(Received May 25, 1974)

The structures of the $AuCl_4^-$ and the $AuBr_4^-$ complexes in aqueous solutions have been determined from X-ray scattering measurements on concentrated solutions of tetrachloroauric and tetrabromoauric acids. Both the tetrachloroaurate(III) and the tetrabromoaurate(III) complexes were found to have a square planar symmetry. The values obtained for the interatomic distances within the complexes are: Au-Cl, 2.29_1 Å; *cis*-Cl-Cl, 3.24 Å; *trans*-Cl-Cl, 4.58 Å; Au-Br, 2.43_2 Å; *cis*-Br-Br, 3.44 Å; *trans*-Br-Br, 4.86 Å.

Gold(III) is known to combine with chloride, bromide and iodide ions to form stable complexes of the type AuX_4^- in acid solutions.[1] A square planar model for the structures of the $AuCl_4^-$ and the $AuBr_4^-$ ions in aqueous solutions has been found to be consistent with Raman spectroscopic measurements.[2] In the solid state the $AuCl_4^-$ and the $AuBr_4^-$ complexes have been shown by X-ray scattering,[3-6] Raman and IR measurements[7,8] to have a square planar structure.

As a preliminary to an investigation of the structures of the mixed halide complexes of gold(III) in aqueous solutions more detailed information was needed on the structures of the $AuCl_4^-$ and the $AuBr_4^-$ complexes in solution. For this purpose X-ray scattering measurements have been carried out on concentrated auric chloride and bromide solutions containing the $AuCl_4^-$ and the $AuBr_4^-$ complexes.

Experimental

Preparation and Analysis of Sample Solutions. A solution of tetrachloroauric acid was prepared by dissolving metallic gold of 99.99% purity in *aqua regia* and removing the nitric acid by repeated evaporation with hydrochloric acid.

Gold was determined gravimetrically as metallic gold after reduction with hydrazine sulphate. Chloride was determined gravimetrically as AgCl after reduction of the gold with hydrazine sulphate. The hydrogen-ion concentration was calculated from the relation $[H^+]=[Cl^-]-3[Au^{3+}]$.

A solution of tetrabromoauric acid was prepared by dissolving metallic gold in a mixture of hydrobromic acid and hydrogen peroxide. The analysis of the solution was made by the same procedure as used for the tetrachloroauric acid solution.

The density of a solution was determined with a pycnometer.

The compositions of the solutions investigated are given in Table 1.

TABLE 1. COMPOSITIONS OF THE SOLUTIONS (in g-atom·l^{-1})

	Tetrachloroaurate soln.	Tetrabromoaurate soln.
Au	3.133	2.766
Br	—	12.78
Cl	13.61	—
O	38.78	36.76
H	81.77	77.99

X-Ray Scattering Measurements. The diffractometer used was the same as that described in a previous paper.[9] Mo$K\alpha$ radiation ($\lambda=0.7107$ Å) was used for the measurements. The slit-openings were 1/12°, 1/4° and 1°. A LiF focusing monochromator was placed between the receiving slit and the scintillation counter. Further monochromatization was obtained by means of a pulse-height discriminator. The scattered intensity was measured at discrete points between $\theta=1°$ and 70°, where 2θ is the scattering angle. Points were taken at angular steps of 0.1° in θ up to $\theta=20°$, and 0.25° to $\theta=70°$. The number of counts collected at each angle corresponded to a standard deviation in the measured intensities of about 0.3%. To check long-time variations in the measured intensity, the measurements at each slit combination were made repeatedly. For each slit-opening the measured intensities after corrections for background radiation (about 0.90 counts per second) were recalculated to a common slit width through the use of measurements in overlapping regions. The amount of incoherent radiation passing through the monochromator was estimated from the spectrum of the X-ray tube and the resolving power of the monochromator as described previously.[9,10] It was also estimated experimentally by comparing, at a high angle ($\theta=65°$), intensity measurements obtained when a zirconium filter was placed between the tube and the sample with corresponding measurements with the same filter placed between the sample and the scintillation counter.

All measurements were carried out in a room thermostated at 25±2 °C.

Treatment of Intensity Data

The measured intensities were corrected for polarization in the sample and in the monochromator, and were normalized to correspond to the sum of the calculated coherent and incoherent scattering in the high-angle region ($\theta\gtrsim50°$) for a unit of volume of solution containing one gold atom. The normalization factors calculated in this way agreed within less than 1% with those calculated by the method of Norman[11] and Krogh-Moe.[12]

The scattering factors used for Au, Br, Cl, and O were those given by Cromer and Waber.[13] For H the values given by Stewart *et al.*[14] were used. Values for the incoherent scattering were those given by Cromer and Mann[15] for Au, by Cromer[16] for Br, Cl, and O, and by Compton and Allison[17] for H. The incoherent scattering was corrected for the Breit-Dirac factor.

Anomalous dispersion corrections were taken from Cromer and Liberman's paper.[18]

TABLE 2. OBSERVED INTENSITY VALUES AS A FUNCTION OF $s=4\pi \sin\theta/\lambda$.
$I(s)$ = observed intensities after normalization, $i(s)$ = reduced intensities (corrected for low-frequency additions to the intensity curves).

10.788	1685	75.1	14.278	937	−2.4			

The measured intensities, $I(s)$, corrected for polarization and normalized to correspond to the stoichiometric unit of volume were used to calculate the reduced intensities, $i(s)$, according to the formula:

$$i(s) = I(s) - \sum_i n_i[(f_i(s)+\Delta f_i')^2+(\Delta f_i'')^2 + \Phi(s)\cdot I_i^{\mathrm{Inco}}(s)] \quad (1)$$

Here $s=4\pi\sin\theta/\lambda$, n_i represents the number of atoms "i" in the stoichiometric unit of volume, f_i is the scattering factor, $\Delta f_i'$ and $\Delta f_i''$ are the real and the imaginary parts of the anomalous dispersion correction, $\Phi(s)$ is the fraction of the incoherent radiation reaching the counter, and $I_i^{\mathrm{inco}}(s)$ is the total incoherent radiation of an atom "i".

