compounds were redistilled before use. The organophosphorus compounds except *N*-methyl diisopropylthiophosphinic amide (IIIc) and *N*-methyldi-*tert*-butylthiophosphinic amide (IIId), were prepared by the methods of literatures.[13–15]

Preparation of IIIc. A benzene (20 ml) solution of 6.2 g (27.1 mmol) of diisopropylphosphinothioic bromide, prepared from diisopropylphosphinous bromide and sulfur, and Et_3N were added to $MeNH_2$ (10 ml) in 20 ml of benzene at 0 °C. Then the mixture was refluxed for 30 min. After removal of the precipitated ammonium salt, distillation of the filtrate gave liquid product (IIIc) (4.2 g, 23.3 mmol) in 86% yield. Bp 85—88 °C/0.2 mmHg. Found: C, 46.76; H, 9.83; N, 7.97%. Calcd for $C_7H_{18}NPS$: C, 46.90; H, 10.12; N, 7.81%.

Preparation of IIId. A benzene (30 ml) solution of 13.7 g (78.2 mmol) of *N*-methyl amino di-*tert*-butylphosphine[10] was added dropwise to 2.51 g (78.2 mmol) of sulfur suspended in 30 ml of benzene. After refluxing for 6 hr and removal of the solvent, liquid (IIId) (8.5 g, 40.7 mmol) was obtained in 52% yield. Mp 115—117 °C. Found: C, 52.19; H, 10.37; N, 7.07%. Calcd for $C_9H_{22}NPS$: C, 52.14; H, 10.90; N, 6.76%.

Preparation of $R_2P(S)NMeAlEt_2$ (Ia—d). The prepa-

ration of *N*-diethylaluminium *N*-methyl dimethylthiophosphinic amide Ia is shown here as an example. Others (Ib—d) were prepared analogously. 5.62 g (45.6 mmol) of IIIa was added slowly to 3.22 g (45.7 mmol) of Et_3Al in 8 ml of benzene at room temperature. During the addition of IIIa, an evolution of gas was observed. The reaction mixture was heated up to 80 °C and refluxed for 1 hr. After the gas evolution had completely stopped, the solvent was removed. The product Ia was distilled under reduced pressure. Ia: bp 87—89 °C/0.06 mmHg (7.51 g, 36.0 mmol, 79% yield based on used Et_3Al). The data are shown in Tables 1—3.

Preparation of $R_2P(S)$-S-$AlEt_2$ (IIa—c). As an example, preparation of diethylaluminium dimethyldithiophosphinate (IIa) is described. 1.3 g (10.5 mmol) of IVa in 10 ml of benzene was added dropwise to 1.2 g (10.5 mmol) of Et_3Al in 10 ml of benzene at room temperature. Gas evolution was observed. The reaction mixture was heated up to 80 °C and refluxed for 1 hr. The distillation gave the liquid product IIa (bp 67 °C/0.13 mmHg) (1.6 g, 7.67 mmol, 73% yield based on used Et_3Al). The data are shown in Table 1—3.

Preparation of $Me_2P(S)$-NMe-$AlMe_2$ (VII). The reaction between 2.4 g (33.3 mmol) of Me_3Al and 4.1 g (33.3 mmol) of IIIa in 25 ml of benzene afforded VII (4.0 g, 23.3 mmol) as white crystals in 70% yield based on used Me_3Al. Mp 132—136 °C. Found: Al, 15.05%; active methyl groups, 2.08 per mol. Calcd for $C_5H_{15}AlNPS$: Al, 15.81%; active methyl groups, 2.00 per mol. IR (in benzene) 1300 (m), 1290 (m), 940 (s), and 925 (s) cm^{-1}. NMR (in benzene) τ 10.22 ($AlCH_3$, 6H, s), 8.75 (6H, double doublet, J_{PCH}=12.8 Hz), and 7.55 (3H, d, J_{PNCH}=18.8 Hz).

Reaction of Ia with Phenyl Isocyanate. An equimolar mixture of 0.845 g (4.08 mmol) of Ia and 0.486 g (4.08 mmol) of phenyl isocyanate in 20 ml of benzene was held at room temperature for 1 day. An absorption band at 2250 cm^{-1} ($\nu_{N=C=O}$) disappeared completely while instead a new band in the range of 1450—1550 cm^{-1} appeared. Then the reaction mixture was heated to 80 °C and refluxed for 15 hr. Hydrolysis of the mixture with dilute hydrochloric acid solution gave a solid as the 1/1 insertion product (0.886 g, 90%). Mp 117°—119 °C. IR (in CCl_4) 3280 (m), 1680 (s), 1310 (s), 1300 (s), 1235 (s), 945 (s), 923 (s), and 690 (m) cm^{-1}. NMR (in $CDCl_3$) τ 7.86 (6H, d, J_{PCH}=13.5 Hz), 6.45 (3H, d, J_{PNCH}=9.0 Hz), 2.5—3.0 (5H, m), and 2.03 (1H, br. s). An authentic sample of the 1/1 insertion product was prepared by an equimolar reaction of phenyl isocyanate with IIIa in benzene. IR and NMR spectra of the obtained 1/1 insertion product were completely consistent with the authentic sample.

Reaction of Ia with Benzaldehyde. To a solution of 0.8 g (7.2 mmol) of benzaldehyde in 5 ml of benzene was added dropwise 1.5 g (7.2 mmol) of Ia in 5 ml of benzene at room temperature. After 18 hr an absorption band at 1700 cm^{-1} ($\nu_{C=O}$) slightly decreased and a new band at 1650 cm^{-1} ($\nu_{C=N}$) appeared. Then the reaction mixture was heated to reflux. Removal of the solvent and distillation under reduced pressure gave the liquid product, PhCH=NMe (0.54 g, 30%) and $Me_2P(S)NMeCH(Et)Ph$ (VI) (bp 90—100 °C/0.35 mmHg) (0.7 g, 40%). Found: C, 60.14; H, 8.55; N, 5.47%. Calcd for $C_{12}H_{20}NPS$: C, 59.92; H, 8.35; N, 5.80%. IR (in CCl_4) 1298 (s), 1288 (s), 1150 (m), 943 (s), 918 (s), and 710 (s) cm^{-1}. NMR (in CCl_4) τ 9.10 (3H, t, J=6.8 Hz), 8.00—8.55 (8H, m, P-CH_3+CH_2CH_3), 7.71 (3H, d, J_{PNCH}=10.5 Hz), 4.66, 4.88 (1H, double triplet, J_{PNCH}=12.8 Hz, J_{HCCH}=7.5 Hz), and 2.5—2.9 (5H, m).

Reaction of VII with Benzaldehyde. When the mixture of 0.8 g (7.3 mmol) of benzaldehyde and 1.3 g (7.3 mmol) of VII in 15 ml of benzene solution was kept at room temperature for 24 hr, and then heated to refluxing for 12 hr, an absorption band at 1700 cm^{-1} ($\nu_{C=O}$) disappeared completely and a new band at 1650 cm^{-1} ($\nu_{C=N}$) appeared. Removal of the solvent and distillation gave, PhCH=NMe (0.26 g, 30%) and $Me_2P(S)NMeCH(Me)Ph$ (VIII) (bp 95—100 °C/0.3 mmHg) (0.6 g, 40%). IR (in CCl_4) 1290 (s), 1280 (s), 1150 (m), 950 (s), 910 (s), and 705 (m) cm^{-1}. NMR (in CCl_4) τ 8.54 (3H, d, J=6.0 Hz), 8.28 (6H, d, J_{PCH}=12.8 Hz), 7.66 (3H, d, J_{PNCH}=11.3 Hz), 4.71, 4.48 (1H, double quartet, J_{PNCH}=13.5 Hz, J_{HCCH}=6.0 Hz), and 2.5—2.9 (5H, m).

Reaction of IIb with Phenyl Isocyanate. To a benzene solution (10 ml) of 0.61 g (5.12 mmol) of phenyl isocyanate was added a benzene solution (10 ml) of 1.05 g (4.43 mmol) of IIb at room temperature. After leaving the mixture for 18 hr, an absorption band at 2250 cm^{-1} ($\nu_{N=C=O}$) disappeared gradually, along with the appearance of a new band at 2050 cm^{-1} ($\nu_{N=C=S}$). Then the reaction mixture was heated to 80 °C and refluxed for 6 hr, resulting the complete disappearence of $\nu_{N=C=O}$. Removal of the solvent and distillation under reduced pressure gave the liquid product, Ph-N=C=S (bp 70—78 °C/0.5 mmHg) (Ph-N=C=S: bp 95 °C/12 mmHg) (0.16 g, 10%). Hydrolytic demetallation of the residue gave an oil of a derivative of the insertion product (IX) (0.770 g, 69%). IR (in CCl_4) 3260 (m), 1705 (s), 1243 (m), 1154 (m), 1028 (s), and 693 (s) cm^{-1}. NMR (in CCl_4) τ 8.95, 8.58 (6H, double triplet, J_{PCCH}=22.2 Hz, J_{HCCH}=6.8 Hz), 7.50—8.20 (4H, m), 2.33—3.33 (5H, m), and 1.86 (1H, br. s). The authentic sample of the 1/1 insertion product was prepared by an equimolar reaction of Ph-N=C=O with IVb in benzene. The 1/1 insertion product obtained showed the same IR and NMR spectra of the authentic sample.

Studies of the Reactions of Amines with Sulfur Trioxide. IV.[1] One-step Synthesis of *N*-substituted Imidobissulfates from Amines[2]

Fujio KANETANI and Hachiro YAMAGUCHI

Department of Applied Chemistry, Hiroshima University, 3-8-2 Senda-machi, Hiroshima 730

(Received February 18, 1974)

The scope and limitations of a one-step synthesis of *N*-substituted imidobissulfates, $RN(SO_3K)_2$ (R=Me, Et, *n*-Pr, *iso*-Pr, *n*-Bu, *iso*-Bu, *sec*-Bu, *tert*-Bu, *n*-C_6H_{13}, *cyclo*-C_6H_{11}, $PhCH_2$-, $PhCH_2CH_2$-, $PhCH(CH_3)$-, or Ph), starting from amines and the sulfur trioxide–triethylamine complex are described. The yields are generally good (55—90%). However, with aniline only a poor (13%) yield was obtained. With *tert*-butylamine, *tert*-butylamidosulfate was obtained quantitatively instead of the expected *tert*-butylimidobissulfate. Bis(cyclohexylammonium) salts of the imidobis(sulfuric) acids are prepared, and their properties are briefly recorded.

In a preceding paper[1] we described a new synthesis of *N*-substituted imidobissulfates (III)[3] by the *N*-sulfonation of the corresponding amidosulfates (II)[3] with various sulfonating agents, particularly with the 2-picoline–sulfur trioxide addition compound. In general, *N*-substituted amidosulfates are readily prepared by the interaction of amines (I) with a variety of sulfonating agents,[4] such as chlorosulfuric acid, pyridine–sulfur trioxide, or sulfur trioxide–trimethylamine. Therefore, the reaction of amines with a suitable sulfonating agent appears to provide a more convenient synthetic route to a wide variety of *N*-substituted imidobissulfates (III).

$$\underset{\text{(I)}}{RNH_2} \xrightarrow{B:SO_3} \underset{\text{(II)}}{RNHSO_3^-HB^+} \xrightarrow{B:SO_3} \underset{\text{(III)}}{RN(SO_3^-HB^+)_2}$$

B: Lewis base

However, only a few reports on the formation of *N*-substituted imidobissulfates in the reaction of amines with a sulfonating agent have been recorded. Reitz *et al.*[5] first suggested that benzylimidobissulfate might have been formed in the action of the pyridine–sulfur trioxide complex on benzylamine. Recently, Vrba and Allan[6] have described briefly the preparation of phenylimidobissulfate (aniline-*N*,*N*-disulfonate) by the reaction of a 1 mol equiv. of aniline with a 2 mol equiv. of the 2-picoline–sulfur trioxide complex in chloroform at 0 °C for 1 hr. Very recently, sulfatoethyl- and sulfatopropylimidobissulfates have been prepared[7] in yields of 72.3 and 53.0% respectively by the *N*-sulfonation of 2-hydroxyethyl- and 3-hydroxypropylamines with pyridine–sulfur trioxide in pyridine. We have shown[8] that, under appropriate conditions, methylimidobissulfate can be obtained as the main product in the gas-phase reaction of methylamine with sulfur trioxide.

We wish now to report a one-step synthesis of *N*-substituted imidobissulfates by the *N*-sulfonation of amines with sulfur trioxide–triethylamine. Unlike the complexes of sulfur trioxide with pyridine bases conventionally used in the early work, sulfur trioxide–triethylamine is much more stable and can conveniently be stored in a refrigirator for long periods of time without decomposition.[9] In addition, the latter complex is fairly soluble in the solvents commonly used for the reaction, such as chloroform, 1,2-dichloroethane, and pyridine bases.[9]

Synthesis. The general procedure simply involves adding an amine to a solution of sulfur trioxide–triethylamine in 2-picoline and allowing the reaction mixture to stand at room temperature for 1—3 days. For each reaction, 6—10 mmol of an amine and a 5—10% molar excess of the sulfonating agent were usually used. After the reaction, the solvent was removed.

The product was then converted into the potassium salt by adding aqueous potassium hydroxide. No difficulty was encountered in separating the imidobissulfate from the amidosulfate which was always formed, generally in a small quantity (except for *tert*-butyl-, 1-phenylethyl-, and phenylamidosulfates). Thus, the imidobissulfate was easily separated from the amidosulfate by extracting the latter with methanol. In the case of cyclohexylimidobissulfate, the separation was best achieved by the use of 85 wt% methanol.

First, we examined the effect of changes in the reaction time and the temperature on the product yields. The results are illustrated in Fig. 1 and Table 1. When *n*-butylamine was used as a substrate, the reaction at room temperature was unexpectedly rapid and was virtually complete in 2 hr; a 70% yield of *n*-butylimidobissulfate was obtained. However, increasing the reaction time to 23 hr improved the yield to 80%. On the other hand, the reaction at 80 °C led to considerably lower yields (50—65%). In the

a) Yields are based on the starting amine and corrected for the purity of the isolated imidobissulfate. b) N. F. Hall and M. R. Sprinkle, *J. Amer. Chem. Soc.*, *54*, 3469 (1932).

case of bulky amines such as *sec*-butylamine, cyclohexylamine, and 2-phenylethylamine, a much longer reaction period (47—82 hr) was required. The yields ranged from 55 to 80% when the reaction was conducted at room temperature. It is noteworthy, however, that the reaction at 90 °C with 1-phenylethylamine as a substrate led to very low yields.

The results with the other amines as substrates are summarized in Table 2.

Benzyl- and 2-phenylethyl- as well as primary alkylimidobissulfates were obtained in yields of 80—93% after a 23-to 48-hr reaction at room temperature. The use of a large excess of sulfur trioxide–triethylamine does not improve the yields, but has a deleterious effect on the product isolation in a pure state. This procedure also works well on a larger (0.1-mol) scale.

TABLE 2. SYNTHESIS OF *N*-SUBSTITUTED IMIDOBISSULFATES BY THE *N*-SULFONATION OF AMINES WITH SULFUR TRIOXIDE–TRIETHYLAMINE[a]

RNH$_2$ R	RNH$_2$ pK_a	RNH$_2$ Amount (mmol)	$(C_2H_5)_3$-N-SO_3 (mmol)	Time (hr)	Yield[b] (%)

Ph	4.58[i]	6.8	14.9	71	13[d,e]

a) Experiments were carried out at room temperature (25—30 °C). b) Yields are based on the starting amine and corrected for the purity of the isolated products. c) *tert*-Butylamidosulfate was obtained quantitatively. d) Isolated main product was the corresponding amidosulfate. e) Isolated as the sodium salt. Anal. Found: N, 4.70; S, 21.50%. Calcd for $C_6H_5O_6NS_2Na_2$: N, 4.71; S, 21.58%. f) H. K. Hall Jr., *J. Amer. Chem. Soc.*, **79**, 5441 (1957). g) C. W. Hoerr and M. R. McCorkle, *ibid.*, **65**, 328 (1943). h) B. M. Wepster, *Rec. Trav. Chim. PaysBas*, **71**, 1171 (1952). i) N. F. Hall and M. R. Sprinkle, *J. Amer. Chem. Soc.*, **54**, 3469 (1932).

Some attempts to prepare *tert*-butylimidobissulfate by this method were unsuccessful, but *tert*-butylamidosulfate was obtained instead in a nearly quantitative yield. A model shows that the amidosulfate is too sterically hindered to undergo further *N*-sulfonation.

Aniline afforded phenylimidobissulfate in only a poor yield.[11] In this case, the main product was phenylamidosulfate. The low yield of the former compound is most probably due to the low basicity of the amido nitrogen of the latter.

The *N*-sulfonation of primary amines with sulfur trioxide–triethylamine proceeds as is shown in the Scheme. The data described above can best be explained by assuming that an equilibrium exists between amidosulfate (II′) and bis(triethylammonium) imidobissulfate (III′). (1) The temperature, (2) the steric requirement of a substituent on the nitrogen, (3) the basicity of the amido nitrogen, and (4) the basicity of the tertiary amine (triethylamine in this case) forming a sulfur trioxide addition compound are important factors governing the equilibrium and, therefore, the yield of III′.

$$\underset{\text{(I)}}{RNH_2} + (C_2H_5)_3N\text{-}SO_3 \rightleftharpoons \underset{\text{(II′)}}{RNHSO_3^-HN^+(C_2H_5)_3}$$

$$\text{(II′)} + (C_2H_5)_3N\text{-}SO_3 \rightleftharpoons RN\begin{matrix}\diagup SO_3^-HN^+(C_2H_5)_3 \\ \diagdown SO_3^-HN^+(C_2H_5)_3\end{matrix} \quad \text{(III′)}$$

Scheme.

The differences in the product yields as well as in the rate of reaction seem to be ascribable mainly to steric factors. Evidently, a large steric requirement of a substituent on the nitrogen atom, as in cyclohexylamine and 2-phenylethylamine, hinders the attack of the bulky sulfonating agent on the amido nitrogen of II′ by blocking the line of approach. Steric strain due to crowding at the imido nitrogen plays an important role in determining the stabilities of III′ and, hence, the position of the equilibrium between II′ and III′. Thus, at higher temperatures, the equilibrium shifts towards II′.

Preparation and Properties of the Bis(cyclohexylammonium) Salts. Amine salts of unsubstituted imidobis(sulfuric) acid were first prepared by Boatman and Sisler.[12] The procedure involves heating diammonium imidobissulfate with an amine in liquid ammonia, water, or an alcohol solution. Free imidobis(sulfuric) acid readily undergoes the hydrolytic cleavage of the sulfur-nitrogen bond in the aqueous solution; hence, it has not hitherto been isolated.[13] Its salts also undergo ready acid-catalyzed hydrolysis.[14] However, Nakano and Yamaguchi[15] have recently prepared eleven bis(tertiary ammonium) salts of unsubstituted imidobis(sulfuric) acid. Their procedure can successfully be applied to the preparation of the bis(cyclohexylammo-

Table 3. Bis(cyclohexylammonium) imidobissulfates

Cyclohexyl	b)	H_2O	8.97 (9.18)	13.76 (14.01)	475	(457.7)
$PhCH_2$	212—212.5	H_2O	9.05 (9.03)	13.58 (13.77)	476	(465.6)
$PhCH(CH_3)$	c)	EtOH[d]	8.88 (8.76)	13.35 (13.37)	513	(479.7)

a) In all cases, the melting points depended on the rate of heating, since thermal decomposition (effervescence) occurred on heating. b) Apparent shrinking occurred at 184.5 °C (placed in the bath at 178 °C). However, no definite melting was observed up to 250 °C. c) An indication of melting was observed at 114—126 °C and a meniscus was formed at 140—150 °C. d) Recrystallization was achieved by dissolving the product in ethanol at room temperature, filtering the solution, and setting aside overnight in a refrigirator (−27 °C).

nium) salts of the primary alkyl-substituted imidobis(sulfuric) acid from the potassium salts obtained above, whereas in the case of sterically-strained *sec*-alkyl-, cycloalkyl-, and 1-phenylethylimidobissulfates, considerable hydrolysis occurs. This disadvantage can, however, be overcome by a direct cation-exchange procedure (see the Experimental section). This procedure can be conducted at room temperature, since the ion-exchange process is carried out under neutral conditions.

The bis(cyclohexylammonium) salts so obtained are summarized in Table 3. All the salts are non-hygroscopic, colorless crystals; they are soluble in water, methanol, and ethanol, and practically insoluble in acetone, ether, and ethyl acetate. The stabilities of the *N*-substituted imidobissulfates are dependent on the basicity of the salt-forming bases as well as on the magnitude of the internal strain due to the steric crowding at the imido nitrogen. Thus, primary alkyl- and benzylimidobissulfates can be recrystallized without appreciable degradation from boiling water or ethanol containing a few drops of cyclohexylamine, although prolonged heating (15—30 min) led to a complete decomposition. On the other hand, bis(cyclohexylammonium) 1-phenylethylimidobissulfate decomposed almost instantly in boiling ethanol to afford ethyl sulfate and 1-phenylethylamidosulfate. All the salts also decomposed partially or completely at their melting points, depending on the rate of heating.

$$C_6H_5CH(CH_3)N(SO_3^-H_3N^+C_6H_{11})_2 + C_2H_5OH \longrightarrow C_6H_5CH(CH_3)NHSO_3^-H_3N^+C_6H_{11} + C_2H_5OSO_3^-H_3N^+C_6H_{11}$$

The *trans*-sulfonation and thermal decompositions of the imidobissulfates are currently being studied and will soon be reported.

Experimental

The melting points were measured in sealed capillaries and corrected. The infrared spectra were recorded for potassium bromide discs on a JASCO IR-S spectrometer. The 1,2-dichloroethane was dried over calcium chloride, distilled, and stored over a molecular sieve (type 3A). The triethylamine and 2-picoline were dried by distillation from potassium hydroxide pellets and stored over a molecular sieve (type 3A). The methylamine (anhydrous) was supplied in a cylinder by the Nitto Chemical Industry, Ltd. The other amines were commercially available and were used without further purification.

Preparation of Triethylamine–Sulfur Trioxide Complex. The complex was prepared by adding triethylamine to a solution of sulfur trioxide in 1,2-dichloroethane at from −5 to 10 °C; mp 90.5—93 °C (from water), (lit,[16] 91.5°); ν_{SO_3} 1055 (s), ν_{SO_3} 1290 (s), δ_{CH} 1400 (m), 1447 (m), and 1465 (m) cm^{-1}.

General Procedure for the Sulfonation of Amines with Sulfur Trioxide–Triethylamine. The quantities of the amine and the sulfur trioxide adduct used for each reaction are given in Tables 1 and 2. The appropriate amine in dry 2-picoline (10 ml) was added, drop by drop, to a stirred solution of the sulfur trioxide–triethylamine complex in dry 2-picoline (20 ml). Stirring was continued for five min., and then the mixture was allowed to stand at a given temperature (−5 to 5 °C and 25—30 °C) or heated at 85—95 °C. The solvent was evaporated off under reduced pressure at a bath temperature below 50 °C, and the residue was dissolved cautiously in cold water (25 ml), neutralized with a potassium hydroxide solution, and treated with charcoal. The filtrate was then evaporated to dryness under reduced pressure, and the residue was extracted with methanol[17] (40—60 ml). The residual solid was dissolved in water (20 ml), and a barium acetate solution (5%) was added until no more precipitate was formed. The filtered solution was evaporated to dryness under reduced pressure; the residue was extracted with methanol (30 ml), filtered, and washed with methanol to give the product (92—99% purity, as calculated from the imido-group equivalent[18]).

Conversion into the Bis(cyclohexylammonium) Salts. (a) An ice-cold solution of the potassium salt (0.7 g in 10 ml) was passed through a column of Amberlite IR-120 (H^+ form) which had been externally cooled to −5—0 °C. The eluate was immediately neutralized with an excess of aqueous cyclohexylamine, and the solution was evaporated to dryness at a temperature below 40 °C while kept alkaline. The residue was recrystallized from an appropriate solvent (see Table 3).

(b) A solution of the potassium salt was passed through a column of Amberlite IR-120 (cyclohexylammonium-salt form), and the eluate was evaporated to dryness. The products so obtained were sufficiently pure for practical purposes. Purer products may be obtained by recrystallization from ethanol containing a drop of cyclohexylamine (room temperature→−27 °C).

We wish to thank the Nitro Chemical Industry, Ltd. for its gift of anhydrous methylamine.

The Reactions of β-Hydroxychalcones and 2-Acetoxy-1,3-diarylpropan-1,3-diones with Lead Tetraacetate

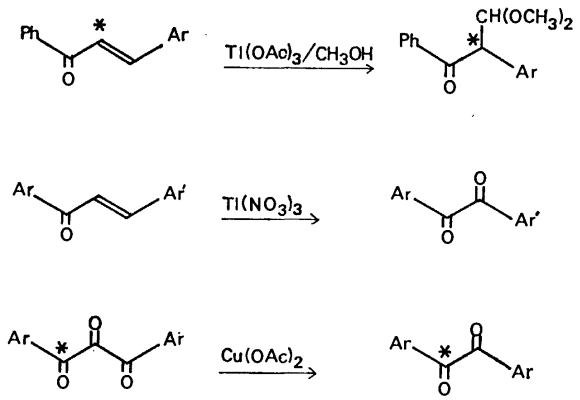
Kazu KUROSAWA and Akira MORIYAMA*

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami, Kumamoto 860

(Received April 13, 1974)

The reaction of β-hydroxychalcone with lead tetraacetate gave benzil. The reaction of 4,4'-dimethoxy-β-hydroxychalcone gave 2-acetoxy-1,3-di(*p*-methoxyphenyl)propan-1,3-dione and 4,4'-dimethoxybenzil. The reactions of 2-acetoxy-1,3-diarylpropan-1,3-diones yielded 2,2-diacetoxy-1,3-diarylpropan-1,3-diones and benzils respectively. The formation of the benzils from β-hydroxychalcones and 2-acetoxy-1,3-diarylpropan-1,3-diones has been shown to involve 1,2-aryl and 1,2-aroyl migration respectively by studies of the oxidations of ^{14}C-labelled compounds.

Carbonyl compounds react with lead tetraacetate to give α-acetoxy derivatives, and β-diketones also react to give mono- and diacetoxy compounds.[1] Our recent results on the reaction of chalcones with lead tetraacetate showed that a chalcone was oxidized to yield 2-acetoxy-1,3-diarylpropan-1,3-dione and 2,3-diacetoxy-1,3-diarylpropan-1-one.[2] This result differs from those of the oxidations of chalcones with thallium(III) acetate and with thallium(III) nitrate, which gave deoxybenzoin derivatives[3] and benzils[4] respectively (Scheme 1).



Scheme 1. Ar and Ar' refer to substituted phenyls.

A re-examination of our previous results revealed the presence of a benzil in the reaction mixture together with the acetates, suggesting that the dione could be rearranged and oxidized to the benzil.

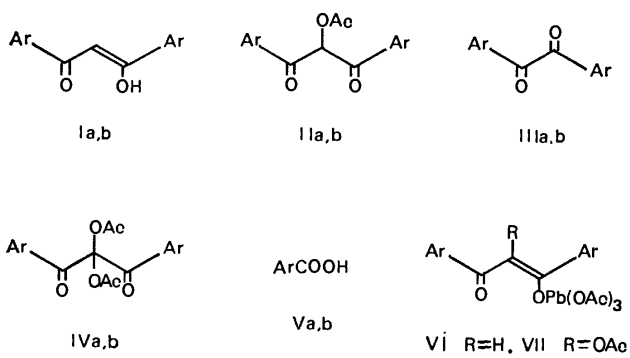
Two β-hydroxychalcones (Ia and Ib), which could be the precursors of the dione, and two 2-acetoxy-1,3-diarylpropan-1,3-diones (IIa and IIb) were prepared; the reactions of these compounds with lead tetraacetate were investigated in the hope of substantiating the rearrangement reaction.

When 4,4'-dimethoxy-β-hydroxychalcone (Ib) was oxidized with lead tetraacetate, three compounds (IIb (2%), IIIb (27%), and Vb (20%)) were obtained. The NMR spectrum of IIb ($C_{19}H_{18}O_6$; mp 96 °C) indicated the presence of two methoxy groups [δ 3.80 (s, 6H)], an acetoxy group [δ 2.30 (s, 3H)], a CH unit [δ 6.89 (s, 1H)], and two *para*-substituted phenyl groups [δ 6.91 (d, 4H) and δ 8.40 (d, 4H)]. The spectroscopic evidence suggested that the IIb has the structure of 2-acetoxy-1,3-di(*p*-methoxyphenyl)propan-1,3-dione. The structure of IIb was confirmed by the fact that the identical acetate was obtained from 2-bromo-1,3-di(*p*-methoxyphenyl)propan-1,3-dione by treating it with sodium acetate in boiling acetic acid. The NMR spectrum of IIIb showed the presence of two *p*-methoxyphenyl groups [δ 6.95 (d, 4H), δ 7.89 (d, 4H), and δ 3.85 (s, 6H)], indicating that IIIb has the structure of 4,4'-dimethoxybenzil. This was identified by comparing their IR spectrum with that of an authentic sample. Vb was shown to be anisic acid by a comparison of its melting point and its IR spectrum with those of an authentic specimen.

Similarly, the reaction of β-hydroxychalcone (Ia) with lead tetraacetate gave IIIa (20%) and Va (10%).

When 2-acetoxy-1,3-di(*p*-methoxyphenyl)propan-1,3-dione (IIb) was oxidized with lead tetraacetate, three compounds (IIIb (10%), IVb (4%), and Vb (11%)) were isolated. The NMR spectrum of IVb ($C_{21}H_{20}O_8$; mp 145—146 °C) indicated the presence of two acetoxy groups [δ 2.14 (s, 6H)], two methoxy groups [δ 3.81 (s, 6H)], and two *p*-substituted phenyls [δ 6.38 (d, 4H) and δ 8.12 (d, 4H)], suggesting that IVb has the structure of 2,2-diacetoxy-1,3-di(*p*-methoxyphenyl)propan-1,3-dione. IIIb and Vb were identified with authentic samples. The reaction of 2-acetoxy-1,3-diphenylpropan-1,3-dione (IIa) was also carried out, giving IIIa (19%), IVa (7%), and Va (6%).

In order to establish the nature of the skeletal rearrangement of the β-hydroxychalcones and the 2-acetoxy-1,3-diarylpropan-1,3-diones, the reactions were



Scheme 2. Ar refers to phenyl in a and *p*-methoxyphenyl in b.

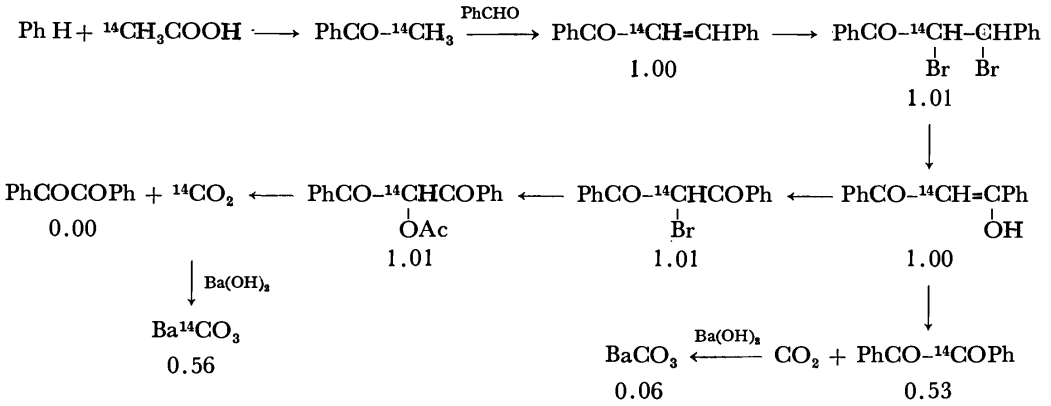

Scheme 3. Syntheses and rearrangement reactions of β-hydroxy[α-^{14}C]chalcone and 2-acetoxy-1,3-diphenyl[2-^{14}C]propan-1,3-dione (the figures under the formulae refer to the specific radioactivities of the compounds relative to chalcone).

repeated using β-hydroxy[α-^{14}C]chalcone and 2-acetoxy-1,3-diphenyl[2-^{14}C]propan-1,3-dione. When 2-acetoxy-1,3-diphenyl[2-^{14}C]propan-1,3-dione was oxidized with lead tetraacetate, inactive benzil (IIIa) and active carbon dioxide as barium carbonate were obtained (Scheme 3). The formation of the inactive IIIa from active IIa has shown clearly that a 1,2-aroyl migration took place and that then the central carbon was lost in the reaction. It has been shown that an aroyl migration is involved in the decarbonylation of 1,3-diarylpropan-1,2,3-trione with cupric acetate[5] (Scheme 1). However, evidence was not available in our case for formulating the reaction intermediate. There may be another pathway yielding carbon dioxide, since an incomplete retention of the radioactivity was observed (the specific radioactivity was 0.56 relative to that of chalcone).

On the other hand, the oxidation of Ia gave radioactive IIIa (the relative specific radioactivity was 0.53) and carbon dioxide (the relative specific radioactivity was 0.06 on barium carbonate). This may indicate that there are at least two pathways which equally lead to benzil: one must involve a 1,2-aryl migration in such a reaction intermediate as VI (Scheme 2), thus yielding the radioactive IIIa, while the other is one *via* IIa, giving the inactive IIIa.

The formation of IIb, IVa, and IVb can be explained by assuming enol intermediates (VI and VII) that are known to be involved in the reaction of ketones with lead tetraacetate.[1] Both IVa and IVb are stable and, therefore, "end products" in the oxidation. This conclusion was confirmed by a separate experiment.

Experimental

All the NMR spectra were recorded for the deuteriochloroform solution with a Hitachi R 24 NMR spectrometer, with tetramethylsilane as the internal reference. The IR spectra were recorded for the chloroform solution with a JASCO IRA-1 grating spectrometer, while the UV spectra were measured for the methanol solution with a Hitachi EPS-3T spectrophotometer. The melting points were determined with a Yanagimoto hot-stage apparatus and were uncorrected. The radioactivity measurements were recorded, for samples crystallized to a constant specific activity, with an Aloka liquid scintillation spectrometer. The scintillator consisted of 0.4% DPO and 0.1% POPOP (Dojindo Chemicals, Kumamoto) dissolved in toluene. Barium carbonate samples were suspended in a gel made up with 4% W/V CAB-O-SIL (Beckmann Instruments Inc,. U.S.A.). Sample counts were repeated twice; the maximum observed error was within ±0.5%.

β-Hydroxychalcone (Ia). β-Hydroxychalcone (Ia) (mp 78 °C) was prepared by the method described in the literature.[6]

4,4'-Dimethoxy-β-hydroxychalcone (Ib). 2-Bromo-1,3-di-(*p*-methoxyphenyl)propan-1,3-dione[7] (1 g) was stirred with zinc powder (3 g) in acetic acid (30 ml) at room temperature for an hour. After the removal of insoluble materials by filtration, water (15 ml) was added to the filtrate. The precipitates were collected and recrystallized from methanol, giving Ib (580 mg, 74%); mp 112—113 °C (lit,[8] mp 114 °C).

2-Acetoxy-1,3-di(p-methoxyphenyl)propan-1,3-dione (IIb). A mixture of 2-bromo-1,3-di(*p*-methoxyphenyl)propan-1,3-dione (2.2 g), anhydrous sodium acetate (4.0 g), and acetic acid (50 ml) was heated under reflux for 5 hr. The reaction mixture was then poured into water and extracted with chloroform. The chloroform was evaporated *in vacuo*, and the residue was allowed to crystallize from ethanol, thus giving colourless prisms (1.3 g, 62%), mp 96 °C, ν_{max}: 1760 and 1690 cm^{-1}; λ_{max} (ε): 291 nm (24700). Found: C, 66.37; H, 5.48%. Calcd for $C_{19}H_{18}O_6$: C, 66.66; H, 5.30%.

2-Acetoxy-1,3-diphenylpropan-1,3-dione (IIa). IIa was obtained in a 65% yield in the manner described above (mp 92—93 °C (lit,[9] mp 90—95 °C)).

Oxidation of β-Hydroxychalcones (Ia and Ib) and 2-Acetoxy-1,3-diarylpropan-1,3-diones (IIa and IIb). A mixture of the substrate (1 mmol), lead tetraacetate (2 mmol for Ia and Ib, and 1 mmol for IIa and IIb), and acetic acid (10 ml) was heated at 100 °C for 3 hr. After the removal of the acetic acid *in vacuo*, the residue was triturated with water and extracted with benzene. The benzene solution was then washed with aqueous sodium carbonate, from which two acids (Va and Vb) were obtained after acidification with concentrated hydrochloric acid. After the removal of the benzene *in vacuo*, the residue was separated on tlc. β-Hydroxychalcone (Ia) yielded IIIa (mp 95 °C (lit,[10] mp 95 °C)) and Va (mp 122 °C). 4,4'-Dimethoxy-β-hydroxychalcone (Ib) gave IIb (mp 96 °C), IIIb (mp 132 °C (lit,[11] mp 133 °C)), and Vb (mp 185 °C). The oxidation of IIa gave IIIa (mp 95 °C), Va (mp 122 °C), and 2,2-diacetoxy-1,3-diphenylpropan-1,3-dione (IVa) (mp 171—172 °C); ν_{max}: 1780 and 1710 cm^{-1}; λ_{max} (ε): 259 nm (22600); δ: 7.2—8.2 (m, 2×

C_6H_5) and 2.14 (s, 2×OAc) (Found: C, 67.13, H, 4.58%. Calcd for $C_{19}H_{16}O_6$: C, 67.06; H, 4.75%). IIb gave IIIb (mp 132 °C), Vb (mp 185 °C), and 2,2-diacetoxy-1,3-di(*p*-methoxyphenyl)propan-1,3-dione (IVb) (mp 145—146 °C); ν_{max}: 1770 and 1700 cm^{-1}; λ_{max} (ε): 299 nm (28100) (Found: C, 63.00; H, 5.07%. Calcd for $C_{21}H_{20}O_8$: C, 62.99; H, 5.04%).

[α-^{14}C]Chalcone. [Me-^{14}C]Acetophenone was prepared by the method described in the literature[3] using sodium [2-^{14}C]acetate (250 μCi, Radiochemical Centre, Amersham, England). [α-^{14}C]Chalcone (mp 55—57 °C) (specific radioactivity: 4.00 μCi/mmol) was prepared by the method described in "Organic Syntheses"[12] in a 76% yield.

[α-^{14}C]Chalcone Dibromide. To a solution of [α-^{14}C]-chalcone (5.0 g) dissolved in benzene (20 ml), we added bromine (3.84 g) at 0 °C. The precipitates (mp 147 °C; 7.25 g; 82%; specific radioactivity, 4.03 μCi/mmol) were used without further purification.

β-Hydroxy[α-^{14}C]chalcone. [α-^{14}C]Chalcone dibromide (7.10 g) was treated with sodium methoxide,[6] thus giving β-hydroxy[α-^{14}C]chalcone (mp 76—77 °C (ethanol); 2.67g; 62%; specific radioactivity, 4.00 μCi/mmol).

2-Bromo-1,3-diphenyl[2-^{14}C]propan-1,3-dione. β-Hydroxy-[α-^{14}C]chalcone (1.48 g) was treated with bromine (1.27 g) in chloroform (10 ml) at 0 °C for an hour to give 2-bromo-1,3-diphenyl[2-^{14}C]propan-1,3-dione (mp 88—89 °C (benzene–light petroleum); 1.56 g; 78%; specific radioactivity, 4.03 μCi/mmol).

2-Acetoxy-1,3-diphenyl[2-^{14}C]propan-1,3-dione. This compound was prepared from 2-bromo-1,3-diphenyl[2-^{14}C]-propan-1,3-dione in the manner described previously (mp 92—93 °C; 51%; specific radioactivity, 4.05 μCi/mmol).

Oxidations of Radioactive Ia and IIa. Radioactive Ia (224 mg) was oxidized with lead tetraacetate (1.33 g) in acetic acid (10 ml) under conditions identical with those described above to give radioactive IIIa (mp 95 °C; 14.2 mg; 7%; specific radioactivity, 2.11 μCi/mmol), Va (mp 122 °C; 6.5 mg; 5%; specific radioactivity, 0.03 μCi/mmol), and carbon dioxide, the latter being later converted to barium carbonate (6.8 mg; specific radioactivity, 0.23 μCi/mmol). The oxidation of the radioactive IIa (282 mg) with lead tetraacetate (444 mg) gave IIIa (mp 95 °C; 32 mg, 14%; specific radioactivity, 0.00 μCi/mmol) and carbon dioxide, which was trapped as barium carbonate (42 mg; 21%; specific radioactivity, 2.25 μCi/mmol).

The authors wish to thank Dr. Emiko Ohoyoshi, of the Radioisotop Centre, and Dr. Kazuta Kitahara and the staff of Faculty of Pharmacology, Kumamoto University, for their kind assistance in the labelling experiments and the measurements.

Synthesis of Sequential Polypeptides of L-Leucine and Glycine

Takayoshi Iio and Sho Takahashi*

Department of Physics, Faculty of Science, Nagoya University, Nagoya 464

**Institute for Chemical Research, Kyoto University, Uji, Kyoto 611*

(Received May 7, 1974)

The following sequential polypetides of L-leucine and glycine were synthesized: $(Leu_3Gly)_n$, $(Leu_2Gly)_n$, $(LeuGly)_n$, and $(LeuGly_2)_n$. Polymerization was achieved by self-condensation of the corresponding peptide *p*-nitrophenyl esters. Hydrolysis of the polypeptides were carried out in 90% aqueous trifluoroacetic acid and the time course of liberation of leucine from each polymer was presented. Apparent first-order rate constants ($\times 10^2$), 1.93, 2.86, 2.91, and 4.4 hr^{-1} were obtained for liberation of leucine from $(Leu_3Gly)_n$, $(Leu_2Gly)_n$, $(LeuGly)_n$, and $(LeuGly_2)_n$, respectively.

A number of studies have been made with homo- or random copolypeptides as a model system to understand the secondary structure of protein.[1] Many basic conclusions derived in those works are useful to investigate protein structure including a prediction,[2] their application, however, is surely limited to only qualitative ground. Interactions between side chains of amino acids in proteins are so much complicated that the studies of sequential polypeptides, in which side chains of amino acids are arranged periodically to amplify interactions between them, are desired and will be promising to analyze the interaction quantitatively. With this aspect we previously reported the studies on $(L\text{-}Ala_xGly_y)_n$,[3] it was considered to be necessary to extend the work with sequential polypeptides having much larger side chain. In this paper we will describe the synthesis of $(L\text{-}Leu_xGly_y)_n$ and the behaviors of some leucine polypeptides toward acid hydrolysis, the succeeding paper will deal the conformational studies of the polypeptides in solution.[4]

Results and Discussion

Synthesis. The synthesis of sequential polypeptides having a defined repeating unit of amino acids are usually achieved by a self-condensation of unit peptide active esters, the method has been considered the best general one.[5] Other methods, such as a treatment of peptide free acids with tetraethyl- or bis-*o*-phenylenepyrophosphite,[6] usually required more drastic condition. Among the *p*-nitrophenyl-,[5] pentachlorophenyl-,[7] and *N*-hydroxysuccinimidyl-esters,[8] which are the most widely used active esters, we preferred the *p*-nitrophenyl esters on account of their good crystallinity over *N*-hydroxysuccinimidyl esters. Lorenzi *et al.*[9] compared the polymerization of *N*-hydroxysuccinimidyl- and *p*-nitrophenyl-esters of peptide in the course of their synthesis of $(AlaProGly)_n$, and showed that there were no differences in both products. Our previous experiences on a number of phenyl esters[10] and peptide esters[3] showing *p*-nitrophenyl esters more soluble than pentachlorophenyl esters supported the use of the former: high solubility of the peptide active esters was essential to avoid intramolecular cyclization during the polymerization.

Synthetic steps to the required polymers are shown in Fig. 1. An attempted synthesis of the tripeptide ester (XVIII) *via* azide coupling of (I) and the hydra-

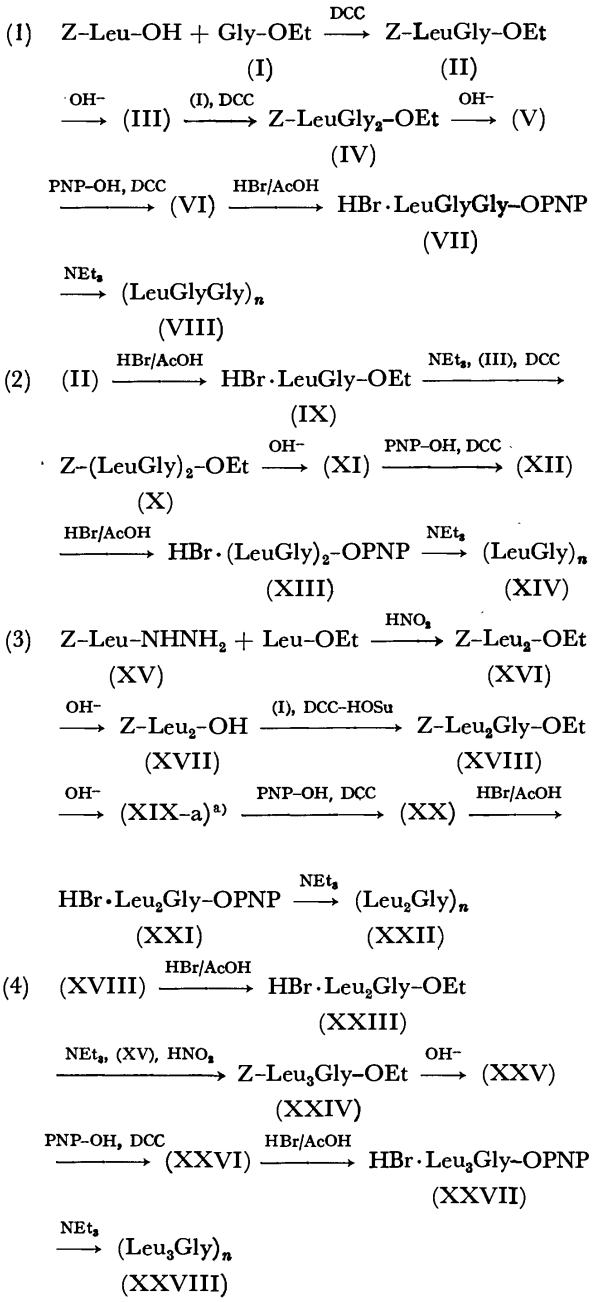

Fig. 1. Steps to the polypeptides, $(Leu_xGly_y)_n$. Abbreviations: Z=benzyloxycarbonyl, PNP=*p*-nitrophenyl. a) Characterized as its dicyclohexylammonium salt, (XIX).

zide of (XVII) in hope to minimize a possibility of racemization of terminal leucine was failed in preparative aspects since the azide derived from XVII was poorly soluble. The use of dicyclohexylcarbodiimide (DCC) in the presence of an equimolar amount of *N*-hydroxysuccinimide (HOSu) was then satisfactorily introduced for a preparative purpose, the resulting XVIII was not distinguished from the product of the azide method in respect of mp; without HOSu, the product had a mp about 10 degrees lower and resisted to further purification.

Concentrated solutions (30—40% in dimethyl sulfoxide) of the polymerizing unit peptide active ester hydrobromides (VII, XIII, XXI, XXVII) were neutralized with triethylamine to afford the polypeptides (VIII, XIV, XXII, XXVIII). The weight average molecular weight was roughly estimated as 30000, 20000, 25000, and 20000 for VIII, XIV, XXII, and XXVIII, respectively, from intrinsic viscosity in dichloroacetic acid.[11]

Hydrolysis of Polypeptides. Estimation of chemical and optical purities of synthetic polypeptides is exclusively achieved by an amino acid analysis and by a measurement of optical rotation on hydrolyzates. The most general condition, hydrolysis in 6 M-hydrochloric acid,[12] was not applicable to the present case by the fact that poor solubilities of leucine polypeptides whose leucine contents were high as in XXII and XXVIII in 6 M or concd hydrochloric acid caused the rate of hydrolysis very slow (after 5 days hydrolysis at 110 °C still precipitates were observed). Among literatures of the synthesis of poly-leucine only two papers reported total hydrolysis: one in 6 M- (40 hr)[13] and the other in 12 M-hydrochloric acid (3—4 days)[14] without comment of results. Other substances used for

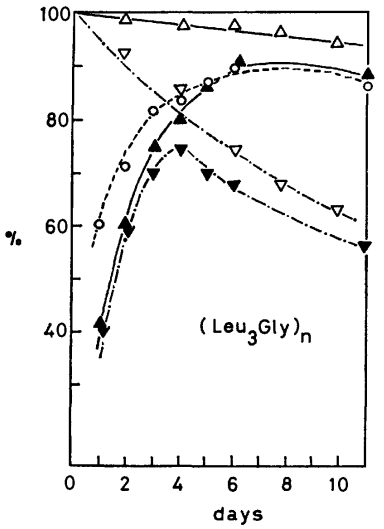

Fig. 2. Hydrolysis of $(Leu_3Gly)_n$ in 90% aq. TFA at 110 °C. Values are given as % of the theoretical values. ○------○: liberation of glycine from the polymer, ▲——▲: liberation of leucine from the polymer, ▼-·-·-▼: optical rotation (at 300 nm) of isolated leucine, △——△: amount of recovered leucine when pure L-leucine was treated in the same condition, and ▽-·-·-▽: optical rotation of L-leucine treated in the same condition.

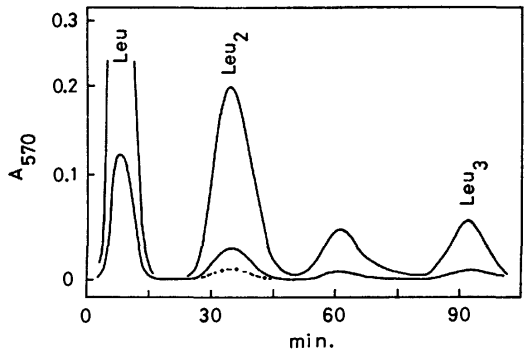

Fig. 3. Amino acid analysis of the hydrolysates of $(Leu_3Gly)_n$. Hydrolysis was carried out in 90% aq. TFA for 3 days (solid line) and 6 days (dotted line). The analyzer column was operated at the standard condition until just berore leucine was eluted, then pH 5.28 buffer was delivered (noted as the time zero on the abscissa). The lower curve was magnified 10 times to yield the upper one.

total hydrolysis, mono-,[15] di-,[16] tri-chloroacetic acid,[15] formic acid,[15] and oxalic acid,[15,17] did not give better results. After looking for another hydrolytic media, especially among perfluoro-acetic, -propionic, and -butyric acid, 90% aqueous trifluoroacetic acid (TFA) was finally adopted as a medium of hydrolysis, and further experiments were carried out with this solvent. The other 90% aqueous perfluoroaliphatic acids or 1:1 mixtures of fluoroacids and concd hydrochloric acid gave approximately similar results in the respect of amino acids liberation upon hydrolysis. Figure 2 illustrated the typical results of the hydrolysis of XXVIII, where liberation of glycine and leucine, values of molecular rotation (at 300 nm) of leucine which was separated on a chromatographic column from the hydrolyzates, and the corresponding results obtained in control experiments were shown. The well-known facts that the rate of hydrolysis of a peptide bond Leu–Leu was about a tenth to a hundredth of those of Leu–Gly, Gly–Leu,[18] and Gly–Gly,[18,19] were clearly reflected in an amino acid analysis of the hydrolyzates (Fig. 3). Figure 3 showed the appreciable amount of Leu_2 and Leu_3 was present in the hydrolyzates. Such fragments also might contribute the molecular rotation in an appreciable manner, this is the reason why optical rotation was measured with isolated leucine itself. Although the molecular rotation of leucine decreased fairly rapidly in this hydrolytic condition (half life 14 days), extrapolation to zero hydrolysis time established that the racemization in XXVIII should be less than 5%. The other polypeptides, VIII, XIV, and XXII, also gave the same result.

Each leucyl peptide bond in the unit (Leu_xGly_y) might have a different rate constant for hydrolysis and thus the appearance of free leucine in the hydrolyzates should be described by a composite of these rate constants.[20] But the actual liberation of leucine from VIII, XIV, XXII, and XXVIII was found to be approximately represented by apparently single first-order kinetics as shown in Fig. 4, at least short period

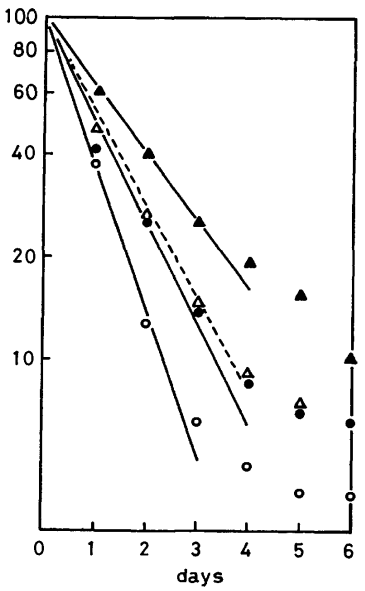

Fig. 4. Semilogarithmic plot of hydrolysis data. The values of 100-x (x is the amount of free leucine yielded from hydrolysis) are plotted against hydrolysis time. ▲——▲: $(Leu_3Gly)_n$, △------△: $(Leu_2Gly)_n$, ●——●: $(LeuGly)_n$, and ○——○: $(LeuGly_2)_n$.

of hydrolysis time was concerned. The estimated apparent-first order rate constants ($\times 10^2$) for appearance of free leucine are 1.93, 2.86, 2.91, and 4.4 hr^{-1} for VIII, XIV, XXII, and XXVIII, respectively, those values would serve as a measure of hydrolysis of leucyl residues from polypeptides.

Experimental

TFA, DCC, and HOSu were purchased from Protein Research Foundation, Osaka. L-Leucine and other reagents were of the purest or reagent grade of commercially available products. All melting points are uncorrected values on a micro hot plate. Viscosities were measured at 25 °C using an Ostwald type viscometer. Optical rotation was measured at 300 nm with a JASCO ORD/UV-5.

Coupling with DCC. DCC reactions were usually carried out at −8 to 0 °C for 4—5 hr, then at 5—8 °C for 12—48 hr with stirring. 1.1 molar equivalent of DCC and 1.2 to 1.5 equivalent of *p*-nitrophenol or an amine component, which was obtained by treating amino acid or peptide ester salts with 1.05 equivalent of NEt_3, were used.[22]

Reaction with HBr/AcOH. Ten mmol of a peptide *p*-nitrophenyl ester was treated with 4 ml of 25% HBr in acetic acid at room temperature for 1—4 hr.

Saponification. NaOH (1.2 equimolar amount) was used.

Hydrolysis. Polypeptide (5 to 10 mg) was suspended in 3 ml of 90% aq. TFA in an ampoule, cooled with liquid nitrogen to solidify, evacuated to 10^{-2} Torr, sealed, and kept at 110 °C. Hydrolyzates were evaporated to dryness *in vacuo*, the residue was dissolved in 0.001 M HCl and analyzed on a JEOL liquid chromatography system according to the method of Spackman *et al.*[21] A JEOL separation system JLC-3 was used to isolate free leucine in hydrolyzates.

Z-Leu-Gly-Gly-OEt (IV). The compound was prepared from (III)[23] and (I) by a DCC reaction in $CHCl_3$ and recrystallized from ethyl acetate–cyclohexane. Yield, 87%, mp 103—105 °C.

Found: C, 59.25; H, 7.25; N, 10.51%. Calcd for $C_{20}H_{29}O_6N_3$: C, 58.95; H, 7.17; N, 10.31%.

Z-Leu-Gly-Gly-OPNP (VI). IV was saponified in methanol with 1.2 M NaOH to afford V, which was esterified by a DCC reaction in tetrahydrofuran. VI was recrystallized from ethyl acetate–ether. Yield, 53%, mp 136—138 °C.

Found: C, 57.73; H, 5.71; N, 11.79%. Calcd for $C_{24}H_{28}O_8N_4$: C, 57.59; H, 5.64; N, 11.20%.

HBr·Leu-Gly-Gly-OPNP (VII). VI was treated with HBr/AcOH to afford VII, which was recrystallized from ethanol–ether. Yield, 48%, mp 191—195 °C (dec.).

Found: C, 43.17; H, 5.19; N, 12.83%. Calcd for $C_{16}H_{23}O_6N_4Br$: C, 42.96; H, 5.18; N, 12.53%.

Z-Leu-Gly-Leu-Gly-OEt (X). II[23] was treated with HBr/AcOH to give IX, which was coupled with III by a DCC reaction in $CHCl_3$. Yield, 85%, mp 157—159 °C (ethanol–ether).

Found: C, 59.72; H, 7.83; N, 11.03%. Calcd for $C_{26}H_{40}O_7N_4$: C, 59.98; H, 7.74; N, 10.76%.

Z-Leu-Gly-Leu-Gly-OPNP (XII). The compound X was saponified in dioxane with 0.43 M NaOH to give XI (obtained as amorphous powder), which was coupled with *p*-nitrophenol by a DCC reaction in tetrahydrofuran. Yield. 67%, mp 168—173 °C (ethanol–ether).

Found: C, 59.80; H, 6.64; N, 12.27%. Calcd for $C_{30}H_{39}O_9N_5$: C, 58.72; H, 6.43; N, 11.41%.

HBr·Leu-Gly-Leu-Gly-OPNP (XIII). XIII, obtained from XII with HBr/AcOH, was recrystallized from ethanol or dioxane. The compound was highly hygroscopic. Yield, 85%, mp 125 °C.

Found: C, 47.05; H, 6.25; N, 12.27%. Calcd for $C_{22}H_{34}O_7N_5Br$: C, 47.15; H, 6.11; N, 12.50%.

Z-Leu-Leu-OEt (XVI). 20 g of Z-Leu-hydrazide (XV) in 150 ml of 1 M HCl and 60 ml of acetic acid was treated with 5.3 g of $NaNO_2$ at −5 °C. The azide was extracted with ether and reacted at the same temperature for 2 hr with ethyl leucinate which was prepared from 19 g of the hydrochloride and 9.9 g of NEt_3. The reaction mixture was kept at 0 °C for 24 hr, then worked up as usual. Yield, 21 g, mp 90—91 °C (ethyl acetate–cyclohexane) (lit, 89—90 °C[25]).

Z-Leu-Leu-Gly-OEt (XVIII). XVI was saponified in acetone with 1 M NaOH to give (XVII) (mp 102—103 °C, lit, 98—101 °C[26]). To a mixture of 14.8 g of I hydrochloride, 10.7 g of NEt_3, and 200 ml of tetrahydrofuran, 36.3 g of XVII and 12.1 g of HOSu were added. The whole mixture was cooled to −15 °C, 22 g of DCC in 70 ml of tetrahydrofuran was added portionwise. After standing at −15 °C for additional 5 hr, then at 0 °C for 2 day, the reaction mixture was worked up as usual. The compound was also obtained from XV and IX or from Z-Leu-Leu-hydrazide[24] and I by the method described in the preparation of XVI. In the last case, treatment of the hydrazide with $NaNO_2$ in HCl–AcOH instantaneously separated the Z-Leu-Leu-azide, part of which was extracted with $CHCl_3$ and was reacted with I. Yield, 29 g, mp 127—128 °C (lit, 111—112 °C[27]) (Found: C, 62.25; H, 8.11; N, 9.26%).

Z-Leu-Leu-Gly-OH, Dicyclohexylammonium Salt (XIX). XVIII was treated in acetone with 1.2 M NaOH to afford the free acid, which was converted into dicyclohexylammonium salt. Yield, 67%, mp 131—133 °C (ethanol).

Found: C, 66.64; H, 9.33; N, 9.47%. Calcd for $C_{34}H_{56}O_6N_4$: C, 66.20; H, 9.15; N, 9.08%.

Z-Leu-Leu-Gly-OPNP (XX). The compound was prepared from XIX and *p*-nitrophenol by a DCC reaction in tetrahydrofuran. Yield, 75%, mp 125 °C (ethanol or ethyl acetate).

Found: C, 60.57; H, 6.60; N, 10.05%. Calcd for $C_{28}H_{36}O_8N_4$: C, 60.42; H, 6.52; N, 10.07%.

HBr·Leu-Leu-Gly-OPNP (XXI). XX was treated with HBr/AcOH to afford XXI, which was recrystallized from ethanol. Yield, 74%, mp 234 °C (dec.).

Found: C, 47.60; H, 6.18; N, 11.10%. Calcd for $C_{20}H_{31}O_6N_4Br$: C, 47.72; H, 6.21; N, 11.13%.

HBr·Leu-Leu-Gly-OEt (XXIII). The compound was prepared from XVIII and HBr/AcOH. Yield, 93%, mp 166—167 °C (ethanol-ether). Found: C, 46.60; H, 7.61; N, 10.08%. Calcd for $C_{16}H_{32}O_4N_3Br$: C, 46.84; H, 7.86; N, 10.24%.

Z-Leu-Leu-Leu-Gly-OEt (XXIV). XXIII (22.4 g) in 100 ml $CHCl_3$ was treated at 0 °C with 5.56 g of NEt_3. The filtrate was added at 0 °C to Z-Leu-azide in 200 ml of ether prepared from 17 g of XV, the solution was kept at 0 °C for 2 day and worked up as usual. Yield, 66%, mp 235—236 °C (ethanol-tetrahydrofuran).

Found: C, 62.36; H, 8.55; N, 9.49%. Calcd for $C_{30}H_{48}O_7N_4$: C, 62.49; H, 8.39; N, 9.72%.

Z-Leu-Leu-Leu-Gly-OH (XXV). XXIV was treated in dioxane with 1 M NaOH to give XXV. Yield, 47%, mp 118—120 °C (tetrahydrofuran-cyclohexane).

Found: C, 61.65; H, 8.00; N, 10.46%. Calcd for $C_{28}H_{44}O_7N_4$: C, 61.27; H, 8.09; N, 10.21%.

Z-Leu-Leu-Leu-Gly-OPNP (XXVI). XXV was coupled with *p*-nitrophenol by a DCC reaction in dimethylformamide-dioxane (1:3). Yield, 50%, mp 208 °C (ethanol).

Found: C, 61.13; H, 7.26; N, 10.51%. Calcd for $C_{34}H_{47}O_9N_5$: C, 60.97; H, 7.07; N, 10.46%.

HBr·Leu-Leu-Leu-Gly-OPNP (XXVII). Prepared from XXVI and HBr/AcOH and recrystallized from dioxane–ether. Yield, 61%, mp 187 °C (dec.).

Found: C, 50.24; H, 6.89; N, 11.08%. Calcd for $C_{26}H_{42}O_7N_5Br$: C, 50.65; H, 6.87; N, 11.36%.

Polymerization of VII, XIII, XXI, and XXVII. 1.1 molar equivalent of NEt_3 was added to a 30—40% solution of VII, XIII, XXI, and XXVII in dimethyl sulfoxide under vigorous stirring. The mixture solidified within several minutes. After standing at room temperature for 2 days, the products were washed with a sufficient volume of ether, dissolved in TFA, and precipitated by adding ether. The procedure of dissolving and precipitation was cycled four times, the precipitates were dried over P_2O_5 and KOH. Yield, 40—60%.

Poly-(Leu-Gly-Gly) (VIII). Viscosity in dichloroacetic acid (DCA): $\eta_{sp}/c=0.267$ ($c=1\%$), $\eta_{int}=0.262$. Amino acid analysis: Leu: Gly=1.0: 1.99 (after 3 day hydrolysis).

Found: C, 52.34; H, 7.61; N, 18.67%. Calcd for $C_{10}H_{17}O_3N_3$: C, 52.85; H, 7.54; N, 18.49%.

Poly-(Leu-Gly) (XIV). Viscosity in DCA: $\eta_{sp}/c=0.151$ ($c=1\%$), $\eta_{int}=0.150$. Amino acid analysis: Leu: Gly=1.0: 0.99 (3 day hydrolysis).

Found: C, 54.13; H, 8.02; N, 15.88%. Calcd for $C_8H_{14}O_2N_2$: C, 56.45; H, 8.29; N, 16.46%.

Poly-(Leu-Leu-Gly) (XXII). Viscosity in DCA: $\eta_{sp}/c=0.221$ ($c=1\%$), $\eta_{int}=0.198$. Amino acid analysis: Leu: Gly=2.0: 0.99 (3 day hydrolysis).

Found: C, 58.89; H, 8.79; N, 15.40%. Calcd for $C_{14}H_{25}O_3N_3$: C, 59.34; H, 8.89; N, 14.83%.

Poly-(Leu-Leu-Leu-Gly) (XXVIII). Viscosity in DCA: $\eta_{sp}/c=0.159$ ($c=1\%$), $\eta_{int}=0.158$. Amino acid analysis: Leu: Gly=3.0: 0.94 (6 day hydrolysis).

Found: C, 58.97; H, 9.00; N, 13.92%. Calcd for $C_{20}H_{36}O_4N_4$: C, 60.58; H, 9.15; N, 14.13%.

We are greatly indebted to Dr. N. Kato at Nagoya University for his kind arrangement of elementary analysis. Thanks are also due to Prof. K. Yamasaki at the same university who kindly made available an ORD spectrometer for the experiment.

The Synthesis of 1,3,4-Benzotriazepin-5-one Derivatives from Isatoic Anhydrides

Masahiko TAKAHASHI, Saburo ONIZAWA, and Tomonobu SATOH

Department of Industrial Chemistry, Faculty of Engineering, Ibaraki University, Hitachi 316

(Received May 9, 1974)

The reaction of isatoic anhydrides (**1**) with 2-pyridylamidrazone afforded *N*-(2-aminophenyl)-2-pyridylamidrazones (**2**), which were then cyclized with acid to 1,3,4-benzotriazepin-5-one derivatives (**3**). The treatment of isatoic anhydride with 2-pyridylcarbonohydrazide gave 1-(2-aminophenyl)-2-(2-pyridinecarbonyl)-hydrazine (**5**), which was then dehydrated with polyphosphoric acid to 3-(2-aminophenyl)-5-(2-pyridyl)-1,3,4-oxadiazole (**6**), but not to **3**.

There have been several reports on the methods of synthesizing 1,3,4-benzotriazepine derivatives, and these compounds have been synthesized in recent years.

Bush[1] used 1-(2-aminobenzyl)-1-phenylhydrazine as the starting material for the 1,3,4-benzotriazepine system. On the other hand, 5-phenyl-1,3-dihydro-2*H*-1,3,4-benzotriazepin-2-ones[2-4] and 5-phenyl-2,3-dihydro-1*H*-1,3,4-benzotriazepines[5] were prepared from 2-aminobenzophenones. Readily-available isatoic anhydrides were also used as starting materials, and 2,3,4,5-tetrahydro-1*H*-1,3,4-benzotriazepin-2,5-diones,[6-7] -5-ones,[8] and 1,4-dihydro-5*H*-1,3,4-benzotriazepin-5-ones[9] were synthesized. 3,4-Dihydro-1*H*-1,3,4-benzotriazepin-2,5-diones[10] were prepared from *N*-alkyl-*N*-carboxyanthranilate.

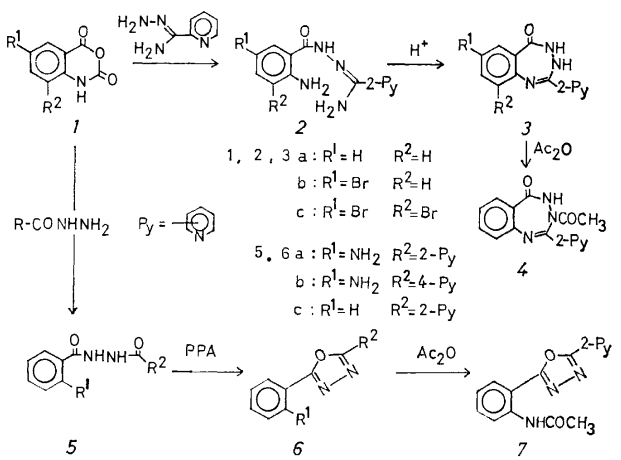
We have previously described the synthesis of 1,2,4-triazin-5-ones by the use of amidrazone.[11] In the present paper we wish to report a new method of synthesizing 1,3,4-benzotriazepin-5-ones by the reaction of isatoic anhydride with 2-pyridylamidrazone.

Results and Discussion

The reaction of isatoic anhydride with amines proceeds smoothly, with the evolution of carbon dioxide, to give *o*-aminobenzoylamide derivatives.[12] Thus, the reaction of readily-available 2-pyridylamidrazone[13] and isatoic anhydride (**1a**) in pyridine at room temperature gave *N*-(2-aminobenzoyl)-2-pyridylamidrazones (**2a**). From the substituted isatoic anhydrides (**1b**, **c**), *N*-(substituted-2-aminobenzoyl)-2-pyridylamidrazone (**2b**, **c**) were similarly obtained. The IR spectra of **2a—c** showed NH and CO stretching absorption bands at 3480—3160 and 1630—1618 cm^{-1} respectively. The deamination and cyclization of **2a** were attempted with acid catalysts or an acidic medium, and the treatment of **2a** with 0.05 M H_2SO_4–MeOH gave a yellow product (**3a**) in a moderate yield. **3a** was also formed on the refluxing of **2a** in acetic acid, but in a lower yield. The IR spectra of **3a** showed NH absorption bands at 3300 and 3190 cm^{-1} and CO and C=N absorption bands at 1675 and 1645 cm^{-1} respectively. The results of elemental analysis and the mass spectra supported the molecular formula corresponding to **3a**. The structure of **3a** of 2-(2-pyridyl)-3,4-dihydro-5*H*-1,3,4-benzotriazepin-5-one was further confirmed by the formation of monoacetate (**4**), which was prepared on the heating of **3a** in acetic anhydride. **3b** was similarly obtained from **2b** in a good yield, but the structure of the product (**3c**) from **2c** was obscure from its spectral data.

Langis[9] reported the synthesis of analogous triazepine derivatives, **3**, from isatoic anhydride by a different route; the reaction of isatoic anhydride with acylhydrazines in EtOH afforded 1-aminobenzoyl-2-acylhydrazine (**5**), which were then dehydrated on heating with polyphosphoric acid to form **3**. Thus, we attempted to identify the structure of **3** by this route.

The treatment of **1a** with 2-pyridinecarbonohydrazide in EtOH gave 1-(2-aminobenzoyl)-2-(2-pyridyl)hydrazine (**5a**). The structure of **5a** was confirmed by analysis and by the spectral data. The dehydration of **5a** with polyphosphoric acid was examined under the condition described in the literature,[9] *i.e.*, at 150 °C for 1 hr. The IR and UV spectra of the product (**6a**) were analogous to those of the 4-pyridyl derivative (**6b**) prepared according to the reported procedure,[9] but were different from those of **3a**. However, the analytical data and the molecular weight determined by means of the mass spectrum of **6a** showed the same molecular formula as **3a**. The IR spectrum of **6a** showed two sharp NH absorption bands at 3440 and 3340 cm^{-1}. The absorption bands at 1640 and 1630 cm^{-1} were assigned to C=N stretching and NH deformation vibrations respectively. These data suggested that the structure of the product was not triazepine, **3a**, but 2-(2-aminophenyl)-5-(2-pyridyl)-1,3,4-oxadiazole. The NMR spectrum of **6a** displayed signals at δ 5.35 (NH_2) and at 6.6—8.9 (aromatic protons). Further confirmation of the structures of **3a** and **6a** could be



Scheme 1.

obtained by the correlation of the mass spectra; the spectrum of **3a** showed the main peaks at *m/e* 238 (M^+, 100%) and 208 (M^+—NH=NH, 59%), whereas in the case of **6a** the main peaks were at *m/e* 238 (M^+, 100%), 237 (M^+—1, 31%), and 120 (M^+—*o*-aminobenzonitrile, 34%).

The structure assignment of **6a** was further confirmed by a comparison of the analytical and spectral data of the monoacetate (**7**) with those of (**4**); elemental analysis and mass spectra gave an identical molecular formula. The IR spectrum of **4** showed two CO absorptions at 1685 and 1670 cm^{-1}, together with the NH absorption. On the other hand, **7** showed one CO absorption at 1690 cm^{-1}. **4** exhibited a mass spectrum characterized by a M^+ ion at *m/e* 280 (30%) in addition to significant peaks at *m/e* 237 (M^+—$COCH_3$, 93%) and 208 (M^+—$NH{=}NCOCH_3$, 100%). The high intense peaks of the spectrum of **7** at *m/e* 280 (100%), 237 (87%), and 120 (78%) were assigned to the M^+, M^+—$COCH_3$, and M^+—(2-CH_3CONH-C_6H_4-CN) ions respectively.

As the cyclization of diacyl hydrazines on treatment with dehydrating agents has already been reported,[14] we also attempted the cyclization of 1-benzoyl-2-(2-pyridyl)hydrazine (**5c**) as a model compound to 2-phenyl-5-(2-pyridyl)-1,3,4-oxadiazole (**6c**) under the same conditions as in the case of the reaction of **5a** to **6a**; we obtained **6c** in a moderate yield.

The structure of **3** was also supported by the hydrolysis of **3a** with hydrochloric acid to **5a** in a 45% yield.

From the above data, the compounds reported by Langies were not the triazepine derivatives **3** but 1,3,4-oxadiazoles, **6**; our results present a new synthetic route to 1,3,4-benzotriazepin-5-one derivatives.

Experimental

All the melting points are uncorrected. The IR, UV, and NMR spectra were measured with a JASCO Model IRA-2 spectrometer (KBr pellets), a Shimadzu Model MPS-50L spectrometer (in MeOH), and a Hitachi Model R-20 spectrometer respectively. A Shimadzu Model UM-3B apparatus was used for the elemental analysis.

N-(2-Aminobenzoyl)-2-pyridylamidrazone (2a). A mixture of 3.26 g (20 mmol) of **1a** and 3.26 g (24 mmol) of 2-pyridylamidrazone in 50 ml of pyridine was stirred at room temperature for 10 hr. The filtration and washing of the resulting precipitate with MeOH gave 4.26 g (84%) of **2a**. Recrystallization from pyridine afforded white needles; mp 223—225 °C. Found: C, 61.48; H, 5.10; N, 27.36%. Calcd for $C_{13}H_{13}N_5O$: C, 61.20; H, 5.14; N, 27.47%. IR: 3480—3200, 1660, 1630 cm^{-1}. UV λ_{max} nm (log ε): 217 (4.43), 250 (3.99), 317 (4.07), 336 (4.07).

N-(2-Amino-5-bromobenzoyl)-2-pyridylamidrazone (2b). A mixture of 2.42 g (10 mmol) of **1b** and 1.63 g (12 mmol) of 2-pyridylamidrazone in 20 ml of pyridine was refluxed for 1 hr. After cooling, the filtration and washing of the precipitate with MeOH gave 1.84 g (58%) of **2b**. Recrystallization from MeOH afforded yellow needles; mp 220—232 °C. Found: C, 46.60; H, 3.63; N, 20.49%. Calcd for $C_{13}H_{12}N_5OBr$: C, 46.72; H, 3.63; N, 20.96%. IR: 3440—3160, 1625 cm^{-1}. UV λ_{max} nm (log ε): 224 (4.61), 250 (4.43), 290 (4.14), 330 (3.95), 363 (4.04).

N-(2-Amino-3,5-dibromobenzoyl)-2-pyridylamidrazone (2c). **2c** was obtained in a 54% yield in the way which has been described for **2b**. Recrystallization from MeOH afforded yellow needles; mp 232—238 °C. Found: C, 37.39; H, 2.68%. Calcd for $C_{13}H_{11}N_5OBr_2$: C, 37.92; H, 3.01%. IR: 3438—3180, 1618 cm^{-1}. UV λ_{max} nm (log ε): 224 (4.41), 248 (4.21), 355 (4.05).

2-(2-Pyridyl)-3,4-dihydro-5H-1,3,4-benzotriazepin-5-one (3a). A solution of 2.0 g (7.8 mmol) of **2a** in 50 ml of 0.05 M H_2SO_4–MeOH was refluxed for 3 hr. After the subsequent concentration and cooling of the solution, the precipitated crystals were filtered by suction and washed with water to remove the inorganic materials and then with MeOH to give 1.10 g (59%) of **3a**. Recrystallization from $CHCl_3$ afforded yellow needles; mp 247—248 °C. Found: C, 65.17; H, 4.36; H, 23.44%. Calcd for $C_{13}H_{10}N_4O$: C, 65.58; H, 4.24; N, 23.54%. IR: 3300, 3190, 3060, 1675, 1645 cm^{-1}. UV λ_{max} nm (log ε): 233 (4.33), 238 (4.31), 276 (4.17), 303 (3.96), 354 (2.95).

A solution of 200 mg of **2a** in 5.0 ml of acetic acid was refluxed for 3 hr. After cooling, the precipitated crystals were filtered by suction and washed with MeOH to give 59 mg (31%) of yellow products. Subsequent recrystallization from $CHCl_3$ afforded yellow needles, whose IR spectra and mp were identical with those of **3a**.

7-Bromo-2-(2-pyridyl)-3,4-dihydro-5H-1,3,4-benzotriazepin-5-one (3b). **3b** was obtained in a 74% yield in the way described for **3a**. Recrystallization from MeOH afforded yellow needles; mp 249—250 °C. Found: C, 49.69; H, 2.81; N, 17.15%. Calcd for $C_{13}H_9N_4OBr$: C, 49.24; H, 2.86; N, 17.68%. IR: 3260, 3180, 3070, 3040, 2930, 1660, 1645 cm^{-1}. UV λ_{max} nm (log ε): 235 (4.40), 279 (4.26), 307 (3.95), 350 (2.79).

Monoacetate (4) of 3a. A solution of 300 mg of **3a** in 5.0 ml of acetic anhydride was refluxed for 2 hr. After cooling, the precipitated crystals were filtered by suction and washed with a small amount of ethyl acetate to give 145 mg (42%) of **4**. Subsequent recrystallization from benzene afforded yellow plates; mp 193—196 °C. Found: C, 64.17; H, 4.29%. Calcd for $C_{15}H_{12}N_4O_2$: C, 64.27; H, 4.32%. IR: 3270, 1685, 1670, 1650 cm^{-1}. NMR ($CDCl_3$): δ 2.48 (s, 3H), 6.9—8.8 (m, 8H), 9.30 (s, 1H).

1-(2-Aminobenzoyl)-2-(2-pyridyl)hydrazine (5a). A mixture of 2.4 g (15 mmol) of **1a** and 2.0 g (15 mmol) of picolinic acid hydrazide in 50 ml of EtOH was refluxed for 20 hr. After cooling, the precipitates were filtered by suction to give 2.2 g (71%) of **5a**. Recrystallization from MeOH afforded white prisms; mp 210—212 °C. Found: C, 60.93; H, 4.67%. Calcd for $C_{13}H_{12}N_4O_2$: C, 60.93; H, 4.72%. IR: 3500, 3380, 3300, 1685, 1675, 1644 cm^{-1}. UV λ_{max} nm (log ε): 250 (4.08), 338 (3.77).

Hydrolysis of 3a to 5a. A solution of 200 mg of **3a** in the mixing solvent of 5.0 ml of 1 M HCl and 5.0 ml of EtOH was refluxed for 2 hr. After cooling, the solution was neutralized with aqueous Na_2CO_3 and then allowed to stand to give precipitates. After the filtration of the precipitates, one recrystallization from MeOH afforded 97 mg (45%) of white crystals, whose mp and IR spectra were in accord with those of **5a**.

2-(2-Aminophenyl)-5-(2-pyridyl)-1,3,4-oxadiazole (6a). A mixture of 500 mg (2.0 mmol) of **5a** and 2.5 g of polyphosphoric acid was heated at 150 °C with gentle stirring for 1 hr. After cooling, the mixture was stirred into 50 ml of water, and the resulting precipitates were filtered off by suction. The filtrate was made alkaline with aqueous NaOH to give additional precipitates. The combined precipitates were washed with a small amount of MeOH to give 330 mg (61%) of **6a**. Recrystallization from MeOH afforded

needles; mp 170—171 °C. Found: C, 65.60; H, 4.13%. Calcd for $C_{13}H_{10}N_4O$: C, 65.53; H, 4.23%. IR: 3440, 3340, 1640, 1630, 1615 cm^{-1}. UV λ_{max} nm (log ε): 220 (4.38), 249 (4.09), 285 (4.12), 358 (4.08).

2-(2-Aminophenyl)-5-(4-pyridyl)-1,3,4-oxadiazole (6b). **6b** was prepared according to the reported produre. Light yellow prisms; mp 191—192 °C (lit,[9] 180—182 °C). IR: 3440, 3320, 3200, 1635, 1625 cm^{-1}. UV λ_{max} nm (log ε): 221 (4.46), 254 (4.19), 275 (4.24), 366 (4.10).

2-Phenyl-5-(2-pyridyl)-1,3,4-oxadiazole (6c). The crude product of **6c** was obtained in the way described for **6a**. The product was chromatographed on silica gel with the eluent of $CHCl_3$ to give 223 mg (48%) of pure **6c**. Recrystallization from MeOH afforded white needles; mp 131—132 °C. Found: C, 69.62; H, 3.95%. Calcd for $C_{13}H_9N_3O$: C, 69.94; H, 4.06%. IR: 3040, 1608, 1588, 1545 cm^{-1}. UV λ_{max} nm (log ε): 263 (4.19), 289 (4.38).

2-(2-Acetamidophenyl)-5-(2-pyridyl)-1,3,4-oxadiazole (7). A mixture of 250 mg (1.1 mmol) of **6a** and 5.0 ml of acetic anhydride was heated at 130 °C for 2 hr. The subsequent removal of the acetic anhydride *in vacuo* gave a solid residue, which was triturated with a small amount of water, filtered, and washed with MeOH to give 223 mg (72%) of **7**. Recrystallization from MeOH afforded white needles; mp 205—206 °C. Found: C, 64.12; H, 4.34%. Calcd for $C_{15}H_{12}N_4O_2$: C, 64.27; H, 4.32%. IR: 3260, 3200, 3060, 1690, 1616 cm^{-1}. UV λ_{max} nm (log ε): 225 (4.38), 242 (4.22), 287 (4.32), 294 (4.32), 315 (4.15). NMR ($CDCl_3$): δ 2.30 (s, 3H), 7.0—8.9 (m, 8H), 11.03 (s, 1H).

The authors are grateful to Dr. Masatoshi Hirayama for the NMR measurements and to the Sankyo Co., Ltd., for the mass measurements.

The Synthesis and Oxidation of 4-(*N*-Arylmethylideneamino)-2,6-di-*t*-butylphenols

Eiichiro MANDA

National Chemical Laboratory for Industry, Honmachi, Shibuya-ku, Tokyo 151

(Received May 20, 1974)

4-(*N*-Arylmethylideneamino)-2,6-di-*t*-butylphenols (I) were synthesized through the condensation of 4-amino-2,6-di-*t*-butylphenol hydrochloride and arylaldehydes, and the infrared and electronic spectra of phenols (I) were discussed. The oxidation of phenol (I) with lead dioxide gave a stable phenoxyl radical (II) in solution, and 4,4′-bis[4-(*N*-arylmethylideneamino)-2,6-di-*t*-butyl-2,5-cyclohexadien-1-one] (III) was isolated as a crystalline oxadation product, which was in equilibrium with the radical (II) in solution.

A number of stable 2,6-di-*t*-butylphenoxyl radicals are known to be derived from 2,6-di-*t*-butylphenol derivatives.[1,2] As for 2,6-di-*t*-butylphenoxyl radicals with a double bond at the 4-position of the phenoxyl ring, a few reports have been published on derivatives with –CH=CH–Ar,[3,4] –N=N–Ar,[5] and –CH=N–Ar[6] groups. The synthesis, properties and oxidation of 4-(*N*-arylmethylideneamino)-2,6-di-*t*-butylphenol (I), which is a novel Schiff base in 2,6-di-*t*-butylphenol derivatives, were studied, and the results will be reported in this paper.

Results and Discussion

Schiff bases are generally synthesized through the condensation of amines and aldehydes in ethanol at room temperature,[7] and the maximum yield is attained at the pH range of the reaction mixture of 6—8.[8] Thus, phenols (I) have been prepared through the condensation of arylaldehydes and 4-amino-2,6-di-*t*-butylphenol hydrochloride in the presence of pyridine, since the free aminophenol is quite an unstable compound. Condensation proceeded very easily, and crystals of phenols (I) precipitated from the reaction mixture in a few minutes. The yields of phenols (I) are given in Table 1. Considerable amounts of red-brown, tarry compounds were obtained as by-products, and they might have originated from the oxidation of 4-amino-2,6-di-*t*-butylphenol hydrochloride. In the absence of pyridine, a methoxy derivative of phenol (I) (19%) was obtained after letting the reaction mixture stand for one hour at room temperature, but no other phenols (I) were obtained even after a long period of condensation. This was caused by a decrease in the pH value of the reaction mixture.

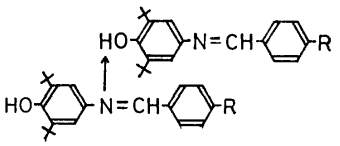
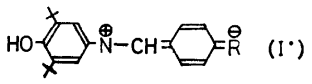
ν, stretching; s, strong; m, medium; w, weak; vw, very weak

The infrared spectra of a carbon tetrachloride solution and a KBr disk of phenol (I) were measured, and the results are given in Table 2. The characteristic ν_{OH} bands were observed at 3630—3150 cm^{-1}, and the $\nu_{C=N}$ bands at 1625—1610 cm^{-1}. The strong band of a free OH group was observed at 3630 cm^{-1} for the carbon tetrachloride solution of each phenol (I). In the solid state, however, the intensity of these bands changed to medium for nitro, methoxycarbonyl and chloro derivatives, and to very weak for unsubstituted and methoxy derivative of phenol (I). Correspondingly, broad bands of associating OH groups appeared at 3410—3150 cm^{-1} for phenols (I), and the intensity of the bands of the unsubstituted and methoxy derivative was stronger than the others. The location of $\nu_{C=N}$ bands tended to shift to lower wave numbers in the solid state than in solution. These observations suggest that, in the solid state, phenols (I) are associating as shown below and the bond orders of OH and C=N bonding become lower than in solution. The location of $\nu_{C=N}$ bands of phenols (I) in solution was almost constantly at 1625 cm^{-1}, and no substituent effect was





observed. This can be explained by the minor participation of a resonance structure (I') since the electron-attracting power of the sp^2 nitrogen atom compensates that of an electron-attracting substituent. The location of ν_{OH} bands of phenols (I) in solution was at 3630 cm^{-1} and was also independent of the substituents. This may be due to the above resonance effect and to the twisting of the bonding between a nitrogen atom and a phenol ring.[9]

Table 3. Electronic spectra of phenol (I) in *n*-hexane

MeO	251.5(1.04)	281(2.06)	338(1.54)

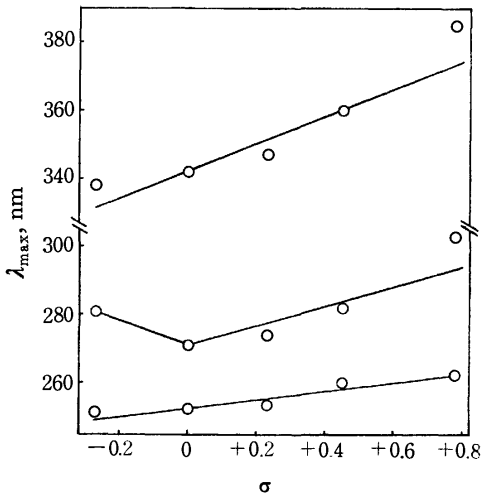

Fig. 1. The correlation of Hammett substitution constants with the wavelength of the absorption maxima of phenols (I)

The electronic spectra of phenols (I) in *n*-hexane were measured and the results are shown in Table 3. Each derivative of phenols (I) has three absorption bands near at 350, 290, and 250 nm, and these bands are similar to those of benzalanilines.[10] Figure 1 gives the correlation of the Hammett substituents (σ)[11] and the wavelength of each absorption maximum. A simple bathochromic effect of the electron-attracting group is observed in the absorption bands at 250 and 350 nm, whereas the same effect is caused by both electron-attracting and electron-releasing group in the bands at 280 nm. These bands may be assigned to result from a charge transfer from the phenol ring to the –N=CH– bonding, from electronic transition throughout the whole π-electron system, and from local excitation without charge transfer.[10]

Phenols (I) in tetrahydrofuran were oxidized with excess amounts of lead dioxide at room temperature

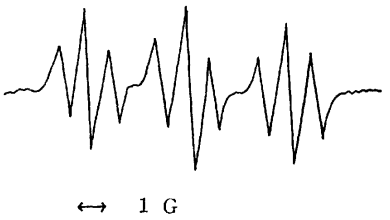

Fig. 2. ESR spectrum of radical (II, R=NO_2)

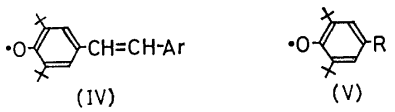
under nitrogen atmosphere. The color of each reaction mixture turned from yellow to red-brown or yellow-green. The ESR measurement of the reaction mixture of each phenol (I) showed the presence of a stable radical, and the spectrum was considered to be made up of a triplet (with an equal intensity) of triplet (with intensity ratio of 1: 2: 1) (Fig. 2). The observed ESR signals may be assigned to the phenoxyl radical (II), since an odd electron on a nitrogen atom gave a triplet signal (with an equal intensity), and then each peak of this triplet was further split to a triplet (with intensity ratio of 1: 2: 1) by two equivalent *m*-ring protons. The observed ESR hyperfine splitting (Hfs) constants of the radicals (II) are given in Table 4.

Table 4. ESR coupling constants of radicals (II)

R	a_{m-H} (gauss)	a_N
NO_2	1.1	3.4
COOMe	1.2	4.2
Cl	1.0	3.9
Unsubst.	1.0	3.8
MeO	1.1	4.8

The small Hfs value of the nitrogen atom is due to the small spin density on the nitrogen atom, which may be caused by the twisting of the bonding between the nitrogen atom and the phenol ring.[9] The absence of hyperfine splitting by a proton of the methine group may be due to the very small spin density on the methine group. This suggests the very small participation of allylic resonance in the radical (II) which was reported with radical (IV).[3] The Hfs value of the *m*-ring



(IV) (V)

proton is independent of the substituents in the radical (II), though a substituent effect was reported with phenoxyl radicals (V).[12] This may be explained by a non-planarity which has been previously been described and by the remoteness of the substituents from the *m*-ring protons.

Yellow crystalline oxidation products were isolated from the reaction mixture of nitro, methoxycarbonyl and chloro derivatives of phenol (I), but unsubstituted and methoxy derivatives gave a tarry material. These crystalline oxidation products of the above three phenol derivatives were not so stable at room temperature and decomposed at their melting points. The results of the isolated crystalline oxidation products are shown in Tables 5 and 6. The results of the elementary analyses

ν, stretching; δ, bending; sh, shoulder. Electronic spectra were taken for cyclohexane solution of 2.0×10^{-5} M.

(Table 5) were in good agreement with the calculated values for a dimer of the radical (II). The absence of the ν_{OH} band (3630 cm^{-1}) and the appearance of the $\nu_{C=O}$ band (1650 cm^{-1}) and the $\nu_{C=C}$ band (1630 cm^{-1}) in their infrared spectra (Table 6) suggest that these oxidation products have the 2,5-cyclohexadienone structure.[13] The chemical structure of the dimer of the radical (II) depends on the way of the recombination reaction of the radical (II), *e.g.*, oxygen-carbon coupling, *etc.* The most probable recombination reaction is coupling at the 4-carbon atom of the phenol ring, since oxygen-oxygen coupling is not known with 2,6-di-*t*-butylphenoxyl radicals,[1,2] and since the spin density at the 4-carbon atom is known to be relatively high,[2] whereas ESR measurement showed quite a low spin density on the methine group of the radical (II). Therefore, each isolated oxidation product is 4,4'-bis-[4-(*N*-arylmethylideneamino)-2,6-di-*t*-butyl-2,5-cyclohexadien-1-one] (III). The mass spectrum of each oxidation product showed not only a weak molecular ion peak of cyclohexadienone (III), but also a weak peak of a larger mass number than the above molecular ion peak (Table 5). These unexpected peaks might arise from the formation of some compound in the ion-chamber of a mass spectrometer through the thermolysis and recombination of samples. The mass number of these peaks suggests that the molecular formula of the generating compound is $C_{43}H_{61}N_2O_3Ar$ (Ar=$C_6H_4NO_2$, $C_6H_4COOCH_3$, and C_6H_4Cl, respectively), since the difference in the unexpected mass number of each sample was equal to that in the molecular weight of the corresponding substituents, thus indicating the existence of one aryl group in each generating compound. The molecular weight measurement of oxidation products in benzene by a vapor pressure osmometer gave smaller values than the values calculated for cyclohexadienone (III) (Table 5). The sample solution for molecular weight measurement showed the same ESR spectra as those observed in the

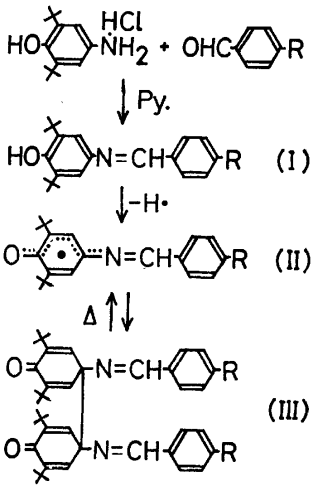

Fig. 3. Reaction path. (I), (II): R=NO_2, COOMe, Cl, H, MeO (III): R=NO_2, COOMe, Cl

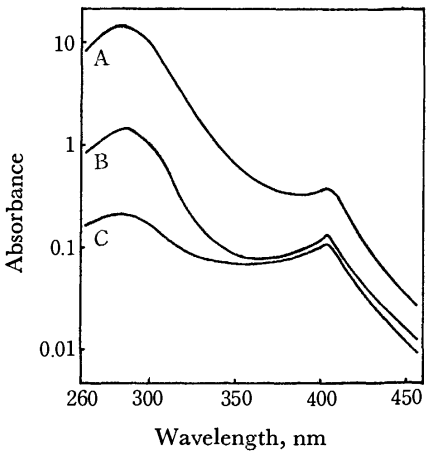

Fig. 4. Electronic spectra of cyclohexadienone (III, R=NO_2) in cyclohexane.

oxidation of phenols (I). The intensity of these ESR signals increased with the rise of temperature, and *vice versa*, and the ESR signals faded gradually at high temperature. These results show the dissociation of cyclohexadienones (III) to radicals (II) in solution, and those radicals then decompose to some other compounds at high temperature. The color of a benzene solution of cyclohexadienone (III) changed from yellow to green with the rise of temperature and returned to yellow upon a lowering of temperature. This color changing can be explained by the above dissociation. The electronic spectra of cyclohexadienones (III) at room temperature showed strong absorption bands near 285 nm and very weak bands near 400 nm (Table 6). The latter bands are due to radicals (II), since the dilution of the sample solution increased the relative intensity of these bands (Fig. 4).

Experimental

4-Amino-2,6-di-t-butylphenol Hydrochloride. 4-Nitroso-2,6-di-*t*-butylphenol[14] (14.1 g, 0.06 mol) and zinc powder (9.8 g, 0.15 mol) were suspended in methanol (180 ml). Hydrochloric acid (35 ml, *ca.* 0.35 mol) was added drop by drop to this suspension over 45 min under refluxing, which was then continued for 30 min after the addition of hydrochloric acid. Then the excess zinc powder was filtered from the reaction mixture, and the solvent (*ca.* 140 ml) was distilled from the filtrate. The concentrate was poured onto cold, degassed water, and the precipitating product was filtered and washed with cold, degassed water and then with cold *n*-hexane. The above isolating process was carried out under a nitrogen atmosphere. The subsequent drying of the product under reduced pressure gave a white powder of crude 4-amino-2,6-di-*t*-butylphenol hydrochloride (13.0 g, 84%, mp 195—203 °C (dec.) (lit,[15] 201—204 °C)), which was used for the preparation of phenols (I) without further purification.

4-(N-Arylmethylideneamino)-2,6-di-t-butylphenols (I). Arylaldehyde in ethanol and pyridine were added to an ethanol solution of 4-amino-2,6-di-*t*-butylphenol hydrochloride, after which the reaction mixture was allowed to stand for 1 hr at room temperature. The precipitating phenol (I) was filtered and washed successively with cold methanol, water and *n*-hexane. Each crude powder of phenol (I) was recrystallized from *n*-hexane. The follwing melting points were observed for each crystal of phenol (I): R=NO_2: yellow-orange needles, 169.0—170.0 °C; R=COOMe: yellow needles, 158.0—160.0 °C; R=Cl: pale yellow needles, 144.0—145.0 °C; Unsubstituted: yellow-orange needles, 151.0—152.0 °C; R=MeO: pale yellow plates, 155.0—157.0 °C. The results of elementary analyses and the molecular weight determination (MS) for prepared phenols (I) were in good agreement with the calculated values.

4,4'-Bis[4-(N-arylmethylideneamino)-2,6-di-t-butyl-2,5-cyclohexadien-1-one] (III). Phenol (I) (2×10^{-4} mol) in dried tetrahydrofuran (20 ml) was put in a Schlenk tube, and lead dioxide (0.09 g, 4×10^{-4} mol) was added to this solution. The reaction mixture was degassed by freezing with liquid nitrogen and brought to room temperature under a nitrogen atmosphere. Oxidation was carried out by shaking the reaction mixture at room temperature for the period shown in Table 5. Then lead oxide was filtered off from the reaction mixture, and the filtrate was evaporated to dryness under reduced pressure. The residual compound was dissolved in degassed cyclohexane (*n*-hexane for the chloro derivative) at room temperature, and the subsequent suitable concentration of this solution under reduced pressure gave yellow crystalline cyclohexadienone (III).

All the melting points were uncorrected. The molecular weight of cyclohexadienone (III) was determined for a benzene solution (0.007 M) at 37 °C with a Mechrolab 302 vapor pressure osmometer. The infrared spectra were recorded with a Shimadzu IR-27G grating spectrophotometer, the electronic spectra, with a Hitachi EPS-2U recording spectrometer, and the ESR spectra, with a Hitachi 771 electron spin resonance spectrometer equipped with a variable temperature accessory.

The author is indebted to Mr. Wasada for measuring the mass spectra.

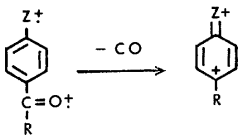
(Received June 21, 1974)

2E Doubly charged ion mass spectra of forty-six aromatic carbonyl compounds were determined. The spectra are quite different from those of singly charged ions. Several characteristic fragmentations including a novel [M−CO] peak are discussed. It is suggested that certain isomer pairs can be differentiated by comparing these spectra even when their conventional spectra are almost identical.

In a recent communication,[1] we have reported a novel rearrangement reaction in 2E doubly charged ion mass spectra[2] of acetophenone derivatives. A driving force for the reaction has also been briefly discussed. As an extension of this work, various aromatic carbonyl compounds were examined by the same technique[3] to elucidate any possible structural correlation in fragmentations, and to illustrate the potential usefulness of this spectra for the structural identification purposes.



Z = NH_2, OH, OCH_3 or Cl

R = H, CH_3, OH, NH_2 or OCH_3

Scheme 1.

Results and Discussion

The $[M-28]^{2+}$ Peaks. The doubly charged ion mass spectra of forty-six aromatic carbonyl compounds are summarized in Table 1 and Figs. 1 and 2. The characteristic [M−28] peak[1] was observed in most of the *p*-substituted compounds and in some of the *m*-substituted ones.

In order to determine the elemental compositions of the ion, the accurate masses were measured at half mass units of the peak in the conventional spectrum. The results were shown in Table 2. For the six compounds examined, the compositions of the [M−28] peak were unambiguously established as [M−CO]. These results indicate that the [M−28] peak has been produced, as previously suggested,[1] by the fragmentation reaction accompanying a rearrangement that involves a carbonyl side chain.

As is seen from Table 1, the carbonyl compounds whose spectra exhibited the intense [M−CO] peaks have electron-donating substituents such as an amino, a hydroxyl, or a methoxyl group. On the contrary, the spectra of *p*-tolualdehyde (**42**), *p*-methylacetophenone (**43**), and *p*-toluic acid (**44**) did not show the corresponding peak. On the other hand, when an electron-withdrawing, but lone pair electron-containing chlorine atom was introduced, the [M−CO] peak appeared as in the case of *p*-chlorobenzoic acid (**20**) or *p*-chlorobenzamide (**21**). These results suggest that the conjugative stabilization due to the lone pair electrons of the substituents in the product ion plays an important role in this fragmentation reaction [Scheme 1].

The intensity of the [M−CO] peak varies with the substituents. Because the molecular ion peaks were absent in most of the spectra, the height of the commonly observed peak at 62 mass units ($C_5H_2^{2+}$ ion)[3] was taken as an internal standard for intensity correlations. It is evident from Table 3 that the intensities of the [M−CO] peak in *p*-substituted compounds are in the decreasing order of NH_2>OH>OCH_3. This is the same order as Hammett's substituent constants,[4] and these findings confirm the significance of the product ion stabilities in this fragmentation reaction. The methoxyl group seems to be not very effective to stabilize the [M−CO] ion. This is also evidenced from the fact that for *meta* substituted compounds the [M−CO] peak appeared only from benzoic acids and benzamides that have an amino, a hydroxyl, or a chloro substituent.

The nature of the carbonyl group also affects these intensity ratios. For the series of compounds with the same substituent, the ratios are in the following decreasing order: aldehydes>methyl ketones>carboxylic acids>acid amides>methyl esters.

Although the spectra of methyl esters of *p*-amino, *p*-hydroxy, and *p*-methoxybenzoic acids (**12—14**) showed the [M−CO] peak, the corresponding ethyl esters (**15—17**) did not afford this peak. In order to compare the behavior of ester alkyl groups, the conventional mass spectrum of ethyl methyl phthalate was measured. It was found that [M−OC_2H_5] peak was much stronger than [M−OCH_3] peak, and therefore, ethoxyl group appeared to be much better leaving group. If we assume that the elimination reactions of CO and of alkoxyl group from the molecular ion are competitive in the doubly charged ion mass spectrum, the absence of the [M−CO] peak in ethyl benzoates seems to be explicable because a simple cleavage reaction with elimination of the ethoxyl group could be much faster than the elimination of CO, when compared to the case of methyl benzoates. In fact, the [M−OC_2H_5] peak was very prominent in these ethyl esters (**15, 16**).

Ar-$COOCH_3$	2.0	0.6	0.4

Other Characteristic Fragment Ion Peaks. Fragment peaks at 62 and 74 mass units were commonly observed. These ions are expected to have the compositions of C_5H_2 and C_6H_2, respectively, and would probably be the same ions as appeared in aromatic hydrocarbons.[3] Particularly for compounds with a hydroxyl or a methoxyl group at *para* or *meta* positions, the 62 peak was very strong and often accompanied by intense peaks at 63 and 64 mass units, whereas these peaks were relatively weak in amino, methyl, or chloro derivatives. On the other hand, a group of intense peaks at 74, 75, and 76 mass units was observed in *p*- or *m*-methoxy and chloro compounds.

A peak at 86 mass units was observed in all acetophenones except for *p*-amino compound, and in methyl substituted benzaldehydes and benzoic acids. This ion would be also a hydrocarbon fragment of C_7H_2.[3] These compounds also exhibited moderately intense peaks at 87, 88, 89, and in some cases at 90 mass units.

The [M—R] peak, resulting from a simple α-cleavage of the carbonyl group, was observed for most of the compounds. Expulsion of carbon monoxide from this ion afforded the [M—R—CO] peak as in ordinary spectra. However, methoxy compounds did not show this [M—R—CO] peak in any appreciable amount. It is of interest that for hydroxy compounds the corresponding peak appeared at 92 mass units rather than at 93. The composition of this 92 ion from methyl *p*-hydroxybenzoate (**13**) was established as C_6H_4O ([M—R—CO—H]), but the structure of the ion is unknown at present. This [M—R—CO—H] peak was also observed in amino and methyl compounds.

Besides these peaks, some other fragmentations are also characteristic of the substituent. For example, amino compounds showed a peak of intermediate intensity at 89 mass units, while methyl compounds afforded a peak at 118 and methoxy derivatives at 78 mass units.

Finally, it is worth noting that the [M—18] peak was the base peak in the spectra of both *p*- and *m*-amino or hydroxybenzamides (**9**, **10**, **31**, **32**), and that the [M—44] peak was significant for *p*-amino or *p*-hydroxybenzoic acid (**6**, **7**).

Discrimination of Isomers. As was discussed in the previous section, the [M—28] peak was characteristic of the compounds that have strong electron-donating substituents. It is, therefore, possible to differentiate the isomer pairs of certain compounds by observing this peak. For example, the conventional spectra of *p*- and *m*-hydroxybenzaldehydes (**1**, **23**) are essentially the same, but in their 2E doubly charged ion spectra only the *p*-compound exhibited a strong [M—28] peak, whereas the peak was negligibly small in the *m*-compound [Fig. 1]. The similar situation was encountered in several other cases, *e.g.*, in *para* and *meta* isomer

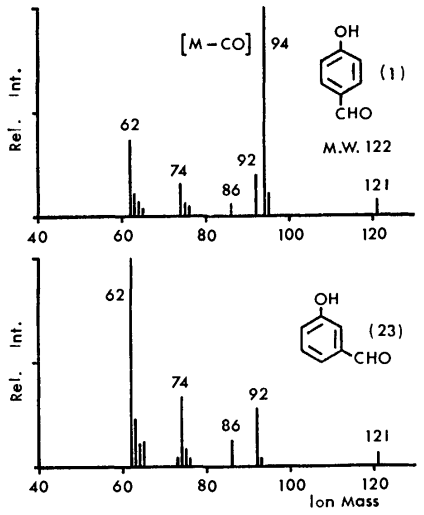

Fig. 1. 2E Doubly charged ion mass spectra of *p*- and *m*-hydroxybenzaldehydes (**1**, **23**).

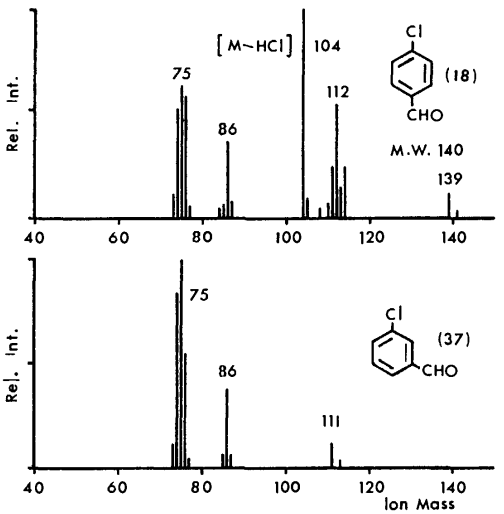

Fig. 2. 2E Doubly charged ion mass spectra of *p*- and *m*-chlorobenzaldehydes (**18**, **37**).

pairs of methoxybenzaldehydes (**2**, **24**), aminoacetophenones (**3**, **25**), and hydroxybenzoic acids (**7**, **29**).

Other characteristic peaks can also be used. Thus, an [M—HCl] peak was very prominent only in *p*-chlorobenzaldehyde (**18**) in doubly charged ion spectra [Fig. 2], while both *p*- and *m*-isomers afforded almost identical spectra in ordinary measurement (singly charged ion spectra).

Conclusion

It is evident from the above results that in doubly charged ion spectra of aromatic carbonyl compounds several different fragmentations were observed from those in conventional spectra. One of the most characteristic peaks of these compounds is the [M—CO] peak. Examination of the substituent effects revealed that the product ion stabilities are the most important factor in this fragmentation reaction.

Although several other structure-spectral pattern-correlations are obtained, the detailed structure of each fragment ion and the precise mechanism of its formation are not elucidated at this stage, and apparently further work is awaited.

On the empirical ground, however, it was found possible to distinguish the isomer pairs of certain compounds by using this spectra. This is of course very limited at present, but it is our hope that after accumulation of many data the 2E doubly charged ion spectrum will be one of the useful diagnostic tools for isomer discrimination and for structural identification of organic compounds.

Experimental

Materials. The most of the compounds were commercial samples of extra pure or guaranteed grade. The following compounds were prepared and characterized by standard procedures: *p*-aminoacetophenone (**3**), *p*-hydroxyacetophenone (**4**), methyl *p*-anisate (**14**), *p*-chloroacetophenone (**19**), *p*-chlorobenzamide (**21**), methyl *p*-chlorobenzoate (**22**), *m*-aminoacetophenone (**25**), *m*-hydroxyacetophenone (**26**), *m*-hydroxybenzoic acid (**29**), *m*-aminobenzamide (**31**), *m*-hydroxybenzamide (**32**), *m*-anisamide (**33**), methyl *m*-aminobenzoate (**34**), methyl *m*-hydroxybenzoate (**35**), methyl *m*-anisate (**36**), *m*-chloroacetophenone (**38**), *m*-chlorobenzamide (**40**), and methyl *m*-chlorobenzoate (**41**).

Doubly Charged Ion Mass Spectra. The spectra were determined with a Hitachi RMU-7 double focusing mass spectrometer by using the previously described method.[3] After the range of mass to charge ratio in ion source was set at *m/e* 600 and the electrostatic sector at 300, the accelerating voltage was adjusted for the desired peak to be observed. Standard operating conditions were as follows: ionizing energy 70 eV, ionizing current 80 μA, source temperature 250 °C, sample pressure $1—5\times10^{-6}$ Torr, and accelerating voltage 1.8 kV.

Accurate Mass Measurements. The accurate mass measurements were carried out on a Hitachi RMH-1 double focusing mass spectrometer. Operating conditions were ionizing energy 70 eV, ionizing current 0.6 mA, source temperature 200 °C, accelerating voltage 6.7 kV and resolution about 30000 (10% valley). Accurate masses of most peaks were determined by using doublets which were made by introducing appropriate reference samples into the spectrometer. In the case of nitrogen containing fragments, the peak appeared between nominal integer masses and, therefore, calculation by using Lagrange's interpolation formula gave reliable results. Data on Table 2 indicate the agreement between the calculated and observed values was satisfactory.

For the peak at 92 mass units from methyl *p*-hydroxybenzoate (**13**), the following result was obtained. Obsd: 46.0133, calcd for $(C_6H_4O)^{2+}$: 46.0131.

Reaction of Group IV Organometallic Compounds. XXXI.[1] The Reaction of *N*-Trimethylsilyl- and -stannyl-(diphenylmethylene)amine with Diketene

Hiroharu SUZUKI, Isamu MATSUDA,* Kenji ITOH, and Yoshio ISHII

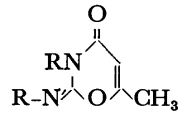
Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received July 15, 1974)

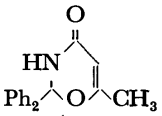
Linear 1/1 adducts and oxazinone derivative were obtained by the reaction of *N*-trimethylsilyl- and -stannyl-(diphenylmethylene)amine; $Ph_2C{=}N{-}MMe_3$ (M=Si, Sn) with diketene. Consecutive demetallation reaction by ethanethiol for the organostannyl 1/1 adduct, and by methanol for the organosilyl 1/1 adduct gave a piperidine derivative and an oxazinone derivative, respectively.

N-Trimethylsilyl- and -stannyl(diphenylmethylene)-amine; $Ph_2C{=}N{-}MMe_3$ ((I) for M=Si and (II) for M=Sn) have been reported to induce insertion and consecutive cyclization reactions with heterocumulene compounds,[1-4] aldehydes,[3] and acrylonitrile.[3]

Diketene is an attractive component for the preparation of six-membered heterocyclic compounds, because the acyl-oxygen bond cleavage of diketene provides a synthetic equivalence of acetylketene; $CH_3CO{-}CH{=}C{=}O$. For example, the addition of diketene to some carbodiimides and the parent diphenylmethyleneamine gave the corresponding oxazinone derivatives III[5] and IV,[6] respectively.



III

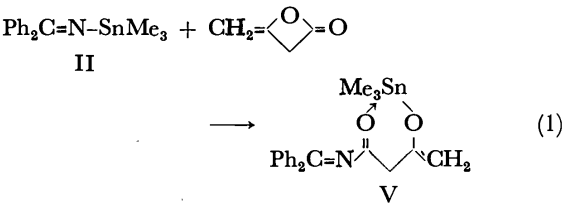


IV

In this paper we describe an insertion of diketene to the metal-nitrogen bond of I and II, and the subsequent cyclization reactions by way of demetallation treatment. The difference of products in both insertion and demetallation steps by changing the metal atom is discussed.

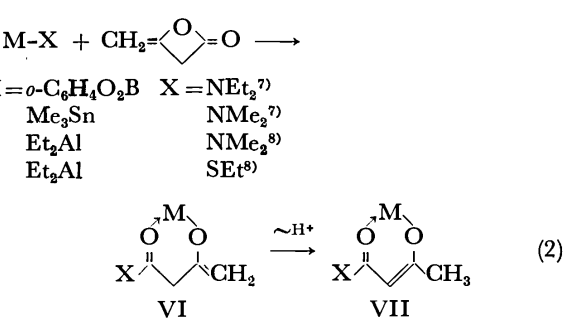
Results and Discussion

The Reaction of N-*Trimethylstannyl(diphenylmethylene)-amine (II).* N-Trimethylstannyl(diphenylmethylene)amine; $Ph_2C{=}N{-}SnMe_3$ (II) reacted exothermically with equimolar amounts of diketene to give the 1/1 adduct (V) as the fairly air-stable crystals in 96% yield. The strong IR absorption band around 1574 cm^{-1} indicates the presence of the carbonyl oxygen atom coordinated to the organotin moiety. Another absorption band at 1673 cm^{-1} was assigned to the C=N stretching frequency. The ^1H NMR spectrum of 1/1 adduct (V) showed resonance peaks at τ 7.05 (2H, m), 5.71 (1H, d, J=1.5 Hz), and 4.43 (1H, m), which were assigned to the methylene and terminal vinylic protons, respectively. The above spectroscopic results are consistent with the depicted structure V in Eq. (1). The participation of the diphenylmethylene group in the 1/1 reaction may be ruled out, since any cyclic product which includes the diphenylmethylene group in the ring skeleton was not obtained at all. Organometallic insertion reactions of diketene have been reported[7,8] to give only one product VII, which involves intramolecular 1,3-shift of a central methylene proton from VI.



(1)

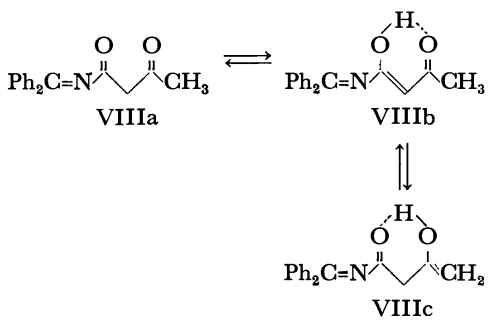
V



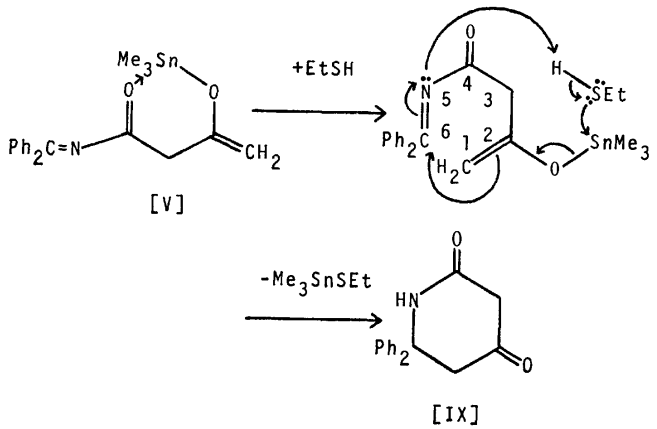
(2)

VI VII

It is noteworthy that the product (V) obtained in the reaction of *N*-trimethylstannyl(diphenylmethylene)-amine with diketene is the first stable organometallic insertion product which does not induce a 1,3-proton shift. The structure of V is also confirmed by the following destannylation reaction. Ethanethiol was added to the 1/1 adduct (V) in order to substitute the trimethylstannyl group with proton. The expected products were the isomers VIIIa—VIIIc; however, the ^1H NMR spectrum of the obtained destannylation product exhibited unexpectedly neither methyl protons nor vinylic protons. Only two pairs of methylene protons (τ 6.95, 2H, s, and τ 6.68, 2H, s) and the one proton attached to the nitrogen atom (τ 2.32, 1H, s, confirmed by D_2O exchange) were observed.



VIIIa VIIIb VIIIc



Scheme 1.

Moreover, two strong absorption bands at 1728 and 1661 cm^{-1} are assigned to a ketone and an amide carbonyl stretching frequencies, respectively. The above-mentioned spectroscopic results are consistent with 6,6-diphenylpiperidin-2,4-dione (IX), whose formation may be shown in Scheme 1. The addition of ethanethiol firstly causes the cleavage of the intramolecular coordinated structure because of the difference in the affinity of the tin atom toward oxygen and sulfur atoms. Then the ring closure is induced exclusively by the nucleophilic attack of the terminal carbon atom C(1) to the *exo* double bond at C(6), accompanied by the elimination of trimethylstannyl ethylsulfide. In the present case, diketene behaves as a component $\dot{C}O\text{-}CH_2CO\text{-}\dot{C}H_2$ to [4+2] cycloaddition. This is quite different from the general behavior of diketene which acts as a synthetic equivalence of $CH_3CO\text{-}CH{=}C{=}O$ as described before.

The Reaction of N-*Trimethylsilyl(diphenylmethylene)amine (I).* *N*-Trimethylsilyl(diphenylmethylene)amine (I) reacted with diketene under more vigorous condition than the tin analogue (II) (60 °C, 14 hr). The 1/1 reaction mixture was purified by vacuum distillation (bp 108.0—116.0 °C/0.02 mmHg) and was confirmed as a 1/1 adduct by analysis, whereas the adduct did not show a simple ^1H NMR spectrum (Fig. 1). The detailed measurement of the proton ratio and coupling patterns revealed the presence of three isomers XI, XIII, and XV, structures of which were given in Scheme 2.

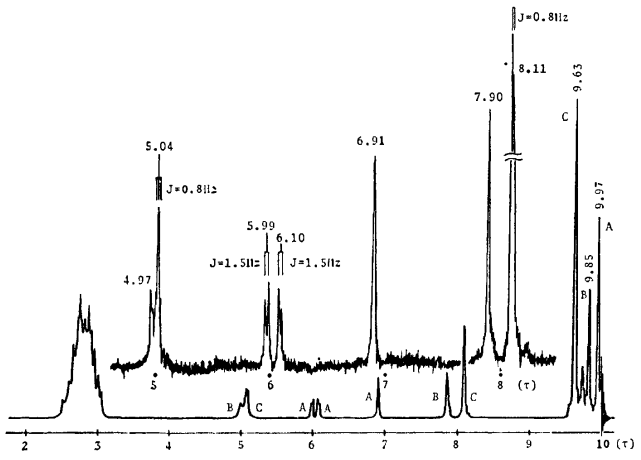


Fig. 1. The ^1H NMR spectrum of distilled mixture (in CCl_4). Resonance peaks A, B, and C were attributed to [XI], [XIII], and [XV], respectively.

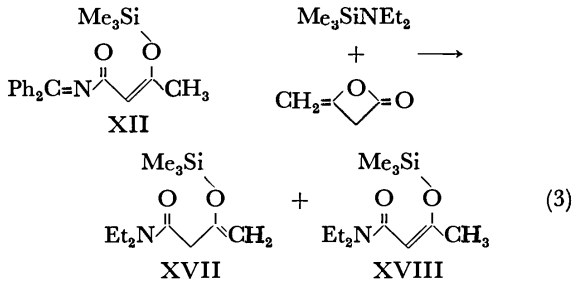
There is the possibility of the presence of the structure XII in the 1/1 adduct as reported in the paper[9] that diketene reacted with equimolar amounts of trimethylsilyldiethylamine to give the mixture of XVII and XVIII as shown in Eq. (3).



(3)

However, it can be excluded because of the absence of the allyl coupling which is expected in the structure XII.

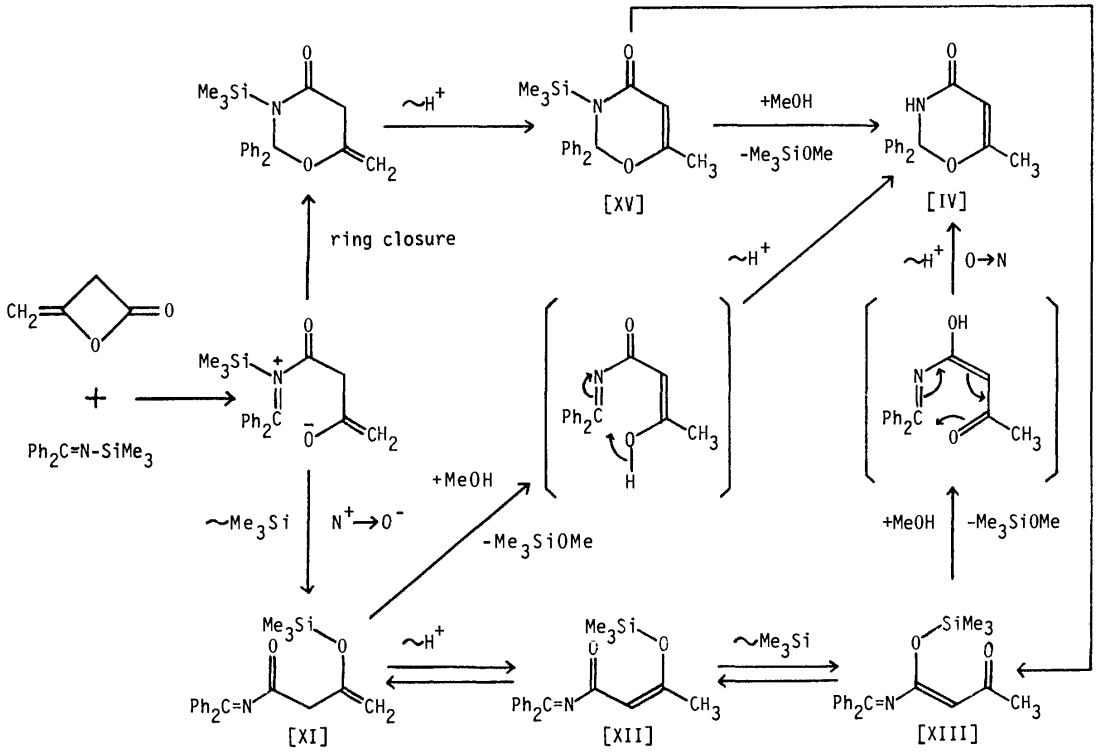
Table 1.

Reaction temp. (°C)	Total yield of XI, XIII, and XV (%)	Isomer ratio XI : XIII : XV
60	73	3.5 : 1 : 8.0
115	68	0.9 : 1 : 1.3
120	71	0.4 : 1 : 0.8

The observed isomer ratio in the 1/1 adducts was dependent on the reaction temperature as shown in Table 1. The isomer ratio of XI and XV decreased, and that of XIII increased as the elevation of the reaction temperature. This result definitely showed XI and XV were convertible to XIII, which would be thermodynamically the most stable product. Although the 1/1 adduct is composed of three isomers, XI, XIII, and XV, only 2,2-diphenyl-3,4-dihydro-6-methyl-2(1*H*)-1,3-oxazin-4-one (IV) was isolated on desilylation reaction. The yields are quantitative from the methanolysis of the purified 1/1 adduct, and 72% from the methanolysis of the 1/1 reaction mixture. The IV has been prepared by [4+2] cycloaddition reaction of the parent amine; $Ph_2C{=}NH$ with diketene.[6] The above results are summarized in Scheme 2.

The first step is a nucleophilic attack of the nitrogen atom in *N*-trimethylsilyl(diphenylmethylene)amine to the carbonyl carbon of diketene. In the second step, two paths are possible. First possibility is the migration of the trimethylsilyl group from the nitrogen to the oxyanion in X to give XI and XIII. Secondly, a direct ring closure accompanying a 1,3-prototropy gives XV, similar to a reaction of the parent diphenylmethyleneamine with diketene.[6]

It is extremely interesting that two isomeric heterocyclic compounds; IX and IV may be obtained from diketene only by changing the organometallic moiety in another component; *N*-organometallyldiphenylmethyleneamine.



Scheme 2.

Experimental

The mp of V was determined in a sealed capillary filled with argon. Analyses of organometallic compounds were carried out by Alfred Bernhardt Mikroanalytisches Laboratorium, West Germany. IR spectra were recorded on Japan Spectroscopic Co., Ltd., IR-S and DS-403G instruments. Proton NMR spectra were measured with Japan Electron Optics Co., Ltd., C-60HL instrument.

N-Trimethylsilyl(diphenylmethylene)amine[2] and *N*-trimethyltannyl(diphenylmethylene)amine[10] were prepared according to the published procedure. Diketene was distilled before use.

Reaction of N-Trimethylstannyl(diphenylmethylene)amine with Diketene. To a solution of 0.870 g (2.53 mmol) of *N*-trimethylstannyl(diphenylmethylene)amine in *ca.* 3 ml of benzene was added 0.268 g (3.19 mmol) of diketene at 0 °C under nitrogen. The reaction proceeded exothermically. The adduct was precipitated as pale yellow crystals by the addition of *ca.* 4 ml of *n*-hexane after the completion of the reaction. This was identified as 1/1 adduct (V), after the purification by reprecipitation from the mixed solvent of benzene and *n*-hexane (2/4) (1.044 g, 96%). Mp 130.0—133.0 °C. Found: C, 56.29; H, 5.54%. Calcd for $C_{20}H_{23}NO_2Sn$: C, 56.11; H, 5.41%. IR (in $CHCl_3$) 1673 and 1574 cm^{-1}. ^1H NMR (in $CDCl_3$) τ 9.57 (Me_3Sn, $J^{117/119}Sn$–C–H=65.0/68.0 Hz), 7.05 (2H, m), 5.71 (1H, d, J=1.5 Hz) and 4.43 (1H, m).

Destannylation of V. Addition of ethanethiol (2 ml) to a benzene solution (15 ml) of the 1/1 adduct (V) (0.900 g, 2.10 mmol) afforded the destannylated product (IX) (0.513 g, 1.94 mmol) as white prisms in 93% yield. Mp 179.5—181.5 °C. Found: C, 77.17; H, 5.72; N, 5.20%. Calcd for $C_{17}H_{15}NO_2$: C, 76.96; H, 5.69; N, 5.27%. IR (in KBr) 3120, 1728, and 1661 cm^{-1}. ^1H NMR (in $CDCl_3$) τ 6.95 (2H, s), 6.68 (2H, s), 2.72 (10H), and 2.32 (NH, br. s).

Reaction of N-Trimethylsilyl(diphenylmethylene)amine with diketene. The mixture of 1.916 g (7.58 mmol) of *N*-trimethylsilyl(diphenylmethylene)amine and 0.819 g (9.75 mmol) of diketene was heated at 60 °C for 40 hr in a sealed tube. The isomer ratio of [XI]: [XIII]: [XV] was decided by the intensities of proton signals of trimethylsilyl group in ^1H NMR spectrum of the reaction mixture. The reaction mixture was purified by vacuum distillation (bp 108.0—116.0 °C/0.02 mmHg) (1.85 g, 73%). Found: C, 71.22; H, 6.68%. Calcd for $C_{20}H_{23}NO_2Si$: C, 71.18; H, 6.78%. In the ^1H NMR spectrum (in CCl_4), the assignment of proton signals are as follows. XI: τ 9.97 (Me_3Si, 9H, s), 6.91 (2H, s), 6.10 (1H, d, J=1.5 Hz), and 5.99 (1H, d, J=1.5 Hz). XIII: τ 9.85 (Me_3Si, 9H, s), 7.90 (3H, s), and 4.97 (1H, s). XV: τ 9.63 (Me_3Si, 9H, s), 8.11 (3H, d, J=0.8 Hz), and 5.04 (1H, q, J=0.8 Hz).

A mixture of XI, XIII, and XV (2.55 g, 7.57 mmol) was desilylated by the treatment with methanol (5 ml). The desilylated product was isolated in 72% yield (1.45 g) and was identified to IV by the comparison with the authentic sample.[6]

Hetera-*p*-carbophanes. IV. The Effect of Rigidity on the Chemical Shifts of Protons in Ansa Chains and Barriers to Rotation of Dioxadioxo[*n*]paracyclophanes[1)]

Kazuhiko SAKAMOTO and Michinori ŌKI*

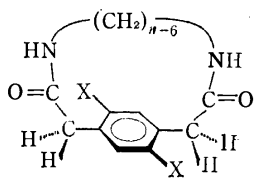
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received June 26, 1974)

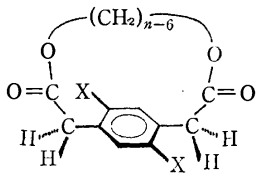
A series of dioxadioxo[*n*]paracyclophanes with or without methyl groups at the benzene ring were prepared and their PMR spectra compared with those of open-chain analogs as well as with those of paracyclophanes. Rigidity of the ansa chain was found to be an important factor in determining the chemical shifts of the ansa chain protons in addition to the ring current effect. Measurement of the PMR spectra at various temperatures revealed that the chemical shifts of the benzylic protons drifted to a small extent according to temperatures and the phenomenon was attributed to the change of solvation. Barriers to rotation of the aromatic rings in $\mathbf{6}_{15}$ and $\mathbf{6}_{16}$ were obtained as 23.3 and 11.0 kcal/mol, respectively. The barrier was discussed from the stand point of rigidity of the ansa chain.

In previous papers, the conformation of amide groups in and the internal rotation of diazadioxo[*n*]paracyclophane derivatives [$\mathbf{1}_n$ (n=12—16), $\mathbf{2}_n$ (n=11—16), $\mathbf{3}_n$ (n=11—16 and 18), and $\mathbf{4}_{18}$ (n=18)] have been reported.[1,2)] The barriers to rotation in these compounds appeared much higher than those in simple polymethylene paracyclophanes. Since these compounds contain rather rigid sp^2-hybridized structures of amide groups, the higher barrier may be attributed to the rigidity of the ansa chain. The barriers to rotation about a single bond of partial double bond characters are considered to be higher in amide groups than in ester groups because for the former it is necessary to raise the temperature to see the coalescence phenomenon of two signals in PMR spectroscopy[3)] (generally barriers are a little less than 20 kcal/mol) whereas it is necessary to cool the solution fairly deeply to observe signals of *s-cis* and *s-trans* forms by PMR spectroscopy for the latter.[4)] Thus it will be interesting to see the barrier height in heteraparacyclophanes containing two ester groups and compare the results with those of other cyclophanes.

In addition to the above point, the selection of the ester derivatives was hoped to give another advantage in studying the barrier to rotation. The amide compounds tend to crystallize out, when the solution is cooled, to give a difficulty in PMR measurements at the low temperature. Thus, although it was possible to obtain upper limits of the barriers for the amides, the precise value was not measured. Esters are known to be more soluble in ordinary solvents and the better solubility may help to see the change in barrier heights by increasing or decreasing the ansa chain length in a more quantitative fashion.



$\mathbf{1}_n$: X=H, n=12—16
$\mathbf{2}_n$: X=CH_3, n=11—16
$\mathbf{3}_n$: X=OCH_3, n=11—16, 18
$\mathbf{4}_n$: X=OC_2H_5, n=18



$\mathbf{5}_n$: X=H, n=11—16
$\mathbf{6}_n$: X=CH_3, n=11—16

This paper describes preparations of dioxadioxo[*n*]-paracyclophane derivatives [$\mathbf{5}_n$ (n=11—16) and $\mathbf{6}_n$ (n=11—16)] and discusses the effect of changing the ansa chain on the barrier to rotation. A part of the results on the internal rotation has been reported briefly.[5)]

Experimental

The syntheses of $\mathbf{5}_n$ and $\mathbf{6}_n$ were accomplished by condensation of α,ω-diols with 1,4-phenylenediacetyl dichlorides[2)] with or without methyl groups under high dilution conditions. The former compounds were of commercial origin except 1,10-decanediol.

1,10-Decanediol. Mp 71.5—72.5 °C (lit,[6)] mp 72—74 °C), was prepared by lithium aluminum hydride reduction of diethyl sebacate in ether in an almost quantitative yield.

Syntheses of Dioxadioxo[n]*paracyclophanes ($\mathbf{5}_n$ and $\mathbf{6}_n$).* The condensation between the chlorides and the diols was carried out in essentially the same method as reported previously.[1)] The crude product was chromatographed on silica gel and fractions eluted with hexane-benzene (v/v 9: 1—1: 1) were collected. Recrystallization from hexane gave the desired products. Melting points, analytical data, and yields for the pure compounds are summarized in Table 1.

Syntheses of Polymethylene Bis(2,5-dimethylphenylacetate)s ($\mathbf{7}_n$). A solution of 10 mmol of 2,5-dimethylphenylacetyl chloride in 10 ml of dry ether was slowly added to a stirred solution of 5 mmol of an appropriate α,ω-diol in tetrahydrofuran. After the addition, the reaction mixture was poured into ice–water. Subsequent work-up of the mixture in a usual manner gave a pale yellow oil. Chromatography of this oil on silica gel, using hexane-benzene mixture as eluent gave a pure compound in an almost quantitative yield. Analytical and some other data are tabulated in Table 2.

Measurement of Spectra. The infrared spectra were recorded on either a Hitachi EPI-G2 infra red spectrometer (4000—400 cm^{-1}) or a Perkin-Elmer 112G grating spectrometer (1750—1700 cm^{-1}). The measurements were run with KBr discs or neat liquids for the former instrument and with solutions in either carbon tetrachloride (*ca.* 0.0005 mol/l) or acetonitrile (*ca.* 0.01 mol/l) for the latter. The PMR spectra were measured on a Hitachi R-20B spectrometer operating at 60 MHz at 34 °C. Samples were dissolved in carbon tetrachloride for conventional measurements and the chemical shifts were recorded using TMS as an internal standard. Lanthanide [$Eu(dpm)_3$ and $Eu(fod)_3$-d_{27}] induced shift measurements were performed in deuteriochloroform solutions analogously to the method as reported previously.[7)] For the

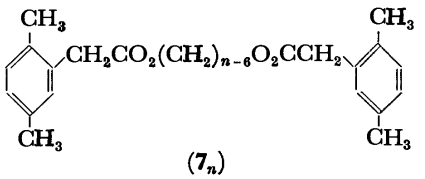
DNMR measurements, the solvent system had to be changed in order to meet the requirement of the properties of solvents, as are shown in Table 5. The temperature reading was calibrated by measuring the chemical shift differences between methylene and hydroxy protons of ethylene glycol at the higher temperatures and those between methyl and hydroxy protons of methanol at the lower temperatures. The mass spectra were recorded on a Hitachi RMU-6L spectrometer.

Results and Discussion

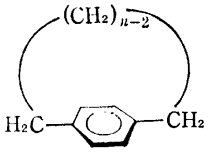
PMR Spectra. PMR spectral data of 5_n and 6_n in carbon tetrachloride solutions at 34 °C are summarized in Table 3 together with those of polymethylene bis(2,5-dimethylphenylacetate)s (7_n). Change in signal shapes of the bridge methylene protons in 5_n and 6_n,



(7_n)

which are remote from the ester moiety, due to the length of the ansa chain is similar with those observed with 2_n and 3_n and reflects rigidity and mobility of the molecules.

The multiplets due to the methylene protons gamma to the oxygen atom of the ester groups in 6_{11} and 6_{12} center at δ 0.45 and 0.80. These chemical shifts are located at the higher magnetic field with respect to those of [*n*]paracyclophanes. Waugh and Fessenden



(8_n)

Table 3. NMR data of dioxadioxo[n]paracyclophanes ($\mathbf{5}_n$ and $\mathbf{5}_n$) and polymethylene bis(2,5-dimethylphenylacetate)s ($\mathbf{7}_n$) in carbon tetrachloride at 34 °C (δ from internal TMS)[a]

a) s=singlet, q=quartet, m=multiplet, and b=broad signal b) relative to O-atom c) Since there were so significant overlapping with the integrals of β—δ-methylene protons in $\mathbf{7}_n$ that it was difficult to estimate the intensities of β- and γ—δ-methylene protons respectively, the intensity of β—δ-methylene protons was shown.

have reported that the central bridge methylene protons in [10]- and [12]-paracyclophanes ($\mathbf{8}_n$) give signals at δ 0.80 and 1.0, respectively, and sustain the ring current effect induced by π-electron delocalization.[8] The difference in chemical shifts in these hetera- and homo-cyclophanes could be attributed to the anisotropy effect of atoms or groups in the most-populated conformation.

It has been well known that the shielding of a nucleus can be expressed as the sum of several terms.[9,10] However, in the comparison of the shielding of bridge methylene protons (σ_{CH_2}) in similar molecules such as $\mathbf{6}_n$ and $\mathbf{7}_n$, the difference in the shielding exerted by atoms or groups other than the aromatic ring may be negligible at the first approximation if the conformations of ester groups are the same with each other. The ester group is known to take the *s-trans*[11] conformation in usual cases, but it takes the *s-cis* in some cases.[4,7,12] Lanthanide induced shift in PMR spectra is reported to be a convenient method for diagnosis of the ester conformation. If the ester is the *s-trans*, the ratio of the lanthanide induced shift *versus* [lanthanide]/[substrate] for the ether methylene is almost the same with that of carbonyl methylene, whereas it is about half when the conformation is *s-cis*.[7] Indeed $\mathbf{6}_n$ has been reported to be *s-trans* by this method.[7] Lanthanide induced shifts of $\mathbf{5}_n$ and $\mathbf{7}_n$ were measured and almost the same lanthanide induced shifts were obtained for CH_2O and CH_2CO in all the cases. Infrared spectra of the $\mathbf{5}_n$ and $\mathbf{6}_n$ gave only one band ($\sim$1730 cm^{-1}) for the carbonyl stretching both in carbon tetrachloride and in acetonitrile.[12] It may be concluded from these data that the ester groups in the dioxadioxo[n]paracyclophanes examined here take *s-trans* conformations. Thus an approximation that the difference, $\Delta\sigma_{CH_2}$, in shielding of the bridge methylene is determined by the ring current effect becomes valid. Contribution of the aromatic rings to σ_{CH_2} in $\mathbf{7}_n$ will be much smaller than that in $\mathbf{6}_n$ because the distance (r) between the aromatic ring and the central methylene protons in question in an extended molecule like $\mathbf{7}_n$ is much larger than that in a folded molecule such as $\mathbf{6}_n$ and the effect is propotional to $1/r^3$.

Table 4. High field shift of the central bridge methylene protons induced by diamagnetic ring current in $\mathbf{6}_n$ (ppm)

Number of ansa chain atoms	n=11	12	13	14	15	16
σ_{CH_2} of $\mathbf{7}_n$ $-\sigma_{CH_2}$ of $\mathbf{6}_n$	0.92	0.50	0.43	0.18	0.16	0.12

Increase of the number of ansa chain atoms causes decrease in $\Delta\sigma_{CH_2}$, as is seen in Table 4. The results are close to the values which are expected from the calculation by the Johnson and Bovey method[13] and indicate that the ansa chain conformation of the smaller chain length are fairly fixed to have the bridge-center just above the benzene ring. In such a conformation, the central part of the ansa chain will never come to the shielding cones of the C–O and/or the C=O bonds of the ester group, of which conformation has been deduced to be *s-trans*. Thus, from the stand point of

anisotropy of the ester group, the chemical shift of the bridge-center methylenes of $\mathbf{6}_n$ should be at the lower magnetic field than those of $\mathbf{8}_n$. The fact that, contrary to the simple discussion, the chemical shifts of the central methylene protons of $\mathbf{8}_n$ is at lower magnetic field than those of $\mathbf{6}_n$ may reflect the more flexibility of the methylene chain in $\mathbf{8}_n$ than that in $\mathbf{6}_n$, if the chain lengths are the same, due to the absence of sp^2 hybridized groups and, on an average, the shielding by the ring current effect in $\mathbf{8}_n$ is the less. The barriers to rotation of the aromatic rings reflect this situation also (see the later discussion).

The benzylic protons of $\mathbf{6}_{11}$—$\mathbf{6}_{15}$ give signals of the AB type at δ 3.4—3.5, whereas those of $\mathbf{5}_{11}$—$\mathbf{5}_{16}$ and $\mathbf{6}_{16}$ do signals of the A_2 type at almost the same magnetic field. The AB type signals for $\mathbf{6}_n$ are expected if the aromatic ring rotates slowly on the NMR time scale because, in these cases, the molecules exhibit chirality due to the plane asymmetry. Thus it appears that the rotation of the aromatic ring in $\mathbf{6}_{11}$—$\mathbf{6}_{15}$ is slow whereas that in $\mathbf{6}_{16}$ is fast at room temperature.

Temperature Dependence of the PMR Spectra. The PMR spectra of $\mathbf{6}_n$ were measured at various temperatures to obtain barriers to rotation of the aromatic ring. However, during the course of the study, an unexpected phenomenon appeared. That is, the differences between the chemical shifts of benzylic methylene protons showed small but definite changes within the range of 1.5—3.0 Hz at the temperatures of 34—190 °C, while the coupling constants remained intact. The changes in the chemical shift differences are linearly correlated with temperatures as shown in Fig. 1. The cause for the change cannot be the change in degrees of association of the solute, since the chemical shift differences observed at different concentrations of $\mathbf{6}_{12}$ in dimethyl-d_6 sulfoxide give the same inclinations of straight lines within experimental errors, as are shown in Fig. 2, although the absolute values of the chemical shifts change to some extent.

Such a temperature dependence may be attributed to either the solvation effect or the population effect: the latter concerns with the change in populations of conformers at various temperatures. Ifthe phenomenon were caused by the population effect, the following consideration would apply. Since the principal group which affects the chemical shifts of the benzylic protons is the aromatic ring, conformations made by rotation about the C_{Ar}–C_{CH_2} bonds may be considered: three possible conformations are shown in Fig. 3. The less stable conformers like **9** and **11** should increase in their populations when the temperature is raised. Interestingly, however, the coupling constants of the gem-hydrogens in conformations in **9** and **11** are expected to be larger than that of conformation **10** from the theory by Pople and Bothner-By.[14] This consideration leads to a conclusion that, if it were the population effect that caused the change in chemical shift differences, the coupling constants should have increased as well at higher temperatures. Since the coupling constants were almost the same at various temperatures, the situation discussed above will not apply to the present case. Thus the solvent effect becomes the reason of choice.

$\mathbf{6}_{13}$	17.3	13.3			
$\mathbf{6}_{14}$	16.6	14.3			
$\mathbf{6}_{15}$	16.7	13.6	189	23.3	HCB[b]
$\mathbf{6}_{16}$	12.1	14.3	−50	11.0	$CDCl_3$–CS_2 (v/v 1:3)

a) The figures in parentheses are the assumed values.
b) HCB: hexachlorobutadiene.

temperature. Thus the barriers to rotation of the aromatic ring in these compounds must be very high. The minimum free energies of activation (see Table 5) are obtained by putting the NMR parameters into the following Eq. (2),[15] where $\Delta\delta_{AB}$'s were obtained by extrapolation of the straight lines shown in Fig. 1 to the coalescence temperature, when applicable.

$$\Delta G_c^{\ddagger} = 4.57T_c\{9.97+\log_{10}(T_c/\sqrt{\Delta\delta_{AB}^2+6J_{AB}^2})\} \quad (2)$$

As the temperature of a solution of $\mathbf{6}_{15}$ in hexachlorobutadiene was raised, the AB quartet signal gradually broadened accompanied by apparent increase in the chemical shift difference. On further warming, the chemical shift difference decreased and finally merged into a single broad peak. The temperature at which this line shape was attained was regarded as the coalescence temperature (Fig. 4).

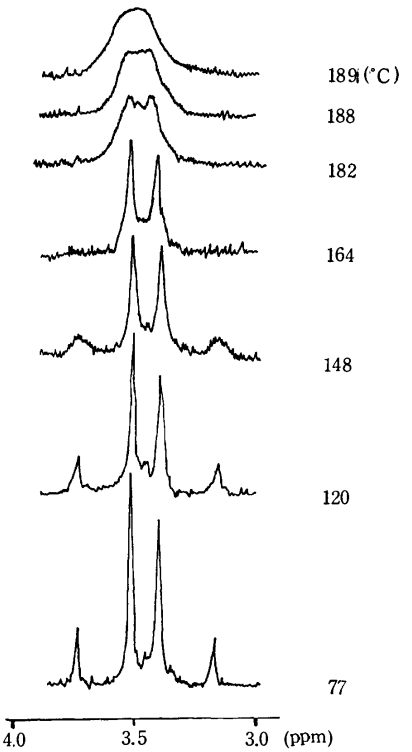

Fig. 4. Temperature dependence of PMR spectrum of $\mathbf{6}_{15}$ in hexachlorobutadiene.

In contrast, a solution of $\mathbf{6}_{16}$ in deuteriochloroform–carbon disulfide had to be cooled to find the coalescence. A chemical shift difference of 12.1 Hz and a coupling constant of 14.3 Hz were obtained at −70 °C. The free energy of activation for rotation in $\mathbf{6}_{16}$ was obtained as 11.0 kcal/mol.

The difference in the free energies of activation for internal rotation between $\mathbf{6}_{15}$ and $\mathbf{6}_{16}$ of the dioxa[*n*]-paracyclophane series is apparently as large as that between $\mathbf{2}_{15}$ and $\mathbf{2}_{16}$ of the diaza[*n*]paracyclophane series. This large difference in the height of barriers is caused by changing the number of methylene groups but one.

Comparison of the barriers and seeking a relation with the rigidity of the ansa chain will be interesting. Unfortunately, however, it is not possible to compare directly the barriers of the $\mathbf{2}_n$ series with those of the $\mathbf{6}_n$ series since the exact values of the former are not known. It might be said that, by and large, the barriers are about the same in both amide chains and ester chains, if the chain lengths are the same (see Table 5).

Rotational barriers for the aromatic rings in 14-substituted [12]paracyclophanes[16] and 1,12-disubstituted [12]paracyclophanes[17] have been reported to be 11—13 kcal/mol and *ca.* 13 kcal/mol, respectively. In contrast, 14,17-disubstituted 1,12-dioxa[12]paracyclophanes have been resolved into optical isomers at room temperature to indicate that the barrier will be more than 25—26 kcal/mol.[18] Apparently, the substitution pattern of the cyclophane must be taken into consideration in discussion of the barrier. Since the compounds discussed here have two methyl groups bonded to aromatic rings, the barrier may best be compared with those compounds resolved by Lüttringhaus and co-workers. Since the compounds of the largest ansa chain which have been resolved into enantiomers are 12 and it has not been possible to resolve a compound with an ansa chain of 14 atoms, it will be natural to assume that the compound of this type having an ansa chain of 14 atoms possesses a barrier lower than 25—26 kcal/mol. Then, since the barrier is lowered by *ca.* 10 kcal/mol by changing the chain length by one at the very critical length, the barrier for a compound having an ansa chain of 15 atoms may be assumed to have *ca.* 15 kcal/mol or less. Now comparison of the estimated barrier with those of the compounds having the ester or the amide groups in the ansa chain clearly indicate that the barrier is heightened by the introduction of these groups. Apparently the flexibility of the ansa chain is reflected to the barrier to rotation of the aromatic ring. Further study is necessary to estimate the effect of the rigidity on the barrier more quantitatively.

We wish to thank Prof. T. Shimanouchi of the University of Tokyo for permission of the use of the Perkin-Elmer 112G spectrometer. Thanks are also due to Dr. H. Nakanishi of National Chemical Laboratory for Industry who gave technical assistance in measurement of the spectra.

(Received July 18, 1974)

The reaction of secondary and tertiary alkyl halides with mercuric thiocyanate in less-polar solvents (*e.g.*, *n*-hexane, di-*n*-butyl ether, and 1,2-dichloroethane) was found to afford predominantly *N*-alkylation products, alkyl isothiocyanates, in contrast to the reaction with potassium salt in DMF. Especially, from *t*-butyl bromide, α-phenethyl bromide and benzhydryl chloride, the corresponding pure isothiocyanates were obtained in good yields. A most probable reaction mechanism is suggested, based on the relative rate data, the stereochemical result of the reaction with optically active α-phenethyl bromide, and the well-known catalytic effect of silver or mercury salt in S_N1 reaction.

The ambident nature of SCN^- has been known for a long time, as illustrated in the following scheme.

$$RX + KSCN \longrightarrow RSCN + KX$$
$$RCOX + KSCN \longrightarrow RCONCS + KX$$

The HASB principle has recently been applied to explain such a mode of attack; that is, alkyl halides react at the soft S atom of SCN^-, while the harder acyl halides react at the harder N atom.[1] In the thiocyanation of certain alkyl halides having a considerable S_N1 reactivity, however, the content of isothiocyanates in the products has been found to reach 35%.[2] This observation is also compatible with the above concept, because the increasing order of hardness of alkyl groups is primary<secondary<tertiary.[1] On the other hand, it has been shown that a change in the reacting site of the nucleophiles is caused by the variation of the counterions in the alkylation of various ambident nucleophiles, such as NO_2^-,[3] CN^-,[4] the anions of 1,3-dicarbonyl compounds,[5] and the anion of formamide.[4] These facts suggest that under appropriate conditions the predominant formation of alkyl isothiocyanates from the corresponding halides might be achieved. In view of the fact that sulfur atom is very powerful nucleophile, it seemed of interest for us to examine whether a preferable attack on the N atom of SCN^- may occur.

Results and Discussion

First of all, we examined the reaction of isopropyl iodide with various metal thiocyanates to know the effect of metal cations on the isomer distribution. The reaction was conducted in less-polar solvent such as *n*-hexane, because the fact is known that in the preparation of alkyl thiocyanates a considerable improvement in yields was achieved by use of polar aprotic solvents.[6] All metal salts used are hardly soluble in *n*-hexane, and the reaction is a heterogeneous process. The results are shown in Table 1. As can be seen from Table 1, $Hg(SCN)_2$ showed the best result for the *N*-alkylation of SCN^-, while other metal salts were less or not satisfactory. Although a predominant attack on the more electronegative (hard) site of the anions has been observed in the alkylation of NO_2^- and CN^- by using silver salts,[4] the attack on the soft S atom was preferred in the alkylation of SCN^- at least in *n*-hexane as solvent by using AgSCN and $Pb(SCN)_2$ as well as KSCN.

mides with $Hg(SCN)_2$ in di-*n*-butyl ether. The reaction mixtures were heterogeneous in all cases. The results are presented in Table 2. As shown in Table 2, isothiocyanates became the predominant isomer when secondary and tertiary bromides were submitted to the reaction, and particularly in cases of the bromides which were capable of forming stable carbonium ions the selectivity was excellent. In addition, a formation of a small amount of the elimination product was observed in the reaction with some bromides. These observations appeared to agree with those expected for S_N1 process.

Since the thermal isomerization of alkyl thiocyanates into isothiocyanates (where alkyl groups are tertiary or aralkyl ones), especially with ease in the presence of $ZnCl_2$, has been known,[7] some controlled experiments on the isomerization were undertaken. For example, when a mixture of *t*-butyl thiocyanate and isothiocyanate (42.6: 57.4) was heated at 70—72 °C for 0.66 hr in di-*n*-butyl ether in the presence of $Hg(SCN)_2$ or $HgBr_2$, the isomer ratio in the resulting mixture was almost unchanged (42.4: 57.6 and 40.9: 59.1, respectively). For a mixture of α-phenethyl thiocyanate and isothiocyanate, a change in the isomer ratio was very little (from 97: 3 to 95.6: 4.4) after heating in di-*n*-butyl ether in the presence of $Hg(SCN)_2$ at 70 °C for 0.75 hr. Similarly, no isomerization was observed in cases of isopropyl and cyclohexyl thiocyanates. Hence, it can be said that the isomer ratios shown in Table 2 are kinetically controlled.

On the other hand, no details on the isomer distribution in the reaction of alkyl halides with alkali metal thiocyanates in polar aprotic solvents have been reported, where the reaction is believed to proceed by S_N2 process. Therefore, we have examined it in DMF solvent using alkyl bromide as alkylating agent. The data are shown in Table 3. Primary and secondary

bromides reacted more readily than tertiary one, as expected, and the obtained alkyl thiocyanates were generally contaminated with few percent of isomeric isothiocyanates, except for some cases. In contrast to the results in di-*n*-butyl ether, the isomerization of α-phenethyl and *t*-butyl thiocyanates to the corresponding isothiocyanates occurred readily in DMF.

The impressive solvent effect on the course of ambident anion alkylations has been mentioned very often.[5] Therefore, the reactions of isopropyl bromide or iodide with $Hg(SCN)_2$ were conducted in various solvents and the effect of solvents on the isomer ratio was studied. The results, which are recorded in Table 4, show that the requirement for the predominant isothiocyanate formation is the use of less-polar solvents such as di-*n*-butyl ether, *n*-hexane, and 1,2-dichloroethane. The isomer ratios were almost constant at least in these solvents. Further, isopropyl iodide reacted more rapidly than the bromide as expected, but the observed isomer ratios for the products obtained from both halides were almost identical. This would be natural if an S_N1 mechanism is operative for this reaction. Of particular interest are the facts that a preference for *N*-alkylation was held even in polar aprotic solvents and that the total yield of two isomers and the product selectivity in a homogeneous system (reaction in DMF) were quite similar to those in a heterogeneous one (reaction in acetonitrile). In addition, the yield of isopropyl thiocyanate formed by the reaction with $Hg(SCN)_2$ in DMF was surprisingly poor (compare the data in Tables 3 and 4), indicating that no considerable amounts of free SCN^- are formed even in a homogeneous system. Significant decreases in the yields of the isomeric mixture for the reaction in DMF and acetonitrile may be ascribed to the strong solvation of the dissolved $Hg(SCN)_2$ species by these solvents, because a strong interaction between metal salts or metal cations with such solvent molecules has been well-known.

In order to obtain further information on the mecha-

nism of the reaction, the studies on the relative reaction rates in alkyl bromides and also on the stereochemistry of the reaction were undertaken. First, by competitive reactions with any two alkyl bromides, the following data were obtained. The observed reactivity

n-BuBr:*i*-PrBr:*t*-BuBr=1:10:10^4 (at 65°C, in *n*-hexane)

$PhCH_2Br$:PhCH(Me)Br=1:7 (at 0—1°C, in *n*-hexane)

order, tertiary≫secondary>primary, appears to confirm that the reaction is essentially pictured as an S_N1 type substitution.[8] Moreover, such an order did not change when the partial rates for each product were compared. Hence, a possibility is considered that both isomeric products are produced *via* a common alkyl cation formed by the attack of $Hg(SCN)_2$ on the halogen atom. That the formation of such a mercury–halogen bond furnishes an important part of the driving force for the ionization is clear from the failure of sulfonates such as isopropyl tosylate to react with $Hg(SCN)_2$ (at 80 °C, for 23 hr, in di-*n*-butyl ether), because sulfonates are known to be generally more reactive than the corresponding bromides toward nucleophiles.[9a] It should be also noted that silver or mercury-salt catalysis of S_N1-like substitution of alkyl halide is quite well-known.[9b]

Second, after treatment of (*R*)-α-phenethyl bromide (optical purity, 62.3%) with $Hg(SCN)_2$ suspended in *n*-hexane (at 0 °C for 1 hr), the isothiocyanate in a mixture of isomeric products (77% yield) was converted into the thiourea derivative by the addition of benzylamine. The isolated *N*-benzyl-*N'*-α-phenethylthiourea after recrystallization from ethanol was almost optically inactive (see Experimental). The same result was obtained by using (*S*)-α-phenethyl bromide (optical purity, 38.7%). Here, there is no possibility that the optically active isothiocyanate was initially formed and then racemized, because no appreciable racemization of (*S*)-α-phenethyl isothiocyanate was observed under reaction conditions (at 0—1 °C, for 1 hr, in *n*-hexane, in the presence of $Hg(SCN)_2$). Further there may be some possibility that in the experiment described above the starting α-phenethyl bromide is racemized catalytically by mercury salt before isothiocyanation. When (*R*)-α-phenethyl bromide was treated with $HgBr_2$ in *n*-hexane (at 0—1 °C, for 1 hr), however, the recovered bromide still retained 22% of optical purity (78% racemization). These results indicate that isothiocyanation proceeds with almost complete racemization. The result that the extent of racemization by $HgBr_2$ agrees well with the total yields of the racemized isomeric mixture of SCN compounds suggest that both reactions proceed through the common ionization step which is rate-determining.

There are some data on the relative reactivity of the S- to the N-end of SCN^- towards carbonium ions. Fava *et al.*[10] found the value $k_S/k_N=5$ toward 4,4'-dimethylbenzhydryl cation in acetonitrile, by estimating the partition of radioactivity. In the solvolysis of 4,4'-dimethylbenzhydryl halides in 65% aqueous acetone containing SCN^-, the same value was obtained.[10] Taft and Cannell[2] obtained the values ranging from 2 to 9, from the product ratio in the reaction of certain carbonium ion precursors. In contrast to these data, much lower values were observed in the reaction of secondary and tertiary alkyl halides with $Hg(SCN)_2$ as described above, regardless of the solvent polarity. For example, the k_S/k_N values calculated from the isomer ratios were 0.41 and 0.18 for isopropyl cation in acetonitrile and di-*n*-butyl ether, respectively, and less than 0.01 for α-phenethyl cation in di-*n*-butyl ether. Such a high selectivity for *N*-alkylation may be correlated with the structure of $Hg(SCN)_2$, which is confirmed to be S-bonded.[11] Since the existence of considerable amounts of free SCN^- in the reaction system is unexpectable as described above, the anion should be present mostly in the form of $XHg(SCN)_2^-$ which is the counter ion at the carbonium ion formation. If this complex ion serves as a source of SCN^-, the reaction with cationic species would occur mainly at the terminal N atom which is the sterically favorable and more electronegative site.

A presumed mechanism for the reaction with secondary and tertiary halides can be summarized in the following scheme.

$$RX + Hg(SCN)_2 \xrightarrow{\text{slow}} R^+ + XHg(SCN)_2^-$$

$$R^+ + XHg(SCN)_2^- \longrightarrow RNCS(\text{major}) + RSCN + HgX(SCN)$$

Finally we must add a short comment on the reaction of primary halides with $Hg(SCN)_2$ in less polar solvents, although no decisive data are available at present. On accounts of considerable instability of primary cations, a push-pull process which involves the push by SCN^-, probably formed in a small amount by the ionization of the dissolved $Hg(SCN)_2$, and the pull by $Hg(SCN)_2$ may be operative in this case together with the mechanism described above. In a similar reaction of alkyl halides with silver nitrate, the contribution of a push-pull mechanism has been already established.[3]

Experimental

All the organic substances, including the solvents, were used after distillation. Commercial metal thiocyanates and $HgBr_2$ (best grade) were used without further purification.

The isomer ratios of alkyl thiocyanates and isothiocyanates were mostly determined by gas chromatography (glc), and in some cases where glc analyses were unapplicable they were determined by titration method or NMR analysis. The glc analyses were carried out with a Shimadzu 5APTF apparatus using Apz-L (1 m) and PEG-6000 (3 m) columns (carrier gas, N_2). The titration method is based on the addition of butylamine to alkyl isothiocyanates.[12] The NMR spectra were obtained on a Varian A-60 spectrometer (solvent, CCl_4; internal standard, TMS). Optical rotations were measured on a JASCO DIP-180 automatic polarimeter.

Reaction of Alkyl Halides with Mercuric Thiocyanate. Several examples of the reaction of isopropyl halides with $Hg(SCN)_2$ are given below.

a) *In* n-*Hexane*: To a stirred suspension of $Hg(SCN)_2$ (12.0 g, 38 mmol) in *n*-hexane (30 ml) isopropyl iodide (6.5 g, 38 mmol) was added slowly at 64—65 °C, and the mixture was kept for 6 hr under stirring. The reaction mixture was cooled and filtered to remove the precipitate of inorganic salts. The solvent in the filtrate was removed, and the

resulting residue was distilled, affording a mixture of isopropyl thiocyanate and isothiocyanate (2.6 g, 69% yield), bp 57—58 °C/45 mmHg. The isomer ratio of S/N by glc was 25/75.

b) *In Di-n-butyl Ether*: In a similar way, isopropyl bromide (9.7 g, 79 mmol) was allowed to react with a suspension of $Hg(SCN)_2$ (24.0 g, 76 mmol) in di-*n*-butyl ether (60 ml) under stirring at 70—75 °C for 8 hr. Since the boiling point of the solvent is close to that of the products in this case, the filtrate was analyzed by glc without the evaporation of the solvent. The observed isomer ratio was 15/85. The amount of isopropyl isothiocyanate in the filtrate was determined by the titration method. Based on this, the total yield was calculated (3.5 g, 44%).

c) *In DMF*: Isopropyl iodide (6.5 g, 38 mmol) was similarly treated with a homogeneous solution of $Hg(SCN)_2$ (12.0 g, 38 mmol) in DMF (30 ml) under stirring at 75—80 °C for 5 hr. The reaction mixture was then cooled, filtered, and poured into a large amount of ether (*ca.* 200 ml), and washed by water (2×100 ml). The ether layer was dried by $MgSO_4$ and evaporated to give an oily residue. Distillation afforded a mixture of the expected thiocyanate and isothiocyanate (0.42 g, 11%), bp 61—64 °C/45 mmHg. By glc, the isomer ratio was found to be 39/61.

Competitive Reactions. To a stirred suspension of $Hg(SCN)_2$ (24.0 g, 76 mmol) in *n*-hexane (60 ml) a mixture of isopropyl bromide (8.5 g, 69.1 mmol) and *t*-butyl bromide (1.05 g, 7.6 mmol) was added slowly at 65 °C. After stirring for 1 hr at that temperature, the mixture was worked up as before. A distillate boiling at 60—62 °C/50 mmHg was collected (0.45 g) and analyzed by glc. The combined yield of isopropyl thiocyanate and isothiocyanate was 0.052% (0.036 mmol) and that *t*-butyl compounds was 50% (3.8 mmol). Then the relative rate for these two bromides was 1:960. In a similar way, the competitive reaction of *n*-butyl and isopropyl bromides (each of 38 mmol) (at 65 °C for 7 hr) afforded the corresponding isomeric mixtures in yields of 1.2 mmol and 12.4 mmol, respectively, indicating a 1:10 relative rate. Similarly, the relative rate of benzyl and α-phenethyl bromides was found to be 1:7 at 0—1 °C. In this case, analysis was carried out by NMR method. The following signals were taken up for analysis: δ values for α-H of benzyl thiocyanate and isothiocyanate was 4.03 and 4.59, and those for α-CH_3 of α-phenethyl thiocyanate and isothiocyanate were 1.78, 1.90(d) and 1.60, 1.70(d).

Stereochemical Data. a) *Reaction of (R)-α-Phenethyl Bromide with $Hg(SCN)_2$ in n-Hexane.* (*R*)-α-Phenethyl bromide, α_D^{20} +105.88° (neat) (optical purity, 62.3%[13]) was prepared from the corresponding optically active alcohol by the procedure of Gerrard.[14] This bromide (3.5 g, 18.9 mmol) was treated with $Hg(SCN)_2$ (9.0 g, 28.4 mmol) in *n*-hexane (30 ml) at 0—1 °C for 1 hr under stirring, and the reaction mixture was worked up as usual. A distillate boiling at 111—112 °C/6.5 mmHg was collected (2.38 g, 77%). This product (1.1 g, 6.74 mmol) was converted into *N*-benzyl-*N'*-α-phenethylthiourea (1.7 g, 94%) by the addition of benzylamine (1.4 g, 13.4 mmol) in ether. Recrystallization from ethanol afforded the pure thiourea, mp 100—101 °C (lit,[11] 100 °C), $[\alpha]_D^{20}$ −0.066 (*c* 5.9, 96% EtOH) (optical purity, 0.26%).[15] Additional crystals obtained from the mother liquor did not show any optical rotation.

Quite similar treatment using (*S*)-α-phenethyl bromide, α_D^{20} −65.74° (neat) (optical purity, 38.7%), gave *N*-benzyl-*N'*-α-phenethylthiourea of $[\alpha]_D^{20}$ −0.020 (*c* 5.9, 96% EtOH), and additional crystals obtained from the mother liquor did not show any optical activity.

b) *Racemization of (R)-α-Phenethyl Bromide with $HgBr_2$ in n-Hexane.* When a solution of the above bromide (1.01 g, 5.47 mmol) in *n*-hexane (10 ml) was treated with $HgBr_2$ (3.0 g, 8.32 mmol) at 0—1 °C for 1 hr, a decrease in the optical rotation from $[\alpha]_D^{20}$ +63.24° to 13.60° (*c* 10.12, *n*-hexane) was observed, which corresponds to 78% of racemization.

c) *Attempted Racemization of (S)-α-Phenethyl Isothiocyanate with $Hg(SCN)_2$ in n-Hexane.* (*S*)-α-Phenethyl isothiocyanate, α_D^{20} +28.76° (neat) was prepared from the corresponding optically active amine by the method of Teventev.[16] This isothiocyanate (7.5 g, 46 mmol) was treated with $Hg(SCN)_2$ (30 g, 95 mmol) in *n*-hexane (100 ml) at 0—1 °C for 1 hr, and it was recovered by distillation after usual work-up procedure. It showed α_D^{20} +28.74° (neat), indicating no loss of the optical activity.

Authentic Samples for Glc Analyses. Alkyl thiocyanates were prepared by the reaction of alkyl bromides with KSCN in DMF,[6] though they were generally contaminated with a small amount of the isomers. Alkyl isothiocyanates were synthesized from the corresponding amines (*via* thiocarbamates) by the method of Martin.[17] Benzhydryl isothiocyanate was isolated from the reaction product by distillation, bp 160—165 °C/4 mmHg, mp 59 °C (from EtOH, lit,[18] 58 °C).

Isotope Effects in the Reactions of ^{80}Br Activated by Isomeric Transition with Various Deuterated Propanes

Enzo Tachikawa and Kenshi Numakura

Division of Chemistry, Japan Atomic Energy Research Institute, Tokai-Mura, Ibaraki 319-11

(Received April 30, 1974)

Product studies of the reactions of recoil ^{80}Br with propanes in binary mixtures with ethane showed that the difference in the energy-loss efficiency of C_3H_8 and C_3D_8 in collision with ^{80}Br was less than 10%. Then, the yields for the substitution of ^{80}Br for atoms or groups have been compared in various deuterated propanes. A reactivity integral-isotope effect has been observed in the yields of products from $CD_3CD_2CD_3$ and $CD_3CH_2CD_3$, except in the case of isopropyl bromide from the latter compound. However, it has been observed only in the yield of iso propyl bromide from $CH_3CD_2CH_3$. These results indicate that the chemical and physical properties of both replaced and residual atoms or groups play a role in the observed isotope effects. With a "complex" formation mechanism, it is suggested that an isotope effect appears mostly when the kinetic energy of the reacting ^{80}Br is at the lower-energy end of the reaction-energy range.

One of the experimental approaches used to obtain valuable information concerning the mechanisms and characteristics of the reactions of energetic atoms is to measure the isotopic variation in the reaction yields from protonated and deuterated reactants. Thus far, the existence of the isotopic preference in the substitution reaction of ^{80}Br for H over D has been demonstrated in CH_4–CD_4[1,2] C_2H_6–C_2D_6[3] and CH_3F–CD_3F[4] systems. However, these observed reactivity integral-isotope effects directly reflect the composite of the primary and secondary isotope effects. The relative importance of the magnitude of these effects can be evaluated through competitive experiments in the intra- and inter-molecular comparisons of various deuterated compounds.

The present paper will deal with the isotopic variation between C_3H_8 and fully- or partially-deuterated propanes in the substitution reaction of the ^{80}Br activated by the isomeric transition. The results obtained cannot be explained solely by the two models so far proposed for the substitution reaction of the recoil tritium atoms; one of them based on the rotational inertia,[6,7] and the other, on the electronegativity[8–10] of the residual group. Instead, the results indicate that a complete explanation must involve an effect combining the physical and chemical properties of the replaced atom or group, and those of the residual group.

Experimental

Sample Preparation and Analysis. The preparation of samples followed the routine procedures used in our previous work for gas-phase bromine hot atom chemistry.[11] The ^{80m}BrBr was formed by irradiating gaseous Br_2 with thermal neutrons for one minute in a JRR-4 reactor at JAERI. The reaction mixture was allowed to stand more than 2 hr to permit a ^{80m}Br^{80}Br parent-daughter equilibium to be established. All the samples contained 65 Torr of oxygen in order to exclude the formation of isopropyl bromide tagged with ^{80}Br by light- or radiation-induced reaction. The total pressure was always kept constant at 710±10 Torr. The reaction products were analyzed by means of a radio-gas chromatograph equipped with a flow-type G-M counter. The results obtained were processed using the BOB 7 series program[12] corrected for the background and for the radioactivity decay of nuclides.

Percentage Yield. The less than 0.1% of propylene present as an impurity in propane significantly interfered with the direct measurement of the total organic yield.[11] Thus, the absolute yield has been measured only from the ^{80}Br–C_2H_6–O_2 (3.2±0.1%) system by a solvent-extraction method. Individual radioactivity yields have been obtained by dividing the activities in the radio-gas chromatogram by the total ^{80}Br activity, as measured with a G-M counter 2 hr after sampling the gases. The relative yields have been normalized to the percentage yields using a conversion factor determined from the sum of the relative yields and from the total organic yield found in the above system. The chief uncertainty involved in this procedure is introduced in the measurement of the total ^{80}Br activity, and the accuracy in the percentage yield obtained is usually limited to ±10%.

Chemicals. Ethane and C_3H_8 of the highest grade were obtained from the Takachiho Chemical Co. The deuterated propanes came from the Merk Sharp and Dohme Co., their listed purities were all 98%. These reagents were used after the freezing-thawing purification had been repeated several times.

Results and Discussion

Bromine-80 activated from the (I.T.) process reacts with hydrocarbons either by an energetic process or by a non-energetic process; the relative importance of the latter depends on the circumstances.

The most common means of identifying energetic reactions is the addition of a chemically-inert moderator to the system. In general, noble gases are used as moderators. Such moderators have no effect on the thermal energy distribution. However, by reducing the excess kinetic energy of an energetic atom in each collision, the moderator will reduce and sometimes eliminate energetic reactions.

Of particular importance is the early recognition that the charge state of the reacting ^{80}Br is primarily controlled by the ionization potential of the constituents of the reaction systems, and that an additional product is formed *via* thermal ionic processes in the presence of an inert gas with a higher ionization potential than that of Br. Thus, the reactions in the binary system have been studied using C_2H_6 as a counterpart as in the previous paper.

Table 1 shows the yield variation in the products in

a) Average of several measurements

C_3D_8–C_2H_6 mixtures, the m.f. of the latter varying from zero to 1.0. With the addition of C_2H_6, the yields of iso- and *n*-propyl bromides, which are formed only from C_3D_8, decrease from 0.15±0.02 and 0.49±0.03 respectively to zero. However, methyl, ethyl, and methylene bromides are formed from the reactions with either constituent; the observed yields are the sum of those from both constituents. The contribution to the overall observed yield from each constituent can be estimated on the assumption that the relative yield distribution among the products from C_3D_8 remains constant over the entire range of the m.f. of C_3D_8. This permits the calculation of the yields of products at any m.f. of C_3D_8 by simply multiplying the percentage yield of *n*-propyl bromide by the constant determined based on the yields found without the addition of C_2H_6.

The corresponding yields of products originating from C_2H_6 can be obtained as the difference between the calculated yield and the observed yield at any measuring point; the yields are shown in Fig. 1. The results show that the yield decreases to zero with an increase in the m.f. of C_3D_8 and that no significant interference of other possible processes exists in the yield variation. This implies that the thermal ionic process is not important in this binary system as the case in the C_3H_8–C_2H_6 system.[11]

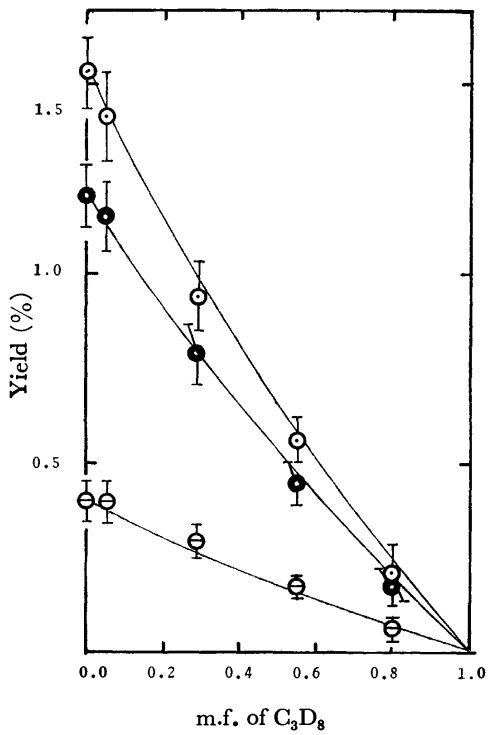

Fig. 1. Estimated and Calculated Yields of Products in Reactions of ^{80}Br with C_2H_6
Estimated yield; ⊙: methyl bromide ●: ethyl bromide, ⊖: methylene bromide, Calculated yield; solid line (equation 1)

The solid lines are the yield curves obtained using this equation;[11]

$$\frac{1}{P}=\frac{\alpha_{(C_3D_8)}}{I}+\frac{\alpha_{(C_2H_6)}}{I}\cdot\frac{f_{(C_3D_8)}+A\cdot f_{(O_2)}}{f_{(C_2H_6)}} \qquad (1)$$

where $A=\alpha_{(O_2)}/\alpha_{(C_3D_8)}$. The f_i is the relative probability of the collision of ^{80}Br with the i component, and where α_i is the average energy loss on collision with the i component. For the calculation, $\alpha_{(C_3D_8)}/\alpha_{(C_2H_6)}$ was equalized to $\alpha_{(C_3D_8)}/\alpha_{(C_2H_6)}$, which had previously been determined as 1.1 with $A=0.65$ in the ^{80}Br–C_3H_8–C_2H_6–O_2 system.[11] The fit of the estimated values on the calculated curve is reasonably good, but at the higher m.f. values of C_3D_8 the deviation becomes large and amounts to roughly 10%. In the present calculation, a little uncertainty in the yield from the major constituent leads to a large uncertainty in the yield from the counterpart; a 10% uncertainty in the former causes roughly 20—30% uncertainty in the latter, which covers the observed deviation in Fig. 1. Thus, the deviation from the solid lines toward the lower yield results mostly from the uncertainty in the yield from C_3D_8, but partly from the moderator-isotope effect[5] between C_3D_8 and C_3H_8. The moderator-isotope effect introduced by replacing H in C_3H_8 by D must be largest between C_3H_8 and C_3D_8, since these are the two extreme compounds. Thus, as for the present analysis, the moderator-isotope effect is considered to be less than 10%. This allows us to compare the yields of products from various deuterated propanes without correction for any difference in the moderating efficiency of these compounds within this limited accuracy.

Reactivity Integral Isotope Effect. Table 2 summarizes the product yields from various deuterated propanes. The *K* values in the table are the yields from fully protomated propane, relative to that from deuterated propane, and are equal to an overall isotope effect in the formation of the products under given conditions.

These results require essentially no correction for the kinetic energy-independent processes of the ^{80}Br atom.

Table 2. Yields of products formed by reactions of ^{80}Br with variously deuterated propanes

Products	Reactant

Total	3.03	2.84		2.19		2.06	

a) $K = \dfrac{\text{Product yield from } CH_3CH_2CH_3}{\text{Product yield from deuterated propane}}$.

In order to make an intermolecular comparison of the product yield, however, the results must be corrected for both the secondary decomposition of the excited primary products[13-15] and the non-equivalence of the ^{80}Br spectrum in each sample.[1,16]

Such unimolecular decomposition processes can be conveniently investigated by pressure-variation experiments, such as were previously carried out with C_3H_8.[11] In the pressure range between 600 to 1600 Torr, the yields of products remained almost constant, and the intermolecular distribution of the ^{80}Br atom among the products was essentially constant. Thus, without further quantitative knowledge concerning the decomposition products, it can only be assumed that a direct comparison of the yields of the individual products requires no significant correction for the secondary decomposition. This is a reasonable assumption since, if such a decomposition occurs, its extent will be as large or greater in protonated than in deuterated compounds. This is the reverse of the isotope effect observed, and any correction for the decomposition tends to further enlarge the isotope effect.

For the second correction for the ^{80}Br atom flux, we need correct knowledge concerning the energy-loss processes of energetic ^{80}Br atoms. However, experimentally, the ^{80}Br atom flux can be controlled by the addition of a large excess of a common molecule as an energy moderator.[16] Table 3 shows the yields of the iso- and *n*-propyl bromides found in the presence of 0.5 m.f. of C_2H_6. The results show a similar trend as in the absence of C_2H_6, a preference for the substitution of H over D atoms.

These results, together with those in Fig. 1 make it reasonably sure that the K values in Table 1 are a good measure of the isotopic variation in the reactivities of various deuterated propanes toward the energetic ^{80}Br atoms.

^{80}Br-for-R Reaction. One of the things shown in Table 1 is that the isotope effect on methyl, ethyl, and methylene bromides appears on both $C_3H_2D_6$ and C_3D_8, but not on $C_3H_6D_2$. These results are not fully predicted either by the rotational inertia effect of the residual group[6] or by the electronegativity[9,10] of the replaced atom or group. The former can predict only an isotope effect on methyl bromide, and the latter essentially no isotope effect.

The absence of the isotope effect on the methyl bromide yield from $C_3H_6D_2$ indicates practically no effect of the D atom in the methylene group on the ^{80}Br-for-ethyl reaction. Thus, the isotope effect on the ^{80}Br-for-ethyl reaction in both $C_3H_2D_6$ and C_3D_8 must originate from the replacement of H by D in the residual methyl group or from that in the methyl in the ethyl group. However, any effect of the D atom separated by C-C bond on the reactivity is generally much less important than that of the D atom attached to the reacting C atom; the observed isotope effect results from the difference in the chemical and physical relaxation of the residual CH_3 and CD_3 groups.

A similar consideration suggests that any consistent explanation for the isotope effect on the ethyl bromide must involve a quick rearrangement of the replaced methyl group for a stable combination between the ^{80}Br atom and the residual ethyl group. These facts indicate that a complete explanation of the isotope effect must be based on the properties of the residual as well as the replaced atom or group.

In the formation of methylene bromide, there are two possible reaction processes; one is the double replacement[17,18] of the H atom and the ethyl group (Reaction 2), while the other is the replacement of two methyl groups (Reaction 3):

$$CH_3CH_2CH_3 + {}^{80}Br \longrightarrow CH_2{}^{80}Br + H + CH_3CH_3 \quad (2)$$

$$CH_3CH_2CH_3 + {}^{80}Br \longrightarrow CH_2{}^{80}Br + 2CH_3 \quad (3)$$

$$CH_2{}^{80}Br + Br_2 \longrightarrow CH_2{}^{80}BrBr + Br \quad (4)$$

Table 3. Yields of *i*- and *n*-propyl bromides in presence of 0.5 m.f. of C_2H_6

Products	Reactant						
	$CH_3CH_2CH_3$ (%)	$CH_3CD_2CH_3$		$CD_3CH_2CD_3$		$CD_3CD_2CD_3$	
		(%)	(K)	(%)	(K)	(%)	(K)
i-Propyl bromide	0.14±0.01	0.10±0.01	(1.4)	0.13±0.01	(1.1)	0.10±0.01	(1.4)
n-Propyl bromide	0.43±0.04	0.40±0.04	(1.1)	0.31±0.03	(1.4)	0.33±0.03	(1.3)

In the former case, the isotopic preference of the substitution of H over D is the origin of the observed isotope effect, while in the latter the rapidity of the adjustment of the two leaving methyl groups to the formation of $CH_2{}^{80}Br$ is the determining factor. At present, no definite conclusion can be drawn. However, the former process seems much more probable than the other, since, in the latter process, both methyl groups can influence the probability of the combination of the resulting methylene with ^{80}Br and an isotope effect nearly twice as large as the observed one can be expected.

^{80}Br-for-H Reaction. Both iso- and *n*-propyl bromides are formed by the ^{80}Br-for-H reaction. In this type of reaction, three kinds of isotope effects resulting from the replacement of H by D in the molecule can be considered. The first kind is the primary isotope effect, an isotopic preference for the substitution of H over D. The second is a secondary isotope effect of D atom attached to the reacting C atom; it is accounted for by the ease of the adjustment for the subsequent stable combination with the ^{80}Br atom with the C-atom. The third is also termed as a secondary isotope effect, but, in this case, the D atom is separated by the C–C bond from the reacting C-atom.

The absence of the isotope effect in the yields of isopropyl bromide from $C_3H_2D_6$ and of *n*-propyl bromide from $C_3H_6D_2$ indicates that the D atom in the methyl group in propane has no measurable effect on the ^{80}Br-for-H reaction in the methylene group, while the D atom in the methylene group has no measurable effect on the reaction in the methyl group. This indicates the absence of the third kind of isotope effect described above.

The first and second kinds of isotope effects cannot be readily distinguished in the present comparison. In principle, an obvious experiment to separate these two possibilities is the measurement of the isopropyl bromide yield from C_3HD_7. However, according to the concept of the inertia model, the second kind of isotope effect is less important when an atom or group larger than a H atom is attached to the same C atom. Thus, the observed isotope effect in the ^{80}Br-for-H reaction may be ascribed principally to the primary isotope effect of the replaced D atom.

When we compare the present isotopic variation in the substitution of H and D with the value of 1.6 ± 0.2 found with the C_2H_6–C_2D_6 pair,[3] a reasonable agreement can be seen.[4] However, those values are much smaller than the value, 2.7 ± 0.3, found with the CH_4–CD_4 pair.[1,2] The only logical explanation of this is that the secondary isotope effect originating from the D atom combined with the reacting C atom is important in methane, but less important in ethane and propane, since in the latter compounds the relaxation of the residual group is essentially controlled by that of the methyl or ethyl group attached to the reacting C atom. This means that the primary isotope effect in the substitution of H(D) can be assigned for a level of 1.4 ± 0.2, and that the large isotope effect in the CH_4–CD_4 pair results from the effect combining the primary and secondary isotope effects.

Origins of Reactivity Integral Isotope Effect. In Table 1 it is obvious that the total organic yield decreases with the number of D atoms in the reactant. A similar trend can also be noticed in the reaction of recoil T with various reactant molecules.[5] These results indicate that the total reactivity integral decreases with the deuteration of the reactant, within an allowance of less than 10% for the moderator isotope effect and with an almost constant extent of unimolecular decomposition of various deuterated products.

When the energetic atom strikes the atoms of a reactant molecule, much of its kinetic energy is transferred into the internal energy of the struck molecule. The atom is, then, imbedded in the electron distribution of the struck molecule and forms a "complex" of a short but still sufficiently long enough lifetime for reasonably normal isotope effects on decomposition to take effect.[5,19] However, it is noticed that the substitution reaction of ^{80}Br for H leaves the resulting products, $R^{80}Br$, with the excitation energy spread over a wide energy range; the average value is estimated to be ~4 eV for RH=cyclopropane.[20]

It is rather unrealistic for a "complex" with such a high excitational energy to show an isotopic preference in its decomposition to the extent observed. One consistent explanation is that the isotope effect in the reaction of ^{80}Br appears mostly when the kinetic energy of the atom is in the lower-energy end of the reaction-energy zone.[21] In these cases, the excess energy of the resulting "complex" is relatively small, and its subsequent decomposition is very sensitive to the properties of the atoms and groups involved. If the formation rates of a "complex" are assumed to be approximately equal for protonated and deuterated molecules, relatively more C–^{80}Br interaction will be ruptured in the latter and the ^{80}Br will emerge very much degraded in energy. This is equivalent to the fact that the reaction probability in a collision of ^{80}Br with C_3D_8 is smaller than in one with C_3H_8 at the lower-energy end of the reaction zone.

Although it has not been confirmed that the same explanation can be applied to the reaction of energetic tritium atoms, this is quantitatively consistent with a trend found in the latter system.[21] The 2.8 eV T atom resulting from the photolysis of TBr shows a much larger isotope effect than does the recoil T atom.[19]

Determination of the *Gauche* Dihedral Angle and the Energy Difference between Rotational Isomers of Bromoacetyl Chloride

Kazutoshi TANABE and Shinnosuke SAËKI

National Chemical Laboratory for Industry, Honmachi, Shibuya-ku, Tokyo 151

(Received January 14, 1974)

Infrared absorption intensities of fundamental bands of bromoacetyl chloride were measured in carbon disulfide solution, an absolute intensity method being applied to determine the energy difference between the rotational isomers. In order to determine the dihedral angle of the less stable isomer, normal frequencies and band intensities were calculated for various angles, the results being compared with observed data. The dihedral angle of the *gauche* isomer was found to be 100° which is in good agreement with the angle in chloroacetyl chloride. The energy difference, 0.91 kcal/mol, determined in carbon disulfide solution is in good agreement with the value obtained by the temperature variation method.

The dihedral angle of the *gauche* isomer of chloroacetyl chloride $CH_2ClCOCl$ was determined to be 105°, by calculating normal frequencies and infrared band intensities for both isomers and comparing the results with observed data.[1] The dihedral angle herewith denotes the angle between C–Cl of CH_2Cl and C=O of COCl, the angles of the *trans* and *cis* isomers being 0 and 180°, respectively. However, 105° for the dihedral angle of the less stable form was in some disagreement with results obtained by the other authors.

Nakagawa *et al.*[2-4] obtained 150° by calculating normal frequencies for skeletal vibrations, while Khan and Jonathan[5] obtained 180°. On the other hand, Bellamy and Williams[6] concluded that the *gauche* dihedral angle is 120°, by considering a polar effect on carbonyl frequencies, and Le Fèvre *et al.*[7] obtained 120° by dipole moment analysis.

It is known that, in rotational isomers with a C–C bond as an internal rotational axis, double bonds such as C=C or C=O bonds are apt to take a *cis* position with a single bond on the opposite side. It thus seems reasonable that the *gauche* isomer of haloacetyl halide takes a dihedral angle of 120°, although the dihedral angle of the less stable isomer of CH_2FCOF was determined to be 180° by microwave spectroscopy,[8] the isomer taking a *cis* form. In the case of $CH_2ClCOCl$, owing to repulsive interaction between the two chlorine atoms in a molecule, the dihedral angle of the *gauche* isomer might decrease from 120 to 105°.

In order to support the result for the *gauche* dihedral angle obtained previously, bromoacetyl chloride molecule was treated by the same method as before. The energy difference between the rotational isomers was determined by applying the absolute intensity method.[1,9]

Experimental

The infrared absorption spectrum of $CH_2BrCOCl$ was observed in a carbon disulfide solution with a Perkin-Elmer Model 180 grating spectrophotometer combined with a digital recorder. The spectrum is shown in Fig. 1. Observed frequencies were calibrated by referring to standard gas spectra[10] within an accuracy of 1 cm^{-1}.

Absorption band intensities were evaluated, by means of a FACOM Model 270-30 electronic computer system by processing encoded paper tapes punched out from the digital recorder. Concentration of solutions was 0.05—0.3 (mol/l), thickness of sealed liquid cells with KBr windows being 0.1—1.0 mm. Absorption intensities were evaluated by averaging intensities obtained for at least ten measurements in various concentrations for individual bands. For absorption bands below 400 cm^{-1}, sealed liquid cells with polyethylene windows were used, the absorption intensities being roughly estimated with a planimeter. Other experimental condifions for the intensity measurement were the same as described previously.[1,9,11-15]

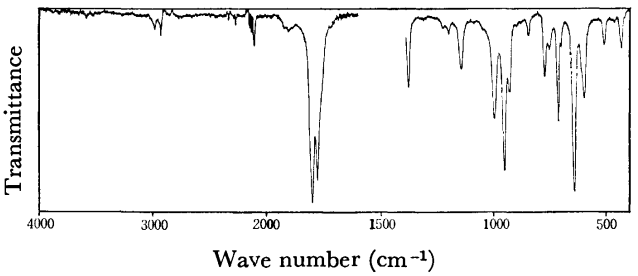

Fig. 1. The infrared absorption spectrum of $CH_2BrCOCl$ observed in carbon disulfide solution.

A Hitachi Model IRH-3 high temperature cell, in combination with a Hitachi Model IRC-2 power regulator, was used for determination of energy difference by the temperature variation method. The temperature of the cell was controlled within 1 °C.

Results and Discussion

In order to determine the dihedral angle of the less stable isomer of $CH_2BrCOCl$, normal frequencies of both isomers were calculated for various angles 60—180°. Force constants based on the local symmetry force field (LSFF) were assumed to take the same values between the rotational isomers. Their values were determined by the least squares method so as to attain the best fit between the calculated and observed frequencies. Since Nakagawa *et al.*[2-4] made assignments for only skeletal vibrations, fundamental frequencies were determined by referring to their assignment and to those of $CH_2ClCOCl$ and $CH_2BrCOBr$.[1]

First the refinement of all the twenty-four force constants was attempted by means of the observed twenty-eight frequency data. Some of the force constants converged showing relatively large standard deviations. Thus three force constants were fixed, and

the other force constants adjusted by the least-squares method. The calculated frequencies and the LSFF force constants with their standard deviations in parentheses are given in Tables 1 and 2, respectively.

The converged values of the force constants show no dependence on the *gauche* dihedral angle, while the calculated normal frequencies show remarkable dependence on the dihedral angle assumed for the less stable isomer. The calculated frequencies for the *trans* ν_{10}, *gauche* ν_{12} bands are in poorer agreement with the observed frequencies, as the dihedral angle of the *gauche* isomer approaches 60°. On the other hand, those for the *trans* ν_8, ν_9, ν_{13}, *gauche* ν_8, ν_{11}, ν_{13}, ν_{14} bands are in poorer agreement as the dihedral angle of the less stable isomer approaches 180° (*cis* form).

In order to examine the agreement more quantitatively, the weighted sum of squared deviations or the residual was computed and plotted against the assumed dihedral angle of the less stable isomer (Fig. 2). The result indicates that the most probable *gauche* dihedral angle is between 90 and 120°. For the angle 150° determined by Nakagawa *et al.*, the residual is much larger than those for angles 90—120°, and their result is not consistent with ours.

For the sake of confirmation, infrared band intensities were computed for various angles assumed for the *gauche* isomer. For intensity parameters, electro-optical parameters based on Gribov's valence-optical theory[16,17] were taken, and their values determined by the least squares method. In order to determine the

population ratio of the rotational isomers, the absolute intensity method was applied. Converged values and standard deviations of intensity parameters and of the *trans* population ratio parameter are given in Table 3. Calculated band intensities are given in Table 4 together with observed intensities for comparison.

As in the normal frequency calculation, the converged values of the intensity parameters show no dependence on the *gauche* dihedral angle, while the calculated intensities depend remarkably on the *gauche* dihedral angle. The calculated intensities for the 1156, 348 cm^{-1} bands are in poorer agreement with the observed values as the dihedral angle approaches 60°, while those for the 658, 612 cm^{-1} bands are in poorer agreement as the dihedral angle approaches 180°. The plot of residuals against the assumed *gauche* dihedral angles is

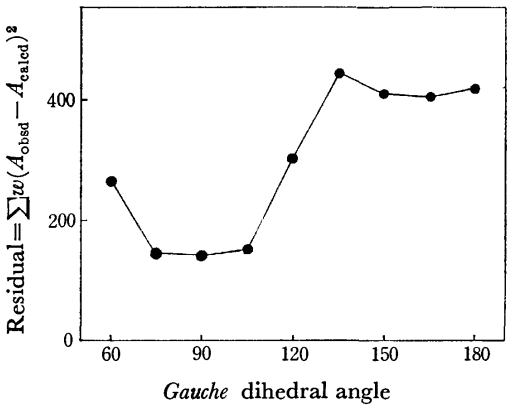

Fig. 3. The plot of residuals against various assumed *gauche* dihedral angles.

given in Fig. 3. This also indicates that the most probable dihedral angle of the less stable isomer is between 75 and 105°.

Taking into account the results from normal frequency calculation and intensity computation at the same time it can be concluded that the dihedral angle of the *gauche* isomer of $CH_2BrCOCl$ is $100\pm10°$. This is in line with the angle 105° obtained for $CH_2ClCOCl$.[1]

Nakagawa *et al.*[2] calculated normal frequencies for skeletal vibrations using UBFF force constants derived from related molecules, and concluded that the *gauche* form is considered to have a dihedral angle of 150°. However, the calculated normal frequencies for vibrational modes other than skeletal vibrations are also affected considerably by the assumed *gauche* dihedral angle (Table 1).

The *gauche* isomer of the haloacetyl halide molecule seems to take a dihedral angle of about 120°. However, if we take into account the repulsive force between the halogen atoms in molecule, the dihedral angle might become smaller than 120°. The angle 150° obtained by Nakagawa *et al.* indicates that the two carbon-halogen bonds approach each other from eclipsed configuration between the C–H and C=O bonds. Such an approach does not seem acceptable; the angle 150° is unconvincing.

The angle we obtained is in good accordance with the concept stated above, and might be more reasonable as the *gauche* dihedral angle of $CH_2BrCOCl$.

The energy difference between the *trans* and *gauche* isomers has been evaluated by the same method as before[1] from the converged value of the *trans* population ratio parameter X (Table 3). The entropy term is estimated from principal moments of inertia and fundamental frequencies for both isomers by the equation

$$\exp\left(\frac{\Delta S}{R}\right) = 2\frac{(I_aI_bI_c)_G^{1/2}\prod(1-e^{-h\nu_G/kT})^{-1}}{(I_aI_bI_c)_T^{1/2}\prod(1-e^{-h\nu_T/kT})^{-1}}$$

From the values of this entropy term and of the *trans* population ratio parameter, the energy difference ΔE is evaluated by

$$\frac{1-X}{X} = \exp\left(-\frac{\Delta E}{RT}\right)\cdot\exp\left(\frac{\Delta S}{R}\right)$$

The value 0.91 ± 0.10 (kcal/mol) is thus obtained (Table 5).

In order to confirm the validity of this value, the energy difference was also determined by the temperature variation method. Absorption intensities for the *trans* ν_8 (at 443 cm^{-1}) and *gauche* ν_{11} (at 520 cm^{-1}) bands were measured in a carbon disulfide solution with a high temperature cell in the temperature range 25—100 °C. Although the boiling point of carbon disulfide is 46 °C and its vapor pressure reaches about 5 atm at 100 °C, the experiment could be carried out at 100 °C owing to the air-tightness of the cell.

Table 5. Energy differences of haloacetyl halide molecules (kcal/mol)

Molecule	Vapor	CS_2 solution
$CH_2ClCOCl$	0.97[5]	1.39[1]
$CH_2BrCOCl$	1.0[2]	0.91[a]
$CH_2BrCOBr$	1.9[2]	0.97[1]

a) This study.

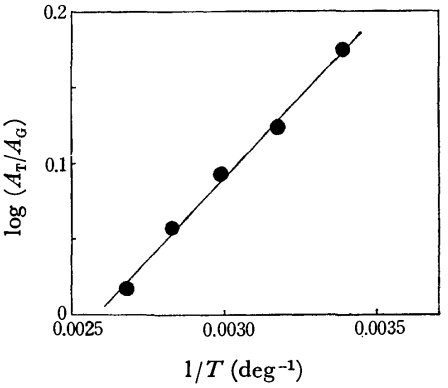

Fig. 4. The van't Hoff plot for determining the energy difference.

The van't Hoff plot for determining the energy difference is given in Fig. 4. From the slope of the least squares fitted straight line, the energy difference of $CH_2BrCOCl$ in carbon disulfide solution was obtained as 0.99 ± 0.10 (kcal/mol). This is in good agreement with the value determined by the absolute intensity method and with the value 1.0 (kcal/mol) obtained by Nakagawa *et al.*

It is of interest to note that in $CH_2ClCOCl$, the energy difference in the vapor phase is smaller than in carbon disulfide solution; in $CH_2BrCOBr$, the former is about twice larger than the latter, and that the situation in $CH_2BrCOCl$ is intermediate between in $CH_2ClCOCl$ and $CH_2BrCOBr$ (Table 5).

The Crystal and Molecular Strucure of Arabinofuranosyladenine Hydrochloride[1]

Tadashi HATA, Sadao SATO, Masakatsu KANEKO, Bunji SHIMIZU, and Chihiro TAMURA

The Central Research Laboratories of Sankyo Co., Ltd., Hiromachi, Shinagawa-ku, Tokyo 140

(Received May 11, 1974)

Crystals of arabinofuranosyladenine hydrochloride are monoclinic, space group $P2_1$, with $a=6.47$, $b=15.56$, $c=6.87$ Å, and $\beta=111.6°$. Intensity data were collected on a four-circle diffractometer with Mo-Kα radiation. The structure was solved by means of Patterson and Fourier methods and refined using block-diagonal least-squares technique. The final *R*-factor for 1681 observed reflections is 4.5%. The sugar conformation is C3′-*endo* and the C(5′)-O(5′) bond is *gauche* to both C(4′)-O(1′) and C(4′)-C(3′). The torsional angle about the glycosidic C–N bond is *anti*, with $\chi_{CN}=29.2°$. The hydrogen-bond scheme is similar to those found in several salts of nucleosides and deoxynucleosides.

9-β-D-Arabinofuranosyladenine (ara-A), first synthesized by Lee *et al.* in 1960,[2] is active against a broad spectrum of DNA virus[3] and inhibits the DNA polymerase.[4] Consequently the conformation of this molecule has been of great interest in comparison with other structurally related nucleosides. In this paper, we describe the molecular and crystal structure of ara-A monohydrochloride (ara-A HCl) with particular attention focussed on conformational aspects and intermolecular interactions of the ara-A cation in the crystalline state.

Experimental

Crystals of ara-A HCl[5] were prepared in our laboratories, and recrystallized from water, in a suitable form for X-ray structure analysis. Crystal dimensions of this salt are; $a=6.47\pm0.02$, $b=15.56\pm0.03$, $c=6.87\pm0.02$ Å, and $\beta=111.6\pm0.3°$ and the space group belongs to $P2_1$. The density was measured by the floatation method in a mixed solution of tetrachloromethane and cyclohexane and found to be 1.544 g/cm³, while the calculated value is 1.558 g/cm³ (if $Z=2$).

A total of 1681 independent reflections were collected on a Rigaku automatic four-circle diffractometer using Zr-filtered Mo-Kα radiation and measured up to $2\theta=60°$ in the θ-2θ scan mode. All data were corrected for the Lorenz and polarization factors but not for absorption.

Determination and Refinement of the Structure

The parameters of the chlorine anion could be obtained from a three-dimensional sharpened Patterson map. After several applications of successive Fourier syntheses a trial structure of the arabinoside emerged except for the hydrogen atoms. The initial refinement for the positional and thermal parameters was carried out by a block-diagonal least-squares technique. Four cycles of this computation dropped the *R*-factor to 8.1%. Then the difference Fourier synthesis was calculated to obtain the hydrogen atoms. These atoms were revealed at reasonable positions. Four more cycles of the least-squares refinement using anisotoropic temperature for the heavy atoms and isotropic factors

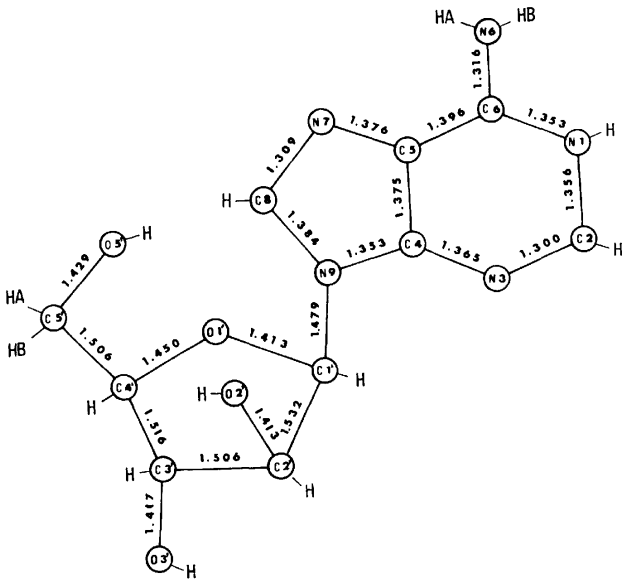

Fig. 2. Bond distances in the arabinofuranosyladenine cation.

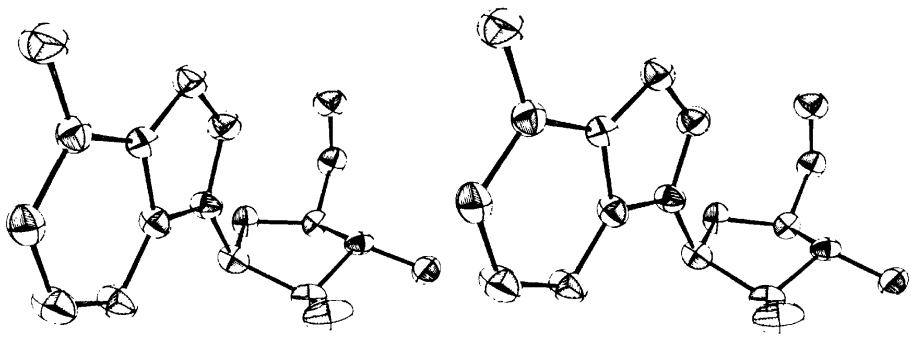

Fig. 1. A stereographic illustration of the arabinofuranosyladenine cation.

for the hydrogen atoms were made. The final R-factor was 4.5% for all observed reflections. Tables 1, 2, and 3 list the positional and thermal parameters, while the observed and calculated structure factors are given in Table 4.[6] A stereographic illustration of the ara-A cation computed by the ORTEP program[7] using these parameters is exhibited in Fig. 1. Bond distances and angles are shown in Figs. 2 and 3 and Table 5.

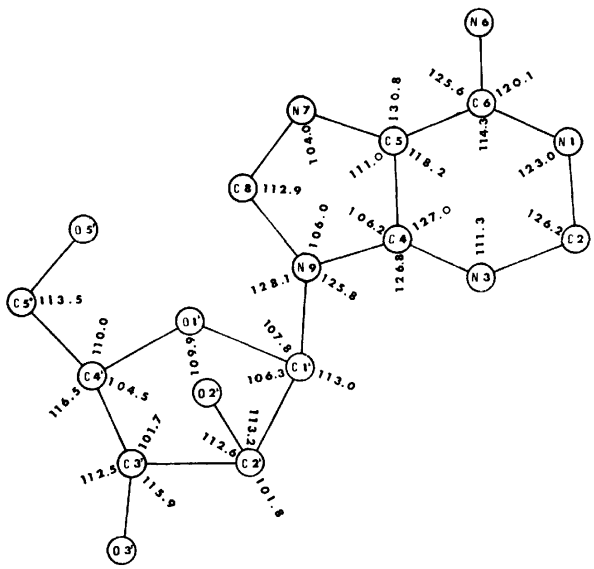

Fig. 3. Bond angles in the arabinofuranosyladenine cation.

Description and Discussion of the Structure

The conformational aspects of the ara-A cation are similar to those usually found in nucleosides and nucleotides. The puckering of this sugar residue is C3'-*endo* in which the atom C(3') is displaced by 0.60 Å from the least-squares plane as constructed in relation to the remaining four atoms in the furanose ring and on the same side as C(5').[8] The torsional angles about the exocyclic C(4')–C(5') bond denoted as ϕ_{OO} and ϕ_{OC} by Shefter and Trueblood[9] are 62.4 and 56.3° respectively, rendering the *gauche-gauche* conformation. The other torsional angle about the glycosidic bond, C(1')–N(9), is *anti* and that of C(8)–N(9)–C(1')–O(1'), χ_{CN},[10] is 29.2°.

The only difference in the molecular features between the ara-A cation and the adenosine cation is the configuration at the carbon atom C(2'); with respect to the furanose ring, the relationship between the OH group and the H atom at C(2') is reversed. The arrangements of atoms around the C(2')–C(1') and C(3')–C(2') bonds are represented in Figs. 4(a) and (b), respectively. The O(2')H group is in the *cis* position N(9) relative to the C(2')–C(1') bond, while oriented *gauche* to O(3') in relation to the C(3')–C(2') bond. Therefore, the torsional angle of O(2')–C(2')–C(1')–N(9), 31.7°, in the ara-A cation becomes smaller than those of 153.7° in adenosine[11] (C3'-*endo*) and 81.5° in the adenosine cation[12] (C2'-*endo*). And there are some short intramolecular non-bonded distances. They are shown in Fig. 5. With respect to the arrangement of atoms around the C(3')–C(2') bond, the O(3')–C(3')–C(2')–O(2') torsional angle of 77.6° in the ara-A cation is larger than those of 45.3° in adenosine and 47.2° in the adenosine cation. In Table 6, these angles are listed.

TABLE 6. TORSIONAL ANGLES IN THE ARA-A CATION AND RELATED COMPOUNDS

Puckering of sugar	ara-A cation[a] C3'-*endo*	Adenosine[b] C3'-*endo*	adenosine cation[c] C2'-*endo*
N(9)-C(1')-C(2')-O(2')	31.7°	153.7°	81.5°
N(9)-C(1')-C(2')-C(3')	89.5	92.4	153.7
O(1')-C(1')-C(2')-O(2')	149.7	86.6	161.6
O(1')-C(1')-C(2')-C(3')	28.5	27.3	36.8
O(2')-C(2')-C(3')-O(3')	77.6	45.3	47.2
O(2')-C(2')-C(3')-C(4')	160.1	79.3	162.6
C(1')-C(2')-C(3')-O(3')	160.9	160.4	77.0
C(1')-C(2')-C(3')-C(4')	38.6	35.8	38.4

a) This study b) Ref. 11 c) Ref. 12

The positioning of the O(2') atom seems to affect the bond lengths of C(2')–C(3') and N(9)–C(1') in arabinosyl nucleoside. The C(2')–C(3') bond length of 1.506 Å is shorter than those in adenosine, 1.528 Å, and in the adenosine cation, 1.529 Å, but close to arabinofuranosyl-4-thiouracil[13] (ara-S[4]-U, C3'-*endo*), 1.508 Å. The bond length of N(9)–C(1') in the ara-A cation, 1.479 Å, is slightly longer than those in adenosine, 1.466 Å, and the adenosine cation, 1.460 Å. This tendency is seen in other arabinoside derivatives which are 1.481 Å (ara-S[4]-U), 1.48 Å (ara-T,[14] Cl' *exo*-Ol' *endo*), 1.471 Å (ara-U,[15] C2' *endo*-Cl' *exo*), and 1.475 Å (ara-C HCl,[16] C2'-*endo*).

As in adenosine hydrochloride, the ring of the base residue is protonated at the N(1) atom. No particular differences can be observed in the overall base residue from those found in other salts[17] regardless of the configuration of the arabinofuranosyl residue.

Figure 6 displays the crystal structure of ara-A HCl projected along the a-axis where the hydrogen-bonds

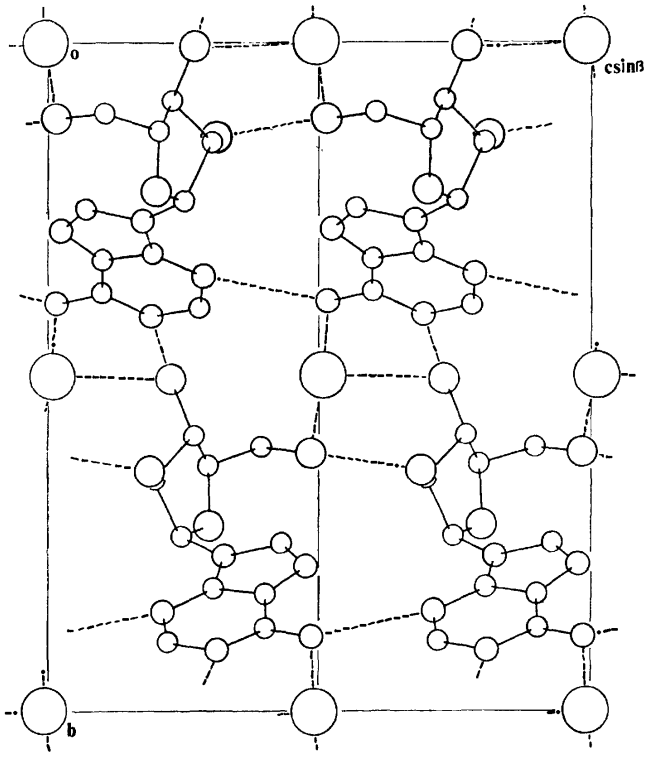

Fig. 6. A projection of the structure viewed down the a-axis. Hydrogen bonds are shown as broken lines.

are indicated by broken lines. Between the cation molecules, there is one hydrogen-bond related by the twofold screw axis and two hydrogen-bonds related by the translational operation. The N(1) atom hydrogen-bonds to O(3′) of the cation at $(1-x, 1/2+y, 1-z)$ in which the N(1) atom acts as a proton-donor, with a N(1)—O(3′) distance of 2.713 Å. The N(6) atom donates one of two hydrogen atoms to N(3) of another cation at $(x, y, -1+z)$ and O(2′) donates its proton to O(5′) at $(1+x, y, 1+z)$ forming usual hydrogen bond distances of 2.966 and 2.728 Å respectively. The chloride anion accepts three hydrogen atoms from O(3′), O(5′), and N(6) with distances of 2.983, 3.124, and 3.284 Å, respectively. Details of the hydrogen-bond distances and angles are given in Table 7.

In order to make a comparison of the hydrogen-bond scheme of ara-A HCl with those of the other HCl salts

Table 7. Hydrogen-bond distances and angles, D–H···A

D–H	A	Distance D–A	Distance H···A	Angle D–H···A
N(1)-H	O(3′)(a)	2.713Å	1.89Å	145°
N(6)-HA	N(3)(b)	2.966	2.05	147
N(6)-HB	Cl^-(c)	3.284	2.43	165
O(2′)-H	O(5′)(d)	2.728	1.88	137
O(3′)-H	Cl^-(e)	2.983	2.16	174
O(5′)-H	Cl^-(f)	3.124	2.42	162

a) at $1-x, 1/2+y, 1-z$. b) at $x, y, -1+z$. c) at $1-x, 1/2+y, -z$. d) at $1+x, y, 1+z$. e) at $x, y, 1+z$. f) at x, y, z.

of nucleoside derivatives, the projections of the crystal structures viewed along the b-axis of ara-A HCl, deoxycytidine hydrochloride (DC HCl),[18] adenosine hydrochloride (A HCl),[12] and arabinofuranosylcytosine hydrochloride (ara-C HCl)[16] are exhibited in Figs. 7(a), (b), (c), and (d). The space group of each crystal is $P2_1$. In these illustrations, the hydrogen-bonds formed between the cations related by a twofold screw axis are drawn by the bold broken lines, and the others are by the normal broken ones. The short intermolecular contacts in the DC HCl assumed to be weak hydrogen-bonds are represented by dotted lines. The noteworthy point in these figures is that some parts in the hydrogen-bond schemes closely resemble each other. In the molecular packings of these crystals, the hydrogen-bonds oriented in a similar manner are listed in the same row of Table 8. Each O(3′)H hydroxy group in all salts donates the hydrogen atom to the chlorine anion in a similar fashion and O(2′)—O(5′) hydrogen-bonds are formed in similar directions except the DC cation, which has no O(2′)H group. On the other hand, in the first three cations in Table 8, the hydrogen-bonds are formed between the cations related by a screw axis. They are N(1)H—O(3′) in the ara-A cation, N(4)H—O(3′) in the DC cation, and N(6)H—O(2′) in the A cation. One of the cations in ara-C HCl does not make hydrogen-bond to the other neighbouring cation related by a screw axis, and no hydrogen-bond forms between O(5′) and Cl^-. The combination of hydrogen-bonds in these molecules distinguishes the molecular arrangement of ara-C HCl from the remain-

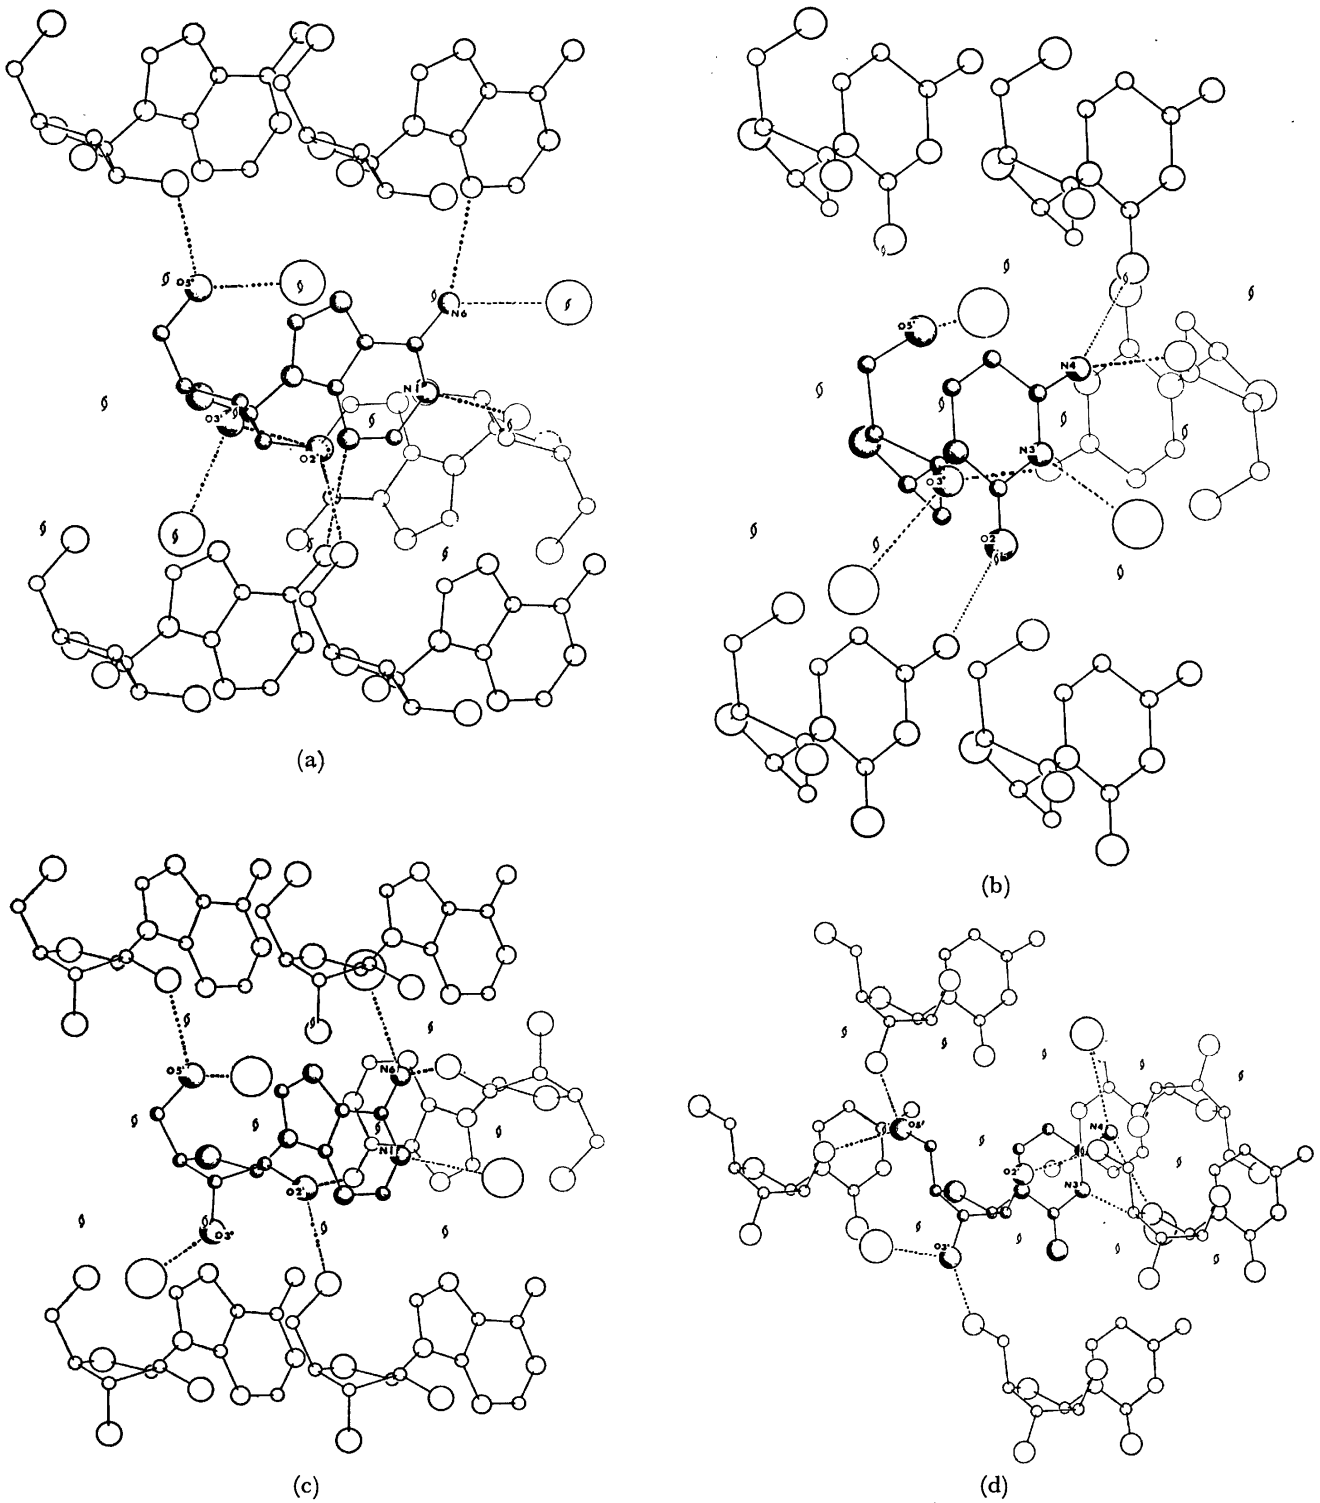

Fig. 7. The crystal structures projected down the b-axis of (a) arabinofuranosyladenine hydrochloride, (b) deoxycytidine hydrochloride, (c) adenosine hydrochloride, and (d) arabinofuranosylcytosine hydrochloride, being drawn from the published parameters. The bold broken lines indicate the hydrogen-bonds related by the acrew axis and the normal broken ones indicate other hydrogen-bonds. The dotted lines indicate weak hydrogen-bonds. Note that the hydrogen-bond schemes in the former three crystals resemble each other.

ing three compounds. The hydrogen-bond net-works of these salts resemble each other in taking an overall view of the crystal structures as shown in Figs. 7(a), (b), and (c). This can be interpreted as indicating that the hydrogen-bond schemes of these nucleoside salts are broadly divided into two categories, one is in ara-C HCl and the other is in the rest of three compounds, thus far.

The Surface Activity of Tetra-*n*-alkylammonium Halides in Aqueous Solutions. The Effect of Hydrophobic Hydration

Kunio TAMAKI

Department of Chemistry, Yokohama City University, Kanazawa-ku, Yokohama 236

(Received May 15, 1974)

Surface tensions are reported for aqueous solutions of a series of homologous tetra-*n*-alkylammonium chlorides, bromides, and iodides (R_4NX) at 25 °C, and the experimental results are discussed with particular reference to the bulk properties of these salts in water. It is found that Me_4NX salts are surface inactive in aqueous solutions and that they may be classified as simple salts. On the other hand, it is found that Et_4NX and higher homologous salts are surface active in aqueous solutions and that the surface activity increases with the number of carbon atoms in the alkyl chains; thus, they are hydrophobic structure-makers in the water phase. The surface tensions for aqueous solutions of Me_4NX salts are only slightly dependent on the kind of counter-ion, such as Cl^-, Br^-, and I^-. In the cases of Et_4NX, Pr_4NX, and Bu_4NX salts, the effectiveness of the anions for the same cation on the surface activity increases progressively in this order: $I^->Br^->Cl^-$.

The physical properties of aqueous solutions of tetra-*n*-alkylammonium salts have been studied by many investigators in terms of the structural changes in liquid water caused by the salts.[1-3] In a previous paper,[4] the surface active properties of tetra-*n*-butylammonium halides in aqueous solutions were discussed with emphasis on the solution behavior of these salts in water. This paper will be concerned with the surface activity of a homologous series of tetra-*n*-alkylammonium chlorides, bromides, and iodides (R_4NX) in aqueous solutions.

Experimental

Pr_4NCl was from Wako Pure Chemical Industries, Ltd., and Pen_4NBr was from Eastman Kodak Co. The other organic chemicals were from Tokyo Kasei Kogyo Co. All the salts were recrystallized from suitable solvents: methanol for Me_4NBr, distilled water for Me_4NI, ethanol for Et_4NI, ethyl acetate for Bu_4NBr and Pen_4NBr, ethanol–diethyl ether mixtures for Pr_4NCl and Bu_4NCl, and ethanol–ethyl acetate mixtures for the other salts. Water was triply distilled.

The surface tensions were measured at 25 ± 0.1 °C by means of the drop-volume method described in a previous paper.[4] Some of the data were checked by the Wilhelmy plate method using a surface tension apparatus, Model ST-1, of Shimadzu Seisakusho Ltd. No surface-ageing phenomenon was observed in this work. With R_4NI salts and Pen_4NBr, measurements were carried out to the solubility limit.

In this work, the solutions were made by weight, and the molar concentration, C, was deduced from the molal concentration, m, and the measured densities. The change in surface tension denoted by $\Delta\sigma$ is defined as; $\sigma_0-\sigma$, where σ_0 and σ are the surface tension of pure water and solution respectively.

Results and Discussion

The Surface Tensions versus *Concentration Curves for R_4NBr.* Figure 1 shows the surface tensions of aqueous solutions of R_4NBr salts as a function of the molal concentration. It may be seen that Me_4NBr slightly raises the surface tension of pure water, whereas Et_4NBr and higher homologous salts reduce the surface tension of pure water, and that the surface activity increases progressively with the number of carbon atoms in the alkyl groups. These facts are reasonably compatible with the results[5] on the surface tensions at 0 °C for the aqueous solutions of Me_4NCl, Et_4NCl, and Pr_4NCl.

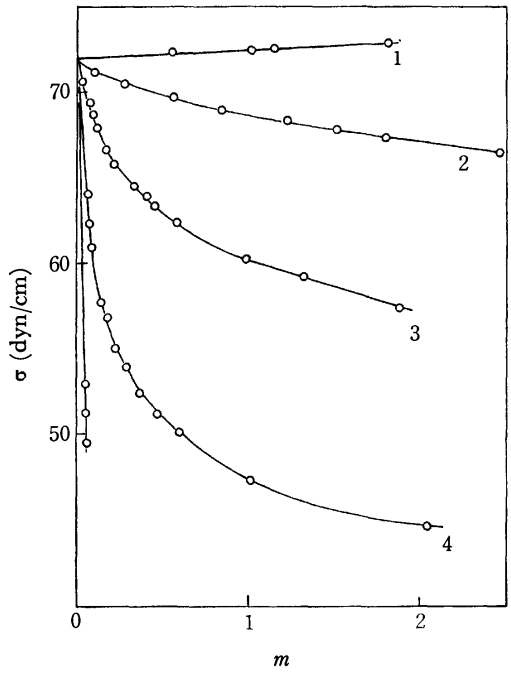

Fig. 1. Surface tension (σ) as a function of molality (m); 1, Me_4NBr; 2, Et_4NBr; 3, Pr_4NBr; 4, Bu_4NBr; 5, Pen_4NBr.

The interaction of simple salts with water may be interpreted in terms of electrostrictive hydration, whereas the interaction of nonpolar organic solutes with water may be interpreted in terms of hydrophobic hydration.[6] The behavior of amphiphilic organic ions in water may be generally discussed in terms of the balance of hydrophobic hydration due to nonpolar groups and electrostrictive hydration due to ionic groups.[7] The phenomenon that the dissolved substance raises the surface tension of pure water has been observed with a variety of simple salts, whether the constituent ions are electrostrictive structure-makers or -breakers.[5] On the other hand, the nonpolar organic solutes, which act as hydrophobic structure-

makers in water, show the effect of reducing the surface tension of pure water.[8] In view of this relation, the shape of the surface tension-*versus*-concentration curve for an amphiphilic organic salt in aqueous solutions is considered to give a rough criterion of the behavior of the salt in water.[8] In view of the above results, Me_4NBr may be considered to act as a simple salt. With Me_4N^+ ion, the interaction of the ionic part with water will surpass the hydrophobic hydration due to methyl groups. In the cases of Et_4NBr, Pr_4NBr, Bu_4NBr, and Pen_4NBr, conversely, the interaction of alkyl groups with water surpasses the electrostrictive hydration due to the central ionic part; consequently, the transfer of these salts from the bulk phase to the surface phase is a spontaneous process. Thus, they are surface active in aqueous solutions.[4] On the basis of this concept, Et_4NBr, Pr_4NBr, Bu_4NBr, and Pen_4NBr are considered to be classifiable as hydrophobic structure-makers in water. In general, these results of classification by the surface tension method are in fairly good agreement with those by other method.[1-3]

In order to compare the strength of the surface activity for these homologous compounds from Et_4NBr to Pen_4NBr inclusive, the Traube factors are obtained using the $\Delta\sigma$ values *versus* the molar concentration curves (not shown). The Traube factor means, in this case, the ratio of the molar concentration of equal $\Delta\sigma$ values when four alkyl chains of a compound are lengthened by every methylene group—*i.e.*, from Et_4NBr to Pr_4NBr, from Pr_4NBr to Bu_4NBr, and from Bu_4NBr to Pen_4NBr. The results are summarized in Table 1. In the case of a homologous series of strong electrolytes with one alkyl chain, such as sodium alkyl sulfates, the surface activity increases by a ratio of about 2 when the chain of an aliphatic compound is lengthened by one methylene group.[9] If we use this relation, the effect of four alkyl groups on the surface activity may be expected to increase by a factor of about 16 ($=2^4$) with an increase of four methylene groups. Therefore, in the case of the surface activity of spherical amphiphilic salts like R_4NBr salts in water, the effect of nonpolar alkyl groups on the surface activity was diminished by about half as compared with that of straight-chain salts.

Effect of Counter-ions. Figure 2 shows the $\Delta\sigma$ values *versus* the molal concentration curves for Me_4NCl, Me_4NBr, and Me_4NI. Figure 3 also shows the $\Delta\sigma$ values *versus* the logarithms of the molal concentration for Et_4NX and higher homologues. It is found that the surface tensions for R_4NX salts are mainly determined by the chain length; however, there are some specific effects due to the variation in counter-ions.

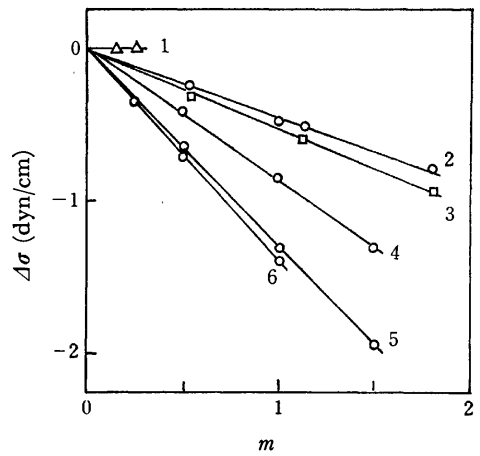

Fig. 2. Change in surface tension ($\Delta\sigma$) as a function of molality (m); 1, Me_4NI; 2, Me_4NBr; 3, Me_4NCl; 4, KI; 5, KBr; 6, KCl.

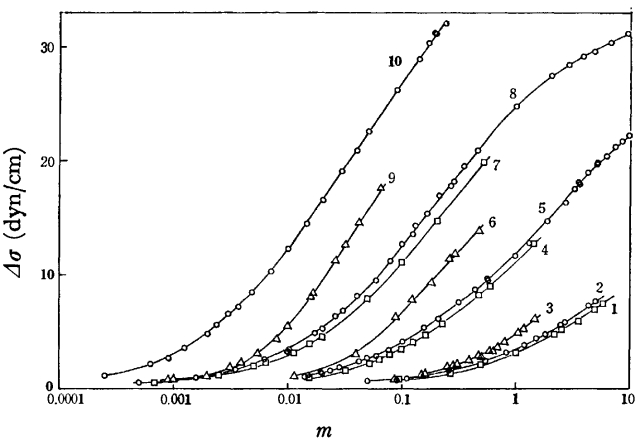

Fig. 3. Change in surface tension ($\Delta\sigma$) as a function of log m; 1, Et_4NCl; 2, Et_4NBr; 3, Et_4NI; 4, Pr_4NCl; 5, Pr_4NBr; 6, Pr_4NI; 7, Bu_4NCl; 8, Bu_4NBr; 9, Bu_4NI; 10, Pen_4NBr.

With Me_4NX salts, the order of raising the surface tension of water is in this order: $Cl^->Br^->I^-$. In the case of alkali halides, the same relation has been reported in the literature[5] as well. For comparison, the results[5] for KCl, KBr, and KI are also plotted in Fig. 2. The overall $\Delta\sigma$ values are slightly larger in the case of Me_4NX salts than in the case of alkali halides; this can probably be interpreted in terms of the effect

of the slightly hydrophobic nature of the methyl groups. The effects of halide ions on the $\Delta\sigma$ values in the case of Me_4NX salts and in the case of alkali halides are comparable with each other. This fact also supports the above conclusion that Me_4NX salts, where $X=Cl^-$, Br^-, and I^-, can be classified as simple salts. As is evident in Fig. 3, the effect of counter-ions on the surface activity for Et_4NX, Pr_4NX, and Bu_4NX salts is quite remarkable; the order of increasing surface activity is $I^->Br^->Cl^-$.

As has been proposed in a previous paper,[8] in the range of low $\Delta\sigma$ values, the $\Delta\sigma$ values are empirically expressed as:

$$\Delta\sigma = AC^{1/2} + BC \quad (1)$$

where A and B are constants. Equation (1) is found to be applicable up to about 7 dyn/cm in the cases of Et_4NX salts and higher homologues. Equation (1) may be converted to:

$$\Delta\sigma/C^{1/2} = A + BC^{1/2} \quad (2)$$

Some examples of the plots of data according to Eq. (2) are shown in Fig. 4. The values of the constants, A and B, are obtained as the intercepts and the slopes respectively of such linear plots; the results are summarized in Table 2. Both A and B values are found to be dependent on the chain length as well as on the kind of counter-ion.

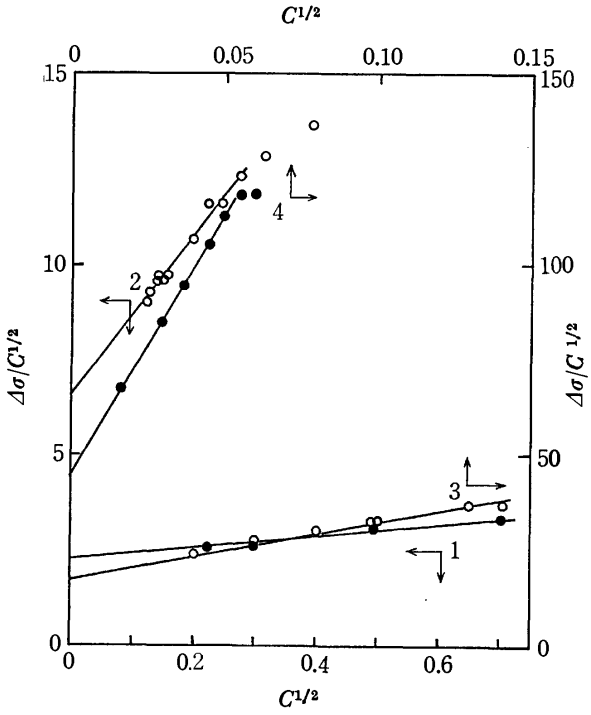

Fig. 4. Plots according to Eq. (2) up to about 7 dyn/cm; 1, Et_4NBr; 2, Pr_4NBr; 3, Bu_4NBr; 4, Pen_4NBr.

TABLE 2. THE CONSTANTS A AND B IN Eq. (2)

	A			B		
	Cl^-	Br^-	I^-	Cl^-	Br^-	I^-
Me_4N^+	0	0	0	−0.5	−0.45	≒0
Et_4N^+	2.4	2.3	1.65	1.1	1.5	3.7
Pr_4N^+	6.6	6.4	4.0	13	19	57
Bu_4N^+	19.5	17	9.0	95	160	440
Pen_4N^+	—	44	—	—	1350	—

The B coefficients are considered to be measures of the surface activity of the salts in water.[8] The value of $-RT \ln B$ is the approximate value of the standard free energy of the transfer of an organic electrolyte from the bulk phase to the surface phase, where R is the gas constant, and T, the absolute temperature. In this case, the standard state for the bulk solution is taken as the state where $C=1$, and the standard state for the surface phase is taken as the state of $\Delta\sigma=1$ dyn/cm. The B value depends on both the chain length and the kind of counter-ion; *i.e.*, it increases with the chain length and with the strength of the electrostrictive structure-breaking action of a counter-ion for a given cation.

From the perfect analogy of Eq. (1) with the equations for other properties such as viscosity, conductivity, and activity coefficient of the aqueous solutions of strong electrolytes, it seems that the A coefficient is related to some type of ion-ion interaction. The A coefficient increases with the chain length, while it decreases with the increase in the size of the counter-ions; *i.e.*, it decreases in the order of $I^-<Br^-<Cl^-$ for each combination of R_4NX salts, as is evident in Table 2. This relation was also found in a previous work[8] for *n*-alkylammonium halides. The less the A values, the more ideal the $\Delta\sigma$ values-*versus*-concentration plots become. From these findings, it may be assumed that the A coefficient is related to the ion-ion interaction of organic salts at the adsorbed layer; *i.e.*, the A coefficient is probably a function which increases with the strength of the adsorbability of organic cations and which decreases in the strength of the interaction of the adsorbed organic ions with their counter-ions at the surface phase.

The Values of Adsorption at the Surface. Lindenbaum and Boyd[10] published the ionic mean activity coefficients for Me_4NX, Et_4NX, Pr_4NX, and Bu_4NX salts in water at 25 °C. From the combination of their results[10] with those shown in Fig. 3, the $\Delta\sigma$ values can be plotted as a function of the activity, as shown in Fig. 5. As the data of the activity coefficient for Bu_4NBr at 25 °C are unavailable, the data for Bu_4NBr

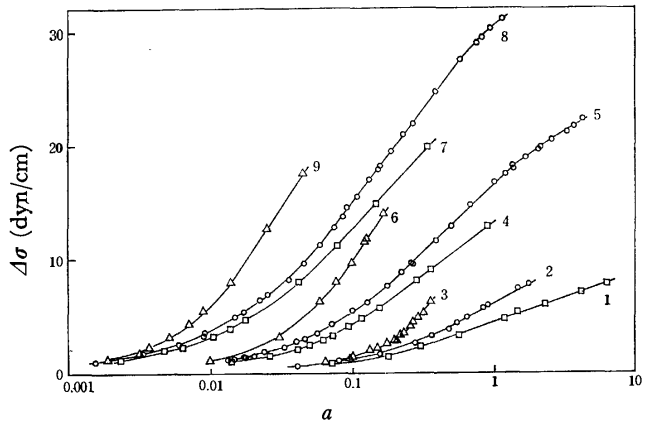

Fig. 5. Change in surface tension ($\Delta\sigma$) as a function of log a; 1, Et_4NCl; 2, Et_4NBr; 3, Et_4NI; 4, Pr_4NCl; 5, Pr_4NBr; 6, Pr_4NI; 7, Bu_4NCl; 8, Bu_4NBr; 9, Bu_4NI.

at 0 °C published by Nomura *et al.*,[11] are used. Because the activity coefficients for Pr_4NBr are independent of the temperature in the range from 0 to 25 °C,[10,11] this procedure is approximately valid. The Gibbs adsorption equation in the form of:

$$\Gamma = (1/2RT)(d\Delta\sigma/d \ln a) \quad (3)$$

will be applied to the data shown in Fig. 5, where Γ is the surface concentration of the solute, and a, the activity. As is shown in Fig. 5, there is fairly wide range of the linear portion on the plots between the $\Delta\sigma$ values and activities for each salt. Using the value of this slope of the linear portion in Fig. 5, the maximum surface concentration for each salt has been calculated; the results are listed in Table 3.

Table 3. The surface concentration at the maximum adsorption (in 10^{-10} mol/cm^2)

	Cl^-	Br^-	I^-
Et_4N^+	0.377	0.622	1.19
Pr_4N^+	0.838	1.05	1.61
Bu_4N^+	1.28	1.43	1.73

The large values of the surface concentration for R_4NI salts are particularly striking, as is evident in Table 3, which may be interpreted in terms of the specific interaction of R_4N^+ ion with I^- ion. The activity coefficients for R_4NI salts in water are very low compared for those of R_4NCl and R_4NBr salts; those for Et_4NI, Pr_4NI, and Bu_4NI salts are especially lower-lying than the Debye-Hückel limiting law.[10,11] These facts imply that R_4NI salts are very stable in water. Many investigators have proposed a specific interaction between R_4N^+ ions and I^- ions in terms of "water structure-enforced ion-pairing,"[12] micelle formation,[10] and structural salting-in.[13] At the surface, the adsorbed R_4N^+ ions will interact to a great extent with I^- ions as counter-ions; therefore, the electrical repulsive potential of the ionized surface will be greatly reduced.[4]

The behavior of R_4NX salts at the surface can probably be deduced if we apply the several surface chemical principles to the results of this work. However, such an attempt is beyond the scope of this paper.

The Behavior of R_4NX Salts in Concentrated Solutions. Some investigators have proposed a micelle formation for R_4NX salts in aqueous solutions. As a critical micelle concentration for Bu_4NBr, Lindenbaum and Boyd[10] reported 0.039 *m* and Rehfeld[14] reported 0.015 *m*. Wirth[15] were of the opinion that the micelle formation occurred above 4.0 *m* in Et_4NBr and above 1.4 *m* in Pr_4NBr solutions. As is evident from the curves for Pr_4NBr and Bu_4NBr in Fig. 3, the $\Delta\sigma$ value increases very rapidly as the concentration is increased, but at higher concentrations this increase is less marked; this situation is somewhat similar to what is seen when the electrolyte forms micelles. It was further observed in this study that the solution of R_4NX salts became highly viscous at higher concentrations, suggesting that the solute-solute interaction plays an important role in such concentrated solutions. However, the behavior of R_4NX salts in concentrated solutions, and especially the possibility of the micelle formation, remain as problems for the future.

Quenching of Excited Mercury Atoms(6^3P_1 and 6^3P_0) in Molecular Collisions

Hiroyuki HORIGUCHI and Soji TSUCHIYA

Department of Pure and Applied Sciences, College of General Education, University of Tokyo, Meguro-ku, Tokyo 153

(Received May 22, 1974)

The lifetime of $Hg(6^3P_0)$ in a gaseous mixture of Ar and N_2 with quenching molecules(Q) was measured by monitoring the decay of the $Hg(6^3P_0)$ concentration following the excitation of Hg by pulsed 253.7 nm radiation. The lifetime in the absence of Q was reduced with the increase in the N_2 pressure, being inversely proportional to the total pressure. This can be attributed to the deactivation by impurities involved in the gas and that by collision on the wall of the reaction cell. Deactivation due to impurities is dominant at a total pressure higher than 50 Torr. With quenchers in the mixture, the lifetime measurement gave the quenching cross-section of $Hg(6^3P_0)$. In addition, the measurement of the stationary concentration of $Hg(6^3P_0)$ made it possible to determine the rate for each of the processes $6^3P_1 \rightarrow 6^3P_0$ and $6^3P_1 \rightarrow 6^1S_0$. Based on the observed ratio, $\alpha = \sigma^2(6^3P_1 \rightarrow 6^1S_0)/\sigma^2(6^3P_0 \rightarrow 6^1S_0)$, quenching molecules are classified into three groups. The first group consists of N_2O, O_2, C_2H_4, C_3H_6, and C_2H_2 with $\alpha = 1.2$. These molecules deactivate $Hg(6^3P)$ to form their triplet states. The second group (CO, NO, H_2, C_3H_8, *i*-,*n*-C_4H_{10}, and $C(CH_3)_4$) in which $\alpha \approx 4$ makes the quenching *via* a short-lived complex $(Hg\text{-}Q)^*$. The last group (CH_4 and C_2H_6) has a value of α larger than 100. This is caused by a weak interaction between potential surfaces of $Hg(6^3P)+Q$ and $Hg(6^1S)+Q$.

In contrast to the $Hg(6^3P_1)$ state, transition from the $Hg(6^3P_0)$ to the ground state (6^1S_0) is weakly allowed by the spin-orbit interaction. The probability calculated by Garstang[1] is $0.18\ s^{-1}$. Thus, the radiative process would be negligible in the deactivation of $Hg(6^3P_0)$ atoms. The lifetime in N_2 has been measured by means of several methods.[2-5] Callear and Norrish[4] suggested that the main quenching process was the collisional deactivation by ground state Hg atoms. However, a very small cross-section (0.03—0.1 Å^2) for the 6^3P_1 quenching by $Hg(6^1S_0)$ was estimated by Waddell and Hurst,[6] and the more recent data of Callear and McGurk[5] indicated that the deactivation was caused mostly by impurities in N_2 gas. The quenching cross-sections of $Hg(6^3P_0)$ by other species were measured by Callear and Williams,[7] who found very small cross-sections and concluded a metastable character of the $Hg(6^3P_0)$ state. However, they later observed a cross-section larger by an order of magnitude than the previous value with use of a new flash device.[5] Their result is consistent with our former measurements.[8]

In this paper we report on the direct measurement of the lifetime of $Hg(6^3P_0)$ in a medium of $Ar+N_2$ mixture together with cross-sections of various molecules for quenching $Hg(6^3P_0)$. The method proposed in the previous paper[9] has been also applied for the measurements of the rates of the processes $6^3P_1 \rightarrow 6^3P_0$ and $6^3P_1 \rightarrow 6^1S_0$. The difference between the collisional processes of $6^3P_1 \rightarrow$ and $6^3P_0 \rightarrow 6^1S_0$ has been discussed.

Experimental

The apparatus and procedure were the same as those described previously,[9] except for the use of pulsed 253.7 nm radiation to excite Hg atoms and to follow a time history of $Hg(6^3P_0)$ concentration. A schematic diagram of the apparatus is shown in Fig. 1. An exciting lamp was a germicidal lamp (Toshiba, 30 W), operated in a pulsed mode. The filament electrodes of the lamp were heated for several minutes by connecting A with B in the switch, which was then moved to the other side. At the final position of the switch, three

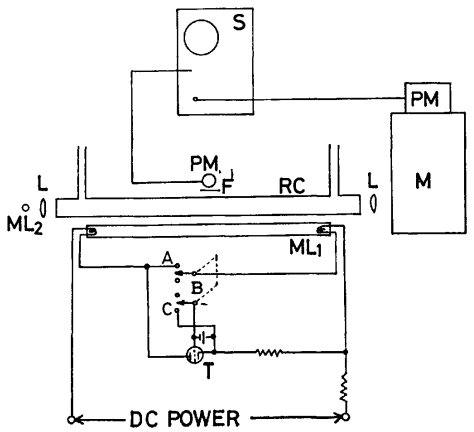

Fig. 1. Schematic diagram of the apparatus.
ML_1: low pressure Hg lamp for 253.7 nm radiation, ML_2: low pressure Hg lamp as a source of 435.8 and 404.7 nm lines, L: quartz lens, RC: reaction cell, M: monochromator, PM: photomultiplier, F: optical filter for 253.7 nm line, S: oscilloscope, T: thyratron.

thyratrons (2D21) made a short circuit between the two electrodes. In this way, the lamp was turned on for a short interval (10—40 ms) during which the connection of B with A changed to that with C, and was turned off in less than 40 μs. The light pulse thus obtained was monitored by a photomultiplier through an interference filter transmitting 253.7 nm radiation, and its out-put was used as a trigger pulse for an oscilloscope (Iwasaki, SS-5004). For the measurement of $Hg(6^3P_0)$ concentration, the 404.7 nm light beam from a low pressure mercury lamp was passed through a reaction cell, whose length and diameter were 100 and 4 cm, respectively. The light beam was fed into a grating monochromator, whose out-put was recorded on the oscilloscope.

Figure 2 shows a typical example of the oscilloscope record. After the exciting lamp is turned on, the intensity of the 404.7 nm line is reduced following an increase of 253.7 nm radiation due to the formation of $Hg(6^3P_0)$ atoms. Turning off of the lamp causes a gradual recovery of the 404.7 nm intensity. The concentration of $Hg(6^3P_0)$ was calculated as described previously. The decay of the $Hg(6^3P_0)$ concentration is exponential against time as seen from Fig. 3,

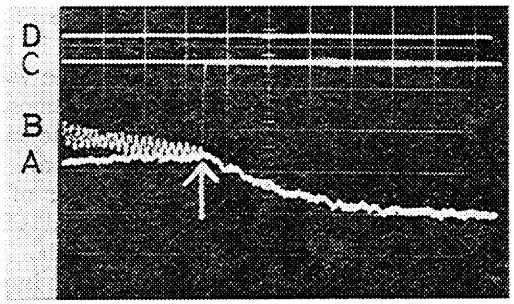

Fig. 2. Oscilloscope trace of the absorption of $Hg(6^3P_0)$ at 404.7 nm after the pulsed irradiation of 253.7 nm radiation into the mixture of $p(NH_3)=1.2\times10^{-2}$, $p(N_2)=0.2$, $p(Ar)=9.8$, and $p(Hg)=1.9\times10^{-4}$ Torr. A: intensity of 404.7 nm line, B: intensity of 253.7 nm radiation (the arrow shows the turning off of the lamp), C: zero for 253.7 nm intensity, D: zero for 404.7 nm intensity, sweep velocity: 5 ms/div.

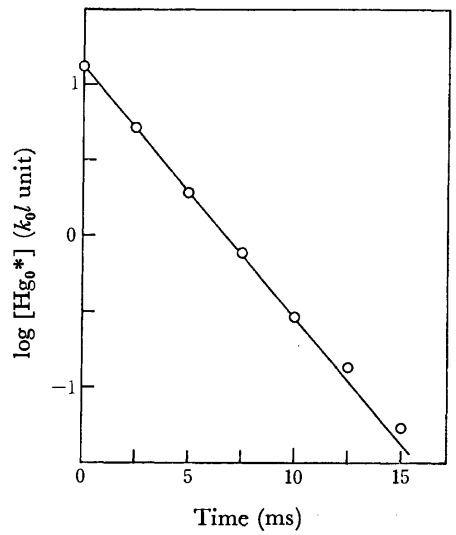

Fig. 3. Decay of the $Hg(6^3P_0)$ concentration obtained from the data given in Fig. 2.

and the lifetime can be defined.

Sample gases employed were commercial. Ar, CO and NO were purified in the same procedure as reported previously. In order to eliminate a trace of O_2, N_2 gas was passed through a U-shaped glass tube packed with small tips of copper at 350 °C. The nominal purity of other gases was: 99.9% for CH_4 and i-C_4H_{10}, 99.7% for C_2H_6, C_3H_8 and n-C_4H_{10}, 99.99% for CO_2, and 99.5% for NH_3. These gases were purified by trap-to-trap distillation in vacuum at liquid nitrogen temperature, their purity being found by gas chromatography to exceed 99.9%. The total pressure of the system was kept constant by adding Ar gas as a diluent to avoid the pressure broadening effect of spectral lines, where Ar could be assumed as a very poor quencher of excited Hg atoms.

Results and Discussion

Lifetime of $Hg(6^3P_0)$ in N_2 and Ar. $Hg(6^3P_0)$ atoms are formed by the reactions:

(i) $Hg + h\nu\,(253.7\,nm) \longrightarrow Hg_1^*$,

(ii) $Hg_1^* \longrightarrow Hg + h\nu\,(253.7\,nm)$,

(iii) $Hg_1^* + N_2 \longrightarrow Hg + N_2$,

(iv) $Hg_1^* + N_2 \longrightarrow Hg_0^* + N_2$,

where Hg, Hg_1^* and Hg_0^* represent Hg atoms of 6^1S_0, 6^3P_1, and 6^3P_0 states, respectively. As reported previously, the rate for Reaction (iii) is negligibly small. Therefore, in a N_2-rich system, all Hg_1^* atoms formed by the 253.7 nm radiation are converted into Hg_0^* atoms. Possible processes for the deactivation of Hg_0^* atoms in a mixture of N_2 and Ar are as follows;

(v) $Hg_0^* + N_2 \longrightarrow Hg + N_2$,

(vi) $Hg_0^* + N_2 \longrightarrow Hg_1^* + N_2$,

(vii) $Hg_0^* + M \longrightarrow Hg + M + h\nu$,

(viii) $Hg_0^* + Hg \longrightarrow 2Hg$,

(ix) $Hg_0^* + Hg \longrightarrow Hg_2^* \longrightarrow 2Hg + h\nu$,

(x)
$$\begin{cases} Hg_0^* + Hg + M \longrightarrow Hg_2^* + M, \\ Hg_2^* \longrightarrow Hg_2 + h\nu\,(335.0\,nm), \\ Hg_2^* + M \longrightarrow Hg_2 + h\nu\,(485.0\,nm), \end{cases}$$

where M stands for N_2 or Ar. Among these processes, Reactions (viii)—(x) cannot be dominant, since the observed lifetime of Hg_0^* is independent of the mercury pressure, as seen from Table 1. Callear and Norrish[4] proposed the cross-section of 18 Å^2 for Reaction (viii). This results in a lifetime shorter than 0.1 ms at $p(Hg)=1.4\times10^{-3}$ Torr, and this is not the case in this experiment. Since their experiment was carried out in a system of atmospheric pressure, there might be a contribution from a termolecular process like Reaction (x). In order to check this possibility, the lifetime was observed under pressures up to 655 Torr. The lifetime is reduced with the increase in the total pressure of the system, and is independent of the mercury pressure in the range of 10^{-4}—10^{-3} Torr. The former fact is due to impurities in the sample gas, and the latter to a small contribution of a termolecular process. The poor efficiency of quenching by Hg_0^*–Hg collisions indicates that potential surfaces of Hg_0^*+Hg and Hg+Hg cross each other at a small internuclear distance where the potential energy is high.[10] Since the radiative transition from the excited state of $Hg_2(^3O_u^-)$ to the ground state is forbidden, Reaction (ix) is impossible. The only possibility is that the excited Hg_2 formed by a collision with a third body makes a spontaneous or a collision-induced transition, *i.e.*, Reaction

Table 1. Lifetime (in ms) of Hg (6^3P_0) in the mixture of Ar+N_2

Total pressure (Torr)	p(Hg) (Torr)		
	1.7×10^{-5}	1.9×10^{-4}	1.4×10^{-3}
1	2.6[a]	2.8[d]	2.6[e]
5	6.6[b]	6.7[d]	7.0[e]
10	10.8[c]	10.0[d]	10.5[e]
50	—	5.0[f]	—
150	—	1.3[g]	1.4[g]
400	—	0.8[h]	0.9[h]
655	—	0.54[i]	0.57[i]

Partial pressure of N_2 (Torr): a) 1.05, b) 1.26, c) 0.52, d) 0.08, e) 0.026, f) 0.05, g) 0.22, h) 4.0, i) 10.0.

(x). However, the spontaneous radiation and the collision-induced radiation rates of $Hg_2(^3O_u^-)$ are 20 s^{-1} and 2.1×10^{-31} $atom^{-2}$ cm^6 s^{-1}, respectively.[11] Thus the rate of Reaction (x) is too small to be measured in the present experiment.

Reaction (vii) for the case of $M=NH_3$ was proposed by Freeman *et al.*,[12] who found that the decay rates of Hg_0 concentration and of luminescence at 347.0 nm were the same. Koskikallio *et al.*[13] found a termolecular mechanism for the deactivation of Hg_0^* by NH_3. This suggests a long-lived complex $Hg–NH_3^*$ emitting the luminescence. However, a luminescence of a similar kind has not been found in N_2, and this suggests that the interaction between N_2 and Hg_0^* may not be strong enough to form a complex with a long lifetime.

The first experimental evidence for Reaction (vi) was reported by Samson.[14] He found a slow decay of 253.7 nm fluorescence after the pulsed irradiation of 253.7 nm light into the N_2–Hg mixture, and attributed the decay to Reaction (vi). More recently, Callear and McGurk[5] also observed a slow decay of fluorescence which they interpreted to be a tracer of Hg_0^* atoms. After the flash excitation of Hg atoms, a quasi-stationary condition for $[Hg_1^*]$ can be assumed since the radiative lifetime of Hg_1^* is very short as compared with the time scale of observation. Then, we get the relation

$$[Hg_1^*]/[Hg_0^*] = k_6[N_2]/(k_2+k_4[N_2]), \quad (1)$$

where Reaction (iii) and the quenching of Hg_1^* by impurities are disregarded. Assuming that this relation holds, the lifetime of Hg_0^* atom can be formulated as

$$1/\tau = [k_2k_6[N_2]/(k_2+k_4[N_2])] + k_5[N_2] + k_Q[Q], \quad (2)$$

where $k_Q[Q]$ represents the contribution of quenching molecules or impurities in a sample gas to the deactivation of Hg_0^*. If we assume a detailed balancing for Reaction (iv) and (vi), the first term in Eq. (2) can be calculated from our previous result for the rate of Reaction (iv). The result is shown in Fig. 4.