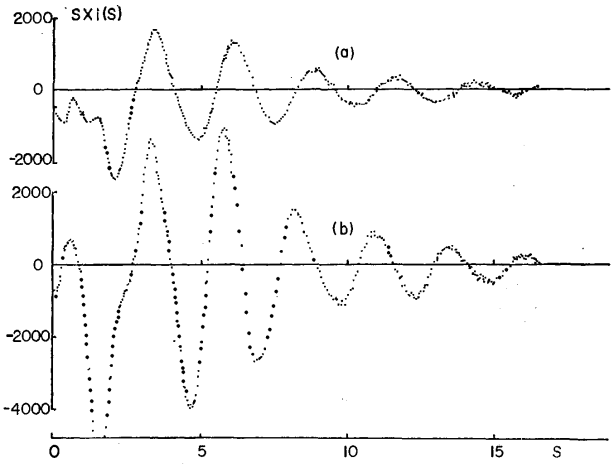

Fig. 1. Observed $s\cdot i(s)$ values for the chloride and the bromide solutions given as a function of $s=4\pi\sin\theta/\lambda$

The reduced intensities, $i(s)$, multiplied by s are shown in Fig. 1 and in Table 2. From these values, the radial distribution curves, $D(r)$, were calculated according to the expression:

$$D(r) = 4\pi r^2\rho_0 + 2r\pi^{-1}\int_0^{s_{\max}} s\cdot i(s)\cdot M(s)\cdot\sin(rs)\mathrm{d}s \quad (2)$$

where ρ_0 denotes the average scattering density of the sample in electron units. The modification function, $M(s)$, was chosen to be $(f_{\mathrm{Au}}^2(0)/f_{\mathrm{Au}}^2(s))\exp(-0.01s^2)$. Spurious peaks below 1 Å in the distribution functions, which could not correspond to interatomic distances, were used to correct the reduced intensity curves for low-frequency additions.

Theoretical intensities due to interatomic interactions were calculated from Eq. (3).

$$i(s) = \sum_i\sum_j f_i(s)f_j(s)\frac{\sin(r_{ij}s)}{r_{ij}s}\exp(-b_{ij}s^2) \quad (3)$$

where r_{ij} is the distance between two atoms "i" and "j", $f_i(s)$ and $f_j(s)$ are the scattering factors, and b_{ij} is the temperature factor corresponding to the interaction between the "i" and "j" atoms.

All calculations were carried out with the use of the KURVLR program.[19]

Analysis of the Intensity Data

The intensity data were first analyzed by means of the radial distribution functions (Fig. 2) calculated

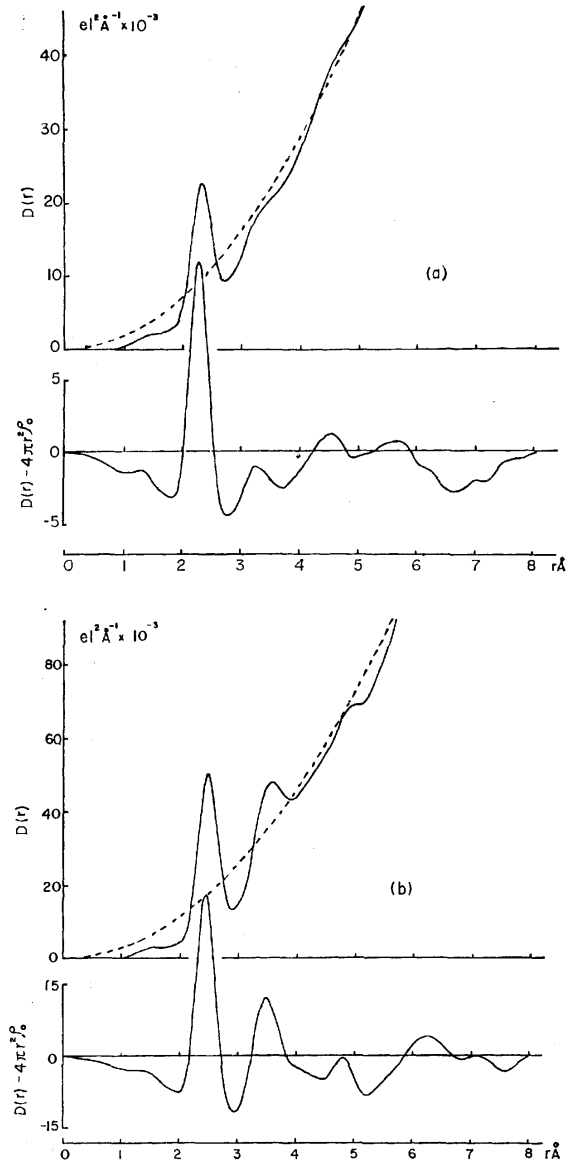

Fig. 2. Radial distribution curves, $D(r)$ and $D(r)-4\pi r^2\rho_0$
(a) The chloride solution. (b) The bromide solution

according to Eq. (2). Distances of gold-halogen and halogen-halogen atoms within a complex were determined from the corresponding peak positions in the distribution functions. The number of such interactions could be roughly estimated from the areas under the peaks.

The first pronounced peak in the radial distribution function (RDF) occurs at 2.3 Å for the chloride solution and 2.4_5 Å for the bromide solution. These peaks can be identified as corresponding to Au-Cl and Au-Br distances within the complexes, since in crystal structure determinations of $KAuCl_4$[6] and of $AuCl_3$,[5] for example, the Au-Cl distances within the planar $AuCl_4^-$ complexes have been found to be around 2.3 Å. Two more pronounced peaks occur in the RDF for the bromide solution: at 3.4 Å ($\simeq\sqrt{2}\times 2.45$ Å) and 4.9 Å ($=2\times 2.45$ Å). Corresponding peaks are present also for the chloride solution but are relatively much smaller.

These two peaks can be identified as Br–Br or Cl–Cl interactions. They occur at distances expected for a planar $AuBr_4^-$ or $AuCl_4^-$ complex. No other marked peaks, which can be related to intramolecular interactions, are present in the RDF functions. The RDF-s therefore are consistent with a square planar symmetry for the $AuCl_4^-$ and the $AuBr_4^-$ complexes.

Refinement of the Structures

In order to get more precise values for the structures of the complexes the influence of intermolecular interactions must be estimated or eliminated. This was done by adjusting the parameter values, derived from the RDF-functions, by means of a least squares procedure in which a minimum was sought for the function

$$\sum_{s_{min}}^{s_{max}} w(s)[i(s)_{obs}-i(s)_{calc}]^2.$$

Intermolecular interactions give their largest contributions to the reduced intensities, $i(s)$, at low s values, while intramolecular interactions are the main contributors at the larger s values. With only intramolecular interactions included for $i(s)_{calc}$ it was found that when the least squares refinements were carried out for different values of s_{min} the resulting parameter values did not show any systematic variations with the chosen s_{min} value for $s_{min}>2.5$ Å^{-1}. It was concluded, therefore, that the intermolecular interactions had a negligible influence on the results, if $i(s)$ values for $s<2.5$ Å^{-1} were excluded from the refinements. Consequently only intensity values for $2.6<s<16.5$ were used for the subsequent least-squares refinements.

The weighting factors, $w(s)$, were chosen to give approximately equal contributions to the least-squares error sum from each experimental $i(s)$ value. For each intramolecular interaction included for the calculation of $i(s)_{calc}$ three parameter values could be refined: the distance, r_{ij}, the temperature factor, b_{ij} and a frequency factor, n_{ij}. Various restrictions on the allowed variations of the values of the parameters could be imposed in the calculations in order to retain a given symmetry during a refinement.

Table 3. Summary of the results of the least-squares refinements

	$AuCl_4^-$	$AuBr_4^-$
A.	$r_{Au-Cl}=2.288[2]$Å	$r_{Au-Br}=2.422[4]$Å
	$b_{Au-Cl}=0.0011[4]$Å^2	$b_{Au-Br}=0.0016[6]$Å^2
	$n_{Au-Cl}=3.5[2]$	$n_{Au-Br}=4.0[2]$
B.		$r_{Au-Br}=2.431[3]$Å
		$b_{Au-Br}=0.0012[3]$Å^2
		$n_{Au-Br}=3.9[1]$
		$r_{Br-Br}=3.44[1]$Å
		$b_{Br-Br}=0.003[1]$Å^2
		$n_{Br-Br}=4.1[2]$
C.	$r_{Au-Cl}=2.291[2]$Å	$r_{Au-Br}=2.432[3]$Å
	$b_{Au-Cl}=0.003[2]$Å^2	$b_{Au-Br}=0.0017[10]$Å^2
	$b_{Cl-Cl}=0.004[2]$Å^2	$b_{Br-Br}=0.006[2]$Å^2
D.	conc.$=2.8[1]$M (=90[4]%)	conc.$=2.72[5]$M (=98[2]%)
	$r_{Au-Cl}=2.291[2]$Å	$r_{Au-Br}=2.433[2]$Å
	$b_{Au-Cl}=0.002[2]$Å^2	$b_{Au-Br}=0.0012[5]$Å^2
	$b_{Cl-Cl}=0.002[2]$Å^2	$b_{Br-Br}=0.006[1]$Å^2

A. Only Au–Cl or Au–Br interactions were included for $i(s)_{calc}$. The distance, the temperature factor and the frequency factor were refined.

B. In this refinement, which could be carried out only for the bromide solution, the Au-Br and the Br–Br interactions were refined independently. The bromide atoms were assumed to be arranged in a square, the size of which was varied in the refinement.

C. The $AuCl_4^-$ and the $AuBr_4^-$ complexes were assumed to form planar squares with the Au atom at the center of the square. The gold-halide distance, the corresponding temperature factor and a temperature factor for the halide-halide interactions were refined.

D. In addition to the parameters used in the previous refinement the concentration of the complexes was varied.

As shown by the results in Table 3 the different restrictions imposed on the refinements do not lead to any significant differences in the resulting parameter values. The independent refinement of the Au–Br and the Br–Br interactions in (B) leads to a ratio between these distances of $3.44/2.431=1.41$ which is close to the expected value of $\sqrt{2}=1.414$ for a square planar complex. In addition the number of Au–Br and of Br–Br interactions per Au atom does not differ significantly from the value of four expected for a AuX_4^- complex. The refinement of the concentration of the AuX_4^- complex in D does not lead to any significant difference from the analytically determined concentration of gold in the solution (Table 1), which indicates that all gold is bonded in AuX_4^- complexes.

Table 4. Final parameter values from the least-squares refinements

$AuCl_4^-$	$AuBr_4^-$
$r_{Au-Cl}=2.291[3]$Å	$r_{Au-Br}=2.432[3]$Å
$b_{Au-Cl}=0.002[2]$Å^2	$b_{Au-Br}=0.0012[5]$Å^2
$b_{Cl-Cl}=0.003[2]$Å^2	$b_{Br-Br}=0.006[2]$Å^2
$n_{Au-Cl}=3.6[2]$	$n_{Au-Br}=3.9[1]$

The best parameter values and the corresponding standard deviations are given in Table 4. The standard deviations are those calculated in the least-squares refinements and do not include possible systematic errors. As judged from the agreement between results obtained when intensities from different s ranges were used for the refinements such systematic errors are probably small and do not exceed the given standard deviations.

To check the calculations the parameter values given in Table 4 were used to calculate peak shapes for the intramolecular interactions. These are compared in Fig. 3 with the radial distribution curves. Subtraction of the calculated peaks from these curves leads to smooth background curves with no indications of residual intramolecular interactions. The $s\cdot i(s)_{calc}$ values are compared in Fig. 4 with the $s\cdot i(s)_{calc}$ values. The differences between observed and calculated values shown in the same figure show that the complexes

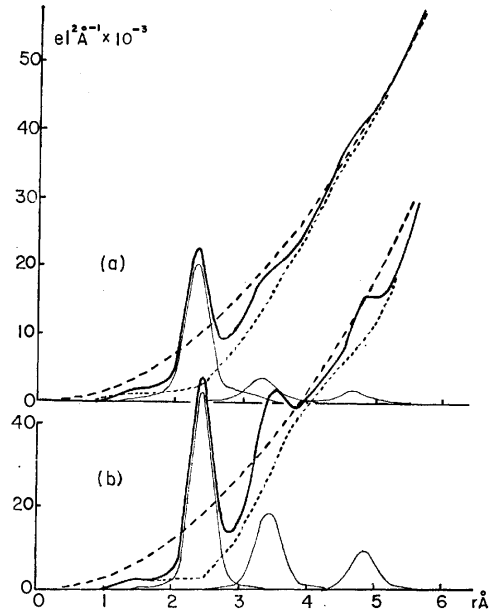

Fig. 3. Comparison between radial distribution curves and peak shapes calculated for the interactions in the AuX_4^- ions using the parameters in Table 4. The difference between the distribution curve and the calculated peaks is shown by the dashed line.
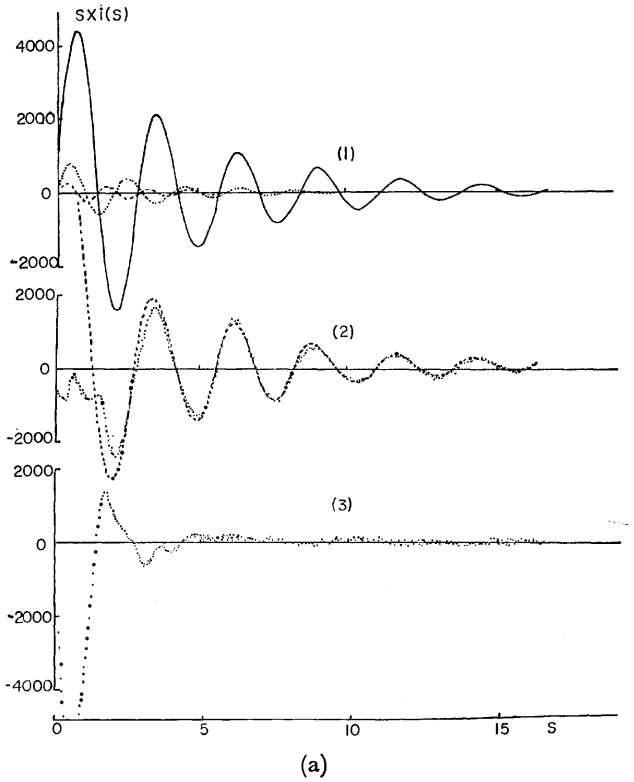
(a) The chloride solution. (b) The bromide solution.

assumed are sufficient to reproduce the observed intensities except for s values below about 3 $Å^{-1}$, where intermolecular interactions can be expected to become important.