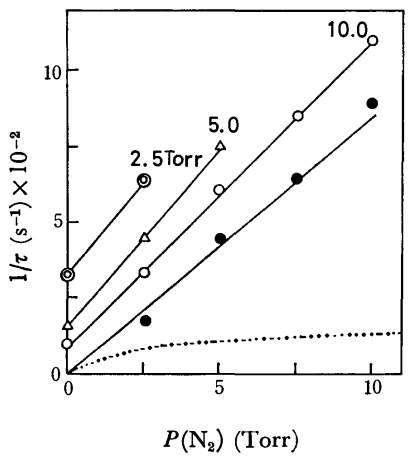

Fig. 4. The reverse of the lifetime of $Hg(6^3P_0)$ in the $Ar+N_2$ mixture against the N_2 pressure.
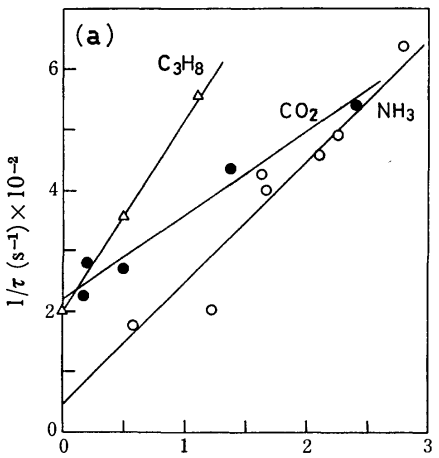
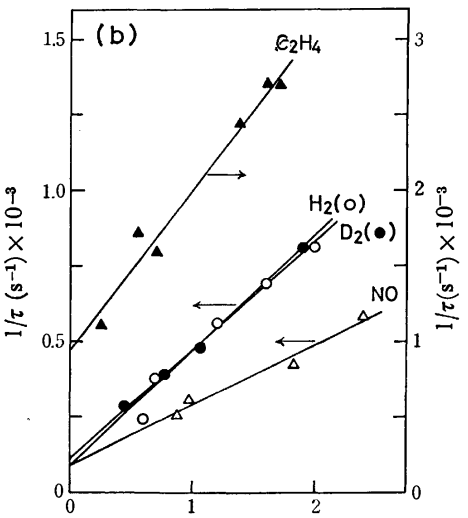
Total pressure is 10 Torr for ○, 5 for △, 2.5 for ◎ with the Hg pressure of 1.9×10^{-4} Torr, and the dashed line is calculated from Eq. (2). The point ● shows the data at 10 Torr from which the calculated value (dashed line) and the one in the absence of N_2 are subtracted.

The experimental relation of the lifetime of Hg_0^* with the partial pressure of N_2 is shown also in Fig. 4. The reciprocal of the lifetime, from which the value of the first term in Eq. (2) is subtracted, is almost proportional to $[N_2]$, its linear slope giving the rate 85 $Torr^{-1}$ s^{-1} or 1.7×10^{-4} Å^2 of the cross-section. However, this cross-section is larger by an order of magnitude than that observed by Berberet and Clark,[3] who used the N_2 gas made from sodium azide. Since N_2 has a very small quenching cross-section, an impurity in the gas which is less pure than the Ar gas may contribute dominantly to the quenching. If an impurity molecule has a quenching cross-section of 10 Å^2, the purity of N_2 should exceed 99.9999% in order to eliminate the impurity effect. Therefore, the value of 1.7×10^{-4} Å^2 for the cross-section should be assumed as an upper limit.

In Fig. 4 also seen is the increase of the lifetime with the increase in the total pressure. This means that Hg_0^* atoms are deactivated by collisions with the



Pressure of NH_3 (Torr$\times2\times10^2$); CO_2, C_3H_8 (Torr$\times10^2$)



Pressure of H_2, D_2 (Torr$\times10^4$); C_2H_4, NO (Torr$\times5\times10^5$)

Fig. 5. The reverse of the lifetime of $Hg(6^3P_0)$ against a pressure of quencher. The experimental condition except for NH_3, C_2H_4 and NO: $p(N_2)=0.2$, $p(Ar)=9.8$, and $p(Hg)=1.9\times10^{-4}$ Torr; for NH_3: $p(Ar)=10.0$; for C_2H_4: $p(N_2)=4.8$, $p(Ar)=5.8$, for NO: $p(N_2)$ 1.3, $p(Ar)=8.7$ Torr.

wall of the reaction cell, and that diffusion to the wall is the rate-determining step. However, at a total pressure higher than 50 Torr, the reduction of the lifetime is found to be due to the deactivation by impurities.

Quenching Rate of $Hg(6^3P_0)$ with Various Molecules. The lifetime of Hg_0* was measured in a gaseous mixture of N_2 and Ar with a small amount of a quenching gas (Q). The reciprocal of the observed lifetime is plotted as a function of a partial pressure of Q in Fig. 5. The experimental data satisfy the Stern-Volmer relation, and the slope of the line gives the deactivation rate of Hg_0*,

$$\text{(xi)}\quad Hg_0^* + Q \longrightarrow Hg + Q.$$

The results are summarized in Table 2 together with the data of Callear and McGurk[5] and Freeman *et al.*[15] to show the general agreement.

Rates for the Processes of $6^3P_1\rightarrow6^3P_0$ and $6^3P_1\rightarrow6^1S_0$. A method was given to obtain the rate constant for each of the two processes from the 6^3P_1 state,

$$\text{(xii)}\quad Hg_1^* + Q \longrightarrow Hg_0^* + Q,$$

$$\text{(xiii)}\quad Hg_1^* + Q \longrightarrow Hg + Q,$$

based on the measurement of a stationary concentration of Hg_0*.[9] This method was applied to the system of Ar and various quenchers. In the previous work, we also measured the stationary concentration of Hg_1* as a function of a partial pressure of Q, and determined the total quenching rate of Hg_1*. However, a weak absorption of the 435.8 nm line made the observed rate unreliable. In addition, a high pressure of Hg (1.9×10^{-4} Torr) caused an imprisonment of 253.7 nm resonant radiation, so that it is difficult to estimate the effective lifetime of Hg_1* accurately. Hence, we adopted the total quenching rate observed by others in this work. Deech *et al.*[16] measured directly the lifetime of Hg_1* excited by a pulsed radiation. The quenching rate determined through this procedure does not depend on the radiative lifetime. Therefore, their data should be more reliable than those determined by the fluorescence method. For the rates which have not been measured by Deech *et al.*, correction factors are sought by comparing the results of Zemansky,[17] Kang Yang,[18] Darwent,[19] and Campbell *et al.*[20] with those of Deech *et al.*, since it would be reasonable to assume that the relative magnitude of cross-sections determined by the fluorescence method in one laboratory is more reliable.

a) $[Hg_1^*]_0$ is the $Hg(6^3P_1)$ concentration in the absence of colliding molecules. All the measurements were carried out in the mixture with Ar at 10 Torr, b) the data of Zemansky[17] multiplied by 1.379 as a correction factor, c) the data of Deech *et al.*,[16] d) the value recommended by Cvetanović,[21] e) the value calculated from σ^2 (i-C_4H_{10})/σ^2(n-C_4H_{10}) determined by Darwent,[19] f) the data of Kang Yang.[18]

Based on Eq. (6) of the previous paper, the rate for either of Reaction (xii) and (xiii) can be calculated. The results are summarized in Table 3. In this experiment, Hg_0* was detected faintly in NO, and not in CO_2, H_2, D_2, N_2O, O_2, C_2H_4, C_3H_6, and C_2H_2, for which upper limits of the rates are given from the detection limit of Hg_0*. It is seen that the rate constant k_{12} of CO depends on its partial pressure; a larger CO partial pressure results in a larger value of k_{12}. This is due to disregard of the reverse reaction of (xii). At room temperature, the rate for this reaction is quite small because of its endothermicity. However, it is probable that Reaction (xii) causes the vibrational excitation of a quenching molecule. If the deactivation rate of a vibrationally excited species is not large like that of N_2 or CO, a population in the excited level increases to more than that in the equilibrium state. Thus, the reverse of Reaction (xii) is accelerated since a large endothermicity is covered by

a) calculated by Vikis and Moser[24] based on the RRKM theory.

the vibrational energy of a quenching molecule, and the lifetime of Hg_0* is reduced by the process in which Hg_0* changes to Hg_1* through the reverse of Reaction (xii) and Hg_1* makes a spontaneous transition to the ground state. We therefore adopt a value of k_{12} for CO by the extrapolation to zero pressure of CO. For other gases except N_2, the rate of the vibrational relaxation is so large that an equilibrium state in the system may be assumed.

The final results of the quenching cross-sections are summarized in Table 4 for each of the processes $6^3P_1 \rightarrow 6^1S_0$, $6^3P_1 \rightarrow 6^3P_0$, and $6^3P_0 \rightarrow 6^1S_0$.

Correlation between the Cross-Sections for Processes $6^3P_1 \rightarrow 6^1S_0$ and $6^3P_0 \rightarrow 6^1S_0$. In Fig. 6, the cross-sections of various quenching molecules for the process $6^3P_1 \rightarrow 6^1S_0$ are plotted as a function of the corresponding cross-sections for that of $6^3P_0 \rightarrow 6^1S_0$. It is concluded that quenching molecules can be classified into three groups, each of which has a constant ratio,

$$\sigma^2(6^3P_1 \rightarrow 6^1S_0)/\sigma^2(6^3P_0 \rightarrow 6^1S_0) = \alpha. \quad (3)$$

Though this classification is made empirically, one group with the same α can be characterized by a collision mechanism.

In the first group which consists of C_3H_6, C_2H_4, C_2H_2, O_2, and N_2O, $\alpha \approx 1.2$, and their lowest triplet energy levels are lower than those of the 6^3P_1 and 6^3P_0 states. Thus, in this group of molecules, a mechanism is suggested to be the electronic-to-electronic energy transfer such as

$$\text{(I)}\quad Hg_{1,0}^* + Q \longrightarrow Hg + Q^T.$$

Burton and Hunziker[22] found the formation of the triplet benzene or naphthalene by collisions with excited Hg atoms. This provides a direct evidence for mechanism (I). The collision process occurs through a non-adiabatic crossing from the potential surface of Hg*+Q to that of Hg+Q^T. The crossing is very

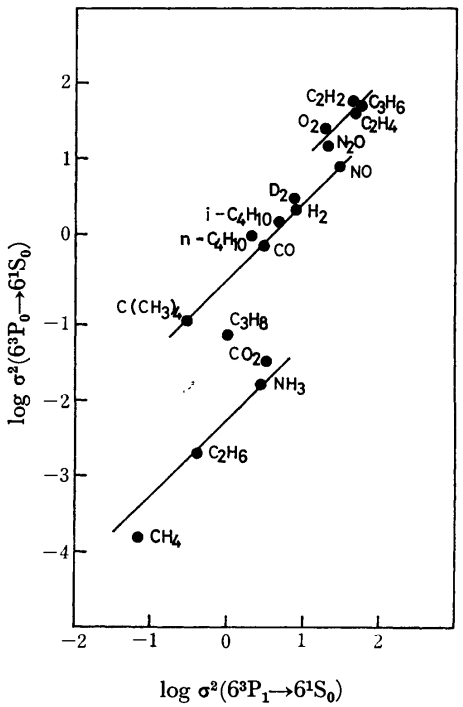

Fig. 6. Correlation of $\sigma^2(6^3P_1 \rightarrow 6^1S_0)$ to $\sigma^2(6^3P_0 \rightarrow 6^1S_0)$ in Å^2.

efficient due to the strong interaction of the 6p electron of Hg with the π^* orbit of quenching molecule. The cross-section is thus close to its gas kinetic one for quenching either of 6^3P_1 and 6^3P_0 states. The potential surface is schematically given in Fig. 7 together with cases for groups II and III.

In the second group which involves H_2, D_2, NO, CO, i-C_4H_{10}, n-C_4H_{10}, $C(CH_3)_4$, and C_3H_8, α is about 4, and their lowest triplet energy levels are higher than or close to that of the 6^3P_1 state. For hydrocarbon

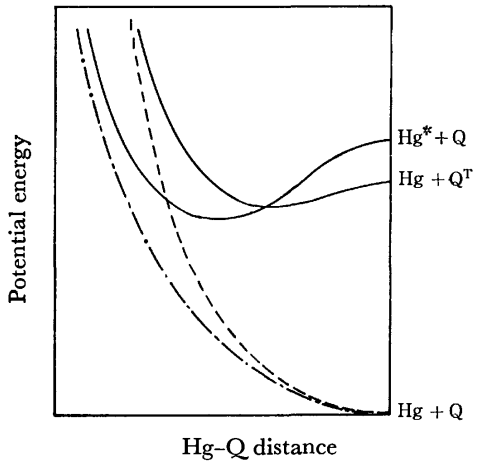

Fig. 7. Schematics of potential surfaces between Hg and Q.

molecules in this group, the quantum yield of H_2 formation is large in the Hg-photosensitized reaction, and the Hg*–CO or –NO collision affords the vibrational excitation of a colliding molecule.[23] This suggests a process *via* a short-lived intermediate:

$$\text{(II)}\quad Hg^* + Q \underset{k_{-a}}{\overset{k_a}{\rightleftharpoons}} (Hg\text{–}Q)^* \begin{cases} \xrightarrow{k_b} \text{decomposition of Q,} \\ \xrightarrow{k_c} \text{vibrational excitation of Q.} \end{cases}$$

Based on this mechanism, the cross-section should be explained as $k_a[(k_b+k_c)/(k_{-a}+k_b+k_c)]$. A large quantum yield of the C–H bond scission of a paraffin hydrocarbon leads to the fact that $k_c \approx 0$ due to a small bond energy of C–H. Assuming the complex (Hg–Q)*, Vikis and Moser[24] applied the RRKM theory to calculate the rate of hydrogen abstraction by excited Hg atoms. The calculated value of the cross-section is larger by an order of magnitude than the present value, but the ratio of α is in agreement for molecules in the second group except neopentane. This means that the difference between the 6^3P_1 and 6^3P_0 quenching is explained simply by the energy content of the complex (Hg–Q)*. In this case, the potential surface between Hg* and Q is weakly attractive, and is crossed by the strongly repulsive surface of Hg+Q as shown in Fig. 7. In the course of sliding down on the latter surface, Q is excited vibrationally or undergoes a decomposition by a mechanism similar to the unimolecular reaction.

The ratio of the quenching cross-section for a hydrocarbon molecule to that of a D-substituted one is of a measurable magnitude. The experimental ratio of $\sigma^2(CH_3CH_2CH_3)$ to $\sigma^2(CH_3CD_2CH_3)$ was determined by Kang Yang[18] as 3.0—8.0, which agreed well with the calculated one by Vikis and Moser based on the RRKM theory. This supports the energy dissipation through the unimolecular decomposition of (Hg–Q)*. However, the situation seems different for H_2 and D_2 because of its small isotope effect. If scheme II is assumed, the rate-controlling step is not the dissociation of (Hg–Q)* for H_2 or D_2, *i.e.*, the rate would be k_a since $k_{-a} \ll k_b$ and $k_c \ll k_b$. The process is a non-adiabatic transition from Hg*+Q to Hg+Q*, and this does not show a large isotope effect. Callear and McGurk[25] proposed two possible mechanisms for quenching Hg* by H_2: an electronically adiabatic route and a non-adiabatic one after H-Hg-H complex was formed by a sideway attack of Hg*.

The third group is characterized by a large ratio of α and by a small cross-section for quenching Hg_1* except NH_3 and CO_2. It is thus probable that there is no crossing between two surfaces of Hg*+Q and Hg+Q, or the crossing point is in an energy region higher than the excitation energy of Hg. Callear and McGurk[5] pointed out a steric hindrance of Hg* inserting into a C–H bond to be the cause of inefficiency of quenching by a simple hydrocarbon such as CH_4 or C_2H_6.

In the quenching of Hg_0* by NH_3, the emission which originated from (Hg-NH_3)* was found by Freeman *et al.*[26] The rate constant for the radiative process

$$Hg(6^3P_0) + NH_3 \longrightarrow (Hg\text{-}NH_3)^* \longrightarrow Hg(6^1S_0) + NH_3 + h\nu$$

was determined to be 3.2×10^{-13} cm^3 molecule^{-1} s^{-1}. This agrees with our result 3.1×10^{-13}. Hence, most of the 6^3P_0 quenching process should be the radiative one. In contrast, $\sigma^2(6^3P_1 \rightarrow 6^3P_0+6^1S_0)$ is of the same order of magnitude as that of a molecule in group II, and the quantum yield of the decomposition of NH_3 at a low pressure is close to 1.[27] Thus, the quenching of Hg_1* by NH_3 should be categorized into group II.

Since the dissociation energy of CO_2 is much larger than the excitation energy of Hg, the reaction scheme for the 6^3P_1 quenching is a triplet formation. The triplet level of CO_2 is uncertain, but the experiment of the thermal decomposition[28] suggests a level near that of the 6^3P state. If this is the case, a small cross-section of the 6^3P_0 quenching may be explained by the fact that the triplet level lies between those of the 6^3P_1 and 6^3P_0 states.

Quantum Yield of Hg(6^3P_0). The quantum yield

of Hg_0* defined as $\sigma^2(6^3P_1 \rightarrow 6^3P_0)/\sigma^2(6^3P_1 \rightarrow 6^1S_0 + 6^3P_0)$ are given in Table 5. The results are compared with those reported by Callear and McGurk.[5] Their data are corrected by using the total cross-sections of the 6^3P_1 quenching that are adopted in this work. The agreement is within a factor of 2 except C_2H_6. As stated already, the process $6^3P_1 \rightarrow 6^3P_0$ has a possibility to cause the vibrational excitation of a colliding molecule. However, there seems to be no distinct correlation between the cross-section and the resonance energy defect. The quantum yield is large for a molecule in group II and III except H_2, D_2, and CO_2. This suggests that the state mixing between the 6^3P_1 and 6^3P_0 states in the (Hg–Q)* complex may result in the transition to the 6^3P_0 state, and that the production of $Hg(6^3P_0)$ is not efficient if there is a large probability of transition from the Hg*+Q surface to the Hg+Q, *i.e.*, the condition $k_{-a} > k_b + k_c$ in scheme (II) is necessary for a large quantum yield.

Contribution of d Orbitals in SiH SiH_2, SiH_3, and SiH_4

Jiro HIGUCHI, Shozo KUBOTA,* Toshio KUMAMOTO,** and Ikuo TOKUE***

Department of Chemistry, Faculty of Engineering, Yokohama National University, Minami-ku, Yokohama 233

(Received May 31, 1974)

Semi-empirical calculations have been carried out for SiH_n ($n=1$, 2, 3, and 4) adopting the electron pair bond approximation using hybrid orbitals with d orbitals of Si determined by minimizing the energy of each ground state. The results are satisfactory as a whole for explaining the experimental data of these molecules. The contribution of d orbitals obtained is not very large, but it is important in discussing the energy levels and molecular structures of some low-lying electronic states. It is also shown that the maximum overlap method is not always adequate in determining hybrid orbitals including d orbitals.

Structures of some molecules containing second-row elements differ from those expected in molecules consisting of hydrogen and/or first-row elements. Examples can be found in such molecules as PCl_5 and SF_6, in which participation of the d orbitals of these rather heavy atoms in bonding is appreciable. This is because the d orbitals give a different angular effect from that of the s and p orbitals in bonding.

In the 3d orbital of second-row atoms, the energy is not so high as compared with those of the 3s and 3p valence electrons. Although the 4s and 4p extra-valence shell orbitals are also not high in energy, their mixing with the valence shell orbitals is expected to be very small in the low-lying electronic states.[1] Thus, for a discussion of the electronic properties of a molecule with second-row atoms, inclusion of the 3d orbital should not be completely ignored, although most calculations of these molecules have not always explicitly taken into account the effect of the d-character.

In the present work, a semi-quantitative calculation including the 3d orbitals has been carried out for the electronic structure of ground state for SiH, SiH_2, SiH_3, and SiH_4 which show some different properties from those of the corresponding CH_n molecules,[2-5] together with some excited states of SiH and SiH_2. In this case, the electron pair bond approximation was adopted since the valence bond method is rather useful in discussing the contribution of d orbital in bonding as compared with the molecular orbital method.

Hybrid Orbitals with d-Character

The spatial configurations of SiH, SiH_2, SiH_3, and SiH_4 were assumed to be of symmetry $C_{\infty v}$, C_{2v}, C_{3v}, and T_d, respectively, the coordinate system of these molecules being taken as shown in Fig. 1. For the first-row elements, the orthonormalized set of hybrid orbitals directed to each bond or non-bonding electron can uniquely be constructed from 2s, 2px, 2py, and 2pz orbitals taking the spatial configuration into consideration if a few external conditions such as equivalence of some orbitals are given. However, a similar set of hybrid orbitals including the d orbitals cannot uniquely be determined even if the same number of external conditions is given, and some additional parameters are necessary.

For SiH, SiH_2, SiH_3, and SiH_4 these hybrid orbitals can be expressed as follows:

SiH:

$$\left.\begin{aligned}\chi_1 &= a_0\chi_s - b_0\chi_{p\sigma} + c_0\chi_{d\sigma}\\ \chi_b &= a_1\chi_s + b_1\chi_{p\sigma} + c_1\chi_{d\sigma}\\ \chi_\pi &= \quad b_\pi\chi_{p\pi} + c_\pi\chi_{d\pi}\end{aligned}\right\} \tag{1}$$

SiH_2:

$$\left.\begin{aligned}\chi_1 &= a_0\chi_s + b_0\chi_{pz} + c_0\chi_{dz^2}\\ \left.\begin{matrix}\chi_{b1}\\ \chi_{b2}\end{matrix}\right\} &= a_1\chi_s + b_1\left[\pm\left(\sin\frac{\theta}{2}\right)\chi_{py} - \left(\cos\frac{\theta}{2}\right)\chi_{pz}\right]\\ &\quad + c_1\left[\frac{1}{2}\left(3\cos^2\frac{\theta}{2}-1\right)\chi_{dz^2} - \frac{1}{2}\left(3^{1/2}\sin^2\frac{\theta}{2}\right)\chi_{dx^2-y^2}\right.\\ &\quad \left.\mp\left(3^{1/2}\sin\frac{\theta}{2}\cos\frac{\theta}{2}\right)\chi_{dyz}\right]\end{aligned}\right\} \tag{2}$$

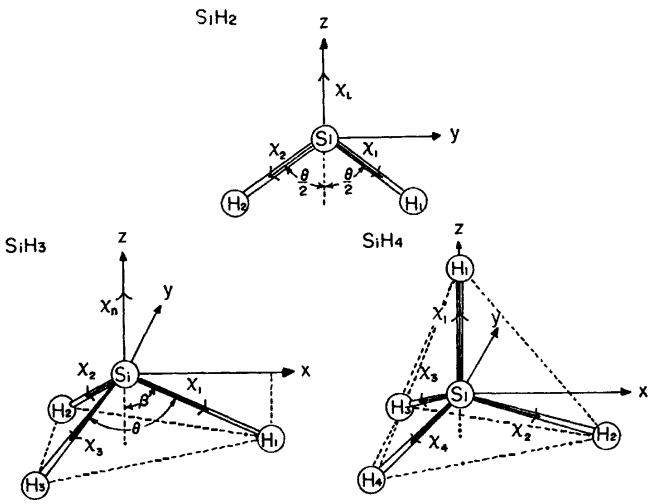

Fig. 1. Coordinate system and hybrid orbitals χ_i's in SiH_n (n=2, 3, and 4).

where l, n, and b denote lone pair, non-bonding and bonding, respectively.

Atomic Orbitals

In the calculation of molecular integrals, the atomic orbitals of Si used are the SCF–AO's (solutions of Hartree-Fock equation in the ^3P state) obtained by Watson and Freeman.[6] Since no 3d orbital is given in their paper, the following orbital was tentatively used:

$$\chi_{3d}^{Si} = 0.1571\chi_{3d}^{STO}(0.25) + 0.7607\chi_{3d}^{STO}(0.50) + 0.1651\chi_{3d}^{STO}(1.00) + 0.0561\chi_{3d}^{STO}(2.00) \quad (5)$$

where $\chi_{3d}^{STO}(\delta)$ is a Slater-type 3d AO with orbital exponent δ. The coefficients of these AO's are chosen so as to give a minimum energy of the ^1D state with electron configuration $3s^23p3d$ by using the above SCF-AO's. The orbital of hydrogen used (χ_H) is the Slater-type 1s AO with orbital exponent 1.00. All the internuclear distances between the silicon and hydrogen are taken to be 1.477 Å, which is the equilibrium distance of SiH_4 molecule.[7]

Method of Calculation

Since the molecular integrals used in semi-empirical valence bond calculations have not always been described with a unified formula, it will be necessary to clarify the definitions used. The procedure is briefly outlined in the following paragraphs. The Hamiltonian of SiH_n (n=1, 2, 3, 4) $\mathcal{H}$ can be expressed in atomic unit as

$$\mathcal{H} = \mathcal{H}_{Si} + \sum_{r=1}^{n}\mathcal{H}_{H(r)} + \sum_{p=1}^{14}\sum_{r=1}^{n}\mathcal{H}_{Si(p)-H(r)} + \sum_{r=s+1}^{n}\sum_{s=1}^{n-1}\mathcal{H}_{H(r)-H(s)} \quad (6)$$

where $\mathcal{H}_{Si}$ and $\mathcal{H}_{H(r)}$ are the atomic term of the Si which includes the 1st to the 14th electrons and that of the r-th hydrogen which includes the $(r+14)$-th electron, respectively, *i.e.*,

$$\mathcal{H}_{Si} = -\frac{1}{2}\sum_{p=1}^{14}\Delta_p - \sum_{p=1}^{14}\frac{14}{r_{Si-p}} + \sum_{p=q+1}^{14}\sum_{q=1}^{13}\frac{1}{r_{p-q}} \quad (p, q = 1\sim14) \quad (7)$$

and

$$\mathcal{H}_{H(r)} = -\frac{1}{2}\Delta_{(r+14)} - \frac{1}{r_{H(r)-(r+14)}} \quad (r = 1\sim n). \quad (8)$$

The $\mathcal{H}_{Si(p)-H(r)}$ and $\mathcal{H}_{H(r)-H(s)}$ are the interatomic interaction terms, *i.e.*,

$$\mathcal{H}_{Si(p)-H(r)} = \frac{1}{R_{Si-H(r)}} + \frac{1}{r_{p-(r+14)}} - \frac{1}{r_{Si-(r+14)}} - \frac{1}{r_{H(r)-p}} \quad (9)$$

and

$$\mathcal{H}_{H(r)-H(s)} = \frac{1}{R_{H(r)-H(s)}} + \frac{1}{r_{(r+14)-(s+14)}} - \frac{1}{r_{H(r)-(s+14)}} - \frac{1}{r_{H(s)-(r+14)}} \quad (10)$$

The treatment is based on the electron pair bond approximation without ionic structure using the hybrid orbitals (1)—(4). Using the Hamiltonian $\mathcal{H}$ (6), the total energy of SiH_n can approximately be expressed as

$$E_{SiH_n} = E_{Si} + \sum_{r=1}^{n}E_{H(r)} + \sum_{r=1}^{n}\sum_{p=1}^{14}(Q_{pr} + c_{p,(r+14)}R_{pr}) + (1-\delta_{1,n})\sum_{r=s+1}^{n}\sum_{s=1}^{n-1}\left(Q'_{rs} - \frac{1}{2}R'_{rs}\right)$$

$$c_{i,j} = \begin{cases} +1 & (i,j\text{: paired orbitals}) \\ -1/2 & (i,j\text{: non-paired orbitals}), \end{cases} \quad (11)$$

where E_{Si} is the energy concerning the Si atom only, $E_{H(r)}$ is the energy of the r-th atom, Q_{ij}'s and R_{ij}'s are the interatomic Coulomb and exchange integrals, respectively,[8] *i.e.*,

$$Q_{pr} = \iint\chi^*_{Si(p)}(p)\chi^*_{H(r)}(r+14)\mathcal{H}_{Si(p)-H(r)} \times\chi_{Si(p)}(p)\chi_{H(r)}(r+14)d\tau_p d\tau_{r+14} \quad (12)$$

$$R_{pr} \simeq \iint\chi^*_{Si(p)}(p)\chi^*_{H(r)}(r+14)\mathcal{H}_{Si(p)-H(r)} \times\chi_{H(r)}(p)\chi_{Si(p)}(r+14)d\tau_p d\tau_{r+14} \quad (13)$$

$$Q'_{rs} = \iint\chi^*_{H(r)}(r+14)\chi^*_{H(s)}(s+14)\mathcal{H}_{H(r)-H(s)} \times\chi_{H(r)}(r+14)\chi_{H(s)}(s+14)d\tau_{r+14}d\tau_{s+14} \quad (14)$$

$$R'_{rs} \simeq \iint\chi^*_{H(r)}(r+14)\chi^*_{H(s)}(s+14)\mathcal{H}_{H(r)-H(s)} \times\chi_{H(s)}(r+14)\chi_{H(r)}(s+14)d\tau_{r+14}d\tau_{s+14}. \quad (15)$$

In Eq. (11), orthogonality among all the orbitals is assumed, except in the evaluation of R_{ij}'s with Eqs. (13) and (15). All the interactions with the inner shells of the Si atom are also included in the same way. The coefficients of the AO's in the hybrid orbitals (1)—(4) are determined so as to minimize the total energy of the corresponding ground state.

In the case of SiH, the treatment is similar to the restricted SCF-LCAO-MO method.[9] For the ground state:

$$^2\Pi\text{: } (\chi_l)^2[(\chi_b)(\chi_H)](\chi_n),^{10} \quad (16)$$

the coefficients of the AO's are determined by solving the following simultaneous equations:

$$\left.\begin{aligned}
&\left[H+Q-\frac{1}{2}R+2J_1-K_1+J_b-\frac{1}{2}K_b+J_{\pi+}-\frac{1}{2}K_{\pi+}\right]\chi_1 \\
&\quad=\varepsilon_{11}\chi_1+\frac{1}{2}\varepsilon_{1b}\chi_b \\
&\left[H+Q+R+2J_1-K_1+J_{\pi+}-\frac{1}{2}K_{\pi+}\right]\chi_b=\varepsilon_{1b}\chi_1+\varepsilon_{bb}\chi_b \\
&\left[H+Q-\frac{1}{2}R+2J_1-K_1+J_b-\frac{1}{2}K_b\right]\chi_{\pi+}=\varepsilon_{\pi\pi}\chi_{\pi+}
\end{aligned}\right\} \quad (17)$$

where

$$H=-\frac{1}{2}\Delta-\frac{14}{r_{Si}}+2J_{1s}-K_{1s}+2J_{2s}-K_{2s}+2J_{2p\sigma}-K_{2p\sigma}+2J_{2p\pi+}-K_{2p\pi+}+2J_{2p\pi-}-K_{2p\pi-} \quad (18)$$

$$J_k\chi_p(p)=\left[\int\chi_k^*(q)(1/r_{p-q})\chi_k(q)d\tau_q\right]\chi_p(p) \quad (19)$$

$$K_k\chi_p(p)=\left[\int\chi_k^*(q)(1/r_{p-q})\chi_p(q)d\tau_q\right]\chi_k(q) \quad (20)$$

$$Q\chi_p(p)=\left[\int\chi_H^*(15)\mathcal{H}_{Si(p)-H(1)}\chi_H(15)d\tau_{15}\right]\chi_p(p) \quad (21)$$

$$R\chi_p(p)=\left[\int\chi_H^*(15)\mathcal{H}_{Si(p)-H(1)}\chi_p(15)d\tau_{15}\right]\chi_H(p). \quad (22)$$

All the calculations were carried out using the two sets of hybrid orbitals with and without d orbitals of Si atom. The most stable structure of the ground state of SiH_2,

$$^1A_1:\ (\chi_1)^2[(\chi_{b1})(\chi_{H(1)})][(\chi_{b2})(\chi_{H(2)})], \quad (23)$$

and that of SiH_3,

$$^2A_1:\ [(\chi_{b1})(\chi_{H(1)})][(\chi_{b2})(\chi_{H(2)})][(\chi_{b3})(\chi_{H(3)})](\chi_n), \quad (24)$$

were determined by changing the bond angle ∠HSiH only. For SiH and SiH_2, the excitation energies to the lower electronic states,

$$\left.\begin{aligned}
&^4\Sigma^-,\ ^2\Delta,\ ^2\Sigma^-,\ ^2\Sigma^+:\ [(\chi_b)(\chi_H)](\chi_\pi)^2(\chi_1) && (25)\\
&^2\Delta:\ (\chi_1)^2[(\chi_b)(\chi_H)](\chi_\delta) && (26)\\
&^2\Sigma^+:\ (\chi_1)^2[(\chi_b)(\chi_H)](\chi_\sigma^*) && (27)
\end{aligned}\right\}\ \text{for SiH}$$

and

$$\left.\begin{aligned}
&^3B_1,\ ^1B_1:\ [(\chi_{b1})(\chi_{H(1)})][(\chi_{b2})(\chi_{H(2)})](\chi_1)(\chi_n) && (28)\\
&^1A_1:\ [(\chi_{b1})(\chi_{H(1)})][(\chi_{b2})(\chi_{H(2)})](\chi_n)^2 && (29)
\end{aligned}\right\}\ \text{for } SiH_2$$

were also calculated using the hybrid orbitals of each ground state. In the vacant orbitals in the ground state, the χ_δ orbital of SiH was taken to be the 3dδ AO of Si, the χ_σ^* was the 3dσ-like orbital which is orthogonal to the χ_1 and χ_b, and the χ_n orbital of SiH_2 which is perpendicular to the molecular plane was assumed to be the 3px AO of Si.[11] In the case of the $^1A_1$ states of SiH_2, only the interaction between configurations (23) and (29) was taken into account so as to give the energies of the $^1\Delta_g$ and the $^1\Sigma_g^+$ states in the linear structure. The other states of SiH_n were calculated in the approximation of single configuration.

Results and Discussion

In the SiH radical, the $D^2\Delta$ and $E^2\Sigma^+$ states are not so high as compared with the lowest $^2\Delta$ and $^2\Sigma^+$ states, while those of the CH are expected to be high-energy excited states. However, no theoretical work has been done for these higher states. Therefore, the excitation energies have been calculated for the low-lying states with configurations (25)—(27). Using the hybrid orbitals determined for the ground state, the lower excited states with configuration (25) obtained are considerably high as compared with the experimental results [$\Delta E_{calc.}(^2\Delta)=5.81$ eV and $\Delta E_{calc.}(^2\Sigma^+)=6.90$ eV, while $\Delta E_{obs.}(^2\Delta)=3.01$ eV and $\Delta E_{obs.}(^2\Sigma^+)=3.84$ eV[12,13]]. This might be due to the fact that the distribution of σ electrons differs a great deal from that of the ground state where the hybridization ratios used in Eq. (1) were determined.[14] On the other hand, the calculated excitation energy of the higher $^2\Delta$ state with configuration (26) is 6.67 eV, in fair agreement with the observed value of the $D^2\Delta$ state [6.02 eV[12,13]]. The agreement might suggest the fact that the distribution of σ electrons in this $^2\Delta$ state does not differ much from that of the ground $^2\Pi$ state. Similarly, the observed higher $^2\Sigma^+$ state ($E^2\Sigma^+$) can be explained to be due to the excitation of one π electron from the ground state $^2\Pi$ into the 3d-like σ orbital (χ_σ^*). The results indicate that the contribution of d orbitals is important in discussing some observed lower electronic states of molecules with second-row atoms.

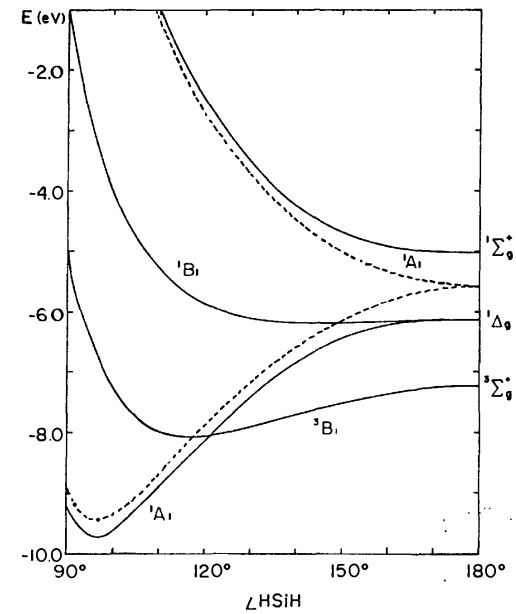

Fig. 2. Lower electronic states of SiH_2 calculated by including d orbitals. The dotted lines indicate the energies of the $^1A_1$ states without interaction between the lowest two configurations. The origin of energy is chosen to be $Si(^3P)+2H(^2S)$.

For the four low-lying states of SiH_2, the potential energy curves were calculated by including the d orbitals of Si as shown in Fig. 2. The dotted lines correspond to the energies without interaction between the lowest two $^1A_1$ configurations. The calculated equilibrium bond angle ∠HSiH in the ground state $^1A_1$ [96°] is in fair agreement with the observed result [92° [2]], while the value of the $^1B_1$ state [145°] is fairly larger than the expeimental [123° [2]]. The calculated energy difference between these states is 3.54 eV while the observed value is 1.93 eV. The disagreement is mainly due to the facts that the electron configuration is apparently different between these states and that

the hybrid orbitals used are determined for the energy of the $^1A_1$ state with configuration (23).

In the case without d orbitals, the bond angle ∠HSiH in each state is generally close to the result with d orbitals and that of the *ab initio* calculation (without d orbitals) by Wirsam.[15] For only the $^1B_1$ state, the bond angle obtained here is fairly large [about 30°] as compared with that of Wirsam, although the energy changes less than 0.5 eV in this vicinity. The difference between the results with and without the d orbitals is not very significant.

In both calculations, the ground state of SiH_2 is obtained as $^1A_1$, in contrast with $^3B_1$ of CH_2. The difference is not essentially due to the effect of the d orbitals, and can be explained by the following electronic properties: If the overalp integral between the valence v orbital (v means s, pσ, *etc.*) and the hydrogen 1s orbital is expressed by S_{vh}, the ratio of $S_{sh}/S_{p\sigma h}$ for SiH_n is fairly smaller than that of CH_n. Accordingly, the stabilization of the Si–H bond due to the inclusion of the s orbital is rather small as compared with that of the C–H bond. The separation between the lowest $^1A_1$ (or $^1B_1$) and $^3B_1$ states of SiH_2 is about three quarters of that of CH_2 near the linear structure.[16] Thus, the $^1A_1$ state of SiH_2 with nearly-rectangular bond angle is located lower than the $^3B_1$ state, in contrast with the case of CH_2.

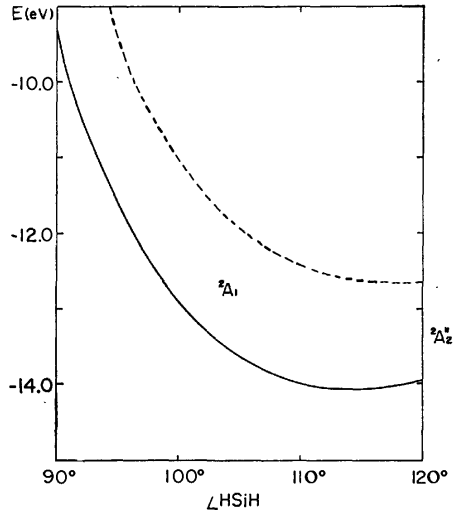

Fig. 3. Electronic energy of $^2A_1$ state of SiH_3 calculated by including d orbitals (full line) and that by disregarding d orbitals (dotted line). The origin of energy is chosen to be $Si(^3P)+3H(^2S)$.

The potential energy curve of the ground state of SiH_3 has been calculated as shown in Fig. 3. The most stable structure obtained is pyramidal (∠HSiH= 114°) by including the contribution of the d orbitals of Si, in consistent with the experimental result,[4] while it is nearly planar (∠HSiH=119°) by disregarding the d-character. The calculated bond angle is in close agreement with the value deduced by Sharp and Symons (113~114°).[17] This might show the facts that the pyramidal structure of SiH_3 is due to an appreciable contribution of the d orbital in the angular effect and that the inclusion of the d orbital is essentially necessary in the calculation of molecules with Si atom.

On the other hand, an *ab initio* calculation by Wirsam[18] and an INDO calculation by Benson and Hudson[19] gave the pyramidal structure for the equilibrium geometry in spite of disregard of the d orbitals. Thus, one may conclude that there are two reasons for the pyramidal structure of SiH_3, in contrast with the nearly-planar structure of CH_3; it is due to the angular contribution of the d orbital of Si and that the stabilization of the Si–H bond due to the inclusion of the s orbital is rather small as compared with the case of the C–H bond.

In general, the energy lowering due to the inclusion of the d orbitals is not very large. The results for the ground states with equilibrium configuration are summarized in Tables 1 and 2. The stabilization energy per Si–H bond differs for the SiH_n molecules each other, this being mainly due to the fact that the contribution of the valence states of the Si atom concerned with each molecule is not quite the same. Actually, the energy lowering increases with decreasing the bond angle ∠HSiH. On the other hand, the contribution

the ∠HSiH (Figs. 4 and 5). However, the energy of d-character of Si atom also increases with decreasing lowering is not exactly parallel with the d-character.

In the present calculation, the contribution of d orbital is not very great but should not be completely disregarded. The d-character in the lone pair and the non-bonding orbitals is very small as compared with that of the bonding orbitals (Table 2). This is understandable from the fact that the hybridization of the d orbitals mainly contributes to the bonding energy. For SiH_2 and SiH_3, the maximum value of d-character in the lone pair and the non-bonding orbitals (0.22 and 0.59%, respectively) appeared near bond angles of 110 and 113°, respectively, while the d-character of the bonding orbitals increases with decreasing the bond angle (Figs. 4 and 5). For SiH_4, the relation where

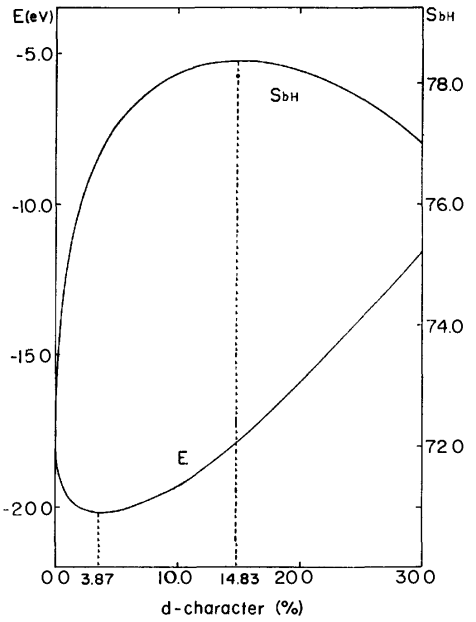

Fig. 6. Effect of d-character for the electronic energy (E) and the overlap integral between χ_{bi} and $\chi_{H(i)}$ [S_{bh}] in SiH_4. The origin of energy is chosen to be $Si(^3P)+4H(^2S)$.

the d-character is equal to the decrease in the p-character due to the inclusion of the d orbitals is exactly satisfied [*cf.* Eq. (4)]. This is also roughly valid for the other SiH_n radicals (Table 2, Figs. 4 and 5).

The maximum value of energy lowering for SiH_4 due to the inclusion of the d orbitals of Si has been obtained to be 2.03 eV at the d-character of 3.87% in the bonding orbital χ_{bi}. On the other hand, the maximum overlapping between the χ_{bi} and the $\chi_{H(i)}$ appeared at the d-character of 14.83% as shown in Fig. 6. This discrepancy may be explained as follows: the stabilization of the Si–H bond due to the exchange energy between the χ_{bi} and the $\chi_{H(i)}$ may increase with increasing the value of the corresponding overlap integral. However, the total energy increases beyond a certain value of the d-character, since the energy of d orbital is rather high as compared with the other valence orbitals of Si. This might suggest the fact that the maximum overlap method[20] is not always adequate in determining the hybrid orbitals with d orbitals.

The present work includes several approximations and assumptions. The atomic orbitals used may not be completely adequate for all the states. Actually, the determination of the 3d orbital is rather tentative but may be allowed for the present purpose. This may be recognized from the fact that the energy levels of Si atom calculated using the present AO's are generally satisfactory in a semi-quantitative sense except that the order of the $^3D(3s^23p3d)$ and $^3P(3s^23p3d)$ states is the reverse of that given in Moore's table.[21] Therefore, the experimental values are not included in the present calculation, although a better result might be obtained by using such values.

The result obtained for the ground state of SiH_n is generally satisfactory as compared with those of other calculations.[15,18,19,22,23] This is partly due to the facts

that the approximation for the exchange integrals (12) and (14) are fairly permissible, as has already been shown by the calculations of CH[9] and CH_2,[24] and that the contribution of ionic structures is not great in the ground states of the molecules. As far as the hybrid orbitals determined for the ground state are used in the approximation of single configuration, the results for the excited states are not so good as in the ground state. However, better results can be expected in a similar treatment if the hybrid orbitals are obtained so as to minimize the energy of the state in question or if the interaction with some other electronic configurations are included.

The authors wish to thank Mr. H. Takahashi for his help in the preliminary calculation of SiH_2.

Polarographic Investigation of Dissolved Oxygen in Nonaqueous Solvent

Taitiro FUJINAGA and Sachiko SAKURA

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606

(Received November 16, 1973)

In a common aprotic solvent, the dissolved oxygen is reduced to superoxide, and then to peroxide with tetraalkylammonium salt as the supporting electrolyte. With alkali metal ion as the supporting electrolyte, it is reduced further to form the third wave. All of these waves are controlled by the successive chemical reaction; namely if the products due to the successive reaction are stable, the reduction potential shifts to more positive direction. When the solvated ion of the supporting electrolyte is small, it forms stable complex with oxygen radicals, hence the reduction waves shift to positive potentials.

The polarographic reduction of oxygen has been investigated in a number of nonaqueous aprotic solvents. In most aprotic solvents such as dimethylformamide, dimethylsulfoxide and acetonitrile, molecular oxygen undergoes two step reduction at the dropping mercury electrode; in the first step, oxygen is reduced to the superoxide anion, and then reduced further to the peroxide anion in the second step. The reaction mechanism of the first wave has been investigated by many authors,[1-4] however, little attention has been drawn to the second wave process. Only a few papers by Johnson *etc*[5] describe that the second reduction wave in 0.1 M Et_4NClO_4–DMSO solution is significantly affected by the addition of alkali metal ions. We found that oxygen was reduced further to form the third wave in the solution of alkali metal ion as the supporting electrolyte.

This paper deals with the results of detailed investigation on the electrolytic reduction of oxygen in aprotic organic solvents, especially with regard to the second and the third waves.

Apparatus and Reagents

Reagents. Dimethylacetamide (DMA) was purified by the double distillation under reduced pressure of nitrogen gas, first over calcium hydride and second over *p*-toluenesulfonic acid. Hexamethylphosphoramide (HMPA) and propylene carbonate (PC) were purified following the method in the previous paper.[6] Tetraalkylammonium perchlorates and alkali metal perchlorates were prepared and purified according to the method described in the previous paper.[6] Dodecyltrimethylammonium chloride was obtained commercially. The polarogram of oxygen was recorded in a solution which was saturated with dried air; air was dried by passing through concentrated H_2SO_4 bubblers before use.

Apparatus. A Yanagimoto polarograph, Type P 8-DP was used to record most current-potential curves. In AC polarography, the PAR (Princeton Applied Research Cooperation, Princeton, N. Y.) polarograph with IR-compensation using three electrodes system was used. The H cell used was the sameas in the previous paper.[6]The silver-silver perchlorate electrode Ag/0.1 M $AgClO_4$ in the solvent was used as the reference electrode. The potential of the reference electrode against the aqueous SCE was +0.439 V, +0.750 V and +0.360 V in DMA, PC, and HMPA, respectively. The DME (A, B) used had *m* values of 1.61_5, 0.80_8 mg/s at an open circiut and $h=62$ cm in DMA. The life times at −2.4 V in 0.05 M Et_4NClO_4–DMA were 3.21_7, 2.64_0 s, respectively. The DME used had *m* values of 0.63_0, and 0.89_0 mg/s at an open circiut and $h=65$ cm, in PC and HMPA, respectively. The drop time at −2.4 V in 0.05 M Et_4NClO_4–PC solution was 1.88_1 s. The drop time at −2.6 V in 0.05 M Et_4NClO–HMPA solution was 1.70_0 s.

Determination of the concentration of oxygen in nonaqueous solution by the iodometric method of Winkler is less satisfactory, especially PC is hardly soluble with water. Assuming that the solvation, if any, of the oxygen molecule should not be radically different in DMA, HMPA, PC, and DMSO, Walden's rule may be applied for the calculation of an approximate diffusion coefficient of oxygen in DMA, HMPA and PC as solvent. At 25 °C the viscosity of DMSO[2] is 1.95 cp, while those of DMA,[7] HMPA[9] and PC[10] are 0.92, 3.23 and 2.53 cp. The diffusion coefficient of oxygen in DMSO[2] is *ca.* 2.76×10^{-5} cm^2 s^{-1}. Hence from Walden's rule the diffusion coefficients of oxygen in DMA, HMPA and PC should be 5.85, 1.67, 2.13×10^{-5} cm^2 s^{-1}. Substituting into the Ilkovič equation, the concentrations of oxygen are *ca.* 0.923, 1.29, and 1.03 mM in DMA, HMPA and PC solution, respectively.

Results

Reduction of the Dissolved Oxygen in DMA. The dissolved oxygen gave three waves in DMA in the presence of 0.05 M alkali metal ion as the supporting

electrolyte, corresponding to one-electron, one-electron, and two-electrons process respectively; a maximum appeared at the third wave when sodium ion was used as the supporting electrolyte. When lithium ion was used as the supporting electrolyte, only the first wave was observed. When 0.05 M tetraalkylammonium ion was used as the supporting electrolyte, the dissolved oxygen gave two waves, each corresponding to one-electron process. Their half-wave potentials are summarized in Table 1. Some typical polarograms are shown in Figs. 1 and 2.

The half-wave potential shifted to negative side with the increase of the radius of the solvated ion. The extent of the shift was the least pronounced with the first wave and more pronounced with the second wave. The third wave was most influenced by the radius of the supporting electrolyte cation, although in many cases except with cesium, rubidium, potassium, tetramethylammonium, and dodecyltrimethylammonium ion, the third wave shifted too negative to be observable before the final rise. In the case of alkali metal ion used as the supporting electrolyte, oxygen is reduced most easily in the presence of cesium ion and least in the presence of lithium ion. With tetraalkylammonium ion as the supporting electrolyte, oxygen is reduced most easily in the presence of tetramethylammonium ion. With the increase of the size of the solvated ion, the shift of the half wave potential to negative becomes pronounced. With 0.05 M tetrahexylammonium ion as the supporting electrolyte, the second wave shifts too negative to appear before the final rise. However, with 0.05 M tetradecyl-dimethyl-benzylammonium (TDDMB) ion, oxygen gave a well-defined second wave, although the size of the cation is larger than tetrahexylammonium ion.

Fig. 3a. Half wave potential of oxygen's reduction and concentration of tetramethylammonium ion.
○ A: the first wave, B: the second wave, C: the third wave in mixed with Me_4N^+ and Bu_4N^+ supporting electrolyte solution, ● 0.05 M Me_4NClO_4 solution, ◑ 0.05 M other tetraalkylammonium ion solution; 1) dodecyltrimethylammonium ion, 2) TDDMB ion, 3) tetraethylammonium ion, 4) tetrapropylammonium ion, 5) tetrabutylammonium ion, 6) tetrahexylammonium ion. 1)~5) the first and the second waves, 6) only the first wave.

The presence of methyl groups may be responsible for the oxygen reduction at a relatively positive potential. Figures 3 and 3a show that the half wave potentials of the second wave of oxygen shift to the positive potential with the increase of the concentration of tetramethylammonium ion and that the numbers of methyl groups in the large cation are also responsible for the positive shift (See the cases of TDDMB ion and dodecyltrimethylammonium ion used as the supporting electrolyte).

The effect of the supporting electrolyte cation on AC polarograms was also examined. The first peak is relatively sharp and high showing that the process is reversible. The peak height of the second wave is about one tenth of that of the first wave, and its shape is distorted. This fact suggests that the process is irreversible. The third peak is not appearing in AC polarogram.

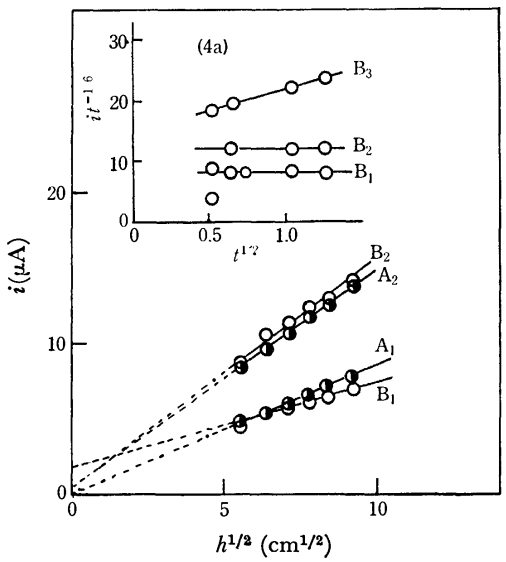

Fig. 4. Change of the limiting currents with the height of the mercury column in DMA solution.
Supporting electrolyte: A) Et_4NClO_4 and B) $CsClO_4$. Each in 0.05 M. Underscript 1, 2, and 3 mean the first, the second and the third wave. With the DME (A).

Fig. 4a. The relationship between $it^{-1/6}$ and $t^{1/2}$ in 0.05 M $CsClO_4$–DMA solution.

Figure 4 shows the relationship between the square root of mercury height and the limiting current of oxygen in tetraethylammonium perchlorate and cesium perchlorate as the supporting electrolyte. With tetraethylammonium ion, the first wave is diffusion-controlled, and the second wave may include a little kinetic current. With cesium ion as the supporting electrolyte, both the first and the second waves may include a little kinetic current. At the potential of the third wave, the drop time increased extraordinary, therefore in Fig. 4a, the values of $it^{-1/6}$ are plotted against $t^{1/2}$ using the mechanical drop time controller. Here, i is the limiting current in μA; t is the controlled drop time. For the first and the second waves, the values of $it^{-1/6}$ are almost independent of $t^{1/2}$, as is to be expected almost for the diffusion-controlled current, but a little kinetic current. For the third wave, however, the values of $it^{-1/6}$ increase with an increase of $t^{1/2}$, showing that a kinetic factor is involved. This conclusion agrees well with the results of AC polarograms and Cyclic voltammograms as the following mention.

With the addition of water in the solution of 0.05 M tetrahexylammonium perchlorate in DMA, the second wave of oxygen begins to appear. With the increase of the concentration of tetrahexylammonium perchlorate over 0.075 M, the second wave also begins to appear.

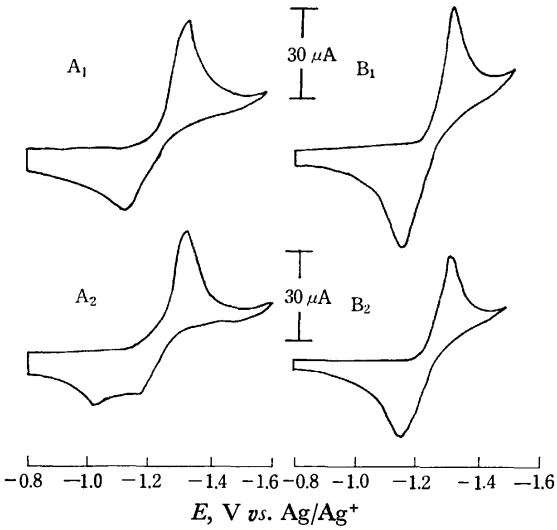

Fig. 5. Cyclic Voltammetry of oxygen in DMA solution.
Supporting electrolyte: A) $KClO_4$ and B) $CsClO_4$. Each in 0.05 M. Scan rate: 1, 100 mV/s and 2, 50 mV/s. Mercury drop is 0.1 μl.

Figure 5 demonstrates the cyclic polarograms of oxygen in the solutions of cesium perchlorate and potassium perchlorate.

When tetraethyl or tetrabuthylammonium perchlorate is used as the supporting electrolyte, electrode process of the first wave of oxygen is reversible, as has been studied already.[11] With alkali metal perchlorate as the supporting electrolyte, the process, however, is not fully reversible: Figure 5 shows that the anodic peak appears at fairly more positive potential than the cathodic peak.

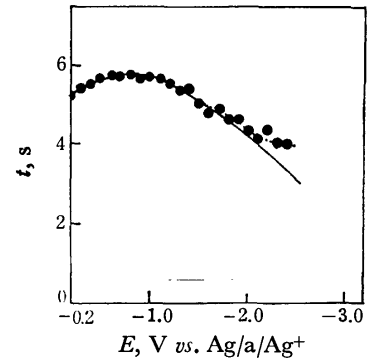

Fig. 6. Electrocapillary curve in 0.05 M $CsClO_4$–DMA solution.
—●— With O_2.
——— Without O_2. With the DME (A).

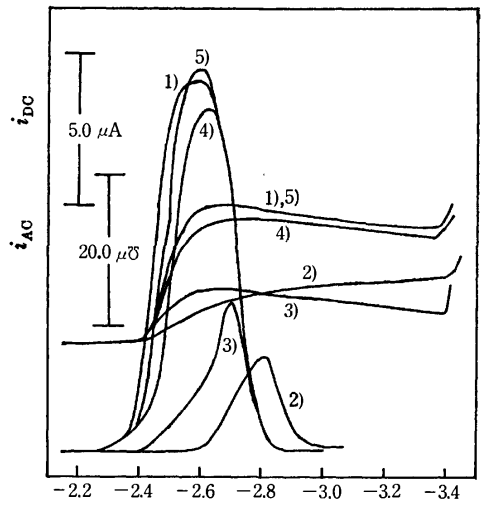

Fig. 7. Effect of oxygen on the reduction of 2.85 mM potassium ion in 0.05 M Bu_4NClO_4-DMA solution. 1) nitrogen gas bubbled to remove oxygen throughly 2) air-O_2 saturated, 3), 4), and 5) nitrogen gas bubbled for 5, 10, 30 s in 2) solution, respectively. Gas flow rate: 12.10 ml/s. With the DME (B).

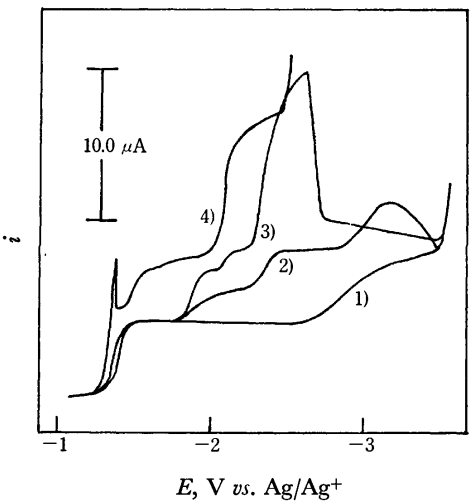

Fig. 8. Effect of the cesium ion on the reduction of oxygen in 0.05 M Bu_4NClO_4-DMA solution. Cesium perchlorate concentrations are; 1) 0, 2) 2.5 and 3) 5.0 mM. 4) is 0.05 M $CsClO_4$ solution. With the DME (B).

In the second and the third waves, no anodic peak appears probably because the seccessive chemical reactions will make the process irreversible.

Figure 6 shows the electrocapillary curves, in the presence and absence of oxygen in 0.05 M cesium perchlorate-DMA solution. In the figure, at a more negative potential than −2.0 V, the drop time is larger in the presence of oxygen than that in the absence. However, the difference can not be seen with the tetraalkylammonium ion as the supporting electrolyte.

Figure 7 shows that the reduction of alkali metal ion is disturbed by the presence of oxygen.

The third wave of oxygen appeared in the presence of alkali metal ion in the tetraalkylammonium ion solution (Fig. 8).

Reduction of the Dissolved Oxygen in HMPA or PC. The values of the half-wave potentials of oxygen in HMPA and in PC are tabulated in Table 2.

In HMPA, similar results to those in DMA are obtained. However, with 0.05 M sodium perchlorate, the second wave overlaps with the third wave which is accompanied by a maximum. With 0.05 M lithium perchlorate, the second wave can be seen. The dependence of negative shift of each waves upon the size

Subscripts of 1, 2, and 3 mean the first, the second and the third wave, respectively. Concentration of the supporting electrolyte is 0.05 M. a); Ref. 9) and 12). b); Measurements are difficult. c); With the controlled drop time 0.40 s used in Fig. 10.

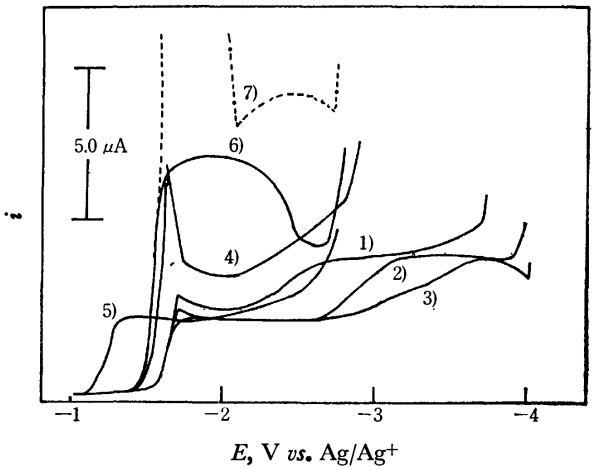

Fig. 9. Polarograms of dissolved oxygen in PC solution. Supporting electrolyte; 1) Et_4NClO_4, 2) Bu_4NClO_4, 3) Hex_4NClO_4, 4) TDDMB-perchlorate, 5) $LiClO_4$, 6) $RbClO_4$ and 7) $CsClO_4$. Each in 0.05 M.

of the cation is more remarkable in HMPA than that in DMA.

In PC, generally oxygen is more easily reduced than in DMA or HMPA. (See the values of half-wave potentials referred to the reduction potential of rubidium ion in Tables 1 and 2). The typical results are shown in Fig. 9. Even in 0.05 M tetrahexylammonium ion as the supporting electrolyte, oxygen gave two waves. With alkali metal ion such as cesium or rubidium ion as the supporting electrolyte, the reduction products of oxygen react with them more strongly in PC than in DMA or HMPA. At the potential of the first wave, the strong adsorption of the reaction product occurrs and the drop time becomes 1.3 times larger than that with tetraalkylammonium ion. If polarograms are measured by controlling the drop time of the DME to be very short (0.40 s) using a mechanical drop time controller, well-defined two waves appear. (Fig. 10)

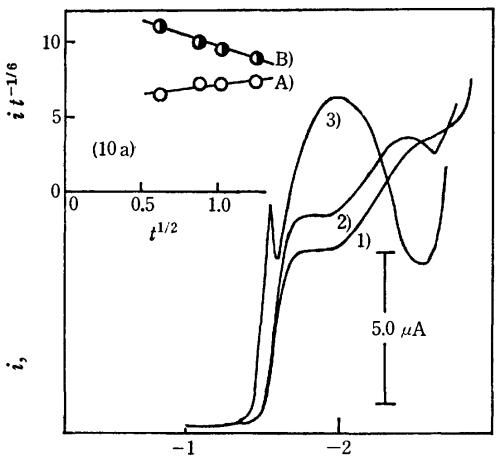

Fig. 10. Polarograms of dissolved oxygen in 0.05 M $RbClO_4$-PC solution. Using the controlled drop time: 1) $t=0.40$, 2) $t=0.80$ s and 3) natural drop time.

Fig. 10a. The relationship between $it^{-1/6}$ and $t^{1/2}$ of Fig. 10.
A) the first wave, B) the second wave

From Fig. 10a which shows the relationship between $it^{-1/6}$ and $t^{1/2}$, both the first and the second waves may be concluded to be kinetic in nature.

The most important determing factor influencing these waves is the degree of solvation of the supporting electrolyte cations in the solvents. The solvation is known to become stronger in the order: PC≪DMA< HMPA.

Discussion

When tetraalkylammonium perchlorate is used as the supporting electrolyte, molecular oxygen is carried to the electrode surface by diffusion and is reduced to the superoxide ion by one-electron process, followed by further one-electron reduction process to the peroxide ion. Complex formation between the anion radical and tetraalkylammonium cation influences the reduction potential of oxygen and the reversibility of the process. In the first wave, the process is reversible and diffusion-controlled and in the second wave, process is irreversible because of the presence of successive chemical reaction.

When alkali metal perchlorate is used instead as the supporting electrolyte, oxygen is reduced similarly as in the case of tetraalkylammonium perchlorate, but the superoxide, the reaction product of the first wave and the peroxide, that of the second wave, both react consecutively with alkali metal ions. Therefore, the first and the second waves appear as kinetic current. The fact that the reduction of alkali metal ion is disturbed by the presence of trace of oxygen (Fig. 7) also indicates the presence of the consecutive reaction between the oxygen anion radicals and the alkali metal ions.

Moreover, when sodium, potassium, rubidium and cesium perchlorates are used as the supporting electrolyte, a third new wave appears at the potential a little in advance to their final rise (the metal reduction); the reduction seemed to proceed by two electron process. (Fig. 2) The reduction process for the third wave may therefore be written as;

$$O_2^{2-} + 2e \rightleftarrows 2O^{2-}$$

From the behaviors of the third wave, which is extremely irreversible and kinetically controlled and from the facts that the third wave appears in the presence of alkali metal ions, it may be concluded that the following consecutive reaction may be taking place at the electrode solution interface;

$$O^{2-} + 2M^+ \longrightarrow M_2O$$

In the solution containing alkali metal ions, the drop time is remarkably increased by the presence of air. It is also due to the fact that chemical reaction between oxygen anion radical and alkali metal ion occurred in the electrical double layer or on the electrode surface strongly.

The chemical reactions mentioned above seem to correlate closely with the size of the solvated ions of the supporting electrolyte. In spite of a large radius

of TDDMB ion, however, the half-wave potential of oxygen is relatively positive in both HMPA and DMA. The presence of methyl groups may be responsible for the oxygen reduction at a relatively positive potential. (Figs. 3 and 3a).

Authors wish to thank Professors R. Takahashi at the Ritsumeikan University and A. Saito at the Kobe University for their kind offer of their polarographic instruments. Authors also appreciate the financial grant by the Ministry of Education in persuing the present research.

Characterization of the Oxalato Complex of Manganese(IV)[1]

Yukichi YOSHINO, Iwao TAMINAGA, Masakazu KOKISO, and Takashi UEHIRO

Department of Chemistry, College of General Education, The University of Tokyo, Meguro-ku, Tokyo 153

(Received November 30, 1973)

The preparation and analysis of the oxalato complex of manganese(IV), referred to as $K_2[Mn(OH)_2(C_2O_4)_2]\cdot 2H_2O$ by Cartledge and Ericks, were reexamined. Measurements of magnetic moment confirmed the unusually low value, 2.48 B.M. at room temperature. The infrared spectra of the complex suggest the presence of oxide bridges between manganese atoms. The electrical conductance of aqueous solution of the complex salt at 0 °C has been measured in various concentrations. The results indicate that the complex anion is dimeric both in solid and in solution. The electronic spectra of the complex in powder and solution states were measured, and some decomposition processes discussed. It was proposed that the complex should be formulated as a dimer with two oxide bridges, $[Mn_2O_2(C_2O_4)_4]^{4-}$.

The preparation and properties of oxalato complex of quadrivalent manganese were first reported by Cartledge and Ericks.[2] Grey measured the magnetic moment of the complex and obtained the value 2.79 B.M. at room temperature.[3] This is much smaller than the spin-only value 3.87 B.M. for an ion of d^3 configuration. However, no detailed explanation has been given so far.

The present paper describes some physico-chemical measurements involving magnetic susceptibility, infrared and diffuse reflectance spectra of the solid complex as well as the electrical conductivity and electronic spectra of aqueous solutions. The results obtained are consistent with formulation of the complex anion as a dimer with two oxide bridges.

Experimental

Preparation of the Complex. The original method of preparation by Cartledge and Ericks[2] was followed with a slight modification. To 0.14 mol of oxalic acid dihydrate dissolved in 250 ml of redistilled water at 0 °C was added 0.04 mol of powdered potassium permanganate and 0.026 mol of patassium oxalate. Under vigorous agitation, the reaction began to take place at 7 °C evolving carbon dioxide, when the reaction mixture was cooled quickly to 0 °C. When the reaction was complete, the solution was filtered through a cold glass filter, the filtrate being collected in a beaker placed in a freezing mixture. To the filtrate was added 70 ml of cold ethanol in portions, the temperature being kept at 0 °C. The precipitated crystals were filtered off rapidly and washed successively with ice-cold 50% ethanol, 99% ethanol and absolute ether. The green crystals thus obtained were dried *in vacuo* over silica gel in a dark refrigerator (−5 °C). Although Cartledge and Ericks reported that under a microscope the solid was a mixture of green and golden yellow crystals, we obtained only green crystals in all runs. Found: K, 21.72; Mn, 15.17; $C_2O_4^{2-}$, 49.10%; Oxid. equiv., 181.2. Calcd for $K_4[Mn_2O_2(C_2O_4)_4]\cdot 4H_2O$: K, 21.65; Mn, 15.21; $C_2O_4^{2-}$, 48.74%; Oxid. equiv., 180.5.

Potassium trioxalatomanganate (III) was prepared by the method of Cartledge and Ericks.[4] Potassium dioxalatomanganate(II) was obtained by the reaction of manganese(II) oxalate and potassium oxalate.

Magnetic Measurements. Magnetic measurements were carried out at room temperature with the usual Gouy apparatus. Temperature dependence of the magnetic susceptibility was measured by the Fonor method[5] with an apparatus constructed at the Cryogenic Center of the University of Tokyo. Magnetic measurement of the aqueous solution of the complex was carried out by the method of Russel *et al.*[6]

Electrical Conductances. These were measured with a Yokogawa model BV-Z-103B conductivity bridge and platinized platinum electrodes. Sample solutions were prepared with CO_2-free water of 0 °C just before each measurement. The cell was thermostated at 0 °C. The temperature equilibrium was attained after 10 min. No significant decomposition took place during the course of measurements.

Spectral Measurements. The infrared spectra were measured by Nujol and hexachloro-1,3-butadiene mull methods with a model 403G infrared spectrophotometer (Japan Spectroscopic Co.). The electronic spectra of the complex in both solution and powder states were measured with Hitachi EPS-2 and 124 spectrophotometers. Temperature was controlled by circulating ice-water through a cell compartment. In order to remove cloudiness from the cell walls, a nitrogen gas stream was passed to the surface of the cell.

Potentiometric Titration. A Toa Electronics Ltd. model HM-5A pH meter with an HP-105 bright platinum electrode and an HC-907 calomel reference electrode was employed.

X-ray Measurements. The X-ray powder patterns were taken with a Rigaku Denki Geigerflex diffractometer using Ni-filtered Cu-$K\alpha$ radiation. Relatively strong peaks were observed at lattice spacings d's(A): 8.58, 7.96, 7.19, 3.63 and 3.30, indicating that the solid sample is crystalline.

Results and Discussion

Magnetic Properties. The magnetic susceptibility of the oxalato complex of manganese(IV) at room temperature increases with the elapse of time. This change is accompanied by the decrease in mass and increase in oxidation equivalent. Thus magnetic measurements were carried out as soon as the samples were prepared. Although somewhat higher values were obtained in earlier runs, repeated preparation and measurement of the susceptibility gave the magnetic moment, $\mu_{eff}=2.48$ B.M. (15.5—18.0 °C), which is definitely much below the spin-only value (*i.e.*, 3.87 B.M.).

The dried complex salt is soluble to some extent in water at room temperature but rapidly decomposes to give a colloidal solution. In the presence of oxalate ions, however, the complex is fairly stable in a cold solution. Thus the magnetic susceptibilities of the complex in oxalate solutions were measured at 3 °C. Results: 2.8 B.M. for 4.94×10^{-3} M solution and 2.7 B.M. for 15.05×10^{-3} M solution.

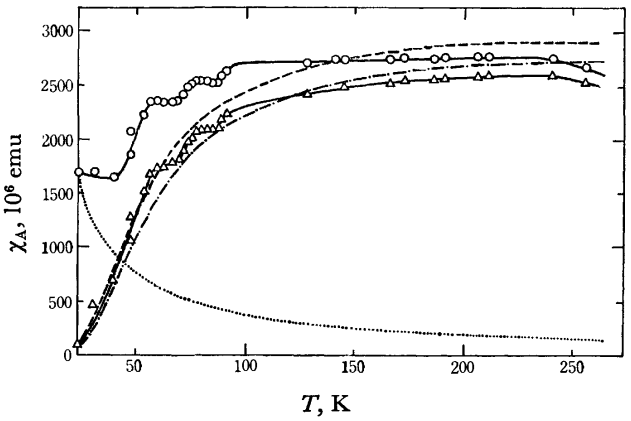

Fig. 1. Temperature dependence of magnetic susceptibility of the oxalato complex of manganese (IV).
—○—: experimental, —△—: experimental corrected for 1.9% Mn(III), ----; ·····: calculated for a binuclear cluster, $S_1=S_2=3/2$, $J=75$ "degrees" (-----) and $J=80$ "degrees" (-·-·-), $g=2.00$ and $N\alpha=0$, ····: 1.9% Mn(III) with $\mu=3.87$ B.M.

In order to clarify the nature of the sub-normal moment, the temperature dependence of the susceptibility was examined in the range 300—23 K. The results are given in Fig. 1. It should be noted that the magnetic behavior of the complex deviates significantly from the Curie-Weiss law; the susceptibility remains nearly constant over the temperature range 240—90 K, but decreases abruptly and stepwise below 90 K. This suggests that there exists a large antiferromagnetic interaction between manganese atoms. Curves calculated by assuming binuclear cluster with $S_1=S_2=3/2$, $g=2.00$, $J=80$ or 75 "degrees" and $N\alpha=0$ are shown in Fig. 1.[7] They might account qualitatively for the temperature independent susceptibility in the higher temperature range, the deviation becoming significant in the lower temperature range. It was found during the course of study on the decomposition of the complex that the reaction is initiated by a trace of manganese(III) and proceeds autocatalytically. Thus, it was assumed that the complex contains some paramagnetic manganese(III) impurities formed during the course of measurement. The experimental values corrected for 1.9% of manganese(III) are plotted in Fig. 1. The curve so obtained fits fairly well the calculated one with $J=75$ "degrees" in the lower temperature range (below 60 K). However, the reason for the stepwise decrease in the susceptibility in the range 90—60 K is not clear.

Infrared Spectra. Main absorption peaks of the IR spectrum of the manganese(IV) oxalato complex are given in Table 1. For the sake of comparison, the IR data for both Mn(III) and Mn(II) oxalato complexes are also given. Tentative assignments of the bands are based on the works of Fujita *et al.*[8,9]

The bands at 3000—3600 cm^{-1} are much broader than expected for hydroxide ion in a complex.[10] They were assigned to the stretching vibrations of O–H of the water molecule.

Only the manganese(IV) complex gives two characteristic bands in the region 600—700 cm^{-1} (Fig. 2).

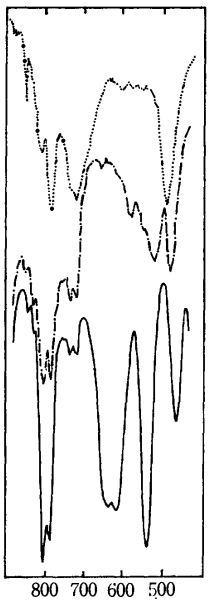

Fig. 2. IR spectra of oxalato complexes of manganese (in Nujol mulls).
——: $K_4[Mn_2O_2(C_2O_4)_4]\cdot 4H_2O$,
-·-·-: $K_3[Mn(C_2O_4)_3]\cdot 3H_2O$
····: $K_2[Mn(C_2O_4)_2]\cdot 2H_2O$

They might be assigned to the stretching modes of Mn_2O_2 bridges expected for binuclear complexes with two oxygen bridges.[11] It is noteworthy in this connection that the bands due to the bridging Mn–O bonds of poly, *catena*-oxo-*N*,*N*′-ethylenebis(salicylideneiminato)manganese(IV) appeared in the same region.[12]

The bond between manganese and oxygen of oxalato

ligand (ν(Mn-O)) becomes stronger as the oxidation state of manganese atom increases. Fujita *et al.* pointed out that, in oxalato complexes of divalent metals, a shift of the M–O stretching band to a higher frequency is accompanied by a shift of the antisymmetric C–O stretching frequency to a higher frequency together with a shift of symmetric C–O stretching band to a lower frequency.[8,9] An analogous relationship exists in the three oxalato complexes of manganese of different oxidation states (Fig. 3).

Electrical Conductance. The electrical conductance of the complex in aqueous solution at 0 °C was measured in the concentration range 10^{-3}—10^{-2} equivalent/l.

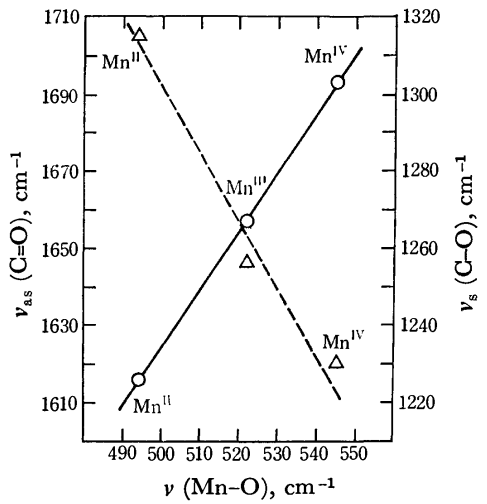

Fig. 3. Relationship between Mn–O stretching frequencies and C=O or C–O stretching frequencies of the oxalato complexes of manganese.
○: ν(C=O), △: ν(C–O).

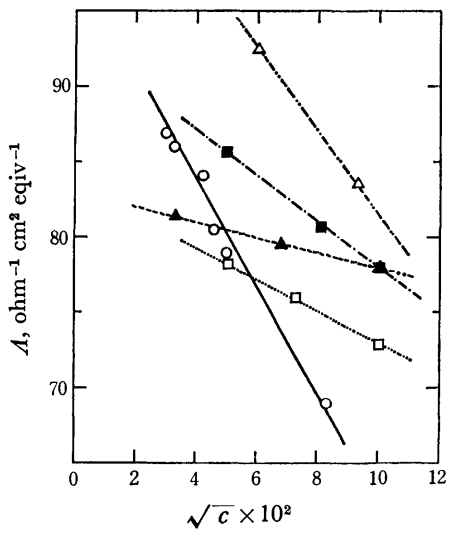

Fig. 4. Equivalent conductance (Λ, ohm^{-1} cm^2 equiv^{-1}) at 0 °C plotted against square root of concentrations (c, equiv/l) for the complex $K_4[Mn_2O_2(C_2O_4)_4]\cdot 4H_2O$ and for typical 1:1, 1:2, 1:3, and 1:4 electrolytes.
○: $K_4[Mn_2O_2(C_2O_4)_4]\cdot 4H_2O$, △: $K_4[Fe(CN)_6]$, ■: $K_3[Fe(CN)_6]$, □: K_2SO_4, ▲: KCl.

The equivalent conductance was plotted against the square root of the concentration (Fig. 4). For comparison, similar plots for salts of different valence types are also shown. The slope of the straight line for the oxalato complex resembles that for 4:1 electrolyte rather than for the 2:1 one.

Electronic Spectra. Cartledge and Ericks reported on the visible absorption spectrum of the complex in oxalic acid solution.[2] We measured the spectra in a wider range involving the ultraviolet region in cold oxalate solutions. The absorption bands tentatively assigned, assuming d^3 configuration in an octahedral ligand field, are listed in Table 2 together with those of the mononuclear complexes of the iso-electronic configuration. As is predicted from the spectrochemical series, the 10Dq ($^4A_{2g}\rightarrow {}^4T_{2g}(F)$) of the oxalato complex of manganese(IV) is larger than that of $[MnF_6]^{2-}$ or $[Cr(C_2O_4)_3]^{3-}$.[13] The second d-d transition peak ($^4A_{2g}\rightarrow {}^4T_{1g}$) may be concealed by a broad charge transfer or inner ligand transition band. The intensities of the spin-forbidden transitions are considerably higher than expected. This might be due to metal-metal antiferromagnetic coupling.[14]

Figure 5 shows a diffuse reflectance spectrum of the solid complex (a) and a spectrum of the complex in a cold oxalate solution in the region 8000—22000 cm^{-1} ((b), Curve I). They are similar in shape and their peak positions are almost the same. We might say that no significant decomposition of the complex takes place in a cold oxalate solution.

When a sample solution containing oxalate was brought to room temperature, the deep green solution turned brown and later changed into pink forming trioxalatomanganate(III) ion. The latter eventually decomposed to give manganese(II) complexes. These changes are clearly seen in the spectral features shown in Fig. 5. As the absorption maximum at 15000 cm^{-1}

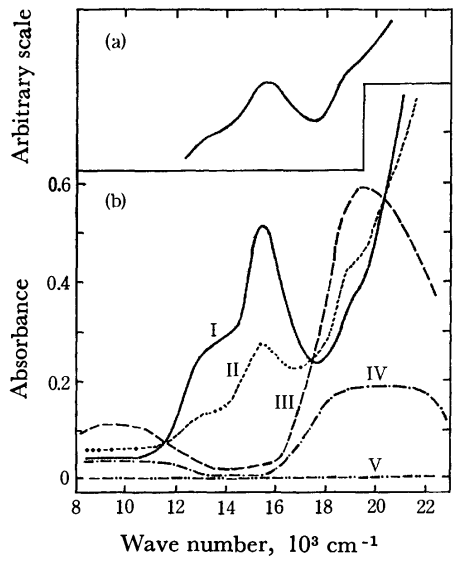

Fig. 5. Decomposition of the oxalato complex of manganese(IV) followed by spectral measurements.
(a) Diffuse reflectance spectrum of the solid complex.
(b) Time and temperature dependence of electronic spectra of the complex: 2.06×10^{-3} M in 0.1 M $Na_2C_2O_4$-$H_2C_2O_4$ solution (pH 4.9).
I: after 12 min, 4 °C, II: after 175 min, 5 °C, III: after 222 min, 18 °C, IV: after 239 min, 18 °C, V: after 12 hr, room temp.

decreases, the peak of trioxalatomanganate(III) at 19200 cm^{-1} increases in the initial stage. There appear three isosbestic points at 11800, 17300, and 20400 cm^{-1}. In connection with these changes, an attempt was made to follow the change in the magnetic susceptibility of manganese in 0.1 M oxalate solution (pH 4.9). Approximate values of the magnetic moment in 1.51×10^{-2} M (Mn) solution at 4—5 °C are as follows:

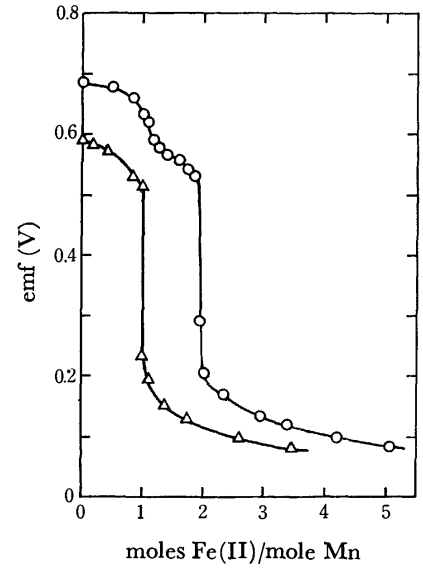

Fig. 6. Potentiometric titration of oxalato complexes of manganese (IV) and manganese (III) at 0 °C.
○: $K_4[Mn_2O_2(C_2O_4)_4]\cdot4H_2O$,
△: $K_3[Mn(C_2O_4)_3]\cdot3H_2O$.

color	: green	brown	red	colorless
μ_{eff} (B.M.):	2.7	3.6	4.6	5.7

These results also confirm the view that the manganese(IV) complex is reduced finally to manganese(II) *via* manganese(III).

Potentiometric Titration. A solution of the complex was titrated with iron(II) solution at low temperature. The result is illustrated in Fig. 6. For the sake of comparison, a titration curve of trioxalatomanganate(III) is also shown. The manganese(IV) complex gives two inflexion points corresponding to the steps, Mn(IV) to Mn(III) and Mn(III) to Mn(II). The standard redox potential, $E°$ for a couple, Mn(IV)-oxalato complex/$[Mn(C_2O_4)_4]^{3-}$ was evaluated as *ca.* 0.95 V (NHE) at 0 °C. This value agrees with that calculated from the literature.[15]

Plausible Formula of the Complex. For the oxalato complex of manganese(IV), Cartledge and Ericks presented a formula $K_2[Mn(OH)_2(C_2O_4)_2]\cdot2H_2O$ on the basis of chemical analysis. However, it seems difficult to explain all the above-mentioned behavior of the complex with this formula.

Although the exact nature of the sub-normal magnetic moment has not been clarified yet, there is hardly any doubt that an exchange interaction between manganese atoms bridged by oxygen atoms exists in the complex anion. The electrical conductance behavior and infrared spectra support a dimeric structure. In this connection, di-μ-oxo structure of tetrakis(bipyridine)-dimanganese(III, IV) complex determined by X-ray diffraction could be compared.[16] Taking into account the above results, we propose as a plausible formula of the oxalato complex of manganese(IV) the following:

$$K_4[(C_2O_4)_2Mn\begin{matrix}O\\O\end{matrix}Mn(C_2O_4)_2]\cdot4H_2O$$

The authors thank Messrs. Suguru Takayama and Kichizo Asai for magnetic measurements at low temperatures. They are also grateful to Dr. Akira Ouchi for a number of helpful discussions. A part of the expense of this study was defrayed by a Grant for Scientific Research of the Ministry of Education.

Reactions of π-Allylic Palladium(II) Complexes of Acetoacetate Esters with Pyridine and Its Derivatives

Shigeru BABA, Tamotsu SOBATA, Tetsuya OGURA, and Shinichi KAWAGUCHI*

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received January 18, 1974)

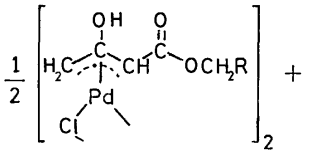
The π-allylic palladium(II) complexes of ethyl and benzyl acetoacetate esters react with pyridine and its derivatives to afford the terminal-carbon-bonded complexes $PdCl(CH_2COCH_2COOCH_2R)L_2$, where $R=CH_3$ or C_6H_5, and L=pyridine or its derivative. The NMR spectra unequivocally establish the bonding type in these complexes. The pyridine and 4-methylpyridine complexes are a mixture of *cis* and *trans* isomers in a ratio of 1:5, while 2-methyl- and 2,6-dimethyl-pyridine complexes are *trans* exclusively. The relative stabilities of these complexes are compared.

In a previous paper[1] we reported on the central-carbon-bonded palladium(II) complexes of acetylacetone obtained by the reactions of bis(acetylacetonato)-palladium(II) with triphenylphosphine or nitrogen bases such as pyridine, diethylamine and *N*-methylbenzylamine. This paper describes the preparation and characterization of the terminal-carbon-bonded palladium(II) complexes of acetoacetate esters.[2]

Results and Discussion

The π-allylic palladium(II) complex of ethyl acetoacetate, di-μ-chlorobis(π-1-ethoxycarbonyl-2-hydroxyallyl)dipalladium(II) [**1**] was prepared by the reaction of diketene with the tetrachloropalladate(II) in ethanol.[3] The corresponding complex of benzyl acetoacetate [**2**] was obtained by the reaction of diketene with dichlorobis(benzonitrile)palladium(II)in dichloromethane containing benzyl alcohol.

π-Allylic palladium(II) complexes of acetoacetate esters reacted with excess pyridine or its derivatives in benzene at room temperature to yield stable terminal-carbon-bonded complexes in high yields (82—95%).



$R=CH_3$ [**1**] or C_6H_5 [**2**]

$\longrightarrow PdCl(CH_2COCH_2COOCH_2R)L_2$ (i)

$R=CH_3$, L=py [**3a**] or 1/2(2,2′-bipy) [**3b**]
$R=C_6H_5$, L=py [**4a**], 2-Me-py [**4b**], 4-Me-py [**4c**], 2,6-Me_2-py [**4d**], or 1/2(2,2′-bipy) [**4e**]

Analytical data of the products are summarized in Table 1. The conversion of the π-allylic linkage of the acetoacetate ligand into the σ-bonding seems to be preceded by the bridge splitting reaction of the dimeric complex. A monomeric π-allylic complex [**5**] was isolated as yellow-green crystals in the reaction of the benzyl ester complex with an equivalent amount of pyridine.

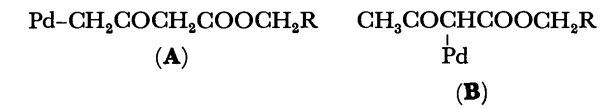
IR Spectra. The IR spectra of the parent π-allylic complexes **1** and **2** have the ν(OH) and ν(C=O) bands at around 3200 and 1670 cm^{-1}, respectively. On the other hand, the product complexes **3** and **4** show no absorption band around 3200 cm^{-1}, but exhibit two strong ν(C=O) vibrations at around 1730 and 1640 cm^{-1} (Table 2). This demonstrates that the π-allylic linkage of the enolate anion of acetoacetate esters was converted into the σ-carbon-bonding of the ketonic tautomer.

Two modes of linkage can be considered for the unidentate carbon-bonding of the acetoacetate ester to palladium(II), terminal-carbon-bonding (**A**) and central-carbon-bonding (**B**).



Structure **B** was realized in the case of acetylacetone, and the ν(C=O) vibrations of the central-carbon-bonded ligand causes absorption at 1665 and 1632 cm^{-1}.[1] If this were also the case for the acetoacetate-ester ligand, the ν(C=O) bands should appear in the 1600—

Table 2. Characteristic IR bands (cm^{-1}) in Nujol[a)]

a) vs: very strong, s: strong, m: medium, w: weak, sh: shoulder. b) Y=$CH_2COCH_2COOCH_2CH_3$, Y′=CH_2-$COCH_2COOCH_2C_6H_5$ c) π-allylic skeletal deformation

1700 cm^{-1} region. Contrary to expectation, the IR spectra of compounds **3** and **4** showed a ν(C=O) band in the 1600—1700 cm^{-1} region and another one in the frequency region higher than 1700 cm^{-1}. The spectra can be interpreted satisfactorily on the basis of structure **A**.

The ν(C=O) vibrations of the keto tautomer of free acetylacetone cause absorption at 1727 and 1707 cm^{-1},[4)] but shift towards the lower frequency region (1665 and 1632 cm^{-1}) by ligation to the palladium atom *via* the central carbon atom.[1)] When the acetoacetate-ester ligand coordinates to the palladium atom *via* the terminal carbon atom, the ν(C=O) band due to the ketonic carbonyl group should shift towards the lower frequency side to an extent similar to that in the case of central-carbon ligation. On the other hand, the ester carbonyl group is situated far from the metal atom and is far less influenced by coordination. Thus, of the two observed ν(C=O) bands of compounds **3** and **4**, the lower frequency band is assigned to the ketonic carbonyl group and the higher frequency one to the ester carbonyl group.

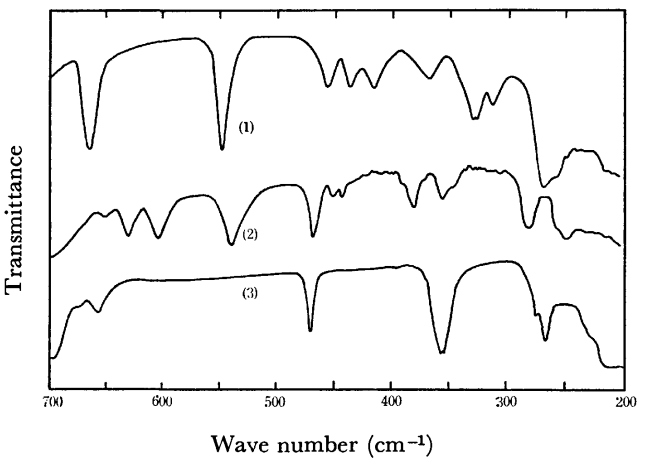

Fig. 1. The IR spectra in the 700—200 cm^{-1} region of the π-allylic palladium(II) complex dimer of ethyl acetoacetate (curve 1), PdCl($CH_2COCH_2COOC_2H_5$)-$(py)_2$ (curve 2) and *trans*-$PdCl_2(py)_2$ (curve 3) in Nujol mull.

For the sake of comparison the IR spectrum of the carbon-bonded bis(pyridine) complex **3a** in the 700—200 cm^{-1} region is shown together with spectra of the parent π-allylic complex **1** and *trans*-$PdCl_2(py)_2$ in Fig. 1. The spectrum of complex **1** is readily interpreted by reference to the metal isotope effect reported by Shobatake and Nakamoto[5)] on the metal-ligand vibrations in π-allyl complexes of palladium(II). Thus the strong band at 548 cm^{-1} (curve 1) corresponds to the 512 cm^{-1} peak in $[PdCl(C_3H_5)]_2$ and is assigned to the CCC bending mode. The three-peaks pattern in the 460—410 cm^{-1} region resembles that of the latter compound in the 410—350 cm^{-1} region, and is ascribed to ν(Pd-allyl) vibrations. The strongest peak at 270 cm^{-1} accompanied by a shoulder at 255 cm^{-1} is similarly attributed to the bridging Pd-Cl stretching vibrations. These assignments are also consistent with those of Adams and Squire[6)] for $[PdCl(C_3H_5)]_2$. Neither a strong peak at 665 cm^{-1} nor bands in the 370—310 cm^{-1} region are observed for $[PdCl(C_3H_5)]_2$. These are considered to be due to the ligand vibrations.

The spectrum of *trans*-$PdCl_2(py)_2$ is very simple (curve 3, Fig. 1). The bands observed at 357 and 268 cm^{-1} are assigned to the ν(Pd–Cl) and ν(Pd–N) vibrations, respectively. Pfeffer *et al.*[7)] observed the ν(Pd–Cl) bands at 358, 356, and 373 cm^{-1}, and the ν(Pd–N) bands at 278, 302, and 306 cm^{-1} for *trans*-$PdCl_2L_2$ with pyridine, 4-methylpyridine and 4-ethylpyridine as L, respectively. Norbury and Sinha also observed the ν(Pd–Cl) bands at 360 and 359 cm^{-1} for *trans*-$PdCl_2(AsPh_3)_2$ and *trans*-$PdCl_2(PPh_3)_2$, respectively.[8)]

The spectrum of PdCl($CH_2COCH_2COOC_2H_5$)$(py)_2$ [**3**] (curve 2, Fig. 1) is much more complicated than that for *trans*-$PdCl_2(py)_2$ (curve 3). As is revealed by the NMR spectra, the compound is a mixture of *cis* and *trans* isomers in a ratio *ca.* 1 : 5. The strong band at 283 cm^{-1} is assigned to the stretching vibration of the Pd–Cl bond *trans* to the alkyl ligand, since the possibility of chloride bridging is excluded by analytical and molecular-weight data (Table 1). The strong *trans*-influence of the alkyl ligand is well-known[9)]. Another band (355 cm^{-1}) and a shoulder (347 cm^{-1}) in the terminal ν(Pd–Cl) region might be ascribed to the ν(Pd–Cl) vibration in the *cis* isomer. The broad band of medium intensity at 250 cm^{-1} is assigned to the ν(Pd–N) vibration. The frequency is a little lower than 268 cm^{-1} in *trans*-$PdCl_2(py)_2$.

Three bands are observed in the 640—500 region where *trans*-$PdCl_2(py)_2$ has no absorption. The strong peak at 540 cm^{-1} is assigned to the ν(Pd–C) vibration. In recent years an increasing number of palladium(II) complexes containing the Pd–C linkage have been reported, but data of the ν(Pd–C) vibration are rather

Table 3. NMR data for methylene protons in the terminal-carbon-bonded palladium(II) complexes of acetoacetate esters[a]

Complex[b]	$CH_2^{(a)}$		$CH_2^{(b)}$		$CH_2^{(c)}$

PdClY'(bipy) [**4e**]		7.13		5.96		4.83

a) Chemical shift (τ) recorded at 60 MHz in $CDCl_3$ with Me_4Si as the internal reference. Signals are singlet unless otherwise stated. b) $Y=CH_2^{(a)}COCH_2^{(b)}COOCH_2^{(c)}CH_3$, $Y'=CH_2^{(a)}COCH_2^{(b)}COOCH_2^{(c)}C_6H_5$. c) Quartet, $J=7$ Hz.

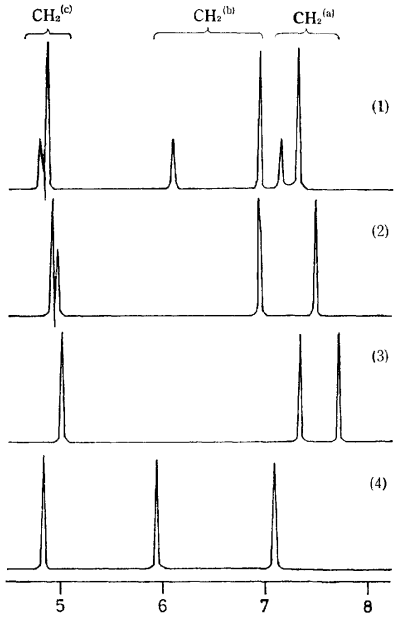

Fig. 2. The NMR spectra of $PdCl(CH_2^{(a)}COCH_2^{(b)}COOCH_2^{(c)}C_6H_5)L_2$ in the methylene signal region recorded at 60 MHz with TMS as an internal reference in $CDCl_3$: L=py (curve 1), 2-Me-py (curve 2), 2,6-Me_2-py (curve 3), or 1/2 (2,2'-bipy) (curve 4).

scarce. The ν(Pd-C) bands in the Pd(2,4-pentanedionato-O,O')(2,4-pentanedionato-C^3)L complexes were observed at 540, 524, 519, and 518 cm^{-1} for L= PPh_3, py, $NHEt_2$, and $NH(Me)CH_2Ph$, respectively.[1] Dietl *et al.* reported that the peak at 487 or 530 cm^{-1} is assigned to the ν(Pd-C) vibration in $[PdCl_2(C_2Me_2)_3]_2$.[10] Other bands appearing in the 700—600 and 500—370 cm^{-1} regions seem to be due to ligand vibrations (curve 2, Fig. 1).

Characteristic IR bands of each of the terminal-carbon-bonded palladium(II) complexes of acetoacetate esters were assigned in a similar way and are given in Table 2.

NMR Spectra. The NMR spectra of products **3** and **4**, summarized in Table 3, unequivocally establish structure **A**. A spectrum of the benzyl ester complex **4e** involving 2,2'-bipyridine as a base exhibits three singlet peaks of equal intensity at 7.13, 5.96, and 4.83 τ (Fig. 2). These are assigned to the three methylene groups; the nearest to palladium, the central and the benzyl methylenes, respectively.

Geometrical isomerism is possible in the case of complexes containing unidentate ligands, both *cis* and *trans* isomers being formed, but not in the case of 2,2'-bipyridine complexes. The spectrum of the pyridine complex **4a** involves two sets of methylene signals. Chemical shifts of the three minor peaks are close to those of the methylene signals of the 2,2'-bipyridine complex **4e**, suggesting that they are attributable to the *cis* isomer of **4a**. The other set of stronger peaks are thus assigned to the *trans* isomer. The intensity ratio of the *trans* and *cis* peaks is nearly equal for each of the three methylene signal pairs amounting to *ca.* 5:1. Isomerization of palladium(II) complexes is usually slow in the absence of free ligands,[11] and the observed figure reflects the relative yield of the two isomers in reaction (i). A single crystal of compound **4a** submitted for X-ray analysis was composed of *cis* molecules.[12]

The same situation was also observed for the 4-methylpyridine complex **4c**. Only three methylene signals, however, were observed for the 2,6-dimethylpyridine complex **4d**. Their chemical shifts are higher than those for the *trans* isomer of the pyridine complex **4a**. Thus it seems reasonable to consider that the *trans* isomer was yielded exclusively in the case of the bis-(2,6-dimethylpyridine) complex, since the *cis* isomer is quite unfavorable because of the steric hindrance of the methyl substituents. The methyl proton signal of the coordinated 2,6-dimethylpyridine is observed as a sharp singlet at 6.62 τ, shifting towards the down-field side by *ca.* 1 τ on ligation. The free ligand added to this solution causes absorption at 7.48 τ, indicating no sign of the ligand exchange.

The spectrum of the 2-methylpyridine complex **4b** exhibits a different pattern. The two peaks observed at 7.48 and 6.93 τ are assigned to the $CH_2^{(a)}$ and $CH_2^{(b)}$ protons, indicating that the complex has the *trans* configuration just as in the case of the 2,6-dimethylpyridine complex. The benzyl methylene protons are observed as two separate peaks at 4.93 and 4.88 τ in the area ratio 3:7. A slight splitting of the $CH_2^{(b)}$ signal can be seen in the 100 MHz spectrum. In the case of the corresponding 2-ethylpyridine complex, the $CH_2^{(b)}$ protons afford two distinct peaks; the area ratio for $CH_2^{(b)}$ signals at 7.00 and 6.95 τ and that for $CH_2^{(c)}$ signals at 4.96 and 4.88 τ are both 3:7. Since the $CH_2^{(a)}$ signal shows no splitting in either case, these features do not suggest the coexistence of *cis* isomers, but seem to indicate that the $CH_2^{(c)}$ and even $CH_2^{(b)}$ protons can occupy two non-equivalent positions.

Splitting of the $CH_2^{(c)}$ and $CH_2^{(b)}$ proton signals is not observed for complexes of symmetric bases such as pyridine, 4-methyl- and 2,6-dimethyl-pyridines, but appears only in the spectra of unsymmetrically 2-substituted pyridine complexes. Steric hindrance for the free rotation of 2-substituted pyridine ligands about the M–N bond in palladium(II)[13] and platinum(II)[14]

complexes has been well documented by studies of variable-temperature NMR spectra. For the present 2-methylpyridine complex **4b** also locked structures might be assumed in which the pyridine rings are fixed perpendicular to the coordination plane of palladium(II). Two conformations are considered; (a) methyl groups of the two 2-methylpyridine ligands exist on the same side of the coordination plane (syn), and (b) they lie on the opposite sides of the square plane (anti). The spectrum of $PdCl(CH_2COCH_2COOCH_2Ph)(2\text{-Et-py})_2$ exhibits a multiplet centered at 8.5 τ which is slightly more complicated than a double-triplet, and another multiplet (nearly double-quartet) at 6.34 τ. These resonances are assigned to the methyl and methylene protons of the ethyl group attached to pyridine, respectively, and seem to disclose the coexistence of the locked syn and anti structures.

Splitting of the $CH_2^{(c)}$ and $CH_2^{(b)}$ proton signals of the 2-alkylpyridine complexes might be related to such a relative conformation of the two pyridine ligands, although the exact locked structure of the dangling benzyl ester ligand is not certain. The reason why the $CH_2^{(a)}$ protons give a single resonance is not clear either, but the rotation of the ester ligand about the Pd–C bond might equal the averaged magnetic circumstances of $CH_2^{(a)}$ protons in the syn and anti configurations.

Substitution of Pyridine Ligands with Other Pyridines. In order to find the relative stability of the complexes containing various pyridine derivatives, substitution of the pyridine ligands with other pyridines was examined. Qualitative results were obtained by substitution reactions for several hours at room temperature, and reveal some interesting features (Table 4).

Table 4. Substitution of pyridine ligands L in $PdCl(CH_2COCH_2COOCH_2C_6H_5)L_2$ with other pyridine derivatives L′ in dichloromethane at room temperature[a)]

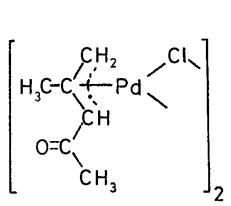
L′ \ L =	py	2-Me-py	4-Me-py	2,6-Me_2-py	bipy
py	—	○	○	×	×
2-Me-py	○	—	○	×	×
4-Me-py	○	○	—	×	×
2,6-Me_2-py	×	×	×	—	×
bipy	○	○	○	○	—

a) ○ indicates the replacement of the ligand L by L′. × indicates no reaction, the starting complex being recovered.

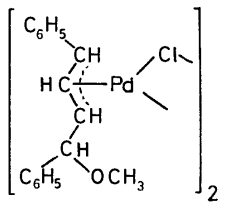
Unsubstituted, 2-methyl-, and 4-methyl-pyridines show similar behavior, being interchangable with each other. The bis(2,6-dimethylpyridine)-complex is very stable, the ligand not being displaced by the other unidentate pyridines. The inertness for substitution reactions can be ascribed to steric shielding of the metal atom by the *ortho*-substituents in the pyridine ligand. On the other hand 2,6-dimethylpyridine is very weak as an attacking nucleophile. It can not substitute any pyridine ligand coordinated to palladium(II). The *ortho*-substituents might retard the nitrogen atom to approach the metal atom. 2,2′-Bipyridine is the most powerful ligand. It can displace any unidentate pyridines in the coordination sphere; once it is bonded to palladium(II), it is not replaced by any unidentate pyridines. Such extraordinary stability must be due to the chelate effect.

Supplementary Discussion. The currently favored mechanism for the syn-anti isomerization in π-allyl complexes involves a σ-bonded intermediate.[15)] π-Allylpalladium(II) complexes have also been widely suggested as intermediates in various catalytic reactions.[16)] The conversion of π-allyl into σ-allyl can usually be detected by NMR-spectral observations. Only a few reports have appeared on the isolated σ-allyl palladium(II) compounds.[17)]

In the present reactions the starting π-allylic complexes gave stable σ-alkyl palladium(II) compounds. However, the σ-2-hydroxyallyl moiety was not retained, but the accompanying tautomeric transformation caused the terminal-carbon-bonded acetoacetate-ester complexes. Similar π-allyl complexes **6**[18,19)] and **7**[20)] react with bases such as pyridine and triphenylphosphine to afford monomeric complexes, but the σ-allylic complexes are not stable enough to be isolated. These results suggest that the neighboring carbonyl group plays some role of stabilizing the σ-carbon bonding.



[6]



[7]

Both the chelating acetylacetonate ligand and π-allylic acetoacetate-ester ligand can be converted into the σ-carbon bonding to palladium(II). However, the former prefers central carbon bonding, and the latter terminal-carbon bonding. This might be due to certain electronic and/or steric factors. The terminal-carbon bonding of a β-dicarbonyl compound to a transition metal has not yet been reported, but $TeCl_2(acac)_2$, obtained as a by-product in the reaction of tellurium(IV) chloride with acetylacetone, was found to be of such a bonding type.[21)] In contrast to the present palladium(II) complex, the acetylacetonate ligand in this tellurium(IV) complex has the enol (hydrogen chelate) form.

Experimental

π-Allylic Palladium(II) Complexes of Acetoacetate Esters. The ethyl acetoacetate complex, di-μ-chlorobis(π-1-ethoxycarbonyl-2-hydroxyallyl)dipalladium(II) [**1**] was synthesized according to Tezuka *et al.*[3)] The corresponding benzyl acetoacetate complex, di-μ-chlorobis(π-1-benzyloxycarbonyl-2-hydroxyallyl)dipalladium(II) [**2**] was prepared by adding diketene dropwise to a dichloromethane solution (12 ml) of dichlorobis(benzonitrile)palladium(II) containing 2 ml of benzyl alcohol at 0 °C. Dark red color of the solution faded gradually and a yellow precipitate appeared in 10—20 min. The product was filtered and washed repeatedly with petroleum ether. Yield: 0.67 g, 81%. Found: C, 39.55; H, 3.40%. Calcd for $C_{11}H_{11}O_3ClPd$: C, 39.66; H, 3.32%.

Tetrahydrofuran and dichloromethane are suitable solvents for recrystallization. Crude products were used without recrystallization in the following reactions.

Reaction of π-Allylic Palladium(II) Complexes of Acetoacetate Ester **1** *and* **2** *with Pyridine or Its Derivatives.* Pyridine (2—3 ml) was added with stirring to a suspension of the ethyl ester compex (0.7 g) in benzene (10 ml). The mixture turned immediately to a clear yellow-green solution. Petroleum ether was added to this solution to separate the precipitate. Yield: 1.0 g, 91%. The product was dissolved in dichloromethane and recrystallized by addition of petroleum ether. The other reaction of π-allylic palladium(II) complexes of acetoacetate esters with pyridine derivative were performed in a similar way, affording the following yields: **3b**, 82%; **4a**, 82%; **4b**, 84%; **4c**, 96%; **4d**, 94%; **4e**, 95%.

The monomeric intermediate chloro(pyridine) (π-1-benzyloxycarbonyl-2-hydroxyallyl)palladium(II) [**5**] was isolated in the following way. Pyridine (0.043 g, 0.54 mmol) was added to a suspension of the starting benzyl-ester complex **2** (0.177 g, 0.53 mmol) in dichloromethane. The resulting clear solution was evaporated to dryness, and the residue was extracted with benzene to remove the final carbon-bonded product **4a**. The remaining residue was then extracted with dichloromethane to obtain the π-allylic monomer **5** in a 45% yield. Found: C, 46.21; H, 3.50; N, 3.30%. Calcd for $C_{16}H_{16}NO_3ClPd$: C, 46.62; H, 3.91; N, 3.39%. Molecular weight could not be determined, since **5** was unstable in solution and readily disproportionated into the dimeric parent complex **2** and the final carbon-bonded bis(pyridine) complex **4a**.

Substitution of Pyridine Ligands with Other Pyridines. To a solution of each complex in dichloromethane, an excess amount of another free ligand was added and allowed to react for 3—4 hr. Petroleum ether was then added to this solution to separate the palladium(II) complex, which was identified by the IR assay.

Measurements. Infrared spectra were measured with JASCO IR-E (4000—600 cm^{-1}) and Hitachi grating EPI-L spectrophotometers. The NMR spectra were recorded at 60 MHz with tetramethylsilane as an internal reference on JEOL C60-HL and PS-100 spectrometers. The molecular weight was determined in dichloromethane at 25 °C by means of vapor pressure osmometry with an apparatus manufactured by Knauer, Germany.

The authors are grateful to Mr. J. Gohda and Miss M. Iwao for the elemental analyses and NMR measurements. Financial aid by the Ministry of Education and supply of diketene by Daicel Co., Ltd. are gratefully acknowledged.

Stereoselectivity in the Formation of Oxalato-L-aspartato-ethylenediaminecobalt(III) Complex[1]

Mitsuaki TAKEUCHI and Muraji SHIBATA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920

(Received March 25, 1974)

The complex [Co(ox)(L-aspH)(en)] has been prepared by the reaction of the dioxalatoethylenediaminecobalt-(III) complex with L-aspartic acid and separated into four diastereoisomers by means of ion-exchange chromatography: *mer*-Δ-, *mer*-Λ- and *fac*-Δ-[Coox(L-aspH)en]·H_2O, and *fac*-Λ-[Coox(L-aspH)en]·$2.5H_2O$. They were characterized by their absorption, CD and PMR spectra. Stereoselectivity has been found in the *mer*-Δ and *fac*-Λ isomers with degrees exceeding 80%. Related isomeric complexes containing L-glutamate or L-leucinate ion in place of L-aspartate have also been investigated, much less selectivity (~60%) being observed.

In order to study stereoselectivity we examined the mixed L-aspartato complexes with glycine,[2] L-alanine,[3] and L-proline.[4] It was found that the stereoselectivity observed can be explained in terms of the interaction between the uncoordinated β-carboxylate group in the chelated aspartate ion and the adjacent ligand.

In the present work, a mixed complex consisting of L-aspartate ion (L-asp), oxalate ion and ethylenediamine was chosen in order to obtain proof for the selectivity. The *mer* isomers of the mixed aminoacidato complexes used in the previous works consisted of three geometrical isomers. The present complex gives only one form for either *mer* or *fac* arrangement with respect to donor N (or O) atoms. Thus, the study on stereoselectivity could be simplified. For the sake of comparison the corresponding L-glutamato and L-leucinato complexes were also studied.

Experimental

Preparation. Preparation and chromatographic separation of the [Coox(L-asp)en]$^-$ complex were carried out as follows: The complex Na[Co(ox)$_2$en]·H_2O[5] (6.7 g, 0.02 mol), L-aspartic acid (2.7 g, 0.02 mol) and NaOH (0.8 g, 0.02 mol) were dissolved in water (250 ml). After the pH of the solution had been adjusted to *ca.* 9.0 with a NaOH solution, activated charcoal (1.0 g) was added and the mixture was allowed to stand for a week at room temperature (~15 °C) with occasional stirring, whereupon the solution turned red-violet. After the removal of a small amount of the precipitate and charcoal by filtration, a portion (50 ml) of the filtrate was charged on a cation-exchange column containing 100—200 mesh Dowex 50 W×8 resin in H-form (7.0×27 cm). Chromatographic separation was carried out by passing water at a rate of *ca.* 0.5 ml/min. The foremost band was of unreacted [Co(ox)$_2$en]$^-$ species. After a while two closely spaced but completely separated violet bands descended the column, followed by other two red bands with a narrow distance. These were collected in fractions and labeled from A-1 to A-4. This separation procedure was repeated several times in order to store up the same fractions. Each stored fraction was concentrated to a small volume with a rotary evaporator at 30 °C. The concentrated solution thus obtained was kept in a refrigerator for a few days in order to precipitate the desired isomer as its hydrogen compound. Each recrystallization was performed from water.

Such complexes as [Coox(en)$_2$]$^+$, [Co(L-asp)(en)$_2$]$^+$[6,7] and [Co(L-asp)$_2$(en)]$^-$[7] were also produced, but they remained at the top of the column during the separation of the desired isomers.

Preparation and chromatographic separation of the [Coox-(L-glu)en]$^-$ complex were carried out as in the case of the aspartato complex; L-glutamic acid (2.9 g, 0.02 mol) was used.

Chromatographic separation gave two bands, violet and red. They were collected in fractions and labeled G-1 and G-2. A pair of diastereoisomers could be isolated by fractional crystallization from G-1. Another pair of diastereoisomers was obtained from G-2 by the following procedure. The solid material (100 mg) obtained by evaporating the fraction was dissolved in a minimum amount of water slightly alkalinized with aqueous NaOH, the pH of the solution being made *ca.* 7.0. The solution was poured into a column containing G-15 Sephadex (2×100 cm), and washing with water was continued at a rate of *ca.* 0.07 ml/min. The red band spread with the elapse of time. After several hours, there appeared a broadened band having different tones of color in the first and second halves. The band was collected in a number of fractions and subjected to CD measurement. The first half showed a (−) sign and the second a (+) sign at the main CD peak. The chromatographic separation was repeated several times in order to store up the fractions with the same sign. The same fractions collected were concentrated and rechromatographed. From the final two fractions thus obtained a pair of diastereoisomers was obtained by evaporating and acidifying with 6 M HCl.

For preparation and separation of the [Coox(L-leu)en] complex, L-leucine (2.6 g, 0.02 mol) and Dowex 50 W×8 resin in Na-form were used. The procedure was the same as in the case of the L-aspartato complex. The chromatographic separation gave three bands violet, red and red in turn. They were collected in fractions labeled L-1, L-2 and L-3. From L-1 a pair of diastereoisomers was obtained by fractional crystallization. Each of the other diastereoisomers was obtained from L-2 and L-3 each.

For all diastereoisomeric complexes, recrystallization was carried out until their main CD peaks became constant.

Formation Ratios. The formation ratios between the bands separated chromatographically were evaluated from the spectral data of the isolated complexes.

Measurements. The absorption spectra were measured with a Hitachi Model 323 Recording Spectrophotometer. The circular dichroism spectra were recorded on a JASCO Model ORD/UV-5 spectropolarimeter. The proton magnetic resonance spectra were recorded on a JEOL JNM-PS-100 NMR spectrometer at *ca.* 22 °C, with deuterium oxide as a solvent. Sodium carbonate and 20% deuterium chloride in D_2O were used for pD adjustment. The values of the chemical shifts were referred to internal sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) or sodium D_4-trimethylsilylpropionate (TMSP). The pD of the PMR sample was measured with a Beckman Model G pH meter.

Results and Discussion

Characterization of Isomers. Elemental analyses, absorption spectra and CD spectra are summarized in Table 1. The geometrical form (*mer* or *fac*) of each isolated compound could easily be identified by its absorption spectrum. The absolute configuration (*Δ* or *Λ*) of a given geometrical isomer was determined from the sign of main CD peak. The CD spectra of the isolated compounds are shown in Figs. 1 and 2. The four possible isomers of the [Coox(L-aminoacidate)-en]-type complex are given in Fig. 3.

The chromatographic separation of the L-aspartato complex into the four isomers was carried out with the cation-exchange resin in H-form. In the beginning, an anion-exchange resin in Cl-form was used for the separation of anionic species $[Coox(L\text{-}asp)en]^-$. An extremely long column was necessary since washing procedure gave a diffuse band on the column and successive elution with an aqueous solution of electrolyte made each band spread considerably. In contrast, complete separation of the four isomers was achieved by the use of the cation-exchanger in a short period of elution. For example, elution for two weeks on an anion-exchanger column could be reduced to two days on a cation-exchange column. This improved procedure was used for the separation of the L-glutamato complex species.

In the case of the L-aspartato complex, four isomers were completely separated in the order *mer-Δ-mer-Λ-*

···· *mer*-Δ (L-leu)

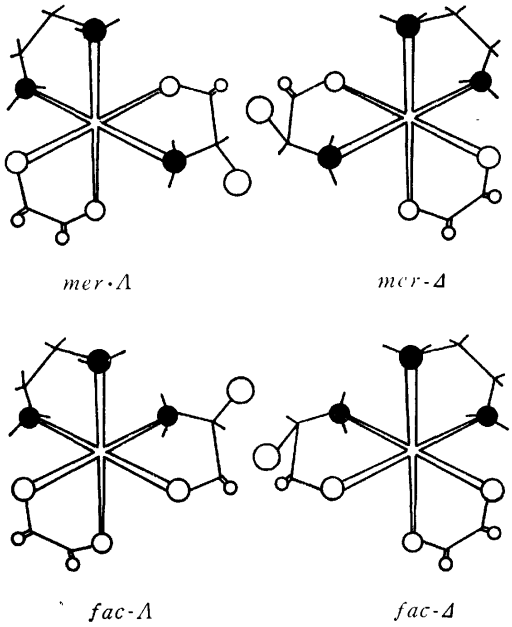

Fig. 3. Possible four isomers of [Coox(L-am)en]-type complex.

fac-Λ-*fac*-Δ, while for the L-glutamato complex only two fractions corresponding to *mer*- and *fac*-forms were obtained. This might be due to the different uncoordinated carboxylate groups (β- and γ-COO^-).

The CD spectra of the Δ and Λ diastereoisomers of *fac*-form exhibit a sharp peak in the first absorption band region (Fig. 1), similar to those of the tris-type complexes of L-amino acids.[4,8,9] On the other hand, the spectra of the Δ and Λ diastereoisomers of *mer*-form exhibit two peaks with the same signs in the first

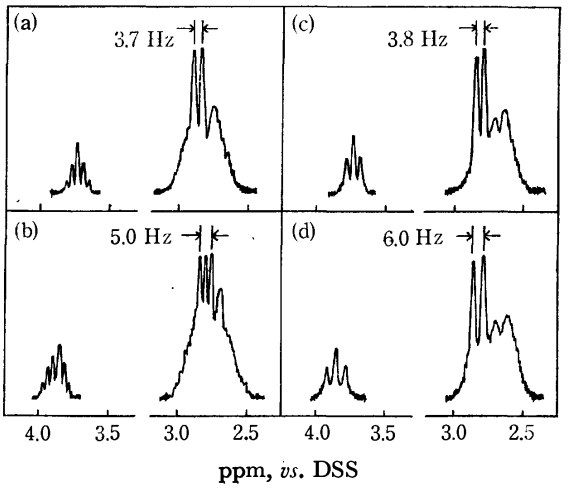

Fig. 4. PMR spectra of [Coox(L-aspH)en] in D_2O (pD 4.3—5.3).
(a) *mer*-Δ isomer (b) *mer*-Λ isomer
(c) *fac*-Λ isomer (d) *fac*-Δ isomer

absorption band region (Fig. 2). The *mer*-Δ isomers of the [Co(L-pro)$_3$][8] and [Co(L-pro)$_2$(L-asp)]$^-$[4] complexes reveal a small shoulder at shorter-wave-length-side in the first absorption band region.

Figure 4 shows the PMR spectra of the four isomers of the L-aspartato complex. It can be seen that the two sharp lines appearing in the vicinity of 2.8 ppm and multiple lines in the vicinity of 3.8 ppm are due to the CH_2 and CH groups, respectively, of the coordinated aspartate ion.[6] The isomers can be classified into those of narrow width (*mer*-Δ and *fac*-Δ) and those of broad width (*mer*-Λ and *fac*-Λ). The difference in line-width may be related to the different orientation of aspartate side-chains in the two types. A similar discussion was given previously.[4]

The isomers of the L-glutamato complex exhibited too complicated spectra for obtaining any information.

The PMR spectra, partly of CH_3 proton resonance, of the four isomers of L-leucinato complex were measured. The results show two well-separated doublets indicating different chemical environments of two CH_3 groups of the isobutyl group for the isomers.

Table 2. Percentage compositions of reaction mixtures

	mer-Λ	*mer*-Δ	*fac*-Λ	*fac*-Δ
[Coox(L-aspH)en]	72	11	14	3
[Coox(L-gluH)en]	48	32	11	9
[Coox(L-leu)en]	49	35	8	8
[Coox(gly)en][a]	84		16	

a) Percentage composition was evaluated from spectral data.[10]

Stereoselectivity. The percentage compositions of all isomers in the reaction mixture are given in Table 2. For comparison, the values for the [Coox(gly)en] are also included. The formation of the *mer* isomer (Λ+Δ) in each complex is more abundant than that of the *fac* isomer (Λ+Δ). The amount of formation of the isomers for the L-glutamato and L-leucinato complexes increases in the order *fac*-Δ≃*fac*-Λ<*mer*-Λ<

TABLE 3. PERCENTAGE COMPOSITIONS OF DIASTEREOISOMERS

	[Coox(L-aspH)en]	[Coox(L-gluH)en]	[Coox(L-leu)en]	$[Co(gly)_2(L\text{-asp})]^{-}$ [2]	$[Co(gly)_2(L\text{-glu})]^{-}$ [9]
mer-Δ	87	60	58	39	50
fac-Δ	82	55	51	11	40

mer-Δ, and that for the L-aspartato complex in the order *fac-Δ*<*mer-Λ*≃*fac-Λ*<*mer-Δ*. The increase of *fac-Λ* can be understood in terms of favorable interaction.

The stereoselectivity in a given complex is expressed in percentage composition of a diastereoisomeric pair. The results are given in Table 3, together with the data of the L-aspartato[2] and L-glutamato[9] complexes. As was expected, a marked stereoselectivity of over 80% was found in both the *mer-Δ* and *fac-Λ* isomers for the L-aspartato complex. This can be understood on the basis of stereo models; a favorable interaction through a hydrogen bond between the β-carboxylate group of the coordinated L-aspartate ion and an amino group of the chelated ethylenediamine is possible for the *mer-Δ* and *fac-Λ* isomers; on the other hand, an electrostatic repulsive interaction between the β-carboxylate group and an oxygen atom of the chelated oxalate ion is possible for the *mer-Λ* and *fac-Δ* isomers.

The stereoselectivity in the $[Co(gly)_2(L\text{-glu})]^{-}$ complex is much less than that in the corresponding L-aspartato complex.[9] This may be due to the lower ability of the γ-carboxylate group to interact with the adjacent group. The *mer-Δ* and *fac-Λ* isomers for the present L-glutamato complex also showed ~60% selectivity. The L-leucinato complex having an isobutyl group as the side-chain of the amino-acidate ion also showed a comparable stereoselectivity. This suggests that such a low selectivity can not be discussed in a similar way to that for the L-aspartato complex.

In the $[Co(gly)_2(L\text{-asp})]^{-}$ complex, the percentage compositions of the *fac-Δ* and *mer-Λ* isomers were reported to be 89 and 61%, respectively.[2] The lower selectivity of the *mer-Λ* isomer is due to the fact that a geometrical isomer for the *mer-Δ* diastereoisomer, *trans*-(N)*cis*(O), is favorable for the interaction of the β-carboxylate group. The present work showed selectivity in the same order as between the *mer-Δ* and *fac-Λ* isomers of the L-aspartato complex. It has been confirmed that the stereoselectivity in a complex containing L-aspartate ion as a bidentate ligand is closely related to a favorable interaction of the β-carboxylate group of the aspartate ion with the adjacent ligand.

(Received May 4, 1974)

Some new binuclear and trinuclear complexes containing μ-aminocarboxylato ligands, $[(NH_3)_5Co(OCORNH_2)Co\,NO_2(acac)_2](ClO_4)_2$ (R = CH_2, $(CH_2)_2$, and $CH(CH_3)$ for glycinato, β- and DL-alaninato ligands) and $[en_2Co\{(OCORNH_2)Co\,NO_2(acac)_2\}_2]ClO_4$ (R = CH_2 and $(CH_2)_2$), have been prepared and characterized on the basis of their elemental analyses, visible and ultraviolet absorption, infrared, and PMR spectra. It was concluded that the NH_2 end of the μ-aminocarboxylato bridge occupies a coordination position *trans* to the NO_2 ligand, and the COO ends of two μ-aminocarboxylato bridges in the trinuclear complex occupy positions *trans* to each other.

It is well-known that an aminocarboxylate anion or its parent acid coordinates to a cobalt(III) ion as a unidentate,[1-7] or a bidentate[8-12] ligand, and in some cases also as a tridentate ligand such as aspartate[13,14] and histidinate.[15] Previously we reported the $[Co(NH_3)_5(aaH)]X_3$,[2] *trans*-$[Coen_2(aaH)_2]X_3$,[3] and *cis*-$[Co(NH_3)_4(aaH)_2]X_3$[1] complexes containing various amino acids (abbreviated as aaH). The amino acid binds to a cobalt(III) ion as a unidentate ligand through its carboxylate group, the $-NH_3^+$ group being free. Recently the complexes of *N*-bonded unidentate amino acids, aminocarboxylates or amino acid esters were also prepared.[5-7] Pellizer *et al.*[16] suggested the occurrence of some μ-aminocarboxylato binuclear complexes in solution in the course of studies on the substitution reaction of a Vitamin B_{12} model complex.

In the present paper, formation and preparation of some μ-aminocarboxylato complexes by the reaction between the $[Co(aa)(NH_3)_5]^{2+}$ or *trans*-$[Co(aa)_2en_2]^{1+}$ ion and the $[Co(NO_2)_2(acac)_2]^-$ ion are reported. The complexes isolated are characterized on the basis of their elemental analyses, visible and ultraviolet absorption, infrared, and PMR spectra. The amino acids and their abbreviations (in parentheses) are as follows: glycine NH_2CH_2COOH (glyH), β-alanine $NH_2CH_2CH_2COOH$ (β-alaH), L- and DL-alanine $NH_2CH(CH_3)COOH$ (L- and DL-alaH), and γ-aminobutyric acid $NH_2CH_2CH_2CH_2COOH$ (γ-ambutH).

Experimental

Preparation of Starting Materials. Pentaammine(amino acid)cobalt(III) Complexes: $[Co(NH_3)_5(glyH)](ClO_4)_3\cdot H_2O$, $[Co(NH_3)_5(\beta\text{-alaH})](ClO_4)_3$, $[Co(NH_3)_5(L\text{-alaH})](ClO_4)_3\cdot 2H_2O$, $[Co(NH_3)_5(DL\text{-alaH})](ClO_4)_3\cdot H_2O$, and $[Co(NH_3)_5(\gamma\text{-ambutH})](ClO_4)_3$, and the pentaammine(aminocarboxylato) complex, $[Co(gly)(NH_3)_5](ClO_4)_2$, were prepared by the method reported.[2] The *trans*-$[Co\,en_2(aaH)_2](ClO_4)_3$ (aaH = glyH, β-alaH, L-alaH and γ-ambutH) complexes were prepared by using the same method as that described.[3] These complexes were recrystallized from aqueous solution by addition of a small amount of ethanol and saturated sodium perchlorate solution. The glycine, β-alanine and γ-aminobutyric acid complexes are new ones.

Found: C, 15.44; H, 4.14; N, 13.42%. Calcd for $[Co\,en_2(glyH)_2](ClO_4)_3 = C_8H_{26}N_6O_{16}Cl_3Co$: C, 15.31; H, 4.18; N, 13.39%.

Found: C, 18.12; H, 4.63; N, 13.11%. Calcd for $[Co\,en_2(\beta\text{-alaH})_2](ClO_4)_3 = C_{10}H_{30}N_6O_{16}Cl_3Co$: C, 18.32; H, 4.62; N, 12.82%.

Found: C, 20.78; H, 4.94; N, 12.26%. Calcd for $[Co\,en_2(\gamma\text{-ambutH})_2](ClO_4)_3 = C_{12}H_{34}N_6O_{16}Cl_3Co$: C, 21.08; H, 5.02; N, 12.29%.

Preparation of $Na[Co(NO_2)_2(acac)_2]$ complex was carried out by the method of Rosenheim and Garfunkel.[17]

Preparation of μ-Aminocarboxylato Binuclear Complexes. $[(NH_3)_5Co(gly)Co\,NO_2(acac)_2](ClO_4)_2\cdot 3H_2O$: The pH of an aqueous solution containing 2.5 g of $[Co(NH_3)_5(glyH)](ClO_4)_3\cdot H_2O$ in 25 ml of water was adjusted to 9.0 with sodium hydroxide (1 M). To this solution was added 1.8 g of $Na[Co(NO_2)_2(acac)_2]$. The resulting solution was kept in a water-bath at 30 °C for two hr and then kept in a refrigerator overnight. The brownish-red needle crystals formed were filtered and washed with a water–ethanol (1: 1) mixture and then with 95% ethanol. From the filtrate another crop of the complex was obtained by adding a saturated solution of sodium perchlorate. Recrystallization was carried out by adding a small amount of saturated sodium perchlorate solution to a concentrated solution and by keeping the mixture in a refrigerator. The separated complex was dried over $CaCl_2$ in a vacuum desiccator. The yield was *ca.* 2.3 g. The complex was readily soluble in water and acetone, but insoluble in absolute ethanol and ether.

Found: C, 18.74; H, 5.16; N, 12.62%. Calcd for $C_{12}H_{39}N_7O_{16}Cl_2Co_2$: C, 18.61; H, 5.09; N, 12.62%.

The same binuclear complex was also obtained from $[Co\,gly(NH_3)_5](ClO_4)_2$ (2.0 g) and $Na[Co(NO_2)_2(acac)_2]$, the yield being *ca.* 2.3 g.

$[(NH_3)_5Co(\beta\text{-ala})Co\,NO_2(acac)_2](ClO_4)_2$. Brown needle crystals were obtained by a similar procedure to that for the μ-gly binuclear complex except for the use of $[Co(NH_3)_5(\beta\text{-alaH})](ClO_4)_3$ (2.6 g) instead of $[Co(NH_3)_5(glyH)](ClO_4)_3\cdot H_2O$. This complex was more soluble in water than the μ-gly complex. The crystals obtained were dried over P_4O_{10} in a vacuum desiccator. The yield was *ca.* 1.5 g.

Found: C, 21.30; H, 5.00; N, 12.93%. Calcd for $C_{14}H_{37}N_7O_{16}Cl_2Co_2$: C, 21.26; H, 4.81; N, 13.36%.

$[(NH_3)_5Co(DL\text{-ala})CoNO_2(acac)_2](ClO_4)_3\cdot 2H_2O$. This complex was prepared by the same method as that employed for the μ-gly binuclear complex except for the use of $[Co(NH_3)_5(DL\text{-alaH})](ClO_4)_3\cdot H_2O$ (2.6 g). The yield was 1.5 g.

Found: C, 20.24; H, 5.18; N, 12.89%. Calcd for $C_{13}H_{39}N_7O_{18}Cl_2Co_2$: C, 20.27; H, 5.11; N, 12.73%.

Preparation of the μ-L-ala binuclear complex was repeatedly attempted in the same way as for the DL-ala complex, but no

pure complex was obtained. Preparation of the binuclear complex of γ-ambut was also unsuccessful, some dark brown crystals of an undesired composition being separated instead.

Preparation of μ-Aminocarboxylato Trinuclear Complexes. $[en_2Co\{(gly)CoNO_2(acac)_2\}_2]ClO_4 \cdot 1.5NaClO_4 \cdot 6H_2O$: The pH of an aqueous solution containing 2.5 g of *trans*-$[Co\text{-}en_2(glyH)_2](ClO_4)_3$ in 40 ml of water was adjusted to pH 9.0 with sodium hydroxide (1 M). To this solution was added 3.0 g of $Na[Co(NO_2)_2(acac)_2]$. The resulting solution was kept in a water-bath at 30 °C for two hours and cooled in an ice-bath. Crystals of the trinuclear complex deposited as brown flakes with addition of a saturated aqueous solution of sodium perchlorate. The crystals were filtered and washed with a saturated aqueous solution of sodium perchlorate, a small amount of ethanol and then with ether.

Recrystallization was performed from cold aqueous solution by addition of a saturated solution of sodium perchlorate, the resulting solution being kept in a refrigerator. The yield was *ca.* 1.3 g. The complex was soluble in water and acetone, but insoluble in absolute ethanol and ether.

Found: C, 25.52; H, 5.04; N, 8.55%. Calcd for $C_{28}H_{64}N_8O_{32}Cl_{2.5}Co_3$: C, 25.38; H, 4.87; N, 8.45%.

$[en_2Co\{(\beta\text{-}ala)CoNO_2(acac)_2\}_2]ClO_4 \cdot 3NaClO_4 \cdot 5H_2O$. A brown complex was obtained as flake crystals by a similar method to that for the μ-gly trinuclear complex. The yield was *ca.* 1.0 g.

Found: C, 23.14; H, 4.52; N, 7.61%. Calcd for $C_{30}H_{66}N_5O_{37}Cl_4Na_3Co_3$: C, 23.72; H, 4.39; N, 7.37%.

Repeated attempts were made to prepare trinuclear complexes containing DL-ala, L-ala and γ-ambut, but were unsuccessful.

Estimation for the Formation of μ-Aminocarboxylato Complex in Solution. The % formation of the μ-gly binuclear complex was estimated as follows. $[Co(NH_3)_5(glyH)](ClO_4)_3 \cdot H_2O$ (2.50 g, 4.67×10^{-3} mol) was dissolved in 25 ml of water (an almost saturated solution was obtained), the pH being adjusted to 9.0 with 1 M-NaOH. The solution was made 50 ml in volume with water and then kept in a water-bath with a thermostat. It was then mixed with an aqueous solution containing 1.78 g (4.67×10^{-3} mol) of $Na[Co(NO_2)_2(acac)_2]$ in 50 ml of water. The mixed solution was transferred to a 100 ml Erlenmeyer flask with a stopper and kept at an appropriate temperature (20.0, 30.0, 40.0 or 50.0±0.1 °C). A 10 ml portion of the reactant solution, picked up at intervals several minutes to several hours after mixing, was quickly poured into a short column (4.5 cm × 5.5 cm) containing 60 ml (syrup state) of cation-exchange SP-Sephadex (C-25). The unreacted complex anion, $[Co(NO_2)_2(acac)_2]^-$, was removed by washing with water. The adsorbed μ-gly binuclear complex was carefully eluted out with 2 M-$NaClO_4$. The unreacted complex cation ($[Co(gly)(NH_3)_5]^{2+}$ or $[Co(NH_3)_5(glyH)]^{3+}$) remained as a red band. The eluted solution was made 100 ml in volume with 2 M-$NaClO_4$ solution. The concentration of the binuclear complex was estimated by comparing the absorbance measured at 405 nm with that of the prepared complex. The absorbance at 405 nm of the unreacted gly complex, $[Co(gly)(NH_3)_5](ClO_4)_2$ or $[Co(NH_3)_5(glyH)](ClO_4)_3$, is negligible in comparison with that of the μ-gly binuclear complex (Fig. 5). Similar tests (at only 30 °C) were also performed for the L-ala, β-ala and γ-ambut complexes.

Tests of the di-μ-aminocarboxylato trinuclear complexes of gly, β-ala and γ-ambut at 30 °C were carried out in the same way as for the μ-gly binuclear complex except for the use of *trans*-$[Co\ en_2(aaH)_2]^{3+}$ (3.98×10^{-3} mol) and $[Co(NO_2)_2(acac)_2]^-$ (7.96×10^{-3} mol).

Measurements. The absorption spectra were measured in aqueous solutions with a Hitachi Model EDS-3T spectrophotometer. The infrared spectra were obtained with a JASCO IR-S infrared spectrophotometer. The PMR spectra were recorded on a JEOL Model MH-100 high-resolution spectrometer with DSS as an internal standard.

Results and Discussion

Formation of μ-Aminocarboxylato Complex. The % formation and pH value *versus* reaction time for the μ-gly binuclear complex at 20, 30, 40, and 50 °C are shown in Fig. 1. Formation of the μ-gly binuclear complex began instantly after mixing two aqueous solutions containing $[Co(gly)(NH_3)_5]^{2+}$ and $[Co(NO_2)_2(acac)_2]^-$, respectively. The maximum formation (*ca.* 72.5%) was observed after 2—3 hr at 30 °C. At higher temperatures (40 and 50 °C) the formation curve reached its maximum a few minutes after mixing and then began to decrease sharply. This indicates that rapid decomposition of the formed μ-gly binuclear complex occurs at higher temperatures. At lower temperature (20 °C) the formation curve indicated lower values than at 30 °C within 5 hr of reaction time, but higher values after 5 hr.

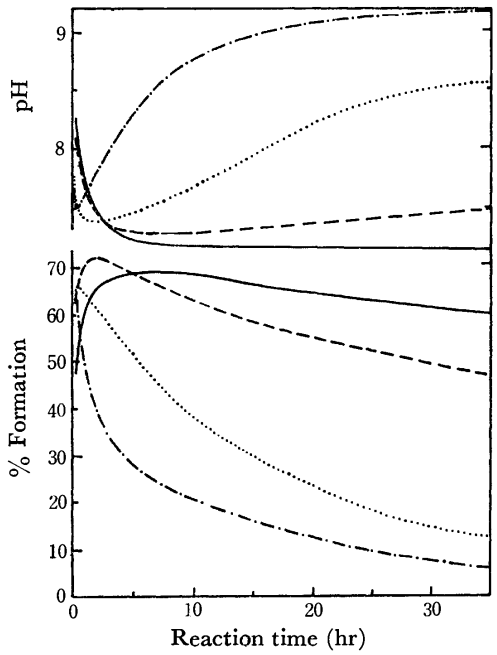

Fig. 1. % Formation and pH *vs.* reaction time for μ-gly binuclear complex at various temperatures, 20 °C (——), 30 °C (----), 40 °C (····), and 50 °C (-·-·-).

In order to coordinate the amino end of the pentaammine(O-glycine)cobalt(III) complex ion to another cobalt(III) ion, the amino end ($-NH_3^+$) should be deprotonated producing free amino group ($-NH_2$). It could be assumed that the pK value of the $[Co(NH_3)_5(glyH)]^{3+}$ is located at around 9. Formation tests and preparation of the μ-aminocarboxylato binuclear complexes were performed with use of pH-adjusted (*ca.* pH 9) solutions of the protonated complexes, $[Co(NH_3)_5(aaH)](ClO_4)_3$. A sharp decrease in the pH at the beginning of the reaction (Fig. 1) indicates the coordination of the amino group, and the increment

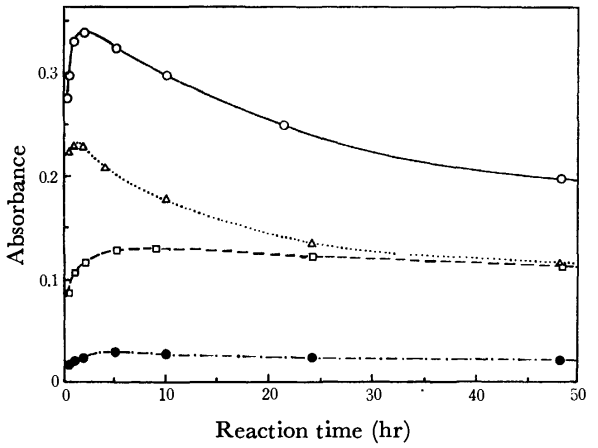

Fig. 2. The plots of absorbance *vs.* reaction time for binuclear complexes. μ-gly (—○—), μ-L-ala (··△··), μ-β-ala (--□--), and μ-γ-ambut (-·●·-).

of the pH with the progress of reaction at higher temperatures (40 and 50 °C) can be attributed to the detachment of the amino group or of ammonia molecule during the course of decomposition of the μ-gly binuclear complex.

The formation cruves of binuclear complexes are compared for gly, L-ala, β-ala, and γ-ambut (Fig. 2). The relative degree of formation is in the order

$$\text{gly} > \text{L-ala} > \beta\text{-ala} > \gamma\text{-ambut.}$$

Formation curves of the di-μ-aminocarboxylato trinuclear complexes for gly, β-ala and γ-ambut at 30 °C are compared in Fig. 3. The formation and decomposition of the μ-gly trinuclear complex proceeds rapidly as compared with those of β-ala and γ-ambut complexes. This phenomenon coincides with the case of the binuclear complexes. The maximum % formation which was estimated experimentally for the μ-gly trinuclear complex (*ca.* 24%) was considerably low as compared with that for μ-gly binuclear complex (72.5%).

The μ-aminocarboxylato binuclear and trinuclear complexes are relatively stable in aqueous solution in the pH region 3—8, but less stable for pH>9. Only one band appeared when these complexes were developed in a cation-exchange resin column, showing that they consist of one species each.

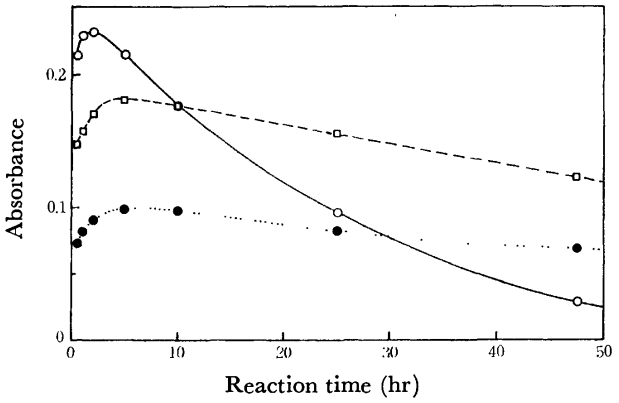

Fig. 3. The plots of absorbance *vs.* reaction time for trinuclear complexes. di-μ-gly (—○—), di-μ-β-ala (--□--), and di-μ-γ-ambut (··●··).

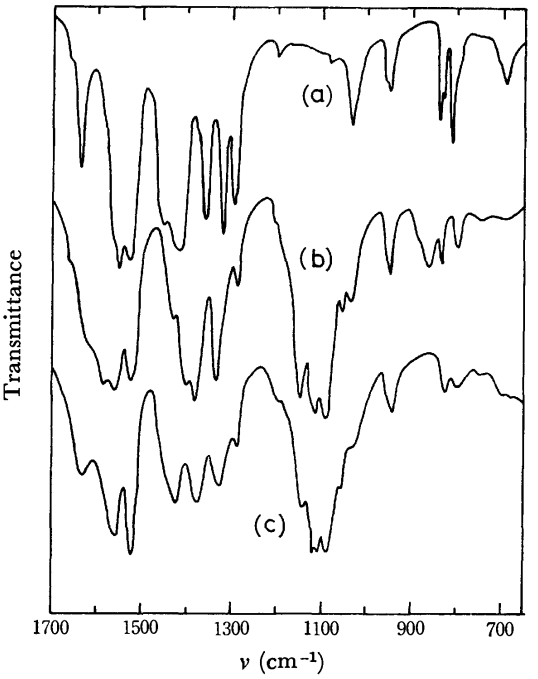

Fig. 4. Infrared spectra of (a) $Na[Co(NO_2)_2(acac)_2]$, (b) μ-gly binuclear, and (c) di-μ-gly trinuclear complexes.

In the preparation of binuclear complexes for L- and β-ala, and γ-ambut, in some cases complexes such as $[Co(NH_3)_5(aaH)][Co(NO_2)_2(acac)_2]_3$ were also separated. These complex-to-complex salts split into two bands brown and orange in color on the column, easily distinguishable from the μ-aa binuclear complexes.

Infrared Spectra. The infrared spectra of μ-gly binuclear and di-μ-gly trinuclear complexes are shown in Fig. 4 together with the spectrum of the starting acetylacetonato complex, $Na[Co(NO_2)_2(acac)_2]$.

These complexes show intense absorption bands in the 1520—1560 cm^{-1} region, which are assigned to the C=O and C=C stretching vibrations of the coordinated acetylacetonate.[18-20] The bands of 825 and 1325 cm^{-1} are assigned to the NO_2^- bending and asymmetric stretching modes,[19] respectively. The medium bands which appear near 1630 cm^{-1} are attributed to the coordinated carboxyl group. They are generally recognized in several aminocarboxylato cobalt(III) complexes. The present μ-aminocarboxylato complexes show intense bands characteristic of ClO_4^- in the 1060—1140 cm^{-1} region. This confirms that the complex ions are electro-positive.

Absorption Spectra. The absorption spectra of the μ-aminocarboxylato binuclear and trinuclear complexes show a similar behavior to that of the starting $Na[Co(NO_2)_2(acac)_2]$ complex (Fig. 5). The absorption spectra of acetylacetonato metal complexes in general have been studied.[18,20,21] Referring to these studies the band peaks observed at 515 and 535 nm for the bi- and tri-nuclear complexes, respectively, are attributed to the d—d transition ($^1A_{1g} \rightarrow {}^1T_{1g}$ in O_h per-

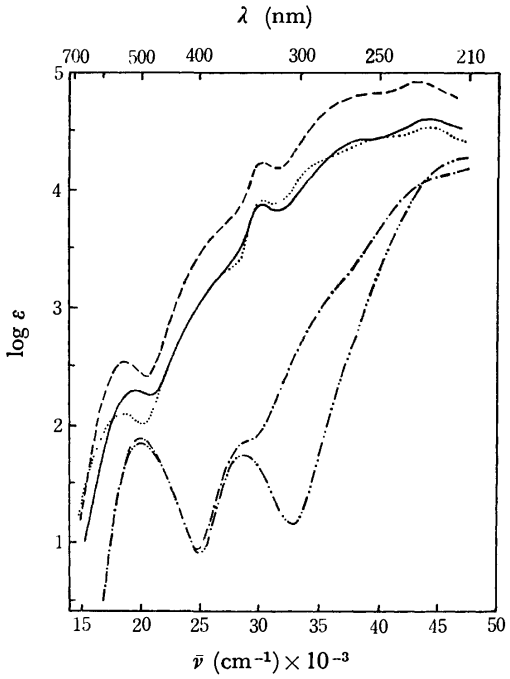

Fig. 5. Absorption spectra of μ-gly binuclear (——), di-μ-gly trinuclear (----), $[Co(NO_2)_2(acac)_2]^-$ (····), $[Co(gly)(NH_3)_5]^{2+}$ (-·-·-), and $[Co(NH_3)_5(glyH)]^{3+}$ (-··-) complex ions in aqueous solutions.

centage).[18] A metal-enolate charge transfer band ($d_\pi \rightarrow \pi^*$) appears in the 330—350 nm region. The broad and shoulder bands near 225 and 260 nm are attributed to the enolate $\pi \rightarrow \pi^*$ transitions. The absorption curves of the μ-gly binuclear and di-μ-gly trinuclear complexes coincided with the summation curves of $[Co(aaH)(NH_3)_5]^{3+}$ and $[Co(NO_2)(NH_3)(acac)_2]$[18] (1 : 1 mixture), and of *trans*-$[Co\ en_2(aaH)_2]^{3+}$ and $[Co(NO_2)(NH_3)(acac)_2]$ (1 : 2 mixture), respectively. These results support the view that the complexes obtained consist of the binuclear and trinuclear compositions. Proposed structures for these bi- and trinuclear complex ions are shown in Figs. 6 and 7.

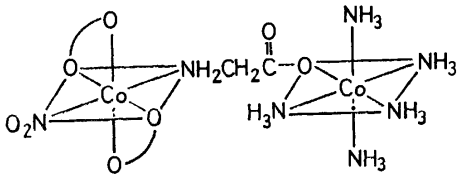

Fig. 6. The structure of μ-gly binuclear complex.

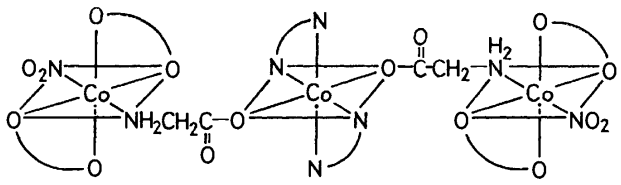

Fig. 7. The structure of di-μ-gly trinuclear complex.

Proton Magnetic Resonance Spectra. The PMR data of the μ-gly binuclear and trinuclear complexes are given in Table 1. These μ-gly complexes show a pair of singlet resonances in the 2.15—2.22 and 5.84—5.88 ppm regions corresponding to the methyl and methin protons, respectively, of acetylacetonato ligands. The singlet resonances suggest that four methyl groups and two methin groups in the μ-gly binuclear complex and eight methyl groups and four methin groups in the di-μ-gly trinuclear complex lie in the same chemical environment. Thus it is reasonable to conclude that the bi- and tri-nuclear complexes take the *trans* structure with respect to the NH_2 group of the μ-glycinato ligand and NO_2^- (Figs. 6 and 7). If these complexes take the *cis* structure, they would show a more complicated pattern of proton resonances.

Table 1. PMR[a] data of gly complexes

Complexes	Chemical shift (ppm)		
	CH_3(acac)	CH_2(gly)	CH(acac)
$Na[Co(NO_2)_2(acac)_2]$	2.14		5.67
$[Co(gly)(NH_3)_5](ClO_4)_2$		3.40	
$[Co(NH_3)_5(glyH)](ClO_4)_3$		3.79	
μ-Gly binuclear	2.15	3.03	5.88
Di-μ-gly trinuclear	2.22	2.85[b]	5.84

a) Internal standard is DSS in D_2O. b) Overlaps with CH_2 of ethylenediamine.

The center cobalt(III) of the di-μ-gly trinuclear complex is also expected to have the *trans* structure with respect to the carboxyl groups of the two μ-glycinato ligands from the appearance of a strong singlet resonance for methylene protons of ethylenediamine at 2.85 ppm.

Boucher and Bailar[18] reported the replacement of one NO_2^- ligand of $[Co(NO_2)_2(acac)_2]^-$ by several amine ligands, and suggested the *trans* structure of the starting dinitro complex and the product nitroamine complexes from the view point of *trans* effect of the NO_2^- ligand. In our case the replacement of one NO_2^- ligand in $[Co(NO_2)_2(acac)_2]^-$ by the amino end of $[Co(aa)(NH_3)_5]^{2+}$ also produces a complex having *trans* structure with respect to the NO_2^- and the amino end. In conclusion it is proposed that the present bi- and tri-nuclear complexes have structures such as shown in Figs. 6 and 7.

Synthesis of Chelating Agents. XI. Synthesis and Chelating Behavior of Diaxial *trans*-Decahydronaphthylene-*trans*-2,3-dinitrilotetraacetic Acid*

Tairoku YANO, Hiroshi KOBAYASHI, and Keihei UENO

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received May 14, 1974)

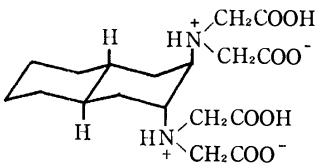
Diaxial *trans*-decahydronaphthylene-*trans*-2,3-dinitrilotetraacetic acid (D[A.A]TA) was synthesized by carboxymethylation of diaxial *trans*-decalin-*trans*-2,3-diamine. The acid dissociation constants as well as chelate stability constants for alkaline earth metal ions were determined by potentiometric titration. The probable structure and chelating behavior of D[A.A]TA in aqueous solutions were discussed in reference to some related complexane ligands.

With hoping to elucidate steric effect on chelate formation with complexane-type ligands, we have synthesized several 1,2-dinitrilotetraacetic acids and precursory diamines of specific configurations.

In continuation of the previous works,[1] this paper deals with synthesis and chelating behaviors of diaxial *trans*-decahydronaphthylene-*trans*-2,3-dinitrilotetraacetic acid (D[A.A]TA), which was derived from diaxial *trans*-decalin-*trans*-2,3-diamine.[2] Two six-membered rings in *trans*-decalin framework are well known to be incapable of inversion from one chair form to another on account of the rigid structure at the ring junctions.

Consequently, two nitrilodiacetic acid substituents in D[A.A]TA are in an antiperiplanar conformation, both pointing along the axial direction, providing configurations in respect to the amino groups are retained intact through the derivation and the cyclohexane ring under consideration takes a chair form.

Although this work had started with an aim of verifying the above anticipation, the presented results indicated that such a conformation was unlikely, in conclusion.



Structure 1

Experimental

Infrared and NMR spectra were measured on a JASCO DS-403G and Varian A-60 instruments, respectively, the latter with an internal reference of TMS or proton in heavy water, which was set at 5.0 ppm downfield from TMS.

Synthesis of Ligand. Diaxial trans-*Decahydronaphthylene*-trans-*2,3-dinitrilotetraacetic Acid* (D[A.A]TA, structure 1). The tetraacetic acid was synthesized by the alkaline condensation of bromoacetic acid with diaxial *trans*-decalin-*trans*-2,3-diamine (D[A.A]). Conditions of typical run was as follows.

A solution of 0.5 g (2.1 mmol) of D[A.A]·2HCl in 20 ml of water was placed in a 100 ml reaction vessel. The solution was made neutral to phenolphthalein with 5 M aqueous sodium hydroxide. Into this solution, a solution of 2 g (14.4 mmol) of bromoacetic acid in 10 ml of water, which had been neutralized in advance with sodium hydroxide solution below 10 °C, was added under stirring and the temperature of the solution was raised to 80 °C. The pH of the reaction mixture was maintained in the range of 9—10 (red to phenolphthalein) with an occasional addition of 5 M aqueous sodium hydroxide. After adding 12.5 mmol of sodium hydroxide, the resulting solution was acidified with conc. hydrochloric acid and was evaporated under reduced pressure. The residue was dissolved in water, followed by adjusting pH of the aqueous solution to 1.8 and stored in a refrigerator for a week to complete the precipitation of free D[A.A]TA. The crude product was then collected by filtration and recrystallized from water. Yield: 420 mg (51%). It decomposed at 186—188 °C. NMR (in D_2O): δ; 1—2.4 ppm (broad band with an appreciable quartet, 14H), 4.13, 3.86, 3.79, and 3.52 (double doublets, $J_{AB}=16.2$ Hz, 8H, two protons were concealed behind the double doublets). IR: ν_{COOH} 1753 cm^{-1}. Found: C, 51.99; H, 7.15; N, 6.59%. Calcd for $C_{18}H_{28}N_2O_8\cdot H_2O$: C, 51.68; H, 7.18; N, 6.70%.

1,3-Bis(cyanomethyl)-trans-*cisoid*-trans-*perhydronaphtho[2,3-d]imidazole.* To a cold solution of diequatorial *trans*-decalin-*trans*-2,3-diamine dihydrochloride (0.12 g, 0.5 mmol) in 0.4 M hydrochloric acid (3 ml), an aqueous 36% formaldehyde (0.16 g, 2 mmol) and sodium cyanide (98 mg, 2 mmol) was successively added and a resulting mixture was kept in a pressure bottle. The mixture was allowed to stand for 3 hr at room temperature with occasional shaking. The precipitate obtained was recrystallized from ethanol. IR: ν_{CN} 2240 cm^{-1}. Mp: 131—132 °C. Yield: 76 mg (59%). NMR (in $CDCl_3$): δ; 0.9—2 ppm (14H), 2.2—2.6 (2H), 3.62 (4H), 3.83 (2H). MS: *m/e***, 258 (M^+), 257 (M^+-1), 231 (M^+-27), 218 (M^+-40). Found: C, 69.91; H, 8.58; N, 21.54%. Calcd for $C_{15}H_{22}N_4$: C, 69.73; H, 8.58; N, 21.84%.

Diaxial trans-*decahydronaphthylene*-trans-*2,3-dinitrilotetraacetonitrile* was synthesized in a similar manner to that described above, except the reaction temperature being 40 °C. IR: ν_{CN} 2235 cm^{-1}. Mp: 167—171 °C. Yield: 49 mg (30%). NMR (in $CDCl_3$): δ; 0.8—1.9 ppm (14H), 2.8—3.1 (2H), 3.77 (8H). MS: *m/e***, 324 (M^+), 286 (M^+-38), 284 (M^+-40), 257 (M^+-67). Found: C, 66.23; H, 7.54; N, 25.34%. Calcd for $C_{18}H_{24}N_6$: C, 66.67; H, 7.41; N, 25.93%.

Determination of Chelate Stability Constants. The details of an apparatus were described previously.[1] A pH measurement was carried out at 25.0 °C in an aqueous solution of ionic

* Contribution No. 335 from the Department of Organic Synthesis, Kyushu University.

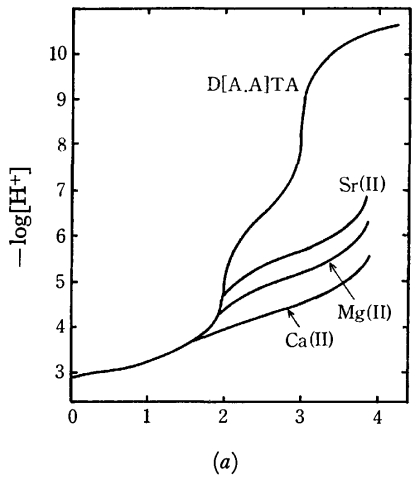
** Measured with a JEOL JMS-01SG by courtesy of Prof. Kawasaki and Miss Kawamura in Faculty of Pharmacy, Kyushu University, to whom the authors are grateful.

strength of 0.10 with potassium nitrate. Calibration of a pH-meter was also described previously.[1] Determination of a chelate stability constant with an alkaline earth metal ion involves direct pH titrations of 100 ml of a ligand solution in which concentration of the ligand was 1×10^{-3} M and a metal ion was present in 1: 1 and 10: 1 mole ratios of a metal nitrate to a ligand.

Calculation of Equilibrium Constants. Acid Dissociation Constants. The titration curve of D[A.A]TA is shown in Fig. 1. The definition of equilibrium constants discussed in this paper, are listed in Table 1. It can be seen from Fig. 1 that the acid dissociations of first two steps, third step and fourth step are clearly separated from each other. Therefore, the acid dissociation constants of the free ligand were calculated by the standard procedure.[3]

Table 1. Definition of equilibrium constants

1) Acid dissociation constnts of D[A.A] TA
$K_1=[H_3A^{1-}][H^+]/[H_4A]$
$K_2=[H_2A^{2-}][H^+]/[H_3A^{1-}]$
$K_3=[HA^{3-}][H^+]/[H_2A^{2-}]$
$K_4=[A^{4-}][H^+]/[HA^{3-}]$
2) Composite acid dissociation constants[4]
$K_3'=[H^+]([HA^{3-}]+[MHA^{1-}])/[H_2A^{2-}]$
$K_4'=[H^+]([A^{4-}]+[MA^{2-}]+[M_2A])/([HA^{3-}]+[MHA^{1-}])$
3) Chelate stability constants of D[A.A]TA
$K_{MHA}=[MHA^-]/[M^{2+}][HA^{3-}]$
$K_{MA}=[MA^{2-}]/[M^{2+}][A^{4-}]$
$K^H_{MHA}=[H^+][MA^{2-}]/[MHA^{1-}]$
$K_{M_2A}=[M_2A]/[M^{2+}][MA^{2-}]$



(*a*)

Fig. 1. Potentiometric titration curves of alkaline earth metal-chelates at 25.0 °C in 0.10 M KNO_3 with molar ratio of metal ion to ligand; 1: 1. Concentration of D[A.A]TA: 1×10^{-3} M.

Chelate Stability Constants. As the two nitrilodiacetic acid groups of the ligand are situated on the opposite sides of the rigid cyclohexane ring, the ligand may form MA type as well as M_2A type chelates. Accordingly, the chelate stability constants for alkaline earth metal ions were calculated by the Schwarzenbach's procedure,[4] assuming the formation of MA, MHA and M_2A type chelates. The procedure of calculation was a standard one, using the composite acid dissociation constants K_3' and K_4' on the titration data of 10: 1 solution.

Computations were carried out by use of a FACOM 230-60 of the Computor Center in Kyushu University.

Results and Discussion

Synthesis. D[A.A]TA was obtained by carboxymethylation of diaxial *trans*-decalin-*trans*-2,3-diamine. Although no direct evidence was provided, it is reasonable on the basis of the employed reaction conditions that configurations in respect to the substituents are regarded to be retained intact.

Cyanomethylation and carboxymethylation were also applied to 2,3-*cis*- and diequatorial 2,3-*trans*-diamine derivatives of *trans*-decalin under various conditions. Both isomeric diamines afforded no definite product except an imidazolidine derivative by cyanomethylation of the diequatorial *trans*-diamine. It is likely that, upon the cyanomethylation of the 1,2-diamino groups in the close vicinity to each other such as the above diamines, an imidazolidine ring closure proceeds prior to the fourth cyanomethylation reaction, giving no tetracyanomethyl derivative.[5,6]

The fact that the expected tetracyanomethyl- and tetracarboxymethyl derivatives were afforded only from the diaxial 2,3-*trans*-diamine in which two amino groups were separated apart from each other, is regarded as an indication of little steric interaction between the two amino groups on the reaction processes, as well as another support for the configuration of D[A.A]TA.

Table 2. Acid dissociation constants and ΔpK (2−1) and ΔpK (4−3) values of D[A.A]TA and related compounds

Compound	pK_1	pK_2	pK_3	pK_4	ΔpK (2−1)	ΔpK (4−3)	Favorable configuration of two NDA groups
D[A.A]TA	2.26	3.04	6.47	10.61	0.78	4.14	skew
t-THDTA[5]	1.9	3.54	5.99	10.30	1.64	4.31	skew
t-1,2-CYDTA[7]	2.40	3.55	6.14	11.70	1.15	5.56	skew
t-1,2-CPDTA[8]	2.41	2.92	7.42	10.31	0.51	2.89	*trans*
EDTA[9]	1.99	2.67	6.16	10.23	0.68	4.07	*trans*
1,3-CYDTA[10]	1.77	2.57	8.55	10.91	0.80	2.36	—
1,4-CYDTA[10]	2.07	2.52	9.04	10.86	0.45	1.82	—

t-THDTA: 1,2,3,4-Tetrahydronaphthylene-*trans*-2,3-dinitrilotetraacetic acid. CYDA: Cyclohexylenedinitrilotetraacetic acid. *t*-1,2-CPDTA: *trans*-1,2-Cyclopentylenedinitrilotetraacetic acid.

Acid Dissociation. Table 2 summarizes the acid dissociation constants of D[A.A]TA, along with those of some related complexane ligands. In the deprotonation process of a tetrabasic complexane, the first two steps and the last two correspond to the dissociation of carboxylic protons and ammonium protons, respectively.

In respect to the magnitude of difference between the pK-values of the first two, ΔpK(2−1), and that between the last two, ΔpK(4−3), the tetrabasic complexanes can be classified into two groups. As discussed previously,[2] a complexane ligand, in which two nitrilodiacetic acid (NDA) groups are far remote from each other, gives a relatively smaller ΔpK values, in comparison with those with two NDA groups in

close proximity to each other. And as far as concerned with acid dissociation process, D[A.A]TA behaves in a quite similar manner to those of the latter group.

If the above presumption is true regarding the spatial relationship between the two NDA groups in this compound, a cyclohexane ring bearing the substituents must take a skew-boat form, in which the vicinal NDA groups can be in a synclinal conformation.

TABLE 3. CHELATE STABILITY CONSTANTS OF D[A.A]TA AND RELATED COMPLEXANES 25.0 °C, μ=0.10 (KNO_3)

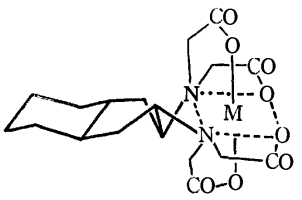
Compound	log K_{MA}		
	Mg(II)	Ca(II)	Sr(II)
D[A.A]TA	10.36	11.54	9.34
t-THDTA[5]	10.28	11.63	9.56
t-1,2-CYDTA[11]	10.3	12.2	9.97
t-1,2-CPDTA[8]	9.05	11.08	9.45
EDTA[12]	8.69	10.70	8.63
1,3-CYDTA[10]	4.64	4.77	—
1,4-CYDTA[10]	4.30	4.19	—
N-Me-IDA[13]	3.44	3.75	2.85

N-Me-IDA: *N*-Methyliminodiacetic acid

Chelate Stability. Stability constants of the alkaline earth metal chelates of D[A.A]TA are listed in Table 3 along with those of some related complexane-type ligands. The value of log K_{M_2A} of D[A.A]TA, being negative, indicated that this ligand formed predominantly a 1:1 chelate with alkaline earth metal ions. The values of K_{MA} also agreed well with those obtained by the Bjerrum's method, where the formation of an M_2A type chelate was neglected.

Tetrabasic complexanes in Table 3 may be classified in respect to the capability of two NDA groups coordinating to a same metal ion. Those with NDA groups which are spatially separated apart from each other, show much lower chelate stabilities than those with the ligand substituents in the vicinity to each other. Each NDA group in the former class, at the extremity, would coordinate independently to a separate metal ion. The log K_{MA} value of such a tetrabasic complexane could be estimated to fall in the range of 3—4, if a statistical correction of 0.3 was applied to those of *N*-methyliminodiacetic acid.

As one can seen in Table 3, D[A.A]TA belongs to the class of the high chelate stability, the value being comparable to that of *t*-1,2-CYDTA, in which two NDA groups are in a synclinal form. Combined with the value of K_{M_2A} of D[A.A]TA, these results provide strong evidences for the conclusion that six donor atom on the D[A.A]TA are in a conformation favorable for coordinating simultaneously to a single metal ion. A molecular model study indicates that D[A.A]TA can work as a hexadentate ligand only in the case where the dihedral angle between the two NDA groups falls in the *syn*-region, and that, in turn, the cyclohexane ring bearing the NDA groups must be in a skew-boat



Structure 2

form, as shown in structure 2.

The enthalpy difference between the chair and skew-boat form in *trans*-decalin is calculated to be 5.5 kcal/mol.[14] The steric instability of the skew-boat form in D[A.A]TA, however, can be compensated enough by the relatively large free energy gain with the formation of coordination bonds.

One might notice that *t*-1,2-CPDTA behaves in similar manner to 1,3- and 1,4-CYDTA rather than to *t*-1,2-CYDTA upon a reaction with proton, while in the reverse manner with divalent metal ions. This would be most probable on account of sizes of cations. When *t*-1,2-CPDTA takes a half-chair form, two NDA groups are in synclinal conformation, possibly coordinating to a metal ion which has much larger radius than proton.

The authors are grateful to the Ministry of Education, Japanese Government, for financial support to this work.

Kinetics of Ligand Isotopic Exchange of Tris(acetylacetonato)gallium(III) and Related β-Diketonato Complexes in Tetrahydrofuran

Chinmoy CHATTERJEE,* Kazuyo MATSUZAWA, Hiroaki KIDO, and Kazuo SAITO**

Department, of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received July 29, 1974)

The rate of isotopic exchange of tris(acetylacetonato)gallium(III)[Ga(acac)$_3$] and acetylacetone-^{14}C(Hacac) in tetrahydrofuran (THF) is expressed by the formula $R=[\text{complex}](k_1+k_2[H_2O]+k_3[\text{Hacac}])$ and the k_1, k_2, and k_3 are $\leq 2\times10^{-6}$ s^{-1}, 0.31×10^{-3} M^{-1} s^{-1} and 0.71×10^{-4} M^{-1} s^{-1}, at 0 °C, respectively. The activation enthalpies and entropies are 18 ± 2 and 19 ± 2 kcal·mol^{-1}, and -13 ± 6 and -20 ± 6 cal·K^{-1} mol^{-1}, for k_2 and k_3, respectively. Trichloroacetic acid gives acid catalysis. A dissociative mechanism through an intermediate containing a unidentate ligand is suggested. The isotopic exchange rate decreases in the sequence In>Ga>Al for a given β-diketonato complex, and with increase in pK_a of the β-diketone for given central metal ions.

Little information is available concerning the kinetics and mechanism of complex formation reactions of gallium(III) ions. Eigen gave the half-life of coordinated water molecules in gallium(III) perchlorate in water to be of the order of 10^{-3} s.[1] Fiat and Connick, and Movius and Matwiyoff studied the exchange of solvent molecules coordinated to Ga(III) in water[2] and dimethylformamide,[3] respectively, and compared the activation parameters with those for aluminium(III). On the basis of small ΔH^* and big minus ΔS^* values, they suggested an S_N2 mechanism for the gallium(III) ions.

We found that the ligand isotopic exchange of tris-type complexes of octahedral aluminium(III) with acetylacetone[4] and dibenzoylmethane[5] in various organic solvents is much slower than that of coordinated solvent molecules in $[Al(H_2O)_6]^{3+}$ in water,[1,2,6] and discussed the mechanism. We have now examined the rate of isotopic exchange of some β-diketonato complexes of aluminium(III), gallium(III), and indium(III), and found that the rate of exchange of tris(acetylacetonato)-gallium [Ga(acac)$_3$] with acetylacetone-^{14}C(Hacac) is measurable in some organic solvents including tetrahydrofuran (THF). Detailed kinetic studies are given and the results compared with those of related complexes.

Experimental

Materials. *The Labelled Ligands*: Acetylacetone-^{14}C (Hacac) was prepared similarly to the method given in Ref. 4, and the specific activity was adjusted to *ca.* 0.02 μCi per mg, the water content being *ca.* 10^{-1} M. Dibenzoylmethane-^{14}C (Hdbm) was synthesized from acetic acid (12 g, 0.2 mol) containing 1 mCi ^{14}C *via* acetophenone by the usual method. On recrystallization from ethanol for three times, the yield was 29% on the basis of acetic acid, the specific activity being *ca.* 0.03 μCi per mg. Benzoylacetone-^{14}C (Hbzac) was similarly prepared by use of ethylacetate in place of ethyl benzoate. The yield was 34%, the specific activity being 0.01 μCi per mg.

The Complexes. Tris(acetylacetonato)gallium(III)was synthesized by a similar method to Moeller and Gulyas's[7] by use of ethanol and gallium(III) chloride in place of dioxane and gallium(III) sulfate respectively. The yield was *ca.* 73%. The product was sublimed at 1 mmHg at 180 to 185 °C to give colorless crystals with mp 190 to 192 °C. Tris-(benzoylacetonato)gallium(III) was prepared from gallium-(III) chloride solution (0.003 mol in 3 ml of water) by adding Hbzac (0.013 mol) in ethanol (30 ml) and adjusting the pH with sodium acetate (1.2 g in 3 ml of water). The product was recrystallized from a mixture of THF and petroleum ether containing Hbzac, and washed with diethylether. The yield was *ca.* 90%. This is a mixture of *mer* and *fac* isomer, but was used without separation for the isotopic exchange studies.

Tris(1-oxo-1,3-diphenyl-2-prope-3-olato)gallium(III) [Ga-(dbm)$_3$] was synthesized from gallium(III) chloride solution (0.002 mol in 2 ml of water) by treating with Hdbm (0.0089 mol in 90 ml ethanol) and sodium acetate solution (0.8 g in 3 ml of water). The crude product was dissolved in THF (11 ml) containing a small amount of Hdbm, filtered and treated with petroleum ether to give colorless crystals, which were washed with chilled diethylether and dried *in vacuo*. mp 284.5~286.5 °C (literature value 284 °C; prepared in dioxane by use of metallic sodium in place of sodium acetate).[8] The yield was *ca.* 80%.

Tris(benzoylacetonato)aluminium(III) [Al(bzac)$_3$] was similarly prepared according to Baly and Desch's method[6] the yield being *ca.* 93%. Bis(1-oxo-1,3-diphenyl-2-prope-3-olato) beryllium [Be(dbm)$_2$] was prepared similarly to [Ga(dbm)$_3$] in aqueous ethanol, and crystallized from THF by adding petroleum ether. The yield was 39%. The corresponding indium (III) complexes were also synthesized similarly to those of the aluminium(III) complexes.[9] They are sensitive towards atomospheric moisture and the organic solvents should be carefully dehydrated.

Trichloroacetic acid, THF, and the reagents for scintillation spectrometry were purified as in the literature.[4]

Kinetic Runs. The essential scheme of the experimental procedure is the same as that in Ref. 4. The gallium(III) complexes are, however, more soluble in various organic solvents, and the rate is much larger than that of the aluminium(III) complexes. Hence the procedure was slightly modified as follows. The complex (0.05 to 0.2 M) and the labelled ligand solution in THF (0.05 to 0.2 M) were kept in a thermostat, mixed swiftly and dispensed into five small glass-stoppered tubes, so that each tube contains *ca.* 2 ml of the reaction mixture. They were kept in the thermostat and taken out one by one at appropriate time intervals. The content was added into chilled petroleum ether (−20 °C) to arrest the exchange reaction. Crystalline complexes precipitated immediately or after certain lapse of time, which were filtered off or decanted, washed with cold diethyl or

* On leave from Indian Association for the Cultivation of Science, Calcutta, India.

** Correspondences should be addressed.

petroleum ether and dried at 60 °C for 2 hr. A weighed amount of the complex (3 to 7 mg) was dissolved in anisole (15 ml) containing 0.4% *p*-terphenyl and 0.01% POPOP [*p*-di(5-phenyl-2-oxazolyl)-benzene] and submitted to scintillation counting.

Measurements. The counting rate was recorded with the automatic counter Unilux IIA from Nuclear Chicago. The absorption spectra were recorded with a Hitachi 124 spectrometer. Water content was measured by Karl-Fischer titration.

Results and Discussion

The absorption spectra of the reaction mixtures remained unchanged throughout the kinetic runs for all the systems, and the recovered complexes were pure. McKay plots gave always linear plots. Hence no other reaction than the isotopic exchange took place under the given experimental conditions.

The rate of exchange, R is expressed by Eq. (1)

$$R = -2.3[3ab/(3a+b)][\log(1-F)]/t \quad (1)$$

where a, b, t, and F stand for the concentrations of the complex and of the free ligand, the lapse of time and the fraction of reaction, respectively.

TABLE 1. INFLUENCE OF THE CONCENTRATION OF COMPLEX AND OF TRICHLOROACETIC ACID ON THE EXCHANGE RATE

[complex]/M	[acid]/M	$[H_2O]$/M	R/M·s	k_0/s^{-1}
0.050	0	0.036	1.1×10^{-6}	2.2×10^{-5}
0.10	0	0.036	2.2×10^{-6}	2.2×10^{-5}
0.13	0	0.036	2.9×10^{-6}	2.2×10^{-5}
0.070	0	0.025		1.4×10^{-5}
0.070	0.0029	0.025		2.2×10^{-5}

0.070	0.0074	0.025		3.6×10^{-5}

at 0 °C; [Hacac]=0.070 M

Tris(acetylacetonato)gallium(III). Kinetic Formula: The R values are proportional to the initial concentration of the complex as shown in Table 1. The variation of k_0 with water concentration under otherwise identical conditions is shown in Fig. 1, indicating the operation of two concurrent paths given in Eq. (2)

$$R = k_0 a = a(k_1 + k_2[H_2O]) \quad (2)$$

Arrhenius plots of k_1 and k_2 at 0, 10, and 20 °C gave almost parallel lines and the ΔH^* are 19±2 and 18±2 kcal/mol, respectively. The dependence of k_0 upon the concentration of free ligand in the presence of differing amounts of water is illustrated in Fig. 2. The gradient indicates the ligand-catalysed rate constants, which are not affected by the water concentration. These results infer the presence of three independent paths as shown in Eq. (3)

$$R = a(k_1 + k_2[H_2O] + k_3 b) \quad (3)$$

The rate constants obtained from the diagrams, and the activation parameters are listed in Table 2. Because of experimental difficulty the error for k's are *ca.* ±10%. Since the contribution of k_1 term is very small, the activation parameters for k_i can be reckoned as those for the k_3 path.

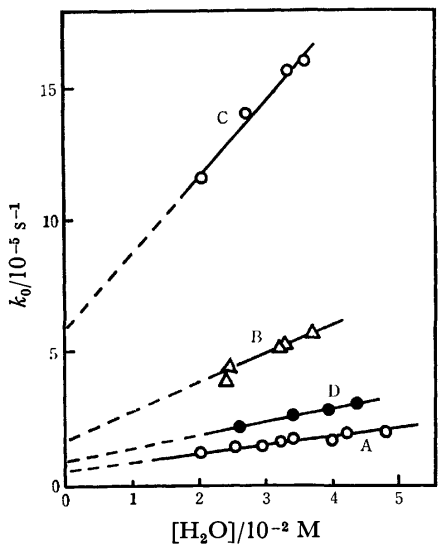

Fig. 1. Relationship between k_0 and water concentration.
A, 0 °C; B, 10 °C; C, 20 °C; D, 0 °C, [trichloroacetic acid]=0.0029 M; [Hacac]=0.070 M (for all).

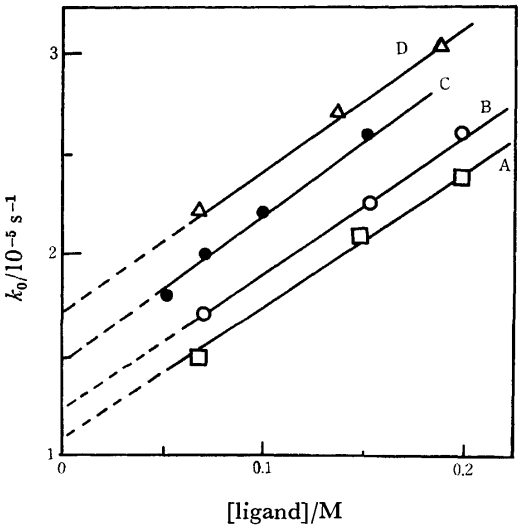

Fig. 2. Influence of ligand concentration upon k_0 in the presence of varying amounts of water for [Ga(acac)$_3$]. 0 °C; $[H_2O]$=A, 0.029, B, 0.036, C, 0.043, and D, 0.050 M.

Trichloroacetic acid catalyses the exchange reaction as shown in Table 1. The extent depends on the water concentration as seen in Fig. 1, and the overall rate in the presence of this acid is given by Eq. (4). Weaker

TABLE 2. KINETIC DATA AND ACTIVATION PARAMETERS FOR THE ISOTOPIC EXCHANGE BETWEEN [Ga(acac)$_3$] AND Hacac-^{14}C IN THF

organic acids failed to give such an acid catalysis.

$$R = a\{k_1'[\text{acid}] + [H_2O](k_2 + k_2'[\text{acid}]) + k_3 b\} \quad (4)$$

The k_1' and k_2' are given in Table 3.

Exchange Mechanism for [Ga(acac)$_3$]: The gallium(III) complex gives much faster isotopic exchange than the aluminium(III) does. The kinetic formulae (3) and (4) are similar to those of the corresponding aluminium(III) complex.[4] We discussed that [Al(acac)$_3$] was in a rapid equilibrium with an intermediate which had one of the ligands as unidentate, and the break of the remaining bond should be the rate-determining step, on the basis of the similarity of $\Delta H^{\neq}$ values for the kinetic terms. Water and acid protons were reckoned to occupy the vacant coordination site and the free end of the unidentate ligand, respectively, and to retard the recombination of the unidentate ligand. Such occupations were considered to affect the $\Delta H^{\neq}$ values little.

The fact that k_2 and k_3 paths for the gallium(III) complex have almost equal activation enthalpies suggests that both paths would have a common rate-determining step. If water and Hacac gave nucleophilic attack towards [Ga(acac)$_3$] itself in the rate-determining step, the $\Delta H^{\neq}$ values should differ significantly, because they must have different affinities towards the substrate. We consider that the common rate-determining step would be the break of the second Ga–O bond of the unidentate ligand as shown in Fig. 3. Both water and Hacac molecule occupy the vacant coordination site of the intermediate to retard the recombination and to facilitate the break of the Ga–O bond of the unidentate ligand to some extent.

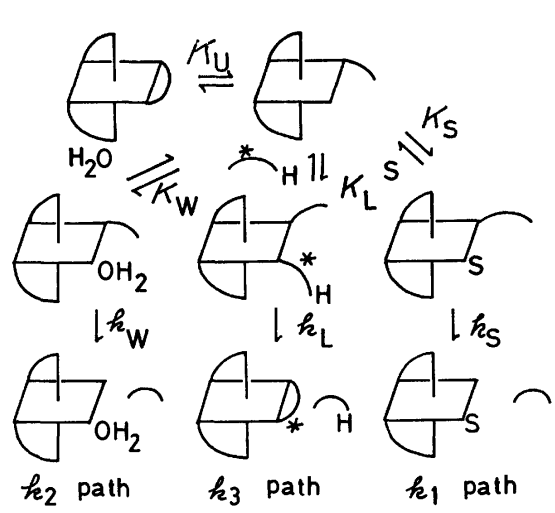

Fig. 3. Plausible reaction mechanism for the isotopic exchange between [Ga(acac)$_3$] and Hacac-^{14}C in THF. S, solvent molecule.

Pinnavaia *et al.* studied site exchange of the mixed ligand complex [Ga(acac)$_2$(dbm)] in benzene by PMR spectroscopy and obtained first-order rate constant 8.8×10^{-2} s^{-1} at 25 °C, the Arrhenius activation enthalpy and $\Delta S^{\neq}$ being 20.6±2.7 kcal/mol and 3.5±8.0 e.u., respectively.[10] They considered that a five-coordinated intermediate mechanism[11] would operate in the site exchange. This result supports our consideration that the nucleophilic interaction of the free ligand operates not on the complex itself but on the intermediate with one unidentate ligand.

When the rate and the equilibrium constants are defined as shown in Fig. 3, the k_1, k_2, and k_3 are written as follows:

$$k_1 = k_s K_s K_u \quad k_2 = k_w K_w K_u \quad k_3 = k_L K_L K_u \quad (5)$$
$$[K_u(K_s + K_w[H_2O] + K_L[L]) \ll 1]$$

The acid-catalyzed term would be interpreted similarly as for [Al(acac)$_3$], k_1' and k_2' terms being related to different proton carriers. The basicity of the unidentate ligand must be small and only a strong acid like trichloroacetic can give acid catalysis.

Comparison with the Mechanism for [Al(acac)$_3$]: There are two differences between the kinetic formulae for [Ga(acac)$_3$] and [Al(acac)$_3$]. The latter has a significant contribution of the k_1 path in THF, whilst the former not. The other difference is the participation of free Hacac in the rate-determining step for [Ga(acac)$_3$]. In the absence of water, (although experimentally impracticable) [Ga(acac)$_3$] and [Al(acac)$_3$] would undergo isotopic exchange *via* the ligand (k_3) and the solvent assisted path (k_1), respectively.

Tervalent gallium has a larger octahedral ionic radius (0.62 Å), than tervalent aluminium (0.51 Å), and the approach of free Hacac to the vacant cooridnation site would be easier to result in larger K_L, and hence larger k_3. Fiat and Connick[2] compared the activation parameters for the water exchange of gallium(III) and aluminium(III) perchlorate solution and suggested S_N2 and S_N1 mechanism for them, respectively. A similar trend is seen here, although the substrate should not be the complex itself but the intermediate with a unidentate ligand.

The affinities between the tervalent ion of gallium and aluminium with water, which are represented by their hydration energies, are almost equal (*ca.* 1% difference for *ca.* 1000 kcal/mol). Hence K_w values for both complexes would not differ much. Larger k_w for [Ga(acac)$_3$] than for [Al(acac)$_3$] should be responsible for larger k_2 for [Ga(acac)$_3$] than for [Al(acac)$_3$]. The difference in $\Delta H^{\neq}$ values of site exchange of gallium(III) and aluminium(III) complexes with given β-diketonato ligands is *ca.* 3 kcal/mol.[10,11] The difference in $\Delta H^{\neq}$ values for the k_2 path in Table 3 is almost

equal to those for the site exchange. The ease of break of the first M–O bond of a given β-diketonato chelate would be paralleled by that of the second M–O bond. The rate-determining step for the site exchange should be either the break of the first M–O bond or the internal rearrangement of the five-coordinated intermediate. No explicit information is given as to the rate-determining step in the literatures,[10,11] but it is very likely that the break of the first M–O bond is the rate-determining step.

TABLE 4. RATE OF ISOTOPIC EXCHANGE OF SOME β-DIKETONATO COMPLEXES OF TYPICAL ELEMENT IONS IN THF

Complex	Temp./°C	b[b)]	$[H_2O]$	k_0/s^{-1}
$[Al(acac)_3]$	25	0.050	0.015	4.2×10^{-6}
$[Al(bzac)_3]$	0	0.050	0.16	3.3×10^{-7}
$[Al(bdm)_3]$	0	0.050	0.015	1.0×10^{-8}
$[Ga(acac)_3]$	0	0.050	0.050	1.9×10^{-5}
$[Ga(bzac)_3]$	0	0.050	0.050	5.0×10^{-6}
$[Ga(dbm)_3]$	0	0.050	0.050	3×10^{-6}
$[In(dbm)_3]$	0	0.050	0.098	$>1\times10^{-3}$
$[Be(acac)_2]$[a)]	30	1.0	—	2.1×10^{-5}
$[Be(bzac)_2]$	50	0.070	0.027	1.4×10^{-6}
$[Be(dbm)_2]$	50	0.070	0.041	1.1×10^{-6}

a) Ref. 13 b) concentration of free β-diketone.

Kinetics of Isotopic Exchange of Related Complexes. The rates are summerized in Table 4. The benzoylacetonato complexes give geometrical isomers, *mer* and *fac*. Their inter-conversion was studied by many authors by NMR spectroscopy and found to be very fast under the given experimental conditions.[10] Hence they were used without separation. Indium(III) complexes were very sensitive towards water in THF and only $[In(dbm)_3]$ allowed kinetic measurements. All the systems listed in Table 4 gave no net chemical change during the kinetic runs under the given conditions and the McKay plots were all linear. The R values were found to be proportional to the complex concentration, and k_0 values are listed. Although detailed kinetic studies were not made, we can compare the overall lability of these complexes with reference to the nature of the metal ions and of the ligands.

The following sequence shows the order of lability of acetylacetonato complexes towards isotopic exchange in organic solvents. The reaction mechanism differs from one another, and was discussed or will be discussed elsewhere.

Ti(IV)[12]>In(III)>Ga(III)>Al(III)[4]>Be(II)[13]>
Pd(II)[14]>Co(III)[15]>Si(IV)[16]>Ge(IV)[17]>Cr(III)[12]

However, so far as the gallium family elements concern, the order of lability is equal to that of water exchange. The order of lability between gallium(III) and aluminium(III) seems to be reversed, when ligands with nitrogen donors are involved (*e.g.* 8-quinolinolato[18] and EDTA[19] complexes). For ligands with oxygen donors only, the order for these two elements seems to be common, although different rate-determining steps may be involved.

Table 4 shows that the lability for a given metal ion decreases in the sequence, Hacac>Hbzac>Hdbm. The pK_a values increase in this order and the metal-ligand bond is expected to increase in this sequence. Although the metal complexes have various reaction paths for isotopic exchange, the basicity of ligands seems to give predominant influence.

The authors thank the Ministry of Education for Grant-in-Aid, and to the Japan Society for the Promotion of Science for Post-doctoral Fellowship to one of us (C.C.).

Ringspaltungsreaktion von Thiadiazolo- und Triazolopyrimidin-Derivaten

Takayuki OKABE, Eiji TANIGUCHI und Kazuyuki MAEKAWA
Landwirtschaftliche Fakultät, Kyushu Universität, Fukuoka 812

(Eingegangen am 14, Mai 1974)

The ring-opening and rearrangement reaction of 7-methyl-5*H*-1,3,4-thiadiazolo[3,2-*a*]pyrimidin-5-ones (I) and the alternative isomeric 7-ones (XI) has been studied. I (R=H) and XI (R=H) gave quantitatively through N-N bond cleavage methylthiouracil (III) by treating with 5% NaOH, while they yielded 4-methyl-2-thiocyanato-6(1*H*)pyrimidone (II) by treating with liquid ammonia. By treating I and XI (R=alkyl) with 5% NaOH, the S-C bond cleaved to produce the corresponding acylaminopyrimidine derivatives (IV and IV') and 3-amino-pyrimidinethione (V and V'). The treatment of 2-hydrazino derivative (I; R=NHNH$_2$) with 5% NaOH gave 1-amino-2-mercapto-7-methyl-5*H*-*s*-triazolo[1,5-*a*]pyrimidin-5-one (VIII) through ring-opening and recyclization. On the other hand, the pyrimidine moiety of I (R=Et and *i*-Pr) cleaved by the action of chlorine to afford 2-amino-1,3,4-thiadiazole (X; R=Et and *t*-Pr).

Indem man Amino-triazol bzw. 2-Amino-1,3,4-thiadiazol oder seine Derivate mit verschiedene β-Ketosäuren oder ihren Derivaten in Gegenwart von Polyphosphorsäure erhitzte, erhielt man Triazolo[1,5-*a*]-pyrimidin, Triazolo[4,3-*a*]pyrimidin. bzw. Thiadiazolo[3,2-*a*]pyrimidine.[1-4]

Diese kondensierten heterocyclischen Verbindungen wurden nicht nur durch Nukleophile substituiert, sondern auch an ihren Triazol- bzw. Thiadiazol-ringen unter Spaltung von den Ringen angegriffen.

Hinsichtlich des Oxadiazolo[3,2-*a*]pyrimidin berichteten Gehlen *et al.*, daß die Ringöffnung am O-Brücke vom Oxadiazolring stattfand.[5] Andererseits, über Thiadiazolo[3,2-*a*]pyrimidin beschrieben Tsuji *et al.*, daß unter gleichen Bedingungen wie die von Gehlen *et al.*, die Spaltung an der N-N-Bindung vom Thiadiazolring vielmehr sich eintrat.[6]

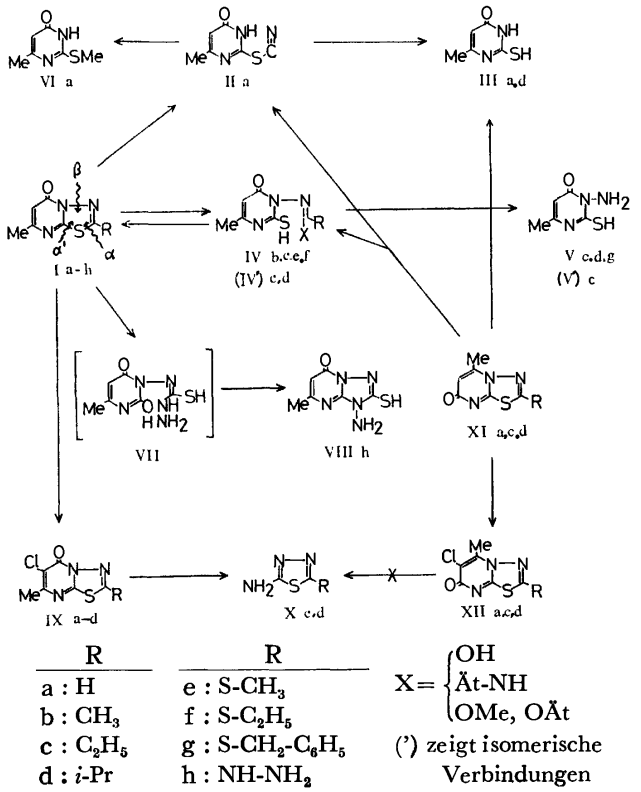

Fig. 1. Spaltung von Thiadiazolo[3,2-*a*]pyrimidin durch Alkali bzw. Chlor

Beide Verfasser isolierten ein Säureamid bzw. Isothiocyanat als Übergangsstoffe jede für sich. Diese Übergangsprodukte gaben demnach durch Hydrolyse mittels Säure 3-Amino-6-methylthiouracil bzw. 6-Methylthiouracil. Nämlich, ist es noch nicht sicher erklärt worden, ob die erste Öffnung des fünfgliedrigen Rings nach Weg α (einschließlich α') oder nach β (Fig. 1) stattfand. Ferner, ob diese Tatsache auf Unterschiede vom Heteroatom (O bzw. S) oder auf Verschiedenheit vom Rest R beruht, läßt es sich noch nicht erläutern.

Um Ringöffnung von der obengenannten heterocyclischen Verbindung mittels Nukleophils zu erklären, wurde dieser Versuch vorgenommen.

Als Folge wurde es gefunden, daß die Öffnung durch Alkali zwar nach Art der Substituenten verschieden war, aber sie vorwiegend nach Weg α (einschließlich α') verläuft. Falls flüssiges Ammoniak oder NaOMe angewendet wurde, so brachte die Öffnungsreaktion mit sich nach Weg β.

Der Weg α übertraf zudem überhaupt α'. Lediglich im Fall, das der Rest R NH–NH$_2$ ist, fand wieder ein Ringschluß nach der Ringöffnung statt, um die Verbindung (VIII h in Fig. 1) zu ergeben.

Andererseits, in Hinsicht auf Öffnung von Pyrimidinring berichteten Bredereck *et al.* schon ein Verfahren, in welchem Triazolopyrimidin mit primärem Amin oder Hydrazin erwärmt wurde.[7] Dunwell und Evans beschrieben, dass 7*H*-Thiazolo[3,2-*a*]pyrimidin-7-on als Spaltungsprodukt mittels Amins im Gegenwart von Tetramethylammoniumhydroxyd Thiazolin-Derivat lieferte.[8] Da Amin jedoch, wie obengennanten, Triazolo- bzw. Thiadiazol-Hälfte zersetzt, wurde die Ringspaltung von Pyrimidin-Hälfte unter Anwendung von Chlor vorgenommen.

Infolgedessen wurde es gefunden, daß Chlor in $CHCl_3$ Lösung bei 0 °C an der höchste Elektronendichte besitzenden C_6-Stelle[9,10] von Thiadiazolo[3,2-*a*]pyrimidin umsetzte. Überflüssiges Chlor verursachte gerade bei 0 °C die Ringöffnung von Pyrimidin-Hälfte, um 2-Amino-5-substituierte-1,3,4-Thiadiazolo-Derivate zu erzeugen.

Andere *s*-Triazolo[4,3-*a*]pyrimidin und Triazolo-[1.5-a] pyrimidin als diese waren beständig unter diesen Reaktionsbedingungen.

Beschreibung der Versuche

1) Darstellung von 3-Acylamino-6-methyl-(bzw. 4-methyl)-thiouracil (IV bzw. IV'), und 3-Amino-6-methyl(bzw. 4-methyl)-thiouracil (V bzw. V') aus I (bzw. XI). Indem man I (R=Me) mit warmer 5% NaOH Lösung einige Stunden lang bewahrte, erhielt man IV (R=Me) mit befriedigender Ausbeute. I (R=Ät) gab aber unter ziemlich milder Bedingung (5% NaOH, Raumtemperatur, 1 stündiges Stehen; oder mit verd. Hydrazin-hydrat) IV (R=Ät). I (R=*i*-Pr) lieferte in gleichen Umständen 3-Amino-6-methyl-4(3*H*)-oxo-2(1*H*)-pyrimidinthion V anstatt IV (R=*i*-Pr), während XI (R=Ät, *i*-Pr) entsprechende isomerische 3-Acylamino-4-methyl-6(5*H*)-oxo-2(1*H*)-pyrimidinthion IV' (R=Et, *i*-Pr) gab.

(a) 3-Acetylamino-6-methyl-4(3H)-oxo-2(1H)-pyrimidinthion (IV, R=CH_3). *Methode A)*: Eine Suspension von 2 g I (R=Me) in 30 ml von 5% NaOH wurde 6 Stunden lang bei Raumtemperatur umgerührt, um aufzulösen. Die Lösung wurde dann mit verd. HCl neutraliziert und i. Vak. eingeengt. Nach Abkühlung wurde der ausgeschiedene Niederschlag gesammelt und mit Eis-Wasser gewaschen. Durch Umkristallisierung aus MeOH erhielt man farblose Nadeln von Schmelzpt. 255—257 °C. Ausbeute 1.4 g (72%).

$\lambda_{max\,(H_2O)}$ 210, 275, 291 nm (ε 10000, 8500, 9200).

Gef.	C 41.51	H 5.02	N 16.22

Aus der nachfolgenden Tatsache läßt sich folgern, daß die Verbindung die durch Spaltung von der S–C Bindung entstandene IVf (X=OÄt), 3-(*S*-Äthyl-*O*-methylformamido)-Verbindung ist. Nämlich ist das IR-Spektrum ganz ähnlich mit dem von IVc (Fig. 2), und ferner verwandelt sich diese Verbindung durch Behandlung mit ÄtONa in seiner äthanolischen Lösung zu If wieder. (Es wurde mittels der Mischprobe und Vergleichung von Massenspektren festgestellt.)

Aus If (R=S–Me) gewann man ebenso $C_8H_{11}OS_2N_3$ (Schmelzpt. 204—205 °C) und diese Verbindung wurde als IVe geschlossen.

IR-Spektren von 3-Acylamino-6-methyl-2-thiouracil (abgeleitet von I) und 3-Acylamino-4-methyl-2-thiouracil (abgeleitet von XI) wurden in Fig. 2 gezeigt.

(c) 3-Amino-6-methyl-4(3H)-oxo-2(1H)-pyrimidinthion (V). *Methode B)*: Eine Suspension von 1.8 g Ic(R=Ät) in 20 ml von 5% NaOH wurde unter Umrührung bei 70—80 °C 7. Stunden lang erhitzt. Nach Abkühlung wurde das Gemisch mit konz. HCl neutralisiert. Der dabei ausgeschiedene Niederschlag wurde gesammelt, mit Wasser gewaschen, und dann aus MeOH umkristallisiert. Ausbeute, 1.1 g (61%).

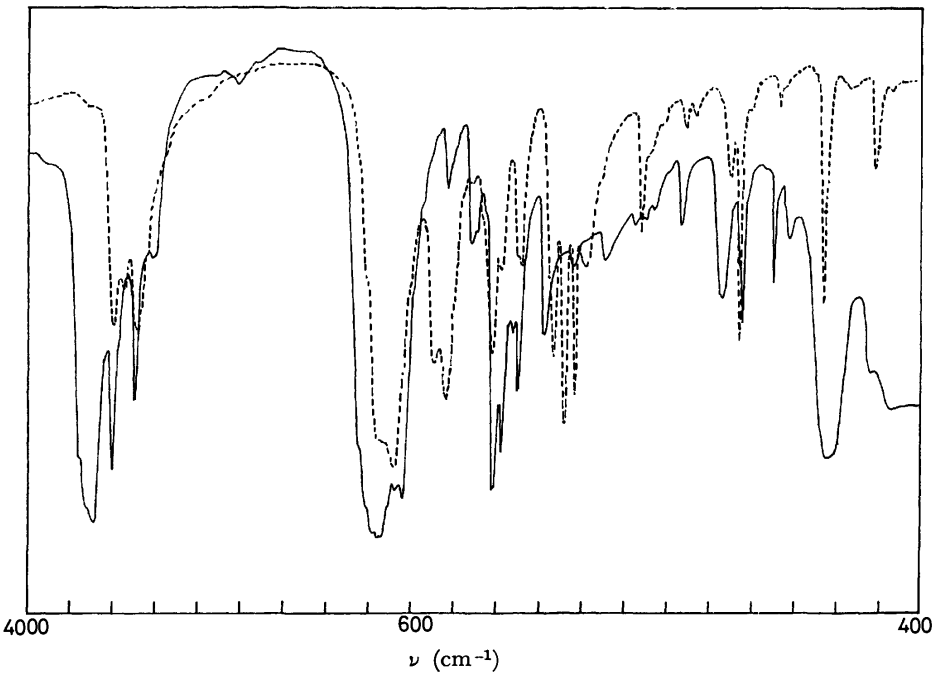

Fig. 2. IR-Spektren von 3-Acylamino-6-methyl(bzw. 4-methyl)-2-thiouracil

weiter nach Verlierung von Benzylthioradikal Ion *m/e* 148 ergab.

Auf diesen Befunde wurde oben erwähnte Verbindung als 1-Amino-2-mercapto-7-methyl-5*H*-*s*-triazolo[1,5-*a*] pyrimidin-5-on geschlossen.

6) Einwirkung von Chlor auf I und XI. Die Umsetzung von I bzw. XI (R=H, Et, *i*-Pr) mit äquivalenter Menge von Chlor in $CHCl_3$ Lösung bei 0—10 °C erzeugte jede für sich entsprechende 6-Chloro-2-alkyl-7-methyl-5*H*-thiadiazolo-[3,2-*a*]pyrimidin-5-on bzw. 6-Chloro-2-äthyl(od. *i*-Pr)-5-methyl-7*H*-thiadiazolo[3,2-*a*]pyrimidin-7-on.

Die Monochlor-Derivate (IX, R=Ät, *i*-Pr) reagierten

dennoch weiter mit überschüssigem Chlor und lieferten jede für sich 2-Amino-5-äthyl, bzw. 2-Amino-5-isopropyl-1,3,4-thiadiazol. Folglich entstanden diese Thiadiazol-Derivate wahrscheinlich durch 6-Chlor-Derivate und nachfolgende Spaltung von Pyrimidinring.

Es ist nennenswert, daß 7-Oxo-Derivat in gleicher Bedingung keine Thiadiazol-Derivat gab.

(a) Umsetzung von Chlor in der Stelle 6 von I: Wenn man in $CHCl_3$ (oder AcOH) Lösung von I (R=H od. Me) unter Kühlung mit Eis-Wasser Chlorgas durchleitet, so kann man Monochlor-Verbindung mit befriedigender Ausbeute erhalten. Sie ist identisch mit 6-Chlor-5*H*-thiadiazolo[3,2-*a*]pyrimidin-5-on, das aus 2-Amino-1,3,4-thiadiazol und 2-Chlor-acetessigsäureäthylester in Gegenwart von Polyphosphorsäure unabhängig synthetisiert wurde.[4]

Aus XI (R=H) wurde man in ähnlicher weise 6-Chlor-Verbindung erhalten. Ausbeute 85%. Schmelzpt. 195—196 °C.

Alkoxythiocyanation and Alkoxyiodination of Olefins with Copper(II) Salts

Akira Onoe, Sakae Uemura,* and Masaya Okano
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611
(Received February 15, 1974)

A simple and convenient method for the preparation of vicinal alkoxythiocyano- and alkoxyiodoalkanes is described. The reaction of olefins with copper(II) salts, such as chloride, bromide and sulfate, and potassium thiocyanate or iodide in alcohols readily affords the compounds in good yields. From vinyl acetates, alkyl vinyl ethers and α,β-unsaturated aldehydes, the products are obtained in the form of dialkyl acetals. The reaction mechanism is discussed.

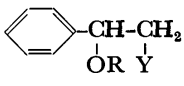
Baird *et al.*[1] reported the preparation of chloroiodoalkanes with the use of copper(II) chloride, metal iodide and olefins in acetonitrile. We found that when the reaction was carried out in alcohol, the main products were alkoxyiodoalkanes instead of chloroiodoalkanes, and that when KSCN was used, alkoxythiocyanoalkanes were obtained. Since the preparation of alkoxyiodo- and alkoxythiocyanoalkanes has so far been restricted to the reaction of olefin with iodine in alcohol in the presence of catalysts such as HgO[2] and $AgClO_4$[3] for the former, and to that with $Tl(OAc)_3$ and KSCN in alcohol for the latter,[4] we wish to report a simple and efficient synthetic method for these compounds using copper(II) salts.

Results and Discussion

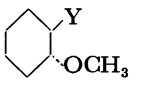
The reaction was carried out by adding olefinic hydrocarbons to a homogeneous alcoholic solution of copper(II) chloride and KSCN or KI at an appropriate temperature, the mixture being kept for 0.3—5 hr. Styrene, cyclohexene, vinyl esters, vinyl ethers and α,β-unsaturated aldehydes were chosen as the olefinic substrates. The products were vicinal alkoxythiocyano- (**1a**—**5a**) or alkoxyiodoalkanes (**1b**—**5b**). The general reaction is illustrated by the following scheme.

$$\text{>C=C<} + 2CuCl_2 + KY + ROH \longrightarrow \text{>C(OR)—C(Y)<} + 2CuCl + KCl + HCl \quad (1)$$

(Y=SCN, I)



1 (**a**, Y=SCN; **b**, Y=I)



2 (**a**, Y=SCN; **b**, Y=I)

Some typical results with the former two and last three olefins are summarized in Tables 1 and 2, respectively. Copper(II) bromide, sulfate, nitrate and iron(III) chloride could also be used in the reaction, although these salts were less effective than copper(II) chloride. All the products obtained from the reaction of cyclohexene were found to be *trans*.

In the reactions of vinyl and isopropenyl acetates, the products (**3a** and **3b**) were isolated in the form of dialkyl acetals, no compounds containing acetoxy group being obtained.

$$CH_2{=}C(R)(OAc) \xrightarrow[R'OH]{CuCl_2,\ KY} YCH_2C(OR')_2\text{-}R \quad (2)$$

3 (**a**, Y=SCN; **b**, Y=I)

The products of the reaction of alkyl vinyl ethers were

a) $CuCl_2$, 100 mmol. b) Based on $CuCl_2$ charged. c) 200 mmol.

4 and/or **3**, the amounts of both products depending on the reaction conditions. Higher temperature and longer time favored the exchange of alkoxy group, giving **3** as the main product.

$$CH_2{=}C(H)(OR) \xrightarrow[R'OH]{CuCl_2,\ KY} YCH_2C(OR')(H) \xrightarrow{R'OH} \textbf{3a or 3b}\ (R{=}H) \quad (3)$$

4 (**a**, Y=SCN; **b**, Y=I)

Under the same or even more drastic conditions, the reaction of diethyl or di-*n*-butyl acetal of acetaldehyde with copper(II) chloride and KSCN or KI gave none or only trace amounts of **3** and/or **4**. The result excludes such reaction schemes as one in which alcohol adds to the double bond at first, followed by the attack of Y. The reaction of acrolein and crotonaldehyde under similar conditions gave the products also in the form of dialkyl acetal. According to Castro *et al.*[5)]

$$RCH{=}CHCHO \xrightarrow[R'OH]{CuCl_2,\ KY} RCH(OR')CH(Y)CH(OR')_2 \quad (4)$$

5 (**a**, Y=SCN; **b**, Y=I)

the reaction of acrolein with copper(II) chloride or bromide in methanol gave **5** (R=H, R′=CH_3, Y=Cl, or Br) in 12—39% yield. They proposed that the reaction proceeds through the addition of methanol to acrolein affording β-methoxypropionaldehyde followed by the attack of chlorine or bromine of copper(II) salt on the α-position of the saturated aldehyde thus formed. In order to see whether the same reaction scheme is operative in our case, the reaction of butyraldehyde with copper(II) chloride was carried out in the presence of KSCN in refluxing methanol for 1 hr. The yield of 1,1-dimethoxy-2-thiocyanobutane,[6)] however, was quite low (19%) as compared with the 89% yield for **5** obtained from crotonaldehyde. This indicates that the reaction scheme proposed by Castro *et al.*[5)] is partly operative, but not important in our case. Thus the main route for the formation of **5** would be the attack of Y on double bond followed by addition of the alkoxy group.

The reaction scheme for the formation of **1**—**5** can be described as follows.

$$2CuX_2 + 2Y^- \longrightarrow 2CuX + Y_2 + 2X^- \quad (5a)$$

$$CuX + Y_2 \rightleftharpoons [CuXY]^-Y^+ \quad (5b)$$

$$\text{>C=C<} + [CuXY]^-Y^+ \longrightarrow \left[\text{>C(Y)—C<}\right][CuXY]^- \xrightarrow{ROH} \text{>C(OR)—C(Y)<} \quad (5c)$$

The first step is the oxidation of thiocyanate or iodide anion by copper(II) salt to form a molecular thiocyanogen or iodine (Scheme 5a, Y=SCN or I). These molecules are activated by complexation with copper(I) salt (Scheme 5b), the electrophilic attack to olefin being followed by addition of the alkoxy group (Scheme 5c). The fact that **1**—**5** are all Markownikov addition products and that the products obtained in the reaction of cyclohexene are *trans*, supports the reaction shceme. In connection with this, the following observations are worth noting. **1** (R=CH_3, Y=I) was obtained in a good yield by refluxing styrene and iodine in methanol in the presence of copper(I) chloride (Table 1). In the absence of copper(I) salt, however, the reaction did not give **1** under similar conditions. Similar phenomena were observed with cyclohexene as a substrate. The reaction of cyclohexene with a mixture of silver(I) thiocyanate and bromine in methanol, which has been known to evolve thiocyanogen,[7)] at 20 °C for 2 hr afforded 19% yield or a trace amount of *trans*-1-

methoxy-2-thiocyanocyclohexane, **2a**, in the presence or absence of copper(I) chloride, respectively.

Nuclear thiocyanation at a *para* position occurred with reactive aromatic compounds such as phenol or *N,N*-dimethylaniline by this reaction system. Thus, *p*-thiocyanophenol [mp 52 °C (recrystallized from H_2O), lit,[8] mp 52—53 °C] was obtained in 51% yield by refluxing phenol, copper(II) chloride and potassium thiocyanate in methanol for 2 hr.

Experimental

The NMR spectra were measured with a Varian A-60 spectrometer in $CDCl_3$, using TMS as an internal standard. The IR and mass spectra were measured with Hitachi EPI-S2 and JEOL JMS-01SG spectrometers, respectively. Glc analysis was carried out on Shimadzu 5APTF and 4BMPF apparatus, using PEG 6000(25%)-Chromosorb W(3 m) and Apiezon L(30%)-Celite(1 m) columns(carrier gas, N_2).

Materials. All the organic materials were distilled before use. Commercial anhydrous $CuCl_2$ and $CuBr_2$ and other inorganic salts were used without further purification.

Preparation of 3a(R=H, R'=CH_3) from Vinyl Acetate. The following is a typical experimental procedure for alkoxythiocyanation, alkoxyiodination being similarly carried out. Vinyl acetate(8.6 g, 0.1 mol) was added at 62 °C under stirring to a greenish-black homogeneous solution of anhydrous $CuCl_2$ (13.4 g, 0.1 mol) and KSCN(9.7 g, 0.1 mol) in methanol(100 ml). In 20 min the color of the reaction mixture turned to pale yellow and a large amount of white precipitate of CuCl was formed. After 3 hr, 400 ml of water was added and then CuCl(8.9 g, 0.09 mol) was filtered. The filtrate was extracted with diethyl ether and the extract was evaporated by a rotary evaporator to *ca.* 20 ml which contained 0.043mol (86% yield) of 1,1-dimethoxy-2-thiocyanoethane **3a**(R=H, R'=CH_3). Distillation gave 4.41 g (0.03 pure compound; bp 106—107 °C/19 mmHg. IR, 2160 (s) mol) of (ν_{SCN}), 1120 (s) (ν_{C-O}) and 1070 (s) (ν_{C-O}) cm^{-1}. NMR, δ 3.12 (d 2H, J=5 Hz), 3.42 (s. 6H), 4.60 (t 1H, J=5 Hz). Found: C, 40.40; H, 6.40; N, 9.47%. Calcd for $C_5H_9NO_2S$: C, 40.80; H, 6.16; N, 9.52%. 2,4-Dinitrophenylhydrazone (2,4-DNP) of **3a**, mp 173—175 °C(yellow crystals, from EtOH).

Identification of the Products. Data on alkoxythiocyanation and alkoxyiodination are given in Tables 1 and 2. **1a**-(R=CH_3), bp 129—130 °C/6 mmHg(lit,[9] 146—147 °C/9 mmHg). **1b**(R=CH_3), bp 94.5 °C/3 mmHg(lit,[2b] 107—108 °C/5 mmHg). **1b**(R=C_2H_5), bp 95.5—96 °C/3 mmHg(lit,[2b] 142—144 °C/14 mmHg). **1b**(R=*n*-C_3H_7), bp 102.5—103 °C/3 mmHg, Found: C, 45.60; H, 5.47%. Calcd for $C_{11}H_{15}IO$: C, 45.53; H, 5.21%. **1b**(R=*n*-C_4H_9), bp 105.5 °C/4 mmHg. Found: C, 47.80; H, 5.87%. Calcd for $C_{12}H_{17}IO$: C, 47.38; H, 5.64%.

2a, bp 108—109.5 °C/18 mmHg. NMR, δ 1.2—2.0(m. 6H), 2.9—3.2 (m. 2H, >CHSCN and >CHOCH$_3$), 3.40(s 3H, OCH$_3$). IR, 2150(s) (ν_{SCN}). **2b**(bp 99.5—101 °C/20 mmHg); identical in glc and NMR with the compounds prepared by the reported method using HgO (red)[2a] or $AgClO_4$[3] as a catalyst, and assigned to *trans*[10] (lit,[2a] bp 114 °C/49 mmHg). *trans*-1-Chloro-2-thiocyanocyclohexane; identical with the compound prepared by the method using $Pb(SCN)_2$ and Cl_2.[8] It was also prepared by the reaction of cyclohexene with $Pb(SCN)_2$ and $SbCl_5$; bp 110—112 °C/4 mmHg(lit,[8] bp 154—156 °C/21 mmHg). *trans*-1-Chloro-2-iodocyclohexane; identical with the compound prepared by the method[1a] from cyclohexene, $CuCl_2$ and I_2 in pentane, bp 66—66.5 °C/4 mmHg (lit,[1a] bp 37 °C/0.2 mmHg).

3a(R=H, R'=C_2H_5), bp 85 °C/5 mmHg. Found: C, 47.62; H, 7.71; N, 7.86%. Calcd for $C_7H_{13}NO_2S$: C, 47.97; H, 7.47; N, 7.99%. **3a**[R=H, (OR')$_2$=O(CH_2)$_2$O], bp 97.5—98 °C/5 mmHg, NMR, δ 3.20 (d 2H, J=3 Hz), 4.00 (m 4H), 5.22 (t 1H, J=3 Hz). Found: C, 48.25; H, 7.88; N, 7.66%. Calcd for $C_5H_7NO_2S$: C, 47.97; H, 7.48; N, 7.99%. **3a**[R=CH_3, (OR')$_2$=O(CH_2)$_2$O], bp 84 °C/3.5 mmHg. NMR(CCl_4), δ 1.45 (s 3H), 3.17 (s 2H), 4.02 (s 4H). **3b** (R=H, R'=CH_3), bp 37 °C/5 mmHg. Found: C, 22.20; H, 4.37%. Calcd for $C_4H_9IO_2$: C, 22.23; H, 4.20%. 2,4-DNP, mp 145—148 °C (yellow crystals, from EtOH). **3b** (R=H, R'=*i*-C_3H_7), bp 55.5 °C/3 mmHg. Found: C, 35.65; H, 6.63%. Calcd for $C_8H_{17}IO_2$: C, 35.30; H, 6.30%.

4a (R=C_2H_5, R'=CH_3), bp 85 °C/5 mmHg. Found: C, 44.46; H, 7.32; N, 8.64%. Calcd for $C_6H_{11}NO_2S$: C, 44.70; H, 6.88; N, 8.69%. **4a** (R=C_2H_5, R'=*t*-C_4H_9), bp 97.5—98 °C/6 mmHg. Found: C, 52.60; H, 8.80; N, 7.08%. Calcd for $C_9H_{17}NO_2S$: C, 53.17; H, 8.43; N, 6.89%. **4a** (R=C_2H_5, R'=CH_2CH_2OH), bp 135—136 °C/8 mmHg. Found: C, 44.35; H, 7.18; N, 7.25%. Reactions of Methylcalcium Iodide. II. Carboxylation, Metalation, and Metal-Halogen Exchange Reactions

Nariyoshi KAWABATA,* Hirotsugu YOSHIMURA, and Shinzo YAMASHITA
Department of Chemistry, Faculty of Polytechnic Science, Kyoto Institute of Technology, Matsugasaki, Sakyo-ku, Kyoto 606
(Received March 22, 1974)

Utility of methylcalcium iodide in several organic reactions in tetrahydrofuran was shown. Carboxylation of methylcalcium iodide at −70 °C gave acetic acid in 57—63% yield. Metallation of indene and fluorene by methylcalcium iodide at −30 °C gave 3-indenyl- and 9-fluorenylcalcium iodides in 99 and 93% yields, respectively. Metal-halogen exchange reactions of methylcalcium iodide with halobenzenes were rather slow.

Although reactions of organocalcium halides have been studied, available data are limited. Yields of products are generally low, particularly in the reactions of aliphatic organocalcium halides. We demonstrated that methylcalcium iodide is a useful organometallic reagent in several organic reactions in tetrahydrofuran.[1] Reactions with ketones, aldehydes and esters gave the corresponding addition products in good yields. Both coupling and addition reactions were observed in the reactions with acid halides. They gave the corresponding ketones in low yields by the reaction with nitriles, reacting slowly with benzyl chloride and 1,1-diphenylethylene, but not reacting with cyclohexene. We have examined the utility of methylcalcium iodide in carboxylation, metalation, and metal-halogen exchange reactions.

Results and Discussion

Bryce-Smith and Skinner[2] reported that carboxylation of phenylcalcium iodide at −50 to −30 °C in tetrahydrofuran afforded benzoic acid in a high yield, whereas that of *n*-butyl- and *n*-pentylcalcium iodides at 20—25 °C in diethyl ether gave the corresponding carboxylic acids in only 10 and 9% yields, respectively. They observed the formation of the corresponding ketones and carbinols besides the carboxylic acids. However, we found that carboxylation of methylcalcium iodide at −70 °C in tetrahydrofuran gave acetic acid in 53—57% yield based on methyl iodide used in the preparation of methylcalcium iodide. Since the yield of methylcalcium iodide was in the range 91—93% based on methyl iodide, the yield of acetic acid based on methylcalcium iodide would be 57—63%. Gas chromatographic analyses also showed the presence of acetone and *tert*-butyl alcohol in 17 and 11% yields based on methyl iodide (18 and 12% yields based on methylcalcium iodide), respectively. The discrepancy of our results with those of Bryce-Smith and Skinner[2] could be partly attributed to the difference in the reaction temperature. The addition of alkylcalcium iodide to calcium carboxylate formed by the reaction of alkylcalcium iodide with carbon dioxide might be more significant at higher temperature.

Kocheshkov and co-workers[3,4] reported that metallation of indene and fluorene by phenylcalcium iodide followed by carboxylation gave the corresponding carboxylic acids in good yields. They stated that metallation of indene, fluorene and related hydrocarbons by alkylcalcium iodides followed by carboxylation afforded the corresponding carboxylic acids in very low yields.[3] However, we found that metalation of indene by methylcalcium iodide at −30 °C followed by carboxylation gave indene-3-carboxylic acid in 99% yield, mp 161 °C.

We used an excess amount of calcium metal in the preparation of methylcalcium iodide. Indene-3-carboxylic acid could be partly derived from the direct metalation of indene by the excess calcium metal. We found that direct metallation of indene by metallic calcium in tetrahydrofuran under similar reaction conditions gave only a trace of indene-3-carboxylic acid after carboxylation. Direct metallation seems to be a rather slow reaction, *e.g.*, Fischer and Stölzle[5] obtained bis(cyclopentadienyl)calcium in 27% yield from calcium metal and cyclopentadiene in 3—4 hr in refluxing tetrahydrofuran.

Kocheshkov and co-workers[3,4] described the formation of indene-1-carboxylic acid. However, the melting point 154 °C shows that the product was indene-3-carboxylic acid. The melting points of indene-1- and indene-3-carboxylic acids were reported to be 73.5—74 °C[6] and 159.5—161 °C,[7] respectively.

We also found that fluorene-9-carboxylic acid was formed in 93% yield by the metallation of fluorene with methylcalcium iodide at −30 °C followed by carboxylation.

Thus the metalation of indene and fluorene by methylcalcium iodide provides an excellent method for preparation of 3-indenyl- and 9-fluorenylcalcium iodides, which is in contrast to that described.[3,4] The discrepancy could be ascribed to low purity of alkylcalcium iodides.

Bryce-Smith and Skinner[2] reported that the reaction of α-bromonaphthalene with phenylcalcium iodide gave α-naphthylcalcium iodide in an excellent yield. However, no information can be found in literature on the metal-halogen exchange reaction of alkylcalcium halides. We found that the reactions of methylcalcium iodide with halobenzenes were rather slow. Reactions of methylcalcium iodide with bromobenzene in tetrahydrofuran at −30 °C gave a trace of benzoic acid after carboxylation. Gas chromatographic analysis also indicated the presence of a nearly quantitative amount of unchanged bromobenzene in the reaction products.

* To whom correspondence should be addressed.

Neither toluene nor biphenyl was detected.

On the other hand, longer reaction time and higher reaction temperature improved the yield to some extent. The reaction at 20 °C for 24 and 45 hr gave benzoic acid in 11 and 36% yields, respectively, after carboxylation. The reactions of methylcalcium iodide with chlorobenzene, bromobenzene and iodobenzene at 23 °C for about 50 hr gave benzoic acid in 21, 42, and 38% yields, respectively. The reaction of *n*-propylcalcium iodide with bromobenzene at 20 °C for 40 hr gave benzoic acid in 80% yield. We used excess calcium metal in the preparation of methyl- and *n*-propylcalcium iodide. The reaction of unchanged calcium metal with halobenzenes to give phenylcalcium halides was significant under these reaction conditions. Still longer reaction time and higher reaction temperature would not markedly improve the yield, since the loss of organocalcium halides by the reaction with the solvent, tetrahydrofuran, becomes significant under the conditions.[1,2]

Experimental

Gas chromatographic analyses were carried out on a Shimadzu GC-4A or GC-4B gas chromatograph using columns of Chromosorb 101 (80—100 mesh) and 20% polyethylene glycol 6000 on Celite 545 (60—80 mesh) for carboxylic acids and other products, respectively. Proton magnetic resonance spectra were obtained with a Varian T-60-A spectrometer using dimethyl-d_6 sulfoxide or carbon tetrachloride as the solvent and tetramethylsilane as an internal standard.

Materials. Methylcalcium iodide and *n*-propylcalcium iodide were prepared in tetrahydrofuran.[8] Tetrahydrofuran was purified by distillation in the presence of benzophenone sodium ketyl under a nitrogen atmosphere. Nitrogen was purified by being passed through a tube containing copper turnings in a furnace at 170 °C followed by drying with phosphorus pentoxide. Methyl iodide, *n*-propyl iodide, chlorobenzene, bromobenzene, iodobenzene, and indene were dried over calcium hydride and distilled. Fluorene was dried by being kept over phosphorus pentoxide in a desiccator. Carbon dioxide was dried by being passed through calcium chloride, silica gel, and concentrated sulfuric acid. Commercial authentic samples and other chemicals were used without further purification.

Procedure. The reaction vessel was a two- or one-necked flask equipped with three-way cocks. Each cock was connected with a nitrogen inlet and a rubber serum cap. Methylcalcium iodide and *n*-propylcalcium iodide were prepared in the flask under nitrogen atmosphere. Various reactants were added to this organocalcium compound with a hypodermic syringe under nitrogen atmosphere. Carboxylation was carried out by passing carbon dioxide through a stainless steel needle.

Reaction of Methylcalcium Iodide with Carbon Dioxide. Carbon dioxide was passed through a suspension of methylcalcium iodide in tetrahydrofuran at −70 °C for 2 hr, after which water was added. The precipitate was washed with diethyl ether, and 20% hydrochloric acid was added to the precipitate. Extraction with diethyl ether and elimination of the solvents and other materials of lower boiling points under a reduced pressure gave a mixture of acetic acid and water. Its NMR spectrum indicated the absence of impurity other than water, and showed the yield of acetic acid to be 57% based on the methyl iodide used in the preparation of methylcalcium iodide.

In another run, carbon dioxide was passed through a suspension of methylcalcium iodide in tetrahydrofuran at −70 °C for 1 hr, and then water and 20% hydrochloric acid were added. The reaction mixture was subjected to gas chromatographic analyses. The yield of acetic acid was 53% based on methyl iodide. Gas chromatographic analyses also showed the presence of acetone and *tert*-butyl alcohol in 17 and 11% yields, respectively, based on methyl iodide in the reaction mixture.

Metallation of Indene by Methylcalcium Iodide. To methylcalcium iodide prepared from 0.35 g (8.8 mmol) of calcium and 0.98 g (6.9 mmol) of methyl iodide was added 0.57 g (4.9 mmol) of indene in 2.0 ml of tetrahydrofuran. The reaction mixture was allowed to stand at −30 °C for 2.5 hr under stirring, and carbon dioxide was passed through the reaction mixture at −70 °C for 1 hr, and then 10.0 ml of 20% hydrochloric acid was added. Extraction with diethyl ether and evaporation of the solvent under reduced pressure left a solid, which was washed with carbon tetrachloride and dried over phosphorus pentoxide under reduced pressure in a desiccator. Purity of the product was checked by its NMR spectrum. Yield of indene-3-carboxylic acid was 0.78 g (99% based on indene), mp 161 °C (lit,[7] 159.5—161 °C). The reaction of 0.12 g (3.0 mmol) of calcium metal with 0.69 g (5.9 mmol) of indene in 15.0 ml of tetrahydrofuran under similar conditions gave a trace of indene-3-carboxylic acid after carboxylation. The result shows that direct metalation of indene by the excess calcium metal, used in the preparation of methylcalcium iodide, was not significant under the above reaction conditions.

Metallation of Fluorene by Methylcalcium Iodide. To methylcalcium iodide prepared from 0.30 g (7.4 mmol) of calcium and 0.82 g (5.8 mmol) of methyl iodide was added, 0.77 g (4.6 mmol) of fluorene in 3.0 ml of tetrahydrofuran, and the mixture was kept at −30 °C for 3 hr under stirring. Carbon dioxide was passed through the mixture at −70 °C for 1 hr, and the reaction mixture was treated in a similar manner to that in the metalation of indene. Yield of fluorene-9-carboxylic acid was 0.91 g (93% based on fluorene), mp 225 °C. Melting points were reported to be in the range 225—232 °C.[9-12]

Reaction of Methylcalcium Iodide with Halobenzenes. To methylcalcium iodide prepared from 0.31 g (7.7 mmol) of calcium and 0.89 g (6.2 mmol) of methyl iodide was added, 0.56 g (5.0 mmol) of chlorobenzene in 2.0 ml of tetrahydrofuran and the mixture was allowed to react at 23 °C for 49 hr under stirring. Passage of carbon dioxide at −70 °C for 1 hr led to the formation of benzoic acid. Gas chromatographic analyses indicated the yield of benzoic acid to be 21% based on chlorobenzene, and the presence of trace of benzene in the reaction products. The reaction of 0.054 g (1.3 mmol) of calcium metal with 0.32 g (2.9 mmol) of chlorobenzene in 6.8 ml of tetrahydrofuran under similar conditions gave a trace of benzoic acid after carboxylation.

To methylcalcium iodide prepared from 0.30 g (7.4 mmol) of calcium metal and 0.85 g (6.0 mmol) of methyl iodide was added 0.75 g (4.8 mmol) of bromobenzene in 2.0 ml of tetrahydrofuran, and the mixture was allowed to react at 23 °C for 49.5 hr under stirring. The reaction mixture was treated in a similar manner. The yield of benzoic acid determined by gas chromatography was 42% based on bromobenzene. Gas chromatographic analysis showed the presence of benzene in 0.4% yield based on bromobenzene. The reaction of 0.12 g (3.0 mmol) of calcium metal with 1.04 g (6.6 mmol) of bromobenzene in 15.0 ml of tetrahydrofuran under similar conditions gave a trace of benzoic acid after carboxylation.

To methylcalcium iodide prepared from 0.27 g (6.7 mmol)

of calcium and 0.83 g (5.8 mmol) of methyl iodide was added 0.89 g (4.4 mmol) of iodobenzene in 2.0 ml of tetrahydrofuran. The mixture was allowed to react at 23 °C for 49.5 hr under stirring, and treated in a similar manner. Gas chromatographic analyses showed the formation of benzoic acid in 38% yield based on iodobenzene, as well as a trace of benzene. The reaction of 0.056 g (1.4 mmol) of calcium metal with 0.59 g (2.9 mmol) of iodobenzene in 7.0 ml of tetrahydrofuran under similar conditions gave 0.64 mmol of benzoic acid (22% based on iodobenzene and 46% based on metallic calcium) after carboxylation. The result indicates the formation of phenylcalcium iodide under the above reaction conditions by the direct reaction of iodobenzene with excess calcium metal.

Reaction of n-*Propylcalcium Iodide with Bromobenzene.* To *n*-propylcalcium iodide prepared from 0.11 g (2.7 mmol) of calcium and 0.36 g (2.1 mmol) of *n*-propyl iodide was added 0.16 g (1.0 mmol) of bromobenzene and the mixture was allowed to react at 20 °C for 40 hr under stirring. A similar treatment of the mixture led to the formation of benzoic acid in 80% yield based on bromobenzene. The yield was determined by gas chromatography.

The authors are grateful to Mr. Akira Matsumura for his assistance in the preliminary experiments of this work.

The Thermal Reactions of Azido-1,3,5-triazines

Ryuichi KAYAMA, Shigeru HASUNUMA, Shizen SEKIGUCHI, and Kohji MATSUI
Department of Chemistry, Faculty of Engineering, Gunma University, Kiryu, Gunma 376
(Received April 20, 1974)

Azido-*s*-triazines containing -Cl, $-OCH_3$, and $-N(CH_3)_2$ groups were synthesized, and their thermal reactions with some hydrocarbons were investigated with respect to the reaction products and the reaction kinetics. With non-olefinic hydrocarbons the reactions were found to proceed *via* a nitrene intermediate; in the reactions with cyclohexane, cyclohexylamino-*s*-triazines and amino-*s*-triazines were obtained. On the other hand, with olefinic hydrocarbons the reactions took place *via* a bimolecular mechanism involving a formation of an intermediate of the triazoline type; in the reactions with cyclohexene, cyclohexenylamino-*s*-triazines were obtained along with amino-*s*-triazines. In both cases, the yields of alkylamino and alkenylamino-*s*-triazines increased with the electron-withdrawing power of the substituents in the *s*-triazine nucleus.

There have been a number of studies of the thermal and photochemical reactions of azido compounds;[1] in recent years the reactions and structures of azido derivatives of nitrogen heteroaromatics such as pyridine,[2,3] pyridazine,[4] pyrimidine,[5-8] pyrazine,[9,10] quinoline,[11] and acridine[12] have been investigated.

Azido-*s*-triazines have been known for a long time; however, little is known about their reactions. In the reactions of azido-*s*-triazines with such nucleophiles as sodium hydroxide[13] and ammonia,[14] the azido group is replaced by hydroxy and amino groups, while some azido-*s*-triazines are known to decompose violently on heating.[13,15] Recently, the presence of a nitrene intermediate was confirmed in the photolysis of azido-*s*-triazine,[16] and amino-*s*-triazines were obtained from azido-*s*-triazines upon irradiation in methanol.[17] However, the details of the thermal and photochemical reactions of azido-*s*-triazines have not yet been revealed. On the other hand, the thermolysis and photolysis of azido-*s*-triazines may provide useful and convenient routes for the preparation of a number of *s*-triazine derivatives which would otherwise be difficult to synthesize. This paper will report on the thermal reactions of azido-*s*-triazines with several hydrocarbons.

Results and Discussion

Syntheses of Azido-s-triazines. Azido-*s*-triazines containing -Cl, $-OCH_3$, and $-N(CH_3)_2$ groups in the *s*-triazine nucleus were prepared by the condensation of the corresponding chloro-*s*-triazines with sodium azide. Table 1 lists the compounds thus obtained. These monoazido-*s*-triazines are thermally-stable compounds. Compound **1** is distillable, while Compound **2** can be sublimed under reduced pressure; all of them decomposed at about 200 °C, showing no significant substituent effect upon their thermal stabilities.

Structure of Azido-s-triazines. It is well known that an azidoazomethine-tetrazole equilibrium exists in 2-azido-nitrogen heteroaromatics; the position of the equilibrium is known to depend upon the solvent, the temperature, and the electronegativity of the heterocyclic ring. Generally, the electron-withdrawing ability of the heterocyclic ring is considered to stabilize the azido form;[18] azido-pyridines exist in equilibrium with the tetrazole form, but the equilibrium lies strongly on the side of the tetrazole,[19] and azido-pyrimidines exist in both the azido and tetrazole forms, while 2-amino-4,6-diazido-*s*-triazine is known to exist in the diazido form.[20]

The IR spectra of these azido-*s*-triazines in KBr discs have a strong and sharp characteristic band near 2100 cm^{-1} assignable to the azido group, suggesting that these compounds exist in the azido form in a solid state. In addition, the PMR spectra of Compounds **2** and **3** in CCl_4, $CDCl_3$, DMSO-d_6, and CF_3COOH at 40 and 60 °C showed a signal assignable to $-OCH_3$ or $-N(CH_3)_2$ as a singlet in every case in spite of the wide diversity in the nature of the solvent (see Table 2), indicating the absence of tautomeric tetrazole, which should possess two kinds of methoxy or dimethylamino groups respectively; azido-*s*-triazines containing ordinary substituents in the *s*-triazine nucleus exist in the azido form not only in a solid state, but also in a solution, regardless of the solvent employed. The fact that the azido form is the sole species in Compound **3**

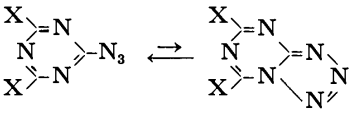
a) TMS was used as the internal standard.

[the bis(dimethylamino)-*s*-triazinyl group is known to be the least electron-attracting group among the common *s*-triazinyl groups][21] suggests that the presence of



X=-Cl, $-OCH_3$, $-N(CH_3)_2$

three ring nitrogen atoms in the heterocyclic nucleus is sufficient for the electron-withdrawing power of the heterocycle to shift the azidoazomethine-tetrazole equilibrium far to the left, regardless of the substituents in the heterocycle.

Reactions of Azido-s-triazines with Hydrocarbons. It is known that acyl azides, such as azido formates and sulfonyl azides, decompose thermally or photochemically to give the corresponding nitrenes, which then react with aliphatic hydrocarbons to give alkylamino derivatives as the insertion products. On the other hand, it is known that, in the thermal reactions with aliphatic hydrocarbons, ordinary aryl azides do not afford the corresponding nitrene insertion products as the major products. Recently, it was reported that, in the reaction of phenyl azide with cyclohexane, *N*-cyclohexylaniline was obtained with aniline.[22] The situation of the *s*-triazinyl group as a aromatic group is of interest because of its strong electron-attracting character.

When the azido-*s*-triazines were heated in cyclohexane at 180—190 °C under pressure, the corresponding amino-*s*-triazines and cyclohexylamino-*s*-triazines were obtained as the major products in every case.

2	OCH_3	15	22
3	$N(CH_3)_2$	17	trace

a) Isolated after methoxydechlorination.

Table 3 lists the yields of these *s*-triazine derivatives.

In the case of Compound **1**, because of the presence of active chlorine atoms in the *s*-triazine nucleus, the formation of a large quantity of a metal-containing decomposition product (the metallic constituents of the by-products are considered to result from the autoclave used) was observed. Therefore, the yields of the major reaction products should increase in the reactions in inert reactors.

From Table 3 it is obvious that the substituents in the *s*-triazine nucleus considerably affect the yields of the products; it can be said that the electron-withdrawing substituents in the *s*-triazine nucleus favor the formation of cyclohexylamino-*s*-triazine and that, in the thermal reactions of aryl azides with aliphatic hydrocarbons, the yields of the alkylamino derivatives become higher with an increase in the acidic character of the aryl group.

On the other hand, when azido-*s*-triazines were heated in cyclohexene under pressure at 180—190 °C, the corresponding amino-*s*-triazines and cyclohexenylamino-*s*-triazines were obtained in every case, as is shown below.

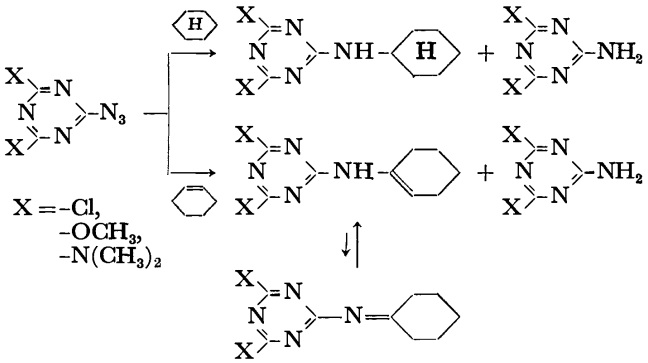

Table 4 lists the yields of the amino- and cyclohexenylamino-*s*-triazines thus obtained. In the reaction of Compound **1** with cyclohexene, the formation of a large quantity of metal containing decomposition product was also observed.

From the concept[23] generally accepted for the structure of ordinary enamines possessing a secondary nitrogen atom, the tautomeric equilibrium between enamine and imino forms in *s*-triazinyl enamines can be expected

to lie far to the side of the imino form. However, in the PMR spectra of cyclohexenylamino-*s*-triazines, the presence of NH and olefinic protons was observed in a ratio of 1 : 1, as is shown in the case of the dimethoxy-*s*-triazine derivative (see Table 5). This fact indicates that the cyclohexenylamino-*s*-triazine exists as the enamine form, suggesting that the strong electron-attracting character of the *s*-triazinyl group prevents the overlap of the lone pair of electrons on the -NH- nitrogen with the π electrons of the enaminic double bond, and that the N→C migration of the NH proton to form the imino form becomes difficult; in ordinary *s*-triazine derivatives the enamine form may be the stable one, as in the cases of *N*-acyl vinylamines[24] and *N*-ethoxycarbonylcyclohexenylamine.[25]

Kinetics of the Reactions of Azido-s-triazines with Hydrocarbons. As has been described above, azido-*s*-triazines react thermally with cyclohexane and cyclohexene to give the insertion and abstraction products of the nitrenes corresponding in appearance. Thus, in order to make clear the progress of the reactions of azido-*s*-triazines with these hydrocarbons, kinetic measurements of the reactions were carried out.

When azido-*s*-triazines were heated in hydrocarbons, an evolution of nitrogen was observed in every case. Therefore, for the kinetic measurements, an increase in the volume of nitrogen evolved was followed with the lapse of time in various substrates. Since a plot of

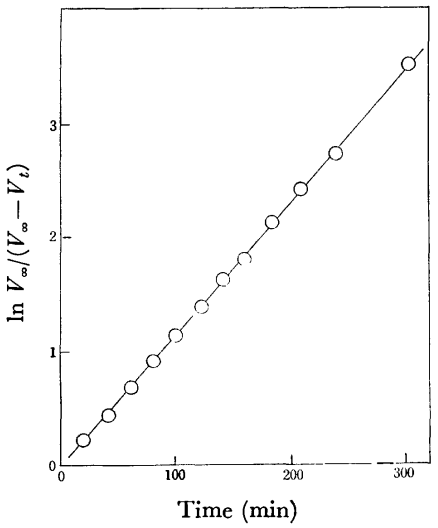

Fig. 1. Decomposition of 2-azido-4,6-dimethoxy-*s*-triazine in acetophenone at 184.3 °C.

ln $V_\infty/V_\infty - V_t$ (where V_t and V_∞ are the volumes of nitrogen evolved at time t and at an infinite time respectively) against the reaction time, t, was found to give a straight line up to about a 90% conversion of the azido-*s*-triazines, as is shown in Fig. 1, the first-order rate constants for the decomposition of azido-*s*-triazines were calculated from the slopes of the straight lines; they are listed in Table 6.

From Table 6 it is obvious that, in the reactions with cyclohexane, decalin, tetralin, diphenyl ether, and dimethyl terephthalate, there was little variation in the rate in spite of the wide diversity in the nature of the substrates, suggesting that the rate-determining step of these reactions is the loss of nitrogen and the formation of an electron-deficient nitrene species. The substrates were assumed to participate merely as solvents. For a detailed discussion of the reactions of azido-*s*-

154.0	—	—	6.48
164.2	—	22.7	11.0
174.2	0.96	39.7	15.6
184.3	2.36	66.9	26.1
194.0	5.45	—	—

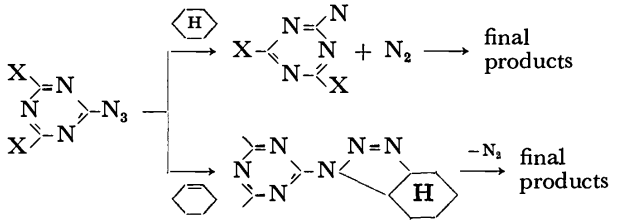
Table 8. Activation parameters for the decomposition of 2-azido-4,6-dimethoxy-*s*-triazine

Substrate	$\Delta H^{\ddagger}$ (kcal·mol^{-1})	$\Delta S^{\ddagger}$ (184.3 °C) (cal·deg^{-1}·mol^{-1})
Decalin	36.7	+4
Cyclohexene	21.0	−23
Methyl oleate	16.8	−34

triazines with these substrates, the temperature dependence of the reaction constant for the decomposition of Compound **2** was measured in decalin; the results are listed in Table 7. From these values, the activation parameters for the reaction were calculated; they are shown in Table 8.

The entropy of activation of +4.0, which is comparable in magnitude to those of the reactions of sulfonyl azides with similar substrates, suggests that the reaction is of the first order involving the nitrene intermediate;[26] it can be generally said that the thermal reactions of azido-*s*-triazines with non-olefinic hydrocarbons proceed *via* a nitrene intermediate.

On the other hand, in the reactions of azido-*s*-triazines with olefinic hydrocarbons, the situation was different from that described above. For example, the rate constants for the reactions of Compound 2 with cyclohexene, 1-tetradecene, methyl oleate, and dimethyl maleate were larger than those for the reactions with non-olefinic substrates and (see Table 5) differed significantly from each other, suggesting that the rate-determining step of these reactions is not the loss of nitrogen from azido-*s*-triazines. Moreover, the entropies of activation were of a large negative value, as is shown in Table 8. Therefore, it is unlikely that the decomposition of azido-*s*-triazines in olefinic hydrocarbons proceeds *via* a nitrene intermediate; it may be reasonable to consider that the reactions of azido-*s*-triazines with olefins take place *via* a bimolecular mechanism involving an intermediate of the triazoline type which decomposes rapidly under the cleavage of the nitrogen to give the final products.[27]



If this reaction process is correct, the amino-*s*-triazines in the reactions with olefins should result from the triazoline intermediates or cyclohexenylamino-*s*-triazines.

When Compound 2 was heated at 120 °C in cyclohexane for 40 hr, merely 5% of the azide was decomposed, forming amino-*s*-triazine in a yield of 6% of the decomposed azide. However, when Compound 2 was heated in cyclohexene at 120 °C for 30 hr, all of the azide was decomposed to yield cyclohexenylamino-*s*-triazines in a yield of 34% and amino-*s*-triazine in a yield of 26%. In addition, the cyclohexenylamino-*s*-triazines gave the corresponding amino-*s*-triazines in good yields upon heating in olefinic substrates under similar reaction conditions, suggesting that the amino-*s*-triazines in the reactions of azido-*s*-triazines with olefins did not result from the nitrene intermediates, but, rather, from the cyclohexenylamino-*s*-triazines. Details of the decomposition of cyclohexenylamino-*s*-triazines are now being studied and will be reported elsewhere.

Experimental

All the melting points are uncorrected.

The infrared spectra were measured in potassium bromide discs on a Jasco D-301 spectrometer. The NMR spectra were recorded on a Varian A-60D spectrometer. The ultraviolet spectra were recorded on a Hitachi-124 UV-VIS spectrometer. The elemental analyses were performed in the Micro-analytical Center of Gunma University.

The identification of the reaction products was performed by means of studying their NMR and infrared spectra, by elemental analyses, by a molecular-weight determination, and by a mixed-melting-point test with an authentic sample.

Materials. A typical preparation is shown in the case of Compound **2**. A solution of 7.5 g (0.115 mol) of sodium azide in 80 ml of water was stirred, drop by drop, into a solution of 13.5 g (0.075 mol) of 2-chloro-4,6-dimethoxy-*s*-triazine in 100 ml of acetone at 40 °C. After stirring for 4 hr at 40 °C, the reaction mixture was poured into 300 ml of ice-water. The precipitate was then filtered and dried to give 9.5 g (84%) of a crude product. The recrystallization of the product from benzene–ligroin gave an analytical sample of Compound **2**. Mp 85—85.5 °C. IR (KBr) cm^{-1}: (N_3) 2140 and (*s*-triazine) 810. DTA: 85 °C (endothermic) and 195 °C (exothermic).

Reactions of Azido-s-triazines with Cyclohexane. Typical examples will be shown in the cases of Compounds **1** and **2**.

1) A solution of 7.0 g (0.037 mol) of Compound 1 in 50 ml of cyclohexane was heated for 7 hr at 180—190 °C in an autoclave. After the solvent had then been evaporated *in vacuo*, the residue was treated with a solution of 5.4 g (0.1 mol) of sodium methoxide in 50 ml of methanol for 12 hr at room temperature. After the insoluble matter had been filtered off, the solution was evaporated *in vacuo*. From the benzene extract of the residue, 2-cyclohexylamino-4,6-dimethoxy-*s*-triazine was obtained in a yield of 23%; mp 123.5—125.5 °C (methanol–water).

2) A solution of 5.0 g (0.026 mol) of Compound **2** in 50 ml of cyclohexane was heated for 7 hr at 180—190 °C in an autoclave. After the reaction mixture had then been cooled to room temperature, the crystal was filtered to give 0.7 g (yield, 16%) of 2-amino-4,6-dimethoxy-*s*-triazine; mp 214—216 °C (lit,[28] 219 °C). The filtrate was evaporated in vacuo; then the residue was purified by silica gel column chromatography [developing solvent, benzene: acetone = 100: 5 by volume] to give 1.5 g (yield 22%) of 2-cyclohexylamino-4,6-dimethoxy-*s*-triazine; mp 127—128 °C (lit,[28] 127—129 °C).

In the reaction of Compound **3** with cyclohexane 2-amino-4,6-bis(dimethylamino)-*s*-triazine (yield, 17%) dioxane (mp 221—222 °C) (lit,[29] 222 °C) was obtained along with a small amount of 2-cyclohexylamino-4,6-bis(dimethylamino)-*s*-triazine.

Cyclohexylamino-s-triazines. A typical preparation of an authentic sample of cyclohexylamino-*s*-triazine is shown below in the case of 2-cyclohexylamino-4,6-bis(dimethylamino)-*s*-triazine. A solution of 2.0 g (0.01 mol) of 2-chloro-4,6-bis(dimethylamino)-*s*-triazine in 30 mol of cyclohexylamine was refluxed for 8 hr, and then the mixture was poured into 300 ml of ice-water. After the mixture had then been

neutralized with hydrochloric acid, the crystal was filtered and dried. Recrystallization from petroleum ether gave 1.3 g of an analytical sample of 2-cyclohexylamino-4,6-bis(dimethylamino)-*s*-triazine. Mp 68—69 °C. Found: C, 58.79; H, 9.40%. Calcd for $C_{13}H_{24}N_6$: C, 59.06; H, 9.15%.

Reaction of Azido-s-triazines with Cyclohexene. A typical example is shown in the case of Compound 2.

A solution of 20.0 g (0.11 mol) of Compound 2 in 200 ml of cyclohexene was heated for 7 hr at 180—190 °C in an autoclave. After the reaction mixture had then been cooled to room temperature, the crystals were filtered off to give 2.0 g (yield, 12%) of 2-amino-4,6-dimethoxy-*s*-triazine; mp 215—216 °C (lit,[28] 219 °C). From the filtrate, 13.0 g of 2-(cyclohexene-1-ylamino)-4,6-dimethoxy-*s*-triazine were obtained as a crystalline precipitate after cooling for 1 night at 0 °C. Mp 92—93 °C (Ligroin). Found: C, 56.14; H, 7.03; N, 23.47%. Calcd for $C_{11}H_{16}N_4O_2$: C, 55.91; H, 6.83; N, 23.72%. Mass: m/e=236. IR, cm^{-1}: (NH) 3150, (C=C) 1670, and (*s*-triazine) 815.

The compound absorbed 1 mol of bromine in chloroform and was oxidized by potassium permanganate in pyridine at room temperature.

Kinetic Measurements. The kinetic measurements were carried out by following the increase in the volume of nitrogen evolved or the decrease in the intensity of the N_3 band of azido-*s*-triazine [Compound **1**=2140 cm^{-1}: Compound **2**=2160 cm^{-1}; Compound **3**=2125 cm^{-1}].

The nitrogen evolation rates were measured by the methods of Overberger[30] and Leffler.[31] 40 ml of a substrate in a 100 ml long-necked flask was immersed in a constant-temperature bath controlled to±0.1 °C using polyethylene glycol and then allowed to reach the equilibrium temperature and pressure.

A weighed amount of the azide, 0.002—0.003 mol in 10 ml of the substrate, was poured into the flask. The flask was connected to the azotometer through a small condenser and a stopcock, and the reading of the volume was adjusted to zero. The stopcock was then closed, the solution was shaken well, and the measurement was started. The volume change in the nitrogen was followed for 90% of the reaction. The infinity volume of gas was determined by the reading after no increase in gas volume was observed (after about 6—7 hr).

In the reactions with cyclohexane, cyclohexene, and diethyl maleate, the kinetic runs were carried out by measuring the decrease in the intensity of the N_3 band.[32] A typical run is shown below in the reaction of Compound **2** with cyclohexane. A solution of Compound **2** in cyclohexane (0.14 mol/l) was heated in a constant-temperature bath in about 20 small glass sealed tubes 12 cm in length and 8 mm in diameter. At intervals of about 10 min the tubes were poured into cold water to stop the reaction, and the IR spectra of the solutions were measured. The first-order rate constant for the decomposition of the azido-*s*-triazine was calculated using Eq. (1):

$$k_1 t = -\ln [\log (T_\infty/T_0)/\log (T_\infty/T_t)] \quad (1)$$

where T_∞, T_t, and T_0 represent the transmittances at an infinite time, at time t, and at time zero respectively.

The Synthesis of 2,4-Dehydrohomoadamantane[1)]

Ryohei YAMAGUCHI, Takeo KATSUSHIMA, and Mituyosi KAWANISI

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606

(Received April 26, 1974)

A synthesis of 2,4-dehydrohomoadamantane (I) is described. a) The UV irradiation of a solution of 4-homoadamantene (IV) in xylene containing a small amount of methanesulfonic acid under nitrogen gave a 2: 1 mixture of I and IV after 7 day; this mixture afforded pure I in a 40% isolation yield. b) The oxidation of 4-homoadamantyl hydrazone (XI) by $Pb(OAc)_4$, NiPO, and MnO_2 (active) gave a 7—11: 1 mixture of I and IV respectively. It was observed that the ratio of I to IV depends on the reaction temperature, and that the oxidation of XI by $Pb(OAc)_4$ at −78 °C gave thirty times as much I as IV. The addition of MeOH as a proton source reduced the ratio of I to IV in the cases of NiPO and MnO_2. The Bamford-Stevens reactions of 4-homoadamatyl tosylhydrazone (II) were effected in aprotic as well as in protic solvents. The ratio of I to IV was inverted under aprotic and protic conditions. The selectivities in the oxidation of XI and the Bamford-Stevens reactions of II were explained by considering the conformations of 4-homoadamantylidene (XII) and the 4-homoadamantyl cation (VIII).