The Au-Cl and the Au–Br distances found here for the complexes in solution (Table 4) are similar to those found in crystals in which $AuCl_4^-$ and $AuBr_4^-$ ions have a planar configuration. In crystals of $Cs_2AgAuCl_6$[3] and $RuAuCl_4$[5] the Au–Cl distances have been reported to be about 2.30 and 2.28 Å, respectively. Somewhat longer distances, 2.42 Å, have been reported for crystals of $Cs_2AuAuCl_6$.[3] Other values for the distances ranging from 2.20 to 2.37 Å with an average value of 2.28_6 Å have been found in $KAuCl_4$.[6] Values ranging from 2.25 to 2.34 Å, with an average value of 2.29_0 Å, have been found in crystals of $AuCl_3$, which contain the dimer Au_2Cl_6.



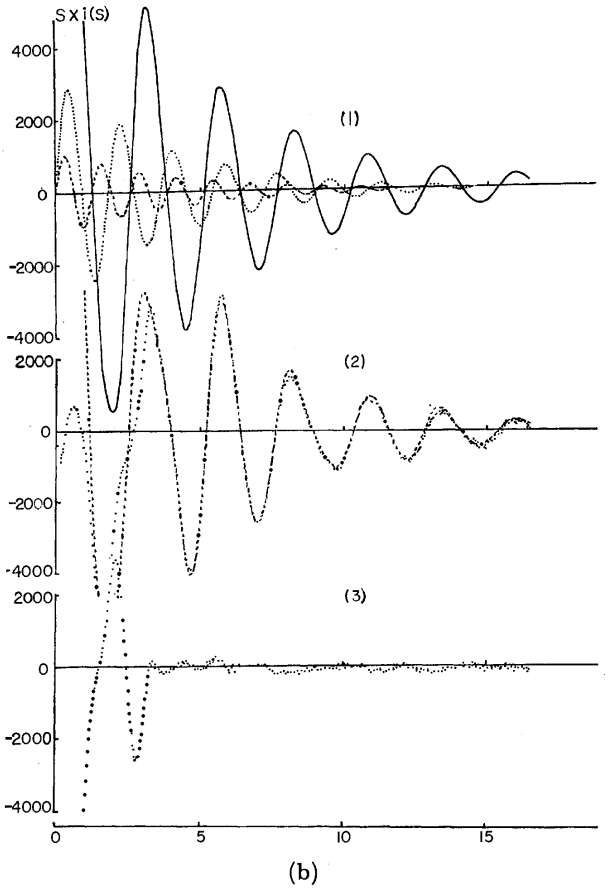


Fig. 4. Observed and calculated $s \cdot i(s)$ values for the chloride solution (a) and the bromide solution (b).
(1) Calculated $s \cdot i(s)$ values for the interactions within an AuX_4^- ion: Au-X full drawn line, *cis*-X-X dotted line and *trans*-X-X dashed line.
(2) Comparison between observed $s \cdot i(s)$ value (dots) and calculated $s \cdot i(s)$ values (dashed line).
(3) Difference between observed and calculated $s \cdot i(s)$ values.

The temperature factors found for the complexes in solution are small and correspond to root mean square values for the variations of the distances of about 0.02 Å for the gold-halide and about 0.03 Å for the halide-halide distances. This indicates a regular arrangement of the atoms in the complexes with no structural differencies between the distances.

This work was carried out at the Institute of Technology in Stockholm and was supported by the Swedish Natural Science Research Council. Computer time was made available by the Computer Division of the National Swedish Office for Administrative Rationaliza-

tion and Economy. We thank Dr. Derek Lewis for revising the English text.

Atomic Absorption Spectrophotometric Determination of Rare Earths (Y, Eu, Gd, Dy, Ho, and Er) in Single Crystals of Magnetic Garnets and Sulfides

Kohei AMETANI

RCA Research Laboratories, Inc., Zushi-machi, Machida-shi, Tokyo 194-02

(Received June 13, 1974)

Atomic absorption spectrophotometric studies were carried out on single-crystal rare-earth magnetic garnets, $(R_1,R_2)_3(Fe,Ga)_5O_{12}$, where R_1 and R_2 are Y, Eu, Gd, and Er, and sulfides RCr_3S_6, where R is Y, Gd, Dy, Ho, and Er. A method using lanthanum chloride to suppress the interference effects of other elements was demonstrated for the atomic-absorption determination of rare earths. Lanthanum chloride is much better than alkaline metal chlorides (NaCl, KCl, and CsCl) and chelating agents (EDTA·2Na and EDTA·$2NH_4$) for removing the interference effects of foreign elements from the yttrium measurement. Similar results with lanthanum chloride are observed with other rare earths. Experimental results for various samples are also presented. The present method has been utilized for several years in our laboratories to analyse rare earths in newly prepared materials.

Atomic absorption spectrophotometry (AAS), as an important analytical tool, can be used to determine more than 60 elements which are major and minor constituents of cements, metals, alloys, glass, agricultural materials, and minerals, *etc.* In the case of rare earths, however, several workers[1-6] have studied the atomic absorption behavior, but very little in the way of applications has been published, presumably because sensitivity is poor in the air-acetylene flame which is routinely used. The rare earths are not totally dissociated in this flame. In a higher temperature flame, such as nitrous oxide-acetylene, the rare earths are generally dissociated but in many cases they are easily ionized and affected by other elements of the compound. Therefore, the determination of rare earths by AAS technique has usually been performed in the presence of easily ionized elements such as alkaline metals[6-8] and lanthanum,[9] so that the sensitivity of rare earths is increased and the interference of associated elements is overcome. In the present work, to establish a condition for the determination of rare earths in single crystals of magnetic garnets $(R_1,R_2)_3(Fe,Ga)_5O_{12}$, ($R_1$ and R_2=Y, Eu, Gd, and Er), and sulfides RCr_3S_6 (R=Y, Gd, Dy, Ho, and Er), we first studied the yttrium absorption in the presence of the following agents; compounds of easily ionized elements (NaCl, KCl, CsCl, and $LaCl_3$) and chelating agents (EDTA·2Na and EDTA·$2NH_4$). Among these agents, it was found that lanthanum chloride is most effective in removing the interference effects of other elements from the yttrium measurement. The usefulness of lanthanum chloride, in contrast with other agents, is demonstrated in the results given in Table 1 for a measurement of 50 ppm yttrium in the presence of foreign elements. Similar results are obtained for other rare earths with lanthanum chloride. Therefore, a method using lanthanum chloride is proposed for the atomic-absorption determination of rare earths which are a major component in crystals of the above-mentioned garnets and sulfides and the results for various samples are presented.