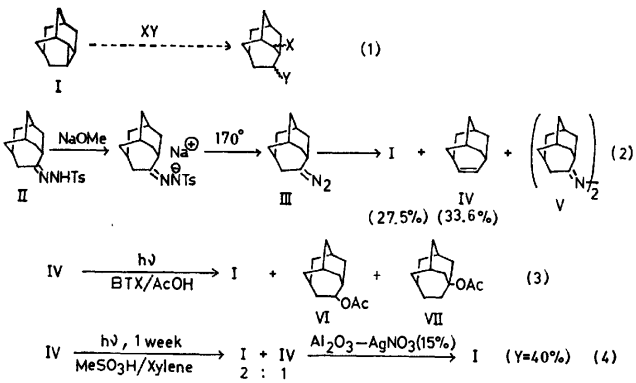
When cage compounds include a cyclopropane ring in their framework, their chemistry is intriguing in view of recent advances in the field of cyclopropane chemistry;[2)] such compounds can be adequate precursors of further substituted cage compounds. For example, 2,4-dehydroadamantane has been used in the stereochemical studies of photobromination of cyclopropanes;[3)] it is also effective as the precursor of a variety of 2- and 2,4-substituted adamantane derivatives.[4)]

Consequently, it is likely that 2,4-dehydrohomoadamantane (I) is a potential precursor of yet-unknown 2- and 2,4-substituted homoadamantane derivatives (Scheme 1, Eq. (1)). As for the synthesis of I, Schleyer *et al.* reported that the Bamford-Stevens reaction of 4-homoadamantyl tosylhydrazone (II) gave I (25.7%) and 4-homoadamantene (IV) (33.6%), along with a small amount of 4-homoadamantyl azine (V)[5)] (Scheme 1, Eq. (2)). According to their procedure, however, not only was the yield of I unsatisfactory, but also a rather larger amount of IV was produced. In this report we wish to describe a synthesis of I *via* a) a "hot" 4-homoadamantyl cation (VIII) generated photochemically and b) 4-homoadamantylidene (XII) generated by the oxidation of 4-homoadamantyl hydrazone (XI).

Results and Discussions

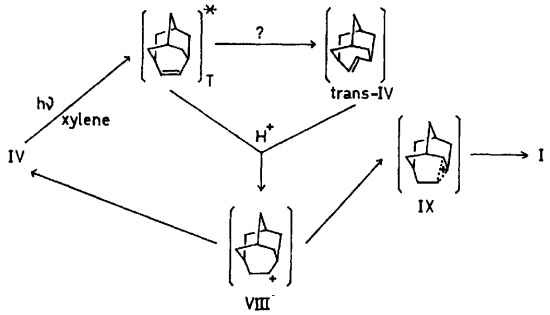
Photochemical Synthesis of I via *"Hot" (Vibrationally-excited) 4-Homoadamantyl Cation.* In a previous communication,[6)] we reported that the BTX-sensitized photochemical reaction of IV in acetic acid afforded I, along with 4- and 3-homoadamantyl acetates (VI and VII) (Scheme 1, Eq. (3)). On the other hand, there have been two reports on the acetolysis of 4-homoadamantyl tosylate giving IV and VI.[7a)] These differences can be explained by assuming a vibrationally-excited nature of the VIII formed photochemically.[7b,8)] In order to obtain I effectively, we investigated the reaction conditions under which no adducts, namely, VI and VII, were produced. Since the formation of adducts is caused by a nucleophilic attack of the protic solvent (in this case, acetic acid) on the cation before the completion of the deprotonation to produce I as well as IV, it is hoped that the use of the proton source with a poor nucleophilicity will increase the yield of I. This was to be the case when use was made of methanesulfonic acid, which has almost no nucleophilicity, as the proton source.

The UV irradiation of a solution of IV in xylene (commercial mixture) containing methanesulfonic acid under nitrogen gave a 2: 1 mixture of I and IV after 7 day; this mixture was chromatographed on a 15% $AgNO_3$-alumina column eluted by petroleum ether, giving pure I in a 40% isolation yield (Scheme 1, Eq. (4)).



Scheme 1.

Upon the replacement of methanesulfonic acid by sulfuric or hydrochloric acid as a proton source, I was not produced, presumably because of the sensitivity of the resulting I toward these acids. The addition of



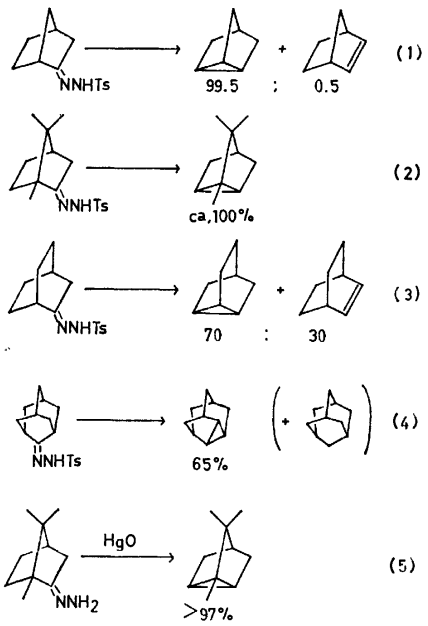
Scheme 2.

tert-butyl alcohol to increase the solubility of methanesulfonic acid (methanesulfonic acid dissolves poorly in xylene) caused only a slight isomerization to I.

The possible mechanism of the photoisomerization of IV to I is depicted in Scheme 2. Since the 4-homoadamantyl cation (VIII), produced according to the general pattern of the polar photochemistry of cycloalkenes,[8] can be expected to be in a vibrationally-excited state, VIII must have the enhanced nature of the nonclassical cation (IX), which can be nicely deprotonated to give I.

Selective Synthesis of I by the Oxidation of 4-Homoadamantyl Hydrazone (XI). The intramolecular γ-C–H insertion of carbene intermediates is one of the most general methods of cyclopropane formation in the skeleton of cage compounds. The Bamford-Stevens reaction, the alkaline-thermolysis of tosylhydrazone, has been repeatedly used to synthesize numerous cage compounds involving cyclopropane rings.[9] The distribution of a cyclopropane and an olefin in the resulting mixture varies according to the structure of the reactants (Scheme 3). For example, Bamford-Stevens reactions of tosylhydrazones of norcamphor and camphor gave exclusively nortricyclene and tricyclene respectively[10,11] (Scheme 3, Eqs. (1) and (2)), but the tosylhydrazone of bicyclo[2.2.2]octan-2-one afforded tricyclo[3.2.1.$0^{2,7}$]-octane (70%) and bicyclo[2.2.2]oct-2-ene (30%)[12] (Scheme 3, Eq. (3)). When the resulting olefin violates Bredt's Rule,[13] only the cyclopropane compound was produced. For example, adamantyl tosylhydrazone gave 2,4-dehydroadamantane (65%) along with a slight amount of adamantane[14] (Scheme 3, Eq. (4)). As mentioned above, in the homoadamantane derivative the Bamford-Stevens reaction of II gave I (27.5%) and IV (33.6%).[5]

Friedman and Shechter successfully explained the distributions of olefins, cyclopropanes, and other transannular insertion products in Bamford-Stevens reactions of tosylhydrazones of 5- to 10-membered ring ketones by a consideration of the conformation of each carbene intermediate; they found that the distribution of the products depended on the conformations of the carbene intermediates.[15] While in a Bamford-Stevens reaction a higher temperature (100—200 °C) is generally required to complete the decomposition of the salt of the tosylhydrazone, the conformation of the carbene intermediate generated at the higher temperature would be different from that of one generated at lower temperature. Therefore, if the corresponding carbene can be produced at a lower temperature, we can expect that the product distribution will be varied. One of the well-known methods of producing a diazoalkane, a precursor of a carbene, at a low temperature is the oxidation of the appropriate hydrazone. As an example of cyclopropane formation by the oxidation of hydrazone, the oxidation of the hydrazone of camphor by mercuric oxide is typical in giving tricyclene exclusively;[16] this result is in good agreement with that of the Bamford-Stevens reaction, and no effect of lowering the reaction temperature was observed upon the distribution of the products in the bicyclo[2.2.1]heptane system, which is highly rigid (Scheme 3, Eq. (5)).

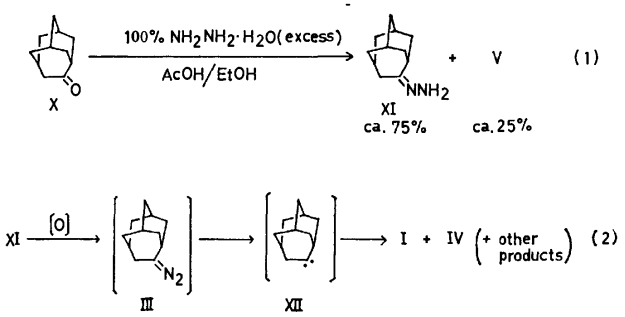


Scheme 3.

In the homoadamantane system, however, we found that the oxidation of 4-homoadamantyl hydrazone (XI) by $Pb(OAc)_4$ at room temperature gave 8 times more I than IV; this result is greatly different from that of the Bamford-Stevens reaction.[17] In order to obtain I exclusively we studied in detail the oxidation of XI, taking the kind of oxidant and the reaction temperature as well as the catalytic effects into consideration. Finally, we will discuss the cause of the selectivity observed in the oxidation of XI in comparison with the Bamford-Stevens reactions under aprotic and protic conditions.

The hydrazone (XI) was prepared by treating 4-homoadamantanone (X) with an excess of hydrazine hydrate, along with V (20—25%) (Scheme 4). This hydrazone is considerably labile and is easily converted into V even at room temperature. Therefore, in the actual process we used the crude XI for the following oxidation immediately after it has been prepared containing an unspecified amount of V; the yields of the products were estimated on the basis of X, the starting material for XI.

Oxidants: Several oxidants were examined for the oxidation of XI (Scheme 4, Eq. (2); the results are summarized in Table 1. While mercuric oxide did not



Scheme 4.

oxidize XI, probably because of its low oxidizing ability, lead tetraacetate ($Pb(OAc)_4$), nickel peroxide (NiPO),[18] and active manganese dioxide (MnO_2)[19] all did oxidize XI. In the case of $Pb(OAc)_4$, 4-homoadamantyl acetate (VI) was produced, while in the case of NiPO as well as MnO_2, 4-homoadamantanol (XIII) and X were produced.

As is shown in Table 1, 7—11 times more I is produced than IV. Since it is thought that both reactions, the oxidation of XI and the Bamford-Stevens reaction of II, must have the same intermediate, 4-homoadamantylidene (XII) generated *via* 4-diazohomoadamantane (III), such a selectivity must result from changing the reaction conditions, especially the reaction temperature.[20] Therefore, we next studied the temperature effect.

Table 1. Oxidation of XI[a]

Oxidant	I+IV (%)[b]	I/IV[c]
HgO	—	—
$Pb(OAc)_4$	37.6	8.7
NiPO	36.8	11.5
MnO_2(active)	43.5	7.2

a) One equivalent of oxidant was used in CH_2Cl_2 solution at room temp. b) Isolated yield. c) Determined by glc (PEG 20M, 180 °C).

Temperature Effect: The oxidation of XI by $Pb(OAc)_4$ was effected at a variety of temperatures. The results are summarized in Table 2.[21] Clearly, a temperature effect was observed; at −78 °C thirty times as much I was produced as IV. These temperature effects imply that some conformational contributions must operate in the transition state (*vide infra*).

Table 2. Temperature effect in the oxidation of XI[a]

Temp.	I+IV (%)[b]	I/IV[c]	VI (%)[b]
Room temp.	37.6	8.7	24
−15 °C	42.6	15.4	23
−30	44.8	23.9	21
−78	63.9	32.4	14

a) One equivalent of $Pb(OAc)_4$ was used in CH_2Cl_2 solution. b) Isolated yield. c) Determined by glc (PEG 20M, 180 °C).

Catalytic Effect: In general, a catalytic effect is regarded as another important factor which may govern a carbene reaction. It is well known that, in the presence of a catalyst, such as copper salt, some selectivity has been observed in carbene reactions.[22] We have tried copper(II) acetylacetonate ($Cu(acac)_2$) and cuprous chloride (CuCl) as catalysts. The former is soluble in organic solvents, and the latter, insoluble. The results were rather disappointing; they are summarized in Table 3. It can safely be said that a catalytic effect hardly works in these cases; under these conditions it is doubtful that the resulting carbene is actually modified by the copper ion.

The Effect of a Protic Solvent: It is well known that, in the presence of an appropriate proton source, a diazo compound is converted to a corresponding carbocation *via* a diazonium ion, the behavior of which is generally very different from that of a corresponding carbene.[11] Since the oxidation of XI by $Pb(OAc)_4$, NiPO, and active MnO_2 is accompanied by the production of acetic acid in the former case, and by that of water in the latter two cases, and since both acetic acid and water are able to become appropriate proton sources, we examined the selectivity of the oxidation reactions in the presence of a larger amount of the proton source. The results are summarized in Table 4. In the cases of NiPO and MnO_2 the addition of methanol diminished the ratio of I to IV; this implies that the selectivity is reduced in the carbocation process. In the case of $Pb(OAc)_4$ the addition of methanol or acetic acid did not cause any marked change in the ratio of I to IV; the reason for this is not clear, but if a carbene formation and a diazonium ion formation would compete each other, in the case of $Pb(OAc)_4$ I and IV would be produced predominantly *via* a carbene, and therefore the ratio of I to IV would not be affected.

Table 3. The oxidation of XI in the presence of copper ion[a]

Copper ion	Temp.	I/IV[b]
$Cu(acac)_2$	Room temp.	11
$Cu(acac)_2$	−15 °C	16
CuCl	Room temp.	8

a) $Pb(OAc)_4$ in CH_2Cl_2 was added to the solution of XI and $Cu(acac)_2$ or CuCl in CH_2Cl_2. b) Determined by glc (PEG 20M, 180 °C).

Table 4. The oxidation of XI in the presence of proton source

Run	Oxidant	H^+-Source	Additive	I/IV[a]
1	$Pb(OAc)_4$	—	K_2CO_3	10.4
2	$Pb(OAc)_4$	AcOH	—	11.6
3	$Pb(OAc)_4$	MeOH	—	9.9
4	NiPO	—	$MgSO_4$	9.5
5	NiPO	MeOH	$MgSO_4$	5.9
6	MnO_2	—	$MgSO_4$	9.5
7	MnO_2	MeOH	$MgSO_4$	4.9

a) Determined by glc (PEG 20M, 180 °C).

Bamford-Stevens Reactions of II in Aprotic and Protic Solvents: In order to compare the results of the oxidation of XI, we effected the Bamford-Stevens reactions of II in aprotic as well as in protic solvents. It has been established that, in an aprotic solvent such as diglyme, the reaction proceeds *via* a carbene, whereas in a protic solvent such as ethylene glycol the reaction proceeds *via* a carbocation (diazonium ion).[11] The results obtained here are summarized in Table 5. In diglyme, more than 2.7 times as much of the IV olefin was produced as of the I cyclopropane, whereas in ethylene glycol more than 1.9—2.5 times as much of I was produced as of IV. It is of interest that the ratio of I to IV under aprotic conditions is inverted in comparison with that under protic conditions. These results are very informative in elucidating the cause of the selectivity.

Table 5. Bamford-Stevens reaction of II

$$\text{II} \xrightarrow[\text{Base, Solvent}]{140\ ^\circ\text{C}} \text{I} + \text{IV}$$

Solvent	Base (equiv.)	I : IV[a)]
Diglyme	NaOMe (3.4)	1 : 2.7
Diglyme	NaH (1.9)	1 : 2.8
Ethylene glycol	Na (1.7)	1.9 : 1
Ethylene glycol	Na (3.4)	2.3 : 1
Ethylene glycol	Na (10)	2.5 : 1

a) Determined by glc (PEG 20M, 180 °C).

Mechanistic Considerations: As has been mentioned above, for an intramolecular carbene insertion reaction the distribution of the products seems to depend on the conformation of the corresponding carbene intermediate. In other words, the choice of the formation of cyclopropane and/or olefin is thought to depend on the degree of overlap of the γ-C–H bond and the β-C–H bond with the vacant sp^2-orbital of (singlet) carbene.

As to the conformation of the homoadamantane system, Schleyer *et al.* have argued on the basis of the obtained results in their studies of the infrared intramolecular hydrogen-bonding-shift of *cis*-4,5-homoadamantanediol and quantitative conformational analysis calculations.[23] According to them, the preferred conformation in the XIV homoadamantane system is essentially untwisted, but this system is so flexible that the dihedral angle varies from 0 to *ca.* 30° (see XIVa and XIVb in Fig. 1). In the XII carbene, the XIIa conformer might be very favorable for γ-C–H insertion producing I, while the XIIb conformer might be very favorable for producing IV. A model investigation[24] tells us that the 2-C–H_a or 9-C–H_a (γ-C–H) bond occupies a more favorable position to overlap with the sp^2-vacant orbital at C-4 (note that the 2-C–H_a or 9-C–H_a bond and the sp^2-vacant orbital at C-4 are coplanar) than 5-C–H_b (β-C–H), while the dihedral angle between the 5-C–H_b (β-C–H) bond and the sp^2-vacant orbital at C-4 is about 30°. For XIIb, the dihedral angle is about 0°, while the 2-C–H_a or 9-C–H_a bond and the sp^2-vacant orbital at C-4 are out-of-plane. At lower temperatures (oxidation conditions), the contribution of the XIIa conformer might be larger than that of XIIb because there is no strain due to the eclipsed form of C-4-H and C-5-H for XIIa, but XIIb might have some torsional strain. At higher temperatures (Bamford-Stevens conditions), the energy difference between XIIa and XIIb might be overcome by the temperature factor and the entropy factor might play an important role, so that the contribution of XIIb might be larger than that of XIIa.

In the VIII carbocation, at lower temperatures the contribution of the VIIIa conformer might be larger than that of VIIIb for the same reasons as in the case of XII. The reduced ratio of I to IV in the carbocation process is caused by the lower γ-C–H insertion ability of VIII than that of XII. At higher temperatures, however, VIIIa might also be more stable than VIIIb, since the VIIIb conformer might have some strain due to the eclipsed form of C-4-H and C-5-H.

We think that the selectivity in the oxidation of XI and the Bamford-Stevens reaction can be well explained by considering the conformations of the XII carbene and the VIII carbocation.

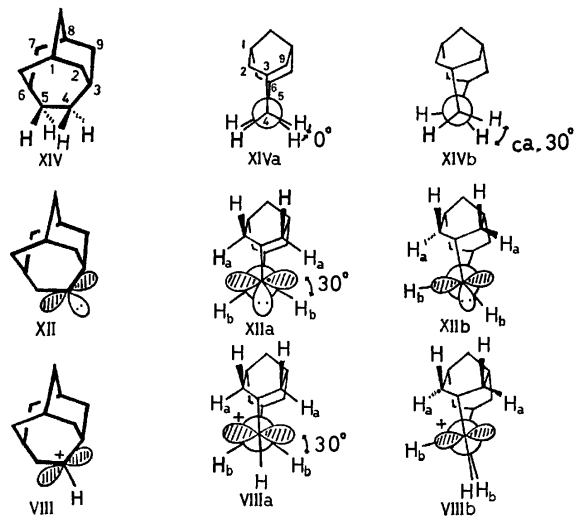


Fig. 1. Conformations of XIV, XII, and VIII.

In conclusion, lowering the reaction temperature in the intramolecular insertion reaction of XII promotes the γ-C–H insertion, thus producing I at the expense of the β-C–H insertion. At −78 °C, the oxidation of XI by $Pb(OAc)_4$ gives I exclusively. To date, this is the most efficient method of obtaining I.

Experimental

All the temperatures are uncorrected. The IR spectra were obtained on a Shimazu IR-27 spectrometer. The MS spectra were taken by using a Hitachi RMS-4 mass spectrometer. The PMR spectra were obtained on an EM-360 spectrometer, TMS being chosen as the internal standard.

Photochemical Synthesis of I. A mixture of IV (500 mg; 3.4 mmol) in 50 ml of xylene (a commercial mixture) containing methanesulfonic acid (0.5 ml) was irradiated by means of a 300 W medium-pressure mercury lamp under nitrogen for 7 day. The glc analysis (PEG 20 M, 180 °C) showed a 2: 1 mixture of I and IV. The reaction mixture was poured into water and neutralized by sodium hydrogen carbonate, and then the organic layer was collected and dried (Na_2SO_4). After the xylene solution has been passed through an alumina column to remove the acid throughly, the xylene was quickly removed under reduced pressure. The residue was chromatographed on a silver nitrate-alumina (15% silver nitrate) column. Elution by petroleum ether (40—50 °C) gave pure I (200 mg, 40%), while elution by petroleum ether-ether (8: 2) gave IV (90 mg). Compound I has the following properties: mp 226—229 °C (sealed tube) (lit,[5] mp 209—210 °C); MS: *m/e* 148 (M^+, 100%); PMR $\delta(CCl_4)$ 0.53—2.33 (broad complex multiplet); ^{13}C-NMR $\delta(CDCl_3$, downfield from TMS, proton-decoupled) 38.80 (CH_2), 32.42 ($2CH_2$), 28.61 ($2CH_2$), 26.79 (2CH), 21.59 (CH), 12.78 (CH), 10.26 (2CH), measured by JEOL PS 100/PFT 100 (25.1 MHz).

Oxidation of XI by $Pb(OAc)_4$. A mixture of X (4.0 g; 24.4 mmol), 100% hydrazine hydrate (4.9 g; 97.6 mmol), and glacial acetic acid (1.7 g; 24.4 mmol) in 80 ml of anhydrous ethanol was refluxed for 4 hr under nitrogen. The reaction mixture was then cooled to room temperature, and

the ethanol was removed under reduced pressure. Methylene chloride (CH_2Cl_2, 100 ml) was added to the residue, and the aqueous layer was separated. The organic layer was washed succesively with a 10% NaOH solution saturated with NaCl and with brine, and then dried ($CaCl_2$). Glc analysis showed that the CH_2Cl_2 solution contained XI (*ca.* 75%; mp 32—34 °C; MS: *m/e* 178 (M^+, 100%), 134 (72%). 93 (69%), 79 (49%); IR (Nujol) 3200, 2840, 1620, 1440, 1345, 1080 cm^{-1}; NMR $\delta(CCl_4)$ 1.15—1.04 (m, 16H), 4.50 (broad s, 2H, NH_2)) and V (*ca.* 25%; mp>290 °C; MS: *m/e* 149 (100%), IR (nujol) 2850, 1615, 1445, 1375, 1085, 940 cm^{-1}; NMR $\delta(CDCl_3)$ 1.25—3.21 (m)).[5] The $CaCl_2$ was filtered off, and $Pb(OAc)_4$ (12 g) free from AcOH in CH_2Cl_2 (120 ml) was added drop by drop to the above filtrate at −78 °C. The reaction mixture was stirred for 1.5 hr at −78 °C and then warmed to room temperature. After 40 ml of water has been added to the reaction mixture to quench the unreacted $Pb(OAc)_4$, the mixture was stirred overnight, filtered, washed succesively with a saturated $NaHCO_3$ solution and with brine, and dried ($CaCl_2$). After the removal of the CH_2Cl_2, the residue was chromatographed on alumina. Elution by *n*-hexane gave 2.29 g of hydrocarbon, which was shown by glc analysis to contain I (2.22 g, 61.5%) and IV (0.07 g, 1.9%). Elution by *n*-hexane–CH_2Cl_2 (1: 1) gave the VI acetate (0.69 g, 13.6%).

When other oxidants were employed, the procedures were essentially the same as that in the case of $Pb(OAc)_4$ except that the hydrazone solution was added to the CH_2Cl_2 solution containing the dispersed oxidant.

The azine (V) was recovered in the cases of NiPO and MnO_2, but not in the case of $Pb(OAc)_4$.

The Oxidation of XI in the Presence of a Protic Solvent. The procedures were essentially the same as that described above. The ratios of I to IV were determined by glc (PEG 20 M, 180 °C) (Table 4). In Run 1, K_2CO_3 was added as a neutralizing agent, but VI was still produced. In Run 2, $Pb(OAc)_4$ in CH_2Cl_2 was added to the solution of XI in CH_2Cl_2–AcOH (1: 1); a larger amount of VI was produced than in Run 1. In Run 3, $Pb(OAc)_4$ in CH_2Cl_2 was added to the solution of XI in CH_2Cl_2–MeOH (1: 1), and VI and 4-methoxyhomoadamantane (XIV) (MS: *m/e* 180 (M^+); NMR $\delta(CCl_4)$ 1.95—2.40 (broad m, 16H), 3.20 (s, 3H, OCH_3), 3.20—3.43 (m, 1H, $CHOCH_3$)[25] were produced. In Runs 4 and 6, $MgSO_4$ was added as a dehydrating agent, but XIII as well as X were produced in both cases. In Runs 5 and 7, the solution of XI in CH_2Cl_2 was added to a solution of CH_2Cl_2–MeOH (1: 1) containing an oxidant (NiPO or MnO_2) and $MgSO_4$; in both cases XIII, XIV, and X were produced.

Bamford-Stevens Reactions in Aprotic and Protic Solvents. 4-Homoadamantyl tosylhydrazone (II) was obtained by the standard procedure.[5,26] A mixture of II (332 mg, 1.0 mmol) and the base (NaOMe, 185 mg, 3.4 mmol; NaH, 100 mg, 1.9 mmol) in diglyme (5 ml, distilled over NaH) was heated at 140 °C for 1 hr. The reaction mixture was then cooled to room temperature and poured into water. The organic material were extracted with petroleum ether, washed with brine, and dried (Na_2SO_4). The solvent was then evaporated, and the residue was chromatographed on alumina. Elution by *n*-hexane gave the mixture of two hydrocarbons, I and IV (67.2 mg, 45%; 90.8 mg, 61%), the ratio of which was determined by glc. Elution by CH_2Cl_2 gave a small amount of V and an unidentified material.

Three kinds of mixtures of II (232 mg, 1.0 mmol) and Na (39 mg, 1.7 mmol; 78 mg, 3.4 mmol; 232 mg, 10 mmol) in 5 ml of ethylene glycol (distilled over Na) were heated at 140 °C for 1 hr. Each reaction mixture was cooled to room temperature and poured into water. The organic materials were extracted with petroleum ether, washed with brine, and dried (Na_2SO_4). The solvent was evaporated, and the residue was chromatographed on alumina. Elution by *n*-hexane gave two hydrocarbons, I and IV (53 mg, 36%; 34 mg, 23%; and 72 mg, 49%, respectively), the ratio of which was determined by glc. Elution by CH_2Cl_2 gave a trace amount of another material, which was presumably β-hydroxyethyl-4-homoadamantyl ether (XV) (MS: *m/e* 210 (M^+), 148 (100%); IR (neat) 3350, 2900, 1450, 1080 cm^{-1}; NMR δ, (CCl_4) 1.10—2.60 (broad m, 17H), 3.31—3.69 (broad m, 5H)), but its exact structure was not investigated further because the specimen was too small.

It was confirmed that I and VI were stable under the reaction conditions (excess base and excess sodium salt of *p*-toluenesulfinic acid in diglyme or ethylene glycol at 140 °C for 1 hr) of the control experiments.

20) Schleyer *et al.* employed a vaccum pyrolysis method and described that III was isolated and at room temperature slowly decomposed to I and IV (45: 55). The ratio of I to IV are very different from that obtained in the oxidaiton of XI at room temperature. A possible explanation of such a difference is that III might partially decompose at 170° (pyrolysis temperature) or the selectivity of the decomposition in solid state might be different from that in solution. But we think that the selectivity depends on the reaction temperature as mentioned in the text. (see ref. 5)

21) With NiPO and MnO_2, it was concluded that the lowest limit of the temperature at which the oxidation took place was 0—5 °C by observation of nitrogen evolved, but the yield was reduced and the ratio of I to IV was almost the same as that in the case of room temperature.

Photochemistry in Micellar System. I. Stabilization of the Radical Anions of Anthraquinonesulfonates[1]

Koji KANO and Taku MATSUO*

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received March 15, 1974)

Micellar effects on the photochemical reactions of sodium 9,10-anthraquinone-2-sulfonate and disodium 9,10-anthraquinone-2,6-disulfonate were studied by means of ESR and electronic spectroscopy. In the presence of anionic and non-ionic surfactants, irradiation of the quinones in aerobic phosphate buffer (pH 8.0) gave the corresponding radical anions, which were incredibly long-living (over several weeks) as compared with irradiation without surfactant. Plausible mechanisms of the micellar effects on the stabilization of the radical anions are discussed.

Micellar effects have been observed for many thermal reactions which indicate a close resemblance between micelle- and enzyme-catalyzed reactions.[2-4] In the case of photochemical reactions, however, only a few investigations have been carried out. Photoinduced substitution of some nitroaromatics was found to be affected by the addition of surfactants in a manner indicative of typical micellar effects.[5] Both anionic and nonionic surfactants have been reported to accelerate the photoreduction of riboflavin and flavin mononucleotide.[6-9] The photodecomposition of *p*-benzoquinone was also found to be accelerated in the presence of anionic surfactants.[10]

In the present paper, micellar effects on the photochemistry of anthraquinone sulfonates are described. In addition to the extensively investigated photofading and phototendering of anthraquinoid vat dyes,[11,12] anthraquinones have been known to be good sensitizers in photooxidation of organic substrates, where a cyclic process involving the semiquinone radical was suggested to play an important role.[13] Reduction-oxidation cycle of quinones is also very important for electron transport in biological membranes. We have studied the photochemistry of sodium 9,10-anthraquinone-2-sulfonate (AQS) in micellar systems, and found that the radical anion ($AQS^{\cdot}$) is extremely stabilized in the presence of surfactants.[14] The behavior of the stabilized radical anions in micellar systems is discussed in detail.

Experimental

Materials. Sodium 9,10-anthraquinone sulfonates and sodium laurate, NaL (Tokyo Kasei Kogyo Co. Ltd.) were recrystallized from water and 50% aqueous methanol, respectively. Sodium lauryl sulfate (NaLS) of three different grades was used; extra pure grade (Tokyo Kasei), that used for biochemistry (Wako Pure Chem.), and NaLS (Tokyo Kasei) recrystallized from 50% aqueous methanol. The results were all the same. Polysorbate-80 (P-80) (Ishizu Pharm. Co.) was used without further purification. Water was distilled and deionized with a column of ion-exchange resin.

The critical micelle concentrations (CMC) of NaLS and NaL were determined by the fluorescent probe method at room temperature. Magnesium 1-anilinonaphthalene-8-sulfonate (ANS) was chosen as a model probe suitable for examining the binding of sodium 9,10-anthraquinone sulfonates. An abrupt increase in fluorescence yields of ANS (1.0×10^{-4} M) in water was observed on the addition of NaLS above 8.5×10^{-3} M and also of NaL above 2.8×10^{-2} M. The values are in good agreement with the CMC of NaLS and NaL in the literature.[2] It is well-known that the CMC of anionic and cationic surfactants are lowered by addition of inorganic salts.[3] Most experiments were carried out in phosphate buffer solutions; the CMC of the anionic surfactants in our systems is expected to be lower than those in pure water.

Irradiation. *Method A*: The solution in a Pyrex tube (ϕ 15 mm) was irradiated with a Riko 100 W high-pressure mercury lamp using a Riko rotary photolysis apparatus RH 400—10 W at room temperature.

Method B: The solution in a quartz cell (10 mm width) placed 5 cm from the center of the lamp, was irradiated with a Riko 100 W high-pressure mercury lamp at room temperature.

ESR Measurement. The ESR spectra of the photolyzed solution in a Pyrex capillary tube (ϕ *ca.* 1 mm) were measured with a JEOL Model JES-ME-3X spectrometer (X-band), using 100 kHz field modulation. Peroxylamine sulfonate was used as standard material for determining the *g*-value.

Results

Spectral Change during Photolysis. Irradiation of AQS and/or disodium 9,10-anthraquinone-2,6-disulfonate (AQDS) in aqueous media without surfactants gives colored stable products, whose major components are hydroxylated anthraquinones.[15,16] Progressive spectral changes during the photolysis (method B) of AQS and AQDS in the aerobic phosphate buffer (pH 8.0) are shown in Fig. 1.

In the presence of NaLS above the CMC,[17] the spectral changes under irradiation (method B) of the aerobic solutions (pH 8.0) of both anthraquinone sulfonates (AQS and AQDS) differ drastically from those shown in Fig. 1. The absorption maxima of the photoproducts from AQS were observed at 378.5, 394.5, ~420, and ~470 nm (Fig. 2). In the case of AQDS, the absorption maxima were found at 382, 401, and 473 nm. These absorption bands gradually disappeared on mixing the solution with air. The bands at 378.5 (AQS) and 382 nm (AQDS) were assigned to the corresponding diol derivatives ($AQSH_2$ and $AQDSH_2$) by comparing the spectra with those of

* To whom inquiries should be addressed.

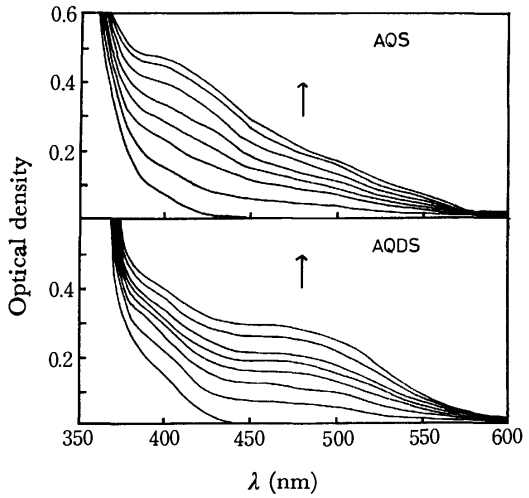

Fig. 1. Progressive spectral changes during photolysis of AQS and AQDS in non-micellar systems: $[AQS]_0 = 5.0 \times 10^{-4}$ M, $[AQDS]_0 = 1.0 \times 10^{-3}$ M, in 0.033 M phosphate buffer (pH 8.0). The spectra were measured at intervals of 20 s.

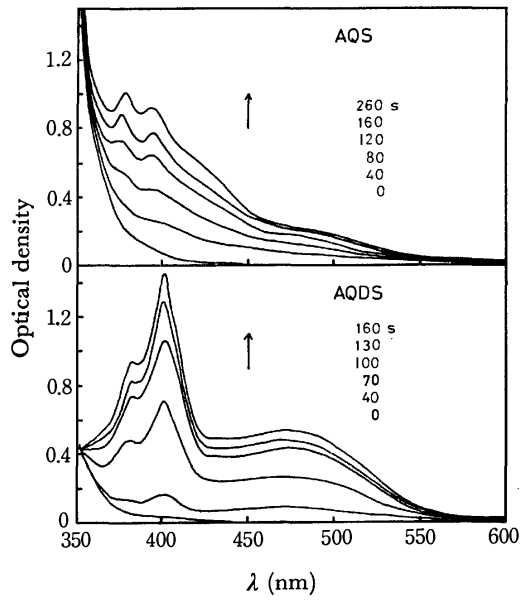

Fig. 2. Progressive spectral changes during photolysis of AQS and AQDS in micellar system: $[AQS]_0 = 5.0 \times 10^{-4}$ M, $[AQDS]_0 = 2.0 \times 10^{-4}$ M, $[NaLS] = 2.0 \times 10^{-2}$ M, in 0.033 M phosphate buffer (pH 8.0).

authentic samples. Essentially, the same absorption bands were observed when NaL and P-80 were used in place of NaLS except for the fact that the absorption at ~470 nm in AQS–NaLS system shifted towards 460 nm in the case of NaL and P-80. The absorption maxima at 394.5 (AQS) and 401 nm (AQDS) coincide with those of the radical anions of AQS ($AQS^{\cdot-}$) and AQDS ($AQDS^{\cdot-}$) obtained by flash technique.[18,19] The absorption bands at 505 nm of $AQS^{\cdot-}$ [18] and at 520 nm of $AQDS^{\cdot-}$,[19] however, could not be detected in the presence of surfactants. These bands were presumably shifted towards shorter wavelengths (~470 and 473 nm) by the influence of surfactants.

ESR Spectra Measurement. An aerobic solution (pH 8.0) of AQS containing NaL near the CMC[20] in a pyrex tube (ϕ 1 mm) was irradiated with a 100 W high-pressure mercury lamp for 20 min, and the yellow solution obtained was examined by means of ESR spectroscopy at room temperature (Fig. 3). The splitting constant (ΔH), number of lines, and g-value were 0.25 gauss, 21, and 2.0042, respectively. No ESR signal was obtained when the aerobic solution (pH 8.0) was irradiated in the absence of surfactants. In the case of AQDS, long-living ESR signals were obtained upon irradiation of the aerobic aqueous solution (pH 8.0) in the presence of NaLS (Fig. 4). The same ESR signals were also observed even in the absence of surfactants, but the spectra disappeared in a few hours after irradiation. The splitting constant, number of lines, and g-value were 0.45 gauss, 11, and 2.0044, re-spectively.

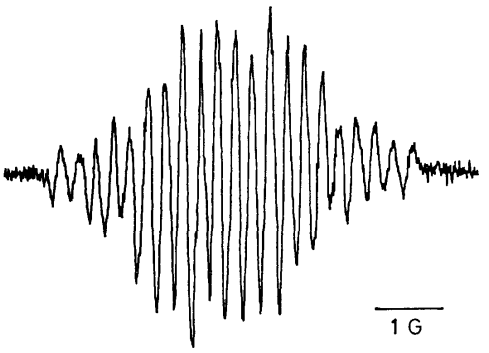

Fig. 3. ESR spectrum of $AQS^{\cdot-}$ generated by the photolysis of aerobic aqueous buffered solution (pH 8.0) of AQS (3.0×10^{-3} M) containing NaL (2.0×10^{-2} M).

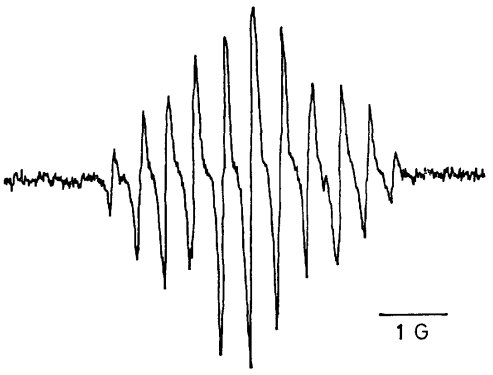

Fig. 4. ESR spectrum of $AQDS^{\cdot-}$ generated during the photolysis of aerobic aqueous buffered solution (pH 8.0) of AQDS (5.0×10^{-3} M) containing NaLS (4.0×10^{-2} M).

As regards the analysis of the hyperfine structure, the above ESR spectra were identified with those of the radical anions of AQS and AQDS.[21]

Phillips *et al.* obtained the ESR spectra of $AQS^{\cdot-}$ during the photolysis of anaerobic alkaline solutions (>pH 11) of AQS.[18,21] They reported that no ESR signal was obtained below pH 11.[18] By the use of flash technique, they also found that $AQS^{\cdot-}$ has a relatively long lifetime in an anaerobic solution (several ms), and rapidly decays in the aqueous solution by

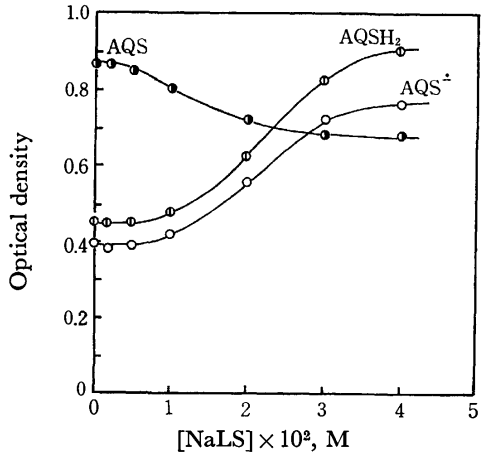

Fig. 5. Effect of NaLS concentration on $AQS^{\cdot-}$ and $AQSH_2$ formation: $[AQS]_0=5.0\times10^{-4}$ M, in 0.033 M phosphate buffer (pH 8.0). The solutions were irradiated for 5 min at room temperature, and the optical density at 256 nm was measured after the photolyzed solutions were diluted by 25-fold with water.

the addition of oxygen.[18] $AQS^{\cdot-}$ we obtained in the presence of NaL lived over two months in a sealed tube even in the case of aerobic solution. Although, $AQDS^{\cdot-}$ has a considerably long lifetime (a few hours) even in the absence of surfactant, it lived over several weeks in the aerobic solution in the presence of NaLS. These observations suggest that both $AQS^{\cdot-}$ and $AQDS^{\cdot-}$ are markedly stabilized in the presence of surfactants.

Effect of Surfactant Concentration on $AQS^{\cdot-}$ Formation. An aerobic aqueous solution (pH 8.0) of AQS containing appropriate amounts of NaLS was irradiated for 5 min (method A). The optical density at the absorption maxima of $AQS^{\cdot-}$ (394 nm), diol derivative ($AQSH_2$, 378.5 nm), and AQS (256 nm) is plotted against the concentration of NaLS in Fig. 5. The

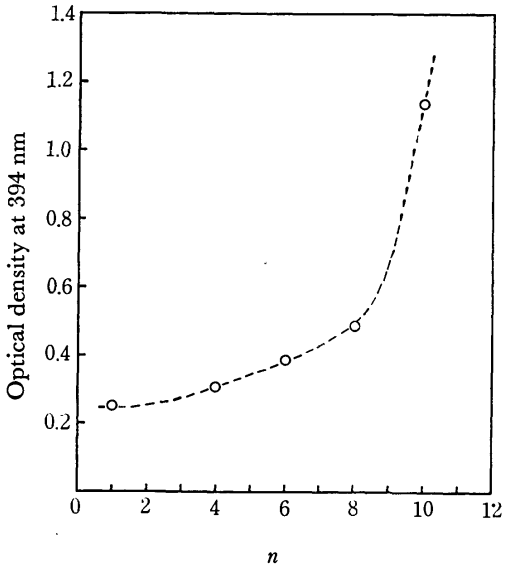

Fig. 6. Effect of alkyl chain length of sodium carboxylate on $AQS^{\cdot-}$ formation: $[AQS]_0=1.0\times10^{-3}$ M, $[CH_3(CH_2)_nCOONa]=2.0\times10^{-2}$ M, in 0.033 M phosphate buffer (pH 8.0). The solutions were irradiated for 20 s at room temperature.

formation of $AQS^{\cdot-}$ and $AQSH_2$ and the disappearance of AQS markedly increased at NaLS concentrations above *ca.* 1.0×10^{-3} M, plateau regions being observed at higher NaLS concentrations. This surfactant concentration profile suggests that the micelles formed by aggregation of the surfactant in aqueous solution contribute to the stabilization of $AQS^{\cdot-}$.

Effect of Alkyl Chain Length of Surfactant on Stabilization of $AQS^{\cdot-}$. An aerobic aqueous solution (pH 8.0) of AQS containing sodium carboxylates ($CH_3(CH_2)_n$-COONa) was irradiated for 20 s (method B). The optical density at 394 nm ($AQS^{\cdot-}$ formation) is plotted against the number of methylene groups (n) in the alkyl chain in Fig. 6. Since the formation of $AQS^{\cdot-}$ becomes significant for $n>8$, it is evident that $AQS^{\cdot-}$ is greatly stabilized by binding with an aggregate of carboxylates capable of forming micelles.

Table 1. Effect of acetone content on stabilization of $AQDS^{\cdot-}$[a]

Aceton, % (v/v)	Φ/Φ_0[b]
0	1
5	0.87
10	0.82
15	0.64
20	0.55

a) Aerobic phosphate buffer solutions (0.033 M, pH 8.0) of AQDS (2.0×10^{-4} M) containing NaLS (2.0×10^{-2} M) and acetone were irradiated at room temperature for 1 min. b) Relative quantum yields were determined by measurement of optical density at 475 nm, absorption maximum of $AQDS^{\cdot-}$.

Effect of Acetone on Stabilization of $AQDS^{\cdot-}$. The effects of acetone were studied in the AQDS-NaLS system. The relative quantum yields for the formation of $AQDS^{\cdot-}$ in solutions containing various amounts of acetone are given in Table 1. The generation of $AQDS^{\cdot-}$ was suppressed with increasing acetone content, as was also the formation of $AQDSH_2$. Not only acetone but *tert*-butanol also greatly reduced the formation of $AQDS^{\cdot-}$ and $AQDSH_2$. The relative quantum yield for the formation of $AQDS^{\cdot-}$ was 0.58 when the aerobic 10% (v/v) aqueous *tert*-butanol solution (pH 8.0) of AQDS (2.0×10^{-4} M) containing NaLS (2.0×10^{-2} M) was irradiated.

Salt Effect on $AQDS^{\cdot-}$ Formation. It is known that ionic-micellar catalysis tends to be significantly affected by addition of electrolyte.[22] We have studied the salt effects on the radical anion formation in the AQDS-NaLS system.

Aqueous solutions (pH 8.1) of AQDS containing

Table 2. Salt effect on $AQDS^{\cdot-}$ formation[a]

Electrolyte	Φ/Φ_0
—	1
$MgSO_4$(2.0×10^{-2}M)	0.48
Na_2SO_4(2.0×10^{-2}M)	0.84

a) $[AQDS]_0=2.0^{-4}\times10^{-2}$M, $[NaLS]=2.0\times10^{-2}$ M in 0.033 M phosphate buffer (pH 8.1).

NaLS and appropriate amounts of salts were irradiated with filtered light (>350 nm). The optical density at 470 nm ($AQDS^{\cdot-}$ formation) was monitored and the relative quantum yields for $AQDS^{\cdot-}$ formation were determined. The results obtained are summarized in Table 2. The formation of $AQDS^{\cdot-}$ was significantly supressed by the addition of Mg^{2+}.

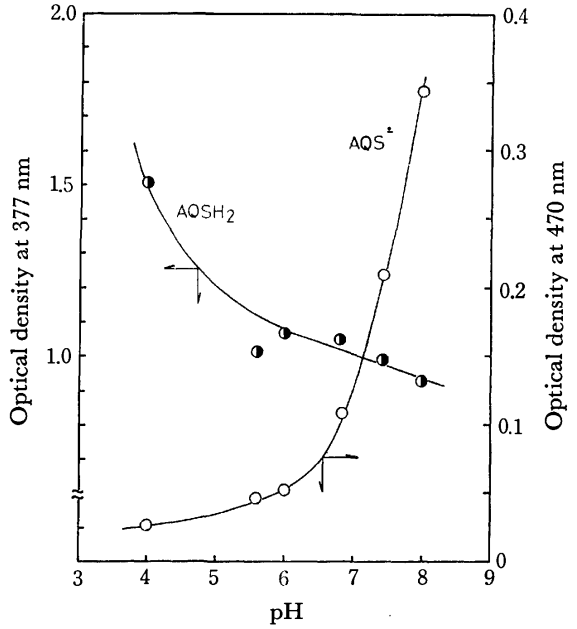

Fig. 7. pH dependence on $AQS^{\cdot-}$ and $AQSH_2$ formation: $[AQS]_0 = 5.0 \times 10^{-4}$ M, [P-80] = 0.2116 g/dl. The phthalate (pH 4.0, 0.1 M) and phosphate buffers (pH 5.6—8.0, 0.033 M) were used. The solutions were irradiated for 10 min under a nitrogen atmosphere at room temperature.

pH Dependence on $AQS^{\cdot-}$ and $AQSH_2$ Formation. The pH dependence on the formation of $AQS^{\cdot-}$ and $AQSH_2$ in the presence of P-80 was examined by the use of phthalate and phosphate buffers (pH 4.0—8.0). Anaerobic solutions of AQS containing P-80 (0.2116 g/dl)[23] were irradiated for 10 min (method A). The formation of $AQSH_2$ and $AQS^{\cdot-}$ was monitored by optical density at 377 and 470 nm, respectively. The pH profile is shown in Fig. 7. The yield of $AQSH_2$ decreased with increasing pH, the formation of $AQS^{\cdot-}$ being apparently enhanced above pH 6.8. Exactly the same pH dependence of the $AQS^{\cdot-}$ formation was reported in the flash photolysis of AQS in the absence of surfactant.[18]

Reaction of Radical Anions with H^+. Since the radical anions of AQS and AQDS are greatly stabilized in micellar systems, the reactivity of $AQS^{\cdot-}$ and/or $AQDS^{\cdot-}$ can be easily investigated. We first studied the reaction of radical anions with H^+.

An aerobic solution of AQDS (2.0×10^{-4} M) in 0.033 M phosphate buffer (pH 8.0) containing 2.0×10^{-2} M of NaLS was irradiated for 3 min (method B). After the photolyzed solution was carefully diluted 20-fold either with water or with 0.75 N sulfuric acid, the UV spectra were measured (Fig. 8). The absorption maxima in water were observed at 262, 273, and 284 nm. The spectra were compared with those of

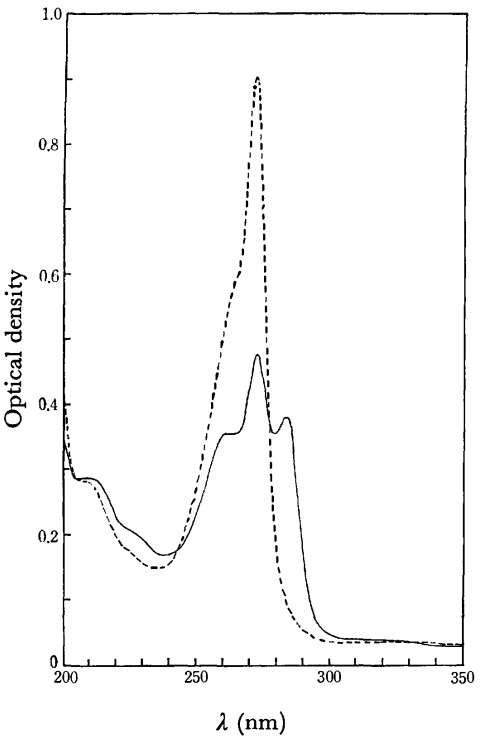

Fig. 8. UV spectra of photolyzed solution of AQDS which were diluted with water (solid line) and with 0.75 N sulfuric acid (dotted line).

authentic samples, and the absorption bands at 262 and 273 nm were assigned to AQDS and $AQDSH_2$, respectively. In the sulfuric acid solution, the absorption band at 284 nm completely disappeared and the intensity of the absorption band at 273 nm ($AQDSH_2$) increased. These spectral data suggest that the absorption band at 284 nm is attributed to $AQDS^{\cdot-}$ and that

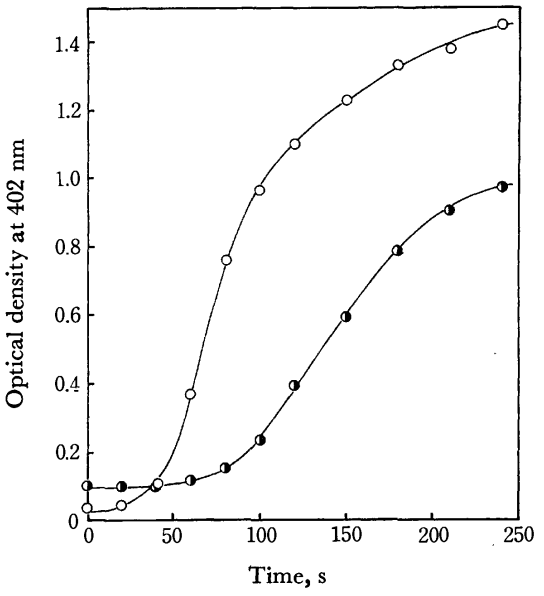

Fig. 9. Effect of Fe^{3+} on $AQDS^{\cdot-}$ formation: the aerobic phosphate buffer solutions (0.033 M, pH 8.0) of AQDS (2.0×10^{-4} M) containing NaLS (2.0×10^{-2} M) were irradiated in the absence (—○—) and in the presence of Fe^{3+} (—◑—, $[FeCl_3] = 5.2 \times 10^{-4}$ M) at room temperature.

$AQDS^{\cdot-}$ reacts with H^+ to produce the anthrahydroquinone.

The same results were obtained in the reaction of $AQS^{\cdot-}$. The absorption maxima of AQS, $AQSH_2$, and $AQS^{\cdot-}$ were observed at 259, 269, and 277 nm, respectively.

Reaction of $AQDS^{\cdot-}$ with Fe^{3+}. We next examined the electron transfer reaction from $AQDS^{\cdot-}$ to ferric ion.

An aerobic aqueous solution (pH 8.0) of AQDS containing NaLS was irradiated in the presence of Fe^{3+} (method B). The formation of $AQDS^{\cdot-}$ monitored at 402 nm is plotted against irradiation time in Fig. 9.

In the absence of Fe^{3+}, the formation of $AQDS^{\cdot-}$ was observed after a short induction period (*ca.* 20 s). In the presence of Fe^{3+}, however, the induction period for the formation of the radical anion was considerably prolonged (*ca.* 60 s), the yield of $AQDS^{\cdot-}$ being reduced. After irradiation, *o*-phenanthroline, 0.1 N sulfuric acid, and sodium acetate–sulfuric acid buffer (pH 4.4) were added to the photolyzed solution. A red solution was obtained and the spectra clearly indicated the formation of *o*-phenanthroline–Fe^{2+} complex (λ_{max} 500 nm). Thus it could be concluded that $AQDS^{\cdot-}$, the primary photoproduct, transfers an electron to Fe^{3+} which affords AQDS and Fe^{2+} as the final products.

Discussion

Phillips *et al.* found that flash photolysis of AQS in air-saturated aqueous solution (pH 3.07) gives two transient species with absorption maxima at 455 and 505 nm.[18] They assigned the transient bands at 455 and 505 nm to the cation and anion radicals of AQS, respectively. From the results the formation of $AQS^{\cdot-}$ was explained by the following reaction:

$$AQS^* + AQS \longrightarrow AQS^{\cdot+} + AQS^{\cdot-} \quad (1)$$

This scheme involving triplet excimer, however, was not supported by the kinetic data obtained by means of ns laser photolysis.[12]

Kuzmin and Chibisov studied the flash photolysis of aqueous AQDS solutions in the presence of inorganic anions (0.1 M) and found that an electron is transferred from inorganic anions (CO_3^{2-}, Cl^-, SO_4^{2-}, NO_3^-, PO_4^{3-}, SO_3^{2-}, SeO_3^{2-}, and SCN^-) to AQDS in the triplet state yielding $AQDS^{\cdot-}$ (two strong bands at 400 and 520 nm) and one-electron oxidized inorganic anions:[19]

$$AQDS^* + X^{n-} \longrightarrow AQDS^{\cdot-} + X^{(n-1)\cdot} \quad (2)$$

In our system also anions such as $CO_2^{\cdot-}$, $OSO_3^{\cdot-}$, HPO_4^{2-}, and $H_2PO_4^-$ coexisted with AQS or AQDS. The radical anions, however, could not be detected by means of ESR and electronic spectroscopy in the case of AQS with no surfactants, the quantum yield for the formation of $AQDS^{\cdot-}$ in the presence of micelles not increasing with addition of SO_4^{2-} (Table 2). $AQS^{\cdot-}$ and $AQDS^{\cdot-}$ were also stabilized in the presence of P-80, non-ionic surfactant, as in the case of NaL and/or NaLS system. The results suggest that the electron-transfer reactions from the above anions to photoexcited quinones are not significant to account for the formation of stabilized anion radicals in our systems.

By the use of pulse radiolysis and flash photolysis techniques, the pK values for the semiquinone radical-anions of AQS and AQDS have been determined to be 3.25[24] and 2.30[19] respectively. However, the pH effects on the $AQS^{\cdot-}$ formation in micellar system

$$A^{\cdot-} + H^+ \overset{K}{\rightleftharpoons} AH\cdot \quad (3)$$

we observed cannot be simply explained by the pK value. Below pH 6.0, only anthrahydroquinone ($AQSH_2$) was formed and the formation of $AQS^{\cdot-}$ became significant above pH 6.8 (Fig. 7). This is similar to the pH effects on the $AQS^{\cdot-}$ transient absorption 800 μs after flash photolysis in non-micellar system.[18] At low pH region, both radical anion and semiquinone radical seem to decay rapidly by the disproportionation:[25,26]

$$2A^{\cdot-} \longrightarrow A + A^{2-} \quad (4)$$

$$A^{2-} + 2H^+ \longrightarrow AH_2 \quad (5)$$

$$2AH\cdot \longrightarrow AH_2 + A \quad (6)$$

At higher pH (6.8—8.0), the photolyzed micellar solutions of AQS and/or AQDS contained A, $A^{\cdot-}$, and AH_2. In addition to $A^{\cdot-}$ (λ_{max} 396 and 472 nm) and AH_2 (λ_{max} *ca.* 380 nm), dianion of A (A^{2-}) was detected by means of electronic spectroscopy (λ_{max} 436 nm)[27] when AQS in 0.1 M NaOH was irradiated in the presence of NaLS. The following two equilibria involving A^{2-} should also be taken into consideration to account for the data obtained at higher pH region:

$$AH_2 + 2OH^- \rightleftharpoons A^{2-} + 2H_2O \quad (7)$$

$$A^{2-} + A \rightleftharpoons 2A^{\cdot-} \quad (8)$$

The anthrahydroquinones ($AQSH_2$ and $AQDSH_2$) are stable only in acidic media. They are very easily oxidized to original quinones in aerobic neutral and alkaline solutions without surfactants. In the presence of the anionic and non-ionic surfactants, however, these diol derivatives were scarcely oxidized even in 0.1 M NaOH. It is evident that the surfactants play an important role to stabilize the diol derivatives.

The surfactant concentration profile indicates that both $AQS^{\cdot-}$ and $AQSH_2$ are stabilized by binding with micelles (Fig. 5). Existence of typical micellar effects is also manifested by the fact that only micelle-forming carboxylates can stabilize $AQS^{\cdot-}$ (Fig. 6). It seems rather odd, however, that the anionic species such as $A^{\cdot-}$ bind with anionic micelles. In general, negatively charged substrates, such as 1-anilinonaphthalene-8-sulfonate (ANS) and *N,N*-dimethyl-1-anilinonaphthalene-5-sulfonate, are adsorbed by cationic and non-ionic micelles, but not anionic ones.[28] The binding constant for anthraquinone sulfonate ion-anion micelle system is thus expected to be quite small.[29] No matter how small the binding constant is, some of the anthraquinone sulfonate will be bound to the micelles. These bound species may give the radical anion on photoexcitation. The long lifetimes of the radical anions suggest that the rate of exchange between the micelles and bulk water is extremely small.

The absorption maxima of $AQS^{\cdot-}$ and $AQDS^{\cdot-}$ in non-micellar systems have been found at 395 and

505 nm[18] and 400 and 520 nm[19] respectively. In the presence of micelles, the longer wavelength absorption bands of the anion radicals exhibit a remarkable blue shift (~35 and 47 nm, respectively). When the charged substrates such as $AQS^{\cdot-}$ and $AQDS^{\cdot-}$ bind with anionic micelles, the substrates are incorporated to the Stern layer surrounded by highly concentrated counter cations. The radical anions within the Stern layer, therefore, might form a contact ion pair with cations in the charged double layer. The pair is expected to absorb at shorter wavelengths than the solvent separated ion pair in non-micellar system. In the case of non-ionic micelles, the contact ion pair may be stabilized at the micelle-water interface.

Organic solvents, such as dioxane and alcohols, influence the reactions in micellar systems.[2,3] Since dioxane and alcohols are not adequate because of their hydrogen donative properties, we examined the effects of organic additives with the use of acetone and *tert*-butanol, both of which markedly inhibit the formation of $AQDS^{\cdot-}$ and $AQDSH_2$ in micellar systems. A possible explanation may be that the CMC of the surfactant increases on the addition of organic additives. An alternative may be that $AQDS^{\cdot-}$ and $AQDSH_2$ are displaced from the micellar phase by the additives.[3] No matter which the case is, it is clear that the binding of $AQDS^{\cdot-}$ and $AQDSH_2$ with micelles is essential for the stabilization of these substrates.

It has been reported that the microviscosity of the NaLS micelle interior increases about 3- to 6-fold with the addition of Mg^{2+}.[30] We have also studied the effects of Mg^{2+} on the photochemistry of AQDS-NaLS system. Addition of Mg^{2+} reduced the formation of both $AQDS^{\cdot-}$ ($\Phi/\Phi_0=0.48$) and $AQDSH_2$ (Table 2). Contribution of the coexisting sulfate ion (SO_4^{2-}) is considered to be small as verified by the addition of Na_2SO_4 ($\Phi/\Phi_0=0.84$). The permeation of $AQDS^{\cdot-}$ and/or $AQDSH_2$ into the micelles might change due to the contraction of charged heads and the increased rigidity of micelle interior as caused by the addition of Mg^{2+}.

All the results indicate that the anthraquinone radical anions and anthrahydroquinones are extremely stabilized by binding with micelles.

It is surprising that neither $A^{\cdot-}$ nor AH_2 is oxidized in the micellar systems in spite of its aerobic alkaline conditions. One reason might be that the hydroxide ion concentration in the microenvironment of anionic micelles is lower than that in the bulk since the electrostatic repulsion keeps hydroxide anions away from the negatively charged micelle surface. Thus the micelle interior would afford a favorable environment for AH_2, which exists as a stable species only at low pH region. In contrast, rapid and complex reactions were observed for AQS and/or AQDS when they were irradiated in the presence of hexadecyltrimethylammonium bromide (cationic surfactant) whose micelle surface is covered with locally concentrated hydroxide ions.

In non-micellar system, $AQS^{\cdot-}$ has been reported to react with oxygen very easily:[31]

$$AQS^{\cdot-} + O_2 \xrightarrow{k} A + O_2^{\cdot-} \quad k\ ca.\ 5\times10^8 M^{-1}\cdot s^{-1} \qquad (9)$$

Recently, the oxygen concentration and/or oxygen mobility in micelle interior were found to decrease appreciably with aging of the micellar system.[30,32,33] We found, however, that $A^{\cdot-}$ and AH_2 were easily stabilized in fresh micellar solutions as well as in old ones. Since many problems remain unsolved as regards the oxygen concentration within micelles,[30,32-34] no detailed discussion could be given. However, it is clear at least that the scavenging of $A^{\cdot-}$ by oxygen is markedly reduced in the presence of anionic and non-ionic micelles.

If the above micellar effects are simply ascribed to the protection of $A^{\cdot-}$ and AH_2 from the attack of oxygen, $A^{\cdot-}$ should also be stabilized in a well-degassed non-micellar system. In the absence of micelles, however, the photolysis of AQS in anaerobic aqueous media afforded only hydroxylated anthraquinones.[15,16] Studies of radiolysis in the micellar system revealed that the reaction of benzene with a hydroxyl radical is considerably inhibited in the presence of anionic, cationic, and non-ionic micelles,[34] and that the hydroxyl radical is rapidly scavenged by the surfactant to produce relatively inert radicals ($k\simeq10^9\ M^{-1}\cdot s^{-1}$).[35] The same type of protection against the hydroxyl radical would operate in the case of anthraquinones in a micellar system, since the hydroxylated anthraquinones have been reported to be formed by the attack of hydroxyl radicals.[12,15,16,24,27]

The radical anions of anthraquinone sulfonates are so stable in the presence of micelles that the reactivity of these radical anions was easily investigated.

The reactions of $AQS^{\cdot-}$ and $AQDS^{\cdot-}$ with H^+ yielded the corresponding anthrahydroquinones. Since pK of AQSH· and AQDSH· are 3.25[24] and 2.90[19] respectively, $AQS^{\cdot-}$ and $AQDS^{\cdot-}$ are protonated in 0.75 N H_2SO_4 to give semiquinone radicals, followed by disproportionation to produce anthrahydroquinones and original quinones:[26]

$$A^{\cdot-} + H^+ \longrightarrow AH\cdot \qquad (10)$$

$$2AH\cdot \longrightarrow AH_2 + A \qquad (11)$$

It is well-known that some quinones and ferric ion play an important role as electron carriers in biological systems. Since micelles are known to be good models of biological membrane, we used a micellar solution to construct a model system of the electron transport across membrane: $AQDS^{\cdot-}$ in NaLS micelles *vs.* ferric chloride in the aqueous phase. An electron was successfully transferred from $AQDS^{\cdot-}$ to Fe^{3+} in this system:

$$AQDS^{\cdot-} + Fe^{3+} \longrightarrow AQDS + Fe^{2+} \qquad (12)$$

Further improvement of the model system is expected to clarify the role of biological membranes in electron transport phenomena.

Conclusion

Remarkably long-living radical anions of 9,10-anthraquinone sulfonates are formed in the presence of micelles of anionic and non-ionic surfactants. All of the experimental data suggest that the stabilization of these radical anions is attributed to micellar effects, which are somewhat novel because the anionic species are

considered to be bound with anionic micelles. The relevant micellar effects can be summarized as follows:

a. Since hydroxyl radicals are efficiently scavenged by the surfactants, hydroxylation of the quinones does not take place in micellar systems.

b. The pH in a micellar system might favor the formation of the radical ions, which are involved in the following equilibria:

$$A^{\cdot-} + H_2O \rightleftarrows AH\cdot + OH^-$$
$$2AH\cdot \rightleftarrows AH_2 + A$$
$$AH_2 + 2OH^- \rightleftarrows A^{2-} + 2H_2O$$
$$A^{2-} + A \rightleftarrows 2A^{\cdot-}$$

c. The decay of the radical ion is extremely retarded because of low reactivities of quenchers such as oxygen in micellar interior.

The fact that the radical anions are stabilized by binding with micelles is interesting in relation to the electron transport in biological membranes.

Nuclear Magnetic Resonance Study of the Kinetics of Ligand Exchange on the Oxovanadium(IV)-malonato Complex

Hiroshi TOMIYASU,* Satoshi ITO,** and Shiro TAGAMI

Department of Chemistry, Faculty of Science, Shinshu University, Asahi, Matsumoto 390

(Received April 26, 1974)

The kinetics of malonate exchange on $VO(mal)_2^{2-}$ has been studied by the NMR line-broadening method. The reaction was found to be dependent on the Hmal and hydrogen-ion concentrations, and the mechanism producing the intermediate complexes, where malonic acid was coordinated partly as an unidentate ligand, was estimated from the rate law. The activation parameters were determined for the acid-independent and acid-catalyzed paths as: $\Delta H^* = 8.6$ kcal/mol, $\Delta S^* = -16.2$ e.u., and $\Delta H^* = 8.9$ kcal/mol, $\Delta S^* = -13.5$ e.u.

A number of kinetic studies of the ligand substitution of various oxovanadium(IV) complexes have been reported. These include H_2O exchange by ^{17}O NMR,[1-3] CH_3CN, glycine and other ligand exchanges by proton NMR,[4,5] the formation of $VOHGly^{2+}$ and $VO(Tart)_2^{2-}$ by the stopped-flow and Temp.-Jump methods,[5-7] and the rapid interaction of axial- or second-sphere water by NMR and ESR.[3,8,9,14]

We found in a previous work that, in the formation of the chelate complex, $VO(Gly)^+$, the rate-determining step was the path from $VOGly^+$, which represents the deprotonated form of $VOHGly^{2+}$, to $VO(Gly)^+$ instead of the formation of $VOHGly^{2+}$, where glycine is coordinated on the equatorial position as a unidentate ligand.[5,7]

This led to the problem of the unusual reactivity of bidentate ligands which are coordinated on VO^{2+} as unidentate ligands. In this work we wish to report the kinetics of malonate exchange on $VO(mal)_2^{2-}$ † in order to discuss the problems which arose from the previous work.

Experimental

The preparation and analysis of the VO^{2+} stock solution were described in a previous paper.[5] Reagent-grade malonic acid (Wako Pure Chemicals, Co. Ltd.) was recrystallized twice from distilled water and dried under reduced pressure. The sodium perchlorate was prepared from stoichiometric amounts of Na_2CO_3 and $HClO_4$ and was purified by recrystallization from an aqueous solution. A JEOL Co. Ltd. JNM-4H-100 NMR spectrometer was used to record the NMR spectra. The peak observed was that of the methylene protons of malonic acid in the bulk phase. The spectrophotometric measurements were made at 25 °C on a Shimadzu MPS-50L spectrometer. The pH of each solution was measured with a Hitachi-Horiba pH meter F-7ss equipped with a glass electrode, Horiba 1026-05T.

Results and Discussion

Absorption Spectrum of the Oxovanadium(IV)-malonate Complex. The absorption spectrum and the electronic structure of the VO^{2+} complexes have been studied elsewhere.[12] The two absorption bands at about 760 and 630 nm which are characteristic of the VO^{2+} ion were observed at slightly shifted wavelengths of 780 and 600 nm in the presence of malonic acid, according to the complex formation. The optical densities of the malonato-complex were much larger than those of the aquo-complex in both bands; therefore, the observed absorbances increased as the concentration of malonic acid or the pH of solution was increased. Under the conditions of malonic acid$>$1.0 M and pH$>$2.8, the complex formation was saturated and no further increase in absorbance was observed. In such conditions, all the VO^{2+} ions were present as dimalonatooxovanadium(IV) ions, $VO(mal)_2^{2-}$, which may be analogous to diglycinatooxovandium(IV), $VO(Gly)_2$, which was studied in earlier works.[5,10] The $VO(mal)_2^{2-}$ thus prepared was very stable, and the absorption spectrum did not change for several days at the pH of 4.5.

NMR Measurements. Swift and Connick derived the relaxation time in a paramagnetic solution from a rigorous solution of the Bloch equation.[11] If the chemical exchange between the metal ion and the ligand controls the relaxation process, the observed relaxation time T_2, is related to the life-time of a ligand staying in the environment of the coordination sphere by;

$$1/T_2 - 1/T_{2a} = P_m/\tau_m \quad (1)$$

where T_{2a} is the relaxation time in the absence of metal ions and where P_m is approximated in a dilute solution as;

$$P_m = n[\text{complex}]/[\text{total ligand}] \quad (2)$$

wher n is the number of coordinated ligands. In this work, [ligand] corresponds to the total concentration of malonic acid, and n is assumed to be 2. Thus, the rate constant for the dissociation of a ligand from the coordination sphere is given by;

$$k' = \tau_m^{-1} \quad (3)$$

Whether or not a chemical exchange controls the relaxation process can be tested by plotting $\log(1/T_2 - 1/T_{2a})$ as a function of the reciprocal temperature. Equation (1) is applicable if the graph of $\log(1/T_2 - 1/T_{2a})$ *vs.* $1/T$ is linear, with a negative slope. The full line-width at the half height of malonate methylene protons is listed in Table 1 for various malonic acid concentrations. The line-width in the absence of VO^{2+}

1.50	1.4	38	$1.4_3\pm0.1_8$
1.50	3.0	25	$1.4_6\pm0.0_9$
1.50	3.0	70	$1.2_3\pm0.1_4$

was very sharp, and, as is shown in Table 2, no broadening was observed within the limits of experimental error in solutions of high malonic acid concentrations, where a relatively high viscosity would be expected compared with that of pure water. Therefore, the effect of the viscosity on the line-width of the malonate methylene proton may be ignored in the solutions studied. From Tables 1 and 2, $\log(1/T_2-1/T_{2a})/P_m$ can be calculated; the plot *vs.* $1/T$ is shown in Fig. 1. It can be seen in Fig. 1 that a linear relationship is obtained over most of the temperature range studied; hence, Eq. (1) is applicable.

The rate constants, k', thus obtained in the low pH range are listed in Tables 3 and 4 at 25 °C. In higher pH values (above 4), the reaction is too slow at 25 °C

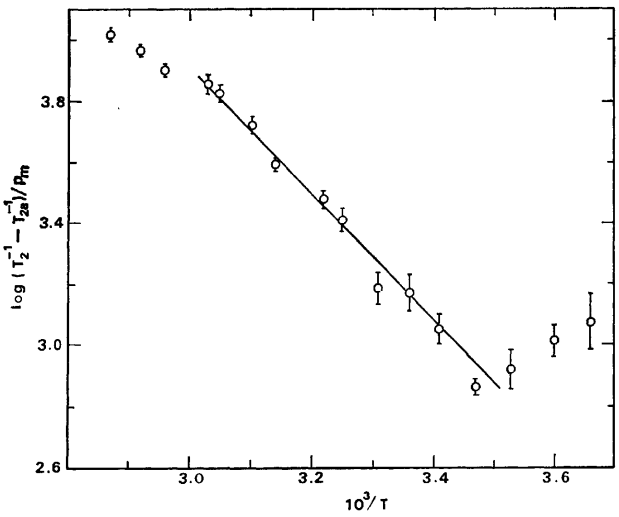

Fig. 1. Plot of line-width of methylene proton of malonic acid as a function of reciprocal temperature.

for us to be able to determine the accurate value of k' from the line-width measurements; therefore, the data listed in Tables 5 and 6 represent the values at 40 °C.

It can be seen in Tables 3 and 4 that k' increases with the concentrations of malonic acid. This suggests that the reaction is first order in relation to both $VO(mal)_2^{2-}$ and malonic acid. Since H_2mal seems unlikely to react with $VO(mal)_2^{2-}$, Hmal or mal must be important for the substitution reaction. However, in the high pH region (pH>4.6), it can be seen in Table 6 that k' becomes smaller as the pH of the solution increases, where [mal] increases, while [Hmal] decreases in this pH region. From these facts, we may

conclude that mal is also inactive and that Hmal is the only species which interacts directry with $VO(mal)_2^{2-}$. The second-order rate constant, k, where $k=k'/[\text{Hmal}]$, is constant within the limits of experimental error, as is shown in Tables 3, 5, and 6 for various malonic acid concentrations.

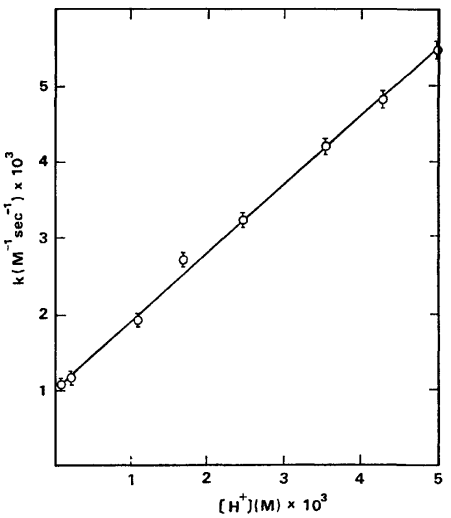

Fig. 2. Plot of rate constant, k, *vs.* hydrogen ion concentration.

The hydrogen-ion dependence for k is shown in Table 4. As can be seen in Fig. 2, the plot of k *vs.* $[H^+]$ is linear; k is given by the following equation:

$$k = k_1 + k_2[H^+] \quad (4)$$

The values of k_1 and k_2 are obtained from the intercept and the slope of Fig. 2 as 1.1×10^3 $M^{-1}s^{-1}$ and 8.4×10^5 $M^{-2}s^{-1}$ respectively. The first term gives the estimated value for k in the high pH region; it agrees very closely with that of 0.91×10^3 $M^{-1}s^{-1}$ which was obtained experimentally from the measurement at pH = 5.5 and 25 °C. The second term corresponds the acid-catalyzed path, which is predominant in the low pH region. In Table 3 the values calculated for k using Eq. (4), k_{cal}, are listed. These values are in satisfactory agreement with the observed values. The activation parameters for both paths were determined from the measurements at pH = 5.50 and pH = 2.45. They are $\Delta H^{\ddagger}=8.6$ kcal/mol, $\Delta S^{\ddagger}=-16.2$ e.u. for the acid-independent path and $\Delta H^{\ddagger}=8.9$ kcal/mol, $\Delta S^{\ddagger}=-13.5$ e.u. for the acid-catalyzed path.

From the potentiometric and spectrophotometric studies,[13] we found that VO^{2+} formed such complexes that bidentate ligands, malonic acid and glycine, are coordinated on the equatorial position as unidentate ligands. Furthermore, in a kinetic study of the formation of the chelate complex, $VO(Gly)^+$,[7] it was found that the rate of chelation from the unidentate complex, $VOGly^+$, was surprisingly slow (35 s^{-1}) compared with that of the formation of $VOHGly^{2+}$ (1.3×10^3 $M^{-1}s^{-1}$)[5] or water exchange on the equatorial positions of the VO^{2+} aquo complex (500 s^{-1}).[1,2] This reaction, which we called the "slow chelation process", was estimated to proceed through the intermediate complex, where the $-COO^-$ and $-NH_2$ of the glycinate ion may be coordinated on the equatorial position and the position above the triangular face of the tetragonal pyramid structure.

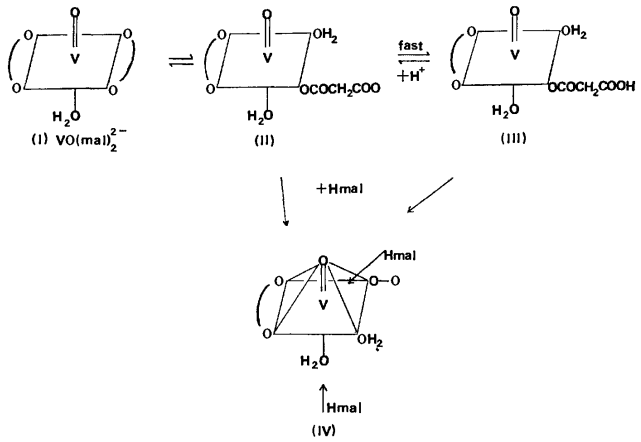

Fig. 3. Reaction scheme of malonate exchange on VO $(mal)_2^{2-}$.

These findings suggest that the first step of malonate exchange on $VO(mal)_2^{2-}$ is the dissociation of one of the chelate rings forming an intermediate complex (II) in Fig. 3, where one of the two malonate ions on equatorial positions is coordinated as a unidentate ligand. In an acidic solution, the (II) complex may be protonated to form a (III) complex. Then, these complexes, (II) and (III), which are analogous in structure to the $VOGly^+$ and $VOHGly^{2+}$ respectively,

could accept the attack of Hmal from the axial position or the position above the triangular face of the tetragonal pyramid structure, as is estimated in the chelation process of $VO(Gly)^+$.

Since the equilibrium between (II) and (III) should be very fast, the rate Eq. (4) can be explained by the following processes: (I)→(II)→(IV) for the acid-independent path and (I)→(II)⇄(III)→(IV) for the acid-catalyzed path. The approximately identical values of ΔH^* for the two paths may support substitution mechanisms similar to those described above.

The authors would like to thank Professor Hiroshi Fukutomi of Tokyo Institute of Technology for his helpful discussions.

Hydrogen Redistribution of Acetone on ZnO Catalysts

Ken-ichi NAGAI, Ken-ichi TANAKA, and Koshiro MIYAHARA
Research Institute for Catalysis, Hokkaido University, Sapporo 060
(Received February 12, 1974)

The hydrogen redistribution reaction between d_0-acetone and d_6-acetone was carried out at −10—60 °C over ZnO catalysts subjected to various modes of pretreatment. The activity of ZnO was several times larger than that of Zn metal, being hardly affected by the conditions of pretreatment below 350 °C and illumination with a mercury lamp. The rate of hydrogen redistribution was proportional to the amount of chemisorbed acetone which obeys the Langmuir adsorption isotherm. The activation heat of redistribution and the heat of acetone chemisorption were estimated to be 14 ± 2 and 10 ± 1 kcal/mol, respectively. The time course of the relative amounts of d_n-acetones, independent of the catalyst or its activity, was reproducible by a calculation based on the stepwise exchange model for the hydrogen exchange of acetone. About half of the chemisorbed acetone was found to be active for the redistribution or exchange of hydrogen. From the results and IR spectrometric study of acetone adsorbed on ZnO, the hydrogen redistribution of acetone was concluded to proceed *via* a chemisorbed acetone with an enol type configuration on a pair of sites, Zn^{2+}–O^{2-}, of ZnO surface.

It is well-known that ZnO catalyzes the dehydrogenation of isopropyl alcohol selectively. The hydrogenation of acetone has been found[1] to proceed on ZnO catalyst in the presence of a large excess of hydrogen at temperatures above *ca.* 100 °C, accompanied by a rapid redistribution of hydrogen in methyl groups of acetone. With regard to this hydrogen redistribution reaction, Hine *et al.*[2] reported that d_6-acetone was dedeuterated in acidic or alkaline aqueous solution, being catalyzed by hydrogen or hydroxyl ion, respectively. It is thus of interest to study the mechanism and nature of the active sites on ZnO surface of the present reaction. The reaction was investigated with a mixture of 85% of d_0-acetone ($(CH_3)_2CO$) and 15% of d_6-acetone ($(CD_3)_2CO$), ZnO and Zn metal subjected to various modes of pretreatment being used as catalyst.

Experimental

Powdered ZnO (Kadox-25 from New Jersey Zinc Co.) or Zn metal, first pressed into a wafer *ca.* 0.2 mm thick, was crushed into few mm wide. A known amount of catalyst was mounted in the bottom of a U-tube reactor of a conventional, closed circulating system, volume *ca.* 250 ml, and was activated by varied pretreatment (Table 1). In order to minimize contamination of the catalyst without cold traps, Apiezon grease of the stop cocks was well degassed prior to the experiment.

Chemically pure d_0-acetone from Wako Chem. Co. and d_6-acetone of 99D% from Merck Co. were dried by passing through a $CaCl_2$-tube and then repeatedly distilled in a vacuum. The sample of d_6-acetone contained d_5- and d_4-acetone in a few percent. Reactions were carried out at −10—60 °C under pressures of 0.5—80 mmHg of acetone. In order to estimate the ratio of the amount of adsorbed acetone active for redistribution to the total acetone adsorbed on ZnO, measurements were made of the adsorption isotherm of acetone, the hydrogen exchange between gaseous d_0-acetone and preadsorbed d_6-acetone and the hydrogen redistribution between d_0- and d_6-acetone over ZnO preliminarily saturated with adsorbed d_6-acetone. During some runs of the reaction of the d_0- and d_6-acetone mixture, the catalyst was illuminated with a mercury lamp of medium pressure (Toshiba H-400-P).

TABLE 1. PRETREATMENT OF THE CATALYSTS

Original form	No. of catalysts	Pretreatment	Visible change
ZnO powder,[a] 0.334 g	I	Evacuated at 300 °C for 1 hr	None
	II	Evacuated at 350 °C for 3 hr	Colored with dark green
	III	Evacuated at 450 °C for 3 hr	Zn deposited on the upper part of the reactor
	IV	Heated at 450 °C for 3 hr in 200 mmHg H_2 and then evacuated at 300 °C for 1 hr	Similar as above
Zn powder,[b] 0.380 g	V	None	None
	VI	Heated at 200 °C for 0.5 hr in 5 mmHg O_2 and then evacuated at 200 °C for 1 hr	None
	VII	Heated at 350 °C for 0.5 hr in 5 mmHg O_2 and then evacuated at 300 °C for 1 hr	None
	VIII	Heated at 400 °C for 0.5 hr in 5 mmHg O_2 and then evacuated at 300 °C for 1 hr	ZnO deposited on the upper part of the reactor

a) Prior to pretreatment, pressed Kadox-25 was heated at 450 °C in few cmHg O_2 for 14 hr, evacuated for 3 hr at 350 °C, heated again in O_2 for 0.5 hr and then cooled to the temperature of pretreatment. b) Prior to pretreatment, pressed Zn powder was heated at 350 °C for 14 hr and then evacuated for 1 hr at 350 °C.

Sampled gases were analyzed with a mass spectrometer (Hitachi RMU-6); ionization voltage 70 V. Relative peak heights of *m/e* 58—65 give relative amounts of d_n-acetones $n=0, 1, —, 6$ since no fragments of acetone were present in this region of the spectra.

Results and Discussion

The initial activity of ZnO catalysts was fairly high but decreased to a steady value after several runs of reaction were repeated followed by evacuation at room temperature (Table 1). Figure 1 shows a typical time course of the reaction with a mixture of 85% d_0- and 15% d_6-acetone carried out on the stabilized catalyst II, with surface area *ca.* 4 m²/g Cat.

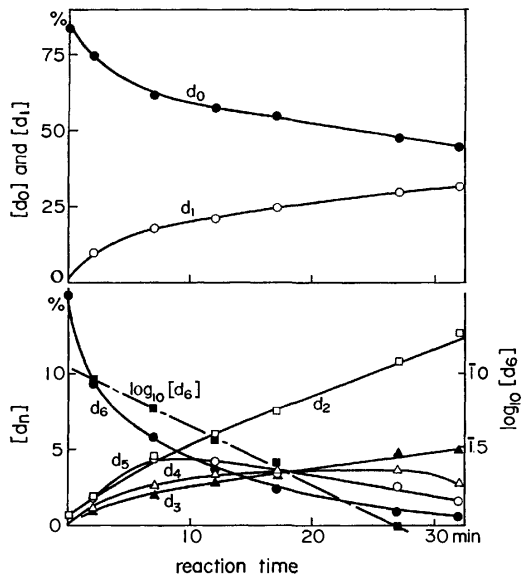

Fig. 1. Time courses of the relative amounts of d_n-acetones formed by the hydrogen redistribution with a 20 mmHg mixture of 85% d_0- and 15% d_6-acetone on ZnO (the catalyst II) at 0 °C.

The relative amounts of respective d_n-acetones depend solely upon the relative amount of d_6-acetone (Fig. 2). This suggests that the hydrogen redistribution reaction obeys the same rate equation, irrespective of the pretreatment of the catalyst. The presence of maxima of d_4- and d_5-acetone in the time courses (Fig. 1) suggests a stepwise hydrogen exchange mechanism, *i.e.*, not more than one hydrogen atom undergoes exchange before desorption of adsorbed acetone molecule. The full curves in Fig. 2 represent the results of simulation by the stepwise mechanism,

$$d_n\text{-acetone} \rightleftarrows a_m + h, \qquad (1)$$

where h is an adsorbed H or D atom and a_m ($m=n$ or $n-1$) is the adsorbed species of acetone loosing h. Provided that the kinetic hydrogen isotope effect on the rate of reaction (1) is negligible and the steady state condition is established for respective a_m's, we can derive the following equations which give the relative amounts of d_n-acetones, $[d_n]$, as a function of $[d_6]$.

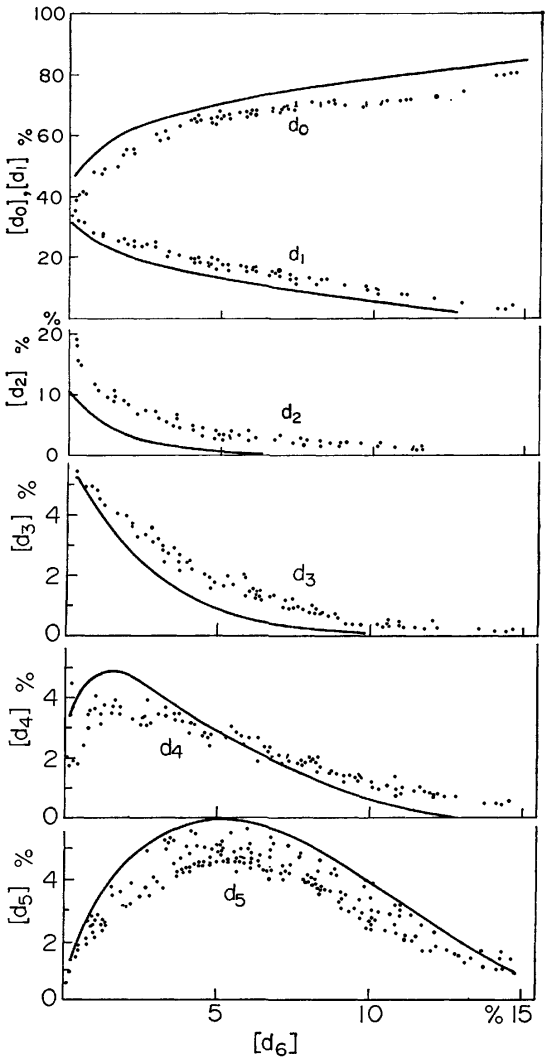

Fig. 2. The relations among the relative amounts of d_n-acetones formed by the hydrogen redistribution with a mixture of 85% d_0- and 15% d_6-acetone. Plots are the experimental results obtained by the use of all the catalysts listed on Table 1 and the full curves are those calculated by Eqs. (2).

$$\left.\begin{aligned} \frac{d[d_n]}{d[d_6]} &= \frac{[a_n](1-x)+[a_{n-1}]x-[d_n]}{[a_6](1-x)-[d_6]} \\ \frac{d[a_n]}{dt} &= \frac{(6-n)[d_n]}{6} + \frac{n[d_{n+1}]}{6} - [a_n] = 0, \end{aligned}\right\} \qquad (2)$$

where x is the D atomic fraction of h, being equal to 0.15 in the present reaction. In spite of the crude approximation in the simulation and no correction being made as regards ^{13}C and H contained in the d_6-acetone sample, observations for all the catalysts were well reproduced.

A linear relation of $\log_{10}[d_6]$ *vs.* time indicates that the rate of $[d_6]$ decrease obeys the first-order rate equation (Fig. 1(b)).

$$-d[d_6]/dt = (v_{ex}M/P_AV)[d_6], \qquad (3)$$

where P_A is the total pressure of acetone, V the volume of reaction system and M the weight of catalyst used. Constant v_{ex} is the exchange rate (ml·mmHg/min·g Cat.) and a measure of catalytic activity. The values

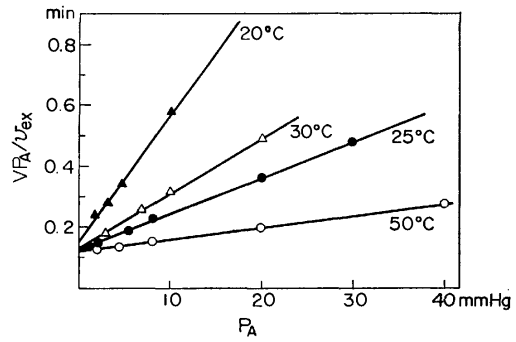

Fig. 3. Dependence of the exchange rate, v_{ex}, on acetone pressure. The experimental condition is similar to the case of Fig. 1.

of v_{ex} obtained for the catalyst II at various acetone pressure and temperatures establish the following relation (Fig. 3).

$$v_{ex} = k_{ex}K_A P_A/(1+K_A P_A), \quad (4)$$

where k_{ex} and K_A are the apparent rate constant of the exchange and the apparent equilibrium constant of acetone adsorption on ZnO catalyst, respectively. The activation heat of the exchange and the heat of acetone adsorption were evaluated to be 14 ± 2 and 10 ± 1 kcal/mol, respectively, from the results given in Fig. 4. The activation heats are nearly the same for all the catalysts. This indicates the same mechanism for all the reactions.

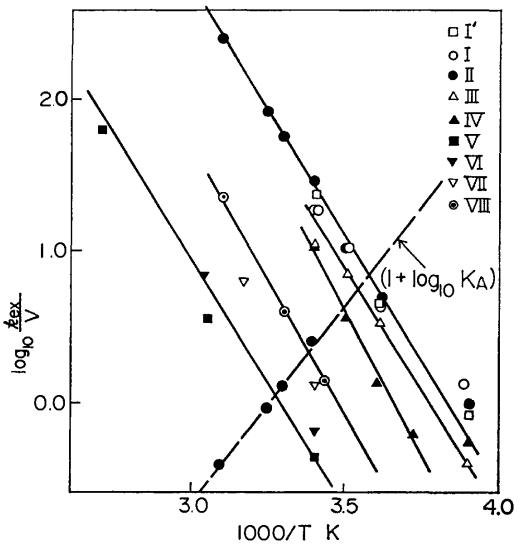

Fig. 4. Temperature dependences of the exchange rate constant, k_{ex}, and the adsorption constant, K_A (mmHg). Annexed figures are the number of the catalyst used.

The ZnO catalyst evacuated at a temperature below 350 °C gives a catalytic activity (Fig. 4), several tens times larger than that of the Zn metal. The activity of ZnO which decreased with evacuation at 450 °C is probably due to the deposition of Zn metal on ZnO surface (Table 1). In contrast, Zn metal became active with preliminary heating in oxygen. The high activity of ZnO as compared with Zn was further proved by use of catalyst VIII consisting of ZnO deposition on the upper part of the U-tube reactor and Zn metal at the bottom. The exchange reaction rate did not change by cooling the bottom of the reactor to −10 °C, where Zn metal was mounted, indicating that the reaction mainly takes place on ZnO deposited on upper part of the reactor wall.

Adsorption isotherms of acetone on the catalyst II were determined at temperatures 0—100 °C and at P_A up to a few mmHg. Saturated adsorption was observed at 0 °C, its amount being estimated to be 1.5 ml/g Cat. The adsorbed amount at 0 °C and 1 mmHg of P_A was 0.93 times this saturated adsorption, whereas it was 0.5 during the course of redistribution reaction according to the value of K_A (Fig. 4) and the adsorption isotherm

$$n = n_\infty K_A P_A/(1+K_A P_A) \quad (5)$$

derived from Eq. (4), where n is the amount of adsorbed acetone active for hydrogen redistribution and n_∞ its saturated value. The difference in the fractions of adsorbed acetone suggests that only a part of adsorbed acetone contributes to the hydrogen redistribution. This result was further supported by the hydrogen exchange reaction between gaseous d_0-acetone and preadsorbed d_6-acetone as follows. The reaction vessel was divided into A and B, the former containing catalyst II. A known amount of d_6-acetone was introduced into A and brought into adsorption equilibrium with the catalyst. d_0-Acetone was then introduced into B at an equal pressure to the residual pressure in A and was mixed with d_6 acetone in A by circulating over the catalyst causing hydrogen redistribution. The deuterium atomic fraction y_∞ in gaseous acetone at exchange equilibrium is given by

$$y_\infty = (N_6+n)/(N_0+N_6+n),$$

where N_0 and N_6 are amounts of gaseous d_0- and d_6-acetone, respectively, and n is the amount of preadsorbed d_6-acetone active for the hydrogen exchange. y_∞ is given by the steady value of y_A (Fig. 5). n was evaluated at 0.62 or 0.56 ml/g Cat. By introducing this value into Eq. (5), n_∞ was evaluated at 0.68 or 0.66 ml/g Cat., which is also *ca.* a half of the amount of saturated adsorption of acetone (1.5 ml/g Cat.). Thus, k_{ex} and K_A are proved to be the rate constant of the hydrogen redistribution and the equilibrium constant of the chemisorption of active acetone for the exchange, respectively.

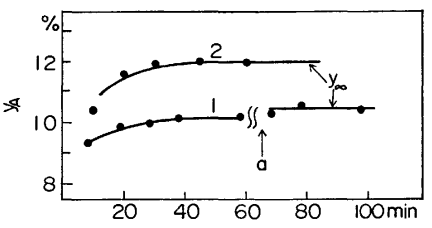

Fig. 5. Hydrogen exchange between d_6-acetone preadsorbed on the catalyst II and gaseous d_0-acetone at 0 °C.
Curve 1: 0.19 g ZnO and 6 mmHg at the adsorption equilibrium, curve 2: 0.5 g ZnO and 10 mmHg. At the time, *a*, of curve 1 the temperature was raised to 40 °C to accelerate the exchange.

The value of n_∞, being *ca.* a half of the monolayer on ZnO surface, indicates that the active sites for the hydrogen redistribution is the normal crystal plane but not the interstitial zinc[3] and/or the anion vacancies,[4] which might be far rarer than the normal lattice points of ZnO surface and have been reported to be active for the oxidation of CO, decomposition of N_2O[5] and so on. For the sake of confirmation catalyst II was illuminated with a mercury lamp of medium pressure in the course of the redistribution reaction. The rate did not change with illumination, indicating that the conduction electrons and/or the interstitial zinc is not responsible for the reaction.

From the above conclusions on the mechanism and the active sites of the exchange reactions and the results of the IR spectrometric study,[1] which established the presence of acetone chemisorbed on ZnO surface dissociatively with an enol-type configuration, the hydrogen redistribution reaction of acetone is supposed to be caused *via* acetone chemisorbed on a pair of sites, Zn^{2+}–O^{2-}, of ZnO surface such as

Kinetic Studies on the Selenization of Silver

Jun-ichiro MIZUSAKI, Kazuo FUEKI, and Takashi MUKAIBO
Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received May 2, 1974)

In order to elucidate the kinetics of selenization of silver by liquid selenium, the Ag/Ag_2Se interface reaction rate, the ionic conductivity of Ag^+ in Ag_2Se layer, the $Ag_2Se/Se(l)$ interface reaction rate, and the over-all reaction rate were determined. The Ag/Ag_2Se interface reaction rate was found to be given by

$$v = 1.6 \times 10^9 \{\exp(-32300/RT)\}(a_{Se}) \quad \text{eqv cm}^{-2}\cdot\text{s}^{-1}$$

The following mechanism was proposed for the interface reaction.

$$2Ag(Ag) + Se(Ag_2Se) \longrightarrow 2Ag^+(Ag_2Se) + Se^{2-}(Ag_2Se)$$

It was found that the driving force of the $Ag_2Se/Se(l)$ interface reaction is very small and Ag_2Se is in equilibrium with Se(l). On an assumption that the over-all reaction is controlled by both the Ag/Ag_2Se interface reaction and the diffusion of Ag^+ in Ag_2Se, the over-all reaction rates were calculated. The results agree with the observed ones.

Tarnishing reaction of metals proceeds in three steps; (i) reaction at the metal/scale interface, (ii) diffusion of electrons and ions through the growing scale and (iii) reaction at the gas (or liquid)/scale interface. Most kinetic studies on dry corrosion are concerned with the measurement and analysis of over-all reaction. If diffusion is rate controlling, the parabolic law holds, and if the interface reactions are rate controlling, the linear law holds. However, neither law holds if the reaction is controlled by both diffusion and interface reactions.

In order to determine the rate-controlling step more precisely, it is desirable to measure the reaction rate of each step separately and to compare the observed over-all reaction rate with the one calculated from the rates of three steps. For example, if step (ii) is rate controlling, the parabolic rate constant is related to the diffusion constant of the slowest diffusion species, as given by Wagner's equation.[1] If step (i) or (iii) is rate controlling, the linear rate constant should be equal to the rate of reaction at either one of two interfaces. Rickert and Tostmann studied the sulfurization of silver by sulfur vapor from this viewpoint.[2] Wagner, Rickert and their co-workers explained the sulfurization of silver and copper by liquid sulfur as controlled by steps (i) and (ii).[3,4] However, no work has been carried out on the reaction controlled by more than one step, with separate measurement of the reaction rate of each step and a comparison of the over-all reaction rate with the calculated one.

The purpose of the present study is to measure the Ag/Ag_2Se interface reaction rate, the ionic conductivity of Ag^+ in Ag_2Se, the $Ag_2Se/Se(l)$ interface reaction rate and the over-all reaction rate of selenization of silver by liquid selenium, and to compare the observed over-all reaction rate with the one calculated from the results of separate measurements.

Tubandt and his co-workers investigated the selenization of silver by solid selenium,[5,6] but that by liquid selenium has not been studied yet. Rickert, in a study on the Ag/Ag_2Se interface reaction,[7] recently found that the reaction rate was proportional to the -1.5—-3.0 power of activity of silver in Ag_2Se. However, we found it to be proportional to the -2 power.[8] This led us to reinvestigate kinetically the Ag/Ag_2Se interface reaction. So far no work on liquid/scale interface reaction seems to have been carried out yet.

Experimental

Materials. Silver (99.9%) and selenium (99.99%) were used. Cylindrical silver selenide was Prepared by the reaction of silver with selenium in a Pyrex tube. The product was sliced into pellets. AgI pellets, 3—7 mm thick, were prepared by pressing AgI powder under a pressure of 7 t/cm^2. Sometimes, $AgI-Al_2O_3$ pellets, 1 mm thick, were employed as an electrolyte. They were prepared by mixing nearly the same amounts of powdery AgI and Al_2O_3 and pressing the mixture.

Measurement of the Rate of Ag/Ag_2Se Interface Reaction. The coulometric titration method was employed. The apparatus is shown in Fig. 1. A pressure of 4 kg/cm^2 was applied to the Ag/Ag_2Se interface with a Pyrex tube to secure contact between the pellets. Since Ag_2Se and AgI tend to deform plastically, Ag/Ag_2Se interface often underwent bending in a cell $Ag/Ag_2Se/AgI/Ag$, and the interface reaction did not proceed uniformly. However, an $AgI-Al_2O_3$ pellet

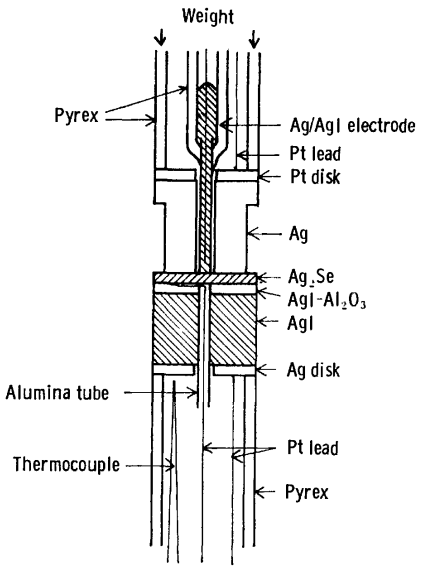

Fig. 1. Apparatus for the coulometric titration method.

unterwent no plastic deformation. Thus a thin AgI-Al_2O_3 pellet was inserted between AgI and Ag_2Se pellets. The detail of this method was described elsewhere.[9,10]

Measurement of the Rate of $Ag_2Se/Se(l)$ Interface Reaction. The apparatus is shown in Fig. 2. Three pellets of Ag, AgI, and Ag_2Se(I), 10 mm in diameter, were assembled in series and pressed with a Pyrex tube, 10 mm in outer and 6 mm in inner diameter. The lower end of the Pyrex tube was finished as flat as possible so that liquid selenium might be kept in the tube without leaking. An Ag/AgI electrode in a small alumina tube, 1.2 mm in outer diameter, was placed in the pyrex tube and the tip was brought to contact with the Ag_2Se(I) pellet.

The reaction rate was measured as an electric current with an ammeter and the potential difference between Ag_2Se-(I) pellet and Ag with a potentiometer. The thickness of the Ag_2Se(II) layer formed, Δx, was calculated by integrating the reaction rate with respect to time.

Measurement of the Selenization of Silver by Liquid Selenium. Wagner's pellet method[1,4,9,11] was used. A silver cylinder, 8 mm in diameter, and an Ag_2Se(I) pellet, 10 mm in diameter,

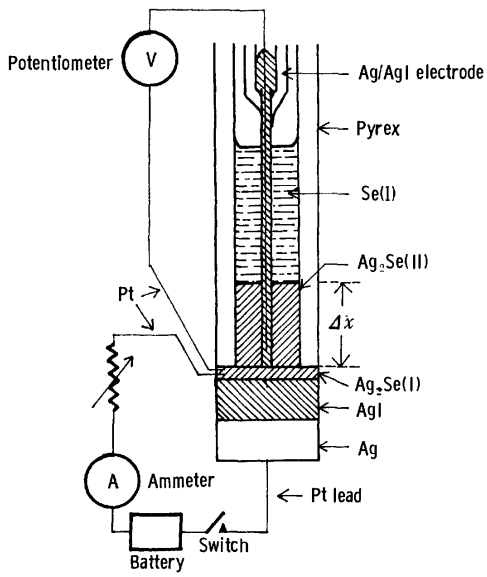

Fig. 2. Apparatus for the measurement of the rate of $Ag_2Se/Se(l)$ interface reaction.

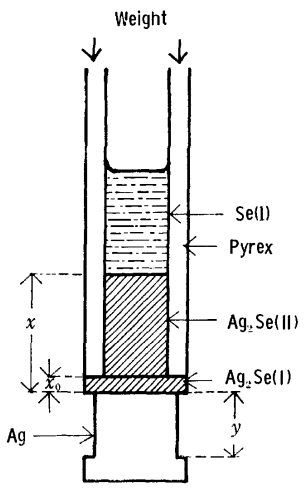

Fig. 3. Apparatus for the measurement of over-all reaction rate.

were assembled and pressed with a Pyrex tube, 10 mm in outer diameter and 6 mm in inner diameter (Fig. 3). A pressure of 4 kg/cm^2 was applied to the Ag/Ag_2Se interface by means of a spring. The lower end of the Pyrex tube was made flat so that the liquid selenium could be kept in the tube without leaking. It was difficult to observe the position of $Ag_2Se/Se(l)$ interface from outside, so the reaction was followed by observing the length of the silver cylinder y by means of a cathetometer. The increased length of selenide scale, $x-x_0$, was calculated from the decreased length of the silver cylinder, y_0-y, where x_0 and y_0 are the thickness of the silver selenide pellet and the length of the silver cylinder at the beginning of the reaction, respectively. Values of x_0 were 0.153 cm (250 °C), 0.070 cm (300 °C), and 0.114 cm (350 °C), and y_0 was 0.3 to 0.8 cm. After the reaction was completed, the thickness of the formed scale was measured and compared with the calculated thickness.

Results and Discussion

Ag/Ag_2Se Interface Reaction. a_{Ag}'', the silver activity of Ag_2Se at the Ag/Ag_2Se interface is calculated from E'', the potential difference between Ag_2Se and Ag by

$$E'' = -\frac{2.303RT}{F}\log a_{Ag}'' \qquad (1)$$

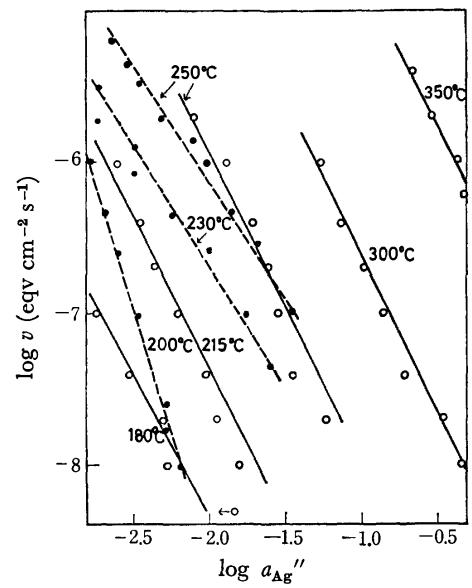

Fig. 4. Plot of log v *vs.* log a_{Ag}''
○: This work. ●: Rickert.

A plot of the logarithm of reaction rate v(eqv cm^{-2} s^{-1}) against log a_{Ag}'' is given in Fig. 4. Solid lines show our results and broken lines the ones by Rickert.[7] The values of n by Rickert vary from −1.5 to −3.0, while ours are close to −2.0, irrespective of the temperature, being essentially the same as $n=-1.9$ to −2.3

Table 1. Values of n

Temperature (°C)	n
180	−2.0±0.5
215	−2.2±0.6
250	−1.9±0.5
300	−1.9±0.4
350	−1.8±0.4

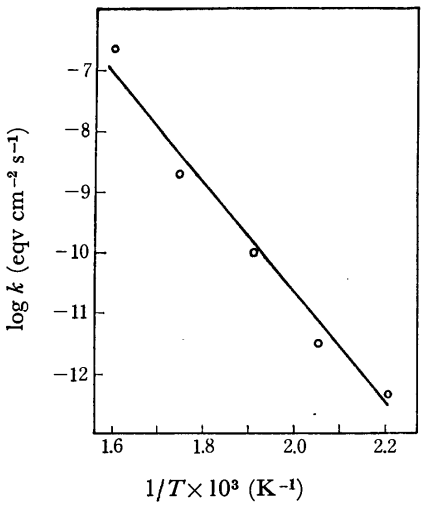

Fig. 5. Arrhenius plot of k.

for the Ag/Ag_2S interface reaction.[9]

The rate constants at $\log a_{Ag}''=0$, k, can be obtained from the intercept of the extrapolated lines with the ordinate. Figure 5 shows the Arrhenius plot of k. We see that linearity holds. Thus, the rate equation is expressed in the forms:

$$v = 4.0\times10^{7}\{\exp(-42000/RT)\}(a_{Ag}'')^{-2} \quad \text{eqv cm}^{-2}\cdot\text{s}^{-1} \tag{2}$$

$$v = 4.0\times10^{7}\{\exp(-42000/RT)\}(a_{Se}''/a_{Se}^{*}) \quad \text{eqv cm}^{-2}\cdot\text{s}^{-1} \tag{3}$$

where a_{Se}'' and a_{Se}^{*} denote the selenium activity in Ag_2Se at the Ag/Ag_2Se interface during the course of reaction and that in equilibrium, respectively. According to Kiukkola and Wagner,[12] ΔG°, the standard free energy of formation of Ag_2Se in a temperature range 167—400 °C is given by

$$\Delta G^\circ = -9.76 - 0.0074T = RT\ln a_{Se}^{*} \quad \text{kcal}\cdot\text{mol}^{-1} \tag{4}$$

by means of which, Eq. (3) can be rewritten as

$$v = 1.6\times10^{9}\{\exp(-32300/RT)\}(a_{Se}'') \quad \text{eqv cm}^{-2}\cdot\text{s}^{-1} \tag{5}$$

Ag_2Se and Ag_2S have the same crystal structure,[13] and the high ionic conductivity of silver ions. Moreover, n is nearly the same. Thus, the same mechanism as in the Ag/Ag_2S interface reaction[9] is proposed for the Ag/Ag_2Se interface reaction:

$$2Ag(Ag) + Se(Ag_2Se) \longrightarrow 2Ag^{+}(Ag_2Se) + Se^{2-}(Ag_2Se) \tag{6}$$

where, (Ag) denote the metal phase and (Ag_2Se) the silver selenide phase.

$Ag_2Se/Se(l)$ Interface Reaction and Ionic Conductivity of Ag^+ in Ag_2Se. When the switch is turned off, $Ag_2Se(I)$ is in equilibrium with liquid selenium (Fig. 2) and the potential difference E° between Ag_2Se and Ag is given by

$$E^\circ = -\Delta G^\circ/2F \tag{7}$$

where ΔG° is the free energy of formation of Ag_2Se. If the silver activity in Ag_2Se in equilibrium with liquid selenium is represented by a_{Ag}^{*}, we have

$$E^\circ = -\frac{2.303RT}{F}\log a_{Ag}^{*} \tag{8}$$

When the switch is turned on, Ag^+ ions are transported from Ag to the $Ag_2Se(I)/Se(l)$ interface through AgI and $Ag_2Se(I)$, while electrons flow from Ag to the $Ag_2Se(I)/Se(l)$ interface through the outer circuit and $Ag_2Se(I)$. Ag^+ ions and electrons arriving at the $Ag_2Se(I)/Se(l)$ interface react with liquid selenium to form $Ag_2Se(II)$. As a result, the $Ag_2Se(II)$ layer grows in the pyrex tube and the Ag/AgI electrode is buried in the $Ag_2Se(II)$ layer. When a constant current I_0 is let to flow constantly, the reaction at the $Ag_2Se(II)/Se(l)$ interface proceeds at a rate $I_0/2F$ and the difference in silver activity takes place at the interface between $Ag_2Se(II)$ and Se(l). If silver activities in $Ag_2Se(II)$ at the $Ag_2Se(II)/Se(l)$ interface and in $Ag_2Se(I)$ are a_{Ag}' and $a_{Ag}(\Delta x)$, respectively, and the thickness of $Ag_2Se(II)$ layer is Δx, the following relations are obtained.

$$E' - E(\Delta x) = \frac{I_0\cdot\Delta x}{\sigma_{Ag^+}\cdot S} \tag{9}$$

$$E' = -\frac{2.303RT}{F}\log a_{Ag}' \tag{10}$$

$$E(\Delta x) = -\frac{2.303RT}{F}\log a_{Ag}(\Delta x) \tag{11}$$

where S is the cross-sectional area of $Ag_2Se(II)$ layer, and σ_{Ag^+} is the ionic conductivity of Ag^+ in Ag_2Se. In Eq. (9), σ_{Ag^+} is assumed to be independent of the silver activity in Ag_2Se.[14,15]

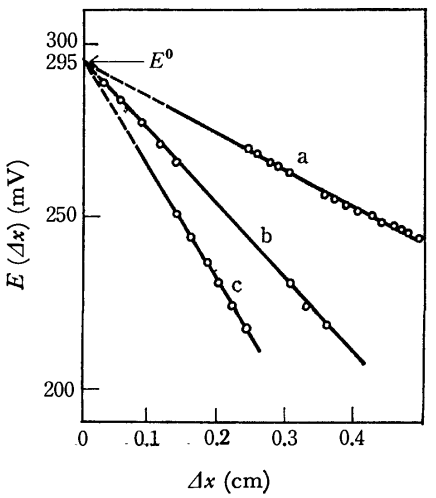

Fig. 6. Plot of $E(\Delta x)$ *vs.* Δx; reaction rate at $Ag_2Se/Se(l)$ interface at 250°C.
a: $I_0\cdot S^{-1}=385$ mA·cm^{-2} b: $I_0\cdot S^{-1}=770$ mA·cm^{-2}
c: $I_0\cdot S^{-1}=1155$ mA·cm^{-2}

Figure 6 shows the plots of $E(\Delta x)$ *vs.* Δx at 250 °C. E' is determined from the intercepts of the extrapolated lines with the ordinate, $\Delta x=0$. E° is shown by an arrow. E' is independent of the current and coincides with E°. It is thus concluded that the interface reaction proceeds with very small driving force, Ag_2Se being actually in equilibrium with Se(l). Equation (9) indicates that σ_{Ag^+} can be obtained from the slope of the plots in Fig. 6. The value 3.6 ohm^{-1} cm^{-1} obtained is in good agreement with the result obtained

by the four probe conductivity measurement by Okazaki.[16]

Contribution of Three Steps to the Over-all Reaction. Wagner and Rickert,[3] and Donner and Rickert[4] treated the sulfurization of silver and copper by liquid sulfur as controlled by both diffusion and metal/scale interface reaction. Ag_2Se and Se(l) are actually in chemical equilibrium during the reaction. The over-all reaction of selenization is considered to be controlled by both the diffusion in Ag_2Se and the Ag/Ag_2Se interface reaction, and Rickert-Wagner's method can be used for the analysis.

For the diffusion step, we have

$$\frac{dx}{dt} = \frac{\sigma_{Ag^+} \cdot V \cdot RT}{2x} \log \frac{a_{Ag}''}{a_{Ag}^*} = -\frac{\sigma_{Ag^+} \cdot V}{2F \cdot x}(E^\circ - E'') \quad (12)$$

and for the reaction at Ag/Ag_2Se interface,

$$\frac{dx}{dt} = \frac{V \cdot S_i \cdot k}{2S_l \cdot F}(a_{Ag}'')^{-2} = \frac{V \cdot S_i \cdot k}{2S_l \cdot F} \exp\left(\frac{2E''F}{RT}\right) \quad (13)$$

where V is the molar volume of Ag_2Se, x the thickness of Ag_2Se layer, S_i the area of Ag/Ag_2Se interface, and S_l the cross-sectional area of the grown Ag_2Se layer. From Eqs. (12) and (13) we obtain the following expressions for x and t.

$$\log x = \log \frac{\sigma_{Ag^+} \cdot S_l}{k \cdot S_i} + \log (E^\circ - E'') - \frac{2E''F}{2.303RT} \quad (14)$$

$$\log (t+t^0) = \log \frac{S_l^2 \cdot \sigma_{Ag^+} \cdot F}{4k^2 \cdot S_i^2 \cdot V} + \log \left\{\frac{RT}{F} - 4(E^\circ - E'')\right\} - \frac{4E''F}{2.303RT} \quad (15)$$

where t^0 is a constant determined by the initial condition $x=x_0$ for $t=0$. Eliminating E'' from Eqs. (14) and (15), and inserting the σ_{Ag^+} value and k value we obtained, we obtain x as a function of t. In Fig. 7, solid lines show the calculated values and open circles the observed values. Agreement between the calculated and observed results is good.

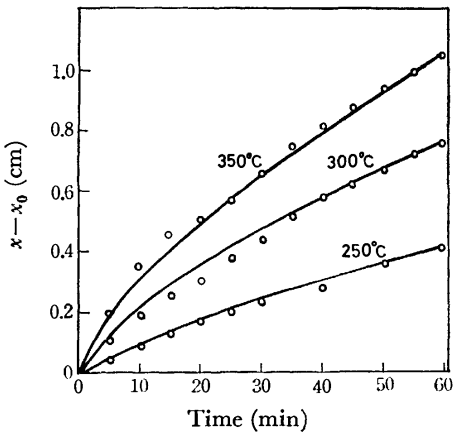

Fig. 7. Plot of $x-x_0$ *vs.* time.
○: observed values ——: calculated values

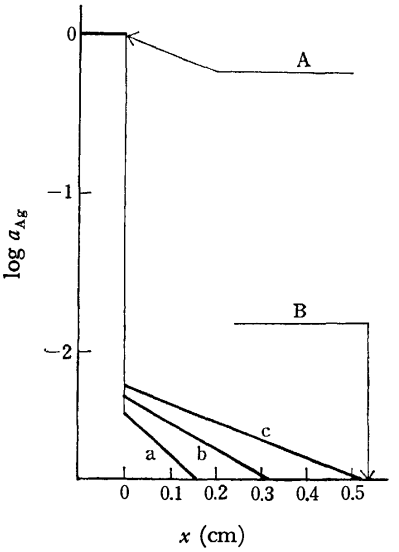

Fig. 8. Distribution of a_{Ag} in Ag_2Se layer under reaction at 250 °C.
a: $t=0$ min b: $t=25$ min c: $t=50$ min
A: Ag_2Se is in equilibrium with metallic silver
B: Ag_2Se is in equilibrium with liquid selenium

The distribution of silver activity during the reaction can be obtained by combining Eqs. (14) and (15). Figure 8 shows the plots of $\log a_{Ag}$ against x. We see that the Ag/Ag_2Se interface reaction is the slowest.

Summary

(1) The Ag/Ag_2Se interface reaction was investigated kinetically. The rate equation is found to be

$$v = 1.6 \times 10^9 \{\exp(-32300/RT)\}(a_{Se}) \text{ eqv cm}^{-2} \cdot \text{s}^{-1}.$$

The following mechanism was proposed.

$$2Ag(Ag) + Se(Ag_2Se) \longrightarrow 2Ag^+(Ag_2Se) + Se^{2-}(Ag_2Se)$$

(2) The rate of $Ag_2/Se(l)$ interface reaction and the ionic conductivity of Ag^+ in Ag_2Se were measured. It was found that Ag_2Se and Se(l) are actually in chemical equilibrium during the course of reaction.

(3) The over-all reaction rate of silver selenization was determined kinetically. Assuming that the selenization is controlled by both the diffusion of Ag^+ ions and the Ag/Ag_2Se interface reaction, the over-all reaction rates were calculated. The calculated values agreed with observed ones.

Determination of the Optical Purity of Amino Acids by Complex Formation.* Determination of Optimum Condition for Rotational Measurement

Yuki FUJII**

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730

(Received February 22, 1974)

A new method has been established for the determination of the optical purity of a small amount of amino acids (alanine, valine, leucine, and glutamic acid). The method utilizes the fact that when an optically active amino acid is dissolved in an alkaline solution of $K[Co(acac_2en)(gly)_2]$, the solution shows much larger optical rotation than the free amino acid in the visible region. 1/50 to 1/100th the amount of an amino acid (about 0.1—0.05 grams) suffices for the determination of optical purity as compared with that needed in the usual method. The optimum conditions for measurement are: wavelength, 500 nm; pH, 10.00; time required to establish the substitution equilibrium, 6—8 hours; concentration of the complex, $(4—5)\times10^{-3}$ mol l^{-1}; concentration of amino acid, $(2—1)\times10^{-2}$ mol l^{-1}.

The optical purity of amino acids is usually determined by their optical rotations at the Na-D line.[1-4] These are generally so small that concentrated solutions (about 0.1—1.0 mol l^{-1}) are needed. For example, a 1.12 mol l^{-1} solution (6M-HCl) of optically pure L-alanine shows α_D-value only $+0.14°$ with a 1 cm cell. Thus, several grams of sample is required for the usual method. The quantity of amino acids handled in biochemical research is so small that it is difficult to measure the optical rotation in such cases. Great improvements have been made in polarimeters and it has become possible to measure the optical rotation of active compounds with an accuracy of 10^{-3} °, but further improvement cannot be expected. Badr *et al.*[5] reported that when an amino acid in anhydrous methanol containing a base is treated with excess carbonyl compound, a considerably large optical rotation is observed in the 250 nm region. The reaction is useful for the assignment of the configuration of a small amount of amino acid, but as it is not quantitative, the method has not been used to determine the optical purity of amino acids.

It was found that cobalt(III)–acac$_2$en-complex, $[Co(acac_2en)(X)_2]^-$ ($acac_2en^{2-}$ = *N,N'*-ethylenebis(acetylacetonimine) dianion, X^-=amino acid anion) has the following characteristics:[6] 1) The amino acidato ligand X^-, coordinated as a unidentate ligand at the axial site of the complex, is labile and easily replaced by an other amino acidato ligand Y^- under alkaline conditions. The reaction between the complex $[Co(acac_2en)(X)_2]^-$ and Y^- can be described by

$$[Co(acac_2en)(X)_2]^- + Y^- \rightleftharpoons [Co(acac_2en)(X)(Y)]^- + X^- \quad (1)$$

$$[Co(acac_2en)(X)(Y)]^- + Y^- \rightleftharpoons [Co(acac_2en)(Y)_2]^- + X^- \quad (2)$$

2) When the amino acidato ligand at the axial site is optically active, the complex shows a much larger optical rotation than the free amino acid in the visible region. These results suggest that if an optically active amino acid is mixed with optically inactive $[Co(acac_2en)(X)_2]^-$ under alkaline conditions, rapid exchange reactions such as (1) and (2) occur, and the mixed solution shows a much larger optical rotation than the solution containing the amino acid only. On this basis, we established a new method to determine the optical purity of a small amount of amino acid. Determination of the optimum condition for rotational measurements is discussed herewith.

Experimental

Preparation of Complexes. $K[Co(acac_2en)(gly)_2]\cdot2H_2O$ was prepared by the method reported.[6] The other complexes were prepared by a method similar to that used for $[Co(acac_2en)(NH_3)_2]Cl\cdot2H_2O$.[7,8] The elemental analysis data of new complexes are as follows: *N,N'*-ethylenebis(benzoylacetoniminato)diamminecobalt(III) chloride dihydrate, $[Co(bzac_2en)(NH_3)_2]Cl\cdot2H_2O$, Found: C, 51.89; H, 5.99; N, 10.26%. Calcd for $C_{22}H_{28}N_4O_2CoCl\cdot2H_2O$: C, 51.72; H, 6.33; N, 10.97%. *N,N'*-Ethylenebis(trifluoroacetylacetoniminato)diamminecobalt(III) chloride monohydrate, $[Co(tfac_2en)(NH_3)_2]Cl\cdot H_2O$, Found: C, 29.83; H, 4.16; N, 11.93%. Calcd for $C_{12}H_{18}N_4O_2CoF_6Cl\cdot H_2O$: C, 30.23; H, 4.24; N, 11.76%.

Reagents. All chemicals were of analytical grade and used without further purification. Specific rotations measured by the usual method are as follows (% given in ( ) is the optical purity of amino acid). L-alanine (100%), $[\alpha]_D^{25}=+15.0°$, D-alanine (100%), $[\alpha]_D^{25}=-14.9°$ (5 g/50 ml of 6M-HCl); L-valine (100%), $[\alpha]_D^{25}=+28.5°$, D-valine (100%), $[\alpha]_D^{25}=-28.5°$ (4 g/50 ml of 6M-HCl); L-leucine (100%), $[\alpha]_D^{25}=+16.3°$, D-leucine (100%), $[\alpha]_D^{25}=-16.3°$ (2 g/50 ml of 6M-HCl); L-glutamic acid (100%), $[\alpha]_D^{25}=+32.4°$, D-glutamic acid (100%), $[\alpha]_D^{25}=-32.3°$ (5 g/50 ml of 2M-HCl). Amino acids of different optical purity were prepared by mixing optically pure amino acid with racemic amino acid (for example, L-alanine (50%) was prepared by mixing L-alanine (100%) with racemic alanine (0%) in a ratio of 1:1).

Measurements. The ORD and CD spectra were recorded at 25 °C on a JASCO Model ORD/UV-5 spectrophotometer with a CD attachment. The absorption spectra were measured at 25 °C with a Shimadzu UV-200 double beam spectro-

photometer. The pH was measured with a Hitachi-Horiba Model F-7 pH-meter at 25 °C.

Results and Discussion

Determination of the Optimum Condition for Rotational Measurement. The molar rotations of L-alanine (100%) and its metal complexes are given in Table 1. The [M]-values of metal complexes containing amino acids are greater than those of free amino acids at special wavelengths, the [M]-values of Co(acac$_2$en)-complex being remarkably large. From a comparison of the [M]-values per one mole of amino acid, we see that the amino acid coordinated to the Co(acac$_2$en)-complex has 100—200 times as large an optical rotation as the free amino acid. The AB, CD, and ORD spectra of solutions prepared by mixing optically inactive K[Co(acac$_2$en)(gly)$_2$] with a large excess (100 times) of alanine under alkaline conditions are shown in Fig. 1. We see that ORD- and CD-intensities of the mixed solutions are in line with the optical purities of the alanine. The results suggest that the optical purity of amino acids can be determined by comparing the rotational (and also CD) value of a solution containing K[Co(acac$_2$en)(gly)$_2$] and optically pure amino acid with that of a solution containing the complex and the amino acid whose optical purity is to be determined. In this case a large excess of amino acid is used. However, when a small excess of amino acid (100%) is mixed with the glycinato complex solution, the resulting solution shows a small optical rotation as compared with that of the complex solution containing a large excess of amino acid (100%). This is due to the incomplete replacement reaction. Thus, the determination of optimum concentrations of the complex and amino acid is very important.

K[Co(acac$_2$en)(gly)$_2$] was used as an optically inactive Co(acac$_2$en)-complex, and alanine, valine, leucine and glutamic acid were examined. Since the chemical and spectral behavior of L- and D-form amino acids is the same except for the inversion of the CD- and ORD-signs, and the four amino acids behave similarly, L-alanine is given here with as an example. Although free amino acid is CD-inactive in the visible region, it becomes CD-active upon complex formation. Both CD- and ORD-intensities were therefore used to investigate optimum conditions.

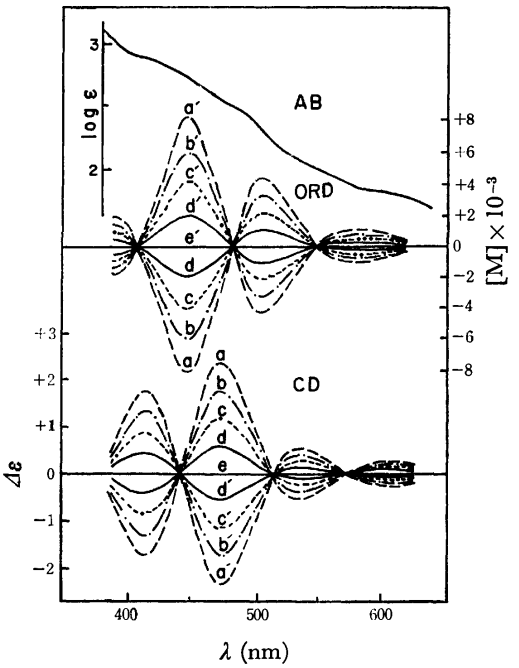

Fig. 1. AB, CD, and ORD spectra of the aqueous solution containing K[Co(acac$_2$en)(gly)$_2$] and a large excess (100 times) of alanine. The solution pH is 10.00. a and a′, L-alanine (100%) and D-alanine (100%); b and b′, L- and D-alanine (75%); c and c′, L- and D-alanine (50%); d and d′, L- and D-alanine (25%); e, racemic alanine.

Wavelength: The mixed solutions show ORD peaks at 380, 450, 500, and 580 nm, and CD peaks at 425, 475, 540, and 600 nm (Fig. 1). Peaks near 600 nm have low intensities, and those near 400 nm are accom-

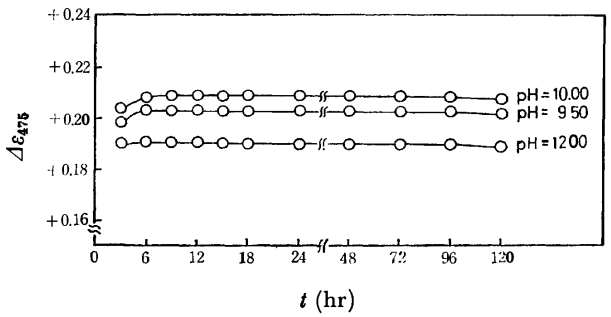

Fig. 2. The time dependence on the substitution equilibrium between K[Co(acac$_2$en)(gly)$_2$] and L-alanine (100%) at various pH. $C_{complex}=2.0\times10^{-3}$ mol l^{-1}, $C_{L-alanine}=2.0\times10^{-2}$ mol l^{-1}, $\mu=0.1$ (Na_2CO_3+$NaHCO_3$), T=25 °C.
$\Delta\varepsilon$ is given by the values for one mole of L-alanine at 475 nm.

panied by strong absorptions, and are therefore not suitable for measurements of CD- and ORD-intensities. The wavelengths of peaks at 475 nm (CD) and 500 nm (ORD) were chosen as their intensities are strong, and their CD- and ORD-signs coincide with the ORD-sign of free amino acids.

Time Dependence: In order to employ complex formation reactions such as (1) and (2) for determination of the optical purity of amino acids, it is necessary for the substitution reaction in solution to be in equilibrium. Thus the time needed to reach equilibrium was examined (Fig. 2). It is seen that 6—8 hr was required and that is less dependent on the pH of the solution. The solutions show constant CD-intensities for 3—4 days, which gradually decrease owing to the racemization of the optically active amino acid in a basic condition. The CD- and ORD-intensities of the mixed solutions were thus measured 10—24 hr after preparation of the solution.

pH-Dependence: The CD-intensity (and also ORD-intensity) depends upon the pH of the solution. The pH-dependence is shown in detail in Fig. 3. The solution shows maximum intensity at pH *ca.* 10. The intensity decreases in low pH region and in an alkaline

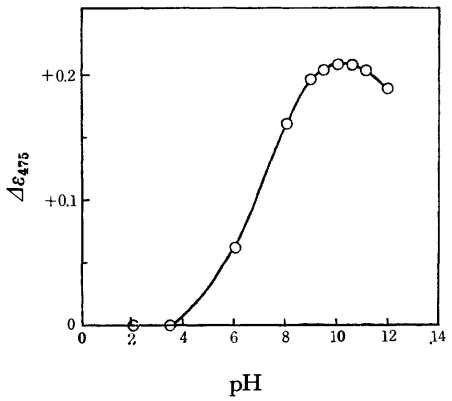

Fig. 3. The pH dependence on the CD-intensities of the mixed solutions containing L-alanine (100%). $\Delta\varepsilon$ is given by the values for one mole of L-alanine at 475 nm. $C_{complex}=2.0\times10^{-3}$ mol l^{-1}, $C_{L-alanine}=2.0\times10^{-2}$ mol l^{-1}, $\mu=0.1$ (Na_2CO_3+$NaHCO_3$), $T=25$ °C.

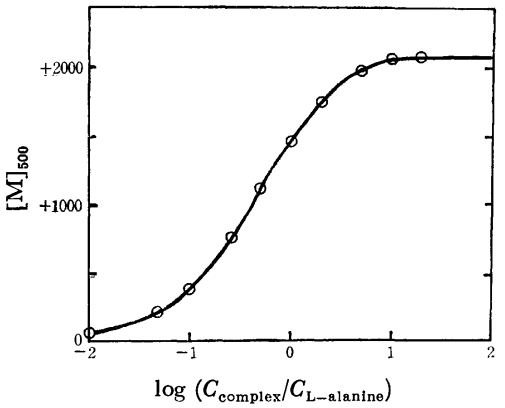

Fig. 4. Molar rotations of the mixed solutions containing K[Co(acac$_2$en)(gly)$_2$] and L-alanine (100%) in various mixing ratio. The pH of the solutions is 10.00. $[M]_{500}$ is given by the values for one mole of L-alanine. $\mu=0.1$ (Na_2CO_3+$NaHCO_3$), $T=25$ °C.

region above pH=10. This decrease seems to be due to the formation of aquo- and hydroxo-complexes in acidic and strongly basic conditions, respectively.

In order to adjust both the ionic strength μ and pH, a 1:1 mixture of Na_2CO_3 and $NaHCO_3$ was added to the solution. The coordination of CO_3^{2-} and HCO_3^- to the complex could be neglected for $\mu=(0.05—0.2)$.

Concentrational Dependence: The ORD-intensities of solutions containing K[Co(acac$_2$en)(gly)$_2$] and L-alanine (100%) in various concentrations are shown in Fig. 4. The results for CD-intensities are given in Table 2. It is observed that the larger the mixing ratio $C_{complex}/C_{L-alanine(100\%)}$, the greater the CD- and ORD-intensities per one mole of L-alanine (100%). Thus, in order to measure the CD- and ORD-intensities in high sensitivity for amino acid, a high concentration of complex and a low concentration of amino acid should be used. However, since the solution shows strong absorption in the visible region, the complex

concentration cannot be made higher than *ca.* 5.0×10^{-3} mol l^{-1}. If a very low concentration of amino acid is used, the solution shows negligibly small CD- and ORD- intensities. Under these circumstances, it is difficult to determine the optimum concentrations. The solution equilibrium was therefore treated theoretically and an estimation of rotational values of the mixed solutions was examined. Results of calculation for the rotational values of the mixed solutions are shown in Fig. 5, where the estimated rotations are indicated by contours. The solid line indicates the α_{500}-value of 0.1° cm^{-1}, which is the minimum limit to obtain a rotational value to three significant figures. The optimum concentrations for rotational measurement are determined to be $C_{complex}=(5-4)\times10^{-3}$ mol l^{-1}, $C_{alanine}=(1-2)\times10^{-2}$ mol l^{-1} (shaded area, Fig. 5).

Theoretical Approach to Solution Equilibrium and Rotational Values of the Mixed Solution. When we mix K[Co(acac$_2$en)(gly)$_2$] with optically active amino acid YH in the initial concentrations of x mol l^{-1} and y mol l^{-1}, respectively, the concentrations of the complexes under equilibrium conditions can be written as follows:

$$C_{[Co(acac_2en)(gly)_2]^-} = [4x^2/(\alpha H_{gly})^2 Z]x \quad mol\cdot l^{-1},$$

$$C_{[Co(acac_2en)(gly)(Y)]^-} = [4xyD/(\alpha H_{gly})(\alpha H_Y)Z]x \quad mol\cdot l^{-1},$$

$$C_{[Co(acac_2en)(Y)_2]^-} = [y^2D^2/(\alpha H_Y)^2 Z]x \quad mol\cdot l^{-1},$$

where $Z=[4x^2/(\alpha H_{gly})^2+4xyD/(\alpha H_{gly})(\alpha H_Y)+y^2D^2/(\alpha H_Y)^2]$, αH_{gly} and αH_Y are αH-values of glycine and YH, respectively. D is a parameter which represents the relative coordinating ability of amino acids, taking the coordinating ability of gly^- as 1.00. Amino acids including glycine were thought to coordinate to Co(acac$_2$en)-complex in their anionic forms, and were assumed to distribute to Co(acac$_2$en)-complex statistically.[6] In the above expression, aquo- and hydroxo-complexes were neglected. The compounds which contribute to the rotation (and CD-intensity) are [Co(acac$_2$en)(gly)(Y)]$^-$, [Co(acac$_2$en)(Y)$_2$]$^-$, free Y^- and YH. Thus, the rotational value (or CD-intensity) at wavelength λ of the mixed solution is given by

$$A_\lambda = F\{B_\lambda x[2xyD/(\alpha H_{gly})(\alpha H_Y)+y^2D^2/(\alpha H_Y)^2]/Z+E_\lambda\} \quad (3)$$

where A_λ is the rotational value (or CD-intensity) at λ of the solution, B_λ the molar rotation (or molar CD-intensity) at λ of [Co(acac$_2$en)(Y)$_2$]$^-$ in which Y^- is an optically pure amino acid anion, E_λ the total rotational value (or CD-intensity) of free Y^- and YH, and F the optical purity of the amino acid YH, given by F=[concentration of optically active amino acid]/[total concentration of amino acid]. The molar rotation (or CD-intensity) of [Co(acac$_2$en)(gly)(Y)]$^-$ was assumed to be $1/2\times B_\lambda$, because the vicinal effect is generally additive.[11,12] If we mix K[Co(acac$_2$en)-(gly)$_2$] with optically pure amino acid, the rotational value (or CD-intensity) of the solution can be calculated by putting F=1. B_λ-values were estimated from the ORD- and CD-intensities of the solution containing K[Co(acac$_2$en)(gly)$_2$] and a large excess of optically pure amino acids. E_λ-values were estimated to be zero because free amino acids show negligibly small optical rotations in low concentrations and they are CD-inactive in the visible region. D-values of the solutions were estimated from the observed CD-intensities of the solutions having various mixing ratio, $C_{complex}/C_{aminoacid(100\%)}$. The values of B_λ and D thus determined are listed in Table 3.

By using these values, the CD- and ORD-intensities of the mixed solutions were calculated by Eq. (3). The results are given in Table 2 and Fig. 4. The

12.00	+0.944	+0.189	0.212

calculated values agree with the observed ones. The pH-dependence of Eq. (3) is given in Table 4. Agreement between the calculated and observed values is good in the pH region 9—10.5, but not in the others. The discrepancy might be due to the formation of aquo- and hydroxo-complexes. It is thus concluded that Eq. (3) holds in the pH region where the formation of aquo- and hydroxo-complexes is negligble.

The coordinating abilities (D-value) of the amino acids depend upon their basicity and steric factor. For the above system, the linear relation between the D-values and pK_2-values (pK_3 for L-glutamic acid) of the amino acids can not be found, since all the amino acids cited have nearly the same pK_2-values (pK_3 for L-glutamic acid) (the amino acid anion coordinates to Co(acac$_2$en)-complex with its amino group,[6] and therefore its pK_2-value was considered). Since the decreasing order of the D-values coincides with the increasing order of the steric crowding of the amino acids, it is assumed that the difference in coordinating ability of the amino acids to Co(acac$_2$en)-complex is mainly dependent on the steric factor.

Calibration Curve. The CD- (475 nm) and ORD- (500 nm) intensities were thus measured with solutions containing K[Co(acac$_2$en)(gly)$_2$] and amino acids of various optical purities. Experimental conditions were as follows: $C_{complex}=4.0\times10^{-3}$mol l^{-1}, $C_{aminoacid}=1.6\times10^{-2}$ mol l^{-1}, pH of the solution=10.00, $\mu=0.1$ (Na_2CO_3+$NaHCO_3$), cell length=1.0 cm, time=10—24 hr. From the results of measurements, calibration curves were obtained for four amino acids. All showed a linear relation between the ORD- (CD) intensities of the mixed solutions and the optical purities of the amino acids, the error being within 1%. It is concluded that we can determine the optical purity of a small amount of amino acid by comparing the ORD- (CD) intensity of a mixed solution containing optically pure amino acid with that of a mixed solution containing the amino acid whose optical purity is to be determined. The ORD- and CD-intensities of solutions prepared by mixing K[Co(acac$_2$en)(gly)$_2$] and optically pure amino acids are given in Table 5.

Table 5. CD- and ORD-intensities of a mixed solution containing K[Co(acac$_2$en)(gly)$_2$] and optically pure amino acid
$C_{complex}=4.0\times10^{-3}$ mol l^{-1}, $C_{amino\ acid}=1.6\times10^{-2}$ mol l^{-1}, pH of the solution=10.00, μ =0.1 (Na_2CO_3+$NaHCO_3$), T=25 °C, Time=(10—24) hr.

Amino acid	α_{500} ($°cm^{-1}$)	$\Delta\varepsilon_{475}$ (cm^{-1})
L-Alanine (100%)	+0.122	$+6.56\times10^{-3}$
D-Alanine (100%)	−0.122	-6.56×10^{-3}
L-Valine (100%)	+0.171	$+12.85\times10^{-3}$
D-Valine (100%)	−0.171	-12.85×10^{-3}
L-Leucine (100%)	+0.225	$+11.41\times10^{-3}$
D-Leucine (100%)	−0.225	-11.41×10^{-3}
L-Glutamic acid (100%)	+0.151	$+6.13\times10^{-3}$
D-Glutamic acid (100%)	−0.151	-6.13×10^{-3}

The solution for rotational measurement is prepared as follows: 20 ml of a 1.0×10^{-2} mol l^{-1} solution of K[Co(acac$_2$en)(gly)$_2$]·2H$_2$O (M.W.=504.48) and 5 ml of a buffer solution (0.2 mol l^{-1} Na_2CO_3+0.2 mol l^{-1} $NaHCO_3$) are mixed together. Then an amino acid (8.0×10^{-4} mol) is dissolved in this solution. The pH of the solution is adjusted to 10.00 by 0.1N-NaOH, the solution being made up to 50 ml with water. The rotational measurement is carried out after the solution is allowed to stand for about 10 hr at 25 °C.

Comparison with the Usual Method. The usual method requires 5—10 grams of amino acids to determine the optical purity. The method established herewith requires only *ca.* 0.1 g (8.0×10^{-4} mol). As small a quantity as 1/50 to 1/100 th of the sample suffices for the determination of the optical purity as compared with that needed in the usual method.

Other Schiff-Base Complexes. Several other cobalt(III)-Schiff-base complexes were examined in order to find other complexes which show larger a optical rotation than K[Co(acac$_2$en)(gly)$_2$] when they react with optically active amino acids, and which cause a more rapid substitution reaction of the axial ligand. The results are shown in Fig. 6. The Co(acac$_2$en)-

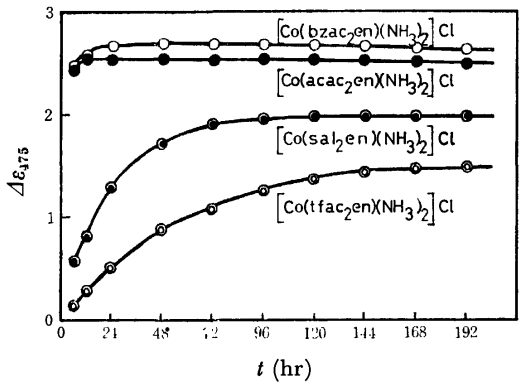

Fig. 6. The time dependence on the CD-intensity (475 nm) of the mixed solution containing Co(III)-Schiff-base complex and L-alanine (100%). $\Delta\varepsilon$ is given by the values for one mole of complex.
$C_{complex}=4.0\times10^{-3}$ mol l^{-1}, $C_{L\text{-alanine}}=8.0\times10^{-2}$ mol l^{-1}, the pH of the solution=9.50, $\mu=0.2$ (Na_2CO_3+$NaHCO_3$), $T=25$ °C.

complex is the most suitable for rotational measurement. All the complexes investigated, [Co(acac$_2$en)(NH$_3$)$_2$]Cl, [Co(bzac$_2$en)(NH$_3$)$_2$]Cl, [Co(tfac$_2$en)(NH$_3$)$_2$]Cl, and [Co(sal$_2$en)(NH$_3$)$_2$]Cl, show AB, CD, and ORD spectra similar to those for K[Co(acac$_2$en)(gly)$_2$] when mixed with L-alanine (100%). A long time is needed to establish the substitution equilibrium except for the Co(acac$_2$en)-complex. Since the chemical and spectral behavior of [Co(acac$_2$en)(NH$_3$)$_2$]Cl is very similar to that of K[Co(acac$_2$en)(gly)$_2$] and the preparation of the amine-complex is easier than that of the glycinato-complex, [Co(acac$_2$en)(NH$_3$)$_2$]Cl might be substituted for K[Co(acac$_2$en)(gly)$_2$].

The author wishes to express his deep thanks to Professor Hayami Yoneda and Associate Professor Yoshihiko Kushi, Hiroshima University, for their guidance and encouragement during the course of the work, and also to Dr. Ushio Sakaguchi and Dr. Katsuhiko Miyoshi for their stimulating discussion and helpful suggestions.

The Selectivity Evaluation of an Ion-selective Electrode with a Liquid Membrane by Electrode Response to a Foreign Ion

Akinori Jyo, Masanori Torikai, and Nobuhiko Ishibashi*

Department of Applied Analytical Chemistry, Faculty of Engineering, Kyushu University, Fukuoka 812

(Received July 13, 1974)

The potential responses of liquid-membrane electrodes to foreign ions were examined. The electrode response obeyed the Nikolsky equation when the selectivity for the foreign ion was nearly equal to or higher than that for the objective ion and when the concentration of the foreign ion in the sample solution was sufficiently higher than that of the ion-exchanger in the liquid membrane. The Nikolsky equation, however, did not hold for the response when the selectivity for the foreign ion over the objective ion was extremely low or when the concentration of the sample was not so high. Such a non-ideal response was ascribed to the variation in the ionic composition at the membrane-solution interface caused by the ion-exchange. From the measurement of the electrode potential under conditions when the response obeyed the Nikolsky equation, the selectivity coefficient for the foreign ion over the objective ion could be obtained successfully as an intrinsic value of the electrode membrane. The selectivity value thus obtained was in good agreement with the value estimated from the Sandblom-Eisenman-Walker theory on the electrode selectivity. The additivity of the membrane potential was also described.

In recent years, many liquid membrane electrodes have been developed for the activity measurements of various inorganic and organic ions in aqueous solutions.[1-4] The selectivities of these electrodes have been evaluated by using several methods, such as the mixed-solution method and the separate-solution method.[5-7] It has been observed, however, that the selectivity values thus obtained are not always constant but vary with the method employed and the conditions of measurement.[5,8,9]

In a previous communication, Yoshida and one of the present authors (N.I.) have briefly reported on one way to evaluate an intrinsic selectivity value for a given electrode.[10] This paper will describe the details of this approach and will present the selectivity values of several liquid membrane electrodes obtained through the approach. The relationship between the selectivity values and ionic parameters, such as the mobility and the ion-partition coefficient, will also be mentioned.

Experimental

Reagents and Sensitive Liquid Membranes. All the chemicals used were of a reagent-grade quality. Aqueous solutions of sodium salts of various inorganic and organic anions were used as sample and reference solutions. In the case of cation-selectivity evaluation, aqueous solutions of alkali metal chlorides and quaternary ammonium chlorides were used. A liquid ion-exchanger membrane consisted of an organic solution of an ion-pair of an objective ion with an ion-exchange-site ion, such as the crystal violet, tris-(bathophenanthroline)iron(II), methyltricaprylylammonium, and dipicrylaminate ions. Nitrobenzene, nitromethane, 1,2-dichloroethane, chloroform, and 1-decanol were used as solvents of the membranes. The liquid membrane solutions were prepared by the same procedures as in previous papers.[11,12]

Potential Measurement. A glass U-tube cell reported on in a previous paper was used for the set-up of the cell (1) in order to evaluate the selectivity of the i-ion-sensitive membrane to the foreign j-ion:[13]

+SCE or Ag–AgCl/Reference Solution (i)/
Liquid Membrane (S–i)/Sample Solution (j)/
SCE or Ag–AgCl− (1)

where S denotes the ion-exchange site in the membrane. The electromotive force of Cell (1) was measured by using a Takeda Riken Electrometer TR-8651. A silver/silver chloride electrode was used as the reference electrode for the study of the cation selectivity. A saturated calomel electrode (SCE) was used in evaluations of the anion selectivities. A sample or reference solution was connected to the reference electrode by means of an agar salt bridge saturated with potassium chloride or ammonium chloride.

Alternatively, the electromotive force of Cell (2) was measured according to Shean's method.[14]

+SCE/Solution (i)/Membrane (i)/Membrane (j)/
Solution (j)/SCE− (2)

Results and Discussion

Electrode Responses for Solutions of Foreign Ions. In the determination of the selectivity coefficient of an ion-selective electrode with a liquid membrane, it is usually assumed that the electrode response for a sample solution containing a monovalent objective ion, i, as well as a foreign ion, j, obeys the following Nikolsky equation (3):

$$E_M = \pm 2.303RT/F \log ((a_i'' + K_{i,j}^{Pot} a_j'')/a_i') \quad (3)$$

where a_i and a_j are the activities of the corresponding ions, i and j. Prime and double prime refer to the reference and sample solutions respectively. The $K_{i,j}^{pot}$ symbol represents the potentiometric selectivity coefficient for the j ion over the i ion. The plus and minus signs at the top in Eq. (3) stand for the responses of cation- and anion-selective electrodes respectively. For a sample solution containing the j ion alone, Eq. (3) reduces to:

$$E_M = \pm 2.303RT/F \log (K_{i,j}^{Pot} a_j''/a_i') \quad (4)$$

From Eq. (4), a plot of E_M against $\log a_j''$ may be expected to be on a straight line with a Nernstian slope under a constant activity of a_i'.

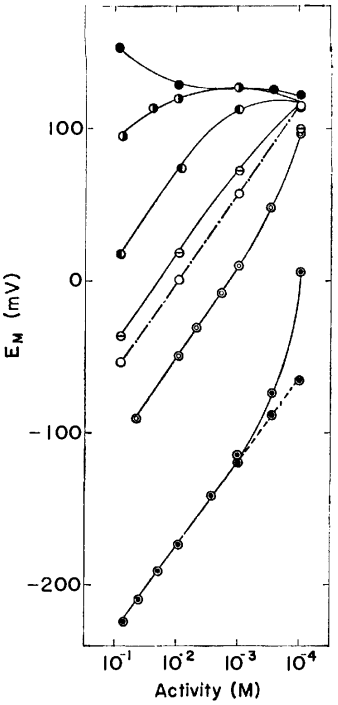

Fig. 1. Potential responses of the hydrogenmaleate ion-selective electrode for the solutions of foreign anions.
Membrane: 10^{-4} M nitrobenzene solution of crystal violet salt of hydrogenmaleate.
Temp. 20 °C.
○: hydrogenmaleate (— - —), ●: acetate, ◑: chloride, ◐: anthranilate, ⊖: trifluoroacetate, ◎: hydrogenphthalate, ⊙: perchlorate (Broken line shows the membrane potential of the cell (2)).

Figure 1 shows the observed potentials of the hydrogenmaleate ion-selective electrode for the sample solutions, each solution containing only a single anion species. The conversions of the concentrations of the ions to ionic activities were made by means of the Debye-Hückel equation, using Kielland's ion-size parameters,[15] except for the activities of hydrogenmaleate, hydrogenphthalate, and trifluoroacetate ions, which were calculated by using the values of the parameters assumed in previous papers.[16,17] The parameter for the anthranilate ion was assumed to be equal to that of the chlorobenzoate ion. For the solution of the objective hydrogenmaleate ion, a Nernstian response was obtained over a wide concentration range.[17] The electrode responses for the solutions of foreign ions, however, were not always Nernstian. Foreign ions (acetate, chloride, trifluoroacetate and anthranilate ions) giving higher potentials than hydrogenmaleate ion do not so seriously interfere with the activity measurement of the hydrogenmaleate ion, as may be understood from their low selectivities as estimated by means of Eq. (4). Potential-activity curves on these kinds of ions have lower slopes at low activity levels than does a Nernstian one, as is shown in Fig. 1. In the cases of acetate and chloride ions, the potentials were unstable in the initial stage of measurement and it took several hours to attain stationary values of potentials. The reproducibility was also relatively poor, especially at low activity levels. For trifluoroacetate and anthranilate ions, the electrode shows stable and reproducible potentials which obey Eq. (4) down to 10^{-3} M, although the potential drifts were observed initially and a period of more than 60 min was required to obtain constant values of the potentials at 10^{-4} M. Foreign ions (hydrogenphthalate and perchlorate ions) giving lower potentials than the hydrogenmaleate ion seriously interfere with the activity measurement of the hydrogenmaleate ion, even if trace amounts of these kinds of ions coexist in the sample solutions. In the activity levels higher than $10^{-2.5}$ M, the electrode potentials were stable and reproducible; they obeyed Eq. (4). On the other hand, remarkable potential drifts were observed initially, and it took several hours to attain constant potentials at activity levels lower than 10^{-3} M. The slopes of the activity-potential curves in such a stationary state were higher than a Nernstian slope.

Thus, the slopes of the potential-activity curves for foreign ions at low activity levels are different from a theoretical Nernstian value. The slope of the potential-activity curve for the foreign ion with a selectivity lower than that of the objective ion is lower than a Nernstian slope, while that for the foreign ion with a higher selectivity is higher. Response patterns similar to those of foreign ions were observed on the responses of the chloride, nitrate, hydrogenphthalate, and perchlorate ion-selective electrodes prepared in this laboratory. As may be seen in Fig. 2, the commercial nitrate ion-selective electrode of Orion 92-07 also showed a similar response pattern.

When the i-ion-selective electrode is immersed in a sample solution containing the j ion alone, the following ion-exchange reaction (5) occurs between the membrane and the sample solution, resulting in the forma-

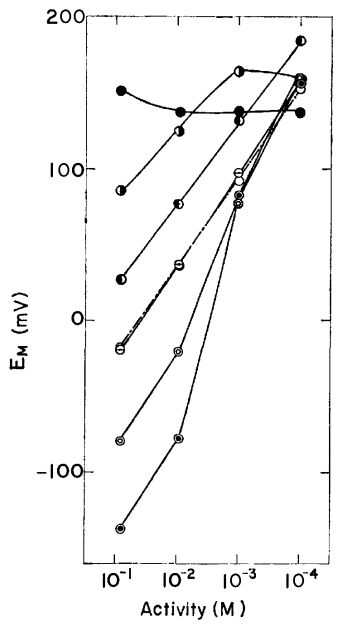

Fig. 2. Potential responses of the nitrate ion-selective electrode (Orion 92-07) for the solutions of foreign anions.
Temp. 20 °C.
○: nitrate (— - —), ●: acetate, ◑: chloride, ◐: bromide, ⊖: chlorate, ⊙: perchlorate, ◎: iodide.

tion of a diffusion layer containing the j ion as well as the i ion:

$$\text{i (Membrane)} + \text{j (Solution)} \rightleftarrows \text{j (Membrane)} + \text{i (Solution)} \quad (5)$$

Hence, it is more realistic to describe the electrode potential or membrane potential by means of Eq. (3), with the activities of the i and j ions on the aqueous side of the interface, $a_i''(0)$ and $a_j''(0)$. Since the ion-exchange process (5) proceeds stoichiometrically in most cases, it may reasonably be assumed that $a_j''(0)$ is approximately equal to $a_j''-a_i''(0)$. Accordingly, the electode response to a foreign anion, j, may be expressed as follows:

$$E_M = -2.303RT/F \log ((a_i''(0)+K_{i,j}^{pot}(a_j''-a_i''(0)))/a_i') \quad (6)$$

If the value of $K_{i,j}^{pot}$ is smaller than unity, the value of $(a_i''(0)+K_{i,j}^{pot}(a_j''-a_i''(0))$ is greater than the value of $K_{i,j}^{pot}\ a_j''$. Therefore, the electrode potential, E_M, is lower than that which would be expected from Eq. (4). If the activity of the j ion in the sample solution, a_j'', is very high, and if $K_{i,j}^{pot}$ is moderately small, the potential will be governed by the $K_{i,j}^{pot}\ a_j''$ quantity. Accordingly, the slope of the potential-activity curve is lower at low concentrations of the j ion and tends to approach a Nernstian slope at higher concentrations. In the cases of the acetate and chloride ions, however, $K_{i,j}^{pot}$ is much smaller than unity and the observed slope is quite different from the theoretical one. This means that the evaluation of $K_{i,j}^{pot}$ by means of Eq. (4) by using the activity of the foreign ion, j, in the bulk of the sample solution and the observed potential is practically difficult. On the other hand, $K_{i,j}^{pot}$ is nearly equal to unity in the cases of the anthranilate and trifluoroacetate ions. Hence, the observed potentials obey Eq. (4) at higher concentrations. Thus, the $K_{i,j}^{pot}$ can be determined by means of Eq. (4).

If a value of $K_{i,j}^{pot}$ is greater than unity, the value of $(a_i''(0)+K_{i,j}^{pot}(a_j''-a_i''(0))$ may be smaller than that of $K_{i,j}^{pot}a_j''$. Consequently, the electrode potential, E_M, becomes higher than that calculated from Eq. (4). The value of $(a_i''(0)+K_{i,j}^{pot}(a_j''-a_i''(0))$ is approximately equal to the value of $K_{i,j}^{pot}\ a_j''$ if the concentration of the j ion in the sample solution is sufficiently higher than that of the ion-exchanger or the objective counter ion in the membrane. At such high activity levels of the j ion, the electrode response, again, would obey Eq. (4); it is also possible to evaluate $K_{i,j}^{pot}$ from the observed potential and the a_j'' activity in the bulk of the sample solution. The responses of the hydrogenmaleate electrode to the perchlorate and hydrogenphthalate ions are examples of this kind of response.

Thus, the observed potential does not always correspond to a true activity of the j ion in the bulk of the sample solution, when the value of $K_{i,j}^{pot}$ differs too greatly from unity.

Additivity of the Electrode Potential or Membrane Potential. When the $K_{i,j}^{pot}$ is nearly equal to or greater than unity, and when the concentration of the foreign ion, j, in the sample solution is sufficiently higher than that of the ion-exchanger in the liquid membrane, the counter ion within the membrane in the neighborhood of the solution-membrane interface is exchanged almost completely by the foreign j ion. That is, Cell (1) is essentially converted into Cell (2). The electrode potential or membrane potential measured under such conditions can be regarded as substantially a kind of bi-ionic potential (B.I.P.) in the liquid ion-exchanger system; it obeys Eq. (4), as was mentioned in the previous section. As is illustrated in Fig. 1, this expectation can be experimentally confirmed by measuring the membrane potential of Cell (2), which consists of two component membranes responsive to hydrogenmaleate and perchlorate respectively. Shean *et al.* have found the additivity of the B.I.P.s arising across the liquid ion-exchanger membranes which consist of a given ion-exchanger in a given solvent of the membrane.[14] An analogous additivity of the potential has been observed on the electrode potential or membrane potential of Cell (1) as follows:

$$E_{M(1,n)} = E_{M(1,2)} + E_{M(2,3)} + \cdots + E_{M(i,i+1)} + \cdots + E_{M(n-1,n)} \quad (7)$$

where $E_{M(1,n)}$ and $E_{M(i,i+1)}$ are the membrane potentials of Cells (8) and (9) respectively.

a) Crystal violet was used as the ion-exchange site in the membrane (1.00×10^{-4} M). b) HMA^- denotes hydrogenmaleate ion. c) HPA^- denotes hydrogenphthalate ion. d) Methyltricaprylylammonium ion was used as the ion-exchange site in the membrane (1.00×10^{-3} M).

Here, 1, 2, —, n-1, and n are monovalent counter ions with the same sign of charge. In order for Eq. (7) to be valid, the following requirements (10) should be satisfied in addition to the conditions of the concentrations of the sample solution and liquid membrane solution mentioned at the beginning of this section:

$$\left.\begin{aligned} &a_i' = a_{i+1}' \quad (i\text{: } 1, 2, \cdots, n-2)\\ &a_i'' = a_{i+1}'' \quad (i\text{: } 2, 3, \cdots, n-1)\\ &K_{i,j}^{Pot} \gtrsim \text{unity} \quad (i\text{: } 1, 2, \cdots, n-1) \end{aligned}\right\} \qquad (10)$$

In Table 1, the membrane potentials of alkali metal ion-selective electrode membranes, which consist of 10^{-4} M nitrobenzene solutions of dipicrylaminates of alkali metals, are summarized. The membrane containing sodium dipicrylaminate gives a potential difference of 473 mV between the solutions of sodium chloride and tetrapropylammonium chloride $(Pr)_4NCl$. This is almost entirely consistent with the algebraic sum of $E_{M(Na,K)}$, $E_{M(K,Rb)}$, $E_{M(Rb,Cs)}$, and $E_{M(Cs,(Pr),N)}$, which is 472 mV. On the other hand, the membrane containing cesium dipicrylaminate yields a potential difference of −155 mV between the solutions of cesium chloride and sodium chloride. This is not equal to the sum of $E_{M(Cs,Rb)}$, $E_{M(Rb,K)}$, and $E_{M(K,Na)}$, which is −183 mV. Thus, the additivity of the potential does not hold when the $K_{i,j}^{pot}$ is considerably smaller than unity. The additivity relation was also observed on the potentials of the liquid membranes responsive to monovalent anions, as is illustrated in Table 2.

When the $K_{i,j}^{pot}$ is sufficiently less than unity or when the concentration of the foreign ion in the sample solution is not sufficiently higher than that of the ion-exchanger in the liquid membrane, Cell (1) is not converted into Cell (2), but into the two ionic cells on the foreign ion and the objective ion. Therefore, the additivity of the potential does not hold under such conditions.

Inter-ionic Selectivity of the Liquid Membrane. From the additivity of the membrane potential, one can obtain the following Eq. (11):

$$K_{i,n}^{Pot} = K_{1,2}^{Pot} K_{2,3}^{Pot} \cdots K_{i,i+1}^{Pot} \cdots K_{n-1,n}^{Pot} \qquad (11)$$

where $K_{i,i+1}^{pot}$ is the selectivity coefficient of the i-ion selective electrode for the $i+1$ ion over the i ion. Judging from the conditions on the additivity of the membrane potential, the selectivity for the 1, 2, —, n ions should increase in the sequence of the numbers. Equation (11) implies that the inter-ionic selectivity of a liquid membrane consisting of a given ion-exchange site and a given solvent of the membrane can be evaluated from the potential measurements of the l-ion selective electrode for the solutions of foreigh ions, 2, 3, —, n. The 1 ion as a reference on selectivity evaluation should have such a degree of extractability

that the ion is sufficiently confined to the membrane for us to obtain the stable potential. Therefore, chloride and sodium ions were selected as our references. In Table 3, the membrane potentials of the chloride ion-selective electrodes for solutions of various anions are listed. The selectivity coefficients in the table are values relative to the reference chloride ion. The selectivity values for monovalent cations are summarized in Table 4, along with the membrane potentials of the sodium ion-selective electrodes. With respect to anion selectivity, nitrobenzene and 1,2-dichloroethane give membranes with a higher inter-ionic selectivity than chloroform. The 1-decanol membrane has a low inter-ionic selectivity. For cations, the nitrobenzene mem-

brane exhibits a slightly higher inter-ionic selectivity than the nitromethane membrane. The selectivity sequence of anions is approximately consistent with the Hofmeister anion series on the nitrobenzene and 1,2-dichloroethane membranes. The chloroform and 1-decanol membranes show a somewhat different order of anion selectivity from the nitrobenzene and 1,2-dichloroethane membranes. Relatively high selectivities for halide ions are observed on the chloroform membrane. On the 1-decanol membrane, the selectivities for perchlorate and borofluoride ions are lowered, while organic anions show a relatively higher selectivity than do inorganic anions.

From the selectivity values in Tables 3 and 4, one can obtain the selectivity coefficient of a given ion-selective electrode for any ion by using Relation (11). The selectivity coefficients of the hydrogenmaleate ion-selective electrode with the nitrobenzene membrane, for example, are thus calculated: the value for perchlorate over hydrogenmaleate (HMA), $\log K_{HMA,ClO_4}^{pot}$, is $\log K_{Cl,ClO_4}^{pot}$ minus $\log K_{Cl,HMA}^{pot}$, which is 2.29, while that for bromide, $\log K_{HMA,Br}^{pot}$, is $\log K_{Cl,Br}^{pot}$ minus $\log K_{Cl,HMA}^{pot}$, which is −1.16, and so on. In Table 5, the calculated selectivity values are compared with the values determined by the usual mixed-solution methods.[5] The values are consistent with each other in order of magnitude.

Relationship between the Selectivity Coefficient and Ionic Parameters. Sandblom and his co-workers have proposed theoretical expressions of the potentials arising across the liquid ion-exchanger membranes.[18,19] According to their theory, the membrane potential in the electrochemical system (1) is given by Eq. (12), when the site and counter ions dissociate completely in the liquid membrane:

$$E_M = \pm 2.303RT/F \log (u_j k_j a_j''/u_i k_i a_i') \qquad (12)$$

a) Concentrations of ion-exchangers in membranes were 1.0×10^{-4}M. b) The concentration of the ion-exchanger was 5.0×10^{-4}M. c) Figures in parentheses are values of the 1,2-dichloroethane membranes containing crystal violet as an ion-exchange site.

where u_i and u_j are the mobilities of the i and j ions, respectively and where k_i and k_j are the partiton coefficients of the corresponding ions between water and the solvent of the membrane. From Eqs. (4) and (12), the selectivity coefficient for the membrane of the complete-dissociation type may be represented by ionic parameters as follows:

$$K_{i,j}^{pot} = u_j k_j / u_i k_i = \lambda_j^\circ k_j / \lambda_i^\circ k_i \qquad (13)$$

where λ_i° and λ_j° are the limiting single-ion conductivities of the i and j ions respectively. Equation (13) implies that the selectivity coefficient of the ion-selective electrode with the liquid membrane of the complete-dissociation type is not dependent on the ion-exchange site species. The counter ion and site ion dissociate almost completely in the nitrobenzene membrane at such low concentrations of the ion-exchanger as 10^{-4} M, as judged from the dissociation constants in the literature.[11,20,21] In Table 6, the selectivity values of the nitrobenzene membranes containing the tris (bathophenanthroline)iron(II) ion as the ion-exchange site are compared with those of the membranes containing the crystal violet site. A good agreement is observed between the values of the two membranes. In Table 7, the selectivity values obtained are also compared with the theoretical values computed from Eq. (13) by employing ionic parameters quoted from the literature.[22-24] The experimental values are in good agreement with the theoretical ones. Since limiting single-ion conductivities are not so different among the ions, the selectivity coefficients may be said to be predominantly governed by the ion-partition coefficients. As is shown in Figs. 3 and 4, a good mutuality between the selectivity values and the reported ion-partition coefficients was also observed on the 1,2-dichloroethane and nitromethane membranes.[20,25] Table 8 shows a comparison of the selectivity values between the 1,2-dichloroethane membranes containing the tris(bathophenanthroline)iron(II) ion and the crystal violet ion as the ion-exchange sites. In these membranes, the selectivity values are also scarcely dependent on the site species.

The authors would like to express their thanks to Mr. Nobuo Yoshida for his helpful discussions. They also greatly acknowledge the financial support of the Ministry of Education (General Research B, Grant No. 847042, 1973).

A Solvated Electron Formed from the Water by the Irradiation of the Recoil Particles of $^{10}B(n,\alpha)^{7}Li$ and $^{6}Li(n,\alpha)T$

Akira YOKOHATA and Satoru TSUDA

Department of Chemistry, Faculty of Engineering, Hiroshima University, Senda-machi, Hiroshima 730

(Received January 23, 1974)

Synopsis. The G values of a solvated electron produced by ionizing radiation from the (n,α) activation of boron and lithium were estimated to be 0.36 ($\pm$0.06) and 0.50 ($\pm$0.05) in neutral aqueous solutions ($ClCH_2COOH$–N_2O), and 0.24 ($\pm$0.05) and 0.46 ($\pm$0.05) in alkaline aqueous solutions ($K_3Fe(CN)_6$–NaOH), respectively.

The dependence of the radical yield in irradiated aqueous solutions on the LET (linear energy transfer) of the radiation has been actively investigated.[1-2] In water radiolysis, the free radical yields decrease and the molecular yields increase with an increase in the LET of the radiation. This effect is believed to be due to an increasing combination of radicals in the spurs and tracks as the density of radicals along the tracks increases.

However, only a few data have been reported[2] regarding the yield of solvated electrons in water irradiated by the radiations of high LET. In this paper, we will report some data obtained with high LET radiations from the $^{10}B(n,\alpha)^{7}Li$ and $^{6}Li(n,\alpha)T$ reactions. Neutral aqueous monochloroacetic acid–nitrous oxide and alkaline aqueous potassium ferricyanide solutions were selected as reaction systems suitable for this purpose.

Experimental

The experiments were carried out in the thermal neutron facility (E-2) of the nuclear reactor at Kyoto University.

The thermal neutron flux, as measured by an Al–Au wire, was in the range from 1.8×10^{10} to 8.6×10^{10} n cm^{-2} s^{-1}, depending upon the exact position of the sample. The flux of the fast neutrons was relatively small. The dose rate of the γ-ray background was measured with a Fricke dosimeter. Each experiment was repeated at least 6 times; the coefficient of variation was less than $\pm$10%.

To determine, in the first instance, whether the presence of boric acid, sodium borate, or lithium sulfate affected the reactions of the solvated electron in irradiated $ClCH_2COOH$–N_2O and alkaline $K_3Fe(CN)_6$ solutions, some experiments using ^{60}Co γ-rays were carried out; these experiments confirmed that they cannot compete significantly with the other solutes for solvated electrons in the range of concentrations using here.

The pH of the $ClCH_2COOH$–N_2O system was adjusted with NaOH. All the chemicals used were of a reagent grade. The N_2O was purified by several distillations on a vacuum line, prior to introduction into the irradiation vessel containing the degassed solution. The amount of N_2O in the solution was determined by the measurement of the pressure drop after the solution had stood for about 24 hr at room temperature.

The irradiation vessels were cleaned with boiling nitric acid and then triply rinsed with distilled water. Eight-ml portions of solutions containing ^{10}B or ^{6}Li were sealed in a silica tube.

The aquopentacyanide ions were spectrophotometrically determined by the method using NaN_3.[3] The presence of boric acid or sodium borate and lithium sulfate did not interfere with those measurements.

Results and Discussion

Neutral Aqueous Monochloroacetic Acid–Nitrous Oxide Solutions. The yield of solvated electrons can be estimated in neutral aqueous monochloroacetic acid–nitrous oxide solutions. The pertinent reactions to be considered are:

$$e^-_{aq} + ClCH_2COO^- \longrightarrow Cl^- + CH_2COO^- \quad (1)$$

$$e^-_{aq} + N_2O \longrightarrow N_2 + O^- \quad (2)$$

$$H + ClCH_2COO^- \longrightarrow H_2 + ClCHCOO^- \quad (3)$$

$$\searrow\ Cl^- + CH_2COO^- + H^+ \quad (4)$$

$$OH + ClCH_2COO^- \longrightarrow H_2O + ClCHCOO^- \quad (5)$$

$$\searrow\ Cl^- + R\ (R;\ \text{radical}) \quad (6)$$

Dainton and Peterson[4] have investigated the γ-radiolysis of aqueous N_2O solutions and shown that this solute has a relatively high reactivity to the solvated electrons, leading to the formation of nitrogen (Reaction 2). Hydrogen atoms, on the other hand, react very slowly with N_2O. This system, therefore, is a useful one for the determination of the yield of solvated electrons. In fact, Eq. (7) has been confirmed by the present authors in their γ-ray experiment with 1×10^{-3} M $ClCH_2COOH$–8×10^{-3} M (or higher concentrations) N_2O at pH=6.5.[5] In the system studied here, the value of $G(N_2)$ calculated from the dose of the γ-ray background in the nuclear reactor was 2.8, consistent with that obtained from the γ-ray irradiation.

$$G_{e^-_{aq}} = G(N_2) \quad (7)$$

Figures 1 and 2 show the relationship between the amounts of N_2 of [B] or [Li], where [B] and [Li] denote the concentrations of $Na_2B_4O_7$ and Li_2SO_4, respectively.

The G values of the solvated electrons were calculated from Eqs. (8) and (9):

$$^{B}G_{e^-_{aq}} = \frac{(N_2)}{[B]\sigma_B\phi t E_0(B)\gamma}\times 100 \quad (8)$$

$$^{Li}G_{e^-_{aq}} = \frac{(N_2)}{[Li]\sigma_{Li}\phi t E_0(Li)}\times 100 \quad (9)$$

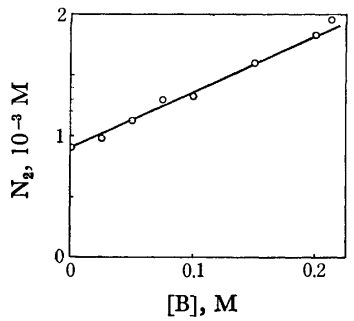

Fig. 1. Relationship between amount of nitrogen formed and concentration of boron.
Thermal neutron flux: 8.6×10^{10} n cm^{-2} s^{-1}
Irradiation time: 135 min
Initial concentration:
1.0×10^{-3} M $ClCH_2COOH-2.6\times10^{-2}$ M N_2O
pH: 6.0 B: $Na_2B_4O_7$

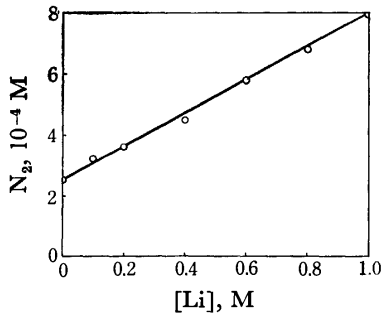

Fig. 2. Relationship between amount of nitrogen formed and concentration of lithium.
Thermal neutron flux: 1.8×10^{10} n cm^{-2} s^{-1}
Irradiation time: 300 min
Initial concentration:
1.0×10^{-3} M $ClCH_2COOH-2.4\times10^{-2}$ M N_2O
pH: 6.0 Li: Li_2SO_4

The boron absorption cross-section, σ_B, is taken as 755×10^{-24} cm^2.[6] The average energy absorbed by the solution from the heavy-particle recoils, E_0(B), is taken as 2.35×10^6 eV per nuclear event. The lithium absorption cross-section, σ_{Li}, is taken as 71×10^{-24} cm^2, and E_0(Li), as 4.78×10^6 eV.[7] Thus, from the slope of the curve, $^{B}G_{e_{aq}^-}$ and $^{Li}G_{e_{aq}^-}$ were estimated to be 0.36 ($\pm$0.06) and 0.50 ($\pm$0.05) respectively.

Alkaline Aqueous Solution of Potassium Ferricyanide. In order to secure further evidence of the yield of solvated electrons, the study was extended to another system, the $K_3Fe(CN)_6$-0.1 M NaOH solution. In this system, attention was directed toward the reaction of e_{aq}^- with $Fe(CN)_6^{3-}$.

It has been reported that aquopentacyanide is formed *via* the following competitive reaction:

$$e_{aq}^- + Fe(CN)_6^{3-} \longrightarrow Fe(CN)_6^{4-} \quad (10)$$

$$\searrow\ Fe(CN)_5OH_2^{3-} + CN^- \quad (11)$$

Then, in the range from 5×10^{-3} M to 1×10^{-2} M $Fe(CN)_6^{3-}$, Eq. (12) was confirmed:[8]

$$G_{e_{aq}^-} \simeq 2G(Fe(CN)_5OH_2^{3-}) \quad (12)$$

where the yield of aquopentacyanide was determined by using the NaN_3 method.[3]

Figures 3 and 4 show that the relation of the yield

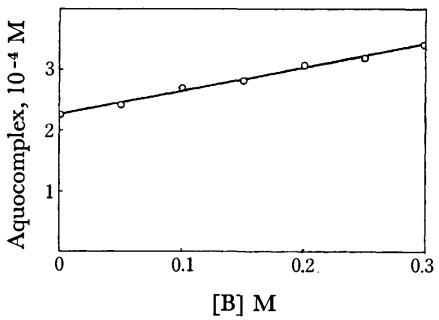

Fig. 3. Relationship between amount of aquocomplex formed and concentration of boron.
Thermal neutron flux: 5.1×10^{10} n cm^{-2} s^{-1}
Irradiation time: 52 min
Initial concentration:
5.0×10^{-3} M $Fe(CN)_6^{3-}$—0.1 M NaOH
B: $Na_2B_4O_7$

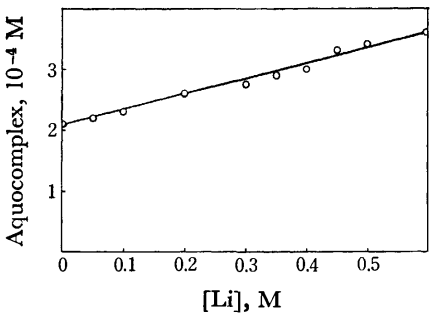

Fig. 4. Relationship between amount of aquocomplex formed and concentration of lithium
Thermal neutron flux: 5.6×10^{10} n cm^{-2} s^{-1}
Irradiation time: 64 min
Initial concentration:
5.0×10^{-3} M $Fe(CN)_6^{3-}$—0.1M NaOH
Li: Li_2SO_4

of the aquocomplex to [B] or [Li] is linear. Thus, the radiolytic yield of the aquocomplex formed by the recoil particles was obtained from the slopes.

By applying the yield of the product to Eq. (12), $^{B}G_{e_{aq}}$ and $^{Li}G_{e_{aq}}$ can be estimated to be about 0.24 ($\pm$0.05) and 0.46 ($\pm$0.05), respectively.

The difference in the yields between the systems of the neutral aqueous potassium ferricyanide solutions, though small, might be caused by the difference in pH.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 47 (11), 2871—2872 (1974)

MCNDO/2 Calculation of the Radiative Lifetimes of the Triplet States of the Nucleic Acid Bases

Mamoru KAMIYA and YUKIO AKAHORI
Shizuoka College of Pharmacy, Oshika, Shizuoka-shi 421

(Received March 22, 1974)

Synopsis. The radiative lifetimes of the lowest excited triplet states of the nucleic acid bases were calculated using a first-order perturbation treatment of the spin-orbit coupling. The calculated lifetimes were in the sequence of pyrimidines> purines; that of thymine was found to be largest. The relation between the radiative lifetimes and biological photodeactivation was discussed.

The electronic properties of the triplet states of the nucleic acid bases are of biological interest. A few experiments have suggested that the excited triplet states, in particular those of the pyrimidine bases, are responsible for the biological photodeactivation of the nucleic acids,[1-4] though the excited singlet states are also assumed to work as precursors in the energy-transfer process.[5] Taking notice of such characteristics of the triplet states, SCFCI and UHF calculations have been carried out for the energy states and electronic populations of the lowest triplets of the nucleic acid bases.[6]

Here, an attempt was made to estimate the radiative lifetimes of the lowest excited tri let states of the nucleic acid bases. That is, the singlet-triplet transition probability induced by spin-orbit coupling was calculated by a first-order perturbation method. The calculation was done according to the all-valence-electron SCF method of Jaffe *et al.*[7] The electric-dipole transition moment between the ground and lowest triplet states is given as:

$$\mathbf{M}(0, \Gamma_r) = \sum_k \{[\langle {}^1\Phi_k|H_{so}|{}^3\Phi_1^{\Gamma_r}\rangle^*/({}^3E_1 - {}^1E_k)]\mathbf{M}({}^1\Phi_0, {}^1\Phi_k)\} + \sum_m \{[\langle {}^3\Phi_m^{\Gamma_r}|H_{so}|{}^1\Phi_0\rangle/({}^1E_0 - {}^3E_m)]\mathbf{M}({}^3\Phi_1^{\Gamma_r}, {}^3\Phi_m^{\Gamma_r})\}$$

where Γ_r is the component of the triplet spin functions. It is chosen as:

$$\Gamma_-: [\alpha(p)\alpha(q) - \beta(p)\beta(q)]$$
$$\Gamma_z: [\alpha(p)\beta(q) + \alpha(q)\beta(p)]$$
$$\Gamma_+: i[\alpha(p)\alpha(q) + \beta(p)\beta(q)]$$

The unperturbed wave function was calculated by the modified CNDO/2 method; the parameters used (in eV units) were as follows:

$-1/2(I_s + A_s)$: 7.176(H), 14.051(C), 19.316(N), 25.390(O)
$-1/2(I_p + A_p)$: 5.572(C), 7.275(N), 9.111(O)
γ_{AA} : 12.845(H), 11.089(C), 12.016(N), 13.599(O)
$\beta_A{}^0$: −12(H), −17(C), −26(N), −45(O)

The two-center Coulomb integral was calculated by the Ohno approximation.[8] The geometries of the heterocyclic rings were assumed as regular hexagon and pentagon, both with the ring-distance of 1.39 Å. The other bond-lengths were chosen as $R_{>C-H}$=1.08 Å, $R_{>C-NH_2}$=1.34 Å, $R_{>N-H}$=1.03 Å, $R_{>C=O}$=1.20 Å, $R_{>C-CH_3}$=1.51 Å, and $R_{>C-H}$=1.12 Å. The atomic

parameters in the spin-orbit Hamiltonian (H_{SO}), which represent the effective electric field acting on the electron, were adopted from the atomic data;[9] 28 cm^{-1} for C, 70 cm^{-1} for N, and 152 cm^{-1} for O. The perturbation calculations were done by mixing the lowest 25 excited states.

The calculated results on the oscillator strength of the S–T transition and radiative lifetime of the lowest triplets are given in Table 1. The average value of the calculated lifetimes of the triplet components is largest in thymine. Admitting that the radiative lifetime does not necessarily play an important role in the photodimerization reaction, which proceeds under severe steric restrictions, this finding is of interest because thymine in irradiated nucleic acids undergoes an efficient dimerization. A low-temperature experiment at 77 K indicates that the lifetimes of the phosphorescence of adenine and guanine residues are 2.5 and 1.25 s respectively.[10] In this case, the agreement between the predicted and experimental data is considerably good. On the whole, this calculation shows that the radiative lifetimes of the triplet pyrimidine bases are rather longer than those of the triplet purine bases.

The numerical calculation was performed using a HITAC 5020–E and 8800/8700 Computers at the University of Tokyo. The authors wish to thank Dr. Fumihiko Hirota of Shizuoka University for his useful discussion and advice.

Charge-transfer and Proton-transfer in the Formation of Molecular Complexes. X.[1] Picric Acid Complexes with 2,5-Dichloroaniline

Yoshio MATSUNAGA, Gunzi SAITO,* and Naoto SAKAI

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received April 13, 1974)

Synopsis. Yellow 2,5-dichloroanilinium picrate was found to isomerize into a red complex of the charge-transfer type at 74 °C with a heat of transition of 4.2 kcal/mol. In addition, a charge-transfer complex with a 1: 3 mole ratio was isolated.

Previously we demonstrated that the picrates of all the anilines with pK_a values of less than 3 isomerize into charge-transfer complexes upon melting if not by an enantiotropic transition.[2] Moreover, the chance of finding complex isomers was recognized to be high in the salts derived from *o*-haloanilines.[1,3] The combinations reported to date include picric acid with *o*-bromo- and *o*-iodo-anilines found by Hertel,[4] and methylpicric acid with *o*-chloro- and *o*-bromo-anilines and trinitrobenzoic acid with *o*-chloroaniline, both found by us.[1,3] As 2,5-dichloroaniline has a pK_a value in the above-mentioned range (that is, 1.57),[5] and as its structure fits into the group of *o*-haloanilines, there is a possibility that its picrate exhibits the phenomenon of complex isomerism. However, it must be added that an isomeric amine, 2,4-dichloroaniline, has been known to form only a salt with picric acid.[4]

When equimolar amounts of the component compounds separately dissolved in hot methanol were mixed, yellow fine crystals were precipitated. The composition appeared to be 1: 1. Calcd for $C_6H_5NCl_2 \cdot C_6H_3N_3O_7$: C, 36.85; H, 2.06; N, 14.32; Cl, 18.13%. Found: C, 36.68; H, 1.99; N, 14.38; Cl, 17.40%. The product is a true phenolate, as is indicated by the presence of the vibrational pattern characteristic of the anilinium ion extending from 2400 to 3000 cm^{-1}. A color change to red was observed at 74 °C. The isomerization into a complex of the charge-transfer type was confirmed by the replacement of the above-mentioned NH_3^+ pattern by the NH_2 bands appearing at 3375 and 3475 cm^{-1}, and also by the change in the electronic spectrum (see Fig. 1). The maximum of the newly-appeared absorption is located close to that of the charge-transfer absorption in the corresponding *s*-trinitrobenzene complex. Nevertheless, the picric acid complex is more deeply colored than the *s*-trinitrobenzene complex, mainly because of the difference in breadth. The heat of transition was estimated to be about 4.2 kcal/mol by use of a differential scanning calorimeter.

When chloroform was employed as the solvent and the mixture was kept in a refrigerator for a few days, the initially-appearing yellow crystals were replaced by red ones. This complex is of a 1: 3 mole ratio and can be kept at room temperature without any noticeable change. Calcd for $C_6H_5NCl_2 \cdot 3C_6H_3N_3O_7$: C, 33.94; H, 1.66; N, 16.49; Cl, 8.35%. Found: C, 33.34; H, 1.50; N, 16.62; Cl, 7.79%. The NH_2 pattern in the vibrational spectrum demonstrates the absence of proton-transfer. As is shown in Fig. 1, the electronic absorption in the visible region is relatively weak if compared with that in the red 1: 1 complex, but the location is essentially the same as that in the latter. Therefore, this 1: 3 complex is undoubtedly

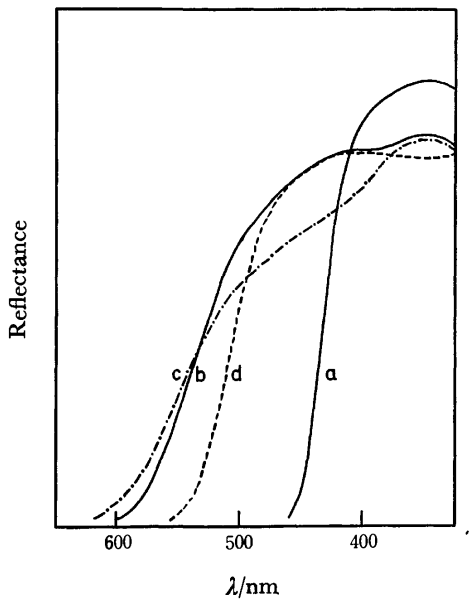

Fig. 1. Reflectance spectra of 2,5-dichloroaniline–picric acid; (a) the yellow 1: 1 salt, (b) the red 1: 1 complex, and (c) the red 1: 3 complex, and (d) the spectrum of the corresponding *s*-trinitrobenzene complex.

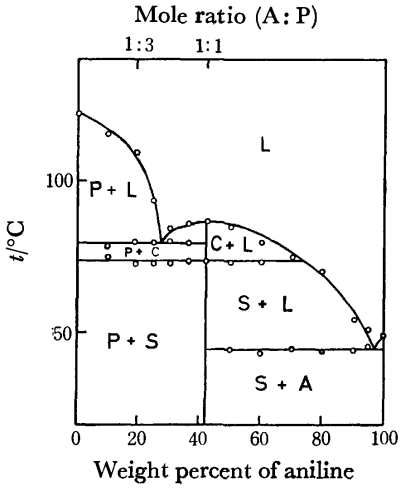

Fig. 2. The 2,5-dichloroaniline–picric acid phase diagram.

* Present address: Department of Chemistry, Emory University, Atlanta, Georgia 30322, U.S.A.

of the charge-transfer type. An endothermic peak of about 4.8 kcal/mol was recorded at 69 °C in the thermogram. Once heated above this temperature, the color turns yellow after storage at room temperature for a few days.

The phase diagram of the 2,5-dichloroaniline–picric acid system was prepared by the calorimetric method in an effort to find out whether or not there is salt with a 1:3 composition. The results presented in Fig. 2 clearly indicate that the 1:1 salt and its isomeric complex of the charge-transfer type are the only compounds formed between picric acid and 2,5-dichloroaniline by direct fusion. At the composition of the red 1:3 complex, the room-temperature phase was a mixture of the 1:1 salt and picric acid. The eutectic point at which the 1:1 complex (C in Fig. 2) and picric acid (P) coexist with liquid (L) was found at 80 °C and at about a 27 weight percentage of aniline, and that at which the 1:1 salt (S) and aniline (A) coexist with liquid, at 45 °C and at a small weight percentage of the acid.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 47 (11), 2875—2876 (1974)

A Mössbauer Study of the Valence States of ^{119}Sn after the EC Decay of ^{119}Sb in Antimony and Tellurium Iodides

Fumitoshi AMBE and Shizuko AMBE

The Institute of Physical and Chemical Research, Wako-shi, Saitama 351

(Received May 2, 1974)

Synopsis. The ^{119}Sn-Mössbauer emission spectra of $^{119}SbI_3$ and $^{119m}TeI_4$ sources showed the formation of Sn(II) and Sn(IV) species after the EC decay of ^{119}Sb in the matrices.

The measurement of the Mössbauer emission spectra enables one to estimate the chemical species produced by nuclear decay in solids.[1] In previous papers,[2-4] we reported a series of studies of ^{119}Sn after the EC decay of ^{119}Sb in metals, oxides, and chalcogenides of antimony and tellurium. This paper will describe an extension of these studies to iodides.

The 38.0 hr ^{119}Sb populates the 23.8 keV Mössbauer level of ^{119}Sn by 100% EC decay. The resonant γ-rays emitted from the level provide useful information on the electronic state of the ^{119}Sn atoms in the solid after the decay. We measured the Mössbauer emission spectra of ^{119}Sn arising in antimony iodide labeled with ^{119}Sb and also those of ^{119}Sn produced by the successive EC decays of 4.7 day ^{119m}Te *via* ^{119}Sb in tellurium iodide.[5]

The procedures for producing the source nuclides and for preparing the ^{119}Sb metal and $^{119m}TeO_2$ were reported elsewhere.[4,6,7] The $^{119}SbI_3$ sources were prepared by reacting the ^{119}Sb metal powder with iodine in refluxing toluene. The product was purified by repeated sublimation in a vacuum at 145 °C, yielding the iodide in the orange modification. The $^{119m}TeI_4$ samples were obtained by evaporating a solution of $^{119m}TeO_2$ in concd hydriodic acid over P_2O_5, SiO_2, and CaO under reduced pressure. The residue was thoroughly ground and then dried over fresh P_2O_5, SiO_2, and CaO in a vacuum until a constant weight ($\pm$0.1%) was attained. The source materials were identified by the Debye-Scherrer patterns, while their purity was checked by the titrimetrical determination of the component elements.

The ^{119}Sn-Mössbauer emission spectra of the iodides were measured against a $BaSnO_3$ absorber (0.9 mg ^{119}Sn/cm^2) by means of a conventional spectrometer with a transducer operated in the constant acceleration mode. Both the source and absorber were maintained at the temperature of liquid nitrogen in a cryostat. The 23.8 keV γ-rays were detected with a 2 mm NaI scintillator through an 80 μm Pd critical absorber for Sn KX-rays. In the case of the $^{119m}TeI_4$ samples, the change in the spectra with the time was followed until a constant value was obtained for the Sn(II)-to-Sn(IV) line-intensity ratio, so that the contribution of the ^{119}Sb arising from ^{119m}Te during the preparation of the samples was eliminated. The data were processed on the FACOM 230—60 and 75 computers of the Institute.

Typical spectra obtained are given in Fig. 1. The Mössbauer parameters of the emission lines, as determined by least-squares fitting, are summarized in Table

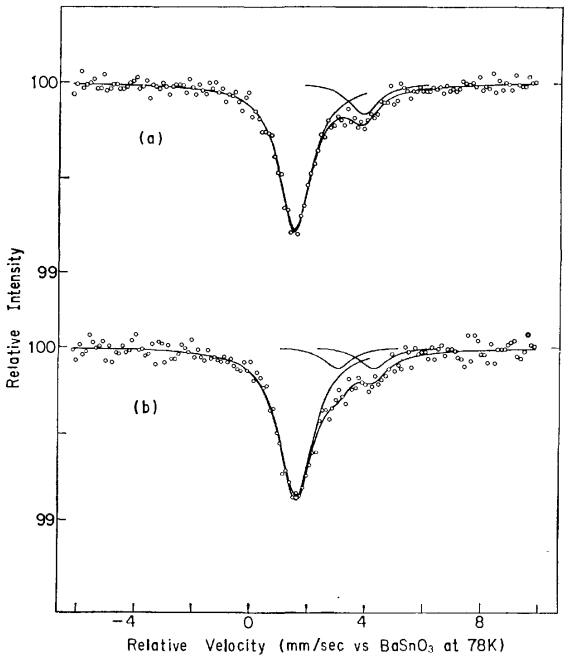

Fig. 1. ^{119}Sn-Mössbauer emission spectra of (a) $^{119}SbI_3$ and (b) $^{119m}TeI_4$ at 78 K against $BaSnO_3$ at 78 K. (In the abscissa a velocity of approach is taken negative.)

TABLE 1. MÖSSBAUER PARAMETERS OF THE EMISSION SPECTRA OF ^{119}Sn IN $^{119}SbI_3$ AND $^{119m}TeI_4$ AND OF THE ABSORPTION SPECTRA OF THE CORRESPONDING TIN IODIDES AT LIQUID NITROGEN TEMPERATURE

Source materials	Emission lines (this work)			Absorption lines (from the literature)

1, together with the corresponding values of the absorption lines of tin iodides reported in the literature.[8,9]

As can be seen in Fig. 1(a), the emission spectra of ^{119}Sn arising in $^{119}SbI_3$ consisted of two lines, which can be attributed to the Sn(IV) and Sn(II) states by comparing their isomer shifts with those of tin iodides (Table 1). Similarly, the $^{119m}TeI_4$ sources gave emission lines in the Sn(IV) and Sn(II) regions. The computer fitting of the spectra with two Lorentzians resulted in a broad Sn(II) line accompanying the dominant Sn(IV) line. The further decomposition of the Sn(II) line into a symmetric doublet gave a quadrupole splitting value of 1.4 mm/s, as is shown in Fig. 1(b) and Table 1, giving rise to an improvement in the χ^2 value by 1.6%.

Since the EC decay is accompanied by a change in the atomic number, the ^{119}Sn atoms arising in the source materials must inevitably be in defect states associated with the local disturbance of the crystal lattice. The recoil energy accompanying the decay of ^{119}Sb is estimated to be much smaller than the threshold energy required to displace an atom from its normal lattice site, while the recoil energy of the EC decay of ^{119m}Te to ^{119}Sb is of the same order of magnitude as the displacement energy.

In SbI_3, each Sb is at the center of a nearly perfect octahedron of iodine atoms.[10] Therefore, the ^{119}Sn-(IV) atoms arising in $^{119}SbI_3$ may be expected to be in an electronic configuration different from that of SnI_4, in which tin atoms are surrounded by a practically regular tetrahedron of iodine atoms.[10] However, no significant difference was found between the isomer shift of the Sn(IV) emission line of $^{119}SbI_3$ and that of the absorption line of SnI_4. Similarly, the isomer shift of the Sn(II) emission line is essentially identical with that of SnI_2. The crystal structure of TeI_4 seems not to have been determined yet. The powder X-ray diffraction pattern and the ^{125}Te-Mössbauer absorption spectrum of TeI_4[11] show that its structure is different from that of SnI_4, the site symmetry of the Te atom not being cubic. However, no significant difference was found between the isomer shift of the Sn(IV) emission line of $^{119m}TeI_4$ and that of SnI_4. The quadrupole splitting observed for the Sn(II) line of the $^{119m}TeI_4$ source is the only parameter found for the emission lines that is different from the corresponding value of the absorption line. SnI_2 has a monoclinic structure consisting of infinite $(SnI_3)_\infty^{n-}$ trigonal prisms, the coordination number of the tin atoms being seven.[12] The Mössbauer absorption spectrum of SnI_2, however, shows no resolvable quadrupole splitting.[9] The large quadrupole splitting of the Sn(II) emission line of $^{119m}TeI_4$ suggests a much more distorted configuration of iodine ligands around the defect ^{119}Sn atom in the TeI_4 matrix.

It is interesting to compare the present results on iodides with those on oxides and chalcogenides reported previously.[4] In the series of antimony chalcogenides, the fraction of Sn(II) increased with the decrease in the electronegativity of the chalcogen ligand. The distribution ratio of ^{119}Sn between the Sn(II) and Sn(IV) states in $^{119}SbI_3$ is closer to that of $^{119}Sb_2S_3$ than to that of $^{119}Sb_2Te_3$. This corresponds to the fact that the electronegativity of iodine is close to that of sulfur. The finding that the ^{119}Sn atoms were distributed between the Sn(II) and Sn(IV) states in $^{119m}TeI_4$ presents an interesting contrast with the result for $^{119m}TeO_2$, for which no Sn(II) species was observed. In $^{119m}TeO_2$, the similarity of the crystal structures of TeO_2 and SnO_2 is considered to exclude the stabilization of ^{119}Sn as Sn(II). The absence of such an effect in TeI_4 as well as the lower electronegativity of iodine may have allowed the stabilization of a part of ^{119}Sn as Sn(II).

We thank Prof. N. Saito for his interest and continual encouragement. We are grateful to the staff of IPCR cyclotron for irradiations and to Mr. Y. Iimura for powder X-ray pattern measurements.

Heat of Evaporation of Polyoxyethylene Dodecyl Ethers

Masao NAKAMURA, Kazuo EDA, and Kiiti KOSIYAMA

Department of Chemistry, Faculty of Science, Tokai University, Hiratsuka, Kanagawa 259-12

(Received May 15, 1974)

Synopsis. The heat of evaporation has been measured by the vapor pressure method for polyoxyethylene dodecyl ethers, $C_{12}H_{25}(OC_2H_4)_nOH$ (n=0, 1, 2, 3, and 4). It has been deduced that the polyoxyethylene chain is in a cyclic state in the vapor phase due to the intramolecular hydrogen bonding of the terminal OH group with an oxygen atom in the chain.

Measurements of heat of solution have been carried out for the study of the dissolved state of surfactant in solution.[1-4] In order to deduce the dissolved state energetically from the heat of solution, we should know the intermolecular cohesive energy of the solute in a pure liquid or solid state. The measurement of heat of evaporation is useful for obtaining the cohesive energy of a pure liquid, since cohesion in the vapor phase is negligible below the normal pressure. We have tried to obtain the relation between the heat of evaporation and degree of polymerization of the polyoxyethylene chain in polyoxyethylene dodecyl ethers, typical nonionic surfactants.

Polyoxyethylene dodecyl ethers, $C_{12}H_{25}(OC_2H_4)_nOH$ (n=0, 1, 2, 3, and 4), were obtained from Nippon Surfactant Industry Co., dodecanol corresponding to n=0. Each sample has a purity above 99% and no distribution of polymerization in the hydrophilic part as verified by gas chromatography.

The heat of evaporation was obtained by the vapor pressure method. The apparatus used was a glass semimicrodistiller (Shibata Glass Co.) with a large gas tank inserted in the vacuum line between the distiller and the pump to eliminate the fluctuation of pressure in the apparatus. The pressure was kept constant, the liquid in the bottle was heated gently with an electric heater, and the temperature was recorded in both vapor and liquid phases. The temperature of liquid phase had slowly risen, several hours after which that of vapor phase rose steeply and remained at a certain temperature. The constant temperature of vapor phase was regarded to be the boiling point corresponding to the pressure.

The results obtained in the pressure range 2—30 Torr are shown in Fig. 1 for polyoxyethylene dodecyl ethers of the degree of polymerization n up to 4 and dodecane. For dodecanol (n=0) and dodecane, the observed values (open circle) agree well with the values in the literature (filled circle).[5] If the molar volume of the liquid phase is neglected in comparison with that of the vapor, and if the vapor phase is assumed to behave as a perfect gas and the molar heat of evaporation $\Delta_e h$ is independent of temperature, then the equation of Clausius-Clapeyron can be written as[6]

$$\ln p = -\frac{\Delta_e h}{RT} + C \qquad (1)$$

where p is the vapor pressure at the absolute temperature T, R the gas constant, and C a constant independent of temperature. The fact that the plots of $\log p$ *vs.* $1/T$ (Fig. 1) lie in a straight line for every sample indicates that the molar heat of evaporation is independent of temperature in the range of measure-

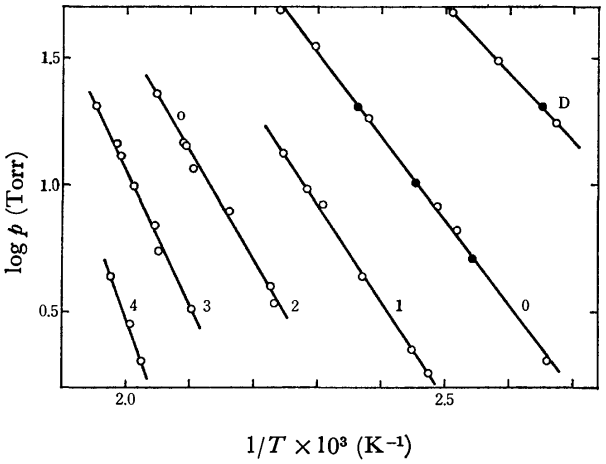

Fig. 1. The variation of vapor pressure with temperature for $C_{12}H_{25}(OC_2H_4)_nOH$ (n=0—4) and dodecane (D).

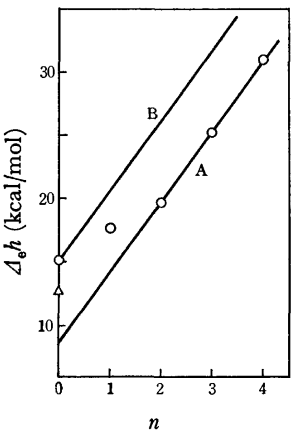

Fig. 2. The relationship between molar heat of evaporation ($\Delta_e h$) and degree of polymerization of $C_{12}H_{25}(OC_2H_4)_nOH$.
△: the value of dodecane

ments.

The molar heats of evaporation obtained from the inclinations of the straight lines are listed in Table 1. The relationship between the molar heat of evaporation $\Delta_e h$ and the degree of polymerization n of the polyoxyethylene chain is shown in Fig. 2. $\Delta_e h$ increases linearly with n in the range 2—4, as shown by the straight line A. Its inclination gives 5.6 kcal/mol of an oxyethylene unit, which corresponds roughly to the molar heat of evaporation of dimethyl ether, 5.1 kcal/mol.[7] This means that the situation does not differ among the molecules in the range, except in the number of oxyethylene units. The extrapolated value of line A to $n=0$, however, is less than the molar heat of evaporation of the dodecanol, which corresponds to $n=0$, by *ca.* 6.6 kcal/mol. This means that the terminal OH groups of polyoxyethylene chain is not in the same state as in the alcoholic OH group. The terminal OH group may be considered to be intramolecular hydrogen bonded with an oxygen atom in the polyoxyethylene chain in the vapor phase, because the exothermic 6.6 kcal/mol corresponds to the energy of a hydrogen bond.[8] It may be reasonable to consider that the polyoxyethylene chain in the liquid state is in a linearly extended state, because it is more probable for the terminal OH group to interact with the neighboring molecule, and the extrapolated value is less than the molar heat of evaporation of dodecane (triangle in Fig. 2).

The molar heat of evaporation of $n=1$ is higher than line A by *ca.* 3.5 kcal/mol, which can be interpreted by the loss of energy of the intramolecular hydrogen bond since the molecule can form a 5-membered ring only. The fact also confirms the concept that the polyoxyethylene chain is cyclic in the vapor phase owing to the intramolecular hydrogen bonding.

If a molecule were to be linearly extended with no intramolecular hydrogen bond as in the liquid phase, the value of $\Delta_e h$ would fall on a straight line B parallel to line A and pass through the value of dodecanol. Thus, the molar cohesive energies of these liquids are equal to the values corresponding to line B minus RT, which is the work of volume expansion at the evaporation of 1 mol of liquid.

The Dipole Moment of Benzaldehyde

Yoshiyuki KAWASHIMA* and Kunio KOZIMA**

Laboratory of Molecular Spectroscopy, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152

(Received May 17, 1974)

Synopsis. The dipole moment and its components along the principal axes were determined by measuring the Stark effects of the rotational transitions. The most probable direction of the moment was discussed.

The microwave spectra of benzaldehyde in the ground and in the excited torsional states have been studied in detail by Kakar *et al.*,[1] especially with regard to the barrier to internal rotation of the aldehyde group. However, its electric dipole moment has not yet been determined by using the spectrum. By the dielectric constant measurements, various values of the moment, ranging from 2.72[2] to 3.03 D,[3] have been obtained in various nonpolar solvents. Therefore, it seemed that it would be interesting to determine the value by means of the Stark effect of the spectrum and to ascertain the orientations of the components of the moment.

Experimental

The microwave spectrum and its Stark effect were measured by using a conventional 100-kHz square-wave Stark modulation spectrometer. The measurements were made at room temperature by using a 3-m absorption cell.

The sample of benzaldehyde, obtained from a commercial source, was purified by distillation *in vacuo* (bp 66—67 °C/12 mmHg).

Results and Discussion

Kakar *et al.*[1] have reported the frequencies of the high J R- and Q-branch transitions, from which they determined the rotational constants. Since lower J transitions are adequate for determining the value of the dipole moment, we searched for the rotational lines of the transitions of $J=4\leftarrow3$. As are shown in Table 1, the transition frequencies for the ground vibrational state could be observed at almost the same values as these calculated from the known rotational constants.[1] These assignments were ascertained by means of their Stark displacements. It is certain that the rotational constants are not affected by the centrifugal distortion.

TABLE 1. OBSERVED AND CALCULATED FREQUENCIES OF THE $J=4\leftarrow3$ TRANSITIONS IN THE GROUND VIBRATIONAL STATE[a)]

Transition	ν_{obsd}(MHz)	ν_{calcd}(MHz)
$4_{04}\leftarrow3_{03}$	10831.41	10831.42
$4_{13}\leftarrow3_{12}$	11741.06	11741.11
$4_{13}\leftarrow3_{13}$	10309.46	10309.54

a) Maximum uncertainty of the observed values is ±0.10 MHz.

TABLE 2. STARK EFFECT AND DIPOLE MOMENT OF BENZALDEHYDE[a)]

Transition		Shift MHz (kV/cm)$^{-2}$ Obsd	Calcd
$4_{04}\leftarrow3_{03}$	$M=1$	−4.37±0.11	−4.32
	$M=2$	9.96±0.10	10.28
$4_{13}\leftarrow3_{12}$	$M=1$	3.02±0.08	2.83
$4_{14}\leftarrow3_{13}$	$M=0$	−6.14±0.11	−6.17
	$M=2$	28.26±0.47	28.17

$\mu_a=2.96_6\pm0.02_7$ D; $\mu_b=1.23_9\pm0.02_8$ D

$\mu_{total}=3.21_4\pm0.03_7$ D

$\theta=\tan^{-1}(\mu_b/\mu_a)=22.67\pm0.72°$

a) Electric-field calibration was made with OCS for which $\mu=0.7152$ D.

By using the transitions shown above, the components of the dipole moment for the ground vibrational state were determined from the second-order Stark effect. The values thus obtained are shown in Table 2, together with the observed and calculated Stark coefficients. The symbols used have their usual meanings. The obtained value of the total dipole moment is higher than those obtained by dielectric constant measurements in various solutions. Of the various values obtained in solutions, the value of 3.03 D in cyclohexane and that of 3.02 D in benzene obtained by Jones *et al.*[3] may be considered to be most plausible.

The principal axes, the a- and b-axes, for this planar molecule, as determined from the molecular parameters reported,[1] are shown in Fig. 1. It is reasonable to consider that the negative end of the C=O bond moment points toward the oxygen atom and that the total dipole moment is mainly due to the C=O bond moment.

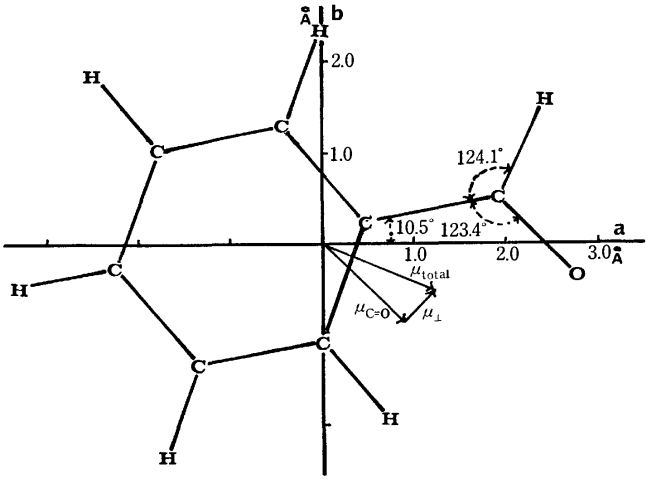

Fig. 1. The principal axes and the direction of the dipole moment of benzaldehyde.

* Present address: Faculty of Science and Engineering, Chuo University, Kasuga 1-chome, Bunkyo-ku, Tokyo 112.

** To whom correspondence should be addressed.

Therefore, of the four possible directions of the total dipole moment, the direction of μ_{total} indicated in Fig. 1 by an arrow is the most probable, for this direction makes the smallest angle of 23.4° with the direction of the C=O bond moment. The direction of μ_{total} makes an angle of 33.2° with the bond joining the carbon atom of the aldehyde group with the carbon atom of the benzene ring. This value is very close to that of 34.6° estimated for the same angle from the value of the dipole moment of the dichloro-derivative.[3] Therefore, the $\mu_{C=O}$ component of the dipole moment parallel to the C=O bond is calculated to be 2.95 D and the $\mu_{\perp}$ component of the dipole moment perpendicular to $\mu_{C=O}$ is 1.28 D. The value of $\mu_{\perp}$ may be due to the inductive effect of the moment of $\mu_{C=O}$ and to the partial migration of the π-electrons of the benzene ring to the C=O bond.

The ESR of Alkyl Phenyl Nitroxide Radicals Studied as Hindered Rotation

Toshio NISHIKAWA and Kazuo SOMENO

National Chemical Laboratory for Industry, Honmachi, Shibuya-ku, Tokyo 151

(Received May 24, 1974)

Synopsis. The ESR spectra were obtained in the series of *N*-methyl, *N*-ethyl, *N*-*n*-propyl, *N*-isopropyl, *N*-*n*-butyl, and *N*-*tert*-butyl phenyl nitroxide radicals. Two tendencies were found in the hyperfine splitting constants and were explained as hindered rotation.

In *N*-alkyl phenyl nitroxide (*N*-alkyl PNO-) radicals, the ESR spectra would be affected because of the hindered motion with respect to the substituted alkyl group. In these radicals, there may exist the two kinds of hindered rotation, about the σ bond between nitrogen and alkyl carbon and about the π bond between nitrogen and phenyl carbon. It is an interesting question whether the hindered-rotation model is applicable to these rather large molecules.

The hyperfine splitting constants were obtained in the series of *N*-methyl, *N*-ethyl, *N*-*n*-propyl, *N*-isopropyl, *N*-*n*-butyl, and *N*-*tert*-butyl PNO radicals. From these data, two tendencies were apparent for a change of the hyperfine splitting constants; we discussed them as hindered rotation and compared our results with Stone and Maki's calculations.[2]

Experimental

N-Alkyl PNO radicals were prepared by the oxidation of the corresponding *N*-alkyl-substituted aniline or *N*,*N*-di-alkyl-substituted aniline by perbenzoic acid. For obtaining *N*-alkyl-substituted PNO, care should be taken with regard to the quantity of oxidizing agent, since an excess of perbenzoic acid produces unsubstituted PNO, which is more stable. The ESR measurements were done in an about 10^{-3} mol/l toluene solution.

Results and Discussion

The observed hyperfine splitting constants are shown in Table 1. Two tendencies can be seen from Table 1:

(A) The hyperfine splitting constants of nitrogen (a_N), the *o*- and *p*-protons ($a_{H(o,p)}$) and the *m*-proton ($a_{H(m)}$) are almost all equal except that of *N*-*tert*-butyl PNO, in which a_N is larger and $a_{H(o,p)}$ is smaller.

(B) The hyperfine splitting constants of alkylprotons ($a_{H(CH_3)}$, $a_{H(CH_2)}$, and $a_{H(CH)}$) may be classified into three groups, according to the number of protons.

Table 1. Observed hyperfine splitting constants for *N*-alkyl PNO (in G)

Alkyl	Methyl	Ethyl	*n*-Propyl	*i*-Propyl	*n*-Butyl	*t*-Butyl
a_N	10.65	10.42	10.31	10.65	10.36	12.44
$a_{H(CH_3)}$	9.69					
$a_{H(CH_2)}$		7.84	7.34		7.28	
$a_{H(CH)}$				3.47		
$a_{H(o,p)}$	2.75	2.80	2.58	2.69	2.74	1.90
$a_{H(m)}$	1.01	1.01	0.90	0.90	1.00	0.90

Table 2. Calculated spin densities for PNO and *N*-alkyl PNO

Position	PNO	*N*-Alkyl PNO
N	0.4425	0.4770
O	0.3272	0.3074
1	−0.0353	−0.0474
2	0.1298	0.1313
3	−0.0592	−0.0603
4	0.1246	0.1210

In MO Parameters, such as

$\alpha_N=\alpha_C+h_N\beta_{CC}$

$\beta_{NO}=k_{NO}\beta_{CC}$

and so on, the following values are used,

$h_N=1.5$ for PNO

$h_N=1.4$ for *N*-alkyl PNO

$h_O=1.3$, $k_{NO}=0.7$

$h_1=1.0$, $k_{N1}=1.0$

The data might be considered to reflect the unpaired spin distribution, arising from two types of hindered rotation.

The tendency (A) seems to suggest that the spin densities on the aromatic-ring carbons are constant independent of the kind of substituted alkyl group, except in the case of *N*-*tert*-butyl PNO.

For the purpose of further discussion, McLachlan's spin-density calculation was carried out with substituted and unsubstituted PNO radicals, as is shown in Table 2.

According to our previous calculations on unsubstituted PNO,[1] an alkyl substitution was treated as the inductive effect on the nitrogen atom as follows:

$$\alpha_{N'} = \alpha_N + h\beta_{CC} \quad (1)$$

while the other MO parameters were taken as having the same values.

On the assumptions that $h=-0.1$, which may be considered acceptable in these cases, and that the same relationship held:

$$\left.\begin{aligned} &a_N = Q_1\rho_N + Q_2\rho_O \\ &a_{H(o)} = Q\rho_2, \quad a_{H(p)} = Q\rho_4 \\ &\text{where } Q_1 = 30.5, \quad Q_2 = -13.6 \\ &\qquad Q = -22.5 \end{aligned}\right\} \quad (2)$$

the splitting constants, a_N, $a_{H(o)}$, and $a_{H(p)}$, were calculated to be 10.37, 2.95, and 2.72 G, respectively.

Thus, the planar structure for *N*-alkyl substitution, except in the case of the *N*-*tert*-butyl group, may be plausible, since the observed splitting constants can be explained by using the same parameters as in *N*-unsubstituted PNO. When the resonance integral between nitrogen and alkyl carbon is decreased, corre-

sponding to the twisting about the bond, the spin densities, ρ_N and ρ_O, are increased, and ρ_2, ρ_4, and ρ_6 are decreased; then the splitting constant, a_N becomes increased and $a_{H(\omega)}$ and $a_{H(o)}$ are decreased. This seems to imply non-planarity for *N-tert*-butyl PNO.

The (B) tendency was interpreted according to Stone and Maki's treatment[2] on the basis that the hindered rotation about the single bond may be assumed in these cases.

When the alkyl proton internally rotates about the equilibrium angle, θ_0, under the potential function:

$$V = \frac{1}{2}V_0(1-\cos 2\alpha) \tag{3}$$

the hyperfine splitting constants for the alkyl proton can be given as the function of the average value of the overlapping angle and the π-spin density of the adjacent nitrogen atom:

$$a_H = B\langle\cos^2\theta\rangle\rho_N \tag{4}$$

where:

$$\langle\cos^2\theta\rangle = \frac{\sum_i g_i\langle\cos^2\theta\rangle_i \exp(-E_i/kT)}{\sum_i g_i \exp(-E_i/kT)}$$

$$\langle\cos^2\theta\rangle_i = \langle\psi_i(\alpha)|\cos^2(\theta_0+\alpha)|\psi_i(\alpha)\rangle$$

The energy value, E_i, and the corresponding wave function, ψ_i, are calculated in the numerical solution of the Mathieu function for the given potential barrier and the moment of inertia.[3]

The above approximation may be considered to be possible, since the spin density on the nitrogen atom, ρ_N, may be regarded as constant independent of the kind of alkyl group, except in the case of *N-tert*-butyl PNO.

For *N*-methyl PNO, it may be considered that the methyl group freely rotates at room temperature. When $\langle\cos^2\theta\rangle$ is one half for free rotation and when $a_{H(CH_3)}$ is replaced by 9.69 G from Table 1, $B\rho_N$ is given as 19.38. When ρ_N is taken as 0.477 from Table 2, B is obtained as 40.8 G, which is close to the value of 41 ± 6 G in Stone and Maki's calculation. This may show that their method is well applicable to *N*-alkyl PNO radicals.

For *N*-ethyl, *N-n*-propyl, and *N-n*-butyl PNO, which have CH_2 protons, it is evident that the rotation may be restricted, since the observed splitting constants become smaller than that for *N*-methyl PNO. In the case of *N*-ethyl PNO, the splitting constant, $a_{H(CH_2)}$, was calculated as 7.82 G when the potential barrier V_0=0.78 kcal/mol, in contrast with the observed value of 7.84 G. Similarly, for *N-n*-propyl PNO, 7.40 G was obtained when V_0=1.40 kcal/mol.

For *N*-isopropyl PNO, which has a CH proton, 3.31 G was obtained as $a_{H(CH)}$ when V_0=2.30 kcal/mol.

Stone and Maki reported in their paper that the potential barriers are 0.34 and 1.11 kcal/mol for CH_2 and CH protons of nitroalkane radicals respectively. The fact that the ratios of the potential barrier with CH to CH_2 are similar between the present data and theirs (3 and 3.3) suggests a resemblance of the hindered rotational models. The larger values in the present case may result from the increase in steric hindrance and the stabilization of π-conjugation due to the aromatic ring.

For a more detailed discussion, it will be necessary to consider the validity of the 2-fold symmetry or to evaluate the non-bonded interaction; those may be difficult problems.

Field Ionization of Highly-excited Helium and Hydrogen Atoms Produced by Electron Impact

Takemasa SHIBATA, Tsutomu FUKUYAMA, and Kozo KUCHITSU

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received June 26, 1974)

Synopsis. The ionization of long-lived highly-excited helium atoms produced by electron impact was observed using an electrostatic field up to 8.3 kV/cm; the decrease of the He^+ intensity produced by collisions of He** with H_2O was measured as a function of the field strength using a mass filter. By use of the theory of Bailey *et al.*, the principal quantum numbers of the highly excited He were estimated to range from 16 to 40. A similar but slower decrease of H^+ due to H** atoms produced by electron impact on H_2O was also observed.

In previous papers[1,2] by the authors long-lived excited states of helium, He* (2^1S and 2^3S) and He** (in the highly-excited states) were produced by electron impact, and the ions formed by collisions with H_2O were detected by a mass filter. The observed ions, H^+, HeH^+, OH^+, and H_2O^+, which exhibited similar dependences on the target pressure and the electron accelerating voltage (with appearance potentials of about 20 eV), were assigned to be those produced by impact of He* on H_2O. On the other hand, another observed species, He^+, varied differently with the target pressure and the accelerating voltage (with an appearance potential of about 25 eV). It was then concluded that the He^+ ions were produced by collisions of He** with H_2O. In parallel with this observation, H^+ ions were observed when H_2O vapor was used in place of He, and their origin was interpreted to be due to highly-excited hydrogen atoms, H**, produced by electron impact dissociation of H_2O.

Various experiments[3-8] and theories[9,10] have shown that highly-excited atoms are ionized by a moderate electric field. For example, field ionization of highly-excited hydrogen atoms were observed by Riviere and Sweetman.[4] They derived an empirical relation for the smallest principal quantum number n of the states which can be ionized by a field of given strength, E_n. In their work, highly-excited hydrogen atoms with n=9—23 and with kinetic energies of 50 keV were produced by charge transfer collisions of protons with gas molecules. According to the calculations of Bailey *et al.*[10] on the ionization probability for hydrogen with n=1—25, E_n is a very slowly-varying function of the time spent by the atom in the field.[5]

The purpose of the present study is two-fold: (1) to confirm by means of field ionization that highly-excited states are in fact produced by electron impact and are involved in the above-mentioned processes, and (2) to estimate, even roughly, the range of their principal quantum numbers using the relationship between the field strength and the fraction of excited states ionized by the field.[8]

Experimental

The apparatus used in the present study was described in the previous paper.[1] A parallel-plate condenser (9 mm × 25 mm with a 3 mm spacing) was placed between the excitation region and collision chamber, as shown in Fig. 1. One of the plates was grounded, and the potential of the other plate was varied from 0 to −2.5 kV. The field strength was calculated from the potential applied to the electrodes divided by the spacing and was estimated to have an uncertainty of about 10%.

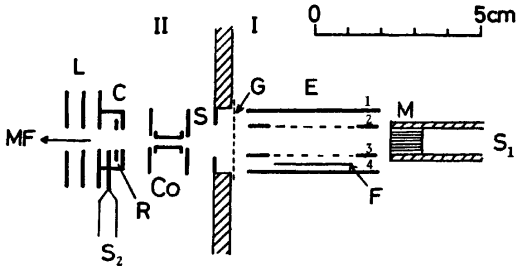

Fig. 1. Apparatus composed of section I for producing long-lived excited atoms by electron impact and section II, in which a parallel-plate condenser Co, a collision chamber C, and a mass filter MF are installed.

The helium gas was introduced into the excitation region through a multichannel orifice M and was subjected to electron impact. The He pressure at source S_1 was about 0.4 Torr. The accelerating voltage of the exciting electrons was about 100 V, and the trap current measured at electrode 1 was about 400 μA. The excited neutral species were separated from accompanying ions by electrostatic potentials and were allowed to collide with the H_2O target in the collision chamber C. The pressure of the target H_2O measured at source S_2 was about 0.3 Torr. The sample pressures were measured using oil manometers. The background pressure outside the collision chamber was about 2×10^{-6} Torr. Ions produced in the collision chamber were measured by a quadrupole mass filter.

Results and Discussion

In Fig. 2, the mass spectra observed with zero electric field (A) and with 0.75 kV applied to the condenser (B) are shown. The variations of the intensities of He^+ and H_2O^+ ions with electric field strength are shown in Fig. 3. The He^+ intensity was found to decrease monotonically with increasing field strength. This behavior can be interpreted as follows: A fraction of the highly-excited states He** are ionized by the field and do not enter the collision chamber. On the other hand, the H_2O^+ intensity did not depend on the electric field; this is because the He* metastable

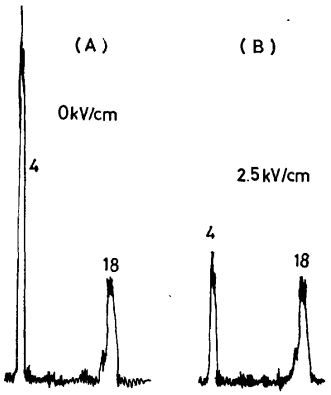

Fig. 2. Mass spectra of the ions produced by collisions of long-lived excited species of He with H_2O.

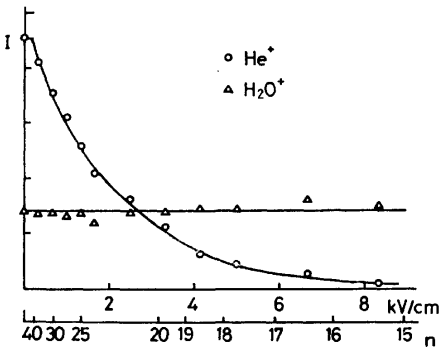

Fig. 3. Ion intensities (in arbitrary units) plotted as a function of electric field strength. The He^+ and H_2O^+ ions are produced by collisions of He** and He* respectively, with H_2O. The principal quantum numbers n which can be ionized by a given field strength are estimated and indicated on the abscissa.

states are not quenched in the range of field strengths applied here.[11] The latter observation also shows that the voltage applied to the condenser plates did not significantly disturb the field in the vicinity of the collision chamber so as to affect the efficiency of the detector.

The principal quantum numbers n which can be ionized by a given field strength E_n were estimated using the theoretical relationship between the lifetime and the electric field strength given by Bailey *et al.*[10] The estimates are indicated along the abscissa of Fig. 3. The correspondence between n and E_n is not unique, however, since the various different states with the same n have different threshold field strengths for ionization. The present estimate shown in Fig. 3 corresponds to the component of the lowest energy given by Bailey *et al.*[12] This choice is given support by the results of Il'in *et al.*;[5] the $n-E_n$ relation they observed in the range $17 \geq n \geq 14$ coincides with that for the lowest components calculated by Bailey *et al.*[10] Figure 3 provides an approximate range of the n values of He** present in the region between the condenser plates, $40 \gtrsim n \gtrsim 16$. Excited states with smaller n probably have lifetimes shorter than the time of flight (about 50 μs) from the excitation region to the electric field, while those with larger n are probably ionized in the excitation region or in its vicinity by a weak electric field.

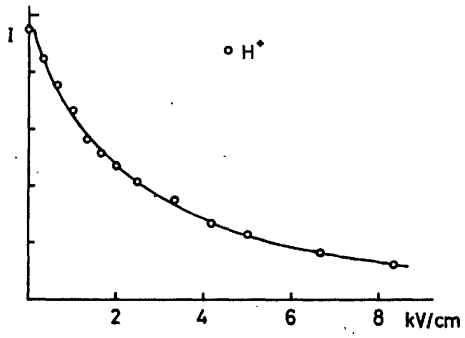

Fig. 4. Ion intensities (in arbitrary units) plotted as a function of electric field strength. The H^+ ion is produced by collision of H** with H_2O.

The corresponding field ionization of the H** species produced from H_2O by electron impact was also observed. The H^+ intensity is plotted as a function of the field strength in Fig. 4. In contrast to the He** case, about 20% of the H^+ intensity observed at zero field was detected even at 8.3 kV/cm. One of the possible explanations for this observation is the following: The highly-excited hydrogen atoms gain kinetic energies as a result of the dissociation of H_2O that are higher than that of the He** atoms (thermal), and hence, the time of flight of H** from the excitation region to the collision chamber is shorter than that of the He**. Therefore, larger fractions of the highly-excited states of hydrogen with shorter lifetimes, *i.e.*, smaller n values, than those of helium can reach the electric field and pass through it without being ionized.

The authors wish to thank Drs. W. Shearer-Izumi and M. Matsuzawa for their critical reading of the manuscript.

The Properties of the Liquid Nitron Nitrate Membrane Electrode

Akira TATEDA and Hiroko MURAKAMI

College of General Education, Kyushu University, Ropponmatsu, Fukuoka 810

(Received February 18, 1974)

Synopsis. The preparation and properties of the nitron nitrate nitrobenzene liquid membrane electrode, which is responsive to nitrate ions, are described. Special attention is given to the selectivity characteristics. High selectivities for NO_3^- over NO_2^-, $C_2H_3O_2^-$, Cl^-, CrO_4^{2-}, and SO_4^{2-} were observed.

Nitron(1,4-diphenyl-3,5-endanilo-4,5-dihydro-1,2,4-triazole) is a gravimetric analytical reagent specific for nitrate.[1] An electrode using nitron as an ion exchange site in a liquid membrane was prepared, but it showed poor selectivity characteristics.[2] This experiment was undertaken in order to investigate further the properties of the nitron nitrate membrane electrodes responsive to nitrate ions, using nitron nitrate dissolved in nitrobenzene.

Experimental

Reagents. Nitron nitrate was prepared by the usual method.[3] Several recrystallizations from hot dilute surfuric acid were performed until a silky white nitron nitrate precipitate was obtained. The other reagents were of an analytical reagent grade and were used without further purification.

Construction of Nitron Nitrate Membrane Electrodes. Nitron liquid membrane electrodes were constructed by using an Orion calcium electrode barrel (92–20) in which a nitron nitrobenzene solution as a liquid ion exchanger and a reference phase were placed, using an Orion membrane (92–20–04) as a separator. The nitron nitrobenzene solution was prepared by shaking a suspension of excess nitron nitrate in a 10^{-2} M $NaNO_3$ solution with the same volume of nitrobenzene. The nitrobenzene phase was separated and filtered to remove any turbidity from the insoluble nitron nitrate. To determine the concentration of nitron in nitrobenzene, a 50 ml portion of the nitrobenzene solution was evaporated to dryness in a platinum crucible at 180 °C; the weight of the residue was 0.456 g/l. The inner-reference phase comprised an Ag–AgCl electrode immersed in an aqueous solution containing 5×10^{-3} M $NaNO_3$ and 5×10^{-3} M NaCl saturated with AgCl.

The cell assembly for the measurement of the potential was:

$$-\text{SCE}|\text{Test soln.}|\text{Membrane}|\text{Ref. soln.}|\text{Ag–AgCl}+$$

The potential measurements were made relative to a Corning 476109 calomel reference electrode with a ceramic junction using an Orion Model 801 digital pH meter at room temperature (16—18 °C). The individual ion activities were calculated from the extended Debye-Hückel equation.

Results and Discussion

Figure 1 shows typical response curves for the nitron liquid membrane electrode in the $NaNO_3$, $Mg(NO_3)_2$, and $Ce(NO_3)_3$ solutions, respectively. It is clear that the nature and type of charge of the cation present do not substantially influence the potentiometric response of the membrane electrodes to nitrate ions with respect to either the linear response or the slope of the calibration curves. Linear responses to the nitrate ion concentrations are obtained over the range from 10^0 to 10^{-3} M; the slope of the linear plot against $-\log a_{NO_3^-}$ is 53—54 mV per decade for the membrane electrode.

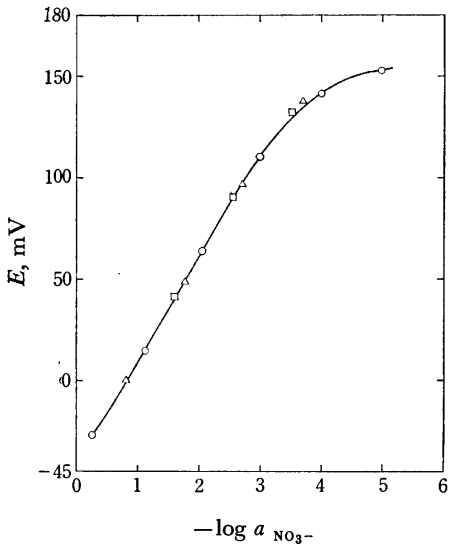

Fig. 1. Response curves for nitron membrane electrode in pure nitrate solutions.
○: $NaNO_3$, △: $Mg(NO_3)_2$, □: $Ce(NO_3)_3$.

Equilibrium potantials (±0.5 mV) are attained within 1—3 min for the membrane electrode.

Figure 2 shows the electrode response to nitrate ions in solutions of various pH values. The pH values of the solutions were adjusted from 2 to 12 by the addition of small amounts of a HCl or NaOH solution. The results show that the electrodes are insensitive to the pH change from 2 to 9 and that, at low concentrations, the pH ranges are somewhat reduced. In alkaline solutions, a sharp potential change in the negative direction is observed because the electrode responds

Table 1. Selectivity constants, K_j of nitron liquid membrane electrode

Anion	K_j	
	Method I[a)]	Method III[a)]
ClO_4^-	1.6×10^{2}	1.9×10^{2}
I^-	14	13
ClO_3^-	1.7	2.4
Br^-	0.13	6.8×10^{-2}
NO_2^-	6.4×10^{-2}	3.3×10^{-2}
$C_2H_3O_2^-$	4.8×10^{-2}	6.0×10^{-3}
Cl^-	6.0×10^{-3}	3.3×10^{-3}
CrO_4^{2-}	2.2×10^{-2}	—
SO_4^{2-}	1.4×10^{-3}	—

a) The same method number in Ref. 4.

preferentially to hydroxide ions.

The selectivity constants, K_j were calculated from the electrode potentials measured in 10^{-1} M solutions of pure $NaNO_3$ and a pure interferant (Method I) and from the graphical method (Method III) in the literature[4]; the results are shown in Table 1.

The performance of the nitron nitrobenzene membrane electrode was compared with essentially the same type of electrode in which nitron had been dissolved in benzylalcohol.[2] Both electrodes show a linear response from 10^0 to 10^{-3} M $NaNO_3$ solutions, but the slope of the linear plot of the nitron nitrobenzene membrane (53—54 mV) is larger than that of the nitron benzylalcohol membrane (40 mV). For the anions tested, the nitron nitrobenzene membrane shows considerably less interference than the nitron benzylalcohol membrane ($K_{Cl^-}=0.294$, $K_{C_2H_3O_2^-}=0.095$, $K_{SO_4^{2-}}=0.102$). There is also a significant difference in the numerical values of the selectivity constants for Cl^-. Therefore, the response curve for the present membrane electrode was also constructed in NO_3^- solutions containing 10^{-2} M NaCl; it is shown in Fig. 3. The results support the idea that the selectivity constant for Cl^- is of the order of 10^{-3}. The selectivity constants depend on the concentrations of both the sample solution and the ion exchanger in the membrane, and deteriorate with an increase in the concentration of the ion exchanger in the membrane.[5] In the case of a hydroxylic solvent like alcohol, nearly equal selectivity

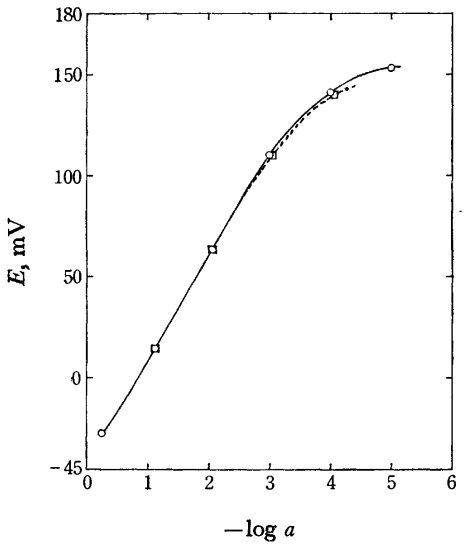

Fig. 3. Response of nitron membrane electrode to NO_3^- and to NO_3^- in 10^{-2} M NaCl.
○: NO_3^-, □: NO_3^- in 10^{-2} M NaCl.

constants are observed because of the solvation of the anions in the organic phase to a degree nearly equal to that of water.[6] From these considerations, the difference of the selectivity constants between the membranes of nitron nitrate in nitrobenzene and in benzylalcohol may be ascribed to the difference in the properties of the solvents, *e.g.* the solubilities of nitron nitrate in the organic phases (0.456 g/l nitrobenzene, 11.5 g/l benzylalcohol[2]).

Binuclear Copper(II) Propionate Complexes with *N*-Arylsalicylideneamines

Tadashi Tokii, Shuji Emori, and Yoneichiro Muto

Department of Chemistry, Faculty of Science and Engineering, Saga University, Saga 840

(Received March 29, 1974)

Synopsis. Two copper(II) propionate complexes with *N*-arylsalicylideneamines have been prepared. The magnetic and spectral properties of these complexes indicate that they have a carboxylate-bridged binuclear structure.

As a part of a program of magnetochemical studies of polynuclear copper(II) complexes, we have been studying a variety of copper(II) alkanoate complexes with salicylideneamines. In this paper we will report the preparative, magnetic, and spectral properties of newly-prepared copper(II) propionate complexes with the compositions of Cu(Sal·N·ph)$C_2H_5CO_2$ and Cu(Sal·N·*p*-tol)$C_2H_5CO_2$, where Sal·N=·O·C_6H_4·CH=N, ph=phenyl, and *p*-tol=*p*-tolyl. For comparison with the corresponding chloride complexes, cryomagnetic and IR spectral measurements have also been made of the Cu(Sal·N·*p*-tol)Cl complex, the preparation and some characterization of which were previously reported.[1]

Results and Discussion

The Cu(Sal·N·*p*-tol)$C_2H_5CO_2$ complex was readily prepared by the reaction of the parent complex, Cu(Sal·N·*p*-tol)$_2$, with copper(II) propionate in hot ethanol. On the other hand, the preparation of Cu(Sal·N·ph)$C_2H_5CO_2$ was found to be much more difficult. We also found that, in the reaction of copper(II) propionate with the salicylideneamine complex, Cu(Sal·N·ph–X)$_2$, where ph–X represents the monosubstituted phenyl group with the X substituent, the preparation of no propionate complexes was accomplished under reaction conditions similar to those above when X=*o*-Cl, *m*-Cl, *p*-Cl, *p*-NO_2, *o*-CH_3, and *m*-CH_3 in Cu(Sal·N·ph–X)$_2$. This fact seems to indicate that both the polar and steric natures of the substituents play an important role in the formation of Cu(Sal·N·ph–X)$C_2H_5CO_2$.

The magnetic susceptibility data in the temperature range of 80—300 K for the propionate complexes are well represented by the Bleaney-Bowers equation:[2]

$$\chi_A = \frac{g^2N\beta^2}{3kT}\left(1+\frac{1}{3}\exp\frac{-2J}{kT}\right)^{-1} + N\alpha \qquad (1)$$

where $-2J$ is equal to the energy separation between the singlet and triplet states, which gives the degree of the strength of the magnetic interaction, and where the other symbols have their usual meanings. By the best fit of the observed cryomagnetic data to Eq. (1), assuming $N\alpha=60\times10^{-6}$ emu/mol, the values of $-2J=101$ cm^{-1} and $g=2.14$ were evaluated for both the propionates (Fig. 1). The close agreement between the observed and calculated temperature dependences indicates that the propionate complexes have a binuclear structure in crystals. The antiferromagnetic interaction ($J<0$) was also reflected in the X-band ESR spectra of these complexes; *i.e.*, the spectra showed a weak signal at about 1500 G which may be assigned to the $\Delta M_s=2$ transition characteristic of magnetically-coupled copper(II) ions.[2]

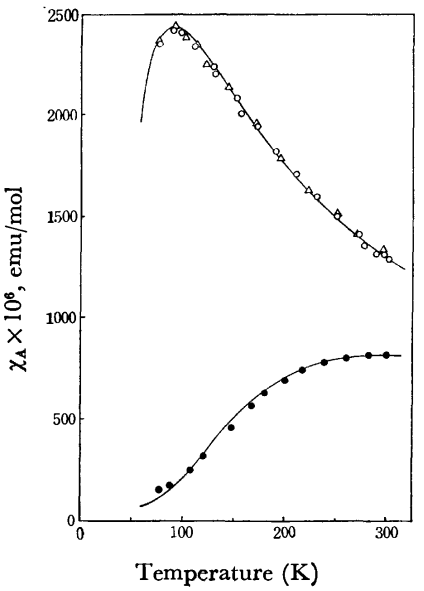

Fig. 1. Variation of magnetic susceptibilities with temperature.
○: Cu(Sal·N·ph)$C_2H_5CO_2$ (μ_{eff}=1.73 B.M. at 26 °C)
△: Cu(Sal·N·*p*-tol)$C_2H_5CO_2$ (μ_{eff}=1.74 B.M. at 23 °C)
●: Cu(Sal·N·*p*-tol)Cl (μ_{eff}=1.35 B.M. at 27 °C)
The solid curves represent the Bleaney-Bowers equation.

The χ_A *vs.* T data of the chloride complex, Cu(Sal·N·*p*-tol)Cl, were also fitted to the theoretical curve calculated from Eq. (1) with the values of $-2J=330$ cm^{-1}, $g=2.15$, and $N\alpha=60\times10^{-6}$ emu/mol (Fig. 1). The $-2J$ value is large and practically the same as the value of 360 cm^{-1} determined by Harris *et al.*[3] for the phenyl complex, Cu(Sal·N·ph)Cl. This indicates the presence of a very much stronger antiferromagnetic interaction in these chloride complexes than in the corresponding propionate complexes.

The reflectance spectral pattern of the propionates, which indicates a square planar configuration around the copper(II) ion, is different from those of the chlorides to which a pseudo-tetrahedral configuration was previously assigned[1,4] (Fig. 2). Furthermore, these spectral and magnetic properties are contrary to the expectation from the linear relation, "higher energy of

(Ar=phenyl or *p*-tolyl group)

d-d bands—lower magnetic moment," established for a series of binuclear copper(II) halide complexes with pyridine *N*-oxides[5] and salicylideneamines.[1,4]

The chloride complexes showed a strong band at *ca.* 1550 cm^{-1}, while the band appears at *ca.* 1530 cm^{-1} for the parent bis-salicylideneamine complexes.[3] This band shift to higher energies indicates that, in these chlorides, the binuclear molecule is formed by phenolic oxygen atoms.[6] On the other hand, no significant band shift was observed for the propionate complexes, suggesting that, in these complexes, no phenolic oxygen-bridged structure exists.

These magnetic and spectral data suggest that the propionates possess a carboxylate-bridged binuclear structure analogous to that of copper(II) propionate *p*-toluidine, $[Cu_2(C_2H_5CO_2)_4 \cdot p\text{-toluidine}_2]_n$, the structure of which was recently determined by X-ray analysis.[7] One of the probable binuclear structures is given in Fig. 3.

The difference in magnetic interaction between the propionate and chloride complexes is attributable to change in structure from carboxylate-bridged to phenolic oxygen-bridged entities. In support of this conclusion, it should be noted that the $-2J$ value determined for the propionate complexes in this study is in good agreement with the value of 105 cm^{-1} reported by Yawney *et al.*[7] for copper(II) propionate *p*-toluidine, for which a pair-by-pair spin-spin coupling between copper(II) ions through the carboxylate groups was suggested to account for the demagnetization.[7]

Experimental

Preparation of the Propionates. A mixture of copper(II) propionate monohydrate and bis-(*N*-arylsalicylideneaminato)-copper(II) in ethanol was stirred on a hot plate for an hour. The mole ratio of $Cu(C_2H_5CO_2)_2H_2O$ to $Cu(Sal \cdot N \cdot Ar)_2$ was 3:1 for the phenyl complex and 1.2:1 for the tolyl complex. The alcoholic solution was then filtered, and the filtrate was concentrated by warming it gently to produce green crystals. The product was filtered off, washed twice with ethanol and once with ether, and dried at *ca.* 70 °C. Anal. Phenyl complex. Found: C, 57.67; H, 4.56; N, 4.11; Cu, 19.18%; Calcd. for $C_{16}H_{15}NO_3Cu$: C, 57.74; H, 4.54; N, 4.20; Cu, 19.09%. Tolyl complex. Found: C, 58.79; H, 4.91; N, 4.03; Cu, 18.33%; Calcd for $C_{17}H_{17}NO_3Cu$: C, 58.86; H, 4.94; N, 4.04; Cu, 18.32%.

Physical Measurements. The magnetic susceptibilities were determined over the temperature range of 80—300 K by the Gouy method using an apparatus which was described previously.[4] The ESR (X-band) spectra were measured on powder samples using a JES-ME-1X spectrometer. The reflectance spectra were obtained on a Hitachi EPR-3T recording spectrophotometer. The IR absorption spectra were recorded on a Hitachi EPI-G2 IR spectrophotometer.

Synthesis of Chelating Agents. XII.[1] Chelating Behavior of 3,3-Dimethylbutane-1,2-diamine-*N,N,N',N'*-tetraacetic Acid with Some Alkaline Earth Metals*

Tairoku YANO, Yuzo YANAGIHARA, Hiroshi KOBAYASHI, and Keihei UENO

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received May 14, 1974)

Synopsis. The chelate stability constants of 3,3-dimethylbutane-1,2-diamine-*N,N,N',N'*-tetraacetic acid with some alkaline earth metal ions were determined at 25.0 °C and at an ionic strength of 0.10 with KNO_3 as supporting electrolyte by a potentiometric method.

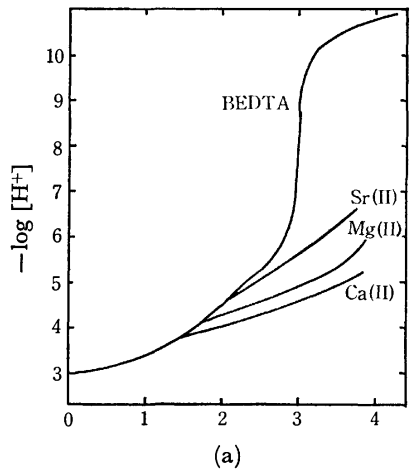
Synthesis and acid dissociation study of 3,3-dimethylbutane-1,2-diamine-*N,N,N',N'*-tetraacetic acid (BEDTA) was previously reported.[2] This note is to report on the chelating behavior of the above ligand with alkaline earth metal ions.

Experimental and Calculation

Potentiometric measurements were carried out at 25.0± 0.1 °C in aqueous solutions and at an ionic strength of 0.10 with KNO_3 as supporting electrolyte. Apparatus and procedures were the same as described previously.[1] A solution of the ligand (10^{-3} M, 100 ml) was titrated with 0.1 N KOH solution free from carbonate ion in the presence of an equimolar amount of an alkaline earth metal ion. The titration curves obtained were shown in Fig. 1. Since BEDTA forms exclusively a 1:1 chelate with a multivalent metal ion,

$$M^{m+} + A^{4-} \rightleftarrows MA^{m-4}$$

the stability constant $K_{MA}(=[MA^{m-4}]/[M^{m+}][A^{4-}])$ was calculated according to the Bjerrum's standard method.[3]



(a)

Fig. 1. Potentiometric titration curves of the alkaline earth metal chelates at 25.0 °C in 0.10 M KNO_3 solution, where the mole ratio of a metal ion to the ligand is 1:1 and the concentration of BEDTA 10^{-3} M.

TABLE 1. STABILITY CONSTANTS OF BEDTA AND RELATED LIGANDS WITH SOME ALKALINE EARTH METALS

Compound	log K_{MA}		
	Mg(II)	Ca(II)	Sr(II)
BEDTA	11.0	11.8	9.4
EDTA[7]	8.69	10.70	8.63
PDTA[8a]	10.29	11.47	9.61
dl-BDTA[8b]	11.33	11.49	10.10

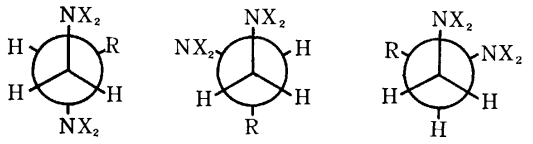
b) *dl*-BDTA: *dl*-Butane-2,3-diaminetetraacetic acid

* Contribution No. 336 from the Department of Organic Synthesis, Kyushu University.

Results and Discussion

Stability constants of BEDTA chelates with alkaline earth metal ions are summarized in Table 1 along with those of some methylated homologues of EDTA. One can readily notice that BEDTA is one of the complexane ligands that give the most stable chelates with alkaline earth metal ions. Among them, calcium(II) ion forms the most stable chelate, and magnesium(II) and strontium(II) afford decreasingly less stable ones. Though this stability order is the same as generally observed in complexane ligands, it is noted that the difference between the stabilities of the calcium(II) and magnesium(II) chelates is relatively small as compared with those of the other EDTA homologues.



(I) (II) (III)

PDTA: X=CH_2COO^-, R=methyl
BEDTA: X=CH_2COO^-, R=*t*-butyl
BEDA: X=H, R=*t*-butyl

Upon chelate formation with a metal ion, the BEDTA tetraanion moiety would take the *syn*-conformation of II preferably to III since the latter, though being also of a *syn*-conformation, would be subject to considerable steric hindrance between *t*-butyl group and the resulting out-of-plane (R) glycinate ring.[4] A study on the rotational isomerism of propane-1,2-diaminotetraacetic acid (PDTA) in a solution showed that among the conformations of the free tetraanion, I, II, and III, the latter two were present to an equal extent.[5] Increased size of the alkyl substituent in BEDTA, however, would favor to the less congested conformation II and, therefore, presumabley causes the increase in the fraction of II, while decreases that of III.

The precursory diamine, 3,3-dimethyl-1,2-diaminobutane (BEDA), was found to form also very stable

complexes as compared with those of homologous 1,2-diamines. This behavior upon chelate formation was also ascribed to the bulkiness of *t*-butyl group which restricted the internal rotation in the free ligand molecule to fix the two amino group in a *syn-clinal* position II favorable to chelate ring formation.[6] Although no direct evidence was obtained, the behavior of the precursory diamine and the molecular model study of BEDTA indicated the predominance of the conformer II in the free tetraanion of BEDTA.

Thus an entropy contribution due to the steric effect, as well as an enthalpy contribution due to the electron-releasing effect of *t*-butyl group, would be responsible for the high stability of the present complexane ligand.

The Spectrophotometric Determination of Boron in Condensed Water from Fumaroles*

Akinori Isozaki and Satori Utsumi

College of Science and Technology, Nihon University, Chiyoda-ku, Tokyo 101

(Received May 29, 1974)

Synopsis. A simple and accurate spectrophotometric method for determining boron in condensed water from fumaroles has been developed. The proposed method is based on the methylene blue-tetrafluoroborate ion pair. It was possible to determine micro amounts of boron with satisfactory results without any interference of foreign ions.

The tetrafluoroborate ion (BF_4^-) forms an ion pair with methylene blue, which may be easily extracted by 1,2-dichloroethane. The present authors have investigated this method in greater detail[1] and applied it to the determination of micro amounts of boron in natural waters[2] and rocks.[3] The determination of boron in condensed water from fumaroles[4-6] has been almost always performed by a titration method using a sodium hydroxide solution and mannitol. However, it seems difficult to determine boron at lower concentrations such as 0.1 ppm. Onishi[7] has determined the BF_4^- in natural waters by a spectrophotometric method on the basis of the methylene blue ion-pair. However, he has not reported in detail about the total boron. There are also some problems regarding the pretreatment of the sample. In the present work, the authors investigated a simple and accurate method for the determination of total boron in condensed water.

Results and Discussion

Reagents and Apparatus. *Standard Boric Acid Solution* (0.25 and 2.5 ppm as boron). *Standard Tetrafluoroboric Acid Solution* (0.25 ppm as boron): Add 50 ml of a standard boric acid solution (2.5 ppm as boron) and 5 ml of 5% hydrofluoric acid to a 500 ml polyethylene measuring flask. After the mixture has been allowed to stand for 24 hr, dilute to exactly 500 ml with water. *Silver Sulfate Solution* (0.01 M): Dissolve 1.5 g of silver sulfate in water and dilute to 500 ml. This solution contains 10 mg of silver ions per 5 ml. A Hitachi double-beam spectrophotometer (Model 124) and 10 mm cells were used to measure the absorbance. The other reagents and apparatus used in this investigation were the same as those described in a previous paper.[1]

Sampling. Fumarolic gas is collected by means of a quartz tube inserted into a fumarole. The cooling parts and sampling flask were also made of quartz.

Procedure. In a 100 ml platinum dish, place the condensed water so that it contains below 1.0 μg of boron, add 1.0 ml of a 0.5 M potassium hydroxide solution and 0.5 ml of a 30% hydrogen peroxide solution, and then dilute to 10 ml with water. Place the platinum dish in a water bath at boiling. After evaporation to dryness, dissolve the cake with 4 ml of a 0.5 M sulfuric acid solution. Transfer the solution to a polyethylene separatory funnel and wash the platinum dish with 13 ml of water. Into the separatory funnel, add 3 ml of a 5% hydrofluoric acid and allow the mixture to stand for 30 min at room temperature. Then add 3 ml of a 0.001 M methylene blue solution and 10 ml of 1,2-dichloroethane, and shake the separatory funnel for 1 min. Transfer the organic layer into another separatory funnel containing 5 ml of a 0.01 M silver sulfate solution and shake it for 1 min. After it has stood for about 20 min, measure the absorbance of the dichloroethane phase at 660 nm, using dichloroethane as the reference. The calibration curve was prepared by taking 0.0, 1.0, 2.0, 3.0, and 4.0 ml of a 0.25 ppm standard boric acid solution. It was reproducible within an error of ±0.02 μg of boron.

Effect of Foreign Ions. In order to confirm the effect of foreign ions, which are usually present in condensed water from fumaroles, and eliminate the interfering ions, the experiments were made both in the presence of 0.5 μg of boron and in its absence. The experimental results are given in Table 1. Sulfide and sulfite ions interfered with the determination of boron under masking with 10 mg of silver ions. However, by this procedure these ions could be decomposed by oxidation with hydrogen peroxide in an alkaline solution. It was found suitable from several experiments to use 0.5 ml of 30% hydrogen peroxide for the oxidation.

Effect of the Volatilization of Boron. When a solution containing borate ions is concentrated or evaporated to dryness, an alkaline solution has been used. On the other hand, BF_4^- exists in a strongly acid-condensed water containing a larger amount of fluo-

ride;** therefore, it is necessary to examine the volatilization of BF_4^-. Several experiments were made in order to examine the volatilization of boron by using a standard boric acid solution or tetrafluoroboric acid solution and by changing the amount of potassium hydroxide, according to the above procedure. As can be seen in Fig. 1, the loss of boron in both cases was insignificant except in the absence of alkali. Therefore, 1 ml of 0.5 M potassium hydroxide was added in the present work.

The Determination of Boron in Condensed Water from Fumaroles. The boron in some condensed waters was determined by the present method. The results listed in Table 2 show good agreement within the limits of experimental error. A colloidal sulfur sometimes exists in condensed water. It was found that the amount of boron adsorbed on sulfur was negligible. The analytical results obtained by a titration method[8] are also shown in Table 2. It was difficult to determine less than 1 ppm of boron by the titration method. Further, it was found that when a sample is rich in BF_4^-, the titration method gives a considerable error in the results because of trouble at pH adjustment from the fundamental experiment. The present method may be applied not only to condensed water from fumaroles, but also to hot spring water and thermal water in active volcanic areas.

The authors are much obliged to Dr. T. Ozawa and Dr. M. Yoshida of the Tokyo Institute of Technology for kindly supplying the samples of condensed water and for their many helpful discussions during this work.

** Onishi[7] reported that in some cases the ratio of the BF_4^--type boron against the total boron is 90%.

The Reaction of Biguanides and Related Compounds. XI.[1] The Interaction of Ethylene Carbonates with Arylbiguanides and Related Compounds.

Mitsuru FURUKAWA, Takatoshi YOSHIDA, and Seigoro HAYASHI

Faculty of Pharmaceutical Sciences, Kumamoto University, Oe-hon Machi, Kumamoto 862

(Received February 12, 1974)

Synopsis. The treatment of arylbiguanides with ethylene carbonates afforded 1-aryl-4,6-diimino-2-oxo-hexahydro-*s*-triazines, which were then readily converted into 1-arylisocyanuric acid by hydrolysis with concentrated hydrochloric acid.