The garnets are dissolved in hydrochloric acid and the sulfides are dissolved in nitric acid. Hydrochloric acid is then used to acidify the sample solution because the atomic absorption of rare earths is reduced in the presence of nitric acid[5,6] and nitrate anions.[5] This acidification for the sulfide analyses is performed after the removal of nitric acid by evaporation with hydrochloric acid. In the case of zirconium and calcium rare-earth silicates,[9] however, rare earths were determined in a nitric acid and lanthanum nitrate medium. In order to demonstrate the applicability of this method for the analyses of individual single crystals a maximum sample weight of 20 mg was used.

Experimental

Apparatus. The atomic absorptions were measured in a nitrous oxide-acetylene flame using a Hitachi Model 208 atomic absorption spectrophotometer and Westinghouse hollow-cathode lamps. The following analytical lines were used; Y, 410.2 nm; Eu, 459.4 nm; Gd, 368.4 nm; Dy, 421.2 nm; Ho, 410.4 nm; Er, 400.8 nm.

Reagents. (1) Standard rare earth solutions: Rare-earth chloride hexahydrates were dissolved in deionized water and standardized by chelatometry using EDTA (1 mg rare earth/ml). These solutions were stocked as 0.1 M hydrochloric acid solution and working solutions were prepared by diluting the stock solutions. (2) Other solutions: Chlorides, except for gallium, as well as sodium and ammonium salts of EDTA were dissolved in deionized water to make the required concentration. Gallium solutions were prepared by dissolving high-purity gallium (99.99%) in nitric acid, removing the excess nitric acid by evaporation with hydrochloric acid, and then dissolving the residue in deionized water. Reagents used were of analytical reagent grade.

Results

Measurements of Yttrium Atomic Absorption in Several Matrices. The effects of several agents on the yttrium atomic absorption are shown in Fig. 1. Agents which increase the yttrium absorption are sodium chloride, potassium chloride, and lanthanum chloride, while the chelating agents decrease the yttrium absorption. In the case of cesium chloride, yttrium absorption was enhanced at lower concentrations of cesium chloride but gradually decreased with increasing cesium chloride concentration.

The effect of these agents in removing the interference of foreign elements from the yttrium absorption

Table 1. Measurement of 50 ppm yttrium in different matrices

Foreign[a] element (ppm)	No Agent (0.1 M HCl)		Agents added[b]					
			NaCl		$LaCl_3$		EDTA·2Na	
	found (ppm)	error (%)	found (ppm)	error (%)	found (ppm)	error (%)	found (ppm)	error (%)
Fe 50	52.3	+ 4.6	55.0	+10.0	49.2	−1.6	50.1	+ 0.2
Ga 500	57.7	+15.4	51.4	+ 2.8	50.0	0	50.3	+ 0.6
Gd 500	38.3	−23.4	42.4	−15.2	53.2	+6.4	16.5	−67.0
Fe 50, Ga 500, Gd 500	37.2	−25.6	43.5	−13.0	51.3	+2.6	25.8	−48.4

a) Elements were added as chloride. b) Solutions were adjusted to 0.1 M hydrochloric acid and the concentration of agents added was 2,000 ppm for both standards and samples.

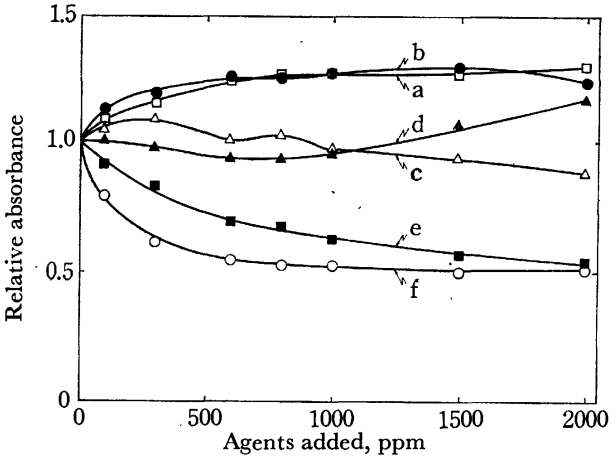

Fig. 1. Effect of several agents on yttrium atomic absorption in 0.1 M hydrochloric acid solution.
(a) NaCl, (b) KCl, (c) CsCl, (d) $LaCl_3$, (e) EDTA·2Na, (f) EDTA·$2NH_4$. Y: 50 ppm.

measurement was examined by adding 2000 ppm of agents to both of the yttrium-standard and the sample solutions. Foreign elements, such as iron, gallium, and gadolinium, were added as chlorides to the sample solutions. Typical results are summarized in Table 1, where sodium chloride and lanthanum chloride are chosen as the enhancement agent for yttrium absorption and EDTA disodium salt for the reducing agent. For comparison, measurements of the solution without the agents are also shown. In the solutions without agents all the foreign elements interfered with the yttrium measurement. Sodium chloride significantly reduced the interference effect of gallium but was not effective for iron and gadolinium. EDTA was useful in the presence of iron and gallium, but the yttrium absorption was greatly reduced by the coexistence of gadolinium. In the lanthanum chloride matrix, the yttrium measurements were generally satisfactory although a small enhancement by gadolinium remained. In comparison with the above-mentioned agents, lanthanum chloride seemed to be the most effective agent for removing the interference effects by foreign elements from the yttrium measurement. Furthermore, lanthanum chloride did not reduce the yttrium absorption as shown in Fig. 1. Therefore, in the work which follows, the measurement of rare earths is performed in the presence of lanthanum chloride with concentrations as high as 10000 ppm.

Effect of Lanthanum Chloride on Rare Earth Atomic Absorptions. As shown in Fig. 2, the absorption of rare earths was enhanced with an increase of lanthanum chloride concentration. For example, comparing the absorption for a solution containing 5000 ppm of lanthanum chloride to one without this agent, the following increased ratios of absorption are observed: Y 1.32, Eu 2.22, Gd 1.51, Dy 1.58, Ho 1.42, and Er 1.22.