A number of previous workers have shown that the addition of carboxylic esters, ketones, and aldehydes to biguanides is followed by the immediate cyclization of the intermediates to amino-*s*-triazines.[2] In continuation of our investigation on the cyclization of systems containing carbonyl groups to biguanides and its homologues, we examined the behavior of ethylene carbonates (**1**) toward arylbiguanides (**2**) and *N*-amidino-*O*-alkylisoureas (**3**).

When **1a** and **2** were heated in ethanol or, preferably, allowed to stand in dimethylformamide (DMF), a product was yielded in a comparatively good yield. The same product was also obtained by treating **1b** with **2** under similar conditions. This result obviously indicates that the ethylene moiety originating from **1a** is not retained in the molecule of the product. The mass spectrum of the product exhibited a strong molecular ion peak corresponding to that of the condensation product of molecular equivalents of **1a** and **2**, with the elimination of ethylene glycol. The infrared (IR) spectrum showed the absorptions assignable to amino and imino groups in the regions of 3450 and 3260 cm^{-1} and that due to a carbonyl group near 1680 cm^{-1}. These results suggest that the products are 2-oxo-hexahydro-*s*-triazines, though two isomeric structures, 1-aryl-4,6-diimino-2-oxo-hexahydro-*s*-triazine (**4**) and 2-arylimino-4-imino-6-oxo-hexahydro-*s*-triazine (**5**), due to the orientation of the cyclization are possible. Although support for **4** was provided by observing the fragment-ion peak probably arising from the arylisocyanate ion formed by the decomposition of the molecular ion in the mass spectrum, a distinction between **4** and **5** on the basis of the results of elemental analyses and the spectral data alone is impossible. In order to elucidate the structure, the product was hydrolyzed with hydrochloric acid to give 1-arylisocyanuric acid

Compd.	Yield (%)	Mp (°C)	Formula	Analysis % Found (Calcd) C	H	N
6a	35	307—308	$C_9H_7O_3N_3$	52.43 (52.68)	3.21 (3.44)	20.52 (20.48)
6b	71	300—301	$C_{10}H_9O_3N_3$	54.86 (54.79)	4.36 (4.14)	18.59 (19.17)
6c	30	269—270	$C_{10}H_9O_4N_3$	51.04 (51.06)	4.13 (3.86)	17.35 (17.85)
6d	60	301—302	$C_9H_6O_3N_3Cl$	44.63 (45.11)	2.70 (2.52)	17.49 (17.53)

(**6**).[3] The IR spectrum of **6** exhibited the characteristic three absorption bands assignable to the carbonyl groups in the region of 1700—1800 cm^{-1}, and the mass spectrum showed the molecular ion as the most abundant peak. Detailed data on **4** and **6** are summarized in Tables 1 and 2.

The formation of **4** probably proceeds step by step as follows: the initial addition of **2** to **1a** may occur theoretically at the central (N^3) or at the equivalent terminal nitrogen atom (N^5), of which only the latter case is capable of yielding *s*-triazine on cyclization. The N^3 atom is inactive, and the nucleophilic attack of this nitrogen is unknown. The interaction of the ester carbonyl group in the intermediate (**7**) would occur rapidly with the N^1 atom rather than with the N^2 atom or more **2**, giving **4**, but not **5** or a bis-compound. The formation of the acyl intermediate, **7**, in the reaction of **2** with carboxylic esters was suggested by Overberger[4] and Shapiro,[5] and elucidated by us.[6]

The reaction of **1a** with **3** is also expected to undergo cyclization to *s*-triazines. However, no formation of any of the *s*-triazines anticipated was observed. The heating of equimolar quantities of **1a** and **3** in ethanol unexpectedly gave *N,N'*-carbonyl-*bis*-guanidine (**8**), whose structure was established by a comparison of it with an authentic sample prepared from **1a** and guanidine.

The IR spectrum of **8** showed the strong absorption assignable to a carbonyl group at 1660 cm^{-1}, and the absorption pattern was quite similar to that of guanidine. Compound **8** would be formed by the reaction of **1a** with the guanidine formed by the decomposition of **3**. The facile decomposition of **3** to guanidine was practically observed. The heating of equimolar quantities of **1a** and guanidine in ethanol also gave a low yield of **8**, as had been expected. On the other hand, when **1a** was treated with one-half equivalent amount of guanidine, a mixture of **8** and ethyl guanidinocarboxylate (**9**)[7] was obtained in a low yield. Compound **9** would be formed by the ester exchange of an intermediate β-hydroxyethyl guanidinocarboxylate with the ethanol used as the solvent. The conversion of **9** to **8** was also observed upon heating with guanidine in ethanol.

Experimental

1-Aryl-4,6-diimino-2-oxo-hexahydro-s-triazine (4). General Procedure: 1) A mixture of arylbiguanide (4 mmol) and ethylene carbonate (4 mmol) in ethanol (20 ml) or in DMF (1 ml) was refluxed for 2 hr or allowed to stand for a few days at room temperature respectively. The precipitates thus deposited were collected by filtration upon cooling. Purification was carried out by neutralizing a solution of the precipitates in an aqueous sodium hydroxide solution with dilute hydrochloric acid. The detailed data are summarized in Table 1. 2) A solution of arylbiguanide (4 mmol) and propylene carbonate (4 mmol) in ethanol (20 ml) was heated for 2 hr under reflux. The precipitates thus deposited were collected by filtration while hot. The precipitates were identified with an authentic sample prepared by Procedure 1 by means of a mixed-melting-point determination and by a comparison of the IR spectra.

1-Arylisocyanuric Acid (6). General Procedure: A suspension of 1-aryl-4,6-diimino-2-oxo-hexahydro-*s*-triazine (2 mmol) in concentrated hydrochloric acid (10 ml) was heated for 12 hr under reflux. The suspended solid was gradually dissolved, and the precipitates were newly separated. The precipitates were collected by filtration while hot and washed with dilute hydrochloric acid. The detailed data are summarized in Table 2.

N,N'-Carbonyl-bis-guanidine (8). Into a solution of sodium ethoxide (0.34 g, 5 mmol) in ethanol (20 ml), we stirred *N*-amidino-*O*-alkylisourea hydrochloride (5 mmol). The precipitates were then filtered off, and ethylene carbonate (0.44 g, 5 mmol) was added to the filtrate. The mixture was heated for 2 hr, and the precipitates thus deposited were collected by filtration. Recrystallization from dilute ethanol gave a 40% yield of colorless prisms; mp>360 °C. Found: C, 21.99; H, 6.67; N, 50.69. Calcd for $C_3H_8ON_6H_2O$: C, 22.22; H, 6.22; N, 51.21. The same compound was also obtained in a 50% yield by the reaction of ethylene carbonate with an excess of guanidine and in a 70% yield by the treatment of guanidine with ethyl guanidinocarboxylate.

Ethyl Guanidinocarboxylate (9). A solution of guanidine (0.30 g, 5 mmol) and ethylene carbonate (0.88 g, 10 mmol) in ethanol (10 ml) was refluxed for 4 hr and then concentrated. The precipitates (0.02 g, 5.8%) of *N,N'*-carbonyl-bis-guanidine were filtered off, and the filtrate was evaporated by distillation and then allowed to stand overnight to give colorless prisms (0.05 g, 6.7%) melting at 93—95 °C.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 47 (11), 2895—2896 (1974)

The Syntheses of Acronycidine and 4,5,8-Trimethoxyfuro[2,3-*b*]quinoline

Tetsuya SEKIBA

Faculty of Chemical Engineering, Toyama Technical College, Hongo, Toyama 930

(Received March 13, 1974)

Synopsis. 2,3-Dihydroacronycidine (VIa) was obtained from 2,3,5-trimethoxyaniline by condensation with diethyl β-benzyloxyethylmalonate, methylation, debenzylation, and then cyclodehydration. The dehydrogenation of VIa gave acronycidine in relatively high yields.

Acronycidine was isolated from the bark of both *Acronychia baueri*[1] and *Melicope fareana*.[2] Its structure was proposed to be 4,5,7,8-tetramethoxyfuro[2,3-*b*]-quinoline (Ia) on the basis of spectral and degradative studies.[3] 4,5,8-Trimethoxyfuro[2,3-*b*]quinoline (Ib) has not yet been found in any natural source, but it is considered useful to synthesize this substance, which may be expected to occur in nature. Govindachari and his co-workers[4] attempted, without success, to synthesize the 2,3-dihydro-derivative of Ia according to the method of Ohta and Mori.[5] They obtained it, therefore, by another route,[6] but never attempted to synthesize Ia. A previous paper[7] reported the successful dehydrogenation of 2,3-dihydrofuroquinoline in dry benzene into furoquinoline with DDQ (2,3-dichloro-5,6-dicyanobenzoquinone).

The present paper will describe convenient syntheses of Ia and Ib from 2,3,5-trimethoxyaniline (IIa)[8] and 2,5-dimethoxyaniline (IIb) by a modification of a method previously reported[7] according to Ohta and Mori's method. By careful heating under reduced pressure, the condensation of IIa and IIb and diethyl β-benzyloxyethylmalonate without any solvent gave the 4-hydroxy-2-quinolone derivatives (IIIa, b), which were then easily methylated with diazomethane into 4-methoxy compounds (IVa, b). Although the attempted cyclodebenzylation of IVa and IVb with PPA was unsuccessful, the debenzylation of IVa and IVb with hydrogen in the presence of 5% Pd–C gave 3-(β-hydroxyethyl)-4-methoxy-2-quinolone derivatives (Va, b). The IR spectra of Va and Vb indicated the presence of a hydroxyl group (*ca.* 3440 cm^{-1}), while the NMR spectra of Va and Vb indicated the absence of the methylene protons and the phenyl protons of the benzyl group, which were present in the spectra of IVa and IVb, and exhibited a signal for one proton (δ *ca.* 3.63 bs ppm) of the hydroxyl group which easily disappeared upon deuterium exchange. The cyclodehydration of Va and Vb with PPE (polyphosphate ester) yielded 2,3-dihydrofuro[2,3-*b*]quinoline derivatives (VIa, b). The structures of VIa and VIb were assigned on the basis of the NMR spectra, which showed signals at δ *ca.* 3.42 t and 4.58 t attributable to two methylene protons of a dihydrofuran-ring system. The dehydrogenation of VIa and VIb by the DDQ method gave furo[2,3-*b*]quinoline derivatives (Ia; acronycidine[1] and Ib; 4,5,8-trimethoxyfuro[2,3-*b*]quinoline). The synthetic acronycidine (Ia) was shown to be identical with a natural specimen by a mixed-melting-point determination and by a comparison of their IR, UV, and NMR spectra* (Table 1).

Experimental

3-(2-Benzyloxyethyl)-4-hydroxy-2-quinolones (IIIa,b). A mixture of IIa (4.5 g) or IIb (3.7 g) and diethyl β-benzyloxyethylmalonate (7.4 g) was heated under reduced pressure (*ca.* 70 mmHg). The temperature was then raised to 180 °C over a period of 30 min, maintained at that temperature for further 30 min, and then raised and kept at 250 °C for 30 min. The cooled reaction mixture was then dissolved in chloroform. The chloroform solution was treated in a way similar to that used in a previous paper.[7] IIIa: Mp 160—161 °C (colorless needles from ethanol) (yield, 65%). IR (cm^{-1}, Nujol): 3360, 1655. UV: λ_{max}^{EtOH} nm(log ε); 220 (4.80), 238(sh) (4.63), 256 (4.50), 265 (4.50), 311.5 (4.34), 326.5 (4.24). NMR ($CDCl_3$): δ 3.97, 4.01, 4.03 (each 3H, s, $-OC\underline{H}_3$), 3.01, 3.78 (each 2H, t, J=7.0 Hz, $-C\underline{H}_2$), 4.36 (2H, s, Ph-$C\underline{H}_2$), 6.93 (1H, s, Ar-$\underline{H}$), 9.04 (1H, s, $-O\underline{H}$), 9.48 (1H, s, $-N\underline{H}$). Found: C, 65.55; H, 5.97; N, 3.64%. Calcd for $C_{21}H_{23}O_6N$: C, 65.44; H, 6.02; N, 3.63%. IIIb: Mp 138.5—140.5 °C (pale yellow cubes from ethyl acetate) (yield, 40%). IR (cm^{-1}, Nujol): 3220, 1635. UV: λ_{max}^{EtOH} nm(log ε); 210 (4.50), 224 (sh) (4.26), 244 (4.25), 253 (4.31), 262 (4.34), 292 (3.99), 304 (3.94). NMR ($CDCl_3$): δ 3.88, 3.96 (each 3H, s, $-OC\underline{H}_3$), 3.00, 3.71 (each 2H, t, J=7.2 Hz, $-C\underline{H}_2$), 4.56 (2H, s, Ph-$C\underline{H}_2$), 6.25, 6.79 (2H, ABq, J=8.4 Hz, Ar-$\underline{H}$), 9.00 (1H, bs, $-O\underline{H}$), 9.55 (1H, bs, $-N\underline{H}$). Found: C, 67.58; H, 5.94; N, 3.86%. Calcd for $C_{20}H_{21}O_5N$: C, 67.59; H, 5.96; N, 3.94%.

3-(2-Benzyloxyethyl)-4-methoxy-2-quinolones (IVa,b). Diazomethane method: IVa: Mp 135—137 °C (pale yellow plates from ethanol) (yield, 96%). IR (cm^{-1}, Nujol): 1635. UV: λ_{max}^{EtOH} nm(log ε); 212.5 (4.62), 236.5 (4.29), 257.5 (4.34), 265.5 (4.42), 316 (4.19), 325(sh) (4.08). NMR ($CDCl_3$):

* The UV, IR, NMR spectra, and mp of natural acronycidine were measured in this laboratory.

UV: λ_{max}^{EtOH} nm(log ε); 209 (4.44), 242 (4.12), 265 (4.32), 299 (3.97), 310(sh) (3.89), 338(sh) (3.24). NMR ($CDCl_3$): δ 3.30 (1H, bs, -O<u>H</u>). Found: C, 58.98; H, 6.20; N, 4.92%. Calcd for $C_{14}H_{17}O_5N$: C, 60.20; H, 6.14; N, 5.02%.

2,3-Dihydrofuro[2,3-b]quinolines (VIa,b). A mixture of Va or Vb (1.0 g) and PPE (15 g) was heated at 120—130 °C for 2 hr. The cooled mixture was then poured into water, and the insoluble materials were filtered off. The aqueous solution was neutralized with diluted aqueous ammonia. The precipitate was collected, washed with water, and recrystallized to give VIa or VIb. VIa: Mp 191—192 °C (lit,[3] 188.5—190.5 °C) (colorless plates from ethanol) (yield, 70%). IR (cm^{-1}, Nujol): 1620, 1505. UV: λ_{max}^{EtOH} nm(log ε); 218.5 (4.56), 258.5 (4.70), 308.5 (3.84), 325(sh) (3.74). NMR ($CDCl_3$): δ 3.88, 3.90, 3.93, 3.96 (each 3H, s, -OC<u>H</u>$_3$), 4.58, 3.42 (each 2H, t, J=7.8 Hz, α,β-C<u>H</u>$_2$), 6.47 (1H, s, Ar-<u>H</u>). Found: C, 61.79; H, 5.83; N, 4.89%. Calcd for $C_{15}H_{17}O_5N$: C, 61.85; H, 5.88; N, 4.81%. VIb: Mp 149.5—151.5 °C (colorless needles from ethanol) (yield, 78%). IR (cm^{-1}, Nujol): 1620, 1505. UV: λ_{max}^{EtOH} nm(log ε); 213 (4.46), 259 (4.46), 295 (3.66), 337(sh) (3.50). NMR ($CDCl_3$): δ 3.86, 3.94, 3.98 (each 3H, s, -OC<u>H</u>$_3$), 4.63, 3.47 (each 2H, t, J=7.8 Hz, α,β-C<u>H</u>$_2$), 6.65, 6.85 (each 1H, ABq, J=7.8 Hz, Ar-<u>H</u>). Found: C, 64.62; H, 5.81; N, 5.34%. Calcd for $C_{14}H_{15}O_4N$: C, 64.36; H, 5.79; N, 5.36%.

Furo[2,3-b]quinolines (Ia,b). A mixture of VIa or VIb (1.0 g) and DDQ (1.0 g) in dry benzene (150 ml) was treated by a method similar to that used in a previous paper.[7] The resulting precipitate was collected and recrystallized to give Ia or Ib (Table 1). The mixed melting point of synthetic Ia with a natural specimen was not depressed. Ia: NMR ($CDCl_3$): δ 3.96, 4.02, 4.31 (3H×4, s, -OC<u>H</u>$_3$), 6.60 (1H, s, Ar-<u>H</u>), 7.00, 7.53 (each 1H, d, J=3.0 Hz, Furan-<u>H</u>). Ib: NMR ($CDCl_3$): δ 3.88, 4.00, 4.28 (each 3H, s, -OC<u>H</u>$_3$), 6.70, 6.92 (each 1H, ABq, J=8.4 Hz, Ar-<u>H</u>), 7.02, 7.60 (each 1H, d, J=2.4 Hz, Furan-<u>H</u>).

The author wishes to express his deep gratitude to Professor Kenji Fukui, Hiroshima University, for his encouragement through the course of this work, and also to Dr. J. A. Lamberton, C S I R O, Australia, for his gift of a natural specimen.

The Alkylation of *m*-Cresol with Propylene by Supported Metal Sulfates

Masahiro NITTA, Katsumi YAMAGUCHI, and Kazuo AOMURA
Faculty of Engineering, Hokkaido University, Sapporo 060

(Received February 4, 1974)

Synopsis. The alkylation of *m*-cresol with propylene over supported metal sulfate catalysts was studied at 250 °C under atmospheric pressure. The activity of the catalyst varied with the kind of sulfate and the calcination temperature, whereas the selectivity to thymol was independent of those factors and depended on the type of carrier instead.

The alkylates of phenols are quite often useful for the processing of raw materials related to perfumery, antiseptics, dyes, and synthetic resins.[1] Thymol (2-isopropyl-5-methylphenol), an important raw material in perfumery, is usually obtained by the liquid-phase reaction of *m*-cresol and propylene in the presence of an acidic catalyst; alkylation in the vapor phase is rare,[2] except for one patent.[1a] Moreover, the details of the catalysis in that patent are unclear.

In this paper, the vapor-phase alkylation of *m*-cresol with propylene over supported sulfate catalysts will be reported in order to clarify the factors governing the activity and the selectivity for thymol formation.

The propylene was obtained from the Mitsubishi Petrochemical Co., Ltd. Commercial *m*-cresol was purified by distillation under reduced pressure; its purity was estimated to be over 99.5% by means of gas chromatography. Porous silica-gel (Davison RD gel) and activated alumina (Nishio Industies Co., Ltd., KHD-24) were used as the catalyst carriers. The sulfates were guaranteed reagents purchased from the Kanto Chemical Co., Inc. Each sulfate was 1.0 mmol per unit of weight of the carrier. All the catalysts were prepared by impregnating the carrier with an aqueous solution of a sulfate for a day and then by drying it at 120 °C in the air. It was assumed that all of the sulfate was supported on the carrier.

The activity test was carried out in a flow system under atmospheric pressure. A catalyst (10—20 mesh) packed in a glass tube reactor was activated at a given temperature for 3 hr in a nitrogen stream before the reaction. The liquid products, which were collected every 20 min, was analyzed by gas chromatography with a column containing lanolin (5 wt%) and LAC (0.5 wt%) supported on Chromosorb AW (2 m, 145 °C).

The acidic properties of the catalysts were measured by the usual *n*-butylamine titration using the Hammett indicators. The surface areas of the catalysts were measured by the BET method.

In this alkylation, the liquid products obtained were thymol and its three isomers, *iso*-thymol, and a small quantity (3 mol%) of an unknown component.* Among those products, the thymol (obtained in a *ca.* 70% yield) is the most desirable, as has been mentioned above. The initial conversion of *m*-cresol by extrapolation to zero time was taken as the catalytic activity, for the conversion decreased gradually with the time. The selectivity of the catalyst was expressed by the ratio of the thymol to all of the thymol isomers, and it was held constant throughout the time on stream. The activities and the selectivities of the various catalysts are shown in Table 1. The activities of the carriers were poor, though they were measurable. It is clear that the addition of the sulfates, with the exception of the Li and Na salts, increases the activity of the carrier. The activity varied with the kind of sulfate. These catalysts gave a high selectivity for thymol formation, though it was difficult to ascertain the equilibrium composition of thymol isomers. The activities seem to have no direct relation to the surface areas. The silica-carrier catalysts showed a selectivity of *ca.* 70%, while the alumina-carrier catalysts showed one of *ca.* 60%. From these facts it can be considered that the activity depends upon the property of the sulfate and that the selectivity depends upon the property of the carrier.

Metal sulfate is a well-known solid acid and catalyzes various reactions.[3] Fukui *et al.* have reported that the sulfates supported on silica-alumina are effective for the ethylation of benzene.[4] They supposed that the modified acid sites of the sulfate produced on the carrier are responsible for the activity. Therefore, the acidities of the present catalysts were measured (Tables 1 and 2). A rough correlation between the acidities (the amount of acid sites having the strength with $H_0 \leqq +3.3$) and the activities was found for a series of catalysts of a given carrier. In spite of its higher acidity, the acid sites of both carriers seem to be ineffective for the alkylation. These facts support Fukui's

proposal. Furthermore, the fact that the activity per unit of weight of the catalyst increased with the $NiSO_4$ content, as is shown in Fig. 1, supports the idea that the effective active sites arise essentially from the sulfate. This has also been domonstrated by the effect of the calcination temperature on the activity, as is shown in Fig. 2. That is to say, the activity of $NiSO_4$–SiO_2 varied with the calcination temperature, though the activity of the carrier itself did not vary. This curve, having its maximum at 350 °C, agrees well with the variation in the acidity of heat-treated $NiSO_4$ which was previously determined by one of present authors and others.[5,6]

The selectivity was held constant in Figs. 1 and 2, independent of the supported amount of sulfate and of the calcination temperature, as would be expected when the carrier was the same. Further, in order to elucidate the selectivity, a few typical solid acid catalysts were tested. The results, shown in Table 2, reveal that the selectivity is not governed by the acid strength of the catalyst. The selectivity of large-pore SiO_2 (80—100 Å) in Table 2 is lower than that of small-pore SiO_2 (22 Å) in Table 1. This suggests that, on the small-pore catalysts, the reactant molecules take a particular adsorbed state favorable to thymol formation. Details of the selectivity will be reported, along with data on other catalysts, at a later date.

The Solid-State Spectra of Several Rhodizonates[1)]

Jun-ichi AIHARA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received February 26, 1974)

Synopsis. The charge-transfer transitions between the anions were observed in the absorption spectra of alkali-metal rhodizonates in the solid state. Ammonium ions enhanced the electronic transition of this kind, whereas the solid-state spectrum of the barium salt was similar to the solution spectrum of the rhodizonate ion.

More than a decade ago, West *et al.* pointed out that the oxocarbons with a general formula of $C_nO_n^{2-}$ may be considered as a new class of aromatic compounds.[2)] The assignment of the vibrational spectra confirmed the presence of aromaticity in the dianion of rhodizonic acid ($C_6O_6^{2-}$).[3)] The electronic spectra of the rhodizonates have often been observed in aqueous solutions.[4)] Though the absorption spectra for the crystals are lacking, some salts are strikingly characterized by deep coloration in the solid state. In order to clarify the electronic structure of these rhodizonates, we attempted to obtain the absorption spectra of the salts in the solid state.

Experimental

The lithium, sodium, potassium, and ammonium rhodizonates were prepared from inositol and the corresponding acetates by the method developed by Preisler and Berger.[5)] The rubidium, cesium, and strontium salts were prepared by the metathesis reaction of the lithium salt. Commercial barium salt was used without further treatment. The absorption spectra of the solid rhodizonates were obtained by applying the Kubelka-Munk function to the diffuse reflection spectra of the samples dispersed in sodium chloride. The gross spectral shapes were in good accordance with those derived from the transmission spectra of the Nujol mulls.

Results and Discussion

Figure 1 shows the absorption spectra of three typical rhodizonates in the solid state. The solution spectrum of rubidium rhodizonate is therein compared to them. As may easily be seen, the solid-state spectrum of the brown barium salt has a close resemblance to that of the aqueous solution. In both absorption spectra, there is a distinct and isolated band in the visible region. The absorption maximum of this principal band is located at 20800 cm^{-1} in the solution spectrum and is followed by an accompanying shoulder near 22700 cm^{-1}. It has been suggested that such a doublet structure is due to the Jahn-Teller distortion in the excited state.[2)] On the basis of the similarity to the solution spectrum, the first absorption band of the barium salt is attributable to the intramolecular transition of the rhodizonate ion except for the perceptible absorption tail on the low-energy side. The corresponding peak and shoulder are present at 19800 and 22500 cm^{-1} respectively in the spectrum of the solid barium salt. The absorption spectrum of the red-brown strontium salt is of the same type as that of the barium salt.

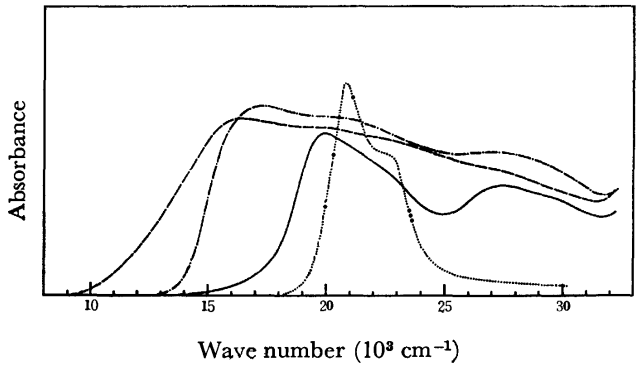

Fig. 1. The absorption spectra of the solid barium (——), rubidium (-·-·-), and ammonium (– – –) rhodizonates, and the aqueous solution of rubidium rhodizonate (····).

On the contrary, the solid rubidium rhodizonate appears almost black; indeed, it exhibits quite a different spectrum, one in which the principal band is considerably diffused around 20000 cm^{-1}. Here, it must be noted that the principal band is noticeably preceded by an intense new absorption band probably centered at about 17000 cm^{-1}. This additional band was found neither in the spectrum of the solid barium salt nor in the solution spectrum. The low-energy portion of the spectrum was found by diffuse reflection spectroscopy to diminish gradually when the sample was ground with sodium chloride. That is, the intensity ratio of the principal band to the additional one increases by this treatment. From this viewpoint, the interionic character of the latter band is strongly supported for this salt. Such a peculiar feature is substantially common to all alkali-metal salts except for the lithium salt, though the colors of the salts vary from the dark green of sodium salt to the dark violet of potassium and cesium salts.

Another clue to this effect is given by the crystal structure of rubidium rhodizonate as determined by X-ray diffraction.[2)] This salt forms a layer-type structure with the planar anions arranged in stacks. A more interesting finding was that the carbon atoms of anions in the adjacent layers approach each other quite closely. The separation distance is 3.30 Å, which is closer than the van der Waals distance. Such a crystal structure is a replica of the crystalline TCNQ (Tetracyanoquinodimethane) anion-radical salt, where the TCNQ anions are stacked face-to-face in the same columns.[6)]

If one remembers that the charge-transfer occurs between the TCNQ anions in the crystal and induces the absorption band in the near infrared region,[7)] the

same effect can be expected in the rubidium rhodizonate crystal. In other words, it may be reasoned by analogy with the columnar structure and the related electronic spectrum of the solid TCNQ salt that the additional absorption band found in the solid-state spectrum of rubidium rhodizonate can be assigned with little difficulty to the charge-transfer transition between the adjacent rhodizonate anions. It must have been this kind of absorption band that MacIntyre and Werkema predicted for the solid potassium squarate ($K_2C_4O_4$).[8] They concluded that the formation of the charge-transfer self-complex can be nicely represented by a crystal structure similar to that of the TCNQ salt.

The black ammonium rhodizonate crystal has similar spectral features, with the additional charge-transfer band further broadened to the lower-energy side. This fact is suggestive of the closer stacking of the rhodizonate anions in the solid. As in the ammonium croconate crystal ($(NH_4)_2C_5O_5$),[9] each ammonium ion is supposedly bonded to two oxygen atoms in the molecular plane below the nitrogen atom, and to two more oxygen atoms in the plane above, so as to enhance the charge-transfer interaction between anions. The charge-transfer band of the dark green lithium salt is similarly broadened.

On the other hand, the proposed structure of the barium salt is a chain polymer,[10] in which each rhodizonate ion is chelated to two different barium ions, giving a square planar arrangement of oxygen atoms about the barium ion. Since such a structure does not always coincide with the most favorable arrangement for the interaction between the anions in the different chains, the long absorption tail of the barium salt may be a result of the weakened interionic charge-transfer interaction. In all cases, the principal band is preserved around 20000 cm^{-1}.

So far, the appearance of the charge-transfer band between the same kind of ions in the crystal has been considered as one of the most distinguished characteristics of the organic ion-radical salt. In conclusion, it should be emphasized that such diamagnetic compounds as alkali-metal rhodizonates also exhibit pronounced charge-transfer bands between anions in the solid state.

Synthetic Photochemistry. V.[1] Azulene Derivatives from the Photoadducts of Methyl Acetopyruvate with Cycloheptatriene

Hitoshi TAKESHITA and Akira MORI

Research Institute of Industrial Science, Kyushu University, Hakozaki, Fukuoka 812

(Received March 14, 1974)

Synopsis. Two azulene derivatives, 1-methoxycarbonyl-3-methylazulene (III) and 1-methoxycarbonyl-2-methylazulene (IV), were obtained by the pyrolysis of the photoproducts of methyl acetopyruvate–cycloheptatriene. IV was understood to be derived from a subsequent photopinacolization of an unisolable $[2+2]\pi$ photoadduct (VIII).

In the course of our studies of the photocycloaddition reaction of methyl acetopyruvate (I) with cycloheptatriene (II),[2] we noticed a characteristic coloration which should indicate a formation of azulene derivatives during the work-up. This paper will discuss the structures and mechanism of the formation of the azulene derivatives.

When the reaction mixture was heated *in vacuo*, a dark colored fraction was obtained after the distillation of most of the volatile fraction. The subsequent silica gel chromatographic separation of this afforded two azulene derivatives, III (blue needles) and IV (blue violet solids).[3] Both III and IV were analyzed to be $C_{13}H_{12}O_2$ arising from 1 : 1 adducts of I and II. Since III and IV both have the aromatic methyl group [δ: 2.61 (III), and 2.85 (IV)] and the methoxycarbonyl group [δ: 3.87 (III), and 4.01 (IV), $\nu_{C=O}$: 1675 (III), and 1677 cm^{-1} (IV)] on the five-membered ring [1H singlet at δ: 8.09 (C_2–H of III), and 7.17 (C_8–H of IV)], the determination of the position of either of the substituents should clarify their structures. In the NMR spectra, III [δ: 9.52 (dd, J=9.5, 2.0 Hz)] and IV [δ: 9.63 (dd, J=10.0, 2.0 Hz)] both have C_5–H signals at a very low field, disclosing the presence of a methoxycarbonyl group at the C_1-position for these compounds. Therefore, by the use of Plattner's well-known rule on the UV- and visible absorption maxima of azulenes[4] [λ_{max}^{MeOH}: 564 (III), and 530 nm (IV). $\lambda^{predict}$: 557 (III), and 519 nm (IV)], their structures have been deduced to be as shown.

Chart 1.

Since the absence of the azulenes in the original reaction mixture has been ascertained by a careful inspection of the NMR spectra of the fractions obtained by silica gel chromatography prior to the distillation, the azulenes must be formed during the distillation.

When the photoadducts of I and II[2] were pyrolyzed, only the ene-reaction product (V) was shown to develop a coloration due to the azulenoid compound, which consisted solely of a blue isomer (III). On the other hand, the most polar fraction of the photoproducts of I and II was also shown to give a coloration due to azulene derivatives by pyrolyzing under a nitrogen atmosphere; indeed, the presence of III and IV in the product mixture was proved by direct comparisons. We failed to isolate azulene-precursors due to the extreme instability and the limited quantity available,[5] but it seems reasonable to consider the precursors of the azulenes as glycol derivatives (VI and VII), which may be supposed to come from a further photochemical reaction of their primary products (V and VIII). Therefore, the following scheme may be proposed:

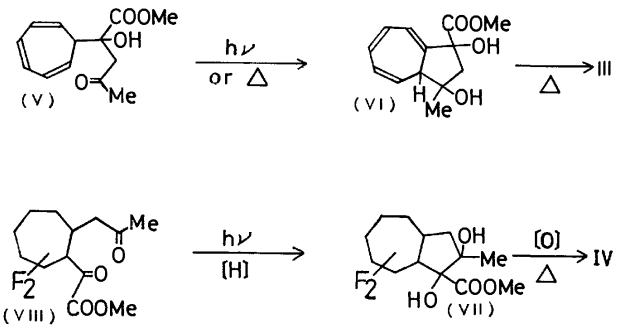

Chart 2.

VI (a 1,3-glycol) can be formed by an intramolecular hydrogen abstraction with the excited carbonyl group of V, and its aromatization needs the elimination of only two moles of water. On the other hand, VII (a 1,2-glycol) corresponds to a photo-reductive pinacolization product of VIII, being a $(2+2)\pi$ cycloadduct. Although VIII has not been detected in the products of I and II, an analogous reaction was reported in the literature;[6] furthermore, the presence of excess II may facilitate the reduction process. The dehydration of VII should give a dihydroazulene derivative, whose type of compounds undergoes a spontaneous aromatization.

It is worthwhile to note that it seems superficially that the formation of III and IV could be interpreted in terms of an "oxabicyclobutane" intermediate.[7] The concept has been frequently mentioned, but never verified.[8] The present results, either, since no product directly linked to compound (IX) has been detected, and since it would be improbable to assume that all the photo-products of IX with II are too unstable to be characterized, do not seem to favor the concept.

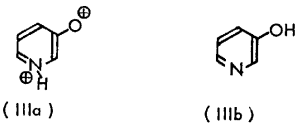

Chart 3.

To date, there have been considerable interests in the non-dehydrogenative preparation of the azulene skeleton by various cyclizations of propenyl-substituted seven-membered derivatives. Indeed, two successful experiments have been reported; Tsuruta *et al.*[9] have obtained 1,2-dicyanoazulene by a thermal rearrangement of 8-(2,2-dicyanovinyl)-heptafulvene, and Watanabe *et al.*[10] have used an acid-induced cyclization of 2-(7-tropyl)-benzaldehyde to afford benz[a]azulene, although uncondensed azulene was not obtained by this method. The formation of III from V thus constitutes a facile synthesis of azulene derivatives; according to one view of the initial photochemical step, this could be a rather general method for the preparation of 1-carboxy-2-, and/or -3-alkyl azulenes.[11] Although the yields, in the present stage, are insufficient, an improvement for the aromatization of V may not be difficult.

Experimental

Pyrolysis of the Whole Photoproduct Mixture of I and II. I (6.00 g) was dissolved in II (100 ml) and dioxane (200 ml), and the mixture was irradiated by means of a 450 W high pressure mercury lamp for 95 hr until it showed a negative ferric chloride test. Then the mixture was distilled under reduced pressure to remove a polymeric material. The higher boiling fraction (bp 172—184 °C/4 mmHg, 3.67 g) developed a dark-coloration by cooling. Silica gel column chromatography of the above afforded blue needles (III, mp 61—62 °C, 85 mg) (Found: C, 78.29; H, 6.13%. Calcd for $C_{13}H_{12}O_2$: C, 77.98; H, 6.04%) and a blue-violet solid (IV, 115 mg) (Found: C, 77.86; H, 6.11%) in addition to the previously-reported products,[2] methyl tropylglyoxalates (140 mg), ene-product (V, 105 mg), (4+2)π-cycloadduct (102 mg), and (6+2)π-cycloadduct (34 mg). The most polar fraction (75 mg) eluted with methanol–ether showed a strong ν_{OH} in the IR spectrum.

Pyrolysis of V; Formation of III. V (300 mg) was sealed in a glass tube and heated at 190 °C for 3 hr. The subsequent fractionation of the mixture afforded III (~3 mg) and methy ltropylglyoxalate (20 mg), together with recovered V (80 mg).

Pyrolysis of the Polar Fractions of Photoproducts; Formation of III and IV. The most polar portion of eluate (0.3 g) of the chromatography was heated in a sealed tube at 190 °C for 30 min. The mixture was then chromatographed through silica gel, and the blue fractions were collected to give III (~1 mg) and IV (~1 mg).

We wish to thank The Ministry of Education for its financial support, and Mr. I. Ohmori, Tohoku University, for his taking part in the experiments.

Pyrolysis of Dialkyl 2-Acyloxyalkylphosphonates

Yoshiki OKAMOTO, Toshikazu KAWAI, and Hiroshi SAKURAI

The Institute of Scientific and Industrial Research, Osaka University, Yamada-kami, Suita-shi, Osaka 565

(Received March 28, 1974)

Synopsis. The pyrolysis of dialkyl 2-acyloxyalkylphosphonates at 220—240 °C gave the corresponding alkyl carboxylates and olefins by the elimination of metaphosphoric acid $(HPO_3)_n$.

Tsurugi and his co-workers[1] reported that the pyrolysis of dimethyl 2-acetoxyethyl- or dimethyl 3-acetoxypropylphosphonate at 550—600 °C gave dimethyl vinyl- or dimethyl 3-propenylphosphonate in 51—58% yields respectively, but in the case of diethyl and dipropyl 2-acetoxyethylphosphonates, the corresponding unsaturated phosphonates could not be obtained.

We have found that dialkyl 2-acetoxyethylphosphonates (I), except in the case of the dimethyl derivative, gave alkyl carboxylates and olefins at 220—240 °C, along with the formation of metaphosphoric acids, $(HPO_3)_n$.

The I compounds were prepared by the reaction of acyl chlorides with the corresponding hydroxy derivatives, derived from dialkyl 2-oxoethylphosphonates by treating them with sodium borohydride.[2]

$$RCOOR'CHCR''HPO(OR''')_2 \quad (I)$$

	R	R′	R″	R‴
I-a	CH_3	C_6H_5	H	C_2H_5
I-b	CH_3	C_6H_5	H	C_3H_7
I-c	CH_3	C_6H_5	H	CH_3
I-d	CH_3	C_6H_5	H	*iso*-C_3H_7
I-e	CH_3	CH_3	H	C_2H_5
I-f	CH_3	H	C_6H_5	C_2H_5
I-g	CH_3	C_6H_5	CH_3	C_2H_5
I-h	C_2H_5	C_6H_5	H	C_2H_5

Diethyl styrylphosphonate (II-a) was prepared from styrene and phosphorus pentachloride by the method of Anisimov.[2] Ethyl hydrogen styrylphosphonate (II-b) was prepared by the hydrolysis of II-a, using sodium hydroxide in ethanol. Styrylphosphonic acid (II-c) was prepared by the hydrolysis of II-a with 6-M hydrochloric acid. Acetyl diethyl phosphate was prepared by the phosphorylation of acetic acid with tetraethyl phosphorous-phosphoric anhydride.[3]

In each run of the pyrolysis of the phosphonate, 0.1 mol of the phosphonate was decomposed in a 10 ml distilling flask heated at the rate of 5 °C/min in a metal bath. The decomposition of the phosphonate began in the range from 220—240 °C and was finished in a few minutes. The pyrolysis products were trapped in a tube cooled with ice water. They were analyzed by means of glc on a 3 m×3 mmϕ column, packed with NDP (20%) on Celite (60—80 mesh), at the column temperature of 90 or 120 °C, using nitrogen gas as the carrier. The glc peaks were identified by comparing their retention times with those of authentic samples. The distillable products from I are given in Table 1.

Table 1. The products obtained by the pyrolysis of I

Phosphonate	Beginning temp. of decomp. °C	Product (Yield %)
I-a	198—100	$C_6H_5CH=CH_2$ (90.7), CH_3COOEt (80.0)
I-b	195—200	$C_6H_5CH=CH_2$ (92.3), CH_3COOPr (84.3)
I-c	340[a]	
I-d	168—170	$C_6H_5CH=CH_2$ (80.9), CH_3COO-IsoPr(68.7)
I-e	195—198	$CH_3CH=CH_2$[b], CH_3COOEt (80.1)
I-f	195—197	$C_6H_5CH=CH_2$ (31.4), CH_3COOEt (46.3)
I-g	198—200	*t*-$C_6H_5CH=CHCH_3$ (42.5), CH_3COOEt (59.0)
I-h	195—197	$C_6H_5CH=CH_2$ (90.0), C_2H_5COOEt (80.9)

a) boiling point. b) undetermined.

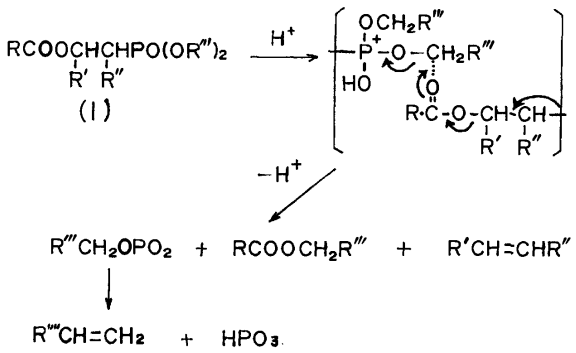
The temperature of the beginning of the decomposition were determined from the TGA curves. In the pyrolysis of those compounds, acetic acid or diethyl α,β-unsaturated phosphonate could not be detected. Ethylene was detected in all cases except I-b, -c, and -d. The analytical values of the pyrolyzed residues of I-a, -b, and -h were approximately in agreement with the $(HPO_3)_n$ formula. The decomposition temperature was affected by the structure of the alkoxy group (R‴O). I-c did not decompose even at 340 °C, its boiling point. I-d began to decompose at 168 °C. When small amounts of phosphoric acid were added, the temperature of the decomposition of I-a fell to 162 °C. The acid effectively catalyzed the initiation of the decomposition. The activation energy of the thermal decomposition of I-a was 33.1±3 kcal/mol, estimated from a TGA curve, on the assumption that the reaction obeyed first-order kinetics;[4] its value hardly changed upon the addition of the acid. The results of the thermal decompositions of II-a, -b, and -c are given in Table 2.

Table 2. The products obtained by the pyrolysis of II

Phosphonate	Beginning temp. of decomp. °C	Products (%)
II-a	260—265	$C_6H_5CH=CH_2$ (65)
II-a[a]	235—240	$C_6H_5CH=CH_2$ (91)
II-b	200—205	$C_6H_5CH=CH_2$ (48)
II-c	265—270	$C_6H_5CH_2CH_3$(22.4), C_6H_5 (25.5)

a) H_3PO_4 (5%) was added.

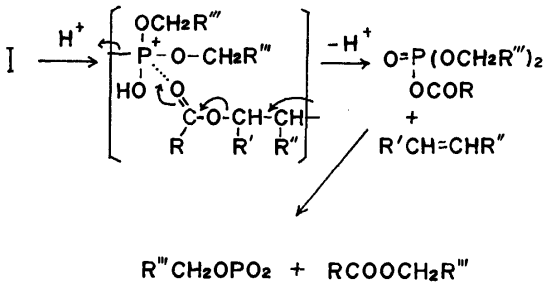
The pyrolysis behavior of II-a, which decomposed at a higher temperature than did I-a or -h, implied that the former is not involved as an intermediate in the thermal decomposition of the latter two. The temperature of the decomposition of II-c was the same as that of I-a, but the yield of styrene from the former was lower than that from the latter. This finding presumably eliminates the possibility of II-c being an intermediate in the pyrolysis of I-a. It was also supported experimentally by the DTA and TGA curves that the pyrolysis did not proceed step by step with the rise in the temperature. The pyrolysis of an equimolar mixture of I-b and -h began at 220 °C to give propyl acetate, ethyl acetate, ethyl propionate, and propyl propionate in the mole ratio of 1.1: 1.0: 1.3: 1.2. When the same mixture was pyrolyzed at 220—230 °C in a 10% solution of paraffinic hydrocarbon (mp 68—70 °C), the alkyl carboxylates mentioned above were given in the mole ratio of 0.9: 1.0: 1.3: 1.0. In the analysis of the phosphonate mixture immediately after the beginning of the decomposition, the ester-exchange between the phosphonates could not be observed. These facts implied that the formation of alkyl carboxylates might involve an intermolecular process. The pyrolysis of I may proceed by means of Scheme 1.



Scheme 1.

The nucleophilic attack of the carbonyl oxygen of the acetoxy group on the methylene carbon of the alkoxy group, followed by the migration of electrons as described in Scheme 1, resulted in the formation of alkyl carboxylate and olefin.

Another possible mechanism (Scheme 2) to account for the formation of those products can be proposed: At first, the nucleophilic attack of carbonyl oxygen occurred on the phosphorus atom and resulted in the formation of acyl dialkyl phosphate, followed by further decomposition in which alkyl carboxylate was given in the manner described above.



Scheme 2.

We found that acetyl diethyl phosphate decomposed to give ethyl acetate in a 70% yield at 170—190 °C.

It was reported that 2-hydroxyphosphonic acid bis-(dimethylamide) underwent thermal decomposition to olefin and phosphoric acid bis-amide at reflux in a toluene solution.[5] In this reaction, it was assumed that the nucleophilic attack of the alkoxy anion on the phosphorus atom and the formation of a four-membered ring transition state were involved.

However, in our experiments, under the same conditions, the analogous transformation of diethyl 2-hydroxy-2-phenylethylphosphonate to olefin and the phosphoric acid diester did not occur, even though trace amounts of phosphoric acid were present, but diethyl α,β-unsaturated phosphonate was obtained in a 60% yield. The difference in behavior may arise from the difference in the electrophilicity of the phosphorus atom. The nucleophilic attack of the carbonyl oxygen of I may preferably occur at the methylene carbon (Scheme 1) rather than at phosphorus (Scheme 2). Scheme 1 resembles that of the pyrolysis of halogenated alkyl phosphates, in which the nucleophilic attack of halogen occurred preferentially at the methylene or methine carbon of an alkoxy group to give alkyl halide in an appreciable yield.[7]

Metal Phosphinylides and Phosphinothioylides. III.[1] Reactions of Lithium Diphenylphosphinylide and Diphenylphosphinothioylide with Acetone and Bromoacetone

Masaaki YOSHIFUJI, Hideyuki GOMI, and Naoki INAMOTO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received May 14, 1974)

Synopsis. Reaction of acetone with $[Ph_2PO]Li$ gave 1-hydroxy-1-methylethyl- (**2a**), 1,1-dimethyl-3-oxobutyldiphenylphosphine oxides (**3a**) and 2,6-bis(diphenylphosphinyl)-2,6-dimethylheptan-4-one (**4a**). The corresponding sulfide **2b** was obtained in the case of $Ph_2P(S)H$, and **3b** and **4b** in the case of $[Ph_2PS]Li$ (**5b**). Bromoacetone reacted with **5b** through substitution reaction.

It has been reported that the reaction of acetone with diphenylphosphinylmagnesium bromide (**1a**), prepared from three molar amounts of phenylmagnesium bromide and diethyl phosphite, gave phosphine oxides **2a** and **4a**, the latter being considered to be formed by addition of **1a** to phorone formed from acetone and ethoxide ion.[2]

$$[Ph_2PX]M + Me_2CO \longrightarrow Ph_2P(X)CMe_2OH$$

1, M=MgBr; a, X=O — **2**
5, M=Li; b, X=S

$$+ Ph_2P(X)CMe_2CH_2COMe$$

3

$$+ (Ph_2P(X)CMe_2CH_2)_2CO$$

4

If **4a** is formed by the suggested mechanism, **3a** should be formed by addition of **1a** to mesityl oxide produced during the course of reaction.

This paper describes reactions of acetone and some ketones with lithium diphenylphosphinylide (**5a**) or diphenylphosphinothioylide (**5b**).

Reaction of **5a** with acetone afforded three phosphine oxides **2a**, expected **3a** and **4a**. The separation of these compounds was difficult, and **2a** and **3a** were isolated only in 7.4 and 20% yields, respectively. **4a** was identified by NMR, which exhibited signals at δ 1.37 (d, J_{PCCH} 16.8 Hz, Me), 2.67 (d, J_{PCCH} 7.8 Hz, CH_2), and 7.3—8.2 (m, Ph), from the crude mixture. The data were in agreement with the reported one.[2]

Reaction of **5b** with acetone did not give **2b**, but gave **3b** (43%), **4b** (23%) and 2-diphenylphosphinothioyl-6-diphenylphosphinyl-2,6-dimethylheptan-4-one (**6**) (4%).

$$Ph_2P(S)CMe_2CH_2COCH_2CMe_2P(O)Ph_2 \quad \mathbf{6}$$

By the reaction of **5b** with mesityl oxide, **3b** was also obtained in 40% yield. No **4b** could be isolated from **5b** and phorone. The following stepwise mechanism would be more reasonable. Slightly excess amount of *n*-butyllithium acts as a base for the condensation of acetone.

$$2Me_2CO \xrightarrow{n\text{-BuLi}} Me_2C{=}CHCOMe \xrightarrow{5} \mathbf{3} \xrightarrow[Me_2CO]{n\text{-BuLi}}$$

$$Ph_2P(X)CMe_2CH_2COCH{=}CMe_2 \xrightarrow{5} \mathbf{4}$$

Formation of **6** indicates desulfurization of **5b** during the course of preparation or reaction,[3] and then oxidation of the phosphorus atom in the intermediate product during the treatment.

Reaction of diphenylphosphine sulfide (**7**) with acetone gave **2b** in 23 and 86% yields in tetrahydrofuran (THF) and in acetone, respectively. The yields were determined by means of NMR, since **2b** decomposed with recrystallization from benzene–ethanol and on silica gel column.

Acetophenone and benzophenone did not react with **5b**.

Reaction of **5b** with bromoacetone gave 2-oxopropyldiphenylphosphine sulfide (**8**) in 65% yield. The result is in contrast to the reaction with chloroacetone,[4] which gives phosphinyl-substituted epoxide.

$$Ph_2P(S)CH_2COMe \quad \mathbf{8}$$

Experimental

All boiling and melting points are uncorrected. ^{1}H-NMR spectra were measured with a Hitachi R-24 spectrometer using TMS as an internal standard. ^{31}P-NMR spectra were measured with a Hitachi R-20B-R-204-PB spectrometer using 85% H_3PO_4 as an external standard. All the reactions were carried out under nitrogen atmosphere.

Reaction of Acetone with 5a. Acetone (5.15 g, 89 mmol) was added to a solution of **5a** prepared from diphenylphosphine oxide[5] (4.07 g, 20 mmol) and *n*-BuLi (21 mmol) in THF (80 ml), and the mixture was stirred for 19 hr at 30 °C and refluxed for 18 hr. After evaporation, the residue was treated with water and extracted with chloroform. Removal of the solvent from the dried extract gave a tarry mixture of **2a**, **3a**, and **4a** (by NMR), which was chromatographed on silica gel with ethyl acetate and methanol to afford **3a** (1.23 g, 20%), mp *ca.* 75 °C (lit,[6] 76.5—77.5 °C), and **2a** (0.39 g, 7.4%), mp 140—142 °C (from acetone) (lit,[2] 144—145 °C), δ_P ($CHCl_3$): −34.2 ppm. Acidification of the aqueous layer gave diphenylphosphinic acid (1.88 g, 43%).

Reaction of Acetone with 5b. A mixture of **5b**, prepared from **7**[7] (4.54 g, 21 mmol) and *n*-BuLi (23 mmol) in THF (60 ml), and acetone (4.57 g, 79 mmol) was stirred for 5 hr and refluxed for 15 hr. After a similar work-up to that with **5a**, ether was added to the residue to precipitate **4b**. The filtrate was chromatographed on silica gel with benzene and chloroform to afford **6**, oily **3b** and tarry products. On adding ether to the tarry products, **4b** precipitated, and **3b** was obtained from the filtrate.

3b: yield 2.82 g (43%). The IR and NMR spectra were in agreement with those of a sample obtained from **5b** and mesityl oxide.

4b: mp 178—179 °C (from EtOH), yield 1.36 g (23%). IR (KBr): 1705 cm^{-1} (C=O); NMR ($CDCl_3$): δ 1.45 (d, J_{PCCH} 18 Hz, 12H, 4Me), 2.81 (d, J_{PCCH} 9.2 Hz, 4H, $2CH_2$),

and 7.4—8.2 (m, 20H, 4Ph); δ_P ($CHCl_3$): −60.3 ppm.

Found: C, 68.96; H, 6.01; S, 11.43%. Calcd for $C_{33}H_{36}OP_2S_2$: C, 68.97; H, 6.31; S, 11.43%.

6: mp 151—152 °C (from EtOH), yield 0.24 g (4%). IR (KBr): 1710 (C=O), 1180 (P=O), and 540 cm^{-1} (P=S); NMR ($CDCl_3$): δ 1.35 (d, J_{PCCH} 16.2 Hz, 6H, P(O)CMe_2), 1.55 (d, J_{PCCH} 17.6 Hz, 6H, P(S)CMe_2), 2.64 (d, J_{PCCH} 8.4 Hz, 2H, CH_2 (P(O) side)), 2.83 (d, J_{PCCH} 9 Hz, 2H, CH_2 (P(S) side)), and 7.3—8.2 (m, 20H, 4Ph); δ_P ($CHCl_3$): −37.0 (P=O) and −62.0 ppm (P=S).

Found: C, 70.75; H, 6.43; S, 5.58%. Calcd for $C_{33}H_{36}O_2P_2S$: C, 70.95; H, 6.50; S, 5.74%.

Reaction of Acetone with **7**. 1) A mixture of **7** (1.49 g, 6.8 mmol) and acetone (12.76 g, 220 mmol) in THF (45 ml) was stirred for 17 hr at room temperature and then refluxed for 16 hr. Removal of THF gave white crystals (1.60 g). The NMR spectrum showed them to be a mixture of **7** and **2b**. The yield of **2b** was estimated to be 23% by means of NMR.

2) A solution of **7** (1.27 g, 5.8 mmol) in acetone (100 ml) was stirred for 19 hr at room temperature and then refluxed for 22 hr. The yield of **2b** was estimated to be 86%; δ_P ($CHCl_3$): −55.6 ppm. The melting point of the mixture was 110—117 °C (lit,[8] **2b**: 118—120 °C).

Reaction of **5b** *with Mesityl Oxide*. To a solution of **5b** prepared from **7** (4.00 g, 18 mmol) and *n*-BuLi (20 mmol) in THF (40 ml) was added mesityl oxide (2.54 g, 26 mmol) in THF (10 ml). The mixture was stirred for 35 hr at room temperature and then for 4 hr at 40 °C. Similar treatment gave a tarry product, which was chromatographed on silica gel with benzene and distilled under reduced pressure to give oily **3b** (2.30 g, 40%), bp 222 °C/1.5 mmHg. IR (neat): 1720 (C=O) and 645 cm^{-1} (P=S); NMR ($CDCl_3$): δ 1.51 (d, J_{PCCH} 18 Hz, 6H, CMe_2), 2.07 (s, 3H, COMe), 2.93 (d, J_{PCCH} 9 Hz, 2H, CH_2), and 7.3—8.3 (m, 10H, 2Ph); δ_P ($CHCl_3$): −60.7 ppm.

Found: C, 68.53; H, 6.41; S, 10.27%. Calcd for $C_{18}H_{21}OPS$: C, 68.33; H, 6.69; S, 10.13%.

Reaction of **5b** *with Bromoacetone*. To a solution of **5b** prepared from **7** (2.22 g, 10 mmol) and *n*-BuLi (13 mmol) in THF (30 ml) was added dropwise bromoacetone[9] (2.19 g, 16 mmol) in THF (20 ml) under ice-cooling, and the mixture was stirred for 16 hr at room temperature. After a similar work-up, the tarry residue was subjected to alumina dry column chromatography with chloroform. No crystals were obtained, but the following NMR spectrum showed that the main product was **8**, 1.82 g (65%). IR (neat): 1720 (C=O) and 620 cm^{-1} (P=S); NMR ($CDCl_3$): δ 2.31 (s, 3H, Me), 3.75 (d, J_{PCH} 15 Hz, 2H, CH_2), and 7.4—8.2 (m, 10H, 2Ph).

One of the authors (N. I.) thanks the Ministry of Education for financial support.

The Reaction of Several *o*-Methoxy Aromatic Aldehydes with Ethylthioxide. Novel Substitution and Condensation

Masaaki IWATA and Sakae EMOTO

The Institute of Physical and Chemical Research, Wako-shi, Saitama 351

(Received June 13, 1974)

Synopsis. The reaction of *o*- and *p*-anisaldehyde with potassium ethylthioxide in diglyme at 90—120 °C gave the corresponding demethylated products, while 2,6-dimethoxybenzaldehyde and 9-(2-*p*-cymenyl)-2-methoxy-1-anthraldehyde afforded two novel condensation and substitution products, VII and VI respectively.

Although many demethylation methods of methyl aryl ethers have been reported, few have referred to the direct demethylation of *o*-methoxy aromatic aldehydes except when Lewis acids have been used. For the establishment of "asymmetric inversion catalysts,"[1] the demethylation of a key intermediate, 9-(2-*p*-cymenyl)-2-methoxy-1-anthraldehyde (IV), was required. IV was not satisfactorily demethylated by Lewis acids, *e.g.*, $AlCl_3$, BBr_3, or BCl_3. Therefore, we attempted the indirect demethylation of methoxy-aromatic aldehydes with the ethylthioxide anion,[2] where the aldehyde group may be first blocked by ethylthioxide to form thioacetal and then regenerated by the use of cupric chloride and cupric oxide.[3] The treatment of *o*- or *p*-anisaldehyde, I or II, by this process gave a satisfactory product; however, the application of the method to some other methoxyaldehydes afforded novel results. The present paper will describe these reactions of ethylthioxide with methoxy-aromatic aldehydes.

For the treatment of methoxy-aromatic aldehydes with ethylthioxide (Process **A**), potassium ethylthioxide, prepared *in situ* by the reaction of potassium metal with ethanethiol in diglyme, was stirred with the compounds from I to V at 95—120 °C. During the reaction, the anisaldehydes, I and II, were changed to the corresponding 2- and 4-bis(ethylthio)methylphenols, which were detected on tlc spots. However, the corresponding bis(ethylthio)methyl-derivatives of 2,6-dimethoxybenzaldehyde (III) or 9-(2-*p*-cymenyl)-2-methoxy-3-anthraldehyde (V) did not give rise to any further demethylation. On the other hand, IV gave only a novel substitution product in which the methoxy group was replaced by the ethylthio group, while the aldehyde group remained. On the basis of the spectral analyses, this was shown to be 9-(2-*p*-cymenyl)-2-ethylthio-1-anthraldehyde (VI).

After the reaction had been accomplished, the mixture was acidified with 6M HCl and extracted with ethyl acetate. The organic layer was dried, and the solvents were evaporated under reduced pressure. The residue was then used in the next reaction.

To regenerate the aldehyde group, (Process **B**), the ethylthio compound described above was refluxed in aqueous acetone in the presence of cupric chloride and cupric oxide.[3] By this process, the bis(ethylthio)-methyl group was converted quantitatively to the aldehyde group in the cases of I, II, and V. However, the bis(ethylthio)methyl derivative of III was condensed with acetone to form (*E*)-2,6-dimethoxybenzalacetone (VII). VI was stable under Process **B**. The results obtained after Processes **A** and **B** are collected in Table 1.

TABLE 1. RESULTS OF THE REACTION OF METHOXY-AROMATIC ALDEHYDES WITH ETHYLTHIOXIDE FOLLOWED BY THEIR TREATMENTS WITH CUPRIC CHLORIDE AND CUPRIC OXIDE IN ACETONE

Starting material	Product	Fate of methoxy[a]	Yield (%)
I	Salicylaldehyde	A	52[b]
II	4-Hydroxybenzaldehyde	A	43[b]
III	(VII)	B	32[b]
IV	(VI)	C	71[b]
V	9-(2-*p*-Cymenyl)-2-methoxy-3-bis(ethylthio)methylanthracene	B	81[c]

a) A. demethylation B. survival C. substitution b) total yield after the processes **A** and **B**. c) yield after the process **A**. The product was converted to the starting material by the process **B**.

In order to establish which, the formation of thioacetal or its demethylation, is first, several methoxy-aromatics were treated with the same reagents as in Process **A**. None of the substances, anisole, *m*-dimethoxybenzene, and 9-(2-*p*-cymenyl)-2-methoxyanthracene, was demethylated or substituted by the ethylthio group, and the starting materials were recovered. Therefore, it may be deduced that the formation of thioacetal precedes demethylation in I, II, III, and V. The abnormal reactivity of the thioacetals of III and V can be explained by the steric requirement and by the potential reactivity of the anthracene derivative to ethylthioxide, respectively. Since VII was prepared directly by the reaction of III with acetone in the presence of cupric chloride, VII is assumed to be formed after the regeneration of the aldehyde group from the bis(ethylthio)methyl group. As regards the condensation mechanism and the general reaction, subsequent works are undertaken.

The novel direct substitution of a methoxy group by

an ethylthio group in IV may be caused by the non-coplanarity between the aldehyde group and the aromatic ring;[1] it is supported by the concept of symbiosis. According to the HSAB principle,[4] the ethylthioxide anion is a soft base and the aryl cation is a soft acid. Therefore, the formation of VI is symbiotically more favored than the demethylation of IV. The problem remained to discover why demethylation occurs with the aid of ethylthioxide, as may be seen in the cases of I, II, and the compounds cited in Ref. 2.

Experimental

The melting points are uncorrected. The IR spectra were recorded on a Shimadzu IR-27 instrument. The NMR spectra were obtained using a Varian HA-100D spectrometer, with TMS as an internal standard. The mass spectra and the exact mass measurements were performed with a Model JMS-O1SG instrument (Japan Electron Optics Laboratory Co.). Merck Art. 7734 was used for the preparative separation of products on a silica gel column by elution chromatography, and Wakogel B-5 UA, for the thin-layer chromatography.

The starting materials, *o*- and *p*-anisaldehydes, (I) and (II), were commercially available. The compounds from III to V were prepared by a previously-reproted method.[1]

The Protection of the Aldehyde Group and Demethylation or Substitution (Process A). General Procedure. Potassium (0.03 mol) was added to a cooled solution of excess amounts of ethanethiol (10—15 ml) and 20 ml of diglyme to form, *in situ*, ethylthioxide. After the complete dissolution of the potassium metal, 0.01 mol of methoxy-aldehyde was added to the solution, after which the mixture was heated with gentle stirring at 95—110 °C for 20—24 hr. The mixture was then acidified with 50 ml of water containing a suitable amount of 6M HCl and extracted twice with 50 ml portions of ethyl acetate. The organic layer was then dried over anhydrous Na_2SO_4, and the solvents were evaporated under reduced pressure. The residue was used in the next reaction.

The Regeneration of the Aldehyde Group by the Deprotection of the Ethylthio Group (Process B). General Procedure. The crude residue was refluxed with cupric chloride (2 mol equiv.) and cupric oxide (4 mol equiv.) in 50 ml of aq. 99% acetone for 1—1.5 hr.[3] After the usual work-up, the residue was chromatographed on a silica gel column to give the products.

The products after the successive treatment of *o*- and *p*-anisaldehydes by Processes **A** and **B** were identified as salicyladehyde and 4-hydroxybenzaldehyde respectively; their structures were determined by a comparison of their spectral data, their behavior on tlc, and their melting points with those of authentic samples.

The successive treatments of 2,6-dimethoxybenzaldehyde (III) with Processes **A** and **B** resulted in the formation of (*E*)-2,6-dimethoxybenzalacetone (VII).[5] Mp 89—91 °C. NMR (CCl_4): δ 2.26 (3H, s, $-COCH_3$), 3.88 (6H, s, $-OCH_3$), 6.49 (2H, d, $J_{3,4}=8.4$ Hz, $C_{3,5}$–H), 6.97 (1H, d, $J_{\alpha,\beta}=16.6$ Hz, C_α–H), 7.18 (1H, d, $J_{3,4}=8.4$ Hz, C_4–H), and 7.77 (1H, d, $J_{\alpha,\beta}=16.6$ Hz, C_β–H) ppm.

The successive treatments of 9-(2-*p*-cymenyl)-2-methoxy-1-anthraldehyde (IV) by Processes **A** and **B** gave 9-(2-*p*-cymenyl)-2-ethylthio-1-anthraldehyde (VI) in a 71% yield; it was a yellow viscous liquid. VI was unstable on exposure to air, and it was difficult to make the elemental analyses coincide. The exact mass measurement: Found (for a parent peak at *m/e* 398) 398.16724. Calcd for $C_{27}H_{26}OS$: 398.17048. IR (neat): $\nu_{C=O}$ 1668 cm^{-1}. NMR (CCl_4): δ 1.27 (6H, d, $J=7.0$ Hz, $-CH(\underline{CH_3})_2$), 1.28 (3H, t, $J=7.0$ Hz, $-CH_2-\underline{CH_3}$), 1.89 (3H, s, Ar–$\underline{CH_3}$), 2.88 (2H, quar, $J=7.0$ Hz, $-\underline{CH_2}-CH_3$), 2.90 (1H, quin, $J=7.0$ Hz, $-\underline{CH}(CH_3)_2$), 7.01 (1H, broad s, C_2'–H), 7.42 (1H, d, $J=9.0$ Hz, C_3–H), 7.93 (1H, d, $J=9.0$ Hz, C_4–H), 8.36 (1H, s, C_{10}–H), and 9.39 (1H, s, –CHO) ppm.

The treatment of 9-(2-*p*-cymenyl)-2-methoxy-3-anthraldehyde (V) by Process **A** produced 9-(2-*p*-cymenyl)-2-methoxy-3-bis(ethylthio)methylanthracene in an 81% yield; it was a fluorescent viscous pale green liquid. It was unstable on exposure to air and it was difficult to make the elemental analyses coincide. However, the structure was confirmed by spectral measurements of the crude sample. NMR (CCl_4): δ 1.24 (6H, t, $J=6.6$ Hz, $-CH_2-\underline{CH_3}$), 1.30 (6H, d, $J=7.8$ Hz, $-CH(\underline{CH_3})_2$), 1.85 (3H, s, Ar–$\underline{CH_3}$), 3.68 (3H, s, $-OCH_3$), 5.44 (1H, s, S–$\underline{CH}$–S), 6.58 (1H, s, C_1–H), 7.06 (1H, broad s, C_2'–H), 8.13 (1H, s, C_4–H), and 8.34 (1H, s, C_{10}–H) ppm. In addition, when this product was treated with the reagents of Process **B**, V was recovered in a quantitative yield.

The author wishes to thank Mr. Jun Uzawa and Mrs. Tamiko Chijimatsu for their NMR spectral measurements, and the staff of the Organic Microanalysis Laboratory in this Institute for their elemental analyses. This study was supported in part by a Grant for Life Science from this Institute.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 47 (11), 2909—2910 (1974)

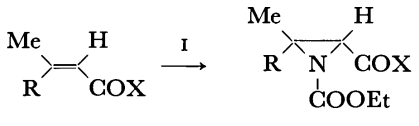
The Reaction of Ethyl Azidoformate with Electron Deficient Olefins and the Thermal Ring Opening of the Resulting Aziridines.

Tamejiro HIYAMA, Hiroaki TAGUCHI, and Hitosi NOZAKI
Department of Industrial Chemistry, Kyoto University, Yoshida, Kyoto 606

(Received July 10, 1974)

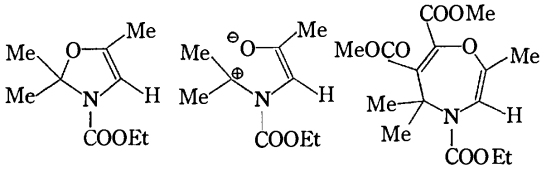
Synopsis. Thermal or photochemical decomposition of ethyl azidoformate in mesityl oxide or in methyl crotonate afforded the corresponding aziridines. Thermal C–C bond cleavage of aziridine-1-carboxylates thus obtained is described.

In continuation of the investigation on the reaction of ethyl azidoformate (I) with carbonyl compounds[1] we have examined the thermal and photochemical decomposition of I in mesityl oxide (IIa) or methyl crotonate (IIb) as a solvent.



IIa R=X=Me IIIa R=X=Me
b R=H, M=OMe b R=H, X=OMe

The azide I solutions in IIa or IIb were irradiated with a mercury lamp. When nitrogen evolution had ceased, the solvent was evaporated *in vacuo* and the residue was distilled to afford the adduct IIIa or IIIb. Thermal decomposition of I in IIa or IIb resulted in the improvement of the yields. Both photolysis and thermolysis gave the *trans* isomer of IIIb exclusively.[2,3] In these reactions none of the products arising from carbonyl attack of I on II has been obtained. The reaction discloses a new route to aziridine-2-carboxylic acids, which are useful intermediates in the preparation of β-hydroxyvaline[4] and β-lactams.[5] Photolytic or thermal decomposition of I in methyl acrylate yielded no nitrene adducts but acrylate polymer only.



IV V VI

Upon heating in refluxing *p*-xylene aziridine IIIa was isomerized to IV.[6] The intermediary azomethine ylide V[7] was characterized by successful trapping with dimethyl acetylenedicarboxylate, which afforded the cycloadduct VI. The structure VI was confirmed spectrometrically (Experimental). The well-established mode of azomethine ylide cycloaddition[8] should give rise to 2,5-dihydropyrroles, which were absent among products of the present thermolysis. The apparently unusual behavior of V is ascribed to the presence of ethoxycarbonyl group on the nitrogen atom instead of the alkyl or aryl group of the recorded cases.[8,9]

The carbon-carbon double bond in II is thus cleft smoothly in the sequence of reactions.

Experimental[10]

Thermolysis of Ethyl Azidoformate in Mesityl Oxide. Ethyl azidoformate (3.0 g, 26 mmol) in mesityl oxide (15 ml) was added drop by drop to mesityl oxide (45 ml) at 130 °C under a nitrogen atmosphere. After the nitrogen evolution having ceased the excess of mesityl oxide was recovered *in vacuo*. Distillation of the residue afforded ethyl 2-acetyl-3,3-dimethylaziridine-1-carboxylate (IIIa) (2.7 g, 56% yield). Bp 73 °C/3 mmHg; IR (neat): 1725, 1365, 1305, 1260, 1240, 1176, 1096, 800 cm^{-1}; NMR (CCl_4): δ 1.24 (s, 3H), 1.27 (t, J=7 Hz, 3H), 1.34 (s, 3H), 2.14 (s, 3H), 2.75 (s, 1H), 4.07 (q, J=7 Hz, 2H); MS: *m/e* (relative abundance) 185 (M^+, 7), 170 (23), 112 (35), 98 (61), 70 (60), 43 (100); Found: C, 58.5; H, 8.3; N, 7.3%. Calcd for $C_9H_{15}NO_3$: C, 58.4; H, 8.2; N, 7.6%.

Photolysis of I in IIa. The azide I (1.00 g) was dissolved in IIa (10 ml) in a quartz tube. The solution was degassed by bubbling nitrogen gas for *ca.* 2 hr and irradiated with a 200 W high-pressure mercury lamp until nitrogen evolution ceased (2 days). Work-up yielded IIIa (0.64 g, 39% yield).

Thermolysis of I in Methyl Crotonate (IIb). Ethyl azidoformate (0.45 g, 3.9 mmol) was decomposed in methyl crotonate (9 ml) at 120 °C. Distillatory work-up gave ethyl 2-methoxycarbonyl-3-methylaziridine-1-carboxylate (IIIb) (0.53 g, 72% yield). Bp 71 °C/3 mmHg; IR (neat): 1752, 1732, 1445, 1332, 1300, 1217, 1194, 795 cm^{-1}; NMR (CCl_4): δ 1.23 (t, 3H), 1.32 (d, J=3 Hz, 3H), 2.70 (s, 1H), 2.73 (q, J=3 Hz, 1H), 3.74 (s, 3H), 4.11 (q, 2H); MS: *m/e* (relative abundance) 187 (M^+, 13), 155 (20), 114 (38), 83 (55), 59 (100); Found: C, 51.1; H, 7.1; N, 7.5%. Calcd for $C_8H_{13}NO_4$: C, 51.3; H, 7.0; N, 7.5%.

Photochemical procedure performed similarly as described for IIIa gave IIIb in 70% yield.

Thermal Isomerization of IIIa. The aziridine IIIa (198 mg, 1.1 mmol) was dissolved in *p*-xylene (10 ml) and the solution heated to reflux for 2 hr under a nitrogen atmosphere. Concentration *in vacuo*, followed by preparative tlc of the residue (silica gel, benzene, R_f 0.6), gave 3-ethoxycarbonyl-2,2,5-trimethyl-4-oxazoline (IV) (86 mg, 43% yield). Bp 90 °C (bath temp.)/3 mmHg; IR (neat): 1700, 1635, 1420, 1215, 1070, 844, 750, 672 cm^{-1}; NMR (CCl_4): δ 1.25 (t, 3H), 1.63 (s, 6H), 1.76 (d, J=1.2 Hz, 3H), 4.07 (q, 2H), 5.80 (q, J=1.2 Hz, 1H); MS: *m/e* (relative abundance) 185 (M^+, 15), 174 (16), 112 (20), 73 (100), 70 (57); Found: C, 58.1; H, 8.1; N, 7.4%. Calcd for $C_9H_{15}NO_3$: C, 58.4; H, 8.2; N, 7.6%.

Reaction of IIIa with Dimethyl Acetylenedicarboxylate. A mixture of IIIa (525 mg, 2.84 mmol) and dimethyl acetylenedicarboxylate (412 mg, 2.90 mmol) was dissolved in *p*-xylene (2 ml) and the solution heated to reflux for 15 hr. Work-up and the subsequent preparative tlc (silica gel, benzene, R_f 0.2) gave 4-ethoxycarbonyl-6,7-dimethoxycarbonyl-2,5,5-trimethyl-4,5-dihydro-1,4-oxazepine (VI) (832 mg, 89% yield). Bp 150 °C (bath temp.)/0.1 mmHg; IR (neat): 1720, 1649, 1436, 1378, 1336, 1237, 1112 cm^{-1}; NMR (CCl_4): δ 1.25 (t, 3H), 1.52 (s, 3H), 1.58 (d, J=1.2 Hz, 3H), 1.60 (s, 3H),

3.74 (s, 3H), 3.75 (s, 3H), 4.04 (q, 2H), 4.70 (q, $J=1.2$ Hz, 1H); MS: *m/e* (relative abundance) 327 (M^+, 5), 312 (13), 270 (4), 238 (14), 198 (21), 166 (100), 119 (12), 116 (3), 98 (13); Found: C, 54.8; H, 6.5; N, 4.2%. Calcd for $C_{15}H_{21}NO_7$: C, 55.0; H, 6.5; N, 4.3%.

The authors are indebted to Dr. Shinsaku Fujita for his valuable discussion. Financial support from the Ministry of Education, the Japanese Government, is acknowledged with pleasure.

Optical Resolution and Configuration of *cis*-β-Phenylglycidic Acid[1)]

Kaoru HARADA and Yousuke NAKAJIMA

Institute for Molecular and Cellular Evolution, Department of Chemistry, University of Miami, Coral Gables, Florida 33134 U.S.A.

(Received March 18, 1974)

Synopsis. DL-*cis*-β-phenylglycidic acid was resolved using (−)-ephedrine. The configurations of α- and β-carbons of the resolved *cis*-(+)-glycidic acid were determined by oxydative and hydrogenolytic reactions.

The chemistry of epoxide has been studied extensively. Reviews have been presented in several articles.[2,3)] Darzens' reaction in the synthesis of glycidic acids has been reviewed.[4)] Several ammonolysis and aminolysis reactions of glycidic acids have been reported.[5-14)]

In previous studies from this laboratory, racemic *trans*-2,3-epoxy-β-phenylpropionic acid,[15)] *trans*-2,3-epoxybutyric acid,[16)] and *trans*-2,3-epoxysuccinic acid[17)] were optically resolved and their absolute configurations were determined.

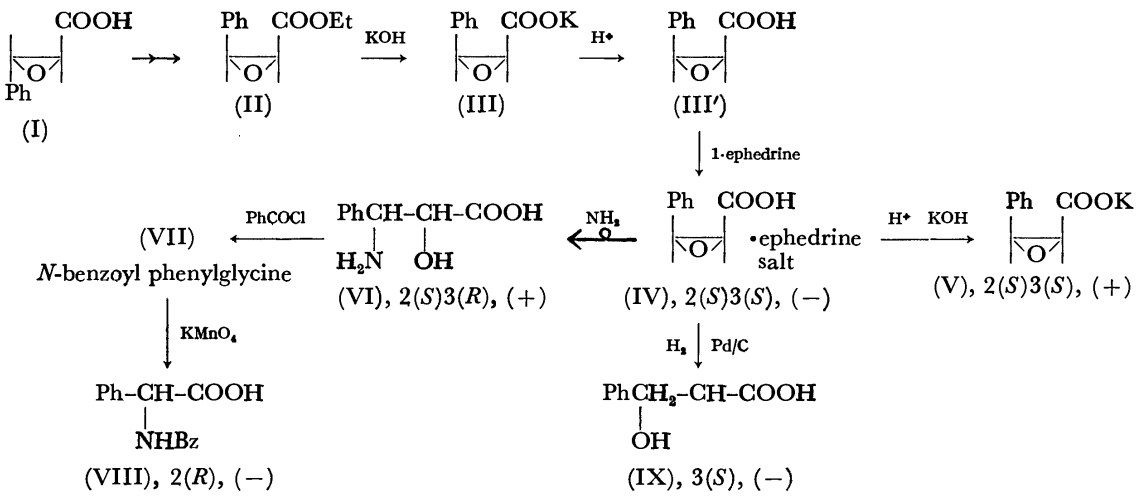
In the present study, *cis*-β-phenylglycidic acid (II) was prepared from the corresponding *trans*-β-phenylglycidic acid (I) [18)] and the *cis*-glycidic acid was subjected to optical resolution. The phenylglycidic acid is an unstable compound in the free state and it decarboxylates easily to form phenylacetaldehyde at room temperature. However, by the use of rapid procedures under cold conditions, the resolution of the *cis*-glycidic acid was carried out without difficulty. The racemic *cis*-glycidic acid (III′) was resolved using (−)-ephedrine. The crystallized glycidic acid-(−)-ephedrine salt (IV) shows levorotatory $[\alpha]_D^{25}$ −27°. From this salt, optically active *cis*-phenylglycidic acid was precipitated as a potassium salt (V). The potassium salt of the *cis*-phenylglycidic acid (V) showed dextrotatory $[\alpha]_D^{25}$ +4.4°. The diastereomeric *cis*-(−)-glycidic acid-(−)-ephedrine salt was syrupy and could not be crystallized. The resolved *cis*-(+)-glycidic acid was treated with aqueous ammonia. Paper chromatography of the ammonolysis products using Shaw-Fox' solvent[19)] and the results obtained by automatic amino acid analysis (Phoenix K-5000), indicated that the product was predominantly phenylisoserine (VI). The presence of a small amount of *threo*-phenylserine was confirmed in the reaction mixture by paper chromatography[19)] and by amino acid analysis.

The phenylisoserine (VI) was benzoylated and the resulting *N*-benzoyl phenylisoserine (VII) was oxidized with potassium permanganate.[15)] (*R*)-(−)-*N*-Benzoylphenylglycine (VIII) ($[\alpha]_D^{25}$ −119.3°) was obtained. Therefore, the configuration of the β-carbon of the phenylisoserine (VI) is (*R*). On the other hand, resolved *cis*-(+)-glycidic acid (IV) was hydrogenolyzed to convert it to (*S*)-(−)-α-hydroxy-β-phenylpropionic acid (IX). The results indicate that the configuration of the α-carbon of the *cis*-(+)-glycidic (V) is (*S*). These results obtained by the use of *cis*-(+)-glycidic acid, together with the consideration of the S_N2-type nucleophilic substitution of the β-carbon of the glycidic acid with ammonia, indicate that the configuration of the resolved (+)-glycidic acid (V) would be 2(*S*), 3(*S*), respectively. The reaction processes are summarized in Scheme 1.

Experimental

Ethyl (±)-cis-β-Phenylglycidate (II). The *cis*-glycidic acid ester (II) was prepared from ethyl *trans*-β-phenylglycidate (I) by the method described in the literature.[18)] The compound (II) was gas chromatographically pure and the retention time was earlier than that of *trans*-β-phenylglycidate. bp 122—125 °C/4.2 mmHg.

Potassium cis-β-Phenylglycidate (III). The compound (II) (10.0 g) in 20 ml of absolute ethanol was added slowly to a solution of potassium hydroxide (5.0 g) in 30 ml of absolute ethanol under cooling. The agitation was continued



Scheme 1

for 3 hr. The precipitated potassium salt was filtered and washed with ethanol repeatedly. Yield, 9.4 g, mp 191—193 °C (decomp.).

Optical Resolution of cis-*β-Phenylglycidic Acid (III')*. Potassium β-phenylglycidate (III) (8.3 g) was dissolved in 60 ml of water. Crushed ice and 40 ml of ether were added to the solution. To this mixture, 40 ml of 1 M hydrochloric acid was added and the liberated free glycidic acid was extracted with ether. Two additional ether extractions (40 ml×2) were carried out. The combined ether solution was dried with anhydrous sodium sulfate. To the dried ether solution, 6.78 g of (−)-ephedrine in 20 ml of ether was added. The mixture was kept at room temperature overnight. The resulting salt seemed to be amorphous; however, crystallization took place. After evaporation of ether, the syrupy residue which contained crystalline salt was digested with 30 ml of acetone and filtered. White crystals (IV) were obtained, yield 3.45 g; mp 138—140 °C. This was recrystallized from ethanol. Yield, 3.0 g; mp 145–146 °C, $[\alpha]_D^{25}$ −27.2° (*c* 2.77, ethanol). Additional crystals (1.18 g) were obtained from the salt mixture.

The resolved (−)-salt (1.0 g) in 15 ml of water was acidified to pH 2 with 6 M hydrochloric acid under ice cooling. The liberated free glycidic acid was extracted with ether. The ether solution was dried with anhydrous sodium sulfate and the solvent was evaporated. The residual oil was dissolved in 5 ml of ethanol. To this, potassium hydroxide (0.17 g) in 1 ml of ethanol was added. The precipitated potassium salt of optically active *cis*-phenylglycidic acid (V) was collected by filtration. Yield, 150 mg; mp 203—204 °C (decomp.), $[\alpha]_D^{25}$ +4.4° (*c* 0.98, H_2O).

Ammonolysis of (+)-β-Phenylglycidic Acid. The crystallized (+)-β-phenylglycidic acid-(−)-ephedrine salt (IV, 3.0 g) was dissolved in 70 ml of concentrated aqueous ammonia. The solution was kept at room temperature for 6 days. The reaction mixture was evaporated to dryness under reduced pressure. Paper chromatography using Shaw-Fox solvent[19] indicates that the major product is *threo*-β-phenylisoserine (R_f 0.33). A small amount of *threo*-β-phenylserine (R_f 0.53) was identified. Amino acid analysis showed that the ratio of phenylisoserine and phenylserine is 29.2: 1. The evaporated reaction mixture was dissolved in a minimum amount of water and the pH was adjusted to 6 using 6 M hydrochloric acid. The precipitated (+)-*threo*-β-phenylisoserine (VI) was recrystallized from water. The VI was paper chromatographically pure. Yield, 1.1 g; mp 256—257 °C (decomp.); $[\alpha]_D^{25}$ +14.9° (*c* 0.737, 6 M HCl).

Found: C, 59.41; H, 6.17; N, 7.65%. Calcd for $C_9H_{11}NO_3$: C, 59.66; H, 6.12; N, 7.73%.

It has been known that Shaw-Fox paper chromatographic solvent[19] resolves diastereomers of threonine and phenylserine. This study indicates that the solvent also resolve diastereomers of phenylisoserine (*threo*-phenylisoserine, R_f 0.33; *erythro*-phenylisoserine, R_f 0.26).

threo-(+)-N-*Benzoylphenylisoserine (VII).* *threo*-(+)-Phenylisoserine (VI) was benzoylated by the usual Schotten-Baumann procedure. The yield was 65% after recrystallization from ethanol-water (3: 7). mp 168—169 °C, $[\alpha]_D^{25}$ +36.5° (*c* 1.45 EtOH).

Found: C, 67.35; H, 5.26; N, 4.79%. Calcd for $C_{16}H_{15}NO_4$: C, 67.36; H, 5.30; N, 4.91%.

Oxidation of N-*Benzoyl*-threo-(+)-*phenylisoserine (VII).* A weight of 0.85 g of VII was dissolved in a mixture of 3 ml of 1 M sodium hydroxide and 5 ml of water. To this, 0.948 g of powdered potassium permanganate was added slowly in a period of 35 min with stirring and cooling. After an additional 15 min of stirring, 0.8 g of sodium sulfite was added and the reaction mixture was stirred for 10 min. The reaction product was treated in a similar way as described in an earlier study.[15] Crude *N*-benzoylphenylglycine (VIII) (200 mg) was obtained. mp 178—182 °C. This was recrystallized from a mixed solvent of water and ethanol (4: 6). Yield, 120 mg; mp 196.5—198 °C; $[\alpha]_D^{25}$ −119.3° (*c* 0.845, ethanol).

Found: C, 70.62; H, 5.15; N, 5.43%. Calcd for $C_{15}H_{13}O_3N$: C, 70.58; H, 5.13; N, 5.49%.

(S)-(−)-α-*Hydroxyphenylpropionic Acid (IX).* The crystallized optically active phenylglycidic acid (−)-ephedrine salt (IV, 1.0 g) in 25 ml of water was hydrogenated with 1.0 g of 5% palladium on charcoal for 2 hr at room temperature. From the reaction mixture, 380 mg of crude (*S*)-(−)-α-hydroxy-β-phenylpropionic acid (IX) was obtained. mp 120—122 °C. This was recrystallized from benzene. Yield, 340 g, mp 123—124 °C; $[\alpha]_D^{25}$ −20.7° (*c* 2.11, H_2O).

Found: C, 65.26; H, 6.17%. Calcd for $C_9H_{10}O_3$: C, 65.05; H, 6.07%.

The Tautomerism of 2-Amino-5-nitrosotropone

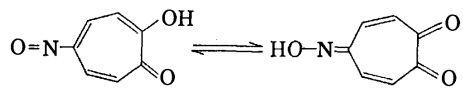
Kimiaki IMAFUKU, Yasuyoshi TAKATA,* and Hisashi MATSUMURA

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami, Kumamoto 860

(Received May 13, 1974)

Synopsis. It was confirmed that 2-amino-5-nitrosotropone (II) exists in its tautomeric form (IIb) by the measurement of its dissociation constant and UV spectra.

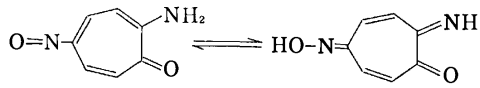
Previously, it was established[1] that the methylation of 5-nitrosotropolone (I) with diazomethane does not give its methyl ether, while its acetylation and benzoylation afforded, respectively, the corresponding acetate and benzoate of tropoquinonemonoxime (Ib).



Ia Ib

In the course of measurements[2] of the dissociation constants of several 4-, 5-, and 6-substituted 2-aminotropones, 2-amino-5-nitrosotropone (II) was found to show an extremely larger pK_a value (5.68) than those of other 2-aminotropones.

In order to reveal these differences between 2-amino-5-nitrosotropone (II) and other 2-aminotropones, we assumed its tautomeric form (IIb), which is similar to Ib, and compared II with 5-nitrosotropolone (I).



IIa IIb

Experimental

Materials. 5-Nitrosotropolone (I) was prepared by the nitrosation of tropolone,[1,3] while 2-amino-5-nitrosotropone (II) was obtained by its ammonolysis.[1]

Measurement of Dissociation Constants. The dissociation constants were measured spectrophotometrically in 50% aqueous methanol at 20 °C using the method of Albert and Serjeant.[4]

The absorption spectra were taken on a Hitachi spectrophotometer (EPS-3T), and the pH values were measured by means of a Hitachi-Horiba pH meter (F-5).

Results and Discussion

The dissociation constants are listed in Table 1. In spite of the strong electron-withdrawing effect of the nitroso group, the pK_a value of 2-amino-5-nitrosotropone (II) is remarkably larger than those of other 2-aminotropones [pK_a=2.63 (5-methyl) to 1.34 (5-chloro)][2] and is close to the pK_a value of 5-nitrosotropolone (I).

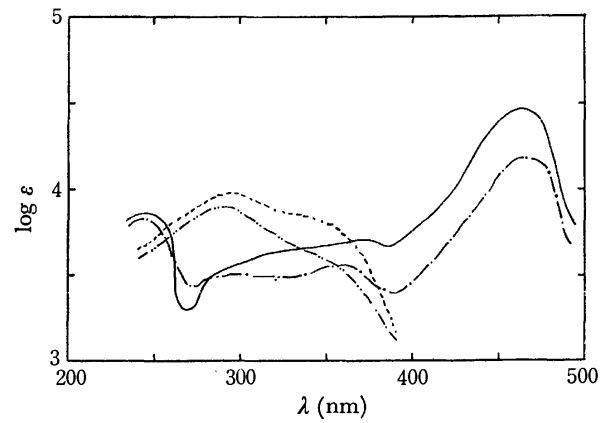


Fig. 1. The UV spectra of 5-nitroso compounds
I: —— pH 7.30, ------ pH 1.31
II: ····· pH 7.52, -·-· pH 1.89

Table 1. Dissociation constants

Compound	pK_a
I	5.63
II	5.68

Furthermore, the two 5-nitroso-substituted compounds (I and II) show very similar spectral patterns in both acidic and basic media, as is shown in Fig. 1.

Consequently, it was revealed that 2-amino-5-nitrosotropone (II) exists also in the tautomeric structure (IIb). It is thought that the pK_a values of I and II are due to the dissociation of the OH group in the oxime form.

In addition, it is known[5] that *p*-nitrosophenol, which exists in similar tautomers, shows a lower pK_a value (6.36) than do other phenols [pK_a=10.26 (*p*-methyl) to 7.15 (*p*-chloro)].

The authors wish to thank Professor Tetsuo Nozoe and the Sankyo Co., Ltd., for the supply of tropolone.

The Application of an MC-SCF Theory to Organic Chemical Reactions

Osamu KIKUCHI and Katsutoshi AOKI

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo 112

(Received November 24, 1973)

MC-SCF equations have been derived with the help of Segal's partition-basis-set technique; these equations can be used for the calculation of the potential curves of many organic reactions. They were applied to two typical organic reactions, and the results were compared with those obtained by CI methods. The corrections of the SCF-CI energies by the MC-SCF procedure were small for the present system.

The Hartree-Fock(HF) wavefunction describes the ground state of a normal molecule passably well, and its mixing with the excited configurations is generally small. However, the HF wavefunction is unreliable for a molecular system in which the interaction between the HF wavefunction and some excited configuration functions is very large. Such a breakdown of the HF method[1] occurs in the study of a thermally-"forbidden" reaction, during which an occupied MO crosses a vacant MO. The part of a potential curve in this region is much more unreliable than the other parts of the potential curve. Multi-configuration(MC) wavefunctions, thus, should be used so as to obtain reliable potential curves for these types of reactions. Here, the criterion of a reliable potential curve is that the potential curve has an equal reliability at all of its points.

Configuration interaction(CI) methods are easy to use, and many potential curves of these types of reactions have been obtained by CI methods.[2] MC-SCF methods have also been applied to some reactions by Basch.[3] In MC-SCF methods, the configurations to be included vary with the type of reaction and with the electronic state under consideration. The SCF equations, thus, must be derived separately for each state of each reaction. As a matter of practical convenience, it would be desirable to have MC-SCF equations which could be used for many types of reactions and many types of states. In this paper, we will consider the configurations which give the most reliable potential curves of many types of reactions, and an MC-wavefunction will be set up. Using Segal's "partition-basis-set" technique,[4] Fock-type equations will be derived for the wavefunction. These equations will then be applied to two reactions, and the results will be compared with those obtained by the CI method.

Theory

First, let us consider the configurations which give the lowest singlet potential curve whose reliability is the same at all of its points. The configurations to be included are determined from the MO correlation diagram of the reaction under consideration. Figure 1 shows two typical features of MO correlation diagrams: in the first case, (a), the crossing of an occupied MO and a vacant MO occurs during the reaction process, while in the second case, (b), the difference between their MO energies becomes small (or two MO's are degenerate) on one side of the diagram. Examples of these cases are: (a) the disrotatory process of the cycloaddition reaction of *cis*-butadiene and (b) the dimerization of the methyl radical to form ethane. In the case of (a), the lowest closed-shell configuration changes near the crossing region. In this region, the mixing of the lower configurations, $(\cdots\phi_i^2\phi_k^0)$ and $(\cdots\phi_k^2\phi_i^0)$, is very large, and neither one of them separately, but a linear combination of them, can be a good approximation to the wavefunction of the lowest state. For the reaction whose MO correlation diagram has the feature (a) or (b) of Fig. 1, the lowest singlet potential curve should be described by the MC-wavefunction including the $\psi=(\cdots\phi_i^2\phi_k^0)$ and $\psi=(\cdots\phi_k^2\phi_i^0)$ configurations, and $\psi=(\cdots\phi_i^1\phi_k^1)$ one, if nescessary.

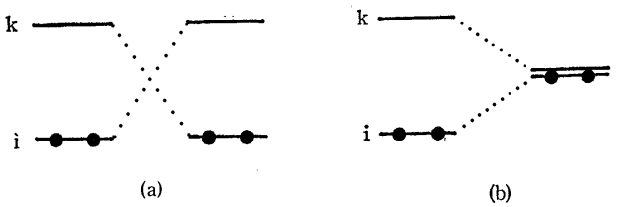

Fig. 1. Typical features appearing in MO correlation diagrams.
(a): Reaction process during which the crossing of an occupied MO and a vacant MO occurs.
(b): Reaction process at one side of which the difference between an occupied MO energy and a vacant MO energy becomes small.

There are actually many chemical processes whose MO correlation diagrams are more complex. In order to obtain MC-SCF equations which can be used for many reactions, two occupied MO's (i and j) and two vacant MO's (k and l) were selected, and all the singly- and doubly-excited singlet configurations derived from these four orbitals were taken into account. The lowest and some excited singlet potential curves of many chemical reactions can be described by this wavefunction. Thus, the MC-wavefunction was written as:

$$\begin{aligned}{}^1\Phi = {} & C_0\Psi_0 + C_1\Psi_i^k + C_2\Psi_i^l + C_3\Psi_j^k + C_4\Psi_j^l + C_5\Psi_{ii}^{kk} \\ & + C_6\Psi_{ii}^{ll} + C_7\Psi_{jj}^{kk} + C_8\Psi_{jj}^{ll} + C_9\Psi_{ii}^{kl} + C_{10}\Psi_{jj}^{kl} \\ & + C_{11}\Psi_{ij}^{kk} + C_{12}\Psi_{ij}^{ll} + C_{13}\Psi_{ij}^{kl}(1) + C_{14}\Psi_{ij}^{kl}(2) \end{aligned} \quad [1]$$

with

$$\sum_i C_i^2 = 1$$

where the configuration functions are:

$$\Psi_0 = |\ldots i\bar{i}j\bar{j}|$$

$$\Psi_i^k = \frac{1}{\sqrt{2}}\{|\ldots i\bar{k}j\bar{j}| + |\ldots k\bar{i}j\bar{j}|\}$$

$$\Psi_{tt}^{kk} = |\ldots k\bar{k}j\bar{j}|$$

$$\Psi_{tt}^{kl} = \frac{1}{\sqrt{2}}\{|\ldots k\bar{l}j\bar{j}| + |\ldots l\bar{k}j\bar{j}|\}$$

$$\Psi_{tj}^{kk} = \frac{1}{\sqrt{2}}\{|\ldots i\bar{k}k\bar{j}| + |\ldots k\bar{i}j\bar{k}|\}$$

$$\Psi_{tj}^{kl}(1) = \frac{1}{2}\{|\ldots i\bar{k}l\bar{j}| + |\ldots k\bar{i}j\bar{l}| + |\ldots\bar{i}\bar{k}jl| + |\ldots ik\bar{j}\bar{l}|\}$$

$$\Psi_{tj}^{kl}(2) = \frac{1}{2\sqrt{3}}\{2|\ldots i\bar{k}j\bar{l}| + |i\bar{k}l\bar{j}| + |\ldots k\bar{i}j\bar{l}| + 2|\ldots k\bar{i}l\bar{j}| - |\ldots\bar{i}\bar{k}jl| - |\ldots ik\bar{j}\bar{l}|\}$$

and where the others are obtained by changing the indices, i and j or/and k and l, in these configuration functions. The electronic energy of [1] is written as:

$$E_{\text{elec}} = E_g + \sum_{p,q} A_{pq}L_{pq} + \sum_{p,q,r,s} B_{pqrs}\langle pq|rs\rangle$$

where p, q, r, and s run over four orbitals, i, j, k, and l; where A_{pq} and B_{pqrs} are expressed by the configuration expansion coefficients (they are given in the Appendix). Also,

$$E_g = \sum_{t}^{\text{occ}} 2I_{tt} + \sum_{t,u}^{\text{occ}} \{2\langle tt|uu\rangle - \langle tu|ut\rangle\}$$

$$L_{rs} = I_{rs} + \sum_{t}^{\text{occ}} \{2\langle tt|rs\rangle - \langle ts|rt\rangle\}$$

$$I_{rs} = \int \phi_r^*(1)H_{\text{core}}(1)\phi_s(1)d\tau$$

$$\langle rs|tu\rangle = \int \phi_r^*(1)\phi_s(1)\frac{e^2}{r_{12}}\phi_t^*(2)\phi_u(2)d\tau$$

where t and u in the first two equations run over the doubly-occupied and i and j orbitals.

A troublesome aspect of implementing the MC-SCF formalism involves the handling of the off-diagonal Lagrangian multipliers, which insure orthonormality between open- and closed-shell orbitals of the same symmetry.[5] Segal has put forward the "partition-basis-set" technique, which simplifies the calculation of the wavefunctions of the excited states of molecules.[4] His method corresponds to a partial variational method, in which the variations of open-shell orbitals are expanded by virtual orbitals. Thus, the MO's obtained by this method are not the optimum ones.[6] However, its simplicity makes it possible to obtain many types of MC-SCF wavefunctions easily. This technique, which has been applied to the calculation of MC-SCF wavefunctions by Basch,[3] was used in the present study. The Fock-type equations obtained are:

$$F_\lambda|\phi_\lambda\rangle = \varepsilon_\lambda|\phi_\lambda\rangle \qquad (\lambda=1, 2, \ldots\ldots, i-1)$$

$$F_p|\phi_p\rangle + \sum_{q\neq p} F_{pq}|\phi_q\rangle = \varepsilon_p|\phi_p\rangle \qquad (p=i, j, k, l)$$

The second equations were converted to eigenvalue forms by rewriting the equations using the operators defined by:

$$F'_{pq} = F_{pq}|\phi_q\rangle\langle\phi_p|$$

and by adding the following quantity to both sides of the equation:

$$\sum_{q\neq p} F'^{\dagger}_{pq}|\phi_p\rangle = \sum_{q\neq p}|\phi_p\rangle\langle\phi_q|F_{qp}|\phi_p\rangle$$

The final eigenvalue forms are:

$$F_\lambda|\phi_\lambda\rangle = \varepsilon_\lambda|\phi_\lambda\rangle \qquad (\lambda=1, 2, \ldots\ldots, i-1) \qquad [3\text{-}1]$$

$$F_p|\phi_p\rangle = \varepsilon_{p'}|\phi_p\rangle \qquad (p=i, j, k, l) \qquad [3\text{-}2]$$

The operators F_λ and F_p are given by:

$$F_\lambda = H_{\text{core}} + \sum_t (2J_t - K_t) + \sum_{r,s}\frac{1}{2}A_{rs}(2f_{rs} - g_{rs})$$

$$F_p = F_{pp} + \sum_{r(\neq p)}\{F_{pr}|\phi_r\rangle\langle\phi_p| + |\phi_p\rangle\langle\phi_r|F_{rp}\}$$

$$F_{pp} = (\delta_{pi}+\delta_{pj})F_\lambda + \frac{1}{2}A_{pp}\{H_{\text{core}} + \sum_t(2J_t - K_t)\} + \sum_{r,s}(B_{pprs}f_{rs} + B_{psrp}g_{rs}) - \sum_r B_{pprp}f_{rp}$$

$$F_{pq} = \frac{1}{2}A_{pq}\{H_{\text{core}} + \sum_t(2J_t - K_t)\} + \sum_{\substack{r(\neq p,q)\\ s(\neq p,q)}} B_{pqrs}f_{rs} + \sum_{r(\neq p,q)}\{B_{pqpr}f_{pr} + B_{pqrq}f_{rq} + B_{prrq}g_{rr}\} + B_{pqqq}f_{qq} + B_{pqpq}f_{pq} \qquad (p\neq q)$$

where t runs over orbitals which are doubly occupied in the Ψ_0 configuration, and where r and s run over four orbitals, i, j, k, and l. The J_t, K_t, and H_{core} operators have their usual meanings, and the f and g operators are defined by:

$$f_{rs}(1)\phi_t(1) = \left(\int\frac{e^2}{r_{12}}\phi_r^*(2)\phi_s(2)d\tau_2\right)\phi_t(1)$$

$$g_{rs}(1)\phi_t(1) = \left(\int\frac{e^2}{r_{12}}\phi_r^*(2)\phi_t(2)d\tau_2\right)\phi_s(1)$$

$_{p}'$ is connected with the Lagrangian multiplier, ε_p, by:

$$\varepsilon_{p'} = \varepsilon_p + \sum_{r(\neq p)}\langle r|F_{rp}|p\rangle.$$

If the variation method is applied so as to minimize the E_{elec} with respect to the LCAO coefficients, $\mathbf{c}$, of

$$\phi_r = \boldsymbol{\chi}\mathbf{c}_r$$

equations equivalent to [3-1] and [3-2] are obtained.

$$\mathbf{F}_\lambda\mathbf{c}_\lambda = \mathbf{c}_\lambda\varepsilon_\lambda \qquad (\lambda=\text{inner MO's}) \qquad [4\text{-}1]$$

$$\mathbf{F}_p\mathbf{c}_p = \mathbf{c}_p\varepsilon_{p'} \qquad (p=i, j, k, l) \qquad [4\text{-}2]$$

where the matrices, $\mathbf{F}_\lambda$ and $\mathbf{F}_p$, are evaluated with the corresponding operator and the set of AO's.

The configuration expansion coefficients and the orbital expansion coefficients are determined by the following process.[3a]

(1) From an initial LCAO-MO set, the CI matrix elements, H_{ab}, are calculated, while the configuration expansion coefficients are determined from the lowest-energy solution of the secular determinant:

$$|H_{ab} - E\delta_{ab}| = 0$$

(2) From the above set of orbitals and the newly-obtained configuration expansion coefficients, the Hermitian matrices, $\mathbf{F}_\lambda$ and $\mathbf{F}_p$, of Eqs. [4] are calculated.

(3) Eq. [4-1] is solved in the usual manner to obtain the set of occupied MO's, ϕ_λ, and the set of orthogonal virtual MO's.

(4) The MO's ϕ_i, ϕ_j, ϕ_k, and ϕ_l, are successively determined by Segal's technique[4] from the virtual MO's obtained in (3).

(5) The procedure reverts to (1), and the process

is continued until the convergency of the total energy and AO bond populations is achieved.

While the excited states, as well as the ground state, can be evaluated by means of this procedure, the wavefunctions obtained by this procedure are not the optimum ones and are not correct to the first-order; that is, Brillouin's theorem does not hold for these wavefunctions.[4,6] First-order accuracy may be achieved by a CI calculation in which all the wave-functions formed by single excitations from the present MC-SCF function are included. This problem was not, however, examined in this paper.

Examples

The present MC-SCF method can be used for the calculations of the potential curves which are described by the wavefunction [1]. It was applied here to two reactions, the cycloaddition of *cis*-butadiene to form cyclobutene, and the dimerization of methylene to form ethylene. The lowest (ground-state) potential curves obtained were compared with those obtained by the CI method, in which the same approximation as in the MC-SCF method was used. The CI method is easy to use for the calculation of the potential curves of forbidden reactions. It is, thus, worth comparing the results obtained by the MC-SCF and CI methods. Semi-empirical method were used in the present applications because they are easily applicable to organic chemical reactions including rather large molecules. The INDO approximation,[7] which is one of the most widely accepted semi-empirical approximations, was used in the second example. In the first example, the MINDO/2 approximation[8] was used, since the MINDO /2-CI calculation for this reaction has already been performed.[9]

The Disrotatory Process of Cycloaddition of cis-*Butadiene to Form Cyclobutene.* The lowest singlet potential curve of this process was calculated for the ideal path, in which the molecule has C_s symmetry. The wavefunction can be described by two configurations, as was pointed out in the previous section:

$$^1\Phi = C|\ldots(5a'')^2| + C'|\ldots(7a')^2|$$

where $5a''$ and $7a'$, which correspond to the i and k orbitals in Fig. 1-(a) respectively, are anti-symmetric and symmetric with respect to the symmetry plane, which bisects the C_2-C_3 bond and is perpendicular to the carbon skeleton. The rotation angle of the CH_2 group was varied from 0°(*cis*-butadiene) to 90°(cyclobutene) in steps of 15°. The other geometrical parameters were gradually varied from those of *cis*-butadiene to those of cyclobutene. At each rotation angle, the SCF MO's of the all-valence electrons were obtained by means of the MINDO/2 method; these values were then used as the initial MO's of the MC-SCF procedure and as the basic MO's in the CI calculation. The total energy is the sum of the electronic energy and the core-repulsion energy, as calculated by means of the MINDO/2 approximation.[8]

The orbital expansion coefficients of $7a'$ and $5a''$ orbitals at $\theta=45°$ are shown in Table 1. The differences between the orbital expansion coefficients obtained by the MC-SCF method and the CI method are small. This was also observed for the orbitals at other points in the reaction process. The differences in configuration expansion coefficients between the two methods are also small (Table 2). Thus, no remarkable difference in the total energy between the two methods was observed during the process (<0.2 eV, Table 3). The overall shapes of both potential curves were similar to that obtained by a larger CI calculation in which 20 configuration functions were included.[9] Thus, a small MC-wavefunction is passable in the semi-empirical study of the present process.

The deviation of the energy obtained by the single-configuration wavefunction from that obtained by two configuration wavefunction largely depends on the rotation angle of the CH_2 group. At $\theta=45°$, the difference is 1.36 eV, which is much larger than those of normal molecules: 0.19 eV for *cis*-butadiene and 0.42 eV for cyclobutene. Thus, MC-wavefunctions should be used in the study of the forbidden reaction so as to obtain a reliable potential curve.

Dimerization of Triplet Methylene to Form Ethylene. The least-motion approach of two triplet ($^3B_1$) methylenes, or the least-motion dissociation of ethylene, was considered. It may be seen in Fig. 2 that the lowest closed-shell configuration changes from (core)$^8\sigma^2\pi^2$ to (core)$^8\sigma^2\sigma^{*2}$ during the dissociation of ethylene to methylenes. The lowest state(ground state) of methylene dimer is sufficiently described by the following configurations:[10]

(core)$^8\sigma^2\pi^2$ at $R_{cc}\sim R_0$, the value of normal ethylene,
(core)$^8\sigma^2\pi^2$ and (core)$^8\sigma^2\pi^{*2}$ at $R_{cc}\sim 2.0$ Å,
(core)$^8\sigma^2\pi^2$, (core)$^8\sigma^2\pi^{*2}$, (core)$^8\sigma^{*2}\pi^2$, (core)$^8\sigma^{*2}\pi^{*2}$, and (core)$^8\sigma\sigma^*\pi\pi^*$ at $R_{cc}>3.0$ Å,

where σ, σ^*, π, and π^* are the MO's of the D_{2h} methylene dimer. The wavefunction of the lowest state of the methylene dimer, whose C–C separation varies from R_0 to ∞, was written as:

$$^1\Phi = C_0\Psi_0 + C_5\Psi_{ii}^{kk} + C_6\Psi_{ii}^{ll} + C_7\Psi_{jj}^{kk} + C_8\Psi_{jj}^{ll} + C_{13}\Psi_{ij}^{kl}(1) + C_{14}\Psi_{ij}^{kl}(2)$$

so that the wavefunction always involves the above configurations whether the lowest closed-shell configuration is (core)$^8\sigma^2\pi^2$ or (core)$^8\sigma^2\sigma^{*2}$. The dissociation of ethylene has been studied by Basch.[3a] In his MC-SCF treatment, the first five configurations in the above wavefunction were taken into account. Thus, his wavefunction does not correctly represent the two $^3B_1$ methylenes at $R_{cc}\rightarrow\infty$.[10]

Calculations were also carried out for several C–C separations with a fixed CH_2 unit in an ideal geometry: CH=1.10 Å and ∠HCH=120°. The INDO approximation[7] was used for this process. The total energy of the lowest singlet state of the methylene dimer is shown in Table 3. The overall shape of the lowest potential curve was similar to that obtained by Basch.[3a] It may be seen from Table 3 that the difference between the single-configuration energy and the MC-SCF energy depends largely on the C-C separation. This was observed between the single-configuration energy and the CI energy calculated with 40 configuration

a) Energies obtained by single-configuration SCF method. The lowest closed-shell configuration at large C-C separation is $(\cdots\sigma^2\sigma^{*2})$ which does not contribute to the lowest singlet state of D_{2h} methylene dimer.

functions. Thus, the breakdown of the HF method in the intermediate region of the process gives a largely unreliable potential curve. The correction of the SCF-CI energy by the MC-SCF procedure was small (Table 3) in the present case, as in the previous example. This may be a result of the limited AO basis in the semi-empirical methods.

As a result, in semi-empirical all-valence electron calculations, the MC-SCF method or a rather large CI method may be sufficient to produce potential curves which remove the error originating from the HF method and which have a reliability comparable to that of the HF molecular ground state of a usual molecule.

The authors wish to express their thanks to Professor Keizo Suzuki for his helpful suggestions. The calculations were carried out by a HITAC 8800 computer at The University of Tokyo.

Appendix

A_{pq} and B_{pqrs} in Eq. (2) are expressed by the configuration expansion coefficients as follows. The others are obtained from the relations, $A_{pq}=A_{qp}$ and $B_{pqrs}=B_{qpsr}=B_{srqp}=B_{rspq}$.

$$A_{ii} = -(C_1^2 + C_2^2 + 2C_5^2 + 2C_6^2 + 2C_9^2 + C_{11}^2 + C_{12}^2 + C_{13}^2 + C_{14}^2)$$

$$A_{jj} = -(C_3^2 + C_4^2 + 2C_7^2 + 2C_8^2 + 2C_{10}^2 + C_{11}^2 + C_{12}^2 + C_{13}^2 + C_{14}^2)$$

$$A_{kk} = C_1^2 + C_3^2 + 2C_5^2 + 2C_7^2 + C_9^2 + C_{10}^2 + 2C_{11}^2 + C_{13}^2 + C_{14}^2$$

$$A_{ll} = C_2^2 + C_4^2 + 2C_6^2 + 2C_8^2 + C_9^2 + C_{10}^2 + 2C_{12}^2 + C_{13}^2 + C_{14}^2$$

$$A_{ij} = -(C_1C_3+C_2C_4+\sqrt{2}\{C_5C_{11}+C_6C_{12}+C_7C_{11}+C_8C_{12}+C_9C_{13}+C_{10}C_{13}\})$$

$$A_{kl} = C_1C_2 + C_3C_4 + \sqrt{2}\{C_5C_9+C_6C_9+C_7C_{10}+C_8C_{10}+C_{11}C_{13}+C_{12}C_{13}\}$$

$$A_{ik} = \sqrt{2}C_0C_1 + \sqrt{2}C_1C_5 + C_2C_9 + C_3C_{11} + \frac{\sqrt{2}}{2}C_4C_{13} + \frac{\sqrt{6}}{2}C_4C_{14}$$

$$A_{il} = \sqrt{2}C_0C_2 + \sqrt{2}C_2C_6 + C_1C_9 + C_4C_{12} + \frac{\sqrt{2}}{2}C_3C_{13} - \frac{\sqrt{6}}{2}C_3C_{14}$$

$$A_{jk} = \sqrt{2}C_0C_3 + \sqrt{2}C_3C_7 + C_1C_{11} + C_4C_{10} + \frac{\sqrt{2}}{2}C_2C_{13} - \frac{\sqrt{6}}{2}C_2C_{14}$$

$$A_{jl} = \sqrt{2}C_0C_4 + \sqrt{2}C_4C_8 + C_2C_{12} + C_3C_{10} + \frac{\sqrt{2}}{2}C_1C_{13} + \frac{\sqrt{6}}{2}C_1C_{14}$$

Synthesis of Methyl Isobutyl Ketone from Acetone and Hydrogen Catalyzed by Palladium Supported on Zirconium Phosphate

Yoshiaki WATANABE, Yoshito MATSUMURA, Yusuke IZUMI, and Yukio MIZUTANI
Tokuyama Soda Co., Ltd., Mikage-cho, Tokuyama, Yamaguchi 745
(Received December 17, 1973)

The one-step synthesis of methylisobutyl ketone from acetone and hydrogen was investigated by using palladium supported on zirconium phosphate, a bifunctional catalyst. Effects of reaction variables on both the conversion of acetone and the selectivity of methylisobutyl ketone were examined. The experiments were carried out with a continuous flow unit at 110—140 °C and 7—25 kg/cm² over a range of liquid hourly space velocity of acetone for 2—15 hr^{-1} with a mole ratio of hydrogen to acetone in the range 0.2—1.45. Under these conditions, the conversion of acetone was 20—40%, the selectivity of methylisobutyl ketone being as much 90—97 mol%. It is suggested that the one-step reaction proceeds *via* a consecutive mechanism.

Interest has been shown in the one-step direct synthesis of methylisobutyl ketone from acetone and hydrogen.

$$2CH_3COCH_3 + H_2 \rightarrow (CH_3)_2CHCH_2COCH_3 + H_2O \quad (1)$$

A number of bifunctional catalysts effective for both condensation and hydrogenation have been proposed for direct synthesis.[1,2] However, such catalysts containing basic substances for aldolization of acetone as KOH–Al_2O_3–Pd and SiO_2–MgO–Pd were found to be impractical because of low yield of methylisobutyl ketone.

Most commercial methods for producing methylisobutyl ketone are based on the conventional three-stage process; the aldol condensation of acetone to form diacetone alcohol catalyzed by a base, the dehydration of the alcohol to mesityl oxide with an acid, and the hydrogenation of the unsaturated ketone to methylisobutylketone with nickel or copper chromite catalyst.

Recently, some bifunctional catalysts containing palladium and cation-exchange resins have been reported for the selective one-step synthesis of methylisobutyl ketone.[3-8]

It was found that zirconium phosphate, an inorganic cation-exchanger, shows an excellent catalytic activity for the selective condensation of acetone to mesityl oxide.[9]

Attempts were made to prepare a bifunctional catalyst suitable for the selective one-step conversion of acetone and hydrogen into methylisobutyl ketone by finely dispersing palladium metal onto zirconium phosphate by means of ion-exchange technique.

The present paper is concerned with the general characteristic of the one-step synthesis of methylisobutyl ketone with the new catalyst.

Experimental

Catalyst Preparation. Palladium chloride (0.5 g) was added to an aqueous solution of zirconium oxychloride ($ZrOCl_2 \cdot 8H_2O$ 97 g/H_2O 3 l) and dissolved by heating. 33 g of phosphoric acid (85 vol%) was diluted with 3 litres of water. The former solution was added to the latter under stirring at room temperature for half an hour. After the reaction, the pH of the reaction mixture was adjusted to 5.0 with ammonia (14%). Stirring was continued for 4 hr, and the reaction mixture was allowed to stand for 24 hr. The resulting precipitate was then filtered, washed with water and dried at 110 °C. The dried gel obtained was crushed into 16—24 mesh particles and calcined at 400 °C for 8 hr in a stream of hydrogen. The palladium content of the resulting catalyst was 0.5 wt.%.

Apparatus and Procedure. Experiments were carried out with a continuous flow unit (Fig. 1). A stainless steel tube, 500 mm in length and 10 mm in inside diameter, was used as a reactor. The reactor was heated electrically with heaters separately controlled. Temperatures at the reaction zone were measured with thermocouples inserted in a thermowell extending longitudinally through the center of the reactor.

The catalyst in the form of 16—24 mesh particles (15 ml) was packed in the middle of the reactor. The remainder of the reactor was filled with porcelain chips and served as a preheating section. The chips were previously confirmed to have no appreciable catalytic activity.

After temperature and pressure had reached difinite levels (usually after 2 hr), the liquid products were collected in a receiver held in a methanol-dry ice bath and analyzed by

means of gas chromatography.

The operating conditions were so chosen that acetone was always kept in the liquid state in the reactor. The major by-products were isopropyl alcohol, mesityl oxide and diisobutyl ketone. Other by-products such as hexanes and higher ketones were found in trace amount.

The conversion of acetone and the selectivity of each component were defined by the following equations:

$$\% \text{ conversion} = \frac{y_{IPA} + 2(y_{MIBK} + y_{MO}) + 3y_{DIBK}}{y_A + y_{IPA} + 2(y_{MIBK} + y_{MO}) + 3y_{DIBK}}$$

$$\% \text{ selectivity} = \frac{y_{IPA},\ 2y_{MIBK},\ 2y_{MO} \text{ or } 3y_{DIBK}}{y_{IPA} + 2(y_{MIBK} + y_{MO}) + 3y_{DIBK}}$$

where y_{IPA}, y_{MIBK}, y_{MO}, y_{DIBK} and y_A denote mole fractions of isopropyl alcohol, methylisobutyl ketone, mesityl oxide, diisobutyl ketone and unconverted acetone, respectively.

Analysis. The product was determined by use of Shimadzu GC-2B gas chromatographic apparatus with the column (3 m in length, 4 mm in diameter) containing 30—60 mesh Shimalite coated with 15% PEG-1,000. Both the column and detector were kept at 95 °C. The flow rate of carrier gas (H_2) was adjusted to 60 ml/min.

Results

Effect of Mass Transfer. Acetone conversion changes with the acetone flow rate at a fixed liquid hourly space velocity (LHSV) and with catalyst particle size (Table 1). The data indicate that the effect of linear velocity on the acetone conversion is insignificant so long as the size of particles remains below 0.5 mm.

Table 1. Effect of mass transfer

Catalyst		Acetone Charge Rate (mol/hr.)	Acetone Conversion (%)
Mesh	Mean Particle Diameter (mm)		
8—12	1.880	0.275	18.3

		0.825	19.5
24—48	0.491	0.275	20.8
		0.550	20.7
		0.825	20.8
48—100	0.221	0.550	20.7
		0.825	20.5

Data obtained at 122 °C, 19.5 kg/cm², 4 hr⁻¹.
Acetone LHSV and 0.4 hydrogen/acetone mole ratio.

Effect of Temperature. The conversion of acetone and the selectivity of each component in the temperature range 110—140 °C are shown in Fig. 2. The conversion of acetone increased monotonously with temperature throughout the range. Although the selectivity gradually decreased with an increase in conversion, it still remained above 90 mol%. The major by-product was diisobutyl ketone, a trimeric condensate of acetone, formation of which being accelerated with a rise in temperature. The amount of another by-product, isopropyl alcohol, was almost unchanged with temperature remaining as low as 2 mol%.

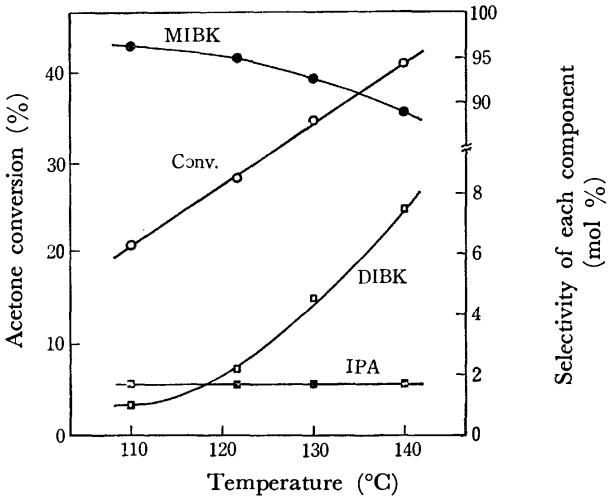

Fig. 2. Effect of temperature.
Data obtained at 20 kg/cm², 4 hr⁻¹ acetone LHSV, 0.4 hydrogen/acetone mole ratio.

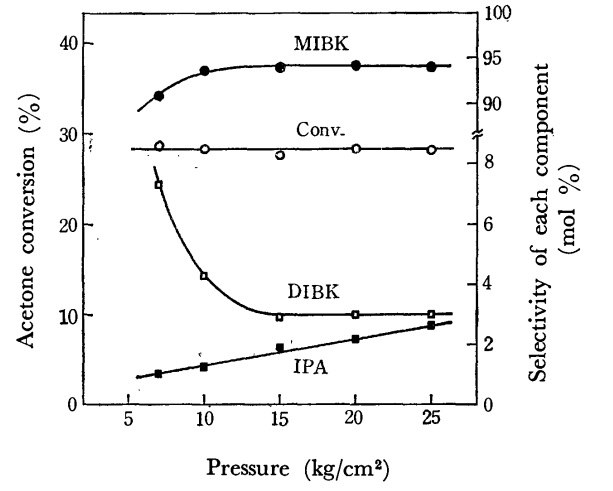

Fig. 3. Effect of pressure.
Data obtained at 120 °C, 4 hr⁻¹ acetone LHSV, 0.3 hydrogen/acetone mole ratio.

No mesityl oxide was detected.

Effect of Pressure. Figure 3 shows the effect of total pressure on the conversion of acetone and the selectivity to each component in the range 7—25 kg/cm². No appreciable change in acetone conversion with pressure was observed. However, the amount of isopropyl alcohol increased gradually with increase in pressure, the change being approximately linear. In contrast, the selectivity to diisobutyl ketone decreased with increase in pressure. The increase in the formation of diisobutyl ketone at a lower pressure or higher temperature suggests that the formation of diisobutyl ketone became dominant in vapour-phase reaction.

Thus, it is always necessary to keep acetone at the liquid phase by high pressure operation in order to obtain a good yield of methylisobutyl ketone.

Effect of Acetone Space Velocity. Figure 4 shows the effect of acetone space velocity on its conversion at 120 °C. Although the conversion decreased with increase in the space velocity, the change was less pro-

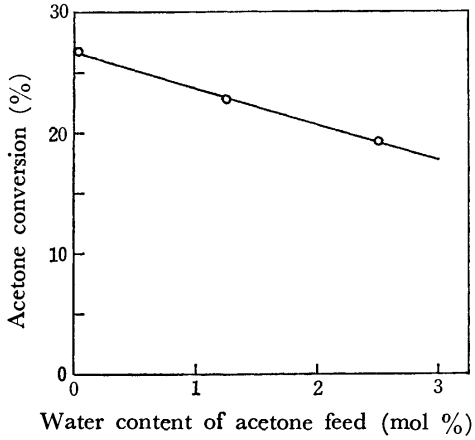

Fig. 7. Effect of water content of acetone feed on acetone conversion.
Data obtained at 120 °C, 20 kg/cm², 4 hr⁻¹ acetone LHSV, 0.3—0.4 hydrogen acetone mole ratio.

nounced in the LHSV range 5.0—15.0.

The formation of both isopropyl alcohol and diisobutyl ketone decreased with increase in space velocity (Fig. 5). These changes became slight for LHSV above 6. Mesityl oxide was detectable in the reaction products at an LHSV higher than 5.0. The change in the selectivity of methylisobutyl ketone was small under the conditions given.

Effect of Mole Ratio of Hydrogen/Acetone. The conversion of acetone remained almost unchanged, whereas the selectivity to isopropyl alcohol and diisobutyl ketone increased with an increase in mole ratio (Fig. 6). The change of selectivity to diisobutyl ketone was noticeable as compared with a slight linear change of isopropyl alcohol. No mesityl oxide was detected under these reaction conditions.

The preferable range of the mole ratio of hydrogen/acetone was deduced to be 0.2—0.4.

Effect of Water in Acetone Feed. The conversion of acetone decreased rapidly with an increase in the water content, the change being approximately linear (Fig. 7).

Since the water content of commercial acetone is usually as low as under 500 ppm, the commercial grade of acetone has no adverse effect upon the conversion of acetone to methylisobutyl ketone.

Discussion

Formation of mesityl oxide as an intermediate product under higher LHSV conditions suggests that the one-step reaction probably proceeds *via* a consecutive reaction mechanism:

$$2CH_3COCH_3 \rightleftharpoons (CH_3)_2C{=}CHCOCH_3 + H_2O \quad (2)$$

$$(CH_3)_2C{=}CHCOCH_3 + H_2 \rightarrow (CH_3)_2CHCH_2COCH_3 \quad (3)$$

The retardation of the acetone conversion into methylisobutyl ketone by the presence of water in the acetone feed is explained in terms of the reversibility of (2).

The conversion of acetone is much higher in the one-step synthesis of methylisobutyl ketone than in the synthesis of mesityl oxide under similar reaction conditions. This can be confirmed by direct comparison with the data.[9] This indicates that, in the direct conversion of acetone and hydrogen into methylisobutyl ketone, the conversion of acetone in (2) is enhanced by a rapid change of mesityl oxide into methylisobutyl ketone by (3).

Formation of isopropyl alcohol is due to the hydro-

Data obtained at 130 °C, 4 hr^{-1} acetone LHSV and 0.8—1.1 hydrogen/acetone mole ratio.

genation of acetone, and another by-product, diisobutyl ketone, is probably formed by further condensation of methylisobutyl ketone with acetone. Formation of diisobutyl ketone is considered to be dominant in vapour-phase reaction. For the sake of confirmation, one-step reaction in vapor-phase was examined. The results indicate that the presumption is reasonable (Table 2).

The authors wish to thank Prof. Yoshinobu Takegami, Kyoto University and Dr. Yasuharu Onoue, Director of Tokuyama Soda Co. for their valuable discussions and advice.

Charge-Transfer Transitions Associated with Tricyanovinyl Aromatics[1)]

Akira SASAKI, Jun-ichi AIHARA, and Yoshio MATSUNAGA[2)]
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received January 26, 1974)

Four tricyanovinyl aromatic compounds were spectroscopically investigated in various phases. The solid-state spectra distinctly display both intra- and inter-molecular charge-transfer bands in the visible region. The formation of the charge-transfer self-complex is, however, markedly hindered in the fluid phases. The dual charge-transfer properties were also examined for these compounds.

When an electron-accepting moiety is directly bonded to an electron-donor molecule within a single electronic conjugate system, the uppermost filled valence orbital will be akin to that of the unsubstituted electron donor, the lowest vacant orbital being localized in the electron-accepting group.[3,4)] As can easily be predicted from such an electronic structure, the first absorption band originates from the so-called intramolecular charge-transfer transition, *i.e.*, the transition between the two orbitals denoted above.

In some cases, specific intermolecular interactions are additionally observed for such a compound. The simultaneous presence of the intra- and inter-molecular charge-transfer transitions was first observed for 2,4,6-trinitro-*p*-terphenyl.[5)] In a previous paper, we ourselves reported that two anisyl-*p*-benzoquinones form charge-transfer self-complexes in the solid state.[6)] In this article, we would like to present other typical examples of intramolecular charge-transfer compounds, tricyanovinyl aromatics.

Experimental

Tetracyanoethylene (TCNE) often reacts with aromatic compounds to give the corresponding tricyanovinyl aromatics. Four tricyanovinyl aromatic compounds were prepared according to the method developed by Sausen *et al.*[7)] The reaction products of *N,N*-dimethylaniline (DMA), pyrrole, indole, and 2,6-xylenol (xylenol) were *p*-(tricyanovinyl)-*N,N*-dimethylaniline (TCV-DMA), 2-(tricyanovinyl)-pyrrole (TCV-pyrrole), 2-(tricyanovinyl)-indole (TCV-indole), and 4-(tricyanovinyl)-2,6-xylenol (TCV-xylenol), respectively. All the absorption spectra were taken by using a Beckman DK-2A spectrophotometer.

Results and Discussion

Figures 1—4 show the absorption spectra of TCV-DMA, TCV-pyrrole, TCV-indole, and TCV-xylenol respectively in two phases. Every solution spectrum is composed of a single absorption band in the visible region. The absorption peaks are located at 19500 cm^{-1} ($\varepsilon_{max}=5.78\times10^4$), 23800 cm^{-1} ($\varepsilon_{max}=2.59\times10^4$), 21900 cm^{-1} ($\varepsilon_{max}=2.13\times10^4$), and 23900 cm^{-1} ($\varepsilon_{max}=2.88\times10^4$) for TCV-DMA, TCV-pyrrole, TCV-indole, and TCV-xylenol respectively in chloroform.

A similar tendency in transition energies is found among the charge-transfer bands of the TCNE complexes with parent aromatic compounds. The combinations of TCNE with DMA, pyrrole, indole, and xylenol induce the characteristic charge-transfer bands with maxima at 14300, 18800, 18600, and 19100 cm^{-1} respectively in chloroform. These values could not be observed accurately enough, since these donor-acceptor systems are quite reactive in solution. However, these charge-transfer bands are consistent with the first bands of the tricyanovinyl compounds in that a similar orderliness in transition energies is found in both cases. Such parallelism enables one to assign the latter bands to the intramolecular charge-transfer transitions. It is strongly suggested that the ionization potentials of the parent compounds increase in this order: DMA≪indole≤pyrrole<xylenol. Actually, the vertical ionization potential of DMA (7.51 eV)[8)] is much

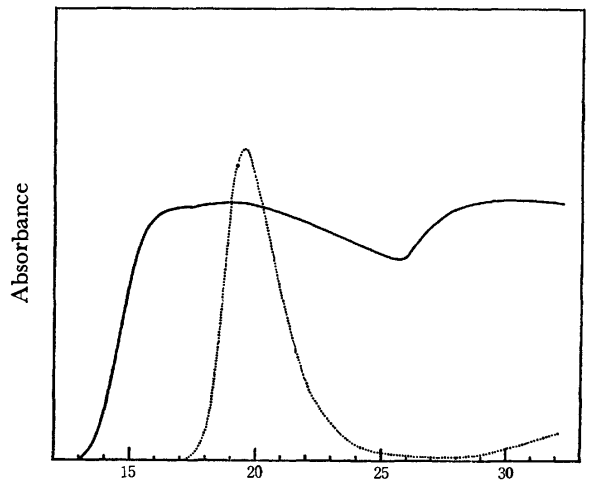

Fig. 1. Absorption spectra of TCV-DMA in chloroform solution (·····), and in the solid state (——).

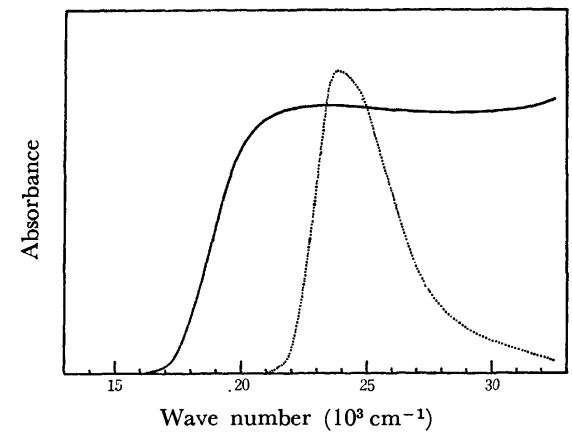

Fig. 2. Absorption spectra of TCV-pyrrole in chloroform solution (·····), and in the solid state (——).

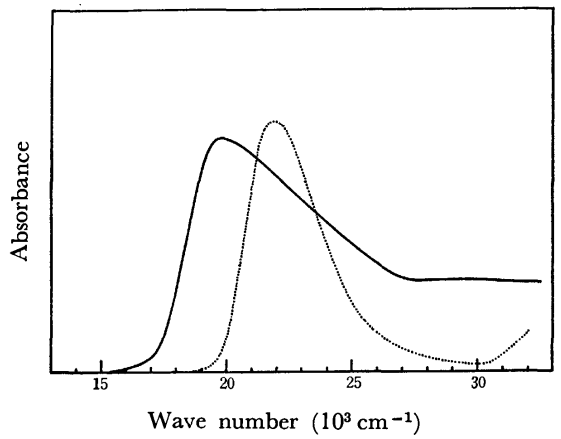

Fig. 3. Absorption spectra of TCV-indole in chloroform solution (·····), and in the solid state (——).

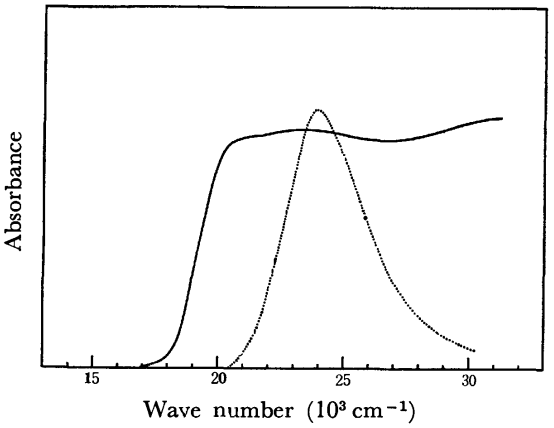

Fig. 4. Absorption spectra of TCV-xylenol in chloroform solution (·····), and in the solid state (——).

lower than that of pyrrole (8.21 eV),[9] though the other ionization potentials have not yet been determined. The smooth and isolated contour of the absorption band also characterizes the intramolecular charge-transfer transition. These absorption bands are very asymmetric, indicating that the 0–0 transitions are the strongest.

In view of the above discussion, the electron-donating orbital is supposedly located in the aromatic portion, whereas the tricyanovinyl group acts as an electron acceptor. Therefore, we can fully expect, in solution, the formation of the self-complex, where there would be a finite overlap between the donor orbital of one molecule and the acceptor orbital of a second molecule. However, the absorption spectra obtained over a 10^2-fold range of concentrations did not show any failure to obey Beer's law. No new bands were detected in the solution spectra.

If one takes into consideration the fact that 2,4,6-trinitro-*p*-terphenyl (TNTP) forms a self-complex in solution,[5] the behavior of tricyanovinyl compounds appears somewhat unusual. For example, the donor portion of TCV-DMA has more electron-donating ability than that of TNTP (diphenyl). The vertical ionization potential of diphenyl is 8.41 eV,[10] which is higher by 0.9 eV than that of DMA. On the other hand, the electron affinity of the trinitrophenyl moiety is considered to be similar to, or, more probably, less than that of the tricyanovinyl group, as will be discussed later. Since the contrast between the donor and acceptor orbitals is more striking for the tricyanovinyl compound, the dimerization in solution must have been hindered by some other effects, such as the unfavorable shapes of the molecular orbitals concerned.

On the other hand, the TCV-DMA crystal is deep blue and is in marked contrast with the deep red solution of the same compound. As is shown in Fig. 1, the gross absorption spectrum of the solid TCV-DMA is quite different from the solution spectrum in that the lower-energy part near 16000 cm^{-1} is much intensified in the former spectrum. The absorption peak around 19000 cm^{-1} in the solid-state spectrum corresponds well to the 19500 cm^{-1} band in the solution spectrum; it is assigned to the intramolecular charge-transfer transition.

Here, it must be noted that the intensified component near 16000 cm^{-1} is considered to be another absorption band. The presence of the two different bands is supported by the shape consideration of the spectrum. There is a distinct break, *i.e.*, an inflection point, around 17500 cm^{-1} in the solid-state spectrum. As may easily be seen, the intensity of the additional band on the low-energy side is comparable to that of the main band arising from the intramolecular transition. The first band can be attributed with little difficulty to the intermolecular transition. The spectral shape of TCV-xylenol also suggests that the solid-state spectrum consists of two different absorption bands in the visible region. By analogy with the case of TCV-DMA, the low-energy portion of the spectrum is considered to be due to the intermolecular interactions.

However, it is not clear whether or not the solid TCV-indole has the same spectral features. The whole spectrum appears to be composed of a single absorption band. The intramolecular absorption is supposedly covered by the predominant intermolecular charge-transfer band.

In connection with the above spectral behavior, one should remember the crystal structure of (2,2-dicyanovinyl)-ferrocene.[11] In the structure, the short distance between the dicyanovinyl moiety and the cyclopentadienyl ring of the adjacent molecule suggests, though not decisively, a donor-acceptor interaction analogous to that found in the molecular complex of ferrocene with TCNE. For another dicyanomethylene compound, 9-(dicyanomethylene)-2,7-dinitrofluorene, such self-complexing is postulated as giving rise to enhanced photoconductivity.[12] Therefore, the intermolecular interactions associated with tricyanovinyl compounds can similarly be considered to be of the charge-transfer type.

Various properties of tricyanovinyl compounds were first systematically studied by Sausen *et al.*[7] They compared these compounds with the corresponding dicyanovinyl compounds. It was then found that the investigated tricyanovinyl compounds show transition energies in ethanol about 0.4 eV lower than those of the dicyanovinyl counterparts. The extinction coefficients are smaller for the former group of compounds.

These facts imply that the tricyanovinyl group is considerably stronger as an electron acceptor than the dicyanovinyl group, and is probably stronger than the dicyanomethylene moiety. The larger electron affinity would more stabilize the charge-transfer self-complex, at least, in the crystal.

One might safely say that the self-complex formation is attained to 100 per cent in the crystal, if it is formed at all. Accordingly, the intensity of the additional band, *i.e.*, the intermolecular charge-transfer band, is comparable to that of the intramolecular charge-transfer band, as was suggested before.

However, the deep blue TCV-DMA crystal easily turns red upon being ground softly with sodium chloride. The dispersed material clearly shows the monomeric spectrum. The low-energy portion of the absorption spectrum diminishes rapidly on grinding. The evaporated film also shows a substantial decrease in the contribution of the intermolecular charge-transfer interactions to the spectrum. Such effects are also encountered among the other three tricyanovinyl compounds, though the change in color is rather modest. This aspect of the compounds in turn emphasizes the fragility of the charge-transfer interactions in the crystal as in solution.

The colors of the molten tricyanovinyl compounds are all similar to those of the corresponding solutions. The monomeric behavior of these compounds even in the pure melts would explain the behavior in solution, where the molecular association constants are obviously negligible. A free molecular motion seems easily to liberate these compounds from the dimerization in fluid phases. Such a situation is quite the same as for *o*-anisyl-*p*-benzoquinone.[6]

In order to estimate further the dual charge-transfer properties, *i.e.*, the electron-donating and -accepting abilities, of tricyanovinyl compounds, we examined the absorption spectra of the mixtures of these compounds with other typical electron donors and acceptors. Figure 5 shows the absorption spectra of TCV-pyrrole in the liquid DMA. The gross absorption spectra are very similar to the other solution spectra of this compound. However, a long absorption tail is noticeably preceded by the main band. For the four tricyanovinyl compounds, an absorption tail always begins at about 15000 cm^{-1}. Accordingly, the absorption tail of TCV-DMA is almost degenerate with the main band in DMA.

Such an absorption tail can be considered as a part of the charge-transfer band arising from the intermolecular interactions. In other words, it is related to the transition from the highest filled orbital of DMA to the lowest vacant orbital of the tricyanovinyl compound. The absorption tail is dependent on the ionization potential of the electron donor. When aniline is employed as a solvent, the edge of the absorption tail advances to about 16500 cm^{-1}. The absorption spectra taken in α-methylnaphthalene do not show any absorption tails. Instead, the absorbance in the higher-energy region around 25000 cm^{-1} increases to some extent. Considering that the absorption tails are preserved at almost the same photon energies in a given solvent for the four tricyanovinyl compounds, the electron-accepting ability should be similar among them. This fact further supports the previously-mentioned idea that the acceptor orbital is mainly localized in the tricyanovinyl moiety of the compound.

Since the absorption peak of the charge-transfer band could not be detected in these systems, the accurate estimate of the electron affinity was made difficult for the tricyanovinyl compound. However, by comparing the absorption edge of any compound to those of many other electron acceptors in the same donor solvent, it is not impossible to determine roughly the electron affinity of the compound. In the present case, the absorption edge of 1,3,5-trinitrobenzene (TNB) is found to fit well that of TCV-pyrrole in DMA, as is shown in Fig. 5. Therefore, the electron affinity of the tricyanovinyl compound is estimated to be similar to that of TNB, which is approximately 1.9 eV.[13]

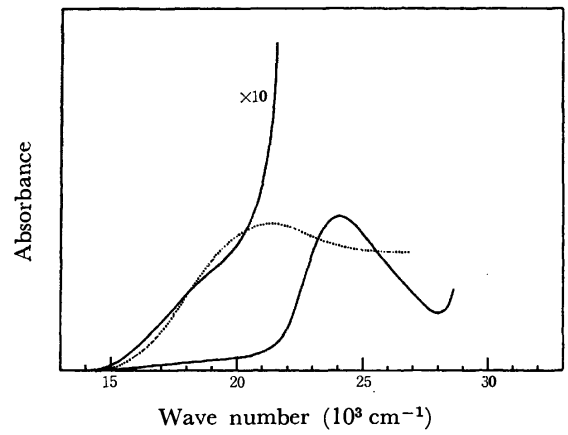

Fig. 5. Absorption spectra of TCV-pyrrole (——), and TNB (·····) in DMA solution.

On the other hand, no combinations of such tricyanovinyl compounds with typical electron acceptors, such as TCNE and chloranil, exhibited any intermolecular interactions supported by the absorption bands. The ordinarily-prepared solution is seemingly too deficient in concentration for the intermolecular charge-transfer to be observed. The small association constants between them are easily inferrable from the case mentioned above, where the additional absorption band of the tricyanovinyl compound is still weak in a pure donor solvent, such as DMA. If any strong acceptor were employed as a solvent, the charge-transfer band could be appreciably detected. At present there are no solvents suitable for this purpose. However, the absorption band of the self-complexed TCV-DMA in the solid suggests that the ionization potential of the isolated TCV-DMA is not very different from that of DMA and is possibly somewhat smaller than that.

In summary, tricyanovinyl aromatics are typical intramolecular charge-transfer compounds. Though they are considered to be at once good electron acceptors and good electron donors, every aspect of the absorption spectra is consistent with quite small association constants of these compounds, either with any other partner molecules or with themselves.

The Infrared Intensities of Stretching Fundamentals in Gaseous and Crystalline Cyanoacetylene

Masakatsu UYEMURA* and Shiro MAEDA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Meguro-ku, Tokyo 152

(Received February 19, 1974)

The absolute intensities of the stretching fundamentals of cyanoacetylene and cyanoacetylene-d were measured in gaseous and crystalline (77 K) states. As had been expected from the previous result for hydrogen cyanide, a striking intensity increase upon crystallization was observed not only for $\nu_{CH(CD)}$ but also for the other fundamentals. The observed intensities were reduced to dipole-moment derivative with respect to the internal coordinates, $\partial\mu/\partial r$. Then, by taking advantage of the strictly linear geometry of hydrogen-bonded chains in the crystals, it was demonstrated that the derivative with respect to the hydrogen-bonded distance, $[\partial\mu/\partial r_{N\cdots H}]$, was primarily responsible for the remarkable change in $\partial\mu/\partial r$; this was in accordance with the previous conclusion for hydrogen cyanide. A discrepancy from this view which appeared for $\partial\mu/\partial r_3$ was interpreted as being mainly caused by the vibronic behavior of π-electrons.

The infrared intensity characteristics of hydrogen-bonded systems are well known and have generally been interpreted in terms of a charge-transfer mechanism.[1-4] However, since there have been rather few quantitative intensity studies of those systems so far, there still seems to be need for such detailed investigations as will give positive evidence for the importance of the charge-transfer contribution. In a previous study of crystalline HCN and DCN, particular attention was given to the fact that not only the C–H (C–D) stretching but also the C≡N stretching absorption was remarkably intensified compared with gaseous ones; the analysis of those changes was then able to deduce a very large dipole-moment derivative properly attributable to the intermolecular charge transfer.[5] In that case, a strictly linear structure of hydrogen-bonded chains in the crystal furnished a very favourable condition for interpreting the results. In order to confirm the above conclusion for the N···H–C hydrogen-bonded system, cyanoacetylene and its deuterated derivative were studied from the same point of view, as these linear molecules are known to form linear hydrogen-bonded chains in a crystal just like hydrogen cyanide.[6]

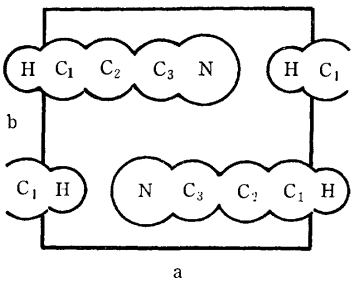

Fig. 1. Crystal structure of cyanoacetylene.

The crystal structure of cyanoacetylene determined by X-ray diffraction at 248 K is shown in Fig. 1, which belongs to the space group C_{2h}^2—$P2_1/m$ and which has two molecules per unit cell. In this structure, a linear hydrogen-bonded chain is surrounded by four parallel and two anti-parallel identical chains at intervals of 3.6 Å, and the $R_{N\cdots H-C}$ distance, 3.27 Å, is slightly longer than that of hydrogen cyanide ($R_{N\cdots H-C}$=3.18 Å).[6]

TABLE 1. CORRELATION DIAGRAM FOR CRYSTALLINE CYANOACETYLENE

	Molecule $C_{\infty v}$	Site C_s	Factor C_{2h}	Activity
ν_1, ν_2	Σ^+	A′	A_g	(*R*)
ν_3, ν_4			B_g	(*R*)
ν_5, ν_6	*II*	A″	A_u	(*IR*)
ν_7			B_u	(*IR*)

According to the correlation diagram, Table 1, each stretching fundamental is predicted to give only one infrared active crystal component, while each degenerate bending has two active components caused by the site-group splitting. The present work deals with the intensities of only stretching fundamentals, because our instrument was not able to cover the whole bending region. As we are primarily interested in the vibrations accompanying hydrogen-bonded stretching, the present result is not affected by the lack of intensity data on bending fundamentals.

Experimental

The HCCCN was kindly offered by Takeda Chemical Industries, Ltd., from their stock. The DCCCN was obtained by mixing the HCCCN with weakly alkaline D_2O, and both samples were distilled within a vacuum line just before the spectroscopic measurements, in order to remove any residual water and colored impurities. Their infrared spectra showed no indication of impurities except for a minute amount of HCCCN in the DCCCN sample, whose deuterium concentration was determined to be 98 mole% in both gas and crystal by measuring the intensity of the residual C–H stretching band.

The gaseous intensities were determined by the Wilson-Wells method.[7] The area of absorption

$$B' = \int \ln(T_0/T)d\nu$$

was measured using a 10 cm-length cell, with helium gas for pressure broadening. Sufficient broadening was achieved at a pressure of less than 170 Torr for every stretching band with a spectral slit width of 1 cm^{-1} or somewhat less. It was confirmed by observing the intensity by varying the total

* Present address: Faculty of Engineering, Tokyo College of Photography, Atsugi, Kanagawa, 243-02.

pressure; the intensity increase from 9 Torr to 170 Torr was a little less than 5%. The good linearity of Beer's law plots obtained to very low concentration seems to support it also. The ν_1, ν_2, and ν_3 frequencies of gaseous HCCCN were essentially identical with those reported by Turrell *et al.*[8] A weak absorption was observed in the ν_4 fundamental region of gaseous HCCCN, whereas no well-defined absorption band was observed in the ν_4 region (750~900 cm^{-1}) of gaseous DCCCN, even under its saturated vapor pressure.

The crystalline spectra were obtained at 77 K by an experimental procedure similar to that used for hydrogen cyanide.[5] In the process of evaluating intensities, the density at 248 K from the X-ray experiment[6] was used temporarily because no value was available for 77 K. The refractive index of the crystal at the wavelength of one micron, where the interference fringes were recorded for measuring the film thicknesses, was tentatively calculated based on the Lorentz-Lorenz formula using the atomic refraction data for the Na-D line.[9]

Results

The observed frequencies are shown in Table 2, together with those reported earlier.[8] In the ν_4 fundamental region of gaseous HCCCN, a broad and weak absorption attributable to the overlap of two parallel bands was observed. We provisionally assigned the 863 cm^{-1} band to ν_4 and the 887 cm^{-1} to $\nu_5+\nu_7$, following Job and King for the latter assignment[8] (Fig.

2). Although Turrell *et al.* reported two additional broad absorptions at about 3200 cm^{-1} and 800 cm^{-1} in an HCCCN crystal, neither of these nor any of the corresponding bands in DCCCN was found in the present study (Fig. 3). The frequencies and breadth of these bands seem to suggest that they originate from the H_2O in HCCCN.[4]

The integrated absorption coefficient, A, was determined from Beer's law plots shown in Figs. 4 and 5, except for the gaseous ν_4 bands, which were so weak under the present observing conditions that no significant plots were obtainable. The $A(\nu_4)$ value of gaseous HCCCN was roughly estimated by comparing the peak height of the P-branch with that of ν_3, while no appreciable intensity was detected for ν_4 of DCCCN, as has been stated before. The values of the intensities thus determined are given in Table 3, in which the effective field correction by means of Polo-Wilson's equation[10] has already been incorporated in the crystalline values.

It should be noticed that the above intensities include errors from various sources; the accuracy of crystalline values can be especially seriously influenced by the slit width used and by the finite range of the frequency in integration. In the present observation, the slit width was normally much less than, or, at most,

equal to, one-half of the band-width, and the integration was carried out over ten times the band width or more. Assuming a Lorentzian shape of the band, the maximum errors due to these sources are estimated at 6% and 7% respectively.[11] Taking other factors into consideration, the composite error is estimated at about 20% for crystals and about 15% for gases, considering some additional sources of error (for example, the uncertainty of the density at 77 K, the inhomogeneity of the film thicknesses, *etc*) in the former case. A criterion of the accuracy may be obtained by examining the validity of the intensity F-sum rule;[12] then, it is seen that the sums:

$$\sum_i (1/\lambda_i)\,|\partial\mu/\partial Q_i|^2$$

for H and D species agree within an error of 9% for the gas and 4% for the crystal, where λ_i is an eigenvalue ($\lambda_i=4\pi^2\nu_i^2$); $\partial\mu/\partial Q_i$ is given immediately below.

The integrated intensity, A, is related to the derivative of the dipole moment with respect to a normal coordinate, Q_i, by:[13]

$$A(\nu_i) = (N\pi/3c^2)\,|\partial\mu/\partial Q_i|^2 \qquad (1)$$

For crystalline intensities, Q_i should be an optically-active (wave vector $K=0$) normal coordinate of the crystal. The transformation to the derivatives with respect to the internal coordinates, r_i, is expressed as;[13]

a) Best combination.

$$\partial\mu/\partial r_i = \sum_j L_{ji}^{-1}\partial\mu/\partial Q_j, \quad (2)$$

where r_i for the crystalline case stands for a translationally-invariant linear combination of molecular r_i's. According to the crystal structure given before, the interaction between different chains of molecules may be much smaller than that due to hydrogen bonding, so that the crystal may be approximated by a one-dimensional chain in the following considerations. Then, the r_i in Eq. (2) for the crystal may be:

$$r_i = (1/\sqrt{n})\sum_j r_i^j \quad (3)$$

where r_i^j is the i-th coordinate of the j-th molecule of a chain and where n represents the number of molecules conforming to the periodic boundary condition.

The L_{ji}^{-1} in Eq. (2) was calculated based on the force constants given in Table 2, which reproduce the observed frequencies with deviations less than 0.5%. The force constant of a hydrogen-bond K(N···H), was obtained assuming a Lippincott-Schroeder potential.[14] Since the sign of $\partial\mu/\partial Q_i$ is not determinable experimentally, eight different sets of values are possible for $\partial\mu/\partial r_i$'s, corresponding to eight different combinations of relative signs among the four $\partial\mu/\partial Q_i$'s. It may be seen in Table 4 that the best consistencies between HCCCN and DCCCN are obtained in the (+−−−) combination for the gas and in the (+−−+) combination for the crystal. The final values of $\partial\mu/\partial r_i$ are given in Table 5, where two alternative sets of the signs are still present. Hereafter, the absolute sign of the derivatives will be defined so that a positive $\partial\mu/\partial r_{s_1}$ represents the increase in the dipole moment in the $^+$HCCCN$^-$ or $^+$HCN$^-$ direction caused by the s-t stretching.

Table 5. $\partial\mu/\partial r_i$ in gaseous and crystalline cyanoacetylene and change of $\partial\mu/\partial r_i$ (D/Å)

	Gas	Cryst.	Change of $\partial\mu/\partial r_i$
$\partial\mu/\partial r_1$	1.28	3.11	1.83
$\partial\mu/\partial r_2$	0.45	2.52	2.07
$\partial\mu/\partial r_3$	−0.44	0.19	0.63
$\partial\mu/\partial r_4$	0.41	2.27	1.86

Finally, it must be pointed out that the observed $\partial\mu/\partial r_3$ value of cyanoacetylene may contain a larger error than the others. That is, the intensity of ν_4, to which C–C stretching is mainly responsible, is extremely weak, so that the major contribution to $\partial\mu/\partial r_3$ comes from the other fundamental intensities through $\boldsymbol{L}^{-1}$ matrix elements, *i.e.* $L_{i,3}^{-1}$ $(i=1,2,3)$.

Discussion

Since the criterion of Table 4 does not disclose the absolute sign of $\partial\mu/\partial r$, it has to be determined on other bases. In the case of hydrogen cyanide, the sign of the gaseous derivatives was already known through the analysis of the vibration-rotation bands;[16] the crystalline one was chosen so that the observed differences, $\Delta(\partial\mu/\partial r)=(\partial\mu/\partial r)_{\text{crystal}}-(\partial\mu/\partial r)_{\text{gas}}$, which were remarkable not only in $\partial\mu/\partial r_{CH}$ but also in $\partial\mu/\mu r_{C\equiv N}$,

could be interpreted consistently in terms of an intermolecular contribution $[\partial\mu/\partial r_{N\cdots H}]$, given below. In fact, only such a choice of the sign made possible a reasonable interpretation; the resulting large negative $[\partial\mu/\partial r_{N\cdots H}]$ value was attributed to the vibrational contribution of the charge-transfer effect in hydrogen bonding.[5]

As for the absolute signs of $\partial\mu/\partial r_1$ in cyanoacetylene,[15] it seems most reasonable to assume that they are positive both in gas and in the crystal, so as to give similar values to those of hydrogen cyanide, because the C-H bond properties cannot be much different between these molecules and the effects of hydrogen bonding may also be alike in view of their similar crystal structures. In fact, any other sign combination proves to give quite an unintelligible situation regarding the interpretation of $\partial\mu/\partial r_1$ and $\partial\mu/\partial r$'s. Table 5 shows the results obtained assuming the absolute sign proposed above.

According to considerations similar to those made before,[5] the observed crystalline derivatives may be expressed as:

$$\partial\mu/\partial r_i = [\partial\mu/\partial r_i] - [\partial\mu/\partial r_{N\cdots H}], \tag{4}$$

where the brackets signify that the derivative is unconstrained by the condition for the optically-active coordinates:[17]

$$r_1 + r_2 + r_3 + r_4 + r_{N\cdots H} = 0. \tag{5}$$

Then, we obtain

$$\begin{aligned}\Delta(\partial\mu/\partial r_i) &= (\partial\mu/\partial r_i)_{\text{crystal}} - (\partial\mu/\partial r_i)_{\text{gas}} \\ &= \Delta[\partial\mu/\partial r_i] - [\partial\mu/\partial r_{N\cdots H}],\end{aligned} \tag{6}$$

where the change of a derivative is resolved into a purely intramolecular part ($\Delta[\partial\mu/\partial r_i]$) and a concurrent intermolecular term ($[\partial\mu/\partial r_{N\cdots H}]$).

Now, it may be noted in Table 5 that the three $\Delta(\partial\mu/\partial r_i)$ values are fairly close each other and comparable to the corresponding values in hydrogen cyanide with the exception of $\Delta(\partial\mu/\partial r_3)$. Therefore, if the previous conclusion that $[\partial\mu/\partial r_{N\cdots H}]$ is primarily responsible for $\Delta(\partial\mu/\partial r_i)$ is essentially valid here, there must be adequate reasons for the abnormally small value of $\Delta(\partial\mu/\partial r_3)$. Therefore, it may be proper to investigate such reasons in (a) the behavior of conjugated π-electrons during vibration, (b) the polarization of σ-electron due to the electrostatic field by neighboring molecules, and (c) the polarization of σ-electrons due to the intermolecular charge transfer through the hydrogen bond. In these effects, the behavior of conjugated π-electrons seems to be most significant, as will be shown below.

Assuming that the dipole moment is simply given by:

$$\mu = \Sigma_i q_i x_i, \tag{7}$$

where q_i and x_i are the charge density and the coordinate of the i-th atom, its derivative with respect to s-t stretching is:

$$\partial\mu/\partial r_{st} = \Sigma_i\{(\partial q_i/\partial r_{st})x_i + q_i(\partial x_i/\partial r_{st})\}, \tag{8}$$

In a simple MO consideration for π-electrons, it may be appropriate to represent the effect of s-t stretching by a change in the resonance integral, β_{st}. Thus, confining ourselves to π-electrons, we may obtain

$$\partial q_i/\partial r_{st} = (\partial q_i/\partial\beta_{st})(\partial\beta_{st}/\partial r_{st}) = \pi_{i,st}(d\beta_{st}/dr_{st}), \tag{9}$$

where $\pi_{i,st}$ is the atom-bond polarizability.[18] It may be noticed here that always $d\beta_{st}/dr_{st} > 0$. In the present approximate consideration, the hydrogen-bonding perturbation to π-electrons may be represented by the change in the Coulomb integrals of C_1 and N; $\Delta\alpha_1$ and $\Delta\alpha_4$. Then, we obtain:

$$\begin{aligned}\Delta\left(\frac{\partial\mu}{\partial r_{st}}\right)_\pi &= \Sigma_i\left(\frac{\partial\pi_{i,st}}{\partial\alpha_1}\Delta\alpha_1 + \frac{\partial\pi_{i,st}}{\partial\alpha_4}\Delta\alpha_4\right)\frac{\partial\beta_{st}}{\partial r_{st}}x_i \\ &\quad + \Sigma_i(\pi_{i,1}\Delta\alpha_1 + \pi_{i,4}\Delta\alpha_4)\frac{\partial x_i}{\partial r_{st}},\end{aligned} \tag{10}$$

where $\pi_{i,j}$ is the atom-atom polarizability;[18] an explicit form of $(\partial\pi_{i,st}/\partial\alpha_j)$ is given in the Appendix. The use of the π-wave function based on a CNDO calculation gives the numerical expression in Table 6.

In Table 6, it is notable that the first term of $\Delta(\partial\mu/\partial r_3)_\pi$ is of a sign opposite to those of the other two. Since the perturbation may be taken such that $\Delta\alpha_1 > 0$ and $\Delta\alpha_4 < 0$, because of either electrostatic and charge-transfer interactions, the first term above may certainly serve to lower the value of $\Delta[\partial\mu/\partial r_3]$, while it raises the other two.

TABLE 6. π-ELECTRON CONTRIBUTION TO $\Delta[\partial\mu/\partial r]$ CALCULATED BY USING CNDO WAVE FUNCTIONS (in atomic units)[a]

r_{st}	$\Delta[\partial\mu/\partial r_{st}]$
r_2	$(18.1\Delta\alpha_1 - 6.1\Delta\alpha_4)(\partial\beta_2/\partial r_2) + (2.4\Delta\alpha_1 - 0.4\Delta\alpha_4)$
r_3	$-(15.5\Delta\alpha_1 - 15.6\Delta\alpha_4)(\partial\beta_3/\partial r_3) + (0.3\Delta\alpha_1 - 0.3\Delta\alpha_4)$
r_4	$(6.0\Delta\alpha_1 - 17.3\Delta\alpha_4)(\partial\beta_4/\partial r_4) + (0.4\Delta\alpha_1 - 2.3\Delta\alpha_4)$

a) The resonance integrals are numbered in the same way as r_i. See Ref. 15.

Besides the π-electron contribution (a) mentioned above, $\Delta[\partial\mu/\partial r_i]$ should be influenced by the σ-electron polarization, which is caused by the electrostatic field (b) and also by the intermolecular charge transfer (c) as described by such resonance structures:

$$\equiv N\ \dot{H}—C\equiv C—C\equiv\overset{+}{N}—H\ \bar{C}$$

$$\equiv\overset{+}{N}—H\ \bar{C}\equiv C—C\equiv N\ H—C$$

However, in view of the fact that C–H bending intensity was almost unchanged in hydrogen cyanide,[5] as is generally observed in hydrogen-bonded systems, the (b) effect does not seem very important. On the other hand, the (c) effect may reduce $\Delta[\partial\mu/\partial r_i]$ more or less except in the case of C–H, resulting in a rather large negative $\Delta[\partial\mu/\partial r_3]$ value in cooperation with the (a) effect. On the other hand, $\Delta[\partial\mu/\partial r_2]$ and $\Delta[\partial\mu/\partial r_4]$ may become less important because the (c) and (a) effects tend to cancel each other out.

The consideration given above, though it is only qualitative, seems to explain the discrepancy in $\Delta(\partial\mu/\partial r_3)$ rather convincingly. We may, then, consider that, in all probability, the present result further demonstrates the importance of the intermolecular dipole-moment derivative $[\partial\mu/\partial r_{N\cdots H}]$. As a rough estimate,

the value of $[\partial\mu/\partial r_{N\cdots H}]$ may be comparable to the observed $\Delta(\partial\mu/\partial r_1)$ value with a negative sign, because the previous estimate, -1.4 D/Å, for hydrogen cyanide seems to be too low because the effect of $\Delta[\partial\mu/\partial r_{C\equiv N}]$ was ignored then.

The authors wish to thank the Takeda Chemical Industries, Ltd., for giving them the cyanoacetylene sample.

Appendix

The atom-bond polarizability, $\pi_{r,st}$, is given in terms of the LCAO MO coefficients as:[18]

$$\pi_{r,st} = \partial q_r/\partial\beta_{st}$$

$$= 4\sum_{j=1}^{m}\sum_{k=m+1}^{n} C_{rj}C_{rk}(C_{sj}C_{tk}+C_{tj}C_{sk})/(\varepsilon_j-\varepsilon_k)$$

($1\sim m$: occuppied MO, $m+1\sim n$: vacant MO) (A1)

Now, for a small perturbation, $\boldsymbol{J}$, in the Hamiltonian matrix, the perturbed orbital energy and LCAO MO coefficients are given by:

$$\varepsilon_j = \varepsilon_j^\circ + \tilde{\boldsymbol{C}}_j^\circ \boldsymbol{J}\boldsymbol{C}_j^\circ,$$

$$\boldsymbol{C}_j = \boldsymbol{C}_j^\circ + \sum_{k\neq j}\{\tilde{\boldsymbol{C}}_k^\circ \boldsymbol{J}\boldsymbol{C}_j^\circ/(\varepsilon_j^\circ-\varepsilon_k^\circ)\}\boldsymbol{C}_k^\circ \quad \text{(A2)}$$

where $\boldsymbol{C}_j$ is a column vector of coefficients for the j-th MO and where the superscript $^\circ$ denotes unperturbed values. On the basis of these equations, the following expressions are obtained straightforwardly for a diagonal term, $J_{u,u}=\Delta\alpha_u$:

$$\partial\pi_{r,st}/\partial\alpha_u = 4\sum_{j=1}^{m}\sum_{k=m+1}^{n}\frac{C_{rj}C_{rk}}{\varepsilon_j-\varepsilon_k}\Bigg\{(C_{sj}C_{tk}+C_{tj}C_{sk}) \times\left[\frac{C_{rj}^{(u)}}{C_{rj}}+\frac{C_{rk}^{(u)}}{C_{rk}}-\frac{C_{uj}^2-C_{uk}^2}{\varepsilon_j-\varepsilon_k}\right]+C_{sj}^{(u)}C_{tk} +C_{sj}C_{ik}^{(u)}+C_{ij}^{(u)}C_{sk}+C_{tj}C_{sk}^{(u)}\Bigg\}, \quad \text{(A3)}$$

$$C_{rj}^{(u)} = \sum_{\substack{l=1\\ l\neq j}}^{n}\{C_{rl}C_{ul}C_{uj}/(\varepsilon_j-\varepsilon_l)\} \quad \text{(A4)}$$

where the superscript $^\circ$ is omitted from every symbol for the sake of brevity.

Group Interactions in Polyelectrolytes. VIII.[1] The Amination of Chloromethylated Polystyrene with Secondary Amines and the Quaternization of the Aminated Polymer

Hiroshi KAWABE

The Institute of Physical and Chemical Research, Wako-shi, Saitama 351

(Received March 8, 1974)

The amination of chloromethylated polystyrene (CMPS) and benzyl chloride with diethyl amine, diethanolamine, and di-*n*-butylamine was investigated kinetically in *N,N*-dimethylformamide (DMF), dimethyl sulfoxide (DMSO), or dioxane. The apparent second-order rate constant decreased as the amination proceeded in the amination of CMPS with diethylamine and di-*n*-butylamine in DMF as well as in dioxane. Although a similar deceleration was also observed in the amination of CMPS with diethanolamine in DMF and DMSO, acceleration was observed during the course of the amination in dioxane. It is assumed that the deceleration and the acceleration are due to the steric obstruction and to the formation of a hydrogen bond by the neighboring groups in the transition state respectively. The intrinsic rate constants of the amination of CMPS were almost the same as those of benzyl chloride. The rate of the amination with diethanolamine was lower than that of the amination with diethylamine because of the inductive effect of the hydroxyl group. The rate constants in different solvents were in this order; DMSO > DMF ≫ dioxane. The aminated CMPS with diethanolamine ($pK_0 = 7.37$) was quaternized with methyl iodide or bromoacetic acid in 50% aq. DMF. The deceleration due to the electrostatic effect of the neighboring groups was observed in the quaternization.

The effect of the species of amines and solvents on the kinetics in the amination of chloromethylated polystyrene (CMPS) was previously investigated by Kawabe and Yanagita.[1-4] Although most of the amination with primary amines such as butylamine isomers conformed to the ordinary second-order rate equation, deceleration was observed during amination with such secondary amines as diethylamine and di-*n*-butylamine. On the other hand, acceleration was observed during amination with 2-aminobutanol in dioxane, though the amination with the amine in *N,N*-dimethylformamide (DMF) and dimethyl sulfoxide (DMSO) obeyed the ordinary second-order kinetics.

In the above reactions, charged groups were not formed on the polymer molecules, because CMPS was aminated with a large excess of primary or secondary amine. On the other hand, in the Menschutkin reaction of polymers, during which quaternary ammonium groups are formed on polymer molecules, the following two different kinetic behaviors were reported; one was an ordinary second-order kinetics, while the other was modified by the deceleration because of the electrostatic repulsion among the charged groups. Noda and Kagawa[5] found that the amination of CMPS with triethylamine in DMF conformed to the second-order kinetics. Fouss *et al.*[6] observed that the rate of the quaternization of poly-4-vinyl-pyridine with *n*-butylbromide in tetramethylene sulfon or propylene carbonate decreased rapidly beyond half-quaternization.

In the present study, the kinetics of the aminations of CMPS and benzyl chloride with diethanolamine has been compared with that of the aminations with diethylamine, and also the quaternization of the CMPS aminated with diethanolamine has been investigated kineticcally.

Experimental

Chloromethylated polystyrene (CMPS). The CMPS was prepared and purified by the procedures described in previous papers.[2-4] The chlorine contents and the molecular weights of the CMPS used in the present study are tabulated in Table 1.

Table 1. Chlorine content and molecular weight of CMPS

Code	Content of Cl %	Degree of chloromethylation	Molecular weight
SC-5	21.15	0.874	10.3×10^4
SC-7	19.53	0.782	
SC-8	22.11	0.931	9.2×10^4
SC-11	21.75	0.909	12.4×10^4

Aminated Chloromethylated Polystyrene (AMPS). Five grams of CMPS (SC-5) were dissolved in 200 ml of DMF, and to the solution we then added 300 ml of a DMF solution containing 60 g of diethanolamine. The reaction mixture thus obtained was kept at 50 °C for 2 days. After it was ascertained that the reaction had proceeded quantitatively, the reaction mixture was cooled to room temperature and was poured into water to precipitate the aminated polymer. The polymer, which was dried *in vacuo*, was easily soluble in DMF, but less soluble in dioxane, methyl ethyl ketone, and benzene. The polymer was dissolved in 25 ml of DMF, and a 45-ml portion of benzene was added to the solution. This solution was poured into 350 ml of ligroin to precipitate the polymer. After two reprecipitations, the polymer was dried *in vacuo* to give a yield of 4.6 g. Elementary analysis and acid-base titration were carried out with this dried sample. The nitrogen content of the sample was found to be 6.10%, and no chlorine was found. The content of amine combined with CMPS was found, by titration, to be 4.23 mmol/g. The value of the nitrogen content calculated from the degree of the amination on the basis of Eq. (1) and the value calculated from the titration data both agreed with that of elementary analysis, as is shown in Table 2.

Table 2. Nitrogen contents of AMPS

Elementary analysis %	Calculated from titration %	Calculated from conversion %
6.10	5.96	5.93

$$[N\%] = \frac{14.01xy \times 100}{221.99xy + 152.61x(1-y) + 104.14(1-x)} \quad (1)$$

In Eq. (1), x is the degree of the chloromethylation of polystyrene, and y is the degree of the amination of the chloromethyl group; $x=0.874$ and $y=1.00$ in this experiment. The figures in the denominators are molecular weights of *N,N*-bis(2-hydroxyethyl)-aminomethyl styrene, chloromethyl styrene, and styrene respectively.

Other Chemicals. The amines, the solvents, and the other liquid chemicals, all of a reagent grade, were distilled before use; they were proved to be pure by their refractive indices. All the other chemicals were of a reagent grade and deionized, decarbonized water was used.

Kinetic Measurements. Amination of CMPS and Benzyl Chloride: The rate of the amination was measured as has been described in a previous paper.[4] The experimental conditions in the amination of CMPS are listed in Table 3. In Run 7, since the reaction mixture was emulsified during the reaction, it was distributed in test tubes dipped in a thermostat to avoid uneven sampling, as has been described in another previous paper.[1]

Quaternization of AMPS: AMPS (N content: 6.10%) was quaternized with mthyl iodide and bromoacetic acid in 50% aq. DMF in a vessel protected from light. The rates of the reactions were measured by the same procedures as those used for the amination. The experimental conditions are shown in Table 4.

Viscometric Measurements. In the amination of CMPS, the viscosity change in the reaction mixture was also checked for Runs 4, 6, 11, and 13 by the procedure described in a previous paper.[4]

Acid-base Titration of AMPS. A portion of AMPS (0.1185 g) was dissolved in 18 ml of DMF, and the solution was diluted to 50 ml by adding water. This solution was titrated first with 8 ml of 0.0989 M HCl; after the addition of 5g of sodium chloride (about a 1.5 M concentration), the solution was back-titrated with 0.1008 M NaOH. The pH of the solution was measured with glass and calomel electrodes by means of a Beckman Model G pH meter. In the back-titration, 15.6 ml of DMF in all was added to avoid the precipitation of the polymer.

Results

Amination with Diethylamine in DMF. As has been described in a previous paper,[1] the amination of benzyl chloride could be expressed by Eq. (2), and the over-all kinetics of the amination of chloromethylated polystyrene (CMPS) in the presence of a large excess of diethylamine ($a \gg b$) could be expressed by Eq. (3):

$$kt = \frac{1}{(a-b)t} \ln \frac{b(a-x)}{a(a-b)} \equiv \bar{k}t \quad (2)$$

$$\beta = x/b = 1 - \frac{k_1-k_2}{2k_1-k_2} e^{-2k_1at} - \frac{k_1}{2k_1-k_2} e^{-k_2at} \quad (3)$$

$$k_1 = \frac{1}{[(2-k_2/k_1)a-b]t} \ln \frac{1-\alpha}{1-(2-k_2/k_1)\beta} \quad (4)$$

$$\bar{k}t = k_2t + C \quad (5)$$

where a and b are the initial concentrations of an amine and the chloromethylgroup respectively, and where x is the concentration of chloride ions after time t; k_1 and k_2 are the rate constants of the elementary reactions which are independent of the neighboring groups and which are dependent on their steric effect respectively. C in Eq. (5) is a constant in a given system: $C=\ln[(1-$

Table 3. Conditions of amination of CMPS

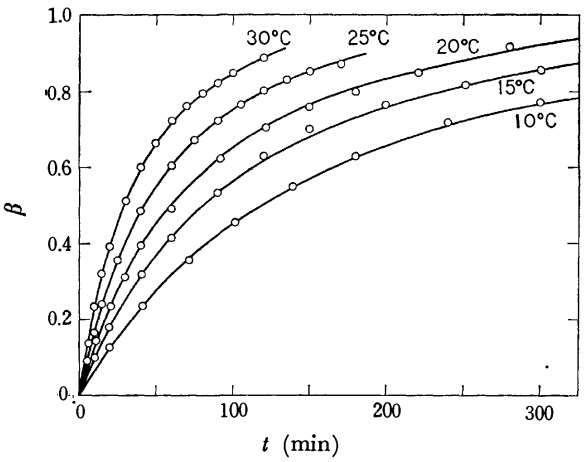

Fig. 1. Amination of CMPS with diethylamine in DMF.
——: calculated on the basis of Eq. (3).

$\chi/a)/(1-\chi/b)]-k_2(a-b)\tau$.[1]

The results of the amination of CMPS with diethylamine at different temperatures are shown in Fig. 1, where the solid lines are these calculated on the basis of Eq. (3). The observed values, represented by the white circles, substantially fall on the calculated lines. The rate constants of the amination of benzyl chloride and CMPS, as computed by Eqs. (2), (4), and (5), are listed in Table 5. The values of E_a, the activation energy, and A, the frequency factors, computed by the mean-squares method are also listed in Table 5.

It was shown in a previous paper[4] that deceleration was observed during the amination of CMPS with di-*n*-butylamine in DMF and that the kinetics could be described by Eq. (3). In the present study, the rate of CMPS at 25 °C has been compared with that of benzyl chloride. The results were:

(Benzyl Chloride) $k_B=1.19\times10^{-2}$ l/mol min
(CMPS $k_1=1.26\times10^{-2}$, $k_2=3.98\times10^{-3}$ l/mol min
$k_2/k_1=0.31$, $k_1/k_B=1.06$

Amination with Diethanolamine in DMF and DMSO. Deceleration such as that described in the preceding section was also observed in the amination of CMPS with diethanolamine. The courses of the aminations in DMF and DMSO could be fully expressed on the basis of Eq. (3). The rate constants of CMPS are listed in Tables 6 and 7, along with the rate constants of benzyl chloride, k_B. In the table are also listed the values of E_a and A, which were computed by the least-squares method.

Amination of CMPS with Diethanolamine in Dioxane. The results of kinetic measurements in the amination of CMPS with diethanolamine in dioxane at 40 °C are shown in Fig. 2. The plot of β against t is represented by a sigmoid curve, which indicates the acceleration during the reaction. The plot of kt against t is nearly represented by two straight lines which intersect at

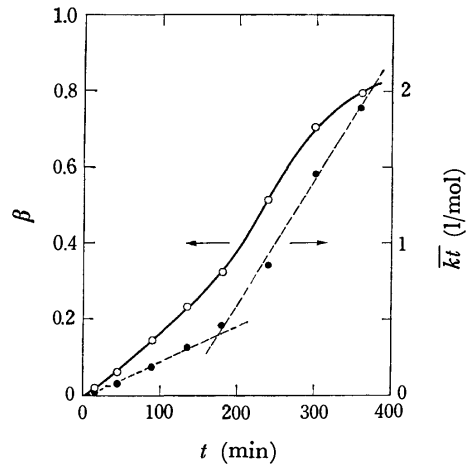

Fig. 2. Amination of CMPS with diethanolamine in dioxane at 40 °C.

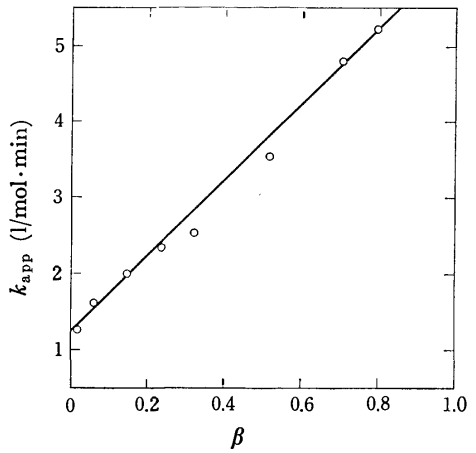

Fig. 3. Plot of k_{app} *vs.* β in the amination of CMPS with diethanolamine in dioxane at 40 °C.

$\beta \approx 1/3$. The rate constant calculated on the basis of Eq. (2) is not constant, but increases with β. The plot of this apparent rate constant, k_{app}, against the β shown in Fig. 3 is represented by a straight line. Such kinetic behavior is analogous to that exhibited in the amination of CMPS with 2-aminobutanol in dioxane, and the line in Fig. 3 may be expressed by this equation:[3]

$$k_{app} = k_0(1+m\beta) \qquad (6)$$
$$k_0 = 1.25\times10^{-3}$$
$$m = 4.0$$

Viscosity Change During the Amination of CMPS. The viscosity ratios $(H\equiv(\eta_{sp}/C_p)/(\eta_{sp}/C_p)_{\beta\to0})$[4] in the amination of CMPS in DMF and DMSO are plotted against β in Fig. 4. The H value decreases with β in the amination with alkyl amines, while it increases with β in the amination with aminoalcohols.

Acid-base Titration of Aminated Chloromethylated Polystyrene (AMPS). AMPS (N%=6.10), which was obtained by the amination of CMPS with diethanolamine, is analogous in its chemical structure to poly[bis-(2-hydroxyethyl)aminomethyl styrene] (N%=6.33). An aq. DMF solution of AMPS was titrated first with hydrochloric acid and then with a sodium hydroxide

solution in the presence of 1.5 M NaCl. The titration curves are shown in Fig. 5, where β_1 is the degree of ionization of the base and where α_1 $(=1-\beta_1)$ is the degree of dissociation of the conjugated acid.

It has been established that the titration data of some polyelectrolytes can be expressed by a modification of the Henderson-Hasselbach equation:[7]

$$pH = pK_a - n'[(1-\alpha_1)/\alpha_1] \qquad (7)$$

where pK_a and n' are empirical constants. This relation is, in general, hard to apply to polymeric bases such as polyethyleneimine and polyvinylamine.[8] However, the titration data of AMPS fit Eq. (7); $pK_a=5.76$ and $n'=1.25$ in the absence of salt, and $pK_a=7.37$ and $n'=1.0$ in the presence of added salt. Accordingly, the pK_a value of 7.37 is considered to represent the intrinsic dissociation constant of AMPS (pK_0), and this value is close to the dissociation constant of bis(2-hydroxypropyl)benzylamine ($pK=7.5$) reported by Boivin.[9]

Quaterinization of AMPS. AMPS could be *N*-methylated easily and completely with methyl iodide in 50% aq. DMF. AMPS was unreactive to chloroacetic acid, while it was quantitatively *N*-carboxymethylated with bromoacetic acid. In both the quaternizations, the deceleration was marked beyond the half-quaternization point. The kinetics of the two reactions can be described by Eqs. (3), (4), and (5), where a is the initial concentration of methyl iodide or bromoacetic acid, b is that of the amine groups of AMPS, and x is the concentration of halogen ions after time t. The courses of these reactions are shown in Fig. 6, where the white circles indicate the observed values and where the solid lines indicate those calculated on the basis of Eq. (3). The course of the latter reaction could also be expressed by Eq. (3). The rate constants of these reactions are tabulated in Table 8.

Halide	Temp. °C	Rate const. $\times 10^2$ l/mol·min		k_2/k_1
		k_1	k_2	
Methyl iodide	30	10.4	5.89	0.57
Bromoacetic acid	30	3.54	2.05	0.58

Discussion

Acceleration and Deceleration during the Amination of CMPS. We observed a stronger acceleration during the amination of CMPS with diethanolamine in dioxane than in amination with 2-aminobutanol.[3] On the other hand, deceleration was observed during the amination of CMPS with diethanolamine in DMF and DMSO, while the kinetics of the amination with 2-aminobutanol obeyed the ordinary second-order kinetics in both the solvents.[4] Comparing this kinetic behavior in the amination with aminoalcohols with that in the amination with the corresponding alkylamines, it was found that the amination with *s*-butylamine (2-aminobutane) conformed to the second-order rate equation in dioxane and DMF and that the amination with diethylamine was decelerated in both dioxane and DMF.[1] Therefore, the hydroxyl groups of the aminoalcohols are obviously involved in the acceleration phenomena in dioxane. It is reasonable to presume that the hydroxyl groups of the already-aminated neighbors form the hydrogen bond with the chlorine of the chloromethyl groups in the transition state of the amination and that the formation of this hydrogen bond is obstructed in dipolar aprotic solvents, such as DMF and DMSO.

The slope of the $\overline{kt}$ *vs.* t plot beyond $\beta \approx 1/3$, which is shown in Fig. 2, is considered to be a rate constant of the chloromethyl group under the accelerating effect of the neighboring groups (k_2);[3] it will be given by $\Delta\overline{kt}/\Delta t$ on the basis of Eq. (5); $k_2 = 8.25 \times 10^{-3}$ l/mol min, $k_2/k_0 = 6.6$ (40 °C).

Comparison between the Rates of CMPS and Benzyl Chloride. In the present study, a comparison of the intrinsic amination rate constant of CMPS (k_p) and the corresponding rate constant of benzyl chloride (k_B), showed that $k_p < k_B$ with diethanolamine ($k_1/k_B = 0.88$ (DMF), $k_1/k_B = 0.83$ (DMSO)), while $k_p > k_B$ with diethylamine ($k_1/k_B = 1.23$ (DMF)) and with di-*n*-butylamine ($k_1/k_B = 1.06$ (DMF)). Table 9 shows the activation parameters in the amination of CMPS and benzyl chloride with diethylamine and diethanolamine; $\Delta H^{\ddagger}$, the enthalpy of activation, $\Delta S^{\ddagger}$, the entropy of activation, and $\Delta G^{\ddagger}$, the free energy of activation, all of which have been calculated for 25 °C by means of

TABLE 9. THERMODYNAMIC QUANTITIES AT 25 °C IN THE AMINATION OF CMPS AND BENZYL CHLORIDE

Amine	Solvent	Chloride	$\Delta H^{\ddagger}$ kcal/mol	$\Delta S^{\ddagger}$ e. u.	$\Delta G^{\ddagger}$ kcal/mol
Diethyl	DMF	CMPS, k_1	11.2±0.2	−36.9±0.7	22.1
		k_2	11.6±0.2	−36.4±0.6	22.5

		k_2	11.4±0.1	−35.0±0.4	21.8
		Benzyl	11.2±0.1	−35.0±0.4	21.6

the equations described in a previous paper.[4]

Although k_p is generally almost the same as k_B, and although there are not many differences in $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ between CMPS and benzyl chloride, some features in regard to these parameters may be deduced from the data obtained thus far. It was previously shown, in the amination with butylamine isomers and 2-aminobutanol in a dipolar aprotic solvent, that $k_p<k_B$; this was attributed to the $\Delta S^{\ddagger}$ value of CMPS being lower than that of benzyl chloride.[1] In addition, it was shown that, in most cases, the $\Delta H^{\ddagger}$ value of CMPS was lower than that of benzyl chloride.[1,4,10] In a dipolar aprotic solvent, the solvation of the transition state plays an important role in the determination of the amination rate, and it may be sterically obstructed by the neighboring groups of the polymer, resulting in the $\Delta S^{\ddagger}$ value for CMPS being lower than that for benzyl chloride. On the other hand, if such an energetic interaction as that due to the London dispersion force is operative between alkyl groups of the amine molecule and non-polar polymer segments at the transition state, it will lower the $\Delta H^{\ddagger}$ value for CMPS as compared with that for benzyl chloride.

In the amination with diethylamine, the fact shown in Table 9 that the $\Delta G^{\ddagger}$ of CMPS is a little lower than that of benzyl chloride ($k_p>k_B$) may be explained by the fact that the lower $\Delta H^{\ddagger}$ value surpasses the lower value of $\Delta S^{\ddagger}$. In the amination with diethanolamine with two hydroxyl groups, however, since the $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ values are almost the same for CMPS and benzyl chloride, it is difficult to explain value of the $\Delta G^{\ddagger}$ of CMPS being little higher than that of benzylchloride ($k_p<k_B$) in terms of the differences in the $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ values.

Effect of Amine on the Amination Rate. The $\Delta G^{\ddagger}$ values in the amination with diethylamine are comparable to those with *n*-butylamine or isobutylamine,[1] and there is little difference in the $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ values. These results may be explained by the face that the steric hindrance by the benzene ring to the alkyl group of the secondary amine in the transition state is not so large as the hindrance to that of *n*-butylamine or isobutylamine, and also by the fact that the basicity of the secondary amine is higher than that of the primary amines. On the other hand, the higher $\Delta G^{\ddagger}$ value with diethanolamine than that with diethylamine is due to the higher $\Delta H^{\ddagger}$ value; this may be ascribed to the inductive effect of the hydroxyl groups, as in the case of 2-aminobutanol.[1]

Effect of the Solvent on the Amination Rate. The $\Delta G^{\ddagger}$ values in the amination with diethanolamine in DMSO are about 1 kcal/mol lower than the corresponding values in DMF. This is due merely to the difference in $\Delta H^{\ddagger}$, as was the case of the amination with 2-aminobutanol.[4] Since both DMF and DMSO are dipolar aprotic solvents, the lower $\Delta H^{\ddagger}$ in DMSO is considered to be caused by the stronger solvation of the transition state in DMSO resulting from its stronger polarity.

Quaternization of AMPS. Charged groups are not formed on polymer molecules in the amination of DMPS with primary and secondary amines, because the hydrochloric acid produced by the reaction is transformed to amine, which is present in a large excess. The deceleration observed in the amination of CMPS is due to the steric hindrance of the neighboring groups. In the reaction of AMPS with methyl iodide and bromoacetic acid in 50% aq. DMF, however, the observed deceleration may be ascribed to the electrostatic interactions, because charged groups (quaternary ammonium groups) are formed on the polymer in these reactions. The assumption of the electrostatic effect is supported, by the acid-base titration data of AMPS, and also by the facts shown in Table 8, which indicates that the k_2/k_1 ratio is almost the same for two reactions with different quaternizing reagents. The facts that the deceleration is marked beyond $\beta\approx 1/2$ and that the over-all kinetics can be followed by Eq. (3) suggest that k_1 represents the intrinsic rate constant and k_2, the rate constant under the influence of two nearest-neighboring charged groups.

The author wishes to express his thanks to Dr. Masaya Yanagita for his valuable discussions. He is also grateful to Mr. Kazuaki Kawamura, Mr. Masayuki Takahashi, and Mr. Jun-ichi Nagase for their helpful assistance in preparing the polymer and in carrying out the measurements.

Effects of Pressure on Organic Reactions. VI.* The Acid-catalyzed Rearrangement of Benzopinacol in Acetic Acid

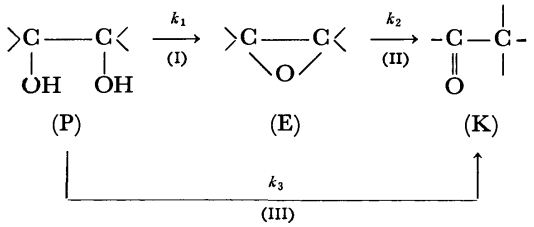
Katsuhiro TAMURA** and Takashi MORIYOSHI

Department of Chemical Engineering, Faculty of Engineering, Tokushima University, Minamijosanjima-cho, Tokushima 770

(Received April 8, 1974)

The rates of the acid-catalyzed rearrangements of benzopinacol and of tetraphenylethylene oxide in acetic acid have been measured in the range of 35—45 °C at pressures up to 983 kg/cm². It was proved under pressures that the rearrangement of pinacol proceeds through two routes, with three processes. The probable mechanism for each process has been discussed in the light of the activation parameters, particularly the volume parameters ($\Delta V^{\neq}$ and ΔV). Consequently, it may be probably inferred that the classical carbonium ion is an intermediate in the rearrangement of oxide, but not in the other two processes, *i.e.*, the conversion of pinacol to oxide and the direct rearrangement to pinacolone, and that the transition states in the two processes of rearrangement must be clearly distinguished.

The acid-catalyzed rearrangement of benzopinacol (P) to β-benzopinacolone (K) has already been studied kinetically by Gebhart and Adams[1] in acetic acid under atmospheric pressure. Their results indicate that P undergoes two concurrent reactions, consisting of three processes (I, II and III), as is shown in Scheme 1; one reaction is an indirect conversion to K through the intermediate formation of tetraphenylethylene oxide (E), and the other, a direct conversion. On the basis of the facts that correlations existed between the acidity function of the medium and the rate constant of each of the reactions involved, and that the entropies of activation ($\Delta S^{\neq}$) were found to be greatly positive, the authors suggested that any process of interest probably takes place by means of the A-1 mechanism, involving the formation of the classical carbonium ion.



Scheme 1

However, their reasoning seems not to be natural in giving the same transition state for different processes; further, the grounds stated by them are not necessarily helpful and decisive for determining the mechanism, as was pointed out by Whalley.[2] In order to find a more plausible explanation for the reaction mechanism, it is a useful tool to measure the volume changes of the reacting species attending the progress of the reaction.

In this paper, we will describe the effects of temperature and pressure on the acid-catalyzed rearrangements of P and E in acetic acid. Both the volume of activation ($\Delta V^{\neq}$) and the volume change of the complete reaction (ΔV) will be discussed together with the other parameters in order to understand the structures of the transition states for the processes under consideration.

Experimental

Materials. P prepared[3] was recrystallized from benzene and ligroin. E prepared[4,5] was recrystallized three times from a mixture of anhydrous ethanol and chloroform (10 : 1). K was prepared from P by boiling it with iodine in glacial acetic acid;[6] it was then recrystallized from benzene and ligroin. All the materials were identified by checking the mp and by elemental analyses. Commercial glacial acetic acid was distilled from potassium permanganate; the distillate was then dried over phosphorus pentoxide and redistilled. The stock solution of perchloric acid used as a catalyst was prepared by diluting commercial, analytical-grade 70% aqueous acid with the purified glacial acetic acid; it was titrated against a standard solution of sodium acetate in acetic acid by means of the potentiometric method. The other chemicals were of a reagent grade and were used without further purification.

Analytical Methods. Both P and K were analyzed by a small modification of the methods described by Gebhart and Adams.[1] The optical densities for the determination of K were measured with a Hitachi Model 139 UV-VIS spectrophotometer.

Kinetic Measurements. All the runs under atmospheric pressure and high pressures were carried out with a pressure apparatus described previously.[7] The reaction mixture was made up by adding the required amount of perchloric acid solution to a preheated acetic acid solution of P. The concentration of the reaction mixture was initially about 0.014 M in P and was 5.74×10^{-4} M in perchloric acid. The first sampling in the kinetic run was made after allowing one hour for thermal equilibrium to be attained; the sample removed was then analyzed for P and K. The same operation was repeated five times at intervals of one or two hours for each run. A similar procedure was also employed in the rearrangement of E at the same concentration of the catalyst as in the case of P. Six samples were taken during a kinetic run and were analyzed only for K. The initial concentration of E was determined from the amount of K produced at the completion of reaction after at least ten half-lives; it was approximately 5.6×10^{-3} M in all the runs.

Measurements of the Partial Molar Volumes. The partial molar volumes of the concerned substances in acetic acid were determined from density measurements according to the usual method. The pycnometers used were of the Ostwald-Sprengel type, with a capacity of about 20 ml.

Results

The reaction manner shown in Scheme 1 can be expected to be true also at high pressures, as is illustrated in Fig. 1, which shows a typical plot of the concentration against the time for a run at 40 °C and 232 kg/cm².

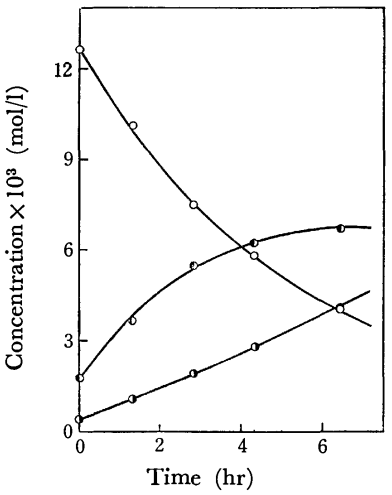

Fig. 1. Variation with time of the concentration at 40 °C and 232 kg/cm².
○: Benzopinacol, ◐: Tetraphenylethylene oxide, ◑: β-Benzopinacolone

Assuming that, in each of the three processes, the first-order rate law is obeyed exactly and that the reverse reaction from E to P does not occur, the concentration ratio, [E]/[P], at an arbitrary time, t, can be represented by the equation:

$$\frac{[E]}{[P]} = \left\{\frac{k_1}{k_p-k_2}+\frac{[E]_0}{[P]_0}\right\}\exp(k_p-k_2)t - \frac{k_1}{k_p-k_2}, \qquad (1)$$

where the k's are the rate constants for the processes shown in Scheme 1, k_p is the sum of k_1 and k_3, and $[E]_0$ and $[P]_0$ are the concentrations of E and P respectively at zero time in kinetics. Since k_p can be determined from the rate of the disappearance of P and k_2, from a separate run for the rearrangement of E to K under the same conditions, it is possible to evaluate k_1 from the slope or the intercept of a straight line obtained from a plot of [E]/[P] against $\exp(k_p-k_2)t$. Finally, k_3 can be calculated from this relation: $k_p = k_1+k_3$. As an example, the plot obtained from the results in Fig. 1 is illustrated in Fig. 2. From the fact that there is a satisfactory linear relationship between [E]/[P] and $\exp(k_p-k_2)t$, the validity of the above assumption is supported for the kinetics at high pressures; this is in agreement with the observations to be described below. The separation of k_p into two components, k_1 and k_3, was thus made from similar plots obtained under various conditions. The rate constants measured for the three processes are listed in Table 1. The mean error is within about a few per cent for k_p and k_2, and somewhat greater for k_1. However, it is apparent from the large difference in numerical value between k_1 and k_3 that the error for k_3 extracted from k_p is over ten times that for k_1. The second-order rate constants were obtained by dividing

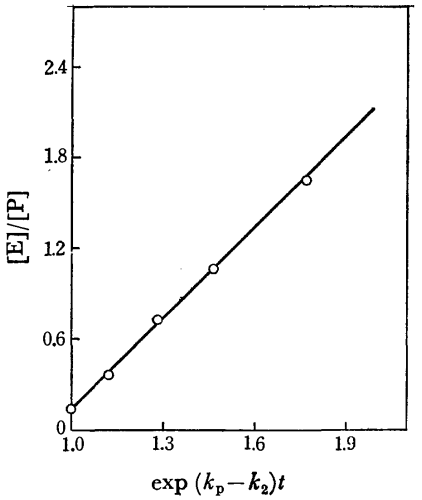

Fig. 2. A plot of [E]/[P] *vs.* $\exp(k_p-k_2)t$ at 40 °C and 232 kg/cm².

Table 1. Rate constants for each process, $k\times10^2$ ($l\cdot mol^{-1}\,s^{-1}$)

Temp. (°C)		Pressure (kg/cm²) 1	232	489	735	983
35	k_p	4.23	4.25	4.38		
	k_1	4.02	3.93	3.92		
	k_2	2.11	2.41	2.70		
	k_3	0.21	0.32	0.46		
40	k_p	8.60	8.69	8.80		8.82
	k_1	8.02	7.90	7.71		6.76
	k_2	3.81	4.40	5.37	6.23	7.32
	k_3	0.58	0.79	1.09		2.06
45	k_p	17.5	17.7	18.0		18.1
	k_1	16.1	15.9	15.7		14.3
	k_2	6.92	8.11	9.71	11.5	13.6
	k_3	1.4	1.8	2.3		3.8

the first-order constants by the concentration of the catalyst, as corrected for the thermal expansion and compression of the solvent, taken by extrapolating the data in the literature.[8]

It may be also verified that, at high pressures, the rate observed cannot be explained in terms of a simplified reaction scheme neglecting the direct rearrangement of P. The concentration values at time t can be calculated from Eq. (1) and the over-all rate equation of P ($[P]=[P]_0e^{-k_pt}$), with the initial concentrations ($[P]_0$, $[E]_0$ and $[K]_0$) in kinetics. For example, in the reaction shown in Fig. 1, the values calculated by assuming that $k_3=0$ and $k_1=k_p$ in Eq. (1) are $[P]=5.83\times10^{-3}$ M, $[E]=6.67\times10^{-3}$ M, and $[K]=2.30\times10^{-3}$ M at $t=259$ min, while the corresponding values obtained from the values of the rate constants ($k_3\neq0$) given in Table 1 are $[P]=5.83\times10^{-3}$ M, $[E]=6.18\times10^{-3}$ M, and $[K]=2.79\times10^{-3}$ M. The experimental values are $[P]=5.81\times10^{-3}$ M, $[E]=6.19\times10^{-3}$ M, and $[K]=2.80\times10^{-3}$ M, in good agreement with the latter. The activation parameters evaluated in the usual way are summarized in Table 2. Our values of

TABLE 2. ACTIVATION PARAMETERS

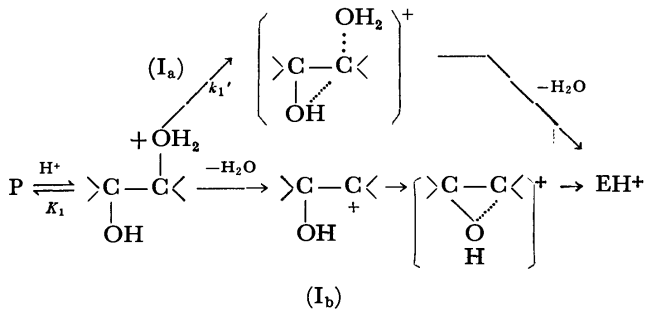
Parameter	Condition	Process I	Process II	Process III
$\Delta V^{\neq}$ (cm³/mol)	35 °C	2.3	−15.5	−44
	40	2.1	−17.6	−34
	45	1.9	−18.6	−28
E_a (kcal/mol)	1 kg/cm²	27.0	23.2	35
	232	27.1	23.8	32
	489	27.1	24.1	29
	735		24.1	
	983	27.5	24.4	24
$\Delta S^{\neq}$[a] (cal/deg·mol)	1 kg/cm²	20.6	7.0	41
	232	20.9	9.2	32
	489	20.9	10.5	23
	735		10.8	
	983	21.8	12.1	8

a) at 45 °C.

E_a and $\Delta S^{\neq}$ at 1 kg/cm² are somewhat different from those of Gebhart and Adams, but the difference seems to be due to the difference in reaction conditions, mainly in the temperature.

Discussion

Volume of Activation and Volume Change of the Reaction. Process I: Two mechanisms can be proposed for this process; they are shown in Scheme 2:



(I$_b$)

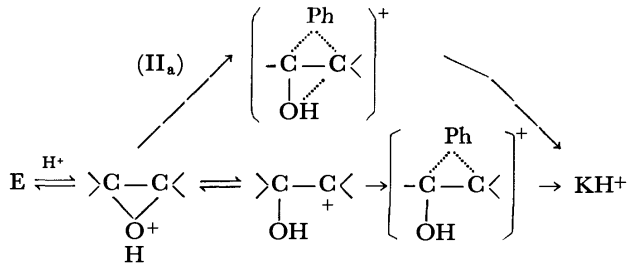
Scheme 2

where the molecules in square brackets denote the transition states. It is generally accepted that the volume of activation is negative in a simultaneous bond-forming and bond-breaking process. The $\Delta V^{\neq}$ in Mechanism (I$_a$) must be a small value near to zero, because the volume contraction described above offsets the increase in volume by the desolvation of solvent around an attacking hydroxyl group and by the dispersion of the electric charge arising from a ring structure formed partly in the transition state. Two possible rate-determining steps postulated in Mechanism (I$_b$), *i.e.*, the elimination of a water molecule and the formation of an oxide ring from a carbonium ion, will lead to a larger positive value of $\Delta V^{\neq}$ than the values observed, judging from the structural and electrostrictive contributions to the volume. The results for the hydrolysis of aliphatic epoxides reported by Koskikallio and Whalley,[9] although different from the present case in the solvent used, give useful information which helps us to choose Mechanism (I$_a$). They concluded that the hydrolysis proceeds by the A-2 mechanism, in which a water molecule attacks the C_α atom from the back and synchronously the C_α–O bond of the oxide ring stretches. The $\Delta V^{\neq}$ value for the reactions of the glycol to oxide becomes 2—3 cm³/mol, calculating from the values of $\Delta V^{\neq}$ and of ΔV for the hydrolyses of ethylene and propylene oxides. The estimated values agree well with those for the present reaction, given in Table 2. This implies that Process I is similar to the reverse hydrolysis of epoxide and that it probably proceeds through Mechanism (I$_a$). The same conclusion may also be expected from the results for trimethylene oxide[10] and epichlorohydrin.[10,11]

P probably consists of two conformers, the *trans*- and *gauche*-types being in equilibrium. The steric factor must largely participate in the reaction, so that in I$_a$ the *trans*-type is more favorable than the *gauche*-one. The results for the hydrolysis of 1,2-epoxy-1,2-dimethylcyclopentane[12] support this theory.

Process III: This process is formally analogous to Process I except for the difference between the two attacking groups, hydroxyl and phenyl. As has been mentioned above, the precision of k_3 is very poor in comparison with that of the other constants, so that the activation parameters evaluated are not correct enough to permit an exact discussion. However, it is noteworthy that the values of $\Delta V^{\neq}$ are large and negative, while those of $\Delta S^{\neq}$ large and positive, as is shown in Table 2, in contrast to the results for aliphatic pinacol reported previously.[13] Such anomalous findings, which have been also obtained for Process II with the same phenyl shift, suggest the participation of π-electrons of the shifting phenyl group besides the usual structural and electrostrictive contributions. This participation can be expected to result in much volume contraction despite the volume decrease being reduced by the charge delocalization, judging from the phenomena pointed out by le Noble *et al.*[14] in solvolysis reactions. If it is permissible to make a further deduction, a random packing may be presumed to occur in the reorganization of the solvent environment due to the changing interaction between the reacting species and the solvent, accompanied by π-participation. These considerations, while leaving some logical doubt, suggest that a synchronous mechanism with a phenyl shift as the slow step, similar to I$_a$, is also probable in this process. Generally, the ring structure with an electric charge dispersed is stable in such a lower dielectric medium as acetic acid. In this mechanism, a *gauche*-conformer is suitable. The results of the rearrangements of 1,2-dimethylcyclopentane-1,2-diol[12] and of *cis*- and *trans*-1,2-diphenylacenaphthene-1,2-diol[15] support the above mechanism.

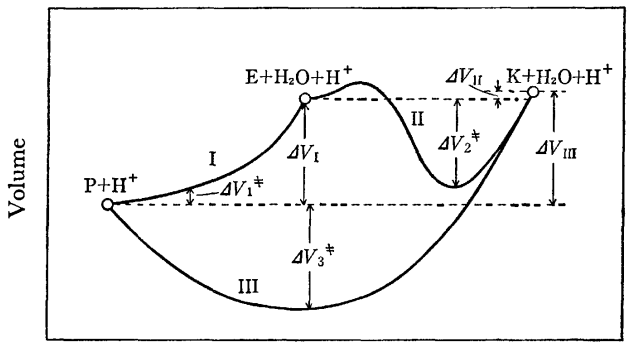
Process II: In the mechanism (II$_a$) shown in Scheme 3, in which the rate-determining cleavage of the C–O bond in the protonated oxide occurs simultaneously with the phenyl shift, there is necessarily a serious steric retardation and an additional energy is required for forming a bicyclic structure. A comparison of the activation parameters for this process with those for



Scheme 3

the others in Table 2 leads us to reject the mechanism as unacceptable. In an alternate mechanism (II_b), two slow steps, *i.e.*, the cleavage of the protonated oxide to the classical carbonium ion and the shift of the phenyl group in the resulting ion, may be postulated. In the mechanism with the former slow step, $\Delta V^{\neq}$ can be expected to be positive because of the stretching of the C–O bond in the oxide ring, accompanied by the dispersion of the ionic charge; this is evidently incompatible with the observed values, even if the volume change for the protonation step is permitted to be somewhat negative. The latter mechanism involves the formation of the carbonium ion besides the protonation in the pre-equilibrium step. The increase in volume by a cleavage of oxide ring is usually in the range from few to several cm^3/mol,[16] but it is somewhat reduced if serious steric hindrance does not occur in the solvation of the resulting carbonium ion. The subsequent slow step can be thought to cause the fairly large contraction of the volume as a result of a ring closure, which is probably subject to such phenyl participation as has been described for Process III, although differing from that only in the absence of a leaving water molecule in the transition state. These considerations lead to the conclusion that this mechanism seems to explain the findings for $\Delta V^{\neq}$ more satisfactorily than the others discussed.

The schematic diagram in Fig. 3, which shows the volume changes along the reaction co-ordinate, provides strong evidence for the suggested structure of the transition state in Process II. In the curve illustrated for this process, the first small peak denotes the position of the carbonium ion as an intermediate. For simplification, there is no indication of any volume change for the proton-transfer step involved in each process. The volume change for that from H_3O^+ in an aqueous solution is usually small and negative,[17] but in such a lower dielectric medium as acetic acid it becomes very negative as a result of the combination of ion-pair formation from dissolved acid and the action of $CH_3COOH_2^+$ as a proton-donor. The partial molar volumes of the concerned substances were determined in order to evaluate the volume change for the complete reaction for each process. The results are given in Tables 3 and 4. From this diagram, along with the values shown in Table 4, it is clear that there is an apparent difference in the volume of the transition state between Processes II and III. If Process II proceeds by way of II_b, as deduced, Process III cannot proceed by way of a mechanism forming a classical carbonium ion in agreement with the reasoning discussed above, because its transition state differs from that of II_b.



Reaction co-ordinate

Fig. 3. Schematic diagram of the volume change along reaction co-ordinate at 40 °C.

Observed Volume of Activation and Its Constituent Terms. If one assumes that there is an equilibrium between the two conformers in P, of which the *trans*-type converts to E, and the *gauche*-one, to K, the over-all reaction rate for P can be expressed by the equation:

$$R = \frac{K_1 k_1' h_0}{1+K'}[\mathrm{P}] + \frac{K' K_3 k_3' h_0}{1+K'}[\mathrm{P}], \tag{2}$$

where K is the pre-equilibrium constant, and k', the rate constant for the slow step, and where the subscripts refer to the corresponding processes. K' is an equilibrium constant between the two conformers, and h_0, Hammett's acidity function ($H_0 = -\log h_0$). Therefore, the apparent second-order rate constants measured for the two processes may be given as follows:

$$k_1 = \frac{K_1 k_1'}{1+K'} \cdot \frac{h_0}{[\mathrm{HClO_4}]} \tag{3a}$$

and

$$k_3 = \frac{K' K_3 k_3'}{1+K'} \cdot \frac{h_0}{[\mathrm{HClO_4}]}, \tag{3b}$$

where $[HClO_4]$ is the concentration of the catalyst. From Eq. (3a), the observed volume of activation for Process I, $\Delta V_1^{\neq}$, is given as a composite quantity:

$$\Delta V_1^{\neq} = \Delta V_1 + \Delta V_1^{\neq'} + \frac{RT\partial \ln\{[\mathrm{HClO_4}]/h_0\}}{\partial P} + \frac{RT\partial \ln(1+K')}{\partial P}, \tag{4}$$

where ΔV_1 is the volume change for the pre-equilibrium step, and $\Delta V_1^{\neq'}$, the volume of activation for the step in which a hydroxyl group attacks the adjacent carbon atom, as is shown in Scheme 2. A similar equation can be also derived from Eq. (3b) for Process III. The fourth term on the right-hand side in Eq. (4) is likely to be negligible because the pressure dependence of K' is probably small; *i.e.*, there is no substantial difference in volume between the two conformers of P. The third term may be estimated approximately in the following way:[13,18] if the change in h_0 with pressure can be assumed to be due to only the change in the concentration of the acid, then:

TABLE 3. PARTIAL MOLAR VOLUMES AT 40 °C

Substance	$\overline{V}$ (cm³/mol)
P	310
E	317
K	318
H_2O	12.2

TABLE 4. VOLUME CHANGES OF COMPLETE REACTION AT 40 °C AND 1 kg/cm²

Process	ΔV (cm³/mol)
I	19
II	1
III	20

$$\frac{RT\mathrm{d}\ln\{[HClO_4]/h_0\}}{dP} = RT\beta\left[1-\frac{\mathrm{d}\ln h_0}{\mathrm{d}\ln[HClO_4]}\right], \quad (5)$$

where β is the compressibility of the reaction mixture, assumed to be approximately that of the solvent. From the results of Ludwig and Adams,[19] $\mathrm{d}\ln h_0/\mathrm{d}\ln[HClO_4]=1.05$ and so:

$$\frac{RT\mathrm{d}\ln\{[HClO_4]/h_0\}}{dP} = -0.12\ \mathrm{cm^3/mol}.$$

This value leads the third term apparently being insignificant under the present conditions, if the assumption for h_0 is actually valid. The dielectric constant of acetic acid increases with an increase in pressure, so the dissociation constant of perchloric acid in acetic acid will increase; this results in an increase in h_0. Hence, the assumption described above would not strictly hold for the present case. Since h_0 under high pressure has not yet, unfortunately, been measured, it is impossible to discuss this subject in detail. The value of $[HClO_4]/h_0$ corrected for the compression and thermal expansion of the reaction mixture will decrease with an increase in pressure, judging from the fact that the concentration of the catalyst at 40 °C increases only 1.074 times[20] at 1000 kg/cm² compared with 1 kg/cm². This consideration brings about a larger negative value for the third term in Eq. (4) than -0.12 cm³/mol; consequently, the net value of $(\Delta V_1+\Delta V_1^{*\prime})$ may be expected to have a larger value than that observed. Similar considerations must also be made for the volume of activation of Process III. Furthermore, since the acidity function term, Eq. (5), is present also in ΔV_2^* derived as a composite quantity for Process II, this term does not need to be considered when comparing the ΔV^* values of the processes.

Entropy of Activation. The results listed in Table 2 can be seen to satisfy roughly the pseudo-thermodynamic relationship:

$$(\partial\Delta V^*/\partial T)_P = -(\partial\Delta S^*/\partial P)_T. \quad (6)$$

The partial derivatives of ΔV^* and ΔS^* for Process III are opposite in direction to those for the rearrangement of aliphatic pinacol.[13] The findings support the reasoning that the former proceeds through a mechanism different from that for the latter, described above. On the basis of the large positive values of ΔS^*, Gebhart and Adams suggested that the classical carbonium ion is an intermediate in the processes under consideration. However, the problem concerning ΔS^* does not seem to be so simple because of the desolvation caused by the shift of the phenyl group.[21] It seems that the most significant part of the positive contribution to ΔS^* for Processes I and III is due to the desolvation in the step of the ring closure of the hydroxyl group or in that of the shift of the phenyl group, with the elimination of water. In addition, the phenyl participation proposed above seems likely to exert a more positive effect on ΔS^* for both processes, II and III. However, in the former the extent of the contribution must certainly be reduced because of the possible solvation of the carbonium ion; this is in qualitative agreement with the findings. Since the entropy change for the proton-transfer step is generally positive, but tends to have values over a relatively wide range dependent on the substrate,[17] those in the present cases are difficult to estimate.

From the results in Table 1, the proportion of the formation of K by the direct rearrangement (III) can be found to increase with the pressure, from 8 to 21% at 45°C between 1 and 983 kg/cm². Evidently, this increase results from the decrease in E_a with the pressure, as is shown in Table 2. Furthermore, a consideration according to the relationship given thermodynamically:

$$\Delta V^* = \left(\frac{\partial\Delta H^*}{\partial P}\right)_T - T\left(\frac{\partial\Delta S^*}{\partial P}\right)_T \quad (7)$$

reveals that the effect of pressure on this process is not entropy-controlling, but enthalpy-controlling.

Deuterium Isotope Effects on the Redox Decomposition of Hydroxymercurated Propene and 2-Butenes in an Aqueous Solution

Sumio SHINODA and Yasukazu SAITO

Department of Synthetic Chemistry, Faculty of Engineering, University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received May 20, 1974)

Kinetic deuterium isotope effects on the redox decomposition of hydroxymercurated propene, *cis*-, and *trans*-2-butenes in an aqueous solution ($CH_3CH(OH)CHRHg^+ \rightarrow CH_3COCH_2R + Hg(0) + H^+$; R=H, CH_3) were determined by following the reaction *in situ* by means of PMR spectroscopy. Taking advantage of the PMR characteristics, the identity of the reaction conditions was confirmed by comparing the rates for the reactant mixtures (*e.g.*, $CH_3CH(OH)CH_2Hg^+ + CH_3CD(OH)CH_2Hg^+$). The mercurials, deuterated on either β-carbon ($CH_3CD(OH)CH_2Hg^+$, $CH_3CD(OH)CHCH_3Hg^+$) or α-carbon ($CH_3CH(OH)CDHHg^+$, $CH_3CH(OH)CDCH_3Hg^+$), gave primary and secondary deuterium isotope effects of 1.35—1.40 and 1.17—1.19 respectively. A possible structure of the activated complex was proposed in accord with the observed nature of the intramolecular hydrogen shift.

The oxidation of olefins by aqueous mercuric salts[1] is known to produce unsaturated aldehydes,[2-5] saturated aldehydes,[3,4] allylic alcohols,[5] or saturated ketones[6] under various reaction conditions. In the case of milder conditions, it has been found[6,7] that propene and 2-butenes are oxidized stoichiometrically to acetone and methyl ethyl ketone respectively. The overall reaction consists of a fast[8] hydroxymercuration of the olefins[9] (Eq. (1)), followed by a rate-limiting redox decomposition of the mercurials thus formed into corresponding ketones (Eq. (2)):

$$CH_3CH{=}CHR + Hg^{2+} + H_2O \longrightarrow CH_3-\underset{OH}{\overset{H}{C}}-\underset{Hg^+}{\overset{H}{C}}-R + H^+ \quad (1)$$

$$CH_3-\underset{OH}{\overset{H}{C}}-\underset{Hg^+}{\overset{H}{C}}-R \longrightarrow CH_3-\overset{O}{\overset{\|}{C}}-\overset{H}{C}-R + Hg(0) + H^+ \quad (2)$$

where R=H, CH_3

The intermediate mercurials are so stable that the second process can be pursued by PMR spectroscopy *in situ*[6] at appropriate temperatures. Prior articles reported data concerning the stoichiometry,[6] the rate equation,[6,7] the rate dependence on the added electrolytes,[7] product analysis from the D_2O solution,[10] and the alkyl-substituent effect on the rate.[11] In the present paper, we wish to report on deuterium isotope effects in the redox decomposition of hydroxymercurated propene and 2-butenes.

In order to measure the kinetic isotope effect accurately, it is desirable to determine the rates for both the labeled and unlabeled reactants in mixed solutions, because the identity of the reaction conditions is thus best assured. As far as the deuterium isotope effect is concerned, PMR spectroscopy appears especially suited for the analysis of reactions on account of its reasonable facility in differentiation between deuterated and undeuterated reactants *in situ*.[12]

With regard to olefin oxidation by other metal ions in an aqueous solution, similar reaction schemes have also been postulated for Pd(II),[13] Tl(III),[13] and Rh(III),[14] for which, in contrast to Hg(II), the redox decomposition of hydroxymetallation adducts has been claimed to occur after the rate-limiting (*e.g.*, hydroxymetallation) process. In view of the established usefulness of isotope effects in the elucidation of reaction mechanisms,[15] it seemed of particular interest to determine directly the isotope effects on the redox-decomposition process, which is possible only in the case of Hg(II) oxidation.

Results

Primary Deuterium Isotope Effect on the Decomposition of Hydroxymercurated Propene-2-d_1. It was previously confirmed that the redox decomposition of hydroxymercurated olefins involves an intramolecular shift of β-hydrogen to α-carbon (Eq. (2)),[1,11] and that the decomposition rate is first order with respect to the mercurial.[6,7] Therefore, if the first-order rate constants for hydroxymercurated propene, $CH_3CH(OH)CH_2Hg^+$ (**1**), and hydroxymercurated propene-2-d_1, $CH_3CD(OH)CH_2Hg^+$ (**2**), are designated by k_H and k_D^{prim} respectively, k_H/k_D^{prim} represents the primary deuterium isotope effect for the intramolecular 1,2-hydrogen shift in the redox decomposition of **1**:

$$CH_3CH(OH)CH_2Hg^+ \xrightarrow{k_H} CH_3COCH_3 + Hg(0) + H^+ \quad (3)$$

$$CH_3CD(OH)CH_2Hg^+ \xrightarrow{k_D^{prim}} CH_3COCDH_2 + Hg(0) + H^+ \quad (4)$$

Figure 1 shows the time-sequential PMR spectra for the decomposition of **1** and **2** in a mixed solution (1.5 m, $[\mathbf{2}]_0/[\mathbf{1}]_0$: 0.20). It is obvious from Fig. 1 that the difference in the rate of decomposition is not very large between **1** and **2**. The concentrations of the reactants during the reaction were determined from the doublet peak for **1** ($CHC\underline{H}_3$; δ 1.21) and the singlet peak for **2** ($CDC\underline{H}_3$; δ 1.20) by planimetry on an expanded scale. The absence of H-D exchange between **2** and the H_2O solvent was confirmed by following the decomposition of **2** alone under identical conditions; no doublet peak appeared at δ 1.21.

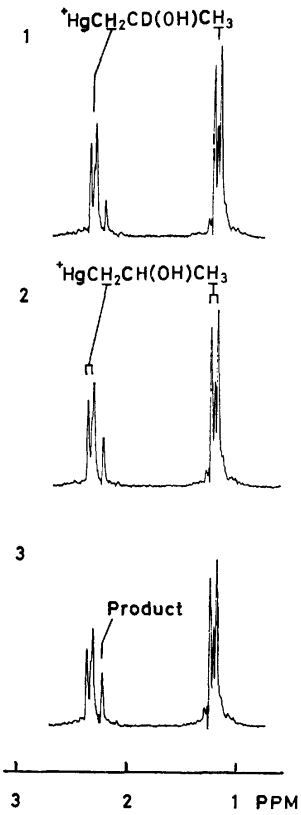

Fig. 1. The time-sequential PMR spectra obtained *in situ* for the redox decomposition of $CH_3CD(OH)CH_2Hg^+$ and $CH_3CH(OH)CH_2Hg^+$ at 38.0 °C in the mixed solution. These spectra were taken with deuterium irradiation at 15.349390 MHz after (1) 9.4 min, (2) 20.5 min, (3) 31.3 min from the moment of raising the solution temperature.

From the time-dependence of the concentrations of **1** and **2**, based on the first-order rate equations (Eqs. (5) and (6)), Eq. (7) is obtained as a formula to give the value of k_H/k_D^{prim}:

$$\log([\mathbf{1}]/[\mathbf{1}]_0) = -k_H t \quad (5)$$

$$\log([\mathbf{2}]/[\mathbf{2}]_0) = -k_D^{prim} t \quad (6)$$

$$\frac{k_H}{k_D^{prim}} = \frac{\log([\mathbf{1}]/[\mathbf{1}]_0)}{\log([\mathbf{2}]/[\mathbf{2}]_0)} \quad (7)$$

Figure 2 is a plot of the right-hand side of Eq. (7) *vs.* the time for solutions of the reactant mixture (1.5 m, $[\mathbf{2}]_0/[\mathbf{1}]_0$: 0.20 and 0.32); from the figure k_H/k_D^{prim} was determined to be 1.40 (±0.05; standard deviation).

Secondary Deuterium Isotope Effect on the Decomposition of Hydroxymercurated Propene-1-d_1. As it is bonded directly to mercury, the α-carbon of the mercurial may undergo a very drastic change during the course of redox decomposition; through this change a secondary kinetic isotope effect can be expected if a deuterium substituent is introduced at that carbon:

$$CH_3CH(OH)CDHHg^+ \xrightarrow{k_D^{sec}} CH_3COCDH_2 + Hg(0) + H^+ \quad (8)$$

In order to determine the isotope effect accurately, the decomposition rates were measured for the mixture

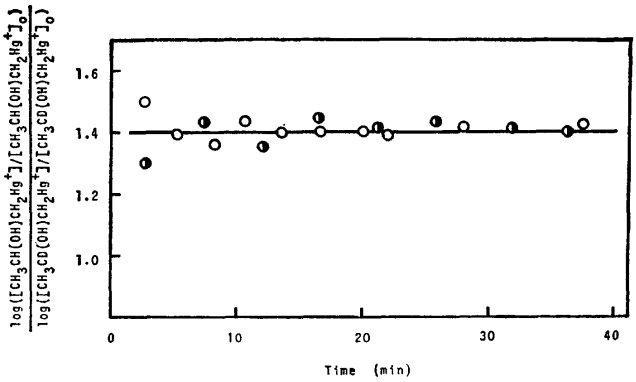

Fig. 2. Plot of $(\log([CH_3CH(OH)CH_2Hg^+]/[CH_3CH(OH)CH_2Hg^+]_0))/(\log([CH_3CD(OH)CH_2Hg^+]/[CH_3CD(OH)CH_2Hg^+]_0))$ *vs.* the time for the redox decomposition of $CH_3CH(OH)CH_2Hg^+$ and $CH_3CD(OH)CH_2Hg^+$ at 38.0 °C in the mixed solution. ○ and ◑ correspond to the ratio of initial concentrations $([CH_3CD(OH)CH_2Hg^+]_0/[CH_3CH(OH)CH_2Hg^+]_0)$ of 0.20 and 0.32 respectively.

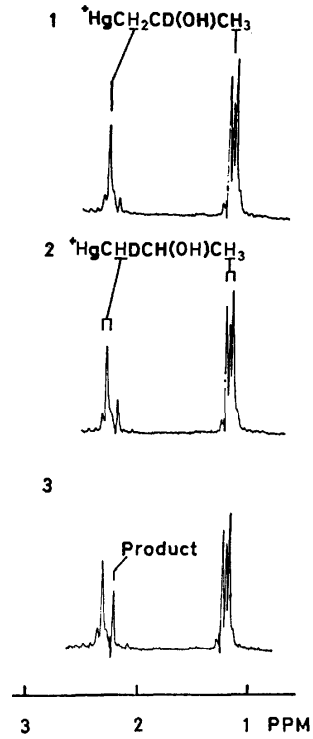

Fig. 3. The time-sequential PMR spectra obtained *in situ* for the redox decomposition of $CH_3CD(OH)CH_2Hg^+$ and $CH_3CH(OH)CDHHg^+$ at 38.0 °C in the mixed solution. These spectra were taken with deuterium irradiation at 15.349390 MHz after (1) 3.0 min, (2) 10.6 min, (3) 32.1 min from the moment of raising the solution temperature.

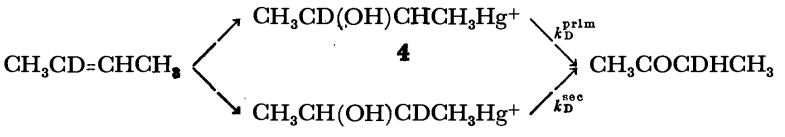
of **2** and $CH_3CH(OH)CDHHg^+$ (**3**) which was obtained by the hydroxymercuration of a mixed gas of propene-2-d_1 and propene-1-d_1. Figure 3 shows the time-sequential PMR spectra for the conversion of **2** and **3** into the product, acetone-d_1, in a mixed solution (1.5 m, $[\mathbf{2}]_0/[\mathbf{3}]_0$: 0.34). The concentration of **3** during the reaction was determined in the same manner



Scheme I.

as before by using the doublet peak at δ 1.21. From a plot of the right-hand side of Eq. (9) *vs.* the time, k_D^{sec}/k_D^{prim} was determined to be 1.20 (±0.05). Accordingly, the value of the secondary deuterium isotope effect is 1.17 (1.40/1.20).

$$\frac{k_D^{sec}}{k_D^{prim}} = \frac{\log([\mathbf{3}]/[\mathbf{3}]_0)}{\log([\mathbf{2}]/[\mathbf{2}]_0)} \quad (9)$$

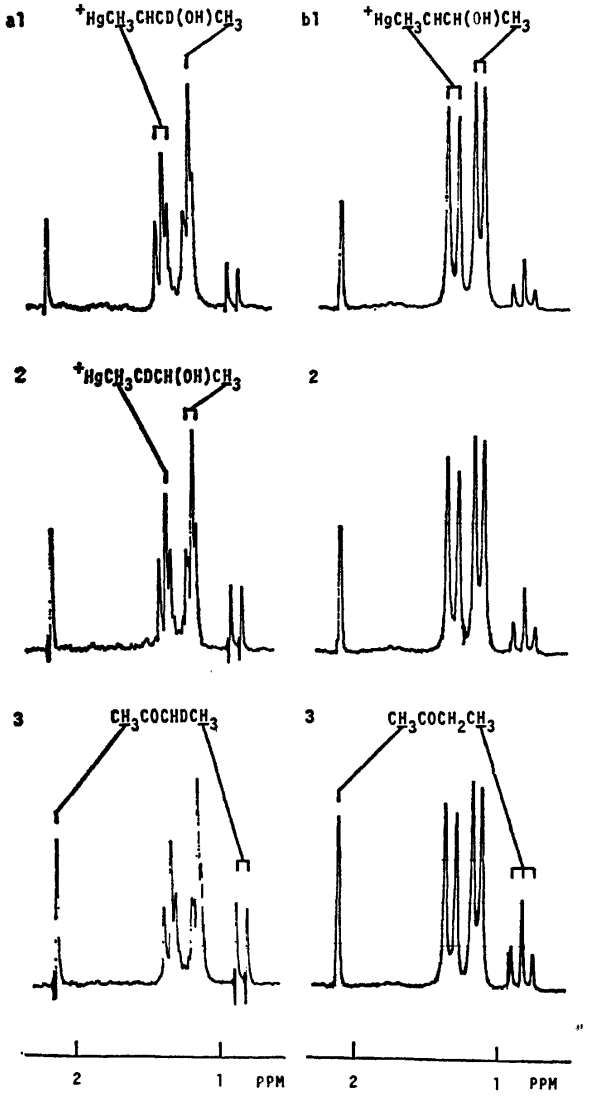


Fig. 4. The time-sequential PMR spectra obtained *in situ* for the redox decomposition of hydroxymercurated *cis*-2-butene-2-d_1 (**a**) and *cis*-2-butene (**b**) at 0.2 °C. These spectra were taken after (**a**) (1) 7.4 min, (2) 20.0 min, (3) 35.8 min with deuterium irradiation at 15.349390 MHz, and after (**b**) (1) 3.0 min, (2) 8.0 min, (3) 21.5 min from the moment of raising the solution temperature.

Deuterium Isotope Effects on the Decomposition of Hydroxymercurated 2-*Butene*-2-d_1. By the hydroxymercuration of 2-butene-2-d_1, two kinds of deuterated mercurials, $CH_3CD(OH)CHCH_3Hg^+$ (**4**) and $CH_3CH(OH)CDCH_3Hg^+$ (**5**), were obtained as an isomeric mixture. By comparing the decomposition rates of **4** and **5** for the mixture (Scheme I), the value of k_D^{sec}/k_D^{prim} was determined with sufficient accuracy.

Figure 4 shows the time-sequential PMR spectra for the redox decomposition of hydroxymercurated *cis*-2-

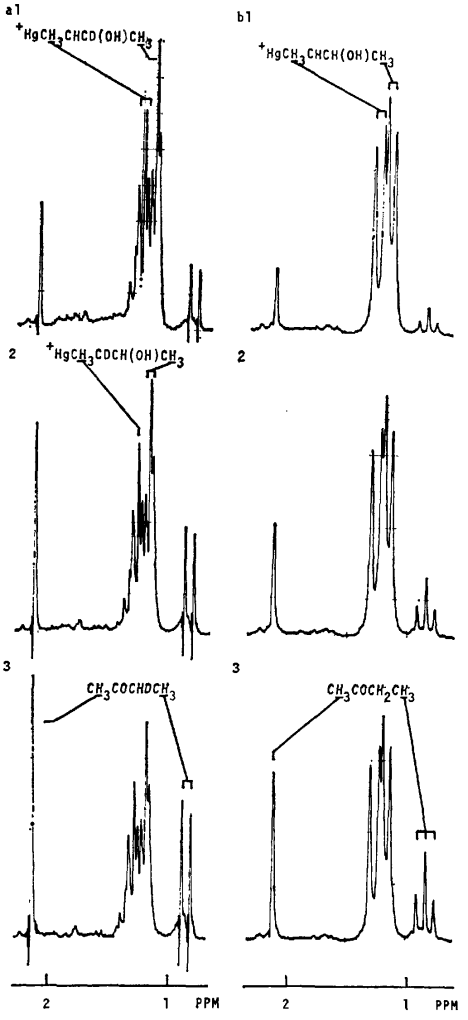

Fig. 5. The time-sequential PMR spectra obtained *in situ* for the redox decomposition of hydroxymercurated *trans*-2-butene-2-d_1 (**a**) and *trans*-2-butene (**b**) at 0.7 °C. These spectra were taken after (**a**) (1) 10.9 min, (2) 31.9 min, (3) 53.7 min with deuterium irradiation at 15.349390 MHz, and after (**b**) (1) 2.8 min, (2) 19.6 min, (3) 33.4 min from the moment of raising the solution temperature.

butene-2-d_1 (**a**) and *cis*-2-butene (**b**). Similar spectral sequences for the *trans*-isomers are shown in Fig. 5. Obviously, a marked contrast in the spectral pattern at δ 0.85 can be seen between the two sequences; this unequivocally indicates that methyl ethyl ketone-3-d_1 ($CH_3COCDHC\underline{H}_3$; doublet) is produced by the decomposition of the deuterated mercurials. This was confirmed by a mass-spectrometric analysis of the product (d_1: 99.2%, d_0: 0.8%) and was consistent with the prior finding that no deuterium incorporation into the product was observed when D_2O was used as the solvent.[11] These facts are decisive evidence for the mechanism of the intramolecular 1,2-hydrogen shift in the redox decomposition.

From a plot of the right-hand side of Eq. (10) *vs.* the time, k_D^{sec}/k_D^{prim} was determined to be 1.15 ($\pm$0.05) for both isomers:

$$\frac{k_D^{sec}}{k_D^{prim}} = \frac{\log ([\mathbf{5}]/[\mathbf{5}]_0)}{\log ([\mathbf{4}]/[\mathbf{4}]_0)} \qquad (10)$$

Experimental difficulties were encountered in following the reaction for mixtures of **4** or **5** with the corresponding undeuterated mercurial because of their inadequate PMR characteristics. Nevertheless, a comparison of the rate constants for deuterated and undeuterated mercurials was possible by pursuing each of the reactions in separated runs under identical reaction conditions (three determinations); a magnitude of isotope effects similar to that for propene was obtained (Table 1).

Table 1. Kinetic deuterium isotope effects on the redox decomposition of hydroxymercurated propene, *cis*- and *trans*-2-butenes

Olefin	Isotope effect $\left(\frac{k_H}{k_D}\right)_{prim}$	Isotope effect $\left(\frac{k_H}{k_D}\right)_{sec}$
propene[a]	1.40	1.17
cis-2-butene[b]	1.35	1.17
trans-2-butene[c]	1.37	1.19

Reaction temperatures are (a) 38.0 °C, (b) 0.2 °C, and (c) 0.7 °C, respectively.

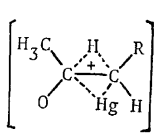
Discussion

The mechanism of the intramolecular 1,2-hydrogen shift in the redox decomposition of β-hydroxyalkylmetal complexes has been proposed for the case of Pd(II)[13] and Rh(III)[14] as well as for the case of Hg(II).[1,10] Further, the lack of glycols in the product has commonly been interpreted as strong evidence against a simple carbonium-ion mechanism through the heterolysis of the carbon-metal σ-bond.[10,13,14] For the redox processes, some such assistance of the metals seems to be required for the hydrogen shift to occur concertedly with the two-electron transfer along the carbon-metal bond.

For the elucidation of transition-state structures, the kinetic isotope effect is considered to be one of the most important methods, since it has definitely been understood on the basis of the partition functions of the reactant and the transition state.[16] Usually, the values of the primary deuterium isotope effect for intramolecular hydrogen migration are small, along with a small angle (60°—90°) between the bonds to the migrating hydrogen in the transition state; according to the detailed calculations of O'Ferrall,[17] the values observed for the present case (1.35—1.40) can reasonably be associated with the three-membered cyclic transition state of the 1,2-hydride rearrangement. In practice, the observed values are close to those of the pinacol rearrangement (~1.6), in which the hydride rearrangement was presumed to be concerted with the breaking of a bond between carbon and a leaving group at the migration terminus; its transition-state structure has been claimed to resemble a non-classical carbonium ion.[18,19]

Secondary isotope effects are understandable in terms of force-constant changes at the position of the isotopic substitution between the reactant and the transition state;[20] substantial force-constant changes are, more or less, incident to the hybridization changes. As is typically observed in S_N1 solvolysis,[21] the secondary deuterium isotope effect of 1.1—1.3 corresponds to the hybridization change of deuterated carbon from sp^3 to sp^2.[22] Therefore, the observed magnitude of secondary deuterium isotope effects in the present case seems to be explained satisfactorily by the sp^2 character of α-carbon in the transition state; this is consistent with the previous suggestion to account for the pattern of the alkyl-substituent effect on the decomposition rate.[11]

As to the stereochemistry of the hydrogen shift in the redox decomposition of hydroxymercurials, an antimode with respect to the leaving mercury was strongly suggested by the product distribution (ketone or epoxide) for hydroxymercurated cyclic olefins.[23] Taking into consideration the foregoing results on deuterium isotope effects, together with the suggested stereochemistry, a structure such as is depicted below may be proposed for the transition state of the redox decomposition of hydroxymercurials. In view of the well-known affinity of mercuric ions for olefinic π-electrons,[24,26] it seems likely that mercury facilitates the *anti*-wise hydrogen shift by anchimeric assistance; this is in contrast to the case of Pd(II), for which *syn*-wise assistance through Pd(II)-hydrogen interaction has been postulated.[27]



(R = H, CH_3)

Experimental

The FMR spectra were recorded on a JEOL PS-100 spectrometer. The deuterium decoupling was carried out with a JEOL OA-1 synthesizer. The mass spectra were obtained using a Hitachi RMU-6 spectrometer.

All the reagents and solvents were of a G. R. grade. The diethyl ether and tetrahydrofuran were dried over calcium chloride, refluxed with metallic sodium, and distilled im-

mediately before use.

Preparation of cis- *and* trans-*2-Butene-2*-d_1. The *cis*- and *trans*-2-bromo-2-butenes were prepared by the procedure of Caldwell[28] (bromination followed by the dehydrobromination of *trans*- and *cis*-2-butenes respectively). The lithiation of each 2-bromo-2-butene by metallic lithium in dry diethyl ether was effected at room temperature by standard procedures.[29] The reaction mixture was quenched at 0 °C with deuterium oxide (Merck, 99.75 atom% deuterated) under a dry-nitrogen-gas stream, with the gas-phase components trapped by a Dewar condenser of liquid nitrogen. The solvent ether was removed by condensation with a Dry Ice–ethanol trap fitted before the liquid-nitrogen trap. The isomeric purities of the products were determined by glpc (20% dimethylsulfolane on Celite) to be 97% and 96% for *cis*- and *trans*-2-butene-2-d_1 respectively. Mass spectral analysis at 58—68 gave 99.5% d_1 and 0.5% d_0 components for each of them.

Preparation of the Mixed Gas of Propene-1-d_1 and Propene-2-d_1. The mixture of 1- and 2-bromopropene was prepared by a similar procedure, but using propene instead of 2-butene as the starting material. The Grignard reagents formed from the mixture of bromopropenes in dry tetrahydrofuran[30] were decomposed at 0 °C with deuterium oxide. The product, a propene-1-d_1 and propene-2-d_1 mixture, was isolated in the manner described above. The isotopic purity of the product was confirmed by mass spectrometry as 99.5% d_1 and 0.5% d_0.

Preparation of Propene-2-d_1. 2-Bromopropene was obtained by the fractional distillation of the bromopropene mixture (isomeric purity of 99.7% by glpc); it was then converted into propene-2-d_1 in the same manner as in the case of the mixture. The isotopic purity of the product (99.5% d_1 and 0.5% d_0) was unchanged from the case of the mixture.

Kinetic Studies in the Redox Decomposition of the Hydroxymercurials. Olefins were transferred *via* a vacuum line into an aqueous solution consisting of 3.00 M of mercuric perchlorate at 0 °C until all the mercuric ions had been consumed by hydroxymercuration. The solutions of hydroxymercurated olefins were diluted with identical amounts of a 3.00 M aqueous mercuric perchlorate solution. A part of the solution was transferred into a PMR sample tube and kept in a Dry Ice-ethanol trap. The reaction was started by inserting the tube into the probe of the PMR spectrometer; by this means the solution temperature was raised up to the probe temperature (calibrated by the relative chemical shifts of ethyleneglycol), and the reaction was pursued by taking the spectra in sequence. For the mixed-reactant systems, the overlapped portions of their peaks were reasonably resolved, as was confirmed by the agreement of the resolved and synthesized line shapes, since each of the spectra was separately obtainable under identical measuring conditions.

During the reaction, no evolution of gas due to olefin formation by deoxymercuration[9] was observed. The PMR-spectral parameters of the hydroxymercurated propene and 2-butenes were tabulated in a prior paper.[6]

The authors wish to express their gratitude to Professor Yukio Yoneda for his helpful discussions and encouragement, and to Professor Richard L. Schowen for his valuable suggestions.

Ligand-Ligand Interaction in $[Zn(1,10\text{-phenanthroline})_2(H_2O)_2](NO_3)_2$ and $[Zn(2,2'\text{-bipyridyl})_3](NO_3)_2$

Takeshi OHNO and Shunji KATO

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560

(Received May 28, 1974)

The interaction between ligands in the excited state and in the ground state was examined by exploring the photophysical behaviors of ligands in the bis- and the tris-bidentate complexes. Although no exciton splitting was observed in the absorption spectra of $[Zn(bipy)_3](NO_3)_2$ and $[Zn(phen)_2(H_2O)_2](NO_3)_2$ at 77 K, the fluorescence yields of both complexes increased in comparison with those of the corresponding mono-bidentate complexes. It is probable that this change is caused by a delocalization of the excited singlet state, because a variation in Franck-Condon factors and a depolarization of the fluorescence accompanied it. In addition to the ligand-ligand interaction 1,10-phenanthroline and 2,2'-bipyridyl suffered from coordination effects. They have larger fluorescence yields and smaller phosphorescence yields than the free molecules. The decrease on the transition rate of the intersystem crossing is probably due to the changes in the energy levels of $^1(n\text{-}\pi^*)$ and $^3(n\text{-}\pi^*)$, caused by the metal-ligand bond using a "non-bonding" orbital in the free ligands.

The photochemistry of ligands in coordination compounds is affected not only by the metal-ligand bond, but also by ligand-ligand interaction. Some kinds of interaction between a ligand in its electronic excited state and ligand(s) in its ground state have been investigated in the case of β-diketonato complexes.[1] While a doubly- or a triply-degenerated state of the bis- or the tris-β-diketonato complexes was not split greatly by ligand-ligand interaction, three phenomena suggesting some weak interaction were observed: (i) an enhancement of spin-orbital interaction, (ii) a depolarization of the fluorescence, and (iii) a variation in the Franck-Condon factors of the radiative transition processes.

These interactions were examined in the cases of bis-1,10-phenanthroline* and tris-2,2'-bipyridyl** complexes of the zinc ion, which have more resolved spectra than the β-diketonato complexes of aluminium. These complexes were also examined with regard to the effects of the zinc-ligand bond on the excited states of the ligands. We will discuss the fact that ligands coordinating to Zn^{2+} have larger fluorescence yields than the free ligands, unlike the expectation based on the "heavy atom effect".[2]

Experimental

Materials. $[Zn(phen)_2(H_2O)_2](NO_3)_2$ and $[Zn(bipy)_3](NO_3)_2$ were prepared by heating a 50% ethanol solution of $Zn(NO_3)_2$ and the corresponding ligand. The prepared complexes were recrystallized from water two times. The free ligands, 1,10-phenanthroline·$2H_2O$ and 2,2'-bipyridyl were recrystallized from ethanol. The water was distilled twice, while Wako G. R. methanol was used without further purification.

Procedure. All the materials were dissolved in a mixture of methanol and water (4 : 1 by volume). Solutions of the mono-bidentate complexes were prepared by the addition of $Zn(NO_3)_2$ (5×10^{-4} M) and free ligand (5×10^{-5} M) to the mixed solvent. The absence of the free ligand is practically supported by the large stability constants ($\log K=6.4$ for $[Zn(phen)]^{2+}$ [3] and $\log K=5.4$ for $[Zn(bipy)]^{2+}$ [4] in an aqueous solution) and the disappearance of the absorption spectrum due to the free bipy.

Measurements. The measurements of the absorption and emission spectra, the emission yields, the emission lifetimes and the emission polarizations at 77 K were carried out in the way reported in the previous paper.[1] The emission spectra were calibrated against the fluorescence spectra of phenol, benzene, naphthalene,[5] and β-naphthole.[6] The corrected spectra agreed with those obtained by Chen's method using rhodamin B.[7]

Results and Discussion

Effect of Coordination on the Excited States of Ligand Absorption and Emission Spectra: As Fig. 1 shows, at the temperature of boiling nitrogen, free bipy in a mixed solvent of metanol and water (4 : 1) has a broad absorption band in the near ultra violet region whereas the absorption band of bipy coordinating to Zn^{2+} was a well-resolved structure and is shifted to a lower frequency (0—0': 32400 cm^{-1}). Such a shifted spectrum has also been found by Schläfer in the case of the mono-bipy complexes of Zn^{2+}, Cd^{2+}, Mn^{2+}, Co^{2+}, Ni^{2+}, and Fe^{2+} in water at room temperature; Schläfer considered these changes to be caused by the Stark effect of central ions on the ligand.[8] This consideration has been proven by Hanazaki and Nagakura on the basis of their P-P-P SCF-CI calculation of π-π^* transitions.[9] However, the lack of any determination of the n-π^* level, a result of the strong π-π^* band, leaves the question open whether the lowest level in n–π^* or π-π^*.***

Moreover, the coordinating bipy emitted a well-resolved fluorescence (see Fig. 2), which took a good mirror image with the absorption spectrum. Consequently, the fine structure of the absorption may safely be attributed not to another electronic transition, but to the vibrational structure of a single electronic transition, because sub-bands of fluorescence other than 0'-0 band are usually assigned to the vibrational structure with no doubt. This is supported by the fact that the fluorescence has a high polarization value (0.40),

* 1,10-phenanthroline will be abbreviated to "phen" heareafter.

** 2,2'-bipyridyl will be abbreated to "bipy" hereafter.

*** For pyridine, n-π is considerably lower (34769 cm^{-1}) than π-π^* (38350 cm^{-1}).[10]

independent of the excitation ligand through $32\sim36\times10^3$ cm^{-1}. According to SCF-CI calculations of the free *cis*-bipy,[9,11] the transition moment to the first excited state of the B_1 symmetry is several tens of times as large as that to the second one of the A_1 symmetry lying 1×10^3 cm^{-1} above. Therefore, the assignments of the sub-bands are most probable.

It has been reported that the free form of phen has three kinds of transitions through $29\sim40\times10^3$ cm^{-1}. They have been assigned to ^1L_b, ^1L_a, and ^1B_a in the order of transition energy by measureing the fluorescence polarization with the excitation wavelength at 77 K[12] and by P-P-P SCF-CI calculations.[13] The coordination of phen to Zn^{2+} brought no essential change in the absorption spectrum, as Fig. 3 shows. However, one can recognize the following three changes; (i) the shoulders of the free form at 30000 and 31560 cm^{-1} disappear, (ii) the 0-0′ bands of the three transitions become more distinct (^1L_b: 29300, ^1L_a; 34200, and ^1B_a: 36900 cm^{-1}), and (iii) they shift to lower frequency by $250\sim600$ cm^{-1} than those of the free form.

The fluorescence of the coordinating phen due to the transition from ^1L_b to the ground state has a structure similar to that of the free form (see Fig. 4). As for the fluorescence polarization, while the free phen has a constant polarization (0.19) on excitation with $29\sim36\times10^3$ cm^{-1}, the coordinating form has a different value (0.15) when observed on excitation to ^1L_b from that (0.11) when observed on excitation to ^1L_a.

Yields of Emissions: While the free bipy emits only a weak phosphorescence at 77 K, the coordinating form emits a very strong fluorescence not only at the low temperature but also at room temperature. The yields of the fluorescence, listed up in Table 1, reach 0.30. The following considerations make it probable that such an appearance of the strong fluorescence originates from changing the lowest singlet excited state from the n-π^* state to the π-π^* state because of its coordination; (i) Coordination through nitrogen atoms of bipy to metal ions, not only Zn^{2+} but also Cd^{2+}, gives rise to a fall in the π-π^* level due to pyridyl-pyridyl interaction in the pseudo planar forms of *cis*-bipy and a rise of n-π^* level due to the coordination using "non-bonding" orbitals on nitrogen atoms. Therefore, the appearance of the strong fluorescence may be attributable to either a fall in the π-π^* level or a rise in the n-π^* level, or to both. (ii) Although no fluorescence was observed in 0.1 M HCl, in which mono-protonated bipy with the planar forms of *cis*-bipy is predominant, fluorescence was observed in an 80% sulfuric acid solution, in which bipy is changed into the di-protonated form of *trans* bipy. Therefore, a fall of π-π^* due to the pseudo planar forms of *cis*-bipy is not always needed for a strong fluorescence. (iii) It is generally believed that because n-π^* has a long radiative lifetime (10^{-7} s) because of a partly-allowed transition, other processes—intersystem crossing and internal conversion—take place much more easily, resulting in the absence of fluorescence. This is the case for pyridine. (iv) Because the coordination of bipy to metal ions raises the n-π^* states as hydrogen bonding and protonation do, the lowest singlet state of the coordinating bipy may be changed from n-π^* to π-π^*, of which, in the free form, the latter seems to be nearer to the former on account of pyridyl-pyridyl interation than in pyridine.

As for phen, the free form of which emits a fluorescence of a medium intensity in addition to a phosphorescence, its coordination to the zinc ion gave rise to an enhancement of the fluorescence and diminution of the phosphorescence (see Table 1). Because such a change in the emission yields was observed a little in 0.1 M HCl and moderately in a 90% sulfuric acid solution, as Table 1 shows, it is probable that a change in the energy level of n-π^* excited states with coordination or protonation results in the variation in the emission yields. However, since the weak lowest band may safely be regarded as a transition to the π-π^* state in all the forms and does not vary in intensity with coordination and protonation, the enhancement of the fluorescence is not caused by a change in the radiative transition rate, but by a change in the non-radiative transition rate. It has been reported that the yield of the phosphorescence of phen is the largest of the nine phenanthrolines.[14] Perkampus *et al.* assumed that the largest intersystem crossing rate was attributable to the small separation between ^1L_b and unknown higher triplet state(s). If the higher triplet state(s) is the n-π^* state, whose level is dependent on the positions of the nitrogen atoms in the free form, the coordination of phen will considerably raise ^{3}(n-π^*) as well as ^{1}(n-π^*) and make the rate of the ^{3}(π-π^*) formation ($^1L_b\rightarrow{}^3$(n-π^*)$\rightarrow{}^3$(π-π^*) or $^1L_b\rightarrow{}^1$(n-π^*)$\rightarrow{}^3$(n-π^*)) slower. This change will give rise to a larger yield of fluorescence, which must be similar to those of other phenanthrolines (0.1$\sim$0.5 in a mixed solvent of ether and ethanol (1 : 1)) and phenanthrene (0.17 in EPA[15]). As Table 1 shows, this is indeed the case.

After all, the variation in the n-π^* levels with their coordination results in a large fluorescence yield in the cases of both bipy and phen. Moreover, the enhancement mechanism is different from that in the case of β-diketonates, in which the metal-ligand bond prevents their excited states from making a radiationless transition to the ground state.[1] It is worthwhile noticing that the fluorescence of ligands is enhanced by coordination to Zn^{2+}, contrary to the expectation deduced from the heavy-atom effect. In the case of porphyrin complexes, in fact, the enhancement of the phosphorescence yield with the complex formation has been accounted for in terms of the heavy-atom effect.[2]

Interaction between Ligands in the Excited State and in the Ground State. Absorption and Emission Spectra: Since the tris-bipy complex of Zn^{2+} has three large ligands with an allowed transition along their longer axes, it may be expected that an exciton interaction among the three ligands removes the three fold degeneracy of the excited state associated with the transition, resulting in some splitting between the states with E and A_2 symmetries as well as in the case of $[Fe(bipy)_3]^{2+}$. However, a comparison of the absorption spectra between the tris- and the mono-bipy com-

plexes showed no difference not even at 77 K. As Fig. 1 shows, the tris-bipy complex has an absorption spectrum very similar to that of the mono-bipy complex. The broad band at the higher-frequency regions in the spectra for the tris-bipy complex is due to the free bipy, which is added to suppress the dissociation of the tris-bipy complex. Further, the band widths of the tris-bipy complex are seen to be the same as those of the mono-bipy complex for the sharpest 0-0′ band (its width: 460 cm^{-1}); therefore, the splitting of the vibronic bands should be very small if any. Such a weak interaction in $[Zn(bipy)_3]^{2+}$ has been suggested in view of the mirror-image relationship.[16] However, these results do not necessarily preclude any ligand-ligand interaction, because the change in the fluorescence yield and the fluorescence polarization may suggest a weak interligand interaction in addition to the circular dichroism of the tris-bipy complexes of Fe^{2+},[17] as will be discussed later.

For $[Zn(phen)_2(H_2O)_2](NO_3)_2$, which easily forms a tris-phen complex in the presence of excess phen, the coordinating nitrogen atoms of two phen are considered to locate at the apices of an octahedron and two H_2O at the vicinal apices. This is supported by the fact that two phen of some bis-phen complexes do not lie coplanar as a result of the repulsion between α-hydrogen atoms of two phen.[18] Therefore, the bis-phen complexes of zinc may also be expected to have such a ligand-ligand interaction, as was proposed in the tris-phen complex of Fe^{2+}.[17]

For the strongest band at 37,050 cm^{-1} (^1B_a in the free phen), which has been expected to have a large exciton interaction,[17] the absorption band of $[Zn(phen)_2(H_2O)_2]^{2+}$ has a similar structure, consisting of a strong peak (0-0′) and a shoulder (0-1′) on 700 cm^{-1} side higher than that of the mono-phen complex, as Fig. 3 shows. Since no splitting of the electronic transition is distinctly recognized, the exciton interaction can not be regarded as a "strong coupling" as defined by Simpson and Peterson.[19] And it is not possible to estimate the weak exciton interaction quantitatively on any vibronic coupling theory, because not all the electronic bands are distinctly resolved into sub-bands.

The difference in the relative intensities of the sub-bands, the Franck-Condon factors, are observed between the absorption spectra of $[Zn(phen)_2(H_2O)_2]^{2+}$ and the mono-phen complex (see Table 2). Generally speaking, the Franck-Condon factors of an intra-ligand transition may be expected to be varied by both the metal-ligand interaction and the ligand-ligand interaction, as are the energy and the total intensity of the transition. It is assumed that the ligand-ligand interaction, which gives rise to a delocalization of the excited state through two ligands and to a smaller distortion and displacement of the excited state, is reflected in the Franck-Condon factors of the lowest band of $[Zn(phen)_2(H_2O)_2]^{2+}$, which is larger than that of the mono-phen complex, and that the metal-ligand interaction is not so large as to change the Franck-Condon factors of the transition in the latter complex. Further, it is noticed that the Franck-Condon factors obtained by the analyses of the fluorescence spectra have a distribution similar to those obtained from the absorption spectra. These considerations show the existence of a weak interaction between a phen in the ground state and a phen in the excited state. On the other hand, it is assumed that, for the strong band (^1B in the free phen), the metal-ligand interaction has an effect on the relative intensities of the sub-bands, which are seen at 37,050 cm^{-1} (0-0′) and 37,800 cm^{-1} for the mono-phen complex, and at 36,800 cm^{-1} (0-0′) and 37,500 cm^{-1} for the bis-phen complex. This assumption is supported by the fact that the intensity of the 0-0′ band is stronger for the mono-phen complex than for the bis-phen complex, in which Zn^{2+} is shared by two phens. Though the variations in the Franck-Condon factors are not clear in the cases of the bipy complexes, a weak interaction between three bipys is probable.

Table 2. Relative intensities of vibronic lines normalized to the intensity of 0′-0

	Fluorescence		
	0′-0	0′-1	0′-2
$[Zn(bipy)]^{2+}$		1.00[a]	0.55
$[Zn(bipy)_3]^{2+}$		1.00[a]	0.52
phen	1.0	3.6	3.4
$[Zn(phen)]^{2+}$	1.0	3.51	2.51
$[Zn(phen)_2(H_2O)_2]^{2+}$	1.0	2.43	1.52

a) It is compared to the intensity of 0′-1 because 0′-0 is reduced by reabsorption.

Yields of Emission: As Table 1 shows, the fluorescence yields of the bis- and the tris-bidentate complexes were significantly greater than that of the corresponding mono-bidentate one; however, the absorption coefficient per ligand is not different. Therefore, it is likely that the fluorescence enhancement is due to a decrease in the rates of the non-radiative processes. Especially, the rate of internal conversion ($S_1 \rightarrow S_0$), which is affected by the Franck-Condon factors ($<0'|v>^2$) with very large v-values, according to Siebrand,[20] can be expected to be less than that of the mono-bidentate complex by taking account of the less distortion and displacement of the lowest excited state of $[Zn(phen)_2(H_2O)_2]^{2+}$. Therefore, it is reasonable to say that the fluorescence enhancement originates from the weak ligand-ligand interaction, as has been proposed in the preceding section.

Polarizations of Emission: Fluorescence in a rigid solvent depolarizes on the excitation of polarized light, when (a) an upper excited state with a moment in a different direction is directly excited, (b) an energy transfer takes place from an excited ligand to another ligand(s) in a complex ion, or (c) a new state with a transition moment along two or three axes is produced by interaction between ligands which individually have a transition moment along one axis. Therefore, the fluorescence polarization of the tris-bidentate complexes gives information about an energy transfer on excitation to the lowest excited state (S_1) or on the appearance of a new excited state. As Table 3 shows,

Table 3. Fluorescence polarization measured in methanol and water (4 : 1) at the temperature of boiling nitrogen on excitation to S_1

	P_F	P_P
$[Zn(bipy)]^{2+}$	0.40	
$[Zn(bipy)]_3^{2+}$	0.05	
phen	0.19, 0.19[a]	−0.25, −0.25[a]
$[Zn(phen)]^{2+}$	0.15, 0.11[a]	−0.12, −0.18[a]
$[Zn(phen)_2(H_2O)_2]^{2+}$	−0.014, 0.05[a]	−0.038, −0.070[a]

a) The value was observed on excitation to S_2 (^1L_a).

the fluorescence of the tris-bipy complex was considerably depolarized as compared with that of the monobidentate complex, on excitation to S_1. Therefore, it is certain that some interactions are operative between ligands in the excited state and the ground state. An energy transfer between ligands is unlikely, because neither excitation nor emission is localized in one ligand; both are delocalized through ligands, as was mentioned in the preceding sections. The next problem is in the estimation of the energy splitting between the two states of E and A_2 symmetry by means of the analysis of the fluorescence polarization. Although the states of E and A_2 symmetry participate in the absorption process because of the splitting between them, it depends on the energy splitting whether or not the upper state of A_2 symmetry participates in the fluorescence process. When the splitting is below 70 cm^{-1}, both E and A_2 are emissive at 77 K, while when it is over 100 cm^{-1}, only the state of E fluoresces practically. As Table 4 shows, the fluorescence polarization is determined by the direction of the transition moment of the emitting state(s). The observed value (0.05) for the tris-bipy complex is the nearest to the ideal value (0.09), which is calculated by assuming both states to be emissive.

The energy splitting (70 cm^{-1}) in $[Zn(bipy)_3]^{2+}$ is similar to that[17] in $[Ni(bipy)_3]^{2+}$, which has been obtained by fitting the measured shape of the circular dichroism to the theoretical one based on the vibronic coupling theory of Perrin and Gouterman.[21] Recently, Mason *et al.*[22] reconstituted the observed intensity of circular dichroism by assuming the interaction to be 350 cm^{-1}, based on the vibronic coupling theory. However, since both the reconstituted spectra of circular dichroism were much more complex than the observed ones, the inter-ligand interaction of 350 cm^{-1} seems to be overestimated. Therefore, it is not improbable that the energy splitting in $[Zn(bipy)_3]^{2+}$ is smaller than 70 cm^{-1}.

Table 4. Ideal polarization of fluorescence on excitation to both states having E and A_2 symmetry

Emissive state	P
E	−0.174
A_2	0.222
E and A_2	0.090

The tris-phen complex is complicated, because the mono-phen complex had a considerable depolarization even, upon excitation to S_1 (^1L_b of the free phen).

Kinetic Studies on Olefin Epoxidation by Peroxo Molybdenum Complex ($MoO(O_2)_2HMPT$)

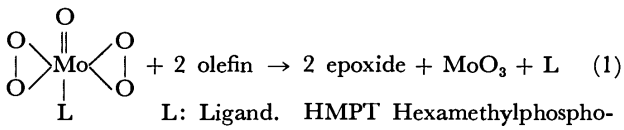
Hironori ARAKAWA, Yoshihiko MORO-OKA, and Atsumu OZAKI

Research Laboratories of Resources Utilization, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo 152

(Received December 14, 1973)

Oxidation of olefin by peroxo molybdenum complex selectively yields epoxide at room temperature. The nature of the interaction of olefin with molybdenum and that of the peroxo molybdenum complex has been investigated in terms of coordination constant K of olefin and rate constant k_2 of decomposition of the peroxo molybdenum-olefin complex, attention being paid to the substituent effect of olefin. The coordination constant increases with the extent of alkyl substitution on double bonded carbon, a tendency opposite to that on Pd(II), or Rh(I). The coordination state of olefin on molybdenum seems to differ from that on Pd(II) or Rh(I), for which π-back donation of metal d-electron is accepted to play an important role. The coordination complex on molybdenum is accordingly assigned to a π-complex with some electron donated to molybdenum. A remarkable steric effect of alkyl substituent is observed, disclosing a difference from the oxidation of uncoordinated olefin. Since k_2 increases with K, revealing a similar substituent effect of olefin, the peroxo oxygen seems to be electrophilic, and the peroxo oxygen-molybdenum bond seems to be rather covalent than ionic, thus giving rise to epoxidation.

The selective epoxidation of olefin by new peroxo complexes of molybdenum(VI) such as $MoO(O_2)_2L$[1] was found by Mimoun *et al.*,[2] followed by the demonstration by Sharpless *et al.*[3] by means of ^{18}O tracer that the peroxo oxygen of complex I is exclusively transferred to the olefin, the oxo oxygen not being involved in the oxidation:



$$+ 2 \text{ olefin} \rightarrow 2 \text{ epoxide} + MoO_3 + L \quad (1)$$

L: Ligand. HMPT Hexamethylphosphotriamide

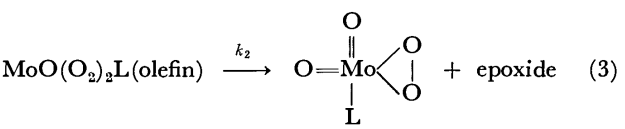
I

Some molybdenum salts act as an effective catalyst for the epoxidation of olefin with organic hydroperoxides.[4] The peroxo species of molybdenum such as I seems to be important as a key intermediate in the oxidation of olefins by organic peroxides. Thus the nature of interaction between molybdenum and olefin calls for further investigation. This has been done in terms of kinetic constants associated with Reaction (1).

According to Mimoun *et al.*,[2] the epoxidation of olefin by I consists of two steps; A reversible coordination of olefin to I to form a one to one adduct (complex II) and an irreversible decomposition of complex II to form epoxide.

$$\underset{\text{I}}{MoO(O_2)_2L} + \text{olefin} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \underset{\text{II}}{MoO(O_2)_2L(\text{olefin})} \quad (2)$$

$$k_1/k_{-1} = K$$



$$\text{epoxide} \quad (3)$$

II III

We determined coordination constants K of olefin to a peroxo molybdenum complex $MoO(O_2)_2HMPT$, and rate constants k_2, for the decomposition of II to epoxides for 22 mono-olefins by kinetic measurements. From the results the nature of active oxygen of peroxo molybdenum complex and that of the interaction between olefin and molybdenum are discussed.

Experimental

Preparation of Peroxo Complex. $MoO(O_2)_2HMPT$ was prepared by the method of Mimoun *et al.*[1] 50 g (0.348 mol) of molybdenum trioxide was suspended in 250 ml of 30% hydrogen peroxide with stirring at 40 °C for 2 hr. 62.3 g of HMPT(0.348 mol) was added dropwise to the suspension and the mixture was stirred for 2 hr at 10 °C. A yellow crystalline precipitate was obtained ($MoO(O_2)_2HMPT\text{-}(H_2O)$). The precipitate was filtered off, washed three times with ethyl ether, and recrystallized from methanol solution at 40 °C; yield 76.2 g (80%). This was allowed to stand for 1 week in a cool and dark place *in vacuo* on phosphoric anhydride to remove water. Removal of water was confirmed by IR spectroscopy.

IR;

ν_{O-O} 865 cm^{-1}, 875 cm^{-1}; $\nu_{MO<}$ *sym* 540 cm^{-1}, *asym* 595 cm^{-1}; $\nu_{Mo=O}$ 965 cm^{-1}; ν_{P-O} 1188 cm^{-1}; ν_{N-P-O} 755 cm^{-1}, 765 cm^{-1}.

Found: C, 20.34; H, 5.25; N, 11.80%. Calcd for $C_6H_{18}N_3O_4PMo$: C, 20.34; H, 5.25; N, 11.92%.

Procedure. All the runs for liquid olefin were carried out under ambient pressure with dry nitrogen in a 30 ml glass flask. The solvent used was dry ethylene dichloride. The reaction was started by addition of olefin to the ethylene dichloride solution of I. All kinetic measurements were made in the solution of a fixed concentration of I with excess olefin. When the initial concentration of olefin was changed, the corresponding amount of parafin was added to keep the total amount of hydrocarbon constant, thus avoiding a change in the solvent effect. The standard composition of the reaction mixture was as follows; $MoO(O_2)_2$ HMPT 0.05 mol/l, ethylene dichloride 9.6 mol/l, olefin 0.5—2.5 mol/l, and paraffin balance. The selectivity to epoxide being higher than 95% with respect to the active oxygen consumed, the reaction rates were measured by increase in the concentration of epoxide which was determined by gas chromatography. The runs for gaseous olefins were carried out with a conventional apparatus for gas absorption under constant pressure. The reaction rates were determined by the rates of absorption of gaseous olefins after the dissolution equilibrium had been attained. It was confirmed that epoxide formation can be followed by the absorption.

Analysis of Kinetic Result. The kinetic constants were determined according to the mechanism and rate equation

given by Mimoun *et al.*[2] If the reaction of Eq. (2) is fast and the reaction of Eq. (3) is rate-determining, the rate of disappearance of the complex I is given by

$$V = -\frac{d[I]}{dt} = \frac{k_2K[\text{olefin}][I]}{1 + K[\text{olefin}]} = k'[I] \quad (4)$$

under the present conditions of excess olefin, where k' is a constant under a fixed excess concentration of olefin, and represents the specific rate of epoxidation. The values of k' were obtained from the first-order plots with respect to I under different concentrations of olefin and plotted against the olefin concentration according to the equation

$$\frac{1}{k'} = \frac{1}{k_2} + \frac{1}{k_2K[\text{olefin}]} \quad (5)$$

Straight lines were obtained for different olefins. k_2 and K were determined from the intercept and slope of the straight line.

For the sake of confirmation, temperature dependence of k_2 and K was examined with cyclohexene in the range 0—30 °C. The Arrhenius plots are shown in Fig. 1. Straight lines were obtained as expected. The activation energy and the heat of coordination are 17.2 kcal/mol and 5.7 kcal/mol respectively.

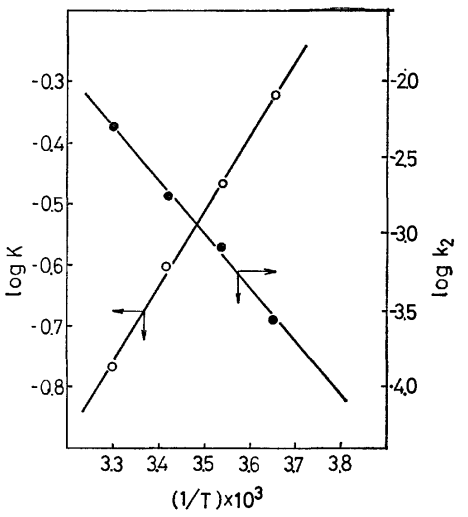


Fig. 1. The Arrhenius plots of k_2 and K with cyclohexene. Condition; olefin concentration: 1.0 mol/l, temperature: 0°C—30°C, solvent: ethylene dichloride.

Results and Discussion

The Effect of Olefin Structure on the Kinetic Constant. The epoxidation of olefins tested were selective and stereo-specific as reported by Mimoun *et al.* The kinetic constants were determined at 20 °C with 22 olefins. Values of k_2 and K are summarized in Table 1, together with the rate of epoxidation k' at 1.0 mol/l of olefin concentration.

The following general trends are indicated.

(1) The larger the reaction rate k', the larger both k_2 and K. There is a parallelism between k_2 and K.

(2) Steric effect is observed in both k_2 and K. The alkyl substitution on the double-bonded carbon

Table 1. Kinetic data of various olefins at 20 °C in ethylene dichloride

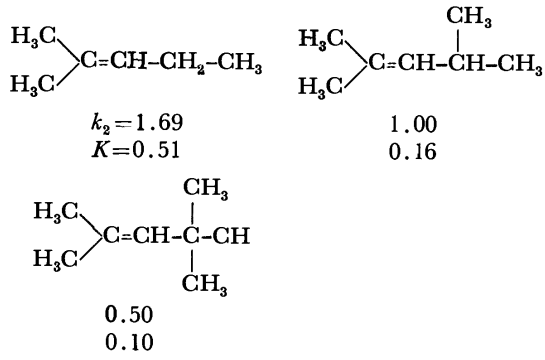
atoms by secondary or tertiary alkyl group instead of primary alkyl group reduces both k_2 and K. For example,



The values for *cis*-olefin are larger than those for the corresponding *trans*-olefin.

(3) In the absence of the steric effect, the values of k_2 and K increase with the number of alkyl substituents;

$$\alpha\alpha\beta\beta > \alpha\alpha\beta > \alpha\alpha,\ \alpha\beta > \alpha$$

where α and β denote the number and position respectively, of the alkyl substitution.

Interaction of Olefin with Peroxo Molybdenum Complex. The nature of metal ion-olefin complex has been extensively investigated in terms of coordination constant or stability constant.[5,6] According to Hartely,[7] metal ions can be classified into two groups by the electronic effect of olefin substituents on the stability of metal ion-olefin complex. The first group (type A), comprising Ag(I) and Cu(I), shows a decrease in stability, while the second group (type B), Ni(0), Pt(0), Pt(II), Rh(I), shows an increase in stability as the electron-withdrawing ability of the olefin substituents increases.

In order to clarify the interaction between olefin and peroxo molybdenum complex, the values of K we obtained are compared with the stability constants of acacRh(C_2H_4)-olefin determined by Cramer.[6] Both constants are plotted in Fig. 2. In order to eliminate the steric effect, comparison is made only for those olefins having primary alkyl substituents. The electronic effect of alkyl substituent is exactly the opposite in the two systems, *viz.*, K_{Mo} increases, while K_{Rh} decreases, with the extent of substitution at the double-bonded carbon. Since the alkyl substituent is electron donating, the above result indicates that Mo(VI) belongs to type A.

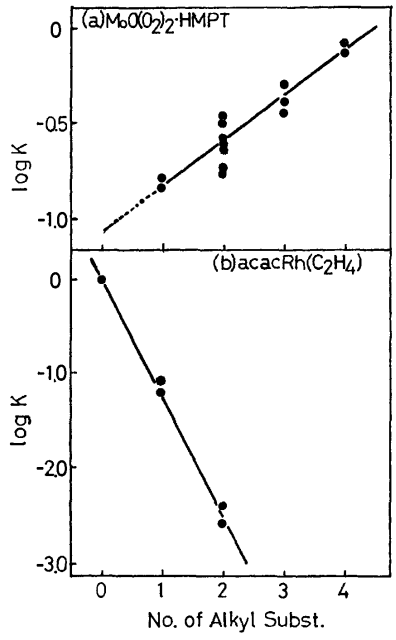


Fig. 2. Variation of coordination constant, K_{Rh} and K_{Mo}, with extent of alkyl substitution.
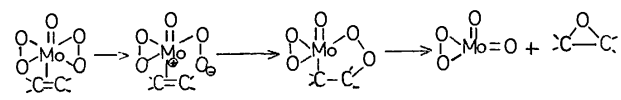
(a): this work, (b): taken from the data in Ref. 6.

The metal ion-olefin interaction has been interpreted in terms of the molecular orbital description of metal-olefin bond. In case of type A ion, the σ (olefin to metal) bond is important. An increase in the availability of the olefinic π-electrons increases the stability of the metal-olefin complex, while in the case of type B ion, the π(metal to olefin) bond is important and the effect of the olefinic π-electrons is opposite. This is demonstrated by the result shown in Fig. 2.

Since the formal charge of molybdenum is Mo(VI), the back-donation of olefin seems unlikely. This was suggested by Mimoun *et al.*, and confirmed by us. The steric effect and the larger coordination constant of *cis*-olefin than of corresponding *trans*-isomer are reported in π-complex.[5-7]

Effect of Alkyl Substitution on k_2. All the data of of k_2 are plotted against K in Fig. 3., where an open circle denotes secondary or tertiary alkyl-substituted olefin. k_2 appears to increase linearly with K. However there are some deviations. i) The k_2 of $\alpha\alpha$ type olefin is substantially less than that of the corresponding $\alpha\alpha\beta$ and even $\alpha\beta$, although K is of the same magnitude. It appears that $\alpha\beta$ disubstitution preferentially increases k_2. The relatively large k_2 of 2,4-dimethyl- and 2,4,4-trimethyl-2-pentene is in conformity with this tendency, while their low values of K may be due to the steric effect. ii) The k_2 of $\alpha\alpha\beta\beta$ type olefins (2,3-dimethyl-2-butene and 2,3-dimethyl-2-pentene) are not so large as expected from its K value. It is obvious that the alkyl substitution favorable for the coordination is not always favorable for the reaction of coordinated olefin, suggesting a steric effect in the reaction.

The general trend of k_2 increasing with K might be understood as a linear free energy relationship. It is also explainable in terms of reaction scheme as suggested by Mimoun *et al.*:



Since the charge transfer from olefin to molybdenum would be increased by the alkyl substitution, resulting in a more positively charged olefin molecule, the nucleophilic attack of peroxo oxygen on the coordinated olefin might be enhanced by the alkyl substitution at the double bonded carbon.

Nature of Peroxo Oxygen in the Molybdenum Complex. The nature of peroxo oxygen is examined by comparing k_2 with rates or rate constants of various addition reactions of oxygen to olefin. Rates or rate constants are plotted against the number of primary alkyl substituents

on double bonded carbon of olefins (Fig. 4). The quoted values are the average of olefins of the same alkyl substituent number, the reactants being peracetic acid,[8] atomic oxygen[8] and singlet oxygen $O_2(^1\Delta_g)$.[9] The last one is accepted to be the active species of dye-sensitized photo-oxidation to form allylic peroxide. These three reactants are admittedly electrophilic and directly attack the unsaturated carbon atom.[10,11]

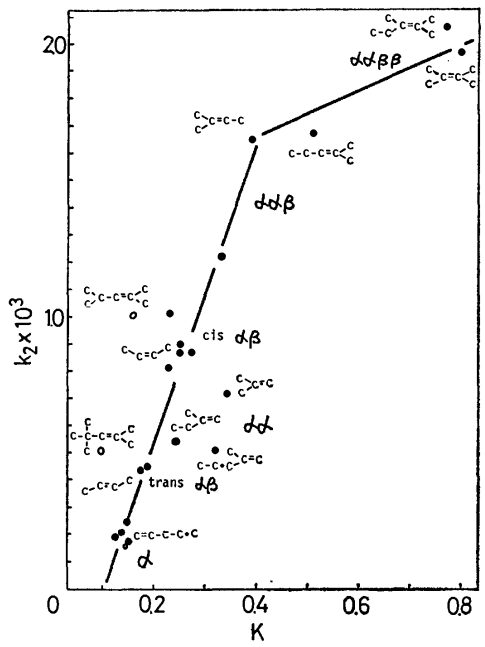


Fig. 3. Correlation between k_2 and K for olefins.

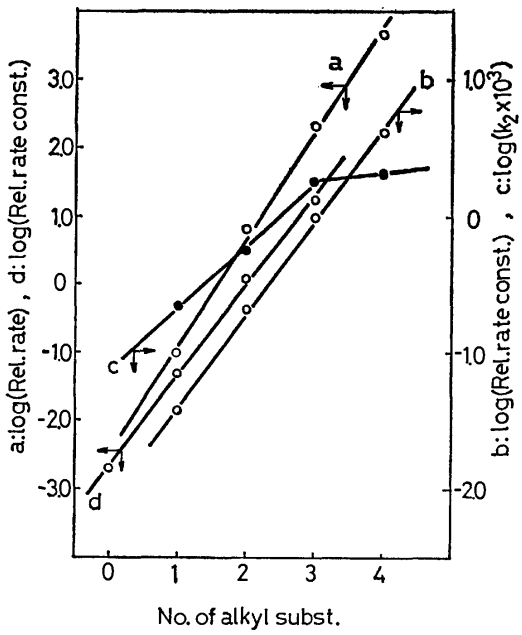

Fig. 4. Relative rate or rate constant of electrophilic oxygen as functions of number of alkyl substituents on double bonded carbon atom.
a: $O_2(^1\Delta g)$ Relative rate. Taken from the data in Ref. 10. b; O(3P) Relative rate constant. Taken from the data in in Ref. 8. c: k_2x10^3 of this work. d: Peracetic acid Relative rate constant. Taken from the data in Ref. 8.

Since k_2 increases with the extent of alkyl substitution as other rate or rate constants (Fig. 4), the peroxo oxygen in $MoO(O_2)_2HMPT$ can be accepted as electrophilic.

The results are in line with the suggestion made by Mimoun *et al.* on the basis of k' instead of k_2 we have examined. This would be expected if k' runs parallel with k_2. However, since k' is a function of k_2, K and olefin concentration, there should be difference between k' and k_2. In fact, k_2 remarkably deviates from the linear relationship with K (Fig. 3), whereas k' is approximately linear with respect to K. A similar feature is obvious in Fig. 4. The k_2 of $\alpha\alpha\beta\beta$ olefin is substantially less than expected from linearity, whereas the linearity is extended to include $\alpha\alpha\beta\beta$ olefin for the other three, non-coordinated oxygen species. Another feature characteristic of k_2 would be the steric effect of olefin, which is not observed with the other three compounds. Such characteristic features observed with k_2 are assumed to be caused by the required coordination of olefin to molybdenum.

The selective epoxidation of olefin by $MoO(O_2)_2$-HMPT complex should be explained in terms of the electrophilic nature of peroxo oxygen. In fact, oxygen anion O^- and superoxide O_2^- having negative values of electron affinity do not give epoxide, whereas the atomic oxygen and $O_2(^1\Delta_g)$ have positive values and give epoxide. Oxygen complexes of group VIII metals are also known to be ineffective for epoxidation. Cook *et al.* estimated the effective charge of coordinated oxygen in $PtO_2(P\phi_3)_2$ as $O_2^{1.8-}$ by means of ESCA.[12] Since the electrophilicity of oxygen depends on its effective charge, the electrophilic nature of peroxo oxygen suggests that the peroxo oxygen has a much lower effective charge than its formal one O_2^{2-}. The higher selectivity of epoxidation by molybdenum complex, in constrast to group VIII metal complexes, may be understood on the basis of different effective charges of O_2 in the complexes.

(Received December 28, 1973)

The vibrational spectra of dichloroethylmethylsilane and 2,2-dichlorobutane have been measured. The vibrational assignments of these molecules have been made in relation to the rotational isomerism. The normal vibration calculations based on the modified Urey-Bradley force field have been carried out and have confirmed for both molecules that, in the liquid state, the *trans* and *gauche* isomers coexist, while the *trans* isomer alone persists in the crystalline state.

A number of studies concerning rotational isomerism around a C–C bond as an axis have been reported.[1] Recently, the existence of the rotational isomers around a C–Si bond in the homologous series of alkylsilanes has become apparent.[2] We have taken an interest in studying the rotational isomerism in the homologous series of alkylsilanes. In this paper, we will deal with the vibrational assignments and the rotational isomerism of dichloroethylmethylsilane and its analogues, *viz.*, 2,2-dichlorobutane.

Experimental

Dichloroethylmethylsilane was prepared from methyltrichlorosilane by adding C_2H_5MgBr.[3] 2,2-Dichlorobutane was prepared by the reaction of ethyl methyl ketone with PCl_5.[4]

The infrared spectra in the 250—4000 cm^{-1} region were recorded on a Perkin-Elmer instrument(Model 621). For the measurements in the crystalline state in this region, the vapor was condensed on a CsI window cooled with liquid nitrogen; the sample was then annealed near the melting point. For the spectra of dichloroethylmethylsilane in the 30—400 cm^{-1} region, a Hitachi Fis-3 far-infrared spectrometer equipped with a cell of polyethylene windows was used. The Raman spectra of dichloroethylmethylsilane in the liquid state were recorded on a JEOL Raman spectrometer (Model JRS-02AS), using an argon-ion laser(488.0 nm) for excitation.

Rotational Isomerism

Figure 1 shows the infrared and Raman spectra of $C_2H_5SiCl_2CH_3$ in the region below 900 cm^{-1}. The $SiCl_2$ stretching vibrations can be expected in the 400—600 cm^{-1} region from a comparison of the spectra with those of $(CH_3)_2SiCl_2$.[5] In the infrared spectra, the very-strong pair band at 546 and 530 cm^{-1} and the strong pair band at 471 and 467 cm^{-1} are observed in the liquid state. In the supercooled liquid state before annealing, the absorption intensities of both the higher-frequency bands of the pairs are weaker than the lower-frequency bands, while the reverse is true in the liquid state. In the crystalline state, both the lower-frequency bands of the two pairs persist, while the disappeared bands again appear with a rise in the temperature. These results indicate that rotational isomers exist in the liquid state, while one isomer persists in the crystalline state. On the other hand, in the Raman spectra, the very-strong pair counterpart at 460 and 470 cm^{-1} and the very-weak pair counterpart at 531 and 540 cm^{-1}, corresponding to the pair bands around 470 and 540 cm^{-1} respectively in the infrared spectra, are observed in the liquid state; they are, therefore, assigned to the $SiCl_2$ symmetric and antisymmetric stretching vibrations respectively.

On the other hand, Fig. 2 shows the infrared

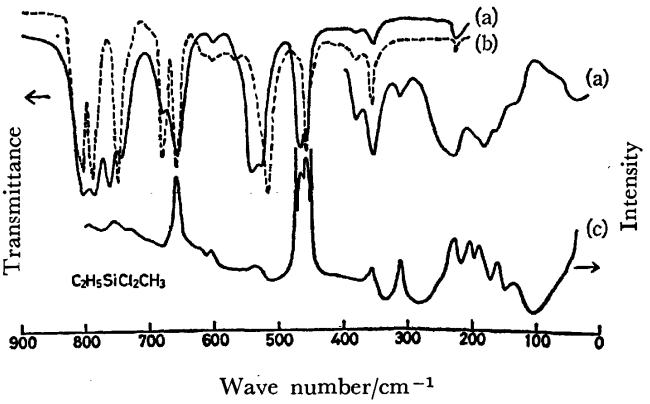

Fig. 1. The vibrational spectra of dichloroethylmethylsilane.

spectra of 2,2-dichlorobutane in the 250—900 cm^{-1} region. For alkyl chlorides, useful information about the rotational isomerism has been obtained from the C-Cl stretching and skeletal deformation vibrations.[1] In this molecule, the very-strong pair band at 692 and 645 cm^{-1} and the strong pair band at 567 and 544 cm^{-1} in the liquid state, clearly separated from each other, are observed; they are easily assigned to the CCl_2 antisymmetric and symmetric stretching vibrations respectively by reference to the spectra of 2,2-dichloropropane,[6] while both the higher-frequency bands of the pairs disappear in the crystalline state. In Fig. 2, the split pattern of the band at 544 cm^{-1} in the crystalline state may be due to the influence of the crystalline field because, in the supercooled liquid state before annealing, this pattern is not observed. The tendency of the CCl_2 stretching vibrations is the same as that of the $SiCl_2$ stretching vibrations. Therefore, it may be expected that, for both molecules, only one isomer with the same molecular form persists in the crystalline state, while two isomers coexist in the liquid state.

The results of the normal vibration calculations, which will be given in Tables 4 and 5, indicate that the antisymmetric and symmetric YCl_2 stretching vibrations (Y=C, Si) for the *gauche* isomer are higher in frequency than those for the *trans* isomer and that, among the skeletal deformation vibrations, the highest-frequency vibration for the *trans* isomer is higher in frequency than that for the *gauche* isomer. The conclusion regarding the molecular form obtained from the skeletal deformation vibration is consistent with that obtained from the YCl_2 stretching vibrations.

Energy Difference between Isomers. For 2,2-dichlorobutane, the relative intensities of the bands at 692 and 645 cm^{-1} assigned to the CCl_2 antisymmetric stretching vibration for the *gauche* and *trans* isomers respectively are measured in the gaseous state at ten different temperatures; in the crystalline state the former disappears, while the latter persists. Figure 3 shows some typical examples of the infrared bands at 301, 320, 343, 368, and 399 K. From the observed optical densities, the energy difference between the isomers

is found to be *ca.* 0.5 kcal/mol, where the *trans* isomer is more stable than the *gauche* isomer. This value is in good agreement with the value estimated by means of the interactions of the atoms in the 1,3 positions lying on parallel bonds which has been presented by Štokr *et al.*[8] However, for dichloroethylmethylsilane, measurements of the relative intensities of the bands cannot

be made because of the overlapping of the bands assigned to the $SiCl_2$ stretching vibrations in the gaseous state.

Vibrational Assignments

The *trans* form of dichloroethylmethylsilane and 2,2-dichlorobutane may have C_s symmetry. The 36 normal modes are reduced by group theory to 21 modes of the A′ species and 15 of A″. The *gauche* form belongs to the trivial point group C_1. All of the 36 modes are of the same symmetry species. All of the fundamental vibrations of the *trans* and *gauche* forms are infrared and Raman-active. The observed frequencies are given in Tables 1 and 2, together with the brief vibrational assignments.

Dichloroethylmethylsilane. It is expected that the vibrations of the $SiCH_3$ group are considerably lower in frequency than the corresponding vibrations of the CCH_3 group because of the difference in the electronegativity of the adjacent atom. Actually, these vibrations of the CCH_3 and $SiCH_3$ groups are observed at different frequencies clearly separated from each other. The infrared spectra of dichloroethylmethylsilane in the 800—1500 cm^{-1} region are not so different in the liquid and crystalline states, and they are close to the superposition of the spectra of ethyltrichlorosilane[9] and methyltrichlorosilane.[10] The infrared spectra in the 400—800 cm^{-1} region are also similar to those of dimethyldichlorosilane.[5] Therefore, the vibrational assignments in the 400—1500 cm^{-1} region can easily be made by a comparison of the spectra with those of analogues. The bands in the region below 400 cm^{-1} may be assigned to the skeletal deformation or torsional vibrations. However, the vibrational assignments in this region cannot be made easily, for a large mode mixing among the several skeletal deformation vibrations must be expected; they are tentatively assigned in Table 4 on the basis of the results of the normal vibration calculations.

2,2-Dichlorobutane. In the infrared spectra in the 300—1500 cm^{-1} region, as too many bands for a unique molecular form are observed in the liquid state and as several bands vanish in the crystalline state, it may be concluded that rotational isomers coexist in the liquid state, while only one isomer persists in the crystalline state. The infrared spectra show that most of the vibrations of the two CH_3 groups may be coincident with each other, because the presence of one CH_3 group is sufficient to account for the number of observed bands. Therefore, the infrared spectra in the 1200—1500 cm^{-1} region can easily be assigned on the basis of a comparison of the spectra with those of analogues, such as CH_3CCl_3[11] and CH_3CH_2X.[12] The bands in the 800—1200 cm^{-1} region may be assigned to the C–C stretching or CH_3 rocking vibrations, but three C–C stretching and four CH_3 rocking vibrations are expected for a unique molecular form and may mix with each other in the same symmetry species. Therefore, the vibrational assignments in this region are made from the results of the normal vibration calculations. On the other hand, the strong infrared bands at 796 and 808 cm^{-1} and the weak Raman counterpart at 793 cm^{-1} are assigned to the CH_2 rocking vibrations. The very-strong pair band around 670 cm^{-1} and the strong pair band around 550 cm^{-1} are easily assigned to the CCl_2 stretching vibrations, as has already been mentioned. The infrared bands in the region below 500 cm^{-1} may be assigned to the skeletal deformation or torsional vibrations. These bands are assigned on the basis of the results of the normal vibration calculations, because large mixings of the modes are expected.

Normal Vibration Calculation

The normal vibrations were calculated on the basis of the modified Urey-Bradley force field in order to determine the molecular forms and the vibrational assignments. The force constants were transferred from those of $CH_3CH_2SiH_3$[13] and $(CH_3)_2SiCl_2$[5] for $C_2H_5SiCl_2CH_3$ and from those of $CH_3CHClCHClCH_3$[14]

a) All the force constants are transferred from ethylsilane[13)] and dimethyldichlorosilane[5)] for dichloroethylmethylsilane and from 2,3-dichlorobutane[14)] and dichloromethane[15)] for 2,2-dichlorobutane. The adjusted force constants are given in brackets. The units of the force constants are in mdyn/Å for stretching, K; bending, H; repulsion, F; and bond-interaction, p; and in mdyn·Å for intramolecular tension, k; and internal rotation, Y.

and CH_2Cl_2[15)] for $C_2H_5CCl_2CH_3$. The following assumptions were made for the force field: 1) the bond-interaction constant, p(C–H), was added in order to reproduce the observed C–H stretching frequencies, 2) the torsional force constant, Y(C–C), was assumed to be the value (3.49 kcal/mol) obtained from the reported far-infrared band for the CH_3 torsion of ethyl chloride[16)] and the Y(C–Si) constant was assumed to be the value(1.65 kcal/mol) of dimethylsilane determined by microwave study,[17)] and 3) for $C_2H_5SiCl_2CH_3$, the force constants, H(H–C–H) and F(H·C·H), were assumed to be the same values for the CCH_3 and $SiCH_3$ groups, while for $C_2H_5CCl_2CH_3$, the force constants, H(H–C–H), H(C–C–H), F(H·C·H) and F(C·C·H), were assumed to be the same values for both the CH_3 groups.

The force constants used in the calculation are given in Table 3. The vibrational frequencies in the region below 1200 cm^{-1} depend more conspicuously upon the azimuthal angle of internal rotation. Therefore, the observed and calculated frequencies in this region are given in Tables 4 and 5, together with the predominant symmetry coordinates in the potential energy distributions. Set I of the calculation in Tables 4 and 5 shows the calculations using all the transferred force constants given in Table 3. A fair agreement is obtained between the observed and calculated frequencies, except for a few vibrations. Especially, the calculated frequencies of the YCl_2 stretching (Y=C, Si) and the highest-frequency skeletal deformation vibrations indicate that, for both dichloroethylmethylsilane and 2,2-dichlorobutane, the bands persisting in the crystalline state are attributable to the *trans* form, while the bands disappearing in the crystalline state are attributable to the *gauche* form. However, as the calculated YCl_2 stretching frequencies indicate that the values of both the force constants, K(C–Cl) and K(Si–Cl), have to be smaller than the transferred values, only these constants, K(C–Cl) and K(Si–Cl), are adjusted in order to reproduce the observed frequencies. We still cannot reproduce the separations between the YCl_2 antisymmetric and symmetric stretching frequencies satisfactorily. Therefore, the bond-interaction constants, p(C–Cl) and p(Si–Cl), are introduced.

The results of the calculations obtained in this modification are given in Set II of the calculation in Tables 4 and 5. The values of the adjusted force constants are K(C–Cl)=1.353, p(C–Cl)=−0.090, K(Si–Cl)=2.226, and p(Si–Cl)=0.174 mdyn/Å. It is inter-

	—	56	56		79	58	58	τ(skel)

a) The observed infrared frequencies in the liquid state are listed, where asterisks indicate the bands disappearing in the crystalline state. The vibrational frequencies below 1200 cm^{-1} are included. Potential energy distributions are shown for the internal symmetry coordinates, where only contributions greater than 20% are included. ν, δ, s, w, t, r, and τ denote the stretching, deformation, scissoring, wagging, twisting, rocking, and torsional modes and a and s denote the antisymmetric and symmetric modes, respectively.

esting to note that the value of p(C–Cl) is negative, while that of p(Si–Cl) is positive. It is also noticeable that the frequency differences of the YCl_2 stretching vibrations between the antisymmetric and symmetric modes and between the *trans* and *gauche* forms for $C_2H_5SiCl_2CH_3$ are smaller than those for $C_2H_5CCl_2CH_3$. This may be because, for the nonlinear YX_2-type molecule, the off-diagonal element of the **G**-matrix between the stretching modes is $\cos\alpha\mu_y$ (μ_y is the reciprocal of the mass of the atom, Y).[7] Therefore, the separation frequency between the antisymmetric and symmetric modes of the YCl_2 stretching may be mainly affected by the mass of the atom, Y, though the quite reverse influence of the corresponding off-diagonal element of the **F**-matrix containing only the repulsive force constant, F(Cl·Y·Cl), in the simple Urey-Bradley force field($F'=-0.1F$) can be expected, and though the couplings of the YCl_2 stretching modes with the other modes are not taken into account. In order to predict well the observed YCl_2 stretching frequencies, the bond-interaction constant, p(Y–Cl), is necessary.

On the other hand, the frequency separation of the YCl_2 stretching modes between the different molecular forms may be mainly influenced by the vibrations of the adjacent groups, which, in combination with the YCl_2 stretching modes, give the off-diagonal **G**-matrix elements containing the azimuthal angle, such as the Y–C–C bending and CH_2 rocking modes for $C_2H_5YCl_2CH_3$ (Y=C, Si). The larger couplings are expected from the perturbation theory[7] when the vibrational frequencies come close to one another. The separations of the YCl_2 stretching modes with both the CH_2 rocking and Y–C–C bending modes for $C_2H_5CCl_2CH_3$ are smaller than those of $C_2H_5SiCl_2CH_3$. Therefore, it can be expected that the separations of the YCl_2 stretching vibrations between the different molecular forms for $C_2H_5CCl_2CH_3$ are larger than those for $C_2H_5SiCl_2CH_3$. This is supported by the results of the potential energy distributions of the modes, given in Tables 4 and 5.

The Crystal Structure of Dichlorobis(acetoxime)palladium

Yukishige KITANO,* Kiyotomi KOBORI,* Masamitsu TANIMURA,* and Yukio KINOSHITA**

Basic Research Laboratories, Toray Industries, Inc., 1,111 Tebiro, Kamakura 248

(Received January 8, 1974)

The crystal structure of dichlorobis(acetoxime)palladium, $PdCl_2(C_3H_6NOH)_2$, has been determined from three-dimensional single-crystal X-ray photographic data. The crystals belong to the monoclinic system (space group $P2_1/a$), with two formula units in a cell with dimensions: $a=8.709\pm0.007$, $b=13.996\pm0.005$, $c=4.756\pm0.006$ Å, and $\beta=95.60\pm0.05°$. The structure was established by the heavy-atom method and was refined by the block-diagonal least-squares procedure. The Pd atoms are spaced at intervals of 4.76 Å along the c-axis and have a *trans* planar coordination, with two Cl atoms at 2.30 Å and two N atoms of the oxime groups at 2.03 Å. The oxime plane is twisted about the Pd–N bond by 72.7° from the coordination plane defined by the Pd, Cl, and N atoms. The complex molecules are hydrogen-bonded with each other in strings of an indefinite length along the c-axis, and the hydrogen-bond distance between the O atom of the oxime and the Cl atom is 3.07 Å.

As part of a systematic study of the crystal structures of the palladium-complexes, the crystal structures of the stable monoxime-palladium complexes have been investigated in order to ascertain the conformational features around the metals. In the previous papers of this series, the crystal structures of $PdCl_2(C_6H_{10}NOH)_2$[1] and $[Pd(\pi\text{-}C_3H_5)Cl]_2C_6H_{10}NOH$[2] were descrived. In this investigation the crystal of dichlorobis(acetoxime)-palladium was subjected to X-ray crystal-structure analysis in order to obtain structural information.

Experimental

Dichlorobis(acetoxime)palladium, $PdCl_2(C_3H_6NOH)_2$, was prepared by mixing palladium chloride and acetoxime[3] and was recrystallized from a tetrahydrofuran solution as a reddish yellow crystal elongated in the c direction. The unit-cell dimensions were determined from Weissenberg and precession photographs, taken about the three axes. The density was measured by flotation in an ethyl iodide-toluene mixture at 25 °C. The crystal data are summarized in Table 1.

The three-dimensional intensity data were collected from equi-inclination Weissenberg photographs taken with Ni-filtered CuKα radiation. The multiple-film technique was used, and the layers from zero to first about the a-axis and those from zero to third about the c-axis were recorded. The relative intensities, estimated visually by comparison with a calibrated intensity scale, were corrected for the usual Lorentz and polarization factors. No corrections were made for the small absorption errors. A total of 841 independent reflections was used for the structure determination.

Systematic absences, $h0l$ with $h=2n+1$
$0k0$ with $k=2n+1$
Space group $C_{2h}^5-P2_1/a$ (No. 14)

Structure Determination

The structure was established by the heavy-atom method. Since there are two molecules in the cell of the $P2_1/a$ space group, the palladium atoms must be at the centers of symmetry. The position of the chlorine atom was readily deduced from a three-dimensional sharpened Patterson synthesis. The successive Fourier syntheses phased initially by the palladium and chlorine atoms enabled the positions of the carbon, nitrogen, and oxygen atoms of the oxime to be determined and resulted in a reduction of R to 0.258. R is defined throughout as $\Sigma||F_o|-|F_c||/\Sigma|F_o|$, where the sums are over the unique, observed non-zero reflections only. The structure thus obtained was refined by the least-squares method. Four cycles of least-squares refinement using individual isotropic temperature factors, followed by one cycle using individual anisotropic temperature factors, reduced R to 0.132. Three more cycles of refinement of the non-hydrogen atoms with anisotropic temperature factors led to a final R-index of 0.083. Throughout the refinement of the structure, equal weights were employed for all the reflections and the atomic scattering factors were adopted from the International Tables for X-ray Crystallography.[4] The main part of the calculations was performed

with the numbering of atoms, as viewed along the c-axis is shown in Fig. 1. Figure 2 represents the mode of hydrogen bonding and the molecular arrangement viewed down the a-axis.

The crystal structure of dichlorobis(acetoxime)palladium closely resembles that of dichlorobis(cyclohexanone oxime) palladium.[1] The palladium atoms at the centers of symmetry are spaced at intervals of 4.75 Å along the c-axis and are coordinated in a square-planar configuration by two chlorine atoms and two nitrogen atoms of the oximes, the Pd–Cl and Pd–N distances being 2.30 and 2.03 Å respectively. As Fig. 2 shows, the complexes are hydrogen-bonded with each other in strings of an indefinite length along the *c*-axis; the distance between the oxygen atoms of the oxime groups and the chlorine atoms is 3.07 Å. The bond distances and angles in this complex are compared with the corresponding ones in $PdCl_2$-$(C_6H_{10}NOH)_2$[1] and $[Pd(\pi\text{-}C_3H_5)Cl]_2C_6H_{10}NOH$[2] in Table 5. The Pd-Cl bond length of 2.30 Å is longer than the value of 2.24 Å in $PdCl_2(C_6H_{10}NOH)_2$, but is in good agreement with those found in $(PdCl_2)_n$ (2.31 Å),[7] $C_7H_8PdCl_2$ (2.31 Å),[8] and $[(C_6H_5CN)$-$PdCl_2]_2$ (2.35 Å).[9] The Pd–N bond length of 2.03 Å

Table 5. Comparison of the selected interatomic bond distances and angle in some palladium-oxime complexes

Atom	$PdCl_2(C_3H_6NOH)_2$[a]	$PdCl_2(C_6H_{10}NOH)_2$[1]	$[Pd(\pi\text{-}C_3H_5)Cl]_2\cdot C_6H_{10}NOH$[2]
Pd-Cl	2.30 Å	2.24 Å	2.41—2.45 Å
Pd-N	2.03	2.08	2.10
N-O	1.41	1.42	1.39

Cl-O	3.07[b]	2.93[b]	3.03[c]
Cl-Pd-N	88.3°	86°	92.1°

a) Present work. b) Intermolecular hydrogen bond. c) Intramolecular hydrogen bond.

is a little shorter than the lengths in $PdCl_2(C_6H_{10}NOH)_2$ and $[Pd(\pi\text{-}C_3H_5)Cl]_2C_6H_{10}NOH$. It, however, agrees well with the values of 2.031 Å in bis-(*N*-isopropyl-3-ethylsalicylaldiminato) palladium,[10] 2.032 Å in the tetragonal form of bis-(*N*-isopropyl-3-methylsalicylaldiminato)palladium,[11] and 2.032 and 2.043 Å in bis(ethylenediamine)palladium(II) chloride.[12]

The C-C bond lengths in the oxime group of 1.44 and 1.53 Å found here are not greatly different from the corresponding values for the other oximes[13] which lie between 1.44 and 1.56 Å. The C–N bond distance of 1.28 Å suggests its double-bond character and is comparable to similar distances in acetoxime and other oximes.[14] Although the present value of 1.41 Å for the N-O bond length appears to be somewhat shorter than the values obtained for acetoxime, it is probably not unwarranted when it is compared with the values of 1.41 Å in formamidoxime,[15] 1.42 Å in $PdCl_2(C_6H_{10}NOH)_2$, and 1.39 Å in $[Pd(\pi\text{-}C_3H_5)Cl]_2C_6H_{10}NOH$.

The palladium coordination plane, as defined by the Pd, Cl, and N atoms, is expressed by the equation:[16]

$$0.048\,X + 0.805\,Y + 0.998\,Z = 0$$

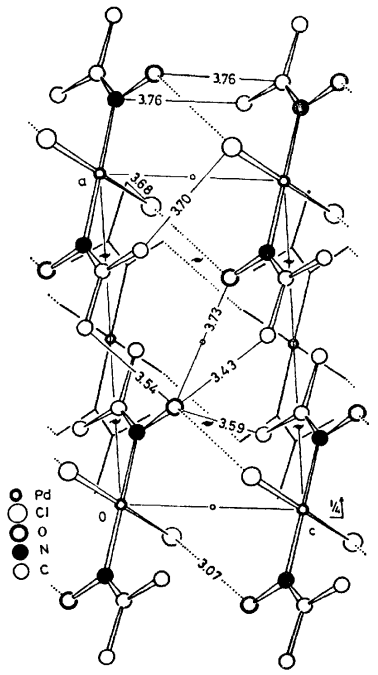

Fig. 3. The crystal structure projected along the b-axis. The intermolecular atomic contacts less than 3.8 Å are shown by solid lines and the hydrogen bonds are shown by dotted lines.

The equation for the best-plane containing O, N, C(1), C(2), and C(3) atoms is:

$$-0.389\,X - 0.748\,Y + 0.920\,Z = 0.024.$$

The deviations of the five atoms from this plane are within 0.01 Å. The chlorine atom at the $(x, y, c+z)$ position, which is connected by a hydrogen bond with the oxygen atom of the oxime, is separated from this plane by 1.54 Å. The dihedral angle between the oxime plane and the palladium coordination plane is 72.7°, which is comparable to the corresponding value of 81.0° between the palladium square-planar plane and the best-plane of the O–N–C$\langle^{C}_{C}$ fragment of the cyclohexanone oxime in $PdCl_2(C_6H_{10}NOH)_2$.

Figure 3 shows the molecular packing projected along the b-axis. The intermolecular atomic contacts less than 3.8 Å are shown by solid lines. The hydrogen bonds are also shown by dotted lines. None of the atoms is significantly shorter than the normal van der Waals contact.

The authors are grateful to Dr. Masaji Ohno for his kindness of supplying the compound.

The Effect of Organic Additives on the Micelle Formation of Dodecylammonium Halides in Aqueous Solutions

Shigeyoshi MIYAGISHI

Department of Industrial Chemistry, Faculty of Technology, Kanazawa University, Kodatsuno, Kanazawa 920

(Received January 14, 1974)

The critical micelle concentration (CMC) of dodecyl ammonium halides and the degree of dissociation of the micelle (α) of dodecylammonium chloride were determined as functions of the concentrations of the organic additives by measuring the conductivity and the emf of the following cell: calomel/1 M-KCl/sample solution/AgCl, Ag. The CMC was raised more in the presence of acetone and dioxane than in that of acetamide, formamide, urea, and methanol, and was diminished by adding alcohols (C_2—C_4). The effect of the alcohols on CMC decreased in the order of the diminished hydration of the counterion, acetone and dioxane were considered to affect the dodecylammonium iodide solution specifically. The dissociation of the micelle was enhanced in the presence of organic additives. Further, we estimated the solubilized amount of the additives from the degree of dissociation of the micelle and attempted to make quantitative estimation of the increment of CMC produced by organic additives.

The micelle formation in an aqueous solution is known to be affected by organic additives, and there have been many investigations concerning the effects of organic additives on the CMC of anionic[1-4] and cationic[1,5,6] surfactants. Shinoda[7] and Shirahama and Kashiwabe[8] explained the decrease in the CMC in the micellar solutions containing alcohols in terms of the solubilization of alcohol into the micelle. On the other hand, some organic additives gave an increment in CMC, and this cannot be explained by their theories. Emerson and Holtzer[1] found qualitative correlations between the hydrophobic nature of an additive and its micellar breaking-up power, but the correlations are limited.

It is well known that the micellar solutions are influenced by changing the counterion. Schick[2] studied the effect of counterion hydration on the CMC and found that the increment in CMC on urea addition increased in the following order: lithium-, sodium- and tetramethyl ammonium dodecylsulfate. He interpreted this order in terms of the structural concept of water.

At present, however, we have not yet obtained enough knowledge to understand the effects of organic additives on the CMC. Therefore, we attempted to study the effects of aprotic and protonic additives on the micellar solutions of dodecylammonium halides by determining their CMC and the degree of dissociation of their micelles, and tried to estimate the solubilized amount from the degree of dissociation.

Experimental

The dodecylammonium chloride (DACl), -bromide (DABr), and -iodide (DAI) were prepared by the neutralization of dodecylamine (bp 100 °C/5 mmHg) with the corresponding hydrohalic acid and were recrystallized five times from ethanol–ether. The organic additives were distilled before use, but urea and acetamide were of a reagent grade and were used without further purification.

The CMC (C) was determined by the electric-conductivity method. The determination of the activity (a) of the counterion was carried out by using the following cell:

$$\mathrm{Hg,\ Hg_2Cl_2\,|\,1\ M\text{-}KCl\,|\,DACl\ soln.\,|\,AgCl,\ Ag}$$

The degree of dissociation of the micelle (α) was then calculated by using Botré *et al.*'s equation:[9]

$$a = \gamma\{C+\alpha(C_t-C)\} \tag{1}$$

where C_t is the concentration of the surfactant. The Silver-silver chloride electrode prepared by the dry method[10] was calibrated by potassium-chloride solution; its activity coefficient, γ, was estimated by means of this equation:[11]

$$\log\gamma = -\frac{A_0\sqrt{C_1}}{1+B_0\sqrt{C_1}} - D_0C_1 \tag{2}$$

where C_1 is the concentration of potassium chloride, and where A_0, B_0, and D_0 are constants.

These experiments were carried out at 35.0 °C because of the low solubility of DABr at 25.0 °C.

Results and Discussion

The Effect of Alcohol on Micelle Formation. The addition of alcohols to the micellar solution is well known to depress the CMC; however, little attention has been paid to the importance of the counterion with respect to the effects of organic additives. The effects of changing the counterion was studied as one of the primary subjects of this investigation. As illustrated in Figs. 1 and 2, the CMC of dodecylammonium halides

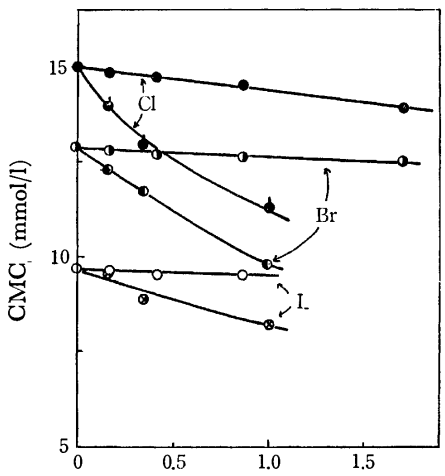

Fig. 1. Effect of ethanol and *n*-propanol on CMC.
●, ◑, ○: ethanol, ⬮, ◐, ⊗: *n*-propanol

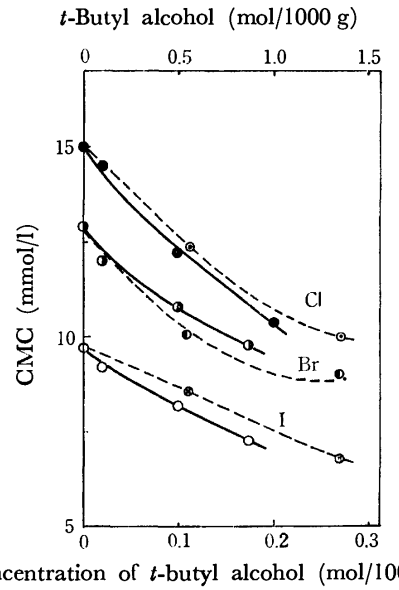

Fig. 2. Effect of butanols on CMC.
——; *t*-butyl alcohol, - - - -: *n*-butanol.

and the effects of alcohols on it decreased in the order of the diminished hydration of the counterion. This order is in line with that of the degree of dissociation of the halide micelles and the salting-out power of the halide anions.[12,13] On the other hand, the depression of the CMC is related to the free energy of the transfer of an alcohol molecule from the water to the micelle phase.[8]

Therefore, the above results suggest that the counterion affects its free energy through the destruction of the water structure around the alcohol molecule and the looseness of the surface charge on a micelle, although the main factor in the depression of the CMC is the carbon number in the alcohol molecule.

The organic additive, in addition to its solubilization effect, modifies the properties of the medium. Figure 3 indicates that the latter effect predominated in the presence of methanol and was influenced almost not at all by changing the counterion.

The Effects of Urea, Formamide, and Acetamide on Micelle Formation. The effect of amide on the CMC has been determined as a function of the amide concentration. The CMC increased with an increase in the

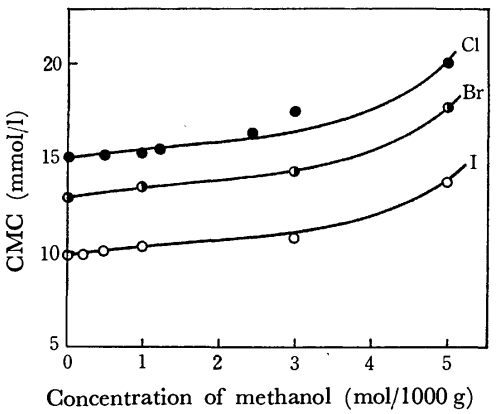

Fig. 3. Effect of methanol on CMC.

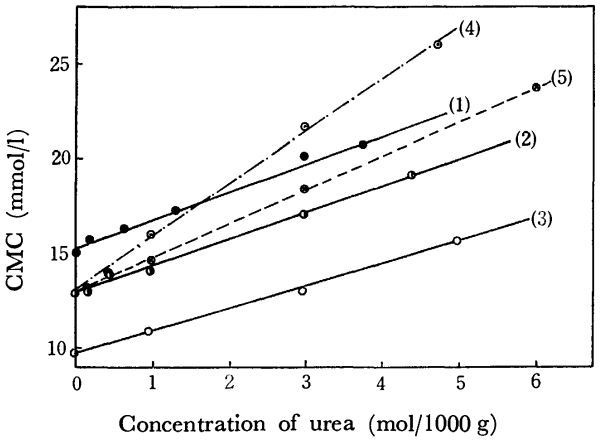

Fig. 4. Effect of amides on CMC.
(1): DACl——urea, (2): DABr——urca, (3): DAI ——urea, (4): DABr——acetamide, (5): DABr—— formamide.

urea concentration, and no significant difference in susceptibility to change in the CMC on urea addition was observed at 35.0 °C among the dodecylammonium halides (Fig. 4). It has been reported by Schick, however, that the increment in the CMC of dodecylsulfates at 10—45 °C on urea addition increased in the order of the diminished hydration of the counterion.[2] This may be attributable to the weaker hydration of halide anions compared with that of alkali cations.

On the other hand, the order of effectiveness in breaking up the micelle was: acetamide>formamide> urea. Urea raises the dielectric constant of water,[14] acetamide lowers it,[14] and formamide may raise it because of its high dielectric constant. Acetamide, furthermore, has a stronger hydrophobic character. The lowering of the dielectric constant and the hydrophobic character are considered to break up the micelle through an increment in the electrostatic repulsion on the micelle surface and a reduction of the interfacial energy between the hydrocarbon chain of single ions and water. Therefore, the above result may be attributable to these two effects. In all the micellar solutions containing alcohols except for methanol, however, the solubilization effect is more significant than these effects.

The Effect of Acetone and Dioxane on Micelle Formation. The alcohols and amides described above were protonic additives; the effects of aprotic solvent—acetone and dioxane—were also studied.

As is shown in Figs. 5 and 6, the addition of acetone or dioxane into the dodecylammonium halide solutions resulted in the increment of CMC, the effect of this on the DAI solution was different, however. In the presence of dioxane, the DAI solution became yellowish and precipitation resulted from the addition of many dioxane. It is known that a complex results from the interaction between acetone and the iodine ion.[15] Accordingly, the addition of the aprotic solvents is considered to affect the DAI solution specifically.

In summary, the CMC of dodecylammonium halide was raised more in the presence of aprotic solvents

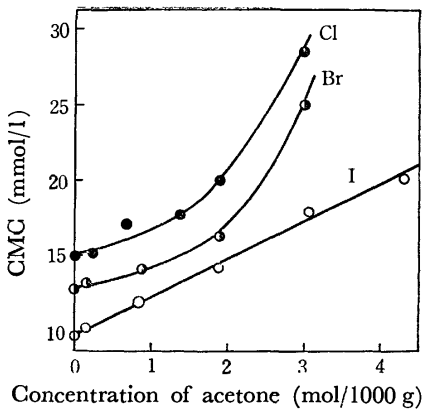

Fig. 5. Effect of acetone on CMC.

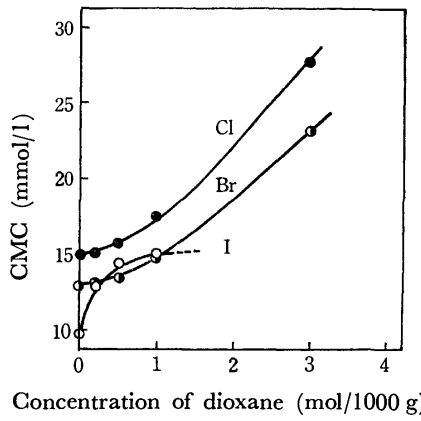

Fig. 6. Effect of dioxane on CMC.

than in that of amides and was depressed by the addition of alcohols; a change in the counterion was more effective on the reduction of the CMC than on its increment.

The Influence of Organic Additives on the Degree of Dissociation of Micelle. The dissociation of an electrolyte is depressed by adding salts or by lowering the dielectric constant of the medium; that of a micelle is also depressed by added salts. Therefore, a micelle may be expected to be less dissociative in the presence of an organic additive with a low dielectric constant. Figure 7, however, shows the opposite results. A sodium tetradecyl sulfate (STS) solution containing dioxane[16] and sodium dodecylsulfate (SDS) and dodecyltrimethylammonium bromide in a 3 M urea solution[17] also gave the same results.

Stern[18] derived the following equation concerning adsorption on the double layer;

$$\frac{n}{N-n} = \frac{AM}{1000} C_i \exp(-\Delta G/kT) \tag{3}$$

where n and N are number of adsorbed molecules on the surface and its maximum number, A is a constant, M is the molecular weight of the solvent, C_i is the concentration of the adsorbate, and ΔG is the free energy of transfer from a bulk solution to the surface.

If a micelle consists of N monomers and N' organic additives and n counterions, n/N may be equal to $1-\alpha$, and when the micelle is large, Stern's equation can be applied to its surface. Thus, we obtain:

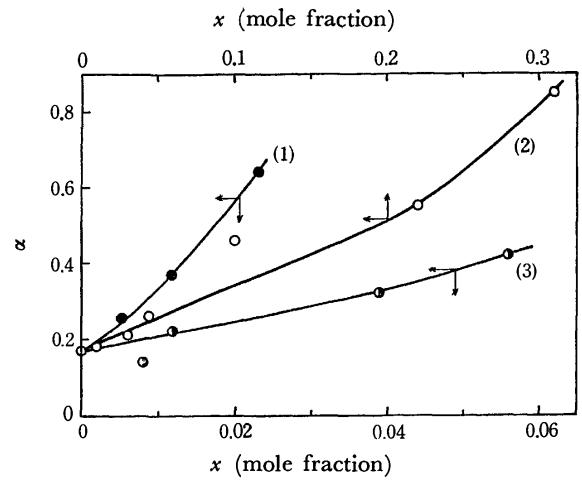

Fig. 7. Effect of organic additives on α in DACl solutions.
1): n-propanol, 2): methanol, 3): acetone.

$$\frac{1-\alpha}{\alpha} = \frac{AM}{1000} C_i \exp(-\Delta G/kT) \tag{4}$$

As ΔG consists of the electrostatic energy, $\Delta G_{\text{elec.}}$, and the chemical energy, $\Delta G_{\text{chem.}}$, Equation (4) becomes:

$$\frac{\alpha}{1-\alpha} = \frac{1000}{AMC_i} \exp(\Delta G_{\text{elec.}} + \Delta G_{\text{chem.}}) \tag{5}$$

The electrostatic energy is given by:

$$\Delta G_{\text{elec.}} = -kT \ln \frac{2000\pi\sigma^2}{DNkTC_i} \tag{6}$$

$$\sigma = x_s \sigma_1 \tag{7}$$

where σ_1 and σ are the charge densities of the micelle containing no and $1-x_s$ organic additives, x_s is the mole fraction of the surfactant in the micelle, and D is the dielectric constant of the solvent. Further, we assume the following two equations;

$$M = M_1(1-x) + xM_2 \tag{8}$$

$$\Delta G_{\text{chem.}} \approx \Delta G_{\text{sol.}} = -\Delta G_2 x - \Delta G_1(1-x) \tag{9}$$

where $\Delta G_{\text{sol.}}$ is the desolvation energy, ΔG_1 and ΔG_2 are solvation energies of water and the organic additive respectively, and x is the mole fraction of the organic additive. Equation (5) can then be rewritten as:

$$\ln \frac{\alpha}{1-\alpha} = \ln \frac{1000}{AM_1C_i} - \ln\left\{1+\left(\frac{M_2}{M_1}-1\right)x\right\} - \ln \frac{2000\pi\sigma_1^2}{D_1NkTC_i} - 2\ln x_s + \ln \frac{D}{D_1} - \frac{\Delta G_1}{kT} + \frac{\Delta G_1 - \Delta G_2}{kT} x \tag{10-a}$$

When the micellar solution does not contain the organic additive, (10-a) becomes (10-b):

$$\ln \frac{\alpha_1}{1-\alpha_1} = \ln \frac{1000}{AM_1C_i} - \ln \frac{2000\pi\sigma_1^2}{D_1NkTC_i} - \frac{\Delta G_1}{kT} \tag{10-b}$$

From (10-a) and (10-b), we obtain:

$$\ln \frac{\alpha}{1-\alpha} = \ln \frac{\alpha_1}{1-\alpha_1} - \ln\left\{1+\left(\frac{M_2}{M_1}-1\right)x\right\} - 2\ln x_s + \ln \frac{D}{D_1} + \frac{\Delta G_1 - \Delta G_2}{kT} x \tag{10}$$

Accordingly, by measuring α and α_1, we can calculate the solubilized amount of the organic additive, x_m

$(=1-x_s)$. The amount of the organic additive in the micelle phase was less than 5% of its amount in the bulk phase; therefore, the value of x was regarded as the total of the added amount. For the values of $(\Delta G_1-\Delta G_2)/kT$, those of hydrochloric acid or sodium hydroxide[19] were used as an expedient; that is, 4.65, 6.28, 7.19, and 14.8 were used for the systems of DACl-methanol, -propanol, -acetone, and STS-dioxane respectively.

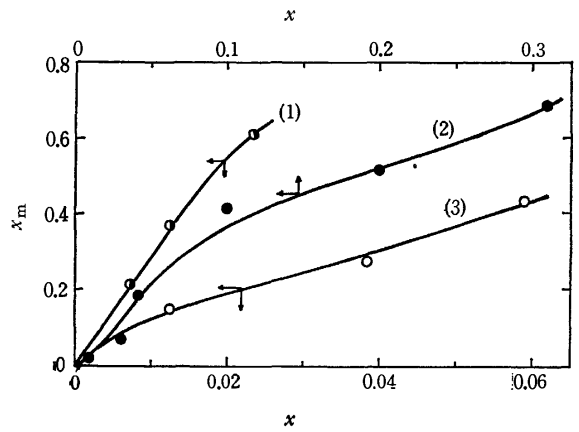

Fig. 8. Solubilization of organic additives in DACl solutions.
1): *n*-propanol 2): methanol, 3): acetone.

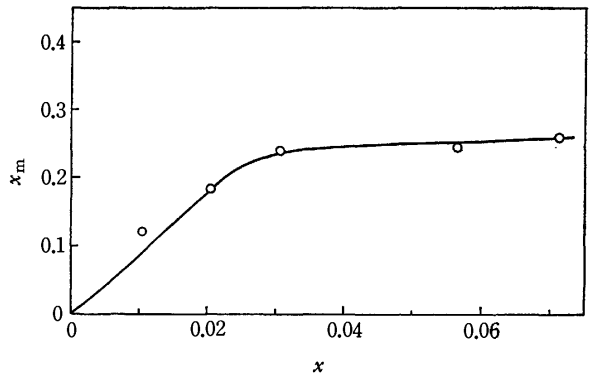

Fig. 9. Solubilization of dioxane in sodium tetradecyl-sulfate solution*.
*; x_m was calculated from α in Ref 14.

As is shown in Figs. 8 and 9, x_m increases with the concentration of the additives and attains a large value in high concentrations. The large value of the solubilized amount can be explained by considering that the large micelle to which Equation (1) can be applied does not exist in high concentrations of the additive. The aggregate, however, changes continuously from the micelle to the oligomer with the concentration of the additive; therefore, it is difficult to divide the micelles into two regions, so we call them all "micelles". According to Uehara *et al.*, however, the CMC and the aggregation number of SDS could be determined in high methanol concentrations.[4]

The Dependence of the CMC on the Concentration of Organic Additives. We attempted to estimate the dependence of the CMC on the additive concentration from the degree of dissociation of a micelle.

In a micellar solution the chemical potential of the surfactant ion in the bulk solution is equal to that in the micelle phase. Therefore,

$$\mu_b^\circ + kT\ln Cf = \mu_m^\circ + kT\ln x_s f_s + e\phi \tag{11}$$

$$e\phi = kT\ln\frac{2000\pi\sigma^2}{DNkTC_1} \tag{12}$$

where μ_b° and μ_m° are the standard chemical potentials of the surfactant ion in the bulk solution and in the micelle phase respectively, f and f_s are the activity coefficients of the surfactant ions in the bulk solution and in the micelle phase respectively, and $e\phi$ is the electrostatic work. In the absence of added salt, C_1 is equal to C; therefore, from Eqs. (7), (11), and (12) we obtain

$$2\ln Cf = \frac{\mu_m^\circ-\mu_b^\circ}{kT} + \ln\frac{2000\pi\sigma_1^2x_s^2}{DNkT} + \ln x_s + \ln f_s \tag{13-a}$$

When the micellar solutions do not contain organic additives, (13-a) becomes:

$$2\ln C_1f_1 = \frac{\mu_m^\circ-\mu_b^\circ}{kT} + \ln\frac{2000\pi\sigma_1^2}{D_1NkT} \tag{13-b}$$

Therefore, we obtain:

$$2\ln C/C_1 + 2\ln f/f_1 = 3\ln x_s - \ln D/D_1 + \ln f_s \tag{13}$$

If the following equation is assumed as a first approximation:

$$\ln f_s - 2\ln f/f_1 = k_1x \tag{14}$$

where k_1 is a constant, we obtain:

$$2\ln C/C_1 = 3\ln x_s - \ln D/D_1 + k_1x \tag{15}$$

As the x_s value is obtained from Eq. (10), Equation (15) finally becomes:

$$\ln\frac{C}{C_1} = \frac{3}{4}\left[\ln\frac{\alpha_1}{1-\alpha_1} - \ln\frac{\alpha}{1-\alpha} - \ln\left\{1+\left(\frac{M_2}{M_1}-1\right)x\right\} + \frac{\Delta G_1-\Delta G_2}{kT}x\right] + \frac{1}{4}\ln\frac{D}{D_1} + \frac{1}{2}k_1x \tag{16}$$

Here, k_1 was taken as fitting with the experimental values. Figures 10 and 11 show the comparison between the theoretical and the experimental values. It is seen that the agreement between the experimental

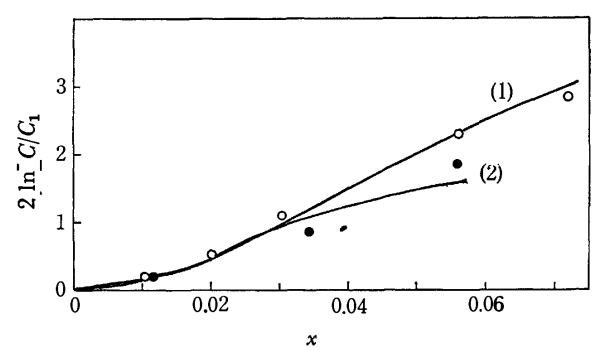

Fig. 10. Comparison of $2\ln(C/C_1)$ values with the calculated values.
(1) Sodium tetradecyl sulfate—dioxane, $k_1=52.3$, (2): DACl—acetone, $k_1=54$. The solid lines are the calculated values.

and theoretical curves is rather good in spite of some approximations.

The author wishes to thank Professor Ryohei Matuura of Kyushu University and Assistant Professor Moire Nishida of Kanazawa University for their helpful discussions and advice.

A Study of the Inosine–Hydrochloric Acid–Water and Inosine–Sulfuric Acid–Water Systems

Yoshihisa SUZUKI and Tadao TOKI

Central Research Laboratories, Ajinomoto Co., Inc., Suzuki-cho, Kawasaki 210

(Received April 1, 1974)

Solubility data have been obtained for the inosine-HCl-H_2O and inosine-H_2SO_4-H_2O systems at 5 °C. The acid hydrolysis of inosine was satisfactorily prevented under the present conditions. Three new acid salts of inosine have been obtained: (1) $C_{10}H_{12}N_4O_5 \cdot HCl \cdot (1/2)H_2O$ in the A-form, (2) $C_{10}H_{12}N_4O_5 \cdot HCl \cdot (1/2)H_2O$ in the B-form, and (3) $C_{10}H_{12}N_4O_5 \cdot H_2SO_4 \cdot 2H_2O$. Their X-ray powder diffraction data are given. All of them are incongruent and decomposed by pure water; however, they are stable in air during storage at room temperature.

In order to contribute to the process design of the separation or purification of inosine, its solubility in several mineral acid solutions was studied. Inosine is known to be susceptible to acid hydrolysis, giving hypoxanthine and D-ribose. However, the hydrolysis was practically negligible at 5 °C within certain periods. The equilibria for the inosine-HCl–H_2O and inosine–H_2SO_4-H_2O systems were satisfactorily determined. No data have been found in the literature concerning the subject of the present study.

Results and Discussion

Table 1 shows the composition data for the inosine–hydrochloric acid-water system at 5 °C. The equilibrium was achieved by the dissolution of the crystals to acid solutions. The mixture was usually shaken overnight at 5 °C. These conditions were generally sufficient to achieve the equilibrium. However, there was a fear of the hydrolysis of inosine in high concentrations of hydrochloric acid, so the shaking period for the equilibrium was shortened to 5 hr when the concentration of hydrochloric acid was higher than 16% (Runs No. 9—11). In spite of the above treatment, we could not completely prevent the hydrolysis in high concentrations of hydrochloric acid. The data obtained in these runs had some deviations (within 10%). On the other hand, there was no significant hydrolysis when the concentration of hydrochloric acid was less than about 10%.

The system shows the formation of two new solid phases which possess the same molecular formula, but different crystal structures. They are both inosine monohydrochloride hemihydrate. The one stable in lower concentrations of hydrochloric acid was named the A-form, and the other, stable in higher concentrations, the B-form. Their X-ray powder diffraction data are shown in Table 2.

a) The scale of the intensity (I/I_0) is so chosen as to make the most intense line have the value 100.

The crystals in the A-form appeared in the region where the concentration of hydrochloric acid is between about 4% (Runs No. 3—5 in Table 1) and about 17% (Runs No. 9—10 in Table 1), while the B-form appears above about 17%. Neither of these two salts could be crystallized from an equimolar solution of inosine and hydrochloric acid. They could be obtained from a solution containing a large excess of hydrochloric acid. Therefore, the salts were concluded to be incongruent and decomposed by pure water. An excess amount of the salts added to pure water could not remain in the salt-form in the residue, but changed into the inosine-dihydrate-form.

On the other hand, they were stable in air during storage for at least one month at room temperature when the mother liquor was completely removed from the crystal surface by washing with an organic solvent such as ethanol. When the removal of the mother liquor was insufficient, the crystals of the salts gradually became dark, probably because the acid in the mother liquor reacted with the ribose moiety of the inosine in the crystal. The solubility of inosine increased with an increase in the concentration of hydrochloric acid up to about 4%, and then gradually decreased with a further increase in the acid concentrations; it became constant beyond a 14% concentration of the acid. It is of interest that the solid phase changes from inosine dihydrate to inosine hydrochloride hemihydrate at a point where a sharp change in the solubility is observed, while inosine hydrochloride in the solid phase changes from the A-form to the B-form at a point where an almost constant solubility is observed.

b) Hx.: Hypoxanthine. c) See Table 1.

Table 3 shows the composition data for the inosine–sulfuric acid–water system at 5 °C. The hydrolysis of inosine in this system was much less than that in the hydrochloric acid system, so, practically, it could be disregarded. This system gave a new solid phase, the monosulfuric acid salt of inosine dihydrate. This acid salt of inosine could be obtained when the concentration of sulfuric acid was higher than 10% (Runs No. 4 in Table 3). These crystals had a plate-like appearance. Although they are incongruent and are decomposed by pure water, they are stable in air during storage for at least one month at room temperature, as in the case of the hydrochloric acid salt of inosine.

The solubility of inosine increased with an increase in the concentration of sulfuric acid until the concentration of sulfuric acid reached about 10%; it gradually decreased beyond that point.

It is interesting that both hydrochloric acid and sulfuric acid form salts with inosine, keeping an equivalent mole ratio in spite of the different valences of the acids.

Experimental

Materials. The inosine used was of a commercial A-grade of the Ajinomoto Co., Inc.; the other materials were of a reagent grade.

Analysis. The inosine was determined by means of the UV absorbance at 250 nm in 0.1 M HCl using the molar extinction coefficient of 11,800. The acids were determined by titration with standard NaOH, using a methyl red-bromocresol green indicator. The chlorine was determined by the Volhard method. The X-ray (Cu$K\alpha$) powder diffraction patterns were used for the identification of the solid phase in equilibrium. The degree of hydration of the crystals was determined by Karl Fischer titration. One-dimensional ascending paper chromatography (PC) was carried out on Toyo-Filterpaper No. 51A, the following solvent system being used: *n*-butanol-acetic acid-water (4 : 1 : 1). The hydrolysis of inosine into hypoxanthine was checked by PC (R_f, inosine, 0.25; hypoxanthine, 0.42), using UV-light.

Preparation of the Crystals. *Inosine Monohydrochloride Hemihydrate in the A-Form:* Inosine (6.0 g) was dissolved in aqueous 13% (w/w) HCl (50 ml), and the resultant solution was cooled in an ice-box for a week. The large prism crystals thus precipitated were filtered out and then dried in air. Yield, 2.1 g; mp 112 °C (colored)-130 °C (decomp. with darkening). One UV-absorbing spot was observed on PC (R_f, 0.25). Found: H_2O, 3.44; Cl, 11.1; Acid for HCl, 11.6%; $\varepsilon_{250\,nm}$ in 0.1 M HCl, 9,940. Calcd for $C_{10}H_{12}N_4O_5 \cdot HCl \cdot (1/2)H_2O$: H_2O, 2.87; Cl, 11.32; Acid for HCl, 11.65%; ε, 10090.

Inosine Monohydrochloride Hemihydrate in the B-Form: Inosine (8.6 g) was dissolved in aqueous 21% (w/w) HCl (50 ml), and the resultant solution was cooled in an ice-box overnight. The precipitated fine prism crystals were filtered out, washed with ethanol and ether, and then dried in air. Yield, 5.9 g; mp 122 °C (colored)-130 °C(decomp. with darkening). One UV-absorbing spot was observed on PC (R_f, 0.25). Found: H_2O, 2.44; Cl, 11.2; Acid for HCl, 11.7%; $\varepsilon_{250\,nm}$ in 0.1 M HCl, 9,940. Calcd for $C_{10}H_{12}N_4O_5 \cdot HCl \cdot (1/2)H_2O$: H_2O, 2.87; Cl, 11.32; Acid for HCl, 11.65%; ε, 10090.

Inosine Monosulfate Dihydrate: Inosine (6.2 g) was dissolved in aqueous 31% (w/w) H_2SO_4 (45 ml), and the resultant solution was cooled in an ice-box overnight. The precipitated plate crystals were filtered out and dried in air. Yield, 7 g; mp 108—112 °C. One UV-absorbing spot on PC was observed (R_f, 0.25). Found: H_2O, 7.47; Acid for H_2SO_4, 25.1%; $\varepsilon_{250\,nm}$ in 0.1 M HCl, 7,890. Calcd for $C_{10}H_{12}N_4O_5 \cdot H_2SO_4 \cdot 2H_2O$: H_2O, 8.96; Acid for H_2SO_4, 24.38%; ε, 7,870.

Solubility Measurement. A sufficient amount of the crystals, usually inosine was added to aqueous HCl (0—20%) or aqueous H_2SO_4 (1—20%) to make a slurry in tightly-capped glass bottles at 5 °C. Inosine hydrochloride in the A-form was used for Runs No. 3, 8 and 10 in Table 1, and the B-form, for Run No. 9. Inosine sulfate was used for Runs No. 5—8 in Table 2. The mixtures were shaken at 5 °C for 16 hr except for Runs No. 9—11 (for 5 hr) in Table 1. Then, the mixtures were quickly filtered with a glass filter. The clear solutions and the wet residues were sampled, diluted to appropriate volumes, and submitted to analysis. The residues were examined by means of the X-ray method.

The authors wish to thank Miss Yoshie Arai for her technical assistance.

The Thermal Reaction of Hydrogen and Nitric Oxide

Kohji TADASA,* Naomi IMAI, and Tetsuo INABA

Faculty of Liberal Arts and Sciences, University of Osaka Prefecture, Sakai, Osaka 591

(Received May 1, 1974)

The kinetics of the H_2–NO pyrolysis was studied at 400 °C; the reaction was found to be first-order in H_2 and to be independent of NO. It is suggested that the reaction proceeds by means of a free-radical chain mechanism: $H_2+NO(surface)\rightarrow HNO+H(1)$, $H+NO\rightleftharpoons HNO$ (2), $2HNO\rightarrow 2OH+N_2$ (3), $OH+H_2\rightarrow H_2O+H(4)$ and $2HNO\rightarrow H_2O+N_2O(5)$. This reaction scheme resembles that proposed for the CH_2O–NO pyrolysis at 500 °C except for the initiating step (1), which takes place on the wall of the vessel in the H_2–NO pyrolysis.

In this laboratory, the effect of nitric oxide on formaldehyde pyrolysis has been studied at 500°C.[1] As the H atom, in the chain decomposition of formaldehyde, is a chain carrier, it is desirable to know the reaction of a system containing H and NO in order to elucidate the above reaction. In order to follow the H_2–NO reaction, the H–NO reaction has been investigated by several workers; Hinshelwood and Mitchell in the range of 700°—805 °C,[2] Graven at 850°—1060 °C,[3] Kaufman and Decker at 900°—1152 °C,[4] and recently Wilde at 800°—1060 °C.[5] Wilde presented the following scheme:

$$H_2 + NO \rightleftharpoons HNO + H$$
$$HNO + NO \longrightarrow N_2O + OH$$
$$OH + H_2 \longrightarrow H_2O + H$$
$$H + NO + M \rightleftharpoons HNO + M$$
$$(2HNO \longrightarrow N_2O + H_2O)$$

No work, however, has been reported on the H_2–NO reaction below 500 °C. In this work, the kinetics of the H_2–NO pyrolysis has been studied mainly at 400 °C, and a reaction scheme has been derived.

Experimental

Materials. The nitric oxide and hydrogen used were obtained from the Takachiho Kagaku Co., Ltd., in research-grade purities of 99.6% and 99.95% respectively. They were used without further purification.

Apparatus. The apparatus used in the present work was similar to that described previously.[1] Two cylindrical vessels were used: an unpacked quartz one of 262 cm^3, with a S/V ratio of 0.83 cm^{-1}, and a packed Pyrex one of 124 cm^3, with a S/V ratio of 11.3 cm^{-1}.

Procedure. The required quantities of hydrogen and nitric oxide were introduced into the vessel, which had been kept at the experimental temperature. The products of decomposition were then separated and collected by means of cold traps and a Toepler gauge, and analysed quantitatively by means of a gas chromatograph.

Water, one of the product, was converted to hydrogen by treating it with the sodium evaporated onto the surface of a glass trap as a thin layer; then its amount was determined, though the measurement was not very accurate. Except for the case of water, the analytical technique used was similar to that described previously.[1]

Results

The products detected in the thermal reaction of the H_2–NO system are nitrogen, nitrous oxide, and water. Figure 1 shows the temperature dependence of each product after a pyrolysis of two hours at temperatures ranging from 20° to 500 °C.

Figures 2 and 3 show the effects of the nitric oxide and hydrogen pressures respectively on each product formation in the thermal reaction at 400 °C. Figures 4 and 5 show the dependences of the nitrogen and nitrous oxide formations in the packed vessel at 400 °C on the nitric oxide and hydrogen pressures respectively. Figures 2—5 demonstrate that the formation of nitrogen is first-order in relation to hydrogen and zero-order in relation to nitric oxide in both the unpacked and packed vessels, while that of nitrous oxide obeys a

different rate low in each vessel. (The amount of water was not determined in the packed vessel.)

Discussion

As is indicated in Fig. 1, the H_2–NO reaction begins to occur at about 300 °C and is accelerated as the temperature increases within the range employed. The facts that the H_2–NO reaction begins to occur at a relatively low temperature and that the main reactions, by which water and nitrogen are formed, are not dependent on the nitric oxide pressure (Fig. 2) predict that an initiation reaction is the surface reaction. This suggestion is confirmed by the results in the packed vessel (Figs. 4 and 5), *i.e.*, the rate of the formation of nitrogen, one of the main products, is increased by the increase in the S/V ratio compared with that in the unpacked vessel (Figs. 2 and 3), even though the rate law is not changed.

In the present laboratory, the pyrolysis of formaldehyde with nitric oxide has been studied at 500 °C; we obtained this stoichiometric relation:[1)]

$$CH_2O + NO \longrightarrow CO + H_2O + (1/2)N_2$$

though it is very rough. In the present work, a similar rough stoichiometry seems to hold:

$$H_2 + NO \longrightarrow H_2O + (1/2)N_2$$

On the other hand, different rate laws are observed in each pyrolysis: *i.e.*, in the CH_2O pyrolysis, it is:

$$-d[CH_2O]/dt = k[CH_2O][NO]$$

while in the H_2 pyrolysis it is:

$$-d[H_2]/dt = k[H_2]$$

with a sufficient amount of NO being present in each case.

The facts hitherto presented suggest a chain mechanism of the H_2–NO pyrolysis, which consists of a different initiating step and of consequent steps analogous to those proposed in the CH_2O–NO pyrolysis:[1)]

$$H_2 + NO(\text{surface}) \longrightarrow HNO + H \quad (1)$$

$$H + NO + M \rightleftharpoons HNO + M \quad (2)$$

$$2HNO \longrightarrow 2OH + N_2 \quad (3)$$

$$OH + H_2 \longrightarrow H_2O + H \quad (4)$$

$$2HNO \longrightarrow H_2O + N_2O \quad (5)$$

In this scheme, Reaction (1) is the chain-initiating step, (2), (3), and (4) are the chain-carrying steps, and (5) the chain-ending step. Reaction (1) is proposed because of the surface effect on this reaction and the independency of the rate in relation to the NO pressure. Reaction (3) has been proposed in the study of the CH_2O–NO pyrolysis[1)] and suggested to be faster than (5) at 500 °C.

Making the usual steady-state assumption of transient species (H, OH, and HNO), the above reaction scheme yields the following rate equation:

$$R_{N_2} = R_3 = (k_3/k_5)R_5 = (k_3/k_5)R_1$$

where R refers to the rate of the reaction shown by a suffix or that of the formation of the product shown by a suffix. If Reaction (1) is first-order in relation to H_2 and zero-order in relation to NO,

$$R_{N_2} = (k_1k_3/k_5)[H_2]$$

The value of k_1 should depend on the amount of the surface area. A similar treatment of the reaction scheme also yields this rate equation:

$$R_{H_2O} = R_4 + R_5 = 2R_3 + R_5$$

If the reaction chain is sufficiently long, R_5 may be neglected compared with R_3. Then

$$R_{H_2O} \simeq 2R_3 = 2R_{N_2}$$

These rate equations satisfy both the kinetics and the

stoichiometry described above. The possibilities of the occurences of the other reactions were examined in a manner described in a previous work and so are omitted here; *cf* Table 1 in Ref. 1.

The above scheme also leads to this equation:

$$R_{N_2O} = k_1[H_2]$$

which is consistent with the results obtained in the unpacked vessel (Figs. 2 and 3). In the packed vessel, however, the rate of the N_2O formation does not follow this equation (Figs. 4 and 5). As another source of nitrous oxide, Reaction (6) may be presumed:

$$HNO + NO \longrightarrow N_2O + OH \quad (6)$$

This reaction has been proposed in the temperature range of 800°—1060 °C[3] and has presumed to take place simultaneously with (5) in the CH_2O–NO pyrolysis at 500 °C.[1]

The rate of the N_2O formation due to (6) may be expressed as:

$$R_{N_2O(6)} = (k_1^{1/2}k_6/k_5^{1/2})[H_2]^{1/2}[NO]$$

This equation appears to agree with the results in the packed vessel (Figs. 4 and 5). Reaction (6) should have a heterogeneous nature at 400 °C, since N_2O seems to be formed predominantly by Reaction (6) in the packed vessel and by Reaction (4) in the unpacked vessel.

The occurrence of (6), in addition to (1)—(5), does not affect the rate equations of the N_2 and H_2O formations.

Reactions (7)[6] and (8)[7] have been proposed between nitroxyl and nitric oxide at lower temperatures:

$$HNO + 2NO \longrightarrow N_2 + H + NO_3 \quad (7)$$

$$HNO + 2NO \longrightarrow HNO_3 + N_2 \quad (8)$$

Reaction (7), followed by (2), causes the chain disproportionation of nitric oxide, which may be represented stoichiometrically as:

$$3NO \longrightarrow N_2 + NO_3$$

(Reaction (7) does not affect the rate of the formation of another product.) Reaction (7) has also been suggested, in the studies of CH_2O–NO photolysis[8] and H_2–NO photosensitization reaction[9] carried out in this laboratory, as taking place in the system containing hydrogen atoms and nitric oxide at lower temperatures. At 500 °C, however, the disproportionation of nitric oxide was indicated not to occur by the study of the CH_2O–NO pyrolysis.[1]

The rate of N_2 formation due to (7) may be represented as:

$$R_{N_2(7)} = (k_1^{1/2}k_7/k_5^{1/2})[NO]^2[H_2]^{1/2}$$

Reaction (7) does not seem to be as important as (3) as the N_2 source in the present conditions because of the disaccordance between the above rate equation and the rate law of N_2 formation observed, and also because of the failure to detect any NO_3 in the products.

Reaction (8) is also omitted, since (8) terminates the reaction chain; thus, the occurrence of this reaction alters the rate law of the main reaction. This has already been examined in a manner described previously.

The Singlet-Triplet Absorption Spectra of Heterocyclic Amine *N*-Oxides. II. Pyridine *N*-Oxide Derivatives

Masumi YAMAKAWA, Kiyoshi EZUMI, Yoshiko MIZUNO, and Tanekazu KUBOTA

Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka 553

(Received July 4, 1974)

The singlet-triplet absorption spectra of various pyridine *N*-oxide derivatives with an electron-donating substituent have been observed by applying the oxygen-intensification technique. The nature of the lowest triplet (T_1) states of these *N*-oxides and the substituent effect on the T_1 state of pyridine *N*-oxide have been discussed experimentally and theoretically. The T_1 states of the above substituted pyridine *N*-oxides were assigned to a π-π^* transition of a ^3L_a (CT) nature; $^3A_1$ for the *p*-substituted pyridine *N*-oxides. All the singlet-triplet absorption bands as well as the singlet π-π^* bands recorded here show a blue shift in polar solvents; this phenomenon is also discussed. Last, the mutual relation between the contact charge-transfer bands and the singlet-triplet absorption bands, both enhanced by compressed oxygen, has been discussed, since, for pyridine *N*-oxides with *p*-$N(CH_3)_2$, *p*-OCH_3, and *m*-NH_2, we could not record the singlet-triplet absorption band clearly.

In our foregoing papers[1,2] we discussed the characteristics of the lowest triplet state (T_1) of such basic heterocyclic amine *N*-oxides as pyridine *N*-oxide and quinoline *N*-oxide, and of nitro-substituted pyridine and quinoline *N*-oxides. The former was obtained by measuring the singlet-triplet (T_1←S) absorption spectra using the technique of high-pressure oxygen perturbation, and the latter, by recording the phosphorescence spectra as well as the T_1←S absorption spectra. As one of the most remarkable conclusions obtained from those studies, the T_1 state of pyridine *N*-oxide (PNO) and 4-nitropyridine *N*-oxide (4NPO) was identified as $^3A_1$ (π-π^*), which corresponds to the $^1A_1$ strong absorption band appearing in a longer-wavelength region;[1,2] this information is valuable for interpreting the primary process of the photochemical reaction of these compounds.[3] As an extension of these investigations, we would like to report, in this paper, on the T_1←S absorption spectra and the contact charge-transfer (CCT) spectra of PNO derivatives with an electron-donating substituent, these spectra being obtained under compressed-oxygen perturbation. The substituent effect on the T_1←S band of PNO as well as the solvent effect on it has also been discussed on the basis of the experimental results and also by applying the PPP SCF–MO–CI calculation.

Experimental

The high-pressure absorption cell employed for recording the T_1←S absorption spectrum under compressed-oxygen perturbation is the same as was described in our previous paper.[1]

The samples used in this paper are listed in Table 1. These, except for 3-aminopyridine *N*-oxide (3APNO), were synthesized and carefully purified by methods previously reported.[4] The 3APNO free base has been obtained by neutralizing its HCl salt with Na_2CO_3 in CH_3OH, and purified by repeated sublimations:[5] mp 124.5—125.0 °C. The above 3APNO HCl salt was crystallized from a reflux solution of a 3M HCl aqueous solution of 3-acethylaminopyridine *N*-oxide, which had been synthesized by the oxidation of the corresponding pyridine base with *m*-chloroperbenzoic acid.[5,6] The solvent used were CH_2Cl_2, CH_3CN, and CH_3OH, all of which were spectrograde in purity; they were dried sufficiently with a Mg ribbon (for CH_3OH alone) or $CaCl_2$, and then rectified carefully.

Results and Discussion

T_1←S Absorption Spectra of PNO Derivatives. The effects of the compressed-oxygen perturbation on the electronic spectra of PNO derivatives with an electron-donating substituent may be experimentally classified

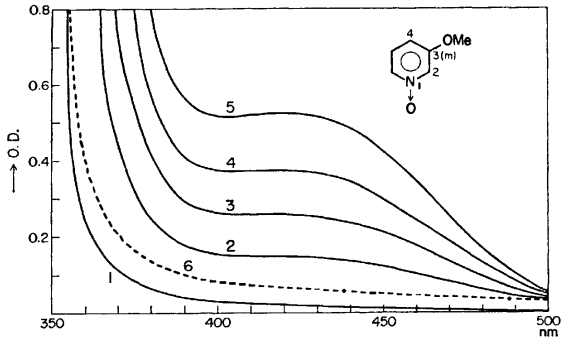

Fig. 1. Singlet-triplet absorption spectra of *m*-methoxy pyridine *N*-oxide (0.925 mol/l in CH_3CN) caused by applied oxygen pressure. The oxygen pressure is 0, 30, 60, 92, and 140 kg/cm² for curves 1, 2, 3, 4, and 5, respectively. Curve 6 is for the spectrum after removal of the oxygen.

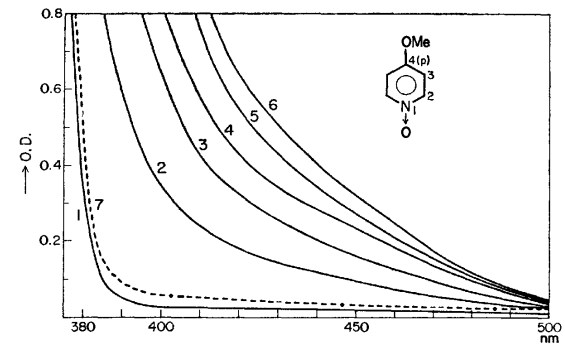

Fig. 2. The spectral change of *p*-methoxy pyridine *N*-oxide (0.290 mol/l in CH_3CN) in visible region with the applied oxygen pressure, which is 0, 37, 65, 93, 120, and 140 kg/cm² for the curves 1, 2, 3, 4, 5, and 6, respectively. Curve 7 is for the spectrum after removal of the oxygen.

Table 1. Observed and calculated transition energies to the lowest triplet state (T_1), observed ^1L_a energy, and observed ^1L_a-T_1 energy separation (in kK unit) for substituted pyridine *N*-oxides

Substituent	T_1←S band			^1L_a band	^1L_a-T_1	T_1 (calcd)	ΔT_1 [b]	T_1* [c]	T_1** [d]

into two groups. In the first group, the T_1←S absorption band appears clearly in a visible region. The substituents belonging to this group are *m*- and *p*-CH_3, *m*- and *p*-Cl, and *m*-OCH_3; all are in a relatively weak interaction between the substituent and the N→O group. A typical example is given in Fig. 1 for *m*-methoxy-PNO. The substituents belonging to the other group are *p*-$N(CH_3)_2$, *m*-NH_2, and *p*-OCH_3; in this group, the T_1←S absorption band is not clearly observed, as Fig. 2 shows for the case of *p*-methoxy-PNO. In this case, however, the oxygen-sensitive end absorption appears in a visible region with quite a strong intensity; the nature of this band will be discussed below. The observed values of the T_1←S absorption spectra are listed in Table 1, along with the other relevant spectroscopic and theoretical data.

The characteristics of the ^1L_a band given in Table 1 have already been discussed in detail;[7] it has the nature of an intramolecular CT band from the *N*-oxide-group oxygen atom to the conjugated residue. In the first paper[1] in this series, we also identified the lowest triplet state (T_1) of PNO as ^3L_a (*i.e.*, $^3A_1$) on the basis of a detailed discussion of the T_1 state of basic heterocyclic amine *N*-oxides. Thus, only the substituent effect on the T_1 state of PNO will be discussed here. Checking the data in Table 1, we can see that the T_1←S band and the ^1L_a band both shift parallel with the electron-donating substituent introduced into PNO. A *p*-substituent with a strong electron-donating ability may be especially effective for the red shift of the T_1←S band, as may be inferred from the values of T_1*, T_1**, and the ^1L_a band listed in Table 1. In Fig. 3 the above relation is illustrated using the observed values, where a linear relation holds qualitatively between the ^1L_a and the T_1←S bands. Conversely, this experimental fact seems to support the idea that the T_1 state of these compounds is of a ^3L_a π-π^* nature.[1,8] Next, let us examine the value of the singlet-triplet separation—in the present case, the ^1L_a—T_1 separation. This value is larger than 12000 cm^{-1} throughout all the compounds, as Table 1 shows. This also supports the idea that the T_1 state is of a π-π^* nature.[9] Moreover, the above ^1L_a—T_1 separation value is in the 12.5—13 kK (1 kK=1000 cm^{-1}) range and is almost constant—*i.e.*, 12.63 kK on the average. The T_1-state energy of the compounds used here may then be calculated from Equation 1:

$$T_1^* = {}^1L_a\,(\text{obsd}) - 12.63 \qquad (1)$$

The values thus obtained are indicated by T_1* and are included in Table 1, in which the T_1* values for the PNO derivatives with *p*-OCH_3, *p*-$N(CH_3)_2$, and *m*-NH_2 substituents are also shown, although attempts to measure these were unsuccessful. The agreement between T_1 (obsd) and T_1* is quite good.

The characters of the T_1 states experimentally discussed hitherto were also supported by the PPP-type SCF-MO-CI calculation, the method of which was the same as was employed for the singlet- and triplet-energy calculation of PNO, *etc.*;[1] *i.e.*, the two-electron repulsion integral, $\gamma_{\mu\nu}$, is estimated by means of the Beveridge and Hinze equation.[10] The parameterization for the atoms pertinent to the pyridine *N*-oxide part

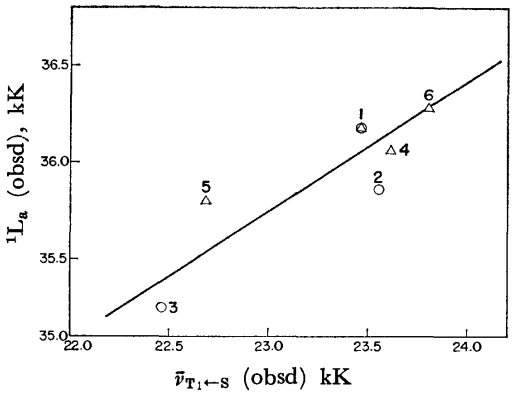

Fig. 3. Mutual correlation between the observed T_1←S absorption band and the observed ^1L_a band for substituted pyridine *N*-oxides. The substituent is *p*-CH_3, *p*-Cl, *m*-CH_3, *m*-Cl, and *m*-OCH_3 for the number 2 to 6, respectively. The number 1 is for pyridine *N*-oxide itself.

is the same as that given in a previous paper.[1] For substituents, the valence-state ionization potential (I_p) and the electron affinity (E_A) were determined by referring to the papers by Zahradnik *et al.*[11] The values of β_{XY}^{core} pertaining to the substituents were also estimated according to Zahradnik *et al.*[11] The values (eV) of I_p and E_A for the substituents are in this order: 25.07 and 13.80 for Cl; 32.90 and 10.00 for -Ö-; 27.30 and 9.30 for -N̈H$_2$; and 25.46 and 8.11 for -N̈(CH$_3$)$_2$. For the CH$_3$ group of the type, >-CH$_3$, the inductive model was adopted; *i.e.*, the I_p of the carbon atom bonded to the CH$_3$ group is reduced by 1 eV.[12] The $-\beta_{XY}^{core}$ (eV)[13] and the bond-length (Å) values pertaining to the substituents are in this order: 0.948 and 1.730 for >C–Cl; 1.000 and 1.356 for >C–Ö- and 1.896 and 1.431 for >C–N̈-. The calculation showed that the nature of the lowest T_1 state is always ^3L_a; $^3A_1$ for *p*-substituted PNO derivatives and that the T_1 energy level is quite a bit lower (12—8 kK for *p*-substituents and 13—5 kK for *m*-substituents) than that of the T_2-energy level. These facts support the discussions about the assignment of the T_1 state on the basis of the experimental results presented above. The calculated T_1 energies are listed in Table 1. The fact that the calculated values are always lower than the observed values is a well-known general tendency in the PPP semi-empirical calculation of T_1-state energy unless a special refinement is used in the estimation of the electron-repulsion terms.[14] However, note that the difference, ΔT_1, between the observed and the calculated T_1 energies is in the range of 7—8 kK, except for the *m*-OCH$_3$ derivative, and almost constant; average $\Delta T_1 = 7.65$ kK. Thus, the observed T_1 energies can also be expressed by Equation 2, the values of T_1** being listed in Table 1:

$$T_1^{**} = T_1(\text{calcd}) + 7.65 \qquad (2)$$

It is noticeable that the T_1** values are quite close to the T_1* values obtained from Equation 1. This may also support the assignment of the present T_1 states. The T_1 energy of the compounds with *p*-OCH$_3$, *p*-N(CH$_3$)$_2$, and *m*-NH$_2$ substituents, whose triplet energies were not obtained here experimentally (*vide infra*), seems to be between T_1* and T_1** values in magnitude (see Table 1).

Solvent effect on the T_1←S Absorption Spectra of PNO Derivatives. It was reported in the foregoing papers[1,2] that the blue-shift phenomenon on the T_1←S absorption band of PNO, *etc.* is observed in polar solvents, especially in protic solvents such as alcohols; this is just like the π-π^* singlet bands of those *N*-oxides behave in solvents.[7] The mechanism was then discussed in detail. We have now examined whether or not this kind of solvent effect is also observed in the T_1←S band of PNO derivatives. As a result, it can safely be said that all of the T_1←S bands recorded on PNO derivatives (see Table 1) show a blue shift due to the solvent change from CH_2Cl_2 to CH_3CN and CH_3OH; methanol particularly brings about a larger blue shift than acetonitrile. Of course, this is attributable to the hydrogen-bonding interaction of methanol with *N*-oxides, as has well been verified.[15,16] These phenomena indicate a smaller solute-solvent interaction at the T_1 excited state than in the ground state;[1] this can reasonably be explained by taking into account the intramolecular charge transfer from the oxygen atom of the *N*-oxide group, or from the substituent, to the conjugated ring residue. In turn, by comparing the magnitude of the above blue-shift ability between the T_1←S and ^1L_a←S (a strong singlet band appearing in the near-ultraviolet region) absorption bands, we have found that the former band shows almost the same magnitude as, or is a little smaller than, that of the latter.[17] However, taking account of the difference in the solute-solvent interaction potential curves among the ground, T_1, and ^1L_a states,[18] and also referring to the light-absorption mechanism according to the Franck-Condon principle,[18] the above fact may suggest that the ability of solute-solvent interaction, especially of hydrogen-bonding interaction, may be larger at the T_1 state than at the ^1L_a state, since the above-mentioned intramolecular charge-transfer effect would be smaller in the T_1 state than in the ^1L_a state.

Contact Charge-transfer Spectra with Oxygen. As has been described above, the compounds with the substituents of *p*-N(CH$_3$)$_2$, *p*-OCH$_3$, and *m*-NH$_2$, where quite a strong resonance of the substituent with the PNO ring is to be expected, do not exhibit a well-defined T_1←S absorption band, but the oxygen-sensitive end absorption appears in the visible region with quite a strong intensity. Keeping these facts in mind, it should also be remembered that many organic compounds bring about contact charge-transfer spectra in the visible-to-near-ultraviolet region by means of interaction with oxygen,[19] and that the smaller the ionization potential of the compounds is, the larger is the red shift of the contact charge-transfer spectra.[20] Our molecular orbital calculation described above led us to the conclusion that the highest MO energies of *p*-N-

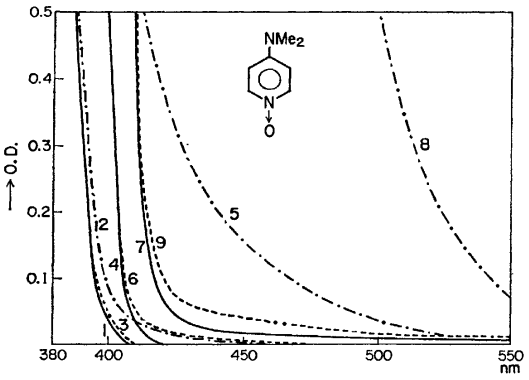

Fig. 4. The effect of oxygen pressure on the absorption spectra in a visible region of *p*-dimethylaminopyridine *N*-oxide at several concentrations in CH_3CN. The sample concentrations for curves 1, 2, and 3 are 6.61×10^{-4} mol/l; for 4, 5, and 6 7.81×10^{-3} mol/l; and for 7,8, and 9 saturated solution. The oxygen pressure is zero for curves 1, 4, and 7; 130 kg/cm^2 for 2, 5, and 8. Curves 3, 6, and 9 are for the spectra after removal of the oxygen.

$(CH_3)_2$, *p*-OCH_3, and *m*-NH_2 substituted PNO's are considerably higher, particularly for the *p*-$N(CH_3)_2$ substituent, than those of the others, so that there is a possibility that the CCT spectra of these compounds occur in quite a longer-wavelength region. In addition, this possibility may be much greater in our case, since those experiments have been done under a high oxygen pressure. For these reasons, the end absorption in the visible region of the CCT spectra observed for the above three substances may cover the $T_1 \leftarrow S$ absorption band enhanced by compressed-oxygen perturbation, so we could not record the $T_1 \leftarrow S$ absorption band clearly in these cases. To check the effect of the oxygen pressure on the visible-end absorption of *p*-dimethylamino-PNO, a typical example, dissolved (in several concentrations) in CH_3CN, the experiments illustrated in Fig. 4 were carried out. The change in the spectra upon introducing compressed oxygen gas or on removing it is reversible. However, a careful check of many experiments of this kind indicates that, although the end absorption is intensified strongly and monotonously with an increase in the oxygen pressure, no absorption maximum appears there (see Fig. 4). One may, then, conjecture that the band maxima of the CCT spectra may exist in a much shorter wavelength region than that shown in Fig. 4.

20) This kind of CCT spectra may be thought to take place by the charge transfer from the highest occupied molecular orbital of electron donors to thee lectron accepting orbitals (degenerated π and $\bar{\pi}$ orbitals) of oxygen (electron acceptor), and to borrow the intensity from strong π-π^* transition of the donor in CCT complexes.[19] In several amines *etc.* the CCT full spectra with maxima were observed by oxygen perturbation.[19]

Radiotracer Studies of the Adsorption of an Ampholytic Surfactant, *N*-dodecyl-β-alanine, at the Aqueous Surface

Takeo Okumura,* Akio Nakamura, Kazuo Tajima, and Tsunetaka Sasaki

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Tokyo 158

(Received July 19, 1974)

A tritiated ampholytic surfactant, *N*-dodecyl-β-alanine, $C_{10}H_{21}$-$(CHT)_2$-NH_2^+-$(CH_2)_2$-COO^-, was synthesized, and the amount of adsorption on an aqueous surface was measured directly by the radiotracer method. The adsorption isotherm near the neutral pH region showed a saturation value of 3.73×10^{-10} mol/cm^2 above the concentration of about 1/5 of the critical micelle concentration in the absence of added salt, and a value of 4.74×10^{-10} mol/cm^2 above the critical micelle concentration in the presence of 1 mol/l NaCl. In the presence of 1 mol/l NaCl, no effect of pH on the adsorption was found. The Gibbs adsorption isotherm applicable to the aqueous ampholytic surfactant was derived. The observed amounts of adsorption in the presence and absence of NaCl were in good agreement with the values calculated from the Gibbs adsorption isotherm, using the surface tension data measured by the Wilhelmy plate method.

Although the bulk properties of aqueous solutions of ampholytic surfactants have been studied by many investigators,[1-4] the studies of such surface properties of aqueous ampholytic surfactant solutions as surface tension and adsorption are rather rare.[3-4] Especially, no direct measurement of the adsorption of an ampholytic surfactant on an aqueous surface has yet been reported as far as the present authors are aware. Such a measurement of adsorption is important, however, from both theoretical and practical points of view, as in the cases of aqueous anionic and nonionic surfactant solutions previously reported.[5-6]

In the present study, a tritiated ampholytic surfactant, *N*-dodecyl-β-alanine(NDA), was synthesized in order to measure the amount of adsorption directly by the radiotracer method, and in order to confirm the applicability of the Gibbs adsorption isotherm derived for an aqueous ampholytic surfactant solution.

Experimental

Materials. Tritiated *N*-dodecyl-β-alanine(TNDA) was synthesized according to the following process, the details of which will be reported elsewhere.[7] Tritiated dodecanoic acid(I), obtained by tritiating dodecenoic acid, was allowed to react with urea for five hours at 170—180 °C to form dodecanoic acid amide(II). By the subsequent reduction of (II) using lithium aluminium hydride in ethyl ether, tritiated dodecylamine(III) was obtained. TNDA was obtained by the reaction of (III) with β-propiolactone in acetonitrile for an hour at 30 °C.[8] A crude product was purified by repeated recrystallizations from a mixture of acetone and ethyl alcohol (1 : 1), followed by drying in a vacuum. Thin-layer chromatography confirmed the absence of unreacted materials in the final product. The infrared spectra of the product, as well as the nonradioactive one used, confirmed the zwitterionic structure.[2] The specific activity of the sample was about 16 Ci/mol.

Sodium chloride was purified by fusing a comercial extra-pure-grade reagent for five hours in a platinum crucible to remove any surface-active contaminants. The water used for preparing the solutions was obtained by first refluxing ordinarily distilled water with acid permanganate, then distilling it from an alkaline permanganate solution, and finally distilling it twice using a Hysil flask. The hydrochloric acid used for controlling the pH of solutions in the acid region was purified by the distillation of a dilute extra-pure-grade reagent. The sodium hydroxide used for controlling the pH in the alkaline region was purified by the recrystallization of extra-pure-grade reagent from triple-distilled water.

Methods and Procedures. The method and apparatus for the measurements of the adsorption by the radiotracer method were similar to those described previously.[5] The total radioactivity over the surface, R_1, and the radioactivity from the bulk solution, R_2, of an aqueous TNDA solution which had attained an adsorption equilibrium were measured by means of a sheet scintillation counter at 30 °C. The radioactivity corresponding to the adsorbed molecules, R_1-R_2, was calculated and multiplied by a conversion factor to obtain the amount of adsorption.[5,6] To eliminate the effects of atmospheric carbon dioxide and the evaporation of the solution, the measurements were made in a humidified nitrogen atmosphere.

The surface tension was measured by the Wilhelmy plate method.[9] To obtain the equilibrium values, the time dependence of the surface tension was self-recorded, and extrapolated to infinite time.[10] The drop weight method was also used for the sake of comparison.

Results and Discussion

Adsorption of NDA. Figure 1 shows the time dependence of the total radioactivity over the surface of TNDA solutions of various concentrations. The time required for attaining a steady value was about 60 minutes for the solutions studied; this is longer than the time observed for the adsorption of sodium dodecylsulfate(SDS),[5] probably because of the adsorption from a relatively dilute solution in the case of NDA as compared with that of SDS. The steady count rate obtained from Fig. 1 was taken as the equilibrium value, R_1, which is plotted against the NDA concentration in Fig. 2. The concentration dependence of the radioactivity due to the bulk of a solution, R_2, was estimated as a straight line passing through the point of origin with the same inclination as that of the linear part of the R_1 *vs.* concentration curve in Fig. 2, as has been confirmed in the case of the direct measurement of R_2.[5,6] The amount of adsorption, Γ^A, at an aqueous surface is obtained as:

$$\Gamma^A = k(R_1-R_2)$$

where k is the conversion factor. Figure 3 shows the relation between the surface concentration of TNDA spread on the surface of a saturated ammonium nitrate solution and the radioactivity due to the spread film. The k value was calculated from the slope as 4.55×10^{-14} mol/cm²/cpm.

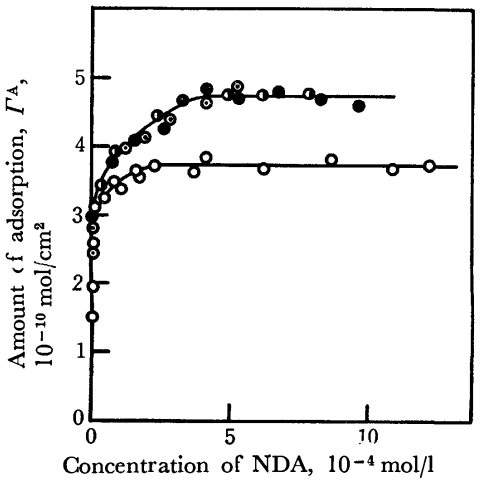

Fig. 4. Adsorption of NDA at aqueous surface.
Addition of ○: 0 mol/l NaCl, near neutral pH, ●: 1 mol/l NaCl, near neutral pH ⊙: 1 mol/l NaCl, pH 2.0 ◑: 1 mol/l NaCl, pH 12.0

The amounts of adsorption, Γ^A, with and without added salt plotted against the concentration of NDA near a neutral pH are shown in Fig. 4. The amounts of adsorption increase with the concentration and attain saturated value of 3.73×10^{-10} mol/cm² above a concentration of about 2×10^{-4} mol/l in the absence of added salt, and value of 4.74×10^{-10} mol/cm² above a concentration of about 4×10^{-4} mol/l in the presence of 1 mol/l NaCl.

The effect of the pH on the adsorption was studied further, since an ampholytic surfactant was expected to be sensitive to changes in the pH. However, the adsorption isotherm for the NDA systems of pH 2 and 12 in the presence of 1 mol/l NaCl showed no detectable change in the amount of adsorption, as is shown in Fig. 4. This may be explained as being due to the contraction of the ionic atmosphere around the polar head caused by the addition of concentrated NaCl, which makes NDA less ionic in nature.

In Table 1, the saturated amount of adsorption of NDA near the neutral pH obtained in the present study is compared with that of sodium dodecylsulfate(SDS),[5] an anionic surfactant, or hexaoxyethylenedodecylmonoether($D(EO)_6$),[6] a nonionic surfactant, with equal lengths of the hydrocarbon chain. The amount is larger for NDA than for the other two substances, perhaps because of the neutralization of the charges of the NDA polar head groups by intra- and/or inter-

Table 1. Saturated amount of adsorption near neutral pH

Surfactants	Amount of adsorption (10^{-10} mol/cm²)
NDA	3.73 (30 °C)
SDS	3.19 (25 °C)[5]
$D(EO)_6$	2.73 (30 °C)[6]

(2) absence of added salt (Wilhelmy plate method)
(3) absence of added salt (drop weight method)

molecular salt formation in the isoelectric region.

Surface Tension. Figure 5 shows the curves of the surface tension *vs.* the concentration of NDA with and without 1 mol/l NaCl. It may be seen in Fig. 5 that, in the absence of added salt, the slope is constant in the region of NDA concentrations from about 2×10^{-4} mol/l to the CMC, while in the presence of added salt the slope gradually increases up to the CMC. The data obtained by the drop weight method in the former case are also plotted in Fig. 5 as filled circles. It may be seen that the values obtained by the drop weight method are higher than those obtained by the Wilhelmy method; the former values cannot be used for further calculation, as will be discussed later.

The Gibbs Adsorption Isotherm. The Gibbs adsorption isotherm is written, in a general form, as[11]

$$-\mathrm{d}\gamma/RT = \sum_i \Gamma_i \,\mathrm{d}\ln a_i \qquad (1)$$

where γ denotes the surface tension, and Γ_i and a_i, the surface excess and the activity of the i'th solute respectively.

1. *The Case of the Absence of Added Salt*: Equation (1) may be rewritten for an ampholytic surfactant solution as:

$$-\mathrm{d}\gamma/RT = \Gamma_{A^\pm}\,\mathrm{d}\ln C_{A^\pm} + \Gamma_{A^+}\,\mathrm{d}\ln C_{A^+} + \Gamma_{A^-}\,\mathrm{d}\ln C_{A^-} + \Gamma_{H^+}\,\mathrm{d}\ln C_{H^+} + \Gamma_{OH^-}\,\mathrm{d}\ln C_{OH^-} \qquad (2)$$

where the subscripts $A^\pm$, A^+, A^-, H^+ and OH^- refer to the zwitterion, the cation, the anion of the ampholyte NDA, the hydrogen ion, and the hydroxide ion respectively. Since the concentration of the surfactant used is of the order of magnitude of 10^{-4} mol/l, the acitivity terms in Eq. (2) may safely be replaced by the concentration.

Further, we obtain the following relations:

$$K_1 = C_{A^\pm}C_{H^+}/C_{A^+} \qquad (3)$$

$$K_2 = C_{A^-}C_{H^+}/C_{A^\pm} \qquad (4)$$

$$K_w = C_{H^+}C_{OH^-} \qquad (5)$$

$$\Gamma_{A^+} + \Gamma_{H^+} = \Gamma_{A^-} + \Gamma_{OH^-} \qquad (6)$$

where K_1 and K_2 express the first and second dissociation constants of NDA, considered as a dibasic acid, and K_w, the dissociation constant of the water. Equation (6) represents the electrical neutrality of the adsorbed ionic species. By substituting the logarithmic forms of Eqs. (3) and (4) into Eq. (2), we obtain:

$$-\mathrm{d}\gamma/RT = (\Gamma_{A^\pm}+\Gamma_{A^+}+\Gamma_{A^-})\,\mathrm{d}\ln C_{A^\pm} + (\Gamma_{A^+}-\Gamma_{A^-}+\Gamma_{H^+})\,\mathrm{d}\ln C_{H^+} + \Gamma_{OH^-}\,\mathrm{d}\ln C_{OH^-} \qquad (7)$$

Here, we used these notations:

$$\Gamma^A = \Gamma_{A^\pm} + \Gamma_{A^+} + \Gamma_{A^-} \qquad (8)$$

as the total adsorption amount of NDA, and

$$C^A = C_{A^\pm} + C_{A^+} + C_{A^-} \qquad (9)$$

as the total bulk concentration of NDA. By substituting Eqs. (5), (6) and (8) into Eq. (7) we obtain:

$$-\mathrm{d}\gamma/RT = \Gamma^A\,\mathrm{d}\ln C_{A^\pm} \qquad (10)$$

Further, from Eqs. (3), (4) and (9) we obtain this relation:

$$\mathrm{d}\ln C_{A^\pm} = \mathrm{d}\ln C^A + [(C_{A^-}-C_{A^+})/C^A]\,\mathrm{d}\ln C_{H^+}$$

which, together with Eq. (10), gives:

$$-\mathrm{d}\gamma/RT\,\mathrm{d}\ln C^A = \Gamma^A[1+K(\mathrm{d}\ln C_{H^+}/\mathrm{d}\ln C^A)] \qquad (11)$$

where:

$$K = (C_{A^-}-C_{A^+})/C^A$$

On the other hand, using Eqs. (3), (4), and (9), we obtain:

$$K = (K_1K_2-C_{H^+}^2)/(C_{H^+}^2+K_1C_{H^+}+K_1K_2) \qquad (12)$$

In the pH region near the isoelectric point, the second term in the brackets of Eq. (11) is calculated using these experimental data: $K_1=3.1\times10^{-4}$, $K_2=1.3\times10^{-10}$ mol/l, $C_{H^+}=10^{-6}$ mol/l and $(\mathrm{d}\ln C_{H^+}\ \mathrm{d}\ln C^A)<0.1$ for the present experimental conditions of $C^A=10^{-4}$ to 10^{-3} mol/l. The order of magnitude is about 10^{-4}, which is negligible compared with unity. Thus, Eq. (11) can eventually be reduced for the NDA solution to a simple form,

$$\Gamma^A = -\mathrm{d}\gamma/RT\,\mathrm{d}\ln C^A \qquad (13)$$

2. *The Case of the Presence of Excess Added Salt*: In the presence of excess NaCl (1 mol/l in the present study) Eq. (1) still holds, since $\mathrm{d}\ln C_{Na^+}=0$, and $\mathrm{d}\ln C_{Cl^-}=0$. Therefore, the calculations are the same as in the case of Eqs. (1) to (5). The electrical neutrality of the adsorbed ionic species is expressed, instead of Eq. (6), as:

$$\Gamma_{Na^+} + \Gamma_{A^+} + \Gamma_{H^+} = \Gamma_{Cl^-} + \Gamma_{A^-} + \Gamma_{OH^-}$$

Therefore, the equation corresponding to Eq. (10) may be written as:

$$-\mathrm{d}\gamma/RT = \Gamma^A\,\mathrm{d}\ln C_{A^\pm} + (\Gamma_{Cl^-}-\Gamma_{Na^+})\,\mathrm{d}\ln C_{H^+}$$

and Equation:

$$-\mathrm{d}\gamma/RT\,\mathrm{d}\ln C^A = \Gamma^A + (K\Gamma^A+\Gamma_{Cl^-}-\Gamma_{Na^+}) \times (\mathrm{d}\ln C_{H^+}/\mathrm{d}\ln C^A) \qquad (14)$$

is obtained instead of Eq. (11).

It should be noted that Eq. (14) holds also for the system in the presence of HCl or NaOH so long as NaCl is present in a larger amount than the other solute. Therefore, if the pH is also kept, or happens to be constant, the second term of Eq. (14) may drop and a

simple equation may result:

$$\Gamma^{A} = -(d\gamma/RT\, d\ln C^{A})_{pH,\ excess\ NaCl} \quad (15)$$

The condition of Eq. (15) was actually satisfied for the ampholyte NDA containing excess NaCl without added acid or alkali.

Calculation of the Adsorption Amount by Means of the Gibbs Adsorption Isotherm. The amount of adsorption, calculated from the data of Fig. 5 by applying Eqs. (13) and (15), is shown by Curves A, B and C in Fig. 6. The figure also contains, for the sake of comparison, the results by Durham[4] by the use of the drop weight method (Curve D). It may be seen that the values obtained by the radiotracer method for the systems both with and without added salt are in good agreement with those calculated from the data obtained by the Wilhelmy plate method (A and C). The values calculated from the data obtained by the drop weight method (B and D) are, however, distinctly higher than the observed ones. The disagreement of the values obtained by the drop-weight method may be ascribed to the application of the Gibbs adsorption isotherm to the nonequilibrium surface tension data.

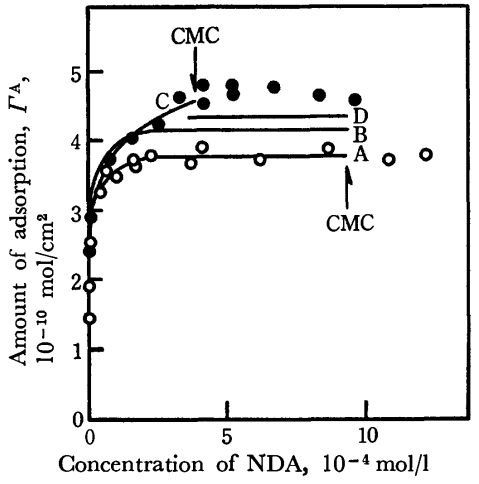

Fig. 6. Observed and calculated values.
Observed values: ○; in the absence of added salt
●; in the presence of 1 mol/l NaCl
Calculated values: in the absence of NaCl; (A) Wilhelmy plate method, (B), (D)[4] drop weight method, in the presence of 1 mol/l NaCl; (C) Wilhelmy plate method.

Thus, the agreement between the calculated and observed values indicates the validity of the Gibbs adsorption isotherm derived in the present study. It is confirmed experimentally that, for aqueous ampholytic surfactant solutions in an isoelectric region, where $K_1K_2 \fallingdotseq C_{H^+}^2$ and where, therefore, $K \fallingdotseq 0$, the Gibbs adsorption isotherm is applicable in a form similar to that used for a nonionic surfactant.[6] This can be also explained by the quasi-nonionic nature of the ampholytic surfactant NDA due to the intra- and/or intermolecular neutralization of the charges of polar heads in the solution of its isoelectric region, as has been pointed out with regard to the dependence of the critical micelle concentration on the temperature and added salt,[2] and with regard to a relatively large amount of the saturated adsorption of NDA mentioned above.

The Adsorption of the Aminoethyl Derivatives of Poly(vinyl alcohol) onto Bemberg Rayon Fibers[1)]

Mitsuo HIGUCHI, Takatoshi KOYAKUMARU,* and Ryoichi SENJU

Department of Forest Products, Faculty of Agriculture, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received July 24, 1974)

A series of aminoethyl derivatives of poly(vinyl alcohol) was synthesized, and their adsorption behavior onto a cellulosic fiber was investigated. The results indicate that the primary factor causing adsorption is the charge interaction at the solid-liquid interface; the adsorption was suppressed as the concentration of a foreign salt (NaCl) exceeded 0.02 M, and polymers bearing no cationic group poly(vinyl alcohol) and its aminoethyl derivatives in the un-ionized state) exhibited no appreciable adsorption. The results also demonstrate that the primary variable controlling the amount of adsorption is the charge density on the polymer; the amount of adsorption increases steeply with an increase in the charge density up to a maximum, and then decreases with the increase in the charge density.

Although numerous papers have been published and a considerable amount of information has been accumulated on the adsorption of macromolecules from solution onto solid surfaces, those concerned with polyelectrolytes are comparatively few and insufficient;[2)] therefore, it seems desirable to accumulate additional experimental data. This paper will present our findings on the adsorption of a polyamine of a hydrophilic nature from aqueous solutions onto a solid of a hydrophilic nature. Incidentally, though more than 50 kinds of cationic polymers have appeared up to the present time in the literature, there are few polymers which have only primary amino groups as ionizable groups and which are, besides, soluble in water over a wide pH range. The present authors synthesized a series of aminoethyl derivatives of poly(vinyl alcohol). These polymers are unique in bearing primary amino groups together with hydroxyl groups and in their hydrophilic nature.

Experimental

Materials. A Bemberg rayon fiber, considered to have the smoothest surface among cellulosic fibers, was used as the adsorbent. The fibers were 1.31 den and 2 mm in length, with round sections 12 μ in diameter. The adsorbent was subjected to five 24 hr soaks in ethanol and four 24 hr soaks in distilled water to remove the scouring agents and any other impurities. The geometrically-calculated surface area of the fibers was 3500 cm^2/g in the wet state.

Aminoethyl derivatives of poly(vinyl alcohol) and cellulose, (henceforth referred to as AEPVA and AEC respectively) were prepared through the Hofmann degradation of the corresponding carbamoylethyl derivatives. The carbamoylethyl derivatives were prepared by means of a Michael reaction of acrylamide, with care taken to avoid the formation of carboxyl groups by using a large excess of acrylamide at low temperatures (10~15 °C). A water-soluble derivative of cellulose was prepared by dissolving cotton linters in a 40% benzyltrimethylammonium hydroxide solution and by then adding a large amount of a 35% acrylamide aqueous solution. Polymers of above 99% conversion of the carbamoylethyl group into the aminoethyl group were used as the adsorbates. The variation in the amino-group content of the polymers was accomplished by the control of the degree of carbamoyl-

ethylation. The aminoethyl derivatives were subjected to fractional precipitation in a 0.5 M sodium acetate aqueous solution, with acetone as the precipitant. All the adsorbates were purified from about 0.1 M NaOH solutions by dialysis in deionized water. The properties of the polymers used are shown in Table 1, while the relationships between the pH and the degree of ionization of the aminoethyl derivatives are shown in Fig. 1.

Adsorption Procedure. A weighed quantity of wet fibers (net 2 g) and 100 ml of a polymer solution of a known concentration were enclosed in a 150-ml polystyrene vessel and shaken for 24 hr at 20 °C. After this process, the pH of the mixture was measured using a Hitachi-Horiba F5 pH meter; then the fibers were filtered off, and the solution was analyzed. The amount of adsorption was calculated from the difference in the polymer concentration measured before and after the adsorption process. The pH of the adsorption system was set by the use of acetic acid, ammonia, HCl, or NaOH.

Analytical Methods. Colloid titration[3] was used to determine the concentration of the aminoethyl derivatives before and after each adsorption run. An aliquot portion of the polymer solution was taken, buffered to pH 4 with acetic acid, and then titrated with a N/500 potassium poly(vinyl sulfate) solution, using toluidine blue as the indicator.

A spectrophotometric method[4] was used for the determination of the concentrations of poly(vinyl alcohol) (PVA) and its hydroxyethyl derivative (HEPVA). The absorbance of the colored PVA-iodine complex formed in the presence of boric acid was measured at 660 mμ.

The degree of ionization of the aminoethyl derivatives was calculated from the results of pH titration. A 200-ml portion of a N/200 AEPVA solution was titrated with M/10 HCl at 20 °C under a N_2 atmosphere by the use of a Hitachi-Horiba F5 pH meter.

Results

Adsorption of PVA and HEPVA. No appreciable adsorption took place in the 3∼12 pH range, in contrast with the cases of the adsorption of PVA from aqueous solutions by titanium dioxide[5] or by sodium montmorillonite.[6] This result demonstrates that neither hydrogen bonding nor hydrophobic interactions come into play to cause adsorption in this cellulose–PVA–water system.

Effect of the pH on the Adsorption of AEPVA. As the example (Fig. 2) shows, the saturation adsorption capacity is greatly dependent on the pH of the system. The amount of adsorption increased as the pH increased, but to only a small extent in the 3∼7 pH range, steeply above pH 8, and attained to a maximum at a pH of about 10.3. Above this point, the adsorption capacity decreased steeply with the increase in pH; no appreciable adsorption took place above pH 12.

Effect of the Amino-group Content. Table 2 shows the amounts of the maximum adsorptions of AEPVA of various amino-group contents at pH 4.5 and 10.9. At pH 4.5, the amount of adsorption decreased with the increase in the amino-group content; this is consistent with the earlier finding that the increase in the charge density on the macromolecule causes a decrease in the adsorption.[2] At pH 10.9, however, the amount of adsorption increased with the increase in the amino-group content. The amount of the ionized amino group in the polymer adsorbed also varied with the amino-group content; this fact indicates that the stoichiometric interaction between the surface charge and the polymer charge does not alays determine the amount of adsorption.

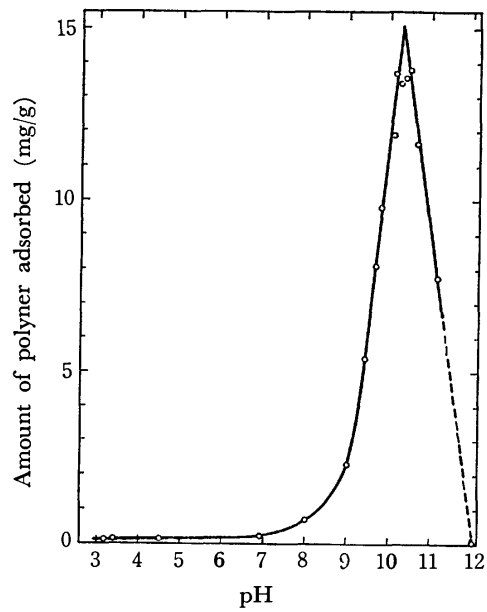

Fig. 2. Variation of the adsorption capacity with pH. Adsorbate: AEPVA-8. Concentration of foreign electrolytes added: 0.001 N.

Table 2. Amounts of maximum adsorption of AEPVA of various amino-group contents at pH 4.5 and 10.9

AEPVA	Amino-group content[a]	Amount adsorbed: Polymer weight (mg/g)		Amount adsorbed: Ionized amino group[b] (eq/g) × 10^6

a) Number of the amino group per vinyl monomer unit. b) Calculated from the amount adsorbed, the amino-group content, and the degree of ionization of the corresponding polymer.

Effect of Molecular Size. Figure 3 shows that the dependence of the amount of adsorption on the molecular size of the polymer is very small in comparison with that on the amino-group content at both pH 4.5 and pH 10.9. This result may confirm that the fiber surface is nonporous with regard to the adsorption of the polymers used.

Effect of Electrolyte Added. Figure 4 shows the effects of the NaCl concentration on the adsorption of AEPVA at pH 4.5 and 10.9. At pH 4.5, the addition of NaCl increased the amount of adsorption until its concentration reached about 5×10^{-3} mol/l; above this point, however, it had an inverse effect, and no ap-

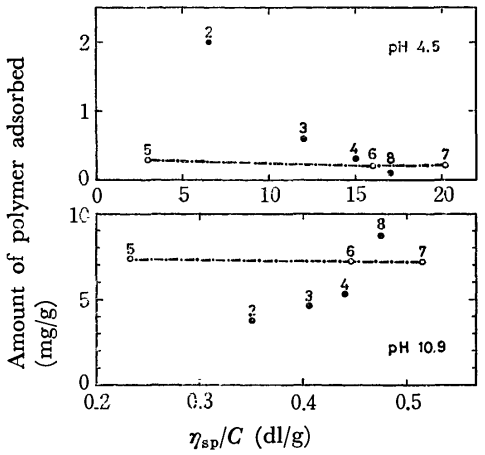

Fig. 3. Plots of the adsorption capacity against a parameter for polymer coil dimension. The numbers, 2~8, denote the code numbers for AEPVA. AEPVA-5, -6, and -7 have the same amino-group content. The variation of the adsorption capacity can be ascribed to the effect of the amino-group content; the dotted lines show very little effect of the size of polymer moleculcs.

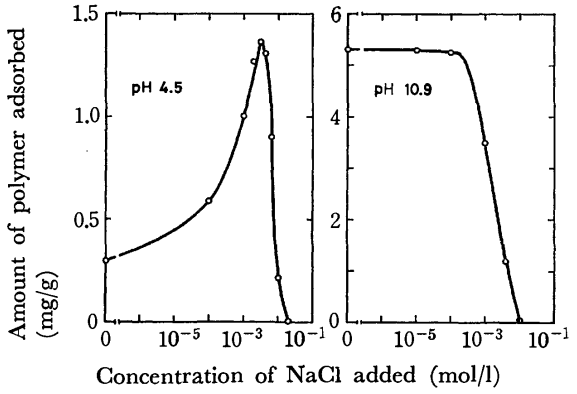

Fig. 4. Variation of the adsorption capacity with the concentration of NaCl added. Adsorbate: AEPVA-4.

preciable adsorption took place when the concentration of NaCl exceeded 2×10^{-2} mol/l. At pH 10.9, the amount of adsorption always decreased as the concentration of NaCl increased. These phenomena suggest that the primary driving force of adsorption is the electrostatic force of attraction between the solid surface and the solute polymer.

Comparison of the Adsorption Behavior of AEPVA with That of AEC. Figure 5 shows the adsorption isotherms for the AEPVA of a flexible chain and for the AEC of a rigid chain. The two polymers used are alike in amino-group content and in molecular weight. At pH 4.5, the adsorption behavior of AEPVA is almost identical with that of AEC; this result suggests that the AEPVA molecules as well as AEC molecules are adsorbed in a stretched (and flat) conformation at the surface. On the other hand, at pH 10.9, there is a remarkable difference between the adsorption isotherm for AEPVA and that for AEC. This may be due to the difference in molecular shape at the surface.

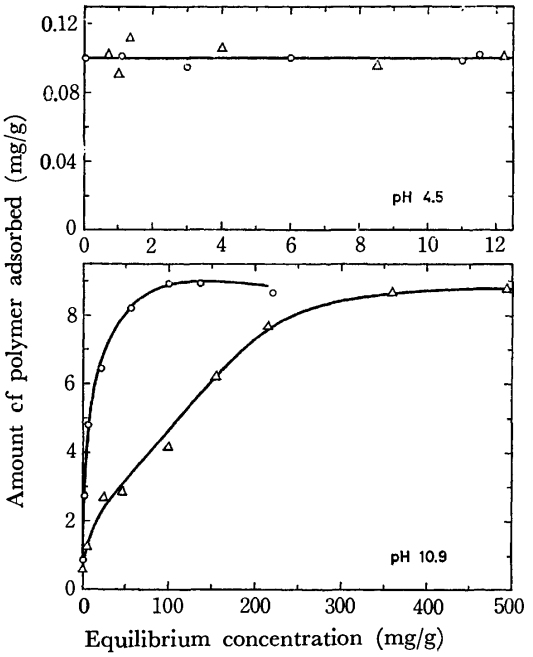

Fig. 5. Comparison of the adsorption behavior of AEPVA with that of AEC.
(○): AEPVA-8, (△): AEC.

Discussion

The results of the adsorption of PVA and the effect of the pH on the adsorption of AEPVA indicate that the aminoethyl group is essential for the adsorption of AEPVA and that the un-ionized amino group plays no important role in the adsorption. Considering these

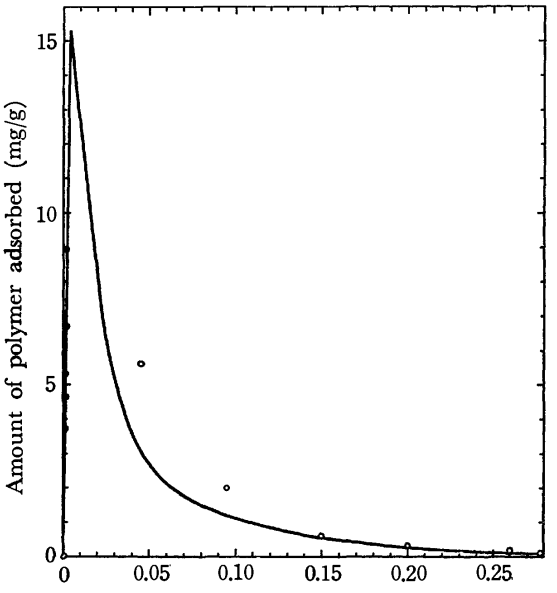

Fig. 6. Dependence of the adsorption capacity on the polymer charge-density.
Solid curve: calculated from the data on the pH-dependence of the adsorption of AEPVA-8 (Fig. 2).
Points: calculated from the data on the absorption of AEPVA of various amino-group contents at fixed pH (○: pH 4.5, ●: pH 10.9).

facts in connection with the fact that the adsorption is suppressed when the NaCl concentration is increased above 0.02 mol/l, we can conclude that the primary factor causing adsorption in this cellulose-AEPVA–water system is the charge interaction at the solid-liquid interface.

It can also readily be noticed that the positive charge on AEPVA is the primary variable controlling the amount of adsorption. The dependence of the maximum amount of adsorption on the charge density of AEPVA is illustrated in Fig. 6. It is clear that the amount of adsorption is a function of the charge density on the polymer, though the variation in the charge density on the fiber surface with the pH is not taken into account in this figure. The adsorption increases steeply in approximate proportion to the charge density up to a maximum, at which the solute polymers bear the ionized amino groups in a ratio of 1 to 200~300 of vinyl monomer units, and then decreases with the increase in the charge density. Incidentally, at the point of maximum adsorption about 500 vinyl monomer units, in a rough estimation, are found per 100 Å^2 of fiber surface; if it were assumed that the polymer molecules are adsorbed in a spherical conformation at the surface, this signifies multilayer surface coverage, while if monolayer adsorption were assumed, it indicates that polymers are attached to the surface by a few segments in long loops extending out into the liquid phase. On the other hand, at the point of the ionized-amino-group content (0.278), only 3 vinyl monomer units are found per 100 Å^2 of fiber surface; this corresponds to only a one-third surface coverage even if a completely flat accommodation at the surface were assumed.

The steep rise in the adsorption capacity in the region of low-charge densities may be ascribed to the increase in the electrostatic force of attraction between the polymer and the fiber surface.

With regard to the decrease in the adsorption capacity with the increase in the charge density in the region of the ionized-amino-group content above 0.004, either of the following two explanations appears to be possible. First, it may be considered that the number of polymer molecules required to fill up the binding sites (anionic sites) of the fiber surface decreases as the positive charge on the polymer increases, thus leading to a reduction in the amount of polymer adsorbed. Another explanation is that the spatial requirement per molecule at the surface increases as the charge density of the polymer increases because of the expansion of the polymer coil by the intramolecular repulsion of the ionic groups, thus causing the reduction of the adsorption. However, in the region of higher charge densities these two explanations may be inadequate, because it is considered that, at some point (with regard to the charge density), polymers start to adsorb in a flat conformation at the surface and that, from some point, the saturation of adsorption takes place, leaving a considerable amount of surface area uncovered. In this region, the reduction of adsorption may be ascribed to the increase in the electrostatic force of repulsion between the adsorbed polymer and the solute polymer.

The authors wish to express their appreciation to Professor Isao Sakata, Faculty of Agriculture, Kyushu University, for his valuable suggestions.

Interaction between Water and Hydroxylated Surface of Silica-Alumina

Tetsuo MORIMOTO, Mahiko NAGAO, and Junichiro IMAI

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama 700

(Received May 13, 1974)

The interaction between water and the fully-hydroxylated surfaces of silica,alumina and silica-alumina has been investigated by measuring the physisorption isotherms of water at three temperatures and by computing the isosteric heat of adsorption and the site energy distribution therefrom. The number of adsorption site evaluated on the surfaces of each of the two component oxides decreases exponentially with the increase in the site energy, whereas that of the silica-alumina samples gives a peak at a relatively high energy region, suggesting the presence of strong water-physisorption sites characteristic to silica-alumina. These results can be elucidated on the basis exponentially of the postulation that new sites having protonic acid character appear when the two component oxides contact with each other, as described previously. Furthermore, it is found that the strength of such new sites for physisorption of water increases with decreasing content of alumina in silica-alumina.

Silica-alumina is one of the solid-acid catalysts; its interactions with basic molecules such as ammonia[1-6] and amines[7,8] are widely studied, while the quantitative investigations on the interactions with water are very few, though the fact that the Lewis acid sites on silica-alumina can transfer to the Brönsted acid sites by adsorbing water molecules is well known.[1,9]

In the preceding paper,[10] the present authors described a finding that the number of sites for the physisorption of water on silica-alumina is more than the number calculated from the simple addition of the values obtained on each component oxide. This result was explained by postulating the appearance of new sites for water physisorption in the vicinity of the contact region of the two component oxides. The postulation predicts the new sites thus formed to have the character of protonic acid sites. The measurements of the infrared spectrum of *n*-butylamine adsorbed on the same samples of silica-alumina substantiated the appearance of strong protonic acid sites which are absent on the surfaces of the individual oxides, the strength of which increases with decreasing amount of alumina in silica-alumina.[11] Here, it must be interesting to study the energetic aspect of the interaction between water molecules and the new sites produced on silica-alumina.

On working the thermodynamics of water physisorption on the surfaces of a metal oxide, however, difficulties arise in the preparation of the surface. The present authors have intended to study the surface properties of metal oxides in relation to the amount of chemisorbed species such as CO_2 and hydroxyl groups.[12-14] During the course of this study, it has become clear that the surface of metal oxides usually adsorbs water at a time physically and chemically at room temperature, the desorbability of the chemisorbed water being dependent upon the nature of the oxides.[12] Furthermore, the rate of chemisorption of water on silica was found to be considerably smaller than that on the other oxides.[10]

The purpose of this work is therefore to prepare with special precautions the fully hydroxylated surfaces of silica-alumina, and then to study the energetics of the interaction of water with them by measuring the physisorption isotherms of water and by evaluating the differential heat of adsorption and the site energy distribution.

Experimental

Materials. The samples used in this study were the same as those used in the previous works.[10,11] Pure silica (S) was prepared by the hydrolysis of ethylsilicate in water. Pure alumina (A) was produced by hydrolysing aluminum isopropoxide in 2-propanol-water mixture. By mixing the two kinds of pure samples in aqueous gel state in an agate ball mill for 30 min, three kinds of silica-alumina samples containing 25, 50, and 75 wt% of alumina (SA-25, SA-50, and SA-75) were prepared. These gels were all washed with distilled water, dried at 100 °C for 20 hr, and calcined at 500 °C for 10 hr in air.

The specific surface area of the samples was determined by means of the BET method using the nitrogen adsorption at the temperature of liquid nitrogen, where the cross-sectional area of a nitrogen molecule was assumed to be 16.2 Å^2. The surface areas of the samples treated at 600 °C for 4 hr in a vacuum of 10^{-5} Torr were found to be 640, 189, 423, 427, 317 m^2/g for samples S, A, SA-25, SA-50, and SA-75, respectively.

Water Adsorption Isotherm. Water adsorption isotherms were measured volumetrically by using a conventional apparatus equipped with an oil manometer which serves to read sensitively the equilibrium pressure. In order to study the thermodynamics of water physisorption, it is necessary to prepare the completely-hydrated surfaces of the samples. For this purpose, the water adsorption procedure was performed in the following way. After degassing a sample at 600 °C for 4 hr, the first adsorption isotherm of water was measured at 25 °C. Next, the sample was exposed to the saturated water vapor at 25 °C for 12 hr in order to prepare the fully-hydroxylated surface, because the rate of surface hydroxylation of silica has been found to be considerably slow in a relatively low pressure of water.[10] Since the temperature at which surface hydroxyl groups start to be removed depends on the nature of oxides,[10,12] it will be delicate to establish the exact condition under which the physisorbed water is removed completely and all the surface hydroxyl groups are left. Here, in order to obtain a surface state reproducible and approximate to that described just above, the sample was subjected to the following treatment. The fully-hydroxylated surface was degassed at 30 °C for 4 hr in a vacuum of 10^{-5} Torr in order to remove physisorbed water, and then the second adsorption isotherm was measured at the same temperature as before. The degassing of the sample under the above condition and the measurement of adsorption isotherm at different temperatures (10, 18, and 25 °C) were further repeated on the same sample taken. The equilibrium

for the second adsorption was attained 30 min after each dose of water vapor. When the second adsorption measurement was carried out repeatedly at the same temperature after degassing the sample, the isotherms obtained were in good agreement with each other, which substantiates the reproducibility of the fully-hydroxylated surfaces of the samples and consequently the reliability of the thermodynamical data of physisorbed water calculated therefrom.

Results and Discussion

The first and second adsorption isotherms obtained on pure alumina are given in Fig. 1. The first adsorption isotherm involves the amounts of both physisorbed and chemisorbed water, while the second adsorption isotherm involves only physisorbed water; the difference between them should consequently be the amount of chemisorbed water.[12,14] Figure 2 shows the adsorption isotherms of water on silica. It can be seen from Fig. 2 that the shape of the adsorption isotherms on silica is quite different from that on alumina; the amount of adsorbed water in the second adsorption on silica is greater than that in the first one, contrary to the case of alumina. This queer phenomenon is considered to be due to a slow rate of rehydroxylation of the silica surfaces, as discussed in the previous paper.[10]

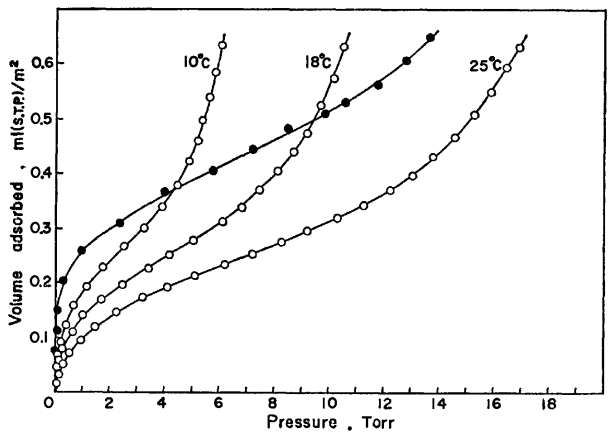

Fig. 1. Adsorption isotherms of water on alumina: ●, first adsorption at 25°C; ○, second adsorption on hydroxylated surface at 10, 18, and 25°C.

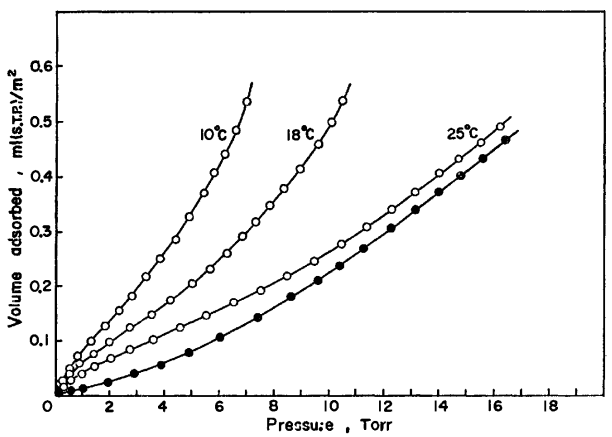

Fig. 2. Adsorption isotherms of water on silica: ●, first adsorption at 25°C; ○, second adsorption on hydroxylated surface at 10, 18, and 25°C.

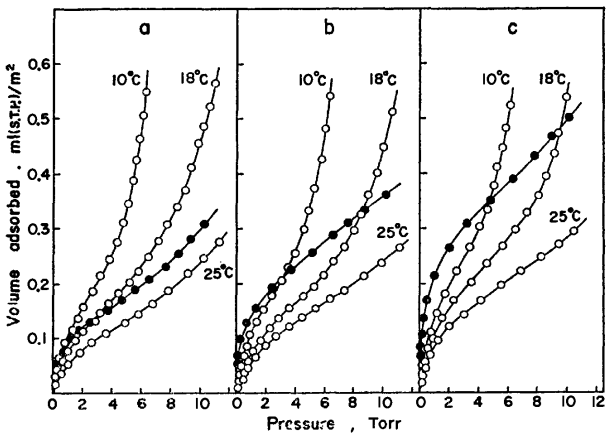

Fig. 3. Adsorption isotherms of water on silica-alumina: (a) SA-25, (b) SA-50, (c) SA-75; ●, first adsorption at 25°C; ○, second adsorption on hydroxylated surface at 10, 18, and 25°C.

The adsorption isotherms of water on the silica-alumina samples (SA-25, SA-50, and SA-75) are illustrated in Fig. 3. The sample SA-25 containing the least amount of alumina gives apparently the same type of isotherms as that of pure alumina, while the isotherms on the other samples are slightly modified from those of the sample SA-25. In addition, the difference between the first and the second adsorption isotherms seems to increase with the increase in alumina content.

From the physisorption isotherms obtained at different temperatures, the isosteric heat of adsorption, q_{st}, can be computed by using the Clausius-Clapeyron equation:

$$\frac{d\ln P}{dT} = \frac{q_{st}}{RT^2} \tag{1}$$

The isosteric heat q_{st} is the heat of adsorption at a constant amount of adsorption, being greater by RT than the differential heat of adsorption. Integrating the Eq. (1), we can obtain the equation (2):

$$\ln P = -\frac{q_{st}}{RT} + C \tag{2}$$

The value q_{st} can be determined from the slope of the linear plot of $\ln P$ *vs.* $1/T$. The value q_{st} thus obtained is represented in Fig. 4 as a function of the surface coverage θ, the latter being referred to the monolayer capacity of water calculated by applying the BET method to the second adsorption isotherm. Figure 4 shows that the q_{st} values obtained on all the samples tested decrease almost exponentially with coverage, which gives an evidence for the surface heterogeneity of hydroxylated surfaces for water physisorption, and that the strength of the sites depends on the nature of the substrates, being greater on aluminol than on silanol. On the surfaces of the silica-alumina samples, the interaction energies lie between those of the two pure oxides, but not additive. The isosteric heats on the surface of SA-25 are relatively larger than the others.

The differential entropy, $\bar{S}_s$, of adsorbed water can

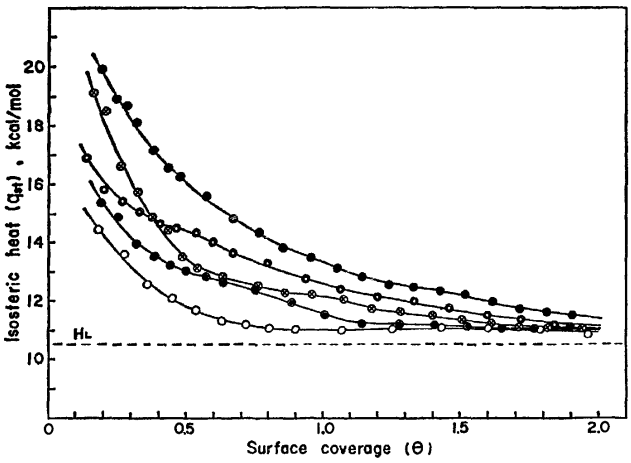

Fig. 4. Isosteric heat of adsorption of water physisorbed on silica, alumina, and silica-alumina: ○, S; ●, A; ◎, SA-25; ⊙, SA-50; ⊗, SA-75. Broken line indicates the heat of liquefaction of water at 25°C.

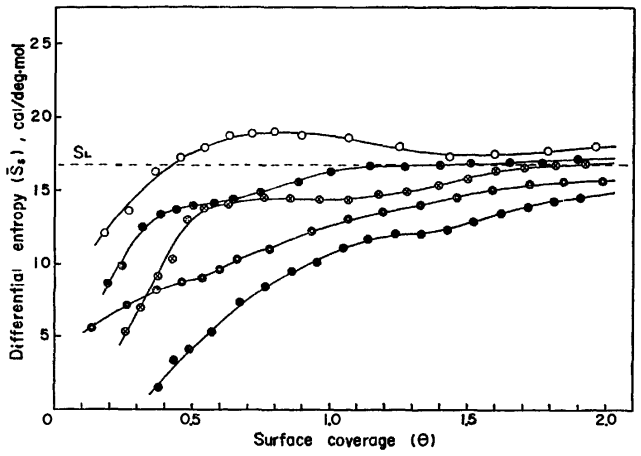

Fig. 5. Differential entropy of physisorbed water on silica, alumina, and silica-alumina: ○, S; ●, A; ◎, SA-25; ⊙, SA-50; ⊗, SA-75. Broken line indicates the entropy of liquid water at 25°C and 1 atm.

be calculated by the following equation:[15,16]

$$\bar{S}_s = -\frac{q_{st}}{T} + R \ln P_0/P + S_g^\circ \qquad (3)$$

Here, P_0 is the standard pressure, P the equilibrium pressure, and S_g° the standard entropy of water vapor (45.11 cal/deg·mol at 25 °C and 1 atm). Figure 5 shows the plots of the differential entropy against the coverage. It can be seen from Fig. 5 that water molecules are adsorbed more strongly on surface hydroxyl groups of alumina with less mobility than on those of silica. The entropy of water adsorbed on the surfaces of silica-alumina lies between those on the two single oxides.

Assuming that the number of adsorbed molecules expresses the number of sites, the site energy distribution can be estimated from the relation:[17]

$$g(\varepsilon) = \frac{dN}{d(H_d)} \qquad (4)$$

Here, N is the number of adsorption sites, and H_d the differential heat of adsorption. Practically, the

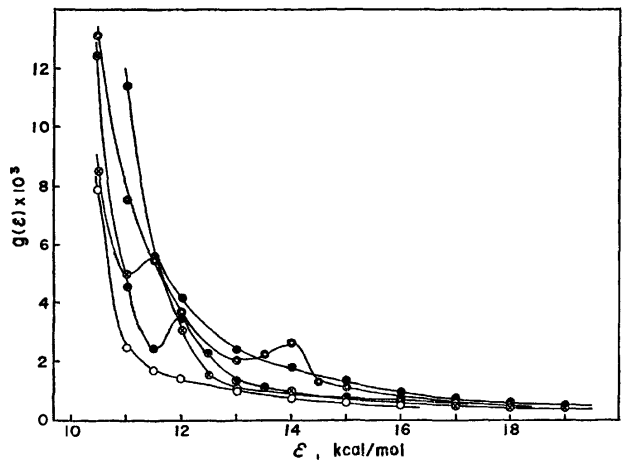

Fig. 6. Site energy distribution for the physisorption of water on silica, alumina, and silica-alumina: ○, S; ●, A; ◎, SA-25; ⊙, SA-50; ⊗, SA-75.

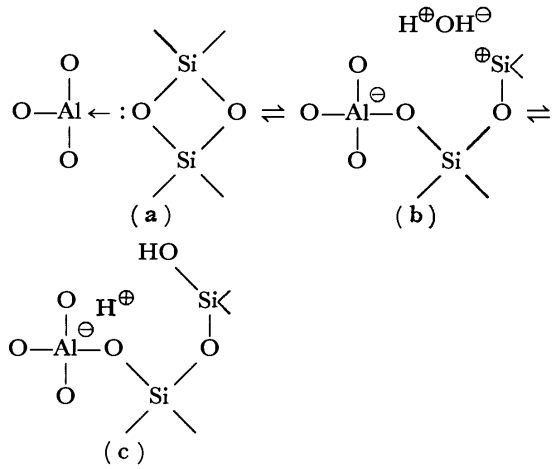
distribution can be calculated by the graphical differentiation of the plot of q_{st} *vs.* adsorbed amount. The site energy distribution curve thus obtained is represented in Fig. 6. Figure 6 shows that the number of adsorption sites with higher energies is much more on alumina than on silica, and that both curves decrease monotonously. On the other hand, the distribution curves on the silica-alumina samples reveal a marked peak at a higher energy region, which is not observed on the surfaces of each of the individual oxides. Furthermore, it is to be noted that the peak appears at the higher energy of adsorption on the silica-alumina samples containing the less amount of alumina: at 14, 12, and 11.5 kcal/mol for SA-25, SA-50, and SA-75, respectively. The appearance of these peaks may probably be associated with the new adsorption sites characteristic of the silica-alumina samples.

It has been known that there exist aprotonic acid sites on the surfaces of silica-alumina degassed at relatively higher temperatures, which can convert to protonic acid sites when exposed to water vapor.[1,9] In the preceding work,[11] it has been found that the infrared spectra of *n*-butylamine adsorbed on the present samples of silica-alumina have the band at 1540—1520 cm^{-1}, which is assigned to the symmetrical NH_3^+ bending vibration, and that the strength of this band decreases and at the same time the frequencies of the band shift to 1520—1503 cm^{-1} by pumping off the sample disk at elevated temperatures; these findings have never been observed on pure silica or alumina. The infrared studies have also led to another conclusion that the strength of the protonic acid sites increases with the decrease in the amount of alumina in silica-alumina. Similar conclusions obtained on the adsorption sites for *n*-butylamine as found by the infrared studies and for water as found by the present investigation seem to be explainable from the same stand point in the following way.

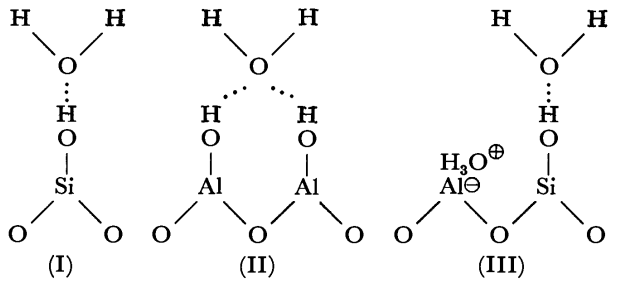
In the previous paper,[10] the formation of the additional physisorption sites for water on silica-alumina, which are absent on the surfaces of each of the component oxides, has been expressed schematically as

follows:



When the surfaces of both alumina and silica contact with each other, aluminum atom will attract the lone pair electrons on the oxygen atoms of silica owing to a strong electron-accepting ability of aluminum atoms (a); this will result in the splitting of Si–O–Si bonds and the formation of Al–O–Si bonds (b). When such surfaces are exposed to water vapor, a water molecule will be chemisorbed through the dissociation (c) to form a proton attached to an aluminum atom and a hydroxyl group bonded to a silicon atom. According to this proposition, a new type of sites formed should have the character of the Brönsted acid. It may be valid to consider that such an acidic site formed on silica-alumina acts as a stronger adsorption site for water compared to surface hydroxyl groups on each component oxide. Thus, the distribution curves on silica-alumina in Fig. 6 can be interpreted to reveal the overlapped effects of both the water adsorption to hydroxyl groups on heterogeneous surfaces through hydrogen bonding and that onto protonic sites, which appear to be relatively uniform in energy, through hydration.

In conclusion, three kinds of adsorbed water may thus be present in the first physisorption layer of water on silica-alumina:



The physisorption mode on silica (I) is possibly due to the fact that the population of surface hydroxyl groups is fairly small (less than 5 OH's/100 Å^2),[18,19] the ratio of H_2O : OH being nearly equal to 1 : 1 as indicated in the previous work,[10] and that the interaction energy is rather smaller and moreover the mobility of the physisorbed water is higher as indicated in the present work.

On the surface of alumina, however, the situation may be different from the case of silica: a water molecule will be physisorbed on two hydroxyl groups (II). This can be led from the fact that the hydroxyl groups of about 14 OH's/100 Å^2 are present on the surface of alumina, the ratio of H_2O : OH being about 1 : 2;[10] this physisorption mode may also be supported by larger adsorption energies (Fig. 4) and smaller entropies of adsorbed water (Fig. 5), compared to those on silica or silica-alumina.

The additional physisorption mode of water (III) will appear on the new sites, which should be produced in the vicinity of the contact region of the two component oxides according to the present preparation method of the samples. The physisorption of water on such new sites, indeed, implies the hydration of proton on the surfaces. The heat of hydration of proton in solution is well known to be very large (258 kcal/g·ion).[20] Abnormally large heats of adsorption of water observed on the surfaces of silica-alumina can thus be interpreted by the hydration of proton sites which also act as the strong Brönsted acid sites. However, the fact that the strength of the site energy is greater on silica-alumina samples containing smaller amount of alumina remains to be solved.

Phase Transition of Solid Hexabromoethane

Tsutomu KOIDE, Masami TSUJINO, Kazuhiro SAWADA, and Tsutomu ODA
Laboratory of Physical Chemistry, The Kyoiku University, Tennoji, Osaka 543
(Received June 12, 1974)

The phase transition point of solid hexabromoethane was found at 177 °C, above which the crystal is a body centered cubic lattice with two molecules in a unit cell, having a cell length of 7.80 Å at 185 °C. From an analysis of entropy change, it seems that random orientations of the molecular axis would occur at the transition point. The influence of halogen substitution is discussed. It was concluded that the phase transition will be dominated mainly by the geometrical properties of the molecules.

Many attempts were made to investigate the molecular behavior in the solid state of a series of hexasubstituted ethane derivatives. Consequently, it was revealed that the molecules easily obtain the freedom of rotational motion in the solid phase below the melting point because they have almost globular molecular shape and lose the freedom at the transition point on cooling.

From X-ray studies,[1] the molecules in the cubic phase (above 71 °C) of hexachloroethane, C_2Cl_6, assume statistically random orientation with their center of gravity at the lattice point.[2] This situation is supported by a small entropy of melting.[3] The orientational freedom of the molecule becomes frozen at the transition points, 45 and 71 °C, below which the crystal is no longer cubic and shows optical anisotropy.[4]

The small entropy of melting was also obtained for hexafluoroethane,[5] C_2F_6. Unfortunately, there is no crystal data of the solid state below the melting point. However, Lewis *et al.*[6] recently investigated the crystal structure below the transition point −169.18 °C[5] by the X-ray and the spectroscopic methods, and they indicated that there remained disorder concerning molecular orientation in the crystal lattice of the low temperature phase. The small entropy of melting and the result of Lewis *et al.* suggest that the molecule of the high temperature phase of C_2F_6 is in a state similar to the case of the highest temperature phase of C_2Cl_6.

The structure of hexabromoethane, C_2Br_6, at room temperature was investigated by Yardley[7] and analyzed in detail by Snaauw and Wiebenga.[8] Snaauw *et al.* also reported existence of two transition points in the solid state at 140—147 °C and about 210 °C from observation under a polarized microscope, and they suggested the highest temperature phase is probably cubic. However, there has been no crystal data on the highest temperature phase of C_2Br_6.

The object of this paper is in the first place to determine the temperature of the phase transition of solid C_2Br_6 by the thermal method and in the second place to discuss on the mechanism of phase transition in the solid state of C_2X_6 type molecules, where X denotes a halogen atom.

Experimental

The apparatus of differential thermal analysis (DTA) was reported in a previous paper.[9] The sample was sealed in a glass cell in order to prevent sublimation of sample.

For X-ray studies, a powder diffractometer (ADG-102 Toshiba Electric Co.) was used for room temperature investigations and a high-temperature X-ray camera was used for high temperature investigations. The powder sample was sealed in a thin walled Pyrex capillary tube. The temperature of the sample was measured by a copper-constantan thermocouple placed near the sample tube. The difference in temperature between the position of the thermocouple and the sample tube was calibrated beforehand.

The sample was prepared by bromination of hexachloroethane with bromine, following Korshak and Matveeva.[10] Aluminum powder, about 0.1 g, was added to a mixture of hexachloroethane (40 g) and bromine (160 g) in a flask at five-minute intervals over about six hours. The total aluminum added was 9.2 g. After the reaction, a solid mixture was treated with ethanol and recrystallized twice from benzene. The sample was further purified by sublimation at 50~55 °C in a vacuum of 10^{-1} Torr. Anal: C 4.8% (found), 4.77% (calcd.). By DTA measurement, the melting point was found to be 200 °C, accompanied by partial decomposition; literature values, 200~210,[10] above 210,[8] 198—199[11] and below 205 °C.[12]

Results

DTA measurement was carried out over a temperature range from −160 to 210 °C with a heating rate 1 °C min^{-1}. Two endothermic peaks appeared on the thermogram at 177 and 200 °C. The peak at 177 °C corresponds to the transition point of the solid phase. On cooling, the transition occurred at 168 °C. The heat of transition was estimated as 1.3±0.1 kcal mol^{-1} from the peak area referring the calibration curve, which corrected by comparison of peak areas of hexachloroethane (transition), naphthalene (melting), benzoic acid (melting) and potassium fluoride (melting). By slow heating under a polarized microscope the crystal, which shows birefrigence, became isotropic at 177 °C.

From X-ray diffracto-diagram of the powder sample, using CuK_α radiation, the following cell dimensions were obtained at room temperature; a=11.95, b=10.72 and c=6.72 Å. They are in good agreement with the results of Snaauw *et al.*,[8] a=12.00, b=10.64, c=6.67 Å, space group D_{2h}^{15} and also Yardley's data. Up to transition point, observed X-ray diagrams were almost the same as that obtained at room temperature.

At 185 °C, we obtained X-ray powder photographs, on which only three lines appeared. Referring to the optical isotropy of the high temperature phase, we could index the reflections with a body-centered cubic lattice containing two molecules in a unit cell. The edge length is 7.80 Å, the calculated density being 3.52 g cm^{-3}.

Discussion

Snaauw *et al.* reported two transition points in solid C_2Br_6 at 140~147 °C and 210 °C by optical observation. Their data are different from present result, 177 °C. We repeated DTA measurement and optical observation several times, but could not find any change at temperatures Snaauw reported. The reason for this discrepancy is not evident. Concerning the transition temperature, the other sample (sample II), prepared by short-time bromination of hexachloroethane (about 2.5 hr), showed two transition points at 162 and 178 °C, and it melted at 211 °C. The values of carbon content 5.06% in this sample II is quite different from the calculated one, 4.77%. A fluorescent X-ray analysis of sample II gives a content ratio as Br : Cl=8 : 1. The molecular formula $C_2Br_{5.33}Cl_{0.67}$ corresponds to 5.06% of carbon content. These results suggest that sample II should contain residual chlorine of hexachloroethane.

Since there are two molecules in the unit cell with a body-centered structure, it is reasonable to place the center of the molecules at the positions, *0,0,0* and *1/2, 1/2, 1/2*, of which the symmetry should be at least *T*-23. On the other hand, if we assume the molecule has a *trans*-configuration, the molecular point symmetry should be D_{3d}. In order that the molecule attains the cubic symmetry, it is necessary to take into account some statistical arrangements for explaining the structure of the crystal, as was done in the X-ray studies of other plastic crystals.[1,2] One of the statistical arrangements of the molecule is that the molecular axis (the central C–C bond) runs parallel to the four body-diagonals of the unit cell with equal probability.

Figure 1 shows the unit cell lengths of the cubic phases of hexasubstituted ethane derivatives as a function of the number of halogen atoms in a molecule. The unit cell length expanded slightly from 7.69 Å in $C_2(CH_3)_6$ to 7.80 Å in C_2Br_6 increasing with an increase in number of bromine atoms in a molecule, except for $C_2(CH_3)_5Br$, as shown by the solid line in Fig. 1. On the other hand, the unit cell length diminished with increasing number of chlorine atoms as shown by the dashed line. On view of carbon–halogen bond distances and van der Waals radii, these relations seem to be rational. As shown in Fig. 2, melting and transition points show gradual change with the molecular weight. The difference between the melting and the transition points reduces from 232 °C in $C_2(CH_3)_6$ to 37 °C in C_2Br_6. C_2F_6 shows especially low melting and transition points. It is probably because the covalent radius and also the van der Waals radius of fluorine are smaller than that of carbon atom or methyl group.

Now we shall infer from the entropy consideration what sorts of molecular motions would be excited on passing through the transition point. Referring to the results of X-ray studies of C_2Cl_6, the following structural model for compounds of general fromula C_2X_6 may be assumed to estimate the contribution of the molecular motion to the entropy. In the highest temperature phase of each substance, the molecular

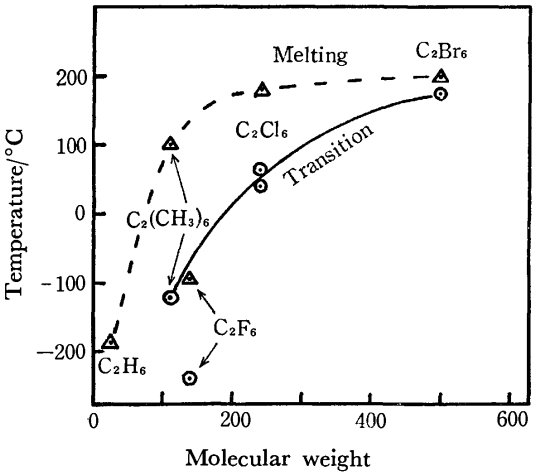

Fig. 2. Melting and transition points of C_2X_6 type crystal as a function of molecular weight.

axis (the central C–C axis) runs parallel to the four body-diagonals in a random fashion. The internal rotation about molecular axis and overall molecular rotation around molecular axis begin to be fully excited. These motions are essentially frozen-in in the lowest phase.

The contribution from the increase of orientational freedom is given by $R \cdot \ln 4$. The increase in entropy by internal rotation is calculable by use of Pitzer's table[13] assuming the potential barrier hindering the internal rotation as shown in Table 1. The contribution from overall axial rotation can be calculated from the following equation

$$\Delta S = R\left[\ln \frac{1}{\pi\sigma}\left\{\frac{8\pi^3 I_m RT}{h^2}\right\}^{1/2} + \frac{1}{2}\right]$$

where I_m is the moment of inertia about the rotational axis and σ is the symmetry number. In this case, $\sigma=3$ was used. The calculated entropy for each type of motion is given in Table 1.

In the case of C_2F_6, the sum of contributions from these motions 9.21 cal mol^{-1} K^{-1} is slightly larger

TABLE 1. CALCULATED AND OBSERVED ENTROPIES

	$C_2(CH_3)_6$	C_2F_6	C_2Cl_6	C_2Br_6
V, kcal mol^{-1}	4.7[16]	4.35[5]	10.8	—
I_m	366.9	307.2	960.58	—

S_{rot}, cal mol^{-1} deg^{-1}	—	4.30	6.63	7.89
S_{ori}, cal mol^{-1} deg^{-1}	2.76	2.17	2.76	2.76
S_{obsd}	3.134[16]	8.59[5]	1.93 (45 °C)[14] 5.66 (71 °C)	2.9±0.2*

V; Hindering potential barrier to internal rotation, S_{ir}; Entropy of internal rotational freedom, S_{rot}; Entropy of overall rotational freedom, I_m; Moment of inertia, S_{ori}; Entropy of orientational freedom, S_{obsd}; Observed entropy, *; Present work

than the observed entropy of transition 8.59 cal mol^{-1} deg^{-1}.[5] Assuming the contribution of reorientational disorder is to be $R\cdot\ln 3$, one obtains calculated total entropy as 8.62 cal mol^{-1} deg^{-1}, showing good agreement with the observed one. Therefore, it may be inferred that the molecule of C_2F_6 obtains at the transition point −169.18 °C the freedoms of internal and overall rotational motions and the degrees of freedom concerning molecular orientation satisfying $R\cdot\ln 3$, which is consistent with the conclusion of Lewis *et al.*,[7] *i.e.* there remains disorder concerning molecular orientation in the low temperature phase.

For the case of C_2Cl_6, any calculated value does not agree with the observed values of transition entropy, 1.93 cal mol^{-1} deg^{-1} at 45 °C or 5.66 cal mol^{-1} deg^{-1} at 71 °C. However, the sum of contributions of the orientational disorder and the internal rotation 7.84 cal mol^{-1} deg^{-1} is almost in agreement with the total observed value 7.59 cal mol^{-1} deg^{-1}. This agreement suggests that the reorientational and internal rotational freedoms should be acquired accompanying phase changes from the lowest to the highest solid phase through the intermediate phase. As no crystal data are found in the literature for the crystal between 45 °C and 71 °C, it is impossible to conclude what sorts of the two motions are activated at each transition point.

By comparison of calculated and observed entropies in the case of C_2Br_6, mechanism of the transition seems to be the occurrence of orientational randomness of the molecular axis.

The observed entropy 3.134 cal mol^{-1} deg^{-1} of $C_2(CH_3)_6$ is larger than the calculated value 2.76 cal mol^{-1} deg^{-1} for a model of molecular orientational disorder. An investigation of the molecular motion of solid $C_2(CH_3)_6$ by nuclear magnetic resonance method[15] revealed that the internal and overall axial rotations are excited, if not fully, even in the low temperature phase. Therefore, the main contribution to the phase transition is considered as the excitation of orientational motion of the molecular axis.

Now, it seems that there exists a general tendency concerning the transition mechanism for C_2X_6 type molecules, where X denotes halogen atoms. Three motions are excited at transition point of C_2F_6, *i.e.* internal, overall axial rotations and orientational disorder. For C_2Cl_6, overall axial rotation is ruled out from these three motions. In the case of C_2Br_6, only orientational disorder is allowed.

The hindering potential barrier against the internal rotation increases from 4.35 kcal mol^{-1} of C_2F_6 to 10.8 kcal mol^{-1} of C_2Cl_6 as shown in Table 1. The hindering potential barrier of C_2Br_6 is not available in the literature, however it seems to be larger than that of C_2Cl_6. The increase of hindering potential barriers is consistent with the enlargement of the geometrical extension of the molecule, *i.e.* van der Waals radii, bond lengths of C–X bond and atomic radii. From these discussions, the influence on the mechanism of phase transition of replacement of X by halogen atoms in C_2X_6 type molecule seems to depend on mainly the variance of geometrical factor of the molecules, which governs the capability of rotational motions.

The authors gratefully acknowledge Professor H. Chihara of Osaka University for reading the manuscript.

Experimental Determination of Ionization Potentials of Organic Amines, β-Carotene and Chlorophyll a

Yoshihiro NAKATO, Takeshi CHIYODA,* and Hiroshi TSUBOMURA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received June 7, 1974)

Ionization potentials(I_p's) of several organic compounds have been determined by the method of photo-current measurements in gas and organic solvents. It has been found that the vapor-phase I_p's, calculated from those determined from the onsets of the photo-currents in solutions by using Born equation for the solvation energies of the cations and a common term for the energy of the electron in solution, agree well with those measured in the vapor phase. Based on this result, the I_p's of molecules in the gas phase can be derived from those measured in the solution. This method is useful for the determination of I_p's of large molecules which cannot be obtained in the gas phase. Some of the I_p's obtained are: 5.6 for 1,1,4,4-tetrakis(dimethylamino)butadiene, 5.7 for 3,3′-dimethyl-2,2′-bibenzothiazolinylidene, 6.4 for β-carotene, 6.1 for chlorophyll a, 6.3 for dihydridobis(π-cyclopentadienyl)tungsten (eV unit). The conditions of lowering the I_p's of organic molecules are discussed.

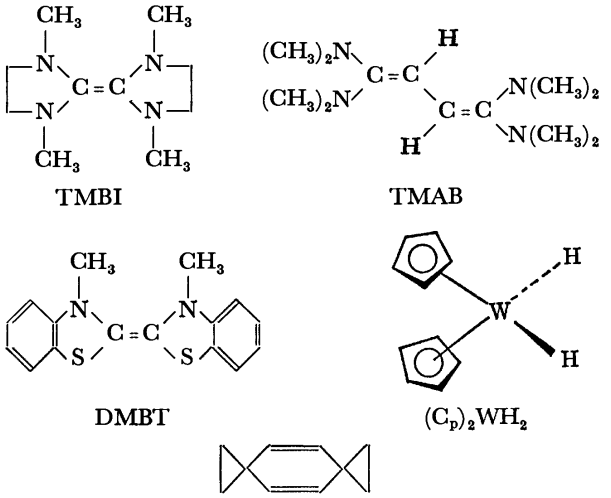
Recently, we found that tetraaminoethylenes have ionization potentials (I_p's) of *ca.* 5.4 eV,[1] which are, to our knowledge, the lowest I_p's of organic compounds reported so far, even comparable with that of the lithium atom. These interesting results stimulated us to search for other organic compounds with still lower I_p's. In this paper, some of the results of our trials along this direction are reported.

All previous methods to obtain the I_p's of molecules are applicable only to compounds with enough vapor pressures.[2,3] For example, no measurements of the I_p's of large molecules, such as chlorophylls, and carotenes, have yet been made. For such molecules, only the photo-electric work functions in the solid phase were reported.[4]

We have studied the photo-ionization of molecules not only in the gas phase but also in solutions, and found a simple relation between the gas phase I_p's and the photo-current threshold in the solution.[5] Based on this relation, it is possible to calculate the gas phase I_p's of large molecules from the photo-current thresholds in the solutions. This new method has been applied in this work to the determinations of the I_p's of some large molecules.

Experimental

The preparation and handling of tetrakis(dimethylamino)-ethylene, (TMAE), and 1,1′,3,3′-tetramethyl-2,2′-biimidazolidinylidene, (TMBI), were described previously.[1,5] 1,1,4,4-tetrakis(dimethylamino)butadiene, (TMAB),[6] and 3,3′-dimethyl-2,2′-bibenzothiazolinylidene, (DMBT),[7] were prepared according to the literature. Dihydridobis(π-cyclopentadienyl)tungsten, $(C^p)_2WH_2$, and dispiro[2.2.2.2]deca-4,9-diene were offered from Nakamura and Otsuka,[8] and Tsuji and Nishida,[9] respectively. A Merck reagent dimethylphenylphosphine was used. All these compounds except dispiro[2.2.2.2]deca-4,9-diene are highly reactive with atmospheric oxygen and were treated in the similar way as TMAE and TMBI.[1,5] Chlorophyll a was prepared from fresh spinach and purified by column chromatography according to the literature.[10] β-Carotene, a Wako GR grade reagent, was used without further purification. A Merck NMR grade tetramethylsilane (TMS) and a Wako spectroquality isooctane were dried with Na–K mirrors in ampoules connected to a vacuum line just before use.



Absorption spectra and photo-ionization curves in the vacuum ultraviolet region were measured with a Nalumi vacuum monochromator. Photo-currents in solutions were measured by using a quartz cell equipped with two parallel platinum plate electrodes. The details of the experimental apparatus and procedure were described elsewhere.[1,5]

Results

The Photo-ionization in the Gas-phase. Figure 1 shows the photo-ionization curve for 1,1,4,4-tetrakis(dimethylamino)butadiene, (TMAB). σ_i^{rel} is the relative photo-ionization cross section, which is calculated by using the equation, $\sigma_i^{rel}=\sigma\cdot i/(I_0-I)$, where σ, i and I_0-I are the relative absorption cross section, the photo-current and the relative light intensity absorbed by the sample vapor, respectively. As in the previous work,[1] the point of appearance of σ_i^{rel} is taken as an upper limit for the first adiabatic ionization potential (I_p), and the maximum of $d\sigma_i^{rel}/dE$, the first derivative of σ_i^{rel}, as the vertical I_p. Because of the relatively low vapor pressure of TMAB, the slit-width of the monochromator had to be broadened, resulting in a somewhat large error.

The photo-ionization curves for dimethylphenylphosphine and dispiro[2.2.2.2]deca-4,9-diene were also measured. In these cases, however, only the adiabatic

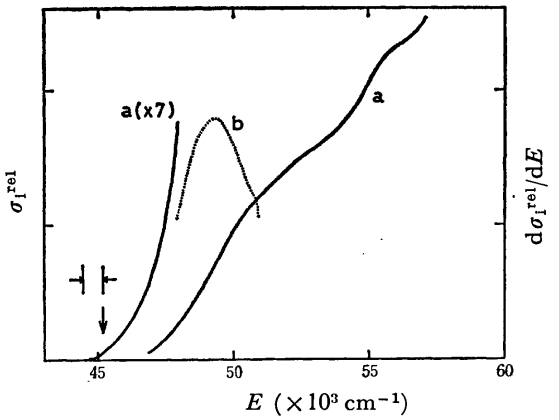

Fig. 1. Gas-phase photo-ionization of TMAB; curve a shows σ_i^{rel} *vs* E and curve b $d\sigma_i^{rel}/dE$ *vs* E. The photoionization threshold is shown by an arrow. The energy spread of the photon beam at the threshold is also indicated.

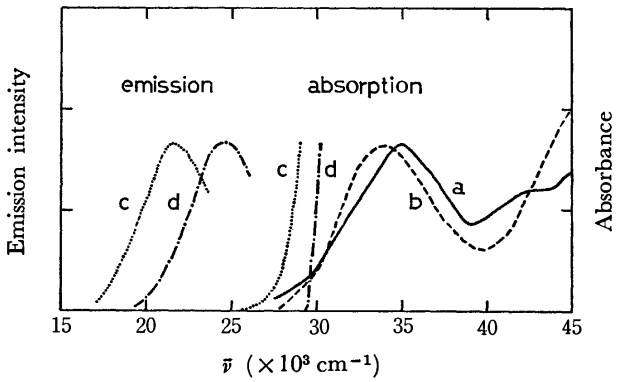

Fig. 2. Absorption and emission spectra of TMAB; curve a for the vapor, curve b for the tetramethylsilane solution at 25°C, curve c for the concentrated 3-methylpentane solution at 25°C, and curve d for the same one at 77 K.

TABLE 1. GAS-PHASE IONIZATION POTENTIALS (eV)

Compounds	Adiabatic ionization potential	Vertical ionization potential
TMAB	5.6±0.10	6.14±0.10
Dimethylphenyl-phosphine	7.58±0.05	——
Dispiro[2.2.2.2]-deca-4,9-diene	7.33±0.05	——

I_p's could be determined since these compounds had relatively high I_p's, near the limit of our experimental apparatus. The observed I_p's are summarized in Table 1.

Figure 2 shows the absorption and emission spectra of TMAB. Both the absorption spectra in the range of 25000—30000 cm^{-1} and the emission spectra are blue-shifted by change from the vapor phase to the liquid solution, and further to the solid solution. These behaviors are quite the same as those of the first absorption band and the emission band of TMAE, which were assigned to the transition between the first Rydberg state and the ground state.[1,5] It can, therefore, be concluded that the first excited singlet state of TMAB is of Rydberg character.

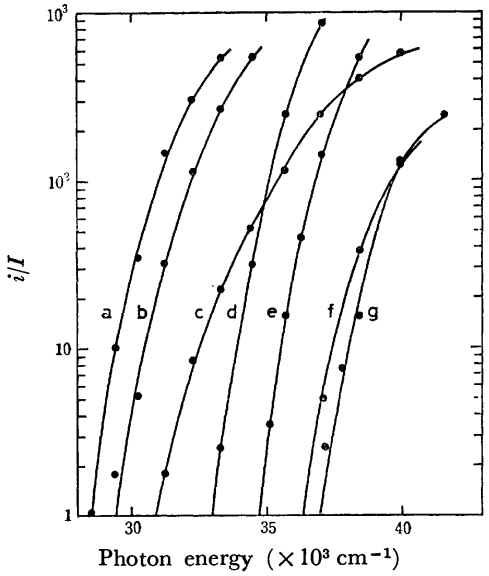

Fig. 3. Photo-ionization curves of various organic compounds in tetramethylsilane; a: TMAE, b: TMBI, c: TMAB, d: DMBT, e: $(C_p)_2WH_2$, f: chlorophyll a. g: β-carotene. All solutions are deaerated. Applied field is 400 V/cm. The half-width of the light of illumination is 10 nm.

The Photo-ionization in Organic Solutions. The photo-currents measured for several organic compounds in tetramethylsilane (TMS) are shown as functions of photon energy in Fig. 3, where the ordinate shows the photo-current (i) divided by the intensity of illumination (I). It should be noted that even the photo-currents of large molecules, such as chlorophyll a and β-carotene, can be measured easily in the solutions. The photo-currents in isooctane show similar behavior.

The photo-current threshold in a solution of a molecule, M, $E_{th}(M)$, is related with the gas-phase I_p, $I_g(M)$, as follows.[5]

$$E_{th}(M) = I_g(M) + S(M) - S(M^+) + E(e) \quad (1)$$

where $S(M)$ is the solvation energy for M and $S(M^+)$ that for the cation, M^+, and $E(e)$ the energy of the electron photoejected into the solvent. $E(e)$ can be taken as the energy of an electron at the bottom of the conduction band of the solvent relative to the vacuum level, which is expressed by $E_s^0(e)$ in Ref. 5 or by V_0 in Ref's. 11 and 12.

$S(M^+)$ can be divided into two parts,

$$S(M^+) = S_B(M^+) + S'(M^+) \quad (2)$$

where $S_B(M^+)$ is the part of the solvation energy relevant only to the mono-positive charge on the cation, M^+, approximated by the Born equation,[13] and $S'(M^+)$ the remaining part of the solvation energy.

$$S_B(M^+) = (e^2/2a)(1-1/\varepsilon_{op}) \quad (3)$$

where a is the radius of the sphere for the cation, M^+, and ε_{op} the optical dielectric constant of the solvent ($\varepsilon_{op}=n^2$, n is the refractive index). The method of calculation of the radius a for the cation, M^+, is given in the Appendix.

Table 2. The values of E(e) calculated from observed ionization energies in the vapor and solutions (eV unit)

Compound	I_g	E_{th}		a(Å)	E(e)	
		in TMS	in *iso*-octane		in TMS	in *iso*-octane
TMAE	5.36±0.02[b]	3.54±0.11	——	3.21	−0.79	——

Table 3. Gas-phase ionization potentials calculated from observed photo-current thresholds in solutions (eV unit)

Compound	E_{th}		a(Å)	I_g[a] calcd from E_{th}	
	in TMS	in isooctane		in TMS	in isooctane
DMBT	4.09±0.14	4.43±0.16	3.70	5.8	5.7
$(C_p)_2WH_2$	4.30±0.15	4.64±0.18	2.50	6.4[b]	6.3[b]
Chlorophyll a	4.50±0.17	——	3.82	6.1	—
β-carotene	4.59±0.18	5.02±0.22	3.30	6.4	6.4

a) The error estimated will be 0.2 eV at most. b) The value obtained from the CT absorption bands is 6.3 eV; Ref. 8.

Under the approximation that $S'(M^+)$ is nearly equal to $S(M)$, Eq. (1) is expressed as

$$E_{th}(M) = I_g(M) - S_B(M^+) + E(e) \quad (4)$$

From the data for the four compounds shown in Table 2, where the ionization potentials both in the gas phase and in the solutions are determined experimentally, E(e) can be calculated by using Eq's. (3) and (4). The results are shown in Table 2, together with the radius a used. It is found that the values of E(e) are nearly constant for each solvent, as expected from the definition. This shows that the Eq's (3) and (4) are fairly good approximations.

Now, based on the values of E(e) obtained above and the Eq's (3) and (4), it is possible to calculate I_g(M) from E_{th}(M). The results are given in Table 3. As expected, the values of I_g(M) calculated from E_{th}(M) in tetramethylsilane (TMS) are in good agreement with those from E_{th}(M) in isooctane.

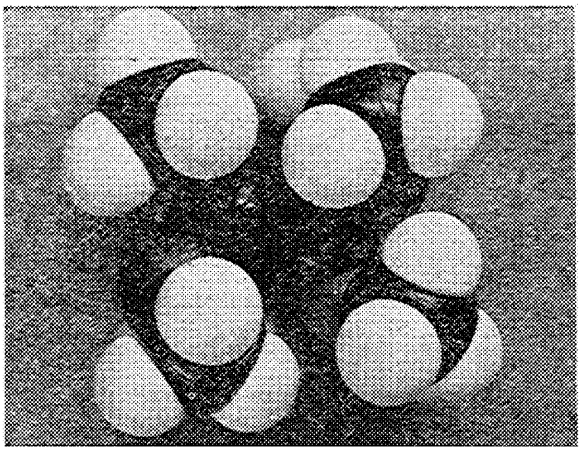
Discussion

As TMAE and TMBI have very interesting properties, both chemically and physically, it seemed to be a challenging problem to seek for organic molecules having still lower ionization potentials. As the results show, this trial has failed so far: All molecules dealt with in this paper have I_p's higher than that of TMAE. Here, we wish to give some criteria for the conditions which can lower the I_p of a molecule based on the present results, as well as those already obtained.

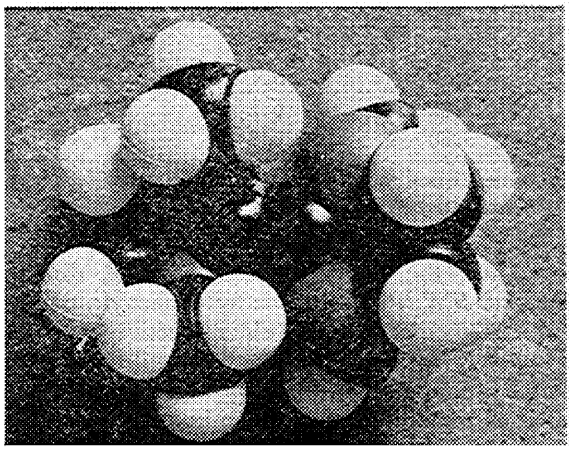
It is well known that, for aromatics and conjugated polyenes, the I_p's become lower with the length of conjugated chain. It is also known that the I_p gets lower, the more amino groups, or preferably dimethylamino groups, are substituted in the conjugated molecules. Thus, the I_p's of benzene, aniline, dimethylaniline, and *N,N,N',N'*-tetramethyl-*p*-phenylenediamine are 9.24, 7.70, 7.14 and 6.20 eV, respectively.[1,14] The lowering of I_p by conjugation is attributed to an increased stabilization of the cations. The effect of amino group is of course due to the non-bonding electrons in the nitrogen atom having itself a low I_p. The effect of methyl substitution, more generally speaking, alkyl substitution, has been attributed to the inductive, or hyperconjugative effect of the substituent. However, we propose another view that the steric repulsion of an alkyl group toward the nitrogen non-bonding electrons might be a reason.

In the case of TMAE, as an example, the four dimethylamino groups are believed to lie nearly perpendicular to the $N_2C{=}CN_2$ plane of the molecule.[1] In this molecule, therefore, the nitrogen lone pairs can hardly conjugate with the π-electrons of the ethylene bond. In TMBI, on the other hand, the nitrogen lone pair orbitals are thought to be nearly parallel to the latter. From these facts, it can be asserted that the conjugational effect will lower the I_p of TMBI compared to TMAE. The fact that the I_p of TMAE is quite low, even lower than that of TMBI seems to be attributable to the large steric repulsion of methyl electrons toward the nitrogen lone pair; in other words, due to the extremely large crowding of the methyl groups aronnd each N atom as is seen clearly from the structure model of TMAE (Fig. 4). These steric repulsions certainly destabilize the nitrogen lone pair electrons in the molecule, leading to the lowering of I_p. On the other hand, the less steric repulsion and the more conjugational effect cansel each other in TMBI, leading to an I_p accidentally almost equal to that of TMAE.

In the present results, the I_p of TMAB (tetrakis-(dimethylamino)butadiene) is found to be slightly



(A)



(B)

Fig. 4. The molecular models of TMAE (A) and TMBI (B).

higher than that of TMAE ($I_p^{adiabatic}$ 5.36, $I_p^{vertical}$ 6.11 eV). This can also be explained in a similar way: Increased conjugated chain length and less crowding around N atoms. In TMAE, the direct repulsion between the N lone pairs might also be responsible for lowering the I_p.[1)]

The sulfur atom included in a conjugated system is also regarded to be a factor to lower the I_p, because of its non-bonding pair with a relatively low I_p. It is significant that DMBT has an I_p comparable to that of TMAE.

Unexpectedly low I_p's for both dispiro[2.2.2.2]deca-4,9-diene and $(C_p)_2WH_2$ are obtained. The I_p of $(C_p)_2WH_2$ was reported to be $\sim$7000 cm^{-1} lower than that of dimethylaniline from their charge transfer absorption bands with several olefins as the common acceptors, being $\sim$6.3 eV, which is in good agreement with the value obtained in this work.

The I_p of dimethylphenylphosphine is higher than that of dimethylaniline(7.14 eV). It was also reported that the I_p of triphenylphosphine was higher than that of triphenylamine.[14)] From these results, it seems that the substitution of the N atom of amino compounds by the P atom is generally ineffective to lower the I_p's.

The I_p's of chlorophyll a and β-carotene obtained here are probably the first reliable ones ever observed. The present method can be applied to other biologically important compounds. The main error seems to originate from the calculation of $S_B(M^+)$ by the use of the Born equation. It seems likely that the Born equation is a good approximation in non-polar solvents, but the calculation of radius a for the solute molecule is somewhat erroneous because of its non-spherical shape(see Appendix). It should, however, be noted that as the radius becomes larger, $S_B(M^+)$ becomes smaller and so does the error. For example, the values of $S_B(M^+)$ are 1.2, 1.0 and 0.9 eV at a=3, 3.5 and 4 Å, respectively. Therefore, the error estimated seems to be 0.2 eV at most.

Appendix

To apply Born equation to a non-spherical molecular ion, an appropriate average radius must be given from the molecular geometry. Let us consider tetramethyl-*p*-phenylenediamine (TMPD) as an example. The molecular shape is approximated as illustrated in Fig. 5. The average radius a was calculated by using the following equation,

$$1/a = \sum_i (1/r_i) \cdot (\Delta S_i \cdot \cos\theta_i / 4\pi r_i^2) \quad (5)$$

where ΔS_i is, as shown in Fig. 5, a fraction of the surface of the molecule, taken appropriately so that the distance between the center of the molecule, 0, and any point on that fraction of the surface does not change largely from an average distance r_i set up for each of the fractions ΔS_i, and θ_i is the angle between r_i and the normal to the plane of ΔS_i. The summation is made over all the surface area. The calculations of a for other compounds have been made in a similar way.

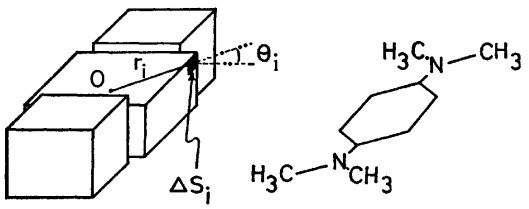


Fig. 5. The molecular shape of TMPD used to calculate the radius a.

The above method can be rationalized by the following argument: Let us consider a non-spherical molecular ion with a center of symmetry, existing in a dielectric medium. By taking dS a planar element of molecular surface, r the distance between the surface element and the center of the molecule and θ the angle between r and the normal to the plane of dS, the element of solid angle, dΩ, is given as follows.

$$d\Omega = dS \cdot \cos\theta / r^2 \quad (6)$$

Under the assumption that the electric charge of the molecular ion, e, is located at its center, the ion-medium electrostatic interaction energy within the region of this elemental solid angle can be expressed as

$$(e^2/2r) \cdot (1 - 1/\varepsilon) \cdot (d\Omega/4\pi)$$

where ε is the dielectric constant of the medium. The total interaction energy is obtained by integrating the above expression,

$$(e^2/2) \cdot (1 - 1/\varepsilon) \cdot \int (1/r)(d\Omega/4\pi) \quad (7)$$

Equation 5 can be regarded as approximating the integral part of Eq. 7 by a summation, and taking it to be $1/a$ so as to make the energy expressed by the Born equation.

The authors wish to thank Professors A. Nakamura and S. Otsuka, and Professors T. Tsuji and S. Nishida for providing $(C_p)_2WH_2$ and dispiro[2.2.2.2]deca-4,9-diene, respectively. We wish also to thank Mr. T. Ohnishi for his assistance in experiment.

The Microwave Spectrum, the r_s Structure and the Dipole Moment of the *TT* Isomer of Diethyl Ether

Michiro HAYASHI and Kazunori KUWADA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-sendamachi, Hiroshima 730

(Received June 27, 1974)

The microwave spectra of six isotopic species of diethyl ether were measured in relation to the molecular form and dipole moment. Transitions of the *TT* (*trans-trans*) isomer could be assigned and the r_s structure of this isomer was obtained by the substitution method. The structural parameters of the *TT* isomer of diethyl ether are; r(CO) 1.408 Å, r(CC) 1.516 Å; α(COC) 112°25′, α(OCC) 108°37′ for the skeleton; r(CH) 1.093 Å, α(CCH) 110°11′, α(OCH) 110°10′, α(HCH) 107°29′ for the CH_2 group and r(CH) 1.090 Å, α(CCH_s) 110°35′, α(CCH_a) 110°15′, α(H_sCH_a) 108°48′, α(H_aCH_a) 108°4′ for the CH_3 group. The dipole moment was determined to be 1.061±0.018 D from the Stark effect measurement for the *TT* isomer. A discussion was made on the structure and the dipole moment of the *TT* isomer of diethyl ether in comparison with those of the similar molecules.

Infrared and Raman spectra of diethyl ether were extensively studied by several authors.[1] They reported that at least two rotational isomers existed in the gaseous and liquid states, one of which was presumably in th *trans-trans* form (the *TT* form).

We measured the microwave spectra of diethyl ether in order to confirm the molecular forms of the isomers. As was already reported in a previous note,[2] the microwave spectra of the *TT* isomer of the normal species of diethyl ether were easily assigned, though the spectra were not so strong and their Stark patterns were not clearly resolved. The measurements were extended to its five isotopic species and the r_s structure of the *TT* isomer could be determined by the substitution method.

The dipole moment of this isomer was determined by the Stark effect measurements of the spectra.

We found very many weak spectra all over the frequency region, which may belong to other isomers. However, they are so complicated that the analysis was abandoned for them.

In the present paper, the r_s structure and the dipole moment of the *TT* isomer of diethyl ether will be given and discussed in comparison with those of the similar molecules such as dimethyl ether and ethyl halides.

Experimental

A commercial product was used for the normal species of diethyl ether. One of the deuterated species ($CH_3CHDOEt$) was prepared by the reaction of a mixture of acetaldehyde and ethanol with hydrogen chloride followed by the reduction of the resultant $CH_3CHClOEt$ with $LiAlD_4$ in *n*-butyl ether.[3] The other deuterated species (CH_2DCH_2OEt) was prepared by the Williamson method, *i.e.*, by treating sodium ethoxide with CH_2DCH_2Br which was prepared by the reaction of ethylene and DBr with $AlBr_3$ as a catalyst.[4] The ^{13}C species were prepared by the Williamson method using $^{13}CH_3CH_2I$ and $CH_3{}^{13}CH_2I$ (90 atom% ^{13}C, Merck Sharp & Dohme, Canada), respectively.

The microwave spectra were measured in the region from 8500 to 34000 MHz with conventional sinusoidal- and square-wave Stark modulation spectrometers at the temperature of dry ice.

The r_s Structure

The *b*-type transition are expected for the *TT* isomer of diethyl ether. The observed transition frequencies with $J \leqq 10$ are shown in Table 1.

The rotational constants were determined by the least-squares technique from all the observed frequencies in the table so as to fit in with a modified rigid rotor expression which was including only the $D_J(J(J+1))^2$ term of the centrifugal distortion contributions. The rotational constants and the moments of inertia are in Table 2. The quantities $P_c(=(I_a+I_b-I_c)/2)$ and and $\Delta P_c(=P_c(\text{isotopic})-P_c(\text{parent}))$ in the table are quite reasonable when comparing with the reported values of other molecules.[5]

Since the moments of inertia in the ground state are available for the normal and each of its singly substituted isotopic species, it is possible to calculate the coordinates of each atom directly from Kraitchman's equations[6] except the x_b coordinate of the oxygen atom which can be solved by the use of the first moment equation. However, the x_b coordinate of the in-plane hydrogen (H_s) is small so that zero-point energy contributions of the vibrations to $\Delta I_a(=I_a(\text{isotopic})-I_a(\text{parent}))$ reduce the reliability of the calculated value from Kraitchman's equation for the x_b coordinate. On the other hand, all the coordinates for the out-of-plane hydrogen (H_a) and the x_a coordinate for the H_s atom are large and Karitchman's equations reliably fix their values. Thus one assumption is required to completely determine the structure of the *TT* isomer from the present data. We chose to assume the CH_a and CH_s bond distances to be equal.

Table 3 lists the coordinates of each atom of the *TT* isomer of diethyl ether. The moments of inertia as calculated from the coordinates are compared with the experimental moments of inertia as shown in Table 2. The deviations $\delta I_g(=I_g(\text{obsd})-I_g(\text{calcd}))$ are sizable and always positive, but this is to be expected for the r_s structure.

The structural parameters as derived from the coordinates are shown in Table 3. The assumption imposed on the CH bond distances of the methyl group has little influence on the structural parameters except $r(CH_s)$ and $\alpha(H_sCC)$. That is, the x_b coordinate of the H_s atom calculated directly from Kraitchman's equation is 0.2020±0.0053 Å which gives the value of −0.2576±0.0023 Å for the x_b coordinate of the oxygen atom. These values give the parameters of 1.409±0.003 Å, 112°13′±16′, 108°31′±10′, 110°13′± 20′ and 109°20′±30′ for r(CO), α(COC), α(OCC),

CH_3 group		CH_2 group		Skeleton	
$r(CH_s)$	1.090 Å (0.004)	r(CH)	1.093 Å (0.003)	r(CO)	1.408 Å (0.002)
$r(CH_a)$	1.090 Å (0.004)	α(CCH)	110°11′ (19′)	r(CC)	1.516 Å (0.003)
$\alpha(CCH_s)$	110°35′ (19′)	α(OCH)	110°10′ (19′)	α(COC)	112°25′ (16′)
$\alpha(CCH_a)$	110°15′ (19′)	α(HCH)	107°29′ (32′)	α(OCC)	108°37′ (10′)
$\alpha(H_sCH_a)$	108°48′ (37′)				
$\alpha(H_aCH_a)$	108° 4′ (33′)				

a) The figures in parentheses indicate the 99% reliability intervals. b) Calculated by the use of the first moment equation from the x_b coordinaties of the other atoms. c) Calculated from the x_a coordinate of the H_s atom and the coordinates of the C and H_a atoms, assuming that $r(CH_s)=r(CH_a)$.

Table 4. The Stark coefficients of the *TT* isomer of diethyl ether

Transition	$\Delta\nu/E^2$ [$\times 10^{-4}$ MHz/(V/cm)^2]	
	Obsd	Calcd
$1_{10} \leftarrow 1_{11}$ $M=1$	0.399±0.006	0.395
$2_{11} \leftarrow 2_{02}$ $M=2$	0.469±0.007	0.463
$3_{12} \leftarrow 3_{03}$ $M=3$	0.498±0.010	0.492
$2_{12} \leftarrow 1_{01}$ $M=1$	0.626±0.020	0.633
$3_{13} \leftarrow 2_{01}$ $M=0$	−0.308±0.010	−0.329
	$\mu=1.061\pm0.018$D	

α(OCH) and $\alpha(H_sCH_a)$, respectively. They are essentially equal to those given in Table 3 within the experimental error limit. On the other hand, the values of 1.103±0.004 Å and 109°32′±17′ are obtained for $r(CH_s)$ and $\alpha(H_sCC)$. However, an asymmetric CH_3 structure derived from these values is less believable than the nearly symmetric CH_3 structure given in Table 3.

Dipole Moment

The dipole moment of the *TT* isomer of diethyl ether was quantitatively determined by Stark-effect measurements of five transitions for the normal species. The spectrometer was calibrated with OCS[7] before and after measurements on diethyl ether.

For the *TT* isomer, the dipole moment has to be parallel to the b-inertial axis from the symmetry. The observed and calculated Stark coefficients[8] are shown in Table 4. By the least-squares technique, the dipole moment was determined to be $\mu=1.061\pm0.018$ D. A value of 1.16 D based on dielectric constant measurements was reported in the literature.[9]

Discussion

A comparison of the r_s structure of the *TT* isomer of diethyl ether with that of *trans*-ethyl alcohol is of primary interest. Unfortunately, this is impossible at present, since the reported structure of *trans*-ethyl alcohol is not the r_s structure but the r_0 structure obtained with several assumptions.[10]

However, a comparison is possible with those of the molecules, of which the r_s structures were reported in the literatures. First, the CO bond distance of the *TT* isomer is essentially equal to that of dimethyl ether[11] while the COC angle is slightly larger than that of dimethyl ether. Second, the CC bond distance is about 0.01 Å shorter than that of propane,[12] slightly shorter than those of ethyl chloride[13] and bromide[14] and about 0.01 Å longer than that of ethyl fluoride,[15] though it is difficult to interprete the significance of this fact.

Third, and most noticeable, both the CCO and HCH angles of the CH_2 group for the *TT* isomer are abnormally smaller than tetrahedral. This anomalous feature of the angles of the CH_2 group may be explained by the tilted ethyl group towards the lone pair electrons of the oxygen atom in the similar manner as the tilted methyl group in dimethyl ether.[11,16]

The dipole moment of the *TT* isomer of diethyl ether is 1.061 D which is smaller than that of dimethyl ether (1.310 D).[11] From the observed dipole moments, the apparent bond moment on the CO bond can be calculated to be 1.167 and 0.952 D for dimethyl ether and diethyl ether, respectively. The decrease of the apparent bond moment for diethyl ether may be interpreted as due to the induction effect[17] of the CO bond moment on the CC bond.

Apparent Dipole Moments and Dielectric Relaxation Times of 1,4-Benzoquinone and Its Derivatives in Solutions

Tohru NAGAI, Hiroaki TAKAHASHI, and Keniti HIGASI*
Department of Chemistry, Waseda University, Shinjuku, Tokyo 160
Leslie E. SUTTON and David WADDINGTON
Physical Chemistry Laboratory, South Parks Road, Oxford, England
(Received August 27, 1974)

Atom polarisations, apparent dipole moments and dielectric relaxation times of 1,4-benzoquinone in various solvents were determined together with those of some of its derivatives in benzene solution. Solvent effects on the apparent dipole moments of 1,4-benzoquinone and its derivatives were examined in comparison with the absorption spectra in the submillimetre region.

In spite of the observation that 1,4-benzoquinone has a centre of symmetry[1] it has been shown to exhibit an apparent permanent dipole moment of appreciable magnitude, 0.67 D, in solution.[2] The observed large dipole moment could be due solely to an exceptionally large atom polarisation[3] if there were no solute-solvent interaction.[4] The observations of polarisation in the vapour phase[3] show that the latter is not a major cause of the apparent moment.

First, in the present work a new determination of the atom polarisation was made for 1,4-benzoquinone by dielectric measurements at an extremely high frequency (96.52 GHz, 3.219 cm^{-1}). The experimental atom polarisation thus obtained was compared with the values calculated by Waddington *et al.*[5] from its absorption spectrum over the whole infrared range.

Secondly, the nature of solute-solvent interaction was investigated by measuring apparent dipole moments and relaxation times of 1,4-benzoquinone in a variety of solvents.

Thirdly, not only 1,4-benzoquinone (A), but also its derivatives, 2,5-dimethyl-1,4-benzoquinone (B), 2,5-dichloro-1,4-benzoquinone (C) and 2,5-di-*tert*-butyl-1,4-benzoquinone (D) were studied using the same procedure.

Experimental

By use of the apparatus and techniques described previously[6] dielectric and optical measurements were carried out at the frequencies 1 MHz, 96.52 GHz and that the Na–D line. The real and unreal dielectric constants ε' and ε'' of the dilute solutions measured at 96.52 GHz are assumed to be linear with the concentration (weight fraction w_2) of the solute.

$$\varepsilon' = \varepsilon_1' + a'w_2 \qquad \varepsilon'' = \varepsilon_1'' + a''w_2 \tag{1}$$

in which subscripts 1 and 2 refer to the pure solvent and to the solute, respectively. Similarly the dielectric constant at any frequency (including the static one, ε_0, and the high frequency limiting value, ε_∞), the squares of refractive indices n_D^2 and the specific volumes v are also assumed to be linear with the concentration.†

$$\varepsilon_0 = \varepsilon_{10} + a_0w_2, \quad \varepsilon_\infty = \varepsilon_{1\infty} + a_\infty w_2 \qquad n_D^2 = n_{1D}^2 + a_D w_2, \quad v = v_1 + bw_2 \tag{2}$$

The total, *i.e.*, low frequency molecular polarisation of the solute at infinite dilution was obtained from the Halverstadt-Kumler equation.[7]

$$P_2 = M_2\left\{\frac{3a_0v_1}{(\varepsilon_{10}+2)^2} + (v_1+b)\frac{\varepsilon_{10}-1}{\varepsilon_{10}+2}\right\} \tag{3}$$

in which M_2 is the molecular weight of the solute. The distortion polarisation P_E+P_A is, in principle, obtainable using a_∞ and $\varepsilon_{1\infty}$ instead of a_0 and ε_{10} in Eq. (3), respectively.[8] The difference $\varepsilon_1'-\varepsilon_{1\infty}$ expresses the effect of dispersion in the microwave region.

$$P_A + P_E = M_2\left\{\frac{3a_\infty v_1}{(\varepsilon_{1\infty}+2)^2} + (v_1+b)\frac{\varepsilon_{1\infty}-1}{\varepsilon_{1\infty}+2}\right\} \tag{4}$$

Similarly, by use of n_{1D}^2 and a_D the molar refraction for the D-line is given by

$$R_D = M_2\left\{\frac{3a_Dv_1}{(n_{1D}^2+2)^2} + (v_1+b)\frac{n_{1D}^2-1}{n_{1D}^2+2}\right\} \tag{5}$$

If the system under consideration is characterized by a single Debye dispersion, then the relaxation time will be obtained from either of the following two equations[9]

$$\tau = \frac{1}{\omega}\frac{a''}{a'-a_\infty} \equiv \tau(1) \tag{6}$$

$$\tau = \frac{1}{\omega}\frac{a_0-a'}{a''} \equiv \tau(2) \tag{7}$$

where ω is the frequency of observation. The limiting value a_∞ is obtainable from Eqs. (6) and (7).

$$a_\infty = a' - \frac{(a'')^2}{a_0-a'} \equiv a_G \tag{8}$$

It is impossible to determine a_∞ experimentally on the basis of Eq. (8) because of other extra dispersions; however, we shall assume tentatively that a_G evaluated from the a' and a'' at a very high frequency (96.52 GHz) would approximate to a_∞. On the basis of the above assumption Eq. (4) can be

* Visiting scientist at the University of Oxford from July to September, 1972, by agreement with the Royal Society, London, the Japan Academy, the Science Council of Japan and the Japan Society for the Promotion of Science.

† The parameter a_∞ in Eq. (2) will be discussed later (see Eq. (8)).

Solute: (A) 1,4-benzoquinone, (B) 2,5-dimethyl-1,4-benzoquinone, (C) 2,5-dichloro-1,4-benzoquinone and (D) 2,5-di-*tert*-butyl-1,4-benzoquinone.

Solvent: [Bz] benzene, [Xy] *p*-xylene, [M] mesitylene, [Dx] dioxan, [CCl_4] carbon tetrachloride, [Hx] *n*-hexane, [Hp] *n*-heptane and [CHx] cyclohexane.

a) The errors in P_2 and R_D are all about ± 0.2 cm^3.

rewritten by using a_G and ε_1' instead of a_∞ and $\varepsilon_{1\infty}$, respectively.[8]

$$(P_E+P_A)_G = M_2\left\{\frac{3a_G v_1}{(\varepsilon_1'+2)^2} + (v_1+b)\frac{\varepsilon_1'-1}{\varepsilon_1'+2}\right\} \quad (9)$$

All the compounds used in this study were obtained from commercial sources. Purchased materials of the best grade were purified by repeated recrystallization from benzene. The melting points of the purified samples were: 1,4-benzoquinone 113 °C, 2,5-dimethyl-1,4-benzoquinone 123 °C 2,5-dichloro-1,4-benzoquinone 160 °C, and 2,5-di-*tert*-butyl-1,4-benzoquinone 150 °C. Solvents: benzene, *p*-xylene, mesitylene, dioxan, carbon tetrachloride, *n*-hexane, *n*-heptane, and cyclohexane of the best grade were carefully purified by distillation before the dielectric measurements.

Results and Discussion

Atom Polarisation. In Table 1 are given several observed basic parameters and the polarisations derived therefrom. Five parameters are slopes a_0(static), a', a'' (96.52 GHz), a_D(optical) and b(volume) obtained from three to four dilute solutions for each solute by use of Eqs. (1) and (2) and the remaining a_G is evaluated from a', a'' and a_0 using Eq. (8). Three polarisations P_2, $(P_E+P_A)_G$ and R_D are calculated from a_0 and Eq. (3), from a_G and Eq. (9) and from a_D and Eq. (5), respectively.

In Table 2 are given three atom polarisations. P_A(exp) is obtained as $(P_E+P_A)_G-R_D$. This procedure for evaluating P_A(exp) has two sources of error. One is that $(P_E+P_A)_G$ is not necessarily equal to P_E+P_A. This is because a_G and ε_1' would differ from a_∞ and $\varepsilon_{1\infty}$, respectively. We may safely assume $\varepsilon_1' \simeq \varepsilon_{1\infty}$ for non-polar solvents; but sometimes a_G appears to be slightly larger than the probable a_∞ values. For instance, $(P_E+P_A)_G$ would be larger than the true distortion polarisation, if it included some of the effects of dipole relaxation, *e.g.*, alkyl acetates.[10]

The other source of error is that R_D is not equal to the electron polarisation P_E at 96.52 GHz which we really want to have. Again R_D is usually slightly larger than P_E at zero frequency, *e.g.*, 1.1—1.4 cm^3 for halobenzenes.[11] However, $(P_E+P_A)_G-R_D$ is probably a good estimate of P_A. P_A(exp) compares well with P_A(calc) calculated from the absorption spectra by Waddington *et al.*[5]

The radio-visible polarisation difference P_2-R_D is found to be larger than P_A(exp) since P_2 represents a total polarisation, *i.e.*, the sum of any orientation polarisation plus the distortion polarisation.

Molar Polarisation P_2 in Various Media. The $(P_E+P_A)_G$ values recorded in Table 1 for 1,4-benzoquinone are almost equal to the P_2 value observed in the vapour phase by Coop and Sutton.[3] This indicates that the $(P_E+P_A)_G$ values are not appreciably affected by solute-solvent interactions.

$(P_E+P_A)_G$ values could not be observed for the relatively dilute solutions which were all that could be obtained in *n*-hexane, *n*-heptane and cyclohexane; but for these the P_2 values (36.0 to 36.8 cm^3) observed at radio frequencies are also equal to the vapour phase value of P_2 (36.55 cm^3) within the limit of experimental error.†† Consequently the dipole moments of 1,4-benzoquinone in these solvents may be taken to be zero.

In solutions of 1,4-benzoquinone in the aromatic solvents, in carbon tetrachloride and in 1,4-dioxan, P_2 is 1—2 cm^3 greater than $(P_E+P_A)_G$. Moreover, a_0 is greater than a_G and a Cole-Cole dispersion seems to exist (Fig. 1). These facts suggest that 1,4-benzoquinone becomes slightly polar in benzene and possibly

†† Recently John Haigh[12] obtained $P_2=36.99\pm0.5$ cm^3 at 29.7 cm^{-1} in benzene which is slightly larger than $(P_E+P_A)_G=36.6\pm0.5$ cm^3 deduced at 3.22 cm^{-1} (96.52 Hz). From the observed absorption peak at 110 cm^{-1} of 1,4-benzoquinone in CCl_4 the fall of polarisation from its maximum situated at about 96 cm^{-1} is expected to occur on both sides of the frequency. Using the Kramers-Kronig relation we calculated the polarisation for the submillimetre region. The results corrected to Haigh's value at 29.7 cm^{-1} are the following: $P(cm^3)/\bar{\nu}(cm^{-1})$ 36.5/0; 36.99/29.7; 37.2/50; 40.8/90; 41.8/96; 41.1/100; 25.4/112; 14.2/120; 21.1/150; 25.2/200.

in other solvents of this group.

Dipole Moments and Relaxation Times. In Table 3 dipole moments and relaxation times for 1,4-benzoquinone and its derivatives in solutions are collected. In this table dipole moments μ were obtained from the following equation,

$$\mu(\mathrm{D}) = 0.0128\sqrt{\{P_2-(P_E+P_A)_G\}T} \qquad (10)$$

where T is the absolute temperature; and the relaxation time $\tau(2)$ is obtained from a' and a'' for $\omega=2\pi(9.652)\times 10^{10}$ and a_0(static) on the basis of Eq. (7). All the $\tau(2)$ values are much smaller than would be expected for the rotation of a dipolar molecule the size of 1,4-benzoquinone. According to Crump and Price,[4] following Anderson and Smyth,[13] the polarity arises from complex formation between molecules of 1,4-benzoquinone (electron acceptor) and solvent (electron donor); and $\tau(2)$ is controlled by the lifetime of the complex, not by the time of rotation of a long-lived dipole. The accuracy of measurement of the moments of the complexes hardly warrants any attempt to correlate them with the base strengths of the solvents; and much the same applies to the relaxation times $\tau(2)$.

Far Infrared Absorption. The effects of solvents upon the submillimetre wave absorption of 1,4-benzoquinone, previously shown by Waddington *et al.*[5] to be a bending mode, are very striking. Two features are immediately apparent. Shifts occur to higher frequencies (so-called blue shifts) and are large. An attempt was made to study the dependence of absorption

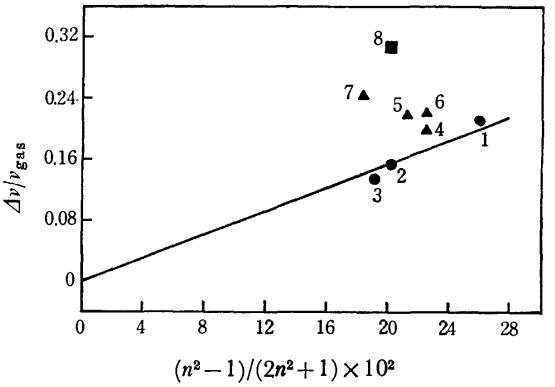

Fig. 2. Solvent dependence of the far-infrared absorption band of 1,4-benzoquinone.
Solvents: 1 carbon disulphide, 2 cyclohexane, 3 *n*-heptane, 4 benzene, 5 carbon tetrachloride, 6 mesitylene, 7 hexafluorobenzene and 8 dioxan.

frequencies upon solvents on the basis of the simple electrostatic treatment given by Kirkwood[14] and by Bauer and Magat.[15] Their model imagines a polar oscillating molecule placed at the centre of a spherical cavity in a continuous dielectric medium of refractive index n. Charges are set up on the walls of the cavity and produce an electric field which reduces the effective force constant of the molecule. The model leads to the equation;

$$\frac{\bar{\nu}_{vap}-\bar{\nu}}{\bar{\nu}_{vap}} = C\frac{(n^2-1)}{(2n^2+1)} \qquad (11)$$

in which C is a positive constant and so allows only the prediction of "red" shifts and cannot explain the observations reported here. If, however, the above equation can be used even when C is negative then a plot of $(\bar{\nu}_{vap}-\bar{\nu})/\bar{\nu}_{vap}$ against $(n^2-1)/(2n^2+1)$ allows us to classify the observations into three groups(Fig. 2). The explanation of the observed frequency increases probably is that the solvent molecules enclathrate and hem in the vibrating solute molecules thus making it more difficult for the quinone molecule to bend. The effectiveness of this process would be expected to increase with increasing solvent-solute attraction. It is hence not unreasonable to suppose that deviation from a linear relationship between the relative shift in the bending frequency $(\bar{\nu}_{vap}-\bar{\nu})/\bar{\nu}_{vap}$ and a function of the dielectric constant of the solvent such as $(n^2-1)/(2n^2+1)$ would indicate the presence of special solvent-solute attractions. These attractions are likely to be due to the solvents behaving as weak electron donors to the 1,4-benzoquinone. The results may be classified into three groups. The *first* group consists of carbon disulphide, cyclohexane, and *n*-heptane the points for which lie on a straight line passing through the gas phase point. This may indicate an interaction due to polarisation of the solvent by the double dipole field of the solute. Deviations from this straight line are observed in the *second* group; benzene, carbon tetrachloride, mesitylene and hexafluorobenzene; and especially in the *third* group; dioxan. These may indicate specific hyperpolarisation which is much the same as donor-acceptor interaction. Hexafluoroben-

Table 3. Dipole moments and relaxation times at 25° C

Solute	Solvent	μ(D)	τ(2)(ps)
(A)	Benzene	0.24	1.76
	p-Xylene	0.28	2.37
	Mesitylene	0.29	2.50
	Dioxan	0.25	1.39
	CCl_4	0.27	2.33
(B)	Benzene	0.36	8.26
(C)	Benzene	0.36	5.25
(D)	Benzene	0.43	3.49

zene is not normally regarded as an electron donor but rather as an electron acceptor. However, it seems possible that the carbonyl groups in 1,4-benzoquinone can act as electron donors to strong electron acceptors.

From an examination of the dielectric data no significant difference was noticed between the *second* and *third* groups and small but finite dipole moments of 0.24—0.29D are observed in these cases (Table 3) whilst the molecules belonging to the *first* group have no dipole moment. This would imply that no interaction of the donor-acceptor type occurs with the molecules of the *first* group.

Concluding Remarks

The following conclusions are reached from the present investigation.

1) 1,4-Benzoquinone is non-polar in the free state.

2) Polarity is produced when 1,4-benzoquinone is transferred from the gaseous phase into solutions in certain solvents such as benzene, dioxan, and carbon tetrachloride.

3) From dipole moments and dielectric relaxation times the above polarity is considered as due not to a conventional permanent dipole moment, but rather as due to some other cause such as the production of short-lived donor-acceptor complexes.

Hydrate Crystals of Alkali Metal-Chloranil and -Bromanil Salts and Their Optical and Magnetic Properties

Shoji HIROMA and Haruo KURODA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received August 28, 1974)

The potassium-chloranil ($K^+ \cdot CA^-$), sodium-chloranil ($Na^+ \cdot CA^-$) and sodium-bromanil ($Na^+ \cdot BA^-$) salts were found to form hydrates when their crystalline powders are exposed to a humid air. In the single crystal spectrum of $K^+ \cdot CA^-$, the charge-transfer band significantly increased its intensity on hydration, exhibiting the same polarization as in the spectrum of the water-free state. It was concluded that CA^- ions in the hydrate crystal are closely stacked on each other to form columns as in the water-free crystal and the charge transfer interaction between CA^- ions is stronger in the hydrate crystal than in the water-free crystal. The spin concentration of $K^+ \cdot CA^-$ markedly decreased on hydration, it being 2.2×10^{22} spins per mol in the state of hydrate while 5.5×10^{23} spins per mol in the water-free state. The hydration resulted in an increase of the intensity of charge-transfer band and a decrease of the spin concentration also in the cases of $Na^+ \cdot CA^-$ and $Na^+ \cdot BA^-$. It is also shown that organic solvents such as acetone, methy ethyl ketone and dichloromethane can enter into the crystal lattice of $K^+ \cdot CA^-$ to form the solvent-containing crystals.

The potassium-chloranil salt, $K^+ \cdot CA^-$, has been reported[1] to exhibit a phase transition in the temperature range, 210—270 K, where it changes from the low spin state to the high spin state. Since this type of phase transition is of general interest in connection with the electronic behaviors of organic radical salts, we investigated the changes of the electronic spectrum of the $K^+ \cdot CA^-$ crystal below and above the transition point by means of a microspectrophotometer equipped with a cryostat at the sample stage.[2] In the course of this investigation, we found that, at the room temperature, the crystal spectrum appreciably changed on pumping out the air from the cryostat, but the original spectrum was recovered when the atmospheric air was introduced. We have concluded that the above spectral change takes place because the $K^+ \cdot CA^-$ crystal absorbs water to be a hydrate when kept in the atmospheric air, but this hydrate easily loses water molecules when kept in vacuum.

In the solution, the chloranil anion is known to be quite unstable in the presence of water. In effect, we need to exclude water thoroughly from the solvent which is used in synthesizing the $K^+ \cdot CA^-$ salt. Therefore it has been generally believed that the $K^+ \cdot CA^-$ salt decomposes when exposed to a humid air. However, we found that this is not necessarily the case. The $K^+ \cdot CA^-$ salt does not decompose, but forms a hydrate in a humid air. We found also that the sodium-chloranil, $Na^+ \cdot CA^-$, and sodium-bromanil, $Na^+ \cdot BA^-$, have a much strong tendency to form hydrates when exposed to the atmospheric air, which are again not very much unstable. It was recently reported also by Tsuda *et al.* that the powder of $Na^+ \cdot CA^-$, obtained by the ordinary procedures of preparation, was in the state of hydrate.[3]

In the present paper, we will report the experimental evidences for the formation of the hydrates of $K^+ \cdot CA^-$, $Na^+ \cdot CA^-$ and $Na^+ \cdot BA^-$, and discuss some of the electronic properties of these hydrates.

Experimental

The crystalline powders of $K^+ \cdot CA^-$, $K^+ \cdot BA^-$, $Na^+ \cdot CA^-$ and $Na^+ \cdot BA^-$ were prepared according to the procedures reported by Torrey and Hunter,[4] by using acetone as the solvent. The water-free powders of these salts were obtained by drying the salt powders over phosphorus pentoxide in a vacuum desiccator (at about 10^{-3} Torr). The powder specimens of various water contents were obtained by exposing the synthesized powders of the salts to the air, with or without controlling the humidity, for different lengths of time.

The X-ray powder diffraction patters were obtained with an automatic recording X-ray diffractometer, Geigerflex (Rigaku Denki), employing CuK_α radiation.

We carried out the differential thermal analysis (DTA) or differential scanning calorimetry (DSC) simultaneously with the thermogravimetric analysis (TGA) by means of a Rigaku TG-DTA (DSC) apparatus with the heating rate, 2.5 °C/min. The powders of KNO_3 and NH_4NO_3 were used as the reference for determining the enthalpy change corresponding to an endothermic peak of a DTA (or DSC) curve.

The polarized absorption spectra of single crystals, in the wave number region from 8000 cm^{-1} to 38000 cm^{-1}, were measured with a microspectrophotometer, a modification of Olympus MSP-IV equipped with a cryostat at the sample stage.[5] The sample crystals of microscopic size were mounted on a thin quartz plate, and placed in the cryostat.

The ESR absorptions of the powder samples were measured at the room temperature with a JEOL-ME spectrometer (at 9.4 GHz). The spin concentration was determined from the integrated intensity by using DPPH as the reference.

The infrared spectra of the powder samples were measured by means of the Nujol mull method.

Results and Discussion

Characterization of the Hydrates. The infrared spectrum of the powder of $K^+ \cdot CA^-$ was found to vary depending on the treatment after the synthesis. The infrared spectra of the two typical cases are compared in Fig. 1(a): the spectrum I was obtained when the salt powder had been kept in the atmospheric air for a few hours after the synthesis, and the spectrum II was obtained when it had been dried in a vacuum desiccator containing silica gel as the desiccating agent. The spectrum I shows absorption bands at 3400, 1630 1000 cm^{-1} whereas these bands are missing in the spectrum II, and, at the same time, other bands of the former spectrum are a little shifted as compared with

the corresponding bands of the latter spectrum.

The infrared spectrum of $K^+ \cdot CA^-$ was previously studied by Iida[6] and by Girlando *et al.*[7] The spectrum II of Fig. 1(a) coincides with the results reported by these authors, and all absorption bands in this spectrum are assignable to the vibrational modes due to the CA^- ion. On the other hand, the 3400, 1630 and 1000 cm^{-1} bands of the spectrum I can be attributed neither to the CA^- ion nor to the neutral molecule of chloranil. It is also hard to find any chemical species that could be responsible for these bands among the possible decomposition products of the CA^- ion. The above bands disappeared when the powder that had given the spectrum I, was dried in a vacuum desiccator. Conversely, the corresponding bands appeared when we exposed the powder that had given the spectrum II, to the atmospheric air for a few hours. The processes described above were comfirmed to be well reversible, and, as we will describe later, we concluded that the spectrum I corresponds to the water-containing state of $K^+ \cdot CA^-$ while the spectrum II to the water-free state.

A similar change of infrared spectrum was observed on the $Na^+ \cdot CA^-$ salt. The infrared spectrum of the $Na^+ \cdot CA^-$ powder which had been kept in the atmospheric air, is shown in Fig. 1(b) as the spectrum I.[8] This is very much similar to the spectrum of the water-containing powder of $K^+ \cdot CA^-$ (spectrum I of Fig. 1(a)), exhibiting absorption bands at 3400, 1630, and 1000 cm^{-1}. In this case, however, the above three bands did not disappear even if we kept the powder in a vacuum desiccator for a week with silica gel, although their intensities were reduced to some extent after the above treatment. The spectrum II of Fig. 1(b) is the one obtained of the powder that had been heated to 120 °C in the ordinary atmosphere. The same spectrum was obtained with a sample which had been dried well over phosphorus pentoxide. These spectra are free from the 3400, 1630 and 1000 cm^{-1} bands, and almost the same as the infrared spectrum of the water-free powder of $K^+ \cdot CA^-$.

In Fig. 1(c), we show the spectrum of the $Na^+ \cdot BA^-$ powder which had been kept in the atmospheric air (spectrum I), and that of the powder which had been heated to 120 °C (spectrum II).[9] As we compare these two spectra, we can see that the former exhibits absorption bands at 3400, 1630 and 940 cm^{-1} while these bands can not be found in the latter. We can consider that the former is the spectrum of the water-containing state of $Na^+ \cdot BA^-$. Interestingly, no indication of the formation of the water-containing state was found in the case of $K^+ \cdot BA^-$. The $K^+ \cdot BA^-$ powder always gave a spectrum nearly the same as that of the water-free powder of $Na^+ \cdot BA^-$. The observed spectrum was in good agreement with the spectrum of the $K^+ \cdot BA^-$ salt reported by Iida,[10] who showed that all observed bands are assignable to the vibrational modes of the BA^- ion.

As we have shown above, the infrared spectrum of the water-containing state is characterized by the presence of the three bands, at 3400, 1630 and 1000 cm^{-1} in the case of $K^+ \cdot CA^-$ and $Na^+ \cdot CA^-$ and at 3400, 1630 and 940 cm^{-1} in the case of $Na^+ \cdot BA^-$. Seemingly it is most reasonable to attribute these bands to the water molecules contained in the salt crystals. A free water molecule is known to have three vibrational modes: the symmetric and antisymmetric stretching vibrations, at 3657 and 3756 cm^{-1} respectively, and the H–O–H bending vibration at 1595 cm^{-1}. Naturally, the infrared absorption bands associated with these vibrational modes are broadened and shifted when the water molecule is contained in the crystal lattice of a salt. In effect, it was reported that the crystals of inorganic hydrates usually show a broad infrared absorption band in the 3000—3500 cm^{-1} region, due to the O–H stretching vibration of water, and one in the 1600—1650 cm^{-1} region, due to the H–O–H bending vibration.[11] Therefore we can attribute the 3400

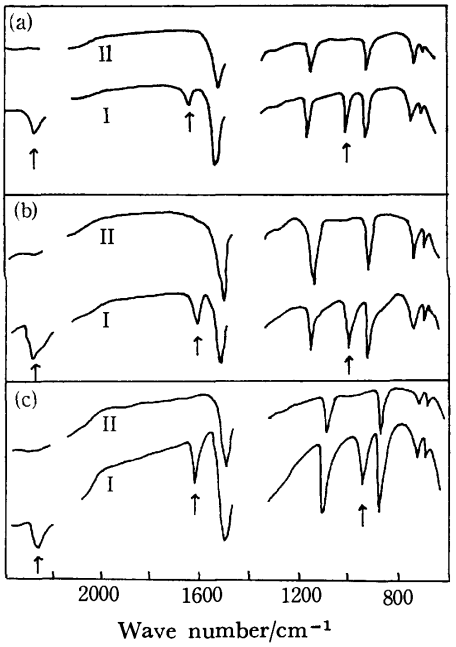

Fig. 1. Infrared spectra of the water-containing states (I) and the water-free states of the salts: (a) $K^+ \cdot CA^-$, (b) $Na^+ \cdot CA^-$ and (c) $Na^+ \cdot BA^-$.
The bands characteristic of the water-containing state are indicated with arrows.

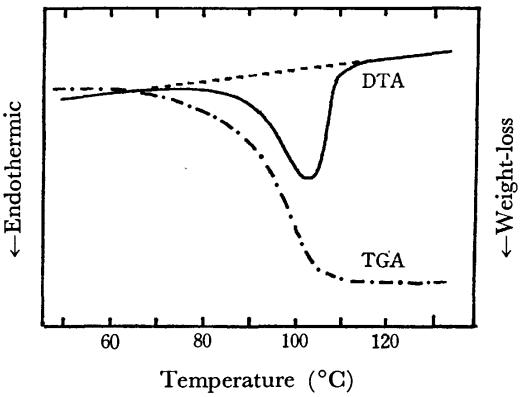

Fig. 2. Differential thermal analysis (DTA) curve and thermogravimetric analysis (TGA) curve of the $Na^+ \cdot BA^-$ powder which has been exposed to the atmospheric air.

and 1630 cm^{-1} bands which are commonly found in the infrared spectra of the water-containing powders of $K^+ \cdot CA^-$, $Na^+ \cdot CA^-$ and $Na^+ \cdot BA^-$, to the O-H stretching and H–O–H bending vibrations of water. There remains a question as regards the origin of the band at about 1000 cm^{-1}. In this connection, it is interesting to see that inorganic hydrates often exhibit infrared absorption bands in the 800—1000 cm^{-1} region, and these bands have been attributed to the librational motion of water molecule in the crystal lattice.[11] Presumably the 1000 cm^{-1} (or 940 cm^{-1}) bands of the present salts can be attributed to the same origin.

We have reproduced in Fig. 2 the DTA and TGA curves obtained of the $Na^+ \cdot BA^-$ powder which had been kept in the atmospheric air. The DTA curve exhibits an endothermic peak in the temperature region, 67—102 °C, where the TGA curve indicates that a weight loss is taking place. By means of the gas chromatography, we examined the chemical species coming out from the powder in the above endothermic process, and were able to confirm that it was entirly composed of water vapor. Similar results were obtained on the air-exposed powders of $K^+ \cdot CA^-$ and $Na^+ \cdot CA^-$, although the height and temperature range of the endothermic peak were different for different salts.

From the DTA-TGA (or DSC-TGA) experiments, we simultaneously determined for each powder sample enthalpy of dehydration and the amount of water per one mol of the salt. These values varied depending on the humidity of the atmosphere in which the powder had been kept and on the time length of keeping the powder in such an atmosphere. The mole ratio of water salt, found for the two typical conditions, are shown in Table 1, where "the normal state" means that the sample powder had been kept for one week in a vacuum desiccator(at about 10^{-3} Torr) containing silica gel, and "the highly-hydrated state" means that the sample powder had been exposed for two days to the air saturated with water vapor at the room temperature. Seemingly the latter corresponds to the state of the maximum water content. It is to be noted that the maximum water mole ratio is more than 6 in the case of $Na^+ \cdot BA^-$ whereas it seems to be about 3 in the cases of $K^+ \cdot CA^-$ and $Na^+ \cdot CA^-$.

In Figures 3(a)—(c), we have plotted the enthalpy of dehydration ΔH per one mol of the salt, against the water mol ratio, n. In the $K^+ \cdot CA^-$ salt, ΔH is proportional to n up to $n=2$, but ceases to increase when $n>2$. This relation between ΔH and n, suggests that there are some changes as regards the state of water molecules in the salt crystals when the water mole ratio exceeds 2. A similar relation between ΔH and n was observed on $Na^+ \cdot CA^-$, in which, although the slope of the ΔH *vs.* n curve changes at about $n=2$, ΔH is still increasing with a further increase of the water content. The enthalpy of dehydration per one mol of water corresponding to the initial linear region of the ΔH *vs.* n plot, was estimated as 11.0 and 14.0 kcal/mol for $K^+ \cdot CA^-$ and $Na^+ \cdot CA^-$ respectively.

The ΔH *vs.* n plot of the $Na^+ \cdot BA^-$ salt is significantly different from the above two salts. In this case, ΔH was found to be proportional to n in a wider range of water content, with the enthalpy of dehydration per one mol of water, 13.3 kcal/mol.

Table 1. Amount of water contained in the powder samples

Salt	Water mole ratio (water/salt)	
	Normal state[a]	Highly-hydrated state[a]
$K^+ \cdot CA^-$	0	2.8
$Na^+ \cdot CA^-$	2.0	3.1
$Na^+ \cdot BA^-$	1.3	6.2

a) see text.

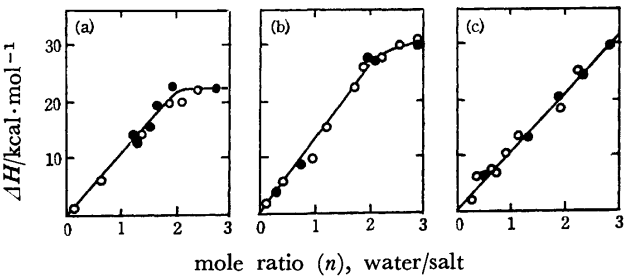

Fig. 3. Relation between the enthalpy of dehydration ΔH (per one mol of salt), and the water mole ratio n; (a) $K^+ \cdot CA^-$, (b) $Na^+ \cdot CA^-$ and (c) $Na^+ \cdot BA^-$. Solid circles are from differential scanning calorimetry and open circles from differential thermal analysis.

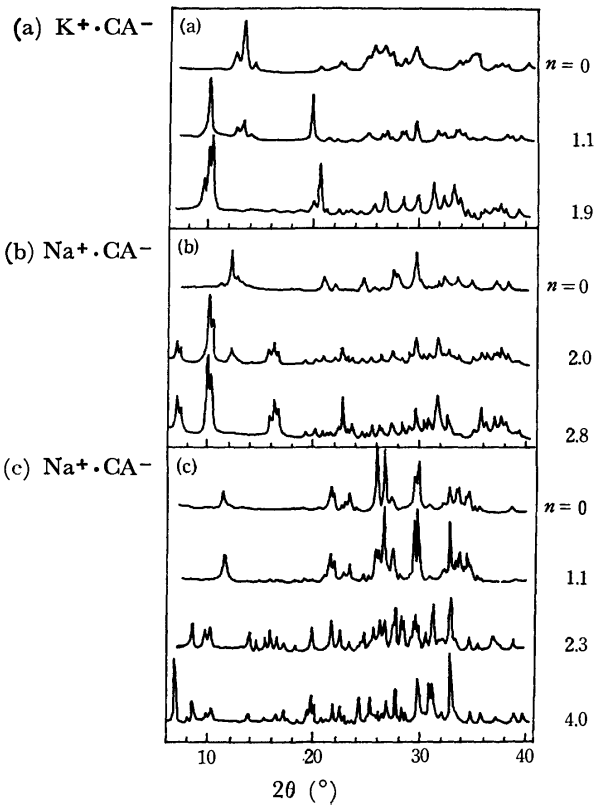

Fig. 4. X-ray diffraction patterns of the salt powders of different water mole ratios; (a) $K^+ \cdot CA^-$, (b) $Na^+ \cdot CA^-$ and (c) $Na^+ \cdot BA^-$.
The value of water mole ratio is indicated at the right of each diffraction pattern.

The X-ray powder diffraction patterns of the three salts at different water contents are reproduced in Fig. 4. Konno *et al.*[12] reported that there are two modifications of the $K^+ \cdot CA^-$ salts, α- and β-form, at the room temperature, and carried out the crystal structure analysis on the α-form crystal. By comparing with the crystal data reported by these authors, we were able to conclude that the X-ray powder diffraction pattern of the water-free sample shown in Fig. 4(a), is the one due to the α-form crystals. According to the reported crystal structure of the α-form crystal, CA^- ions are stacked on each other with equal intervals to form columns parallel to the c axis, and such CA^- columns are mutually held together through K^+ ions without leaving such a space that can accommodate water molecules. Therefore, a considerable change must take place in the crystal structure in order to accommodate water molecules in the crystal lattice to form a hydrate crystal. In effect new peaks were observed in the diffraction patterns of water-containing samples. When the water mole ratio was in the range $0<n<2$, the diffraction pattern was consisting of the peaks due to the hydrate crystals and those due to the water-free crystals, and the relative intensities of the former peaks increased on increasing the water mole ratio. The above change in the powder diffraction pattern implies that the water molecules are not distributed uniformly among the crystals in the powder, but the powder is, in reality, a mixture of the water-free crystals and the hydrate crystals. Thus the observed water mole ratio of a powder sample should be interpreted as the average value over such an heterogeneous system.

When the water mole ratio of the $K^+ \cdot CA^-$ powder is about 2 or higher, the powder diffraction pattern shows peaks different from those of the hydrate crystals mentioned above (see the diffraction pattern of the sample with $n=1.9$ in Fig. 4(a)). These peaks are likely to be due to another type of hydrate with a higher water content. We will tentatively call this as hydrate II and the other as hydrate I. The powder diffraction patterns indicated that the powders of the water mole ratios, $2<n<3$, are composed of the crystals of hydrate I and hydrate II, and the latter content increases with the increase of the water mole ratio of the powder. As we compare the change in the powder diffraction pattern and the relation between ΔH and n shown in Fig. 3, it is most likely that hydrate I has the water mole ratio of approximately 2, and hydrate II a value higher than that, possibly about 3.

The water-containing samples of $Na^+ \cdot CA^-$ showed the X-ray diffraction patterns which consisted of the peaks due to the water-free crystals and those due to the hydrate crystals. With the increase of the water mole ratio of the powder, the former peaks decreased their intensities, but did not disappear until the water mol ratio exceeded 2.5. We noted also that the position of the diffraction peaks of the hydrate crystal little changed throughout the studied region of the water mole ratio, while their intensities relative to each other varied a little depending on the water content. These facts seem to suggest that the hydrate crystal formed in the initial stage of hydration has a composition corresponding to the water mole ratio higher than 2, and its structure has a space to accommodate more water molecules without causing a significant change in the skelton of the crystal structure.

The behavior of the $Na^+ \cdot BA^-$ salt was found to be markedly different from those of the above two salts. The diffraction pattern of the powder sample of which water mole ratio was 1.1, was not very much different from that of the water-free sample (see Fig. 4(c)). This seems to indicate that, in the first stage of hydration, water molecules can enter into the lattice of the water-free crystal of $Na^+ \cdot BA^-$ without any significant change of the crystal structure. The second stage of hydration was found to take place as the water mole ratio of the powder was about 2, where new peaks started to appear in the powder diffraction pattern. Another type of diffraction pattern was observed with the samples of a higher water mole ratio. Thus we can presume that there are three or more different stages of hydration in the case of $Na^+ \cdot BA^-$.

Crystal Spectra of the Hydrates. We studied the effects of hydration on the electronic spectra of the single crystals of the salts using a microspectrophotometer equipped with a cryostat at the sample stage of the microscope system of the spectrometer. We used the cryostat as the sample cell for the purpose to control the ambient atmosphere and temperature of the sample crystal. On each salt, we first measured the absorption

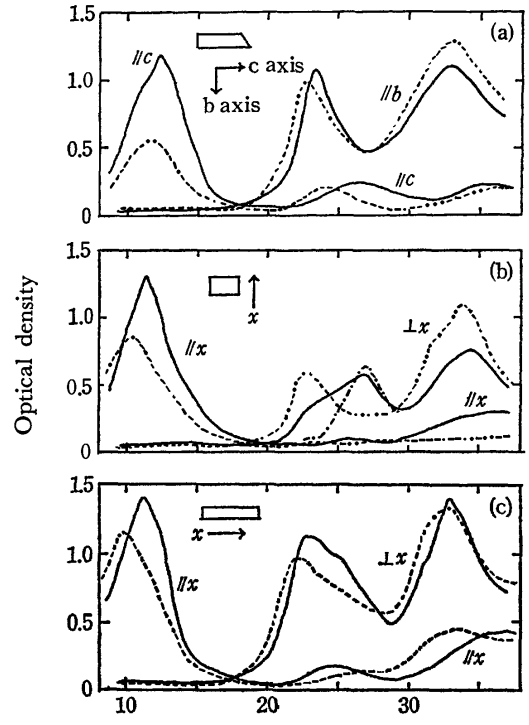

Fig. 5. Polarized absorption spectra of single crystals of $K^+ \cdot CA^-$ (a), $Na^+ \cdot CA^-$ (b) and $Na^+ \cdot BA^-$ (c): —— hydrated state, - - - - water-free state.
(The lowest $^2B_{1u} \leftarrow {}^2B_{2g}$ band observed at a highly-hydrated state of the $Na^+ \cdot CA^-$ crystal is indicated in Fig. 5 (b) with —·—·—)

spectrum of the sample crystal in the atmospheric air, then pumped out the air from the sample cell and, if necessary, heated the crystal to about 100 °C for a short while, and then measured again the absorption spectrum at the room temperature without breaking the vacuum of the sample cell.[13] The results of such experiments are shown in Fig. 5. Unfortunately there was no way to know the water content of the sample crystal at the condition of the spectral measurement, but we can consider that, in each case, the sample crystal was originally in the state of hydrate with the water mole ratio of about 2,[14] and was converted to the water-free state by the treatment given within the sample cell of the spectrometer.

In the case of the $K^+ \cdot CA^-$ salt, the crystal changed to the water-free state without any heat-treatment as soon as the air was pumped out from the sample cell, and the reverse change to the hydrate took place as the atmospheric air was introduced into the sample cell. In our previous paper,[2] we discussed the assignment of each absorption band of the spectrum of the water-free crystal, and attributed the 11.5×10^3 cm^{-1} band of the *c*-axis spectrum to the charge transfer between CA^- ions, the 24.0×10^3 cm^{-1} band of the same spectrum to the lowest $^2A_u \leftarrow {}^2B_{2g}$ transition of the CA^- ion, and the 23.1×10^3 and 32.7×10^3 cm^{-1} bands of the *b*-axis spectrum to the lowest and next $^2B_{1u} \leftarrow {}^2B_{2g}$ transitions of the CA^- ion, respectively.

The most prominent difference between the hydrate form and the water-free form was found in the region of the charge-transfer band, where the intensity decreased as the crystal changed from the hydrate form to the water-free form, and increased in the reverse process. The differences were less prominent in the region of local excitation bands. However, as compared with the spectrum of the water-free form, the first band of the *b*-axis spectrum of the hydrate was shifted to higher energy by about 500 cm^{-1} with a little increase of intensity, while the second band of the same spectrum remained at the same position with a little decrease of intensity, and, in the *c*-axis spectrum, the band due to the $^2A_u \leftarrow {}^2B_{2g}$ transition was shifted to higher energy by about 1200 cm^{-1}.

The above-described features of the spectrum of the hydrate resemble in all respects those of the crystal spectrum of the low-temperature phase of the water-free form. We can derive several conclusions concerning the hydrate crystal from these results. First of all, we can conclude that, like in the water-free crystal, CA^- ions in the hydrate crystal must be closely stacked on each other to form the CA^- columns parallel to the crystal axis corresponding to the c axis of the water-free state. Second, we can conclude that the interaction between the neighboring CA^- ions in such a column, is much stronger in the hydrate than in the high temperature phase of the water-free form. This means either that the intervals of CA^- ions in the column have uniformly decreased from those in the water-free crystal or that the CA^- ions are taking a dimeric arrangement in the CA^- columns of the hydrate crystal. Presumably, in the hydrate crystal, the separation between CA^- columns is larger than in the water-free crystal, so that water molecules are located in the space thus produced between the columns.[15]

The crystal structure analysis has not yet been carried out on the $Na^+ \cdot CA^-$ salt. We observed the spectrum for the two polarizations, parallel and perpendicular, respectively, to the *x axis* that is illustrated in Fig. 5(b). In this case, we needed to heat the sample crystal for a short while to about 100 °C in the vacuum of the sample cell in order to convert the hydrate to the water-free state. The spectra of the water-free state thus obtained resembled the spectra of the water-free crystal of $K^+ \cdot CA^-$. Consequently, the first absorption band, at 10.3×10^3 cm^{-1}, completely polarized in the *x* direction, can be assigned to the charge transfer band, and the 22.7×10^3 and 33.8×10^3 cm^{-1} bands of the $\perp x$ spectrum to the local excitation bands associated with the two $^2B_{1u} \leftarrow {}^2B_{2g}$ transitions of the CA^- ion. However, we noted that the intensity of the charge-transfer band, relative to those of the local excitation bands, is appreciably higher in the water-free $Na^+ \cdot CA^-$ $\parallel$ crystal than in the water-free $K^+ \cdot CA^-$ crystal. Thus we can consider that CA^- ions in the crystal of $Na^+ \cdot CA^-$ are forming columns parallel to the *x* axis, with the interaction between CA^- ions stronger than in the CA^- column of the $K^+ \cdot CA^-$ crystal.

The hydrate crystal exhibits the charge transfer band stronger than that of the water-free form, with a shift of the band maximum by 1300 cm^{-1} to higher energy. Interestingly, the first band of the $\perp x$ spectrum was significantly different from the corresponding band of the water-free form: it showed a maximum at 26.7×10^3 cm^{-1} together with a shoulder at 23×10^3 cm^{-1}, whereas the maximum was located at 22.7×10^3 cm^{-1} in the spectrum of the water-free state. Furthermore, the 23×10^3 cm^{-1} shoulder disappeared when we increased the humidity of the air in the sample cell (see Fig. 5(b)). It has been reported that the CA^- dimer is formed in the solution, and this dimer exhibits the local excitation band associated with the lowest $^2B_{1u} \leftarrow {}^2B_{2g}$ transition, at 26.3×10^3 cm^{-1}, while the corresponding band is located at 23.1×10^3 cm^{-1} in the spectrum of the CA^- monomer.[16] In comparion with the above data the appearance of the 26.7×10^3 cm^{-1} band in the spectrum of the highly-hydrated state is likely to be an indication of the strong interaction between CA^- ions. Possibly, CA^- ions are taking a dimeric arrangement in the CA^- column of the hydrate of $Na^+ \cdot CA^-$.

The spectra of the water-free and hydrate states of $Na^+ \cdot BA^-$ are shown in Fig. 5(c). We observed the spectra for the two polarizations, parallel and perpendicular respectively to the elongated direction of the crystal (the *x* direction in Fig. 5(c)). In this salt, it was necessary to heat the crystal to about 100 °C to convert it to the water-free state.

The solution spectrum of the BA^- ion exhibits absorption bands at 22.2×10^3 and 30.3×10^3 cm^{-1} respectively (see Fig. 6). These two absorption bands correspond to the two $^2B_{1u} \leftarrow {}^2B_{2g}$ bands (at 22.2×10^3 and 31.1×10^3 cm^{-1}) of the solution spectrum of the CA^- ion. Thus we can attribute the two absorption

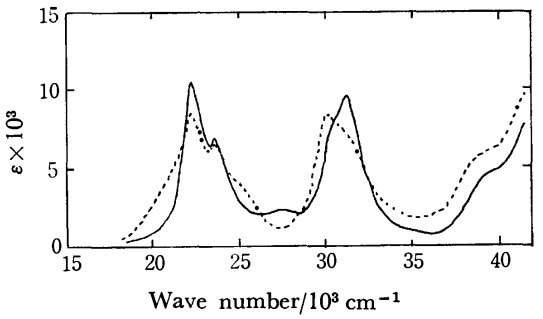

Fig. 6. Absorption spectrum of the CA^- ion (——) and that of the BA^- ion (- - - -) in the acetonitrile solutions of $K^+ \cdot CA^-$ and $K^+ \cdot BA^-$, respectively.

bands in the $\perp x$ spectrum of the $Na^+ \cdot BA^-$ crystal to the local excitations associated with the above two transitions of the BA^- ion, and the near-infrared band in the $\parallel x$ spectrum to the charge-transfer band.

We can consider that, in the crystal of $Na^+ \cdot BA^-$, BA^- ions are stacked along the crystal axis parallel to the *x direction*, with a considerably strong interaction between BA^- ions.

As in the cases of other two salts, the charge-transfer band is shifted to higher energy as a result of the hydration, with a little increase of intensity: the maximum is located at 11.3×10^3 cm^{-1} in the spectrum of the hydrate while it is at 9.6×10^3 cm^{-1} in the spectrum of the water-free state. Interestingly, the intensity of the charge-transfer band decreased for further increase of the degree of hydration, and the charge-transfer band almost disappeared in the highly-hydrated state.