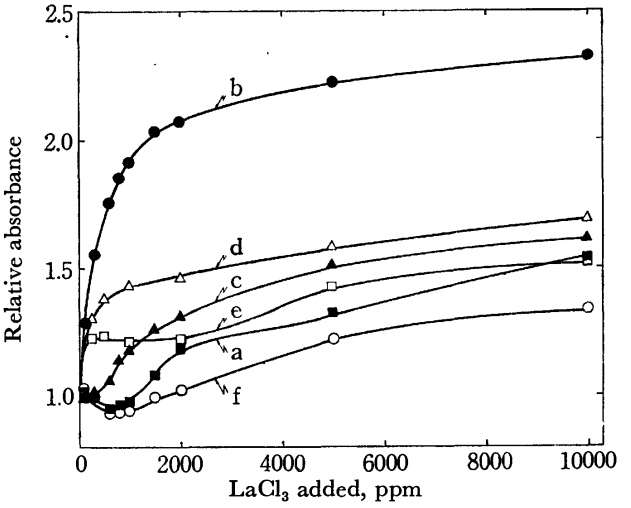

Fig. 2. Effect of lathanum chloride on atomic absorptions of rare earths in 0.1 M hydrochloric acid solution.
(a) Y 50 ppm, (b) Eu 50 ppm, (c) Gd 500 ppm, (d) Dy 50 ppm, (e) Ho 50 ppm, (f) Er 50 ppm.

As a demonstration of the usefulness of lanthanum chloride in removing the interference effects of foreign elements from the rare earth measurements, the results of yttrium and europium are tabulated by comparing with the results obtained without lanthanum chloride in Table 2. The matrix matching is the same between standard and sample solutions with respect to the concentrations of lanthanum chloride and hydrochloric acid. As seen from Table 2, the results with lanthanum chloride are much better than without. For the measurement of yttrium, the interference effect of gadolinium is overcome by the use of 5000 ppm of lanthanum chloride, although a small effect of gadolinium does remain if only 2000 ppm is used, as shown previously in Table 1. It was observed that lanthanum chloride,

Table 2. Comparison of measurements for yttrium and europium with and without lanthanum chloride added.

Analyte	Foreign[a] element (ppm)	Sample Solution: No $LaCl_3$ (0.1 M HCl) found (ppm)	error (%)	5,000 ppm $LaCl_3$[b] found (ppm)	error (%)
Y 50 ppm	Cr 50	64.5	+29.0	49.0	−2.0
	Fe 50	52.3	+ 4.6	49.9	−0.2
	Ga 500	57.7	+15.4	49.3	−1.4
	Ba 50	51.7	+ 3.4	50.1	+0.2

	Er 100	55.0	+10.0	50.0	0
	Fe 100, Ga 500, Gd 500, Er 100	73.6	+47.2	49.9	−0.2
	Ga 2500, Gd 2500	91.4	+82.8	49.2	−1.6

a) Elements were added as chloride. b) The concentration added the was same between standards and samples, and solutions were adjusted to 0.1 M hydrochloric acid.

for concentrations between 5000 and 10000 ppm, suppresses the interference effects of foreign elements. It was also confirmed that the concentration of gallium and gadolinium can be increased up to 1000 ppm for the measurement of yttrium in the lanthanum chloride matrix. At concentrations higher than 1000 ppm of gallium and gadolinium, the interference effects of these elements were not suppressed by the addition of lanthanum chloride.

In the case of europium, the usefulness of lanthanum chloride is more striking than for yttrium. The error in the europium measurement is about 50 to 80% in the presence of gadolinium or gallium for solutions without lanthanum chloride, but is only 1 to 2% with its addition. Similar effects with lanthanum chloride were observed in measuring other rare earths such as gadolinium, dysprosium, holmium, and erbium. The error in the measurement of the rare earths due to the effects of all the foreign elements examined for the garnet and sulfide analyses was reduced to within 1 to 2% in the 5000 ppm of lanthanum chloride matrix, while the interference effects in solutions without this agent remained. Therefore, it is concluded that the present method using lanthanum chloride is useful for the measurement of rare earths in the presence of several foreign elements.

Analysis of Samples. Analyses were performed for a mixture of oxides with a known composition prior to the analysis of the actual samples. Results are given

Table 3. Results of mixed oxides analysis

Sample[a]	Analyte	wt% calcd	wt% obsd	R[b]
1	Y	35.34	35.2	1.2
2	Y	30.98	30.7	0.3
	Eu	5.88	5.9	0.1
3	Y	26.91	26.6	0.9
	Gd	11.90	11.7	0.3
4	Eu	15.71	15.4	0.1
	Er	34.58	34.8	0.3
5	Gd	46.60	47.1	0.6

a) Oxides were mixed with the following mole ratio;
1, 3.0 Y_2O_3: 3.8 Fe_2O_3: 1.2 Ga_2O_3
2, 2.7 Y_2O_3: 0.3 Eu_2O_3: 3.7 Fe_2O_3: 1.3 Ga_2O_3
3, 2.4 Y_2O_3: 0.6 Gd_2O_3: 4.0 Fe_2O_3: 1.0 Ga_2O_3
4, 1.0 Eu_2O_3: 2.0 Er_2O_3 : 4.3 Fe_2O_3: 0.7 Ga_2O_3
5, 3.0 Gd_2O_3: 5.0 Ga_2O_3
b) Difference between the maximum and minimum observed values.

in Table 3 for yttrium, gadolinium, europium, and erbium determinations, where oxides of rare earths are mixed with iron and gallium oxides. All the oxides have a purity of at least 99.9%. Twenty mg of the mixtures were dissolved in concentrated hydrochloric acid and the sample solutions were diluted to an appropriate concentration of analytes. The final sample solutions were adjusted to 0.1 M hydrochloric acid and 5000 ppm of lanthanum chloride. The same adjustment was carried out for the standards and the atomic absorptions were then measured. Each value shown in Table 3 is an average of at least three atomic absorption measurements of the same sample solution. The difference between the maximum and minimum observed values is shown in the "R" column. In all cases the tabulated results in Table 3 agree, within 1 to 2%, with the calculated values, and this technique is applicable to the analysis of rare earths.

The results for single crystal magnetic-garnet and sulfide samples are shown in Table 4, where sample weights from 10 to 20 mg were used. The garnets, except for $Gd_3Ga_5O_{12}$, were flux grown by Wada and Harada of these Laboratories while the sulfides were grown by Takahashi and Yamada,[10] also of these Laboratories, using chemical vapor transport. The $Gd_3Ga_5O_{12}$ sample was obtained from Lambda/Airtron. The garnets were dissolved in concentrated hydrochloric acid and the solutions were diluted to an appropriate concentration of analytes. Sulfides were dissolved in concentrated nitric acid containing bromine and the excess nitric acid was removed by evaporation with hydrochloric acid, and the solutions were then diluted. The final solutions in both cases were adjusted to 0.1 M hydrochloric acid and 5000 ppm of lanthanum chloride. The standard solutions were adjusted to similar hydrochloric acid and lanthanum chloride concentrations. Each value shown in Table 4 is the average of three atomic absorption measurements for the same sample solution. As shown in Table 4, the results are generally in good agreement with the calculated values. The measurement of other components in the garnets, such as iron and gallium, was performed

in a separate experiment, and the resultant data supported these results. For the sulfide analyses, the observed wt% values were sometimes lower than the calculated values, because of white insoluble materials (mostly silica) in the dissolution of samples.[10] In the case of $HoCr_3S_6$ a remarkably large amount of such insoluble residues were found. The values presented in Table 4 are not corrected for the insoluble residues. In another experiment, a chromium and sulfur analysis indicated that the rare earth content observed in this work was in agreement with the stoichiometric amount expected for the intended composition.[10]

The results of Table 2 to 4 substantiate the usefulness of this measurement method for the determination of rare earths in magnetic garnets $(R_1,R_2)_3(Fe,Ga)_5O_{12}$ (R_1 and R_2=Y, Eu, Gd, and Er), and sulfides RCr_3S_6 (R=Y, Gd, Dy, Ho, and Er). This method, therefore, has been utilized in our laboratories for the analysis of rare earths in newly prepared materials, using, at times, only 2 mg of a sample.

The author would like to express his sincere appreciation to Drs. Bernard Hershenov and Fumio Okamoto of these Laboratories for critical reading of the manuscript and helpful suggestions. He is also indebted to Drs. Yasuo Wada and Tatsuo Takahashi, and Messrs. Shigeo Harada and Osamu Yamada of these Laboratories for providing samples.

The Effect of Pressure on the Diels-Alder Reaction[1)]

Kazuyoshi SEGUCHI, Akira SERA, and Kazuhiro MARUYAMA
Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606
(Received August 24, 1973)

The effect of pressure on the Diels-Alder reaction was investigated. The observed activation volume was found to have a significant correlation with the activation free energy of the reaction. A correlation diagram between the activation volume and the activation free energy was proposed. By this diagram, the position of the transition state in the Diels-Alder reaction was discussed, and the activation volume was suggested to be a good diagnostic probe for the position of the transition state. The importance of the contribution of the volume contraction resulting from secondary orbital interaction to the apparent activation volume was pointed out.

There has been only a little concern in the literature about the position of the transition state in an organic reaction along its reaction coordinate.[2)] In this respect, investigators have used the postulates of Hammond[3)] and of Swain and Thornton,[4)] the ρ-value,[5-7)] the kinetic isotope effect,[7)] Brönsted's α-value,[2)] and some quasi-thermodynamic parameters[8)] for the examination of the relative positions of the transition states. Although the Diels-Alder reaction is exothermic, its transition state has been believed to resemble the product in a geometric sense. Moreover, the Diels-Alder selectivity-reactivity relationship[9)] has been understood unsatisfactorily. It is, therefore, of great importance to ascertain the relative position of the transition state for the Diels-Alder reaction.

The present paper will be concerned with experimental evidence for the displacement of the position of the transition state along the reaction coordinate in the Diels-Alder reaction. For this purpose, the activation volume of the reaction (Eq. (1)[10)]) was employed as a new parameter:

$$-RT(\partial \ln k/\partial P)_T = \Delta V^{\ddagger} \quad (1)$$

It is well-known that the Diels-Alder reaction is a typical bimolecular, concerted, cleanly second-order reaction, and that it is almost insensitive to solvent change.[11)] In the present instance, the observed changes in the values of $\Delta V^{\ddagger}$ are referred to differences in the structural term, $\Delta_1 V^{\ddagger}$.[12)] This will make discussion rather simple, because one can eliminate the contribution of the solvation term, $\Delta_2 V^{\ddagger}$,[12)] in $\Delta V^{\ddagger}$, which occasionally introduces a puzzling effect on $\Delta V^{\ddagger}$.

Results and Discussion

The effects of the pressure on several Diels-Alder reactions have been investigated in order to elucidate the reaction mechanisms.[13-16)] We examined representative Diels-Alder reactions under pressures in the range from 1 to 900 kg/cm². *n*-Butyl chloride was employed as the solvent to make it possible to compare the present data with others, and because of the availability of its compressibility data.[17)] Typical rate plots at various pressures are shown in Fig. 1 for the reaction of 2,3-dimethylbutadiene with dimethyl fumarate. Since the plots of log *k* against the pressure showed a good linearity for all the reactions examined (for example, see Fig. 1), the activation volumes were calculated by Eq. (1) using the least-squares fit of the data to the following linear expression:

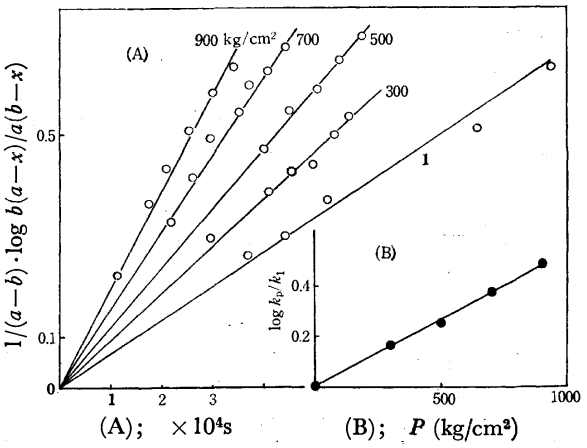

Fig. 1. (A): Rate plots under pressure for the reaction of 2,3-dimethylbutadiene with dimethyl fumarate.
(B): Plot of log k_p/k_1 against pressure for the same reaction.

$$\ln k = a + bP \quad (2)$$

The observed values of the activation volume ($\Delta V_c^{\ddagger}$) were corrected by means of the following equation to give those of the molal concentration basis ($\Delta V_x^{\ddagger}$), taking into account the compressibility of the solvent (κ_0):[17,18)]

$$\Delta V_x^{\ddagger} = \Delta V_c^{\ddagger} - \kappa_0 RT \quad (3)$$

The volume change of the reaction was estimated from measurements of the partial molal volumes of the reactants and the product.

Correlation of Activation Free Energy with Activation Volume. The apparent values of the rate constants, the activation volumes, and the volume changes in the Diels-Alder reactions are tabulated in Table 1. Although several reactions in Table 1 are known to give isomeric product mixtures, we referred to the apparent values of the activation volumes and the volume changes of the reactions because a) the difference in the activation volumes between the *endo*- and the *exo*-isomer producing processes ($\delta\Delta V^{\ddagger}=\Delta V^{\ddagger}_{exo}-\Delta V^{\ddagger}_{endo}$) were found to be quite small[19)] and b) in addition, the volume difference between the *endo*- and the *exo*-adducts has been reported to be negligible as well.[16a)] In the reactions where maleic anhydride was employed as a dienophile, $\delta\Delta V^{\ddagger}$ must be taken into account.[19)] In these cases, however, low *exo*: *endo* isomer ratios were usually found (1: 99 or less). Accordingly, the apparent values of $\Delta V^{\ddagger}$ could safely be

Table 1. Volume parameters for the Diels-Alder reaction in *n*-butyl chloride

Reaction No.	Diene–Dienophile	Temp. (°C)	Rate Constant (l/mol s)	$\Delta V^{\ddagger}$ (cm³/mol)	ΔV (cm³/mol)	Ref.

used as a mechanistic probe of the reaction.