Spin Concentrations of the Hydrates. All salts studied here showed ESR absorptions due to the anion radicals, CA^- or BA^-, but their intensities were found to be markedly affected by hydration. In Table 2, we listed the observed spin concentrations of the powder samples. The spin concentration was generally higher in the water-free state than in the water-containing state. In particular, a marked difference was found in the case of $K^+ \cdot CA^-$: the spin concentration of the water-free powder corresponds to almost 90 percent of the theoretical value that is expected when we assign one free spin to each CA^- ion, whereas that of the water-containing state corresponds to only 5 percent of this theoretical value. The latter is nearly the same as the spin concentration of the low temperature phase of the water-free state. In the cases of $Na^+ \cdot CA^-$ and $Na^+ \cdot BA^-$, the spin concentration was very low even in the water-free state, but it decreased further in the water-containing state. Interestingly, however, the spin concentration of the $Na^+ \cdot BA^-$ powder increased again as the water mol ratio exceeded 4, and reached a value of about 5×10^{23} spin per mol at the state of the highest water mole ratio.

If we compare the results described above with the effects of hydration on the crystal spectra, it is quite evident that there is a close correlation between the spin concentration and the intensity of charge-transfer band. In the case of the $K^+ \cdot CA^-$ salt, the hydration results in an appreciable increase of the intensity of charge-transfer band, which is accompanied by a marked decrease of spin concentration, and, in the cases of other salts also, the spin concentration is always found to be lower when the intensity of charge-transfer band is higher.

Table 2. The spin concentrations of the powder samples (spins per mol of the salt)

Salt	Water-free state	Water-containing state[a)]
$K^+ \cdot CA^-$	5.5×10^{23}	2.2×10^{22} ($n=1.9$)
$Na^+ \cdot CA^-$	3.9×10^{22}	2.7×10^{22} ($n=2.0$)
$Na^+ \cdot BA^-$	6.3×10^{22}	1.0×10^{22} ($n=2.3$)

a) The water mole ratio of the powder sample is given in the parentheses.

In our previous paper,[2)] we have shown that the intensity of charge-transfer band of the water-free $K^+ \cdot CA^-$ crystal increases as the salt changes from the high spin state to the low spin state on lowering the temperature below the transition point, and there is a close correlation between the temperature dependence of spin concentration and that of the intensity of charge-transfer band. We pointed out that the above correlation can be understood in the following way; If we assume a dimeric arrangement of CA^- ions in the CA^- columns of the $K^+ \cdot CA^-$ crystal of the low temperature phase, there will be a singlet state and a triplet state associated with the interaction between CA^- anion radicals, in which the former state will be a little stabilized in respect to the latter state because of the charge-transfer interaction, consequently, the population of such a singlet state will increase while that of the triplet state will decrease on lowering the temperature, and, since the intensity of charge transfer band is governed by the singlet population whereas the spin concentration is governed by the triplet population, the former increases while the latter decreases as the temperature is lowered.

As we have shown in the preceeding section, the crystal spectra indicate that the charge-transfer interaction between the neighboring CA^- ions in the CA^- columns is much stronger in the hydrated state of the $K^+ \cdot CA^-$ crystal than in the water-free state. Therefore, we can presume that the singlet state associated with the interaction between CA^- ions has been much stabilized in the hydrate than in the water-free crystal. This must result in the higher singlet population and lower triplet population in the hydrate crystal as compared with the water-free crystal, hence a higher intensity of the charge-transfer band and a lower spin concentration. These are in accord with the observations. Presumably, the same model can be applied for understanding the effects of hydration on the spin concentrations of other salts.

Solvent-containing Forms of $K^+ \cdot CA^-$. We have confirmed from the infrared spectrum and X-ray powder diffraction pattern that the $K^+ \cdot CA^-$ powder prepared from the acetone solution is usually not containing solvent molecules. This was also the case when methyl ethyl ketone or dichloromethane was used as the solvent. However, we found that the solvent-containing form of $K^+ \cdot CA^-$ can be prepared by exposing the salt powder which has been brought to a

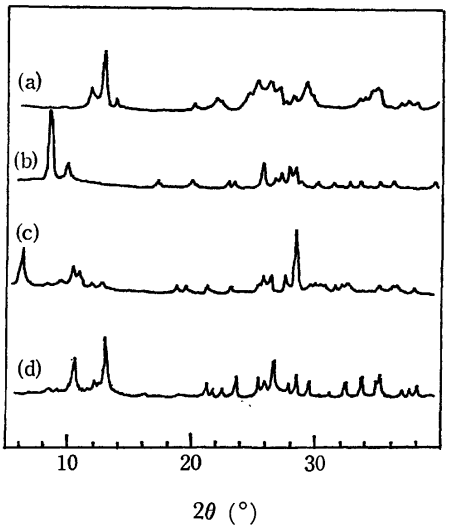

Fig. 7. X-ray diffraction patterns of the solvent-free and solvent-containing powders of $K^+ \cdot CA^-$.
(a): Solvent-free, (b): acetone, (c): methyl ethyl ketone, (d): dichloromethane.

nearly water-free state, to the solvent vapor for a sufficiently long period.

The X-ray powder diffraction patterns of such solvent-containing states are shown in Fig. 7, together with the diffraction pattern of the solvent-free state. We can see that the diffraction patterns of the solvent-containing states are different both from that of the water-free state and from those of the hydrates, of which diffraction patterns have been shown in Fig. 4.

In the infrared spectra of the solvent-containing states, we were able to find the bands due to the included solvent molecules: for instance, the bands at 1710 cm^{-1} (C=O stretching) and 1230 cm^{-1} (C–C=O antisymmetric stretching) in the case of acetone, and at 725 and 700 cm^{-1} (C–Cl stretching) in the case of dichloromethane.

The solvent molecules are liberated when we heat the solvent-containing crystals. By means of the DSC-TGA experiment, we determined the amount of the solvent contained in the salt, and the enthalpy of solvent evolution. The maximum amount of the included solvent and the enthalpy of solvent evolution per one mol of the solvent are shown in Table 3 together with the observed spin concentration of the solvent-containing powder.

Table 3. Properties of the solvent-containing states of $K^+ \cdot CA^-$

Solvent	Maximum amount of solvent[a] (mole ratio, solvent/$K^+ \cdot CA^-$)	Enthalpy of solvent evolution[b] [Kcal/mol of solvent]	Spin concentration [spins/mol of $K^+ \cdot CA^-$]
Acetone	0.90	19	7×10^{21}
Methyl ethyl ketone	0.55	20	3.2×10^{23}
Dichloromethane	0.33	13	2.0×10^{23}

a) The amount of solvent obtained on the powder sample which had been kept for a sufficiently long period in the solvent vapor. b) The value obtained by dividing the value of the enthapy change corresponding to the endothermic peak of DTA curve, due to the solvent evolution, by the amount of the solvent initially contained in the sample.

The results described above prove that the solvent molecules do enter into the crystal lattice of $K^+ \cdot CA^-$ to form the solvent-containing forms. At present, we do not know the reason why we did not obtain the solvent-containing crystal on synthesizing the salt from the acetone solution. We noted that the formation of the solvent-containing form becomes rather difficult if we completely remove water from the powder of $K^+ \cdot CA^-$. This might have bearings on the phenomenon mentioned above.

In the visible absorption spectra of the solvent-containing crystals, the charge-transfer band was observed with the same polarization as that of the spectrum of the solvent-free crystal. Therefore we can consider that CA^- columns of the $K^+ \cdot CA^-$ crystal are not destroyed on forming the solvent-containing crystals, and the solvent molecules are likely to be located in the space between CA^- columns.

Transition-metal Complexes of Pyrrole Pigments. X.*[1] Divalent and Trivalent Manganese Chelates of Dipyrromethenes

Yukito MURAKAMI, Kazunori SAKATA, Kenji HARADA, and Yoshihisa MATSUDA

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received November 29, 1973)

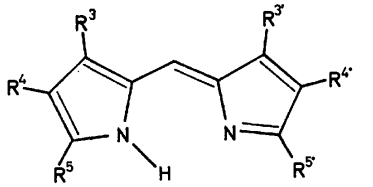
The solution spectra of two tris(dipyrromethenato)manganese(III) complexes and of one bis(dipyrromethenato)manganese(II) as well as the diffuse reflectance spectrum for the latter were examined. The high spin state was confirmed for all the manganese complexes by magnetic susceptibility measurements. For the tris-complexes, one broad low energy band (~9500 cm^{-1}) is assigned to the $^5A_{1g} \leftarrow {}^5B_{1g}$ transition and one pair of higher energy bands (~14000 cm^{-1}) are attributed to the $^5B_{2g} \leftarrow {}^5B_{1g}$ and $^5E_g \leftarrow {}^5B_{1g}$ transitions for a D_{4h} symmetry as a consequence of Jahn-Teller effect. In the bis-complex, manganese(II) is placed in a tetrahedral ligand field and one group of ligand-field bands lying below 16000 cm^{-1} are assigned to: $^4T_1(^4G) \leftarrow {}^6A_1(^6S)$, $^4T_2(^4G) \leftarrow {}^6A_1(^6S)$, and ^4E, $^4A_1(^4G) \leftarrow {}^6A_1(^6S)$ in an increasing order of energy. The exceedingly high intensity of these bands is ascribed to the covalent nature of coordinate bonds. A strong IR band due to the skeletal stretching mode of the dipyrromethene moiety was observed in the 1600 cm^{-1} range and shifted slightly toward lower energy upon metal-coordination.

Our previous investigations on the structural aspects of the first transition-metal complexes of dipyrromethenes have clarified the three major facts. Firstly, metal ions, which are in the divalent state of favorable stability, form the metal chelates of a 2 : 1 molar ratio of ligand to metal without any other additional ligand. These bis-complexes have a distorted tetrahedral structure, and the extent of this distortion very much depends on the coordination behavior of a central metal and the bulkiness of 5,5'-substituents in a ligand. If the central metals have an electronic configuration favorable for the planar coordination (*e.g.*, Cu(II) and Ni(II)), the yielded complexes come close to the planar geometry to an extent that the steric interaction between 5- and 5'-substituent groups of different ligand molecules in the same complex allows. Consequently, the structure of these complexes depends on the bulkiness of the substituent groups placed at 5- and 5'-positions.[2] On the other hand, when the electronic configuration of the central metals is in favor of the formation of tetrahedral geometry (*e.g.*, Co(II)), the bulkiness of 5,5'-moieties is not significant factor controlling the coordination structure. The covalent nature of coordinate bonds in these cases tends to distort the geometry from regular tetrahedron toward planar.[2]

Secondly, the central metals, which possess the slightly stable trivalent state relative to the divalent, yield tris-complexes with dipyrromethene ligands having no bulky 5,5'-substituents. However, when either or both of these positions are occupied with methyl or bulkier groups, only bis-complexes are obtained. An appropriate example is seen for the iron chelate system.[1]

Thirdly, the reaction of a metal ion, the trivalent state of which is much more stable than the divalent, and a 5,5'-substituted dipyrromethene gives only a complex of the distorted octahedral structure. This type of complex consists of two dipyrromethene molecules and an additional ligand, as observed for chromium(III) by the formation of acetatobis(3,3',5,5'-tetramethyldipyrromethenato)chromium(III).[3]

In the present work, the correlation between the valency state of manganese in a complex and the nature of the 5,5'-substituents placed in the ligands is to be elucidated by employing 3,3',4-trimethyl- (**1**), 3,3',4,4'-tetramethyl- (**2**), and 3,3',5,5'-tetramethyldipyrromethene (**3**) as bidentate ligands.



1: $R^3=R^{3'}=R^4=CH_3$, $R^{4'}=R^5=R^{5'}=H$
2: $R^3=R^{3'}=R^4=R^{4'}=CH_3$, $R^5=R^{5'}=H$
3: $R^3=R^{3'}=R^5=R^{5'}=CH_3$, $R^4=R^{4'}=H$

Experimental

Ligands. The synthetic procedures for the present ligands have been described previously.[1,2,4]

Tris(3,3',4-trimethyldipyrromethenato)manganese(III). 3,3',4-Trimethyldipyrromethene hydrochloride (0.4 g) and manganese dichloride tetrahydrate (0.2 g) were suspended in 100 ml of methanol. Crystalline precipitates of green luster developed from the dark reddish reaction mixture upon dropwise addition of dilute aqueous ammonia. The precipitates were recovered by filtration after the mixture being allowed to stand in a freezer for some time. The crystalline solid was extracted with chloroform. After evaporation of the solvent *in vacuo*, the residue was recrystallized from ethanol-chloroform as fine crystals of green luster; yield 0.10 g (36%).

Found: C, 70.11; H, 6.39; N, 13.47%; mol wt (osmometry),[5] 610. Calcd for $C_{36}H_{39}N_6Mn$: C, 70.79; H, 6.45; N, 13.76%; mol wt, 610.7.

Tris(3,3',4,4'-tetramethyldipyrromethenato)manganese(III). Dilute aqueous ammonia was added dropwise into the suspension of 3,3',4,4'-tetramethyldipyrromethene hydrochloride (0.15 g) and manganese dichloride tetrahydrate (0.07 g) in 40 ml of methanol. Reddish orange precipitates developed immediately. After heating on a water-bath (75 °C) for one minute, the reaction mixture was allowed to stand in a freezer for some time. The crystalline solid of green luster was recovered and extracted with chloroform. To the extract was added the same volume of acetone to precipitate fine crystals of green luster; yield 0.06 g (44%).

Found: C, 68.17; H, 6.79; N, 11.80%; mol wt,[5] 590.

Bis-complex[b]	297.0	14234	14489	5.87	5.92	5

a) Tris(3,3',4-trimethyldipyrromethenato)manganese(III). b) Bis(3,3',5,5'-tetramethyldipyrromethenato)manganese(II).

Calcd for $C_{39}H_{45}N_6Mn$: C, 71.76; H, 6.95; N, 12.88%; mol wt, 652.3.

Bis(3,3',5,5'-tetramethyldipyrromethenato)manganese(II).[6] Six ml of an aqueous solution of manganese dichloride tetrahydrate (0.12 g) was mixed with an ethanol solution (20 ml) containing 3,3'5,5'-tetramethyldipyrromethene (free base, 0.12 g). Aqueous ammonia (28%, 2 ml) was added dropwise into the solution with stirring. Developed precipitates of green luster was recovered after the reaction mixture being allowed to stand in a freezer for one day. The solid was recrystallized from *n*-hexane as fine crystals of green luster; yield 0.10 g (88%).

Found: C, 68.68; H, 6.68; N, 12.23%; M^+, 453.[7] Calcd for $C_{26}H_{30}N_4Mn$: C, 68.86; H, 6.69; N, 12.12%; mol wt, 453.58.

Physical Measurements. Electronic spectra covering the 7000—30000 cm^{-1} range were recorded on a Hitachi EPS-2 spectrophotometer for chloroform solutions at room temperature. Since bis(3,3',5,5'-tetramethyldipyrromethenato)-manganese(II) gradually decomposed in chloroform for long standing, its spectral measurement was performed immediately after the solution was prepared. Diffuse reflectance spectrum for the bis-complex was measured by a Hitachi EPU-2 spectrophotometer equipped with a R-3 reflectance attachment, MgO being used as a reference sample. Infrared spectra in the range of 200—4000 cm^{-1} were measured with a JASCO DS-403G spectrophotometer by a Nujol mull technique. Magnetic susceptibility measurements of solid samples were carried out by the Faraday method. Calibrations were made by the aid of $Hg[Co(NCS)_4]$, while diamagnetic corrections were performed by using Pascal's constants.

Results and Discussion

The reaction of the manganese(II) salt with 5,5'-unsubstituted dipyrromethenes (**1** and **2**) resulted in the formation of the corresponding manganese(III) complexes having a ligand to metal ratio of 3 : 1 (tris-complex), while the same metal salt reacted with 5,5'-dimethyl-substituted ligand **3** to give the 2 : 1 dipyrromethene-manganese(II) complex (bis-complex). For the dipyrromethene-manganese chelate system, the trivalent manganese state appears to be electronically more stable than the divalent due to the ligand-field stabilization effect brought about by octahedral coordination unless other factors such as steric effects come into play. The introduction of methyl groups at 5,5'-positions gives out a significant steric interaction among these substituents of different ligand molecules in the same complex to such an extent that the formation of a tris-complex is completely inhibited. Similar state of affairs has been observed for the dipyrromethene-iron chelate system.[1]

Magnetic Susceptibilities. The results of magnetic susceptibility measurements are listed in Table 1. It became apparent that the tris-complexes as well as the bis-complex hold a spin-free state. It is quite interesting to note that the present tris-complexes are in a high-spin ground state on the contrary to the low-spin state of the corresponding tris-complex of iron(III).[1]

Electronic Spectra. The electronic absorption

spectra for the tris-complexes are shown in Fig. 1, while the absorption and diffuse reflectance spectra for the bis-complex in Fig. 2. Lower intensity bands lying below 16000 cm^{-1} are apparently due to ligand-field transitions for all the manganese complexes in reference to the ligand-field bands for the other transition metal complexes previously studied.[1,2,4]

Ligand-field spectrum for each tris-complex consists of one broad band at 9500 cm^{-1} and one pair of bands in the 14000 cm^{-1} range. The electronic configuration [core]$3d^4$ (spin-free) produces E_g ground state in fields of octahedral symmetry. This state is susceptible to Jahn-Teller forces which causes the removal of the orbital degeneracy. The existence of a lower energy band at 9500 cm^{-1} and the correlation between this and the coexisting higher energy bands can not be elucidated reasonably in terms of other phenomena, such as spin-orbit coupling, solvent interaction, *etc.*, which may cause the removal of degeneracy. An electronic splitting of this magnitude can occur only if sizable effective distortions of the nuclear geometry from a regular tetrahedron. Jahn-Teller effects of this nature provide distortion to D_{4h} symmetry along with the removal of the E_g degeneracy. Thus, transitions may occur between components of the E_g (under O_h) ground state and from the ground state to the components of T_{2g}, which is less seriously split (Fig. 3). The broadness of the low-energy band ($\sim$9500 cm^{-1}) can also be attributed to the nature of potential energy surfaces for Jahn-Teller split E_g state.[8] Similar spectral behaviors have been observed for some manganese(III) complexes,[8] *e.g.*, tris(tropolonato)manganese(III), tris(2,4-pentanediono)manganese(III), potassium hexafluoromanganate, *etc.* It is not obvious whether the Jahn-Teller effects cause static or dynamic splitting of the E_g ground state for these manganese(III) complexes. Nevertheless, under assumption that the ground state becomes B_{1g} due to the effective D_{4h} field with axial elongation (Fig. 3), the transition energies can be represented as follows.[9]

$$E(^5A_{1g}\leftarrow{}^5B_{1g}) = 4Ds + 5Dt$$

$$E(^5B_{2g}\leftarrow{}^5B_{1g}) = 10Dq$$

$$E(^5E_g\leftarrow{}^5B_{1g}) = 3Ds - 5Dt + 10Dq$$

Spectral assignments and the ligand-field parameters thus evaluated are summarized in Table 2 along with some reference data from literatures.

Ligand-field spectrum for the bis-complex consists of three bands in a region lying below 16000 cm^{-1} as shown in Fig. 2. The tetrahalomanganate(II) complexes have been shown to assume tetrahedral coordination and their spectra analyzed[10] quantitatively by the aid of the secular equations of Tanabe and Sugano.[11] Similar interpretation would be applied to the present bis-complex, since structural require-

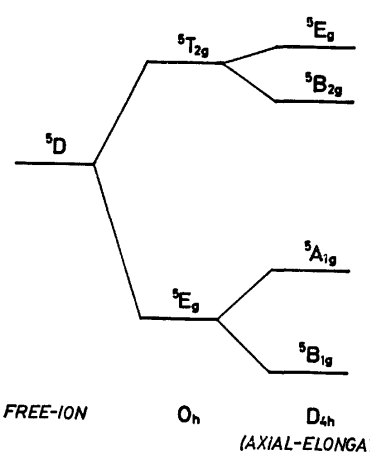

Fig. 3. Energy level diagrams for high-spin d^4 configuration under O_h and D_{4h} symmetries (not to scale).

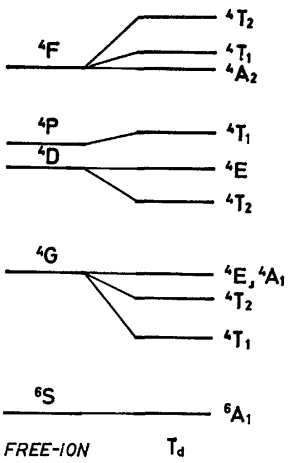

Fig. 4. Energy level diagram for high-spin d^5 configuration under T_d symmetry (not to scale).

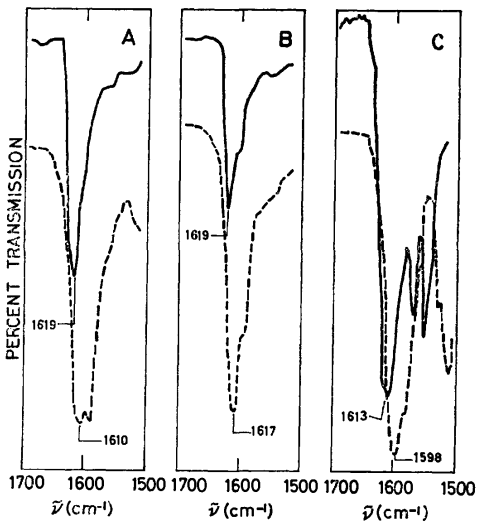

Fig. 5. Infrared spectra of manganese chelates (- - - -) and dipyrromethene free base (——) by a Nujol mull technique: A, 3,3′,4-trimethyldipyrromethene and its manganese(III) chelate; B, 3′3′,4,4′-tetramethyldipyrromethene and its manganese(III) chelate; C, 3,3′,5,5′-tetramethyldipyrromethene and its manganese (II) chelate. Number refers to the skeletal vibrational mode of the dipyrromethene moiety.

ment of the present dipyrromethene ligand forces manganese(II) to occupy a tetrahedral ligand field. The present ligand-field bands are tentatively assigned as follows (refer to Fig. 4).

$^4T_1(^4G) \leftarrow {}^6A_1(^6S)$: 13800 cm^{-1} (ε 165)

$^4T_2(^4G) \leftarrow {}^6A_1(^6S)$: 14900 cm^{-1} (ε 168)

$^4E, {}^4A_1(^4G) \leftarrow {}^6A_1(^6S)$: 16100 cm^{-1} (ε ~97 sh)

Since the higher energy ligand-field bands are hidden in the present case due to the presence of high intensity bands attributable to charge-transfer and ligand $\pi \rightarrow \pi^*$ transitions, the critical spectral analysis, to an extent as performed for the tetrahalomanganate system, was not attempted.

In spite of these interpretation for the bis-complex, absorption intensity of these bands is exceedingly high for the ordinary spin-forbidden transitions. If covalent nature of the coordinate bond increases, the orbital angular momentum for the ground state cannot be referred to pure A_1 state any longer. Thus, this interaction tends to act in favor of transition probability increase.[12] In addition, the covalent interaction may provide any tendency to distort a tetrahedrally coordinated complex toward planar geometry as postulated for other dipyrromethene complexes of divalent first-transition metals.[2,3]

Vibrational Spectra. The IR absorption spectra for manganese chelates, covering the 1500—1700 cm^{-1} region, are shown in Fig. 5. A strong band due to the skeletal stretching mode of the dipyrromethene moiety appears in the 1600 cm^{-1} range. These bands show a slight shift upon metal-coordination.

In the far-infrared region, 700—200 cm^{-1}, the bis-complex shows an absorption peak of medium intensity in the 400—350 cm^{-1} range in a manner similar to the cobalt(II), nickel(II), copper(II), and iron(II) chelates of some dipyrromethenes reported previously.[1,2] This band can be associated with the metal-ligand (M—N) stretching mode: 379 cm^{-1} for bis(3,3′,5,5′-tetramethyldipyrromethenato)manganese(II). On the other hand, we failed to assign such a vibrational mode to the tris-complexes.

The authors wish to acknowledge partial support of this work by the Asahi Glass Foundation for the Contribution to Industrial Technology. Thanks are also due to the Research Institute of Yoshitomi Pharmaceutical Co., Ltd. for mass spectral measurements and to Drs. Shigeo Kida and Hisashi Okawa of our University for magnetic susceptibility measurements.

Transition-metal Complexes of Pyrrole Pigments. XI. Zinc(II) Chelates of Some Dipyrromethenes*

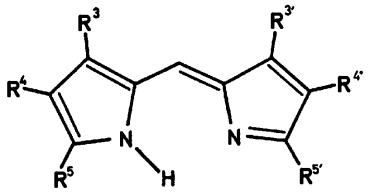
Yukito MURAKAMI and Kazunori SAKATA

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received March 11, 1974)

The zinc(II) chelates of five dipyrromethenes which have methyl substituents to a various extent, as well as that of 5,5′-diphenyldipyrromethene, have been prepared. The behaviors of methyl resonances upon metal-coordination were classified into three cases: (1) a down-field shift, but not greater than that of the corresponding ligand hydrochloride (3,3′-$C\underline{H}_3$); (2) nearly no change in chemical shift (4,4′-$C\underline{H}_3$); and (3) a profound up-field shift, the methyl resonance of the corresponding ligand hydrochloride showing a down-field shift on the contrary (5,5′-$C\underline{H}_3$). A marked change in chemical shift for the methine proton upon zinc(II)-coordination is related to conjugation in the chelate ring—the presence of aromaticity. As a whole, methyl resonances for the zinc chelates are consistent with the tetrahedral coordination geometry. Electronic absorption peaks for the zinc chelates, which were located in the lowest energy region with the highest intensity, were assigned to the intra-ligand $\pi\rightarrow\pi^*$ transition and the metal→ligand charge-transfer as well. Vibrational absorption bands appearing in the 1600 cm^{-1} range and in the 400—350 cm^{-1} region have been assigned to the skeletal stretching mode of the dipyrromethene moiety and the metal-ligand stretching mode, respectively, for the zinc chelates.

In order to make a further exploration into the coordination ability of various pyrrole pigments, the zinc(II) chelates of six dipyrromethenes (**1**—**6**) have



1: $R^3=R^{3'}=R^4=R^{4'}=CH_3$, $R^5=R^{5'}=H$
2: $R^3=R^{3'}=R^5=CH_3$, $R^4=R^{4'}=R^{5'}=H$
3: $R^3=R^4=R^5=CH_3$, $R^{3'}=R^{4'}=R^{5'}=H$
4: $R^3=R^{3'}=R^5=R^{5'}=CH_3$, $R^4=R^{4'}=H$
5: $R^3=R^{3'}=R^4=R^{4'}=R^5=R^{5'}=CH_3$
6: $R^5=R^{5'}=C_6H_5$, $R^3=R^{3'}=R^4=R^{4'}=H$

been prepared in this work. From our structural investigations on various divalent metal chelates of substituted dipyrromethenes, cobalt(II) was found to coordinate tetrahedrally to dipyrromethene molecules.[1-3] In connection with the coordination behavior of cobalt(II) ion, the zinc(II) ion, which has a good tendency of typical tetrahedral coordination, was employed to yield the corresponding dipyrromethene complexes. The structural aspects of the present zinc-(II) complexes as well as dipyrromethene ligands were investigated primarily by means of NMR spectroscopy. An additional information was also obtained by electronic and vibrational spectroscopy. Although Fergusson *et al.* carried out NMR studies on zinc(II), cadmium(II), mercury(II), and palladium(II) complexes of some dipyrromethenes,[4,5] their information is rather limited due to non-systematic utilization of dipyrromethene ligands with respect to substituent groups. The present study provides a thorough information on the proton resonance signals due to methyl groups substituted at all positions of the dipyrromethene skeleton as well as on their correlations.

Experimental

Ligands. The synthetic procedures for the present ligands have been described previously.[1,2]

Metal Chelates. Bis(3,3′,4,4′-tetramethyldipyrromethenato)-zinc(II): Zinc chloride (anhydrous, 50 mg) dissolved in 2 ml of water was added with stirring to an ethanol (15 ml) solution of the ligand hydrochloride (0.1 g) at room temperature. After addition of 3% aqueous ammonia (0.5 ml), the mixture was heated at 80 °C for 2 min with stirring and subsequently allowed to cool down to room temperature. Repeated recrystallization from chloroform–ethanol gave olive-green crystals; yield 41 mg (42%).

Found: C, 67.34; H, 6.58; N, 12.03%. Calcd for $C_{26}H_{30}N_4Zn$: C, 67.31; H, 6.52; N, 12.08%.

Bis(3,3′,5-trimethyldipyrromethenato)zinc(II): The reaction of the ligand hydrochloride (0.1 g) and zinc chloride (anhydrous, 80 mg), following the above procedure, gave reddish orange crystals; yield 57 mg (58%).

Found: C, 65.85; H, 5.79; N, 12.88%. Calcd for $C_{24}H_{26}N_4Zn$: C, 66.13; H, 6.01; N, 12.86%.

Bis(3,4,5-trimethyldipyrromethenato)zinc(II): The reaction of the ligand hydrochloride (0.4 g) and zinc chloride (anhydrous, 0.26 g), following the above procedure, gave olive-green crystals; yield 0.25 g (64%).

Found: C, 65.88; H, 5.93; N, 12.99%. Calcd for $C_{24}H_{26}N_4Zn$: C, 66.13; H, 6.01; N, 12.86%.

Bis(3,3′,5,5′-tetramethyldipyrromethenato)zinc(II): The reaction of the ligand hydrochloride (0.1 g) and zinc chloride (anhydrous, 50 mg), following the above procedure, gave orange crystals; yield 63 mg (64%).

Found: C, 67.17; H, 6.57; N, 12.00%. Calcd for $C_{26}H_{30}N_4Zn$: C, 67.31; H, 6.52; N, 12.08%.

Bis(3,3′,4,4′,5,5′-hexamethyldipyrromethenato)zinc(II): A mixture of the ligand hydrochloride (0.1 g), zinc acetate dihydrate (80 mg), and urea (0.8 g) in 15.5 ml ethanol was refluxed for 2 hr and subsequently allowed to cool down to room temperature. Repeated recrystallization from benzene gave orange crystals; yield 68 mg (70%).

Found: C, 69.49; H, 7.25; N, 10.97%. Calcd for $C_{30}H_{38}N_4Zn$: C, 69.29; H, 7.37; N, 10.78%.

Bis(5,5′-diphenyldipyrromethenato)zinc(II): A mixture of the ligand (free base, 0.5 g) and zinc acetate dihydrate (0.26 g) in 45 ml of ethanol was refluxed for 2 hr, and subsequently

a) Measured in chloroform-*d* with TMS as an internal reference.

allowed to cool down to room temperature. Repeated recrystallization from chloroform–ethanol gave olive-green crystals; yield 0.39 g (70%).

Found: C, 76.39; H, 4.69; N, 8.33%. Calcd for $C_{42}H_{30}N_4Zn$: C, 76.89; H, 4.61; N, 8.54%.

Spectral Measurements. A Varian A-60 spectrometer was used to obtain NMR spectra in chloroform-*d* at room temperature. Chemical shifts were reported in ppm from internal TMS and calibrated by the use of chloroform signal as the secondary reference. Ultraviolet and visible spectra in chloroform were recorded on a Hitachi Model EPS-2 spectrophotometer at room temperature. Infrared and far-infrared spectra covering the 4000—200 cm^{-1} range were measured with a JASCO Model DS-403G grating spectrophotometer at room temperature, where Nujol mull technique was adopted.

Results and Discussion

NMR Spectra. Methyl Group Resonances: (a) Ligands. The hydrochloride of 3,3',5-trimethyldipyrromethene (**2**–HCl) showed methyl-proton peaks at 2.68 and 2.39 ppm with 1 : 2 ratio of signal intensity. Thus, the former signal was assigned to methyl-protons placed at the 5-position, while the latter to those at the 3- and 3'-positions. On the basis of these assignments, all the methyl resonances have been assigned for dipyrromethene hydrochlorides as listed in Table 1. A positive charge on the hydrochloride forms of dipyrromethenes is apparently delocalized throughout the dipyrromethene skeleton according to these data. The removal of positive charge results in the up-field shift of methyl resonances as shown in Table 1 for the free-base forms.*

* Fergusson *et al.*[4)] assigned the methyl resonances: 3,3'-C<u>H</u>$_3$', δ 2.58 and 5,5'-C<u>H</u>$_3$, 2.45 for 4,4'-diethoxycarbonyl-3,3',5,5'-tetramethyldipyrromethene (free base); 3'-C<u>H</u>$_3$, δ 2.62 and 5'-C<u>H</u>$_3$, 2.46 for 3,4'-diethoxycarbonyl-5-chloro-3',4,5'-trimethyldipyrromethene. Their assignments for 3(3')-C<u>H</u>$_3$ and 5(5')-C<u>H</u>$_3$ should be interchanged in reference to our present study.

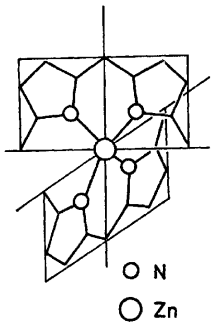

Fig. 1. Plausible spatial arrangement of the ligand molecules around zinc(II).

(b) Zinc Chelates. The metal nucleus in various zinc complexes generally demonstrates the tetrahedral coordination geometry by utilizing its $(4s)(4p)^3$ hybrid orbitals. The coordination geometry for the dipyrromethene chelates is shown schematically in Fig. 1. Consequently, the methyl groups substituted at the 5- and 5'-positions are to be placed in the shielding zone provided by a pyrrole ring as well as a chelate ring of another dipyrromethene moiety in the same chelate molecule. The behaviors of methyl resonances upon metal-coordination can be classified into three cases relative to those of the corresponding ligands (free base): (1) a down-field shift but not greater than the methyl resonance of the corresponding ligand hydrochloride (3,3'-C<u>H</u>$_3$); (2) nearly no change in chemical shift, even though that of the corresponding ligand hydrochloride shows down-field shift (4,4'-C<u>H</u>$_3$); and (3) a profound up-field shift, the methyl resonance of the corresponding ligand hydrochloride showing a down-field shift on the contrary (5,5'-C<u>H</u>$_3$). All the down-field shifts can be attributed to the deshielding effect due to positive charge provided by either proton or zinc(II). The tetrahedral coordination geometry undoubtedly gives out the unique behavior of methyl resonances classified as (3). An apparent non-variation

of methyl resonances classified as (2) seems also due to some structural coordination effect—minor shielding effect.

Methine Group Resonances: A marked change in chemical shift for the methine proton upon zinc(II)-coordination should be directly related to conjugation in the chelate ring. The methine proton is significantly deshielded on protonation as observed for the porphyrin nucleus.[6] This is attributed to delocalization of a positive charge throughout the dipyrromethene molecule, which leaves out a partial positive charge on the methine carbon atom. The proton NMR investigations of acetylacetonate and porphyrin complexes have shown that no deshielding of the methine proton could be detected.[7,8,9] Consequently, the behavior of methine group resonances for the present zinc(II) chelates can be cited as an evidence for the presence of aromaticity in the chelate ring due to coordinate bonds of significant covalent character. In conclusion, the methyl resonances for the zinc chelates are consistent with the tetrahedral geometry as depicted in Fig. 1.

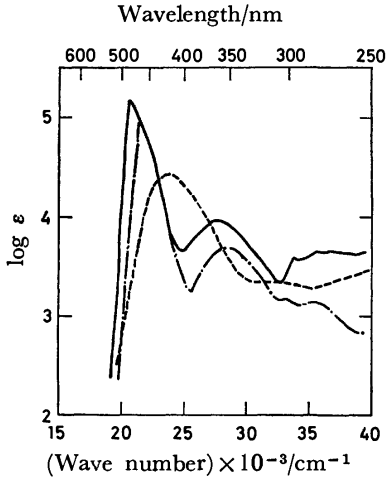

Fig. 2. Electronic absorption spectra for 3,3′,5-trimethyldipyrromethene and the zinc(II) chelate in chloform at room temperature: ——, zinc(II) chelate; —·—, ligand hydrochloride; - - - -, ligand free base.

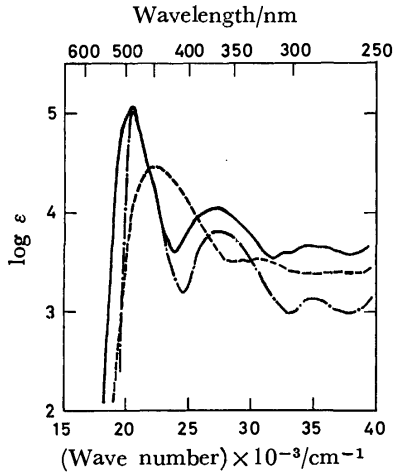

Fig. 3. Electronic absorption spectra for 3,3′,4,4′,5,5′-hexamethyldipyrromethene and the zinc(II) chelate in chloroform at room temperature: ——, zinc(II) chelate; —·—, ligand hydrochloride; - - - -, ligand free base.

Electronic Spectra. Visible and ultraviolet spectra for the ligands in free base and hydrochloride forms as well as for the zinc chelates are shown in Figs. 2 through 4 for the selected cases. The ligands in free base forms show the most intense $\pi\rightarrow\pi^*$ band in the lowest energy range (Table 2). The $\pi\rightarrow\pi^*$ transition energy decreases as a number of methyl groups substituted in the dipyrromethene skeleton increases (Fig. 5). This phenomenon can be attributed to the hyperconjugation effect due to methyl groups. Upon protonation to a pyrrole-nitrogen (hydrochloride species), the $\pi\rightarrow\pi^*$

Table 2. Electronic absorption bands appearing in the lowest energy range for dipyrromethene ligands and zinc(II) chelates[a]

Ligand	Form	Transition energy in cm^{-1} (ε)
1	Free base	23300(28000)
	HCl salt	20900(68900)
	Zn chelate	20000(120000), 20700(93800)
2	Free base	23700(26200)
	HCl salt	21500(91900)
	Zn chelate	20700(144000), 22000sh(70600)
3	Free base	25200(23200)
	HCl salt	21400(64500)
	Zn chelate	20600(97300), 21800sh(75900)
4	Free base	22700(32300)
	HCl salt	21200(109000)
	Zn chelate	20500(166000), 21300sh(100000)
5	Free base	22300(29400)
	HCl salt	20500(107000)
	Zn chelate	19800sh(84400), 20500(117000), 21100sh(65300)
6	Free base	19500(44400)
	HCl salt	18100(94700)
	Zn chelate	18100(84700), 18900sh(95200), 19600(114000)

a) Measured in chloroform at room temperature.

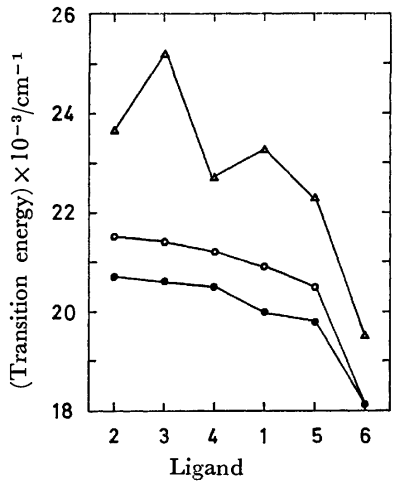

Fig. 5. Correlations between lowest electronic transition energy and nature of substituent groups in the dipyrromethene skeleton for ligand free bases(△), ligand hydrochlorides(○), and zinc(II) chelates(●): a number of methyl group increases from left to right (except **6**).

band further shift to a lower energy region (Figs. 3—5) along with an increase in its intensity. In a manner as pointed out by Corwin and Brunings for di-*N*-methyldipyrromethenes,[10,11] the steric interaction between *N*-protons in di-*N*-protonated dipyrromethenes seems to give out a significant effect on their electronic structure, thus raising the occupied π-energy levels relative to the free-base ligands. The intensity increase may be attributed to the polarity effect provided by the presence of a positive charge in the dipyrromethene skeleton. The effect of methyl-substitution (red-shift) is seen to be similar to that observed for the free-base ligands (Fig. 5). The electronic transition appearing in the lowest energy region for the zinc chelates are accompanied with multi-peaks (Table 2, Figs. 2—4), often along with a slight red-shift relative to that for the corresponding ligand hydrochlorides. The bands may be assigned to the $\pi \rightarrow \pi^*$ transition of similar origin as described for the ligands. On the other hand, the metal→ligand charge-transfer transitions, as generally observed for transition-metal complexes in a similar energy region, may be expected to appear in this region. Thus, we do hold the possibility of co-occurrence of charge-transfer and $\pi \rightarrow \pi^*$ transitions in the same range, although Fergusson *et al.* simply assigned these bands to the intra-ligand $\pi \rightarrow \pi^*$ transition and a band in the 28000 cm^{-1} range to the metal→ligand charge-transfer.

Vibrational Spectra. A strong band due to the skeletal stretching mode of the dipyrromethene moiety appears in the 1600 cm^{-1} range as listed in Table 3 for the free ligands and the corresponding zinc chelates. A slight shift of this band to lower energy is observed for each ligand upon metal-coordination.

Table 3. Infrared absorption band assigned to the skeletal stretching mode of the dipyrromethene moiety for ligands and zinc chelates

Ligand	Form	IR band in cm^{-1}
1	Free base	1619
	Zn chelate	1610
2	Free base	1622
	Zn chelate	1603
3	Free base	1625
	Zn chelate	1605
4	Free base	1613
	Zn chelate	1599
5	Free base	1611
	Zn chelate	1596
6	Free base	1618
	Zn chelate	1612

In the far-infrared region, 700—200 cm^{-1}, there was observed an absorption peak of medium intensity in the 400—350 cm^{-1} range in a manner similar to the cobalt(II), nickel(II), copper(II), iron(II), and manganese(II) chelates of some dipyrromethenes.[1,2,12,13] This band can be associated with the metal-ligand stretching mode: **3**-Zn, 383 cm^{-1}; **4**-Zn, 386 cm^{-1}; **5**-Zn, 363 cm^{-1}. We refrained from assigning a band of this origin for some zinc chelates due to the complexity of absorption spectra caused by ligand-nature.

Studies of the Substituent Effect on the Stability Constants of Bis(2-hydroxy-4 or 5-substituted acetophenonato)copper(II)

Masami HARUTA, Zen-ichi YOSHIDA,* and Hisanobu OGOSHI*

Research Laboratory for Chemical Fibers, Nitto Boseki Co., Ltd. Koriyama-shi, Fukushima-ken 963

**Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606*

(Received April 9, 1974)

The dissociation constants of eleven 2-hydroxy-4 or 5-substituted acetophenones were determined in a 22.5% water-dioxane-mixed solvent system at 25 and 40 °C by potentiometric titration. They were then discussed in terms of the electronic effect of the substituents and the linear-free-energy relationship. The stability constants bis(2-hydroxy-4 or 5-substituted acetophenonato)copper(II) were also determined under the same experimental conditions; a linear relationship between the dissociation constants and the stability constants was obtained for bis(2-hydroxy-4 or 5-substituted acetophenonato)copper(II). No significant difference has been found in the effects of 4- and 5-substituted groups on the stability constants.

The dissociation constants of eleven 2-hydroxy-4 or 5-substituted acetophenones were determined in 22.5% water-dioxane at 25 and 40 °C by potentiometric titration.

The values obtained were discussed in terms of the electronic effect of the substituents and the linear free-energy relationship. The stability constants of bis-(2-hydroxy-4 or 5-substituted acetophenonato)copper (II) were also determined under the same experimental conditions, and a linear relationship between the dissociation constants and the stability constants was discussed in comparison with those of bis(4- or 5-substituted salicylaldehydato)copper(II).

Although several studies of the stability constants for metal complexes, especially copper complexes, of salicylaldehyde and its derivatives have been reported,[1-4] few studies of copper complexes of *o*-hydroxyacetophenone derivatives have appeared so far.[5] It would be interesting to study the stability constants of the copper complex of *o*-hydroxyacetophenone derivatives which have no steric factors in the course of the complex formation and to compare them with those of the copper complexes of the corresponding salicylaldehyde derivatives.

Since *o*-hydroxyacetophenone derivatives, salicylaldehyde derivatives, and their metal complexes are not very soluble in water, nonaqueous or mixed solvent systems are usually employed for the measurement of the equilibrium constants. The use of such solvents, however, raises the question of the interpretation of the potential obtained from a cell containing a glass electrode and a liquid junction error. Therefore, the calibration of the glass electrode must be made for the solvent system. An empirical calibration for pH-meter reading was made by the method reported by Van Uitert and Haas[6] for the 22.5% water–dioxane system at 25 and 40 °C.

The electronic effect of the substituent on the dissociation constants(pK_a) of 2-hydroxy-4 or 5-substituted acetophenones were interpreted in terms of the linear free-energy relationship.

The stability constants of bis(2-hydroxy-4 or 5-substituted acetophenonato)copper(II) were compared with those of bis(4- or 5-substituted salicylaldehydato)-copper(II). A linear relationship between the pK_a and the stability constant has been predicted by Calvin,[1] assuming that the enthalpy change for the complex formation is predominant over the entropy change to the stability constant. On the contrary, Jones *et al.*[2] have shown a non-linear relationship between the pK_a's and the log K's for salicylaldehyde derivatives and their copper complexes; they explained their result in terms of the interaction of the d_ϵ-electron of the cupric ion. Since it has since been found, though, that the latter work involves some experimental errors together with the use of a ligand determined incorrectly,[7] the determination of the stability constants of bis(4- or 5-substituted salicylaldehydato)-copper(II) should be reexamined in order to elucidate the electronic effect of the substituent on the complex formation.

Experimental

Materials. 2-Hydroxyacetophenone, 4-methyl, 5-methyl, 4-chloro, 5-chloro, 4-bromo, 5-bromo, and 4-nitro derivatives of 2-hydroxyacetophenone were prepared by the usual Fries-rearrangement of the corresponding substituted phenyl acetates. 4-Methoxy and 5-methoxy derivatives were obtained by the Friedel-Crafts reaction of acetyl chloride with resorcinol and hydroquinone dimethyl ether respectively.[8] 2-hydroxy-5-nitroacetophenone was synthesized by the nitration of 2-hydroxyacetophenone. All of these compounds were purified by recrystallization. Dioxane was purified by a previously reported method.[9] Sodium perchlorate was recrystallized twice from water at 50 °C. Potassium chloride was purified by the Pinching and Bates method.[10] Hydrochloric acid was distilled twice, and the middle fraction was used. Deionized water was distilled under a nitrogen atmosphere.

The other reagents employed in this study were commercially available and were used without further purification.

Preparation of Bis(2-hydroxy-4 or 5-substituted acetophenonato)-copper(II). The general procedure was as follows: About 0.5 g of the ligand was dissolved in methanol containing an equivalent amount of potassium hydroxide; then the mixture was diluted with the same volume of water. A one half equivalent of cupric chloride was dissolved in a small amount of water and added to the ligand solution. The copper chelate was collected by filtration, washed with 50% aqueous methanol, and dried at room temperature *in vacuo*. The results of elemental analyses are summarized in Table 4.

Titration. The titration apparatus employed was the same as that reported in a previous paper.[11] Titration was carried out by the method reported by Irving and Rossotti.[12] The ionic strength was maintained at 0.3 with potassium

TABLE 1. DISSOCIATION CONSTANTS OF 2-HYDROXY-4 OR 5-SUBSTITUTED ACETOPHENONES IN 22.5% AQUEOUS DIOXANE AT 25 AND 40 °C

Substituent	$pK_{a25\,°C}$	$pK_{a40\,°C}$	$\Delta\Delta G_i$ (kcal/mol)
4-OCH_3	10.475	10.267	+0.43
5-OCH_3	10.849	10.631	−0.08
4-CH_3	11.127	10.902	−0.46
5-CH_3	11.395	11.162	−0.82
H	10.794	10.578	0.00
4-Cl	9.780	9.591	+1.38
5-Cl	10.148	9.948	+2.26
4-Br	9.680	9.494	+1.52
5-Br	9.959	9.766	+1.14
4-NO_2	8.617	8.460	+2.97
5-NO_2	7.265	7.144	+4.81

nitrate, while the temperatures were 25.0±0.1 °C and 40.0±0.1 °C. The metal solution was standardized by the usual EDTA-titration method.[13]

Correction of pH Meter Reading. An empirical calibration of the glass electrode in 22.5% aqueous dioxane at 25.0 and 40.0 °C (±0.1 °C) was carried out by the method reported by Van Uitert and Haas.[6]

A Hildebrand-type platinum electrode, 3000-10T, of the Hitachi-Horiba Manufacturing Co., was platinized[14] in each measurement and employed as a hydrogen electrode. A silver-silver chloride electrode** was used as the reference electrode.

The standard potential of the reference electrode and the mean activity coefficient of hydrogen chloride were obtained by interpolation from the data of Harned and Owen.[15] The conversion factors(U_H) were obtained by means of the relationship between the pH meter reading(B) and the hydrogen-ion concentration ([H]).

Determination of the Dissociation Constants(pK_a). The dissociation constants of 2-hydroxy-4 or 5-substituted acetophenones were obtained by the usual titration method with a pair of glass and calomel electrodes at 25.0 and 40.0 °C (±0.1 °C) and were calculated by means of Irving and Rossotti's equation.[16] The pK_a's were corrected by the Van Uitert and Haas method.[6b] The values thus obtained are shown in Table 1.

Calculation of the Stability Constants. The stability constants of bis(2-hydroxy-4 or 5-substituted acetophenonato) copper(II) were calculated by the method reported in a previous paper.[11]

Results and Discussion

The conversion factor and the correction factor for the 22.5% aqueous dioxane system were found to be reasonable in comparison with the values obtained by a graphic method.[6]

According to the generalized equation of the linear free-energy relationships,[17] the dissociation constants and the difference in the free energy change can be expressed as follows:

$$\log(K_i/K_0) \equiv X_i \text{ or } \sigma_i\rho_i$$
$$\Delta\Delta G_i = \Delta G_i - \Delta G_0 = -2.303RT\sigma_i\rho_i$$

** Kindly prepared and provided by Toa Electronics, Ltd., Tokyo.

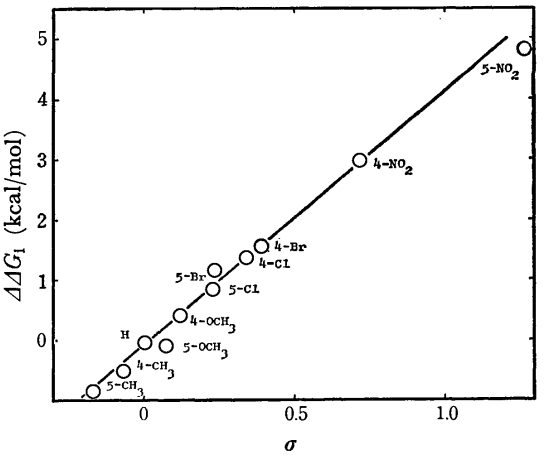

Fig. 1. Correlation of the difference of the free energy change ($\Delta\Delta G_i$) for the dissociation constant of 2-hydroxy-4 or 5-substituted acetophenones with Hammett σ constants.

where the i and 0 subscripts indicate the values for 2-hydroxy-4 or 5-substituted acetophenones and 2-hydroxyacetophenone respectively. Figure 1 shows the relation between the $\Delta\Delta G_i$ values of 2-hydroxy-4 or 5-substituted acetophenones and the Hammett σ constants. Bekkum's σ value(σ=0.076) for the 5-methoxy derivative[18] and the polarizability effect (σ=1.27) for the 5-nitro derivative[19] are used to evaluate the effect of those substituents. Those two plots deviate from the linear relationship.

In the case of the 5-nitro derivative, a remarkable precipitation of the complex was found in the course of titration, whereas no such precipitation was observed for the other ligands. Some experimental error may be involved in the stability constant for bis(2-hydroxy-5-nitroacetophenonato)copper(II) for the 5-nitro de-

rivative under the conditions here employed. Typical titration curves for some complex formations are illustrated in Fig. 2, while in Fig. 3 the formation curves for typical complexes are presented, with a dotted line indicating the precipitation of the complex. Among these complexes, the 5-nitro and 4-chloro derivatives showed poor solubility under the present conditions. A comparison of the formation curves indicates that a similar type of complex formation may occur during the titration. The stability constants obtained are summarized in Table 2.

It has been reported that a linear relationship can be established for the dissociation constants of salicylaldehyde derivatives and the stability constants of bis(substituted salicylaldehydato)copper(II).[7] A similar trend was confirmed in the eleven bis(4- or 5-substituted salicylaldehydato)copper(II) complexes. Slightly convex curves were obtained in the cases of 2-hydroxyacetophenone derivatives and pentane-2,4-dione derivatives.[2,6c] These trends have been explained by Jones *et al.*[2] in terms of the σ and π-electronic effects of the substituents. That is, the nitro group acts as a σ and π-electron acceptor, whereas the chloro group acts as a σ-acceptor and π-donor. Therefore, larger stability constants may be expected for the nitro derivatives than the chloro derivatives. The predominant stabilization of the complexes is attributed to the "back donation" of the d_ε-electron of the copper ion. However, the above-mentioned hypothesis, which was proposed for the interpretation of the stability constants salicylaldehyde complexes, has been criticized by Postmus *et al.*,[7] since the structure of 4-chlorosalicylaldehyde was not correctly identified. Some experimental error may indeed be included in the determination of the stability constant of the 5-nitro derivative.

The linear relationship between the stability constants and the dissociation constants, which has been predicted by Calvin[1] in view of the thermodynamic functions for the formation of the complex, is expressed as follows:

$$\log K = a\ \mathrm{p}K_a + b$$

where log K is the stability constant(log K_{MA}, log K_{MA_2}, log β), pK_a is the dissociation constant of the ligand, and a and b are constants. The constants, a and b, obtained from the plot of the stability constant against pK_a are presented in Table 3, along with those of

Table 3. Values of the constants(a, b) in equation $\log K = a\,pK_a + b$, and the correlation coefficients(r) for copper(II) complexes of 4 or 5-substituted salicylaldehydes and 2-hydroxy-4 or 5-substituted acetophenones in 22.5% aqueous dioxane at 25 °C

	$\log K_{MA}$			$\log K_{MA_2}$			$\log \beta$

a) Obtained from per cent ash as copper oxide.

bis(4- or 5-substituted salicylaldehydato)copper(II).

The a constants for the salicylaldehyde derivative were found to be larger than those for the 2-hydroxyacetophenone derivative in all cases. This fact indicates that the effect of the substituent of the salicylaldehyde derivatives on the stability constant is more significant than the effect of that of the 2-hydroxyacetophenone derivatives. This finding may be interpreted in terms of the difference in polarizability between the two series of ligands induced by the cation.[20]

The stability constant of a metal complex is strongly dependent on the basicity of its ligand. An electron-donating substituent group increases the electron density on the keto oxygen atom or the phenolic oxygen atom; this, in turn, results in an enhancement of the stability constant of the metal complex. The position of the substituent does not make any essential difference in the stability constants. It seems that the 4-substituent group increases the electron density on the keto oxygen atom, whereas the 5-substituent group enhances the electron density on the phenolic oxygen atom. Therefore, these trends can be explained in terms of classical substituent effects as a whole, such as the Hammett σ values.

Synthesis of Chelating Agents. X. Chelating Behavior of 1,2-Diamines with Specific Configurations: *cis*- and Diequatorial *trans*-Diamino-*trans*-decalins, *cis*- and *trans*-Diaminotetralins and 3,3-Dimethyl-1,2-diaminobutane*

Tairoku YANO, Hiroshi KOBAYASHI, and Keihei UENO

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received May 14, 1974)

Stability constants were determined at 25 °C for the metal chelates of racemic *cis*- and diequatorial *trans*-2,3-diamino-*trans*-decalins, *cis*- and *trans*-2,3-diaminotetralins and 3,3-dimethyl-1,2-diaminobutane (BEDA), where Cu(II), Ni(II) and Zn(II) are metal ions. Alicyclic *trans*-diamines afforded 1 : 1 complexes more stable than those with *cis*-isomers, regardless of the metal ions. Stability of the metal chelates with BEDA is comparable to that of the *trans*-diamines. The difference in stability of the *trans*- and *cis*-diamine complexes increased in the order Cu-, Zn- and Ni ions. Upon formation of 1 : 2 complexes, it became greater with Ni ion, but practically no difference was observed with the others. An explanation was given on the basis of stereochemistry of the diamines and coordination structures of the divalent metal ions.

Chelating behavior with transition metal ions has been extensively studied for various aliphatic 1,2-diamines capable of internal rotation around the axis of 1,2-carbon atoms, such as ethylenediamine and 2,3-diaminobutane.[1]

In order to elucidate stereochemical effects of the chelating agents on their metal complex formation, we have studied the synthesis of complexanes with certain conformations. This paper deals with the chelating behavior of some precursory 1,2-diamines such as 2(*ax*), 3(*eq*)-dimaino-*trans*-decalin [D(A,E)], 2(*eq*), 3(*eq*)-diamino-*trans*-decalin [D(E,E)], *cis*-2,3-diaminotetralin [T(A,E)], *trans*-2,3-diaminotetralin [T(E,E)] and 3,3-dimethyl-1,2-diaminobutane [BEDA].[2,3] In these diamines, the stereochemical relationship between the two amino groups is considered to be restricted to a certain extent by their less flexible carbon framework or the steric hindrance of bulky substituents.[4]

Experimental

Potentiometric measurements were carried out in a jacketed 100 ml titration vessel, maintained at 25.0±0.1 °C by circulation of thermostated water through the outer jacket. Ionic strength of a solution was adjusted to 0.10 by addition of potassium nitrate for the diaminodecalins D(E,E) and D(A,E) and *cis*-diaminotetralin T(A,E). Potassium chloride was used for *trans*-diaminotetralin T(E,E), since potassium nitrate caused precipitation during the course of titration, particularly for copper(II) ion even in a lower pH region.

A Hitachi-Horiba model P pH-meter fitted with glass(1026)- and calomel(2010) electrodes was calibrated by titration of an acetic acid solution with a 0.1 M potassium hydroxide free from carbonate ion, to give $-\log [H^+]$. After each measurement the acetic acid solution was again titrated in order to reconfirm the variation in pH-meter reading to be within 0.02.

Titration curves for a metal ion were obtained on two solutions (1 : 1 and 1 : 2 metal to ligand ratios). The total concentration of each ligand was kept constant at 1.0×10^{-3} M, while that of a metal ion was varied correspondingly 1.0×10^{-3}—5.0×10^{-4} M. Computations were carried out by use of a FACOM 230-60 of the Computer Center in Kyushu University. Preparation of the ligand materials was described previously.[2,3]

Results and Discussion

Dissociation Constants. The dissociation constants of the conjugate acids of T(E,E) and T(A,E) were calculated as dibasic acids according to Schwarzenbach.[5] The results are summarized in Table 2 along with those of some related diamines.

The pK_{a2} values of diaminotetralins are approximately 1 unit lower than those of the other alicyclic diamines. A similar comparison for aminocyclohexane and 2-aminotetralin, with pK_a values 10.64[6] and 9.80,[7] respectively, showed that the base strengths of tetralin derivatives are much weaker than those expected from Taft's polar effect of a phenethyl group,[8,9] indicating the existence of a direct field effect.

Stability Constants. Titration curves of the diaminodecalins are shown in Figs. 1 and 2. Similar curves were obtained for the diaminotetralins and BEDA.

The equilibria on the chelate formation might be represented as follows.

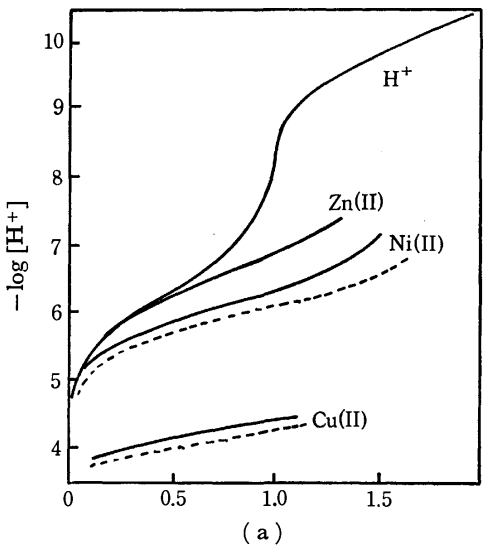

Fig. 1. Potentiometric titration curves of D(A, E) in the presence of various cations, —— 1 : 2 solution, and ---- 1 : 1 solution.

(Table 1). The results suggest that even in the 1 : 1 solution, the disproportionation reaction (4) takes place, to give a complex ML_2. Stability constants of of the diaminotetralins and BEDA (Table 2) are thus obtained only from the titration data of the 1 : 2 solutions, where those of BEDA complex with zinc(II) could not be obtained because of fluctuation of pH-meter readings probably due to an extremely slow reaction to attain equilibrium.

Stability of the 1 : 1 metal chelate increases in the order T(A,E), T(E,E), *c*-CYDA,** D(A,E), *t*-CYDA,** and D(E,D), in general agreement with the increase in the total basicity of the diamino group, as expressed by ($pK_{a1}+pK_{a2}$), irrespective of metal ion.

Plots of $\log K_{ML}$ against the total basicity of diamines (Fig. 3) indicate that the 1,2-diamines can be classified into three groups: the alicyclic diamines of *trans*-configuration (line A), those of *cis*-configuration (line B) and acyclic diamines capable of rotational isomerism, such as ethylenediamine and propylenediamine (line C). The data for each group fall on straight lines parallel to each other.

According to the conformation theory regarding a cyclohexane ring, it is well-known that a conformation with an *axial* bulky substituent is less stable than one with the same group in the *equatorial* position. If one refers to the conformation of the metal chelates with the ligand of a *trans*-group against those with the ligand of a *cis*-group, either one of amino group must be in the *axial* position of the ligand molecule for the latter chelate group. The coordination of aquo ion to this site might cause considerable steric hindrance. In the case of the former groups, however, both amino groups are in the *equatorial* position, so that the coordination of an aquo ion to these sites causes little steric hindrance.

Thus the vertical difference between the correlation lines of a *trans*-group and a *cis*-group could be regarded as values proportional to the stabilization free energy of the *trans*-group over the *cis*-group upon metal complex formation with respective metal ions. The difference is the highest in the nickel chelates, and ascribable to the octahedral hexacoordination structure of nickel(II) ion, which is the most bulky in comparison with tetrahedral zinc(II) and square planar copper(II). A small separation between the correlation lines of *trans*- and *cis*-diamine copper complexes might be regarded to indicate a loose aquation along the axis perpendicular to the square coordination plane of copper ion, to form a distorted octahedral structure in the 1 : 1 chelates.

Diamines with free internal rotation show a relatively lower chelate stability despite their higher

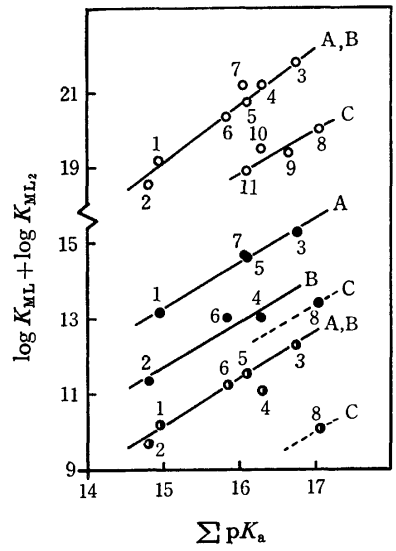

Fig. 4. Relationship of the 1 : 2 chelate stabilities against the total basicities of 1,2-diamines. Notation and references are the same as described in Fig. 3.

** *c*- and *t*-CYDA are abbreviations of *cis*- and *trans*-1,2-diaminocyclohexanes, respectively.

basicities. This can be explained by the loss of freedom in the internal rotation with the chelate ring formation. It should be noted that BEDA is aligned with the *trans*-diamines on a line. A bulky *t*-butyl group hinders the internal rotation in the free ligand molecule to fix the two amino groups in a *gauche* position favorable to form a chelate ring. The entropy loss upon chelation becomes to a certain extent similar to that of alicyclic *trans*-diamines of rigid structures.

Relationships between the stability of 1 : 2 metal-diamine complexes, as expressed by $(\log K_{ML}+\log K_{ML_2})$, and the total basicity (Fig. 4) differ somewhat from those observed (Fig. 3). The data for copper- and zinc complexes of the *trans*- and *cis*-diamines can be correlated with single lines, in contrast to nickel chelates, in which each *trans*-diamine afforded 1 : 2 complexes more stable than those of the *cis*-isomer.

The *dl-trans*- and *dl-cis*-diaminodecalins may possibly afford two and four kinds of diastereomeric 1 : 2 copper complexes, respectively, with respect to the configurations of chelate rings around the central metal atom. Molecular model study suggests that the coordinated diamines would be sterically hindered with a ligand, if present on the *z*-axis, in two of the diastereomeric complexes with the *cis*-diamines. The *dl-trans*- and *cis*-diaminocyclohexanes can also afford two diastereomeric copper complexes, and the coordinated diamines in one diastereomer with the *cis*-diamine is subject to steric hindrance with a ligand on the *z*-axis to a greater extent than in the other.

The situation in the nickel complexes would be similar to the above if the 1 : 2 chelates took configurations in which the four amino groups were arranged in a square plane.

Thus the results seem to suggest that the completion of a square ligand field with four amino-nitrogen atoms on the *x-y* plane in the 1 : 2 copper chelates leads to dissociation of aquo-ligands on the *z*-axis,[10] while in the nickel chelates aquo-ligands on the *z*-axis remain intact even in the 1 : 2 chelates.

The fact that the data on the 1 : 2 zinc chelates of *trans*- and *cis*-diamines fall on a single correlation line can be regarded as an evidence for a very small inter-ligand interaction in the tetrahedral coordination sphere of zinc(II) ion. If this is the case, the separation between correlation lines in the 1 : 1 zinc chelates should be ascribed to penta- or hexacoordination structures[11] of 1 : 1 diamine–zinc complexes in aqueous solutions rather than to the tetrahedral structure. The former structure would be transformed into the latter with completion of a coordination sphere by four amino groups in 1 : 2 complexes.

ESR and Optical Absorption Studies of Various Bis(*N*-salicylidenealkylaminato)copper(II) Complexes with Tetrahedrally-distorted Coordination Geometry

Hiroshi YOKOI

Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Katahira, Sendai 980

(Received June 11, 1974)

The ESR and visible absorption spectra of a number of bis(*N*-salicylidenealkylaminato)copper(II) complexes with different kinds of alkyl groups were measured in toluene. The coordinations of these complexes in toluene are distorted towards a tetrahedral geometry to varying extents; the relationship between the degree of the distortion and the ESR and visible absorption parameters was systematically investigated. Especially, the experimental fact that the absolute values of the hyperfine coupling constant with the copper nucleus decrease with an increase in the degree of distortion was discussed. A configurational equilibrium between two species with different degrees of the distortion was found to exist for the complexes with R=isopropyl and cyclohexyl in toluene.

A number of crystal structure determinations of bis(*N*-salicylidenealkylaminato)copper(II) complexes by three dimensional X-ray methods have been carried out,[1-6] and some of the complexes have been revealed to adopt tetrahedrally-distorted configurations in crystals, depending on the nature of the alkyl groups. Many other physicochemical measurements of these complexes in various states have been made in order to obtain some information about the stereochemistry and related properties.[7] There have been a few ESR reports on various copper(II) complexes with tetrahedral-coordination geometry.[8-10] It seems, however, that a satisfactory method for the precise interpretation of the ESR parameters of those complexes has not yet been established. In the present work, therefore, ESR and optical absorption studies of a series of bis(*N*-salicylidenealkylaminato)copper(II) complexes with many different kinds of alkyl groups, which are distorted towards a tetrahedral configuration to varying extents in solutions, have been carried out systematically.

Experimental

Materials. 11 kinds of bis(*N*-salicylidenealkylaminato)-copper(II) complexes were prepared and purified according to the usual method,[11] using commercial reagents; all the complexes are listed in Table 1, and hereafter they will be designated as Cu(*N*-R-sal)$_2$. Commercial toluene was purified by successive shaking with sulfuric acid and sodium hydroxide, followed by drying over sodium, and, finally, fractional distillation.

ESR and Visible Absorption Measurements. The ESR spectra of the above-mentioned complexes in toluene at a concentration of 1.0×10^{-2} mol/l were measured at room temperature and at the temperature of liquid nitrogen by means of a Hitachi 771 X-band ESR spectrometer. The visible absorption spectra of the complexes in toluene were recorded at room temperature on a Cary 14 spectrometer, using 1-cm quartz cells.

Results and Discussion

The crystal structures of the Cu(*N*-R-sal)$_2$ complexes with R=methyl,[1] *n*-propyl,[3] and *n*-butyl[5] are known to adopt normal planar configurations. On the other hand, X-ray analytical studies have revealed that the complexes with R=isopropyl[4] and *t*-butyl[6] in crystals are distorted towards a tetrahedral configuration because the alkyl groups are sufficiently bulky to prevent normal planar complexes from being formed. There is, however, an unexpected observation that Cu(*N*-ethylsal)$_2$ is distorted from planarity.[2] It appears, therefore, that intermolecular forces, *i.e.*, crystal packing forces, play an important and delicate role in determining the distortion. It is now unambiguous that the complexes with bulky alkyl groups in toluene are similarly distorted towards a tetrahedral configuration. The dipole-moment measurements of these complexes in dioxane and benzene suggest that this holds true.[12] This fact has also been supported by optical absorption spectral studies in such inert solvents as benzene and in various solid states.[12]

In this work, the visible absorption spectra were again measured at room temperature for all the present complexes in toluene in order to obtain systematic information about the coordination geometry; all the observed spectra are shown in Fig. 1. This figure indicates that the d-d spectra of the complexes appear

A: R=methyl. B: R=ethyl, *n*-propyl, *n*-butyl, isobutyl, *n*-amyl, and *n*-hexyl. C: R=cyclohexyl. D: R=isopropyl and *s*-butyl. E: R=*t*-butyl.

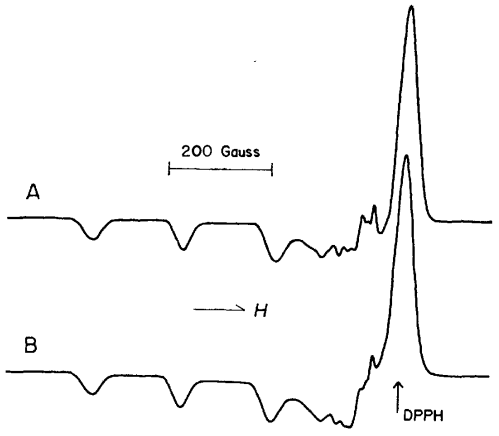

Fig. 2. X-band ESR spectra of the Cu(*N*-R-sal)$_2$ complexes with R=ethyl (A) and *n*-hexyl (B) in toluene at 77 K.

as shoulders on the longer-wavelength side of the near-ultraviolet intense bands, except for Cu(*N*-*t*-butyl-sal)$_2$, whose d-d spectrum appears only as a peak. It is difficult, therefore, to discuss these d-d spectra in detail. Two important observations, however, can be made in Fig. 1. One is the tendency for the intensities of the d-d spectra to increase in the spectral order of I to V, while the d-d spectra shift to longer wavelengths in the same spectral order. This tendency is consistent with the dependence of the spectral change on a distortion of the coordination geometry towards tetrahedron.[13,14] The other is the fact that the Cu(*N*-R-sal)$_2$ complexes with R=ethyl, *n*-propyl, *n*-butyl, isobutyl, *n*-amyl, and *n*-hexyl exhibit almost the same spectra, while the d-d spectra of the complexes with *R*=α-branched alkyl (*s*-alkyl) groups, *i,e.*, isopropyl, *s*-butyl, *t*-butyl, and cyclohexyl, become more intense than those of the R=α-non-branched alkyl groups.

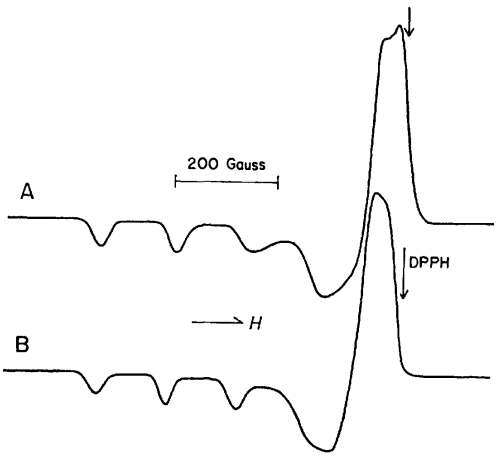

Fig. 3. X-band ESR spectra of the Cu(*N*-R-sal)$_2$ complexes with R=*s*-butyl (A) and *t*-butyl (B) in toluene at 77 K.

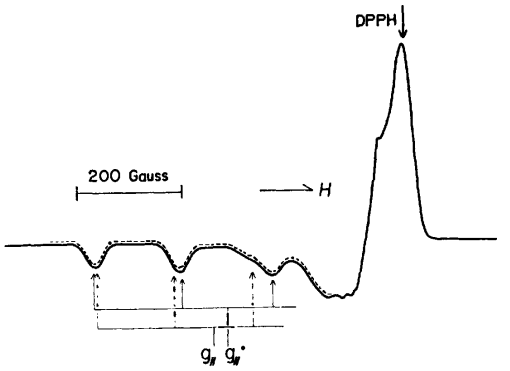

Fig. 4. X-band ESR spectrum of Cu(*N*-isopropyl-sal)$_2$ in toluene at 77 K (see the text as to the dotted line, $g_{\parallel}$, and $g_{\parallel}'$ written in the figure).

A similar classification of the Cu(*N*-R-sal)$_2$ complexes could also be made on the basis of ESR results. The ESR spectra of the complexes with R=ethyl, *n*-propyl, *n*-butyl, isobutyl, *n*-amyl, and *n*-hexyl were similar to one another; two of them are shown in Fig. 2. Cu(*N*-methyl-sal)$_2$, however, was different from the above-mentioned group of complexes in that its ESR spectrum was made up by the superposition of a spectrum due to those mentioned above and of a spectrum due to a triplet-state dimer.[15] On the other hand, the ESR spectra of the complexes with R=*s*-butyl, *t*-butyl, isopropyl, and cyclohexyl, the former three of which are shown in Figs. 3 and 4, were quite different in line shape from those in Fig. 2; the spectrum of the last complex was similar to the one in Fig. 4. The spectra in Fig. 3 are different in both line width and line position from those in Fig. 2. A detailed discussion of Fig. 4 will be given later. All the ESR parameters, which are listed in Table 1, were determined on the assumption that all the *g* and *A* tensors are of an axial or nearly axial symmetry. This assumption is supported by the experimental fact that the ESR spectra in Fig. 3 are of an axial type of line shape.

The expressions for the principal values of *g* and *A* tensors in terms of the coefficients in one-electron LCAO MOs have already been given in detail for the copper-

(II) complexes, whose coordination around the metal ion is a flattened tetrahedron.[8,9] It has been revealed experimentally and theoretically that, for each of the complexes, the $g_{//}$ value increases with an increase in the degree of the distortion towards a tetrahedral coordination geometry, and that there is a slight increase in the $g_{\perp}$ value (or g_x and g_y) up to the limit of a small degree of distortion.[10] It can, furthermore, be reasonably estimated from the equation of $A_{//}$ that the $|A_{//}|$ value also decreases with an increase in the degree of the distortion, since then the increases in both the $g_{//}$ value and the square value of the mixing coefficient of the 4p atomic orbital in the equation effectively contribute to a decrease in the $|A_{//}|$ value.[8,9]

The ESR data listed in Table 1 clearly indicate that the $g_{//}$ values of the Cu(*N*-R-sal)$_2$ complexes with R= methyl, ethyl, *n*-propyl, *n*-butyl, *n*-amyl, and *n*-hexyl increase slightly in this order of complexes, and that the $|A_{//}|$ values also decrease slightly in the same order. It is obvious that Cu(*N*-isobutyl-sal)$_2$ also belongs to this group. In this order of complexes, however, the two neighbors between which the largest differences in the $g_{//}$ and $|A_{//}|$ values were detected are the complexes of R=methyl and ethyl, as may be seen in the table. This fact, combined with the visible absorption spectral results shown in Fig. 1 and the crystal structural result that even Cu(*N*-ethyl-sal)$_2$ can adopt a tetrahedrally-distorted configuration,[2] suggest that all the complexes of this group except Cu(*N*-methyl-sal)$_2$ may have similar structures, with a slight distortion towards tetrahedral coordination geometry in toluene. On the other hand, the $g_{//}$ values of the complexes with R=*s*-butyl and *t*-butyl are remarkably large, and their $|A_{//}|$ values are remarkably small, compared with those of the above-mentioned group of complexes. This fact, combined with the visible absorption spectral results and the crystal structural results for Cu(*N*-*t*-butyl-sal)$_2$, indicates that the coordination geometry of these two complexes in toluene is highly distorted towards tetrahedron.

It is a noteworthy experimental fact that the $|A_0|$ values of the complexes with R=α-branched alkyl groups become considerably smaller than those of the complexes with R=α-non-branched alkyl groups, as is shown in Table 1. For Cu(*N*-*t*-butyl-sal)$_2$, furthermore, the decrease in the $|A_0|$ value was found to be comparable in magnitude to that in the $|A_{//}|$ value. A_0 is written in terms of the Fermi contact term for the free ion, κ, by this relation:[8,9]

$$A_0 = -(P_d a^2 + P_p b^2),$$

where $P_{d,p}=2\gamma\mu_0\mu_N\langle r^{-3}\rangle_{3d,4p}$, μ_N being the nuclear magneton and γ being the nuclear gyromagnetic ratio, and where a and b are the mixing coefficients of the 3d and 4p atomic orbitals in the ground-state unpaired-electron molecular orbital. One has $P_d : P_p = 828.7 : (925\pm40)$[8,9] and $P_d = 0.036\ cm^{-1}$.[16] The equation of A_0 states that A_0 is almost independent of any distortion towards a tetrahedral configuration. The above-mentioned experimental fact, therefore, is clearly in conflict with an estimation derived from this equation. Freeman and Watson have revealed, through an unrestricted Hartree-Fock calculation of the spin-polarization of the 4s electrons by an exchange interaction with the 3d unpaired electron for a copper atom in the $3d^94s^2$ configuration, that the spin-polarization of the 4s electrons contributes to a weakening of the isotropic Fermi contact interaction.[17,18] The small $|A_0|$ values of the complexes with R=*s*-butyl and *t*-butyl, therefore, can be interpreted in terms of an increase in the electron density on the 4s orbital with an increase in the degree of distortion. This interpretation is plausible in view of the fact that the charge neutralization on the metal ion is facilitated by electron donation from the ligand orbitals to the metal 4s orbital, rather than by that to the metal 3d orbital, because the interaction between the ligand and 3d orbitals is weakened by the tetrahedral distortion. On the basis of this interpretation, the degree of decrease in the $|A_0|$ value would give a measure of the electron density on the metal 4s orbital. The possibility that there may be another mechanism of decrease in the $|A_0|$ value, however, can not be excluded, because there has been no information about the spin-polarization of all the s-electrons caused by an exchange interaction with the metal 4p unpaired electron inevitably produced in the unpaired-electron molecular orbital.

The dipole moments of a number of the Cu(*N*-R-sal)$_2$ complexes have been measured in dioxane and benzene.[13,7] The results have revealed that the complexes of R=isopropyl and *t*-butyl do have substantial permanent dipole moments, and that the values increase in this order: *n*-propyl$\sim$*n*-butyl$<$isopropyl$\sim$*s*-butyl$<$*t*-butyl. These data, however, do not distinguish between a configurational equilibrium as is found for many nickel(II) complexes[7] and the existence of a single structural species. The ESR spectrum of Cu(*N*-isopropyl-sal)$_2$ in toluene, which is shown in Fig. 4, is different in line shape from the types of spectra in both Figs. 2 and 3. The dotted line in the low-field part of Fig. 4 is a spectrum simulated according to the superposition of the types of spectra in both Figs. 2 and 3 with $g_{//}'$ and $g_{//}$ at the intensity ratio of 3 to 2; actually, the spectrum of Fig. 3(A) itself was utilized for the spectral simulation. The dotted-line spectrum is in satisfactory agreement with the observed one, especially at the part of the hyperfine absorption lines of $I_z=1/2$, as may be seen in Fig. 4. Thus, we may conclude that a configurational equilibrium between two complex species with different degrees of the tetrahedral distortion exists for this complex in toluene. Such is also the case with Cu(*N*-cyclohexyl-sal)$_2$, since this complex showed an ESR spectrum analogous to that of Cu(*N*-isopropyl-sal)$_2$. On the other hand, the ESR line shapes shown in Fig. 3 suggest that the complexes of R=*t*-butyl and *s*-butyl may be dissolved as a single structural species in toluene.

The author wishes to thank Professor Taro Isobe for his encouragement throughout this work; thanks are also due to Mr. Makoto Chikira for many helpful suggestions relating to this work.

Binuclear Metal Complexes. XI.[1] Substituent Effect upon Magnetisms of Binuclear Oxovanadium(IV) and Copper(II) Complexes of the Schiff Bases, 2,6-Bis[*N*-(2-hydroxy-5-substituted-phenyl)iminomethyl]-4-methylphenol

(Received June 17, 1974)

Binuclear oxovanadium(IV) and copper(II) complexes, M_2(fsalap-R)(OMe) (R=H, CH_3, Cl, and NO_2) were synthesized and characterized, where H_3fsalap-R denotes 2,6-bis[*N*-(2-hydroxy-5-substituted-phenyl)iminomethyl]-4-methylphenol and the metal ions are connected by the phenolic oxygen and a methanolate ion. The cryomagnetic properties of the complexes except Cu_2(fsalap-NO_2)(OMe) could be interpreted on the basis of the Bleaney-Bowers equation. It was found that the $-2J$ values for the oxovanadium(IV) complexes increase in the order $(VO)_2$(fsalap-CH_3)(OMe) < $(VO)_2$(fsalap-H)(OMe) < (VO_2)(fsalap-Cl)(OMe), while those for the copper(II) complexes decrease in the order Cu_2(fsalap-CH_3)(OMe) > Cu_2(fsalap-H)(OMe) > Cu_2(fsalap-Cl)(OMe). These facts could be reasonably explained in terms of the difference in structures and spin-exchange mechanisms between the oxovanadium(IV) and the copper(II) complexes. $(VO)_2$(fsalap-NO_2)(OMe) showed a very strong antiferromagnetic spin-exchange interaction ($-2J=545$ cm^{-1}) compared with the other complexes (180—280 cm^{-1}). On the other hand, the magnetism of Cu_2(fsalap-NO_2)(OMe) could be interpreted in terms of the Ising model.

Since both oxovanadium(IV) and copper(II) ions have one unpaired electron in each of their 3d-shells, magnetic exchange interactions of binuclear oxovanadium(IV) complexes are to be discussed in relation to those of binuclear copper(II) complexes. Many binuclear copper(II) complexes have been studied extensively.[2] On the other hand, relatively less number of binuclear oxovanadium(IV) complexes have been synthesized.[3-10] It seems interesting to synthesize binuclear oxovanadium(IV) and copper(II) complexes with the same ligand system and to compare their magnetic properties, but only few have been reported concerning such kind of research.[4,11,12] Ginsberg *et al.* synthesized binuclear oxovanadium(IV) and copper(II) complexes of the Schiff bases prepared from 5-R-salicylaldehydes and 4-R′-2-aminophenols.[4] They found that the magnitude of the spin-exchange interaction for the copper(II) complexes increases with the decreasing order of electron-withdrawing abilities of R groups. However, they could not find such regularity for the oxovanadium(IV) complexes.

In the preceeding papers of this series,[13-18] it was shown that 2,6-diformyl-4-methylphenol and its Schiff bases form stable binuclear complexes with copper(II) and nickel(II) ions. In the present study, the Schiff bases, 2,6-bis[*N*-(2-hydroxy-5-substituted-phenyl)-iminomethyl]-4-methylphenol, were used for the preparation of binuclear oxovanadium(IV) and copper(II) complexes. The Schiff bases are abbreviated to H_3-fsalap-R, in which R is H, CH_3, Cl or NO_2, the substituents being attached to 4-position of 2-aminophenol. The complexes obtained were characterized as a binuclear complex bridged by the phenolic oxygen in the 2,6-diformyl-4-methylphenol moiety and methanolate ion (Fig. 1). The complexes are denoted by M_2-(fsalap-R)(OMe). Their magnetic properties were investigated over the temperature range 77.4—300 K and discussed on the basis of the Heisenberg model and/or the Ising model.

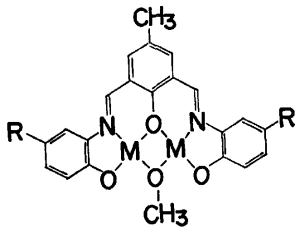

Fig. 1.

Experimental

Syntheses. The synthetic method of 2,6-diformyl-4-methylphenol is described elsewhere.[15]

$(VO)_2$(fsalap-H)(OMe). Vanadium(IV) oxodichloride (500 mg) was dissolved in absolute methanol(30 ml), and the solution was filtered to remove any insoluble materials. To this solution was added a methanolic solution(30 ml) 2,6-diformyl-4-methylphenol(164 mg) and 2-aminophenol (218 mg). Orange crystals immediately separated. After the reaction mixture was stirred at 60 °C for 3 hr, the crystals were collected, thoroughly washed with absolute methanol and dried under vacuum.

Found: C, 51.46; H, 3.60; N, 5.37%. Calcd for $C_{22}H_{18}N_2O_6V_2$: C, 51.99; H, 3.57; N, 5.51%.

$(VO)_2$(fsalap-CH_3)(OMe). This complex was obtained by nearly the same method mentioned above except for using 2-amino-4-methylphenol(264 mg) instead of 2-aminophenol. The mixture was stirred for 3 hr at 60 °C to give orange-brown crystals, which were collected, washed with absolute methanol and dried under vacuum.

Found: C, 53.95; H, 4.03; N, 5.31%. Calcd for $C_{24}H_{22}N_2O_6V_2$: C, 53.75; H, 4.13; N, 5.22%.

$(VO)_2$(fsalap-Cl)(OMe). 2,6-Diformyl-4-methylphenol (164 mg) and 2-amino-4-chlorophenol(288 mg) were dissolved in absolute methanol (40 ml), and the mixture was neutralized with 1M sodium methoxide solution(3 ml). Then this solution was added to a solution of vanadium(IV) oxodichloride (500 mg) in methanol (30 ml). Orange-brown crystals which separated were filtered and dried under vacuum.

Found: C, 45.63; H, 3.04; N, 4.66%. Calcd for C_{22}-

$H_{16}N_2O_6Cl_2V_2$: C, 45.78; H, 2.79; N, 4.85%.

$(VO)_2$(fsalap-NO_2)(OMe). 2,6-Diformyl-4-methylphenol (164 mg) and 2-amino-4-nitrophenol(308 mg) were dissolved in the mixture of absolute methanol (25 ml) and dioxane (25 ml). This solution was then added to a solution of vanadium(IV) oxodichloride(500 mg) in absolute methanol (30 ml), and the whole was stirred at 60 °C for 3 hr to give yellowish brown crystals. They were collected, washed with methanol and dried under vacuum.

Found: C, 43.93; H, 2.78; N, 9.22%. Calcd for $C_{22}H_{16}N_4O_{10}V_2$: C, 44.17; H, 2.70; N, 9.36%.

Cu_2(fsalap-H)(OMe)·CH_3OH. This complex was obtained by the similar method to that for $(VO)_2$(fsalap-H)(OMe) except for using copper(II) acetate monohydrate (440 mg) instead of vanadium oxodichloride. It forms brown crystals, containing one molecule of methanol.

Found: C, 52.42; H, 3.88; N, 5.44%. Calcd for $C_{22}H_{18}N_2O_4Cu_2\cdot CH_3OH$: C, 52.56; H, 4.22; N, 5.33%.

Cu_2(fsalap-CH_3)(OMe). This complex was prepared by the similar method to that for $(VO)_2$(fsalap-CH_3)(OMe), using copper(II) acetate monohydrate(440 mg). It forms orange-brown crystals.

Found: C, 54.51; H, 4.46; N, 5.34%. Calcd for $C_{24}H_{22}N_2O_4Cu_2$: C, 54.44; H, 4.19; N, 5.29%.

Cu_2(fsalap-Cl)(OMe). The synthetic procedure of this complex resembles that for $(VO)_2$(fsalap-Cl)(OMe) except for using copper(II) acetate monohydrate (440 mg) instead of vanadium(IV) oxodichloride. It forms orange-brown crystals.

Found: C, 47.04; H, 2.95; N, 4.88%. Calcd for $C_{22}H_{16}N_2O_4Cl_2Cu_2$: C, 46.33; H, 2.83; N, 4.91%.

Cu_2(fsalap-NO_2)(OMe)·$2H_2O$. This complex was obtained by treating a methanolic solution of copper(II) acetate monohydrate(440 mg) with a solution of 2,6-diformyl-4-methylphenol(164 mg) and 2-amino-4-nitrophenol(308 mg) in methanol–dioxane(1 : 1, 50 ml). Brown crystals which separated were filtered and washed with methanol. It contains two molecules of water.

Found: C, 42.71; H, 2.97; N, 9.11%. Calcd for $C_{22}H_{16}N_4O_8Cu_2\cdot 2H_2O$; C, 42.11; H, 2.89; N, 8.93%.

Measurements. Infrared spectra were measured with a 215 Hitachi Infrared Grating Spectrophotometer in the region 4000—650 cm^{-1}, using KBr-disk and hexachlorobutadiene-mull methods. ESR spectra(X-band) of polycrystalline samples were measured with a JEOL ESR-apparatus model JESME-3X at −100 °C and at room temperature. Magnetic susceptibilities were measured by the Faraday method in the range from liquid nitrogen temperature to room temperature. Pascal's constants[19] were used for diamagnetic correction. Mercuric tetrathiocyanatocobaltate(II) was used as a magnetic standard. The effective magnetic moments at room temperature were calculated from the expression, $\mu_{eff}=2.828\sqrt{(\chi_A-N\alpha)T}$

Results and Discussion

In the IR spectra of the complexes no absorption band due to the formyl group was found in the region 1700—1620 cm^{-1} and a strong band was found around 1600 cm^{-1}. This band may be attributed to the C=N stretching vibration. The V=O stretching vibration of $(VO)_2$(fsalap-R)(OMe) (R=H, CH_3, and Cl) was observed near 990 cm^{-1}. On the other hand, the V=O stretching vibration of $(VO)_2$(fsalap-NO_2)(OMe) shifted to a region of considerably low frequency (900 cm^{-1}). This fact implies that $(VO)_2$(fsalap-NO_2)(OMe) has a different molecular structure from other oxovanadium(IV) complexes. In the spectrum of Cu_2(fsalap-NO_2)(OMe)·$2H_2O$ was observed a broad band around 3200 cm^{-1}, which was assigned to the O–H vibration of water. This complex showed a loss of weight corresponding to two moles of water, when it was heated at 70 °C for several hours under vacuum. It recovered the weight when it was left standing in the atmosphere at room temperature. Therefore, it should be noted that Cu_2(fsalap-NO_2)(OMe) possesses a different structure from other Cu_2(fsalap-R)(OMe) complexes.

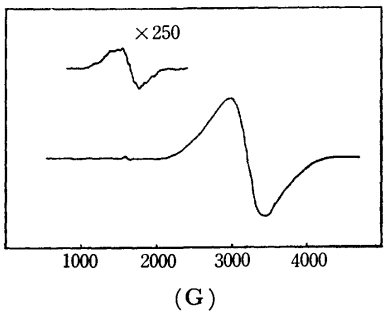

Fig. 2. ESR spectrum of $(VO)_2$(fsalap-H)(OMe) at room temperature.

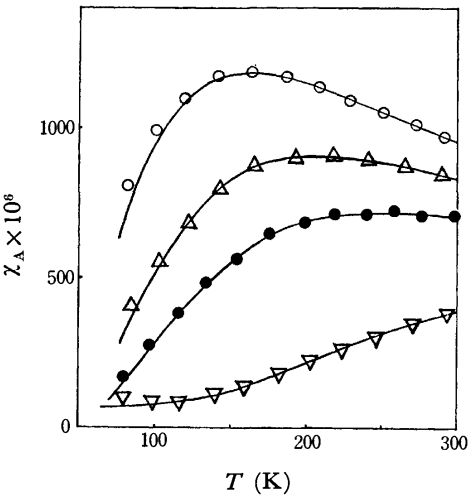

Fig. 3. Temperature dependeuce of magnetic susceptibilities of (○) $(VO)_2$(fsalap-CH_3)(OMe), (△) $(VO)_2$(fsalap-H)(OMe), (●) $(VO)_2$(fsalap-Cl)(OMe), and (▽) $(VO)_2$(fsalap-NO_2)(OMe).

The ligand field bands of the complexes could not be identified because of the intense absorption due to the ligand in visible region.

The ESR spectra of the complexes (polycrystalline sample) were measured. All spectra resemble each other. As an example the spectrum of $(VO)_2$(fsalap-H)(OMe) is shown in Fig. 2. A broad band around 3200 Guass (2000 G width) and a weak band near 1600 G were tentatively assigned to the $\Delta M_s=1$ and $\Delta M_s=2$ transitions respectively. All of these data are consistent with the structure given in Fig. 1.

The effective magnetic moments of the complexes at room temperature are lower than the spin-only value, 1.73 B.M.. The magnetic susceptibilities were measured at various temperatures. As shown in Figs. 3 and 4, the magnetisms of the complexes except Cu_2-

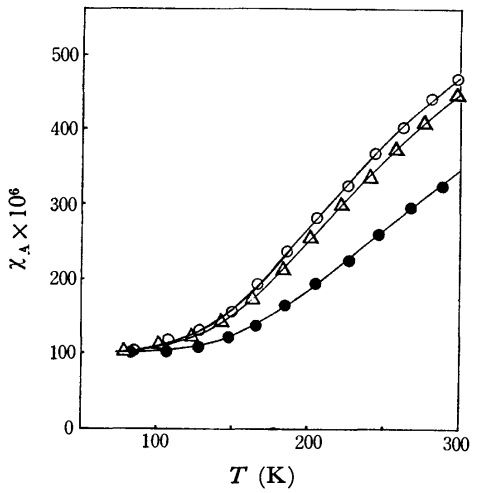

Fig. 4. Temperature dependence of magnetic susceptibilities of (●) Cu_2(fsalap-CH_3)(OMe), (△) Cu_2-(fsalap-H)(OMe), and (○) Cu_2(fsalap-Cl)(OMe).

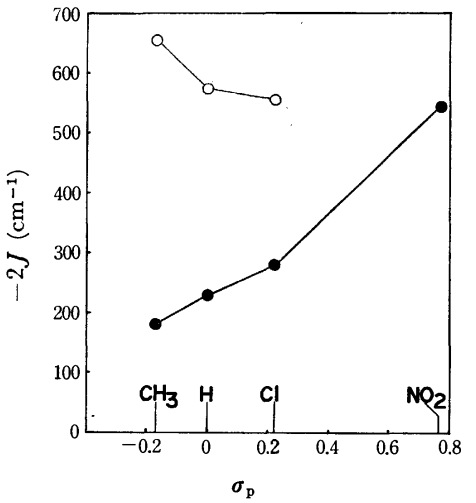

Fig. 5. The relations between the $-2J$ values and Hammett's σ_p values for (●) $(VO)_2$ (fsalap-R)(OMe) and for (○) Cu_2 (fsalap-R) (OMe).

(fsalap-NO_2)(OMe) (anhydrous form) can be interpreted on the basis of the Bleaney-Bowers equation,[20]

$$\chi_A = \frac{Ng^2\beta^2}{3kT}\left[1+\frac{1}{3}\exp(-2J/kT)\right]^{-1} + N\alpha,$$

where J is the exchange integral between a magnetically coupled pair and $N\alpha$ is the temperature independent paramagnetism. The agreements between theoretical and experimental $\chi_A - T$ curves are satisfactory when the parameters, g, J and $N\alpha$, are assumed as listed in Table 1. Slight deviations from the theoretical curves at low temperature may be attributed to a trace of paramagnetic impurities. The effective magnetic moments of the complexes are also given in Table 1.

As seen in Table 1, with the increasing order of electron-withdrawing abilities of the substituents the $-2J$ value (singlet-triplet energy separation) increases in the case of the oxovanadium(IV) complexes, but decreases in the case of the copper(II) complexes, This is more clearly shown by Fig. 5 in which the $-2J$ values are plotted *versus* Hammett's σ_A values.

It is well known that many oxovanadium(IV) complexes have square-pyramidel structures with the oxygen atom at the apex, vanadium atom being slightly lifted from the vasal plane. The electron-donating substituent at the 4-position in 2-aminophenol moiety increase the electron density on the phenolic oxygen atom and *vice versa*. According to an electrostatic model,[12] it is expected that the deviation of vanadium atom from the vasal plane is the largest for $(VO)_2$(fsalap-CH_3)-(OMe) and the smallest for $(VO)_2$(fsalap-Cl)(OMe) among the present complexes. Since the direct coupling between d_{xy}-orbitals is expected to be the dominating factor for the spin-exchange interaction in binuclear oxovanadium(IV) complexes,[12,22,23] the overlapping of d_{xy}-orbitals increases in the order $(VO)_2$-(fsalap-CH_3)(OMe) < $(VO)_2$(fsalap-H)(OMe) < $(VO)_2$-(fsalap-Cl)(OMe), whereby the $-2J$ value increasing in this order.

Table 1. Magnetic parameters and effective magnetic moments of complexes

M_2(fsalap-R)-(OMe) M	R	$-2J$ (cm^{-1})	g	$N\alpha\times10^6$	μ_{eff} (K)
VO	CH_3	180	1.87	60	1.46(291.0)
VO	H	230	1.86	40	1.37(291.2)
VO	Cl	280	1.81	45	1.25(298.0)
VO	NO_2	545	1.95	70	0.85(295.7)
Cu	CH_3	655	2.15	100	0.70(288.5)
Cu	H	570	2.15	100	0.88(298.1)
Cu	Cl	555	2.15	100	1.04(298.1)
Cu	NO_2				1.18(288.3)

On the other hand, the majority of copper(II) complexes have tetragonal structures. It has been revealed[24,25] that the spin-pairing interaction in the binuclear copper(II) complexes increases when the equatorial bonds are strengthened. This can be interpreted in term of a superexchange pathway through p_π(Cu)-p_π(bridging atom)-d_π(Cu) orbitals.[12,26-28] Our finding that the $-2J$ value decreases in the order Cu_2(fsalap-CH_3)(OMe) > Cu_2(fsalap-H)(OMe) > Cu_2-(fsalap-Cl)(OMe) is consistent with the above rule, because the electron density on the 2-aminophenolic oxygen atom decreases in this order and accordingly the Cu–O bond is weakened in the same order.

It is noteworthy that $(VO)_2$(fsalap-NO_2)(OMe) shows a very strong antiferromagnetic spin-exchange interaction and its V=O stretching vibration is observed at 900 cm^{-1}. Since such a shift of the V=O band to the low-frequency region is attributable to the intermolecular ···V=O···V=O··· interaction,[4,29] it is natural to assume the polymeric structure given in Fig. 6 for $(VO)_2$(fsalap-NO_2)(OMe). Hence the configuration around vanadium(IV) ion might not be distorted tetragonal-pyramidal but pseudo-octahedral. In fact the deviation of vanadium(IV) ion from the plane in *N,N'*-1,3-propylenebis(salicylaldiminato)-oxovanadium(IV),[29] whose linear chain structure of ···V=O···V=O··· bonding was demonstrated on the basis of X-ray analysis, is only 0.31 A, which is much

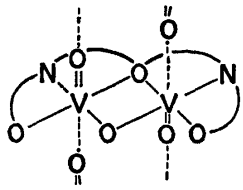

Fig. 6.

smaller than 0.54—0.58 A in the common oxovanadium(IV) complexes.[30,31] Accordingly the equatorial bonding system,  , is made more coplanar, and this will bring about larger overlapping between the vanadium d_{xy}-orbitals. The intermolecular spin-exchange interaction *via* ···V=O···V=O··· bonds is very weak compared with the intramolecular spin-exchange interaction, since the magnetism of $(VO)_2$(fsalap-NO_2)-(OMe) can be interpreted in terms of the Bleaney-Bowers equation. Such anomalous magnetisms have been reported for other binuclear oxovanadium(IV) complexes of the nitro-substituted Schiff bases.[4] It is likely that the strongly electron-withdrawing nitro group attached to the 4-position of 2-aminophenol moiety reduces the electron density on the phenolic oxygen atom, thereby weakening the ligand-field and allowing the axial coordination to the vanadium(IV) ion.

The magnetic property of Cu_2(fsalap-NO_2)(OMe) (anhydrous form), on the other hand, could not be interpreted on the basis of the Bleaney-Bowers equation. Its magnetism can be interpreted in terms of the Ising model. According to this model, the effective magnetic moment is expressed by the equation,[32]

$$\mu_{eff}^2 = \frac{1}{4}[\exp(4K) + (2+K^{-1})\exp(2K) - K^{-1} \times \exp(-2K) + 5][\exp(2K) + \exp(-2K) + 2]^{-1},$$

where K is J/kT. The good agreement of the experimental μ_{eff} values with this equation is shown in Fig. 7. Therefore, it is clear that Cu_2(fsalap-NO_2)(OMe) has a polymeric structure. However, further detailed information about the molecular structure can not be obtained at present. The high electron-withdrawing ability of the nitro group seems to play an important role in the formation of polymeric structure.

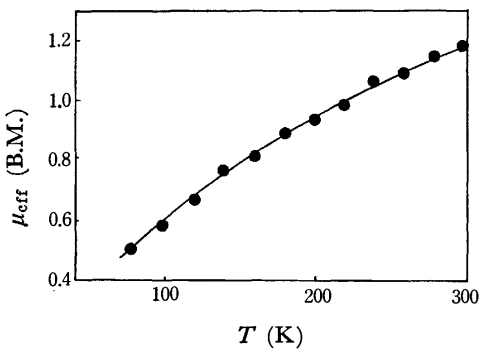

Fig. 7. Temperature dependeuce of the effective magnetic moment of Cu_2(fsalap-NO_2)(OMe). The solid line is theoretically obtained by assuming $g=2.15$ and $J=-225\ cm^{-1}$.

Binuclear Metal Complexes. XIII.[1] Syntheses and Magnetic Properties of Thiocyanato-Bridged Binuclear Copper(II) Complexes

Tomoko ICHINOSE, Yuzo NISHIDA, Hisashi OKAWA,* and Sigeo KIDA

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received July 26, 1974)

Three binuclear copper(II) complexes, Cu_2(fsal-NMe_2)$(NCS)_3$, Cu_2(fsal-NEt_2)$(NCS)_3$ and Cu_2(fsal-pa)-$(NCS)_3$, have been synthesized and characterized, where Hfsal-NMe_2, Hfsal-ENt_2 and Hfsal-pa denote the Schiff bases prepared by the condensation reaction of 2,6-diformyl-4-methylphenol with *N,N*-dimethylethylenediamine, *N,N*-diethylethylenediamine and 2-pyridylmethylamine, respectively. It was demonstrated that the complexes essentially consist of a binuclear unit of the thiocyanato-bridged skeleton,  . The cryomagnetic properties could be explained on the basis of the equation for the tetranuclear cluster formed with two binuclear units linked by the out-of-plane bonding. The magnetisms and structures of the complexes were discussed in comparison with those of the Cu_2(fsal-NR_2)X_3 (X=Cl, Br).

It is well known[2-7] that the Schiff bases of 2,6-diformyl-4-methylphenol form binuclear copper(II) complexes, in which copper(II) ions are connected by two different groups, *i.e.*, the phenolic oxygen and an anion, X^-, such as Cl^-, Br^-, OH^-, OR^-, N_3^-, and $C_3H_3N_2^-$ (the conjugate base of pyrazole). However, no binuclear copper(II) complexes possessing thiocyanato-bridging group has been obtained. In the preceeding paper of this series,[5] we reported the syntheses and magnetisms of some binuclear copper(II) complexes of the Schiff bases derived from 2,6-diformyl-4-methylphenol and *N,N*-dialkylethylenediamines (See Fig. 1). Their magnetic properties were well explained in terms of the Bleaney-Bowers equation and it was found that the magnitude of the spin-exchange integral, $-J$, decreased in the order X=OH>Br>Cl.

The object of this study is to synthesize the thiocyanato-bridged binuclear copper(II) complexes and to investigate their magnetic properties in comparison with those of the corresponding hydroxo-, chloro-, or bromo-bridged complexes.

The ligands used in this work are the Schiff bases derived from 2,6-diformyl-4-methylphenol and amines such as *N,N*-dimethylethylenediamine, *N,N*-diethylethylenediamine, and 2-pyridylmethylamine (the ligands are abbreviated to Hfsal-NMe_2, Hfsal-NEt_2, and Hfsal-pa respectively). On treating these ligands and diisothiocyanatodipyridinecopper(II) in acetonitrile, green prisms were obtained. Based on the results of elemental analyses, the complexes are formulated as Cu_2(fsal-NR_2)$(NCS)_3$ (R=Me and Et) and Cu_2(fsal-pa)$(NCS)_3$. The structures of these complexes were investigated on the basis of the infrared spectra, electronic spectra and magnetic measurements. The spin-exchange interactions between copper(II) ions were studied by measuring the temperature variation of magnetic susceptibility.

Experimental

Syntheses. The synthetic method of 2,6-diformyl-4-methylphenol was described elsewhere.[8] *N,N*-Dimethylethylenediamine, *N,N*-diethylethylenediamine and 2-pyridylmethylamine were of commercial origin.

Cu_2(fsal-NMe_2)$(NCS)_3$. 2,6-Diformyl-4-methylphenol (165 mg), and *N,N*-dimethylethylenediamine (176 mg) and diisothiocyanatodipyridinecopper(II) (675 mg) were mixed in acetonitrile (100 ml) and the mixture was stirred at room temperature for 20 hr. The green precipitate which separated was collected, recrystallized from dimethyl sulfoxide-methanol and dried over P_2O_5 under a reduced pressure.

Found: C, 39.62; H, 4.62; N, 16.00; Cu, 20.20%. Calcd. for $C_{22}H_{31}N_7OS_3Cu_2$: C, 39.72; H, 4.50; N, 16.21; Cu, 21.01%.

Cu_2(fsal-NEt_2)$(NCS)_3$. This complex was prepared by a method similar to that for Cu_2(fsal-NMe_2)$(NCS)_3$ except for using *N,N*-diethylethylenediamine (232 mg) instead of *N,N*-dimethylethylenediamine. The green product was recrystallized from acetonitrile and dried over P_2O_5 under a reduced pressure.

Found: C, 43.61; H, 5.24; N, 14.69; Cu, 18.93%. Calcd for $C_{24}H_{35}N_7OS_3Cu_2$: C, 43.62; H, 5.34; N, 14.84; Cu, 19.23%.

Cu_2(fsal-pa)$(NCS)_3$. This complex was synthesized by the reaction of 2,6-diformyl-4-methylphenol (165 mg), 2-pyridylmethylamine (216 mg) and diisothiocyanatodipyridinecopper(II). The green product was recrystallized from acetonitrile and dried over P_2O_5 under a reduced pressure.

Found: C, 44.28; H, 2.90; N, 14.92; Cu, 20.58%. Calcd for $C_{24}H_{19}N_7OS_3Cu_2$: C, 44.71; H, 2.97; N, 15.21; Cu, 19.71%.

Measurements. Infrared spectra were measured with a Hitachi 215 grating spectrophotometer on a KBr disk. Electronic spectra were measured with a Hitachi EPS-3T recording spectrophotometer. Magnetic susceptibilities were measured by the Faraday method over the range from liquid nitrogen temperature to room temperature. Effective magnetic moments were calculated from the equation, $\mu_{eff}=2.828\sqrt{(\chi_A-N\alpha)T}$, where χ_A is the atomic magnetic susceptibility corrected for diamagnetism and $N\alpha$ is the temperature-indepenent paramagnetism. Pascal's constants[9] were used for the correction of diamagnetism.

Results and Discussion

Infrared absorption bands, ligand-field bands (reflectance on solids) and effective magnetic moments at room temperature of the complexes are given in Table 1. The complexes obtained have the composition of L (organic ligand moiety) : Cu : NCS^-=1 ;

* To whom correspondence should be addressed.

Table 1. IR bands, d-d bands, and effective magnetic moments of complexes

	IR (cm^{-1})				Reflectance (kK)	μ_{eff} (K) (B.M.)
	C≡N	C-S	C=N	skeletal		
$Cu_2(fsal\text{-}NMe_2)(NCS)_3$	2080 2070	815 700	1635 1630	1550	15.2	1.57(298.0)
$Cu_2(fsal\text{-}NEt_2)(NCS)_3$	2080 2070	810 730	1640 1627	1550	14.3	1.62(297.0)
$Cu_2(fsal\text{-}pa)(NCS)_3$	2080 2060	820 720	1640	1550	14.3	1.57(296.0)

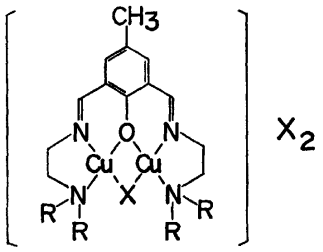

Fig. 1.

2 : 3. Therefore, the structures of the complexes are expected to be similar to those of the previously reported complexes given in Fig. 1. In fact the infrared spectra of $Cu_2(fsal)\text{-}NR_2)(NCS)_3$ are very similar to those of the corresponding $Cu_2(fsal\text{-}NR_2)X_3$[5] (X=Cl or Br, the halogenobridged complexes given in Fig. 1) in the region 4000—650 cm^{-1}, except some additional absorption bands observed for the present complexes. Hoskins *et al.*[7] studied the structure of the binuclear nickel(II) complex of 2,6-bis(thiosemicarbazonomethyl)-4-methylphenol and found that it has a skeleton  , *i.e.*, nickel(II) ions are connected by the phenolic oxygen and a $C_2H_5O^-$ group. Judging from this fact and from the infrared spectra of $Cu_2(fsal\text{-}NR_2)(NCS)_3$ similar to those of $Cu_2(fsal\text{-}NR_2)X_3$, it is likely that the present complexes have a skeleton  (Y=$^-$SCN or $^-$NCS).

In the infrared spectra of the complexes the band due to a skeletal vibration of the benzene ring is observed at 1550 cm^{-1}. This implies that the phenolic oxygen is concerned with bridging.[10] Two C-N stretching vibrations of thiocyanate group were found in the region 2080—2060 cm^{-1}, suggesting that there are two kinds of thiocyanate group of different bonding modes in the complexes. There are also two bands in the regions 820—810 and 730—700 cm^{-1}, which may be assigned to the C-S stretching vibrations of thiocyanate group. The band at 820—810 cm^{-1} may be due to the Cu-NCS bond, since this band is very close in frequency to the ν_{C-S} band of [Cu(tren)NCS]NCS, whose copper(II)-NCS linkage was demonstrated from the X-ray investigation.[11] The band at 730—700 cm^{-1} is located at lower frequency side compared with the ν_{C-S} band (745—750 cm^{-1}) of non-coordinated thiocyanate ion. In general the C-S stretching vibration of the soft metal complexes such as $(Et_4N)_2[Pd(SCN)_4]$ containing M-SCN bond are found in the region 720—690 cm^{-1}.[12] Therefore it is natural to assign this band to the C-S stretching vibration of the S-bonded thiocyanate group. It is well known that thiocyanate is always coordinated to a copper(II) ion with its N-atom. In addition to this the >S-C≡N bridging mode is known,[13] whereas the >N=C=S bridging have never been demonstrated. Thus it is very likely that two copper(II) ions are connected by the >S-C=N group and the N-bonded thiocyanates coordinate to copper(II) ions in the apical positions. It seems that the steric requirement of the ligands favors the formation of the binuclear copper(II) complex with the  skeleton.

All complexes show effective magnetic moments smaller than the spin-only value at room temperature. The magnetic susceptibilities were measured over a temperature range from liquid nitrogen temperature to room temperature. The magnetic parameters for $Cu_2(fsal\text{-}NMe_2)(NCS)_3$ can be estimated as $g=1.99$, $N\alpha=60\times10^{-6}$ c.g.s., e.m.u. and $-2J=205$ cm^{-1} from the best fit of the χ_A values to the Bleaney-Bowers equation,[14]

$$\chi_A=\frac{Ng^2\beta^2}{3kT}\left[1+\frac{1}{3}\exp\left(-2J/kT\right)\right]^{-1}+N\alpha$$

However, it seems unreasonable to assume the g value smaller than 2.0 for copper(II) complexes. When the $-2J$ value is chosen so as to fit the χ_A value calculated from the Bleaney-Bowers equation to the experimental χ_A value at room temperature, assuming $g=2.15$ and $N\alpha=60\times10^{-6}$ c.g.s., e.m.u. (which are very common values for copper(II) complexes), significant deviation is observed between the experimental and theoretical χ_A-T curves as shown in Fig. 3. $Cu_2(fsal\text{-}NEt_2)(NCS)_3$ and $Cu_2(fsal\text{-}pa)(NCS)_3$ displayed similar magnetic behaviors. The facts mentioned above imply that the present complexes are not binuclear.

Recently Hoskins *et al.*[15] reported that the cobalt(II)-cobalt(III) complex of the Schiff base derived from 2,6-diformyl-4-methylphenol and 2-aminophenol has a tetranuclear structure, in which the planar binuclear units are linked by out-of-plane bonds. Therefore, it is likely that the present complexes also have a similar structure and show a magnetic property of a tetranuclear cluster. Based on the tetranuclear structure given in Fig. 2, the spin Hamiltonian may be described as

$$\mathcal{H}=-2J_{13}S_1S_3-2J_{24}S_2S_4-2J_{12}S_1S_2-2J_{23}S_2S_3-2J_{14}S_1S_4-2J_{34}S_3S_4.$$

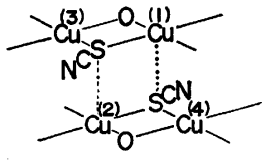

Fig. 2.

On assuming $J_{13}=J_{24}=J$, $J_{12}=J_{23}=J_{14}=J'$ and $J_{34}=0$, the magnetic susceptibility is expressed by the equation,

$$\chi_A = \frac{3g^2}{32T} \times \frac{\begin{array}{l}10\exp[(J+3/2J')/kT]+2\exp[(-J-J'/2)/kT] \\ +2\exp[(-J'/2+\sqrt{2J'^2-2JJ'+J^2})/kT] \\ +2\exp[(-J'/2-\sqrt{2J'^2-2JJ'+J^2})/kT]\end{array}}{\begin{array}{l}4\exp[(J+3/2J')/kT]+2\exp[(-J-J'/2)/kT] \\ +\exp[-Q(11)/kT]+\exp[-Q(22)/kT] \\ +\exp[-Q(33)/kT]+\exp[-Q(44)/kT] \\ +3\exp[(-J'/2+\sqrt{2J'^2-2JJ'+J^2})/kT] \\ +3\exp[(-J'/2-\sqrt{2J'^2-2JJ'+J^2})/kK]\end{array}} + N\alpha,$$

where $Q(11)$, $Q(22)$, $Q(33)$ and $Q(44)$ have the same meaning as was given by Hatfield *et al.*[16] As is shown in Fig. 3, the magnetic properties of the complexes can be well explained on the basis of the equation. The magnetic parameters, $-J$, $-J'$, g and $N\alpha$, obtained from the best fit of experimental χ_A values to the equation are listed in Table 2. Accordingly, it is evident that $Cu_2(fsal\text{-}NR_2)(SCN)_3$ and $Cu_2(fsal\text{-}pa)(NCS)_3$, which are essentially binuclear complexes with  linkage, exhibit the magnetic behavior of a tetranuclear cluster, because of the out-of-plane linkage between two binuclear units. The most probable molecular structures of the complexes are given in Fig. 4.

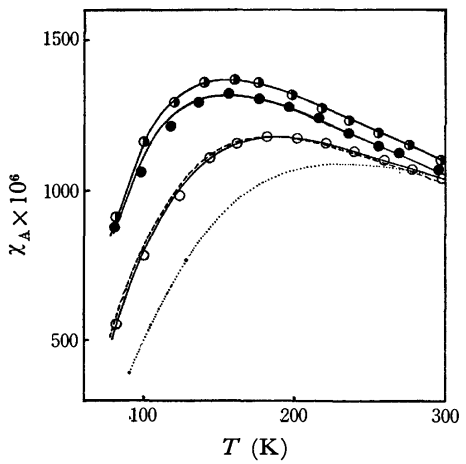

Fig. 3. Variation of molar suceptibilities per copper atom of (○) $Cu_2(fsal\text{-}NMe_2)(NCS)_3$, (◑) $Cu_2(fsal\text{-}NEt_2)(NCS)_3$ and (●) $Cu_2(fsal\text{-}pa)(NCS)_3$ as a function of temperature.
solid lines : theoretical curves based on the tetranuclear cluster using the parameters given in Table 2.
broken line : theoretical curve based on the Bleaney-Bowers equation using the parameters $g=1.99$, $N\alpha=60\times10^{-6}$ c.g.s. e.m.u. and $-2J=-205$ cm^{-1}.
dotted line : theoretical curve based on the Bleaney-Bowers equation assuming $g=2.15$, $N\alpha=60\times10^{-6}$ c.g.s. e.m.u. and $-2J=260$ cm^{-1}.

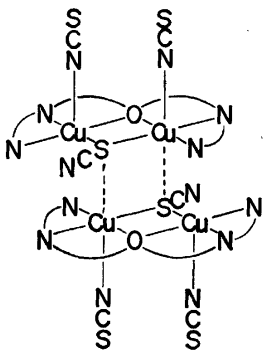

Fig. 4. Most probable structure of the complexes.

Table 2. Magnetic parameters of complexes

	$-J$ (cm^{-1})	$-J'$ (cm^{-1})	g	$N\alpha\times10^6$ (c.g.s.e.m.u.)
$Cu_2(fsal\text{-}NMe_2)(NCS)_3$	105	15	2.18	43
$Cu_2(fsal\text{-}NEt_2)(NCS)_3$	87.5	20	2.17	50
$Cu_2(fsal\text{-}pa)(NCS)_3$	87.5	25	2.15	45

As is seen in Table 2, the $-J'$ values are of the order of 1/7~1/4 of the $-J$ values. It is also seen that the $-J$ value is decreased when the $-J'$ value is increased. It is generally observed that the larger spin-exchange interaction operates between the copper(II) ions, the more coplanar the  plane becomes.[17,18] It is compartible with this trend that the largest $-J$ value was observed for $Cu_2(fsal\text{-}NMe_2)(NCS)_3$ whose d-d band is highest in energy among those of the presently studied complexes. We were unsuccessful to obtain $Cu_2(fsal\text{-}N\text{-}i\text{-}Pr_2)(NCS)_3$. This fact implies that the bulky substituents attached to the nitrogen sterically hinder the complex formation of this type of structure.

Six-coordinate Copper(II) Complexes Derived from the Reactions of Bis(acetylacetonato)- and Bis(ethyl acetoacetato)-copper(II) with Some Bidentate Nitrogen Bases

Takeo KURAUCHI,* Masanori MATSUI, Yukio NAKAMURA,** Shun'ichiro OOI, Shinichi KAWAGUCHI, and Hisao KUROYA

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received July 22, 1974)

Green-to-blue six-coordinate mixed complexes, $Cu(acac)_2(en)$ and $Cu(etac)_2(diamine)$(acac=acetylacetonate anion; etac=ethyl acetoacetate anion; diamine=ethylenediamine, trimethylenediamine, 2,2′-bipyridine or 1,10-phenanthroline) have been isolated by the reactions of the respective parent β-diketonate with the corresponding diamine in dry dichloromethane. On the other hand, the reaction of $Cu(acac)_2$ with en in the mole ratio of one-to-two in dichloromethane saturated with water has resulted in purple crystals of $Cu(acac)_2(en)_2\cdot 2H_2O$. This compound has been shown by X-ray analysis to consist of a square-planar copper(II) cation, coordinated by two ethylenediamine molecules, and two planar acetylacetonate anions, the plane of which is not perpendicular to, but slanted against, the CuN_4 plane. One oxygen atom of the anion participates in the N-H···O hydrogen bonding with an NH_2 group of the ethylenediamine molecule, while the other occupies the axial position of $Cu(en)_2^{2+}$ (Cu···O: 2.79(1) Å). Therefore, the compound can be designated by the formula $[Cu(en)_2]\cdot(acac)_2\cdot 2H_2O$. The water hydrogen atoms seem to take part in the hydrogen bonding with the anion oxygen atoms.

It is well-known that the bis(β-diketonato)copper(II) complexes may behave as Lewis acids and react with nitrogen bases to form addition compounds.[1] Several five-coordinate addition compounds of square-planar bis(β-diketonato)copper(II) complexes with heterocyclic nitrogen bases have been isolated.[2-6]

The Lewis acidity of the bis(β-diketonato)copper(II) complexes is affected by the relative electron-withdrawing power of the β-diketonate ligand.[7,8] When, for example, the highly electronegative CF_3-group is introduced in plane of the CH_3-group in acetylacetone, the affinity of the copper atom for the axial ligand is enhanced and the addition of two molecules of a monodentate nitrogen base proceeds quite readily. Thus, many six-coordinate addition compounds of bis(trifluoroacetylacetonato)-,[6,9] bis(hexafluoroacetylacetonato)-[6-8] and bis(thenoyltrifluoroacetonato)-[6,10] copper(II) complexes with monodentate nitrogen bases have been isolated thus far. Similar 1 : 2 adducts of the monodentate nitrogen base are also produced with the copper(II) complexes in which the central methine proton of the parent acetylacetonate ligand is replaced by another electron-withdrawing substituent, such as a nitro- or cyano-group.[11]

On the other hand, there have been only a few reports concerning the reactions of bis(β-diketonato)-copper(II) with bidentate nitrogen bases. A stable 2,2′-bipyridine adduct of bis(hexafluoroacetylacetonato)copper(II) was isolated, as its structure was determined by means of single-crystal X-ray analysis.[12] More recently, another research group has also described the reaction of the same copper(II) complex with some chelating diamines including ethylenediamine.[13,14]

We wish now to report on the reactions of bis(acetylacetonato)copper(II), $Cu(acac)_2$, with ethylenediamine (en), and of bis(ethyl acetoacetato)copper(II), $Cu(etac)_2$, with en, trimethylenediamine (tn), 2,2′-bipyridine (bipy), and 1,10-phenanthroline (phen).

Results and Discussion

Six complexes have been isolated; they are listed in Table 1, together with their analytical and magnetic data. All these complexes have normal magnetic moments as monomeric copper(II) compounds.

The 1 : 1 Complex Yielded by the Reaction of Bis(acetylacetonato)copper(II) with Ethylenediamine in Dry Dichloromethane. The reaction of $Cu(acac)_2$ with equimolar en in dry dichloromethane gave a pale green precipitate, composed of the 1 : 1 adduct of the parent complex with en. The same adduct was also obtained by the reaction of the parent complex suspended in dry ether

a) This band is obscured by the intense absorption of the acetylacetonate ligand.

with en. The product can hardly be dissolved in usual organic solvents at room temperature without partial dissociation. However, it can be recrystallized from hot benzene. It is decomposed in moist air and turns violet, but it is stable for a long time under dry conditions.

The ligand-field spectrum of $Cu(acac)_2$ shows two indefinite absorption maxima at about 15.0 and 18.0 kK,[1] while that of the mono-pyridine adduct has only one broad absorption maximum at 15.2 kK.[15-17] On the other hand, the diffuse reflectance spectrum of the present 1 : 1 adduct of $Cu(acac)_2$ with en has two definite absorption maxima, one appearing at 14.6 kK, accompanied by an indefinite shoulder at about 13.6 kK, and the other, at 8.7 kK (Fig. 1, 1a and Table 2). These spectral features fit in well with the step-by-step change in the stereochemistry around the copper atom from square-planar $Cu(acac)_2$ through the five-coordinate pyridine adduct to the tetragonally-distorted octahedral environment, as was shown for the bis(acetylacetonato)- or bis(hexafluoroacetylacetonato)-copper(II)-pyridine system by Funch and Ortolano.[7] Recently, very similar spectra have been reported for the bis(pyridine) adducts of the copper(II) γ-nitro- and γ-cyano-acetylacetonates.[11]

The IR spectra of the 1 : 1 adduct of $Cu(acac)_2$ with en in the higher-frequency region, except for 1700—1500 cm^{-1}, can be understood, on the whole, as an overlap of the spectra of the acetylacetonate ligand and coordinated en. By a recent isotopic study[18,19] of the IR spectra of $Cu(acac)_2$, two absorption bands in the carbonyl region were definitely assigned: the band at 1578 cm^{-1} mainly to the C=O stretching vibration, and the second one, at 1527 cm^{-1}, to the antisymmetric vibration of the C—C—C segment of the chelate ring. On the other hand, in the IR spectra of the en adduct, the band assignable to the carbonyl stretching is shifted to the higher-frequency side (1615 cm^{-1}), while the other is shifted to the lower-frequency side (1501 cm^{-1}). These shifts may be caused by a weakening of the copper-ligand bond due to the coordination of diamine. Similar spectral features have also been observed for $Mn(acac)_2(en)$.[20] Characteristic bands attributable to the diamine ligand are listed in Table 3; they were assigned by reference to the literature[21] and also to the deuteration effect. There are no bands due to free diamine in the frequency region higher than 3320 cm^{-1}, indicating that both nitrogen atoms of the diamine are linked to the copper atom.

Figure 2 shows the far-IR spectra of the complex, together with those of $Cu(acac)_2$ and $Cu(etac)_2$ as references. The spectra of $Cu(acac)_2$ (1) have three bands between 600 and 280 cm^{-1}, two of which (455 and 291 cm^{-1}) are assigned to the pure Cu–O stretching modes.[22] In the case of the 1 : 1 en adduct (1a), the band near 450 cm^{-1} disappeared, while three intense bands (572, 545 and 490 cm^{-1}) and one broad band (415 cm^{-1}) appeared. The former bands are assigned to the ring vibrations of the en chelate ring, while the latter is assumed by reference to the literature[23] to be an overlap of the Cu–O (415 cm^{-1}) and the Cu–N (405 cm^{-1}, shoulder) stretching vibrations.

It is obvious from the analytical and spectroscopic results presented above that the 1 : 1 en adduct with

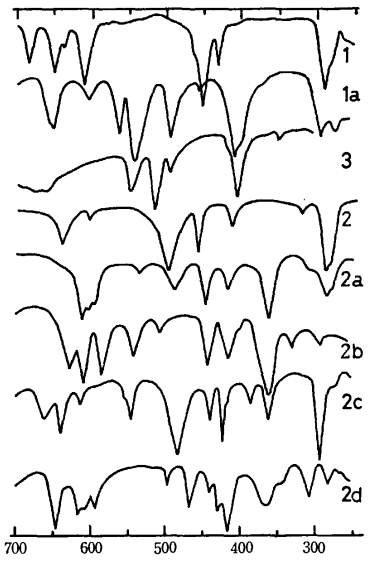

Fig. 2. The far-IR spectra of: (1), $Cu(acac)_2$; (1a), $Cu(acac)_2(en)$; (2), $Cu(etac)_2$; (2a), $Cu(etac)_2(en)$; (2b), $Cu(etac)_2(tn)$; (2c), $Cu(etac)_2(bypy)$; (2d), $Cu(etac)_2(phen)$ and (3), $[Cu(en)_2](acac)_2 \cdot 2H_2O$.

$Cu(acac)_2$ is the first example of an isolated stable adduct which has an octahedral stereochemistry around the copper atom, without any electron-withdrawing substituent in the acetylacetonate ligand. This stability may be attributed to the chelating effect of the diamine ligand. However, its thermal stability is not so high as that of the corresponding manganese complex,[20] which begins to decompose at around 95 °C. The thermogravimetric analysis, as is shown in Fig. 3 (1), indicates that $Cu(acac)_2(en)$ begins to decompose at around 35 °C, thus liberating en, which was identified by a method described previously.[20] The weight loss below 72 °C amounts to 19% just fitting the calculated value of 18.7% for the en content in this adduct. When a sample was heated further, a rapid weight loss occurred because of the sublimation of the residual bis-chelate.

Martell and Calvin[24] pointed out that the formation of a quadridentate imine from acacH and en is catalyzed by Cu(II) ions in aqueous solutions. Candlin, Taylor and Thompson[25] also assumed that the reaction probably involves the attack of en on the coordinated acetylacetone. However, our results have revealed that such a reaction does not occur, at least not in dichloromethane at room temperature. It might occur at higher temperatures, although attempts to cause the primary amine adducts of bis(β-diketonato)nickel(II) to undergo a Schiff-base rearrangement in nonpolar solvents were unsuccessful,[26] as was an attempt to prepare an imine from the bis(haxafluoroacetylacetonato)ethylenediaminecopper(II) complex by a gas-phase template reaction.[13c]

The 1 : 1 Complexes Yielded by the Reactions of Bis(ethyl acetoacetato)copper(II) with Some Diamines in Dichloromethane. Only the en adduct was isolated in several attempts to prepare diamine adducts with $Cu(acac)_2$. On the contrary, the reactions of $Cu(etac)_2$ with en, tn, bipy, and phen gave the corresponding 1 : 1 diamine adducts. This may be due to the Lewis acidity of the parent complex, enhanced by the substitution of the ethoxy group into the acetylacetonate ligand.[3] All these complexes were isolated as green-to-blue crystals. They are stable in air relative to $Cu(acac)_2(en)$, but are unstable in solution and partially dissociate into $Cu(etac)_2$ and the diamine.

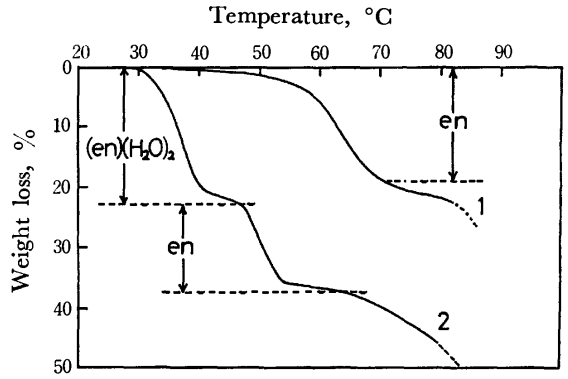

Fig. 3. The thermogravimetric curves of: (1), $Cu(acac)_2(en)$ and (2), $[Cu(en)_2](acac)_2 \cdot 2H_2O$.

The diffuse reflectance spectra of these adducts (Fig. 1, 2a-2d and Table 2) exhibit shifts similar to those observed for $Cu(acac)_2(en)$, but a new maximum does not appear around 8 kK. Thus, a question is raised whether or not these complexes have an octahedral stereochemistry around the copper atom. However, the maximum absorptions of these spectra differ clearly from those of five-coordinate pyridine or the substituted pyridine adducts of $Cu(etac)_2$, in which only one broad absorption maximum is observed, at 14.1 kK.[3,16] Moreover, a discrepancy similar to the one mentioned above in the reflectance spectra is also observed between the two spectra of dihydrate and the bis(pyridine) adduct of copper(II) hexafluoroacetylacetonate.[7] There is no doubt, in light of the spectral similarity with diamine adducts of copper(II) hexafluoroacetylacetonate and the IR spectral evidence to be presented in the next paragraph, that these complexes have a six-coordinate octahedral stereochemistry around the copper atom.

The IR spectra of parent complexes in the higher-frequency region are also composed of those due to the ethyl acetoacetate ligand and those due to the coordinated diamine. However, a significant and diagnostic difference caused by the coordination of a diamine is observed in the $\nu(C{=}O)$ region. These spectra exhibit two or three medium-to-strong bands between 1700 and 1500 cm^{-1}: (a) $Cu(etac)_2(en)$, 1653(s), 1615(m), 1517(s) cm^{-1}; (b) $Cu(etac)_2(tn)$, 1652(s), 1610 (m), 1521(s) cm^{-1}; (c) $Cu(etac)_2(bipy)$, 1660(s), 1613 (s), 1517(s) cm^{-1}; (d) $Cu(etac)_2(phen)$, 1646(s), 1514 (s) cm^{-1}. Of those listed above, one medium band of each aliphatic diamine adduct was assigned to the NH_2 deformation mode on the basis of the deuteration effect, while the strong band at 1613 cm^{-1} of the bipy adduct was assigned to the bipy-ring vibration.[27] The remaining two bands on each adduct around 1650 and 1515 cm^{-1} were assigned mainly to the C=O stretching vibration and the antisymmetric vibration of the C-

C–C segment of the chelate ring, by reference to the assignment of the acetylacetonate complex. The higher-frequency shift of the former band and the lower-frequency shift of the latter band from those (1600 and 1536 cm^{-1}) in the parent complex, $Cu(etac)_2$, are both larger than the corresponding shifts in the case of $Cu(acac)_2(en)$. This may suggest that the weakening of the copper-ligand bond strength by the coordination of diamine is larger than in the case of $Cu(acac)_2(en)$. Relevant shifts were also noticed in the region of ester absorption bands: that is, the "ester C–O–R bands" (1291(s) and 1184(s) cm^{-1}) of the parent $Cu(etac)_2$ shift to 1237(s), 1173(s) (en complex), 1234(s), 1173(s), (tn complex), 1277(s), 1117(s) (bipy complex), and 1226(s), 1165(s) (phen complex) cm^{-1} respectively. Such large shifts of the "ester C–O–R" bands to the lower-frequency side are accompanied by a shift of the carbonyl C=O band to the higher-frequency side, disclosing a significant weakening of the "ester carbonyl" (C=O)-copper bond strength in comparison with that of the parent $Cu(etac)_2$.

The spectra of both en and tn adducts exhibit characteristic bands due to the diamine ligand at 3320, 3260, and 3160 cm^{-1} and at 3320(sh), 3270, and 3160 cm^{-1} respectively. They also have no bands due to free diamine in the frequency region higher than 3320 cm^{-1}. This may indicate coordination by both nitrogen atoms of the diamines. The coordination of phen to the copper atom is evidenced by the splitting of the strong bands at 728 and 850 cm^{-1}.[27] In the spectra of the bipy adduct, the shift and split of the characteristic band (751 cm^{-1}) of the free bipy ligand to 777 and 785 cm^{-1} may also reveal the complexation of bipy to the copper atom.[27,28]

The far-IR spectra of $Cu(etac)_2$ and its 1 : 1 diamine adducts are shown in Fig. 2(2, 2a—2d). The band at 454 cm^{-1} assignable to the ν(Cu–O) in the spectra of parent complex (2) will be shifted to the lower-frequency side by the addition of diamine. Hence, for adducts containing aliphatic diamine the bands at 446 cm^{-1} (en complex, 2a) and 443 cm^{-1} (tn complex, 2b) were assigned to the ν(Cu–O) vibrations, and the new strong bands at 363 cm^{-1} (en complex, 2a) and 360 cm^{-1} (tn complex, 2b), to the ν(Cu–N) vibrations. In the case of adducts containing heterocyclic diamine, their spectra are more complicated because of their many ligand vibrations. The ν(Cu–O) bands of the bipy and phen adducts (2c and 2d) can not be unequivocally assigned, although they are expected to appear in the 400—450 cm^{-1} region. The bands at 296 cm^{-1} (bipy complex, 2c) and 279 cm^{-1} (phen complex, 2d) were also assigned to the ν(Cu–N) vibrations, according to the literature.[29]

From all the above discussion, it may be concluded, with regard to the structure of the 1 : 1 diamine adducts, that the apical positions are occupied by the two carbonyl oxygen (or ester carbonyl oxygen) atoms of the four originally-coordinating oxygen atoms of planar chelate, and that the equatorial plane is composed of the residual two oxygen atoms and two nitrogen atoms of the diamine ligand, as is shown in Fig. 4. Such a

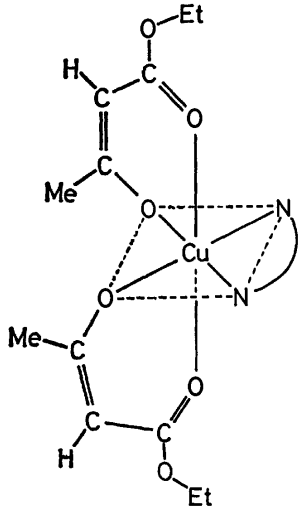

Fig. 4. The suggested structure of $Cu(etac)_2$(diamine).

structure has also been proposed for $Cu(etac)_2$ in pyridine.[30]

Graddon and Watton[3] isolated the bis(pyridine) adduct of $Cu(etac)_2$, but concluded that the second molecule of pyridine was only filling spaces in the crystal lattice and was not coordinated to the copper atom. Therefore, the 1 : 1 diamine adducts of $Cu(etac)_2$ isolated here seem to be the first examples of stable adducts with an octahedral stereochemistry around the copper atom.

The 1 : 2 Complex Yielded by the Reaction of Bis(acetylacetonato)copper(II) with Ethylenediamine in Wet Dichloromethane.[31] The reaction of $Cu(acac)_2$ with en in the mole ratio of one-to-two in wet dichloromethane gave a violet precipitate composed of two en molecules, two acetylacetonate anions, and two water molecules per copper atom. It dissolves in water to give a violet solution, and in methanol to result in a blue solution with some decomposition, but it is insoluble in non-polar organic solvents.

The diffuse reflectance spectrum of the compound is entirely different from that of $Cu(acac)_2$ (Fig. 1 (3) and Table 2). With only one absorption maximum at 18.9 kK, it can be compared with the spectra of the oxyanion salts of the square-planar cations $Cu(en)_2^{2+}$; for the sulphate, nitrate, and perchlorate, the maxima are observed at 17.6, 18.6, and 18.8 kK respectively.[32] The shifts to a higher frequency are attributed to the reduced interaction of the copper atom with the oxygen atoms of the acetylacetonate ligand. This compound may be compared with bis(ethylenediamine)copper(II) perchlorate as to its copper-oxygen bonding character, which may be ionic rather than covalent.

The IR spectrum of the compound differs little from that of $Cu(acac)_2(en)$ except for the additional bands due to the lattice water. It has a broad band assignable to the ν(C=O) vibration at 1607 cm^{-1}, and also a strong band assignable to the antisymmetric vibration of the C–C–C segment of the acetylacetonate ligand at 1508 cm^{-1}. It also has bands due to the coordinated diamine at 3200 (shoulder) and 3100 cm^{-1}. As was pointed out

by George and Robinson,[33] the bands at 1206 and 768 cm^{-1} in the anhydrous sodium acetylacetonate are split, but they are not split in the dihydrate. These bands are assigned to the C–H in-plane and out-of-plane deformations; their splitting suggests that some interactions occur between adjacent ions in the lattice. However, in our compound, only the former band is split. Even if two moles of en are forced to react with one mole of $Cu(acac)_2$ in dry dichloromethane, only the 1 : 1 complex is formed. Water molecules seem to play a very important role in changing the linkage mode of acetylacetonate ligands.

The far-IR spectra of the compound, as is shown in Fig. 2(3), are very simple, and the sharp band at 403 cm^{-1} is easily assigned to the ν(Cu–N) vibration by comparison with those of $Cu(acac)_2(en)$. As is to be expected from the diffuse reflectance spectrum of the compound, no bands due to the ν(Cu–O) vibration appeared in the frequency region measured. This also suggests that the compound has a square-planar cation, $Cu(en)_2^{2+}$, and two acetylacetonate anions.

It seemes interesting to examine the thermal property of the compound because of the anionic character of the acetylacetonate group. As is shown in Fig. 3(2), it decomposed rapidly at temperatures above 30 °C and lost one en and two water molecules below 47 °C, where the curve has a slightly gentle slope. When the temperature of the sample was further raised, the thermogravimetric curve showed the same pattern as that of the 1 : 1 adduct. All this behavior in the thermogravimetric analysis may be represented by the following equation;

$$[Cu(en)_2](acac)_2\cdot 2H_2O \rightarrow Cu(acac)_2(en) \rightarrow Cu(acac)_2$$

It is interesting that the acetylacetonate anions recombine with the copper atom, forming chelate rings by displacing en molecules.

The conductivity of this compound in a 10^{-3} M aqueous solution is 170 $ohm^{-1}\cdot cm^2\cdot mol^{-1}$. This value falls between those of 1 : 1- and 1 : 2-electrolytes, suggesting the occurrence of a dissociation such as the following;

$$[Cu(en)_2](acac)_2\cdot 2H_2O \rightleftarrows [Cu(en)_2]^{2+} + 2acac^- + 2H_2O$$

This dissociation is also evidenced by the visible spectrum of the compound in an aqueous solution.

To ascertain the bonding nature of the acetylacetonate anions and the role of water molecules in this compound, a single crystal X-ray analysis was performed.

A perspective drawing of the complex is shown in Fig. 5. The copper atom lies on a crystallographic center of symmetry and has a square-planar coordination by four N atoms of the two en molecules, which are in a *gauche* conformation. The mean Cu–N bond length is 2.00 Å; this value is comparable with those found in $[Cu(en)_2](BF_4)_2$ (2.02 Å),[34] $[Cu(en)_2](NO_3)_2$ (2.03 Å),[35] and $[Cu(en)_2](NCS)(ClO_4)$ (2.02 Å).[36] The bond lengths and angles are summarized in Table 4.

The acetylacetonate anion is planar; the equation of the plane is given in Table 5. Moreover, the anion has an approximate mirror plane which is perpendicular

to the plane of the anion and which bisects the C(4)—C(5)—C(6) bond angle. Although this suggests a complete delocalization of π electrons in the anion, the accuracy of the bond length and angle is not great enough to allow a definite conclusion to be reached.

The hexacoordinate copper(II) compounds are well-known to show Jahn-Teller distortions. Thus, the four Cu–O bonds in the equatorial plane of the tris(hexafluoroacetylacetonato)cuprate(II), $Cu(hfac)_3^-$, average 2.015(5) Å, and the two axial bonds 2.176(7) Å.[37] The mixed complexes, $Cu(hfac)_2(py)_2$[38] and $Cu(hfac)_2$-

(bipy),[12] show the *cis* octahedral CuO_4N_2, and the Cu–O distances *trans* to the Cu–N bonds in the equatorial plane are 1.998(4) Å for the pyridine complex and 1.967(4) Å for the bipy complex, while the axial Cu–O distances are 2.283(6) and 2.296(4) Å respectively.

In the present complex, the Cu–O distances are much more longer than the Jahn-Teller elongation. Of the two oxygen atoms in the acetylacetonate anion, O(1) occupies the axial position of $[Cu(en)_2]^{2+}$ and the Cu···O distance is 2.79 Å. This value is comparable with that (2.793 Å) found in bis(hexafluoroacetylacetonato)bis(*N*,*N*-dimethylethylenediamine)copper(II), $Cu(hfac)_2(dmed)_2$[13b] indicating that there exists only a weak interaction between Cu and O(1). In $[Cu(en_2](acac)_2 \cdot 2H_2O$, the tetragonality ratio, $T=R_S/R_L$, defined by Hathaway,[39] where R_S and R_L are the mean equatorial and axial bond lengths, is 0.68.[40] This value is close to those for the Cu(II) complexes with the square-planar structure[41]; hence, the Cu–O(1) bond can be regarded as essentially ionic in character.

On the other hand, O(2) is close to N(1) (O···N, 3.02 Å), the axial N(1)–H bond protruding towards O(2) with the N(1)–H···O(2) angle of 175°. The interatomic distance between the H and O atoms is estimated to be 2.06 Å, which is considerably smaller than the sum of the Van der Waals radii of these atoms. Thus, N–H···O hydrogen bonding seems to exist between N(1) and O(2), though the direction of the N(1)···O(2) bond is nearly perpendicular to the plane of the anion.

The mode of interaction between the cation and the anion in the present complex is similar to that in $Cu(hfac)_2(dmed)_2$,[13b] but the structure of the former is different from that of the latter. In the hfac analogue, the plane of hfac is almost perpendicular to the plane defined by Cu and four N atoms (interplanar angle, 90.7°), while the Cu···O–C angle is 166.7°. In the present complex, however, the plane of the anion is not perpendicular to the CuN_4 plane, but is, rather, slanted against it (interplanar angle, 34°), with the Cu···O–C angle of 126°; the relative orientation of the cation and the anion is much less favorable to the formation of a covalent Cu–O bond.

The crystal structure viewed down the *b* axis is shown in Fig. 6. There are O–H···O and N–H···O hydrogen bonds in the crystal; they are indicated by dashed lines in the figure. Although no hydrogen

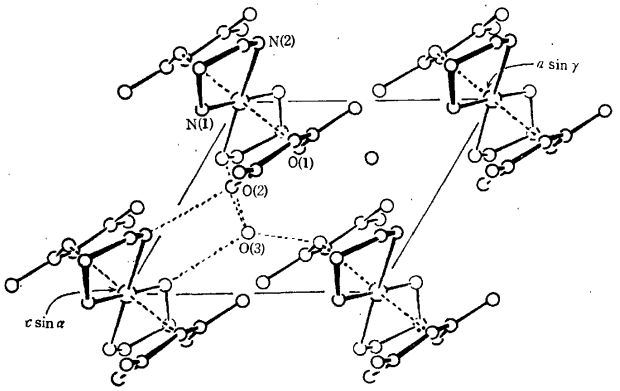

Fig. 6. Crystal structure viewed along *b* axis. The thin dashed lines indicate hydrogen bonds.

Table 6. Interatomic distances and angles related to the hydrogen bonds

A—H···B		A···B	H···B	A-H-B	Positions* of A	B

N(1)	O(3)	N(2)	93.0(3)	3	1	2

* Numercials refer to the following equivalent positions:
1 x, y, z 2 $-x, -y, -z$ 3 $-x, -y, 1-z$
4 $x, y, 1+z$ 5 $1-x, 1-y, 1-z$

atom could be found in the final difference synthesis, these hydrogen bonds were confirmed by deducing the positions of hydrogen atoms.[42] The data of the hydrogen bonds are summarized in Table 6. All the hydrogen atoms in NH_2 groups participate in the N–H···O hydrogen bonding. The oxygen atom of a water molecule is surrounded tetrahedrally by O(1) $(1-x, 1-y, 1-z)$, O(2) (x, y, z), N(1) $(-x, -y, 1-z)$, and N(2) $(-x, -y, -z)$ at distances of 2.79, 2.83, 2.97, and 3.04 Å respectively; hence, both of the water H atoms seem to take part in hydrogen bonds, in which the O(1) and O(2) atoms act as proton acceptors. It is noteworthy that the O(2) atom participates not only in the "intermolecular" hydrogen bonding, but also in the "intramolecular" N(1)–H···O(2) hydrogen bond as an acceptor.

Experimental

Materials. The $Cu(acac)_2$[43] and $Cu(etac)_2$[44] were synthesized according to the literature and were recrystallized twice from benzene–chloroform and dichloromethane respectively. Commercial en and tn were distilled over metallic sodium just before use. Analytical-grade bipy and phen-monohydrate were used without further purification. The dichloromethane was purified by the usual methods described previously.[45] The diethyl ether was dried with calcium chloride and distilled over sodium. The mercury(II) tetraisothiocyanatocobaltate(II) was prepared according to Figgis and Nyholm[46] and used as a reference substance for

the magnetic measurements (Found: C, 9.73; N, 11.39%).

Measurements. The IR spectra in the 4000—650 cm^{-1} region were measured with a Jasco IR-E Infrared Spectrophotometer, and those in the 700—250 cm^{-1} region, with a Hitachi grating infrared spectrophotometer EPI-L. The diffuse reflectance spectra were recorded with a Hitachi-Perkin Elmer 139 Spectrophotometer or a Hitachi EPU-2 Recording Spectrophotometer. The conductivity was measured by the use of a Yanagimoto Conductivity Outfit, NY-7. The magnetic susceptibilities were measured at room temperature by the Faraday method, with a Shimadzu Magnetic balance and employing mercury(II) tetraisothiocyanatocobaltate(II) as a reference substance. The diamagnetic corrections were calculated from Pascal's constants. The thermogravimetric analyses were performed using a thermo-spring-balance C-282 of Hamada Denki Seisakusho, Ltd., under reduced pressure. The rate of temperature elevation was fixed at 10 °C/hr.

Preparations of Complexes. Bis(acetylacetonato)ethylenediaminecopper(II) $Cu(acac)_2(en)$: To a solution of $Cu(acac)_2$ in dry dichloromethane, we added, drop by drop with magnetical stirring, a solution of equimolar en in dry dichloromethane. The pale-green precipitate thus produced was transferred from the reaction vessel *via* polyethylene tubing to a filtering apparatus set up in a desiccator containing phosphorus pentoxide. It was then recrystallized from dry benzene. Mp 112 °C (decomp.). The same compound was also prepared by the reaction of $Cu(acac)_2$ suspended in dry ether with equimolar en in dry dichloromethane.

The corresponding deuterated en complex was prepared by the following method: ethylenediamine-d_4 was prepared by repeated fractional distillation from heavy water solutions and characterized by means of its NMR spectra. Into a solution of 0.1 g of $Cu(acac)_2$ in 10 ml of dry dichloromethane, we stirred a few drops of en-d_4 until a small amount of pale green precipitate was formed. The precipitate thus produced was filtered rapidly and submitted to the measurement of its IR spectra.

Bis(ethyl acetoacetato)ethylenediaminecopper(II), $Cu(etac)_2(en)$: This complex was prepared in a manner similar to that used for the corresponding acetylacetonate complex and was recrystallized from benzene. Mp 144 °C (decomp.).

Bis(ethyl acetoacetato)trimethylenediaminecopper(II), $Cu(etac)_2(tn)$: To a solution of $Cu(etac)_2$ in dichloromethane, we added an equimolar amount of tn in dichloromethane. After a while a pale green precipitate was produced; this was filtered out and dried *in vacuo*. Mp 130 °C (decomp.).

Bis(ethyl acetoacetato)(2,2'-bipyridine)copper(II), $Cu(etac)_2(bipy)$: About three times as many moles of bipy were added to a solution of $Cu(etac)_2$ in dichloromethane. After refluxing for 3 hr, the solvent was evaporated until a green powder was produced. The mixture was filtered, washed with acetone to exclude any unchanged materials, and dried *in vacuo*. Mp 124 °C (decomp.).

Bis(ethyl acetoacetato)(1,10-phenanthroline)copper(II), $Cu(etac)_2(phen)$: A small excess of phen-monohydrate was added to a solution of $Cu(etac)_2$ in dichloromethane. After heating for about ten minutes, the solution was concentrated by evaporation under reduced pressure; then petroleum ether was added to the concentrate to produce a green precipitate. It was filtered and recrystallized from dichloromethane–petroleum ether. Mp 115 °C (decomp.).

Bis(ethylenediamine)copper(II) acetylacetonate dihydrate, $[Cu(en)_2](acac)_2\cdot 2H_2O$: Into a solution of $Cu(acac)_2$ in wet dichloromethane, we added, drop by drop with vigorous stirring, a solution containing two times as many moles of en in dichloromethane. A violet precipitate thus formed was filtered out and recrystallized from warm (below 50 °C) benzene containing a small amount of en. Mp 62 °C (decomp.).

X-ray-data Measurement. Parallelepiped crystals of $[Cu(en)_2](acac)_2\cdot 2H_2O$ were obtained by recrystallization from a 1 : 1 mixture of benzene and dichloromethane containing a small amount of en. Because of the remarkable air- and moisture-sensitivity, crystals used for the X-ray work were sealed into thin-walled glass capillaries.

Crystal Data: $Cu(C_2H_8N_2)_2(C_5H_7O_2)_2\cdot 2H_2O$, $M=418$, triclinic, $a=7.730(7)$, $b=11.53(1)$, $c=7.007(7)$ Å, $\alpha=72.7(1)°$, $\beta=121.8(1)°$, $\gamma=100.2(1)°$, $V=506.7$ Å^3, $Z=1$, $D_c=1.73$ g·cm^{-3} (D_m not measured, because of the instability of the crystal in air), $\lambda(CuK\alpha)=1.5418$ Å, $\mu(CuK\alpha)=19.6$ cm^{-1}; space group $P\bar{1}$ or $P1$, shown to be the former from the subsequent satisfactory solution and refinement of the structure.

The unit-cell dimensions were determined by a least-squares analysis of the $\sin^2\theta$ values from high-angle reflections on zero-level Weissenberg photographs calibrated with aluminum powder.

The intensity data were measured visually from equi-inclination Weissenberg photographs (layers $hk0$—5) by the multiple-film technique with $CuK\alpha$ radiation. The crystal used for the collection of intensity data had dimensions of $0.7\times0.4\times0.2$ mm. Although preliminary data were recorded about the other axes, photographs suitable for intensity measurements could be obtained only about the c axis. Corrections were applied for the Lorentz and polarization factors and for the absorption. A total of 1550 independent reflections were obtained, of which 115 were too weak to be measured.

Determination and Refinement of the Crystal Structure. The positions of all the non-hydrogen atoms were found from a three-dimensional Patterson synthesis on the assumption that the space group was $P\bar{1}$. The atomic coordinates and thermal parameters were refined by the block-diagonal-matrix least-squares method, the function minimized being $\sum w(|F_o|-|F_c|)^2$. At every termination of several cycles of the least-squares calculation, the layer scales were calculated so that relative $\sum|F_o|=\sum|F_c|$ for each of the layers; the new scales thus obtained were then used in the following calculation.

Table 7. The final atomic coordinates, temperature factors and their e.s.d.s.

* B_{11}	B_{22}	B_{33}	B_{12}
0.0263(6)	0.0076(1)	0.0286(5)	0.0073(4)
B_{13}	B_{23}		
0.0349(8)	−0.0014(4)		

The anisotropic thermal parameters for Cu atom is of the form

$$\exp[-(B_{11}h^2+B_{22}k^2+B_{33}l^2+B_{12}hk+B_{13}hl+B_{23}kl)].$$

Continued refinements ($w=1.0$ for all reflections) with isotropic temperature factors reduced R to 0.16. In the subsequent refinements, the following weighting scheme was employed:

$$w = 0.5 \text{ for } |F_0| < |F_{\min}|$$
$$w = 1.0 \text{ for } |F_{\min}| \leq |F_0| \leq |F_{\max}|$$
$$w = |F_{\max}|/|F_0| \text{ for } |F_{\max}| < |F_0|$$

$|F_{\max}|$ and $|F_{\min}|$ were varied as is indicated by the $|F_0|$ and $(\sin\theta/\lambda)$ analyses of $\sum w(|F_0|-|F_c|)^2$. Four further cycles of the calculation were made using anisotropic thermal parameters for the copper atom, and R was improved to 0.13. All the layer scales were almost invariant as compared with the preceding ones, the maximum change being within the range of one per cent. Four reflections, thought to be suffering from extinction errors (010, 111, 121, $\bar{1}11$), were omitted in the final refinement, which led to a convergence at R 0.12 ($|F_{\max}|=7.9$ and $|F_{\min}|=2.6$). In the final cycle of refinement, all the shifts were $<0.3\,\sigma$. The atomic scattering factors for neutral copper, oxygen, nitrogen, and carbon atoms, as well as the correction for the real part of the anomalous dispersion for the copper atom, were taken from Ref. 47. The final list of coordinates and thermal parameters is given in Table 7. A complete list of the observed and calculated structure factors is preserved by the Chemical Society of Japan (Document No. 7425). All the computations were carried out by means of the FACOM 270—30 computer at Osaka City University.[48]

The authors are indebted to Dr. H. Kobayashi of Kyoto University for her help in the magnetic measurements and also to Mr. J. Gohda for the elemental analyses. Financial aid by the Ministry of Education is also acknowledged.

Circular Dichroism Spectra of Cobalt(III) Complexes Containing Amino-Alcohols

Toshikazu NISHIDE, Kazuko OGINO,* Junnosuke FUJITA,** and Kazuo SAITO

Department of Chemistry, Faculty of Science, Tohoku University, Aramaki, Sendai 980

(Received August 5, 1974)

Several cobalt(III) complexes containing amino-alcohol (amOH) chelate rings, $[Co(amOH)(NH_3)_4]X_3$, $[Co(amOH)(en)_2]X_3$ and $[Co(amOH)(R\text{-chxn})_2]X_3$ (en=ethylenediamine, chxn=*trans*-1,2-diaminocyclohexane, $X^-=Cl^-$, Br^- or ClO_4^-, amOH=2-aminoethanol, 2-amino-1-propanol, 1-amino-2-propanol, *etc.*) were synthesized and separated into optical isomers. Their circular dichroism (CD) spectra change remarkably by the change in pH of the solution. The changes were ascribed to the dissociation of the alcoholic proton of coordinated amOH. The complexes containing a deprotonated chiral amO^- chelate ring exhibit strong vicinal CD bands in the first and second absorption band region. The signs and the magnitudes of these CD bands seem to depend mainly on the conformation of the amO^- chelate ring.

Extensive studies have been made on the circular dichroism (CD) spectra of cobalt(III) complexes containing diamine and aminocarboxylate chelate rings.[1] However there has been little work on the optical activity of amino-alcohol complexes.[2,3] In the previous communication,[3] we reported CD spectra of Λ-$[Co(etaH)(en)_2]^{3+}$ (etaH=2-aminoethanol, en=ethylenediamine) and Δ- and Λ-$[Co(S\text{-praH})(en)_2]^{3+}$ (praH=2-amino-1-propanol) complexes. The CD behavior of these complexes was found to be considerably different from that of $[Co(diamine)_3]^{3+}$ or $[Co(am)(en)_2]^{2+}$ (am^-=aminocarboxylate ion); the deprotonated *S*-pra^- chelate ring gives an exceptionally large vicinal contribution to the optical activity. We have extended the work to several other coablt(III) complexes containing an amino-alcohol chelate ring.

Experimental

Ligands.† Amino-alcohols except *S*-leucinol and *S*-2-amino-1-propanol were obtained commercially. *S*-Leucinol was kindly supplied by Mr. K. Ohashi of Ibaragi University. *S*-2-Amino-1-propanol was synthesized by the method of Vogl and Pöln.[4] *trans*-1,2-Diaminocyclohexane(chxn) was resolved into optical isomers by the method of Treptow.[5]

Syntheses of Aminoalcoholtetraammine Complexes, $[Co(amOH)(NH_3)_4]X_3$ (amOH=etaH, *S*-praH, *S*-leuH, *R*-abnH *and R and S*-ispraH). The etaH complex was prepared by the following procedure. $[CoCl(H_2O)(NH_3)_4]SO_4$ (2 g) was added to a mixture of 1 M sodium hydroxide (5 ml), water (1 ml), 2-aminoethanol (0.4 ml) and one drop of 28% aqueous ammonia. The solution was heated at 65—75 °C for 2.5 hr, cooled in an ice bath for 1 hr, and filtered. The filtrate was passed through a column ($\phi 2\times 20$ cm) containing the anion exchanger Dowex 1X4 in the bromide form. The eluate was treated with hydrobromic acid to adjust the pH to 1—2 and evaporated to dryness under reduced pressure at 40—50 °C. The residue was dissolved again in about 40 ml of water and filtered. Addition of a few drops of 40% hydrobromic acid to the filtrate gave orange crystals, which were filtered off, washed with methanol and air-dried. Recrystallization was carried out from water containing hydrobromic acid. Found: C, 5.71; H, 4.65; N, 16.66%. Calcd for $CoC_2H_{19}N_5OBr_3$: C, 5.61; H, 4.48; N, 16.37%.

Other complexes, $(-)_D$-$[Co(S\text{-praH})(NH_3)_4]Cl_3$, $(-)_D$-$[Co(S\text{-leuH})(NH_3)_4]Cl_3\cdot 3H_2O$, $(+)_D$-$[Co(R\text{-abnH})(NH_3)_4]Cl_3\cdot H_2O$ and $[Co(R,S\text{-ispraH})(NH_3)_4](ClO_4)_3$ were synthesized by a method similar to that for the etaH complex. For *S*-praH complex, Found: C, 11.43; H, 7.07; N, 22.77%. Calcd for $CoC_3H_{21}N_5OCl_3$: C, 11.68; H, 6.86; N, 22.70%. For *S*-leuH complex; Found: C, 17.91; H, 7.97; N, 17.74%. Calcd for $CoC_6H_{32}N_5O_4Cl_3$: C, 17.85; H, 7.99; N, 17.35%. For *R*-abnH complex; Found: C, 14.15; H, 7.66; N, 20.32%, Calcd for $CoC_4H_{25}N_5O_2Cl_3$: C, 14.12; H, 7.40; N, 20.57%. For *R,S*-ispraH complex; Found: C, 7.57; H, 4.08; N. 13.99%. Calcd for $CoC_3H_{21}N_5O_{13}$: C, 7.20; H, 4.23; N, 14.00%.

The complex $(-)_D$-$[Co(R\text{-ispraH})(NH_3)_4]Cl_3\cdot 2.5H_2O$ was obtained by the following method. $[Co(R,S\text{-ispraH})(NH_3)_4](ClO_4)_3$ (0.4 g) was adsorbed on an SP-C-25 Sephadex column ($\phi 5\times 95$ cm) and eluted with 0.2 M potassium antimony *d*-tartrate at a rate of 0.6 ml/min. The column gave two separated orange bands. The $(-)_D$-isomer was eluted first and the $(+)_D$-isomer followed. The antimony *d*-tartrate salt of the $(-)_D$-isomer was converted into chloride by passing the first eluate through a column ($\phi 2\times 10$ cm) of SP-C-25 Sephadex, and eluting the adsorbed band with 0.5 M hydrochloric acid. The eluate was evaporated to a small volume under reduced pressure below 35 °C, and filtered. The filtrate was dried up in a vacuum desiccator over diphosphorus pentoxide. The complex was hygroscopic powder. Found: C, 10.41; H, 7.30; N, 19.87%. Calcd for $CoC_3H_{26}N_5O_{3.5}Cl_3$: C, 10.19; H, 7.41; N, 19.81%. $(+)_D$-$[Co(S\text{-ispraH})(NH_3)_4]Br_3\cdot 2.5H_2O$ was obtained similarly from the second eluate described above by use of a column containing anion exchanger Dowex 1X4 in bromide form. Found: C, 7.01; H, 5.48; N, 14.67%. Calcd for $CoC_3H_{26}N_5O_{3.5}Br_3$: C, 7.39; H, 5.38; N, 14.38%.

Syntheses of Aminoalcoholbis(ethylenediamine) Complexes. a) *cis*-$[CoBr(R,S\text{-ispraH})(en)_2]Br_2$. To *trans*-$[CoBr_2(en)_2]Br$ (5 g) in dimethyl sulfoxide (DMSO) (100 ml) was added *R,S*-ispraH (0.9 g) with stirring. The solution was stirred overnight and filtered. Ethanol and ether were added to the solution and then it was kept in a refrigerator for crystallization. Red-violet crystals were collected, washed with ethanol and air-dried. Found: C, 17.30; H, 5.34; N, 13.90 %. Calcd for $CoC_7H_{25}N_5OBr_3$: C, 17.02; H, 5.10; N, 14.18%.

b) $[Co(R,S\text{-ispraH})(en)_2]Br_3\cdot 2.5H_2O$ and $[Co(N\text{-MeetaH})(en)_2]Cl_3\cdot 2H_2O$. These complexes were prepared

a) The spectra of [M(amOH)]$^{3+}$ complexes were obtained by dissolving the salt of [M(amOH)]$^{3+}$ in acidic solutions (pH<2), and those of [M(amO)]$^{2+}$ complexes in solutions whose pH is above 5, unless otherwise stated.
b) Spectral data were obtained in an aqueous solution of [Co(*N*-Meeta)$(en)_2$]$(ClO_4)_2$.

by a method similar to that for [Co(etaH)$(en)_2$]$Br_3\cdot H_2O$ by Buckingham *et al.*[6] Anal. For 1-amino-2-propanol complex; Found: C, 15.21; H, 5.25; N, 13.11%. Calcd for $CoC_7H_{30}N_5O_{3.5}Br_3$: C, 15.60; H, 5.61; N, 13.00%. For *N*-methylethanolamine complex, Found: C, 20.89; H, 7.71; N, 17.80%. Calcd for $CoC_7H_{29}N_5O_3Cl_3$: C, 21.20; H, 7.37; N, 17.66%.

c) [Co(*N*-Meeta)$(en)_2$]$(ClO_4)_2$. This complex was obtained by adding lithium perchlorate to an aqueous solution of [Co(*N*-MeetaH)$(en)_2$]$Cl_3\cdot 2H_2O$ neutralized with sodium hydroxide. Found: C, 18.60; H, 5.66; N, 15.38%. Calcd for $CoC_7H_{24}N_5O_9Cl_2$: C, 18.59; H, 5.35; N, 15.49%.

*Separation of Λ,Δ-[Co(*R,S*-isopraH)$(en)_2$]$^{3+}$ Complexes.* a) *Λ*-(+)$_D$-[Co(*R*-isopraH)$(en)_2$]$Cl_3\cdot 3H_2O$. *Λ,Δ*-[Co(*R,S*-iso-

praH)$(en)_2$]$Br_3 \cdot 2.5H_2O$ was separated into four isomres by means of column chromatography. Two grams of the complex was adsorbed on an SP-C-25 Sephadex column (ϕ 3×90 cm) and the adsorbed orange band was eluted with 0.2M potassium antimony *d*-tartrate at a rate 0.5 ml/min. The eluate was fractionated into 25 ml portions. The CD spectrum of each fraction was checked, and the fractions were grouped into three parts (A,B,C) in the order of elution. The first part (A), about one tenth of the total eluate, was poured on an SP-C-25 Sephadex column (ϕ3×96 cm) again and eluted with 0.2 M potassium antimony tartrate. First several portions of the eluate showed the same CD curves. They were combined, adsorbed on an SP-C-25 Sephadex column (ϕ 1.7×10 cm) and eluted with 0.5 M hydrochloric acid. The eluate was evaporated to a small volume under reduced pressure below 35 °C, filtered and stored in a vacuum desiccator over diphosphorus pentoxide. The hygroscopic powder thus obtained was assigned to Λ-[Co(*R*-isopraH)$(en)_2$]$Cl_3 \cdot 3H_2O$ as shown later. Found: C, 20.50; H, 7.60; N, 16.37%. Calcd for $CoC_7H_{31}N_5O_4Cl_3$: C, 20.58; H, 7.54; N, 16.89%.

b) Λ-$(+)_D$-(*S*-isopraH)$(en)_2$]$(ClO_4)_3$. The last a few fractions of the eluate(A) in the second elution (with 0.2 M potassium antimony tartrate) described above were found to contain only one isomer by measurement of CD. These portions were combined and passed through the anion exchange resin column containing Dowex 1X8 in the perchlorate form to give perchlorate salt. The hygroscopic powder was assigned to Λ-[Co(*S*-isopraH)$(en)_2$]$(ClO_4)_3$ as shown later. Found: C, 15.38; H, 4.72; N, 12.71%. Calcd for $CoC_7H_{25}N_5O_{13}Cl_3$: C, 15.21; H, 4.56; N, 12.68%.

The fractions B and C mentioned in (a) were found to be mixtures of Λ-[Co(*S*-isopraH)$(en)_2$]$^{3+}$ and Δ-[Co(*S*-isopraH)-$(en)_2$]$^{3+}$, and Δ-[Co(*S*-isopraH)$(en)_2$]$^{3+}$ and Λ-[Co(*R*-isopraH)-$(en)_2$]$^{3+}$ isomers respectively. But the latter two isomers were not isolated.

*Syntheses of Aminoalcoholbis(*R-trans-*1,2-diaminocyclohexane)-complexes.* *a)* Λ-$(-)_D$-[Co(etaH)(*R*-chxn)$_2$]$(ClO_4)_3$. A mixture of *trans*-[$CoCl_2$(*R*-chxn)$_2$]Cl[5] (1 g) and 2-aminoethanol (0.2 ml) in DMSO (50 ml) was stirred for two days. The solution was treated with ethanol (150 ml) and ether (700 ml) and kept in an ice bath for 6 hr. The supernatant was decanted and the remaining oily residue was dissolved again in water (50 ml) and hydrolyzed at pH 9 (pH-stat) with 1 N sodium hydroxide. After 2 hr, the pH of the solution was adjusted to 1.5 with 6 M hydrochloric acid. The solution was evaporated to a small volume under reduced pressure at 40 °C and passed through an SP-C-25 Sephadex column (ϕ3×77 cm). Elution with a mixture of 0.15 M sodium *d*-tartrate and 0.09 M hydrochloric acid gave several portions showing the same CD curves, which were combined and concentrated under reduced pressure. After removal of sodium salt by filtration, 60% perchloric acid and sodium perchlorate were added to the filtrate. Orange crystals were filtered off and dried in air. The CD specturm remains unchanged after three times recrystallization from water. The absolute configuration of this complex was assigned to Λ as shown later. Found: C, 26.20; H, 5.72; N, 10.54%. Calcd for $CoC_{14}H_{35}N_5O_{13}Cl_3$: C, 26.00; H, 5.46; N, 10.83%.

b) Λ-$(-)_D$-[Co(*S*-praH)(*R*-chxn)$_2$]$(ClO_4)_3$. This complex was synthesized by a method similar to that for the etaH complex (a) using *S*-praH instead of etaH and purified by recrystallization from water. Found: C, 27.18; H, 5.77; N, 10.33%. Calcd for $CoC_{15}H_{37}N_5O_{13}Cl_3$: C, 27.26; H, 5.64; N, 10.60%.

Measurements. The absorption spectra were recorded with a Hitachi 323 Recording Spectrophotometer. The CD spectra were obtained with a JASCO Model ORD/UV-5 Spectrometer with CD attachment. The pH of the solution was adjusted to appropriate values either with perchloric acid or with sodium hydroxide solution. The acid dissociation constants of the complexes were determined with a Metrohm Combi Titrator 3D at 25 °C.

Results and Discussion

Acid-base Equilibria of Amino-alcohol Complexes. Absorption and CD spectra of the amino-alcohol complexes obtained in this work changed markedly with change in pH of the solution. The spectra of *S*-2-amino-1-propanoltetraammine complex at three pH's are shown in Fig. 1. Several isosbestic points are observed. The spectral changes are instantaneous and reversible, and attributed to an acid-base equilibrium of the alcoholic proton:

$$M(amOH)^{3+} \rightleftharpoons M(amO)^{2+} + H^+$$

where M denotes Co(diamine)$_2$ or Co$(NH_3)_4$ moiety. pH Titration of the complexes gave pK_a values of *ca.* 3.6, 3.2 and 3.2 for [Co(amOH)$(NH_3)_4$]$^{3+}$ (amOH =etaH, *S*-praH, *S*-leuH, *S*-abnH and isopraH), [Co-(amOH)$(en)_2$]$^{3+}$ (amOH=etaH, *S*-praH and isopraH) and [Co(*S*-praH)(*R*-chxn)$_2$]$^{3+}$, respectively at 25 °C and ionic strength *ca.* 0.05. Thus the spectra of these complexes at pH below ~2 should be those of the protonated form, M(amOH)$^{3+}$ and the spectra at pH above~5 those of the deprotonated form, M(amO)$^{2+}$. The absorption spectrum of [Co(*N*-Meeta)$(en)_2$]$(ClO_4)_2$ in an aqueous solution was almost identical with that of [Co(*N*-MeetaH)$(en)_2$]$Cl_3 \cdot H_2O$ in an alkaline solution. This result supports the existence of acid-base equilibria. The reversible change of CD spectra upon pH change implies that the racemization or epimerization of the present amino-alcohol complexes is slow. Low pK_a values of hydroxyl group of coordinated alcohols have been reported for several complexes.[6,7]

Numerical data of the absorption and CD spectra of the complexes are shown in Table 1.

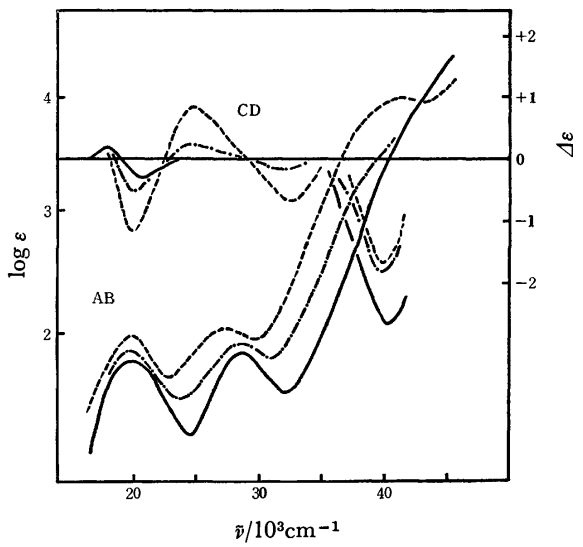

Fig. 1. Absorption and CD spectra of $(-)_D$-[Co(*S*-praH)$(NH_3)_4$]Cl_3 at pH 1.36 (——), at pH 2.75 (—·—) and at pH 9.50 (----).

CD Spectra of Tetraamminecobalt(III) Complexes. The CD spectra of $[Co(S\text{-amOH})(NH_3)_4]^{3+}$,[8] with protonated hydroxyl group are shown in Fig. 2. The patterns are similar to that of $[Co(NH_3)_4(S\text{-pn})]^{3+}$ (pn=1,2-diaminopropane)[9-11], a positive and a negative CD band are seen from lower to higher wave number in the first absorption band region, while the CD magnitude in the second absorption band region is almost zero except for $[Co(S\text{-isopraH})(NH_3)_4]^{3+}$. A large negative CD band is observed in the charge transfer region. The similarity suggests that both *S*-amOH and *S*-pn chelates in the complexes are in a similar conformational structure, *δ-gauche*.[9-11]

Since the complexes of the type, $[Co(S\text{-amOH})(NH_3)_4]^{3+}$ are approximated to C_{4v} symmetry, the positive and the negative CD band in the first absorption band region may be assigned to the $A_1 \rightarrow E$ and the $A_1 \rightarrow A_2$ component, respectively.[12]

$(+)_D$-$[Co(isopraH)(NH_3)_4]^{3+}$ shows the positive $A_1 \rightarrow E$ and the negative $A_1 \rightarrow A_2$ CD bands in the first absorption band region. Therefore, the isopraH in this isomer will be in *δ-gauche* conformation with an equatorial methyl group, and consequently of *S* absolute configuration. The CD magnitude of the $A_1 \rightarrow E$ band is greater than that of the $A_1 \rightarrow A_2$ band in contrast to the other *S*-amOH complexes. The relative CD magnitudes of the $A_1 \rightarrow E$ and the $A_1 \rightarrow A_2$ components may be related to the difference in the position of substituents on chelate rings. The isopraH has methyl group at α position to the hydroxyl group while the other *S*-amino-alcohols the substituents at β position.

The CD spectra of the deprotonated complexes, $[Co(S\text{-amO})(NH_3)_4]^{2+}$ are reproduced in Fig. 3. All the complexes including the *S*-isopra⁻ complex show a similar pattern; a weak positive and a strong negative CD band in the first absorption band region, a fairly strong positive CD band in the second absorption band region (~25000 cm^{-1}) and two strong negative CD bands in the charge transfer region (~33000 and 37000—40000 cm^{-1}). This result confirms the previous assignment of the absolute configuration for the isopraH in the $(+)_D$-isomer.

The positive and the negative CD bands in the first absorption band region may be also assigned to the

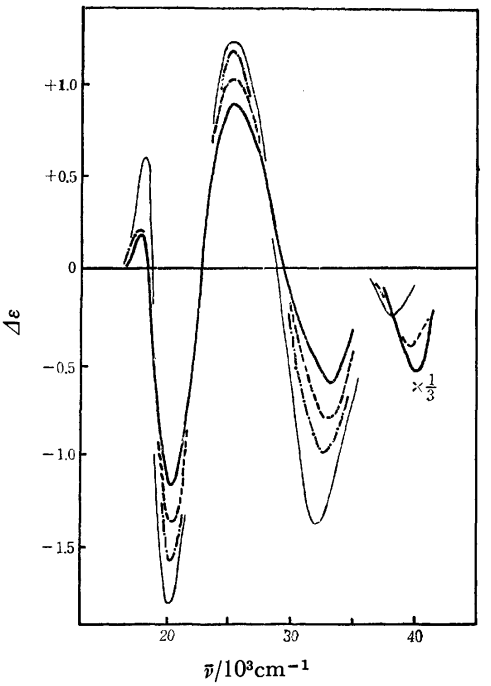

Fig. 3. CD spectra of $[Co(S\text{-amO})(NH_3)_4]^{2+}$ complexes (deprotonated form).
——: *S*-pra⁻ complex ----: *S*-leu⁻ complex
—·—: *S*-abn⁻ complex : *S*-isopra⁻ complex

$A_1 \rightarrow E$ and the $A_1 \rightarrow A_2$ component, respectively. The magnitude of the latter component is markedly enhanced in the deprotonated complexes as compared with that in the protonated complexes. The strong CD band at about 25000 cm^{-1} in the second absorption band region is quite characteristic of the deprotonated complexes. The CD corresponding to the second absorption band of a cobalt(III) complex is generally very weak, since this absorption is intrinsically magnetic dipole forbidden. The CD peak positions at about 25000 cm^{-1} do not coincide with the second absorption maxima at about 27600 cm^{-1}, and there seems to exist a band component at about 25000 cm^{-1} in the absorption spectra (see Fig. 1). The deprotonated isopra⁻ complex which contains an asymmetric carbon atom adjacent to the alcoholic oxygen atom gives the biggest CD peaks among the *S*-amO⁻ complexes in the first and the second absorption band region.

Very recently, Hawkins *et al.*[11] reported the CD of the tetraammine complexes containing *S*-lactic acid, *S*-2-amino-1-propanol, *S*-alanine and *S*-1,2-diaminopropane in 0.1 M perchloric acid, in aqueous solution and in 0.005 M potassium hydroxide solution. The CD spectra of *S*-2-amino-1-propanol complex show a strong pH-dependence as those in our study. A similar pH-dependence is also exhibited in the *S*-lactato complex.

CD Spectra of Bis(ethylenediamine)cobalt(III) Complexes. The absorption and CD spectra of *Λ*-$[Co(etaH)(en)_2]^{3+}$, *Λ*-$[Co(S\text{-praH})(en)_2]^{3+}$ and *Λ*-$[Co(S\text{-praH})(en)_2]^{3+}$ and their conjugate bases were reported in the previous communication.[3] The spectra of two isomeric isopraH complexes and their conjugate bases are shown in Figs. 4 and 5. The CD spectra of the protonated complexes

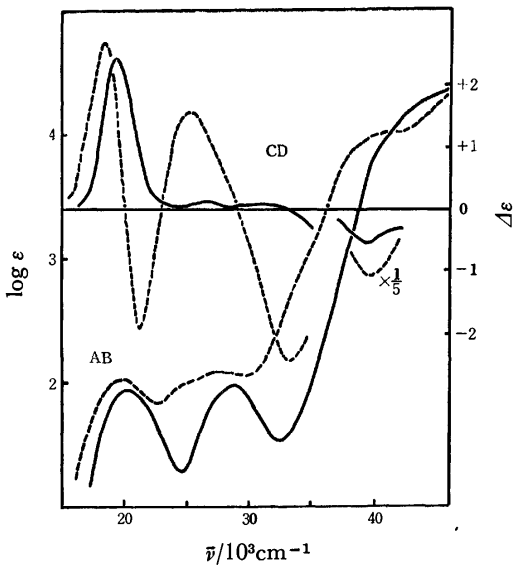

Fig. 4. Absorption and CD spectra of *Λ*-[Co(*S*-isopraH)(en)$_2$]$^{3+}$ (protonated form) (——) and *Λ*-[Co(*S*-isopra)(en)$_2$]$^{2+}$ (deprotonated form) (---).

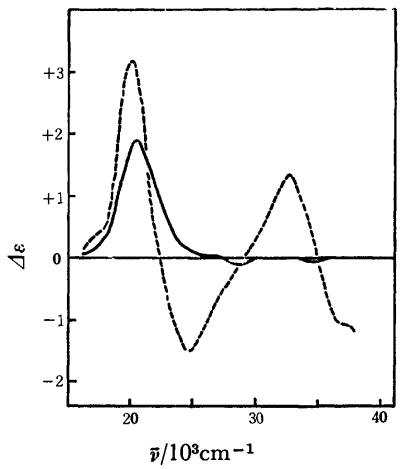

Fig. 5. CD spectra of *Λ*-[Co(*R*-isopraH)(en)$_2$]$^{3+}$ (protonated form) (——), and *Λ*-[Co(*R*-isopra)(en)$_2$]$^{2+}$ (deprotonated form) (----).

[Co(amOH)(en)$_2$]$^{3+}$ resemble those of [Co(diamine)$_3$]$^{3+}$ and [Co(am)(en)$_2$]$^{2+}$. A strong and a weak CD band are observed in the first and the second absorption band region, respectively.

The absolute configurations of the amino-alcohol complexes can be assigned on the basis of the sign of the main CD band at about 20000 cm^{-1}. Thus the complexes shown in Figs. 4 and 5 are assigned to *Λ* configuration. The absolute configuration of 1-amino-2-propanol in these complexes can be assigned from comparison of their CD spectra with those of the ethylenediamine analogs of *S*-praH and *S*-pra$^-$.[3] As the CD curves of the isopraH and isopra$^-$ complexes in Fig. 4 are similar to those of the corresponding *Λ*-[Co(*S*-praH)(en)$_2$]$^{3+}$ and its conjugate base respectively, the absolute configuration of isopraH in this isomer will be assigned to *S*. In an analogous manner, the absolute configuration of isopraH in the other isomer, whose CD curves are given in Fig. 5, was assigned

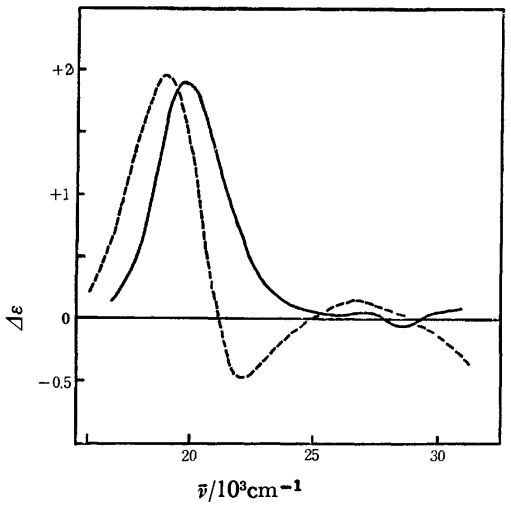

Fig. 6. Configurational effects of [Co(*R*-isopraH)(en)$_2$]$^{3+}$ (protonated form) (——) and [Co(*R*-isopra)(en)$_2$]$^{2+}$ (deprotonated form) (----).

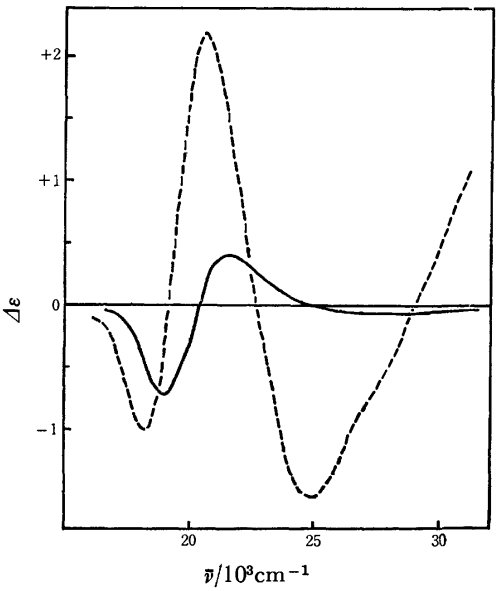

Fig. 7. Vicinal effect curves of [Co(*R*-isopraH)(en)$_2$]$^{3+}$ (——) (protonated form) and [Co(*R*-isopra)(en)$_2$]$^{2+}$ (----) (deprotonated form).

to *R*.

The CD magnitudes of the deprotonated complexes [Co(amO)(en)$_2$]$^{2+}$ are considerably enhanced as compared with those of their conjugate acids. The characteristics of the CD spectra of the deprotonated complexes are the appearance of two strong bands with opposite signs at 20000—21000 cm^{-1} and about 25000 cm^{-1}. In the absorption spectra of these complexes, a shoulder is observed at about 25000 cm^{-1}. These shoulder bands may also be related to the strong CD bands at about 25000 cm^{-1}, as seen in the tetraammine complexes with deprotonated amO$^-$.

It is known that the contributions of the configurational and vicinal effects are additive in the CD spectra of a series of cobalt(III) complexes containing five-membered chelate rings.[10,13] The configurational and the vicinal effects in the CD spectra of two isomeric

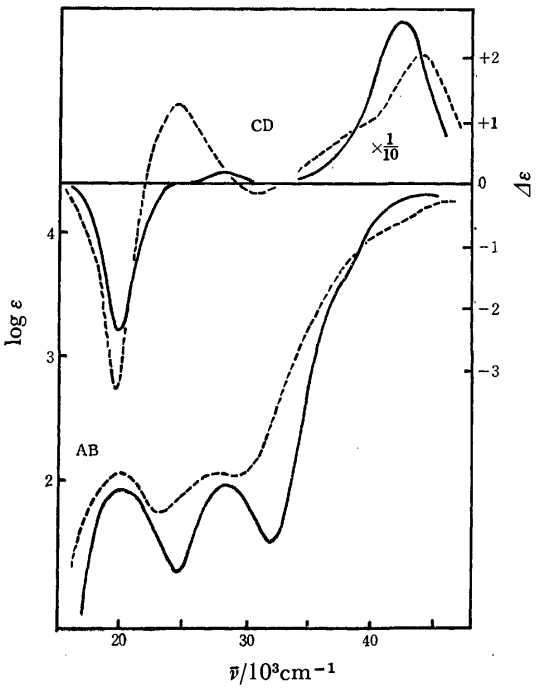

Fig. 8. Absorption and CD spectra of Δ-[Co(*S*-praH)-(*R*-chxn)$_2$]$^{3+}$ (protonated form) (——), Δ-[Co(*S*-pra)-(*R*-chxn)$_2$]$^{2+}$ (deprotonated form) (----).

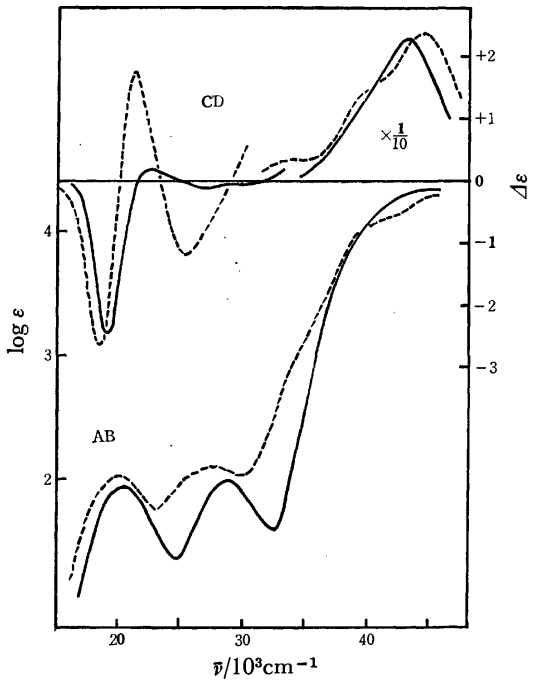

Fig. 9. Absorption and CD spectra of Δ-[Co(etaH)-(*R*-chxn)$_2$]$^{3+}$ (protonated form) (——), Δ-[Co(eta)-(*R*-chxn)$_2$]$^{2+}$ (deprotonated form) (----).

[Co(isopraH)(en)$_2$]$^{3+}$ and their conjugate bases, are estimated as shown in Figs. 6 and 7. The vicinal effect curves in Fig. 7 resemble the CD curves of the corresponding tetraammine complexes, indicating that the additivity of the two effects holds in these complexes. The configurational effect curves are similar between the protonated and the deprotonated complexes, while the vicinal effect curves are considerably different from each other, the CD magnitude of the deprotonated complexes being enhanced considerably. A similar result has been obtained for the CD spectra of Δ- and Λ-[Co(*S*-praH)(en)$_2$]$^{3+}$ and their conjugate bases.[3] Thus the enhanced CD magnitude of the deprotonated complexes may be attributed to the vicinal effect of an amino-alcoholate chelate ring. The similarity of the vicinal effect curves of *S*-pra$^-$ and *S*-isopra$^-$ complexes implies that the conformation of the five-membered chelate ring contributes to the CD more than does the position of substituent on the chelate ring. The CD band at $\sim$25000 cm^{-1} of Δ- or Λ-[Co(amO)(en)$_2$]$^{2+}$ depends only on conformation of amO$^-$ chelate ring because the configurational effect curve has no bands in this region.

The enhanced CD magnitude of the deprotonated amino alcoholato complexes might be related to the coordinated alcoholate oxygen atom with two sets of nonbonding electron pairs. Recently Kipp and Haines[14] reported that [Co(*R*-lac)(diamine)$_2$]$^+$(lac^{2-}= divalent lactate ion) complexes exhibit strong CD. These complexes also possess coordinated alcoholate oxygen atom.

*CD Spectra of Bis(*R-trans-1,2-*diaminocyclohexane)cobalt-(III) Complexes.* The absorption and CD spectra of [Co(amOH)(*R*-chxn)$_2$]$^{3+}$ complexes and their conjugate bases are shown in Figs. 8 and 9. The absolute configurations of the complexes around the cobalt(III) ion were assigned from the sign of the main CD band in the first absorption band region of the protonated complexes. In the present study Λ-isomers were formed too little, and we have isolated only the Δ-isomer for each complex.

The CD spectrum of Δ-[Co(*S*-praH)(*R*-chxn)$_2$]$^{3+}$ would consist of the configurational and the vicinal effects due to *S*-praH and the two *R*-chxn chelate rings. The *R*-chxn chelate ring will take λ-*gauche* conformation and consequently the C–C bond in the chelate ring is *lel*[15] to the pseude-three fold axis of the Δ-complex. The *S*-praH chelate ring will have the C–C bond *ob*[15] to the pseudo-three fold axis.

The CD spectra of Δ-[Co(*S*-praH)(*R*-chxn)$_2$]$^{3+}$ and its conjugate base are similar to those of Δ-[Co(*S*-praH)-(en)$_2$]$^{3+}$ and its conjugate base(see Table 1 and spectra in Ref. 3) respectively. This similarity indicates that these ethylenediamine chelate rings take λ(*lel*) conformation preferentially. The *S*-pra$^-$ chelate ring must give strong vicinal effect similarly to the en and the chxn complex and seems to have given similar patterns to them. The CD spectra of Δ-[Co(etaH)(*R*-chxn)$_2$]$^{3+}$ and its conjugate base are cosiderably different from the corresponding ethylenediamine analogs (see Table 1 and spectra in Ref. 3). The difference might be related to the difference in the conformation of etaH or eta$^-$ in the *R*-chxn and the en complexes. The complex ion Λ-[Co(eta)(en)$_2$]$^{2+}$ shows only small CD bands at 25970 cm^{-1}. The CD band in this region has been shown to depend only on the conformation of the amO$^-$ chelate ring. The conformation of eta$^-$ chelate ring in the en complex is thus considered to be in equilibrium between δ and λ, and the equilibrium to be in favor of the δ only to a small extent.

On the other hand, Δ-[Co(eta)(*R*-chxn)$_2$]$^{2+}$ exhibits fairly strong CD bands at 21280 cm^{-1} and 25320 cm^{-1} and the whole CD curve is almost enantiomeric with that of Λ-[Co(*S*-pra)(en)$_2$]$^{2+}$. Since the *S*-pra$^-$ chelate ring in the ethylenediamine complex will take δ conformation stereoselectively, the eta$^-$ chelate ring in Δ-[Co(eta)(*R*-chxn)$_2$]$^{2+}$ may be mostly in λ conformation. The stereoselectivity of the conformation of eta$^-$ chelate ring in the bis(*R*-chxn) complex seems to be much larger than that in the bis(en) complex. Such a large stereoselectivity might be brought about by the steric interaction between the eta$^-$ and *R*-chxn chelate rings.

It is concluded that an amino-alcoholate chelate ring without asymmetric atoms can give strong vicinal effect when it takes a chiral conformation stereoselectively.

Absorption Spectra. The first absorption bands of all the deprotonated amino-alcoholate complexes are at somewhat lower wave number than those of the corresponding protonated amino-alcohol complexes. However, the wave number differences are small compared with that observed for aqua- and hydroxo-pentaammine complexes which belong to the same [CoN$_5$O] type as the present amino-alcohol complexes.

It the second absorption band region, on the other hand, the spectra of the tetraammine complexes exhibit somewhat different behavior from those of the bisdiamine complexes. The tetraammine complexes with deprotonated amO$^-$ have the second absorption maxima at lower wave numbers than those of the protonated complexes by *ca.* 150 cm^{-1}. However, most of the bisdiamine complexes with deprotonated amO$^-$ give their second absorption bands at only slightly lower wave number than those of the protonated complexes, and exhibit a distinct shoulder band at about 25000 cm^{-1}. Such a shoulder band is the most pronounced in [Co(*N*-Meeta)(en)$_2$]$^{2+}$ among the amino-alcoholate complexes studied here. As stated previously, all the complexes containing deprotonated chiral amino-alcoholate chelate ring show a strong CD band in this region, $\sim$25000 cm^{-1}. Thus, it may be concluded that all the deprotonated complexes have an absorption component at about 25000 cm^{-1}, even though there is no obvious shoulder in the absorption spectra as in the tetraammine complexes. In such complexes the shoulder band might have been masked by the main component of the second absorption band. The apparrent second absorption maximum is thus seen at a relatively lower wave number.

A similar shoulder in the second absorption band region has been reported for several complexes; [Co(OH)(edta)]$^{2-}$,[16] (edta^{4-}=ethylenediaminetetraacetate ion), [Co(OH)(penten)]$^{2+}$ [17] (penten=*N*,*N*,*N*',*N*'-tetrakis(2'-aminoethyl)-1,2-diaminoethane) and *mer*-(*trans*-NH$_3$)-[CoCO$_3$(am)(NH$_3$)$_2$][18] (am$^-$=aminocarboxylate ion). The nature of these shoulder bands is not clear at present. However, all the complexes including the present aminoalcoholate complexes are those containing both chelate rings and coordinated oxygen atom with two sets of nonbonding electron pairs. [Co(guH)(en)$_2$]$^{3+}$ and [Co(gu)(en)$_2$]$^{2+}$ (guH=guanylurea) show also a broad second absorption band but the structures of these complexes remain uncertain.[19]

The authors wish to thank Mr. K. Ohashi of Ibaragi University for supplying *S*-leucinol and also Ministry of Education for Grant in Aid.

A Polarographic Investigation of the Reactions between Nitrate Ions and Chromium(II)–Cyclohexanediaminetetraacetate, Chromium(II)–Trimethylenediaminetetraacetate, and Chromium(II)–*N*-(2-Hydroxyethyl)ethylenediaminetriacetate Complexes

Nobuyuki TANAKA, Taisaku KANO, Hiroshi OGINO, and Akifumi YAMADA

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received April 1, 1974)

Kinetic studies of the reactions between nitrate ions and Cr(II)-Y complexes, where Y represents cyclohexanediaminetetraacetic acid (CyDTA), trimethylenediaminetetraacetic acid (TRDTA), and *N*-(2-hydroxyethyl) ethylenediaminetriacetic acid (HEDTA), have been carried out. The reaction mechanisms of these complexes at the dropping mercury electrode were found to be expressed by the following equations:

$$\begin{array}{lll} \text{Cr(III)-Y} + \text{e} & \longrightarrow & \text{Cr(II)-Y} \\ \text{Cr(II)-Y} + \text{H}^+ & \overset{K}{\rightleftharpoons} & \text{Cr(II)-HY} \\ \text{Cr(II)-Y} + \text{NO}_3^- & \overset{k_1}{\longrightarrow} & \text{Cr(III)-Y} \\ \text{Cr(II)-HY} + \text{NO}_3^- & \overset{k_2}{\longrightarrow} & \text{Cr(III)-Y} \end{array}$$

The formation constant, K, and the rate constants, k_1 and k_2, were determined in 0.1 M acetate buffer solutions of $\mu=0.5$ by procedures including a curve-fitting method; the results were $K=2.0\times10^4$ M^{-1}, $k_1=0.55$ M^{-1} s^{-1} and $k_2=2.8$ M^{-1} s^{-1} for Cr(II)-CyDTA, $K=2.4\times10^5$ M^{-1}, $k_1=1.0\times10^2$ M^{-1} s^{-1}, and $k_2<3$ M^{-1} s^{-1} for Cr(II)-TRDTA and $k_1\sim2\times10^3$ M^{-1} s^{-1} for Cr(II)-HEDTA.

It was reported in a previous paper[1] that chromium(II)–EDTA complexes which were formed by the electroreduction of ethylenediaminetetraacetatoaquochromate(III) ions were oxidized by nitrate ions at the surface of the electrode; a catalytic reaction took place in solutions containing both chromium(III)–EDTA and nitrate ions. The stoichiometry and the rate constant of the reaction were determined, and the reaction mechanisms were discussed.[1]

In this paper, the polarographic investigation of the reaction between nitrate ions and Cr(II)–Y at the dropping mercury electrode is presented, where Y represents CyDTA, TRDTA, and HEDTA. The stoichiometry and the mechanisms of the reaction are discussed, and the formation constant of the acid complex of Cr(II)-Y, and the second-order rate constants of the reactions between nitrate ions and Cr(II)–Y and Cr(II)–HY are presented.

Experimental

Sodium cyclohexandiaminetetraacetatochromate(III), Na[Crcydta]·4H$_2$O, sodium trimethylenediaminetetraacetatochromate(III), Na[Crtrdta]·4H$_2$O, and *N*-(2-hydroxyethyl)-ethylenediaminetriacetatochromium(III), [Cr(H$_2$O)hedta], were prepared according to Tanaka *et al.*,[2] Ogino *et al.*[3] and Bustin and Early[4] respectively. All the chemicals used were of a guaranteed grade.

Current-potential curves were obtained with a pen-recording polarograph, Yanagimoto Graphrecorder, with an automatic potential scanner. The dropping mercury electrode (DME) used in the measurement of the limiting current of Crcydta$^-$ had a rate of mercury flow (m) of 1.86 mg s^{-1} and a drop time (t_d) of 5.00 s, as measured in an air-free solution containing a 0.1 M acetate buffer (pH 4.9) at -0.5 V *vs.* SCE and at a pressure of 50 cm of mercury. The DME used in the measurement of Crtrdta$^-$ and Cr(H$_2$O)hedta had an m value of 1.34 mg s^{-1} and a t_d value of 4.75 s in an air-free solution containing a 0.1 M acetate buffer (pH 4.9) and 0.4 M sodium perchlorate at -1.34 V *vs.* SCE and at a pressure of 60 cm of mercury.

The potential of DME was referred to the saturated calomel electrode (SCE). The temperature of the electrolytic solution was maintained at 25±0.2 °C by means of a thermostated bath. Dissolved oxygen in the electrolytic solution was removed by bubbling pure nitrogen gas through the solution. Extra pure nitrogen gas (99.999%) was used in determining the stoichiometric ratio of the Cr(II) complexes to the nitrate ion of the reaction. No maximum suppressor was used in the cases of Crcydta$^-$ and Cr(H$_2$O)hedta. As the reduction wave of Crtrydta$^-$ gave a maximum, 2 μM LEO was added in determining the limiting current of Crtrdta$^-$.

The measurements were made in 0.1 M acetate buffer solutions. The ionic strength was adjusted to 0.5 with sodium perchlorate, unless otherwise stated. The stoichiometry of the reactions of the Cr(II) complex with the nitrate ion was determined by the method reported in a previous paper.[1]

The controlled potential electrolysis was carried out with a Yanagimoto Controlled Potential Electrolyser. The working electrode was a mercury pool, while the auxiliary electrode was a platinum wire which was connected to the electrolytic solution through a sodium chloride agar bridge. The potential of the working electrode was referred to the SCE. Nitrogen gas was bubbled through the solution continuously to provide stirring and to remove atmospheric oxygen.

Results

Polarograms of Crcydta$^-$, Crtrdta$^-$, and Cr(H$_2$O)hedta Obtained at Various Concentrations of Nitrate Ions. The polarographic waves of Crcydta$^-$, Crtrdta$^-$, and Cr(H$_2$O)hedta obtained in acetate buffer solutions were of a one-electron diffusion-controlled reduction. Upon the addition of nitrate ions to these solutions, the limiting currents of these waves increased in height. Figure 1 shows as examples the reduction waves of Crcydta$^-$ in the absence and in the presence of nitrate ions. Current $\bar{I}_c$ in Fig. 1 was found to be independent of the

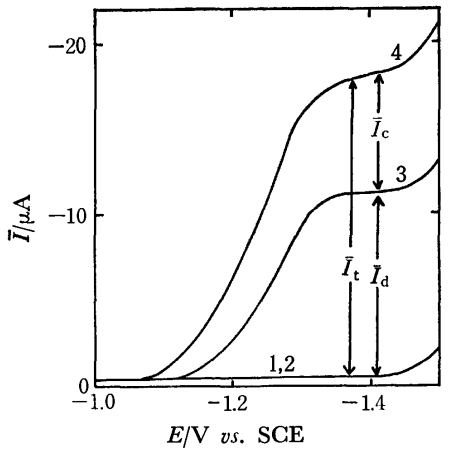

Fig. 1. Polarograms obtained with the solutions containing (1) 0.1M acetate buffer (pH 4.9), (2) (1)+0.25 M $NaNO_3$ (3) (1)+4 mM Crcydta$^-$ and (4) (3)+0.17 M $NaNO_3$.

height of mercury, indicating that $\bar{I}_c$ was kinetic in nature; that is, it was a catalytic current.

Apparent Rate Constants of the Reactions between Nitrate Ions and Cr(II)-CyDTA, Cr(II)-TRDTA, and Cr(II)-HEDTA. Let us consider the electrode processes given by the equations,

$$\begin{array}{l} O + ne \longrightarrow R \\ \uparrow \qquad\qquad \downarrow \\ R + Z \xrightarrow{k} O \end{array} \qquad (1), (2)$$

where O, R, and Z represent, respectively, the oxidant, the reductant, and the substance which is neither reduced nor oxidized at the potential at which O is reduced. The rate constant, k, of the chemical reaction given by Eq. (2) is calculated by means of Eqs. (3) to (7):[5-7]

$$\Psi(\chi_1) = \frac{\bar{I}_t + 2.37\times10^4\, nm^{1/3}t_d^{1/2}DC_o}{\bar{I}_d + 2.37\times10^4\, nm^{1/3}t_d^{1/2}DC_o} \qquad (3)$$

$$= (7/6)\chi_1^{-7/6}\left[2\int_0^{\chi_1}\chi^{2/3}f(\beta)d\chi + \int_0^{\chi_1}\chi^{1/6}\exp(-\chi)d\chi\right] \qquad (4)$$

$$f(\beta) = \int_0^1 \frac{\beta\exp(-\beta^2\chi_1)}{\{1-(1-\beta^2)^{7/3}\}^{1/2}}d\beta \qquad (5)$$

$$\chi_1 = \alpha k C_Z t_d \qquad (6)$$

where D is the diffusion coefficient and where C_O and C_Z are the concentrations of O and Z respectively, Z being present in a large excess of O. α is the stoichiometric ratio of R to Z of Reaction (2). In this study, the Cr(III)–Y, Cr(II)–Y, and nitrate ions correspond to O, R, and Z respectively, and α was determined to be 8 from separate experiments. When $\chi_1 > 10$,

$$\Psi(\chi_1) = 0.812\chi_1^{1/2} + 1.92\chi_1^{-7/6} \qquad (7)$$

The rate constants which were obtained by means of Eq. (7) for the reactions between nitrate ions and Cr(II)–CyDTA, Cr(II)–TRDTA, and Cr(II)–HEDTA under various conditions are given in Tables 1 and 2 and Figs. 2 and 3, in which k_{app} corresponds to k in Eq. (6). The values of k_{app} thus obtained were found to be independent of [Cr(III)–Y] and [NO_3^-].

The catalytic currents of Crcydta$^-$ obtained at the

given concentration of nitrate ions and the apparent rate constants calculated thereform increased with the increase in the concentration of hydrogen ions, as is shown in Table 1. However, they did not change upon the addition of the free ligand CyDTA, as long as the other conditions were the same. These results seem to indicate that the acid complex of Cr(II)–CyDTA, Cr(II)–HY, is formed, but not aquochromium(II); the latter reacts with nitrate ions very slowly.[8] In the case of Crtrdta$^-$, the catalytic current and the apparent rate constants calculated therefrom were found to decrease with the increase in the concentration of hydrogen ions, as is shown in Table 2. This tendency is opposite to that obtained with Crcydta$^-$. The height of the catalytic current did not change upon the addition of the free ligand TRDTA, just as in the

case of Crcydta$^-$. From the measurements of the half-wave potentials of Crtrdta$^-$ at various concentrations of hydrogen ions, it was found that Cr(II)–TRDTA formed the acid complex, CrHtrdta$^-$.[9] This suggests that no appreciable amount of aquochromium(II) exists in the solution, while the acid complex, CrHtrdta$^-$, does.

The apparent rate constant of the reaction between nitrate ions and Cr(H_2O)hedta$^-$ decreased with the increase in the hydrogen-ion concentration (see Curve 1 in Fig. 2). This pH-dependency of the apparent rate constant became smaller upon the addition of free HEDTA (Curve 2 in Fig. 2). When 4 mM of free HEDTA was present in the solution, the apparent rate constants were found to be almost independent of the hydrogen-ion concentration (Curve 3 in Fig. 2).

The apparent rate constants which were obtained at the same concentration of hydrogen ion increased with an increase in the concentration of free HEDTA, but gave a maximum value at a certain concentration of free HEDTA and then decreased, as is shown in Fig. 3. The increase in the apparent rate constant at lower concentrations of free HEDTA may be explained by considering that aquochromium(II) is formed in the absence of free HEDTA, while the formation of aquochromium(II) is prevented by the addition of HEDTA. On the other hand, the decrease in the apparent rate constant with an increase in the concentration of free HEDTA is not completely understood; it may, however, be due to the reaction between free HEDTA and the reduction intermediates of nitrate ions.

Discussion

It is considered that the mechanisms of the catalytic electrode reactions of Cr(III)–Y taking place in the presence of nitrate ions may be indicated as follows:

$$\text{Cr(III)-Y} + e \longrightarrow \text{Cr(II)-Y} \quad (8)$$

$$\text{Cr(II)-Y} + H^+ \overset{K}{\rightleftharpoons} \text{Cr(II)-HY} \quad (9)$$

$$\text{Cr(II)-Y} + NO_3^- \xrightarrow{k_1} \text{Cr(III)-Y} \quad (10)$$

$$\text{Cr(II)-HY} + NO_3^- \xrightarrow{k_2} \text{Cr(III)-Y} \quad (11)$$

where K is the formation constant of the acid complex and k_1 and k_2 are the second-order rate constants of the reactions given by Eqs. (10) and (11) respectively. When Y is CyDTA or TRDTA, the electrode reactions are considered to proceed by the mechanisms given by Eqs. (8) to (11). When Y is HEDTA, the reaction seems to proceed by the mechanisms given by Eqs. (8) to (10) or by Eqs. (8) to (11), unless free HEDTA exceeds a certain amount. In the latter case, Reaction (10) proceeds as fast as Reaction (11).

If the reaction proceeds according to Eqs. (8) to (11), the apparent rate constant is given by the following equations:

$$-\frac{d[Cr(II)]_t}{dt} = 8k_{app}[Cr(II)]_t[NO_3^-] \quad (12)$$

$$K = \frac{[Cr(II)-HY]}{[Cr(II)-Y][H^+]} \quad (13)$$

$$[Cr(II)]_t = [Cr(II)-Y] + [Cr(II)-HY] \quad (14)$$

$$k_{app} = \frac{k_1 + k_2K[H^+]}{1 + K[H^+]} \quad (15)$$

With the apparent rate constants and the hydrogen-ion concentrations, the formation constant, K, and the rate constants, k_1 and k_2, were obtained by the curve-fitting method; they are given in Table 3.

The value of k_2 is larger than k_1 in the cases of Cr(II)-EDTA and Cr(II)–CyDTA. This seems reasonable,

Table 3. Rate constants of the reaction between Cr(II)Y (Y: CyDTA, TRDTA, and HEDTA) and nitrate ions, and the formation constant of Cr(II)-HY.

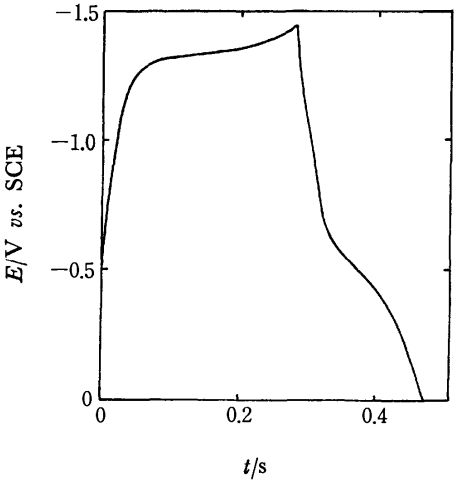

Fig. 4. Chronopotentiogram for the reduction and the subsequent reoxidation of 0.64 mM Crtrdta$^-$ obtained at current density of 5.19×10^{-4} A/cm^2 in the solution containing 0.1 M acetate buffer (pH 4.0) and 0.4 M $NaClO_4$.

because the electrostatic repulsion of acid complexes with nitrate ions is smaller than that of the normal complexes, Cr(II)–EDTA and Cr(II)–CyDTA. The k_2 value of Cr(II)–EDTA is of the same order as the k_1 value of Cr(II)–HEDTA; this is probably because the complexes are similar in both charge and structure. In the case of Cr(II)–TRDTA, on the other hand, k_2 is smaller than k_1. A current-reversal chronopotentiogram of Crtrdta$^-$ indicated an irreversible nature of the electrode reaction; it is shown in Fig. 4. This seems to suggest that the structure of the acid complex of Cr(II)–TRDTA changes rapidly to a structure similar to aquochromium(II), which can react with nitrate ions only slowly.

The magnitudes of the k_1 values of Cr(II)–CyDTA, Cr(II)-TRDTA, and Cr(II)–EDTA are in the following order:

Cr(II)-TRDTA > Cr(II)-EDTA > Cr(II)-CyDTA

The above order may be compared with the standard potentials of these complexes, which are −1.29,[9] −1.220,[11] and −1.198[12] V *vs.* SCE for Cr(III, II)-TRDTA, Cr(III, II)–EDTA, and Cr(III, II)–CyDTA respectively. The correlation between the rate constant and the standard potential is apparent. However, as Cr(III, II)–EDTA and Cr(III, II)–CyDTA have almost the same standard potentials, the difference in the k_1 values of Cr(II)–EDTA and Cr(II)–CyDTA may come from the difference in structure. The standard rate constants of the electrode reactions of $Cr(H_2O)edta^-$ and Crcydta$^-$ show a similar tendency; those of $Cr(H_2O)edta^-$ and Crcydta$^-$ are 0.21 cm s^{-1} [11] and 0.029 cm s^{-1} [12] respectively.

Nitrosylrhenium(^{14}NO and ^{15}NO) Complexes

Eiichi MIKI, Kunihiko MIZUMACHI, and Tatsujiro ISHIMORI

Department of Chemistry, College of Science, Rikkyo University, 3-Chome, Nishi Ikebukuro, Toshima-ku, Tokyo 171

(Received June 21, 1974)

The ^{15}NO-complexes for $M_2[ReX_5(NO)]$ (M=Rb, Cs, and pyH; X=Cl and Br) were prepared. The ^{15}N-isotopic shift for their N–O stretching vibrations, *ca.* 40 cm^{-1}, supports the view that the oxidation state of the NO group is I, while that of the rhenium atom is II. The Re–(NO) stretching and the Re–(NO) bending vibrations were observed in the 610—620 cm^{-1} region. A new compound, *cis*-(pyH)$[ReCl_4(NO)_2]$, was prepared, the oxidation state of its rhenium atom being considered to be I, and that of the NO group, I.

The isotopic effects of ^{15}N-substitution in the NO group for several transition-metal nitrosyl complexes on the IR spectra have been measured.[1,2] From the comparison of the observed isotopic shifts with the calculated ones, a few rules were established: the isotopic shift of the metal–(NO) stretching vibration is smaller than that of the metal–(NO) bending vibration, independent of the metal–(NO) bond angle; the isotopic shifts of the N–O stretching vibrations observed on NO^+ complexes are almost equal to those calculated by assuming a linear arrangement of a metal–N–O, and are larger than those observed on NO^- complexes; the isotopic shifts of the N–O stretching vibrations decrease with the deviation of the metal–(NO) bond angle from linearity.

On the basis of these facts, the oxidation states of the rhenium atom and the NO group for $M_2[ReX_5(NO)]$ (M=Rb, Cs, and pyH; X=Cl and Br) were investigated. A new compound, *cis*-(pyH)$[ReCl_4(NO_2)]$, was prepared and characterized on the basis of spectroscopic evidence. This compound is the first one formulated containing a O–N–Re–N–O skeleton.

Experimental

Syntheses. $M_2[ReX_5(NO)]$ was prepared by means of a modification of Bandyopadhyay's procedure.[3] The starting materials, $Ag_2[ReCl_6]$ and $K_2[ReBr_6]$, were synthesized from $KReO_4$ by the method of Watt and Thompson.[4] The ^{15}NO-complexes were prepared in a vacuum line by the use of 5—6 mmol of ^{15}NO(^{15}N atom%=95 and 96.8) on the same scale as that used for preparing the ^{14}NO-complexes.

$Cs_2[ReCl_5(NO)]$: A 5-mmol portion of NO gas derived from KNO_3 was trapped in a reaction vessel containing 1.7 mmol of a finely-powdered $Ag_2[ReCl_6]$ by cooling with liquid nitrogen. A green product, $Cs_2[ReCl_5(NO)]$ (*ca.* 100 mg), was then obtained by the procedure shown in Ref. 3. The crude product thus obtained was then washed well with a cold 6 M hydrochloric acid solution to remove any impurities, then it was washed with ethanol and dried under a vacuum. Found: Cs, 39.5; Re, 28.5; N, 2.23; Cl, 26.61%. Calcd for $Cs_2[ReCl_5(NO)]$: Cs, 40.32; Re, 28.24; N, 2.12; Cl, 26.89%. $\mu_{eff.}$ (at 291 K)=1.62 B.M. g(at 296 K)=2.01.

$M_2[ReBr_5(NO)]$ (M=Rb and Cs): A 6-mmol portion of NO gas was trapped in a reaction vessel containing 2 mmol of a finely-powdered $K_2[ReBr_6]$ and then heated at *ca.* 400 °C for 12 hr. A dark brown sublimate which was deposited on the wall of the vessel was dissolved in a hot 90% ethanol solution and then refluxed for 12 hr. The resulting brown filtrate was evaporated to dryness on a boiling-water bath. The solid residue thus obtained was dissolved in 25 ml of a hot 5 M hydrobromic acid solution and refluxed for 6 hr at 90 °C to give a greenish brown solution. An 8-mmol portion of rubidium bromide was added to the filtrate, and the mixture was condensed to *ca.* 10 ml on a boiling-water bath. The brown precipitate thus obtained, $Rb_2[ReBr_5(NO)]$, was filtered out, washed with cold concentrated hydrobromic acid, and dried in a vacuum. Yield, 220—500 mg. Found: Rb, 21.6; Re, 23.7; N, 1.69; Br, 50.61%. Calcd for $Rb_2[ReBr_5(NO)]$: Rb, 21.73; Re, 23.67; N, 1.78; Br, 50.79%. $\mu_{eff.}$ (at 291 K)=1.61 B.M. g(at 87 and 296 K)=2.06. $Cs_2[ReBr_5(NO)]$ was prepared by the same procedure; 5 mmol of NO gas, 1 mmol of $K_2[ReBr_6]$, and 8 mmol of caesium bromide were used. Yield, 250—270 mg. Found: Cs, 29.9; Re, 21.7; N, 1.72; Br, 44.97%. Calcd for $Cs_2[ReBr_5(NO)]$: Cs, 30.15; Re 21.12; N, 1.59; Br, 45.32%. $\mu_{eff.}$ (at 291 K)=1.66 B.M. g(at 296 K)=2.08.

$(pyH)_2[ReCl_5(NO)]$ and cis-*$(pyH)[ReCl_4(NO)_2]$*: A mixture of 5 mmol of NO gas and 1.7 mmol of powdered $Ag_2[ReCl_6]$ was heated at *ca.* 320 °C for 5 hr. The brown sublimate thus obtained was dissolved in 100 ml of 99.5% hot ethanol, and the solution was refluxed for 6 hr. The greenish brown filtrate was evaporated to dryness on a water bath, dissolved in 30 ml of an 8 M hydrochloric acid solution, and refluxed for 21 hr at 95 °C to give a dark green solution. 5 mmol of pyridinium chloride in 5 ml of an 8 M hydrochloric acid solution was added to the filtrate, and the mixture was refluxed at 95 °C for 35 hr. The green solution thus obtained was evaporated on a boiling-water bath. The residue was then boiled with 20 ml of 99.5% ethanol for 1 min. The green extract was condensed in a vacuum line to *ca.* 10 ml with the aid of liquid nitrogen to precipitate olive green needles; (pyH)$[ReCl_4(NO)_2]$. Yield, 100 mg. Found: C, 13.49; H, 1.73; N, 8.87; Cl, 30.04%. Calcd for (pyH)$[ReCl_4(NO)_2]$: C, 12.83; H, 1.29; N, 8.98; Cl, 30.29%. χ_g(at 295 K)$=-0.06\times10^{-6}$(c.g.s.). After the olive green needles had been filtered out, a large excess of ether was added to the filtrate to give a green product, $(pyH)_2[ReCl_5(NO)]$. Yield, 50 mg. Found: C, 21.66; H, 2.28; N, 7.74; Cl, 30.44%. Calcd for $(pyH)_2[ReCl_5(NO)]$: C, 21.69; H, 2.18; N, 7.59; Cl, 32.02%. g(at 296 K)=2.02.

Apparatus. The IR spectra of the compounds as Nujol and hexachlorobutadiene mulls were recorded from 200—4000 cm^{-1} on JASCO DS-402G and JASCO model IR-F spectrophotometers. The wave numbers of the observed bands were calibrated with polystyrene film, 1,2,4-trichlorobenzene, and water vapour. The Raman spectra of the solid-state samples were measured from 100—700 cm^{-1} on a JASCO R-800 spectrometer equipped with an Ar ion laser, and on a Narumi 750Z-1200 double monochromator equipped with a He-Ne laser. The magnetic susceptibility was measured by the Gouy method at room temperature. Electron-spin resonance measurements were carried out in a pure powdered solid at room temperature and at the temperature of liquid nitrogen using a JEOL-ME3X spectrometer. The G-values were measured by shift from an external dilute manganese oxide in a magnesium oxide standard. The nuclear magnetic resonance spectra were measured on a

Results and Discussion

$M_2[ReX_5(NO)]$ (M=Rb, Cs, and pyH; X=Cl and Br). The wave numbers, isotopic shifts, and assignments of the IR and the Raman bands due to the ReNO group for the mononitrosyl complexes are shown in Table 1. The N–O stretching vibrations were observed in the 1720—1740 cm^{-1} region. The isotopic shifts upon ^{15}NO-substitution are 37—44 cm^{-1}, and are almost equal to those for the NO$^+$ complexes which were studied in Ref. 1.

Of the IR and Raman bands in the 100—700 cm^{-1} region, only the strong ones in the 610—620 cm^{-1} region shifted downwards by 3—9 cm^{-1} upon ^{15}NO-substitution for all the compounds. These bands are considered to be due to the skeletal vibrations between the rhenium atom and the NO group. The isotopic shifts observed on the IR spectra were found to be larger than those observed on the Raman spectra.

The ^{15}N-isotopic shifts of the N–O stretching, the Re–(NO) stretching, and the Re–(NO) bending vibrations were calculated from the wave numbers of the ^{14}NO-complexes by assuming a linear arrangement of Re–N–O and using a Valence Force Field. For the NO$^+$ complexes, the calculation of the isotopic shifts by means of the three-body model of the metal and the NO group is useful for assigning distinctly the skeletal vibrations when the metal and the ligands other than the NO group are much heavier than nitrogen and oxygen.[1,2] The calculated isotopic shifts of the N–O stretching, Re–(NO) stretching, and Re–(NO) bending vibrations are 40, 5, and 14 cm^{-1} respectively, while their calculated force constants are 11, 6.9, and 0.4 mdyn/Å respectively. The good agreement of the observed isotopic shift for the N–O stretching vibration with the calculated one is considered to support the theory that the oxidation state of the NO group is I, and that, therefore, that of the rhenium atom is II.

The isotopic shift observed on the 610—620 cm^{-1} band(3—9 cm^{-1}) is smaller than that calculated for the Re–(NO) bending vibration (14 cm^{-1}). The isotopic shift observed on the Raman bands is almost equal to that calculated for the Re–(NO) stretching vibration, while the isotopic shift observed on the IR bands is larger than that calculated for the Re–(NO) stretching vibration. These suggest the possibilities that the band due to the Re–(NO) stretching vibration accidentally overlaps with that due to the Re–(NO) bending one, and that the relative intensity of the Re–(NO) stretching band to the Re–(NO) bending one observed on the IR spectra is smaller than that observed on the Raman ones. However, another possibility, that the intensity of one of the skeletal vibrations is too weak to be observed, can not be excluded.

On the basis of IR and Raman studies of the $[MX_5(NO)]^{n-}$ anion (M=Ru, Os, and Ir; X=Cl, Br, and I),[5] the IR bands at 308(vs, b)[6] with a shoulder at 297 cm^{-1}, and 278 cm^{-1}(m) for $Cs_2[ReCl_5(NO)]$ can be assigned to the Re–Cl stretching E mode, ν_{10}, and the A_1 one, ν_4, respectively, and the IR band at 331 cm^{-1}(m) and the Raman one at 329 cm^{-1}, to the Re–Cl stretching A_1 mode, ν_3. The two Raman bands at 166 and 142 cm^{-1} are assigned to the Re–Cl deformation vibrations. The three IR bands at 330(m), 300(vs, b), and 275 cm^{-1}(m) for $(pyH)_2[ReCl_5(NO)]$ are assigned to the Re–Cl stretching vibrations, ν_3, ν_{10}, and ν_4 respectively, for the Cs-salt, while the IR bands at 250(m) and *ca.* 230 cm^{-1}(w) are considered to be due to the pyridinium ion. The Raman band at 212 cm^{-1} for $Rb_2[ReBr_5(NO)]$ and that at 207 cm^{-1} for $Cs_2[ReBr_5(NO)]$ can be assigned to the Re–Br stretching A_1 mode, ν_3, and the IR band at 221 cm^{-1}(vs) for the Rb-salt and that at 218 cm^{-1}(vs) for the Cs-salt, to the Re–Br stretching E one, ν_{10}.

cis-(pyH)$[ReCl_4(NO)_2]$. The IR bands at 1896 (vs), 1795(vs, b), and 1760 cm^{-1}(m) (the N–O stretching vibrations) shifted to 1859, 1756, and 1726 cm^{-1} respectively. The four IR bands in the 490—610 cm^{-1} region shifted upon ^{15}NO-substitution (from 610(s),

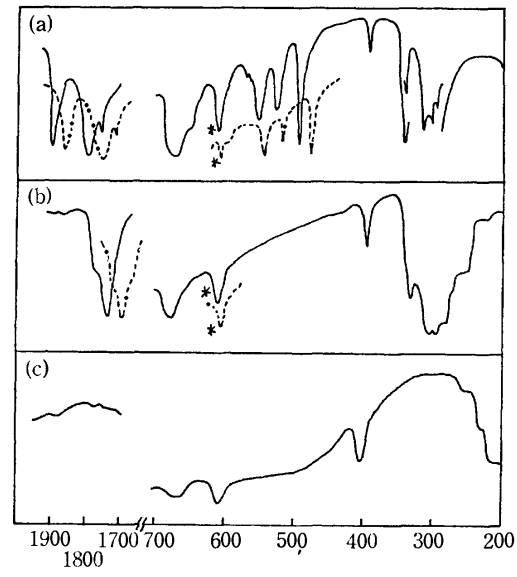

Fig. 1. IR spectra of *cis*-(pyH)$[ReCl_4(NO)_2]$ (a), $(pyH)_2[ReCl_5(NO)]$ (b), and pyHCl (c). ^{14}NO-complex, ——; ^{15}NO-complex(^{15}N atom%=95), ----; in (a) and (b). *; overlapped with the band due to the pyridinium ion.

550(s), 526(s), and 491 cm^{-1}(vs) to 608, 542, 521, and 477 cm^{-1} respectively), as is shown in Fig. 1. The two very strong N–O stretching bands at 1896 and 1795 cm^{-1} suggest the presence of two NO groups in this compound, in a *cis* position to each other. The observed isotopic shifts for the N–O stretching vibrations are about 40 cm^{-1}; hence, the oxidation state of two of the NO groups may be considered to be I.

The ^{15}N-isotopic shifts for the six IR bands in the 490—1900 cm^{-1} region can reasonably be explained on the basis of an O–N–Re–N–O skeleton. If this skeleton belongs to the C_{2v} point group, the number of IR-active bands should be eight. The bands at 1896 and 1795 (and 1760) cm^{-1} can be assigned to the N–O antisymmetric and symmetric stretching vibrations respectively, and the four bands in the 490—610 cm^{-1} region, to the Re–(NO) stretching, its bending, and the N–Re–N bending vibrations. Such a phenomenon was also observed on $[Ir(NO)_2(P(C_6H_5)_3)_2]ClO_4$[1], in which the O–N–Ir–N–O skeleton belongs to the C_{2v} point group.

Two chemical formulae, *cis*-(pyH)$[ReCl_4(NO)_2]$, in which the oxidation state of the rhenium atom is I, and *cis*-$[ReCl_3py(NO)_2]Cl$, in which it is II, are possible, judging from the elementary analyses. However, the latter can be excluded on the basis of the IR spectra. An IR study of pyridine complexes and pyridinium salts has shown that the bands at about 1530—1540 and 1280—1330 cm^{-1} are observed on the pyridinium salts, but not on the pyridine complexes; these are assigned to the N–H deformation vibration and the combination bands involving the N–H deformation.[7] These bands were observed at 1528(s) and 1328(m) for (pyH)$[ReCl_4(NO)_2]$, at 1538(vs) and 1318(m) for pyHCl, and at 1530(s) and 1322 cm^{-1}(m) for $(pyH)_2[ReCl_5(NO)]$. The bands at 393(m) and *ca.* 670 cm^{-1} (vs, b) can be assigned to the ring deformations due to the pyridinium ion, and the other deformation vibration band may overlap with the 610 cm^{-1} band assigned to the skeletal vibrations between the rhenium atom and the NO group.[8] On the basis of the ^{15}N-isotopic shift of the N–O stretching vibrations for *cis*-(pyH)$[ReCl_4(NO)_2]$, the oxidation state of the NO group is considered to be I, —that of the rhenium atom I. The IR spectra for pyHCl, $(pyH)_2[ReCl_5(NO)]$, and *cis*-(pyH)$[ReCl_4(NO)_2]$ are shown in Fig. 1. The bands at 342(s), 311(vs), 300(vs), and 298 cm^{-1}(vs) can be assigned to the Re–Cl stretching vibrations.

The NMR studies of pyHCl and *cis*-(pyH)$[ReCl_4(NO)_2]$ were carried out in $CDCl_3$ and DMSO-d_6, using tetramethylsilane as the internal standard. According to a study of pyHX(X=Cl, Br, and I) by Kotowycz *et al.*,[9] the triplet at δ 8.1—8.3, the triplet at δ 8.6—8.8, and the doublet at δ 8.9—9.1 for (pyH)$[ReCl_4(NO)_2]$ are considered to be due to the C–H protons in the *meta*-, *para*-, and *ortho*-positions respectively. The C–H proton shifts were not so much affected, but the N–H proton shift was sensitive to the counterions, the solvents used, and a trace of water, as is shown in Ref. 9. For pyHCl, the singlet at δ *ca.* 13 in DMSO-d_6 may be assigned to the N–H proton; this peak shifted to a higher magnetic field upon the addition of water to the solvent. The singlet at δ 7.8 for (pyH)$[ReCl_4(NO)_2]$ in DMSO-d_6 may be due to the N–H proton; it shifted to a higher magnetic field upon the addition of water, as was observed on the N–H proton for pyHCl. The integration of the spectra of (pyH)$[ReCl_4(NO)_2]$ and pyHCl in DMSO gives a ratio of the C–H protons to the N–H proton of 5 : 1. The NMR data also suggest the presence of the pyridinium ion in (pyH)$[ReCl_4(NO)_2]$.

The nitrosyl complexes of rhenium so far investigated are not so numerous,[10-12] and the oxidation states of rhenium atoms are 0, I, and II. *cis*-(pyH)$[ReCl_4(NO)_2]$ is the first compound containing an O–N–Re–N–O skeleton in which the oxidation state of the rhenium atom is I.

The authors are indebted to Prof. H. Tadano of Rikkyo University for the measurements of the ESR spectra, and to Mr. H. Saito of Rikkyo University and to Mr. M. Arita of the Japan Spectroscopic Co. Ltd. for the measurements of the Raman spectra. Thanks are also due to Prof. J. Y. Satoh, Dr. C. A. Horiuchi and Miss. K. Suzuki of Rikkyo University for their valuable suggestions and measurements of the NMR spectra.

The Gas-chromatographic Behavior of Perhaloalkanes

Ren IWATA, Yoshihiro MAKIDE, and Takeshi TOMINAGA*

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received July 1, 1974)

The retention indices of perhaloalkanes (perbromochlorofluoroalkanes, *etc.*) were measured by using a gas chromatograph with a squalane, Silicone DC 550, or Methoxy polyethylene glycol 350 column, and the correlation of the retention index with various physicochemical parameters was investigated. The retention index was found to correlate linearly with the composition of the halogen atoms in the perhaloalkane molecules; the correlation diagram appears to be of special analytical importance. The relationship between the retention index and the boiling point was also studied. The retention index was correlated linearly with the molar refractivity of the perhaloalkanes, irrespective of the polarity of the columns. The molar refractivity appears to be the inherent parameter which is most adequate for considering the regularity of the retention index. The effect of the polarity of the stationary phase on the retention index was also investigated.

In the course of our study of the recoil and radiolysis reactions in perchlorofluoroalkanes,[1-3] it became necessary to investigate systematically the gas-chromatographic behavior of perhaloalkanes (perbromochlorofluoroalkanes, *etc.*). If the correlation between the retention data and certain physicochemical parameters is established, it may facilitate the identification of unknown products gas-chromatographically without the need to refer to pure standard substances which are not readily available and without the aid of other, complementary means of analyses.

A number of works have been published on the gas-chromatographic behavior of homologous organic compounds. However, perhaloalkanes have received only a little attention,[4,5] and no systematic study of perbromochlorofluoroalkanes had been reported before our preliminary work.[6] The object of the present article is to determine the Kováts retention indices[7] for a number of perhaloalkanes and to study the correlation of those retention indices with various physicochemical parameters.

Experimental

Materials. CBr_3F, $CBrClFCClF_2$, $CBrClFCBrF_2$, and CBr_2FCBrF_2 were synthesized chemically in this laboratory. $CBrClF_2$, $CBrCl_2F$, $CBrF_2CF_3$, and $CBrF_2CClF_2$ were prepared by the γ-irradiation of mixtures of perchlorofluoroalkanes and bromine.[2] The other perhaloalkanes used in this work were obtained commercially from Matheson Gas Products, Inc., PCR, Inc., and the Tokyo Chemical Industry Co.

Determination of Retention Times and Retention Indices. The retention times were measured at a constant temperature between 0 and 100 °C by using a gas chromatograph equipped with a thermal conductivity detector. A water bath was used to keep the column temperature constant over the 0-60 °C range. A stainless steel column (I.D.: 3mm; length: 5m) was packed with squalane, Silicone DC 550, or Methoxy polyethylene glycol 350, 20%-coated on acid-washed Chromosorb W (80-100 mesh). The flow rate of the helium was 15 ml/min. The adjusted retention times obtained at 30 °C were first converted to specific retention volumes,[8] and then these in turn were converted to retention indices according to the following formula:

$$I_x = 100 \cdot \left[z + \frac{\log V_{g(x)} - \log V_{g(z)}}{\log V_{g(z+1)} - \log V_{g(z)}} \right]$$

where I_x denotes the retention index of a compound, x; $V_{g(x)}$, the specific retention volume of x, and $V_{g(z)}$ and $V_{g(z+1)}$, the specific retention volumes of two successive normal alkanes with carbon numbers of z and $z+1$ respectively, which were chosen so that $V_{g(z)} \leq V_{g(x)} < V_{g(z+1)}$.

Results and Discussion

The retention indices obtained for perhaloalkanes indicate an additivity with respect to the number of halogen atoms. Figures 1 and 2 reveal the correlation of the retention index, as measured by means of a Silicone DC 550 column, with the number of halogen atoms in perhalomethane and perhaloethane molecules respectively. The observed values for the γ-radiolysis products (closed circles in Figs. 1 and 2) are plotted nearly at the expected lattice positions of the correlation network. When a halogen atom is replaced by another halogen atom, the increase in the retention index due to the substitution was in the order: Br–for–Cl < Cl–for–F < Br–for–F. Furthermore, the magnitude of the change in the retention index for the same type of halogen substitution remains nearly identical, irrespective of the number of carbon atoms in the perhaloalkane molecules. This fact reveals that the regularity in the retention indices of C_1 and C_2 perhaloalkanes can be ascribed to the property inherent in each halogen atom rather than to that in a perhaloalkane molecule as a whole. We obtained diagrams similar to Figs. 1 and 2 for perhalomethanes and perhaloethanes on squalane and Methoxy polyethylene glycol 350 columns. The correlation was still good, irrespective of the polarity of the stationary phase, whereas the change in the retention index due to halogen substitution was enhanced by increasing the polarity.

While such a correlation appears to be very useful for analytical purposes, it cannot account for the essential nature of the observed regularity.[9] A linear correlation was obtained between the retention index and the boiling point, as is illustrated for perhaloalkanes on a squalane column in Fig. 3. The slope of the correlation curve (straight line) for perhaloethanes is larger than that for perhalomethanes. A similar relationship was obtained with a Silicone DC 550 column. Unlike on such a non-polar or slightly polar column, some plot-points deviate from the linear correlation

on a strongly polar Methoxy polyethylene glycol 350 column (Fig. 4), since the presence of bromine in the perhaloalkane molecules tends to increase their retention indices systematically (for example, the broken line in Fig. 4).

It is known that molar refractivity is an additive quantity and can be approximated by summing up the refractivities of the atoms composing the molecule.

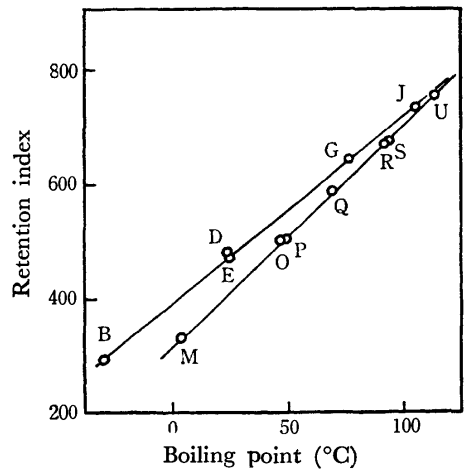

Fig. 3. Correlation between the retention index measured with a squalane column and the boiling point of perhaloalkanes.

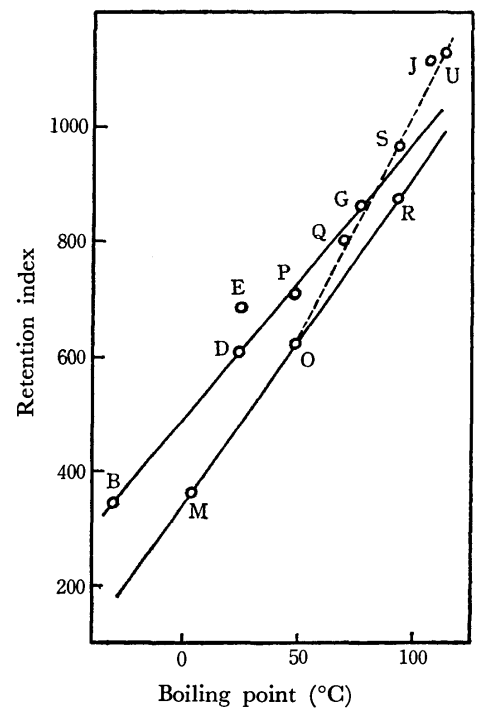

Fig. 4. Correlation between the retention index measured with a Methoxy polyethylene glycol 350 column and the boiling point of perhaloalkanes.

The molar refractivity can be linearly related to the electron polarizability taking part as dispersion and induction energies in the solvent-solute interactions. Hence, the molar refractivity can be taken as the parameter of the interaction between the solute (perhaloalkanes) and the solvent (stationary phase). The relationship between the molar refractivity[10] and the retention index of perhaloalkanes, as measured with a Silicone DC 550 column, is shown in Fig. 5. A linear correlation was observed with perhaloalkanes containing the same number of carbon atoms. Unlike the case of the correlation with the boiling point, the slopes of the correlation curves (straight lines) are nearly identical, irrespective of the number of carbon atoms.

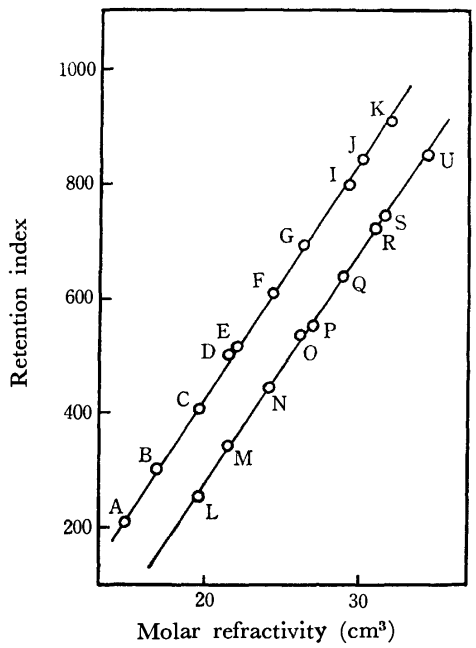

Fig. 5. Correlation between the retention index measured with a Silicone DC 550 column and the molar refractivity of perhaloalkanes.

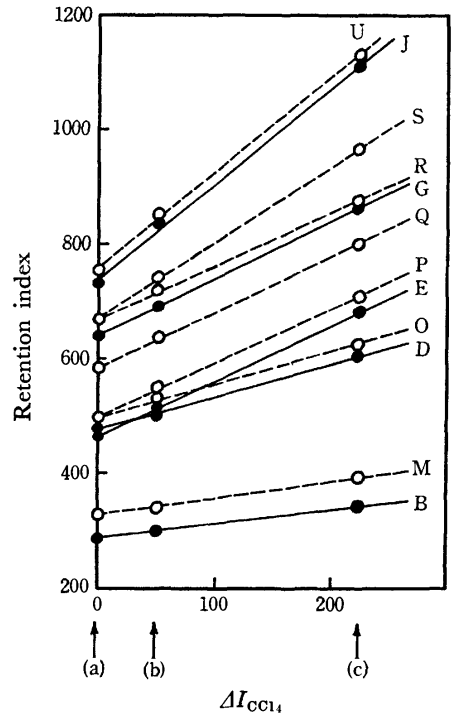

Fig. 6. The relationship of the retention index with the polarity of the stationary phase (in terms of ΔI_{CCl_4}). (a): squalane, (b): Silicone DC 550, (c): Methoxy polyethylene glycol 350.

Almost identical relationships were obtained with squalane and Methoxy polyethylene glycol 350 columns. These observations reveal that, for the perhaloalkanes studied in this work, the molar refractivity may be the inherent parameter, which is most suitable for considering the regularity of the retention index.

As in the case of Rohrschneider's characterization of the stationary phase,[11] we have investigated the influence of the polarity of the stationary phase on the retention indices of the perhaloalkanes. For convenience in comparing the polarity, the increase in the retention index of carbon tetrachloride obtained with an arbitrary polar stationary phase over that obtained with the non-polar stationary phase (squalane) is given as follows:

$$\Delta I_{CCl_4} = I_{CCl_4}(\text{polar}) - I_{CCl_4}(\text{non-polar})$$

Then, the value of ΔI_{CCl_4} obtained with an arbitrary stationary phase is presumed to be a measure for indicating the polarity of the stationary phase. In Fig. 6 are plotted the retention indices of perhaloalkanes against ΔI_{CCl_4}, or the polarity of the stationary phase. It is worth mentioning that the retention indices of all the perhaloalkanes studied in this work are correlated linearly with this measure. Since the retention indices for a new stationary phase can be predicted by measuring the retention index of CCl_4 with that stationary phase, the relationship illustrated in Fig. 6 appears to be very useful for the selection of a new stationary phase.

The present authors wish to express their thanks to Professor Nobufusa Saito, the University of Tokyo, for his encouragement and support.

Oxidation Activity and Acidity of V_2O_5–P_2O_5 Catalyst

Mamoru Ai and Sadao Suzuki

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received January 9, 1974)

The oxidations of 1-butene, butadiene, and hydrogen in a large excess of air were carried out over various V-P oxide catalysts with different P_2O_5 contents. The oxidation activities were compared with the dehydration activity for isopropyl alcohol, which was used as a measure of the acidity of the catalysts. The surface area and the acidity per unit of surface area sharply decrease with an increase in the P_2O_5 content up to about 20 mol% P_2O_5, while with a further increase in the P_2O_5 they remain almost unchanged. The activity per unit of surface area for the oxidation of butene and butadiene, as well as that for the isomerization of butene, changes in the same direction as the acidity per unit of surface area. The equilibrium constant for the adsorption of olefin changes analogously. The activity per unit of surface area for the oxidation of hydrogen is not affected by the P_2O_5 content. The effects of the P_2O_5 introduced into V_2O_5 on the activity and selectivity are discussed from the viewpoint of the acidic nature of the catalysts.

The oxidation of olefins to carboxylic acids, usually performed at very high conversions using small amounts of olefins in excess air, belongs to the category of the selective oxidations, different from the oxidation to epoxide and those to dienes and aldehydes. The basic requirements for the acid-formation reaction have not yet been satisfactorily defined, since only a few fundamental studies have been made of it, in contrast to the numerous studies of the two above-cited types of oxidations.[1,2] The catalysts used for the acid-formation reactions are generally mixed metal oxides based, in most cases, on V_2O_5, but sometimes on MoO_3, WO_3, SeO_2, As_2O_5, *etc.* It should be noted that all of those substances are typical acidic oxides.

In the oxidation of butadiene to maleic anhydride, most V_2O_5-based catalysts give a relatively high selectivity of 50—60 mol%, while when butene is used as the starting material, the high selectivity of 40—50 mol% is limited to the V_2O_5-based catalysts containing large amounts of P_2O_5. We found in earlier studies[3–5] that the inclusion of P_2O_5 in V_2O_5 increases the selectivity in the first step in the series of consecutive steps from butene to maleic anhydride···that is, in the step of allylic oxidation; $C_4H_8 \rightarrow C_4H_6$.

The present paper is an attempt to make an improvement in the study of the P_2O_5 effect by introducing the idea that the acidic nature of the catalyst governs to a considerable extent the activity and selectivity of the mild oxidations.[6–10]

Experimental

The vapor-phase oxidation of 1-butene, 1,3-butadiene, and hydrogen, the dehydration of *iso*-propyl alcohol (IPA), and the dehydrogenation of ethanol were carried out over a series of vanadium-phosphorus (V_2O_5–P_2O_5) catalysts, while varying the P_2O_5 content from 0 to 67 mol%, in an ordinary continuous-flow-type reaction system, The concentrations of butene, butadiene, hydrogen, IPA, and ethanol were, unless otherwise indicated, about 0.67, 0.67, 3.0, 1.65, and 2.2 mol% in air respectively. The total flow rate (at 25 °C) was kept constant at 1.5 l/min, and the amount of the catalyst used was 2—20 g. The reactor and the experimental and analytical procedures were the same as those employed in previous works.[3–10]

The catalysts used in these experiments were prepared as follows; the required quantities of NH_4VO_3 and H_3PO_4 were dissolved in hot water, together with oxalic acid, if necessary, after which 10—20 mesh pumice was mixed with the solution; then the mixture was evaporated with vigorous stirring. The amount of pumice was 500 ml (about 150 g)/g atom of vanadium and phosphorus. The catalyst was subsequently calcined, under flowing air, at 500 °C for about 4 hr.

Results

Surface Area. The surface area of the catalysts was measured by the BET method using nitrogen at −195 °C (Table 1). It falls markedly with an increase in the P_2O_5 content up to 20 mol% P_2O_5.

Acidity of the Catalyst. Since it is difficult to measure directly the acidity of the V_2O_5–P_2O_5 catalysts, we used the activity for the dehydration of IPA as a measure of the acidity, much as in previous works.[7,8]

A gaseous mixture of IPA and air was passed over 2—10 g of the catalyst at temperatures of 160—220 °C.

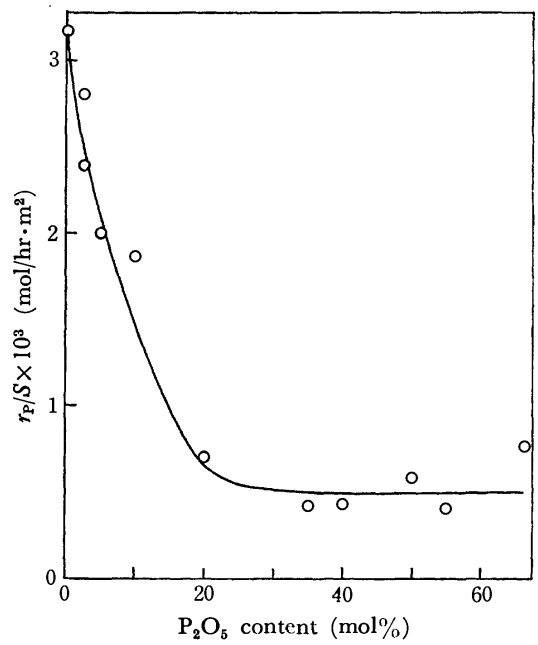

Fig. 1. Rate of IPA dehydration per unit surface area (r_P/S) as a function of the P_2O_5 content. Temp= 185°C, IPA=1.65mol% in air.

55/45	1.05	0.4					2.5	0.8
67/33	1.0	0.9			0.45		3.1	0.5

As has been reported in the previous papers,[7-10] propylene was the main product and the rate was almost independent of the IPA concentration at about 185 °C.

The initial rate of the dehydration at 185 °C, r_p (mol/hr·g-cat), was chosen as a measure of the acidity (Table 1). The activity per unit of surface area, r_p/S (mol/hr·m^2), is plotted as a function of the P_2O_5 content in Fig. 1. r_p/S falls sharply with the P_2O_5 content in the P_2O_5<20 mol% region and remains almost unchanged with a further increase in the P_2O_5.

Basicity of the Catalyst. As the basicity of the simple V_2O_5 catalyst is very small (the amount of the adsorption of acetic acid vapor at 150 °C, as measured by means of a chromatographic method,[11] was 1—2 μmol/g-cat, while that of CO_2 at 20 °C, as measured by a conventional static apparatus, was $1—2\times10^{-2}$ ml/g-cat (0.5—1 μmol/g-cat)), it seems hard to get reliable data on the basicity of the V_2O_5–P_2O_5 catalysts by these methods.

It has been reported[12-16] that the dehydrogenation of alcohol is related to the basic properties of the catalyst, although the reaction mechanism has not yet been established firmly. Since, on the V_2O_5–P_2O_5 catalysts, the activity for the dehydrogenation of IPA is very small compared with that for its dehydration, the reaction of ethanol was carried out in a manner similar to that of IPA. The initial rate of the dehydration of ethanol to acetaldehyde at 260 °C, r_a (mol/hr·g-cat), and the ratio of acetaldehyde/ethylene are listed in Table 1. These results suggest that the basic properties of the catalyst also decrease upon the addition of P_2O_5.

Isomerization of Butene. The oxidation of butene over V_2O_5-type catalysts is always accompanied by its isomerization, which is generally said to be attributable to acidic or basic sites of the catalyst. As a measure of the isomerization activity, we adopted for convenience the ratio of (*cis*-2-C_4H_8+*trans*-2-C_4H_8)/(1-C_4H_8+*cis*-2-C_4H_8+*trans*-2-C_4H_8); I under these conditions: temperature of 260 °C, 1-butene of 0.67 mol% in air, a catalyst of 5~20 g. The results are also listed in Table 1. Figure 2 shows the relation between the isomerization activity per unit of area (I/S) and the acidity per unit of area (r_p/S). The *cis*-2-C_4H_8/*trans*-2-C_4H_8 ratio is about 1.2 for every catalyst. These results indicate that the isomerization of olefin is catalyzed by acidic sites of the catalyst.[17]

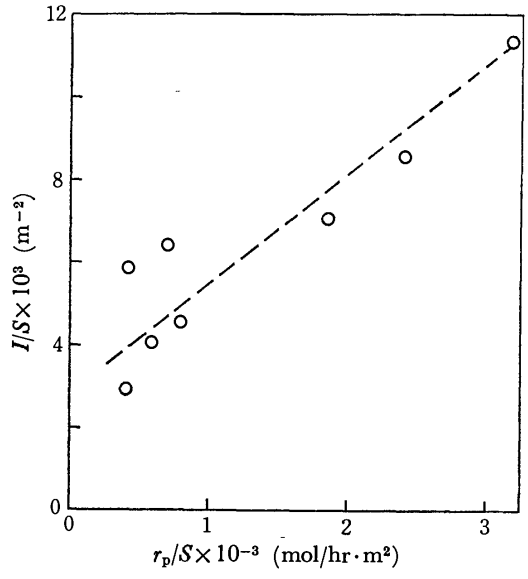

Fig. 2. Relation between I/S and r_p/S.
Isomerization; 260°C, 0.67mol% 1-C_4H_8 in air,
$$I=\frac{(cis\text{-}2\text{-}C_4H_8+trans\text{-}2\text{-}C_4H_8)}{(1\text{-}C_4H_8+cis\text{-}2\text{-}C_4H_8+trans\text{-}2\text{-}C_4H_8)}$$
The variation in these activities has been effected by changing the P_2O_5 content.

Oxidation Activity for Olefins. The effects of the P_2O_5 content on the activity for the oxidation of such olefins as 1-butene and butadiene were examined. The reaction was carried out at 330 °C. The initial rates of the overall consumption of butene and butadiene, r_B and r_B' (mol/hr·g-cat), were also obtained; they are listed in Table 1. The activities for butene and butadiene vary in a similar way and fall sharply with the P_2O_5 content when the P_2O_5 catalyst is less than 20 mol%.

Figure 3 shows the relation between the oxidation activities for olefins per unit of surface area, r_B/S and r_B'/S, and the acidity per unit of surface area. It is found that the oxidation activity for olefins increases with an increase in the acidity of the catalyst.

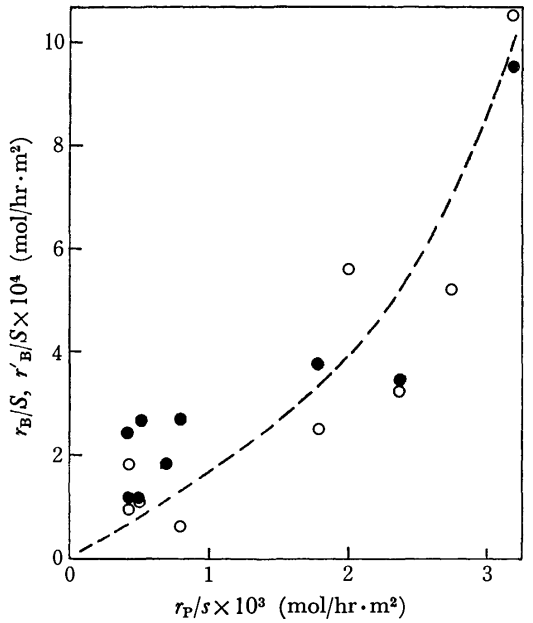

Fig. 3. Oxidation activities for olefins *versus* dehydrantio activity for IPA. The variation in these activities has been effected by changing the P_2O_5 content. ●=butene oxidation (r_B/S), ○=butadiene oxidation (r'_B/S), at 330°C.

Oxidation Activity for Hydrogen. It has been established that hydrogen and parafinic hydrocarbons act upon metal-oxide catalysts as electron donors to some extent. However, this tendency might be so weak that the oxidation activity for these compounds is really governed by the availability of surface oxygen rather than by the activation of the reactant.[18] This leads us to consider that the oxidation activity for hydrogen reflects the availability of oxygen in some measure at least.

Since hydrogen was quite stable compared with olefins and IPA over the V_2O_5–P_2O_5 catalysts, a high temperature of more than 400 °C was required to achieve appreciable conversion. The initial rates of hydrogen consumption at 435 °C, r_H (mol/hr·g-cat) and r_H/S (mol/hr·m²), are plotted as a function of the P_2O_5 content in Fig. 4. It is found that the activity decreases with the P_2O_5 content, but the activity per unit of surface area remains almost unchanged within the range of experimental error.

Adsorption of Olefin. Information on the affinity of olefin for the catalysts may be obtained if the oxidation rates conform to the following Langmuir-Hinshelwood type equation:

$$r = k\cdot N_a\cdot N_0\cdot\left(\frac{KP}{1+KP}\right)\cdot\left(\frac{K_0{}^nP_0{}^n}{1+K_0{}^nP_0{}^n}\right)$$

where r is initial rate of oxidation, k is the rate constant, N_a and N_o are the numbers of sites available for olefin and oxygen, K and K_0 are the equilibrium constants for the adsorption of olefin and oxygen, and P and P_0 are the partial pressures of olefins and oxygen respectively. When oxygen is in a large excess with respect to olefin and P_0 remains constant, $N_0\cdot K_0{}^n\cdot P_0{}^n/(1+K_0{}^nP_0{}^n)$ is a constant value for any one catalyst. Therefore, the above equation can be simplified as:

$$r = k'\cdot\frac{KP}{1+KP},$$

where $k'=k\cdot N_a$.(availability of surface oxygen).

To test this equation, another series of butadiene oxidations was carried out at 330 °C by changing the initial concentration from 0.24 to 1.9 mol% in air (partial pressure=0.24×10^{-2}—1.9×10^{-2} atm). The value of r was obtained at each P for every catalyst. Figure 5 shows a plot of P/r against P.

Good linear relations were obtained between P/r and P for every catalyst; this indicates the validity of the above equation. The values of k' and K were

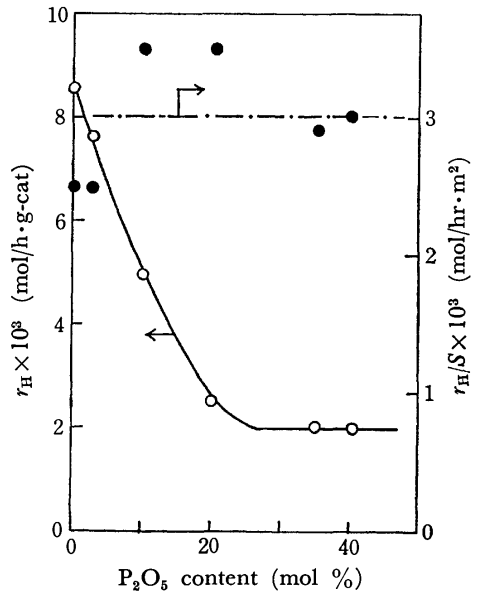

Fig. 4. Oxidation rate of hydrogen (r_H) and the specific rate r_H/S) as a function of the P_2O_5 content. Temp=430°C, hydrogen=3 mol% in air, ○=r_H, ●=r_H/S.

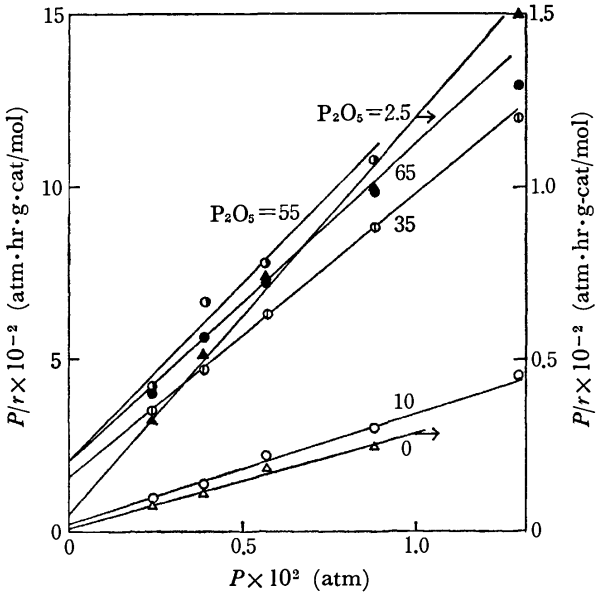

Fig. 5. Test of equation; $r=k'\cdot\frac{KP}{1+KP}$: a plot of P/r *versus* P.

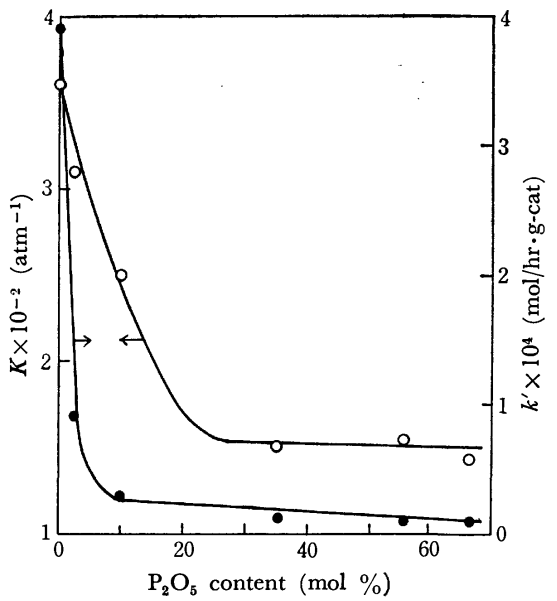

Fig. 6. The values of K and k' *versus* the P_2O_5 content. ○=K, ●=k'.

calculated from the slopes and from the intersections with the ordinate. They are plotted as a function of the P_2O_5 content in Fig. 6. K decreases with the P_2O_5 value up to about 20 mol% P_2O_5, much like the acidity, r_p/S (Fig. 6).

The temperature-dependency of k' and K was also examined (Table 2). The activation energies of the oxidation (E) were in the neighborhood of 20 kcal/mol, and the effect of the P_2O_5 content on the value of E was not clear. The values of K were almost independent of the temperature. It was also found that the amount of butadiene adsorbed on the simple V_2O_5 measured directly by a static apparatus was about 0.1 ml STP/g-cat, almost independent of the temperature in the region of 20—200 °C, and that no adsorption of butadiene was detected by a usual gas-chromatographic technique.[19] These results also suggest that the bond of olefin on the V_2O_5-type catalyst is so loose that the heat of the adsorption cannot be obtained.

Table 2. Values of k' and K

Catalyst P/V	Temp (°C)	$k'\times10^4$ (mol/hr·g)	E (kcal/mol)	$K\times10^{-2}$ (atm^{-1})
0/100	283	1.17	20	4.1
	294	1.63		3.9
	305	2.3		4.2

	305	0.43		2.3
50/50	317	0.18	25	1.2
	330	0.29		1.0

Discussion

The introduction of P_2O_5 to V_2O_5 causes a decrease in both (1) the surface area and (2) the acid-base properties. The action is remarkable only in the low P_2O_5 range. Probably, the active species of V_2O_5 are gradually modified into other kinds of species with the inclusion of P_2O_5 up to about 20 mol%, while a further increase in the P_2O_5 content causes no substantial change in the nature of the active species.

The decrease in the surface area may be, in part, associated with the fact that a sort of fusion appears at the beginning of the calcination, especially for the catalysts containing relatively high P_2O_5 values.

It should be noted that P_2O_5 is a unique additive which decreases the acidity as well as the basicity of the V_2O_5 catalyst (the additions of all the other oxides, such as Al_2O_3, WO_3, MoO_3, SO_3, and TiO_2, which increase the acidity of the V_2O_5 catalyst decrease the basicity).[20]

By taking into account the fact that the affinity of the catalyst for such basic compounds as olefins reflects the acid strength, the results shown in Fig. 6 suggest that the acid strength of the catalyst also decreases with an increase in the P_2O_5 content and changes in the same direction with the acidity, as has often been observed.[21]

The results shown in Fig. 4 suggest that the availability of surface oxygen (r_H/S) is almost uninfluenced by the P_2O_5 addition. However, this does not accord with the fact that the basicity of the catalyst, which is supposed to be related to the activation of an electron-acceptor-type reactant (oxygen),[20,22] decreases with the P_2O_5 addition. Even if the availability of oxygen decreases with the P_2O_5 addition, it may be considered, from the results of Fig. 3, that the activity for the oxidation of olefins on the acidic-metal oxides is predominantly dependent on the activation of olefins; this phenomenon may be attributed to the acidic sites of the catalyst, as has already been observed by us in the cases of MoO_3–Bi_2O_3–P_2O_5,[6] MoO_3–P_2O_5–X_nO_m,[9] MoO_3–P_2O_5,[10] and V_2O_5–MoO_3.[23] Recently a similar conception has been proposed by Haber *et al.*[24]

Concerning the selectivity to maleic anhydride,[5] the acidic property may be a requirement for satisfactory catalysts for such a type of partial oxidation as basic reactant→acidic product, because the acidic catalysts are active in relation to the basic reactant and inactive in relation to the acidic product. This conception holds well for the oxidation of butadiene.[6,8,20,22] However, in the case of butene oxidation. another factor must also affect the selectivity. When butene is oxidized over V_2O_5-based catalysts not containing P_2O_5, the C–C fission, probably at the double bond,[25] takes place in preference to the allylic C–H fission and the main products are oxygen-containing compounds with a lower number of carbon atoms, such as acetic acid, which are easily oxidized to CO_2 or CO, while in the case of butadiene, the C–C fission is not the main reaction.[20] It is, therefore, conceivable that the selectivity of butene to maleic anhydride is greatly controlled by the C–C fission of butene.[3-5]

The decrease in the activity for the C–C fission of butene due to the P_2O_5 addition is probably attributable either to the acidic or basic properties of the catalyst. The addition of such metal oxides as Al_2O_3, TiO_2, MoO_3, and WO_3 decreases the basicity of the V_2O_5 catalyst. However, it promotes the oxidation of butene to acetic acid.[20] Therefore, it should be considered

that the activity for the C–C fission is related to the acidic property—strictly speaking, the acid strength. That is to say, the catalyst must be acidic in order to get acidic products, but the acidic nature is necessary in an appropriate strength for the maximum selectivity from butene; too high a acid-strength destroys the C–C bond of butene and decreases the selectivity.

We would like to consider that the addition of P_2O_5 to V_2O_5-based catalysts plays a role in lowering the acid strength to a proper extent and, consequently, in suppressing the C–C fission of butene and increasing the selectivity in the step of allylic oxidation: $C_4H_8 \rightarrow C_4H_6$.

(Received January 30, 1974)

Relative stabilities of 1-bicyclo[2.2.2]octyl (**9**), 1-benzobicyclo[2.2.2]-octenyl (**10**), 1-dibenzobicyclo[2.2.2]octadienyl (**11**), and 1-tribenzobicyclo[2.2.2]octatrienyl(**12**) radicals were obtained by means of the relative rates of the free radical bromine abstraction from the corresponding bridgehead bromides by a silyl radical. It was found that **9** and **12** were more stable than expected. The observed order of stability **9**>**10**>**12**>**11** can not be explained by the usual concepts alone. The extra stabilization of **9** or **12** (or destabilization of **10** or **11**) was interpreted in terms of the local symmetry (or local asymmetry) of these radicals.

In the course of studies on factors influencing radical stability, much attention has been given to the stability of a strained radical in connection with the stable conformation of a free radical.[1] A preferred planar or nearly planar geometry of a simple, unrestricted alkyl radical has been generally accepted from vacuum ultraviolet[2] and electron spin resonance[3] spectroscopy, formation of a racemized product from from an optically active substrate[4] as well as theoretical calculations.[5] The direct kinetic investigation of the decomposition of a series of bridgehead peresters[6] (or azo derivatives[7]) having different bridgehead planarities such as adamantyl, bicyclo[2.2.2]octyl, and bicyclo[2.2.1]heptyl has shown that the decomposition rates were depressed with increasing bridgehead nonplanarity but not so dramatically as in solvolysis reactions. The instability of a strained bridgehead radical was further demonstrated by decarbonylation of a similar series of bridgehead aldehydes[8] and also by unsuccessful bridgehead hydrogen abstraction from strained bicyclo[2.2.1]heptane[9] or bicyclo[2.1.1]hexane[10] in contrast to the ready abstraction of the bridgehead hydrogen of less strained adamantane[11] or bicyclo[2.2.2]octane.[12] All the results seem to suggest that strain, particularly angle strain, is the determining factor of the bridgehead radical stability. It has also been reported[13] that the relative rates of hydrogen abstraction from a series of aliphatic polycyclic hydrocarbons by the trichloromethyl radical were correlated with a computer analysis of the change in strain energy in going from the ground state to the radical. In this connection, a curious observation was reported by Wiberg and coworkers, who were able to show the synthetic utility of the free radical bridgehead substitution on bicyclo[1.1.1]pentane *via* the 1-bicyclo[1.1.1]pentyl radical having the greatest deviation from planarity ever known.[14]

For these highly strained substrates for which no direct kinetic data are available, the bridgehead-to-bridge reactivity ratios in the free radical substitutions (halogenation, chlorocarbonylation, *etc.*) on the parent hydrocarbons (Table I) might be measure of the bridgehead radical stability. As illustrated in the relative reactivities of some polycyclic hydrocarbons toward autoxidation,[15] bridgehead reactivities are generally more sensitive to a structural change than bridge reactivities, presumably because of the ease with which the bridge radical (compared with the bridgehead) takes planarity or near planarity. The variation in the ratios of the bridgehead-to-bridge reactivity (Table 1) is not fully understood from the consideration of the bridgehead angle strain alone but can be interpreted by taking the geometrical symmetry of the bridgehead also into consideration. Of the compounds (Table I) only those which yield symmetrical radicals such as adamantane, bicyclo[2.2.2]octane and bicyclo[1.1.1]-pentane or those which yield radicals of similar symmetry only with respect to the vicinal carbons (this might be called "local symmetry") such as bicyclo-[3.3.0]octane, have appreciable bridgehead reactivities. This might be called local symmetry effect. An experimental evidence of this hypothesis of a local symmetry effect is presented in this paper.

TABLE 1. BRIDGEHEAD-TO-BRIDGE REACTIVITY RATIOS OF SOME POLYCYCLIC HYDROCARBONS IN FREE RADICAL SUBSTITUTIONS[a]

Substrate	Mode of substitution	Reactivity ratio	Ref.
Adamantane	chlorination, bromination	3—5	11a
	clorocarbonylation	3.7	b
Bicyclo[2.2.2]octane	chlorination	6.9	12
Bicyclo[3.3.0]octane	chlorocarbonylation	2.9	c
Bicyclo[2.2.1]heptane	chlorination	0	9
	chlorocarbonylation	0	c
Nortricyclane	chlorination	0	d
Bicyclo[2.1.1]hexane	chlorination	0	10
Tricyclo[3.3.0.$0^{2,6}$]-octane	chlorination	0	e
Bicyclo[3.1.0]hexane	chlorination	0	f
Bicyclo[1.1.1]pentane	chlorination	7	14b
	chlorocarbonylation	17	14b

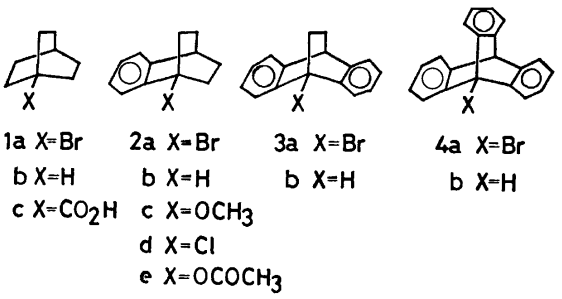
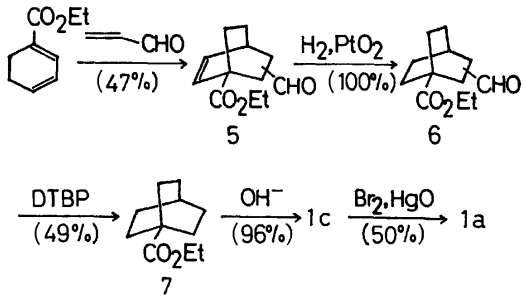
Results

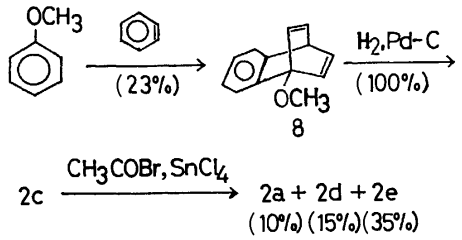
A series of bridgehead bromides (**1a**, **2a**, **3a**, or **4a**) containing the bicyclo[2.2.2]octane framework was prepared. **1a** was prepared (Scheme 1) by the Hunsdiecker reaction of the corresponding acid (**1c**)[16] obtained by a slight modification of the procedure of Doering *et al.*[17]





Scheme 1.

The procedure of Suzuki and Morita for converting 1-methoxybicyclo[2.2.2]octanes into 1-halobicyclo[2.2.2]octanes[18] was applied to the synthesis of **2a**. Thus, the 1,4-adduct of benzyne to anisole was, after hydrogenation, converted into **2a** on treatment with acetyl bromide-stannic chloride or stannic bromide (Scheme 2).



Scheme 2.

The 1,4-addition of 9-bromoanthracene with ethylene[19] or benzyne[20] gave **3a** or **4a**, respectively, in moderate yields.

The reductive debromination of a bromide (**1a**, **2a**, **3a**, or **4a**) with methyldichlorosilane in cyclohexane was carried out in a degassed, sealed tube in the presence of a catalytic amount of di-*tert*-butyl peroxide (DTBP) at 120 °C. The reaction proceeded at an appreciable rate even in the case of **4a**. The only detectable product, besides those from silanes, was the corresponding hydrocarbon (**1b**,[17] **2b**,[21] **3b**,[21] or **4b**[20]).

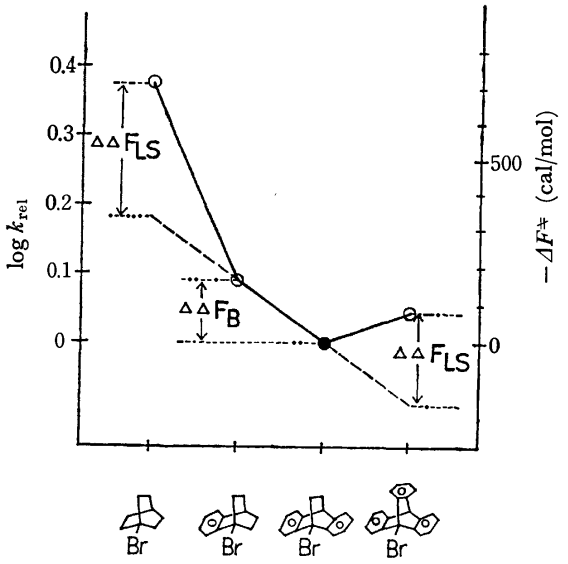


Fig. 1. Logarithmic relative rates of the bromine abstraction from **1a**, **2a**, **3a**, and **4a** by methyldichlorosilyl radical.

That the yield of the reaction was always nearly quantitative indicates that no appreciable side reaction took place.

In order to obtain the relative reactivity of a bromide, a competitive reaction was carried out, in which a bromide (**1a**, **2a**, or **4a**) competed with **3a** (standard) for the attack of the silyl radical. Relative reactivities thus obtained were **1a** (2.36±0.06), **2a** (1.24±0.04), **3a**(1, standard), and **4a** (1.11±0.04). The logarithms of the relative rates (or the relative free energies of activation) are shown in Fig. 1.

Discussion

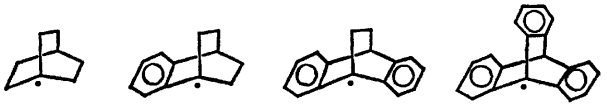
Ready Formation of Strained Radicals. As already given in many examples,[22] the present reductive debromination can be understood in terms of a radical chain mechanism involving the bromine abstraction from **1a**, **2a**, **3a**, or **4a** by the methyldichlorosilyl radical followed by the hydrogen transfer to the bridgehead radical thus formed (**9**, **10**, **11**, or **12**) from the parent hydrosilane. It is remarkable that the strained radicals **10**, **11**, or **12** can be generated with a rate not much differing from that of **9**, although the triptycyl radical

$$(tert\text{-}C_4H_9O)_2 \rightarrow tert\text{-}C_4H_9O\cdot$$

$$tert\text{-}C_4H_9O\cdot + HSiCl_2CH_3 \rightarrow tert\text{-}C_4H_9OH + \cdot SiCl_2CH_3$$

$$\cdot SiCl_2CH_3 + RBr \rightarrow BrSiCl_2CH_3 + R\cdot$$

$$R\cdot + HSiCl_2CH_3 \rightarrow RH + \cdot SiCl_2CH_3$$



9 **10** **11** **12**

(**12**) is believed to be very unstable in spite of its apparent structural similarity to the stable trityl radical.[23] An attempt to obtain **12** *via* bridgehead hydrogen abstraction of triptycene was unsuccessful.[23a] The instability of **12** was further demonstrated by the observa-

tion that **12** generated by thermolysis of triptoyl peroxide readily abstracted hydrogen even from benzene.[23b] The results show the potentiality of the silyl radical method in ready formation of a strained bridgehead radical which is, otherwise, less accessible. A report was given of a similar ready formation of the strained 1-norbornyl radical from 1-bromonorbornane *via* the bromine abstraction by an organotin radical.[24] A significant exothermicity of the bromine abstraction by a silyl radical[25] might be the principal cause of the reduction in the activation energy, which, in turn, necessarily gives a small structural effect on the rate of abstraction. The electroneutral or weakly nucleophilic character of a silyl radical[26] should also be taken into account. The bridgehead carbon is thus almost electroneutral in the transition state of the bromine abstraction. Destabilization might diminish, which originates from steric (strain) or inductive effect on a carbonium ion-like transition state encountered in a usual hydrogen abstraction[27] or a perester decomposition.[28]

Relative Reactivities. It is noteworthy that the change in the reactivities is not monotonic in going from **1a** to **4a** (Fig. 1). The differences are small but they exceed experimental errors as judged from the reproducibility of the relative rates and accuracy of the glpc analysis. Although the stepwise introduction of a benzo substituent into bicyclo[2.2.2]octane framework lowers the reactivity at first, **4a** has equal or even higher reactivity than **3a**. A benzo substituent would be expected to reduce the bridgehead reactivity because of possible increase in steric crowding around the bridgehead and in the bridgehead strain. On the contrary, an electronegative inductive effect of a benzo substituent might accelerate the reaction by dispersing a possible negative charge developing in the transition state due to the nucleophilic character of a silyl radical,[26] although its nucleophilicity is extremely small. Effects of successive benzo substitution (steric, strain, or inductive) should be additive, and the overall benzo effects cumulative. If no particular effect is caused by a benzo substituent, the reactivity should monotonously decrease or increase in going from **1a** to **4a**. but this is not the case (Fig. 1). Decreasing rates with increasing benzo substituents show that strain and/or steric decelerating effect surpass the inductive accelerating effect. If the reactivity difference between **2a** and **3a**, 170 cal mol^{-1}, is taken to be inherent decelerating benzo effects ($\Delta\Delta F_B$), the present abnormal benzo effects are characterized by the unexpectedly high reactivities of symmetrical **1a** and **4a**. Asymmetrical **2a** or **3a** suffers from abnormal destabilizing effect due to its lack of local symmetry. It should be concluded that an extra stabilization contributes to radicals **9** and **12** (or destabilization to **10** and **11**), which might be correlated with the geometrical symmetry of **9** and **12**. The gap between observed and predicted (from additivity of $\Delta\Delta F_B$, dashed line in Fig. 1) reactivities of **1a** and **4a** ($\Delta\Delta F_{LS}$), *ca.* 300 cal mol^{-1}, is thus ascribed to the local symmetry effect. Introduction of a benzo substituent into symmetrical bicyclo[2.2.2]octane is an appreciable perturbation to the geometry (one bond is shortened and three C–C–C angles at the bridgehead position become nonequivalent) and the local symmetry effect might disappear (or the local asymmetry destabilization appears). Removal of methylene from bicyclo[2.2.2]octane to give bicyclo[2.2.1]heptane would cause a much greater disturbance. The very low reactivity of the bicyclo[2.2.1]heptane bridgehead[9] might, in part, be attributed to the very asymmetrical nature of the 1-bicyclo[2.2.1]heptyl radical; the main reason is the increase in angle strain of this radical.[13] On the other hand, it is highly plausible that the local symmetry makes the bicyclo[1.1.1]pentyl[14] or cubyl[29] radical "stable" for its appreciable angle strain.

Although the theoretical interpretation of a local symmetry effect has not been accomplished* the origin of the effect would be related to the mode of the rehybridization of a radical in such a way that the hybridization energy is sensitive to local symmetry. The present effect should be considered in light of the nonplanarity of some strained secondary (*e.g.* cyclopropyl[30]) radicals with an electronegative α substituent (*e.g.* fluorine[31]). The contributing factors to the geometry of a radical might be: (1) hybridization energies, (2) repulsions of the bonding electrons, and (3) nonbonded interactions between the groups at the ends of the bonds. A planar geometry would be preferable from the viewpoint of minimization of repulsions between bonding electrons and between groups. Since the radical is in the middle of the sp^2 hybridized planar carbonium ion and the sp^3 hybridized tetrahedral carbanion, the hybridization energy of the radical would be less sensitive to planarity[32] than the carbonium ion or carbanion. The energy difference between planar and pyramidal structures should be reduced as is usually the case.[6–8] Factors other than planarity such as symmetry might contribute significantly to the hybridization energy of the radical of a given structure. At the sacrifice of some unfavorable increase in repulsions between bonds the cyclopropyl radical may prefer a nonplanar geometry because of a compensating stabilizing hybridization in a pyramidal or more symmetrical structure with respect to the three angles around the radical center. The enhanced configurational stability of α-fluorocyclopropyl radical[31] may be interpreted on similar grounds. The electron withdrawal by a fluorine substituent reduces the importance of repulsion between bonding electrons, making the hybridization energy the determining factor of the structure. A refined molecular orbital calculation may support the present arguments. It has been shown that the hypothetically strained methyl radical took

* The C_1—C_4 rear-lobe interaction is not important in the present system. The unimportance of the rear-lobe effect has been suggested by the ESR spectrum of the 1-bicyclo[2.2.2]octyl radical see, P. J. Krusic, T. A. Rettig, and P. von R. Schleyer, *J. Amer. Chem. Soc.*, **94**, 995 (1972). An Extended Hückel calculation has also shown that the C_1—C_4 atomic bond population in the 1-bicyclo[2.2.2]octyl cation was negative, showing antibonding, see T. Yonezawa, K. Shimizu, H. Morimoto, and H. Kato, *Nippon Kagaku Zasshi*, **90**, 142 (1969).

a pyramidal structure.[33]

It is anticipated that both the nonplanarity of a strained (nonbridgehead) radical and the local symmetry stabilizing effect on a strained bridgehead radical have the same principle.

Experimental

Materials and Analysis. Melting points were uncorrected. IR spectra were obtained with a Hitachi 215 spectrophotometer. NMR spectra were taken in $CDCl_3$ with TMS as a standard and were recorded with a Varian T-60 spectrometer. Mass spectra were obtained with a Hitachi mass spectrometer. Glpc analyses were performed with a Yanagimoto 550T gas chromatograph using a poly(ethylene glycol) or silicone DC 550 column. Cyclohexane was shaken with concentrated sulfuric acid and distilled over sodium after repeated washing with water. Methyldichlorosilane was distilled prior to use. DTBP was used as received.

*1-Bromobicyclo[2.2.2]octane (**1a**).* A mixture of 30 g of 1-carbethoxy-1,3-cyclohexadiene[34] and 80 g of acrolein was heated at 150 °C under reflux for 90 hr. Distillation at 100—110 °C/1.5 mmHg afforded 19 g (47%) of the Diels-Alder adduct **5**, which was hydrogenated in an equal volume of acetic acid at atmospheric pressure in the presence of platinum oxide. After removal of the catalyst and most of the solvent, 15 g of DTBP was added (in three portions) and the mixture was heated at 130 °C for 20 hr under dry, oxygen free nitrogen. Distillation at 98—100 °C/10 mmHg (lit. 96—98 °C/12 mmHg,[34] 75—76 °C/3 mmHg[35]) afforded 8.1 g 49%) of the decarbonylated ester **7**, which was hydrolyzed[34] to give **1c** in a 96% yield. **1a** was prepared in *ca.* 50% yield by the Hunsdiecker reaction of **1c**[16]; mp 61—62 °C (lit. 58.8—59.5 °C,[16] 66—68 °C[34]); IR(KBr): 1453, 968, and 815 cm^{-1}; NMR: τ 7.53—8.00 (6H, m, methylene vicinal to Br) and 8.00—8.35 (7H, m, other methylene and bridgehead); Mass: *m/e* 190 and 188 (M^+, relative intensity 5.6), 109 (100), and 81 (40).

*1-Bromobenzobicyclo[2.2.2]octene (**2a**).* A mixture of benzenediazonium-2-carboxylate (from 10 g of anthranilic acid and 20 ml of iso-amyl nitrite[36]) and 200 ml of sodium dry anisole was heated at 70 °C for 15 hr. The anisole was expelled and the residue was distilled. A fraction boiling at 104—105 °C/6 mmHg was collected (4.3 g), and was found to be a mixture[37] of the 1,4-adduct **8** and benzobicyclo[2.2.2]-octadien-2-one[38] (approximately 6 : 1[37]). The mixture was hydrogenated in methanol under atmospheric pressure in the presence of palladium charcoal. The catalyst was removed by filtration and a calculated amount of tosylhydrazine was added. The mixture was refluxed for 15 hr to convert the undesired ketone into hydrazone and then passed through a silica gel column. After removal of methanol, the residue was distilled at 107 °C/2.7 mmHg to give 2.9 g of **8**; IR (neat): 1330, 1163, 1123, 1102, 1070, 1060, and 746 cm^{-1}; NMR: τ 2.30—2.95 (4H, m, aromatic), 6.45 (3H, s, methyl), 7.05 (1H, broad s, bridgehead), and 7.80—8.75 (6H, m with peaks at 7.97, 8.13, 8.42, and 8.57, methylene). To an ice-cooled mixture of 500 mg (2.6 mmol) of **8** and 640 mg (5.2 mmol) of acetyl bromide was added ten drops of anhydrous stannic chloride. The mixture was stirred at room temperature for 3 hr and at 80 °C for 15 hr, poured on ice and extracted with methylene chloride. The methylene chloride was distilled off and the residue was chromatographed on a silica gel column. Elution with petroleum ether gave 140 mg (25%) of a mixture of the bromide **2a** and the chloride **2d** (1 : 1.5). Further elution with petroleum ether–methylene chloride (1 : 1) afforded 220 mg (37%) of the acetate **2e**. Pure **2a** was obtained by means of a preparative glpc after the column chromatographic separation of **2e**. When stannic bromide was used instead of stannic chloride, **2a** and **2e** were obtained in a 1 : 3 ratio but in much lower total yield.

2a had mp 83.5—84.5 °C; IR(KBr): 962, 898, 860, 747 cm^{-1}; NMR: τ 2.17—2.47 (1H, m, aromatic (peri)), 2.53—2.97 (3H, m, other aromatic), 6.95 (1H, broad s, bridgehead), and 7.20—8.83 (8H, m with major peaks at 8.02 and 8.22, methylene); Mass: *m/e* 238 and 236 (M^+, 6.0), 210 and 208 (40), 157 (46.7), and 129 (100).

2d had IR(neat): 1035, 970, 913, 872, 755, 737, and 697 cm^{-1}; NMR: τ 2.20—2.60 (1H, m, aromatic (peri)), 2.60—3.00 (3H, m, other aromatic), 7.00 (1H, broad s, bridgehead), and 7.40—8.80 (8H, m, methylene); Mass: m/e 194 (M^+, 26), 192 (M^+, 73), 166 (32), 165 (49), 164 (64), 163 (67), 129 (100), 128 (76), and 127 (53).

2e had IR(neat): 1740, 1248, 1092, 1040, and 750 cm^{-1}; NMR: τ 2.55—3.00 (4H, m, aromatic), 7.02(1H, broad s, bridgehead), 7.78 (3H, s, methyl), and 7.30—8.65 (8H, m with peaks at 7.45, 7.90, 8.06 and 8.28); Mass: m/e 216 (18), 174 (100), 146 (84), and 145 (76).

*1-Bromodibenzobicyclo[2.2.2.]octadiene (**3a**).* To a solution of 5 g of 9-bromoanthracene and 50 mg of 2,5-di-*tert*-butylhydroquinone in 150 ml of chlorobenzene in an autoclave was introduced ethylene to a pressure of 60 atm. The mixture was heated at 150 °C for 40 hr under stirring (maximal pressure was 110 atm). After distillation of most of the chlorobenzene the residue was chromatographed on a silica gel column. **3a** was obtained by elution with petroleum ether. Recrystallization three times from petroleum ether gave *ca.* 2 g of pure **3a** in white powder; mp 137.5—138 °C; IR(KBr): 1457, 1300, 1160, 1140, 1030, 915, 823, 755, and 738 cm^{-1}; NMR: τ 2.10—2.50 (2H, m, aromatic (peri)), 2.57—3.05 (6H, m, other aromatic), 5.67 (1H, broad s, bridgehead), 7.55—7.95 (2H, m, methylene vicinal to Br), and 7.95—8.35 (2H, m, other methylene); Mass: *m/e* 286 and 284 (M^+, 6.1), 258 and 256 (100), 205 (3.8), 204 (7.0), 203 (10), 202 (12), 177 (25), and 176 (32).

*1-Bromotribenzobicyclo[2.2.2]octatriene (1-Bromotriptycene **4a**).* A mixture of 3 g of 9-bromoanthracene and benzenediazonium-2-carboxylate (from 8.2 g of anthranilic acid and 16 ml of iso-amyl nitrite) in 240 ml of ethylene chloride was heated at 70 °C for 15 hr. Evaporation of the solvent gave a tarry material, which was chromatographed on a silica gel column. Crude **4a** eluted with benzene was repeatedly washed with petroleum ether to remove unchanged 9-bromoanthracene. Pure **4a** (1 g) was obtained as white powder by recrystallization from benzene; mp 253—254.7 °C (lit,[39] 246—248 °C); IR(KBr): 1450, 1290, 1155, 1033, 925, 850, 840, 820, and 738 cm^{-1}; NMR: τ 2.10—2.35 (3H, m, aromatic (peri)), 2.45—3.15 (9H, m, other aromatic), and 4.53 (1H, s, bridgehead); Mass: *m/e* 334 and 332 (M^+, 37) and 253 (100).

Reductive Debromination. A solution of *ca.* 30 mg of a bromide (**1a**, **2a**, **3a**, or **4a**), *ca.* 300 mg of methyldichlorosilane and a catalytic amount of DTBP in 3 ml of cyclohexane was degassed and sealed. The mixture was heated at 120 °C for 1—3 hr. The crude reaction mixture was then analyzed by glpc. Identification of the product (**1b**, **2b**, **3b**, or **4b**) was made on the basis of the glpc retention time and IR spectrum. Authentic **1b** was obtained by the procedure of Doering *et al.*[17] All the other authentic hydrocarbons (**2b**, **3b**, and **4b**) were prepared by the addition of benzyne to benzene,[21] naphthalene,[21] and anthracene,[20] respectively, followed by hydrogenation when necessary (in the case of **2b** and **3b**). Controlled experiment showed that the reaction did not

Derivatives of 1,2-Dithiole-3-thiones. VII.[1] Study of Reaction of Thiocarbonyl *S*-Imide with Amines

Seizo TAMAGAKI, Keishi SAKAKI, and Shigeru OAE*

(Received February 12, 1974)

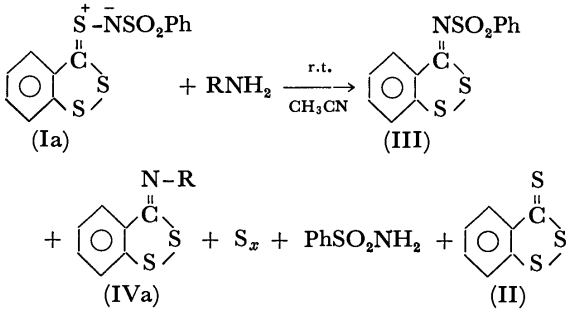
Thiocarbonyl *S*-imide of 4,5-benzo-1,2-dithiole-3-thione reacted with primary and secondary amines of various types to give both rearranged and amine-exchanged imines. By kinetical studies a plausible mechanism involving the addition and elimination of amine on the tetravalent sulfur atom was proposed.

Thiocarbonyl *S*-imides (>C=S̈–N̄–) are isoelectronic nitrogen-analogs of sulfines (>C=S̈–Ō) or thiocarbonyl ylides (>C=S̈–C̄<). Thiocarbonyl *S*-imides are thus expected to resemble sulfines or ylides in both chemical and physical properties. However, we have recently initiated the preparation of a stable thiocarbonyl *S*-imide of 1,2-dithiole-3-thione,[2] the characteristics of its chemistry not having been fully explored.

We wish to report detailed mechanistic aspects of the reaction of the thiocarbonyl *S*-imide (I) with various amines, in which a nucleophilic attack of amines on the sulfur atom at the initial step of the reaction is involved. As in the nucleophilic substitution on the divalent sulfur of sulfenyl chloride, the trivalent sulfur of sulfonium, or the tetravalent sulfur of sulfoxide or sulfilimine, the nucleophilic attack on the tetravalent sulfur atom of thiocarbonyl *S*-imide appears to proceed *via* a somewhat similar path.

Results

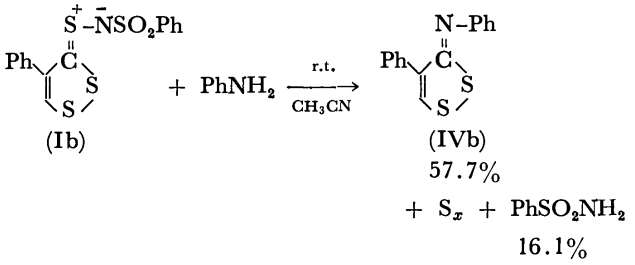
The reaction of the thiocarbonyl *S*-imide of 4,5-benzo-1,2-dithiole-3-thione (II) with an equimolar amount of a primary aryl or alkyl amine at room temperature in acetonitrile afforded the corresponding rearranged product, (*N*-benzenesulfonyl-4,5-benzo-1,2-dithiole-3-imine (IIIa)), the amine-exchanged product (*N*-aryl- or alkyl-4,5-benzo-1,2-dithiole-3-imine (IVa)), the benzenesulfonamide, elemental sulfur, as well as a small amount of the trithione:



Similarly, treatment of the *S*-imide (Ib) of 4-phenyl-1,2-dithiole-3-thione with aniline gave *N*,4-diphenyl-1,2-dithiole-3-imine (mp 166—167 °C) in a moderate yield.

Results for the reactions of the thiocarbonyl *S*-imide (I) with various amines, including secondary and tertiary amines, are summarized in Table 1.

In order to find the rate-determining step of the



reaction, a kinetic study was undertaken by observing the disappearance of the characteristic UV absorption band due to the thiocarbonyl *S*-imide at nearly 500 nm in acetonitrile, using about 15 mol excess amine, so as to keep the pseudo-first-order condition. The first-order dependence of the rate on the imide concentration was clearly observed. A typical run is given in Table 2.

The first-order dependence of k_{obsd} on the amine concentration is also shown in Fig. 1. The fact that the rate was found exactly proportional to the initial concentration of the amine indicates that at the rate-determining step of the reaction the attack of amine occurs on the sulfur atom without any concomitant base- or acid-catalyzed proton donation and/or removal. Namely, like the addition of primary amines to simple carbonyl compounds[3] the reaction is not the base-catalyzed nucleophilic substitution reaction. The sec-

ond-order rate constants (k_2) can be easily obtained from the values of k_{obsd}, by dividing them by the concentration of amine. The resulting data are summarized in Tables 3 and 4. The second-order rate constants for the reaction of a few para-substituted thiocarbonyl *N*-benzenesulfonyl imides with *p*-substituted anilines are given in Table 3.

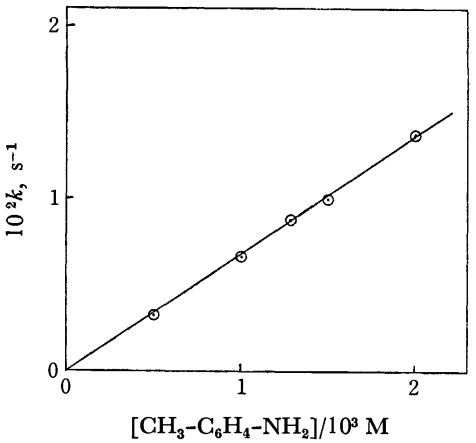

Fig. 1. Dependence of reaction rate on amine concentration in CH_3CN at 24.8°.

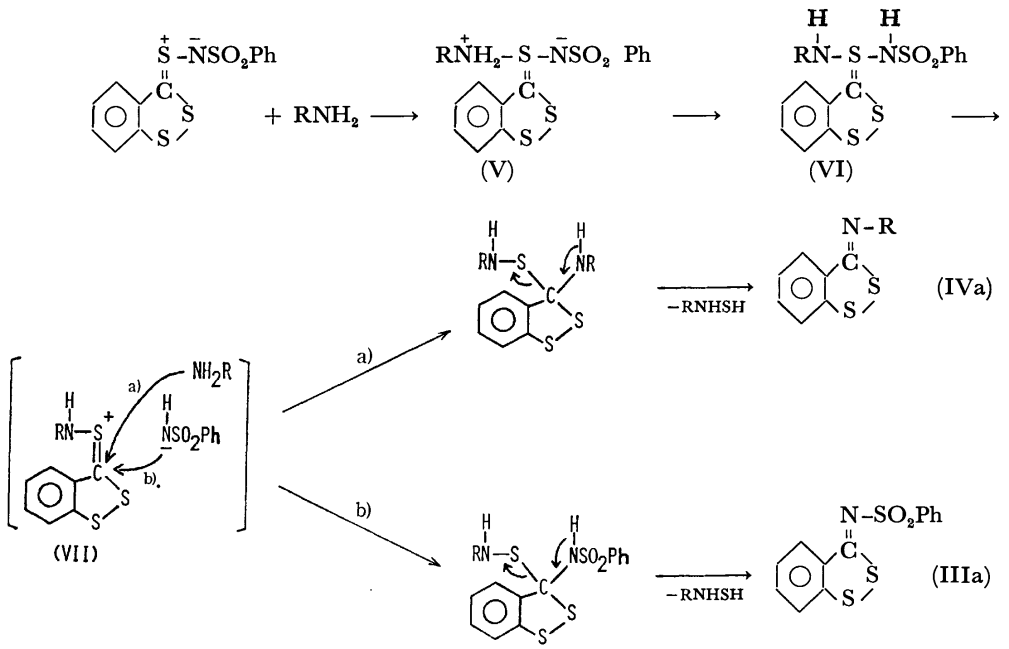
Discussion

The products as well as their relative yields thus obtained (Table 1) indicate that the initial attack of amine on the tetravalent sulfur atom of thiocarbonyl *S*-imide moiety yields both the rearranged (III) and the amine-exchanged (IV) products as outlined in Scheme 1.

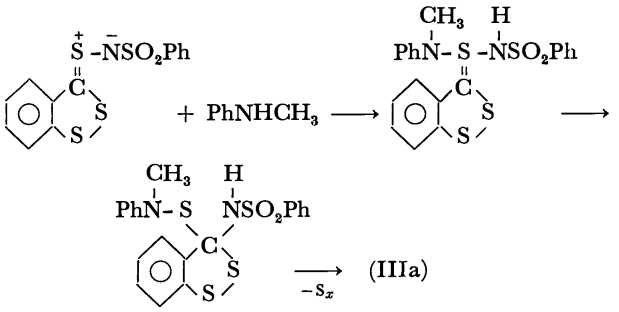
The initially formed dipolar intermediate (V) could break down through the symmetrical intermediate (VI) eventually to the ion pair (VII). Subsequently there are two competitive reactions: a) attack of a foreign amine molecule on the carbon-3, giving the amine-exchanged imine (IVa) upon elimination of RNHSH, and b) the intramolecular nucleophilic addition of the sulfonamide anion to the carbon-3, eventually leading



Scheme 1.

to the *N*-benzenesulfonyl imine (IIIa).

The above pathway does not contradict with the following finding that treatment of *N*-monomethylaniline with Ia afforded exclusively IIIa alone, since the second proton-transfer, which is required in the overall reaction sequence to form IVa, would be prohibited for any amine having only one proton on nitrogen atom.



Scheme 2.

As shown in Scheme 2, tertiary amines bearing no protic hydrogen attached to a nitrogen atom cannot be expected to react at all under similar conditions. In fact, a carefully purified tertiary amine, DABCO ($pK_a=8.7$), did not yield the rearranged product (IIIa). Anomalous results (Table 1) where treatment of Ia with 20 mol excess tertiary amines such as *N,N*-dimethylaniline and triethylamine gave the rearranged imine (IIIa) in yields similar to cases for secondary amines can be attributed to the contamination of a considerable amount of the corresponding secondary amines.

As one can see from Table 3 a straight line was obtained by plotting log k_2 values against the Hammett sigma values. The rho values of $\rho_x=+0.13$ and $\rho_y=-3.5$ were obtained for the respective reactions. Evidently, the reaction involves a nucleophilic attack of aniline molecule. The remarkably large and negative ρ_y value due to *p*-substituents on the nucleophile as well as the small ρ_x value due to *p*-substituents on the leaving group seem to suggest that this substitution is not a true S_N2 process. A more plausible mechanism would be one including the intervention of an unsymmetrical addition complex in which both the entering and the leaving groups are bound to the central sulfur atom of the intermediate of either trigonal bipyramid or square pyramid with or without involvement of 3d-orbitals.[4] Such a hypervalent intermediate involving the central sulfur atom has been reported in other substitution reactions[5] and in some cases isolated.[6] For example, the formation of a metastable addition intermediate at divalent sulfur was postulated in the reaction between triphenylmethylsulfenyl chloride and *n*-butylamine.[7] Evidence for the existence of the tetracoordinated sulfur complex as an intermediate has been reported by Givens and Kwart for chlorination of sulfenyl chloride[8] and by Trost *et al.* for the reaction of the sulfonium salts with organometallic compounds.[9]

In our case, the marked solvent effect on the rate, *i.e.*, the faster rate in polar CH_3CN than in nonpolar THF by a factor of 3.6, and the large negative activation entropy (Table 4) indicate the existence of a rigid,

Table 4. Temperature effect on reaction rate in CH_3CN

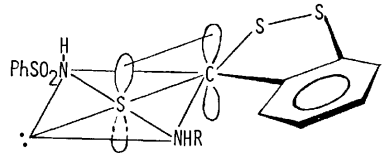
33.75	8.20
29.25	7.47
26.70	7.20
20.40	6.10

a) X=H, Y=CH_3; $E_a=4.0$ kcal/mol, $\Delta S^{\neq}=-59.0$ e.u.

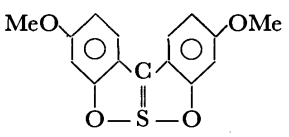
polar, and solvation-susceptible intermediate. Moreover, the activation energy of 4.0 kcal/mol implies that no bond cleavage takes place at the transition state. Thus, the intervention of a stable unsymmetrical intermediate (V) is more likely. The markedly small activation energy would eliminate the direct carbon attack where the activation barrier would be very large since the aromaticity ought to be destroyed. An insignificant increase in the rate of only less than two fold even by adding ten equimolar amounts of protic acid to aniline indicates also that the sulfonamide anion does not leave the reaction center at the transition state. If an S_N2 mechanism were in operation, a prior protonation should be required and the addition of acetic acid would result in a marked acceleration of the rate However, this was not found to be the case.

We may thus conclude that one more likely pathway should involve the initial formation of an unsymmetrical addition complex which, upon a stepwise proton switch from the aniline nitrogen of the charge-separated pentavalent intermediate to the sulfonamide nitrogen carrying the formal negative charge, gives a symmetrical complex that undergoes the subsequent cleavage of the old S–N bond to give the products shown in Scheme 1.

The addition complex could have a structure quite close to a square pyramid (VIII) where the attacking and leaving groups occupy *cis* or *trans* positions to each other, rather than a trigonal bipyramid. In fact, a structurally similar planar compound (IX),[10] isoelectronic around the sulfur atom, has recently been synthesized.



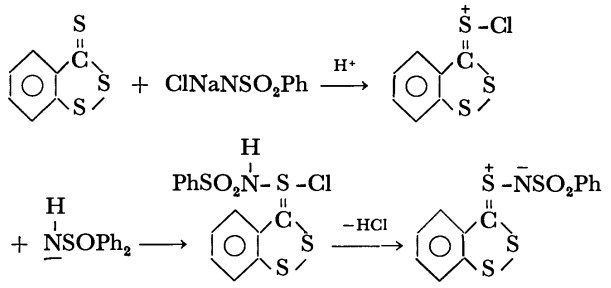
(VIII)



(IX)

It should be emphasized that such a mechanism of the displacement on the sulfur atom is somewhat similar to that of the formation of the thiocarbonyl *S*-imide itself (I) from trithione and chloramine-B, where the reaction involves the initial formation of the chlorosulfonium-like salt followed by the displacement at the sulfur atom,[11] as was already established in detail

in the formation of the sulfilimine.[12]



Experimental

Materials. Thiocarbonyl *S*-imides were prepared by the method described previously.[2] To the benzotrithione dissolved in methanol was added a solution containing a slight excess of the *p*-substituted or unsubstituted chloramine with stirring at room temperature. After a few minutes red colored crystalline thiocarbonyl *S*-imide was filtered and washed with pure water and methanol. A typical reaction of thiocarbonyl *S*-imide with aniline is as follows: one equimolar amount of thiocarbonyl *S*-imide (Ia) (339 mg, 1 mmol) and *p*-chloroaniline (127.5 mg, 1 mmol) was mixed with stirring in acetonitrile at room temperature. After ten minutes the solvent was distilled off and residual crystals were dissolved in a small amount of $CHCl_3$. The solution was fractionated with thin layer chromatography on Kieselgel using benzene as an eluant. Each fraction was extracted with $CHCl_3$-EtOH (9 : 1), filtered off and evaporated. The product was purified by recrystallization from benzene or benzene-hexane. Physical properties and spectral data of thiocarbonyl *S*-imides and rearranged products are given in Tables 5 and 6, and analytical values of the rearranged products in Table 7.

Solvent. Commercial acetonitrile was dried over phosphorus pentoxide and distilled just before use.

Kinetics. A typical procedure is as follows: thiocarbonyl *S*-imide (I) (3.39 mg, 0.01 mmol) was dissolved in 50 ml acetonitrile. *p*-Methylaniline (160.5 mg, 1.5 mmol) was also dissolved in 50 ml of the same solvent, the solution being diluted to one tenth of concentration. Both solutions were kept at 25 °C in a thermostat. Each solution (1.5 ml) was then mixed quickly in a UV cell which was also kept at the same temperature. Thus, the concentrations of thiocarbonyl *S*-imide and *p*-methylaniline at the initial reaction stage were 0.1 mmol/l and 1.5 mmol/l, respectively. Determination of the reaction rate was carried out as follows. The UV recorder was set at a certain wave length (490 nm due to thiocarbonyl *S*-imide). As soon as the reaction was initiated by mixing each solution, the recorder pen was started moving. Thus the chart obtained shows the decrease of thiocarbonyl *S*-imide concentration with time. The pseudo-first order rate constants were calculated by the integral form (2) of the differential equation (1), where a signifies the initial concentration of the thiocarbonyl *S*-imide reacted at a given time t from the start, while k is the pseudo-first-order rate constant.

$$\frac{dx}{dt} = k(a-x) \quad (1)$$

$$\ln\frac{a}{a-x} = kt \quad (2)$$

The Photochemical Raction of 2-Alkoxy-1,4-naphthoquinones with Olefins. II. The Formation of Tetrahydropyran-ring Compounds[1)]

Tetsuo OTSUKI

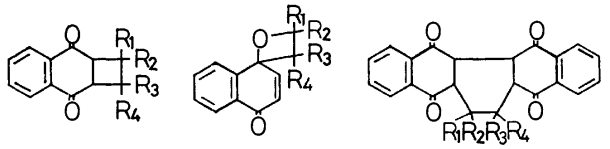
Department of Chemistry, Faculty of Home Economics, Kyoto Women's University, Kyoto 605

(Received April 3, 1974)

The photochemical reaction of 2-alkoxy-1,4-naphthoquinones with numerous types of olefins was investigated. The reaction was found to proceed smoothly in possible combinations of quinones and olefins to give photo-addition compounds in good yields. The structure of the addition compounds was determined to be **10** by their elemental analyses, mass, IR, PMR, and chemical reactions. The photo-addition reaction is characterized by the formation of a tetrahydropyran ring. This type of photo-addition reaction has not been previously known. The scope and limitations of the new photochemical reaction were described.

The photochemistry of quinones is one of the most attractive fields of study because quinones have been found to play an important role in nature. The irradiation of quinones with olefins produces addition compounds which are difficult to be prepared by any another method.[2)] Such a photochemical reaction of quinones has been found to provide a versatile synthetic route to form C–C and/or C–O bonds.[2)] The photochemistry of 1,4-naphthoquinone with olefins has been investigated by several workers,[3–5)] but systematic investigations in the field have been sparse.

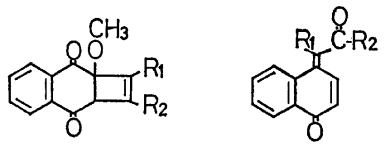
1,4-Naphthoquinone gives, in general, 1,4-naphthoquinhydrone in photochemical reactions with olefins which have active hydrogen atoms such as allylic hydrogen atoms. Olefins with no active hydrogen atoms give, on the other hand, addition compounds in photochemical reactions with 1,4-naphthoquinone, though the yields are relatively poor. The photo-addition compounds can be classified into three structural types: **1**, **2**, and **3**. The mechanism of the



1 **2** **3**

formation of **3** has been investigated in detail.[6)] The low yields of the photo-addition products and the complicated features in the photo-addition reaction of 1,4-naphthoquinone with olefins originate partly from hydrogen-atom abstraction from olefins due to the relatively higher positive oxidation potnetial of 1,4-naphthoquinone.[7,8)]

Since 2-alkoxy-1,4-naphthoquinones have lower positive oxidation potentials compared with that of 1,4-naphthoquinone itself,[7,8)] it seemed that it would be interesting to scrutinize the photochemical reactivities of the former to olefins. Although the photochemical reactions of 2-methoxy-1,4-naphthoquinone with some acetylenic compounds have been reported to yield



4 **5**

cyclobutene derivatives **4**, as well as their rearranged compounds **5**,[9–12)] no reaction mechanisms have been elucidated thus far.

In this work, the photochemical reactions of 2-alkoxy-1,4-naphthoquinones with olefins were examined, and it was found that the reactions proceed quite smoothly to give a novel type of photo-addition compound.

Results and Discussion

The 2-alkoxy-1,4-naphthoquinones examined here are 2-methoxy-, 2-ethoxy-, 2-isopropoxy-, and 2-allyloxy-1,4-naphthoquinone. The olefins selected in this work are 1-hexene, 1-heptene, 1-octene, cyclohexene, cyclooctene, 1,4-cyclooctadiene, bicyclo[2.2.1]hept-2-ene, bicyclo[2.2.1]hept-2,5-diene, styrene, and indene. A benzene solution of a mixture of a 2-alkoxy-1,4-naphthoquinone and an olefin was subjected to photochemical reaction by irradiation with a high pressure Hg arc lamp at room temperature. Neither the precipitation of 2-alkoxy-1,4-naphthoquinhydrones nor any coloration was observed during the course of the reaction, even when olefins had active hydrogen atoms, such as 1-hexene. The reaction proceeded smoothly; this is one of the extremely different features of 2-alkoxy-1,4-naphthoquinones compared with 1,4-naphthoquinone. Photo-addition compounds were obtained in fairly good yields in every case examined here.

The yields of the photo-addition compounds are tabulated in Table 1.

The structures of the photo-addition compounds were determined by the following procedures. As a typical example, the photochemical reaction of 2-methoxy-1,4-naphthoquinone with styrene will be illustrated. After the usual work-up of the reaction mixture, white needles were obtained as the main reaction product in a 69% yield. Elemental analysis and molecular-weight determination by mass spectrometry revealed that the photo-addition compound was composed of one molecule of the 2-methoxy-1,4-naphthoquinone moiety and one molecule of the styrene moiety. The addition compound contained both a hydroxyl group and a carbonyl group, judging from an inspection of its infrared and electronic spectra. The PMR spectrum (Fig. 1) showed seven characteristic groups of lines. The PMR signals corresponding to H_c disappeared after the treatment of the chloroform solution with D_2O. The nuclear spin-spin interactions among H_a, H_b, H_d, and H_e were confirmed by the spin-decoupling technique.

Table 1. The yields of the photo-additon compounds obtained in the reaction of 2-alkoxy-1,4-naphthoquinones with olefins

2-Alkoxy-1,4-naphthoquinone	Olefin	Photo-addition compound	Yield[a] (%)	Mp (°C)
2-Methoxy-1,4-naphthoquinone	1-Hexene	**10a**	25	—

2-Methoxy-1,4-naphthoquinone	Cyclohexene	**10d**	39	—
2-Methoxy-1,4-naphthoquinone	Cycloöctene	**10e**	74	191.0—198.0
2-Methoxy-1,4-naphthoquinone	1,4-Cycloöctadiene	**10f**	29	184.0—186.0
2-Methoxy-1,4-naphthoquinone	Bicyclo[2.2.1]hept-2-ene	**10g**	50	214.0—217.0
2-Methoxy-1,4-naphthoquinone	Bicyclo[2.2.1]hept-2,5-diene	**10h**	35	199.0—201.0
2-Methoxy-1,4-naphthoquinone	Styrene	**10i**	69	164.0—164.5
2-Methoxy-1,4-naphthoquinone	Indene	**10j**	73	225.0—227.0
2-Ethoxy-1,4-naphthoquinone	Styrene	**10k**	60	168.0—169.0
2-Isopropoxy-1,4-naphthoquinone	Styrene	**10l**	7.1	117.0—118.0
2-Allyloxy-1,4-naphthoquinone	Styrene	**10m**	27	139.0—140.0

a) The yields were calculated on the basis of the starting quinones consumed.

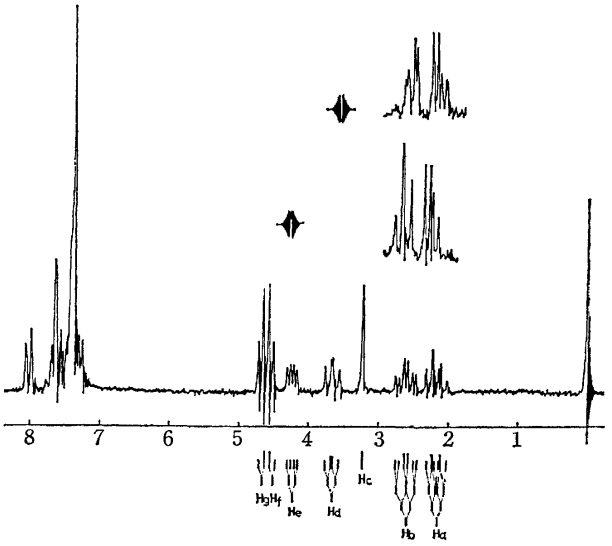

Fig. 1. PMR spectrum of the photo-addition compound.

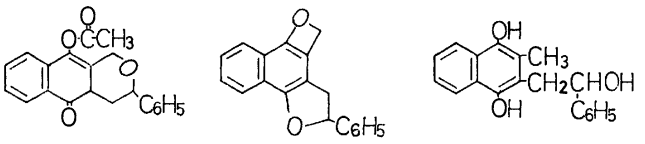
When 2-deuteriomethoxy-1,4-naphthoquinone was subjected to the same photochemical reaction, the PMR signals corresponding to H_f, and H_g (Fig. 1) of the photo-addition compound disappeared. On the other hand, the PMR signals corresponding to H_d disappeared completely when 2-methoxy-3-deuterio-1,4-naphthoquinone was used in the reaction. These results indicate that the protons, denoted by H_d, H_f, and H_g, of the photo-addition compound originated from the 2-methoxy-1,4-naphthoquinone moiety. From these results, the structure **6** could be proposed as the most probable one for the addition compound. In order to ascertain the structure **6**, the addition compound was submitted to the following chemical reactions. Upon treatment with acetyl chloride, an acetylated product was obtained. This acetylated product was confirmed to be **7** by its IR, PMR, and mass analyses. The Clemmensen reduction of the photo-addition compound gave a mixture of the two compounds. Their structures were assigned to **8** and **9**



7 **8** **9**

respectively on the basis of an inspection of their IR, PMR, and mass spectra. A similar reaction was reported by the Clemmensen reduction of eleutherins.[13]

Taking these results into account, the structure of the photo-addition compound should be the structure **6**.

The photo-addition compound is characterized by containing a tetrahydropyran ring. A similar type of photochemical reaction was found to proceed in all the 2-alkoxy-1,4-naphthoquinones examined here with a variety of olefins. The structures of the photo-addition compounds obtained here are concluded to have a tetrahydropyran ring and to be **10** on the basis of analyses of their mass, IR, and PMR spectra and their elemental analyses.

The photo-addition reaction could be initiated by the excitation of 2-alkoxy-1,4-naphthoquinones by irradiation, and the addition reaction may proceed *via* radical intermediates to give compounds characterized by containing a tetrahydropyran ring.

To give **10**, the 1,4-naphthoquinone moiety of 2-alkoxy-1,4-naphthoquinones should migrate from the oxygen atom to the α-carbon atom of the alkoxy group during the course of the photochemical reaction; the diradical should then add to olefins to give a final product. Two different routes seem to be plausible

m	H-	CH_2=CH-	C_6H_5-	H-	H-	H-

for the migration.

When the migration proceeds *via* Route (i), the scrambling of the hyrdogen atom at Position Three in the starting quinones should be observed. However, this is not the case, as was determined by the reaction of deuterium-labelled quinone derivatives. That is, the PMR signal corresponding to H_d in the photo-addition compound (see **6**) disappeared completely when 2-methoxy-3-deuterio-1,4-naphthoquinone was used as the starting quinone. From this fact only Route (ii) remains as a possible route for the migration of the 1,4-naphthoquinone moiety.

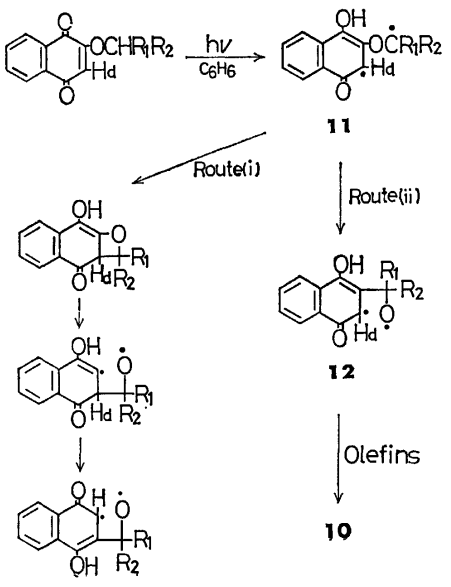

Table 2. Yield dependencies of the photo-addition products on 2-alkoxy groups

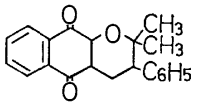
R_1, R_2 of the alkoxy groups		Yield of the product **10**[a]	
H	H	**10 i**	69 %
H	CH_3	**10 k**	60 %
CH_3	CH_3	**10 l**	7.1%

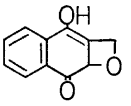
a) The yields were calculated on the basis of the starting quinones consumed.

On the other hand, when three quinones with different alkoxy groups were submitted to photochemical reactions with styrene under the same conditions, the yields of similar types of photo-addition compounds vary with the structures of the alkoxy groups. The results obtained are summarized in Table 2. Taking into account the stability of the diradical **11**, the trend of the yields for the photo-addition compounds (**10 i**, **10 k**, and **10 l**) is explicable. The most stable diradical having one of the two radical centers on the tertiary carbon atom (**11**, R_1, R_2=CH_3); an intremediate derived from the reaction of 2-isopropoxy-1,4-naphthoquinone shows the least tendency to yield **10 l**. In this case, another type of photo-addition compound **13** was obtained as the main reaction product; this is the compound produced by the simple addition of **11** to styrene.

In the absence of olefins, compound **14** was isolated as a photochemical reaction product of 2-methoxy-1,4-naphthoquinone. The formation of **14** is feasible *via* the generation of a free radical **11** (R_1,R_2=H), the subsequent 1,2-migration of the 1,4-naphthoquinone



13



14

moiety to **12**, and the final ring closure. All of the results described above confirm the intermediacy of the free radical **11**, and the subsequent 1,2-migration process.

Tetrasubstituted olefins, such as 2,3-dimethylbut-2-ene and tetraphenylethylene, however, give no photo-addition products, but only compound **14** in the photochemical reaction with 2-methoxy-1,4-naphthoquinone. This is presumably because of their sterical requirements.

Experimental

Starting Materials. *2-Methoxy-1,4-naphthoquinone*:[14] 2-Hydroxy-1,4-naphthoquinone (5.0 g), methanol (80 ml), and concd. sulfuric acid (1.2 ml) were heated under reflux for 5 hr. 2-Methoxy-1,4-naphthoquinone precipitated as yellow needles was isolated by a usual work-up and was recrystallized from ethanol (4.0 g); mp 178.0—180.5 °C. Found: C, 70.48; H, 4.25%. Calcd for $C_{11}H_8O_3$: C, 70.21; H, 4.29%. IR(KBr disk); 1680, 1650 cm^{-1} (C=O). UV max($CHCl_3$); 274 nm (log ε=4.22), 355 nm (log ε=3.54).

PMR(CCl_4); δ: 3.88 (3H, singlet), 6.02 (1H, singlet, 7.56—8.08 ppm (4H, multiplet).

2-Ethoxy-1,4-naphthoquinone:[15] By treating 2-hydroxy-1,4-naphthoquinone (2.5 g) with ethanol (30 ml) in the presence of concd. sulfuric acid (1.0 ml) for 8 hr, 2-ethoxy-1,4-naphthoquinone was obtained as yellow needles (1.5 g); mp 118.0—119.0 °C. IR(KBr disk); 1680, 1640 cm^{-1} (C=O). PMR(CCl_4); δ: 1.56 (3H, triplet, J=7.0 Hz), 4.08 (2H, quartet, J=7.0 Hz), 6.02 (1H, singlet), 7.60—8.10 ppm (4H, multiplet).

2-Isopropoxy-1,4-naphthoquinone:[16] 2-Hydroxy-1,4-naphthoquinone (1.0 g), isopropyl alcohol (20 ml), and the boron trifluoride ether complex (3.0 ml) were heated at 70 °C for 7 hr. After cooling, 2-isopropoxy-1,4-naphthoquinone precipitated was collected by filtration, washed with an aqueous solution of sodium hydrogencarbonate until the filtrate was colorless, and then washed once with isopropyl alcohol (0.7 g); mp 111.5—112.0 °C. IR(KBr disk); 1680, 1660 cm^{-1} (C=O). PMR(CCl_4); δ: 1.44(6H, doublet. J=6.0 Hz), 4.56(1H, septet, J=6.0 Hz), 6.00(1H, singlet), 7.58—8.10 ppm (4H, multiplet).

2-Allyloxy-1,4-naphthoquinone:[16] 2-Hydroxy-1,4-naphthoquinone (1.0 g), allyl alcohol (20 ml), and the boron trifluoride ether complex (3.0 ml) were heated at 70 °C for 5 hr. After cooling, water (80 ml) was added to the reaction mixture. 2-Allyloxy-1,4-naphthoquinone precipitated was collected by filtration, washed with an aqueous solution of sodium hydrogencarbonate until the filtrate was colorless, and then recrystallized from ligroin as yellow needles (0.45 g); mp 98.0—100.0 °C. IR(KBr disk); 1680, 1650 cm^{-1} (C=O). PMR(CCl_4); δ: 4.60(2H, broad doublet, J=4.0 Hz), 5.52 (2H, multiplet), 6.00(1H, multiplet), 6.16(1H, singlet), 7.64—8.20 ppm (4H, multiplet).

Olefins: All the olefins used here were commercially available and were purified by distillation before use.

General Procedures. 2-Alkoxy-1,4-naphthoquinone (1 mmol) and olefin (2 mmol) were dissolved in benzene (20 ml) and irradiated in a glass tube by means of a high pressure Hg arc lamp (300 W) through a 5-cm thick water layer. After the 2-alkoxy-1,4-naphthoquinone had been consumed completely, the benzene was distilled off under reduced pressure. Then the reaction mixture was purified by chromatography on silica gel and then further purified by recrystallization from an appropriate solvent.

Identification of the Photo-addition Compound: *6'-n-Butyltetrahydropyrano*[c-*2,3*]-*1-hydroxy-4-oxo-3,4-dihydronaphthalene* (**10a**); yellow oil (yield, 25%). Mass; m/e=272 (M^+). IR(liq. film); 3480 (OH), 2920, 2840 (CH), 1680 cm^{-1} (C=O). PMR (CCl_4); δ: 0.96 (3H, CH_3, broad triplet), 1.40 (6H, aliphatic protons, broad multiplet), 1.64—1.90(2H, C-5' CH_2, multiplet), 2.84(1H, C-6' CH, multiplet), 3.28(1H, C-4' CH, triplet, J=10.0 Hz), 3.80 (1H, OH, singlet), 4.34, 4.56(2H, C-2' CH_2, AB-quartet, J=6.0 Hz), 7.24—7.92 ppm (4H, aromatic protons, multiplet).

6'-n-Pentyltetrahydropyrano[c-*2,3*]-*1-hydroxy-4-oxo-3,4-dihydronaphthalene* (**10b**); white needles from *n*-hexane (yield, 50%); mp 80.0—81.0 °C. Mass; m/e=286(M^+). Found: C, 75.78; H, 8.05%. Calcd for $C_{18}H_{22}O_3$: C, 75.49; H, 7.74%. IR(KBr disk); 3360 (OH), 2920, 2840 (CH), 1670 cm^{-1} (C=O). PMR(CCl_4); δ: 0.92 (3H, CH_3, broad triplet), 1.36 (8H, aliphatic protons, broad multiplet), 1.64—1.90 (2H, C-5' CH_2, multiplet), 2.92 (1H, C-6' CH, multiplet), 3.28 (1H, C-4' CH, triplet, J=10.0 Hz), 3.92 (1H, OH, singlet), 4.34, 4.56 (2H, C-2' CH_2, AB-quartet, J=6.0 Hz), 7.22—7.96 ppm (4H, aromatic protons, multiplet).

6'-n-Hexyltetrahydropyrano[c-*2,3*]-*1-hydroxy-4-oxo-3,4-dihydronaphthalene* (**10c**); white needles from *n*-hexane (yield, 67%); mp 101.0—101.5 °C. Mass; m/e=300(M^+). Found: C, 76.21; H, 8.32%. Calcd for $C_{19}H_{24}O_3$: C, 75.97; H, 8.05%. IR(KBr disk); 3320 (OH), 2920, 2840 (CH), 1680 cm^{-1} (C=O). PMR(CCl_4); δ: 0.92 (3H, CH_3, broad triplet), 1.36 (10H, aliphatic protons, broad multiplet), 1.64—1.90 (2H, C-5' CH_2, multiplet), 2.92 (1H, C-6' CH, multiplet), 3.30 (1H, C-4' CH, triplet, J=10.0 Hz), 3.50 (1H, OH, singlet), 4.38, 4.58 (2H, C-2' CH_2, AB-quartet, J=6.0 Hz), 7.28—7.96 ppm (4H, aromatic protons, multiplet).

5',6'-Tetramethylenetetrahydropyrano[c-*2,3*]-*1-hydroxy-4-oxo-3,4-dihydronaphthalene* (**10d**); yellow oil (yield, 39%). Mass; m/e=270(M^+). IR(liq. film); 3350 (OH), 2920, 2840 (CH), 1660 cm^{-1} (C=O). PMR($CDCl_3$); δ: 0.80—3.25 (10H, aliphatic protons, multiplet), 3.42 (1H, C-4' CH, doublet, J=8.0 Hz), 4.48, 4.64 (2H, C-2' CH_2, AB-quartet, J=6.0 4.80 (1H, OH, singlet), 7.24—8.10 ppm (4H, aromatic protons, multiplet).

5',6'-Hexamethylenetetrahydropyrano[c-*2,3*]-*1-hydroxy-4-oxo-3,4-dihydronaphthalene* (**10e**); white crystals (yield, 74%); mp 191.0—198.0 °C (decomp.). Mass; m/e=298(M^+). IR(KBr disk); 3360 (OH), 2920, 2840 (CH), 1660 cm^{-1} (C=O). PMR($CDCl_3$); δ: 0.90—3.00 (14H, aliphatic protons, multiplet), 3.04 (1H, C-4' CH, doublet, J=8.0 Hz), 4.52, 4.64 (2H, C-2' CH_2, AB-quartet, J=6.0 Hz), 4.72 (1H, OH, singlet), 7.36—8.12 ppm (4H, aromatic protons, multiplet).

5',6'-3''-Hexenylenetetrahydropyrano[c-*2,3*]-*1-hydroxy-4-oxo-3,4-dihydronaphthalene* (**10f**); white crystals (yield, 29%); mp 184.0—186.0 °C (decomp.). Mass; m/e=296(M^+). IR(KBr disk); 3320 (OH), 3000, 2910, 2840 (CH), 1670 cm^{-1} (C=O). PMR($CDCl_3$); δ: 1.00—2.80 (11H, aliphatic protons and OH, multiplet), 3.16 (1H, C-4' CH, doublet, J=10.0 Hz), 4.68 (2H, C-2' CH_2, broad singlet), 5.52 (2H, C-5'' and C-6'' CH's, broad doublet), 7.28—7.96 ppm (4H, aromatic protons, multiplet).

Bicyclo[*2.2.1*]*heptano*[*2'',3''*-e]*tetrahydropyrano*[c-*2,3*]-*1-hydroxy-4-oxo-3,4-dihydronaphthalene* (**10g**); white crystals from chloroform (yield, 50%); mp 214.0—217.0 °C. Mass; m/e=282 (M^+). Found: C, 76.49; H, 6.63%. Calcd for $C_{18}H_{18}O_3$: C, 75.56; H, 6.44%. IR(KBr disk); 3420 (OH), 2960, 2930, 2880 (CH), 1670 cm^{-1} (C=O). PMR($CDCl_3$); δ: 1.04—2.16 (7H, aliphatic protons, multiplet), 2.42 (2H, aliphatic protons, multiplet), 2.82 (1H, OH, singlet), 2.90 (2H, aliphatic protons, multiplet), 4.56, 4.72 (2H, C-2' CH_2, AB-quartet, J=6.0 Hz), 7.24—7.92 ppm (4H, aromatic protons, multiplet).

Bicyclo[*2.2.1*]*hept-5''-eno*[*2'',3''*-e]*tetrahydropyrano*[c-*2,3*]-*1-hydroxy-4-oxo-3,4-dihydronaphthalene* (**10h**); white crystals from chloroform (yield 35%); mp 199.0—201.0 °C. IR(KBr disk); 3380 (OH), 2960, 2880 (CH), 1665 cm^{-1} (C=O). PMR($CDCl_3$); δ: 1.22—2.00 (3H, aliphatic protons, multiplet), 2.60 (1H, OH, singlet), 2.76 (2H, aliphatic protons, multiplet), 3.06 (2H, aliphatic protons, multiplet), 4.64, 4.78 (2H, C-2' CH_2, AB-quartet, J=6.0 Hz), 6.04 (2H, C-5'' and C-6'' CH's, multiplet), 7.24—7.96 ppm (4H, aromatic protons, multiplet).

6'-Phenyltetrahydropyrano[c-*2,3*]-*1-hydroxy-4-oxo-3,4-dihydronaphthalene* (**10i≡6**); white needles from benzene (yield, 69%); mp 164.0—164.5 °C. Mass; m/e=292(M^+). Found: C, 78.03; H, 5.45%. Calcd for $C_{19}H_{16}O_3$: C, 78.08; H, 5.52%. IR(KBr disk); 3250 (OH), 2940 (CH), 1675 cm^{-1} (C=O). UV max ($CHCl_3$); 290 nm (log ε=3.48). PMR($CDCl_3$); δ: 2.16 (1H, C-5' CH, multiplet), 2.58 (1H, C-5' CH, multiplet), 3.22 (1H, OH, singlet), 3.62 (1H, C-4' CH, double doublet, J=8.0, 12.0 Hz), 4.18 (1H, C-6' CH, double doublet, J=6.0, 10.0 Hz), 4.56, 4.64 (2H, C-2' CH_2, AB-quartet, J=6.0 Hz), 7.24—8.10 ppm (9H, aromatic protons, multiplet).

Indeno[*2″,3″-e*]*tetrahydropyrano*[c-*2,3*]-*hydroxy-4-oxo-3,4-dihydronaphthalene* (**10j**); white needles from benzene-petroleum ether (yield, 73%); mp 225.0—227.0 °C (decomp.). Mass; *m/e*=304 (M^+). Found: C, 79.22; H, 5.28%. Calcd for $C_{20}H_{16}O_3$: C, 78.93; H, 5.30%. IR(KBr disk); 3320 (OH), 2920 (CH), 1675 cm^{-1} (C=O). PMR($CDCl_3$); δ: 2.04 (1H, OH, singlet), 2.64 (1H, C-5′ CH, multiplet), 3.04 (2H, C-1″ CH_2, double doublet, J=6.0, 10.0 Hz), 3.19 (1H, C-2′ CH_2, AB-quartet, J=6.0 Hz), 7.10—8.00 ppm (8H, aromatic protons, multiplet).

2′-Methyl-6′-phenyltetrahydropyrano[c-*2,3*]-1-*hydroxy-4-oxo-3,4-dihydronaphthalene* (**10k**); white needles from benzene (yield, 60%); mp 168.0—169.0 °C. Found: C, 78.73; H, 5.73%, Calcd for $C_{20}H_{18}O_3$: C, 78.41; H, 5.92%. IR(KBr disk); 3280 (OH), 2980 (CH), 1680 cm^{-1} (C=O). PMR($CDCl_3$); δ: 1.16 (3H, CH_3, doublet, J=6.0 Hz), 2.16 (1H, C-5′ CH, multiplet), 2.58 (1H, C-5′ CH, multiplet), 2.94 (1H, OH, singlet), 3.62 (1H, C-4′ CH, double doublet, J=8.0, 12.0 Hz), 4.18 (1H, C-6′ CH, double doublet, J=6.0, 10.0 Hz), 4.70 (1H, C-2′ CH, quartet, J=6.0 Hz), 7.22—8.10 ppm (9H, aromatic protons, multiplet).

2′,2′-Dimethyl-6′-phenyltetrahydropyrano[c-*2,3*]-*1-hydroxy-4-oxo-3,4-dihydronaphthalene* (**10l**); white needles from benzene (yield, 7.1%); mp 117.0—118.0 °C. Mass; *m/e*=320(M^+). Found: C, 78.55; H, 6.22%. Calcd for $C_{21}H_{20}O_3$: C, 78.72; H, 6.29%. IR(KBr disk); 3320 (OH), 2990, 2920 (CH), 1680 cm^{-1} (C=O). PMR($CDCl_3$); δ: 0.92 (3H, CH_3, singlet), 1.46 (3H, CH_3, singlet), 2.16(1H, C-5′ CH, multiplet), 2.58 (1H, C-5′ CH, multiplet), 2.92 (1H, OH, singlet), 3.62 (1H, C-4′ CH, double doublet, J=8.0, 12.0 Hz), 4.18 (1H, C-6′ CH, double doublet, J=6.0, 10.0 Hz), 7.20—8.16 ppm (9H, aromatic protons, multiplet).

6′-Phenyl-2′-vinyltetrahydropyrano[c-*2,3*]-*1-hydroxy-4-oxo-3,4-dihydronaphthalene*(**10m**); white needles from benzene yield, 27%); mp 139.0—140.0 °C. Mass; *m/e*=318(M^+). IR(KBr disk); 3280 (OH), 3060, 3020, 2880 (CH), 1680 cm^{-1} (C=O). PMR($CDCl_3$); δ: 2.16(1H, C-5′ CH, multiplet), 2.58(1H, C-5′ CH, multiplet), 3.00(1H, OH, singlet), 3.80(1H, C-4′ CH, double doublet, J=8.0, 12.0 Hz), 4.12(1H, C-6′, CH, double doublet, J=6.0, 10.0 Hz), 5.04—6.16(4H, vinyl protons and C-2′, CH, multiplet), 7.22—8.18(9H, aromatic protons, multiplet).

6′,6′-Dimethyl-5′-phenyltetrahydropyrano[b-*2,3*]-*1,4-dioxo-1,2,3,4-tetrahydronaphthalene* (**13**); white needles (yield, 41%); mp 91.0—92.0 °C. Mass; *m/e*=320(M^+). Found: C, 79.07; H, 5.85%. Calcd for $C_{21}H_{20}O_3$: C, 78.75; H, 6.25%. IR(KBr disk); 2970(CH), 1690, 1680 cm^{-1}(C=O). PMR (CCl_4); δ: 0.68(3H, CH_3, doublet, J=6.0 Hz), 0.90(3H, CH_3 doublet, J=6.0 Hz), 2.14(1H, C-4′ CH, multiplet), 2.83(1H, C-4′ CH, multiplet), 3.60—4.00(3H, C-2′, C-3′ and C-5′ CH's, multiplet), 7.24 (5H, aromatic protons, singlet), 7.60—8.24 ppm(4H, aromatic protons, multiplet).

Oxetano[b-*3,2*]-*1-hydroxy-4-oxo-3,4-dihydronaphthalene* (**14**); white crystals (yield, 9%); mp 213.0—218.0 °C (decomp.). Mass; *m/e*=188(M^+). IR(KBr disk); 3450(OH), 1685 cm^{-1} (C=O). PMR(CCl_3); δ: 3.20(1H, CH, singlet), 4.80, 5.28 (2H, CH_2, AB-quartet, J=6.0 Hz), 5.30(1H, OH, singlet), 7.40—8.24 ppm (4H, aromatic protons, multiplet).

Acetylation of a Photo-addition Compound. A photo-addition compound (**6**) (50 mg) was treated with acetyl chloride (2.5 ml) in 1,2-dichloroethane (10 ml) at room tempreature. After having been stirred for 8 hr, the solution was poured onto crashed ice and extracted with chloroform. The chloroform layer was then separated and dried on anhydrous sodium sulfate, and then the reaction mixture was purified by thin layer chromatography on silica gel. An acetylated product (**7**) was isolated as yellowish crystals; mp 160.0—164.0 °C. Mass; *m/e*=334(M^+). IR(KBr disk); 2920 (CH), 1735, 1680 cm^{-1} (C=O). PMR($CDCl_3$); δ: 1.96(3H, $COCH_3$, singlet), 2.50—3.10(2H, C-5′ CH_2, multiplet), 3.60—4.40(2H, C-4′ and C-6′ CH's, multiplet), 4.54, 4.78(2H, C-2′ CH_2, AB-quartet, J=10.0 Hz), 6.90—8.24 ppm (9H, aromatic protons, multiplet).

Clemmensen Reduction of Photo-addition Compound. A photo-addition compound (**6**) (500 mg), toluene (5 ml), amalgamated zinc (10 g), and concd. hydrochloric acid (12 ml) were heated for 8 hr. Two reaction products, **8** and **9**, were then isolated from the reaction mixture using thin layer chromatography on silica gel. The physical properties were as follows; product **8**; white needles; mp 137.0—139.0 °C (decomp.). Mass; *m/e*=274 (M^+). Found: C, 83.06; H, 5.35%. Calcd for $C_{19}H_{14}O_2$: C, 83.20; H, 5.15%. IR(KBr disk); no absorption signals due to OH or C=O. PMR ($CDCl_3$); δ: 3.14 (2H, CH_2, multiplet), 4.82 (1H, CH, double doublet, J=4.0, 10.0 Hz), 5.44 (2H, CH_2, AB-quartet, J=15.0 Hz), 7.14—7.90 ppm (9H, aromatic protons, multiplet). product **9**; colorless oil. Mass; *m/e*= 276 (M^+-18 (H_2O)). IR(liq. film); 3580, 3400 cm^{-1} (OH). PMR(CCl_4); δ: 2.56 (3H, CH_3, singlet), 3.18 (2H, CH_2, doublet, J=6.0 Hz), 4.82 (1H, CH, triplet, J=6.0 Hz), 7.10—8.00 (9H, aromatic protons, multiplet).

The author wishes to express his gratitude to Professor Kazuhiro Maruyama, Kyoto University, for his invaluable suggestions and encouragement. He also wishes to thank the Ministry of Education for the financial support granted for this research.

Spectrophotometric Studies of the Acidities of Dichlorophene and Hexachlorophene

Hiroyasu INOUE and Naomi ASAOKU

Department of Applied Chemistry, Faculty of Technology, Kanagawa University, Kanagawa-ku, Yokohama 221

(Received April 13, 1974)

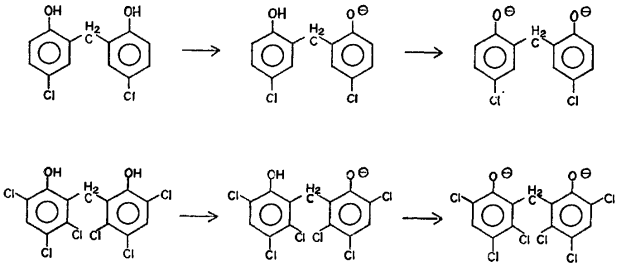
It has been found that dichlorophene (bis-(2-hydroxy-5-chlorophenyl)methane) and hexachlorophene (bis-(2-hydroxy-3,5,6-trichlorophenyl)methane) have abnormally high acidities as compared with the corresponding reference compounds, *i.e.*, 2-methyl-4-chlorophenol and 2,4,5-trichlorophenol respectively. The values of pK_a for the first and second ionizations of dichlorophene in a mixed solvent of ethanol and water (1 : 1) were determined to be 9.10 and 13.1, and those of hexachlorophene, to be 5.87 and 11.9, at 18 °C. On the basis of the infrared spectra, these observations could be interpreted in terms of the additional stabilization of the resulting mono-anions of these bis-phenolmethanes by means of the intramolecular hydrogen bondings between the OH and O^- groups.

The acidities of organic compounds are more or less influenced by various types of intra- and intermolecular interactions. For many substituted phenols, the effects of intra- and intermolecular hydrogen bondings on their acidities have been widely studied.[1] It is well known that salicylic acid is a stronger acid than *o*-methoxybenzoic acid, and this has been attributed to the additional stabilization of the resulting mono-anion of salicylic acid by the intramolecular hydrogen-bonding between the COO^- and OH groups.[2-6]

In the present investigation, the acidities of two bis-phenolmethanes, dichlorophene (bis-(2-hydroxy-5-chloro phenyl)methane), and hexachlorophene (bis-(2-hydroxy-3,5,6-trichlorophenyl)methane), are compared with those of 2-methyl-4-chlorophenol and 2,4,5-trichlorophenol respectively, which can be regarded as reference compounds for the above bis-phenolmethanes because their ultraviolet spectra resemble well those of the respective bis-phenolmethanes. If, in the bis-phenolmethanes, there take place some intramolecular interactions between the two moieties separated by the methylene group, their acidities may be expected to be different from those of the reference compounds. In fact, when water is added to a solution of hexachlorophene in ethanol, a new absorption band appears at 320 nm, with an intensity depending upon the concentration of the added water; this band disappears when the solution is made acidic, thus suggesting that hexachlorophene ionizes partly even in a neutral aqueous solution. On the other hand, this is not the case for 2,4,5-trichlorophenol. Accordingly, we will deal with the factors accounting for the abnormally high acidities of the bis-phenolmethanes as studied by means of ultraviolet and infrared spectroscopies.

Results and Discussion

Figures 1 and 2 show the spectral changes on the variation in the pH values of solutions of dichlorophene and hexachlorophene respectively in a mixed solvent of ethanol and water (1 : 1 in volume). These spectral changes can safely be attributed to the first and second ionizations of the phenolic hydroxyl groups of these bis-phenolmethanes. In Figs. 1 and 2 the solid and the broken lines represent the spectral changes due to the first and the second ionizations respectively. The absorption intensities of the newly-appearing bands change with a change in the pH value of the solutions, as is shown in Fig. 3. As may be seen from this figure, the second ionization of each compound occurs in a distinctly higher pH region than the first ionization.



Therefore, the pK_a values for the first and second ionizations of these bis-phenolmethanes can be determined from the absorbances of the newly-appeared bands by the application of the usual equation. The results are summarized in Table 1, in which the results for 2-methyl-4-chlorophenol and 2,4,5-trichlorophenol obtained in the same manner are also presented for the sake of comparison. As may be seen from this table, the pK_a values for the first ionizations of the bis-phenolmethanes are significantly smaller than those of the

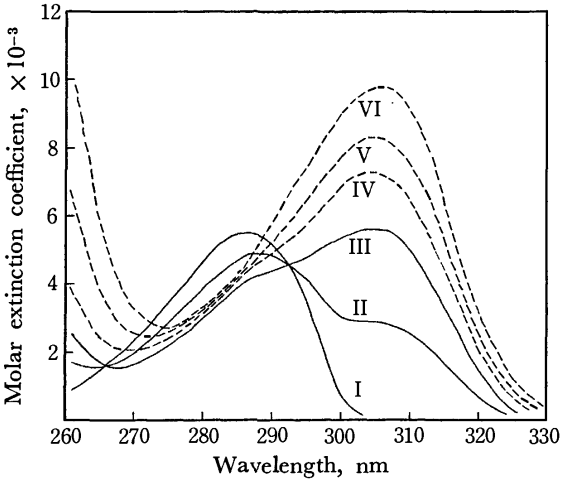


Fig. 1. Spectral change of the solution of dichlorophene in mixed solvent of ethanol and water (1 : 1) on variation of pH.

●: Dichlorophene, at 304 nm, ○: Hexachlorophene, at 320 nm

respective reference compounds. On the other hand, the pK_a values for the second ionizations are fairly large. These results strongly suggest that an intramolecular interaction takes place for each of the bis-phenolmethanes in the ionized species.

Next, the interaction of the bis-phenolmethanes with triethylamine in *n*-hexane was studied. It has been established that various types of interactions exist between such phenols as *p*-nitrophenol and triethylamine, including the formations of a simple hydrogen bond, a hydrogen-bonded ion pair, a solvent-separated ion pair, and dissociation into individual ions, depending upon the solvent employed.[7,8] The spectral changes on the addition of triethylamine to a *n*-hexane solution of the present bis-phenolmethanes are shown in Fig. 4. As for hexachlorophene, the first ionization into the ions, probably the ion pair, is considered to occur in *n*-hexane on the addition of triethylamine, judging from the spectra shown in Fig. 4. In the case of dichlorophene, however, the ionization does not occur; however, the hydrogen bonding with triethylamine does seem to take place, because the addition of triethylamine causes a small shift of the absorption band (from 286 nm to 293 nm) compared with the case of the ionization. By the application of the method of Rose and Drago,[9] the equilibrium constants for the first ionization of hexachlorophene in *n*-hexane and for the formation of the hydrogen bond between dichlorophene and triethylamine were determined to be 29500 and 5900 at 25 °C respectively. 2,4,5-Trichlorophenol undergoes only the hydrogen-bonding with triethylamine in *n*-hexane. That the difference in the pK_a values determined in aqueous ethanol reflects the different types of interactions for hexachlorophene and 2,4,5-trichlorophenol with triethylamine in *n*-hexane clearly indicates that the abnormally high acidity of hexachlorophene can not be attributed to the effect of the solvation of the ionized species.

It is expected that the presence of two hydroxyl groups

Table 1. The pK_a values for the first and the second ionizations in aqueous ethanol

	pK_a(I)	pK_a(II)
Hexachlorophene	5.87(18°), 5.69(40°)	11.9(18°)
2,4,5-Trichlorophenol	8.44(18°), 8.25(38°)	
Dichlorophene	9.10(18°), 8.83(38°)	13.1(18°)
2-Methyl-4-chlorophenol	10.89(18°), 10.13(38°)	

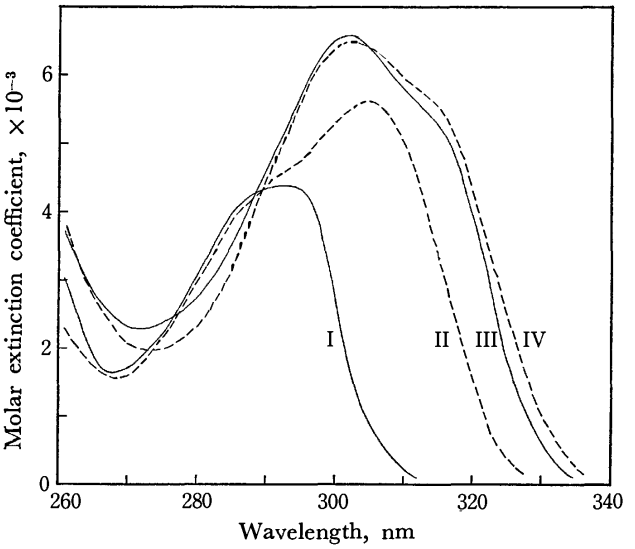

Fig. 4. Absorption spectra.
I: Dichlorophene in *n*-hexane containing triethylamine, II: Dichlorophene in aqueous ethanol, pH: 9.9, III: Hexachlorophene in *n*-hexane containing triethylamine, IV: Hexachlorophene in aqueous ethanol, pH: 6.7

in each of the bis-phenolmethanes is essentially related to the abnormal ease of the first ionizations. In fact, according to Higuchi *et al.*,[10] *o*-methylhexachlorophene has a pK_a value of 8.22 and hexachlorophene monosuccinate has a pK_a value of 8.14 for the ionization of the phenolic group. These values are very close to the pK_a value of 2,4,5-trichlorophenol. Hence, it can be considered that two hydroxyl groups of the bis-phenolmethanes take part in an intramolecular interaction. Although intramolecular hydrogen bonding has been known to be formed in bis-(2-hydroxy-3-*t*-butyl-5-methylphenyl)methane between the two hydroxyl groups judging from the fact that this compound has its infrared absorption at 3500 cm^{-1} as a broad band,[11] such intramolecular hydrogen bonding does not occur in the case of hexachlorophene. This can be deduced from the fact that the OH stretching band is sharp in shape and appears at 3525 cm^{-1}, similarly to that of 2,4,5-trichlorophenol, as is shown in Fig. 5. However, in the case of the resulting mono-anion, an intramolecular hydrogen bond may be expected to be formed between the OH and O^- groups because of the relatively strong electronegativity of the latter. From the spatial point of view, these groups are perhaps brought close together by twisting around the C(methylene)—C(ring) bond axes.

In order to ascertain whether or not such a hydrogen bond was present, the infrared absorption spectrum of the mono-anion of hexachlorophene was measured, using tetrachloroethylene as the solvent and triethylamine as the base.[12] The results are presented in Fig. 5. The sharp band of the OH stretching vibration at 3525 cm^{-1} diminishes on the addition of triethylamine, and a broad band appears around 2100 cm^{-1}. This spectral change is due to the first ionization, and the band at

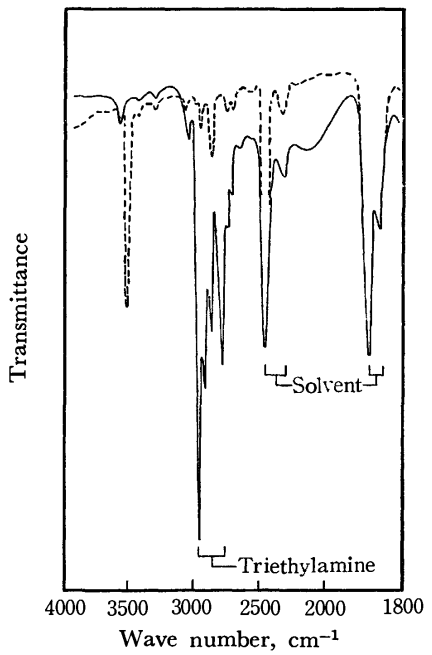

Fig 5. Infrared spectra of hexachlorophene in tetrachloroethylene.
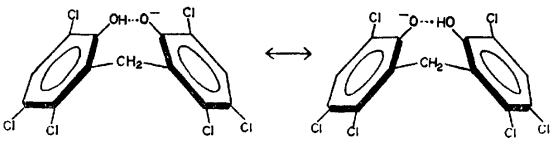
----: Absence of triethylamine, ——: Presence of triethylamine

2100 cm^{-1} can be assigned to the OH stretching vibration of the resulting mono-anion, because no other band appears on the addition of the base in the relatively higher wave number region. The very low wave number and the broadening of this band indicate that the mono-anion has an intramolecular hydrogen bond between the OH and O^- groups. Moreover, judging from the surprisingly low wave number, this hydrogen bond seems to be extraordinarily strong, and the following intramolecular proton transfer may occur in the anion.



The formation of such an intramolecular hydrogen bond may cause an additional stabilization of the resulting mono-anion. Consequently, the difference in the pK_a values for hexachlorophene and 2,4,5-trichlorophenol may be ascribed to the presence of this intramolecular hydrogen bond in the former. This may also be the case for dichlorophene. Also, the abnormally high acidity of salicylic acid has been interpreted in terms of an intramolecular hydrogen-bonding between the hydroxyl and carboxylic groups. However, in the case of salicylic acid the hydrogen bond is formed even in the neutral species. This is in contrast with the situation with hexachlorophene.

As for hexachlorophene, its high acidity as compared with that of dichlorophene may be attributed to the additional inductive effect of the chlorine atoms at the 3- and 3'-positions.

The stabilization of the mono-anions of the bisphenolmethanes by the intramolecular hydrogen bond should result in higher $pK_a(II)$ values than those of the corresponding reference compounds. This is indeed the case, as is shown in Table 1. However, the high $pK_a(II)$ values may also be attributed to some extent to the repulsion of the charge in the resulting di-anions.

Experimental

Materials. All the materials used here were obtained commercially and were purified by repeated recrystallizations from a suitable solvent for each compound.

Procedures. The values of pK_a were determined spectrophotometrically by the use of the following equations;

$$pK_a(I) = pH + \log \frac{\frac{D}{A} - \varepsilon_m}{\varepsilon_n - \frac{D}{A}}$$

$$pK_a(II) = pH + \log \frac{\frac{D}{A} - \varepsilon_d}{\varepsilon_m - \frac{D}{A}}$$

where A is the initial concentration of acids and where D and ε are, respectively, the absorbance and the molar extinction coefficient. The subscripts, n, m, and d, denote neutral species, the mono-anion, and the di-anion respectively. A

mixture of ethanol and water (1 : 1) was used as the solvent.

The ultraviolet absorption spectra were measured with a Shimadzu Spectrophotometer QV-50, using 1 cm quartz cells. The cell box was maintained at a constant temperature by passing water from a constant-temperature bath through the cell box. The infrared absorption spectra were recorded on a Hitachi Infrared Spectrophotometer EPI-G3, using a 0.5 mm NaCl cell.

The Synthesis of Coenzyme Q

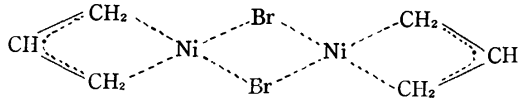
Seiichi INOUE, Ryohei YAMAGUCHI, Kenji SAITO, and Kikumasa SATO

Department of Applied Chemistry, Faculty of Engineering, Yokohama National University, Ooka, Minami-ku, Yokohama 233

(Received April 17, 1974)

A new, efficient synthesis of coenzyme Q is described. The bromination of 2,3-dimethoxy-5-methyl-*p*-benzoquinone gives 6-bromo-2,3-dimethoxy-5-methyl-*p*-benzoquinone, which is then converted to the corresponding hydroquinone diacetate by the action of zinc dust in acetic anhydride. 6-Bromo-2,3-dimethoxy-5-methylhydroquinone diacetate is reacted with 1,1-dimethyl-π-allylnickel bromide in hexamethylphosphoramide at 60 °C to afford a 70% yield of 2,3-dimethoxy-5-methyl-6-prenylhydroquinone diacetate, which is hydrogenolyzed with lithium aluminum hydride in ether and then oxidized with aqueous ferric chloride to give coenzyme Q_1 in a 76% yield. Similarly, coenzyme Q_2, Q_9, and Q_{10}, and 6′, 10′, 14′-hexahydrocoenzyme Q_4 are synthesized by the reaction of the aryl bromide with π-geranyl-, π-solanesyl-, π-decaprenyl-, and π-phytylnickel bromide respectively and by subsequent treatment with $LiAlH_4$ and $FeCl_3$. The stereochemistry of the products is also described.

A new synthetic method which involves a selective carbon-carbon bond formation between π-allylnickel halide complexes (**1**) and organic halides has recently been reported by Corey and Semmelhack,[1] and the intrinsic value of this coupling reaction for the synthetic chemistry has been shown in the syntheses of various

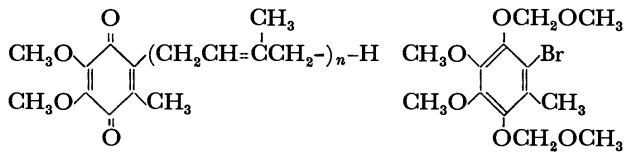


1

natural substances, α-santalene,[1] epi-β-santalene,[1] ethyl geranate,[2] geranyl acetate,[2,3] coenzyme Q_1,[4,5] and vitamin K.[6]

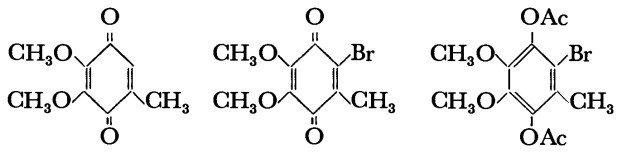
We wish to report here a new synthesis of coenzyme Q (**2**) employing the promising allylation reaction of π-allylnickel bromides.

In a previous work, we utilized 6-bromo-2,3-dimethoxy-5-methylhydroquinone bis(methoxymethyl) ether (**3**) for the construction of the aromatic moiety of coenzyme Q_1.[4] It was found that the regeneration of the hydroquinone in the later stage of synthetic sequences could be achieved conveniently by the acid-catalized solvolysis of the bis(methoxymethyl) ether in methanol. However, **3** is not crystalline and is rather unstable, so it must be purified carefully by column chromatography. Therefore, we investigated another synthetic equivalent of **3**.



2 **3**

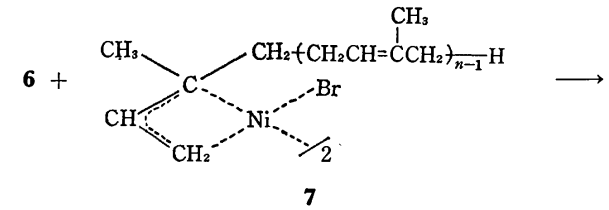
The bromination of 2,3-dimethoxy-5-methyl-*p*-benzoquinone (**4**)[7] afforded 6-bromo-2,3-dimethoxy-5-methyl benzoquinone (**5**),[4] which was then converted to the



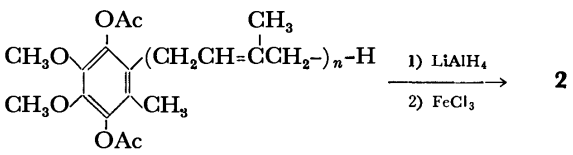
4 **5** **6**

corresponding hydroquinone diacetate **6** by the action of zinc in acetic anhydride.

When **6** reacted to 1,1-dimethyl-π-allylnickel bromide (**7**, $n=1$)[8] in hexamethylphosphoramide (HMPA) at 60 °C for 7 hr, 2,3-dimethoxy-5-methyl-6-prenylhydroquinone diacetate (**8**, $n=1$) was obtained in a 70% yield. By this fact, the diacetate **6** was found to be as sufficiently reactive toward **7** ($n=1$) as the corresponding bis(methoxymethyl) ether **3**, which had afforded the coupling product with **7** ($n=1$) in HMPA at 60 °C in a 57% yield.[4] All earlier attempts at the alkaline hydrolysis or acid-catalyzed hydrolysis of **8** ($n=1$) to the corresponding hydroquinone had failed. Finally, the diacetate **8** ($n=1$) was treated with excess $LiAlH_4$ in ether at reflux for 24 hr and then oxidized with aqueous $FeCl_3$ to afford coenzyme Q_1(**2**, $n=1$) in a 76% yield. The IR and NMR spectra were satisfactory for the structure **2**($n=1$).



7



8

Although the nature of π-allylnickel complexes, except for π-geranylnickel bromide,[1] possessing in their own molecule some olefin moieties which may act as stable π-ligands, has not yet been clarified, the above results distinctly suggest the possibility of synthesizing the higher homologues of coenzyme Q. Such an anticipation was successfully realized, as will be indicated below. The bromide **6** reacted to π-geranylnickel bromide (**7**, $n=2$)[8] in HMPA at 60 °C to afford 6-geranyl-2,3-dimethoxy-5-methylhydroquinone diacetate (**8**, $n=2$) (88% yield), which was then converted, by the removal of the acetate groups with $LiAlH_4$

and by subsequent oxidation by aqueous $FeCl_3$, to coenzyme Q_2 (**2**, $n=2$) in a 75% yield.

The procedure was also extended to the synthesis of the higher homologues of coenzyme Q. The bromide **6** reacted to π-solanesylnickel bromide (**7**, $n=9$)[8] in HMPA at 70 °C for 10 hr. After purification with a silica-gel column we obtained 6-solanesyl-2,3-dimethoxy-5-methylhydroquinone diacetate (**8**, $n=9$) (45 % yield), which was then converted to coenzyme Q_9 (**2**, $n=9$) by the above-described procedure (71% yield); this substance melted at 26—28 °C (lit,[10] mp 45 °C for naturally-occurring coenzyme Q_9). The synthesis of coenzyme Q_{10} (**2**, $n=10$) was similarly effected by the reaction of π-decaprenylnickel bromide (**7**, $n=10$)[8] with **6** in HMPA at 75 °C for 7 hr (40% yield), followed by the treatment of **8** ($n=10$) with $LiAlH_4$ and then aqueous $FeCl_3$ to give **2** ($n=10$) in a 69% yield; mp 20—22 °C (lit,[10,11] mp 49 °C for the natural coenzyme Q_{10}).

The low melting points of our products are attributable to the coexistence of the *cis* isomer[12] in regard to the first double bond in the side chain originating in the π-allyl moiety of **7**. This was supported by the 100 MHz NMR spectroscopy measurement; the calculation of the peak areas of olefinic methyl protons revealed that the *trans*-to-*cis* ratio of the product was 55 : 45. For the synthetic utility and isolation of all-*trans*-coenzyme Q, a higher *trans* stereoselectivity is needed. For the investigation of the stereoselectivity of this coupling reaction, the geranyl side chain was not a suitable model, because the NMR spectrum of **2** ($n=2$) showed complicated olefinic methyl signals at δ 1.5—1.7, so the determination of the *trans*-to-*cis* ratio was very difficult.[13] For this purpose, the phytyl side chain or a much higher (*i.e.* solanesyl or decaprenyl) side chain was suitable. We have already found[6] that the conduction of the coupling reaction in lesser coordinative polar solvents, such as *N*,*N*-dimethylacetamide (DMAc) or *N*-methyl-2-pyrrolidone (MPD), and at lower temperature leads to higher *trans*-to-*cis* ratios of the coupling products in the synthesis of vitamin K. A similar solvent effect was also observed in the present work. The reaction of **6** with π-phytylnickel bromide in DMAc or MPD gave the *trans* isomer of the coupling product (6′,10′,14′-hexahydrocoenzyme Q_4) above a 70% stereoselectivity. In the synthesis of coenzyme Q_9 with **6** and **7** ($n=9$) in DMAc at 60 °C, the products **8**($n=9$) (48% yield) and, therefore, **2** ($n=9$) were both 74 : 26 mixtures fo *trans* and *cis* forms.

The isolation of the all-*trans*-coenzyme Q_9 was effected by silica-gel column chromatography, eluting with *n*-hexane–diisopropyl ether (90 : 10). The first several fractions eluted contained only the *cis*-isomer, while the all-*trans* compound (mp 42—4 °C) was eluted in the rather late fractions in a high *trans* recovery.

The efficacy of the synthesis of **2** by the π-allylnickel complex allylation process depends on the unreactivity of σ- or π-allylnickel complexes toward the ester function and the facile reactivity thereof toward the trigonal carbon halides. This procedure avoids the disadvantages of several kinds of side reactions, which render the product isolation much difficult. The sole by-product of the present method, hydrocarbons arising from the thermal decomposition of **7**, can easily be separated, and the unchanged diacetate **6** is recovered quantitatively. This method seems to be highly effective for the synthesis of naturally-occurring isoprenoid quinones and related substances, including coenzyme Q, vitamin K, and tocophenols,[14] for which there exists only a very limited synthetic methodology.

Investigations are continuing from the mechanistic point of view and concerning reaction conditions which would realize a much higher stereoselectivity.

Experimental

The melting points were taken on a hot-stage apparatus and are uncorrected. The spectral measurements were determined with the following instruments; IR, a Hitachi Model 215 spectrophotometer; NMR, a JEOL Model C-60 or PS-100 spectrometer in a carbon tetrachloride or deuteriochloroform solution, with tetramethylsilane as the internal reference; UV, a Hitachi Model EPS-3T spectrophotometer.

6-Bromo-2,3-dimethoxy-5-methyl-*p*-benzoquinone (**5**),[4] geranyl bromide, phytyl bromide, solanesyl bromide,[9] and decaprenyl bromide[9] were obtained by the methods described in the literature, their physical properties agreed with those previously reported. Reactions involving π-allylnickel complexes were carried out under nitrogen or argon.

6-Bromo-2,3-dimethoxy-5-methylhydroquinone Diacetate (6). A solution of 5.0 g of **5** in 20 ml of acetic anhydride containing a few drops of pyridine was warmed to 60—65 °C, and then 7.5 g of zinc dust was added to this solution. The mixture was stirred well until the red color faded and was then kept at 60 °C for a further 30 min. The mixture was filtered, and the residue was washed with acetone. The combined

Table 1. Summary of the yields and stereoselectivity of the coupling reaction

General Preparative Method of π-Allylnickel Bromide (7). To a stirred solution of a 15% benzene solution of nickel carbonyl (*ca.* 1.5-fold excess), a 15% benzene solution of the allylic bromide was added drop by drop over 1—1.5-hr period at 50 °C; the mixture was then stirred for a further 2—3 hr. The resulting solution was cooled to below 10 °C, and the benzene and excess nickel carbonyl were removed under reduced pressure. The red residue was the corresponding π-complex and was used directly in the next reaction.

Coenzyme Q_1 (2, n=1). 1,1-Dimethyl-π-allylnickel bromide (**7**, $n=1$) was prepared from 4.5 g of 1-bromo-3-methyl-2-butene and 8.7 g of nickel carbonyl by means of the above-described procedure. After the removal of the benzene, 36 ml of HMPA and 5.2 g of **6** in 36 ml of HMPA were added to the dark residue at 10 °C. The mixture was heated to 60 °C for 7 hr, and then poured into water and extracted with petroleum ether. The extract was washed with water, dried ($MgSO_4$), and freed of the solvent. The crude product (5.1 g) was found by NMR assay to consist of 70% of **8** ($n=1$) and 30% of **6**, but **8** could not be isolated by silica gel column chromatography.[15] This mixture (1.3 g) was dissolved in 30 ml of dry ether and reduced by the use of 0.8 g of $LiAlH_4$ at reflux for 24 hr. The excess $LiAlH_4$ was decomposed by the addition of a small portion of ethanol and ethyl acetate, neutralized by an aqueous saturated ammonium chloride solution, and extracted with ether. The extract was concentrated to a small volume, oxidized by aqueous $FeCl_3$ at room temperature for 3 hr, and extracted with ether. The extract was washed with water, dried ($MgSO_4$), and evaporated. The crude product was chromatographed on silica gel, using *n*-hexane–diisopropyl ether (80 : 20) for elution, to give 0.5 g of coenzyme Q_1 (**2**, $n=1$). All the spectral data were identical with those previously obtained in our laboratory.[4]

Coenzyme Q_2 (2, n=2). π-Geranylnickel bromide (**7**, $n=2$) was prepared from 8.7 g of geranyl bromide and 10.3 g of nickel carbonyl by means of the above-described method. After changing the solvent to 40 ml of HMPA, 5.3 g of **6** in 35 ml of HMPA were added at 10 °C, and the mixture was treated at 60 °C for 7 hr. When the reaction mixture was worked up in the usual manner, 7.2 g of a crude product was obtained. This was found by NMR assay to be a mixture of **8** ($n=2$) (88%) and **6** (12%), but the removal of the **6** by the use of the silicagel column was very difficult.[16] This mixture (1.5 g) was reduced by the use of 0.7 g (of $LiAlH_4$ in dry ether at reflux for 24 hr, and then worked up in the usual manner. The ether extract was concentrated to a small volume and then oxidized by aqueous $FeCl_3$ at room temperature for 3 hr. The organic layer was washed with water, dried ($MgSO_4$), and freed of the solvent. The crude product was chromatographed on silica gel; subsequent elution with *n*-hexane–diisopropyl ether (80 : 20) gvae 0.7 g of coenzyme Q_2 (**2**, $n=2$). The estimated yield of **2** ($n=2$) from **8** ($n=2$) was 75%. IR (neat) 2930, 1650, 1610, 1450, 1270, 1210, 1160, 1100, 1010, 950, and 740 cm^{-1}; NMR ($CDCl_3$) δ 4.96 (2H, t, 2-CH=), 3.97 (6H, s, $2CH_3O$), 3.16 (2H, d, $ArCH_2$), 1.99 (4H, bs, methylene chain), 1.97 (3H, s, $ArCH_3$), 1.72, 1.67 (3H, 2s, *trans* and *cis* olefinic CH_3), 1.63 1.56 (each 3H, 2s, terminal olefinic CH_3);[13] UV λ_{max} (*n*-hexane) 270 nm (15600).

Found: C, 71.87; H, 8.35%. Calcd for $C_{19}H_{26}O_4$: C, 71.67; H, 8.23%.

6′,10′,14′-Hexahydrocoenzyme Q_4. π-Phytylnickel bromide was prepared from 1.9 g of phytyl bromide and 1.3 g of nickel carbonyl; after the solvent had been changed to 30 ml of DMAc, 1.3 g of **6** was added, and the mixture was treated under the conditions shown in Table 1. The reaction mixture was then worked-up in the usual manner, and silica-gel-column chromatography afforded the corresponding diacetate: IR (neat) 2930, 1770, 1485, 1475, 1370, and 1195 cm^{-1}; NMR ($CDCl_3$) δ 5.00 (1H, t, –CH=), 3.86 (6H, s, $2CH_3O$), 3.25 (2H, d, $ArCH_2$), 2.26, 2.24 (each 3H, 2s, 2AcO), 2.08 (3H, s, $ArCH_3$), 1.72 (3H, bs, olefinic CH_3), 1.20 (21H, bs, methylene chain), 0.88 (12H, d, side-chain CH_3).

Found: C, 72.77; H, 10.16%. Calcd for $C_{33}H_{54}O_6$: C, 72.49; H, 9.95%.

To a suspension of 0.7 g of $LiAlH_4$ in 40 ml of dry ether, 1.00 g of the hydroquinone diacetate in 20 ml of ether was added, and the mixture was treated at reflux for 7 hr. After extraction, the extract was concentrated to a small volume and oxidized by aqueous $FeCl_3$ at room temperature for 3 hr. The crude product, obtained by the usual work-up, was chromatographed on silica gel; subsequent elution with *n*-hexane–diisopropyl ether (70 : 30) gave 0.61 g of 6′,10′,14′-hexahydrocoenzyme Q_4 (72%); IR (neat) 2920, 1645, 1602, 1457, 1375, 1285, 1260, and 1202 cm^{-1}; NMR ($CDCl_3$) δ 4.94 (1H, t, –CH=), 3.97 (6H, s, $2CH_3O$), 3.19 (2H, d, $ArCH_2$), 2.00 (3H, s, $ArCH_3$), 1.78, 1.72 (3H, 2s, *trans* and *cis* olefinic CH_3), 1.20 (21H, bs, methylene chain), 0.88 (12H, d, side-chain CH_3).

Found: C, 75.60; H, 10.60%. Calcd for $C_{29}H_{48}O_4$: C, 75.61; H, 10.50%.

Coenzyme Q_9 (2, n=9). π-Solanesylnickel bromide (**7**, $n=9$) was prepared from 6.0 g of solanesyl bromide and 1.6 g of nickel carbonyl. After the solvent had been changed to 40 ml of DMAc, a 1.6-g portion of **6** was added and the mixture was treated under the conditions shown in Table 1. After a usual work-up, followed by silica gel column chromatography, pure coenzyme Q_9 hydroquinone diacetate **8** ($n=9$) was obtained; IR (neat) 2920, 1770, 1660, 1480, 1450, 1370, 1260, 1200, 1190, and 1100 cm^{-1}; NMR ($CDCl_3$) δ 5.14 (9H, m, 9–CH=), 3.85 (6H, s, $2CH_3O$), 3.22 (2H, d, $ArCH_2$), 2.35, 2.31 (each 3H, 2s, 2AcO), 2.02 (35H, bs, methylene chain and $ArCH_3$), 1.62 (30H, bs, side chain CH_3).

Found: C, 79.29; H, 10.29%. Calcd for $C_{58}H_{88}0_6$: C, 79.09; H, 10.06%.

To a suspension of 0.8 g of $LiAlH_4$ in 20 ml of dry ether, we added 1.4 g of **8** ($n=9$) in 25 ml of ether, after which the mixture was refluxed for 7 hr. The reaction mixture was then worked-up into ether and oxidized by aqueous $FeCl_3$ at room temperature for 3 hr. The crude product, obtained by the usual work-up, was chromatographed on silica gel; subsequent elution with *n*-hexane–diisopropyl ether (75 : 25) gave 0.9 g of coenzyme Q_9(**2**, $n=9$) (71%); mp 26—28 °C; IR (neat) 2920, 1650, 1605, 1450, 1380, 1285, 1265, 1205, 1150, and 1100 cm^{-1}; NMR ($CDCl_3$) δ 5.15 (8H, m, 8–CH=), 4.96 (1H, t, –CH=), 4.00 (6H, s, $2CH_3O$), 3.19(2H, d, $ArCH_2$), 2.00 (35H, bs, methylene chain and $ArCH_3$), 1.72 (s, *trans* olefinic CH_3 on C–3′), 1.68 (s, *cis* olefinic CH_3 on C–3′ and terminal *cis* CH_3), 1.60 (24H, olefinic CH_3); UV λ_{max} (*n*-hexane) 272 nm (ε 4200).

Found: C, 81.59; H, 10.64%. Calcd for $C_{54}H_{82}O_4$: C, 81.54; H, 10.39%.

Isolation of all-trans-Coenzyme Q_9. Silica gel (72 g) was used to fill up a column (20 mm × 450 mm) with *n*-hexane. After the adsorption of 700 mg of the coenzyme Q_9 (mp 31 °C, *trans* : *cis* = 71 : 29), it was eluted with *n*-hexane–diisopropyl ether (90 : 10). The eluted solution was divided into 13 fractions, each 30 ml. The first 3 fractions contained only the *cis* isomer (119 mg), while the 7—13 fractions (total, 369 mg) had a mp of 42—44 °C, showing no melting-point depression upon mixing with the natural coenzyme Q_9. The NMR spectrum also supported the all-*trans* structure. The *trans* recovery amounted to 76%.

Coenzyme Q_{10} (**2**, $n=10$). π-Decaparenylnickel bromide (**7**, $n=10$) was prepared from 10.0 g of decaprenyl bromide and 4.5 g of nickel carbonyl. After the solvent had been changed to 30 ml of HMPA, 2.0 g of **6** in 20 ml of HMPA was added at room temperature and the mixture was treated at 75 °C for 7 hr. After a usual work-up and silica gel column chromatography, eluting with *n*-hexane–diisopropyl ether (75 : 25), 2.2 g (40%) of **8** ($n=10$) were obtained; IR (neat) 2910, 1765, 1440, 1370, 1190, 1100, and 1020 cm^{-1}; NMR (CCl_4) δ 4.92 (10H, m, 10–CH=), 3.70 (6H, s, $2CH_3O$), 3.10 (2H, d, $ArCH_2$), 2.20 2.18 (each 3H, 2s, 2AcO), 1.95 (39H, bs, methylene chain and $ArCH_3$), 1.55 (33H, bs, side-chain CH_3).

Found: C, 79.54; H, 10.50%. Calcd for $C_{63}H_{96}O_6$: C, 79.70; H, 10.19%.

To a suspension of 0.5 g of $LiAlH_4$ in 20 ml of dry ether, we added 0.8 g of **8** ($n=10$) in 15 ml of ether; the mixture was then refluxed for 24 hr. After the decomposition of the excess $LiAlH_4$, the mixture was neutralized and extracted with ether. The extract was concentrated to a small volume and then oxidized by aqueous $FeCl_3$ at room temperature for 3 hr. The crude product, obtained by the usual work-up, was chromatographed on silica gel to give 0.5 g (69%) of coenzyme Q_{10} (**2**, $n=10$): mp 20—22 °C; IR (neat) 2900, 1650,1610, 1450, 1390, 1270, 1210, 1155, 1105, and 750 cm^{-1}; NMR (CCl_4) δ 4.92 (10H, m, 10–CH=), 3.84 (6H, s, $2CH_3O$), 3.05 (2H, d, $ArCH_2$), 1.92 (39H, bs, methylene chain and $ArCH_3$), 1.55 (33H, bs, side-chain CH_3); UV λ_{max} (*n*-hexane) 272 nm (ε 12300).

Found: C, 82.31; H, 10.69%. Calcd for $C_{59}H_{90}O_4$: C, 82.08; H, 10.51%.

The authors are greateful to the Japanese Ministry of Education for its grant-in-aid for scientific research.

Synthesis of Dimeric and Trimeric 2-(*p*-Tolyloxy)ethyl Acetate-Formaldehyde Polymer Model Compounds

Akira NINAGAWA, Haruo MATSUDA, and Sumio MATSUDA

Department of Petroleum Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received April 22, 1974)

The dimeric and trimeric 2-(*p*-tolyloxy)ethyl acetate-formaldehyde polymer model compounds and the halogenated compound of the dimer were synthesized. 2,2'-Methylenebis(5-methyl-1,2-phenyleneoxy)diethyl acetate was synthesized by the reaction of 2-(*p*-tolyloxy)ethyl acetate with formaldehyde in acidic media. 2-[2-(2-Acetoxyethoxy-3-chloro-5-methylbenzyl)-4-methylphenoxy]ethyl acetate was prepared by the reaction of 6-chloro-4,4'-dimethyl-2,2'-methylenediphenol with 2-chloroethanol, followed by treatment with acetic anhydride, and 2-[2,6-bis(2-acetoxyethoxy-5-methylbenzyl)-4-methylphenoxy]ethyl acetate from 2,6-bis(2-hydroxy-5-methylbenzyl)-4-methylphenol.

A high molecular weight polymer was obtained[2] by the reaction of 2-(*p*-tolyloxy)ethyl acetate with formaldehyde in acetic acid solution in the presence of perchloric acid as a catalyst.

We have synthesized the dimeric and trimeric 2-(*p*-tolyloxy)ethyl acetate-formaldehyde polymer model compounds and the halogenated compound of the dimer.

Synthesis of the Dimeric Compounds. The dimer of 2-(*p*-tolyloxy)ethyl acetate-formaldehyde polymer model compounds and the halogenated compound were synthesized as shown in Chart 1. The reaction of 4,4'-dimethyl-2,2'-methylenediphenol(**1**) with 2-chloroethanol and sodium gave 2-[2-(2-hydroxy-5-methylbenzyl)-4-methylphenoxy]ethanol(**5**) in an 83% yield, but not 2,2'-methylenebis(5-methyl-1,2-phenyleneoxy)-diethyl acetate (**8**). 6-Chloro-4,4'-dimethyl-2,2'-methylenediphenol(**2**) gave 2-[2-(2-hydroxyethoxy-3-chloro-5-methylbenzyl)-4-methylphenoxy]ethanol(**6**) in a 75% yield. **6** was acetylated with acetic anhydride to form 2-[2-(2-acetoxyethoxy-3-chloro-5-methylbenzyl)-4-methylphenoxy]ethyl acetate (**7**).

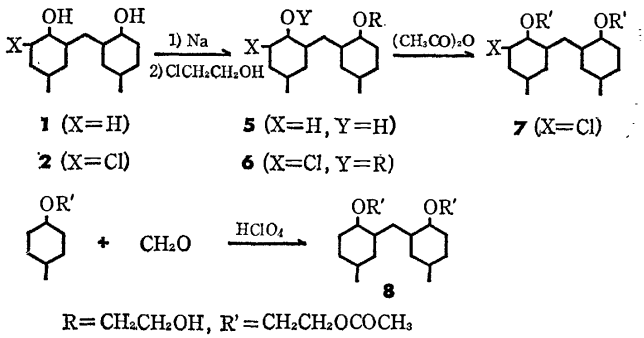

Chart 1.

The reaction of 2-(*p*-tolyloxy)ethyl acetate with formaldehyde in acetic acid solution in the presence of perchloric acid as a catalyst gave **8**.

Synthesis of the Trimeric Compounds. The reaction of 2,6-bis(2-hydroxy-5-methylbenzyl)-4-methylphenol(**3**) with 2-chloroethanol and sodium gave mono, di, and tri ethanol derivatives; 2-(2-hydroxyethoxy-5-methylbenzyl)-6-(2-hydroxy-5-methylbenzyl)-4-methylphenol(**9**), 2,6-bis(2-hydroxyethoxy-5-methylbenzyl)-4-methylphenol(**10**), and 2-[2,6-bis(2-hydroxyethoxy-5-methylbenzyl)-4-methylphenoxy]ethanol(**11**). The tri

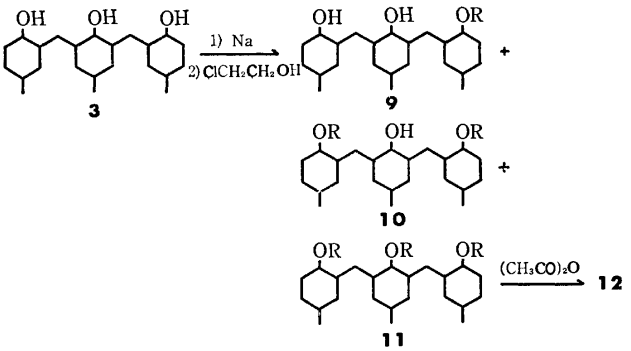

Chart 2.

ethanol derivative(**11**) was acetylated to give the desired compound; 2-[2,6-bis(2-acetoxyethoxy-5-methylbenzyl)-4-methylphenoxy]ethyl acetate(**12**)(see Chart 2).

2-(2-Hydroxyethoxy-3-chloro-5-methylbenzyl)-6-(2-hydroxyethoxy-5-methylbenzyl)-4-methylphenol(**13**) was isolated in a low yield from the reaction product of 2-(2-hydroxy-3-chloro-5-methylbenzyl)-6-(2-hydroxy-5-methylbenzyl)-4-methylphenol(**4**) with 2-chloroethanol and sodium.

Hydrogen Bonds of the Oligomeric Phenols. The presence of hydrogen bonds has been postulated to explain the peculiar behavior of certain phenolic resin intermediates.[3] Infrared spectroscopic,[4-7] potentiometric,[8-10] and kinetic[11] results showed the presence of intramolecular OH···OH-bonds in a number of polyphenols of novolak type. The IR spectral data of the oligomeric phenols are given in Table 1. Compound **1** exhibits three OH absorptions in carbon tetrachloride in line with the previous IR studies.[7] The concentration-independent band at 3553 cm^{-1} has been assigned to an intramolecular OH···OH-bond. The band at 3605 cm^{-1} can be assigned to the stretching vibrations of the free OH group, while the broad concentration-dependent band at 3300 cm^{-1} is assigned to the closed ring of H-bonds resulting from dimeric association. On account of the intramolecular OH··· OH-bond as illustrated in I, the reactivity of the hydrogen-bonded OH group of **1** might be lower than that of the free OH group.

Compound **2** has a more complex spectrum, show-

Table 1. Hydroxy stretching frequencies, ν(OH) of the oligomeric phenols in carbon tetrachloride

Compound	Concn. (mM)	ν (cm^{-1})	ε	Concn. (mM)	ν (cm^{-1})	ε	Assignments
p-Cresol	25	3615	211				Free
		3480	8				Inter
2-Chloro-*p*-cresol	25	3610	12				Free
		3553	108				Intra OH···Cl
1	25	3605	98	2.5	3605	180	Free
		3460	116		3470	132	Intra OH···OH
		3300 br	154				Inter
2	25	3610	63	2.5	3615	68	Free
		3532	151		3532	160	Intra OH···Cl
		3490	121		3495	116	Intra OH···OH
		3375	123				Inter
		3240	85				Inter
3	4.0	3590	32				Free

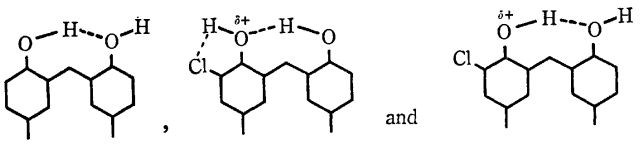
		3240	152				Inter

All the samples were examined in 1.0 mm. cells. br, broad. sh, shoulder.

ing three concentration-independent bands in the OH region. The band at 3610 cm^{-1} is characteristic of the free OH group. Two bands at 3545 and 3490 cm^{-1} can be assigned to an intramolecular OH···Cl-bond and an intramolecular OH···OH-bond, respectively. Thus, we suggest that two conformers (II-a and II-b) are present in compound **2**.



I II-a and II-b

The intramolecular OH···OH-bond of type II-a might be weaker than that of **1** on account of the electron withdrawing of Cl-atom and the fact that the OH···Cl-bond is weaker than the OH···OH-bond, while the H-atom having the H-bond of type II-b might easily be released from phenol nucleus.

Actually, 2-chloro-*p*-cresol, which has mainly a *cis*-form[12] involving an intramolecular OH···Cl-bond (3553 cm^{-1}), gave 2-chloro-4-methylphenoxy-ethanol in a 70% yield.[13] The bonding shift of the intramolecular H-bond of **1** (Δ145 cm^{-1}) is higher than that of **2** (Δ120 cm^{-1}).

This stronger intramolecular H-bond might disturb the addition reaction.

Compound **3** shows the presence of three OH absorptions. From the previous results,[4] we assign two bands at 3590 and 3350 cm^{-1} to an intramolecular OH···OH···OH-bond, two H-atoms being involved in an intramolecular H-bond. Compound **4** shows three OH absorptions. Two bands at 3525 and 3148 cm^{-1} are assigned to an intramolecular OH···OH···OH···Cl-bond. The broad, concentration-dependent, band at 3240 cm^{-1} is assigned to the intermolecular H-bonds.

However, these spectroscopic studies can give no explanation for the present synthetic results.

Experimental

General. Melting points are uncorrected. ^{1}H-NMR spectra were taken on a JEOL Model PS-100 spectrometer in a deuterochloroform or carbon tetrachloride solution, with tetramethylsilane as an internal standard. Chemical shift values are given in terms of τ. IR spectra were obtained on a Hitachi EPI-G2 or a Hitachi Model 225 spectrophotometer. Mass spectra were obtained on a Hitachi RMU-6 mass spectrometer at 70 eV.

Materials. 2-(*p*-Tolyloxy)ethyl acetate; bp 92—94 °C/2 mmHg[2] [lit,[2] 104—110 °C/5 mmHg], 2-chloro-*p*-cresol; bp 82—83 °C/13 mmHg[14] [lit,[14] 195—197 °C], 4,4′-dimethyl-2,2′-methylenediphenol(**1**); mp 123—125 °C[15] [lit,[15] 126 °C], 6-chloro-4,4′-dimethyl-2,2′-methylenediphenol (**2**); mp 168—172 °C[16] [lit,[16] 170 °C], 2,6-bis(2-hydroxy-5-methylbenzyl)-4-methylphenol(**3**); mp 214—217 °C[15] [lit,[15] 215 °C], and 2-(2-hydroxy-3-chloro-5-methylbenzyl)-6-(2-hydroxy-5-methylbenzyl)-4-methylphenol(**4**); mp 188—190 °C[17] [lit,[17] 187 °C] were prepared by the methods in the literature. All other reagents were commercial products.

*2-[2-(2-Hydroxy-5-methylbenzyl)-4-methylphenoxy]ethanol(**5**).* A mixture of **1** (45.6 g) and sodium (11 g) in ethanol (140 ml) was stirred for 16.5 hr at 80 °C. 2-Chloroethanol (41.6 g) was then added to the solution and refluxed for 20.5 hr. After being cooled, the product which separated was recrystallized from ligroin to give colorless plates (**5**); yield, 44 g (83%), mp 99—100 °C. IR(KBr); 3375 and 3240 cm^{-1}. NMR ($CDCl_3$, 5.0%); 2.88—3.48 (6H, m, phenyl), 5.01 (2H, b, OH), 5.76—6.30 (6H, m, CH_2CH_2 and $PhCH_2Ph$), 7.74(3H, s, CH_3), and 7.79 (3H, s, CH_3). MS; *m/e* 272 (M^+). Found: C, 75.18; H, 7.38%. Calcd for $C_{17}H_{20}O_3$: C, 74.97; H, 7.40%.

5 (2.7 g) was refluxed with acetic anhydride (20 ml) for 5 hr to give 2-[2-(2-acetoxy-5-methylbenzyl)-4-methylphenoxy]ethyl acetate; yield, 3.1 g, mp 50—51.8 °C (from ligroin). IR(KBr); 1750 cm^{-1}. Found: C, 70.69; H, 6.66%.

Calcd for $C_{21}H_{24}O_5$: C, 70.77; H, 6.79%.

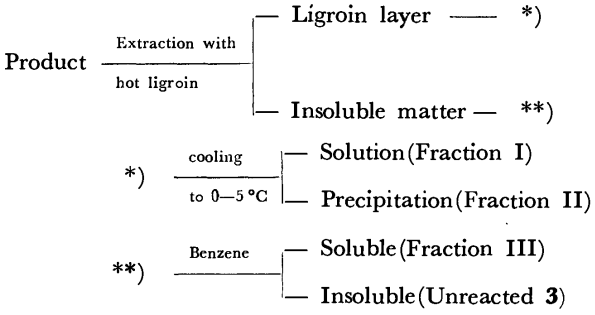
2-[2-(2-Acetoxyethoxy-3-chloro-5-methylbenzyl)-4-methylphenoxy]-ethyl Acetate (7). **2** (105 g) was added to a solution of sodium (22.1 g) in ethanol (280 ml). After being stirred for 14 hr at refluxing temperature, 2-chloroethanol (80.5 g) was added to the reaction mixture at room temperature and the mixture was refluxed for 17 hr. The precipitated sodium chloride was removed and the filtrate was cooled to 0 °C to give white crystal (105 g); 2-[2-(2-hydroxyethoxy-3-chloro-5-methylbenzyl)-4-methylphenoxy]ethanol (**6**). yield, 85%; mp 114—116 °C (from a mixture of benzene and ligroin). IR(KBr); 3440 and 3390 cm^{-1}. Found: C, 64.52; H, 6.78%. Calcd for $C_{19}H_{23}O_4Cl$: C, 65.05; H, 6.61%.

A mixture of **6** (70 g) and acetic anhydride (204 g) was refluxed for 13 hr. After the solvents had been removed, benzene solution of the residue was washed successively with sodium hydroxide solution and water, dried over anhydrous sodium sulfate, and then distilled to give **7** (70 g) as a colorless viscous liquid; bp 205—210 °C/0.001 mmHg. IR(neat); 1735 cm^{-1}. NMR (CCl_4, 10%); 3.04—3.50 (5H, m, phenyl), 5.58—6.15(8H, m, $C\underline{H}_2C\underline{H}_2$), 6.13(2H, s, $PhC\underline{H}_2$-Ph), 7.72(3H, s, $PhC\underline{H}_3$), 7.82(3H, s, $PhC\underline{H}_3$), 8.02(3H, s, $COC\underline{H}_3$), and 8.06 (3H, s, $COC\underline{H}_3$). MS; *m/e* 434(M^+). Found: C, 63.21; H, 6.19%. Calcd for $C_{23}H_{27}O_6Cl$: C, 63.52; H, 6.26%.

2,2'-Methylenebis(5-methyl-1,2-phenyleneoxy)diethyl Acetate (8). Perchloric acid (10 ml) was added to a solution of 2-(*p*-tolyloxy)ethyl acetate (14.4 g) and paraformaldehyde (0.7 g) in acetic acid (70 ml). The reaction mixture was stirred for 30 hr at 30 °C. After completion of the reaction, the mixture was poured into water and washed with water. Oily product was recrystallized from benzene to give **8** (7.2 g); colorless plates, mp 98—101 °C. IR(KBr); 1730 cm^{-1}. NMR ($CDCl_3$, 15%); 2.98—3.41(6H, m, phenyl), 5.53—6.04(8H, m, $C\underline{H}_2C\underline{H}_2$), 6.01(2H, s, $PhC\underline{H}_2Ph$), 7.78(6H, m, $PhC\underline{H}_3$), and 7.95(6H, s, $COC\underline{H}_3$). MS: *m/e* 400(M^+). Found: C, 68.72; H, 7.21%. Calcd for $C_{23}H_{28}O_6$: C, 68.98; H, 7.05%.

After **8** (2.0 g) was refluxed in methanol (17 ml) containing NaOH (0.5 g) for 2 hr, the reaction mixture was poured into ice water. White precipitate was recrystallized from benzene to give 2,2'-methylenebis(5-methyl-1,2-phenyleneoxy)diethanol (1.5 g); mp 105—107 °C. IR(KBr); 3350 cm^{-1}. Found: C, 72.26; H, 7.68%. Calcd for $C_{19}H_{24}O_4$: C, 72.13; H, 7.65%.

*Reaction of **3** with 2-Chloroethanol.* **3** (52 g) was added to a solution of sodium (12.4 g) in ethanol (250 ml). After being kept at 80 °C for 25 hr, 2-chloroethanol (45 g) was added to the solution and refluxed with stirring for 20 hr. After the reaction, the reaction mixture was concentrated to give a residue which separated three compounds according to the given scheme.



The compound(Fraction I) easily soluble in ligroin was recrystallized from ligroin. Colorless needle crystals were obtained, mp 146—149 °C. Yield, 0.82 g. IR(KBr): 3360 and 3250 cm^{-1}. NMR($CDCl_3$, 14%); 1.98—2.44(2H, b, O$\underline{H}$), 2.90—3.36(8H, m, phenyl), 5.82—6.18 (8H, m, $C\underline{H}_2$-$C\underline{H}_2$), 6.17(2H, s, $PhC\underline{H}_2Ph$), 6.20(2H, s, $PhC\underline{H}_2Ph$), 7.40—7.60(1H, b, O$\underline{H}$), 7.73(3H, s, $C\underline{H}_3$), and 7.77(6H, s, $C\underline{H}_3$). MS; *m/e* 392(M^+). Found: C, 76.14; H, 7.14%. Calcd for $C_{25}H_{28}O_4$: C, 76.50; H, 7.19%. The compound was concluded to be 2-(2-hydroxyethoxy-5-methylbenzyl)-6-(2-hydroxy-5-methylbenzyl)-4-methylphenol (**9**). A solution of **9** (0.2 g) in acetic anhydride (10 ml) was treated by the previous method to give acetylated compound (0.1 g); colorless needle, mp 95—97 °C. IR(KBr); 1750 cm^{-1}. Found: C, 71.73; H, 6.62%. Calcd for $C_{31}H_{34}O_7$: C, 71.80; H, 6.60%.

The hot ligroin soluble compound(Fraction II) was recrystallized from benzene to give 2,6-bis(2-hydroxyethoxy-5-methylbenzyl)-4-methylphenol(**10**); colorless plate, mp 115—120 °C, yield, 3.5 g. IR(KBr); 3400 cm^{-1}. NMR($CDCl_3$, 5.0%); 2.90—3.45(8H, m, phenyl), 4.60—5.50(3H, b, O$\underline{H}$), 5.85—6.30(8H, m, $C\underline{H}_2C\underline{H}_2$), 6.14(2H, s, $PhC\underline{H}_2Ph$), 7.75 (6H, s, $C\underline{H}_3$), and 7.83 (3H, s, $C\underline{H}_3$). MS; *m/e* 436(M^+). Found: C, 74.09; H, 7.46%. Calcd for $C_{27}H_{32}O_5$: C, 74.29; H, 7.39%. The acetylation of **10** gave oily product. IR(neat); 1730 cm^{-1}. Found: C, 70.04; H, 6.87%. Calcd for $C_{33}H_{38}O_8$: C, 70.44; H, 6.81%.

2-[2,6-Bis(2-hydroxyethoxy-5-methylbenzyl)-4-methylphenoxy]ethanol(**11**) was obtained by repeated crystallizations from the fraction III, with benzene as a solvent; mp 118—121 °C, yield, 2.2 g. IR(KBr): 3400 cm^{-1}. NMR ($CDCl_3$, 2.0%); 2.85—3.45(8H, m, phenyl), 5.90—6.40(15H, m, $C\underline{H}_2C\underline{H}_2$ and O$\underline{H}$), 6.60(4H, s, $PhC\underline{H}_2Ph$), 7.72(3H, s, $C\underline{H}_3$), and 7.83(6H, s, $C\underline{H}_3$). MS; *m/e* 480(M^+). Found: C, 72.45; H, 7.48%. Calcd for $C_{29}H_{36}O_6$: C, 72.48; H, 7.55%.

*2-[2,6-Bis(2-acetoxyethoxy-5-methylbenzyl)-4-methylphenoxy]ethyl Acetate(**12**).* A sample of **11** (1 g) was refluxed with acetic anhydride (20 ml) to give **12** (0.8 g); colorless plate, mp 64—65 °C (from ligroin). IR(KBr); 1735 cm^{-1}. NMR ($CDCl_3$, 5.0%); 2.90—3.40(8H, m, phenyl), 5.50—6.00(12H, m, $C\underline{H}_2C\underline{H}_2$), 6.04(4H, s, $PhC\underline{H}_2Ph$), 7.78(6H, s, $PhC\underline{H}_3$), 7.86(3H, s, $PhC\underline{H}_3$), 7.97(3H, s, $COC\underline{H}_3$), and 7.99(6H, s, $COC\underline{H}_3$). MS; *m/e* 606(M^+). Found: C, 69.02; H, 6.93%. Calcd for $C_{35}H_{42}O_9$: C, 69.29; H, 6.98%.

*Reaction of **4** with 2-Chloroethanol.* **4** (46 g) was added to a solution of sodium (9.9 g) in ethanol (150 ml). The resulting solution was stirred at 80 °C for 22 hr, 2-chloroethanol (36 g) then being added. The mixture was refluxed for 22 hr. After being cooled, the residue which separated was recrystallized from a mixture of ligroin and dioxane to give 2-(2-hydroxyethoxy-3-chloro-5-methylbenzyl)-6-(2-hydroxyethoxy-5-methylbenzyl)-4-methylphenol (**13**); colorless plate, mp 143—145 °C, yield, 3 g. IR(KBr): 3400 cm^{-1}. NMR ($CDCl_3$, 7.0%); 2.89—3.45(7H, m, phenyl), 5.26—6.35 (15H, m, $PhC\underline{H}_2Ph$ and $C\underline{H}_2C\underline{H}_2$), 7.25(3H, s, $C\underline{H}_3$), 7.79(3H, s, $C\underline{H}_3$), and 7.84(3H, s, $C\underline{H}_3$). MS; *m/e* 470(M^+). Found: C, 68.90; H, 6.67%. Calcd for $C_{27}H_{31}O_5Cl$: C, 68.85; H, 6.63%. Acetylated compound of **13** was an oily substance. IR (neat); 1750 cm^{-1}. Found: C, 66.52; H, 6.22%. Calcd for $C_{33}H_{37}O_8Cl$: C, 66.38; H, 6.25%.

Nitration of 9,10-Dimethylanthracene and 9,10-Diethylanthracene[1]

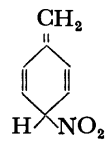
Hitomi SUZUKI, Hajime YONEDA, and Terukiyo HANAFUSA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-sendamachi, Hiroshima 730

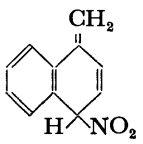
(Received April 23, 1974)

9,10-Dimethylanthracene gave 9-nitromethyl-10-methylanthracene as a major product, when treated with fuming nitric acid in dichloromethane at low temperatures. In contrast, 9,10-diethylanthracene yielded 9-nitro-10-hydroxy-9,10-diethyl-9,10-dihydroanthracene, which in refluxing alcohol was readily converted into 9,10-dialkoxy-9,10-diethyl-9,10-dihydroanthracene. Possible reaction sequences for the side-chain nitration have been discussed.

The mechanistic course of side-chain nitration of polymethylated aromatics proceeds along one of two paths depending on the nature of the substrate involved. Action of nitric acid upon polymethylbenzenes at low temperatures usually leads to the formation of benzyl nitrates.[2] In contrast, a similar treatment of polymethylnaphthalenes results in side-chain nitration, giving 1-naphthylnitromethanes as a major porduct.[3] Formation of these unusual products has been explained in terms of a nitromethylene cyclohexadiene intermediate (I or II), derived from the nitroarenium ion by proton release from the activated alkyl side-chain.[4] Thus, a marked difference in the modes of reaction observed for the benzene and the naphthalene series of compounds would be attributed to the presence of a fused benzene ring in the latter systems. If the dichotomy between the reaction courses taken in the nitration of benzenes on the one hand and of naphthalenes on the other comes from the difference in the relative stabilities of I and II, 9,10-dimethylanthracene (III) is expected to behave in a manner analogous to polymethylnaphthalenes, giving a side-chain nitrated product (VI), since the initial attack of nitronium ion on the hydrocarbon occurs at 9-position to form the arenium ion (IV), from which a nitromethylene cyclohexadiene (V) flanked with fused benzene rings on both sides would be formed (Scheme 1). The relative stability of the intermediate dienes should increase in the order I<II<V with an increase in the number of intact benzene rings. 9,10-Dimethyl- and 9,10-diethylanthracenes (III and IX) were prepared, their behavior towards the nitrating agent being investigated.



I

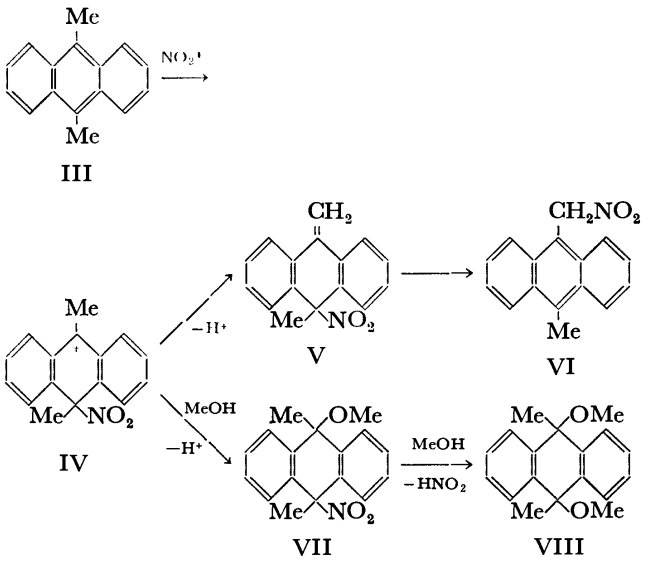


II

A dilute solution of III in purified dichloromethane was treated with two equivalent amounts of nitric acid (d=1.5) at −10—−5 °C in the dark. Chromatography of the crude product on deactivated alumina gave rise to the isolation of a new crystalline compound (VI), mp 197—198 °C, as the main product (82%); molecular formula $C_{16}H_{13}NO_2$, infrared bands (NO_2) at 1546 and 1360 cm^{-1}, and proton resonances at δ 3.20 (s, 3H), 6.51 (s, 2H), 7.50—7.75 (m, 4H), and 8.23—8.55 (m, 4H). The mass spectrum showed the expected peaks at m/e 251 (M^+) and 205 (M^+-NO_2). The results are in line with its formulation as 9-nitromethyl-10-methylanthracene (VI). Its identity was further confirmed by an independent synthesis; 9-methylanthracene was chloromethylated to 9-chloromethyl-10-methylanthracene,[5] which was then treated with silver nitrite in acetonitrile to yield VI.

When III was treated with the nitrating agent in commercial dichloromethane of GR grade and the crude product mixture was passed over a deactivated alumina column, an appreciable amount of another nitro-compound (VII), with a composition fitting $C_{17}H_{17}NO_3$ best, was obtained besides VI. Proton NMR spectrum showed peaks at δ 1.64 (s, 3H), 2.16 (s, 3H), 2.91 (s, 3H), and 7.26—7.91 ppm (m, 8H). A molecular ion peak at m/e 283 is in line with the hypothesis that one more carbon atom is added to anthracene during the reaction. Additional peaks were observed at m/e 268 (M^+-Me), 253 (M^+-2Me), 237 (M^+-Me-MeO or M^+-NO_2), 222 (M^+-Me-NO_2), and 206 (M^+-MeO-NO_2). In the infrared spectrum, there were strong bands at 1535 and 1348 cm^{-1} (NO_2), and 1100 cm^{-1} (C-O-C). Heating of VII in methanol caused facile replacement of the nitro group by the methoxy group, giving a compound (VIII) with composition $C_{18}H_{20}O_2$. Proton NMR spectrum of VIII showed resonance at δ 1.63 (s, 6H), 2.80 (s, 6H), and 7.28—7.79 ppm (m, 8H) with an intensity ratio 3 : 3 : 4. Its mass spectrum showed peaks at 268 (M^+), 253 (M^+—Me), 237 (M^+—MeO), 222 (M^+—Me—MeO), and 206 (M^+—2MeO), its infrared spectrum indicating the presence of ether linkage (1100 cm^{-1}). Chemical and spectral data of VII and VIII are in line with the formulation of the former compound as 9-nitro-10-methoxy-9,10-dimethyl-9,10-dihydroanthracene and the latter as 9,10-dimethoxy-9,10-dimethyl-9,10-dihydroanthracene. *cis*-Configuration can be assigned to VIII by comparison with known spectral data.[6] Discrepancy in the results from the reactions in commercial dichloromethane and purified dichloromethane would be attributed to the presence of a very minor amount of methanol as an impurity or an antioxidant. A possible course for the formation is indicated in Scheme 1.

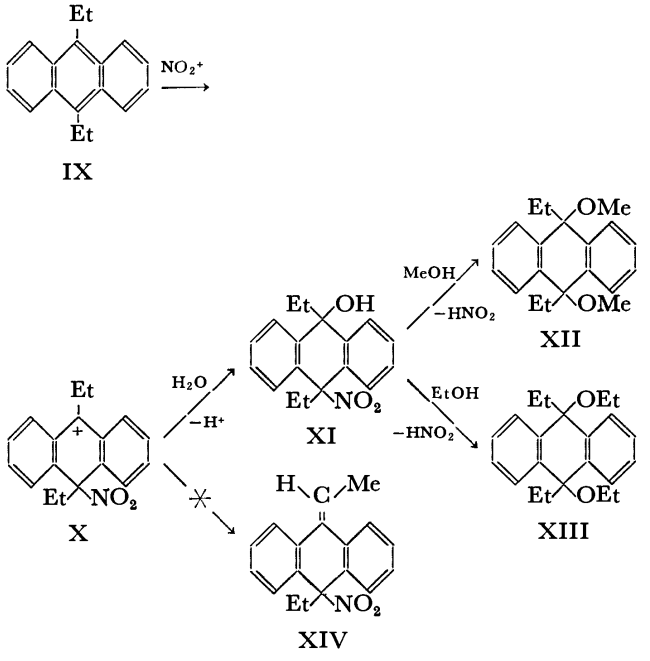
It is assumed that nitronium ion attacks hydrocarbon III to form arenium ion IV, which will release a proton from the activated methyl group at 10-position to form a methylene cyclohexadiene V, which is then transformed into nitromethyl compound VI. In the presence of methanol, the arenium ion IV would scavenge the nucleophile to form an addition product



Scheme 1.

VII rather than to release proton from the side-chain to form V.

When 9,10-diethylanthracene (IX) was allowed to react with nitric acid in purified dichloromethane, a single crystalline product with the composition $C_{18}H_{19}NO_3$ was isolated in a 47% yield. It showed infrared bands at 3540 (OH), 1542, and 1358 cm^{-1} (NO_2), and ^1H NMR peaks at δ 0.31 (t, 3H), 0.50 (t, 3H), 2.11 (q, 2H), 2.34 (s, H), 2.89 (q, 2H), and 7.30—8.01 ppm (m, 8H). The results are in line with the structure, 9-nitro-10-hydroxy-9,10-diethyl-9,10-dihydroanthracene (XI). When refluxed in methanol, XI was converted into a mixture of *cis*- and *trans*-9,10-dimethoxy-9,10-diethyl-9,10-dihydroanthracenes (XII), the former being predominant on prolonged heating.[6] A similar treatment of XI in ethanol led to the formation of 9,10-diethoxy-9,10-diethyl-9,10-dihydroanthracene (XIII).



Scheme 2.

Nitration of IX is in contrast to that of pentaethylbenzene, which gave 2,3,4,5-tetraethyl-α-methylbenzyl nitrate as the sole significant product.[7] Failure of IX to undergo reactions on the side-chain might be taken as an evidence for the intermediacy of a nitromethylene cyclohexadiene V in the side-chain substitution. Conversion of the arenium ion (X) into the diene (XIV) forces the ethylidene group to be coplanar with the *peri*-hydrogen atoms subjected to a considerable steric interaction. Thus, X would take up an anion to form an adduct XI rather than to release α-proton to form XIV (Scheme 2).

A sharp change in the modes of reaction towards the nitrating agent on passing from benzenes to naphthalenes and anthracenes would reflect the diminished tendency of the intermediate dienes II and V toward aromatization. With less stable diene I derived from polymethylated benzene, the initial process could involve heterolytic scission of the carbon-nitrogen bond to give a benzyl cation-nitrite ion pair. The benzylic cation carries most of its positive charge on the *exo*-cyclic carbon atom. Thus, it tends to recombine with the ambident nitrite ion at benzylic carbon atom through the more negative oxygen atom, giving benzyl nitrite which will be oxidized to the corresponding nitrate. With the more stable dienes II and V derived from polymethylated naphthalene and anthracene, their tendency to aromatize decreases due to the presence of one or two intact benzene nuclei. This corresponds to the partial formation of a positive charge on the *exo*-cyclic carbon atom, when the fission of the nitrogen-carbon bond takes place.[8] Thus, the combination of 1-naphthylmethylium and 9-anthrylmethylium ions with the ambident nitrite ion would occur preferably through the less negative nitrogen atom rather than oxygen atom, leading to the formation of side-chain nitro compounds.

Alternative explanations can be given for the conversion of nitromethylene cyclohexadienes into side-chain substitution products. The side-chain nitration might proceed via S_E2' mechanism which involves the attack of nitronium ion on the terminal methylene carbon of II or V, redistribution of electrons to regain the aromatic system, and the concomitant departure of the nitro group from the ring. The side-chain nitrooxylation might take place through a formally reversed sequence, S_N2' mechanism, which involves attachment of the nitrate ion to the terminal methylene carbon of I, departure of the nitro group as an anion, and reorganization of the system to aromatic nucleus.

Experimental

All melting points are uncorrected. Infrared spectra were measured in Nujol mulls with a Jasco DS-402G spectrophotometer. Proton NMR spectra were obtained for deuteriochloroform solutions on a Varian T-60 spectrometer with TMS as an internal standard.

9,10-Dimethylanthracene (mp 180—181 °C;[9] ^1H NMR: δ 3.07(s, 6H), 7.36—7.71 (m, 4H), and 8.20—8.55 ppm (m, 4H)) was prepared by the LAH reduction of 9,10-bis(chloromethyl)-anthracene,[10] and 9,10-diethylanthracene (mp 144—145

°C;[11] ^{1}H NMR: δ 1.39 (t, 6H), 3.49 (q, 4H), 7.41—7.78 (m, 4H), and 8.28—8.63 ppm (m, 4H)) was obtained by the reduction of 9,10-diethyl-9,10-dihydroxy-9,10-dihydroanthracene with stannous chloride in methanol.[12]

Purification of Dichloromethane Used as Solvent for Nitration. Commercial dichloromethane (GR grade as well as for spectroscopic use, Tokyo Kasei, Nakarai, Wako, and Katayama) was shaken several times with one-fifth its volume of concentrated sulfuric acid and then thoroughly washed with water. This was then shaken with 5%-aqueous sodium hydroxide, washed thoroughly with water, refluxed over calcium hydride for two hours, and finally distilled through an efficient column; the first and last portions of the distillate were discarded.

9-Nitromethyl-10-methylanthracene (VI). A warm solution of 9-chloromethyl-10-methylanthracene[5] (1.14 g) in acetonitrile (10 ml) was added all at once to a magnetically stirred solution of silver nitrite (1.0 g) in acetonitrile (5 ml). The mixture was stirred overnight and silver chloride was removed by filtration. The residue obtained after removal of the solvent was taken up in hot ethanol, from which VI separated as fine needles. Mp 196—198 °C. Yield, 0.5 g.

Found: C, 76.23; H, 5.25; N, 5.51%. Calcd for $C_{16}H_{13}NO_2$: C, 76.47; H, 5.22; N, 5.57%.

Procedure for the Nitration of 9,10-Dialkylanthracenes. 1) A solution of 9,10-dialkylanthracene (0.002 mol; 0.41 g for III and 0.47 g for IX) in purified dichloromethane (5 ml) was vigorously stirred with external cooling at −12 to −2 °C, and a solution of nitric acid (d=1.5; 0.002 mol, 0.86 ml) in the same solvent (4 ml) was added through a syringe over a period of 30 min. The mixture was kept in the dark at −10 to −5 °C for 3 hr and then quenched by the addition of water. The organic layer was separated, washed with dilute aqueous sodium hydrogen carbonate, and dried over anhydrous magnesium sulfate. The crystalline solid obtained after removal of the solvent was examined by infrared and proton NMR spectroscopy as well as by thin-layer chromatography.

Crude product (0.50 g) from III was crystallized from benzene to give VI as slightly yellow needles, mp 197—198 °C. Yield, 0.41 g (82%).

Found: C, 76.53; H, 5.27; N, 5.25%. Calcd for $C_{16}H_{13}NO_2$: C, 76.48; H, 5.21; N, 5.57%.

Crude product (0.59 g) from IX was recrystallized from a mixture of carbon tetrachloride and light petroleum to give XI as ivory-colored needles, mp 138—139 °C. Yield, 0.27 g (46%).

Found: C, 72.44; H, 6.40; N, 4.42%. Calcd for $C_{18}H_{19}NO_3$: C, 72.71; H, 6.44; N, 4.71%.

2) A solution of III (2.06 g, 0.01 mol) in dichloromethane (GR grade, 100 ml) was treated with nitric acid (d=1.5, 0.43 ml; 0.02 mol) in a similar manner to that for 1). A crude product (2.14 g) obtained after ordinary work-up was found to be a mixture of several compounds, as shown by a complicated feature of its proton NMR spectrum; at least eight prominent peaks were observed in the aromatic and aliphatic methyl proton regions (δ 1.64, 1.69, 1.78, 2.16, 2.36, 2.84, 2.91, and 3.20 ppm). Chromatography of this mixture on alumina gave VII from benzene eluates as needles, mp 152—155 °C. Yield, 0.75 g.

Found: C, 71.73; H, 5.99; N, 4.73%. Calcd for $C_{17}H_{17}NO_3$: C, 72.07; H, 6.05; N, 4.94%.

Alcoholysis of Addition Products. The addition product was dissolved in excess alcohol and heated under reflux for a few minutes. Evaporation of the solution gave the corresponding bis-alkoxy ether in a good yield.

VIII (*cis*): mp 161—166 °C.

Found: C, 80.34; H, 7.51%. Calcd for $C_{18}H_{20}O_2$: C, 80.56; H, 7.51%.

XII (*cis*): mp 147—149 °C. ^{1}H NMR: δ 0.76 (t, 3H), 2.02 (q, 2H), 2.71 (s, 3H), and 7.23—7.78 ppm (m, 8H).[6,13] *trans*-Isomer exhibited absorptions at δ 0.27 (t, 3H), 2.08 (q, 2H), 2.90 (s, 3H), and 7.23—7.78 ppm (m, 8H).

XIII: mp 125—126 °C. ^{1}H NMR: δ 0.26 (t, 3H), 1.10 (t, 3H), 2.11 (q, 2H), 3.02 (q, 2H), and 7.20—7.80 ppm (m, 8H).

Found: C, 81.15; H, 8.75%. Calcd for $C_{22}H_{28}O_2$: C, 81.44; H, 8.70%.

The presence of only one set of signals in the proton NMR spectrum of XIII suggests that the obtained compound is one of the two possible geometrical isomers, probably *cis*, and not their mixture.

Expenses for this work were defrayed by a grant from the Ministry of Education.

α,β-Unsaturated Carboxylic Acid Derivatives. VI. New Synthesis of N-Acyl-α-dehydroamino Acid Esters[1]

Chung-gi SHIN, Katsumi NANJO, Eiichi ANDO, and Juji YOSHIMURA*

Laboratory of Organic, Chemistry, Faculty of Technology, Kanagawa University, Rokkakubashi, Kanagawa-ku, Yokohama 221

**Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152*

(Received April 25, 1974)

A new synthetic route to α,β-unsaturated *N*-acyl-α-amino acid esters (*N*-acyl-α-dehydroamino acid esters) is described. The dehydroamino acid esters were prepared by the dehydration of α-(*N*-acylhydroxyamino) acid esters (**10**), derived from the acylation of α-hydroxyamino acid esters (**2** and **6**), and by the elimination of carboxylic acid from α-(*N*-acyl-*O*-acetyl), α-(*N,O*-diacetyl, dipropionyl and diethoxycarbonyl-hydroxyamino) acid esters, obtained by the acylation of **2**, **6** and **10**, in the presence of triethylamine.

It is known that synthetic methods of 2-(2-substituted-acetamino)-2-alkenoic acids,[2] *i.e.*, *N*-acyl-α-dehydroamino acids (**4** and **8**) were derived in the following ways. Greenstein *et al.* and Wieland *et al.* reported the preparation of several *N*-acyl-α-dehydroamino acids (**4**; free acid) by treating a mixture of α-oxocarboxylic acids and acetonitrile[3] or acetamide[4] with dry hydrogen chloride or concentrated sulfuric acid, respectively. However, the yields are low, and isolation and purification of the products is difficult.[3-5] A convenient synthesis of *N*-chloroacetyl-α-dehydroamino acid esters by the condensation of several ethyl α-oxocarboxylates with chloroacetamide in the presence of concentrated sulfuric acid or phosphoryl chloride was recently reported.[6]

Bergmann *et al.*[7] and other workers[8-10] described another preparative method of **4** *via* the corresponding 4-alkylidene and arylidene-2-substituted-oxazolones.

Shin *et al.* reported that compound **4** was obtained by acylation of β-substituted-α-amino-α-alkenoic acid esters obtained by the reduction of the corresponding nitroolefins or β-methoxy-α-nitro compound.[11]

This paper deals with another route for the preparation of *N*-acyl α-dehydroamino acid esters from the α-hydroxyamino acid esters (**2** and **6**) *via* α-(*N*-monoacylhydroxyamino) (**10**) and α-(*N,O*-diacylhydroxyamino) acid esters (**3** and **7**).

Results and Discussion

Preparation of 2 and 6. *t*-Butyl α-hydroxyamino carboxylates (**2**) were obtained by the reaction of *t*-butyl α-bromocarboxylates (**1**),[12] obtained by the esterification of the corresponding acid bromide with hydroxylamine in methanol in the presence of triethylamine in good yields. However, ethyl α-hydroxyamino carboxylates (**2**), which could not be obtained directly by the reaction of ethyl α-bromocarboxylates with hydroxylamine, were prepared by the esterification of the free α-hydroxyamino carboxylic acids (**2**; R^1=H)[13] obtained by the saponification of **2** (R^1=*t*-Bu) with concentrated hydrochloric acid.

By a method reported recently,[11b] ethyl 2-hydroxyamino-3-methoxy-3-phenylpropanoate (**6**) was prepared by the reduction of ethyl 3-methoxy-2-nitro-3-phenylpropanoate (**5**), derived from ethyl 2-nitrocinnamate and methanol in the presence of sodium methoxide, with aluminum-amalgam in ether at room temperature.

The IR spectra of the products (**2**) and (**6**) showed N–OH and N–H bands at 3450—3250 and 3275—3150 cm^{-1} regions. The results are summarized in Table 1.

Acylation of 2 and 6. Acylation of **2** and **6** was performed mainly by the following two routes. When an equimolar mixture of **2** or **6**, pyridine and acyl chloride was stirred in dry benzene at room temperature, the corresponding *N*-acyl derivatives (**10**) were obtained as crystals, together with a reddish syrup, which was confirmed to be the *O*-acyl isomers (**9**).[14]

Further acetylation of **10** with acetic anhydride at 100—110 °C for half an hour gave the corresponding *N,O*-diacyl derivatives (**3** and **7**) in good yields. These compounds were also obtained directly from **2** or **6** under similar conditions by use of more than 2 equimolar amounts of acid anhydride or ethyl chloroformate, respectively. Only the *N*-phthaloylglycyl-*O*-acetyl derivatives (**3** and **7**) were obtained as colorless needles or prisms.

Structures of the monoacyl (**9** and **10**) and diacyl derivatives (**3** and **7**) were characterized by elementary analysis and infrared spectrum. **10** showed deep violet coloration with methanolic ferric chloride. Isomerization of **9** to **10** even in the absence of alkali[14] at room temperature was confirmed by the coloration. The syrup (**9**) could not be isolated in a pure state. It showed a N–H band in the 3300—3100 cm^{-1} region, the absorption shifting towards 3450—3250 cm^{-1} region (OH band) with the progress of isomerization. The results are summarized in Tables 2 and 3.

Synthesis of N-Acyl-α-dehydroamino Acid Esters. Treatment of **3** or **7** with more than 2 equimolar amounts of triethylamine in dry benzene under reflux or at room temperature gave the expected α-dehydroamino acid esters (**4** and **8**) in pure state in good yields. It was found that **10** was directly dehydrated to give **4** in higher yield than in the above experiment, by refluxing in benzene for a longer time in the presence of triethylamine. Structures of these α-dehydroamino acid esters were confirmed by elementary analyses and their infrared absorption spectra which were similar to those of the α-dehydroamino derivatives obtained earlier.[5,6,9,11,15] The results are summarized in Table 4.

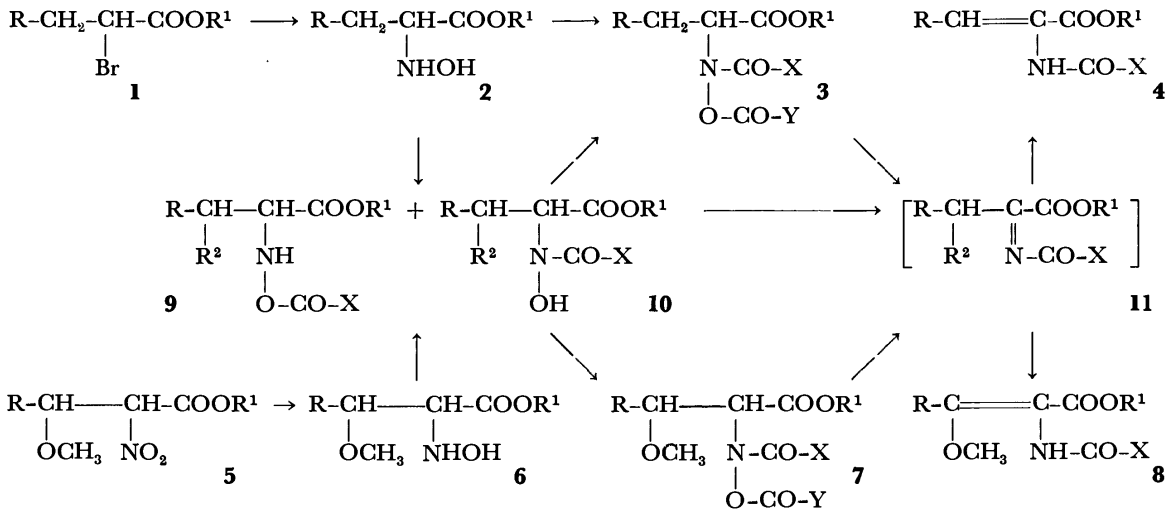

Scheme 1

Conversion of **3**, **7** and **10** into **4**, **8** and **4**, respectively, is deduced to proceed through the corresponding *N*-acyl-α-imino intermediate (**11**), which subsequently isomerizes to a more stable form.[15] This is supported by the fact that ethyl α-(*N*-acyl-hydroxyamino)-β-methoxycarboxylates react with ethanolic ammonia to afford 4-imidazolidone derivatives instead of the expected 2,5-piperazinedione derivatives[14] and that chloroacetylation of ethyl 2-imino-3-methylbutanoate gives the isomerized compound; ethyl 2-(2-chloroacetamido)-3-methyl-2-butanoate.[15]

Experimental

All boiling and melting points are uncorrected. The IR spectra were recorded with a Hitachi EPI-S2 Spectrometer.

Material. Ethyl 3-methoxy-2-nitro-3-phenylpropanoate (**5**) was prepared by the method reported.[11b] Yield 91.6%, colorless prisms from benzene and petroleum ether, mp 81—83 °C. IR(KBr): 1760, 1565, 1380 cm^{-1}. Found: C, 57.01; H, 6.17; N, 5.46%. Calcd for $C_{12}H_{15}NO_5$: C, 56.71; H, 5.97; N, 5.53%.

*t-Butyl α-Bromoalkanoates (**1**).* α-Bromoalkanoic acid bromide (0.443 mol) was added dropwise, with stirring, to a mixture of pyridine (0.447 mol) and *t*-butyl alcohol (120 ml) at a temperature below 30 °C. After being stirred at room temperature for 6 hr, the reaction mixture was allowed to stand overnight at room temperature. After removal of the pyridinium salt separated out, benzene (300 ml) was added to the resulting solution, which was washed successively with water, 3M-hydrochloric acid twice, saturated aqueous solution of sodium hydrogen carbonate and then finally with water. The benzene layer was dried over anhydrous magnesium sulfate and then evaporated. The residual oil was distilled under reduced pressure to give colorless oil. *t*-Butyl 2-bromopropanoate, yield 87.1%, bp 64—65 °C/18 mmHg (bp 62 °C/13 mmHg).[12] *t*-Butyl 2-bromobutanoate, yield 86.7%, bp 71—75 °C/12 mmHg. Found: C, 43.51; H, 6.55%. Calcd for $C_8H_{15}O_2Br$: C, 43.32; H, 6.73%. *t*-Butyl 2-bromopentanoate, yield 84.0%, bp 98—100 °C/19 mmHg. Found: C, 45.77; H, 6.98%. Calcd for $C_9H_{17}O_2Br$: C, 45.57; H, 7.18%.

*t-Butyl α-Hydroxyaminoalkanoates (**2**).* When a solution of **1** (0.37 mol), hydroxylamine (made from hydroxylamine hydrochloride (0.41 mol) and sodium (0.41 mol)) and triethylamine (0.37 mol) in methanol (300 ml) was refluxed for 30 hr and then evaporated, a residual syrup was obtained. After addition of dry ether (300 ml) to the syrup and removal of the triethylamine hydrogen bromide separated out, the ether layer was evaporated to give a residual syrup, which was gradually crystallized or distilled under reduced pressure. The results are summarized in Table 1.

*α-Hydroxyaminoalkanoic Acids (**2**; $R^1=H$).* *t*-Butyl α-hydroxyaminoalkanoate (**2**; 0.246 mol) was dissolved in concentrated hydrochloric acid (350 ml) and then the solution was allowed to stand at room temperature for a day. After evaporation of the reaction solution under reduced pressure, the acidic residual syrup was dissolved in water (30 ml) and maintained within the pH range 6—7 with concentrated aqueous ammonia. After being allowed to stand overnight in a refrigerator, the colorless crystals separated out were collected and then washed with cold water. Recrystallization from water gave colorless prisms. 2-Hydroxyaminobutanoic acid, yield 78.0%, mp 189—191 °C (mp 193—194 °C).[13] 2-Hydroxyaminopentanoic acid, yield 78.3%, mp 192—194 °C (mp 194—195 °C).[13]

*Ethyl α-Hydroxyaminoalkanoates (**2**; $R^1=Et$).* When concentrated sulfuric acid (40 ml) was added dropwise, with stirring, to a suspension of **2** ($R^1=H$, 0.125 mol) in ethanol (100 ml) under cooling, the crystals gradually dissolved. The solution was allowed to stand at room temperature for two days and poured into ice water (200 ml) and then neutralized with solid sodium bicarbonate. After extraction of the reaction solution with ether several times, the ether extracts were washed with water and then dried over anhydrous magnesium sulfate. After concentration of the extracts, the residual syrup was distilled under reduced pressure to give pale yellow oil (See Table 1).

*Ethyl 2-Hydroxyamino-3-methoxy-3-phenylpropanoate (**6**).* This compound was prepared by the reduction of **5** according to the method reported.[11b] Recrystallization from benzene and petroleum ether gave colorless prisms, yield 28.9%, mp 84—85 °C. IR(KBr): 3400, 3250, 1738 cm^{-1}. Found: C, 60.66; H, 7.20; N, 6.03%. Calcd for $C_{12}H_{17}NO_4$: C, 60.24; H, 7.16; N, 5.85%.

*Ethyl and t-Butyl α-(N-Acyl-hydroxyamino)alkanoates (**10**).* To a solution of **2** (0.0272 mol) and pyridine (0.0272 mol) in dry benzene (40 ml) was added with stirring a solution of appropriate acyl chloride (0.0272 mol) in dry benzene (15 ml)

dropwise at room temperature. After stirring for several hours, the resulting benzene layer was washed successively with water, aqueous solution of sodium hydrogen carbonate, 3M-hydrochloric acid and then finally with water. The benzene solution was dried over anhydrous magnesium sulfate and then evaporated. The residual crystals were collected, washed with water and then recrystallized. The results are summarized in Table 2.

Reaction of **6** *with Phthaloylglycyl Chloride.* To a solution of **6** (0.0083 mol) and pyridine (0.0087 mol) in dry benzene (20 ml) was added with stirring a solution of phthaloylglycyl chloride (0.0092 mol) in dry benzene (10 ml) dropwise at room temperature. After stirring for several hours, crystals separated out were collected and washed with water. Recrystallization from ethanol gave colorless needles, which were identified as ethyl 3-methoxy-3-phenyl-2-(*N*-phthaloylglycylhydroxyamino)propanoate (**10**), yield 65.1%, mp 170—172 °C. IR (KBr): 3300, 1700, 1664 cm^{-1}. Found: C, 62.25; H, 5.05; N, 6.76%. Calcd for $C_{22}H_{22}N_2O_7$: C, 61.96; H, 5.20; N, 6.57%.

The benzene filtrate was washed successively with water, 3M-hydrochloric acid and with water, and dried over anhydrous magnesium sulfate and then evaporated. The residual oil was chromatographied on silica-gel column with benzene and the effluent was condensed under reduced pressure to give a pale yellow syrup, which was identified as ethyl 3-methoxy-3-phenyl-2-(*O*-phthaloylglycylhydroxyamino)propanoate (**9**), yield 8.5%. IR(KBr disk): 3250, 1730 cm^{-1}. Found: C, 62.31; H, 5.29; N, 6.38%. Calcd for $C_{22}H_{22}N_2O_7$: C, 61.96; H, 5.20; N, 6.57%.

t-*Butyl 2-(*N,O-*Diacetyl- or Dipropionyl-hydroxyamino)pentanoate (***3***;* R^1*=Et).* A mixture of *t*-butyl 2-hydroxyaminopentanoate (0.053 mol) and appropriate acid anhydride (27 ml) was heated at 100—110 °C for half an hour. After concentration of the reaction solution under reduced pressure, the residual syrup was distilled under reduced pressure to give colorless oil (See Table 3).

t-*Butyl 2-(*N,O-*Diethoxycarbonylhydroxyamino)pentanoate (***3***;* R^1*=Et).* To a solution of *t*-butyl 2-hydroxyaminopentanoate (0.0265 mol) and pyridine (0.053 mol) in dry benzene (40 ml) was added dropwise with stirring a solution of ethyl chloroformate (0.053 mol) in dry benzene (10 ml) at room temperature. After stirring for 3 hr and removal of pyridinium salt separated out, the benzene layer was concentrated to give a syrup. The syrup was distilled under reduced pressure to give colorless oil (See Table 3).

Ethyl and t-*Butyl α-(*O-*Acetyl-*N-*phthaloylglycyl-hydroxyamino)-alkanoates (***3***) and Ethyl 3-Methoxy-3-phenyl-2-(*O-*acetyl-*N-*phthaloylglycylhydroxyamino)-propanoate (***7***).* A mixture of **10** (0.00585 mol) and acetic anhydride (22 ml) was heated at 100—110 °C for half an hour. After concentration of the reaction solution under reduced pressure, a viscous syrup, which was gradually crystallized, or crystals were obtained. The results are summarized in Table 3. Ethyl 3-methoxy-3-phenyl-2-(*O*-acetyl-*N*-phthaloylglycyl-hydroxyamino)propanoate (**7**) was also obtained in 45.5% yield as colorless needles from ethanol, mp 124—126 °C. IR(KBr): 1800, 1720 cm^{-1}. Found: C, 61.34; H, 5.15; N, 6.07%. Calcd for $C_{24}H_{24}N_2O_8$: C, 61.53; H, 5.16; N, 5.98%.

Ethyl and t-*Butyl* N-*Acyl-α-amino-α-alkenoates (***4***).* *a) From 3*: A solution of **3** (0.0011 mol) and triethylamine (0.0026 mol) in dry benzene (10 ml) was stirred at room temperature for 24 hr. After being allowed to stand at room temperature for over a day, the reaction solution was neutralized by 3M-hydrochloric acid and washed with water and then dried over anhydrous magnesium sulfate. Evaporation of the benzene layer under reduced pressure gave colorless crystals or syrup. The results are summarized in Table 4.

b) From ***10***: When a solution of **10** and triethylamine in dry benzene was refluxed for 12 hr in an analogous manner to the case of **3**, compound **4** was obtained in good yield (See Table 4).

*Ethyl 3-Methoxy-3-phenyl-2-(*N*-phthaloylglycylamino)-2-propenoate (***8***).* In an analogous manner to the case of **3**, compound **7** was treated with triethylamine to give compound **8** in 87.5% yield as colorless needles from benzene, mp 178—179 °C. IR(KBr): 3250, 1725, 1660 cm^{-1}. Found: C, 64.76; H, 4.96; N, 6.89%. Calcd for $C_{22}H_{20}N_2O_6$: C, 64.70; H, 4.94; N, 6.86%.

Restricted Rotation Involving the Tetrahedral Carbon. XI. Barriers to Rotation and Conformational Preferences of Substituted 9-Isopropyltriptycenes[1]

Fumio SUZUKI, Michinori ŌKI, and Hiroshi NAKANISHI*

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

**National Chemical Laboratory for Industry, Shibuya-ku, Tokyo 151*

(Received May 14, 1974)

Several 9-isopropyltriptycene derivatives were prepared by addition of benzynes to 9-isopropylanthracenes. Rotation about the C_9-C_{pr} bond of these compounds is found to be frozen at room temperature on the NMR time scale. Those compounds which carry a substituent at 1-position exist as *dl*-isomers, at least overwhelmingly. No sign of existence of *meso*-isomer is found. On the other hand, 9-isopropyl-2,4-dimethyltriptycene exists as a mixture of *d*, *l*, and *meso* isomers, composition of which is almost 1 : 1 : 1. Repulsive nonbonding interaction is a decisive factor to determine the conformational preference. Approximate methods for line shape analysis of two methyl groups in an isopropyl group are discussed. Activation energies for rotation about the C_9-C_{pr} bond increase with the increase in the size of 1-substituent except for the methyl group. The smaller effective size of the methyl group than that expected from the van der Waals radius is attributed to cogwheeling arrangement of methyl and isopropyl groups at the transition state of rotation and/or the higher energy level of the ground state due to the severe interaction between methyl and isopropyl groups.

Considerable efforts have been made to measure the restricted rotation about C_{sp^3}-C_{sp^3} bonds and conformational preferences by means of dynamic nuclear magnetic resonance spectroscopy.[2] Extensive studies on substituted ethanes show that the effects of substituents on conformational equilibria and on rotational barriers are not directly correlated with the size of van der Waals radii of the substituent.[2,3] These data reveal that barrier to rotation and conformational preference can not be explained in terms of simple steric repulsion. Several theoretical investigations suggest that attractive interactions are important in determining the conformational energies of halogenated ethanes[4] and Wolfe proposed the *gauche* effect.[5] Others suggested that there exists an attractive interaction between the C–H group and lone pair of electrons in other cases.[6] We thought it of interest to see whether this kind of interaction is present in cases where steric overcrowding is very severe. We have been able to isolate very stable rotamers of a 9-*t*-butyltriptycene type compound (**1**) at room tempreature.[7] Since the scale model of this compound shows that the substituent at 1-position and the methyl group of *t*-butyl type substituent are located within the sum of van der Waals radii, this type of compound should be suitable for testing the intramolecular interaction in an extreme case.

This paper deals with the intramolecular interaction and the mode of interchange among rotational isomers. It has been shown that dimethyl 9-isopropyl-9,10-dihydro-9,10-ethenoanthracene-11,12-dicarboxylate (**2**) exists as *dl* isomers, almost exclusively, and

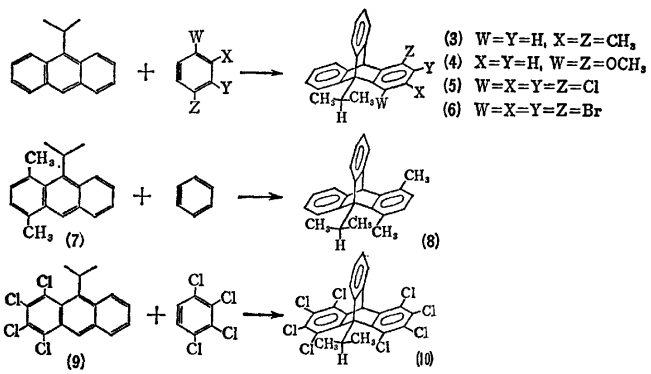
(2)

internal rotation of the isopropyl group is to and fro motion rather than the full rotation.[8] It would be of interest to estimate the generality of the observation of this sort. Several 9-isopropyltriptycene type compounds were prepared and their PMR spectra examined at various temperatures. A method of approximation of line shape analysis of the isopropyl group is also proposed.

Experimental

Syntheses. 9-Isopropyltriptycenes were prepared by treating 9-isopropylanthracenes with benzynes, as illustrated in the following schema. Some new 9-isopropylanthracene derivatives were synthesized by the Grignard reaction of substituted anthrones with isopropylmagnesium bromide followed by dehydration.



1,4-Dimethyl-9-isopropylanthracene (7). To a solution of isopropylmagnesium bromide, prepared from 3.7 g (0.03 mol) of isopropyl bromide, 0.7 g (0.03 mol) of magnesium and 100 ml of ether, was added 2.2 g (0.01 mol) of 1,4-dimethylanthrone[9] in small portions at room temperature. After stirring for 30 min, 50 ml of benzene was added and the reaction mixture refluxed for 1 hr. After cooling to 0 °C, the mixture was treated with dilute hydrochloric acid. The organic layer was separated, dried and evaporated. The residue dissolved in 150 ml of carbon tetrachloride was warmed on a steam bath with 30 g of phosphorus pentoxide for 2 hr.

Table 1. The NMR data of 9-isopropyltriptycenes in deuteriochloroform at 34 °C (δ ppm)

Compound	Isopropyl methyls	Other methyls	Isopropyl methine	Bridge head proton	Aromatic protons
3	1.86(6H, d, J=6.4 Hz)	2.18(2H, s) 2.40(2H, s) 2.22(1H, s) 2.50(1H, s)	3.52(1H, sept, J=6.4 Hz)	5.48(1H, s)	6.52—7.75(10H, m)
8	1.75(3H, d, J=6.7 Hz) 1.87(3H, d, J=6.7 Hz)	2.43(3H, s) 2.56(3H, s)	3.96(1H, sept, J=6.7 Hz)	5.51(1H, s)	6.60(2H, s) 6.62—7.90(8H, m)
4	1.75(3H, d, J=6.7 Hz) 1.78(3H, d, J=6.7 Hz)	3.16(3H, s) 3.24(3H, s)	3.82(1H, sept, J=6.7 Hz)	5.78(1H, s)	6.43(2H, s) 6.70—7.90(8H, m)
5	1.75(3H, d, J=6.8 Hz) 1.87(3H, d, J=6.8 Hz)		4.35(1H, sept, J=6.8 Hz)	5.92(1H, s)	6.91—8.00(8H, m)
6	1.74(3H, d, J=6.8 Hz) 1.85(3H, d, J=6.8 Hz)		4.57(1H, sept, J=6.8 Hz)	6.01(1H, s)	6.78—7.72(8H, m)
10	1.77(6H, d, J=6.9 Hz)		5.35(1H, sept, J=6.9 Hz)	6.64(1H, s)	7.05—8.30(8H, m)

The supernatant liquid was decanted, washed with water and dried. The solvent was removed and the residue was chromatographed on neutral alumina. Elution with hexane gave the desired compound, mp 110—112 °C, in *ca.* 30% yield (7 g). NMR ($CDCl_3$, δ from TMS): 1.69 (6H, d, J=6.6 Hz), 2.68 (3H, s), 2.84 (3H, s), 4.44 (1H, sept, J=6.6 Hz), 6.98—8.74 (7H, m). The compound was used for the preparation of a triptycene derivative **8**.

*1,2,3,4-Tetrachloro-9-isopropylanthracene (**9**)*, mp 172—173 °C, was similarly prepared from 1,2,3,4-tetrachloroanthrone[10] and isopropylmagnesium bromide. The yield was *ca.* 10%. Found: C, 57.22; H, 3.22; Cl, 39.48%. Calcd for $C_{17}H_{12}Cl_4$: C, 57.02; H, 3.38; 39.60%.

*2,4-Dimethyl-9-isopropyltriptycene (**3**).* To a refluxing mixture of 0.36 g (0.015 mole) of magnesium, 2.04 g (0.01 mol) of 9-isopropylanthracene and 70 ml of dry tetrahydrofuran was added 2.0 g (0.01 mol) of 3,5-dimethyl-2-fluoro-1-bromobenzene[11] in 20 ml of dry ether with stirring. Heating and stirring were continued for 5 hr. The mixture was cooled and treated with water. Organic layer was separated after adding 100 ml of ether, dried over sodium sulfate, and evaporated. The residue was taken up in benzene and chromatographed on alumina. Elution with hexane-benzene gave pure **3**, mp 154.5—156.5 °C, in 0.48 g (*ca.* 15%) yield. Found: C, 92.40; H, 7.15%. Calcd for $C_{25}H_{24}$: C, 92.55; H, 7.45%. The product was a mixture of **3** and 1,3-dimethyl-9-isopropyltriptycene. Isolation of the latter was tedious, but no attempt was made by other means.

Assignments of the structure are based on the PMR spectra. **3** gave signals as shown in Table 1, whereas 1,3-dimethyl-9-isopropyltriptycene at 1.75 (3H, d, J=6.7 Hz), 1.88 (3H, d, J=6.7 Hz), 2.25 (3H, s), 2.52 (3H, s), 3.70 (1H, sept, J=6.7 Hz), 5.10 (1H, s), and 6.72—7.80 (8H, m). The features indicate the chemical shifts of the bridge head protons. **3** gives the signal at 0.38 ppm down field from the corresponding signal of the isomer. This means that the bridge head proton of **3** suffers from the van der Waals shift because of the proximity of a methyl group at 4-position. Nearly the same chemical shift as the bridge head proton of **8** may be taken as another support for the structure. This assignment is also consistent with the presence of two rotamers in **3** and the absence of the *meso* form in the isomer.

*1,4-Dimethyl-9-isopropyltriptycene (**8**).* To a refluxing solution of 1.2 g (0.01 mol) of butyl nitrite and 2.44 g (0.01 mol) of 1,4-dimethyl-9-isopropylanthracene in 20 ml of dichloromethane was added 1.37 g (0.01 mol) of anthranilic acid in 20 ml of ether with stirring. Heating and stirring were discontinued after 0.5 hr and the solvent was evaporated. The residue was taken up in benzene and chromatographed on alumina. Elution with hexane-benzene gave 1.3 g (40% yield) of **8**, mp 199—201 °C. The compound was purified by recrystallization from chloroform-ethanol. Found: C, 92.50; H, 7.67%. Calcd for $C_{25}H_{24}$: C, 92.55; H, 7.45%.

*1,2,3,4-Tetrachloro-9-isopropyltriptycene (**5**)*, mp 267—269 °C, was similarly prepared by treating 9-isopropylanthracene in dichloromethane with a benzyne produced from tetrachloroanthranilic acid[12] in dry acetone; yield 26%. Recrystallization from hexane-benzene afforded a pure sample. Found: C, 63.55; H, 3.69; Cl, 32.52%. Calcd for $C_{23}H_{16}Cl_4$: C, 63.64; H, 3.73; Cl, 32.66%.

*1,2,3,4-Tetrabromo-9-isopropyltriptycene (**6**)*, mp 290—292 °C, was prepared by treating 9-isopropylanthracene with a benzyne produced from tetrabromoanthranilic acid;[13] yield 15%. We failed to obtain satisfactory analytical results probably because of poor combustibility. Purity of the compound was checked by its PMR spectrum. High resolution mass spectrum showed a molecular ion peak at 607.7838, while that of the calculated value is 607.798.

*1,2,3,4,5,6,7,8-Octachloro-9-isopropyltriptycene (**10**)*, mp 303—304 °C, was similarly prepared with the use of tetrachloroanthranilic acid, butyl nitrite and 1,2,3,4-tetrachloro-9-isopropylanthracence; yield *ca.* 5%. This compound also gave unsatisfactory analytical results. Purity was checked by its PMR spectrum. The high resolution mass spectrum showed a molecular ion peak at 567.8287. The calculated value is 567.830.

*1,4-Dimethoxy-9-isopropyltriptycene (**4**).* A suspension of phenylsodium,[14] prepared from 2.25 g (0.02 mol) of chlorobenzene, 0.92 g (0.04 mol) of sodium, and 20 ml of benzene, was added dropwise to a stirred solution of 1.72 g (0.01 mol) of 2-chloro-1,4-dimethoxybenzene[15] and 2.04 g (0.01 mol) of 9-isopropylanthracene in 20 ml of benzene at room temperature under a nitrogen atmosphere. Stirring was discontinued after 3 hr and the mixture was treated with water. The organic layer was separated, dried over sodium sulfate and evaporated. The residue was taken up in benzene and chromatographed on alumina. Elution with benzene followed by recrystallization from chloroform-ethanol gave pure **4** mp 156—158 °C, in 1.1 g (30%) yield. Found: C, 84.03; H, 6.54%. Calcd for $C_{25}H_{24}O_2$: C, 84.21; H, 6.79%.

Spectral Measurement. The PMR spectra were recorded on a Hitachi R-20B spectrometer operating at 60 MHz. The samples were dissolved in appropriate solvents to make up *ca.* 10% (wt/vol) solution. Temperatures were read by the difference in chemical shifts of protons of ethylene glycol and are believed to be accurate within an error of ± 1 °C. T_2 was measured from the line-width of the proton signal of tetrachloroethane added in the sample solution.

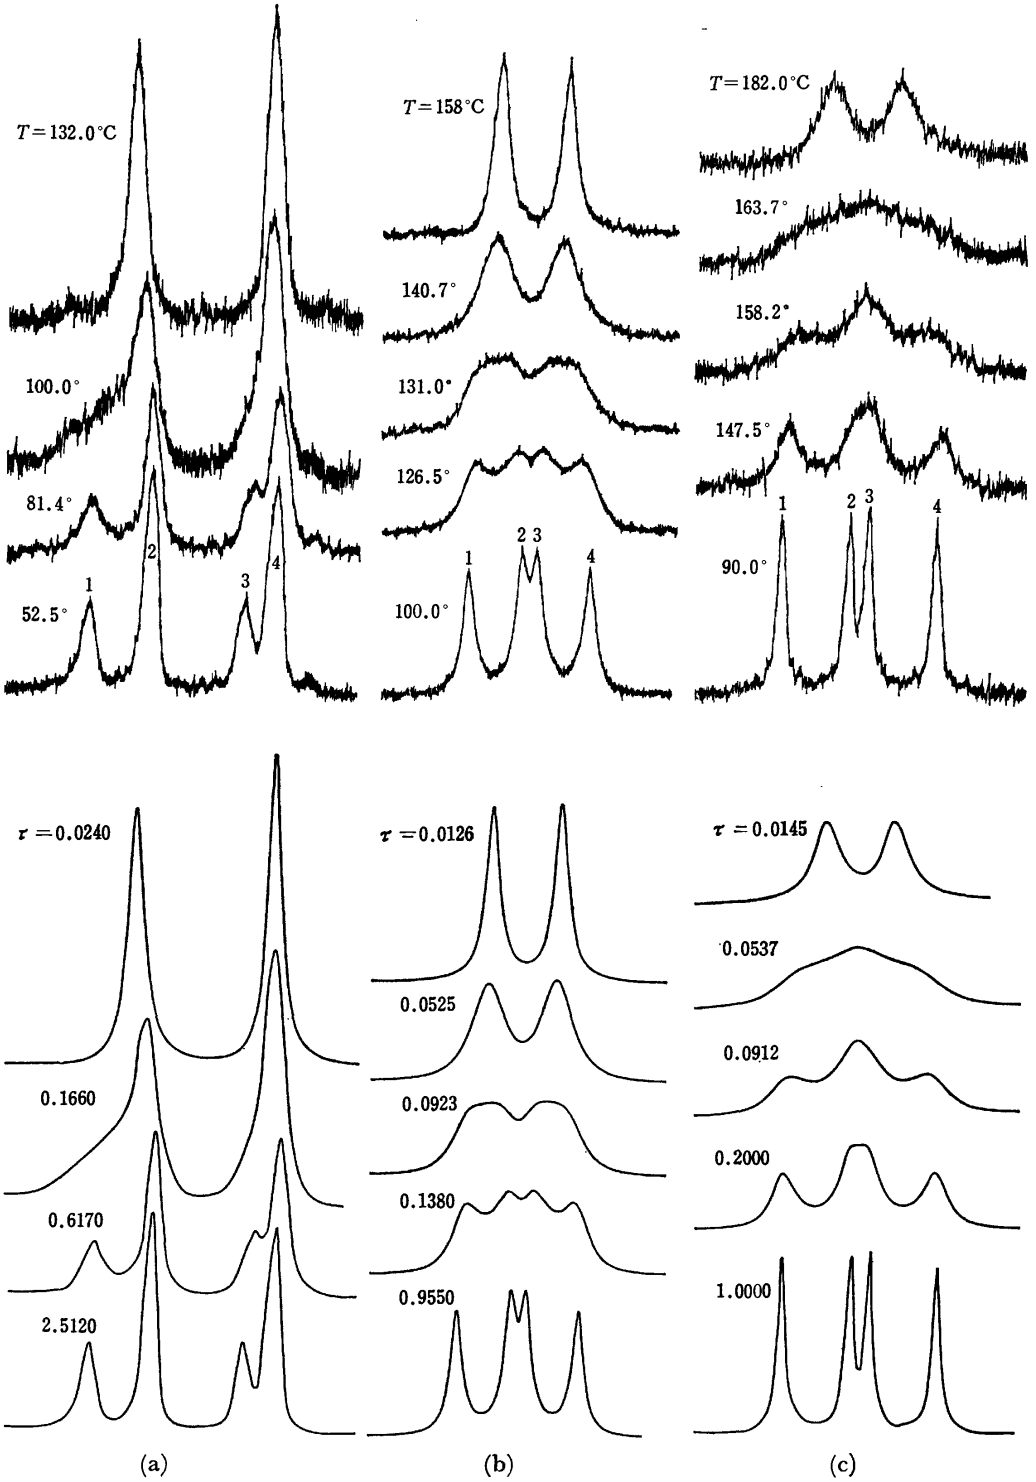


Fig. 1. The observed and calculated spectra of 9-isopropyltriptycenes at various temperatures: a) compound **3**, b) compound **8**, c) compound **5**.

Calculation. Calculation was carried out with a FACOM 270/30 computer. A computer program named EXNMRO[8] was written along lines described in the Line Shape Analysis. Theoretical spectra were calculated to get a best fit with the observed spectra by varying the rate constants. Agreement between the experimental and theoretical spectra was excellent (Fig. 1). Logarithms of the rate constants of rotation obtained at various tempreatures are plotted against $1/T$. A good linear relationship was obtained and the activation energy was calculated. Other kinetic parameters were obtained by putting these data into Eyring's equations. The results are shown in Table 2.

Line Shape Analysis

Since the rotation of an isopropyl group corresponds to the exchange of two methyl groups, six protons which couple with a methine proton should be taken into ac-

Table 2. Activation parameters for rotation (at 25 °C)

count in the line shape analysis. In terms of spin notation, the process is an exchange of the A_3B_3X spin system since resonance frequency of the methine proton is far apart from those of methyl protons. Strictly speaking, complete line shape analysis of this system should be carried out by the density matrix method,[16,17] which is applied to a spin exchange system having spin-spin couplings. However, the exchanging seven-spin system requires the treatment of two 7×7, two 147×147, two 735×735, and one 1225×1225 dimension matrices in the spin function representation. It is practically impossible to calculate theoretical spectra of this system.

As a means to overcome this difficulty, we might use the composite particle method, in which the spin system of an isopropyl group is regarded as AML, the angular momentum operators I of A, M and L being 1/2, 3/2 and 3/2, respectively. The computation time, however, is still too long for the exchanging system to be analyzed in our laboratory.

Fortunately, the chemical shift of the methine proton of isopropyl group is far apart from the two chemical shifts of methyl protons (Table 1). Mixing transition between the spins of methine and methyl protons might be small. As a good approximation, four peaks of the methyl groups could be analyzed by means of the modified Bloch equation[18] which is applicable to spin systems including no spin couplings instead of the density matrix method. Computation time will be greatly reduced in this approximation. When the modified Bloch equation method is applied to this system, the small effect of mixing transition between the spins of methine and methyl protons of the isopropyl group can be included in the "natural" line width terms of the four peaks of the two doublets due to the methyl groups. Thus, in our calculation, the apparent line width equals the real natural line width plus the line width broadened by the small spin couplings between methine and methyl protons.

The line widths of the four peaks corresponding to methyl protons in the observed spectra differ from each other with compounds **3**, **4**, **5** and **8** at temperatures where the internal rotation about the C_9-C_{pr} bond is frozen. This means that the mixing transition is neither negligibly small nor considerably large, since the line widths of the four peaks should be the same in the former case and the lines should be split further in the latter case. Therefore the above consideration seems to lead to a good approximation.

Since the degree of mixing transition effect remains unchanged for all temperatures, *i.e.*, the off-diagonal elements in the imaginary parts of the density matrices of the spin system of isopropyl group are independent of temperature, the ratios of "natural" line widths of the four peaks of the methyl groups will not vary with temperature. The four "natural" line widths were determined by visual fitting of calculated spectra with the observed. Actually, the ratios described above are almost the same for all the compounds examined at low temperatures.

In the line shape analysis using the modified Bloch equation method, absorption intensity $I(\omega)$ at each frequency is given by

$$I(\omega) = \frac{1}{\pi} Re(-\mathbf{P}\cdot[i(\boldsymbol{\Omega}-\boldsymbol{\omega})+\mathbf{D}]^{-1}\cdot\mathbf{1})$$

where notations of matrices ($\mathbf{P}, \boldsymbol{\Omega}, \boldsymbol{\omega}, \mathbf{D}, \mathbf{1}$) refer to those used in the work of Johnson[17]. Re standing for the real part of the matrices.

The dimension of matrices is four for compounds **4**, **5** and **8**, since two pairs of doublet peaks exchange in rotation of the isopropyl group. In these compounds, the *meso* form does not exist. Thus *d* and *l* isomers give two kinds of methyl signals, the chemical shifts of which are influenced by peri-substituents. Rotation of the isopropyl group is considered to be not a full rotation but a to and fro motion.

In the spectrum of compound **8**, the methyl peaks are denoted by (1, 3) and (2, 4), as in Fig. 1. It is reasonable to assume that peaks 1 and 3 exchange with peaks 2 and 4 and that probabilities of spin transfer of 1→3 or 4, and 2→3 or 4 are zero, since it is not likely that the lower level of one methyl group exchanges with the higher level of the other. Thus a matrix of the probability of spin transfer is as follows:

$$\mathbf{D} \equiv \begin{pmatrix} -1 & 1 & 0 & 0 \\ 1 & -1 & 0 & 0 \\ 0 & 0 & -1 & 1 \\ 0 & 0 & 1 & -1 \end{pmatrix}$$

For compound **4**, the same **D** matrix can be used in calculation of spectra, because the spectra show similar line shapes as with compound **3** at various temperatures.

Compound **5**, however, shows a different pattern. Two pairs of doublet peaks for the methyl groups are shown in Fig. 1. A similar consideration for compound **8** leads to the use of the following **D** matrix for compound **5**:

$$\mathbf{D} \equiv \begin{pmatrix} -1 & 0 & 1 & 0 \\ 0 & -1 & 0 & 1 \\ 1 & 0 & -1 & 0 \\ 0 & 1 & 0 & -1 \end{pmatrix}$$

In the case of compound **3**, the difference in chemical shifts of two methyl groups was so small that the signal appeared as a doublet. This is reasonable since **3** carries no substituent at peri positions and the calculation outlined above is made impossible. However, *meso* form (**11b**) coexists with *dl* forms (**11a** and **11a'**) in this case and the former gives methyl signals at different chemical shifts from those of the latter in the aromatic methyl region. Thus it was possible to perform line shape analysis in this region using the modified Bloch equation method.

Since the chemical shifts of the protons of *d* and *l* forms are the same and the observed signals of both aromatic methyl protons split into two peaks, respectively, in the ratio of 2 : 1 (Fig. 1), the populations of *d*, *l*, and *meso* isomers are considered to be the same. This means that the ground state levels for the respective forms are the same. The rates of exchange, $d \rightleftharpoons l$ and d(or l)$\rightleftharpoons$*meso*, can be assumed to be the same also, since there is no substituent at the peri positions and populations are equal. The transition states can also be considered to be the same. Taking the above into account, matrices are written as follows and calculation can be performed using only one rate constant.

$$\mathbf{P} \equiv \begin{pmatrix} 1 & 2 & 1 & 2 \end{pmatrix}$$

$$\mathbf{D} \equiv \begin{pmatrix} -1 & 1 & 0 & 0 \\ 1 & -1 & 0 & 0 \\ 0 & 0 & -1 & 1 \\ 0 & 0 & 1 & -1 \end{pmatrix}$$

Results and Discussion

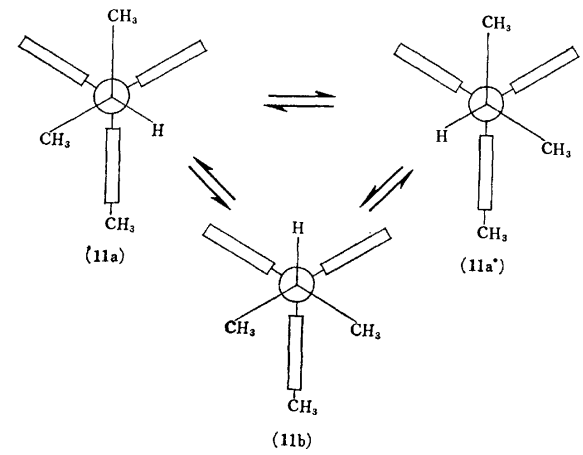
Conformational Preferences. PMR data of the triptycenes **3**, **4**, **5**, **6**, **8** and **10** in deuteriochloroform at 34 °C are summarized in Table 1. Compounds **4**, **5**, **6** and **8** show a pair of doublets for the methyl groups of the isopropyl group. The intensities are equal for the pair. Rotation about C_9-C_{pr} bonds should be frozen on the NMR time scale. The appearance of two doublets may be accounted for by assuming either the presence of *dl*-isomers only (absence of *meso* isomer) or an accidental overlap of the chemical shifts of the two kinds of methyls (*cf. e.g.* the Newman type projection **12**). Either way could be chosen for this case, but the former is taken herewith because the feature of the spectra did not change in other solvents and it is unlikely that the chemical shifts of the two methyl groups coincide in compounds **5** and **6**, in which chlorine and bromine atoms give a strong effect on the chemical shifts.[19] One might argue that the chemical shifts of the methyl group in the *meso* form coincide with one of the doublets. However, if this were the case, the intensities of the two doublets should have been different.

Compound **3** shows only a doublet for the methyl groups of the isopropyl group. However, in the aromatic methyl region, four peaks can be seen, the relative intensities being 1 : 2. This indicates that the compound exists as a mixture of *meso* and *dl* forms but the chemical shifts of two methyl groups of the isopropyl group in the *dl* form happens to be the same. The coincidence of chemical shifts is not surprising as this compound carries no substituent at peri-possition and the magnetic environments for the two methyl groups do not differ much. The intensity ratio of 1 : 2 may be interpreted by assuming that *meso* (**11b**), *d*, and *l* (**11a** and **11a'**) isomers are of the same potentials and exist with 1 : 1 : 1 population ratio. Lack of peri-substituent should again be the cause of this phenomenon.

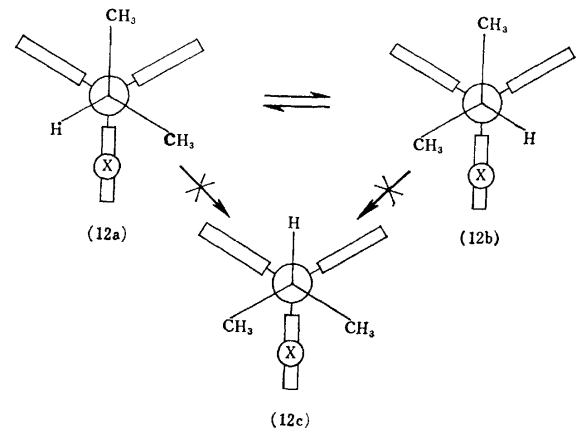
The ratio racemate/*meso* was measured in the temperature range 0—60 °C. The ratio of 2.0 was constant throughout the range. This is a strong support for the idea that the *meso* and the *dl* isomers are of the same energy. Preference of the *dl* isomers is of the statistical origin.

Compound **10** gives only one doublet for the isopropyl methyl groups. Because of the large magnetic effect of chlorine,[19] it is not reasonable to assume that the chemical shifts of the two methyl groups coincided under the conditions examined. Rather, the sole presence of a *meso* form, which gives the same chemical shifts for the methyls, is a more plausible reason for the phenomenon. This assumption is consistent with the idea that an isomer with the least repulsion exists, since a *dl* isomer of this compound would have the severe steric interaction between one of the methyls and two chlorine atoms at peri-positions.

The overwhelming preference of the *dl* isomer in



Scheme 1.



Scheme 2.

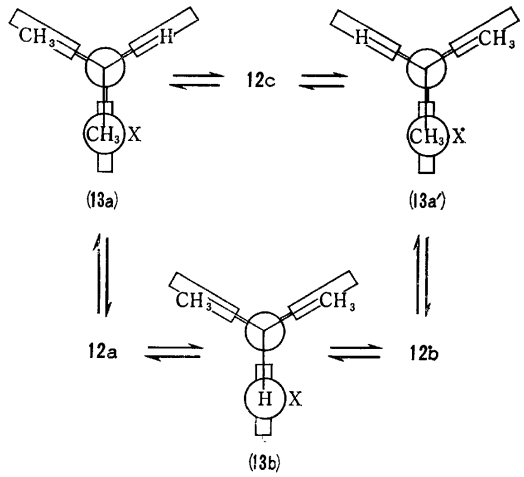
Fig. 2. Possible conformations of 9-isopropyltriptycenes.

1-substituted 9-isopropyltriptycenes was rather surprising. It can arise with either thermodynamic control or kinetic control. Thermal equilibration was attempted to shed light on this problem. The PMR spectra, after heating at 200 °C for 24—100 hr, did not show any change from those prior to heating. The possibility that the barrier leading to the *meso* form (**13a** and **13a'**; *vide infra*) is too high to produce any such isomer cannot be ruled out completely, but the long heating could produce at least a small fraction of the *meso* form, if it were thermodynamically feasible. Thermal equilibration was possible with an analogous compound under similar conditions.[20] Thus the population of these conformers seems to be controlled by the thermodynamic effect.

It is concluded that conformational equilibria (Fig. 2) of 9-isopropyltriptycene derivatives are mostly determined by the repulsive term of the van der Waals interaction between the methyl group and the substituent. No piece of evidence for the attractive interaction between the methyl group and lone pair electrons was obtained. The strong conformational preference may be attributed to the extreme closeness between the two groups concerned.

Rotational Barriers. As the temperature was raised, methyl signals of **3**, **4**, **5** and **8** gradually collapsed, whereas those of **6** and **10** remained intact up to 200 °C. From the chemical shift difference between the two methyl groups and temperature independence up to 200 °C, the barrier to rotation about the C_9–C_{pr} bond of **6** is estimated to be at least 26 kcal/mol. Since the bromine at 1-position must eclipse a methyl group at the transition state, this conformation becomes very unstable. If rotation about the C_9–C_{pr} bond should take place in compound **10**, change in chemical shifts should also have been observed, since the rotation should result in formation of *dl*-isomers. The lack of temperature dependence of the spectra indicates that the barrier to rotation about the C_9–V_{pr} bond of this commpound is also very high.

While the mechanism of exchanging process in **3** is the full rotation about the C_9–C_{pr} bond (scheme 1), that for the isopropyl group of compounds **4**, **5**, and **8** seems to be the exchange between two racemic forms for the following reasons (Scheme 2). If significant population of a *meso* isomer should result by rotation about the bond in question, temperature dependence of the chemical shifts of both methine and methyl protons is expected. Particularly since the chemical shift of the methine proton of compound **3** and that of compound **5** differ so much from each other and the former can be taken as a model of the chemical shift of the *meso* form of compound **5**, drift in chemical shift should arise. However, such is not the case. A comparison should be made of the models of transition states. If a methyl group eclipses a substituent at a peri-position, the energy of the conformation (**13a** and **13a'**) should be higher than a conformation (**13b**) in which hydrogen eclipses the substituent. The former is the transition state of *meso*⇌*dl* and the latter that of *dl*⇌*ld*. Thus the racemization process or to and fro motion of the isopropyl group is more likely to occur with greater ease. The to and fro motion seen in the 9-isopropyltriptycene type compound seems to be the general motion for compounds including **2**.



The spectra at various temperatures were simulated by the use of a computer along the lines discussed in Line Shape Analysis. The Arrhenius plots yielded good linear relationships, kinetic parameters being obtained. The results are given in Table 2.

The extreme proximity of interacting groups should be responsible for the extremely high barriers to rotation involving the isopropyl group. Even the barrier of **3** is higher than that of compound **2** ($\Delta G_c^{\ddagger}=17.7$ kcal/mol, $T_c=64$ °C).[8] This means that the triptycene skelton is more effective than 9,10-(dimethoxycarbonyletheno)-9,10-dihydroanthracene skeleton in raising the barrier. Similar phenomena have also been observed.[20]

The barrier to rotation, as judged from either E_a or $\Delta H^{\ddagger}$, increases as the size of substituent at 1-position increases, except for the methyl case. The magnitude of change in barriers due to the substituent size is surprisingly large. This is in striking contrast to the small change in ethane derivatives. The reason for this contrast must be the rigidity of the triptycene skeleton and extreme proximity of the substituent at 1-position. The barriers to rotation seem to be also interpreted by nonbonding repulsions.

The barrier to rotation of compound **8** is rather small. Since the van der Waals radius of a methyl group is 2.0 Å and that of bromine 1.95 Å, these two substituents are often cited to possess nearly the same van der Waals radii. However, in the present case, the methyl group in compound **8** seems to be much smaller than the bromine in a similar situation (compound **6**), and even smaller than the chlorine and methoxyl groups. This is again in sharp contrast to the fact that the methyl group is often considered to be larger than the chlorine and methoxyl groups.[21] A reasonable explanation for this anomaly may be given by considering two factors, rise of ground state because of the larger size of the methyl group which increases the nonbonding repulsion, and the characteristic structure of the methyl group which contains three hydrogens and a carbon atom. In the usual sense, the methyl group is considered to be a symmetrical

top because it rotates almost freely. Halogen atoms behave similarly. However, in a situation where the steric conditions are severe as in the present case, the methyl group may not be considered to be a symmetrical top any longer but a rotating tetrapod. Under these circumstances, the isopropyl group and the methyl group may be considered as a pair of gears. At the transition state, these two gears may take cogwheeling arrangement (**14**) which reduces the effective size of the methyl group. A similar situation was found for 9-methyltriptycene derivatives.[1)]

Molybdenum(V) Chloride as a Reagent for *cis* Chlorination of Olefins

Sakae UEMURA,* Akira ONOE, and Masaya OKANO

Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

(Received May 27, 1974)

Treatment of nonconjugated olefins such as *cis*- and *trans*-2-butenes, *cis*-2-octene, and cyclohexene with $MoCl_5$ in CCl_4 gave *vic*-dichloroalkanes whose *cis*-isomer was formed predominantly, the ratio of *cis*- to *trans*-addition being 4.9—12.1, together with monochloroalkanes. Preferential formation of *exo-cis*-dichloride was observed in the case of norbornene and norbornadiene. Bromochlorination and chloroiodination of olefins, and aromatic bromination and iodination were carried out with mixtures of $MoCl_5$ and halogens. The reaction scheme for chlorination is discussed.

Chlorine reacts with olefins *via* both homolytic and heterolytic pathways, stereochemistry of the addition depending on the kind of olefins. Thus, the addition occurs non-stereospecifically with conjugated olefins, *cis* addition usually predominating, while with nonconjugated linear olefins it proceeds with high *trans* stereospecificity.[1] Chlorination of nonconjugated olefins by other chlorinating agents, however, shows a somewhat different stereospecificity from that by chlorine; *i.e.*, *cis*-addition sometimes predominates in the reaction of *cis*- or *trans*-2-butene with $CuCl_2$[2] and in the chlorination of 1-alkylpropene with (dichloroiodo)-benzene.[3] $SbCl_5$ is an effective reagent for the *cis*-chlorination of nonconjugated olefins such as 2-butene, 2-octene and cyclohexene.[4] In the course of further studies on olefin chlorination by other metal or metalloidal chlorides we found that *cis*-chlorination also occurred by $MoCl_5$ with higher *cis* stereospecificity than in the case of $SbCl_5$. Although the chlorinating action of $MoCl_5$ was noted in the chlorination of aromatic hydrocarbons,[5] no report seems to have been given on the direct chlorination of olefins. We describe here the results of the chlorination of olefins by $MoCl_5$ in CCl_4, together with those of the mixed halogenation of olefins and aromatic halogenation with mixtures of $MoCl_5$ and halogens.

Results and Discussion

Chlorination. The reaction was carried out by adding or introducing olefinic hydrocarbons into a pale red-brown homogeneous solution of $MoCl_5$ in CCl_4 or CH_2Cl_2 at appropriate temperature, followed by stirring for 0.25—10 hr under N_2 atmosphere. The products were *vic*-dichloroalkanes(**1**) (*cis* and *trans*) and monochloroalkane(**2**) (Scheme 1).

$$\mathrm{RCH\text{-}CHR' \xrightarrow[CCl_4]{MoCl_5} RCH(Cl)\text{-}CHR'(Cl) + RCH_2CHR'(Cl)} \quad (1)$$

(**1**) (**2**)

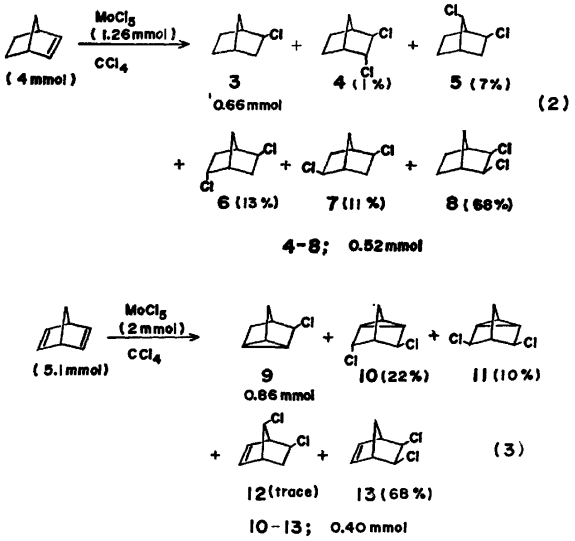
Some results are summarized in Table 1. Compared to the chlorination by $SbCl_5$,[4] the yield of **1** was lower, while the selectivity for *cis*-chlorination was much higher. Separate experiments using isomeric dichlorobutanes and dichlorocyclohexanes revealed that no interconversion occurred between *cis*-**1** and *trans*-**1** under the present reaction conditions. We see from Table 1 that elongation of the reaction time does not affect so much the ratio of *cis*- to *trans*-addition in the chlorination of cyclohexene despite the increase in the yield of **1** (Compare Runs 6 and 7). This shows that the observed ratio of *cis*- to *trans*-addition is kinetically controlled.

The reaction in other chlorinated solvents such as chloroform and dichloroethane gave no satisfactory results, *viz.*, none of **1** and **2** was obtained in the former solvent, while the yield of **1** and **2** as well as the *cis*-selectivity was quite low in the latter one. No chlorination occurred in more polar solvents such as acetonitrile, nitromethane, alcohols, DMF, and DMSO, probably because of the reactions of $MoCl_5$ with these solvents forming such salts as $Mo_2Cl_6L_3$, $MoOCl_3$ and/or $MoOCl_3L_2$.[6-8] No reaction occurred with ethyl fumarate and ethyl maleate, but a small amount of **1** (<5% yield) was obtained from the reaction of styrene together with a lot of dimeric compound. When the chlorination of cyclohexene was carried out in the presence of *m*-dinitrobenzene or oxygen, no change in the yield or in the *cis*/*trans* ratio of **1** was observed, suggesting that the reaction is not of a radical nature.

In the case of norbornene and norbornadiene the reaction proceeded in CCl_4 at room temperature to give the various chlorinated compounds as illustrated in schemes 2 and 3, the yields of the dichlorinated compounds being 40—45% and 20—25%, respectively. Although the polymerization of norbornene by using $MoCl_5$ as catalyst is known,[9] only a slight amount of polymerization product was obtained under the present reaction conditions. The kind of product and its distribution differed very much from those in the chlorination by Cl_2 or $SbCl_5$. The characteristic feature of this reaction is a preferable formation of **8** and **13**, *exo-cis*-dichlorocompounds, which were hardly obtained at all in the chlorination by $SbCl_5$. **4**—**7** were the main products in the chlorination of norbornene by $SbCl_5$, while nortricyclyl chloride(**9**) and *exo*-2-*syn*-7-dichloronorbornane were mainly obtained by using Cl_2 gas.[7] In the case of norbornadiene chlorination by Cl_2 gave **10**—**12** as the main products,[10] but we found such a case also in the reaction by $SbCl_5$. Thus, although the dissociation of $MoCl_5$ to $MoCl_4$ and Cl_2 has been reported,[11] possible chlorination with chlorine arising from this dissociation can be excluded.

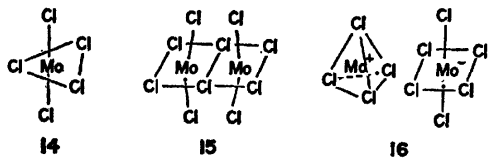
In order to consider the reaction scheme of chlorination, it is desirable to know the structure of $MoCl_5$

* To whom correspondence should be addressed.



in solution. It is known that the crystal structure of $MoCl_5$ consists of a dimeric molecule with the chlorine atoms forming two distorted octahedra which have a common edge (**15**).[12] However, different views are given on the nature of $MoCl_5$ in solution; it is monomeric in solution (**14**) and solvated;[7] it preserves its dimeric state in CCl_4.[12] Another kind of dimeric species, namely a polarized dimer complex which may be illustrated as **16**, was also considered in the direct aromatic chlorination by $MoCl_5$ where aromatic compound itself was used as a solvent.[5b] Thus it is possible that such an equilibrium (Scheme 4) is present in the solution of $MoCl_5$. Assuming that this equilibrium is involved in CCl_4, the predominant formation of **8**, **13** and other *cis*-dichlorides can be most reasonably explained by a concerted molecular addition of **14** or **15** to olefins, as has been proposed for the *cis*-chlorination by $SbCl_5$.[4]

$$2MoCl_5 \rightleftarrows (MoCl_5)_2 \rightleftarrows MoCl_4^+MoCl_6^- \qquad (4)$$



14 **15** **16**

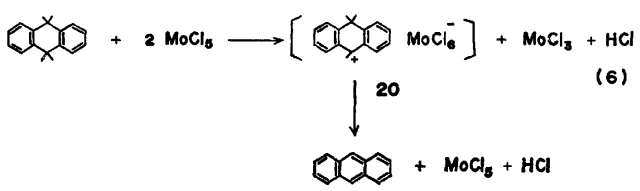
On the other hand, as to the minor formation of *trans*-dichlorides, **16** seems to be the attacking species, reacting with olefin to give carbonium ion intermediate(**17**) followed by the attack of chloride ion (Scheme 5). Formation of the dichlorides, **4**—**7** and **10**—**12**,

$$\underset{\mathbf{16}}{>C{=}C<} \longrightarrow \underset{\mathbf{17}}{[>C(Cl)-C^+<]MoCl_6^-} \rightarrow \mathbf{1}(trans) \qquad (5)$$

could also be explained by this scheme where the intermediate carbonium ions would be nonclassical ones; *i.e.*, **18** for **4**—**7** and **19** for **10**—**12**. By comparison of the results of the chlorination by $MoCl_5$ with those by $SbCl_5$, the two following differences are evident. Selectivity for *cis*-chlorination is higher in the former case; *exo-cis*-dichlorides are formed preferably from norbornene and norbornadiene in the former, but none in the latter where the reaction was carried out at various concentrations of $SbCl_5$. The results might suggest that $MoCl_5$ mainly exists in the form of **14** or **15** in CCl_4, while in the case of $SbCl_5$ the more polarized form of **15** seems to have a rather large contribution in the same solvent. The difference could be attributed to the stronger Lewis acidity (the ability of the chloride ion abstraction from another molecule) of $SbCl_5$ than $MoCl_5$.

18 **19**

As to a source of hydrogen chloride which may add to olefin to give **2**, two possibilities are conceivable; the decomposition of $MoCl_5$ to $MoOCl_3$ and HCl[8] by moisture, and hydride ion abstraction by $MoCl_5$ from olefin to give the molybdenum salt of allylic cation, $MoCl_3$, and hydrogen chloride, as was proposed in the case of the reaction with $SbCl_5$.[4] The former possibility does not seem to be important, since even in a careful experiment under N_2 in a dried condition the formation of **2** was observed, its amount being unaffected. Moreover, if hydrogen chloride arises only by the hydrolysis of $MoCl_5$, the amount of **2** in Run 8 (Table 1) should be larger than that in Run 6, since the time before the addition of olefin is much longer in Run 8 than in Run 6. In order to ascertain the latter possibility, we attempted the reaction of dihydroanthracene with $MoCl_5$ in CCl_4 just as in the case of $SbCl_5$.[13] Formation of anthracene was observed (see Experimental), although it was impossible to isolate hexachloromolybdate salt of 9-anthracenium cation. This shows that the molybdenum salt such as **20** can exist in solution (Scheme 6) by considering the reported observation using $SbCl_5$,[13] and consequently that $MoCl_5$ can abstract the hydride ion from certain organic compounds. In the chlorination of cyclohexene and octenes, resinous products were always obtained, probably because of the formation of dienes by elimination of hydrogen from olefin as described in scheme 6, and their polymerization. The reaction of 1,3-cyclooctadiene with $MoCl_5$ readily gave the polymerized product under the same conditions. We thus propose that the important source of hydrogen chloride is the hydride ion abstraction from allylic position of olefins by $MoCl_5$.



Mixed Halogenation of Olefins and Aromatic Halogenation. Bromochlorination and chloroiodination of olefins[14a] and the aromatic halogenation[14b] were carried out by using mixtures of antimony chlorides and halogens in

$$2\,\rangle C{=}C\langle + MoCl_5 + X_2 \rightarrow 2\,\rangle C(X)-C\langle(Cl) + MoCl_3 \qquad (7)$$

$$2\,ArH + MoCl_5 + X_2 \rightarrow 2\,ArX + MoCl_3 + 2HCl \qquad (8)$$

CCl_4 or CH_2Cl_2 as solvent.[14a] We found that similar reactions occurred by using $MoCl_5$ instead of $SbCl_5$. The reactions of olefins with a mixture of $MoCl_5$ and Br_2 or I_2 gave *trans*-bromochloro- or chloroiodo-alkanes respectively according to the stoichiometry shown in scheme 7 (Table 2), and the nuclear halogenation of benzene, toluene, halobenzenes occurred under similar conditions by use of aromatic compounds as substrates instead of olefins (Scheme 8 and Table 3). From a synthetic view point, however, the reactions using $MoCl_5$ were inferior to those with $SbCl_5$: The yield in the mixed halogenation was lower, the bromochlorination was accompanied by side reactions, the selectivity in aromatic halogenation was lower, and the aromatic compounds with electron-withdrawing groups such as nitrobenzene and ethyl benzoate could not be halogenated. In the reactions (Schemes 7 and 8),

the mixed halogens such as BrCl and ICl may be formed *in situ*, and the k_T/k_B value and the *o*/*p* ratio in the competitive halogenation (Table 4) suggest that the attacking species is not Br^+ or I^+ but the mixed halogen itself activated by $MoCl_5$, as in the reaction with $SbCl_5$.[14b] The larger k_T/k_B value and smaller *o*/*p* ratio in the $MoCl_5$ case than in the $SbCl_5$ case show that $MoCl_5$ is a weaker Lewis acid than $SbCl_5$ in line with the results of Friedel-Crafts aromatic acylation.[15]

Experimental

Commercial *trans*-2-butene(contains 1% of the *cis*-isomer) and *cis*-2-butene(contains 2.4% of the *trans*-isomer) were used without further purification. All the other organic substrates and solvents were purified by distillation before use. Commercial $MoCl_5$ (99% pure), Br_2, and I_2 were used without purification.

All the reactions were carried out by the method reported previously[4,14] by using $MoCl_5$ in the place of $SbCl_5$ or $SbCl_3$. Identification of the products in Tables 1, 2, and 3 except for 2-chloro-3-iodobutanes was described previously.[4,14]

Reaction of Norbornene with $MoCl_5$. To a solution of $MoCl_5$ (0.345 g, 1.26 mmol) in CCl_4(50 ml) was added norbornene (0.375 g, 3.99 mmol) at 25 °C and the resulting mixture was stirred for 2 hr under N_2. Aqueous NaOH was then added to stop the reaction. After the usual work-up, the organic layer was evaporated to *ca.* 20 ml. Acetone was added to give a small amount of white organic precipitates of norbornene polymer which were filtered off. The filtrate was analyzed by glc and found to contain **3** (0.664 mmol), **4**(0.006 mmol), **5**(0.035 mmol), **6**(0.068 mmol), **7** (0.060 mmol), and **8**(0.352 mmol) as organic products. The yield of the sum of **4**—**8** was 41.5% based on $MoCl_5$ charged. The identification of **4**—**7** was reported in a previous paper.[4] An authentic sample of **3** for glc was prepared by the method using norbornene and hydrogen chloride.[16] **8** was isolated from the combined distillates of several runs by preparative glc, its NMR spectrum being identical with the reported one.[10,17]

Reaction of Norbornadiene with $MoCl_5$. A similar reaction to that described above by using $MoCl_5$ (2.0 mmol) and norbornadiene (5.1 mmol) in CCl_4 (100 ml) gave **9**(0.86 mmol), **10**(0.088 mmol), **11**(0.040 mmol), **12**(trace), **13**(0.273 mmol), and a slight amount of norbornadiene polymer. The yield of the sum of **10**—**13** was 20.1%. Identification of the products was carried out as follows. Authentic samples of **9** and **12** for glc were prepared by the reported methods from the reactions of Cl_2 with norbornene[18] and norbornadiene,[10] respectively. NMR spectrum of **12** which was isolated by preparative glc was identical with the reported one.[19] Each of **10**, **11**, and **13** was isolated from the combined distillates of several runs by preparative glc. Each NMR spectrum was identical with the reported one.[19,20]

Reaction of Dihydroanthracene with $MoCl_5$. To a solution of $MoCl_5$ (0.52 g, 1.88 mmol) in CCl_4 (80 ml) was added dihydroanthracene (0.153 g, 0.86 mmol) dissolved in CCl_4 (20 ml) at 25 °C and the resulting mixture was stirred for 1 hr under N_2. Aqueous $NaHCO_3$ was then added. The organic layer was separated, washed with water, dried over Na_2SO_4, and concentrated to *ca.* 20 ml which was revealed by glc to contain 0.31 mmol of unreacted dihydroanthracene and 0.34 mmol of anthracene. A similar reaction by using $MoCl_5$ (2.03 mmol) and dihydroanthracene (1.02 mmol) for 5 hr gave 0.38 mmol of anthracene.

erythro- *and* threo-*2-Chloro-3-iodobutanes.* *trans*-2-Butene (2.2 g, 39.2 mmol) was bubbled at 25 °C for 30 min under stirring into a solution of CH_3CN(50 ml) containing anhydrous $CuCl_2$(1.46 g, 10.9 mmol) and I_2(2.83 g, 11.1 mmol). Glc analysis of ether extract after the usual work-up of the reaction mixture showed the presence of 15.8 mmol of *erythro*-2-chloro-3-iodobutane(72% yield) as porduct. Distillation gave 2.1 g of pure compound; bp 55.5 °C/18 mmHg(lit,[21] bp 34.8—35.3 °C/5 mmHg). NMR ($CDCl_3$) δ 1.68(d. 3H, J=6.5 Hz), 2.01 (d, 3H, J=6.5 Hz), 3.98 (quintet 1H, J=6.5 Hz), 4.28(quintet 1H, J=6.5 Hz).

A similar reaction of *cis*-2-butene(41 mmol) with $CuCl_2$ (10 mmol) and I_2(10.8 mmol) gave *threo*-isomer in 61% yield. Distillation gave 1.2 g of pure compound; bp 58—58.5 °C/18 mmHg (lit,[21] bp 33.2—33.5 °C/4 mmHg). NMR($CDCl_3$) δ 1.62(d, 3H, J=6.5 Hz), 1.93(d. 3H, J=6.5 Hz), 4.11(m. 1H), 4.49(m. 1H).

Analytical Instruments. The NMR spectra were determined by means of a Varian A-60 spectrometer in $CDCl_3$ and CCl_4 using TMS as an internal standard. Glc analysis was carried out with two Shimadzu apparatuses 5APTF and 4BMPF[EGSS-X(15%)-Chromosorb-W(3m), PEG 6000 (25%)-Chromosorb-W(3m), and Apiezon-L (30%)-Celite (1m) columns; carrier gas, N_2].

The Thermal Polycondensation of Glycine in the Presence of Urea

Yasuaki KŌZAI, Yoshiyuki IKEDA, and Masakazu YOSHIDA

Department of Chemistry, Faculty of Science, Kōnan University, Okamoto, Higashinada-ku, Kōbe 658

(Received May 29, 1974)

After the discovery of the polycondensation of glycine to form the glycine oligomer by heating in the presence of urea in a sealed tube, we investigated in order to establish the optimum reaction conditions as well as to study the reaction mechanism. The optimum conditions are attained when a mixture of 0.0133 mol (1 g) of glycine and 0.0016 mol (0.1 g) of urea is heated at about 160 °C for 20—30 hr. Under these conditions, an oligomer, composed of glycine units, with a polymerization degree of 17—18 is obtained with a 50—52% yield. The mechanism of oligomer formation is considered to be as follows: first, the urea is melted and part of it is used for converting the glycine to the corresponding amide. The glycinamide thus formed and the glycine dissolve locally in the molten urea, resulting in condensation between them. A repetition of the condensation leads to longer peptide chains.

The thermal polycondensation of glycine has long been investigated. Oligomers of glycine are formed by heating in the presence of glycerine,[1] the hippuric ester,[2] and mineral acids.[3] Recently, Oró and and Guidry[4] obtained the glycine oligomer with a polymerization degree of 12—18 by heating glycine in the presence of aqueous ammonia at 140—160 °C in a sealed tube, and Okamoto and Nakahara[5] reported that polyglycine with a high molecular weight was obtained by heating glycine in phosphoric acid.

The present authors also have investigated the thermal polycondensation of glycine for several years; so far they have obtained glycine oligomers with a polymerization degree of 10—20 by heating glycine in a sealed tube in the presence of water, inorganic acids, salts, and organic bases,[6] and organic acids.[7] We have also reported that the *N*-terminal of the oligomer thus obtained is acylated if organic acids are employed.

The authors chose urea as another possible effective polycondensation agent because it would not only act as a solvent, but would also be thermally decomposed into a biuret to evolve the NH_3 gas and would promote conversion to amide when heated with a carboxylic acid. They examined the thermal polycondensation of glycine in the presence of urea with a considerably high yield of the glycine oligomer. Then, some further examinations were made in order to establish the optimum reaction conditions and in order to clarify the reaction mechanism and the properties of the oligomer obtained. In this paper, the experimental data and results will be reported.

Experimental

Thermal Polycondensation. The sample, placed in a nitrogen-filled sealed tube (I.D., 1 cm; length, about 25 cm) was heated in a temperature-controlled oil bath at various temperatures for various periods of time. After the heating, the content of the tube was taken out and washed well with hot water. Then the residue was dialyzed for 24 hr in water which had been treated by an ion-exchanger and dried in a vacuum dessicator to obtain the glycine oligomer. Although the hot water contained a certain amount of unchanged glycine and a glycine oligomer with a polymerization degree of below 4, no attempt has been made to examine them.

Measurements. The average polymerization degree of the oligomer was determined by the Sōrensen formol titration method (*C*-terminal determination) and the Van Slyke amino-nitrogen determination method (*N*-terminal determination) after the oligomer had been dissolved in 50% aqueous calcium chloride.

The IR spectra were measured by means of the Hitachi EPI-S2 infrared spectrophotometer.

Results and Discussion

Reaction Conditions and Properties of Oligomer. In order to examine the effect of the amount of added urea on the thermal polycondensation of glycine, a a given amount of urea (0—0.01 mol) was added to 0.0133 mol (1 g) of glycine, after which the mixture was heated at a constant temperature (130—170 °C) for 20 hr. Figure 1 shows the results. The optimum amount of urea depends upon the heating temperature. An excess of urea leads to lower yields of the oligomer. In our experiments, the highest yield of the oligomer was obtained when the reaction mixture was heated at about 160 °C in the presence of 0.0016 mol of urea. A pale yellow oligomer was obtained in a yield of about 51%. The relationship between the amount of urea and the polymerization degree of the oligomer is shown in Fig. 2. This shows that, as the amount of urea increases, the polymerization degree of the oligomer grows higher at the *C*- and *N*-terminal determinations, but the difference between them gradually

becomes greater and the polymerization degree in the latter case indicates a more or less higher value. This seems to be due to an irreversible decomposition of the glycine oligomer, judging from the facts that the reaction product in the sealed tube turned black or brown with urea concentrations higher than 0.005 mol, that the oligomer taken out of the tube was yellowish brown or brown, and that a reduction was observed in the yield of the oligomer.

Next, in order to examine the effects of the heating temperature and heating time, 0.0133 mol (1 g) of glycine and 0.0016 mol (0.1 g) of urea were mixed and heated to 140—180 °C for 0—100 hr. Figure 3

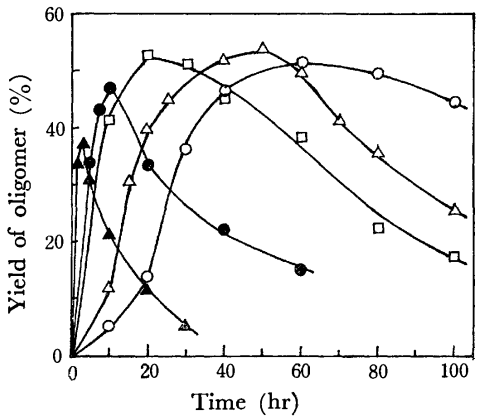

Fig. 3 Effects of heating temperature and heating time on the thermal polycondensation of glycine in the presence of urea.

○: 140°C, △:150°C, □: 160°C, ●: 170°C, ▲: 180°C

shows the results. According to the figure, the yield of the oligomer at each heating temperature increases with the heating temperature to reach a maximum. A higher temperature emphasizes this trend, but decreases the maximum yield of the oligomer. The relations between the heating temperature and the heating time for the yields higher than 50% are as follows:

Temperatures	Heating times
140 °C	60—70 hr
150 °C	40—60 hr
160 °C	20—30 hr

The polymerization degree of the oligomer obtained under these conditions and that of the oligomers which provided the maximum yields at 170 °C and 180 °C were measured by means of the *C*- and *N*-terminal determinations. The results are tabulated in Table 1. This table shows that the polymerization degrees increase with the heating temperatures. When the heating temperature reaches 170 °C, however, a gradual deviation between the values obtained by the *C*- and *N*-terminal determinations becomes significant. As is shown in Fig. 4, a similar trend can be observed in the relations between the heating time and the polymerization degree of the oligomer at 160 °C. As elevated heating temperatures and extented heating times decreased the yields of the oligomer, as the mixtures turned dark, as the internal pressure of the sealed tube increased, and as CO_2 gas was detected in the NH_3-rich gas, an irreversible decomposition of the glycine oligomer might occur, as has been mentioned previously.

Table 1. Relation between heating temperature and polymerization degree of glycine oligomer
Glycine: 0.0133 mol (1 g), Urea: 0.0016 mol (0.1 g)

Heating temperature (°C)	Heating time (hr)	Polymerization degree of oligomer	
		C-terminal determination	*N*-terminal determination
140	60	11.0	12.0
150	50	13.2	13.8
160	20	16.5	17.0
170	10	18.1	20.2
180	3	19.4	22.5

Glycine: 0.0133 mol (1 g), Urea: 0.0016 mol (0.1 g), Temperature: 160°C.
○: *C*-terminal determination, ●: *N*-terminal determination

From the experimental results so far obtained, it can be concluded that the optimum conditions for the polycondensation of glycine in the presence of urea occur when a mixture of 0.0133 mol (1 g) of glycine and 0.0016 mol (0.1 g) of urea is heated at 160 °C for

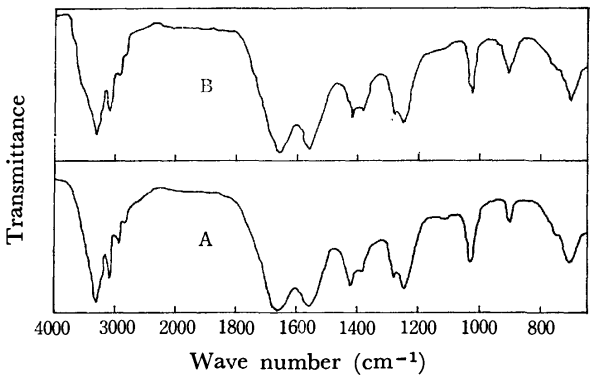

Fig. 5 Infrared absorption spectra (KBr).
A: Glycine oligomer obtained in the presence of urea,
B: Glycine oligomer obtained in the presence of water.

20—30 hr, with the polymerization degree of 17—18 and a yield of 50—52%. The oligomer thus formed is a pale yellow powder. It is soluble in concentrated aqueous solutions of calcium chloride, lithium bromide, or phosphoric acid, as well as in trichloroacetic acid, while it is very slightly soluble or insoluble in ordinary organic solvents and slightly soluble in an alkaline aqueous solution, presenting a distinct color change in a biuret reaction. The substance is influenced by heating in such a way that it begins to discolor at 230 °C, turns brown at 260 °C, and is completely carbonized at 280 °C. Furthermore, as is shown in Fig. 5, the IR spectrum of the oligomer found in the presence of urea coincides with that of the glycine oligomer obtained in the presence of water;[6] it showed typical peptide absorptions at 3300, 3070, 1648, and 1256 cm^{-1}, and a specific absorption at 1030 cm^{-1} based on the -Gly-Gly-connection. From the spectral analysis, it may be considered that the oligomer is composed of a single glycine unit.

Reaction Mechanism. As glycine undergoes polycondensation in the presence of urea with the evolution of CO_2, urea and glycine must first react with each other to form glycinamide. As is shown in Table 2, the polycondensation of glycine and glycinamide does not take place in the absence of glycerine, but the polycondensation of glycinamide alone does. However, a short heating treatment of the two substances in glycerine results in polycondensation between them, and through repeated condensation reactions, the peptide chains become longer with a considerably high yield of the glycine oligomer. Accordingly, urea may be considered to act as a solvent, just like glycerine, as well as converting glycine to glycinamide. Likewise, the use of a biuret instead of urea seems to give almost the same polycondensation results, as is shown in Table 3. Therefore, it may be considered that, as in the the case of urea, the biuret reacts with glycine to form glycinamide and acts as a solvent. Cyanuric acid, however, seems to show no such characteristics.

Table 2. Thermal polycondensation of glycine in the presence of glycinamide

Glycine: 0.0133 mol (1 g), Heating temperature: 160 °C

Reaction conditions			Oligomer

Dopaquinone and Related Compounds. The Reaction with Cyclopentadiene

Yoshimori OMOTE and Toshihiko KOMATSU

Department of Chemistry, University of Tsukuba, Sakura, Niihari, Ibaraki 300-31

(Received June 6, 1974)

The trapping of *o*-quinones produced during the oxidation of 4-substituted catechols(I, R=CH_3, $CH_2CH_2CO_2H$, $CH_2CH_2NH_3Br$, $CH_2CH(NH_3Cl)CO_2CH_3$) in the presence of cyclopentadiene affords adducts, which are changed into 8-substituted 5,6-diacetoxy-1,4-dihydro-1,4-methanonaphthalenes(IV, R=CH_3, $CH_2CH_2CO_2H$, $CH_2CH_2NHCOCH_3$, $CH_2CH(NHCOCH_3)COCH_3$) by treatment with acetic anhydride-pyridine Dopaquinone (IIe) is trapped with cyclopentadiene, followed by acetylation and methylation with acetic anhydride–pyridine–methanol (13 : 2 : 2) to give the *N*-acetyl-2-(5,6-diacetoxy-1,4-dihydro-1,4-methanonaphthyl-8)-L-alanine methyl ester (IVd).

In a previous report we described the synthesis of dopaquinone protected by methylation and benzoylation.[1] However, free dopaquinone was labile to be isolated or trapped by *o*-phenylenediamine. We have continued to inquire into the method of trapping *o*-quinone[2] and have succeeded in proving the presence of free dopaquinone by trapping with cyclopentadiene.

Results and Discussion

The UV spectrum with time intervals of the equimolar mixture of the *N*-benzoyl-DOPA methyl ester (I, R=$CH_2CH(NHCOC_6H_5)CO_2CH_3$) and *o*-chloranil indicates a decrease in *o*-chloranil absorption at 350 and 410 nm as well as an increase in a new absorption near 380 nm attributable to the formation of a new *o*-quinone (Fig. a). On the contrary, the spectral change of the mixture of dopamine hydrobromide(I, R=$CH_2CH_2NH_3Br$) and *o*-chloranil does not show any formation of the *o*-quinone in spite of the decrease in *o*-chloranil (Fig. b). It is known that DOPA and dopamine are easily oxidized into the corresponding indoline derivatives.[3] Consequently, a similar reaction seems to have occurred in the latter case.

For the purpose of trapping this intermediate, the reaction with cyclopentadiene was examined. Substituted *o*-benzoquinones(II) are known to give adducts(III) with cyclopentadiene.[2] Also, it is known that these adducts can be acetylated in the reaction mixture to give a stable catechol diacetate(IV).[2b,2c] These reactions were applied to the trapping of the *o*-benzoquinone. As a typical model experiment, 4-

methylcatechol(Ia) was oxidized with *o*-chloranil in the presence of cyclopentadiene, the reaction mixture being warmed with acetic anhydride–pyridine to afford Compound IVa. The structure of IVa was confirmed by the NMR, IR, and UV spectra and elemental analysis. Furthermore, IVa was quantitatively hydrogenated to give Va.

Cyclopentadiene is known to give an adduct with *o*-chloranil,[4] but under the present experimental conditions it does not react with *o*-chloranil and only reacts selectively with the newly-formed *o*-quinones. The characteristic feature of this trapping method is that the labile adduct of an *o*-benzoquinone with cyclopentadiene is, without isolation, transformed into a stable compound by acetylation.

The trapping transformation is applied to the oxidation of dihydrocaffeic acid (Ib), and the IIb quinone is thus trapped in the form of an acetyl compound, IVb. The cyclic isomer of IIb, a lactone,[5] is not found. Next, the trapping of dopamine hydrobromide (Ic) was examined, Compound IVc was thus obtained. This is chemical proof of the dopaminequinone adduct with cyclopentadiene (IIIc). It is obvious that cyclopentadiene adds to IIc under conditions similar to those described above, without cyclization into an indoline derivative, the free amino group in IIc doing no harm to the trapping.

Finally, the trapping experiment was successful in giving Compound IVd from the DOPA methyl ester (Id) and IVd from DOPA itself. In the case of DOPA, the isolation of IV, R=$CH_2CH(NHCOC_6H_5)CO_2H$, is very difficult. Therefore, the isolation of IVd was carried out after the esterification of the carboxyl group with methanol.

Experimental

1,4-Dihydro-8-methyl-1,4-methanonaphthalene-5,6-diol Diacetate (IVa). *(a)*: An ethereal solution of *o*-chloranil (2.00 g) was slowly added to a solution of 4-methylcatechol (1.00 g) in 20 ml of ether with stirring under nitrogen at −78 °C. After the mixture had been stirred for 1 hr, cyclopentadiene (1 ml) was added, the mixture was then stirred for an additional 4 hr at −78 °C and for 12 hr at room temperature. After the evaporation of the solvent, a mixture of acetic anhydride (35 ml) and pyridine (1 ml) was added to the residue, and the mixture was heated at 80—90 °C for 2 hr. A precipitate of tetrachlorocatechol diacetate was then removed, and the filtrate was evaporated and chromatographed on silica-gel to yield 1.66 g (74%) of IVa; white solid (sublimed); mp 90—91 °C; UV λ_{max}^{EtOH} (ε): 271 (430) and 280(355) nm; NMR ($CDCl_3$): δ 2.20(s, 3H), 2.23(m, 2H), 2.25(s, 6H), 3.82(m, 1H), 3.95(m, 1H), 6.48(s, 1H), and 6.73(m, 2H); IR (KBr): 3000, 2930, and 1770 cm^{-1}. Found: C, 70.58; H, 5.97%. Calcd for $C_{16}H_{16}O_4$: C, 70.57; H, 5.92%.

(b) A solution of *o*-chloranil (400 mg) in THF (10 ml) was added to a mixture of Ia (200 mg) and cyclopentadiene (0.2 ml) in THF (10 ml) at −78 °C. After the evaporation of the solvent, the residue was treated as has been described in *(a)*.

(c) At room temperature, a solution of *o*-chloranil (600 mg) in THF was added to a mixture of Ia (300 mg) and cyclopentadiene (1 ml) in THF. After 5 hr stirring and the removal of the solvent, the residue was treated with acetic anhydride–pyridine to yield 544 mg of IVa (75%).

(d) A solution of cerium(IV) sulfate (1.27 g) in 20% aqueous sulfuric acid (20 ml) was added to a mixture of Ia (200 mg) and cyclopentadiene (1 ml) in THF (20 ml) under nitrogen at −5 °C. After having been stirred overnight at room temperature, the mixture was extracted with ethyl acetate, washed, dried, and treated with acetic anhydride–pyridine to give 179 mg of IVa (37%).

(e) An aqueous solution of hydrochloric acid(2M, 2 ml) was added to a solution of Ia (300 mg) and cyclopentadiene (1 ml) in THF (30 ml), a solution of *o*-chloranil (600 mg) was then dropped into the mixture at room temperature, and the mixture was stirred for 5 hr. The yield was 483 mg (66.5%).

3-(5,6-Diacetoxy-1,4-dihydro-1,4-methanonaphthyl-8-)propionic Acid(IVb). Dihydrocaffeic acid (500 mg) gave 508 mg (56%) of IVb by the method (*b*) described in the preceding section; white needles from benzene; mp 131—132 °C; UV λ_{max}^{EtOH} (ε): 273(800) and 280(760) nm; NMR($CDCl_3$): δ 2.23(s, 3H), 2.25(m, 2H), 2.27(s, 3H), 2.4—3.0(m, 4H), 3.83(m, 1H), 4.02(m, 1H), 6.55(s, 1H), 6.75(m, 2H), and 7.77 (broad s, 1H, D_2O exchangeable); IR (KBr): 3200—3500, 1765, and 1700 cm^{-1}. Found: C, 65.39; H, 5.57%. Calcd for $C_{18}H_{18}O_6$: C, 65.44; H, 5.49%.

N-Acetyl-2-(5,6-diacetoxy-1,4-dihydro-1,4-methanonaphthyl-8-)ethylamine(IVc). Dopamine hydrobromide(Ic, 500 mg) gave 304 mg (42%) of IVc by the (*c*) method except that methanol was used instead of THF; glassy solid; NMR ($CDCl_3$): δ 1.90(s, 3H), 2.25, 2.30(s, 3H×2, and 2H), 2.75 (t, J=7 Hz, 2H), 3.28(t, J=7 Hz, 2H), 3.85(m, 1H), 4.00 (m, 1H), 6.30(broad m, 1H, D_2O exchangeable), 6.50 (s, 1H), and 6.75(m, 2H); IR (KBr): 3400, 3300, 2950, 1770, and 1650 cm^{-1}.

The N-Acetyl-2-(5,6-diacetoxy-1,4-dihydro-1,4-methanonaphthyl-8-)-L-alanine Methyl Ester(IVd) from DOPA methyl Ester. DOPA methyl ester hydrochloride (Id, 1.00 g) gave 668 mg (41%) of IVd by the (*c*) method; glassy solid; NMR ($CDCl_3$): δ 1.77(s, 3H), 2.24 2.29(s, 3H×2, and 2H), 3.10(d, J=7 Hz, 2H), 3.68(s, 3H), 3.83(m, 1H), 3.97(m, 1H), 4.83(q, J=7 Hz, 1H), 6.23(broad d, J=7 Hz, D_2O exchangeable), 6.45(s, 1H), and 6.75(m, 2H).

N-Acetyl-2-(5,6-diacetoxy-1,4-dihydro-1,4-methanonaphthyl-8-)L-alanine Methyl Ester(IVd) from DOPA. DOPA (Ie, 500 mg) was dissolved in hydrochloric acid (2M, 2 ml) and diluted to 30 ml with THF, to this mixture a solution of *o*-chloranil (625 mg) in THF was then added under nitrogen at room temperature, followed by the addition of cyclopentadiene (2 ml). After stirring for 2 hr, the solvent was removed and the residue was placed in a mixture of methanol (20 ml), acetic anhydride (130 ml), and pyridine (20 ml). The mixture was heated with stirring at 90—100 °C for 1 hr. Then the solvent was removed, and precipitates of tetrachlorocatechol diacetate were separated by filtration. Ethyl acetate was added to the filtrate, which was then washed with water, dried over anhydrous sodium sulfate, and evaporated to afford a residue which was subsequently purified by column chromatography on silica-gel, and eluted by ethyl acetate–benzene. The yield was 140 mg (14%) of IVd.

1,2,3,4-Tetrahydro-8-methyl-1,4-methanonaphthalene-5,6-diol Diacetate(Va). The catalytic hydrogenation of IVa with platinum oxide in acetic acid gave Va quantitatively as colorless prisms from cyclohexane; mp 99—100 °C; UV λ_{max}^{EtOH} (ε): 266(290) and 273(250) nm; NMR ($CDCl_3$): δ 1.0—2.0(m, 6H), 2.26(s, 3H), 2.29(s, 6H), 3.32(m, 1H), 3.43(m, 1H), and 6.67(s, 1H); IR(KBr): 2950 and 1765 cm^{-1}. Found: C, 70.11; H, 6.60%. Calcd for $C_{16}H_{18}O_4$: C, 70.05; H, 6.61%.