It can be clearly seen in Table 1 that a reaction with a larger rate constant is associated with a more negative activation volume. The activation volume of a particular reaction may be determined by several factors;[20] nevertheless, the activation free energy was shown to have a good correlation with the activation volumes. This relationship is shown in Fig. 2 for the reactions of cyclic and acyclic dienes respectively. The observed correlation of these two classes of dienes are not identical, but are separated in a rather parallel manner. In general, an acyclic diene is thought to be an equilibrating mixture of *s-cis* and *s-trans* isomers; the former will react as an effective diene with a given dienophile.[21] This means that the inherent rate for the *s-cis* isomer must be larger than the observed rate. The intervention of this *cis-trans* equilibration must be responsible for the separated trend shown in Fig. 2.

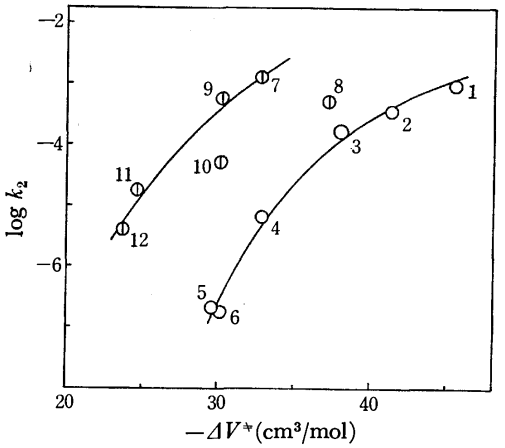

Fig. 2. Correlation of log k_2 with activation volume for the Diels-Alder reaction: numerals correspond to reaction numbers in Table 1; ○, acyclic diene; ⊕, cyclic diene.

An alternative explanation may be that the separated trend is caused by the $\Delta V^{\ddagger}$ term instead of the $\Delta F^{\ddagger}$ term. The geometry of a molecule is responsible for the magnitude of the partial molal volume of the molecule. The reaction of an acyclic diene with methyl acrylate, for example, necessarily proceeds through a monocyclic transition state, while that of a cyclic diene with the same dienophile must have a bicyclic transition state. Consequently, the differences in geometry in both the starting materials and the transition states may result in the differences in the activation volumes, which are responsible for the two separated lines in Fig. 2. However, this seems unlikely because the separated lines under consideration do not coalesce even if $\Delta F^{\ddagger}$ is plotted against $\Delta V^{\ddagger}/\Delta V$, a parameter indicating only the degree of progress for a given reaction and having no relation with the geometry of the reacting molecules and their transition states (see below).

The problem of symmetry in the Diels-Alder transition state is still unsettled. However, theoretical[22] and experimental[16a,23] evidence seems to indicate that, in most of the reactions, a concerted transition state is preferred. In this discussion, we will deal with the present Diels-Alder reactions as concerted cycloaddition reactions.[24] The basic assumption is that the volume of addends in the Diels-Alder reaction decreases monotonously along the reaction coordinate except in special cases (a strong CT-complexing, large secondary orbital interaction, a highly dipolar transition state, *etc.*). In other words, the volume profile along the reaction coordinate may have no extremum, as is depicted in Fig. 3. Furthermore, the structural term, $\Delta_1 V^{\ddagger}$, has been considered to reflect the extent of bond formation.[25] Accordingly, the value of the activation volume ($\Delta V^{\ddagger}$) may safely be anticipated to be a parameter in scrutinizing the relative position of the transition state.

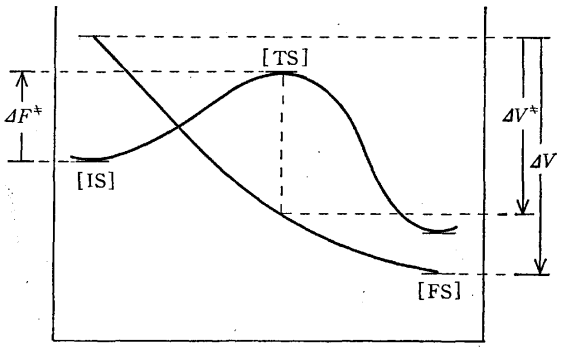

Fig. 3. A schematic diagram of free energy and volume changes for the Diels-Alder reaction: [IS] denotes an initial state, [TS] a transition state, and [FS] a final state.

As is illustrated in Fig. 3, a Diels-Alder reaction characterized by a more negative activation volume may be expected to have a more product-like transition state in respect to the molal volume (and probably to the structure). From an inspection of Table 1, it seems that this interesting concept is equivalent to saying that the transition state for the more reactive Diels-Alder reaction (lower activation free energy) must have a more product-like structure in the sense of the molal volume, and *vice versa*. In Fig. 4 a schematic energy diagram of this generalization for a more reactive (H) and a less reactive (C) Diels-Alder reactions is illustrated, together with the volume parameter. It should be mentioned, however, that the activation volumes of the reactions in which maleic anhydride (MA) was used as a dienophile are more negative than anticipated (see Table 1). The reason for this will be discussed in the succeeding paragraph.

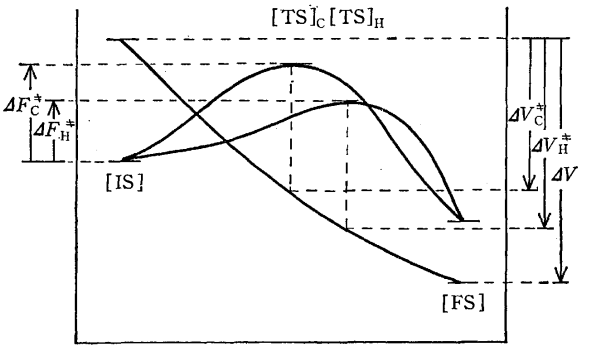

Fig. 4. A shematic diagram of free energy and volume changes for a hot (H) and a cold (C) Diels-Alder reactions: [IS] denotes an initial state, [TS] a transition state, and [FS] a final state. Subscripts H and C correspond to the hot and cold reactions.

Volume Contraction Due to Secondary Orbital Interaction. Recent investigations of the pressure effect on the Diels-Alder reactions revealed that the activation volume of the reaction consisted not only of the structural term, $\