N-*Acetyl-2-(5,6-diacetoxy-1,2,3,4-tetrahydro-1,4-methanonaphthyl-8-)-ethylamine(Vc)*. Colorless prisms from benzene; mp 140 °C; UV λ_{max}^{EtOH} (ε): 267(460) and 274(420) nm; ($CDCl_3$): δ 1.0—2.0(m, 6H), 1.96(s, 3H), 2.29(s, 3H), 2.31(s, 3H), 2.80(m, 2H), 3.3—3.6(m, 2H×2), 5.85(broad m, 1H, D_2O exchangeable), and 6.71(s, 1H); IR (KBr): 3250, 3070, 2960, 1770, and 1640 cm^{-1}. Found: C, 66.32; H, 6.63; N, 4.13%. Calcd for $C_{19}H_{23}O_5N$: C, 66.07; H, 6.71; N, 4.06%.

The N-*Acetyl-2-(5,6-diacetoxy-1,2,3,4-tetrahydro-1,4-methanonaphthyl-8-)-*L*-alanine Methyl Ester(Vd)*. Glassy solid; UV λ_{max}^{EtOH}: 267 and 274 nm; NMR ($CDCl_3$): δ 1.0—2.0(m, 6H), 1.97(s, 3H), 2.23(s, 3H), 2.28(s, 3H), 3.06(d, J=7 Hz, 2H), 3.46(m, 2H), 3.67(s, 3H), 4.81(broad q, J=7 Hz, 1H), 6.30(broad d, J=7 Hz, 1H, D_2O exchangeable), and 6.60(s, 1H); IR (KBr): 3400, 3300, 2970, 1770, 1750, and 1660 cm^{-1}; MS: *m/e* 403 (M^+).

Reactions of Group IV Organometallic Compounds. XXX.[1] Stepwise Addition of Isocyanates and Isothiocyanates with *N*-Trimethylstannyl(diphenylmethylene)amine

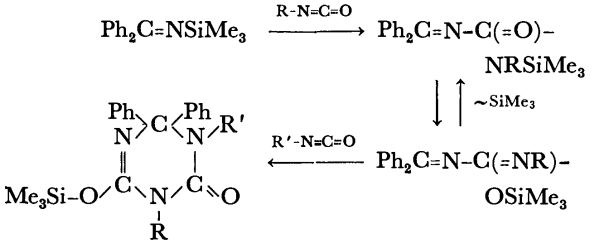
Hiroharu SUZUKI, Kenji ITOH,* Isamu MATSUDA, and Yoshio ISHII

Department of Synthetic Dhemistry, Faculty of Engineering, Nagoya University, Nagoya 464

(Received June 24, 1974)

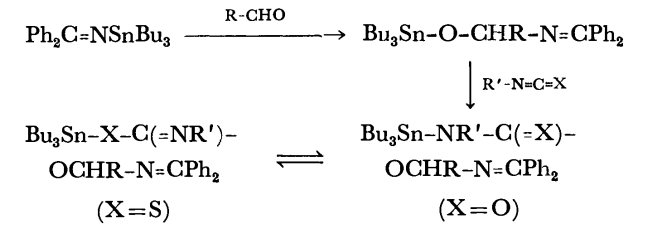
Stepwise addition of two isocyanates to *N*-trimethylstannyl(diphenylmethylene)amine, $Ph_2C{=}NSnMe_3$, gives 3,4-dihydro-1,3-dialkyl-4,4-diphenyl-6-trimethylstannoxy-1,3,5-triazin-2(1*H*)-one (II) by a polar [4+2] cycloaddition of the 1/1 adduct and the second isocyanate. The isothiocyanate adducts of $Ph_2C{=}NSnMe_3$ react with either isocyanates or isothiocyanates to yield the corresponding consecutive insertion products (IV).

In a previous paper[2] on the insertion reaction of *N*-trimethylsilyl(diphenylmethylene)amine with isocyanates or isothiocyanates, it was reported that the amine with isocyanates in a 1/2 ratio yielded 3,4-dihydro-1,3-dialkyl-4,4-diphenyl-6-trimethylsiloxy-1,3,5-triazin-2(1*H*)-one by a polar [4+2] cycloaddition.



R=R'=Me and Ph

Several reactions of *N*-organostannyl(alkylidene)-amines have been reported. Harrison[3] found many insertion reactions of $Ph_2C{=}NSnBu_3$ with unsaturated bonds including isocyanates and isothiocyanates. We were interested in the fact that the Sn–O bond of aldehyde adducts added to isocyanates or isothiocyanates results in consecutive insertion products.

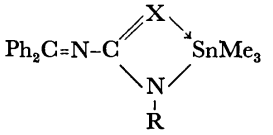


Lappert *et al.*[4] investigated various hydrogen abstraction, and insertion reactions of $R_2C{=}NSnMe_3$. They pointed out two aspects of the insertion reactions; (1) the N–H bond of trace $Ph_2C{=}NH$ showed a catalytic action, (2) the nucleophilic attack of the nitrogen atom was the primary step, resulting in a polar intermediate. This paper deals with the stepwise reactions of *N*-trimethylstannyl(diphenylmethylene)amine; $Ph_2C{=}N{-}SnMe_3$, with R–N=C=X (X=O and S), in order to determine whether the stepwise reaction is a polar [4+2] cycloaddition[2] or a consecutive insertion reaction.[3]

Results and Discussion

Structure of 1/1 Insertion Products. Equimolar reaction of $Ph_2C{=}NSnMe_3$ with R–N=C=X gave the corresponding insertion products, $Ph_2C{=}N{-}C(=X){-}NR{-}SnMe_3$ (1a—1e) in line with results reported.[3,4] Spectroscopic data for 1/1 insertion products are shown in Table 1.

The appearance of satellites of the methylamino proton signals in the case of Ia and Ib (R=Me) suggests that the trimethyltin group is attached to the nitrogen atom. However, the values of $J_{Sn-N-CH}$ (Ia, 24 Hz; Ib, 12 Hz) are much lower than those of $Me_3Sn{-}NMe_2$ (J^{117}=39.2 Hz and J^{119}=41.0 Hz).[5] The depression of the coupling constant is consistent with the weakening of the Sn–N bond by the coordination of the lone pair to tin atom.



I: R=Me and Ph, X=O and S

This is strongly supported by the low frequency of the carbonyl stretching bands of the isocyanate adducts (Ia and Ic). It is reasonable to conclude that the coordination of the sulfur atom of Ib ($J_{Sn-N-CH_3}$= 12 Hz) is stronger than that of oxygen atom of Ia

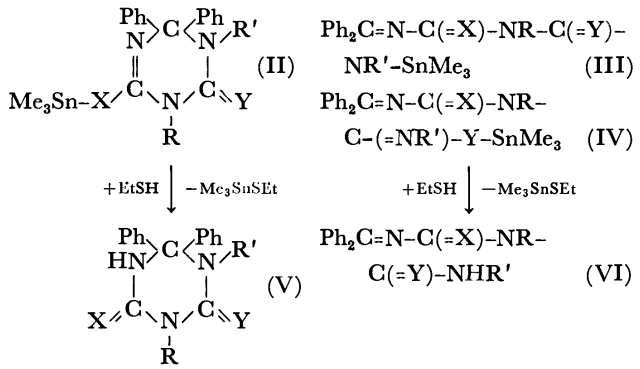
($J_{Sn-N-CH_3}$=24 Hz). Diphenylmethylenealkyl-ureas or thioureas, $Ph_2C{=}N{-}C(=X){-}NHR$, were obtained by the destannylation of Ia—Ie with ethanethiol. Their UV spectra showed $\pi\rightarrow\pi^*$ transition bands around 248—258 nm characteristic of the heterodiene linkage ($>C{=}N{-}\overset{|}{C}{=}N$).

Consecutive Reactions of 1/1 Adducts. The subsequent addition of the second heterocumulene to the 1/1 adducts can occur in two ways: a polar [4+2] cycloaddition yielding 3,4-dihydro-1,3-dialkyl-4,4-diphenyl-6-trimethylstannoxy-1,3,5-triazin-2(1*H*)-one(II). The destannylation of II giving hexahydro-1,3-dialkyl-4,4-diphenyl-1,3,5-triazin-2,4-dione (V); a consecutive insertion of the second heterocumulene into the Sn–N bond of the 1/1 adduct giving either of the two possible linear insertion products, III or IV. Both linear adducts III and IV afford the same *N,N'*-dialkylmethylenebiuret (VI) by destannylation.



Both the two pathways are actually operating, and the primary heterocumulene component of 1/1 insertion reactions plays the most important role in controlling the subsequent reactions.

(a) Annelation Reactions of Isocyanate 1/1 Adducts: When the isocyanate 1/1 adduct (Ia or Ib) was treated with methyl or phenyl isocyanate, crystalline products were isolated in good yields. They were concluded to be 1/2 adducts by analyses, NMR and IR spectra. The destannylation of isolated 1/2 adducts proceeded quantitatively by means of ethanethiol. None of the destannylation products showed a $\pi\rightarrow\pi^*$ transition due to a heterodiene linkage, $>C{=}N{-}\overset{|}{C}{=}O$. This supports the cyclic structure (V: X=Y=O) and is not consistent with the linear structure (VI: X=Y=O). Much stronger evidence of the cyclic structure (V) was obtained from the mass spectra of the destannylation products. Two destannylation products (runs a and c) showed peaks due to $[Ph_2C{=}N{-}CH_3]^+$ (m/e=195) and $[Ph_2C{=}N{=}CH_2]^+$ (m/e=194). The appearance of these peaks suggests the direct bonding of diphenylmethylene with the alkylamino group (R'–N) introduced by the second isocyanate, and are explained by the cyclic structure (V). The destannylation product of run b (order of addition: methyl then phenyl isocyanate) showed M^+–MeNCO peak (m/e=300). The presence of M^+–MeNCO is fully consistent with structure (V), because fragmentation of the linear structure (VI) should occur from the terminal position (only M^+—PhNCO would appear; direct elimination of the central component M^+—MeNCO, not being detectable). The IR spectrum of run d is also consistent with the cyclic structure (V: R=R'=Ph, X=Y=O); the carbonyl stretching frequencies at 1730 and 1657 cm^{-1} were similar to those of 1,3,5-triazindiones (1720 and 1680 cm^{-1}).[6] Mixed mp analyses, IR, and NMR spectra were the same as those of authentic hexahydro-1,3-dialkyl-6,6-diphenyl-1,3,5-triazin-2,4-dione (V).[2] Thus, the consecutive insertion process, giving III or IV then VI, is excluded, and the annelation products of isocyanate 1/1 adducts with the second isocyanate are concluded to be 3,4-dihydro-1,3-dialkyl-4,4-diphenyl-6-trimethylstannoxy-1,3,5-triazin-2(1*H*)-one (IIa—IIe) by a polar [4+2] cycloaddition.

The treatment of IIa and IId with ethanethiol afforded the corresponding hexahydro-1,3-dialkyl-6,6-diphenyl-1,3,5-triazin-2,4-dione (Va—Vd) quantitatively. This method provides a synthetic route for the preparation of triazindiones with three different

Table 2. The [4+2] cycloaddition of isocyanate adducts; 3,4-dihydro-1,3-dialkyl-4,4-diphenyl-6-trimethylstannoxy-1,3,5-triazin-2(1*H*)-one (II) and their demetallation products; hexahydro-1,3-dialkyl-6,6-diphenyl-1,3,5-triazin-2,4-dione (V)

substituents on the nitrogen atoms such as Vb and Vc. The yields and properties of these [4+2] cycloaddition products (IIa—IId) and their destannylation products (Va—Vd) are summarized in Table 2.

An atempt to react phenyl isothiocyanate with isocyanate 1/1 adducts (Ia and Ic) was unsuccessful, resulting in the recovery of starting materials. The less reactive phenyl isothiocyanate cannot add to 1/1 isocyanate adducts (Ia and Ic), since the nucleophilicity of the nitrogen atom in Ia or Ic is depressed by the electron-withdrawing group.

(b) Insertion Reactions of Isothiocyanate 1/1 Adducts: Further reactions of Ib or Id (isothiocyanate 1/1 adducts) with other isocyanates or isothiocyanates were found to proceed by a consecutive insertion reaction in a similar manner to those reported by Harrison.[3] The demetallation products of 1/2 adducts were concluded to be *N*-diphenylmethylene-*N'*,*N''*-dialkylthio- or dithiobiuret, which showed apparent $\pi\rightarrow\pi^*$ transitions due to the heterodiene linkage, >C=N–C=S, around 269~292 nm (log $\varepsilon\simeq4$). The fragmentation pattern of the destannylation products from the reaction of Ib with methyl isocyanate is consistent with the linear structure (VI), $[Ph_2C{=}N{-}C{=}S]^+$ (*m/e*=224), $[Ph_2C{=}N]^+$ (*m/e*=180), $[Ph_2C{=}N{-}C(=S){-}NMe]^+$ (*m/e*=253). Thus a further reaction of isothiocyanate adducts (Ib or Id) with either isocyanate or isothiocyanate should give the corresponding linear products(III or IV). No ^{117}Sn, or ^{119}Sn satellite band corresponding to the CH_3–N proton signal were observed in the NMR spectra of the products obtained in the case of runs e and f. Only linear structure (IV) is consistent with these spectroscopic properties.

a) Calculated values in parentheses. b) The demetallated products, Va and Vd, were identified with the authentic samples.

The consecutive insertion products of isothiocyanate 1/1 adducts [IVe—IVh] are summarized in Table 3.

(c) Mechanism of the Subsequent Reaction of the 1/1 Adducts: The drastic variation of the addition depending on the first component of the 1/1 adducts is illustrated by the following scheme.

	X	Y	R	R′		X	Y	R	R′
a	O	O	Me	Me	e	S	S	Me	Me
b	O	O	Me	Ph	f	S	O	Me	Me
c	O	O	Ph	Me	g	S	O	Ph	Ph
d	O	O	Ph	Ph	h	S	S	Me	Ph

Scheme

The primary step of addition of the Sn–N bond to the heterocumulene was assumed to occur by the nucleophilic attack of the nitrogen atom[4] giving a zwitterionic intermediate(VII). When X=O (run a∼d) the positive charge on C(1) is enhanced largely by the conjugated carbonyl group and is stabilized by resonance with the two phenyl rings. Thus the nucleophilic ring closure occurs between N(6) and C(1). The following migration of the trimethylstannyl group from the ammonium nitrogen to the oxygen atom yields the 1,3,5-triazin-2(1*H*)-one derivatives [IIa∼IId]. The positive charge on C(1) is small when X=S (run e∼h), since the thiocarbonyl group is weakly electron-withdrawing as compared with the carbonyl group. Consequently, the anionic center(Y) captures the electrophilic trimethylstannyl group giving the corresponding consecutive insertion products [IVe∼IVh]. In Harrison's case,[3] the aldehyde adducts did not have an electron-withdrawing group at C(3), and the formal charge on C(1) is consequently zero. The [4+2] cycloaddition reaction would therefore be impossible.

Experimental

Mps were determined in sealed capillaries filled with argon. Analyses were carried out by Alfred Bernhardt Mikroanalytisches Laboratorium, West Germany. IR spectra were recorded with a Japan Spectroscopic Co., Ltd. IR-S instrument. ^{1}H NMR spectra were measured with a Japan Electron Optics Lab. Co., Ltd. C-60HL instrument. *N*-Trimethylstannyl(diphenylmethylene)amine was prepared according to Chan and Rochow.[7] Isocyanates and isothiocyanates were distilled before use.

Reaction of N-*Trimethylstannyl(diphenylmethylene)amine with one Molar Equivalent of Benzoyl Isocyanate.* A colorless solution was obtained by addition of benzoyl isocyanate (0.692 g, 4.71 mmol) to a solution of *N*-trimethylstannyl(diphenylmethylene)amine (1.77 g, 5.15 mmol) in *ca.* 6 ml of benzene at 0 °C. The reaction was completed instantaneously. The 1/1 adduct (Ie) precipitated as white needles by the addition of *ca.* 4 ml of *n*-hexane was washed with *n*-hexane and dried *in vacuo* (2.19 g, 95%). Mp 52.0—54.0 °C. Found: C, 58.78; H, 5.05%. Calcd for $C_{24}H_{24}N_2O_2Sn$: C, 58.69; H, 4.92%. IR (in C_6H_6): 1673 and 1626 cm^{-1}. ^{1}H NMR (in $CDCl_3$): τ 9.68 (Me_3Sn, $J^{117/119}$ Sn–C–H=55.0/58.0 Hz). Equimolar reactions of *N*-trimethylstannyl(diphenylmethylene)amine with other isocyanates or isothiocyanates were carried out under similar reaction conditions (at 0 °C under an atmosphere of nitrogen). The yields and results of elemental analyses of the 1/1 adducts are summarized in Tables 1 and 4, respectively.

*Reaction of 1/1 Adduct (Ia) with Methyl Isocyanate. Formation of 3,4-Dihydro-1,3-dimethyl-4,4-diphenyl-6-trimethylstannoxy-1,3,5-triazin-2(1*H*)-one (IIa)*: To a solution of 0.81 g (2.02 mmol) of the 1/1 adduct of methyl isocyanate in 2 ml of *n*-hexane was added 0.129 g (2.26 mmol) of methyl isocyanate at 0 °C under nitrogen. White needles which separated out in a few minutes were washed with *n*-hexane and recrystallized from a mixed solvent of *n*-hexane and benzene (1/1). This was identified as 1/2 adduct (IIa) (0.835 g, 77%). Elemental analysis and ^{1}H NMR spectrum identified the crystal as 3,4-dihydro-1,3-dimethyl-4,4-diphenyl-6-trimethylstannoxy-1,3,5-triazin-2(1*H*)-one (IIa) containing 1 equivalent of benzene of crystallization. Mp 149.0—152.0 °C. Found: C, 58.63; H, 5.80%. Calcd for $C_{20}H_{25}N_3O_2Sn+C_6H_6$: C, 58.24; H, 5.83%. IR (in C_6H_6) 1688 and 1621 cm^{-1}. ^{1}H NMR (in $CDCl_3$): τ 9.88(Me_3Sn, $J^{117/119}$ Sn–C–H=54.0/56.0 Hz), 7.43 (Me–N), 6.96 (Me–N). Preparation of other 3,4-dihydro-4,4-diphenyl-1,3,5-triazin-2(1*H*)-ones; IIb (1-methyl-3-phenyl), IIc (1-phenyl-3-methyl), and IId (1,3-diphenyl) was achieved similarly. Yields and spectroscopic results are summarized in Table 2, and analytical data in Table 4.

Treatment of IIa with Ethanethiol. Formation of Hexahydro-1,3-dimethyl-6,6-diphenyl-1,3,5-triazin-2,4-dione (Va): Addition of ethanethiol to a benzene solution of the 1/2 adduct (IIa) afforded the destannylated product (Va) as white prisms. Mp 238.0—239.0 °C. IR (in KBr) 1723 and 1648 cm^{-1}. This compound was identified as the triazindione [Va] which could be prepared independently by the hydrolysis of the 1/2 adduct of *N*-trimethylsilyl(diphenylmethylene)amine with

methyl isocyanate. Preparation of other *s*-triazindiones Vb, Vc, and Vd was achieved similarly. Yields, mp, and IR data are given in Table 2 and elemental analysis data in Table 4.

Reaction of 1/1 Adduct (Id) with One Equivalent of Phenyl Isocyanate. To a solution of 0.910 g (2.65 mmol) of *N*-trimethylstannyl(diphenylmethylene)amine in *ca.* 2 ml of benzene was added 0.350 g (2.59 mmol) of phenyl isothiocyanate at 0 °C under the atmosphere of nitrogen. On addition of phenyl isothiocyanate the color of the reaction mixture turned yellowish brown. The reaction mixture was left overnight at room temperature. Its IR spectrum showed the formation of 1/1 adduct [Id]. A solution of 0.314 g (2.64 mmol) of phenyl isocyanate in *ca.* 4 ml of benzene was then added at 0 °C. The mixture was warmed up to room temperature and allowed to stand for 15 hr. White prisms of the 1/2 adduct (IVg) separated out quantitatively were washed with benzene and recrystallized from a mixed solvent of *n*-hexane and benzene (4/6). Mp 164.5—166.0 °C. Found: C, 60.05; H, 4.91%. Calcd for $C_{30}H_{29}N_3OSSn$: C, 60.22; H, 4.89%. IR (in C_6H_6) 1698 and 1355 cm^{-1}. ^1H NMR (in $CDCl_3$) τ 9.72 (Me_3Sn, $J^{117/119}$ Sn–C–H= 56.0/58.0 Hz).

Destannylation of IV. Addition of ethanethiol to the benzene solution of 1/2 adduct (IVg) gave the destannylated product (VIg) as white prisms. Mp 252.0—254.0 °C. IR (in KBr) 1703 cm^{-1}. λ_{max}^{EtOH} 279 nm (log ε=4.50). Consecutive insertion reactions of the isothiocyanate 1/1 adducts (Ib or Id) with another isocyanate or isothiocyanate were performed under similar reaction conditions. The yields and the results of the elemental analyses are summarized in Tables 3 and 4, respectively.

Synthesis of Butirosin B and Its 3′,4′-Dideoxy Derivative[1]

Daishiro IKEDA, Tsutomu TSUCHIYA, Sumio UMEZAWA, and Hamao UMEZAWA*

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Yokohama 223

**Institute of Microbial Chemistry, Kamiosaki, Shinagawa-ku, Tokyo 141*

(Received June 26, 1974)

The total synthesis of butirosin B (**5**) is described. Its 3′,4′-dideoxy derivative (**11**) has been synthesized, a cyclic carbamate derivative (**2**) being used as the key compound. The dideoxy derivative (**11**) was prepared by hydrogenation of a 3′,4′-unsaturated derivative (**10**) obtained by the reaction of a di-*O*-mesyl derivative (**9**) with sodium iodide and zinc dust. The dideoxy derivative (**11**) was found to have significant activity against resistant bacteria producing phosphotransferase I.

Butirosins[2] and the related antibiotic, ribostamycin[3] show an interesting contrast. Chemically, butirosin B is an acylated derivative of ribostamycin with (*S*)-4-amino-2-hydroxybutyryl side chain attached to the C-1 amino group of the 2-deoxystreptamine moiety. A comparison of the antibacterial spectrum of butirosin B and that of ribostamycin showed that butirosin has a broader spectrum, inhibiting kanamycin-resistant bacteria which produce kanamycin phosphotarnsferase I.[4] The present paper deals with the syntheses of butirosin B and its 3′,4′-dideoxy derivative from ribostamycin. Since ribostamycin has been synthesized,[5] the present synthesis constitutes the total synthesis of butirosin B.

As the starting material we used tetra-*N*-benzyloxycarbonyl-3′,4′;2″,3″-di-*O*-cyclohexylidene-5″-*O*-(1-methoxycyclohexyl)ribostamycin (**1**), an intermediate in the synthesis of 3′,4′-dideoxyribostamycin.[6] The derivative (**1**) has one hydroxyl group adjacent to the 1-*N*-benzyloxycarbonyl group, other hydroxy and amino groups being protected. When sodium hydride was added in a solution of **1** in DMF at room temperatures, smooth reaction occurred to give tri-*N*-benzyloxycarbonyl-3′,4′;2″,3″-di-*O*-cyclohexylidene-5″-*O*-(1-methoxycyclohexyl)ribostamycin 1,6-carbamate (**2**) in 78% yield. The IR spectrum showed a sharp peak at 1770 cm^{-1}, indicating the presence of a cyclic carbamate.[7] The structure of (**2**) was also confirmed by its NMR spectrum. A method was given for simultaneous blocking of adjacent amino and hydroxyl groups in a trans-diequatorial configuration by carbamate-ring formation, the above reaction being used as an alternative method. Formation of cyclic carbamate can be viewed as an anchimeric attack of the C-6 alkoxide-ion on the urethane carbonyl at C-1.

Treatment of the carbamate (**2**) with a limited amount of barium hydroxide in aqueous dioxane selectively cleaved the carbamate ring, to give an aminol (**3**) in 70% yield. The aminol was then condensed with (*S*)-2-hydroxy-4-phthalimidobutyric acid[8] (HPBA) by the active ester method to give the acylated product (**4**), which was treated successively with hydrazine in 80% ethanol to remove the phthaloyl group, with palladium black and hydrogen to remove the benzyloxycarbonyl groups and with 1M hydrochloric acid to remove the cyclohexylidene groups, giving butirosin B (**5**). The R_f values on ppc and tlc, the optical rotation, the IR and NMR spectra and the antibacterial activity[1] were identical with those of the natural specimen of butirosin B.

We undertook to prepare a modification of butirosin B. Butirosin A is active against kanamycin-resistant bacteria producing phosphotransferase I but inactivated by bacteria producing phosphotransferase II[3] (*e.g.*, *E. coli* JR 66/W677) by phosphorylation of the 3′-hydroxyl group. Synthesis of 3′,4′-dideoxybutirosin B was therefore undertaken.

Compound **4** was taken as the starting material and the 5″-protecting group was selectively removed by controlled acid-hydrolysis to give **6**. After acetylation, the tri-*O*-acetyl derivative (**7**) was further treated with acetic acid to give the diol (**8**). Mesylation then gave the 3′,4′-di-*O*-mesyl derivative (**9**). Similar treatment of **9** with sodium iodide and zinc dust in DMF to that for the preparation of 3′,4′-dideoxykanamycin B (under stricter conditions) gave 3′,4′-dideoxy-3′-eno derivative (**10**) in yield of 73%.[9] Hydrogenation of the double bond followed by the removal of the protecting groups gave 3′,4′-dideoxybutirosin B (**11**). In order to confirm the structure, **11** was partially hydrolyzed to give 1-*N*-((*S*)-4-amino-2-hydroxybutyryl)-3′,4′-dideoxyneamine.[1]

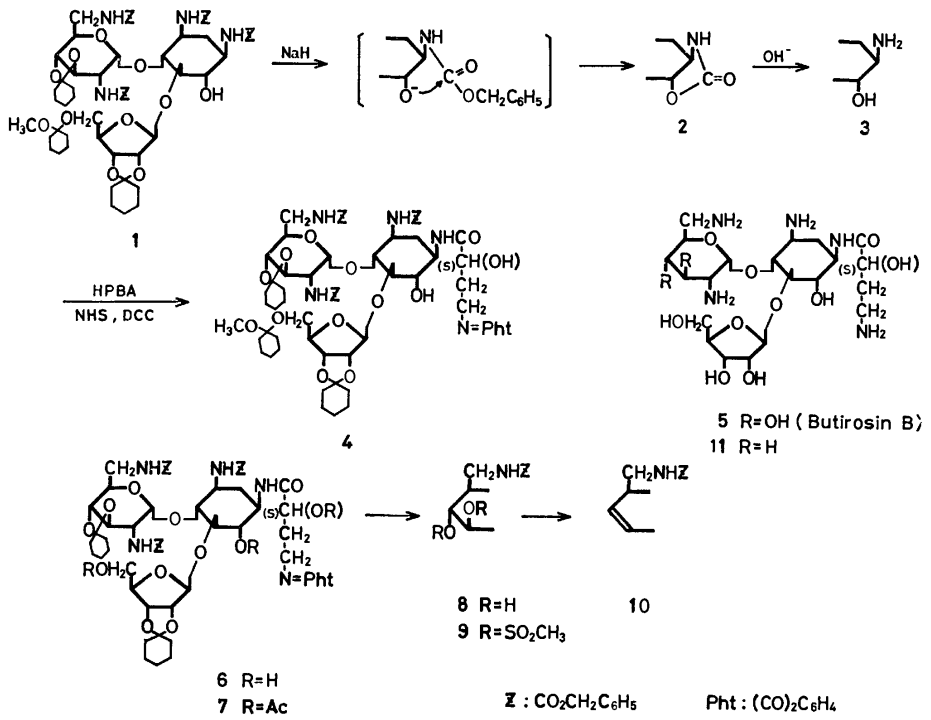
3′,4′-Dideoxybutirosin B was found to be active[1] against kanamycin-resistant bacteria producing phosphotransferase II as expected.

Experimental

Thin layer chromatography (tlc) was carried out on silica gel and the spots were visualized with sulfuric acid. Paper chromatography (ppc) was performed on Toyo-Roshi paper No. 50. The spots were detected with 0.5% ninhydrin in pyridine.

3,2′,6′-Tri-N-benzyloxycarbonyl-3′,4′; 2″,3″-di-O-cyclohexylidene-5″-O-(1-methoxycyclohexyl)ribostamycin 1,6-Carbamate (2). 50% Oily sodium hydride (97 mg) was added to an ice-cold solution of **1** (1.30 g) in dry DMF (15 ml), after displacement of the air in the reaction vessel with nitrogen, and the mixture was stirred at room temperature for 2 hr. On tlc with benzene–ethyl acetate (3 : 2), the solution showed a single spot at R_f 0.40 (**1**: 0.87). The pale-yellow solution was neutralized with acetic acid, evaporated, and the residue was poured into a mixture of chloroform and water with stirring. The organic layer separated was washed with water, dried with Na_2SO_4 and evaporated. The resulting syrup was chromatographed on a short column of silica gel with benzene–ethyl acetate–triethylamine (60 : 30 : 0.5) to give a solid, 930 mg (78%), $[\alpha]_D^{25}$ +14.4° (*c* 2, $CHCl_3$); IR(KBr): 1770, 1720, 1530 cm^{-1}.

Found: C, 63.55; H, 7.03; N, 4.68%. Calcd for $C_{61}H_{78}$-



N_4O_{18}: C, 63.42; H, 6.80; N, 4.85%.

NMR (in $CDCl_3$): τ 8.8—8.2 (30H, cyclohexylidene), 6.82 (3H s, OCH_3), ~2.67 (15H, $CH_2C_6H_5$).

3,2',6'-Tri-N-benzyloxycarbonyl-3',4';2'',3''-di-O-cyclohexylidene-5''-O-(1-methoxycyclohexyl)ribostamycin (3). A barium hydroxide solution (2.5 ml, containing 68 mg of barium hydroxide octahydrate) was added to a solution of **2** (500 mg) in dioxane (2 ml), and the mixture was stirred at 98 °C for 40 min. The solution became neutral. On tlc with benzene–methanol (7 : 1), the solution gave two spots of R_f 0.11 (**3**) and R_f 0.75 (**2**) in almost equal strength. Another aliquot (2.5 ml) of barium hydroxide solution was added and the solution was treated as above. The solution became weakly alkaline and, on tlc, gave three spots of R_f 0.11 (major), 0.75 (slight) and 0.87 (slight). After introducing carbon dioxide, the solution was evaporated and the residue was extracted with chroloform. The solution was washed with water, dried with Na_2SO_4 and evaporated. The residue (485 mg) was chromatographed on a column of silica gel with benzene–ethyl acetate (3 : 1) and then with benzene–methanol–triethylamine (70 : 10 : 0.5) to give a solid, 342 mg (70%), $[\alpha]_D^{27}$ +16.7° (*c* 2, $CHCl_3$); weakly ninhydrine positive; IR (KBr): 1720, 1530 cm^{-1}.

Found: C, 63.69; H, 7.28; N, 4.90%. Calcd for $C_{60}H_{80}N_4O_{17}$: C, 63.81; H, 7.41; N, 4.96%.

3,2',6'-Tri-N-benzyloxycarbonyl-3',4';2'',3''-di-O-cyclohexylidene-1-N-((S)-2-hydroxy-4-phthalimidobutyryl)-5''-O-(1-methoxycyclohexyl)ribostamycin (4). To an ice-cold solution of HPBA (62 mg, 1.3 mol eq.) and *N*-hydroxysuccinimide (NG) (27 mg, 1.3 mol eq.) in THF (2 ml) was added dicyclohexylcarbodiimide (54 mg, 1.3 mol eq.) and the mixture was stirred for 1 hr in the cold. A solution of **3** (200 mg, 1 mol eq.) and triethylamine (30 mg) in THF (2 ml) was added to the resulting suspension containing dicyclohexylurea, and the mixture was stirred at room temperature overnight. On tlc with benzene–ethyl acetate (1 : 1), the mixture showed three spots of R_f 0.7, 0.4 (**4**) and 0. After filtration, the solution was evaporated and the residue was chromatographed on a column of silica gel with benzene–ethyl acetate–triethylamine (60 : 40 : 0.5) to give a solid, 161 mg (67%), $[\alpha]_D^{27}$ +9.9° (*c* 2, $CHCl_3$); IR (KBr): 1710, 1655, 1530 cm^{-1}.

Found: C, 63.58; H, 6.56; N, 5.04%. Calcd for $C_{72}H_{89}N_5O_{21}$: C, 63.56; H, 6.59; N, 5.15%.

NMR (in $CDCl_3$): τ 9.0—7.5 (~36H, cyclohexylidene, $(CH_2)_2$, two OH (?)), 6.82 (3H s, OCH_3), 2.73—2.6 (15H, $CH_2C_6H_5$), 2.28 (4H, $(CO)_2C_6H_4$).

1-N-((S-4-Amino-2-hydroxybutyryl)ribostamycin (Butirosin B) (5). 80% Hydrazine hydrate (3 g) was added to a suspension of **4** (198 mg) in 80% aqueous ethanol (4.5 ml), and the mixture was heated at 60 °C for 2 hr. On tlc with ethyl acetate–methanol (1 : 1), the clear solution showed a ninhydrin-positive spot (R_f 0.15). The solution was evaporated and the residue was extracted with chloroform. The solution was evaporated and the residue was extracted with dioxane. The solution was filtered and to the filtrate (2 ml) were added water (1 ml) and a few drops of acetic acid and the mixture was hydrogenated with palladium black at 40—45 °C overnight. The reaction mixture was filtered, evaporated, and the residue was dissolved in 1M hydrochloric acid (1 ml). The solution was heated at 55° C for 1 hr. Addition of acetone gave a solid, which was chromatographed on a column of CM-Sephadex C-25 (NH_4^+ form, 20 ml) with water (100 ml) and aqueous ammonia of 0.05—0.5 M (linear increase). Butirosin B was eluted with *ca.* 0.4 M ammonia. Evaporation of the solution gave a soild, 51 mg (63%), $[\alpha]_D^{30}$ +34° (*c* 2, H_2O) [lit,[2] +33° (*c* 1.5, H_2O)]; ppc, $R_{f\,\text{ribostamycin}}$ 0.53 (1-butanol–pyridine–water–acetic acid (6 : 4 : 3 : 1)], the value being identical with that of natural butirosin B; IR (KBr): 1640, 1560 cm^{-1}.

Found: C, 43.65; H, 7.49; N, 12.08%. Calcd for $C_{21}H_{41}N_5O_{12}\cdot H_2O$: C, 43.97; H, 7.56; N, 12.21%.

NMR (in D_2O): τ 8.3—7.7 (5H), 4.6 (2H m, H-1', 1'').

3,2',6'-Tri-N-benzyloxycarbonyl-3',4';2'',3''-di-O-cyclohexylidene-1-N-((S)-2-hydroxy-4-phthalimidobutyryl)ribostamycin (6). A solution of **4** (440 mg) in 40% acetic acid–acetone (1 : 9, 10 ml) was allowed to stand at room temperature for 2 hr. 40% Acetic acid (0.6 ml) was added and the solution was allowed to stand for 6 hr. On tlc with benzene–ethyl

acetate (1 : 2), the solution showed three spots at R_f 0.72 (**4**, slight), 0.43 (**6**, major) and 0 (slight). The latest one increased with prolonged reaction. The solution was poured into a mixture of chloroform and sodium hydrogen carbonate solution with stirring. The organic layer was washed with water, dried with Na_2SO_4 and evaporated. The residue (410 mg) was chromatographed on a column of silica gel with benzene–ethyl acetate (1 : 2). After complete elution of **4** (100 mg), the eluant was changed to chloroform-methanol (27 : 1, **6** is scarcely soluble in the first solvent system, but soluble in this system). A solid (290 mg, 71%) obtained was reprecipitated from chloroform–*n*-hexane, $[\alpha]_D^{28}$ +16° (*c* 2, $CHCl_3$).

Found: C, 62.34; H, 6.33; N, 5.55%. Calcd for $C_{65}H_{77}N_5O_{20}$: C, 65.54; H, 6.22; N, 5.61%.

NMR (in $CDCl_3$): τ 8.9—7.5 (~26H), 4.9 (6H, $CH_2C_6H_5$), ~2.7 (15H two peaks, $CH_2C_6H_5$), 2.25 (9H incomplete d, $(CO)_2C_6H_4$).

1-N-*((S)-2-Acetoxy-4-phthalimidobutyryl)-6,5″-di*-O-*acetyl-3,2′, 6′-tri*-N-*benzyloxycarbonyl-3′,4′;2″,3″-di*-O-*cyclohexylideneribostamycin (**7**).* A sample (320 mg) of **6** was treated with acetic anhydride and pyridine in the usual manner to give a solid, 311 mg (88%, reprecipitated from benzene–*n*-hexane), $[\alpha]_D^{25}$ +9° (*c* 1.7, $CHCl_3$).

Found: C, 62.22; H, 6.27; N, 4.99%. Calcd for $C_{11}H_{83}N_5O_{23}$: C, 62.04; H, 6.09; N, 5.10%.

NMR (in $CDCl_3$): τ 7.94, 7.85 and 7.78 (each 3H s, Ac).

1-N-*((S)-2-Acetoxy-4-phthalimidobutyryl)-6,5′-di*-O-*acetyl-3,2′, 6′-tri*-N-*benzyloxycarbonyl-2″,3″*-O-*cyclohexylideneribostamycin (**8**).* A solution of **7** (300 mg) in 60% acetic acid–acetone (4 ml+ 5 ml) was allowed to stand at 60 °C for 75 min. On tlc with benzene–ethyl acetate (1 : 3), the solution showed a single spot of R_f 0.42. The solution was evaporated and the residue was shaken with a mixture of chloroform and saturated sodium hydrogen carbonate solution. From the organic layer, a solid of **8** was obtained, 252 mg (90%, reprecipitated from chloroform–*n*-hexane), $[\alpha]_D^{25}$ +1.5° (*c* 1.7, $CHCl_3$).

Found: C, 60.69; H, 6.11; N, 5.15%. Calcd for $C_{65}H_{75}N_5O_{23}$: C, 60.32; H, 5.84; N, 5.41%.

NMR (in $CDCl_3$): τ 8.8—8.3 (10H, cyclohexylidene), 8.2—7.6 (4H), 7.97, 7.87 and 7.82 (each 3H s, Ac), 4.9 (6H, $CH_2C_6H_5$), 2.70 and 2.65 (5H s, 10H s, respectively, $CH_2C_6H_5$), 2.20 (4H incomplete d).

1-N-*((S)-2-Acetoxy-4-phthalimidobutyryl)-6,5″-di*-O-*acetyl-3,2′, 6′-tri*-N-*benzyloxycarbonyl-2″,3″*-O-*cyclohexylidene-3′,4′-di*-O-*mesylribostamycin (**9**).* Mesyl chloride (45 mg) was added to a solution of **8** (240 mg) in pyridine (5 ml), and the solution was allowed to stand for 37 °C overnight. On tlc with benzene–ethyl acetate (1 : 1), the solution showed two spots at R_f 0.18 (monomesyl derivative) and 0.39 (**9**). Mesyl chloride (20 mg) was added and the solution was heated at 60 °C for 2 hr. After addition of a drop of water, the solution was evaporated and the residue was dissolved in chloroform. The solution was washed successively with potassium hydrogen sulfate solution, sodium hydrogen carbonate solution and water, dried over Na_2SO_4, and evaporated to give a syrup, which was reprecipitated from chloroform–*n*-hexane to give a solid of **9**, 258 mg (98%), $[\alpha]_D^{20}$ −9° (*c* 2, $CHCl_3$); IR 1175 cm^{-1}.

Found: C, 55.82; H, 5.63; N, 4.79; S, 4.27%. Calcd for $C_{67}H_{79}N_5O_{27}S_2$: C, 55.84; H, 5.49; N, 4.83; S, 4.42%.

NMR (in $CDCl_3$): τ 7.93, 7.86 and 7.77 (each 3H s, Ac), 7.23 and 6.96 (each 3H s, SO_2CH_3).

1-N-*((S)-2-Acetoxy-4-phthalimidobutyryl)-6,5″-di*-O-*acetyl-3,2′, 6′-tri*-N-*benzyloxycarbonyl-2″,3″*-O-*cyclohexylidene-3′,4′-dideoxy-3′-enoribostamycin (**10**).* Sodium iodide (2.1 g; dried at 110 °C for 2 hr), zinc dust (1.0 g; dried at 110 °C for 2 hr) and molecular sieves (100 mg; Union Carbide Co., Grade 3A, dried at 260 °C for 3 hr) were added to a solution of **9** (200 mg) in DMF (4 ml; dried over CaH_2 and distilled in vacuo just before use), and the mixture was stirred at 89.5—90 °C (oil bath temperature) for 1 hr. The temperature was maintained strictly in the above range with a thermostabilizer. Temperature fluctuation caused a decrease in the tlc with benzene–ethyl acetate (1 : 1), the mixture showed a spot at R_f 0.48 (**10**) and trace spots at R_f 0.56 (**9**) and 0. Chloroform (20 ml) was added and the mixture was filtered with the aid of chloroform (20 ml). The filtrate was washed successively with saturated sodium chloride solution, sodium thiosulfate solution and water, dried over Na_2SO_4 and evaporated. The syrup was chromatographed on a short column of silica gel with benzene–ethyl acetate (1 : 1) to give a solid of **10**, 128 mg (73%), which was reprecipitated from chloroform–*n*-hexane, mp 99—102 °C, $[\alpha]_D^{23}$ −24.5° (*c* 2, $CHCl_3$).

Found: C, 61.77; H, 5.71; N, 5.56%. Calcd for $C_{65}H_{73}N_5O_{21}$: C, 61.94; H, 5.84; N, 5.56%.

NMR (in $CDCl_3$): τ 7.99, 7.90 and 7.83 (each 3H s, Ac), 4.38 (2H slightly broadened s, H-3′,4′).

1-N-*((S)-4-Amino-2-hydroxybutyryl)-3′,4′-dideoxyribostamycin (3′,4′-Dideoxybutirosin B) (**11**).* A sample of **10** was treated as in the preparation of butirosin B from **4**, giving **11**, yield 80%, $[\alpha]_D^{16}$ +25° (*c* 1.8, H_2O), $R_{f\,\text{butirosin B}}$ 1.73 (ppc with 1-butanol-pyridine-water-acetic acid (6:4:3:1)), R_f 0.24 (tlc with chloroform-methanol-17% ammonia (1 : 4 : 3)).

Found: C, 46.74; H, 7.70; N, 13.13%. Calcd for $C_{21}H_{41}N_5O_{10}\cdot H_2O$: C, 46.57; H, 8.00; N, 12.93%.

NMR (in D_2O): τ 9.0—7.5 (~10H), 4.6 (2H m, H-1′,1″).

(Received June 26, 1974)

The titled compound (**5**) has been prepared from 3′,4′-dideoxyneamine or ribostamycin *via* 1,6-cyclic carbamate intermediates (**2** and **12**). 3′,4′-Dideoxygenation, which is the key step in the synthesis from ribostamycin, was accomplished by the hydrogenation of 3′,4′-unsaturated derivative which was prepared from the corresponding 3′,4′-di-*O*-mesyl derivative by the action of sodium iodide and zinc dust in DMF. The title compound was found to have an improved antibacterial spectrum broader than 3′,4′-dideoxyneamine.

As described in the preceding paper,[2)] 3′,4′-dideoxygenation of butirosin B was found to give a compound having a broader antibacterial spectrum than butirosin B. The recognition of the remarkable effects of combination of 3′,4′-dideoxygenation and N-1 acylation with (*S*)-4-amino-2-hydroxybutyryl group led us to the synthesis of N-1 acylated derivative of 3′,4′-dideoxyneamine. Since neamine forms a large portion of kanamycin B and ribostamycin, and appears to play an essential role in the antibacterial action of these antibiotics, we were interested in studying the above-mentioned modification of neamine. The present paper deals with the synthesis of 1-*N*-[(*S*)-4-amino-2-hydroxybutyryl]-3′,4′-dideoxyneamine (**5**).

The selective acylation of C-1-amino group of 2-deoxystreptamine moiety is generally difficult, however, in the present synthesis, the N-1-acylation has been achieved through a cyclic carbamate intermediate by a method[3)] similar to that described for butirosin synthesis.[2)]

When tetra-*N*-benzyloxycarbonyl-3′,4′-dideoxyneamine (**1**), which has been prepared from 3′,4′-dideoxyneamine,[4)] was treated with sodium hydride in DMF, the cyclic 1,6-carbamate (**2**) was obtained in 62% yield. Selective hydrolysis of the cyclic carbamate group with a limited amount of barium hydroxide in aqueous dioxane yielded 3,2′,6′-tri-*N*-benzyloxycarbonyl 3′,4′-dideoxyneamine (**3**). Acylation of the C-1-amino group with (*S*)-2-hydroxy-4-phthalimidobutyric acid[5)] (HPBA) in the presence of *N*-hydroxysuccinimide (NHS) and dicyclohexylcarbodiimide (DCC) gave the N-1-acyl derivative (**4**), which, on deblocking, led to the title compound (**5**).

An alternative synthesis of the title compound (**5**) has been achieved by a route from ribostamycin. Methanolysis of tetra-*N*-benzyloxycarbonylribostamycin[6)] (**6**) gave tetra-*N*-benzyloxycarbonylneamine (**7**) in high yield. Direct benzyloxycarbonylation of neamine has also been attempted, however, in this case, separation of the product from inorganic material was unusually troublesome.

Selective cyclohexylidenation of **7** has been accomplished in a manner similar to that described in the synthesis of 3′,4′-dideoxyneamine,[4)] affording **8**. Mesylation gave the 3′,4′-di-*O*-mesyl derivative (**9**), which, on treatment with sodium iodide and zinc dust in DMF by the procedure previously reported,[2,7)] furnished the 3′,4′-unsaturated derivative (**10**) in 76% yield.

Decyclohexylidenation of **10** by acid hydrolysis gave **11**, which was then treated with sodium hydride in DMF to give the cyclic carbamate **12**. The carbamate was selectively hydrolyzed by alkaline treatment to give **13**. Finally, N-1-acylation of **13** with HPBA, NHS and DCC followed by hydrogenation and deblocking afforded **5**, which was identical with the specimen prepared by the foregoing method.

Retention of configuration at C-2 of the side chain in **5** was confirmed by acid hydrolysis,[8)] which gave (*S*)-4-amino-2-hydroxybutyric acid.

The N-1-acylated derivative (**5**) of 3′,4′-dideoxyneamine showed enhanced antibacterial activity broader than 3′,4′-dideoxyneamine, exhibiting activity against various strains of sensitive and resistant bacteria[1)] as expected.

Experimental

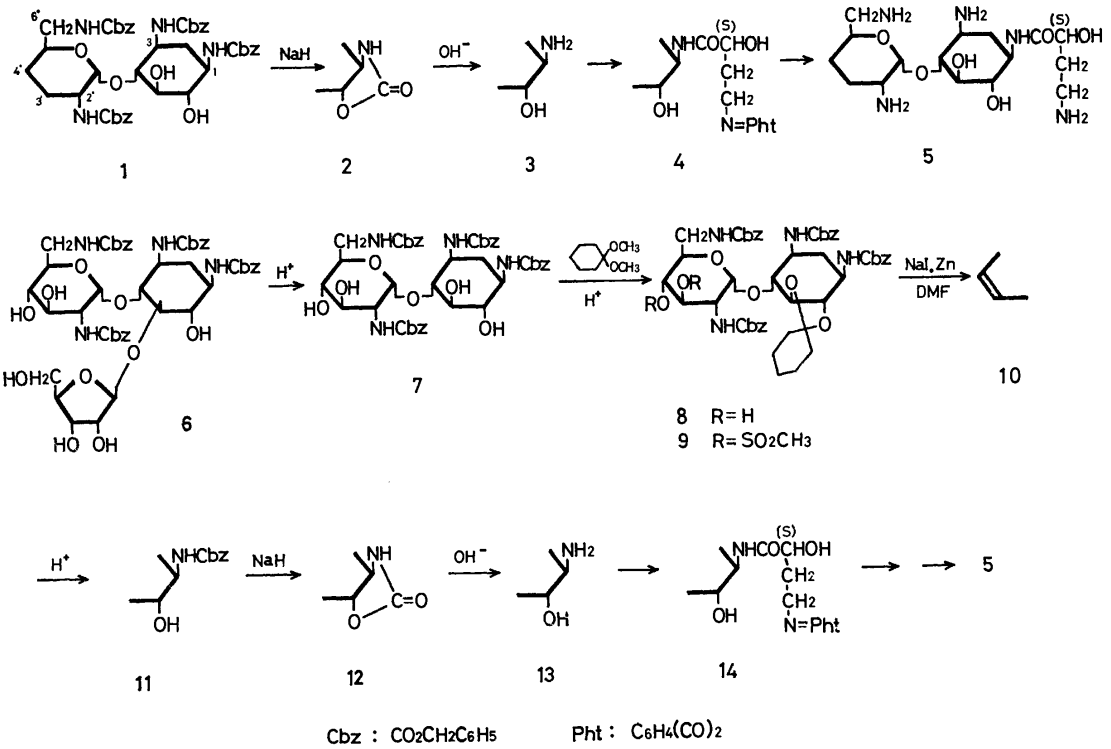
1,3,2′,6′-Tetra-N-*benzyloxycarbonyl-3′,4′-dideoxyneamine (**1**).* Prepared in the usual manner,[9)] $[\alpha]_D^{15}$ +45° (*c* 2, $CHCl_3$).

3,2′,6′-Tri-N-*benzyloxycarbonyl-3′,4′-dideoxyneamine 1,6-Carbamate (**2**).* A solution of **1** (1.34 g) in DMF was ice-cooled and, after replacement of the atmosphere with nitrogen, 50% oily NaH (235 mg) was added and the mixture was stirred for 30 min. The clear solution was allowed to stand overnight at ~5 °C. On tlc with $CHCl_3$–EtOH (20 : 1), the solution showed a single spot (R_f 0.25) except **1** (R_f 0.33). After neutralizing the solution with AcOH, the solution was poured into a mixture of $CHCl_3$–H_2O with stirring. The organic layer was washed with H_2O, dried (Na_2SO_4), and evaporated to give a yellow syrup. The syrup was chromatographed on a short column of silica gel with $CHCl_3$–EtOH (20 : 1) to give a solid, which was reprecipitated from $CHCl_3$–*n*-hexane, 683 mg (62%), $[\alpha]_D^{25}$ +58° (*c* 1.9, $CHCl_3$); IR (KBr): 1770, 1710, 1535 cm^{-1}.

Found: C, 61.92; H, 5.99; N, 7.67%. Calcd for $C_{37}H_{42}N_4O_{11}$: C, 61.83; H, 5.89; N, 7.80%.

3,2′,6′-Tri-N-*benzyloxycarbonyl-3′,4′-dideoxyneamine (**3**).* To a solution of **2** (620 mg) in dioxane (12 ml), an aqueous $Ba(OH)_2$ solution (5 ml, which contained 150 mg of $Ba(OH)_2 \cdot 8H_2O$) was added and the mixture was stirred at 60 °C for 1 hr. Another aliquot (5 ml) of $Ba(OH)_2$ solution was added and the solution was stirred for further 1 hr. On tlc with C_6H_6–EtOH (10 : 1), the mixture showed spots of R_f 0.06 (**3**, major), 0.16 (slight), 0.25 (slight) and 1 (**2**, slight). Carbon dioxide was introduced and after filtration, the solution was evaporated to give a solid (590 mg). The solid showed no peak near 1760 cm^{-1}. Since purification of the solid was tedious, the crude solid was used for the next step without purification.

3,2′,6′-Tri-N-*benzyloxycarbonyl-3′,4′-dideoxy-1*-N-[(S)-2-hydroxy-



4-phthalimidobutyryl)neamine (4). To an ice-cold solution of HPBA (136 mg) and NHS (69 mg) in THF (4 ml), DCC (120 mg) was added and the mixture was stirred for 1 hr in the cold. A suspension of well dried **3** (crude 290 mg) and triethylamine (30 mg) in dioxane (3 ml) was added and the mixture was stirred at room temperatures overnight. On tlc with $CHCl_3$–EtOH (20 : 1), the mixture showed a spot of **4** at R_f 0.33. After filtration, the solution was evaporated and the residue was chromatographed on a column of silica gel with $CHCl_3$–EtOH (20 : 1) to give a solid, 240 mg (62%), which was recrystallized from MeOH, mp 228—230 °C, $[\alpha]_D^{22}$ +32° (*c* 1.5, $CHCl_3$); IR (KBr): 1705, 1690, 1655, 1535 cm^{-1}.

Found: C, 61.34; H, 5.93; N, 7.39%. Calcd for $C_{48}H_{53}N_5O_{14}\cdot H_2O$: C, 61.20; H, 5.89; N, 7.43%.

1-N-[(S)-4-Amino-2-hydroxybutyryl]-3',4'-dideoxyneamine (5). *a) From 4:* To a solution of **4** (111 mg) in dioxane-80% aqueous EtOH (1 : 1, 2 ml), 80% hydrazine hydrate (80 mg) was added and the mixture was heated at 60 °C for 2 hr. On tlc with EtAc-MeOH (1 : 1), the solution showed a ninhydrin-positive spot (R_f 0.13). The solution was evaporated and the residue was dissolved in 50% aqueous dioxane (2 ml). After addition of a drop of AcOH, the solution was hydrogenated with Pd black at 40—45 °C overnight. The mixture was filtered, evaporated, and the residue was chromatographed on a column of CM-Sephadex C-25 (NH_4 form, 10 ml) with H_2O and then with aqueous ammonia of 0.2—0.5 M. At about 0.4 M ammonia, **5** was eluted; a solid, 25 mg (53%), $[\alpha]_D^{22}$ +38° (*c* 0.85, H_2O); IR (KBr): 1650, 1560 cm^{-1}; R_f 3',4'-dideoxyneamine 0.47 (ppc with 1-BuOH–pyridine–H_2O–AcOH (6 : 4 : 3 : 1)).

Found: C, 46.92; H, 8.52; N, 17.24%. Calcd for $C_{16}H_{33}N_5O_6\cdot H_2O$: C, 46.93; H, 8.62; N, 17.10%.

b) From 14: To a solution of **14** (101 mg) in dioxane-80% aqueous EtOH (1 : 1, 3 ml), 80% hydrazine hydrate (96 mg) was added and the solution was heated at 60 °C for 2 hr. On tlc with $CHCl_3$–MeOH–17% NH_3 (2 : 1 : 1), the solution showed a single spot (R_f 0.2) except **14** (R_f 0.7). The solution was evaporated and the residue was dissolved in 50% aqueous dioxane (3 ml). After addition of a drop of AcOH, the solution was hydrogenated with Pd black and then the product was purified similarly as described above to give a solid, 40 mg (93%), $[\alpha]_D^{20}$ +36° (*c* 1.2, H_2O). The IR and NMR spectra were identical with those of the specimen prepared from **4**.

1,3,2',6'-Tetra-N-benzyloxycarbonylneamine (7). A solution of **6** (28.4 g) in 0.4 M methanolic hydrogen chloride (300 ml) was allowed to stand at room temperature. After 10 min, a solid began to precipitate. After overnight standing, the upper clear layer showed, on tlc with $CHCl_3$–EtOH (10 : 1), a spot of R_f 0.1 (**6** and methyl riboside; both gave the same R_f value) and the precipitate showed a spot of R_f 0.4 (**7**). The mixture was filtered and the solid was washed with hot MeOH to give a solid (19.24 g). From the methanol solution, another crop of the solid (2.43 g) was obtained. Total yield 21.7 g (88%). The solid was reprecipitated from hot dioxane–H_2O, $[\alpha]_D^{20}$ +44° (*c* 0.8, DMF); IR (KBr): 1705, 1695, 1535; 730, 695 cm^{-1}.

Found: C, 61.19; H, 5.87; N, 6.39%. Calcd for $C_{44}H_{50}N_4O_{14}$: C, 61.53; H, 5.87; N, 6.52%.

1,3,2',6'-Tetra-N-benzyloxycarbonyl-5,6-O-cyclohexylideneneamine (8). To a solution of **7** (10 g) in DMF (50 °C, 100 ml), *p*-toluenesulfonic acid (390 mg) and 1,1-dimethoxycyclohexane (12 ml) were added and the solution was heated at 55 °C (bath temperature) under stirring *in vacuo* (25 Torr) for 1 hr. Another aliquots of *p*-toluenesulfonic acid (195 mg) and 1,1-dimethoxycyclohexane (11 ml) were added and the solution was again treated as above for 1.5 hr. After overnight standing at room temperatures, the solution showed, on tlc with $CHCl_3$–EtOH (25 : 1), spots of R_f 0.8 (dicycolhexylidene derivative), 0.3 (**8**, major) and 0.15 (slight, 3',4'-*O*-cyclohexylidene isomer). The solution was poured into $NaHCO_3$ solution to give a precipitate (12.35 g). The solid was then treated with hot benzene to remove the benzene-soluble products (4.98 g; R_f 0.8 and 0.3 (slight)). The benzene-insoluble product (R_f 0.3 and 0.15 (slight)) was reprecipitat-

ed from $CHCl_3$–ether to give a solid, 5.72 g (52%), mp 185.5—187 °C, $[\alpha]_D^{20}$ +5.3° (*c* 0.9, $CHCl_3$); IR (KBr): 1705, 1535 cm^{-1}.

Found: C, 64.22; H, 6.29; N, 5.74%. Calcd for $C_{50}H_{58}N_4O_{14}$: C, 63.95; H, 6.23; N, 5.97%.

NMR (in DMSO-d_6): τ 8.5 (10H, broad, cyclohexylidene), 2.57 (20H s, $CH_2C_6H_5$).

1,3,2',6'-Tetra-N-*benzyloxycarbonyl-5,6*-O-*cyclohexylidene-3',4'-di*-O-*mesylneamine* (**9**). A sample of **8** was treated similarly as described in the preparation of compound **9** in a preceding paper;[2] yield 98%, $[\alpha]_D^{20}$ +11° (*c* 0.9, $CHCl_3$), R_f 0.35 (tlc with $CHCl_3$–EtOH (50 : 1)); IR (KBr): 1350, 1175 cm^{-1} (ν SO_2).

Found: C, 57.34; H, 5.76; N, 4.93; S, 5.89%. Calcd for $C_{52}H_{62}N_4O_{18}S_2$: C, 57.03; H, 5.71; N, 5.12; S, 5.85%.

NMR (in $CDCl_3$): τ 7.20 and 6.92 (each 3H s, SO_2CH_3).

1,3,2',6'-Tetra-N-*benzyloxycarbonyl-5,6*-O-*cyclohexylidene-3',4'-dideoxy-3'-enoneamine* (**10**). To a solution of **9** (1.60 g) in dry DMF (30 ml), sodium iodide (17 g) and zinc dust (7.8 g) were added and the mixture was stirred at 95—96 °C (oil bath temperature) for 1.5 hr. On tlc with $CHCl_3$–EtOH (50 : 1), the mixture showed spots at R_f 0.25 (**10**, major) and 0 (trace). The solution was then treated with $CHCl_3$ as described for compound **10** in the preceding paper[2] and the resulting solid was chromatographed on silica gel and $CHCl_3$–EtOH (50 : 1) to give a solid, 1.00 g (76%), which was recrystallized from EtOH, mp 198—199.5 °C, $[\alpha]_D^{20}$ −23° (*c* 0.8, $CHCl_3$); IR (KBr): 1705, 1525 cm^{-1} (peaks at 1350 and 1175 cm^{-1} in **9** had disappeared).

Found: C, 66.38; H, 6.29; N, 6.14%. Calcd for $C_{50}H_{56}N_4O_{12}$: C, 66.36; H, 6.24; N, 6.19%.

NMR (in $CDCl_3$): τ 4.43 (2H incomplete s, H-3',4').

1,3,2',6'-Tetra-N-*benzyloxycarbonyl-3',4'-dideoxy-3'-enoneamine* (**11**). To a solution of **10** (903 mg) in $CHCl_3$ (15 ml). *p*-toluenesulfonic acid hydrate (21 mg) in MeOH (7 ml) was added and the solution was heated at 50 °C for 1.5 hr. After triethylamine (0.03 ml) was added, the solution was evaporated to give a solid, which was washed throughly with H_2O; yield 810 mg (98%). The solid was recrystallized from EtOH, mp 234—238 °C, $[\alpha]_D^{20}$ −26° (*c* 0.8, dioxane).

Found: C, 64.02; H, 5.92; N, 6.77%. Calcd for $C_{44}H_{48}N_4O_{12}$: C, 64.07; H, 5.87; N, 6.79%.

NMR (in DMSO-d_6): τ 4.31 (2H incomplete s, H-3',4'), 2.5—3.0 (4H, disappeared on deuteration, $NHCO_2$-).

3,2',6'-Tri-N-*benzyloxycarbonyl-3',4'-dideoxy-3'-enoneamine 1,6-Carbamate* (**12**). The solution of **11** (917 mg) in DMF (10 ml) was treated with 50% NaH (167 mg) as described for the preparation of **2**. The reaction completed in 2 hr. The crude product (880 mg) was chromatographed on a column of silica gel with $CHCl_3$–EtOH (15 : 1) to give a solid, 577 mg (73%), which was reprecipitated from $CHCl_3$–*n*-hexane, $[\alpha]_D^{20}$ −19° (*c* 1, dioxane); R_f 0.35 (tlc with $CHCl_3$–EtOH (15 : 1); **11**: R_f 0.40); IR (KBr): 1770, 1700, 1525 cm^{-1}.

Found: C, 62.03; H, 5.82; N, 7.88%. Calcd for $C_{37}H_{40}N_4O_{11}$: C, 62.00; H, 5.63; N, 7.82%.

NMR (in $CDCl_3$): τ 4.43 (2H incomplete s, H-3',4').

3,2',6'-Tri-N-*benzyloxycarbonyl-3',4'-dideoxy-3'-enoneamine* (**13**). To a solution of **12** (361 mg) in aqueous dioxane (12 : 13, 12 ml), anhydrous Na_2CO_3 (447 mg) was added and the mixture was heated at 80 °C for 2 hr. The solution was cooled and then filtered from precipitants. The filtrate was evaporated to give a solid, which was extracted with chloroform. The solution was evaporated to give a solid, 287 mg (83%), which was reprecipitated from $CHCl_3$–*n*-hexane, $[\alpha]_D^{20}$ −19° (*c* 1.1, $CHCl_3$); R_f 0.5 (tlc with $CHCl_3$–MeOH–17% NH_3 (2 : 1 : 1); **12**: R_f 0.65); IR (KBr): 1700, 1535 cm^{-1}.

Found: C, 62.31; H, 6.08; N, 7.65%. Calcd for $C_{36}H_{42}N_4O_{10}$: C, 62.60; H, 6.13; N, 8.11%.

NMR (in $CDCl_3$): τ 4.33 (2H broad s, H-3', 4').

3,2',6'-Tri-N-*benzyloxycarbonyl-3',4'-dideoxy-3'-eno-1*-N-[*(S)-2-hydroxy-4-phthalimidobutyryl*]*neamine* (**14**). The active ester prepared from HPBA (138 mg), NHS (66 mg) and DCC (184 mg) in THF was treated with **13** (227 mg) in dioxane containing triethylamine (38 mg) in a manner as described for the preparation of **4**. The crude product (550 mg) was dissolved in $CHCl_3$ and the solution was washed with water. The product was chromatographed on a column of silica gel with $CHCl_3$–EtOH (15 : 1) to give a solid, 155 mg (51%), which was recrystallized from EtOH, $[\alpha]_D^{20}$ −32° (*c* 1.3, dioxane); R_f 0.25 (tlc with $CHCl_3$–EtOH (15 : 1); **13**: R_f 0); IR (KBr): 1780 (5-membered imide), 1710, 1640, 1540 cm^{-1}.

Found: C, 62.76; H, 5.65; N, 7.33%. Calcd for $C_{48}H_{51}N_5O_{14}$: C, 62.53; H, 5.58; N, 7.60%.

NMR (in DMSO-d_6): τ 4.37 (2H, H-3',4'), 2.08 (4H s, $(CO)_2C_6H_4$).

Reactions of Ethylene with Chloroform Initiated by Amine–Ferrous Chloride System

Teruzo ASAHARA, Manabu SENŌ, and Noritaka OHTANI

Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106

(Received July 2, 1974)

The reactions of ethylene with chloroform initiated by alkylamine–ferrous chloride systems were examined in detail. Two main products, α,α,α-trichloroalkanes (I) and α,α,ω-trichloroalkanes (II), were obtained. Their composition was independent of the kind of amine but dependent upon the total carbon number of alkylamine. When amines having higher alkyl groups were used, the main product was α,α,ω-trichloropropane (II-1). When lower alkylamines were used, the main products were α,α,α-trichloroalkanes which contained considerable amounts of higher telomers. The results support the view that the reactions proceed according to the "caged free radical" process.

A number of reports on the radical reaction of olefins with polyhaloalkanes have been presented and various initiators have been explored for this reaction. The peroxides afforded telomers in most cases, whereas some transition metal complexes gave a 1 : 1 adduct in a good yield.[1] It was previously reported that amine–cupric chloride,[2] triethyl phosphite–iron chloride,[3] *N*-chloroalkylamine–ferrous chloride,[4] and others[5] also give a 1 : 1 adduct of ethylene with carbon tetrachloride as the main product. We suggested that a "caged radical" process would proceed along with the so-called "free radical" propagating process.[6] In order to confirm the above reaction mechanism, the reaction of ethylene with chloroform initiated by amine-ferrous chloride was investigated in detail and the results are given in this paper. A combination of ethylene and chloroform is suitable for this purpose, since "free" trichloromethyl radical adds readily to ethylene as compared with other higher olefins,[1g] and two products, α,α,α-trichloroalkanes (I) and α,α,ω-trichloroalkanes (II), could be derived in the reaction of ethylene with chloroform. The former is the product of the peroxide-initiated reaction and, therefore, considered to be formed *via* a "free radical" propagating process, and the latter is considered to be formed mainly *via* a "caged radical" process.

Experimental

Materials. Ethylene (purity 99.8%), amines and metallic salts of commercial special grade were used without further purification. Commercial chloroform was purified through an activated alumina column and the purity was examined by gas chromatography.

Reactions of Ethylene with Chloroform. The reaction was carried out in a 200 ml stainless steel autoclave with a magnetic stirrer. Chloroform (1 mol) and a certain amount of initiators were placed in the autoclave and the air inside was replaced several times with ethylene. After ethylene was charged to 20 kg/cm² at 30 °C, the autoclave was heated up to 130 °C. After the reaction, the autoclave was chilled to room temperature and the reaction mixture was washed with 1 M hydrochloric acid to remove amine and metallic salts.

Analyses of the Products. The reaction products were analysed by a temperature-programmed gas chromatograph using a 2 m column of Silicone DC 550 at 40—200 °C. *n*-Hexane was used as an internal standard. Authentic samples were prepared by the following method. α,α,α-Trichloroalkanes $CCl_3(C_2H_4)_nH$ (I) (n=1,2,3), α,α,ω-trichloroalkanes $CHCl_2(C_2H_4)_nCl$ (II) (n=1,2), and α,α,α,ω-tetrachloroalkanes $CCl_3(C_2H_4)_nCl$ (IV) (n=1,2) were prepared by the reaction of ethylene with chloroform initiated by di-*t*-butylperoxide (DTBP), by that of ethylene with chloroform initiated by the iron chloride–hexamethylphosphoric triamide (HMPA) system[5] and by that of ethylene with carbon tetrachloride initiated by DTBP, respectively. The products were purified several times by fractional distillation and the purity was confirmed by glc. α,α-Dichloroalkanes $CHCl_2(C_2H_4)_nH$ (III) (n=1,2) and γ,γ-dichloroalkanes $HC_2H_4CCl_2(C_2H_4)_nH$ (VII) (n=1,2) were prepared by the reactions of the corresponding aldehydes or ketones with phosphorus pentachloride and purified by distillation. For quantitative analyses of α,γ,γ-trichloroalkanes $ClC_2H_4CCl_2(C_2H_4)_nH$ (V) (n=1,2) and α,γ,γ,ω-tetrachloroalkanes $ClC_2H_4CCl_2(C_2H_4)_nCl$ (VI) (n=1), type I and IV telomers with the same molecular weights as those of V and VI, respectively, were used.

Results and Discussion

Several initiator systems were examined and the results are summarized in Table 1. In the presence of iron particles, the reaction had an induction period (about 30 min) and proceeded very slowly. Ferrous chloride gave the same products as those in the case of iron particles at a rather slow reaction rate. *n*-Butylamine greatly accelerated the reaction, whereas di-*n*-butylamine was not effective. A combination of ferrous chloride (0.002 mol) with di-*n*-butylamine (0.02 mol), however, induced the reaction without an induction period (the decrease in ethylene pressure, $-\Delta P$= 6 kg/cm² for 90 min). An equimolar mixture of amine with iron particle or ferrous chloride increased the reaction rate. In the case of di-*n*-butylamine–iron particle system, the reaction rate changed considerably in the course of reaction; the reaction proceeded slowly at first 70 min ($-\Delta P$=4 kg/cm²) and then the rate was greatly increased. A similar stepwise change in the reaction rate was seen in the *n*-butylamine-iron particle system though the extent of change was not so large.

In the absence of amine, dichloromethyl radicals which act as initiating radicals are possibly formed:

$$Fe + 2\,CHCl_3 \longrightarrow FeCl_2 + 2\cdot CHCl_2 \quad (1)$$

$$Fe + CHCl_3 \longrightarrow FeCl_3 + \cdot CHCl_2 \quad (2)$$

The possibility of radical formation by the reaction of polyhaloalkane and amine in the absence of metal has been examined.[7] When *n*-butylamine was added

to ethylene and chloroform in the absence of added metal, a considerable amount of telomers of type I was obtained. Although it is uncertain whether trace of metal is necessary for the reaction or not, it is probable that the surface of the autoclave would effect the reaction. As the reaction is very low in the absence of added metal and the change of the reaction rate in the course of reaction is observed for the amine-iron particle system, it is considered that what induces the initiation reaction is not iron metal, but mainly ferrous ions. The radical formation possibly takes place, for the most part, according to Eq. 3. Through the interaction of chloroform with ferrous chloride activated by amines, dichloromethyl radical is formed.

$$Fe^{2+}L_k + CHCl_3 \rightleftharpoons [Fe^{3+}L_kCl^- \cdot CHCl_2] \quad (3)$$

X

L=amine

Results of reactions using various amine-ferrous chloride systems are shown in Table 2. The reactions were continued until the ethylene pressure fell down to 25 kg/cm² from the initial value of about 50 kg/cm² at 130 °C, and the compositions of the products were compared at the same value of ethylene conversion. It was found that the composition of products was independent of the kind of amine, but dependent upon the total carbon number of alkylamine. The main products are α,α,α-trichloroalkanes (I) when the number of alkyl carbons of amines is less than six. The ratio of α,α,ω-trichloroalkanes (II) to the total products increases as the alkyl group becomes larger, II becoming a main product for alkylamines having more than eight carbons.

The molecular weight distributions of each type product for the triethylamine–ferrous chloride system are shown in Fig. 1. The amount of the n=2 telomer of type I, α,α,α-trichloropentane (I-2), is comparable to that of the 1 : 1 adduct, α,α,α-trichloropropane (I-1), a considerable amount of n=3 telomers being also produced. The molar distribution of $\alpha,\alpha,\alpha,\omega$-tetrachloroalkanes (IV) is similar to that of I. The distribution curves of I and IV remain unchanged when

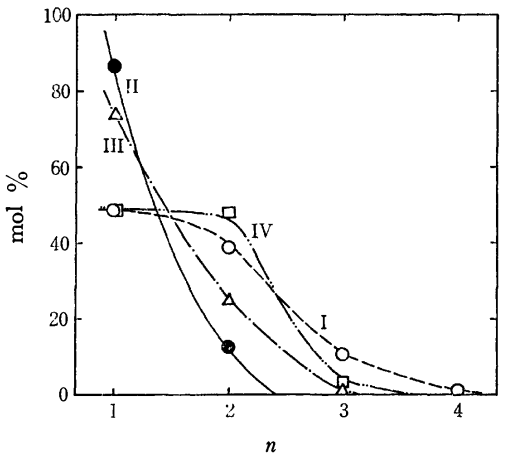

Fig. 1. Product distribution of each type telomer.

amines other than triethylamine are used. For the products of type II, however, the 1 : 1 adduct, α,α,ω-trichloropropane (II-1), is produced almost exclusively. The distribution curve of α,α-dichloroalkane (III) lies between the curve of II and that of I or IV.

The results can be explained by a reaction mechanism in which a "caged radical" process proceeds along with a "free radical" propagating process. When bulky molecules of amine coordinate ferrous ions, most of the dichloromethyl radicals formed according to Eq. 3 are trapped within a cage formed by the coordinating amine and add to ethylene invading into the cage (Eq. 4).

$$X + C_2H_4 \longrightarrow \underset{X_1}{[Fe^{3+}L_kCl^- \cdot C_2H_4CHCl_2]} \quad (4)$$

$$X_1 \longrightarrow Fe^{2+}L_k + \underset{\text{II-1}}{ClC_2H_4CHCl_2} \quad (5)$$

$$X_1 + CHCl_3 \rightarrow Fe^{3+}L_kCl^- + \underset{\text{III-1}}{HC_2H_4CHCl_2} + \cdot CCl_3 \quad (6)$$

$$X_1 + C_2H_4 \longrightarrow \underset{X_2}{[Fe^{3+}L_kCl^- \cdot (C_2H_4)_2CHCl_2]} \quad (7)$$

$$X \longrightarrow Fe^{3+}L_kCl^- + \cdot CHCl_2 \quad (8)$$

$$\cdot CHCl_2 + nC_2H_4 + CHCl_3 \rightarrow \underset{\text{III}}{CHCl_2(C_2H_4)_nH} + \cdot CCl_3 \quad (9)$$

$$\cdot CCl_3 + nC_2H_4 + CHCl_3 \rightarrow \underset{\text{I}}{CCl_3(C_2H_4)_nH} + \cdot CCl_3 \quad (10)$$

$$CHCl_2(C_2H_4)_n \cdot + Fe^{3+}L_kCl^- \rightarrow \underset{\text{II}}{CHCl_2(C_2H_4)_nCl} + Fe^{2+}L_k \quad (11)$$

$$CCl_3(C_2H_4)_n \cdot + Fe^{3+}L_kCl^- \rightarrow \underset{\text{IV}}{CCl_3(C_2H_4)_nCl} + Fe^{2+}L_k \quad (12)$$

The ω,ω-dichloropropyl radical in the cage would take part in three ways in the following steps of the reaction. For the most part, the radical abstracts chlorine atom from ferric chloride to afford II-1 (Eq. 5). The hydrogen abstraction from chloroform around the cage may partly occur and α,α-dichloropropane (III-1) and "free" trichloromethyl radical are formed (Eq. 6). The chain propagating reaction in the cage (Eq. 7) would rarely occur, because other ethylene molecules should be supplied into the cage. When smaller amines are used, the dichloromethyl radical would be relatively mobile and get out of the cage, and then a "free radical" propagating process would take place to form telomers of type III and trichloromethyl radicals (Eqs. 8 and 9).

Trichloromethyl radicals afford telomers I by the chain reaction (Eq. 10). Chloride abstraction reactions of ω,ω-dichlorolakyl radical and ω,ω,ω-trichloroalkyl radical from chloride complex give telomers II and IV, respectively (Eqs. 11 and 12).

ω,ω-Dichloroalkyl free radical is expected not to differ much from ω,ω,ω-trichloroalkyl free radical in reactivity against chloroform, ethylene, or chloride complex. According to the above reaction scheme, the product of type II is formed both in the caged radical process of Eq. 5 (mainly 1 : 1 adduct) and in the free radical process of Eq. 11 (mainly high telomers). It is seen from Fig. 2 that the ratio of II-1 to the total amount of type II products increases as the composition ratio of II to the total products increases. This can be explained by the predominant occurrence of the "caged process". Conversely, as the "free radical" process becomes predominant, the molecular weight distribution of II would gradually resemble that of I or IV with the decrease in the product ratio of II. Figure 2 shows that this is the case. The variation in total yield or the conversion of chloroform at a definite ethylene conversion in Table 2 is explained in the same way.

The effects of reaction time, ethylene pressure, and reaction temperature on the composition ratio of products were examined and the results are shown in Tables 3, 4, and 5, respectively. With the elongation

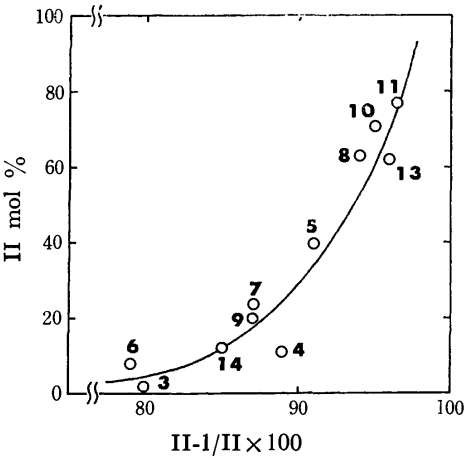

Fig. 2 Ratio of II-1 to Type II products.

TABLE 3. EFFECT OF REACTION TIME ON Et_3N-$FeCl_2 \cdot 4H_2O$ SYSTEM[a]

15	13	10	64	10	6	5	5	—
20	15	5	62	13	7	5	8	tr

a) Reaction was continued until $-\Delta P = 10$ kg/cm² at 130 °C. Other reaction conditions are the same as those given in Table 2.

Table 5. Effect of reaction temperature for Et_3N-$FeCl_2 \cdot 4H_2O$ system[a)]

Temp. °C	Time min	Conv. of $CHCl_3$ %	Product mol%						
			I	II	III	IV	V	VI	VII
110	230	15	31	25	16	11	8	3	6
120	120	15	28	24	19	11	9	3	5
130	46	17	27	20	18	13	11	5	6

a) Reaction conditions except reaction temperature are the same as those given in Table 2.

of reaction time, the composition ratios of products of types I and IV decreased, accompanied by an increase in the ratios of V, VI, and VII for all the amine–ferrous chloride systems examined. The products of types I and IV, having a trichloromethyl group, may react as a telogen in the same manner as for chloroform and give products of types V, VI, and VII.[1f)] The slight increase of II with an increase in reaction time seems to be connected with the change in ethylene pressure. The ratio of II is slightly greater at a low ethylene pressure compared with that at a high pressure as is shown in Table 4. The increase in reaction temperature scarcely affects the composition ratio of products. The ratio of II tends to increase somewhat at lower temperatures.

It should be noted that the amine–cuprous chloride system shows a similar tendency to the amine–ferrous chloride system. The main products in the case of $EtNH_2$–CuCl were of type I, whereas those in the case of $BuNH_2$–CuCl and Bu_2NH–CuCl were of ty peII. The reactions in the amine–cuprous chloride system probably proceed according to a similar mechanism to that in the amine–ferrous chloride system.

The authors would like to express their thanks to Mr. H. Nojiri for assistance in the experiments.

Studies on the Synthesis of Histidine Peptides. I. N^{im}-Tosylhistidine Derivatives as Starting Materials[1,2]

Toshiyuki FUJII* and Shumpei SAKAKIBARA**

Peptide Institute, Protein Research Foundation, Ina 476, Minoh, Osaka 562

(Received July 20, 1974)

N^{α}-Nps-, Z(OMe)-, Z-, Boc-, and Aoc-derivatives of N^{im}-tosylhistidine were synthesized as materials for the syntheses of histidine-containing peptides, and the reactivity of the N^{im}-tosyl group was examined under several conditions commonly used for peptide syntheses. Although the N^{im}-tosyl group was somewhat more unstable than N^{im}-benzyl group, the use of the tosyl derivative was found to be advantageous in several points: the enhancement of the solubility of its peptide derivatives, the suppressive effect of racemization during its coupling reactions, and the high removability of the tosyl group under mild conditions.

Although several different procedures for the incorporation of histidine residues into peptides have been published by many workers, those methods still have several problems.[3] Histidine-peptides can be synthesized without the protection of the imidazole group, but only limited, mild conditions have to be used for their coupling reactions because of the remaining presence of active hydrogens in the side chains. Further, the strict purification of the each intermediate is indispensable to obtain the final product in a reasonable purity. To improve the situation, the following N^{im}-protective groups have been proposed by many workers: benzyl,[4] benzyloxycarbonyl,[5] trityl,[6] adamantyloxycarbonyl,[7] 2,2,2-trifluoro-1-acylaminoethyl,[8] piperidinocarbonyl,[9] dinitrophenyl,[10] diphenylmethyl,[11] trinitrophenyl,[12] and *t*-butyloxycarbonyl.[13] These protective groups are each characteristic and may be useful in specific cases, but we cannot declare that all the problems involved in the synthesis of histidine peptides have been solved. Especially when histidine peptides are synthesized by the solid-phase method, the histidine residue is preferably incorporated into resin as a form of an N^{im}-protected derivative, which is highly soluble in methylene chloride or chloroform. Further, it may be desirable for the N^{im}-protecting group to be stable during successive coupling reactions and readily removable under mild conditions in the final stage. The present study will introduce a new N^{im}-protecting group which is useful for the relief of those problems.[1]

Originally, the tosyl group had been recognized as a stable amino-protecting group, and sodium treatment in liquid ammonia was the only practical procedure to remove the protective group from the peptide derivatives. Recently, however, the same group attached to the guanido group of arginine has been demonstrated to be removable[14] in anhydrous hydrogen fluoride (HF) at 0 °C.[15] Therefore, we checked the stability of the tosyl group attached to the imidazole moiety of histidine, and found that the group is also removable under the same conditions in anhydrous HF.[1] Thus, several derivatives of the N^{im}-tosylhistidine were synthesized in order to examine their applicability to the synthesis of histidine peptides.

Syntheses of Several N^{α}*-protected Derivatives of* N^{im}*-tosylhistidine.* The N^{im}-tosylhistidine derivatives were synthesized *via* two different procedures, shown in Schemes 1 and 2. One route started from the histidine methyl ester[16] (Method A), and the other route, from N^{α}-Z-histidine[5] (Method B). In Method A, the histidine methyl ester was acylated with acyl chlorides or azides, and the remaining unacylated histidine methyl ester was removed as completely as possible at this stage. The mono- and di-acylated histidine methyl esters thus obtained were saponified to obtain N^{α}-acyl-histidine, which was then tosylated using tosyl chloride in the saponification mixture (Scheme 1). If the saponification mixture is contaminated by the unreacted histidine ester, N^{α}, N^{im}-ditosylated histidine should be formed and its removal from the final product must be problem. Generally, the acylation of the

histidine methyl ester gives a mixture of mono- and di-acyl esters, depending on the reaction conditions and on the reactivity of the reagents used. When two moles of Aoc- or Boc-chloride were used as the acylating reagent, the histidine methyl ester was acylated to form diacyl esters; in this stage, the unchanged histidine methyl ester was removed completely by simple washing with water, since the diacyl histidine ester is almost insoluble in water. When Aoc- or Boc-azide was used as the reagent, the N^{α}-acyl histidine ester was formed as the major product, even if two moles of the reagent were used; in this case, care must be taken to extract the product from the reaction mixture completely because the mono-acyl esters are somewhat soluble in water. In the present study, mono- and di-Boc-histidine esters were isolated as crystals in order to confirm their properties, as will be shown in the Experimental section.

In the case of the synthesis of the Nps-derivative, the formation of the mono-Nps-histidine methyl ester was predominant.[17] Although the N^{α}-Nps-histidine methyl ester has been reported to be a crystalline material, we could not crystallize it in the present study; thus, it was purified by silica-gel-column chromatography. The histidine benzyl ester[18] was also used as a starting material for the same purpose.

In one experiment, the N^{α}-Nps-histidine methyl ester was converted to the tosyl derivative, and then we attempted to obtain N^{α}-Nps-N^{im}-tosyl-histidine by saponification. However, we were unsuccessful because of the susceptibility of the N^{im}-tosyl group to caustic alkali.

In the case of the synthesis of the Z(OMe)-derivative using the azide method, there was no difficulty in washing out the unreacted histidine ester from the reaction mixture, since both the mono- and di-Z(OMe)-histidine esters were almost insoluble in water; the mixture of the mono- and di-acylated derivatives was directly saponified to obtain N^{α}-Z(OMe)-histidine, which was then further converted to the N^{im}-tosyl derivative, as has been shown before.

In Method B, N^{α}-Z-histidine[5] was tosylated with tosyl chloride; the product was treated with anhydrous hydrogen bromide in acetic acid to obtain N^{im}-tosyl-histidine, which was then treated with the respective acyl chlorides or azides to obtain N^{α}-protected-N^{im}-tosyl-histidines (Scheme 2). This procedure gave products identical with those obtained by Method A, but the yields were generally lower than those obtained by means of Method A. This may be attributed to the partial decomposition of the tosyl group during the HBr treatment and to the acylation reactions. The catalytic hydrogenolysis of the N^{α}-Z-N^{im}-tosyl-histidine with a palladium catalyst was attempted in order to obtain N^{im}-tosylhistidine, but the attempt was unsuccessful; during the reaction, the N^{im}-tosylhistidine formed was precipitated out over the catalyst and further hydrogenolysis was disturbed.

Generally, N^{α}-acylated histidines which are obtained by the direct acylation of histidine are soluble in water, and troublesome procedures are necessary to remove any unchanged histidine from the reaction mixture. Therefore, the direct synthesis of N^{α}-acyl-N^{im}-tosyl-histidine from free histidine was concluded to be impractical.

The physical constants and analytical data of N^{α}-protected-N^{im}-tosylated histidine derivatives synthesized by Methods A and B are listed in Table 1.

Stability of the N^{im}-*Tosyl Group.* N^{α}-Protected-N^{im}-tosyl-histidines, such as N^{α}-Boc-, N^{α}-Z(OMe)-, and N^{α}-Nps-derivatives, were found to decompose gradually during storage at room temperature. This decomposition may be caused by the enhanced acidity of their own carboxyl groups resulting from the presence of the tosyl group in their side chains. Therefore, the storage of these compounds in the form of DCHA salts was considered to be practical.

The stability of the N^{im}-tosyl group was compared with that of other protective groups under various conditions commonly used for peptide synthesis; the data are summarized in Table 2. The tosyl group was removed easily in aqueous 1 N sodium hydroxide at room temperature, but 50% of this group survived in 25% aqueous ammonia at room temperature during

a) At room temp. 1 hr. b) At 15 °C 30 min. c) At 0 °C 1 hr.

one hour's treatment. From these facts, it was concluded that the N^{im}-tosyl group was little more stable than the N^{im}-Z group under alkaline conditions; the N^{im}-Z group is known to be removed not only in caustic alkali, but also in aqueous ammonia.[5] Only about 10% of the tosyl group was removed in 2 M HBr in acetic acid or in 4 M HCl in dioxane during one hour's treatment at roo mtemperature, while the complete removal of the group was observed during further storage overnight at room temperature.

As has been pointed out before, the N^{im}-tosyl group was readily cleaved in anhydrous HF at 0 °C within 30 min. When Nps-containing compounds weret reated by HF, the addition of skatole as a scavenger was effective, as will be shown in the second paper of this series.

One of the characteristics of the N^{im}-tosyl group was that it was almost unaffected by anhydrous trifluoroacetic acid during short treatment at room temperature; thus, Aoc-, Boc-, Z(OMe)-, and Nps-groups can be removed selectively from peptides containing the N^{im}-tosylhistidyl residue. This property was successfully used in the synthesis of Angiotensin II by the solid-phase procedure.[19]

The N^{im}-tosyl group did not interfere with the catalytic hydrogenolysis of other groups; however, a small amount of the tosyl group was found to be cleaved during the removal of *N*-benzyloxycarbonyl groups. This may be explained by a nucleophilic attack of the formed amino group during the hydrogenolysis. Bergmann and Zervas have pointed out that the N^{im}-acetyl group migrates to other amino groups under physiological conditions.[20] Later, Sakiyama *et al.*[4b] reported the same phenomenon with di-Z-histidine, in which the N^{im}-Z-group was observed to transfer to the amino group of the glycine methyl ester in dioxane at 50—60 °C. In the present study, although N^{α}-Boc-N^{im}-tosylhistidine was treated with the glycine methyl ester under the same condition, no migrated product was detectable within one hour in a reaction mixture. After six hours, however, the formation of the tosylglycine methyl ester was observed in a yield of more than 6.5%.

The N^{im}-tosyl group remained unchanged at room temperature for 24 hr. in the presence of two equivalents of triethylamine in dimethylformamide; this property should also be counted as an advantage of this protecting group in peptide synthesis.

Finally, it was noteworthy that the N^{im}-tosyl group was readily removed at room temperature in the presence of excess 1-hydroxybenzotriazole (HOBT), which is widely used as a convenient reagent for peptide synthesis.[21] During the reaction, the formation of 1-(tosyloxy)benzotriazole as the main product was confirmed. Those facts indicate that Geiger's procedure should always result in the formation of imidazole-free peptides, even if an N^{im}-tosyl derivative is used as the starting material. This procedure has also been successfully applied to the synthesis of histidine-peptides, as will be shown in the following report.

On the contrary, the N^{im}-Z group was found to be much more stable against the same reagent.

Experimental

The melting points were measured by the capillary method and were not corrected. Thin-layer chromatography (tlc) was carried out on Merck's Silica Gel G using the following solvent systems: (1) chloroform–methanol–acetic acid (95 : 5 : 3), and (2) *n*-butanol–acetic acid–water (4 : 1 : 1). The IR spectra were determined on a Shimadzu IR-27G Spectrometer, and the UV spectra, on a Hitachi ESP-2U spectrometer.

N^{τ}-Aoc-His–OMe (II-a) and N^{α},N^{im}-di-Aoc-His–OMe (III-a). Aoc-azide (15.7 g, 100 mmol) was added to a solution of His-OMe (I) in dry pyridine (20 ml), which had been isolated from His-OMe·2HCl (12 g, 50 mmol) following the procedure of Wünsch;[22] the mixture was then allowed to react for 3 days at 30 °C under stirring. The pyridine was removed under reduced pressure, the remaining oil was flushed with benzene, the residue was dissolved in ethyl acetate, and a small amount of an insoluble material was removed by filtration. *n*-Hexane was added to the filtrate until a part of the product precipitated out. After the mixture had been kept in a refrigerator for 5 hr, the crystals were collected by filtration and recrystallized from ethyl acetate to afford II-a; wt. 9.8 g (70%); mp 122—124 °C, $[\alpha]_D^{22}$ −13.0° (*c*, 2.2, pyridine). Found: C, 54.89; H, 7.58; N, 14.89%. Calcd for $C_{13}H_{21}O_4N_3$: C, 55.11; H, 7.47; N, 14.83%.

The filtrate of the crude crystals and mother liquor of the recrystallization were combined and concentrated under reduced pressure, and the residual oil was redissolved in ethyl acetate. The solution was washed well with water, dried over anhydrous sodium sulfate, and concentrated again to a residue, which was then used in the following reaction as N^{α}, N^{im}-di-Aoc-His-OMe without further purification.

Aoc–His(Tos) (IV-a via Method A). Compound II-a (9.5 g) and the oily residue obtained above were dissolved together in methanol (30 ml), after which the solution was treated with 1 N aqueous sodium hydroxide (100 ml) at room temperature. The saponification of the ester group and the

deacylation of the N^{im}-Aoc group were monitered by tlc using the (1) solvent. After the completion of the reactions had been confirmed by tlc, an aqueous solution of sodium carbonate (18 g in 300 ml) was added to the mixture and a solution of tosyl chloride (17.6 g, 90 mmol) in dioxane (50 ml) was stirred, drop by drop, into the mixture at room temperature. Stirring was continued for 4 hr; then water (500 ml) was added, and the mixture was washed three times with 100-ml portions of ether to remove the excess tosyl chloride. The aqueous phase was acidified to pH 2 with 0.5 M sulfuric acid, and the separated oily material was extracted with ethyl acetate. The extract was washed well with water, dried over anhydrous sodium sulfate, and concentrated to dryness under reduced pressure. The residue was recrystallized from ethyl acetate–*n*-hexane to obtain needles; wt. 15.8 g (75% from I·2HCl). The melting point, the $[\alpha]_D$ value, and the results of elemental analysis are shown in Table 1.

Z-His(Tos)·DCHA (VII·DCHA). Tosyl chloride (9 g, 47 mmol) was added, portion by portion, to a solution of Z-His (VI) (10 g, 35 mmol)[5b] and sodium carbonate (7 g) in water (100 ml) over a 30-min period under vigorous stirring at 10—15 °C. Stirring was continued for an additional 4 hr at room temperature, and then the reaction mixture was washed twice with 50-ml portions of ether to remove the excess tosyl chloride. The aqueous phase was then acidified to pH 2 with 1 N sulfuric acid. The separated oil was extracted three times with 100-ml portions of ethyl acetate. The extracts were combined, and the combined solution was washed with water, dried over anhydrous sodium sulfate, and concentrated under reduced pressure. The residue was redissolved in ethyl acetate (100 ml), and dicyclohexylamine (5.5 g) was added to the solution; the crystalline materials thus formed were separated by filtration and recrystallized from methanol–ethyl acetate as needles; wt, 15.4 g (70.5%). The melting point, the $[\alpha]_D$ value, and the results of the elemental analysis of this compound are shown in Table 1.

Aoc-His(Tos) (IV-a via Method B). A suspension of VII·DCHA (10 g, 16 mmol) in 1 N sulfuric acid was vigorously shaken with ethyl acetate, and the extract was concentrated under reduced pressure. The residue was treated with 4 N HBr in acetic acid (20 ml) for 1 hr at room temperature. Then, the product was precipitated by the addition of dry ether (200 ml), and the precipitate was washed well by decantation with dry ether. After having been dried in a vacuum desiccator over sodium hydroxide, the solid mass was dissolved in methanol (100 ml), and the solution was neutralized with dry pyridine (6 ml) until precipitation occurred. The precipitates were collected by filtration and washed well with methanol; wt. 3.5 g (51.7%); mp 140—145 °C. This material (3.1 g, 10 mmol), which corresponds to VIII, was then dissolved in 5% aqueous sodium bicarbonate (50 ml). Aoc-azide (1.7 g, 10 mmol) was added to the solution, together with triethylamine (1.6 ml), and the mixture was stirred at room temperature for 2 days. Some insoluble materials thus formed were filtered off, and the filtrate was acidified to pH 2 with 1 N sulfuric acid. The separated oily material was extracted with ethyl acetate, and the extract was washed with water, dried over sodium sulfate, and concentrated to dryness under reduced pressure. The residue was recrystallized from ethyl acetate–*n*-hexane; wt. 2.6 g (63%); mp 109.5—110.5 °C, $[\alpha]_D^{22}$ +10.3° (*c* 1, pyridine). The melting point showed no depression upon mixing with the same compound as synthesized by Method A.

Boc-His(Boc)-OMe (III-b). A solution of Boc-chloride in tetrahydrofuran, which had been prepared from *t*-butylalcohol (148 g) and phosgene (200 g) using an improved procedure described by Sakakibara *et al.*,[23] was stirred vigorously into a suspension of His–OMe·2HCl (I·2HCl) (120 g, 0.5 mol) and triethylamine (280 ml, 2 mol) in chloroform (800 ml) at 0—5 °C. Stirring was continued for an additional 2 hr at room temperature, and then chloroform (500 ml) was added to the reaction mixture. The chloroform solution was washed well with water, 1 N sulfuric acid, and a saturated sodium chloride solution successively, and then dried over anhydrous sodium sulfate. The dried solution was concentrated to dryness. A part of this material was crystallized from ether–*n*-hexane for analysis; mp 95—98 °C, $[\alpha]_D^{22}$ +13.0 °C (*c* 1, THF). Found: C, 54.95; H, 7.39; N, 11.71%. Calcd for $C_{17}H_{27}O_6N_3$: C, 55.27; H, 7.37; N, 11.38%.

Boc–His(Tos) (IV-b). The crude di-Boc-His-OMe obtained above was dissolved in methanol (340 ml), and aqueous 1 N sodium hydroxide (450 ml) was added to the solution at 10—15 °C. After 2 hr, a 10% solution of sodium carbonate (2 l) was added to the reaction mixture, and the whole mixture was washed well with ether. A solution of tosyl chloride (124 g, 0.65 mol) in dioxane (300 ml) was added to the washed solution under vigorous stirring at 10 °C. After the stirring had been continued for 3 hr at room temperature, the reaction mixture was washed well with ether, the aqueous phase was acidified to pH 2 with 1 N sulfuric acid, and the separated oily material was extracted with ethyl acetate. The extract was washed with a saturated sodium chloride solution, dried over anhydrous sodium sulfate, and evaporated to dryness under reduced pressure. The residue was recrystallized from ethyl acetate to afford colorless needles; wt. 107 g (52% yield from I). The melting point, the $[\alpha]_D$ value, and the results of elemental analysis are shown in Table 1. The DCHA salt of Compound IV-b was prepared and then recrystallized from methanol–ethyl acetate; mp 160—162 °C, $[\alpha]_D^{22}$ +26.5° (*c* 1, MeOH). Found: C, 61.25; H, 7.95; N, 9.46; S, 5.38%. Calcd for $C_{30}H_{46}O_6N_4S$: C, 61.01; H, 7.79; N, 9.49; S, 5.13%.

N^{α}-Boc-His-OMe (II-b). This material was obtained much as in the case of N^{α}-Aoc-His-OMe (II-a), using 1.5 equivalents of Boc-azide as the reagent. The yield was 75%; mp 124—125 °C, $[\alpha]_D^{22}$ −13.5° (*c* 1, pyridine). Reported:[22] mp 124—125 °C, $[\alpha]_D$ −13.1° (*c* 2, pyridine).

Z(OMe)–His(Tos) (IV-c). Compound IV-c was synthesized *via* Method A (Scheme 1) in the same manner as IV-a, without any isolation of acylated histidine esters; it was then crystallized as the DCHA salt in an overall yield of 82%. The melting point, the $[\alpha]_D$ value, and the results of elemental analysis are shown in Table 1.

Nps-His-OMe (II-d). Nps-chloride (19 g, 0.1 mol) was added, portion by portion, to a suspension of I·2HCl (12 g, 50 mmol) and triethylamine (28 ml, 0.2 mol) in methanol (150 ml) at 5—10 °C over a 30-min period. The mixture was agitated vigorously during the reaction. After 2 hr, water (500 ml) was added to the reaction mixture, and then it was acidified to pH 2 with 1 N sulfuric acid. The mixture was washed well with three 200-ml portions of ethyl acetate; then excess sodium bicarbonate was added to the mixture, and an oily material thus separated was extracted with ethyl acetate. The extract was washed with water, dried over anhydrous sodium sulfate, and concentrated under reduced pressure in a water bath below 40 °C. The oily residue was charged on the top of a silica-gel column (5×150 cm), using a mixture of $CHCl_3$–MeOH–pyridine (95 : 5 : 3), and the column was eluted with the same solvent system. The main fraction was collected and concentrated under reduced pressure to obtain Compound II-d as an oily material; 13.4 g (83%). Reported:[17] mp 134—136 °C.

Nps–His(Tos) (IV-d via Method A). The oily com-

pound, II-d (13.4 g), obtained above was dissolved in dioxane (125 ml) and then treated with aqueous 2 N sodium hydroxide (45 ml) over a period of 1 hr at 10—15 °C. After triethylamine (11 ml) had been added to the reaction mixture, a solution of tosyl chloride (11 g, 58 mmol) in dioxane (20 ml) was stirred into the mixture at 10 °C over a 45-min period. Stirring was continued for an additional 1 hr at 10—15 °C; then the mixture was neutralized to pH 7 with 1 N sulfuric acid, and the dioxane was removed by distillation under reduced pressure below 40 °C. Water (300 ml) was added to the residual solution, the solution was acidified to pH 2 with 1 N sulfuric acid, and an oil which separated was extracted with ethyl acetate. The ethyl acetate extract was washed with water, dried over anhydrous magnesium sulfate, and concentrated under reduced pressure at below 40 °C. The residual solid was washed with ether and recrystallized from ethyl acetate–*n*-hexane; wt. 14.4 g (75%). The melting point, the $[\alpha]_D$ value, and the results of elemental analysis are shown in Table 1.

Nps-His(Tos)-OMe (V-d). A solution of tosyl chloride (1.4 g, 7.4 mmol) in dioxane (5 ml) was stirred into a mixture of Compound II-d (2 g, 6.2 mmol) and triethylamine (1.4 ml) in dioxane (20 ml) at 5—10 °C over a 15-min period. Then the reaction mixture was diluted with water (50 ml), and the oil which separated was extracted with ethyl acetate. The extract was washed successively with 1 N sulfuric acid, water, aqueous 5% sodium bicarbonate, and water, and dried over anhydrous magnesium sulfate. The dried solution was concentrated to a residue under reduced pressure, and the solid was washed with ether and recrystalliyed from ethyl acetate; wt. 2.37 g (80.0%). The melting point, the $[\alpha]_D$ value, and the results of elemental analysis are shown in Table 1.

Nps-His(Tos)-OBzl. This compound was derived from His-OBzl-2Tos-OH[18] in a 72% yield in the same manner as has been described above. The melting point, the $[\alpha]_D$ value, and the results of elemental analysis are shown in Table 1.

Migration of the Tosyl Group from Boc-His(Tos) (VI-b) to Gly-OMe. Compound IV-b (4.1 g, 10 mmol) was added to a solution of the glycine methyl ester in absolute dioxane (40 ml); the free ester was then isolated from the hydrochloride (2.6 g, 20 mmol) using a procedure involving chloroform-ammonia.[22] The mixture was kept for 6 hr at 50—60 °C; then the solvent was distilled off under reduced pressure and the residue was redissolved in ethyl acetate (30 ml). The solution was shaken well with water (20 ml), washed further successively with 1 N sulfuric acid, aqueous 5% sodium bicarbonate, and water, and dried over anhydrous sodium sulfate. The dried solution was concentrated to an oil under reduced pressure, and the residue was dissolved in methanol. An aqueous 0.1 N sodium hydroxide solution (10 ml) was added to the solution, and the mixture was allowed to react for 1 hr at room temperature. Then, the methanol was removed by evaporation, and the aqueous layer was washed with ethyl acetate and acidified to pH 2 with 6 N sulfuric acid. The acidified solution was extracted well with ethyl acetate, and the extract was dried over anhydrous sodium sulfate and concentrated to a residue under reduced pressure; the residue was then recrystallized from ethyl acetate-petroleum ether; wt. 150 mg, mp 149—150 °C (reported value: 149—150 °C[24]). The IR spectrum of this material was identical with that of an authentic Tos–Gly. The melting point of a mixture of the product and the authentic Tos–Gly showed no depression. The presence of Bos-His in the water-layer was confirmed by tlc using the (2) solvent.

Treatment of Boc–His(Tos)–Gly–OBzl with HOBT. HOBT (0.87 g, 6.4 mmol) was added to a solution of Boc–His(Tos)–Gly–OBzl[25] (1.8 g, 3.2 mmol) in tetrahydrofuran (30 ml), after which the mixture was kept for 1 hr at room temperature. The solution was concentrated to residue under reduced pressure, and the residue was taken in ethyl acetate (70 ml). The ethyl acetate solution was shaken with 1 N sulfuric acid, and the aqueous layer was separated and then neutralized with sodium carbonate to pH 8. The aqueous solution was extracted with two portions of ethyl acetate (100 ml), and the combined extract was washed with a saturated sodium chloride solution and dried over anhydrous sodium sulfate. The dried solution was concentrated to a residue, which was subsequently recrystallized from ethyl acetate; wt. 10 g (78%); mp 138—140 °C, $[\alpha]_D^{22}$ −33° (*c* 1, THF). This material was confirmed to be Boc–His-Gly-OBzl by elemental analysis and by a study of its spectral data. Anal. Found: C, 59.72; H, 6.56; N, 13.66%. Calcd for $C_{20}H_{26}O_5N_4$: C, 59.69; H, 6.51; N, 13.92%. IR ν_{max}^{Nujol}: 3420, 3350, 3230, 1740, 1725, 1600, 1515, 1230, 1212, 1100 cm^{-1}. UV λ_{max}^{EtOH}: absence of 233 nm (ε 10530) [attributable to the N^{im}-tosyl group of Boc–His(Tos)–Gly–OBzl].

The original ethyl acetate layer, which was shaken with 1 N sulfuric acid to extract out the Boc–His-Gly-OBzl, was washed with aqueous sodium carbonate to remove the excess HOBT, after which the organic layer was washed further with water and then dried. The dried solution was concentrated under reduced pressure, and the residue was recrystallized from ethyl acetate; wt. 0.7 g (75.5%); mp 82—84 °C. Elemental analysis showed this material to be 1-(tosyloxy)-benzotriazole. Anal. Found: C, 54.19; H, 4.01; N, 14.46; S, 10.85%. Calcd for $C_{13}H_{11}O_3N_3S$: C, 53.98; H, 3.83; N, 14.53; S, 11.06%. The IR and UV spectra of this material were identical with those of an authentic sample.

1-(Tosyloxy)-benzotriazole. HOBT (2.7 g, 20 mmol) and Tos-chloride (3.8 g, 20 mmol) were dissolved together in tetrahydrofuran (50 ml), and then triethylamine (2.8 ml) was slowly added to the mixture. The materials thus precipitated were filtered off, and the filtrate was concentrated to a residue under reduced pressure. The residue was recrystallized from ethyl acetate; wt. 2.6 g (89.7%); mp 84—85 °C. IR ν_{max}^{Nujol}: 1617, 1592, 1400, 1395, 1200, 1186 cm^{-1}, absence of 3270 cm^{-1} (attributable to the *N–OH* band of HOBT). UV λ_{max}^{THF}: 236.5 nm (ε 17230).

Treatment of Boc–His(Z)–Gly–OBzl with HOBT. When Boc–His(Z)–Gly–OBzl (0.54 g, 1 mmol) was treated with HOBT as has been described above the starting material was recovered in an 89% yield under the same reaction conditions. Mp 107—108 °C, $[\alpha]_D^{22}$ +53° (*c* 1, THF). Found: C, 62.70; H, 6.28; N, 10.43%. Calcd for $C_{28}H_{32}O_7N_4$: C, 62.67; H, 6.01; N, 10.44%.

Thiocarbonyl Ylides. Attempted Preparation and Related Reactions[1]

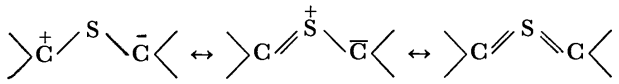
Shuichi MITAMURA, Masaaki TAKAKU, and Hitosi NOZAKI*

Department of Industrial Chemistry, Kyôto University, Yoshida, Sakyô-ku, Kyôto 606

(Received July 22, 1974)

The attempted preparation of thiocarbonyl ylides (I) by the proton abstraction of thiouronium salts (III) has disclosed a fast isomerization of I to enethiols (V) (Y=H) and an alternative desulfurization to enediamines (VII) (Y=Ph), the by-products being olefins (VIII) and sulfides (IX). The second route to I examined consists of the reaction of tetramethylthiourea (II) with diazomalonate, which gives rise to enediamine (VII_g). Rotation about the C=C bond of enediamines is discussed on the basis of IR and NMR spectra.

Thiocarbonyl ylides should be resonance hybrides involving 1,3-dipole[2] and tetravalent sulfur.



Recently Kellogg[3] reported that the thermally-induced loss of nitrogen from 1,3,4-thiadiazolines afforded transient thiocarbonyl ylides, which then cyclized to thiiranes or alternatively reacted with azo compounds to give $[4_s+2_s]$ cycloadducts. Middleton[4] isolated a stable thiocarbonyl ylide in the reaction of thiourea with dicyanocarbene.

The present authors attempted to obtain thiocarbonyl ylides (I) based on tetramethylthiourea (II) by the deprotonation of the corresponding thiouronium salts (III) and by the reaction of II with carbene IV (Scheme 1). These reactions failed to give the expected ylides (I), but, instead, they afforded four products: enethiols (V),[5] enediamines (VII), olefins (VIII), and sulfides (IX) in the yields listed in Table 1.

Novel thiouronium salts (IIIa—IIIf) were readily prepared in good yields from II and halides, XCHRY (X=halogen: R=H or Ph: Y=COOEt, COOMe, COPh, Ph). The results of analyses are listed in Table 2, while the yields, the melting points, and the IR and NMR spectra are shown in Table 3.

Base Treatment of Thiouronium Salts (III). The

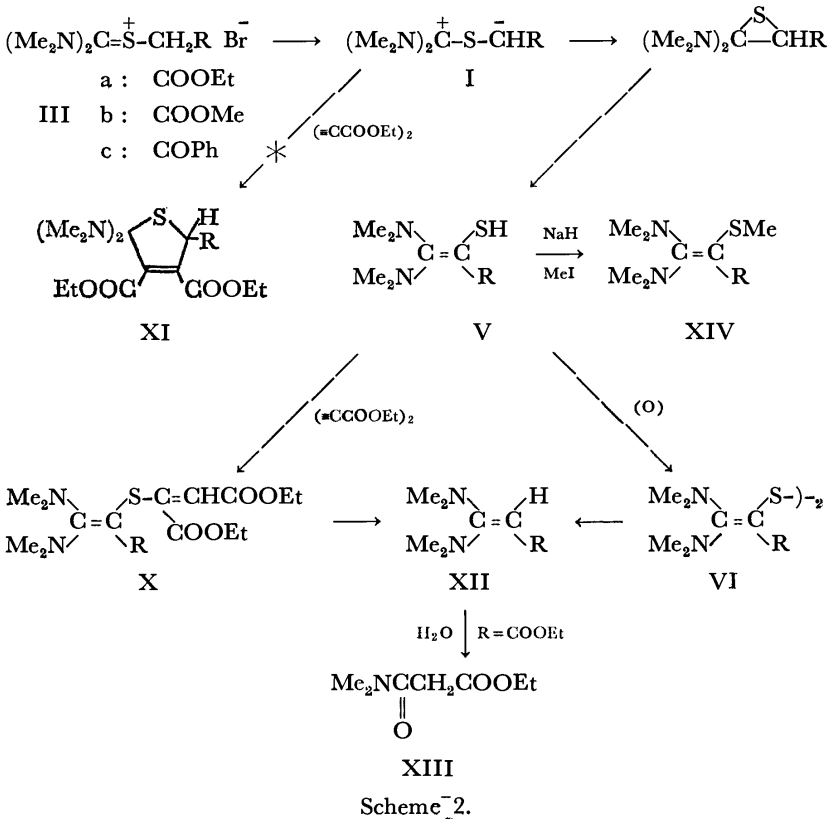

Scheme 2.

deprotonation of III may result in the formation of transient ylides (I). However, they do experience a fast isomerization to enethiols (V), which also are labile compounds; various products arising therefrom have been isolated to prove the intermediacy of these species.

A mixture of IIIa and excess diethyl acetylenedicarboxylate in tetrahydrofuran (THF) was treated with triethylamine to afford an adduct (Xa) in a 73% yield (Scheme 2). Similarly, IIIb gave Xb in a 70% yield. The isomeric structures, XIa and XIb, were excluded as follows. The mass spectra (Fig. 1) exhibited four fragment peaks due to carbon-sulfur bond fission. The desulfurization of Xa with Raney nickel afforded diethyl succinate and ethyl 3,3-bis(dimethylamino)acrylate (XIIa), whereas that of Xb gave diethyl succinate

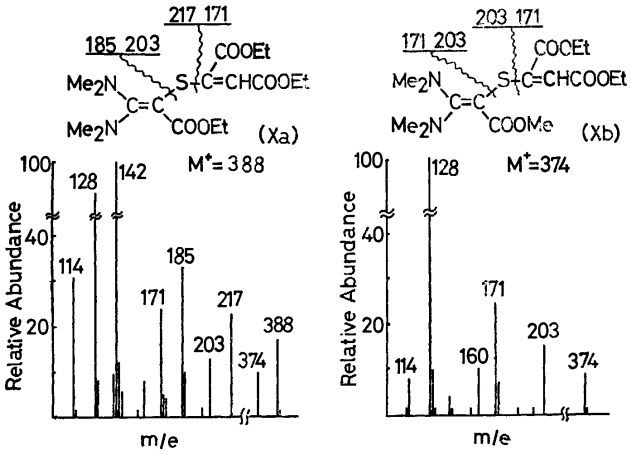

Fig. 1. Mass spectra of Xa and Xb.

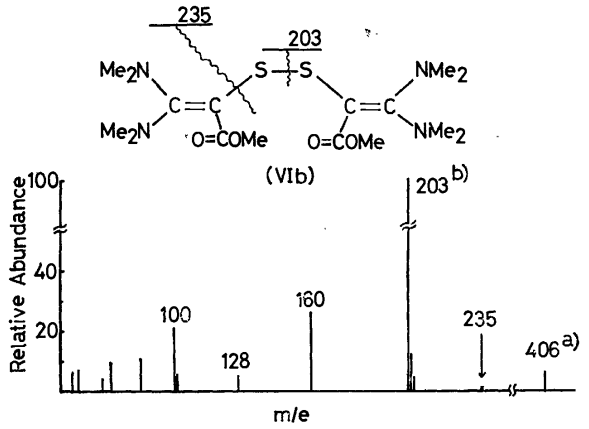

Fig. 2. High resolution mass spectrum of VIb.
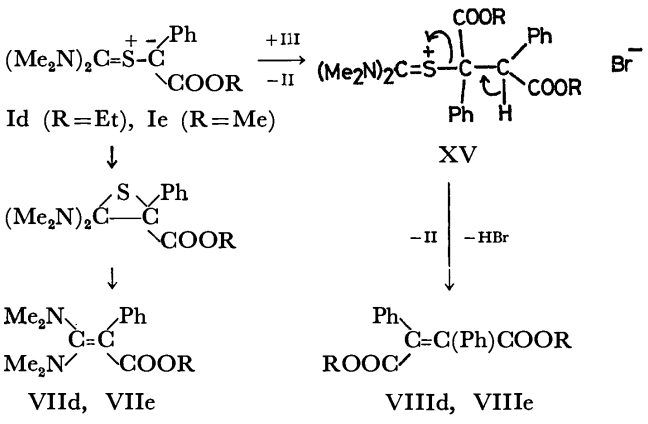
a) Exact mass: 406.171, Calcd for $C_{16}H_{30}N_4O_4S_2$: 406.171. b) Exact mass: 203.086, Calcd for $C_8H_{15}N_2O_2S$: 203.085.

and XIIb. The hydrolysis of XIIa yielded ethyl *N,N*-dimethylmalonamidate (XIII), which was alternatively prepared from ethyl chloroformylacetate and dimethylamine.

The treatment of IIIa with equimolar sodium hydride in THF or dimethyl sulfoxide (DMSO), followed by a work-up, afforded VIa, which is the oxidative dimer of Va. Similarly, that of IIIb gave VIb. The spectral data, including the high-resolution mass spectrum of VIb (Fig. 2), were consistent with the structure. The desulfurization of VIa gave XIIa, and that of VIb yielded XIIb. When a solution of IIIa in carefully degassed THF was treated with 2 mol of sodium hydride and then with methyl iodide, there obtained a methylthio compound (XIVa) along with VIa. Applying a similar procedure to IIIb in dimethylformamide (DMF) gave XIVb.

The treatment of IIIc with sodium hydride in DMSO yielded VIc, whereas sulfide (IXc) was the predominant product in THF (Scheme 1, Table 1). DMSO seems to play the role of oxidant. In the presence of diethyl acetylenedicarboxylate, the salt IIIc failed to give the expected adduct (Xc).

The prerequisite for the formation of the enethiols, V, is the presence of a methylene group adjacent to the



Scheme 3.

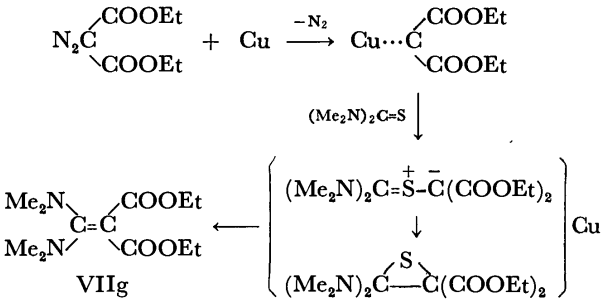
sulfur atom in III, or Y=H. The treatment of IIId or IIIe (Y=Ph) must, therefore, take a different course (Scheme 3). When IIId was treated with sodium hydride in THF, an enediamine (VIId) was obtained in a 44% yield, along with elemental sulfur (22%), II(42%), and an oil whose IR suggested the possibility of its being VIIId. Similarly, IIIe gave VIIe (31%), and an olefinic ester (VIIIe) which was a *ca.* 1 : 1 mixture of (*Z*) and (*E*) isomers.

The formation of VIId and VIIe can be explained as is shown in Scheme 3. The ylides, Id and Ie, may be cyclized to thiiranes, which are then decomposed spontaneously to VIId or VIIe and sulfur. In the presence of dimethyl acetylenedicarboxylate, no addition product was obtained and the product distributions were not affected. These results indicate that the decomposition of Id and Ie is a fast process.

A possible account of the formation of VIIIe is given also in Scheme 3. In analogy to the recorded thermal decomposition of methylphenylsulfonium phenacylide to tribenzoylcyclopropane,[6] the nucleophilic ylide (Ie) may attack the salt IIIe to afford XV, whose Hofmann elimination then gives VIIIe. Such an intermolecular reaction of the labile ylide Ie might be possible if Ie is generated close enough to the unchanged IIIe.

Finally, under appropriate conditions, the sulfides, IXa, IXc, and IXf, were obtained from IIIa, IIIc, and IIIf respectively. The S-benzylthiouronium salt, IIIf (R=Ph, Y=H), gave IXf and II upon treatment with sodium hydride, neither VIf nor VIIf and was obtained (see Table 1). The direct precursor of IX is not yet known.

Reaction of II with Diazomalonate. A cyclohexane solution of II and diethyl diazomalonate was heated



Scheme 4.

Table 4. Spectral features of β,β-bis(dimethylamino)-α,β-unsaturated carbonyl compounds XVI

Compd.	R	R′	IR ($\nu_{C=O}$ cm^{-1})	NMR (δ NMe_2 in $CDCl_3$)[c]

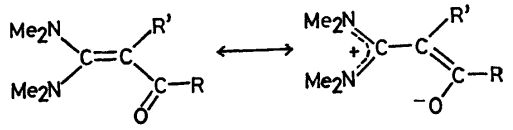
a) Obtained in neat liquid film. b) Obtained in KBr tablet. c) Measured at 23 °C.

under reflux for 12 hr in the presence of copper powder to afford VIIg in a 25% yield. An attempted photoreaction[7] of the components failed. No nitrogen evolution was observed in the absence of the copper catalyst in the dark, either.

We are tempted to assume the intermediacy of a copper carbenoid[8] (Scheme 4), but the exact nature of catalysis is not yet known. Copper salts or chelates gave much inferior yields of VIIg. Copper powder may effectively facilitate the desulfurization step.

Characteristic Spectra of Enediamines (XVI). Table 4 shows the spectral features of XVI, including the wave numbers of the carbonyl stretching and the NMR signals of the dimethylamino groups measured in deuteriochloroform at room temperature. The implications of these data may be summarized as follows. 1) The CO stretching vibrations occur at lower frequencies than those of regular α,β-unsaturated esters or ketones. 2) The *N*-methyl proton signals appear approximately 0.5—0.7 ppm downfield from ordinary ones.[9] 3) Though the two dimethylamino groups should be nonequivalent on the assumption of a restricted rotation about the C=C bond,[10] the chemical shifts of all the dimethylamino protons coincided except for those of XIIa. Such characteristic data point to the idea that the contribution of a betain form, XVI′, is predominant in contrast to usual α,β-unsaturated carbonyl compounds.



XVI XVI′

Experimental

All the mps and bps are uncorrected. The microanalyses were performed at the Elemental Analyses Center of Kyôto University. The NMR spectra were taken with a JEOL C-60H spectrometer at 60 MHz or a Varian HA 100 spectrometer at 100 MHz. The mass spectra were obtained on a Hitachi RMU-6L spectrometer, a Hitachi RMU-6D spectrometer, or a Hitachi RMS-4 spectrometer. The high-resolution mass spectrum of VIb was obtained on a JMS-OlSG spectrometer.

S-Ethoxycarbonylmethyl-N,N,N′,N′-tetramethylthiouronium Bromide (IIIa). A solution of II (6.7 g, 50 mmol) and ethyl bromoacetate (8.4 g, 50 mmol) in acetone (100 ml) was stirred for 3 hr at room temperature to give white precipitates of IIIa (13.8 g, 92%). The spectral data and the elemental analyses of IIIa are shown in Tables 2 and 3.

The other thiouronium salts (IIIb—IIIf) were prepared in a similar way.

Ethyl 3,3-Bis(dimethylamino)-2-[1,2-bis(ethoxycarbonyl)vinylthio]acrylate (Xa). Into a suspension of IIIa (3.0 g, 20 mmol) and diethyl acetylenedicarboxylate (3.4 g, 20 mmol) in THF (70 ml), triethylamine (3.0 g, 30 mmol) was added, drop by drop, under a nitrogen atmosphere at room temperature. The reaction mixture was then stirred for 12 hr, diluted with water (200 ml), and repeatedly extracted with chloroform. The combined extracts were washed with water, dried (magnesium sulfate), and concentrated *in vacuo*. The residual oil was purified by column chromatography (silica gel, chloroform) to yield an oil which solidified upon trituration with ether. Recrystallization from ethanol-hexane gave Xa (2.8 g, 73%); mp 91—92 °C. IR (KBr): 1733, 1705, 1660, 1590, 1530, 1150, 1069, 770 cm^{-1}. NMR (δ, $CDCl_3$): 1.22 (t, 3H), 1.24 (t, 3H), 1.33 (t, 3H), 2.86 (s, 12H), 4.12 (q, 2H), 4.16 (q, 2H), 4.30 (q, 2H), 5.50 (s, 1H). The mass spectrum of Xa is shown in Fig. 1. Found: C, 52.9; H, 7.3%. Calcd for $C_{17}H_{28}N_2O_6S$: C, 52.6; H, 7.3%.

Similarly, methyl 3,3-bis(dimethylamino)-2-[1,2-bis(ethoxycarbonyl)vinylthio]acrylate (Xb) was obtained in a 70% yield as colorless crystallines; mp 79—80 °C (recrystallized from ethanol-hexane). IR (KBr): 1740, 1705, 1661, 1590, 1529, 1150, 1069, 770 cm^{-1}. NMR (δ, $CDCl_3$): 1.24 (t, 3H) 1.35 (t, 3H), 2.88 (s, 12H), 3.68 (s. 3H), 4.12 (q, 2H), 4.30 (q, 2H), 5.56 (s, 1H). The mass spectrum of Xb is shown in Fig. 1. Found: C, 51.6; H, 7.1%. Calcd for $C_{16}H_{26}N_2O_6S$: C, 51.3; H, 7.0%.

Di[2,2-bis(dimethylamino)-1-(ethoxycarbonyl)vinyl] Disulfide (VIa). To a stirred suspension of IIIa (6.0 g, 20 mmol) in THF (200 ml), sodium hydride (0.90 g of a 52% dispersion in mineral oil, 20 mmol) was added in one portion. The reaction mixture was stirred until the evolution of hydrogen had stopped (*ca.* 3 hr). After it had then been filtered, the filtrate was evaporated to give a yellow solid of VIa, which was subsequently washed with ether. The crude product (3.6 g, 83%) was recrystallized from ethanol; mp 142—143 °C. IR(KBr): 1633, 1510, 1050, 766 cm^{-1}. NMR (δ, $CDCl_3$): 1.23(t, 6H), 2.96 (s, 24H), 4.07 (q, 4H). Found: C, 49.6; H, 8.1; S, 14.8%. Calcd for $C_{18}H_{34}N_4O_4S_2$: C, 49.8; H, 7.9; S, 14.7%.

Similarly, di[2,2-bis(dimethylamino)-1-(methoxycarbonyl)-vinyl] disulfide (VIb) was obtained in a 42% yield as a yellow solid; mp 163—164 °C (from ethanol). IR (KBr): 1640, 1515, 1056, 767 cm^{-1}. NMR (δ, $CDCl_3$): 2.95 (s, 24H), 3.57 (s, 6H). The high-resolution mass spectrum of VIb is shown is Fig. 2. Found: C, 47.3; H, 7.6; S, 15.6%. Calcd for $C_{16}H_{30}N_4O_4S_2$: C, 47.3; H, 7.4; S, 15.7%.

thyl 3,3-Bis(dimethylamino)-2-(methylthio)acrylate (XIVa). THF (100 ml) was completely degassed *in vacuo* (1 mmHg) for

3 hr at −60 °C. To this, sodium hydride (1.0 g of a 51.9% dispersion in mineral oil, 22 mmol) and IIIa (2.3 g, 7.7 mmol) were added successively under a nitrogen atmosphere at room temperature. After stirring for 12 hr, methyl iodide (1.5 g, 106 mmol) was added, drop by drop. The mixture was then stirred for 3 hr and filtered, after which the filtrate was concentrated *in vacuo* to afford an oil. Chromatography on a silica-gel column with benzene, ether, and ethanol as the eluents gave II (84 mg, 8.3%), VIa (200 mg, 12%), and XIVa as a colorless oil which solidified upon trituration with hexane at −50 °C (300 mg, 17%). Recrystallization from hexane gave an analytical sample; mp 31—32 °C. IR (KBr): 1645, 1517, 1210, 1056, 767 cm^{-1}. NMR (δ, CCl_4): 1.27 (t, 3H), 2.03 (s, 3H), 2.78 (s, 6H), 2.88 (s, 6H), 4.07 (q, 2H). Mass spectrum (*m/e*): 232 (M^+). Found: C, 52.4; H, 9.1%. Calcd for $C_{10}H_{20}N_2O_2S$: C, 51.7; H, 8.7%.

Methyl 3,3-Bis(dimethylamino)-2-(methylthio)acrylate (XIVb). Sodium hydride (3.0 g of a 51.9% dispersion in mineral oil, 65 mmol) was washed three times with hexane and then suspended in DMF (100 ml). To this, *S*-methoxycarbonylmethyl-*N,N,N',N'*-tetramethylthiouronium bromide (IIIb) (5.7 g, 20 mmol) was added in small portions under a nitrogen atmosphere at room temperature. After the evolution of hydrogen had ceased (*ca.* 1 hr), methyl iodide (5.0 g, 35 mmol) was added, drop by drop. The mixture was then stirred for 1 hr, diluted with water (200 ml), neutralized by the addition of ammonium chloride, and extracted with chloroform. After drying (magnesium sulfate), the combined extracts were distilled *in vacuo* to yield XIVb as a colorless oil (320 mg, 7.3%); bp 88—90 °C/0.07 mmHg. IR (neat): 1651, 1525, 1210, 1060, 770 cm^{-1}. NMR (δ, CCl_4): 2.03 (s, 3H), 2.81 (s, 6H), 2.89 (s, 6H), 3.61 (s, 3H). Found: C, 49.6; H, 8.6%. Calcd for $C_9H_{18}N_2O_2S$: C, 49.5; H, 8.3%.

Ethyl 3,3-Bis(dimethylamino)acrylate (XIIa). To a solution of VIa (2.2 g, 5 mmol) in ethanol (100 ml), Raney nickel (W-2) (36 g) was added. The mixture was stirred at room temperature for 2 hr and filtered, and the filtrate was distilled *in vacuo* to afford XIIa as a colorless oil (1.4 g, 76%); bp 76.5—77 °C/1 mmHg. IR (neat): 1675, 1555, 1158, 1050, 780 cm^{-1}. NMR (δ, $CDCl_3$): 1.26 (t, 3H), 2.79 (s, 6H), 2.87 (s, 6H), 3.96 (s, 1H), 4.09 (q, 2H). Mass spectrum (*m/e*): 186 (M^+). Found: C, 57.5; H, 10.0%. Calcd for $C_9H_{18}N_2O_2$: C, 58.0; H, 9.7%.

Similarly, the desulfurization of VIb afforded methyl 3,3-bis(dimethylamino)acrylate (XIIb) as a colorless oil in a 68% yield; bp 87—88 °C/4 mmHg. IR (neat): 1675, 1550, 1120, 1054, 779 cm^{-1}. NMR (δ, $CDCl_3$): 2.81 (s, 6H), 2.88 (s, 6H), 3.62 (s, 3H), 3.96 (s, 1H). Mass spectrum (*m/e*): 172 (M^+). Found: C, 55.6; H, 9.6%. Calcd for $C_8H_{16}N_2O_2S$: C, 55.8; H, 9.4%.

Desulfurization of Xa. Raney nickel (W-2) (2 g) was added to a solution of Xa (250 mg, 0.64 mmol) in ethanol (50 ml). After stirring for 15 min at room temperature, the mixture was filtered and the filtrate was concentrated to afford an oil, which consisted of diethyl succinate and XIIa. Identification was made by a comparison of the IR spectra and the retention times of glc (High vacuum silicone grease 30%) with those of authentic samples. The yield of diethyl succinate, as calculated from the peak area in glc, was 80%, while that of XIIa was 56%.

Similarly, the desulfurization of Xb with Raney nickel afforded diethyl succinate (68%) and XIIb (40%).

Ethyl N,N-Dimethylmalonamidate (XIII). Ethyl hydrogen malonate (3.5 g, 26 mmol) was added, drop by drop, to thionyl chloride (20 ml); the solution was heated at 50 °C for 2 hr and then under reflux for 1 hr. After cooling, the solution was concentrated *in vacuo* to yield ethyl chloroformylacetate.[11] An excess of anhydrous dimethylamine gas was passed through a solution of ethyl chloroformylacetate in ether (50 ml) to give white precipitates. The reaction mixture was then filtered, and the filtrate was distilled *in vacuo* to yield XIII as a colorless oil (4.5 g, 94% based on ethyl hydrogen malonate); bp 94—96 °C/1 mmHg. IR (neat): 1735, 1645, 1250, 1170, 1030 cm^{-1}. NMR (δ, CCl_4): 1.30 (t, 3H) 2.91 (s, 3H), 3.02 (s, 3H), 3.32 (s, 2H), 4.16 (q, 2H). Found: C, 52.7; H, 8.2; N, 8.8%. Calcd for $C_7H_{13}NO_3$: C, 52.8; H, 8.2; N, 8.8%.

Hydrolysis of XIIa. A solution of XIIa (0.48 g, 2.6 mmol) and *p*-toluenesulfonic acid (5 mg) in THF-water (1 : 1, 50 ml) was stirred at room temperature for 3 days and then extracted four times with chloroform (70 ml). The extracts were combined, shaked with an aqueous sodium bicarbonate solution, washed with water, dried (magnesium sulfate), and concentrated *in vacuo* to give an oil which consisted of XIIa and XIII. Identification was made by a comparison of the IR spectra and the retention times of glc (Polyethylene glycol-$AgNO_3$ 30%) with those of authentic samples.

Di[2,2-bis(dimethylamino)-1-benzoylvinyl] Disulfide (VIc). Sodium hydride (0.50 g of 51.9% dispersion in mineral oil, 11 mmol) was washed with *n*-hexane and then suspended in DMSO (50 ml). Into this, *S*-phenacyl-*N,N,N',N'*-tetramethylthiouronium bromide (IIIc) (3.3 g, 10 mmol) was stirred in small portions at room temperature. After the evolution of hydrogen had stopped (*ca.* 30 min), the brown-red solution was diluted with water (100 ml), and extracted four times with chloroform (150 ml); the combined extracts were then washed three times with water (100 ml), dried (magnesium sulfate), and concentrated *in vacuo* to give an oil. This oil solidified on trituration with ether to yield a yellow solid of VIc (1.56 g, 64%). Recrystallization from ethanol upon the addition of ether gave an analytical sample; mp 192—195 °C. IR (KBr): 1600, 1590, 1510, 1400, 710, 660 cm^{-1}. NMR (δ, $CDCl_3$): 2.85 (s, 24H), 7.2—7.6 (m, 10H). Found: C, 62.4; H, 7.1%. Calcd for $C_{26}H_{34}N_4O_2S_2$: C, 62.6; H, 6.9%.

Reaction of S-[α-(Methoxycarbonyl)benzyl]-N,N,N',N'-tetramethylthiouronium Bromide (IIIe) with Sodium Hydride. Sodium hydride (0.50 g of a 51.9% disperion in mineral oil, 11 mmol) was suspended in THF (50 ml). To this, IIIe (3.6 g, 10 mmol) was added under a nitrogen atmosphere at room temperature. The mixture was stirred for 5 days and then filtered, after which the filtrate was concentrated *in vacuo* to afford an oil, which was subsequently chromatographed on a silica gel column. From the benzene eluent, we obtained a mixture of dimethyl 2,3-diphenylfumarate and dimethyl 2,3-diphenylmaleate (VIIIe) as a colorless solid (0.17 g, 12%). The (Z) and (E) isomers could not be separated, but the intensities of the methoxy protons in NMR indicated that the ratio of the (Z) to the (E) isomers was *ca.* 1. IR (nujol): 1720, 1500, 1275, 1225, 1210, 1010, 725, 700 cm^{-1}. NMR (δ, CCl_4): 3.46 (s, 3H), 3.77 (s, 3H), 7.0—7.4 (m, 10H). Mass spectrum (*m/e*): 296 (M^+). Recrystallization from ethanol gave an analytical sample; mp 103—107 °C.[12] Found: C, 72.9; H, 5.3%. Calcd for $C_{18}H_{16}O_4$: C, 73.0; H, 5.4%.

The benzene–ether eluent (4 : 1) gave II (0.43 g, 34%), which was identified by a comparison of its IR spectrum with that of authentic sample.

From the ether eluent, we obtained methyl 3,3-bis(dimethylamino)-2-phenylacrylate (VIIe) (0.77 g, 31%) as a colorless solid. Recrystallization from hexane gave an analytical solid. Recrystallization from hexane gave an analytical sample; mp 69 °C. IR (KBr): 1632, 1520, 1180, 1050,

770, 690 cm^{-1}. NMR (δ, CCl_4): 2.75 (broad s, 12H), 3.57 (s, 3H), 6.7—7.2 (m, 5H). Found: C, 67.9; H, 8.4; N, 11.2%. Calcd for $C_{14}H_{20}N_2O_2$: C, 67.7; H, 8.1; N, 11.3%.

Reaction of S-[α-*(Ethoxycarbonyl)benzyl*]-N,N,N′,N′-*tetramethylthiouronium Bromide (IIId) with Sodium Hydride.* To a stirred suspension of sodium hydride (0.50 g of a 51.9% dispersion in mineral oil, 11 mmol) in THF (50 ml), IIId (4.0 g, 11 mmol) was added under a nitrogen atmosphere at room temperature. The mixture was then stirred for 24 hr and filtered, after which the filtrate was concentrated *in vacuo* to afford an oil, which was subsequently chromatographed on a silica gel column. The benzene eluent gave elemental sulfur (74 mg, 22%) and an oil (0.57 g) whose IR (neat, 1725, 1690, 1600, 1450, 1370, 1200, 1010, 720, 680 cm^{-1}) suggested the presence of Ph- and EtOOC- groups. The benzene-ether eluent (4 : 1) gave II (0.59 g, 42%). The ether eluent gave ethyl 3,3-bis(dimethylamino)-2-phenylacrylate (VIId) as a colorless solid (1.23 g, 44%); mp 63 °C (from hexane). IR (KBr): 1642, 1514, 1290, 1170, 1050, 770, 695 cm^{-1}. NMR (δ, CCl_4): 1.22 (t, 3H), 2.74 (s, 12H), 4.05 (q, 2H), 6.7—7.2 (m, 5H). Found: C, 68.9; H, 8.4%. Calcd for $C_{15}H_{22}N_2O_2$: C, 68.8; H, 8.5%.

Treatment of IIIa with Triethylamine. To a suspension of IIIa (6.0 g, 20 mmol) in THF (100 ml), triethylamine (6.0 g, 60 mmol) was added, drop by drop, under a nitrogen atmosphere at room temperature. The mixture was stirred for 2 weeks, diluted with water (300 ml), and extracted with chloroform (200 ml). The combined extracts were dried (magnesium sulfate) and then concentrated *in vacuo* to give an oil. Chromatography on a silica gel column, with benzene, ether, and methanol as eluents, gave predominantly diethyl thiodiglycolate (IXa) as a colorless oil; bp 89 °C/2 mmHg (lit,[13] bp 105 °C/3 mmHg) (0.70 g, 34%). IR (neat): 1730, 1270, 1150, 1025 cm^{-1}. NMR (δ, CCl_4): 1.30 (t, 6H), 3.32 (s, 4H), 4.11 (q, 4H). Found: C, 46.8; H, 7.1; S, 15.8%. Calcd for $C_8H_{14}O_4S$: C, 46.6; H, 6.8; S, 15.5%.

The other products were II (0.87 g, 29%) and VIa (0.24 g, 5.5%), which were identified by a comparison of their IR spectra with those of authentic samples.

Treatment of IIIc with Triethylamine. To a stirred suspension of IIIc (9.9 g, 30 mmol) in THF (100 ml), triethylamine (10 g, 0.10 mol) was added, drop by drop, under a nitrogen atmosphere, after which the mixture was stirred at room temperature for 24 hr. Working up the product, followed by chromatographic separation on a silica gel column with benzene and ether as eluents, yielded diphenacyl sulfide (IXc) (1.12 g, 28%); mp 74—75 °C (from ethanol) (lit,[14] 74 °C). IR (KBr): 1690, 1595, 1450, 985, 750, 685, 645 cm^{-1}. NMR (δ, $CDCl_3$): 4.00 (s, 4H), 7.2—8.1 (m, 10H). Found: C, 71.5; H, 5.2%. Calcd for $C_{16}H_{14}N_2S$: C, 71.1; H, 5.2%.

Another product, II (1.90 g, 48%), was identified by comparison of its spectrum with that of an authentic specimen.

Treatment of S-*Benzyl*-N,N,N′,N′-*tetramethylthiouronium Bromide (IIIf).* Sodium hydride (0.25 g of a 51.9% dispersion in mineral oil, 55 mmol) was washed with *n*-hexane and then suspended in THF (30 ml). To this stirred mixture, IIIf (1.75 g, 50 mmol) was added under nitrogen. After the mixture had been stirred for 5 days at roon temperature and filtered, the filtrate was concentrated *in vacuo* to give an oil. Chromatography on a silica gel column, with benzene and ether as eluents, gave dibenzyl sulfide (IXf) 124 mg, 23%); mp 45—46 °C (lit,[15] mp 49 °C). IR (neat): 1600, 1598, 1455, 755, 683 cm^{-1}. NMR (δ, CCl_4): 3,47 (s, 4H), 7.17 (s, 10H). Mass spectrum (*m/e*): 214 (M^+). The by-product was tetramethylthiourea II (68 mg, 8.5%).

Diethyl Bis(dimethylamino)methylenemalonate (VIIg). To a stirred mixture of II (6.6 g, 50 mmol) and copper powder (1.0 g) in cyclohexane (50 ml), diethyl diazomalonate (1.86 g, 10 mmol) was added at room temperature under nitrogen. The reaction mixture was then heated under reflux for 12 hr and filtered, after which the filtrate was evaporated *in vacuo* to give an oil, which was chromatographed on a silica gel column. After the elution of II with ether, the residue was eluted with chloroform. The combined extracts were dried (magnesium sulfate) and concentrated *in vacuo* to afford an oil, which solidified upon trituration with ether at −30 °C to yield a colorless solid of VII g (0.65 g, 25%); mp 64 °C (from *n*-hexane) (lit,[16] mp 67—68 °C). IR (KBr): 1658, 1625, 1560, 1520, 1275, 1210, 1060, 905, 796 cm^{-1}. NMR (δ, $CDCl_3$): 1.28 (t, 6H), 2.97 (s, 12H), 4.17 (q, 4H). Found: C, 55.9; H, 8.7; N, 10.9%. Calcd for $C_{12}H_{22}N_2O_4$: C, 55.8; H, 8.6; N, 10.7%.

The authors are grateful to the Staff of the Sankyo Co. for determining the high-resolution mass spectra. Financial support from the Ministry of Education, the Japanese Government, and from the Toray Science Foundation is acknowledged with pleasure.

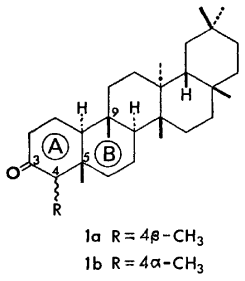
Synthesis and Photochemical Reaction of 1,5,5,9-Tetramethyl-2-decalone

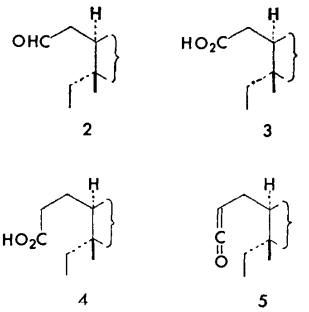
Tochiro TATEE, Takahiko TSUYUKI, Reiko AOYAGI, and Takeyoshi TAKAHASHI
Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113
(Received July 31, 1974)

1,5,5,9-Tetramethyl-2-decalone (**6**) was synthesized from 5,5,9-trimethyl-1-decalone (**7**) and irradiated in *n*-hexane under a nitrogen atmosphere using a high pressure mercury lamp. Oxygen was passed through the reaction mixture in the dark to give a seco-nor acid, 1-carboxymethyl-2-ethyl-2,6,6-trimethylcyclohexane (**8a**) and a seco acid, 1-(2-carboxyethyl)-2-ethyl-2,6,6-trimethylcyclohexane (**9a**).

In the photochemical reaction of cycloalkanones, α-cleavage to form a biradical is well known as one of the primary photoreactions.[1] The biradical undergoes elimination of carbon monoxide and/or hydrogen shift to afford an unseturated aldehyde and/or a ketene, depending on the structural requirement.[2] In protic solvents such as alcohols or aqueous solvents, the ketene immediately reacts with the solvents to afford an ester or a carboxylic acid, respectively. However, the ketene formed in aprotic solvents is inert to the (aprotic) solvents.

In the previous papers[3] we reported the photochemical reaction of friedelin (**1a**) in *n*-hexane and isolation of 5α-ethyl-10β-formylmethyl-des-A friedelane (**2**), 10β-carboxymethyl-5α-ethyl-des-A-friedelane (**3**), and 10β-(2-carboxyethyl)-5α-ethyl-des-A-friedelane (**4**). Since a 3,4-seco-friedelin skeleton bears no hydrogen atom on the δ-carbon atoms, the acyl-alkyl biradical produced from **1a** could not afford a δ-unsaturated aldehyde, but could lead to the ketene (**5**).[3] During the subsequent separation work-up, the ketene (**5**) gave the seco acid (**4**) by addition of water, while the seco-nor aldehyde (**2**) was formed by autoxidation of the ketene (**5**); **2** was further oxidized by air to give the seco-nor acid (**3**).[3]

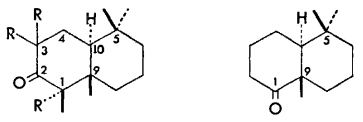


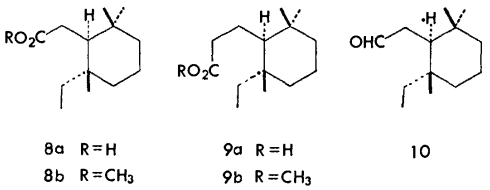


In order to examine the general formation of the seco-nor product in a system such as friedelin (**1a**), photochemical behavior of 1,5,5,9-tetramethyl-2-decalone (**6**), as a simple bicyclic model compound corresponding to the A/B ring of **1a**, was investigated.

In this paper, we wish to describe the synthesis of 1,5,5,9-tetramethyl-2-decalone (**6**) from 5,5,9-trimethyl-1-decalone (**7**) and the formation of 1-carboxymethyl-2-ethyl-2,6,6-trimethylcyclohexane (**8a**), 1-(2-carboxyethyl)-2-ethyl-2,6,6-trimethylcyclohexane (**9a**), and 2-ethyl-1-formylmethyl-2,6,6-trimethylcyclohexane (**10**) in the photochemical reaction of **6** in *n*-hexane followed by oxygen introduction in the dark.

5,5,9-Trimethyl-1-decalone (**7**)[4] was treated with methylmagnesium iodide to give two alcohols (**11**)





and (**12**) in 63% and 20% yield, respectively, which were separated by silica gel chromatography. Assignment of the hydroxyl group was easily accomplished by PMR measurement using $Eu(dpm)_3$ as a shift reagent (Figs. 1 and 2). The signal due to the methyl group geminal to the hydroxyl group suffered the most significant shift in each alcohol. The shift for the

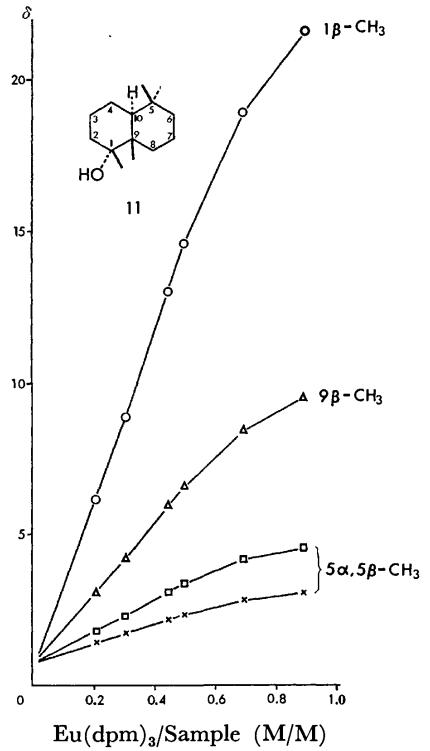


Fig. 1. Induced paramagnetic shifts for the alcohol **11**. [$Eu(dpm)_3$ was added to a 7% (w/v) soln of **11** in CCl_4].

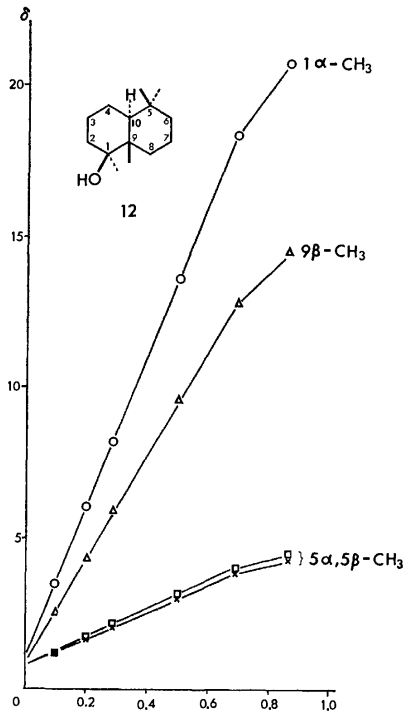

Fig. 2. Induced paramagnetic shifts for the alcohol **12**. [Eu(dpm)$_3$ was added to a 7% (w/v) soln of **12** in CCl_4].

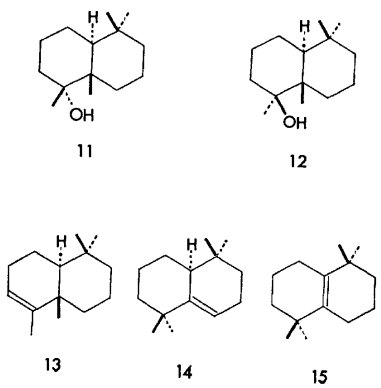
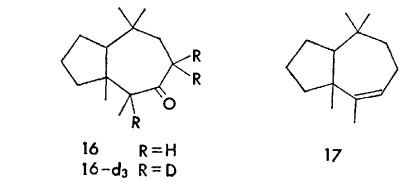
angular methyl group of **11** was smaller than that of **12**. Each alcohol (**11** and **12**) was subjected to dehydration with iodine at 140 °C yielding an olefin mixture (**13**, **14**, and **15**) whose ratio was 61 : 8 : 31 and 6 : 18 : 76, respectively. The olefin mixture was separated by silver nitrate-impregnated silica gel chromatography. The main olefin (**13**) obtained by the dehydration of the alcohol (**11**) showed the presence of an olefinic methyl (δ 1.58, d, J=2 Hz), an olefinic proton (δ 5.18, m), and three tertiary methyls (δ 0.87, 0.89, and 1.02; each s) in the PMR spectrum. The structure of **13** was further supported by the formation of the ketone (**6**) (*vide infra*).

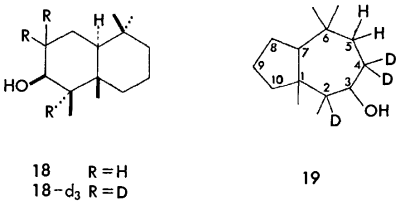
Treatment of the olefin mixture with *p*-toluenesulfonic acid in chloroform gave a mixture of **14** and **15** in a ratio of 1 : 4; **13** was absent in the resulting mixture. The mixture of **14** and **15** was separated by a column of silica gel impregnated with silver nitrate. Each olefin (**14** or **15**) gave the same equilibriating



mixture of **14** and **15** in a ratio of 1 : 4 by treatment with *p*-toluenesulfonic acid. The structures of these olefins (**14** and **15**) were also confirmed by their PMR and IR spectral data.

The olefin mixture (**13**, **14** and **15**) derived from the alcohol (**11**), without separation, was subjected to hydroboration and subsequent Jones' oxidation to give 1,5,5,9-tetramethyl-2-decalone (**6**) and several minor oxidation products, which were not further examined. The structure of the main product (**6**) was supported by the PMR and IR spectral data. However, an alternative structure (**16**) might be possible to explain the spectral data for **6**. The ketone (**16**) would be derived from an olefin (**17**) which might be formed by a skeletal rearrangement during dehydration of the alcohol (**11**). In order to confirm that the Jones' oxidation product possesses a decalone skeleton, it was deuterated to give the deuterated ketone (**6**-d_3), which





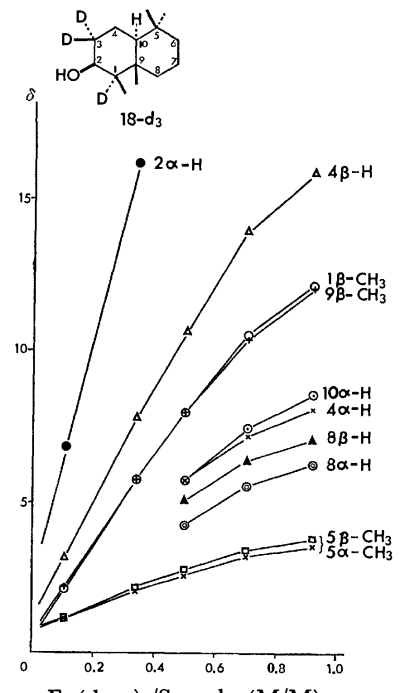


Fig. 3. Induced paramagnetic shifts for the alcohol **18**-d_3. [Eu(dpm)$_3$ was added to a 8% (w/v) soln of **18**-d_3 in CCl_4].

was converted with sodium borohydride into an alcohol (**18**-d_3). The PMR spectral measurement of **18**-d_3 using Eu(dpm)$_3$ as a shift reagent was then effected. The signals due to 4β, 4α, 10α, 8β, and 8α-hydrogens were separated distinctly (Fig. 3). A triplet (J=13 Hz) due to the 4β-hydrogen coupled with the 4α-hydrogen (geminal) and the 10α-hydrogen (trans) was observed (cf. Experimental). These results are in good accordance with those reported for friedelan-3β-ol.[5] If the alcohol had a structure **19**, which might be derived from the olefin (**17**), the signal due to 5α- and 5β-hydrogens must have been observed as an AB quartet. This was not the case in reality. Thus the structure of the decalone, obtained by Jones' oxidation was shown to be **6** except the configuration at C-1.

The induced paramagnetic shift experiments on **6** using Eu(fod)$_3$-d_{27} as a shift reagent showed a large shift for the signals due to a secondary methyl at C-1 (δ 0.89) and a tertiary methyl at C-9 (δ 0.73), while a smaller shift for the signals due to two tertiary methyls at C-5 (δ 0.88 and 0.98)(Fig. 4). These methyl signals suffer a solvent shift when the solvent was replaced from deuteriochloroform to deuteriobenzene (Table 1). A small downfield shift (Δ −0.02 ppm) observed for the C-1 methyl of **6** was parallel to the shift (Δ −0.10 ppm) observed for the 4β(equatorial)-methyl of friedelin (**1a**), while different from an appreciable upfield shift (Δ +0.25 ppm) for 4α(axial)-methyl of 4-epifriedelin (**1b**).[6] The methyl group at C-1 of **6** was thus inferred to be equatorial (1β).

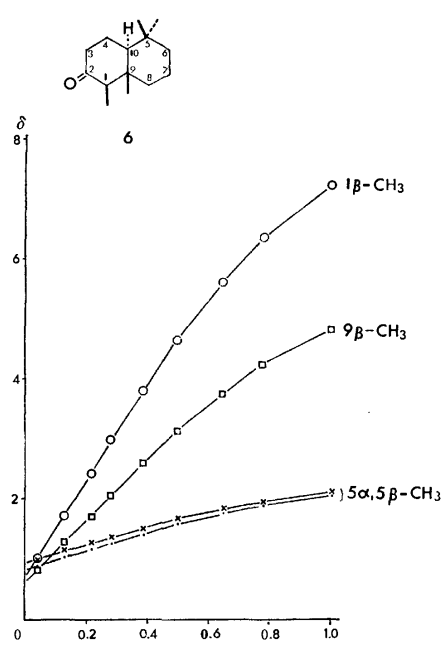

Fig. 4. Induced paramagnetic shifts for the ketone **6**. [Eu(fod)$_3$-d_{27} was added to a 5% (w/v) soln of **6** in CCl_4].

1,5,5,9-Tetramethyl-2-decalone (**6**) was irradiated in *n*-hexane with a high pressure mercury lamp under a nitrogen atmosphere at room temperature and then slow stream of oxygen was introduced into the solution in the dark. The reaction product was subjected to GC-MS examination and the formation of the seco-nor aldehyde, 2-ethyl-1-formylmethyl-2,6,6-trimethylcyclohexane [**10**; *m/e* 196 (M^+ $C_{13}H_{24}O$)] was suggested. However, a further confirmation was not furnished, because of lack of the material.

The reaction product was separated by silica gel chromatography to give an acid fraction. On treatment with diazomethane, the acid fraction was converted into the methyl esters in about 10% yield from **6**, which were found to consist of two components (**8b** and **9b**). The mixture of the esters was separated by preparative glc to give two esters. One methyl ester with lower R_f value on tlc showed a molecular ion peak at *m/e* 240 and was shown to be identical with 2-ethyl-1-(2-methoxycarbonylethyl)-2,6,6-trimethylcyclohexane (**9b**) in respect to IR, mass, glc, and tlc, which was prepared by the photochemical reaction of **6** in methanol.

The other methyl ester gave a molecular ion peak at *m/e* 226. This suggested that the ester would be a methyl ester derived from a seco-nor acid, 1-carboxymethyl-2-ethyl-2,6,6-trimethylcyclohexane (**8a**). This was confirmed by the synthesis of the seco-nor ester, 2-ethyl-1-methoxycarbonylmethyl-2,6,6-trimethylcyclohexane (**8b**) from the seco ester (**9b**) by the Barbier-Wieland degradation *via* a diphenylcarbinol (**20**) and a diphenylethylene derivative (**21**). Therefore, the structure of the original seco-nor acid was shown to be 1-carboxymethyl-2-ethyl-2,6,6-trimethylcyclohexane (**8a**). The formation mechanism of **8a** from 1,5,5,9-tetramethyl-2-decalone (**6**) could be inferred to be the same as that of the seco-nor acid (**3**) from friedelin (**1a**).[3]

Experimental

IR spectra were measured on a Hitachi EPI-G2 spectrometer. Mass spectra were taken on a Hitachi RMU-6-Tokugata mass spectrometer operating at 70 eV with an indirect inlet system unless otherwise stated. High resolution mass spectra were taken using a Hitachi RMH-2 mass spectrometer operating at 70 eV. PMR spectra were measured using a JEOL JNM PS-100 (100 MHz), a Hitachi R-20 (60 MHz) or a Hitachi R-24 (60 MHz) spectrometer. Chemical shifts were expressed in δ downfield from TMS as an internal standard and coupling constants in Hz. Gas chromatography-mass spectrometry (GC-MS) was performed on a Hitachi gas chromatograph model K-53 connected with the mass spectrometer mentioned above. Analytical gas chromatography (glc) was carried on a Shimadzu gas chromatograph model GC-4APF, and preparative gas chromatography was carried on a Hitachi gas chromatograph model K-53. Thin layer chromatography (tlc) was carried out on Kieselgel G (E. Merck) in 0.25 mm thickness. For column chromatography, Wakogel C-200 (Wako Pure Chemical Ind.) was used. All melting points were determined on a hot block and reported uncorrected. Liquid samples for elemental analyses were purified by rechromatography on silica gel.

*1-Hydroxy-1,5,5,9-tetramethyl-*trans*-decalins (**11** and **12**).* To the Grignard reagent prepared from methyl iodide (15 g) and magnesium (1 g) in dry ether (15 ml) at 0 °C was added a solution of 5,5,9-trimethyl-1-decalone (**7**[4]; 1.84 g) in dry ether (30 ml). The reaction mixture was stirred for 1.5 hr at 0 °C, then decomposed with aqueous ammonium chloride solution, and extracted with ether three times. The ethereal layer was washed with brine twice, and dried over magnesium sulfate. Evaporation of the solvent gave a residue (2.16 g), which was chromatographed on a column of silica gel (100 g) using the following solvents as eluents: light petroleum–ether (20 : 1) frs 1—4, each 150 ml; fr 5, 100 ml; frs 6—12, each 50 ml; light petroleum–ether (10 : 1) frs 13—22, each 50 ml; light petroleum–ether (5 : 1) frs 23—30, each 75 ml. Fractions 4—13 gave 1α-hydroxy-1β,5α,5β,9β-tetramethyl-*trans*-decalin (**11**; 1.26 g, 63%) as an oil, IR (liquid) 3480 cm^{-1}; PMR ($CDCl_3$) δ 0.84, 0.88, 0.97, and 1.08 (each 3H, s, t-CH_3); mass *m/e* 210 [M^+ ($C_{14}H_{26}O$); 13%] and *m/e* 81 (100%): Found: C, 79.81; H, 12.40%. Calcd for $C_{14}H_{26}O$: C, 79.93; H, 12.46%. Fractions 16—23 afforded 1β-hydroxy-1α,5α,5β,9β-tetramethyl-*trans*-decalin (**12**; 0.41 g, 20%), mp 52—53 °C (sublimation at 50 °C/1 mmHg), IR (Nujol) 3430 cm^{-1}; PMR ($CDCl_3$) δ 0.86 (6H, s, 2$\times$*t*-CH_3), 1.03, and 1.28 (each 3H, s, t-CH_3); mass *m/e* 210 [M^+ ($C_{14}H_{26}O$); 7%] and *m/e* 81 (100%); Found: C, 79.66; H, 12.23%. Calcd for $C_{14}H_{26}O$: C, 79.93; H, 12.46%.

*1,5,5,9-Tetramethyl-2-decalone (**6**).* The alcohol (**11**; 2.00 g) was heated at 140 °C and iodine (34 mg) was added at 5 min intervals over a period of 20 min. To the reaction mixture, after cooling, ether was added, and the ethereal solution was washed with aqueous sodium thiosulfate and sodium hydrogen carbonate solutions and with brine, and then dried over magnesium sulfate. On evaporation of the solvent, a residue (1.58 g) was obtained, which was shown to be a mixture of three olefins in a ratio of 61 : 8 : 31 for **13**, **14**, and **15**, respectively, by glc analysis (column: C-20M, 150 °C; N_2 65 ml/min; retention time: 10.3, 6.3, and 5.5 min for **13**, **14**, and **15**, respectively). The olefin mixture obtained from the alcohol (**12**; 295 mg) and iodine (6 mg) at 140 °C was shown to consist of **13**, **14**, and **15** in a ratio of 6 : 18 : 76 by glc analysis.

The former olefin mixture (65 mg) obtained from **11** was dissolved in light petroleum and passed through a column of silica gel (7 g) impregnated with 20% silver nitrate. Elution with light petroleum (each 20 ml) gave the olefin (**13**; 30 mg, frs 4 and 5) as an oil; IR (liquid) 1660 and 795 cm^{-1}; PMR ($CDCl_3$) δ 0.87, 0.89, 1.02 (each 3H, s, t-CH_3), 1.58 (3H, d, J=2 Hz, C=C–CH_3), and 5.18 (1H, m, C=CH); MW 192.1858, Calcd for $C_{14}H_{24}$: 192.1876; mass *m/e* 192 (M^+, 9%) and *m/e* 41 (100%).

The latter olefin mixture (280 mg), obtained from the alcohol (**12**), was dissolved in chloroform (5.5 ml). After *p*-toluenesulfonic acid (51 mg) was added, the resulting solution was allowed to stand at 60 °C for 4hr. Extraction with ether and usual treatment gave an oil, which was shown to be a mixture of **14** and **15** in a ratio of 1 : 4 by glc analysis. The mixture was chromatographed on a column of silica gel (22 g) impregnated with 20% silver nitrate. Elution with light petroleum (each 10 ml) afforded the olefin (**15**; 137 mg, from frs 1 and 2) as an oil; IR (liquid) neither absorption band due to C=C–H nor C=C was observed. PMR ($CDCl_3$) δ 0.97 (12H, s, 4$\times$*t*-CH_3); mass *m/e* 192 [M^+($C_{14}H_{24}$); 15%] and *m/e* 177 (100%). From the fractions 4—6, the olefin (**14**, 7 mg) was obtained as an oil; IR (liquid 3050 and 1635 cm^{-1}; PMR ($CDCl_3$) δ 0.81, 0.88, 1.01, and 1.05 (each 3H, s, *t*-CH_3) and 5.45 (1H, m, C=C–H); mass *m/e* 192 [M^+ ($C_{14}H_{24}$), 13%], *m/e* 136 (39%, a peak due to retro-Diels Alder fragmentation), and *m/e* 55 (100%).

Treatment of each olefin (**14** and **15**) in chloroform with *p*-toluenesulfonic acid as described above gave an oil, which was shown to consist of **14** and **15** in a ratio of 1 : 4 by glc analysis.

To the crude olefin mixture (**13**, **14**, and **15**; 1.49 g; obtained by the dehydration reaction of **11**) in tetrahydrofuran (20 ml) was added a tetrahydrofuran solution (20 ml) of diborane prepared from boron trifluoride etherate (15 g) and sodium borohydride (2 g). The mixture was kept at room temperature for 70 min and the excess diborane was decomposed by addition of water (1.8 ml). The organoborane solution, kept at 40 °C, was oxidized with 3M sodium hydroxide (3 ml) and 30% hydrogen peroxide (3 ml). After the reaction mixture was kept at room temperature for 1 hr, potassium carbonate (9 g) and water were added. Extraction with ether and usual work-up afforded a residue (1.77 g).

The crude alcohol, obtained above, was dissolved in acetone (20 ml) and oxidized with Jones' reagent (2 ml) at 0 °C. The reaction mixture was stirred for 40 min and then diluted with brine (40 ml). Extraction with ether and usual work-up gave a residue (1.57 g), which was subjected to column chromatographic separation on silica gel (200 g) and eluted with light petroleum–ether (20 : 1, each 60 ml). On removal of the solvents (frs 6—12), 1,5,5,9-tetramethyl-2-decalone (**6**; 838 mg, one spot on tlc) was obtained in 45% yield from **11**. Mp 55—56 °C (from light petroleum), IR (Nujol) 1715 cm^{-1}; PMR ($CDCl_3$) δ 0.73, 0.88, 0.98 (each 3H, s, *t*-CH_3), and 0.89 (3H, d, J=7 Hz, *s*-CH_3); mass *m/e* 208 [M^+($C_{14}H_{24}O$), 5%] and *m/e* 41 (100%); Found: C, 80.41; H, 11.51%. Calcd for $C_{14}H_{24}O$: C, 80.71; H, 11.61%. 2,4-Dinitrophenylhydrazone (crystallized from ethanol): mp 159—160 °C, Found: C, 61.60; H, 7.26; N, 14.27%. Calcd for $C_{20}H_{28}N_4O_4$: C, 61.84; H, 7.27; N, 14.42%.

*1,3,3-Trideuterio-1,5,5,9-tetramethyl-2-decalone (**6**-d_3).* 1,5,5,9-Tetramethyl-2-decalone (**6**; 46 mg) in tetradeuteriomethanol (1 ml) was allowed to stand with 2 drops of 30% sodium deuterioxide (isotopic purity: 99 atom % D) in deuterioxide. Diluted hydrochloric acid was added and the mixture was extracted with ether three times, washed with aqueous sodium hydrogen carbonate solution and with brine, and dried over magnesium sulfate. After evaporation of the

solvent, a residue (38 mg), without further purification, was subjected to mass spectrometric analysis with a direct inlet system operating at 70 eV. The deuterated decalone (**6**-d_3) was shown to consist of -d_3 (71%), -d_2 (25%), and -d_1 (4%). IR (liquid) 1715 cm^{-1}; PMR (CCl_4) δ 0.71, 0.82, 0.89, and 0.98 (each 3H, s, t-CH_3).

*1,3,3-Trideuterio-2β-hydroxy-1,5,5,9-tetramethyldecalin (**18**-d_3).* The above-obtained decalone-d_3 (**6**-d_3; 26 mg) was dissolved in methanol (0.5 ml), cooled with ice-salt, and reduced with sodium borohydride (10 mg). After the solution was maintained at 0 °C for 30 min, acetic acid (2 drops) was added. The reaction mixture was extracted with ether, washed with aqueous sodium hydrogen carbonate solution and with brine, and dried over magnesium sulfate. Evaporation of the solvent gave a residue (32 mg), which was chromatographed on a column of silica gel (3 g) and eluted with light petroleum–ether (20 : 1) to afford 1,3,3-trideuterio-2β-hydroxy-1,5,5,9-tetramethyldecalin (**18**-d_3; 21 mg), IR (Nujol) 3360 cm^{-1}; PMR spectral data using Eu(dpm)$_3$ was shown in Fig. 3. Signals due to a proton at C-4β appeared at δ 16.00 as a triplet ($J_{4\alpha,4\beta}=13$ and $J_{4\beta,10\alpha}=13$ Hz) [Eu(dpm)$_3$/**18**-d_3 (M/M): 0.92].

*Photochemical Reaction of 1,5,5,9-Tetramethyl-2-decalone (**6**) in n-Hexane Followed by Introduction of Oxygen in the Dark.* A solution of 1,5,5,9-tetramethyl-2-decalone (**6**; 185 mg) in *n*-hexane (650 ml) was irradiated with a high pressure mercury lamp (100 W, Rikosha) under a nitrogen atmosphere for 11 hr at room temperature. After the irradiation, dry oxygen was passed through the solution for 6 hr in the dark. On evaporation of the solvent, a residue (199 mg) was obtained, which was examined by GC-MS and the formation of 2-ethyl-1-formylmethyl-2,6,6-trimethylcyclohexane (**10**) was inferred [column: OV-17, 150 °C, He 0.8 kg/cm^2; retention time 4.2 min; mass *m/e* 196 (M^+($C_{13}H_{24}O$), 6%) and *m/e* 69 (100%)].

The reaction mixture was chromatographed on silica gel (20 g). After the starting ketone (**6**) was eluted with light petroleum–ether (20 : 1), elution with ether afforded an acid fraction (62 mg), which was treated with diazomethane to give a mixture (20 mg) of methyl esters (**8b** and **9b**; 20% silver nitrate-impregnated silica gel tlc showed two spots, R_f 0.42 and 0.38 for **8b** and **9b**, respectively). The mixture was separated by preparative glc (column: OV-17, 140 °C, N_2 1 kg/cm^2, retention time 3.8 min and 7.7 min for **8b** and **9b**, respectively).

The methyl ester (**8b**), an oil, showed IR (liquid) 1745 cm^{-1}; mass *m/e* 226 [M^+($C_{14}H_{26}O_2$), 2%] and *m/e* 69 (100%). IR, tlc, glc, and mass of this substance were identical with those of the authentic specimen prepared from **9b** by the Barbier-Wieland degradation (*vide infra*).

The other methyl ester (**9b**), an oil, showed IR (liquid) 1745 cm^{-1}; mass *m/e* 240 [M^+($C_{15}H_{28}O_2$), 1%] and *m/e* 69 (100%). This substance was identified to be 2-ethyl-1-(2-methoxycarbonylethyl)-2,6,6-trimethylcyclohexane by comparison (IR, tlc, glc, and mass) with the authentic sample prepared by photoreaction of **6** in methanol (*vide infra*).

*2-Ethyl-1-(2-methoxycarbonylethyl)-2,6,6-trimethylcyclohexane (**9b**).* 1,5,5,9-Tetramethyl-2-decalone (**6**; 201 mg) in methanol (750 ml) was irradiated with a high pressure mercury lamp 100 W, Rikosha) under nitrogen for 20 hr. After evaporation of the solvent, the residue (254 mg) was chromatographed on silica gel (20 g). Elution with light petroleum–benzene (100 : 1) and removal of the solvents afforded the methyl ester (**9b**; 179 mg, 77%) as an oil, IR (liquid) 1745 cm^{-1}; PMR ($CDCl_3$) δ 0.82, 0.88, 0.90 (each 3H, s, t-CH_3), 2.20—2.53 (2H, m, $CH_2CO_2CH_3$), and 3.65 (3H, s, CO_2CH_3); mass *m/e* 240 [M^+($C_{15}H_{28}O_2$), 1%] and *m/e* 69 (100%); Found: C, 74.83; H, 11.96%. Calcd for $C_{15}H_{28}O_2$: C, 74.95; H, 11.74%.

*2-Ethyl-1-methoxycarbonylmethyl-2,6,6-trimethylcyclohexane (**8b**).* To the methyl ester (**9b**; 150 mg) dissolved in tetrahydrofuran (20 ml) was added bromobenzene (950 mg) and magnesium (150 mg), and the reaction mixture was heated under reflux for 2.5 hr. After usual treatment, the residue (660 mg) was chromatographed on silica gel (20 g) and elution with light petroleum–ether (50 : 1) gave a diphenylcarbinol (**20**; 222 mg, 98%), as an oil. IR (liquid) 3600, 3550, and 3460 cm^{-1}; PMR ($CDCl_3$) δ 0.70, 0.78, and 0.80 (each 3H, s, t-CH_3); mass *m/e* 346 [$(M-H_2O)^+$; 8%] *m/e* 71 (100%); Found: C, 86.15; H, 9.71%. Calcd for $C_{26}H_{36}O$: C, 85.66; H, 9.95%.

The diphenylcarbinol (**20**; 200 mg) in benzene (3 ml) was refluxed with iodine (9 mg) for 4 hr. To the reaction mixture aqueous sodium thiosulfate solution was added. Extraction with ether and usual work-up afforded a residue (210 mg), which was passed through a column of silica gel (10 g) and eluted with light petroleum. A diphenylethylene derivative (**21**; 170 mg, 90% from **20**), as an oil, was obtained, IR (liquid) 1660 cm^{-1}; PMR ($CDCl_3$) δ 0.68, 0.76, 0.88 (each 3H, s, t-CH_3), 2.00—2.37 (2H, m, -CH_2-CH=C), and 6.07 (1H, t, $J=7$ Hz, CH=C); mass *m/e* 346 [M^+ ($C_{26}H_{34}$), 5%] and *m/e* 71 (100%); Found: C, 90.33; H, 9.99%. Calcd for $C_{26}H_{34}$: C, 90.11; H, 9.89%.

The diphenylethylene derivative (**21**; 138 mg) in acetic acid (10 ml) was oxidized with chromium trioxide (0.4 g) in acetic acid (6 ml) and water (0.3 ml) at room temperature for 69 hr. The excess oxidizing reagent was destroyed by addition of methanol, and usual treatment gave a residue (183 mg), which was dissolved in ether and allowed to stand with diazomethane in ether. After evaporation of the solvent, the residue (196 mg) was subjected to separation by silica gel (20 g) column chromatography. Elution with light petroleum–ether (100 : 1) gave the methyl ester (**8b**; 68 mg, 75% from **21**), an oil, IR (liquid) 1745 cm^{-1}; PMR ($CDZl_3$) δ 0.81, 0.84, 0.90 (each 3H, s, t-CH_3), 2.25 (2H, d, $J=5$ Hz, $CH_2CO_2CH_3$), and 3.64 (3H, s, CO_2CH_3); MW 226.1920, Calcd for $C_{14}H_{26}O_2$: 226.1930; mass *m/e* 226 [M^+($C_{14}H_{26}O_2$), 1%] and *m/e* 69 (100%).

ESR Study on Molecular Motion of CO_2^- Radical Adsorbed on Zeolite

Ove EDLUND,† Junkichi SOHMA, and Kunihisa SOGABE*

College of Engineering, Hokkaido University, Sapporo 060

* *College of Science, Hiroshima University, Hiroshima 730*

(Received December, 17, 1973)

Synopsis. Molecular motion of $^{13}CO_2^-$ radical adsorbed on zeolite was quantitatively analysed from the temperature variation of the separation of hyperfine structure of ESR spectra from $^{13}CO_2^-$ radicals.

CO_2 molecules enriched with ^{13}C were adsorbed on a Linde X-type zeolite, which had been heat-treated at 500 °C for 5 hr. Free radicals were produced from the adsorbed CO_2 by γ irradiation. ESR spectra of these systems were reported by one of the authors (K.S.) and his collaborators.[1] They found that the spectra change with temperature. In the ESR spectra consisting of three bands, the central part is the spectrum originated from the $^{12}CO_2^-$ radical and the wings are the doublet ascribed to the ^{13}C ($I=1/2$) coupling of $^{13}CO_2^-$ radical. The wings of the spectrum observed at 77 K show the so-called amorphous pattern,[2] the characteristic line-shape for an anisotropic hyperfine (hf) coupling of radicals trapped in an amorphous matrix. This pattern can be simulated by the program of Lefebvre and Maruani.[3] The principal value of the hf coupling tensor giving the best fit pattern to the observed one at 77 K were obtained as $A_x=150.0$ G, $A_y=156.0$ G, $A_z=197.5$ G. The principal values of the hf coupling tensors of the spectra observed at temperatures 180, 190, and 200 K were determined in a similar way and are listed with other ESR parameters in Table 1.

TABLE 1. THE PRINCIPAL VALUES OF THE g-TENSOR AND THE A-TENSOR, AND THE LINE WIDTH $\Delta H_{1/2}$, WHICH GIVE THE BEST FIT TO THE OBSERVED LINE-SHAPE, AND THE CORRELATION TIMES τ

Temp.	g-tensor		A-tensor (G)		ΔH (G)	$\tau\times10^8$ (s)
77 K	g_x	1.9975	A_x	150.0	5.5	
	g_y	2.0032	A_y	156.0		
	g_z	2.0015	A_z	197.5		
180 K	g_x	1.99998	A_x	154.1		
	g_y	2.00155	A_y	158.7	7.0	4.29
	g_z	2.00073	A_z	190.7		
190 K	g_x	2.00073	A_x	157.5		
	g_y	2.00073	A_y	161.0	7.0	2.09
	g_z	2.00073	A_z	185.0		
200 K	g_x	2.00073	A_x	160.0		
	g_y	2.00073	A_y	162.6	7.0	1.34
	g_z	2.00073	A_z	180.9		

ESR spectra of free radicals produced from adsorbed CO_2 are shown in Fig. 1. The shapes of the wings of the spectra become more isotropic with increasing temperature. At 77 K the CO_2^- radicals are almost completely frozen, the anisotropy of the coupling tensor being clearly observed. At 200 K no shoulder appears in the wing peaks and the doublet appears nearly symmetrical. The symmetric pattern indicates that the anisotropy of the hf coupling tensor is almost averaged out by the random motion of the adsorbed radicals at such a high temperature. The results indicate that the radicals adsorbed on the zeolite become more mobile at higher temperatures. In the process from the frozen state to the mobile one, *i.e.* in the temperature range 77—200 K, the anisotropy of the coupling tensor is partially averaged due to the gradually activated molecular motion of the radical. We can obtain quantitative information on the molecular motion of the adsorbed radical from the observed partial averaging of the anisotropic hf coupling tensor, based on the theory developed by Moriuchi and Sohma.[4] According to their theory partial averaging of each principal value of the hf coupling tensor is given by

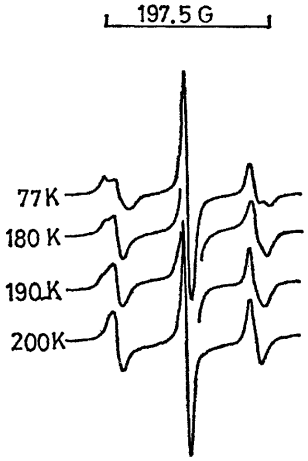

Fig. 1. Temperature variation of observed spectra of the CO_2^- radicals adsorbed on zeolite. The separation of the outermost peaks, 197.5 G, at 77 K, corresponds to the A_z principal values of the hyperfine coupling tensor.

$$\langle A_x\rangle_{Av} = a + A_{xo}\frac{2}{\pi}\tan^{-1}\frac{\tau}{T_2'}$$

$$\langle A_y\rangle_{Av} = a + A_{yo}\frac{2}{\pi}\tan^{-1}\frac{\tau}{T_2}$$

$$\langle A_z\rangle_{Av} = a + A_{zo}\frac{2}{\pi}\tan^{-1}\frac{\tau}{T_2'}$$

where a is the isotropic component of the coupling constant, A_x, A_y and A_z are the principal values of the

† On leave from Swedish Research Council's Laboratory, Studsvik, Nyköping, Sweden.

hf coupling tensor, and A_{xo}, A_{yo} and A_{zo} the anisotropic components of each principal value in the completely frozen state; τ is the correlation time of the molecular motion and T_2' is related to the inverse of the experimentally determined line width, that is $T_2'=1/\pi\cdot\Delta H_{1/2}$ in Lorentzian line-shape, $T_2'=(\ln 2/\pi)^{1/2}\,1/\Delta H_{1/2}$ in the Gaussain one. Experimentally determined principal values of the hf coupling tensor at each temperature result from partial averaging of the anisotropic hf coupling tensor due to the molecular motion of the responsible radical, $^{13}CO_2^-$ in this case, at this temperature. The isotropic coupling constant a was experimentally obtained by the equation $a=1/3(A_x+A_y+A_z)$ and the observed values of each component at 77 K, since one can assume that molecular motion at 77 K is completely frozen. T_2''s are determined from the line widths, experimentally determined by simulation with the observed spectrum at each temperature. The results are listed in Table 1. Since the peak corresponding to A_z appears most clearly in the doublet and changes distinctly with temperature, we used the observed value of the A_z-component at each temperature in order to estimate τ at this temperature. The correlation times are plotted against $1/T$ in Fig. 2. The activation energy for this molecular motion of the adsorbed CO_2^- radical on the zeolite was determined to be 4.1 kcal/mol.

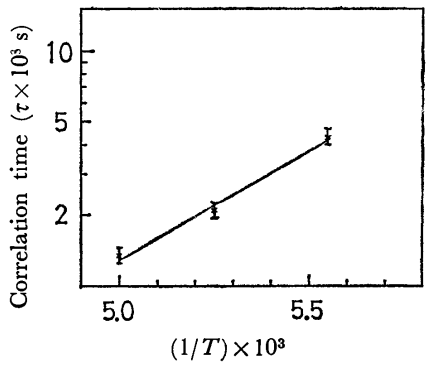

Fig. 2. The Arrhenius plot of the correlation times estimated from the partial averaging of the A_z component.

The observed ESR spectra and their analysis give us quantitative information on the molecular motion of the adsorbed CO_2^- radicals on the zeolite. The molecular motion of the adsorbed CO_2^- is completely hindered at 77 K but liberated gradually from 180 K until free random motion is attained at 200 K.

The authors thank Dr. A. Hasegawa, Hiroshima University, for his valuable discussion. One of the authors (O.E.) wishes to express his sincere thanks to the Japan Society for Promotion of Science for the fellowship which enabled him to work at Hokkaido University.

Ionic Equilibria in Micellar Solutions

Keishiro SHIRAHAMA

Department of Chemistry, Faculty of Science and Engineering, Saga University, Honjo-machi, Saga 840

(Received March 30, 1974)

Synopsis. Ionic equilibria in micellar solutions are discussed on the basis of micelle-monomer equilibrium, mass-conservation, and electroneutrality. The present treatment gives a larger degree of counterion dissociation from micelles than ever estimated. Another conclusion is a decreasing concentration of monomeric surface-active ion as micellar concentration increases.

Since Botré *et al.* firstly applied the membrane potential measurement to elucidate a degree of dissociation of counterion from micelles,[1] many investigators have followed the same kind of trials by using either ion-exchange membrane or pNa glass electrode.[2-5] As a starting point of discussion, Eq. (1) has been assumed,

$$a = \gamma(C_0 + \alpha n C_m) \quad (1)$$

where a is the activity of counterion, γ activity coefficient, α a degree of counterion dissociation from micelle, n aggregation number of a micelle and C_m a micellar concentration. This expression is based on "*formal separation*"[1] of counterions originated from micelles and those from free surfactant ions. However no one can make this distinguishment *a priori*.

Alternatively, we express, as an approximation, the pseudo-phase model for a 1 : 1 type ionic surfactant forming a micellar solution in the absence of extraneous electrolyte,

$$C_c C_s f_\pm^2 = (C_0 f_0)^2 \quad (2)$$

where f_0 and $f_\pm$ are the activity coefficients of surfactant at cmc and at any arbitrary concentration above cmc, C_c and C_s are the concentrations of, respectively, counterion and surface-active ion in equilibrium with micelles. Eq. (2) is considered to hold to a good approximation, even when a more general mass action law model is taken into account. Furthermore one obtains Eq. (3) as a consequence of mass balance,

$$C = C_s + nC_m \quad (3)$$

where C is the total (analytical) concentration of the surfactant. Electroneutrality also requires the following relation.

$$C_c = C_s + \alpha n C_m \quad (4)$$

Combing Eq. (3) with Eq. (4), one has

$$C_c = C_s + \alpha(C - C_s) \quad (5)$$

or introducing Eq. (2), one obtains

$$C_c = (C_0^2/C_c)(f_0/f_\pm)^2 + \alpha[C - (C_0^2/C_c)(f_0/f_\pm)^2] \quad (6)$$

Note that Eq. (1) can be reproduced only if C_s is replaced by C_0, or at the limit $C \to C_0$.

Rearrangement of Eq. (6) gives

$$C_c - (C_0^2/C_c)(f_0/f_\pm)^2 = \alpha[C - (C_0^2/C_c)(f_0/f_\pm)^2] \quad (7)$$

With the knowledge of C, C_c and the activity coefficients, α can be calculated. In order to do so, the potentiometry of micellar solution is very useful. Such potentiometry is schematically shown in Fig. 1, where an electronic potential, E motivated from the counterion activity is plotted against log C. Tracing $C \to B \to A \to C_c$, one obtains C_c at a total concentration C. It is rather difficult to estimate the ratio of the activity coefficients in micellar solution. In the present treatment as well as any other theories using a parameter α, all the effects arising from micelles are included in the parameter, and the coexisting coions and counterions (unbound) are considered to behave as if they were in a solution of the same concentration. This idea is identical with so-called additivity rule well accepted in the field of polyelectrolyte solutions.[6] Therefore we

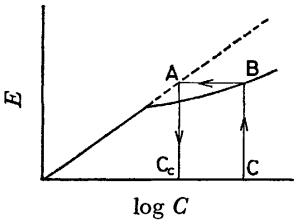

Fig. 1. A schematic representation of potential E *vs.* log C profile.

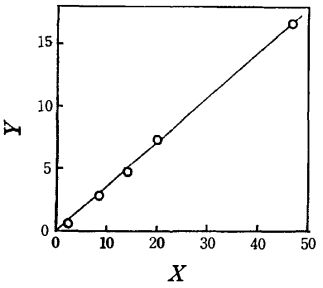

Fig. 2. Y *vs.* X plot. See the text for detail. The original data are already published by us.[5]

TABLE 1. THE DEGREE OF COUNTERION DISSOCIATION OF SODIUM DODECYLSULFATE

Author		Degree of dissociation α previous	Degree of dissociation α present	Ref.
Botré *et al.*	(1959)	0.16		1
Shedlovsky *et al.*	(1963)	0.22	0.32	2
Satake *et al.*	(1969)	0.25	0.40	4
Shirahama	(1972)	0.29	0.36	5
Birch and Clarke	(1972)	0.25	0.30[a]	13

a) They calculated the value of α on the basis of mass-action law, which also predicts a decrease of surface-active ion above cmc, as in the present treatment.

set $(f_0/f_\pm) \fallingdotseq 1$. In Fig. 2 $Y=C_c-(C_0^2/C_c)$ is plotted against $X=C-(C_0^2/C_c)$ for sodium dodecylsulfate. As is seen, a linear relation with the slope α is obtained. The published data are recalculated for sodium dodecylsulfate and shown in Table 1, from which it is clear that, in any case, the value of α is larger than those ever estimated by the assumption of Botre *et al.*, or Eq. (1). Another conclusion obtainable from Eq. (2) and an increasing counterion concentration even above cmc (experimental facts) is that the concentration of monomeric surface-active ion in equilibrium with micelles is decreasing as the total concentration increases. The same results have been derived in a little different manner in the works of Elworthy *et al*,[7] and of Birch and Clarke.[13] It is misleading that the monomer concentration in equilibrium with micelles is constant. Thus, the studies based on the incorrect assumption, such as conductivity,[8] surfactant-polymer interaction,[9] calorimetry,[10] solubilization,[11] and nmr[12] are required to be re-investigated.

The author thanks Prof. M. Tanaka of Fukuoka University and Mr. K. Tsujii of Kao Soap Co., Ltd. for their interest and discussion on the present topics.

Dissociative Electron Attachment to (Chloroethyl)benzenes in γ-Irradiated Organic Glassy Matrices

Takayuki SAITO and Hiroshi YOSHIDA
Faculty of Engineering, Hokkaido University, Kita-ku, Sapporo 060

(Received May 17, 1974)

Synopsis. Free radicals formed from (1- and 2-chloroethyl)benzene in γ-irradiated organic matrices were studied with a fluroescence spectrophotometer. The observed spectra suggest the transformation of phenetyl radical primarily formed from (2-chloroethyl)benzene to α-methylbenzyl radical and indicate interaction between the α-methylbenzyl radical, formed from both (1- and 2-chloroethyl)benzene, and chloride anion before complete dissociation.

There is a current interest in radiation chemistry in condensed media in studies of the relaxation process[1] before the formation of thermodynamically stable intermediates such as trapped electrons and anions. Recently, we have studied the formation of benzyl radical from benzyl derivatives and obtained spectroscopic evidence that the benzyl associates temporarily with fragment anion when formed through dissociative electron attachment in organic glassy matrices.[2]
In order to see the generality of this behavior, the study was extended to (1- and 2- chloroethyl)benzene by means of a fluorescence spectrophotometric method. The method has great advantages in studying intermediates formed in γ-irradiated matrices on account of its high sensitivity, applicability to non-transparent specimens and the possibility to distinguish a spectrum from other overlapping ones. Prominent results are: (1) a temporary association is evidenced also between α-methylbenzyl radical and chloride anion and (2) phenetyl radical transforms readily to α-methylbenzyl radical in the matrices at 77 K.

3-Methylhexane was used as non-polar solvent after being purified several times by washing with a sulfuric acid–nitric acid mixture and then with water and drying with anhydrous calcium chloride and calcium hydride. Ethanol of spectro-grade was used without further purification as a polar solvent. Solutes of analytical grade, ethylbenzene, (1-chloroethyl)benzene and (2-chloroethyl)benzene, were used without further purification. The effect of purification was checked once for 2-chloroethylbenzene, no difference in results being found.

Solution of 10^{-1}—10^{-2} M concentration was prepared in a vacuum of about 10^{-6} Torr, for desired combination of solvent and solute, and sealed in tubes of pure quartz (originally for ESR). The samples were frozen into glassy state, irradiated with ^{60}Co γ-rays to a dose of about 3×10^{5} rad or with UV light from a high pressure mercury lamp, and examined with a recording fluorescence spectrophotometer (Hitachi, Model MPS-2A) at 77 K.

Typical examples of emission and excitation spectra of α-methylbenzyl radicals generated in different ways are given in Fig. 1. The emission spectra are observed in visible region with a 0-0 band at about 470 nm. Excitation spectra are observed in visible, near-UV (at about 320 nm) and far-UV (at about 270 nm) regions. However, spectral lines of excitation source (Xe lamp) interfered accurate recording of the weak visible excitation spectra. The emission spectra were recorded by excitation at the peak of the near-UV excitation spectra, though the shape of the emission spectra was not affected by the excitation wavelength. The near-UV and far-UV spectra were recorded by observation at the maximum point of the emission spectra. Characteristics of the recorded spectra are summarized in Table 1.

Ethylbenzene. Free radicals generated from ethylbenzene were studied for comparison. The spectra obtained by photolysis in the non-polar matrix (Fig. 1A) are close to those of photolytically generated benzyl radicals,[2] except that the strong 0-0 band in the emission spectrum indicates a partial removal of the forbidden nature of this band by methyl substitution, and thus they are attributed to the α-methylbenzyl radical. Porter and Starachen reported the absorption spectrum in the near-UV region (maximum at 322.2 nm) of the α-methylbenzyl radical formed by the photolysis of ethylbenzene in ether–isopentane–ethanol mixed glass.[3] The present spectra are consistent with theirs.

The γ-irradiation gives the same spectra as those in Fig. 1A, irrespective of solvent (Table 1). This in-

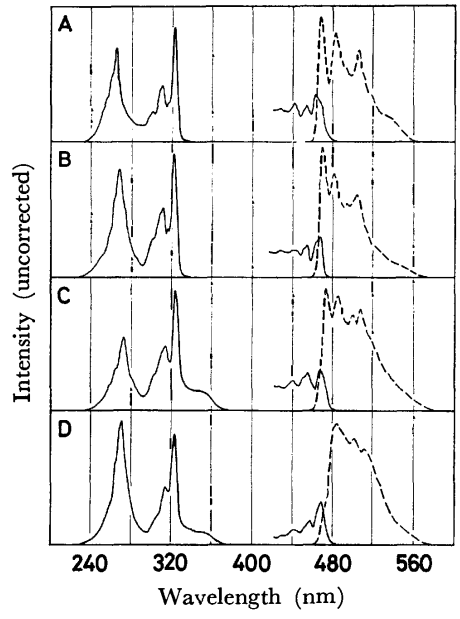

Fig. 1. Emission (——) and excitation (——) spectra of α-methylbenzyl radicals generated (A) from ethylbenzene by photolysis in 3-methylhexane, from (1-chloroethyl)benzene by γ-irradiation (B) in ethanol and (C) in 3-methylhexane, and (D) from (2-chloroethyl)benzene by γ-irradiation in 3-methylhexane.

TABLE 1. EXCITATION AND EMISSION SPECTRA OBSERVED AT 77 K OF α-METHYLBENZYL RADICALS GENERATED PHOTOLYTICALLY OR RADIOLYTICALLY IN ORGANIC GLASSY MATRICES

Parent molecules	Matrices	Generation method	Excitation spectra		Emission spectra
			Near-UV band λ_{max} (nm)	350 nm band	λ_{max} (nm)
$C_6H_5CH_2CH_3$	3MHx[a]	Photolysis	322	—	467.5

dicates the formation of α-methylbenzyl radicals also by radiolysis. Although radiation chemical processes involved are not known in detail, it is unconceivable that the methylbenzyl radical is formed through the electron attachment to ethylbenzene. A hydrogen atom or some other radical might be formed as a counterpart of the methylbenzyl radical by the homolytic C–H bond rapture. Radical formation may be possible by energy transfer from solvent to solute.[4] An alternative may be charge neutralization between ethylbenzene cation and electron to form excited ethylbenzene, as proposed for the formation of benzyl radical from toluene in aqueous solution.[5]

(1-Chloroethyl)benzene. When α-methylbenzyl radicals are generated from (1-chloroethyl)benzene by γ-irradiation, the spectra differ depending on the nature of matrices, polar or non-polar. The spectra in the polar matrix are the same as those of normal methylbenzyl radicals (compare Fig. 1B with Fig. 1A), whereas the spectra in the non-polar matrix (Fig. 1C) differ in the following way. (1) The visible emission and near-UV excitation spectra are more or less red-shifted. Although the band structure in the far-UV spectrum is not resolved, its peak also red-shifts from 267.5 to 272.5 nm. (2) The band width of the spectra becomes broader in the non-polar matrix, as seen clearly in the visible emission spectra. (3) A new broad excitation spectrum is observed around 350 nm. These observations are completely analogous to those for benzyl radicals formed from benzyl chloride.[2] The methylbenzyl radical is generated with chloride anion as a counterpart through dissociative electron attachment to (1-chloroethyl)benzene. The first two observations are qualitatively interpreted to be due to the local Coulombic effect of nearby anion, as in the case of radical cation spectra perturbed by counter anions.[6] The effect of the counter anion is dominant in the non-polar matrix but almost absent in the polar matrix because of the solvent polarization and anion solvation. According to the assignment of electronic transitions given to benzyl-type radicals,[7] the new spectrum may possibly be due to the $2^2B_2 \rightarrow 1^2B_2$ transition, hidden by the intense near-UV spectrum of the $2^2A_2 \rightarrow 1^2B_2$ transition in the absence of the effect of nearby anion.[2] The association between the α-methylbenzyl radical and the anion temporarily occurs after the dissociative electron attachment to (1-chloroethyl)benzene in the glassy matrix. The efficiency of methylbenzyl radical formation by photolysis is too low to record spectra.

(2-Chloroethyl)benzene. The dissociative electron attachment to (2-chloroethyl)benzene results in the formation of phenethyl radical as a primary intermediate. However, the spectra observed after γ-irradiation indicate that α-methylbenzyl radicals are trapped in the irradiated matrices. The phenethyl radical is unstable even in rigid matrices and readily transforms to the methylbenzyl radical, $\dot{C}_6H_5CH_2CH_2 \rightarrow C_6H_5\dot{C}HCH_3$. In this case also, the methylbenzyl radicals formed by γ-irradiation show spectra dependent on the polarity of the matrix. In the polar matrix, the spectra are the same as those of the "free" methylbenzyl radical (Fig. 1B). In the non-polar matrix, the effect of a nearby anion is seen in the excitation spectra (Fig. 1D). Although the 0-0 band of the emission spectrum is not resolved in this case, it is evident that the spectrum is also red-shifted and the band width is extremely large.

When (2-chloroethyl)benzene is photolyzed, the counterpart of the methylbenzyl radical is necessarily a chlorine atom rather than a chloride anion. In fact, photolysis in the non-polar matrix gives spectra typical of the "free" methylbenzyl radical (Table 1). This observation strongly supports the view that the perturbed spectra of the α-methylbenzyl radical formed by dissociative electron attachment are attributed to the temporary radical-anion pair before complete dissociation.

On the Additivity of π-Bond Energies in Linear Polyenes

Jun-ichi AIHARA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received May 24, 1974)

Synopsis. The additivity of π-bond energies in linear polyenes was confirmed by taking nonaromatic [infinity]-annulene and -polyene as reference compounds. The π-bond energies determined by Hess and Schaad were found to be oriented to polyenes of a medium size.

Dewar and his collaborators, using the LCAO–SCF–MO method, have found that the bond energies of acyclic polyenes are additive.[1,2] One can readily calculate the total energy of any acyclic polyene merely by summing the energies of all its bonds. Figeys applied the LCAO–BETA method to the calculation of the total energies of linear polyenes[3] and indicated that linear polyene can be represented in terms of localized single and double C–C bonds, in agreement with their finding.

In 1971, Hess and Schaad found that a similar treatment of the HMO π-energies allows the calculation of π-bond energies in a much simpler way.[4] They classified the single and double C–C bonds further into eight types according to the number of attached hydrogen atoms; they determined the corresponding eight π-bond energies, which are listed in Table 1.

TABLE 1. HMO π-BOND ENERGIES OF CARBON-CARBON BONDS OF ACYCLIC POLYENES CALCULATED BY HESS AND SCHAAD[4]

Designation	Type of bond	Calculated π-bond energy (β)
E_{23}	$H_2C{=}CH$	2.0000
E_{22}	$HC{=}CH$	2.0699
E_{22}'	$H_2C{=}C$	2.0000
E_{21}	$HC{=}C$	2.1083
E_{20}	$C{=}C$	2.1716
E_{12}	HC–CH	0.4660
E_{11}	HC–C	0.4362
E_{10}	C–C	0.4358

The total π-energy of any acyclic polyene was then found to be very accurately calculated with these π-bond energies in an additive manner. This means that the π-bonds in polyene are quite localized at the conventionally-written double bonds. In this connection, we reexamined the additivity of π-bond energies of linear polyenes within the framework of the HMO theory, and without any additional assumptions.

Results and Discussion

The total HMO π-energy (E_{HMO}) of linear polyene is calculated from the following simple expression:[5]

$$E_{\mathrm{HMO}}([\mathrm{N}]\text{-polyene}) = 2\,\mathrm{cosec}\frac{\pi}{2\mathrm{N}+2} - 2. \tag{1}$$

Similarly, the total HMO π-energy of annulene is evaluated using the following expression:[5]

$$E_{\mathrm{HMO}}([\mathrm{N}]\text{-annulene}) = \begin{cases} 4\,\mathrm{cosec}\dfrac{\pi}{\mathrm{N}} & \text{for } [4n+2]\text{-annulene} \\ 4\cot\dfrac{\pi}{\mathrm{N}} & \text{for } [4n]\text{-annulene.} \end{cases} \tag{2}$$

In the above expressions, N is the number of carbon atoms in linear polyene (1) or annulene (2). The energies obtained from the expressions (1) and (2) are given in units of β.

It is generally accepted that, as the ring of annulene becomes very large, the $(4n+2)$ π rule on aromaticity no longer operates, and the annulene is considered to be a nonaromatic cyclic polyene.[6] Assuming that the π-bond energies are additive, [infinity]-annulene can be employed as one of the reference compounds in determining the π-bond energies. When N is large enough, the total π-energy of [N]-annulene can be expressed with the use of Hess and Schaad's notation (See Table 1) as:

$$E_{\mathrm{HMO}}([\mathrm{N}]\text{-annulene}) \sim \frac{\mathrm{N}}{2}(E_{22}+E_{12}). \tag{3}$$

Therefore, the π-bond energy of the unit structure in annulene, which is a combination of CH=CH and CH–CH bonds, is estimated at the nonaromatic limit as:

$$E_{22}+E_{12} = \lim_{\mathrm{N}\to\infty}\frac{E_{\mathrm{HMO}}([\mathrm{N}]\text{-annulene})}{\left(\frac{\mathrm{N}}{2}\right)} = \frac{8}{\pi} = 2.5464791\cdots\cdots . \tag{4}$$

The same quantity can be derived from the following expression concerning linear polyenes:

$$E_{22}+E_{12} = \lim_{\mathrm{N}\to\infty}\{E_{\mathrm{HMO}}([\mathrm{N}+2]\text{-polyene}) - E_{\mathrm{HMO}}([\mathrm{N}]\text{-polyene})\} = \frac{8}{\pi} \tag{5}$$

The coincidence between the above two values supports strongly the absence of aromaticity in large annulene, as was expected.[6] In this sense, Hess and Schaad's estimate of the limiting REPE (resonance energy per π-electron) of annulene at 0.0053β appears to be unlikely.[7]

On the other hand, the difference in the total HMO π-energies between [infinity]-annulene and the corresponding linear polyene is associated with the π-bond energy of the $CH_2{=}CH$ type (E_{23}). That is,

$$2E_{22}+E_{12}-2E_{23} = \lim_{\mathrm{N}\to\infty}\{E_{\mathrm{HMO}}([\mathrm{N}]\text{-annulene}) - E_{\mathrm{HMO}}([\mathrm{N}]\text{-polyene})\} = 2 - \frac{4}{\pi} = 0.7267605\cdots\cdots \tag{6}$$

Table 2. π-Energies in units of β of linear polyenes

N	E_{HMO}	E_A	$E_{HMO}-E_A$	E_{HS}	$E_{HMO}-E_{HS}$
4	4.4721	4.3662	0.1059	4.4660	0.0061
6	6.9879	6.9127	0.0752	7.0019	−0.0140

30	37.4873	37.4704	0.0169	37.4327	0.0546
32	40.0328	40.0169	0.0159	39.9686	0.0642
34	42.5783	42.5634	0.0150	42.5045	0.0738
36	45.1240	45.1099	0.0142	45.0404	0.0836
38	47.6698	47.6563	0.0134	47.5763	0.0935
40	50.2156	50.2028	0.0128	50.1122	0.1034
42	52.7615	52.7493	0.0122	52.6481	0.1134
44	55.3074	55.2958	0.0116	55.1840	0.1234
46	57.8534	57.8423	0.0111	57.7199	0.1335
48	60.3994	60.3887	0.0107	60.2558	0.1436
50	62.9455	62.9352	0.0103	62.7917	0.1538

Therefore, as long as the π-bond energies are additive, the total π-energy of linear [N]-polyene can reasonably be estimated by combining Eqs. (4) and (6) as follows:

$$E_A([N]\text{-polyene}) = \frac{N}{2}(E_{22}+E_{12}) - (2E_{22}+E_{12}-2E_{23})$$

$$= \frac{4(N+1)}{\pi} - 2. \qquad (7)$$

Table 2 shows the total π-energies of linear polyenes estimated by using Eq. (7) (E_A), together with those estimated from Table 1 (E_{HS}).

As may easily be seen, the total HMO π-energies are excellently reproduced by the present treatment. It must be noted that E_A was derived simply on the assumption of the additivity of π-bond energies. Since there is no arbitrariness in deriving Eq. (7), E_A is a unique solution for linear polyene. The deviation of E_A from E_{HMO} is generally very small, and at its maximum at N=4, for which E_A is only 2.37 percent less than E_{HMO}. Even though every π-bond energy can not be evaluated by the present consideration, we can safely say that the additivity of π-bond energies was verified in this manner. The small energy difference between E_A and E_{HMO} might be considered as a kind of stabilization energy, though it is not well grounded. This apparent stabilization energy is a result of taking [infinity]- annulene and -polyene as reference compounds; it may be related to the stability of relatively small polyenes.[8] The energy difference diminishes gradually on going to longer polyenes.

In this sense, the total π-energies determined by using Hess and Schaad's π-bond energies (E_{HS}) appear to be influenced by the above effect. Since their intention was to attain the best additivity of π-bond energies for acyclic polyenes of a medium size,[4] the additivity itself is considerably better for polyenes with N-values less than 22. The energy deviation of E_{HS} from E_{HMO} is suppressed at less than 0.22 percent of the total π-energy in that range of N. However, we could not find any meaning in the energy deviation, as it is not systematic with respect to N. It is totally dependent on the choice of π-bond energies. Some parts of the energy deviation are possibly due to the arbitrary assignment of the value to two of the eight π-bond energies made by Hess and Schaad.[4] The energy deviation of E_{HS} from E_{HMO} as well as the percent energy deviation increases monotonously beyond N= 22.

As is indicated in Eq. (4), the π-bond energy of the unit structure of annulene was estimated at 2.5465β, which is quite comparable to the value determined from Table 1 (2.5359β). On the other hand, the quantity defined by Eq. (6) (0.7268β) is somewhat larger than the corresponding value determined from Table 1 (0.6058β). Such a discrepancy is suggestive of the peculiar contribution of the edge double bonds in polyene.

The above discussion has been made on the basis of the simple HMO theory, in which the effect of bond alternation was completely disregarded for the sake of simplicity. As long as the effect of the more striking bond alternation near both edges of the polyene[5] is assigned simply to E_{23} only, it must be slightly larger than was expected by Hess and Schaad.[4] This fact also suggests that, when the additive π-bond energies derived from relatively small polyenes are used to spurious estimate the resonance energies of cyclic systems, spurious results might sometimes be produced.

We are grateful to the Hokkaido University Computing Center for the use of their FACOM 230—60, on which all the calculations were performed.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 47(12), 3171—3172 (1974)

Formation of Erbium and Holmium Mixed Complexes with Complexane and Carbonate Ion

Tomitsugu TAKETATSU

College of General Education, Kyushu University, Fukuoka 810

(Received February 16, 1974)

Synopsis. The formation of erbium and holmium mixed complexes with one species of complexanes and carbonate ion in alkaline solution (pH 10.5—10.7) was investigated spectrophotometrically. The results suggest that carbonate ion additionally combines with the EDTA and CyDTA chelates, while does not with the DTPA chelates.

In a previous paper[1], the mechanism of formation and composition of erbium and holmium chelates with one of complexanes and 5-sulfosalicyclic acid in alkaline solution were investigated. It is well known that tripositive rare earth salts, especially the heavier rare-earth salts are dissolved in a potassium carbonate solution because the carbonate complex forms.[2,3] The formation of the erbium and holmium carbonate complexes causes a remarkable enhancement of the intensity in the hypersensitive bands of the metal ions.[4] Though the rare earth–complexane chelates are very stable, the enhancement of the intensity is not remarkable.[1] In the present paper, the formation of the mixed complexes has been studied by inquiring the enhancement of the intensity of a hypersensitive band with increasing concentration of carbonate ions added to the alkaline solutions of the rare earth-chelates of ethylenediaminetetraacetic acid (EDTA), *trans*-1,2-cyclohexanediamine-*N,N,N',N'*-tetraacetic acid (CyDTA), and diethylenetriamine-*N,N,N',N'',N''*-pentaacetic acid(DTPA).

Experimental

All the absorption spectra were measured with a Hitachi EPS-3T automatic recording spectrophotometer.

The preparation of the reagents and the experimental procedure were carried out by the similar manner described in the previous paper.[1] A potassium hydroxide solution for adjusting pH was stored in a reagent bottle with a soda lime tube.

Results and Discussion

The absorption spectra of the alkaline solution (pH 10.5—10.7) containing various combination of erbium and holmium (Ln), one species of the complexanes and the carbonate ion were recorded between 340 and 650 nm. As references the characteristic spectra in the region of 380 nm for erbium and 450 nm for holmium, obtained from these systems with the corresponding spectra of the rare earth–carbonate complexes (pH 10.5—10.7) and the rare earth chlorides (pH 2.0) are given in Figs. 1 and 2. From the results, the absorption spectra of the Ln-EDTA-CO_3^{2-} and Ln-CyDTA-CO_3^{2-} systems are quite different from that of the Ln–EDTA and Ln–CyDTA systems, respectively,

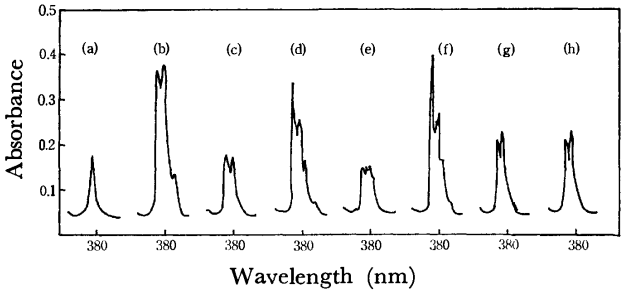

Fig. 1. Absorption spectra of aqueous solutions of erbium-complexane-CO_3^{2-} systems. (a) $ErCl_3$, (b) Er : CO_3^{2-} = 1 : 40.4, (c) Er : EDTA = 1 : 1.1, (d) Er : EDTA : CO_3^{2-} = 1 : 1.1 : 2.1, (e) Er : CyDTA = 1 : 1.3, (f) Er : CyDTA : CO_3^{2-} = 1 : 1.3 : 2.0, (g) Er : DTPA = 1 : 1.3, (h) Er : DTPA : CO_3^{2-} = 1 : 1.3 : 2.0. The ratio represents mole ratio (concentration of Er^{3+} is 0.02276 M).

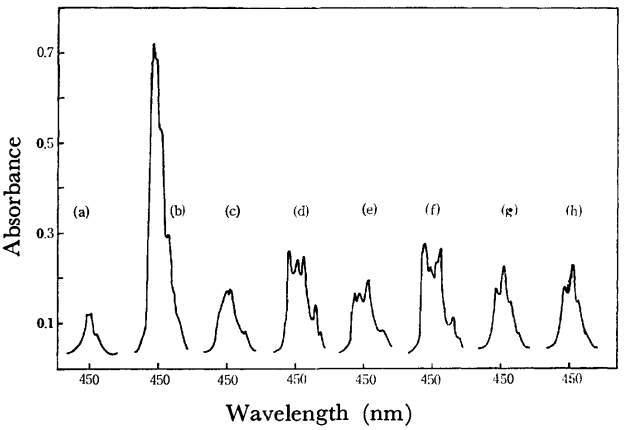

Fig. 2. Absorption spectra of aqueous solution of holmium-complexane-CO_3^{2-} systems. (a) $HoCl_3$, (b) Ho : CO_3^{2-} = 1 : 39.2, (c) Ho : EDTA = 1 : 1.3, (d) Ho : EDTA : CO_3^{2-} = 1 : 1.3 : 2.0, (e) Ho : CyDTA = 1 : 1.3, (f) Ho : CyDTA : CO_3^{2-} = 1 : 1.3 : 2.0, (g) Ho : DTPA = 1 : 1.3, (h) Ho : DTPA : CO_3^{2-} = 1 : 1.3 : 2.0. The ratio represents mole ratio (concentration of Ho^{3+} is 0.02348 M).

and also from that of the Ln–CO_3^{2-} systems.

As Fig. 3 shows, the absorbance at the maximum of the absorption band in the Er-CyDTA system increases with increasing concentration of carbonate ions, and becomes almost constant in the region above one of $[CO_3^{2-}]/[Er^{3+}]$ mole ratio. Similar results were obtained from the Er–EDTA, Ho–EDTA, and Ho-CyDTA systems. Moreover, the continuous variation method was applied to study the mole ratio at which CO_3^{2-} combines with the chelates. The composition

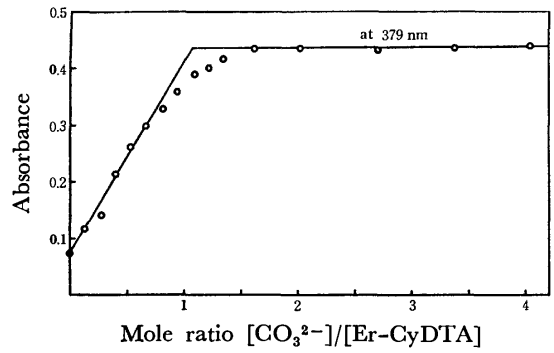

Fig. 3. Variation in absorbance as a function of mole ratio of [CO_3^{2-}]/[Er-CyDTA]. (concentration of Er^{3+} is 0.02276 M)

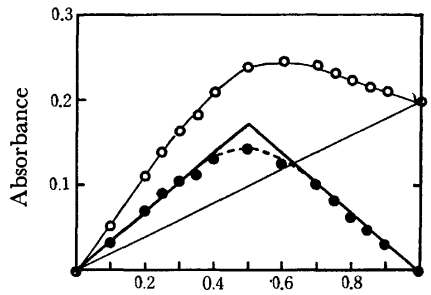

Fig. 4. Continuous variation plots in Er-CyDTA and CO_3^{2-} system. (at 379 nm)

of the rare earth–EDTA and –CyDTA chelates is well known to be 1 : 1 mole ratio.[5,6] The result obtained, for instance, from the Er–CyDTA–CO_3^{2-} system is shown in Fig. 4. The total concentration of Er–CyDTA and CO_3^{2-} ion was maintained at 0.02276 M. The peak (at 379 nm) at mole fraction [Er-CyDTA]/([Er-CyDTA]+[CO_3^{2-}]) of 0.5 indicates combining ratio of 1 : 1. Similar results were obtained from all the other systems. Therefore, the combining ratio of these mixed complexes can be estimated to be Ln : complexane : CO_3^{2-}=1 : 1 : 1. The spectra obtained from the Ln-complexane-CO_3^{2-} systems were affected neither by an addition of excess CO_3^{2-} ion nor by that of excess EDTA and CyDTA. Accordingly, it is deduced that the formation of the mixed complexes is based on an addition reaction of the second ligand CO_3^{2-} ion to the rare earth-complexane chelates. The difference in the absorption spectra between the Ln–DTPA and Ln-DTPA-CO_3^{2-} systems is scarcely recognized as Figs. 1 and 2 show.

From these results, it is considered that the coordination sites of the rare earth ions are not completely occupied by the coordination center of hexadentate EDTA and CyDTA, while completely occupied by that of octadentate DTPA, that is, the preferred coordination number of the metal ions seems to be 8 than 6.

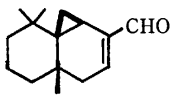
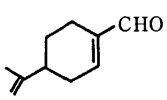
Synopsis. Three cyclic α,β-unsaturated aldehydes (**1**—**3**) were oxidized with an equivalent of Caro's acid in methanol, giving both simple oxidation products and the corresponding norketones in moderate yields.

The Baeyer-Villiger oxidation of α,β-unsaturated ketones has been investigated extensively with various acids.[1] However, only a few reports were given on the reactions of α,β-unsaturated aldehydes[2] with Caro's acid. In connection with the chemical reactivity of thujopsene,[3] we have examined the oxidations of a few cyclic, α,β-unsaturated aldehydes. The results are given in this paper.

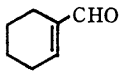
Three aldehydes, (−)-*cis*-thujopsenal (**1**), (−)-perillaldehyde (**2**) and 1-cyclohex-1-enecarbaldehyde (**3**), were used as starting materials. Oxidation was carried out in methanol with an equivalent of Caro's acid. The products were separated and purified by gas, thin layer and column chromatography and identified by spectral data (see Experimental). The results are summarized in Table 1.



1



2



3

Methyl esters (**5**, **7** and **9**), formed by simple oxidation, and the corresponding norketones (**4**, **6** and **8**) were formed with moderate yields, the ratios apparently depending on the steric structures of starting aldehydes. The norketones might be produced *via* cyclohexenyl formates as depicted in the Scheme. In general, the major products of the Baeyer-Villiger oxidation of α,β-unsaturated ketones are the epoxy esters, which are no doubt derived from the enol esters.[1a] Norketones might be formed by the facile methanolysis of enol formates.

Experimental

Melting points were determined with a Büchi melting-point apparatus and are uncorrected. The homogenity of each compound was confirmed by tlc over silica gel (Merck G) and/or by glc (Shimadzu GC-1C) over 15% Silicon OV-17 Uniport (column A) and diethylene glycol succinate on Shimalite (B), using naphthalene as an internal standard. The UV and IR spectra were measured in ethanol and CCl_4, respectively. The NMR spectra were obtained in CCl_4, at 60 and/or 100 MHz, unless otherwise stated, TMS being used as an internal reference. Abbreviations "s" and "m" denote singlet and multiplet, respectively.

Oxidation of (−)-cis-Thujopsenal (1). To a solution of **1**[3] (4.4 g), mp 74—75 °C, prepared by SeO_2 oxidation[4] of thujopsene, in anhydrous methanol kept at 10 °C was added dropwise Caro's acid (10.4 g), prepared from ammonium persulfate (4.6 g) and 85% sulfuric acid (5.8 g), for 30 min. The solution was stirred at 15 °C for 4 hr, then poured into ice-water and extracted with ether. The ether solution was washed with water, dried over anhydrous Na_2SO_4 and evaporated to leave a crude product (4.1 g), which crystallized partially and was found to contain 6 components by glc (column A, 180 °C). The crystalline material was collected by filtration and then recrystallized from ethyl acetate to give pure colorless crystals (1.6 g), mp 108—109 °C, identified as thujopsene anhydrodihydroketone[5] (**4**) by direct comparison with the authentic specimen; Mass, *m/e* 206 (M^+); UV, λ_{max} 207 nm (ε 5500); IR, ν_{max} 3020, 1690 and 1679 cm^{-1}; NMR ($CDCl_3$), δ 0.59, 1.10 and 1.17 (each 3H, s, CH_3) Found: C, 81.34; H, 10.49%; mol wt (Rast, benzene), 205. Calcd for $C_{14}H_{22}O$: C, 81.55; H, 10.68%; mol wt, 206.3.

The mother liquors obtained by filtration and recrystallization were evaporated and purified by preparative tlc with 3 : 97 mixture of ethyl acetate and *n*-hexane to give colorless crystals (0.33 g), mp 105—106 °C, identified as methyl thujopsenate[6] (**5**); IR, ν_{max} 3010, 1718, 1713, 1652, and 1086 cm^{-1}; NMR, δ 0.72 1.11 and 1.17 (each 3H, s, CH_3), 3.65

(3H, s, $COOCH_3$), and 6.41 (1H, m, olefinic H). Found: C, 77.25; H, 9.59%; mol wt (Rast), 246. Calcd for $C_{16}H_{24}O_2$: C, 77.38; H, 9.74; mol wt, 248.4.

Oxidation of (−)-Perillaldehyde (2). Aldehyde **2** (3.0 g), bp 92.5—93.5 °C/5 mmHg (Nippon Terpene Co. Ltd.) purified by treatment with $NaHSO_3$ was oxidized in methanol (24 g) with Caro's acid (10.4 g) in the same manner as **1** afforded an oily product (2.7 g), consisting of 4 components (glc, column B, 145 °C). The product was separated by preparative tlc using a 1 : 9 mixture of ethyl acetate and *m*-hexane to give two compounds, colorless (0.57 g) and pale yellow oil (0.9 g), in pure state. The former was identified as 4-isopropenylcyclohexanone[7] (**6**); UV, λ_{max} 205 nm (ε 1000); IR, ν_{max} 1717, 1645 and 892 cm^{-1}; NMR, δ 1.73 (3H, s, CH_3) and 4.80 (2H, s, exo CH_2). Found: C, 78.10; H, 10.15%. Calcd for $C_9H_{14}O$: C, 78.21; H, 10.21%.

The latter was identified as methyl 1-(4-isopropenylcyclohex-1-ene)carboxylate[8] (**7**); IR, ν_{max} 1712, 1646, 1245, and 887 cm^{-1}; NMR, δ 1.70 (3H, s, CH_3), 3.64 (3H, s, $COOCH_3$), 4.72 (2H, s, exo CH_2), and 6.82 (1H, m, olefinic H). Found: C, 73.20; H, 8.82%; mol wt (Rast), 179. Calcd for $C_{11}H_{16}O_2$: C, 73.30; H, 8.95%; mol wt, 180.3.

Oxidation of 1-Cyclohex-1-enecarbaldehyde (3). The oxidation of **3**[3] (3.3 g), bp 67—68 °C/13 mmHg, in methanol (25 g) was carried out with Caro's acid (15.6 g) in the same way as for **1** and an oily product (2.6 g). The product was found to consist of 6 components by glc (column A, 165 °C), from which two compounds, cyclohexanone (**8**) (0.88 g) methyl 1-cyclohex-1-enecarboxylate[9] (**9**) (0.26 g), were isolated in pure state by preparative glc with a 2 m × 10 mm column of 20% Silicone SE-30 on Chromosorb W. Ester (**9**) gave the following data; IR, ν_{max} 1718, 1712, 1648, and 1083 cm^{-1}; NMR, δ 3.59 (3H, s, $COOCH_3$) and 6.82 (1H, m, olefinic H). Found: C, 68.35; H, 8.48%. Calcd for $C_8H_{12}O_2$: C, 68.55; H, 8.63%.

Absolute Configuration of Some Chiral Cyclopropanes

Kazuyoshi NISHIYAMA, Jun'ichi ODA, and Yuzo INOUYE
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

(Received June 19, 1974)

Synopsis. The absolute configurations of (1*S* : 2*R*)-(−)-*cis*-, and (1*S* : 2*S*)-(+)-*trans*-1-phenylcyclopropane-1,2-dicarboxylic acids, and (1*S* : 2*R*)-(−)-*cis*-, and (1*S* : 2*S*)-(+)-*trans*-1-phenyl-1,2-bis(acetoxymethyl)cyclopropanes were established by correlation to (*R*)-(−)-2,2-diphenylcyclopropane-1-carboxylic acid.

During the course of studies on asymmetric synthesis, we found that establishment of the absolute configuration of a series of chiral cyclopropanes is necessary.

Absolute assignment of configuration is given to *trans*-, (**3**) and *cis*-1-phenylcyclopropane-1,2-dicarboxylic acids (**4**), and *trans*-, (**5**) and *cis*-1-phenyl-1,2-bis(acetoxymethyl) cyclopropanes (**6**) by chemical transformations. These chiral cyclopropanes are correlated to (−)-2,2-diphenylcyclopropane-1-carboxylic acid (**1**) of the known (*R*)-configuration[1] through the key compound, methyl cyclopropane-1,1,2-tricarboxylate[2] (**2**).

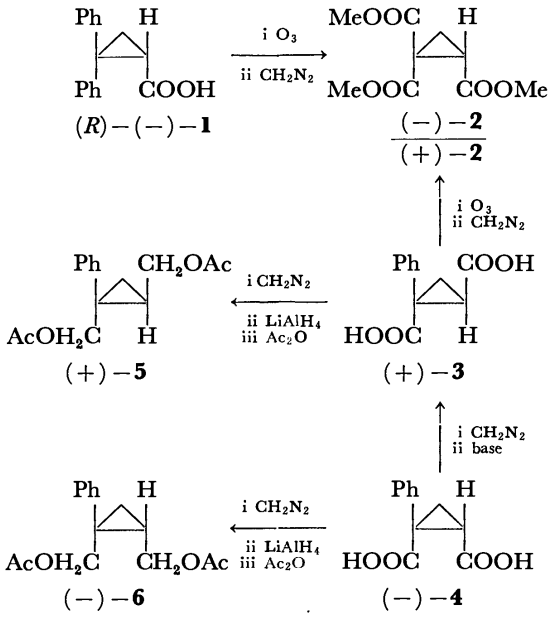
(*R*)-(−)-2,2-Diphenylcyclopropane-1-carboxylic acid, −231°, was ozonized to give, after esterification of the ozonolysis product with diazomethane, methyl cyclopropane-1,1,2-tricarboxylate (**2**) having a rotation of −134.8°. The *R*-configuration is thus assigned to (−)-(**2**).

Methyl (+)-*trans*-1-phenylcyclopropane-1,2-dicarboxylate +134.0°, derived from the partially resolved acid (**3**), +85.8°, was converted in the same manner as described above into (+)-(**2**) with a dextrorotation +124.6°. From the conversion, the *S*-configuration can be assigned to the chiral carbon-2 in the parent (+)-(**3**) and consequently, the *S*-configuration of another chiral carbon-1 in (+)-(**3**) reasonably follows from the *trans*-geometry of carboxyl groups.

The optical purity of (+)-(**2**) derived from (+)-(**3**) is 92.4% based on the maximum rotation +134.8°, so that the value 92.8° is given to (+)-(**3**) as its maximum rotation, which is in good agreement with the value 92.9° attained by optical resolution *via* brucine salt. The agreement not only warrants the fact that neither racemization nor fractionation occurred during ozonolysis and the subsequent work-up in the present transformations, but also provides evidence for stereochemical integrity of compounds involved.

The base-catalyzed isomerization of methyl (−)-*cis*-1-phenylcyclopropane-1,2-dicarboxylate obtained by esterification of the corresponding free acid (−)-(**4**), −185.3°, afforded (+)-*trans*-(**3**)-ester with a dextrorotation of +126.1°, which is evidently epimeric at the ring carbon-2. It follows that (−)-(**4**) is assigned to the (1*S* : 2*R*)-configuration and should possess the maximum rotation −212.0°.

The lithium aluminum hydride reduction of optically pure (+)-(**3**), followed by acetylation of the reduction mixture gave the corresponding diol acetate, (+)-1-phenyl-*trans*-1,2-bis(acetoxymethyl)cyclopropane (+)-(**5**), +5.4°, while the same treatment of (−)-*cis*-(**4**)-ester −178.8° afforded (−)-1-phenyl-*cis*-1,2-bis(acetoxymethyl)cyclopropane −45.5°, (−)-(**6**). The (1*S* : 2*S*)-configuration of (+)-(**5**) and (1*S* : 2*R*)-configuration of (−)-(**6**) are evident, the maximum rotation of the latter being inferred to be −52.1°.



The Brewster calculation of conformational asymmetry[3] predicts the sign and magnitude of molecular rotation in fair agreement with those observed.

	$[M]°_{calcd}$	$[M]°_{obsvd}$
(*R*)−(**2**)	−135	−291
(1*S* : 2*S*)−(**3**)	+135	+191
(1*S* : 2*R*)−(**4**)	−210	−437
(1*S* : 2*S*)−(**5**)	+60	+14
(1*S* : 2*R*)−(**6**)	−90	−137

Experimental

Specific rotations were measured on a Perkin Elmer 241 polarimeter at 25 °C in 1% methanol solution unless otherwise stated.

Ozonolysis. According to the procedure we previously described,[4] (−)-2,2-diphenylcyclopropane-1-carboxylic acid $[\alpha]_D$ −231.1° (chloroform) was ozonized in acetic acid at room temperature and the resulting product was esterified by the standard method with diazomethane to give, after isolation by preparative vpc, methyl cyclopropane-1,1,2-tricarboxylate (−)-(**2**). The IR- and NMR-spectra were identical with those of the authentic specimen.[2] n_D^{30} 1.4477, $[\alpha]_D$ −134.8°.

In the same way, (+)-*trans*-1-phenylcyclopropane-1,2-dicarboxylic acid $[\alpha]_D$ +85.5°, (+)-(**3**), prepared and resolved according to McCoy,[5] gave (+)-(**2**) whose identity was fully substantiated by means of spectroscopy, n_D^{30} 1.4477, $[\alpha]_D$

+124.6°.

Epimerization of methyl (−)-*cis*-1-phenylcyclopropane-1,2-dicarboxylate (50 mg: $[\alpha]_D$ −178.8°; (−)-(**4**)-methyl ester) was effected by treating with methyl phenylacetate (100 mg) and sodium hydride (30 mg) in DMF (1.5 ml) at 40 °C for 1 hr and, after neutralization, the product was subjected to preparative vpc to give pure (+)-(**3**)-methyl ester (28 mg); $[\alpha]_D$ +126.1°.

Resolution of (±)-(**3**), mp 198.5—199 °C,[5] and of (±)-(**4**), mp 152.5—153 °C[5] was performed *via* the brucine salt by fractional crystallizations from methanol eventually to give (+)-(**3**), mp 144 °C, $[\alpha]_D$ +92.9° (methyl ester, n_D^{25} 1.5153, $[\alpha]_D$ +144.3°), and (−)-(**4**), mp 154 °C, $[\alpha]_D$ −185.3°, (methyl ester, n_D^{25} 1.5133, $[\alpha]_D$ −178.8°) respectively.

For the lithium aluminum hydride reductions, the method by Inamasu *et al.*[6] was followed: (+)-(**3**)-methyl ester $[\alpha]_D$ +144.3° gave, after purification by preparative vpc, (+)-1-phenyl-*trans*-1,2-bis(acetoxymethyl)cyclopropane (+)-(**5**), n_D^{25} 1.5004, $[\alpha]_D$ +5.4°, while (−)-(**4**)-methyl ester $[\alpha]_D$ −178.8° yielded the *cis*-counterpart (−)-(**6**), n_D^{25} 1.5018, $[\alpha]_D$ −45.5°. Identification of each was obtained by IR- and NMR- spectroscopies.

Partial support of this work by a grant (966047) in aid from the Ministry of Education is gratefully acknowledged (J. O.).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 47(12), 3177—3178 (1974)

Olefin Disproportionation by Molybdenum(0) Complexes and Aluminum Halides[1)]

Masanobu HIDAI, Takashi TATSUMI, and Yasuzo UCHIDA

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo 113

(Received June 21, 1974)

Synopsis. $MoN_2(PPh_3)_2 \cdot PhMe$ and $Mo(CO)(PPh_3)_2$ were activated by aluminum halides to give catalysts effective for the disproportionation of 2-pentene.

Halide complexes of molybdenum or tungsten in combination with organoaluminum have been known to be effective for olefin disproportionation.[2-4)] We wish to report new molybdenum catalyst systems, free of metal alkyls, for the disproportionation of 2-pentene. Metal alkyl-free catalysts comprised of tungsten combounds have been briefly reported before.[5,6)]

Treatment of $MoN_2(PPh_3)_2 \cdot PhMe$[7)] (**1**) with $AlCl_3$ in bromobenzene afforded a brown suspension, which was effective for the disproportionation of 2-pentene to 2-butene and 3-hexene at ambient temperature. The system became active with an increase in the Al/Mo ratio, but the large excess of $AlCl_3$ promoted the alkylation of the solvent (Table 1). In the evaluation of other molybdenum(0) complexes, it was found that $Mo(CO)(PPh_3)_2$ (**2**) also was a satisfactory catalyst precursor. $AlCl_3$ could not produce catalytic systems in combination with other molybdenum(0) compounds, except that some activity was produced with *trans*-$Mo(N_2)_2(Ph_2PCH_2CH_2PPh_2)_2$[7)] (Table 2).

To determine the effectiveness of Lewis acids as cocatalyst with **1**, parallel preparations were made with several aluminum and other metal halides. Among the aluminum halides the order of the activity was $AlCl_3 \gg AlBr_3 > AlEtCl_2$ (Table 3). With **2** the activity decreased in the same order. The system derived from other aluminum compounds such as AlI_3, $AlEt_2Cl$, or $AlEt_3$ was not effective. Other metal halides such as LiCl, $MgCl_2$, $BF_3 \cdot Et_2O$, $TiCl_4$, $MoCl_5$, $FeCl_3$, $ZnCl_2$, or $SnBr_4$ were ineffective, whereas very little activity was produced by $ZrCl_4$. It is likely that traces of moisture provides HCl from $AlCl_3$ and that it is an alternative cocatalyst. Treatment of **2** with HCl in bromobenzene afforded a reddish brown suspension, which exhibited, however, no activity.

Lewis acid	Acid/Mo ratio	Reaction time, hr	Olefin yield, mol%		
			C_4	C_5	C_6
$AlCl_3$	9	2	6.8	64	6.8
$AlBr_3$	12	20	3.7	39	4.7
$AlEtCl_2$	20	20	1.6	82	1.0
$ZrCl_4$	9	24	0.3	43	0.3

The reaction of **2** with $AlCl_3$ in bromobenzene yielded a reddish brown complex, which had a band at 1900 cm^{-1} assigned to ν(CO) in its IR spectrum. This band is *ca.* 90 cm^{-1} higher than that of **2**. The shift is reasonable because the electron density in the molybdenum atom would be decreased by the interaction of molybdenum(0) base with the Lewis acid, resulting in a decrease in back π-bonding from the molybdenum to the CO ligand. Bencze and Markó have recently reported highly reactive adducts of halocarbonyl complexes of tungsten with $AlCl_3$, which also show higher shifts of ν(CO).[8)] In the reaction of **2** with $AlEtCl_2$ or $AlBr_3$, ν(CO) was similarly shifted to higher frequency by 15 cm^{-1} or 165 cm^{-1}, respectively. Accordingly, the increment of ν(CO) falls in the usually accepted order of Lewis acidity, $AlBr_3 > AlCl_3 > AlEtCl_2$, while the order of effectiveness for the disproportionation was $AlCl_3 \gg AlBr_3 > AlEtCl_2$.

When $AlCl_3$ was added to **1** in bromobenzene, the absorbance at 1905 cm^{-1} attributed to ν(NN) disappeared. Since N_2 is a weaker π-acceptor than CO, a decrease in back donation from the molybdenum must weaken the Mo–N_2 bond so much, resulting in liberation of N_2 from the complex. Other molybdenum(0) complexes such as *cis*-$Mo(CO)_2(Ph_2PCH_2CH_2PPh_2)_2$ and

trans- $Mo(CO)_4(PPh_3)_2$ were also observed to interact with $AlCl_3$; $\nu(CO)$ bands of these complexes were shifted to higher frequencies by *ca.* 70—100 cm^{-1}. As described above, they were, however, not effective as catalyst precursors. The molecular weight of **2** was found to be 1290 by the vapor pressure osmometric method, indicating that **2** has a dimeric structure (Calcd 1296). Since **1** can be easily converted to **2** in the presence of CO and has the empirical formula analogous to **2**, it may also have a dimeric structure. It is to be noted that the 6-coordinate mononuclear molybdenum(0) complexes did not afford active catalyst systems by the addition of aluminum halides, but that the complexes, **1** and **2**, presumed to have unusual dimeric structures showed a remarkable catalytic activity.

Recently Lewandos and Pettit have reported that arene-$W(CO)_3$ complexes can act as catalyst precursors for olefin disproportionation.[9] These systems are, however, not notably effective, and prolonged heating to 98 °C is necessary in order to activate the catalyst systems. We have observed that **2** itself also exhibited very little disproportionation activity at 98 °C, while the addition of $AlCl_3$ markedly stimulated the activity. Although Wang and Menapace suggested a W(IV) (d^2) catalytic intermediate in the WCl_6-*n*-BuLi sistem,[10] Mo(IV) (d^2) complexes such as $MoCl_4(EtCN)_2$ or $MoCl_4(PPh_3)_2$ could neither act as catalysts by themselves nor be activated by $AlCl_3$.

The systems using bromobenzene or chlorobenzene as the solvent were clearly superior to those using benzene or *n*-hexane (Table 4). In the case of the latter solvents the system became almost heterogeneous, suggestive of active species having some ionic character. The complex **1** was recovered quantitatively after being allowed to stand for a long time in bromobenzene or chlorobenzene, ruling out the posibility that the oxidative addition of the solvent occurred. The disproportionation was completely inhibited using iodobenzene, which rapidly reacted with **1**. If the catalyst was prepared in toluene and 2-pentene was added, almost exclusive and rapid alkylation of toluene took place.

Table 4. Solvent effect

1: 0.05 mmol, $AlCl_3$: 0.45 mmol, 2-pentene: 9.4 mmol, solvent: 4 ml, reaction time: 2 hr.

Solvent	Olefin yield, mol%		
	C_4	C_5	C_6
PhMe	0	2.8	0
PhH	0.7	44	0.7
PhCl	6.8	64	6.8
PhBr	19	43	19
PhI	0	100	0

It has been established that in the transition metal-olefin interaction, two factors are operating, *i.e.*, σ-donation from the olefin to the metal and back π-bonding from the metal to the olefin. The magnitude of the contribution of these two factors are partly dependent on the electron density on the metal atom. The fact that $AlCl_3$ is the most effective cocatalyst with the molybdenum complexes may be explained in terms of moderate decrease in the electron density on the molybdenum by adduct formation, as indicated by the increase in $\nu(CO)$. The most active catalyst systems reported for homogeneous olefin disproportionation are composed of halide complexes of either molybdenum or tungsten and organoaluminum compounds. In those systems metal halides are supposed to react with organoaluminum to produce, transiently, molybdenum(0) or tungsten(0) complexes with formation of aluminum halides, leading to catalyst systems similar to our combinations. We may conclude that in the catalyst systems previously reported, organoaluminum functions not only as a reducing agent but also as an electron modifier of the reduced molybdenum or tungsten.

Substituent Effect in the Nucleophilic Attack by the Bromide Ion on the *p*-Tolyl-Substituted Phenyliodonium Ions

Yorinobu YAMADA, Koichi KASHIMA, and Makoto OKAWARA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

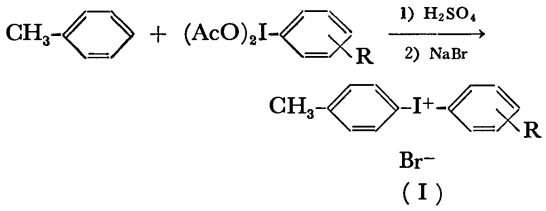
(Received September 9, 1974)

Synopsis. *p*-Tolyl-substituted phenyliodonium bromides were prepared and their nucleophilic substitution reactions were carried out in the DMF solution and molten state. Their substituent effects were discussed from the reaction products and the spectra of the iodonium salts.

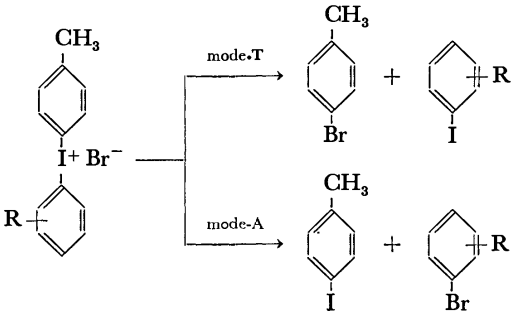
Beringer *et al.* have reported the syntheses of various diaryliodonium salts and their reactions in the solution.[1] In general, the nucleophile tends to attack the more electron-deficient phenyl-1-carbon. We have already reported the influences of the ligand and steric effect on the reaction of various iodonium salts.[2] However, a systematic investigation has not been undertaken to determine the effect of various substituents on the nucleophiles in the reaction of diaryliodonium salts.

In the present paper, we wish to report the syntheses of various *p*-tolyl-substituted phenyliodonium bromides and their reactions in both solution and molten states.

p-Tolyl-substituted phenyliodonium bromides (I) were synthesized from toluene and substituted phenyliodoso acetate. *p*-Tolyl-*p'*-carboxyphenyliodonium bromide was synthesized from *p*-iodobenzoic acid and toluene in the presence of potassium persulfate in concd. sulfuric acid according to the Beringer's method.[3] These results are summarized in Table 1. The thermal decomposition of the iodonium bromides (I) was carried out in both DMF solution (100 °C, 10 hr) and molten state (235 °C, 5 min). The results are shown in Table 2. As can be seen from this Table, the mode-T reaction, in which the bromide ion attacks the tolyl group to give *p*-tolyl bromide and substituted phenyl iodide, and the mode-A reaction, in which the bromide ion attacks the substituted phenyl group to give the substituted phenyl bromide and *p*-tolyl iodide, were found to occur competitively in both DMF solution and molten state.

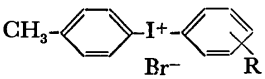


(I)



These results show that the mode-A reaction is inclined to occur in the reaction of I with electron-withdrawing substituents such as the nitro group. On the other hand, the mode-T reaction tends to occur in the reaction of I with electron-releasing substituents such as the methoxy group. The product ratios suggest that the reaction proceeds by an aromatic bimolecular nucleophilic substitution mechanism. Furthermore, there is no significant difference between the solution and molten reaction. It is of interest that the mode-A reaction is difficult to occur in the reaction of I with the *p'*-chloro group compared to that of I with the *m'*-chloro group. It can be deduced from the contribution of the resonance structure, in which the bond between iodonium ion and *p'*-chlorophenyl-1-carbon acquires some double bond character owing to the lone pair of *p'*-chloro group, to the reaction tendency. Such a resonance effect has been observed also in the case of *p*-chlorophenyl-2-thienyliodonium bromide.[2c]

TABLE 1. SYNTHESES OF *p*-TOLYL-SUBSTITUTED PHENYLIODONIUM BROMIDE



Substituent R-	Yield (%)	Mp (°C)	Elemental analyses (%) Found C	Found H	Found Halogen	Calcd C	Calcd H	Calcd Halogen

p-Cl	40.0	60.0	30.9	69.1
m-Cl	34.6	65.4	19.4	80.6
p-COOH	13.3	86.7	7.5	92.5
p-NO_2	3.7	96.3	—	—

Table 3. UV spectra of *p*-tolyl-substituted phenyliodonium bromide in methanol

Substituent R-	λ_{max} (nm)	log ε_{max}
p-MeO	247	4.21
m-Me	232	4.47
H	232	4.38
p-Cl	238	4.38
m-Cl	233	4.20
p-COOH	239	4.44
p-NO_2	253	4.32

From the UV spectra of I (Table 3), the increase in λ_{max} in going from unsubstituted or *m'*-chloro substituted to *p'*-chloro substituted iodonium bromide suggests the presence of such a conjugated system. The increase in λ_{max} of the iodonium bromides with the electron-withdrawing substitutents such as the nitro and carboxyl groups at the *p'*-position and their cleavage tendencies suggest the presence of the resonance structure owing to the hyperconjugation effect of *p*-methyl group enhanced by the *p'*-electron-withdrawing substituent. In these cases, the mode-A reaction becomes to be increasingly liable to occur owing to both the inductive and resonance effects.

Experimental

All the melting points are uncorrected. The ultraviolet spectra were measured with a Hitachi EPS-3T-type spectrometer. A Hitachi 023-5051-type gas chromatograph analyzer was used with a column (stainless 1 m) packed with Silicone SE 30 on Celite 545 at 100 °C.

p-Tolyl-Substituted Phenyliodonium Bromide (I). *p*-Tolyl-substituted phenyliodonium bromides were prepared by a procedure like that given for *p*-tolyl-*p'*-methoxyphenyliodonium bromide. To a well-stirred mixture of 5.28 g (15 mmol) of *p*-methoxyphenyliodoso acetate, 2.76 g (30 mmol) of toluene, and 50 ml of acetic anhydride kept below 10 °C there was added 12 ml of concd. sulfuric acid. After having been stirred at room temperature for 3 hr, the reaction mixture was diluted with 200 ml of ice-water, extracted with ether until color was no longer removed and treated with active carbon. The aqueous layer was added to 10.3 g (100 mmol) of sodium bromide dissolved in 50 ml of water, giving 4.0 g *p*-tolyl-*p'*-methoxyphenyliodonium bromide.

p-Tolyl-p'-carboxyphenyliodonium Bromide. To a solution of 2.98 g (12 mmol) of *p*-iodobenzoic acid in 100 ml of concd. sulfuric acid there was added with stirring 6.5 g (42 mmol) of potassium persulfate at −10 °C and then, after 15 min, 16 g (174 mmol) of toluene at −20 °C. The mixture was stirred at −10 °C for 1 hr and at 0 °C for 3 hr and then was processed as in the preceding manner to give 2.5 g of *p*-tolyl-*p'*-carboxyphenyliodonium bromide.

Pyrolysis Reaction of p-Tolyl-Substituted Phenyliodonium Bromide in the Molten State. About 0.2 g of *p*-tolyl-substituted phenyliodonium bromide was enclosed in a Pyrex tube. The ampoule was then placed in an oil bath kept at 235 °C for 5 min. After the end of the pyrolysis reaction the pyrolysate was disolved in a small quantity of ether and the amounts of *p*-iodotoluene and *p*-bromotoluene were determined by a gas chromatograph. Chlorobenzene was used as an internal standard.

Reaction of p-Tolyl-Substituted Phenyliodonium Bromide in DMF Solution. The reaction of iodonium bromide was conducted by a procedure like that given for *p*-tolyl-*p'*-methoxyphenyliodonium bromide. *p*-Tolyl-*p'*-methoxyphenyliodonium bromide (0.214 g, 0.2 mol) dissolved in 50 ml of DMF was held at 100 °C for 10 hr. At the end of the reaction the mixture was poured into cold water, extracted with ether two times and the extract was dried over anhydrous magnesium sulfate. After removing the solvent by distillation, the residue was redissolved in a small quantity of ether and then treated in the same manner as shown above. In every case the concentration was held at 0.25 mol/l.

(Received August 4, 1973)

Synposis. Effects of solution pH and molecular oxygen on the quantum yields of methylene blue-sensitized photolysis of diazonium salt have been studied in aqueous solutions, using thioacetamide as an activator. The quantum yield increased with an increase in pH when other parameters were kept constant. The presence of oxygen at pH (<7) promoted dye sensitization, but at pH (>7) dominance of the pathway of oxygen quenching of the excited dye triplet caused its suppression. The polymerization of acrylamide in the deaerated solution was readily initiated by dye-sensitized photolysis. A mechanism involving an electron transfer to diazonium cation from unprotonated semimethylene blue formed by a photoredox reaction between excited triplet dye and thioacetamide was in line with these observation.

The methylene blue (MB) sensitized photolysis of 4-diazodiphenylamine sulfate (4DS) solutions containing sodium *p*-toluenesulfinate (STS) or 1,4-diazabicyclo-[2,2,2]octane (DABCO) as an activator was studied by flash photolysis and continuous illumination.[1,2] The mechanism of photolysis was shown to be an electron transfer (see the simplified reaction scheme).

$$MB^{+*} + STS \rightarrow MB\cdot\cdot\cdot STS \xrightarrow{O_2} MB\cdot + STS\text{-}O_2\cdot \quad (1)$$

$$MB^{+*} + DABCO \rightarrow MB\cdot\cdot\cdot DABCO \rightarrow MB\cdot + DABCO\cdot \quad (2)$$

$$MB\cdot + 4DS \rightarrow MB^{+} + \text{diphenylamine radical} + N_2 \quad (3)$$

Here the primary reaction takes place between MB triplet (MB^{+*}) and STS or DABCO (called "activator") with the formation of a complex consisting of a semi-MB ($MB\cdot$) and a half-oxidized activator radical (sulfonyl radical or DABCO cation radical). In the STS system, oxygen was necessary for the dye sensitization at pH below 7. This could be explained in terms of an attack of oxygen on the sulfonyl radical component in a complex, which caused the escape of a semi-MB from the complex (the second step of reaction (1)). The semi-MB was considered to decompose 4DS according to (3). In the absence of oxygen, the complex reverted rapidly to MB and STS in the ground state. The quantum yield markedly decreases if low concentration of STS is chosen for fulfilling the dominance of the pathway of oxygen quenching of triplet MB.[3] The suppression of dye sensitization by oxygen indicates that oxygen quenches triplet MB. In order to understand the operation of dye-sensitized diazo systems, it is important to study a dye-sensitizing system containing other activators such as thioacetamide. Using MB, 4DS and thioacetamide (TAA) which act as an activator, effects of solution pH and oxygen on the quantum yield of MB-sensitized photolysis of 4DS were studied. All the experiments were performed at room temperature 23±1 °C. The solutions were degassed to 10^{-4} mm Hg by the usual freeze-pump-thaw cycle. Experimental procedures were the same as those described previously.[1,2] Oxygen concentrations in aqueous solutions under various partial pressures of oxygen gas were calculated by use of Bunsen's absorption coefficient 0.03 (at 23 °C).[4] Figure 1 shows the absorption spectra of the aerobic solution containing 2.0×10^{-5}M MB, 5.0×10^{-3}M thioacetamide (TAA) and 4.0×10^{-5} M 4DS at pH 6.0 before and after irradiation. Photo-excitation of MB brought about the sensitized photolysis of 4DS as represented by the decrease of an absorption maximum of 4DS at 380 nm. 4DS was stable in the dark at pH lower than 8.4. In the absence of TAA no significant sensitization occurred. The presence of oxygen at pH 6.0 promotes dye sensitization, since quantum yields were about 0.13, and 0.05 for the aerobic and deaerated systems containing 2.0×10^{-5} M MB, 5.0×10^{-3} M TAA, and 4.0×10^{-5} M 4DS at pH 6.0, respectively. Oxygen effect on

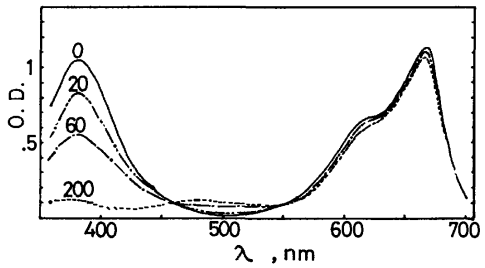

Fig. 1. Absorption spectra of 4DS solutions containing MB and TAA under an aerobic condition.
Numbers indicate the irradiation time (s) of red light (2.1×10^{-6} Einstein absorbed/l·s). Cell thickness is 1 cm. [4DS]=4.0×10^{-5} M, [TAA]=5.0×10^{-3} M, [MB]=2.0×10^{-5} M, pH 6.0.

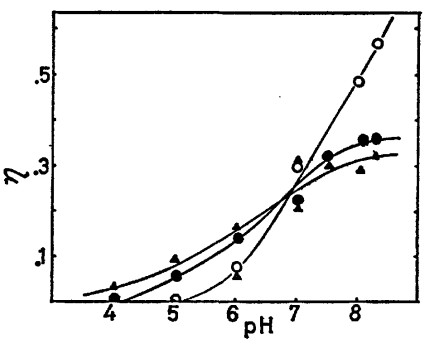

Fig. 2. Dependence of quantum yields (η) on solution pH [4DS]=3.8—4.2×10^{-5} M, [TAA]=5.0×10^{-3} M, [MB]=2.0×10^{-5} M, ○: N_2-bubbled, ●: aerobic, △: deaerated, ▲: O_2-bubbled.

quantum yields of dye-sensitized photolysis of 4DS is shown for the deaerated, N_2-bubbled, aerobic, and O_2-bubbled solutions, together with pH effect in Fig. 2. In the deaerated, N_2-bubbled, aerobic and O_2-bubbled systems, oxygen concentrations were taken to be $\sim 10^{-11}$ M, $\sim 10^{-9}$ M, 3×10^{-4} M, and $1 \sim 2 \times 10^{-3}$ M, respectively. The quantum yield in all systems increased with an increase in pH. It increased with an increase in oxygen concentration at pH below 7, whereas the reverse was the case at pH above 7.

In the deaerated system containing 1M acrylamide, MB excitation efficiently induced the free radical polymerization of acrylamide accompanied by sensitized photolysis of 4DS. The pH dependence of monomer conversion and the amount of MB bleached and 4DS decomposed under the exposure to the red light for 15 s is shown in Fig. 3. The rates of the sensitized photolysis and polymerization increased with an increase in pH. The molecular weights of polymers were of the order of millions. No significant polymerization of acrylamide was observed in the absence of 4DS or TAA. The results suggest that the photopolymerization of acrylamide in the deaerated TAA system is initiated by diphenylamine radical formed *via* an electron transfer from semi-MB to 4DS as reported for STS or DABCO systems.[2] At higher pH where the sensitized photolysis of 4DS was observed, a greater part of the MB triplet should be in an unprotonated form, since pK_a of protonated MB-triplet was 6.7.[5] Thus, little MB bleaching during polymerization can be explained in terms of an electron transfer causing the regeneration of MB^+ (reaction 3).

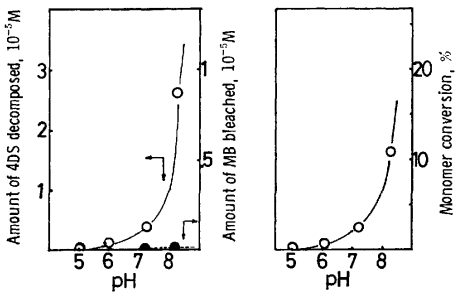

Fig. 3. Effect of solution pH on the sensitized photolysis of 4DS, MB photo-bleaching, and monomer conversion.
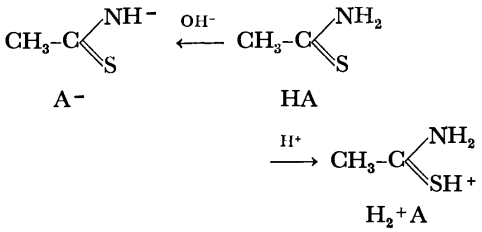
Intensity of red light: 2.2×10^{-6} Einstein absorbed/l·s.
$[MB]_{ini} = 2.0 \times 10^{-5}$ M, $[TAA]_{ini} = 5.0 \times 10^{-3}$ M,
$[4DS]_{ini} = 3.8$—4.0×10^{-5} M, $[Acrylamide]_{ini} = 1$ M,
Irradiation time: 15 s.

At pH above 7, oxygen suppression of the dye-sensitized photolysis of 4DS might be related to a quenching mechanism of triplet MB such as singlet oxygen mechanism.[3] If oxygen quenching of triplet MB or semi-MB alone is taken into account, oxygen effect on quantum yield at a pH less than 7 should be similar to that at a pH above 7. However, oxygen at pH (<7) promoted dye sensitization (Fig. 2). When aerobic aqueous solutions containing 2.0×10^{-5} M MB and 5.0×10^{-3} M TAA in the pH region 5~9 were exposed to red light, the dissolved oxygen was consumed by TAA. According to studies of thionine-sensitized photooxygenation of allylthiourea by Kramer and Maute,[6] the primary reaction takes place between thionine triplet and allylthiourea accompanied by the formation of semithionine radical and allylthiourea cation radical. Oxygen is involved only after the radicals have been formed.

The effectiveness of dissolved oxygen at pH (<7) suggests a mechanism in which molecular oxygen reacts with a charge-transfer complex formed between triplet MB and TAA to form semi-MB effective for dye sensitization, and which was disscussed for the STS system.[2] An attempt to check the above possibility by flash photolysis (400 J, 20 μsec) was unsuccessful since the amount of transient MB-bleaching observed in solutions containing MB and TAA was too small to measure the effect of oxygen or 4DS on the transient bleaching. The spectral changes of TAA in more alkaline or acidic solutions are attributed to the reaction:[7]



(4)

TAA is neutral in the pH region we worked with, since pK_a's of HA and $H_2{}^+A$ are 13.4 and −1.9, respectively. The pK_a of $H_2{}^+A$ was determined from a relationship ($[HA]/[H_2{}^+A] = K_a/h_+$) between $[HA]/[H_2{}^+A]$ and acidity function ($H_+ = -\log h_+$) in sulfuric acid solutions. Thus, it seems unreasonable that a loss of electron donating power derived from a protonation of TAA brought about a decrease in the quantum yield at lower pH. The space cause of the difference in quantum yield with different pH is unknown.
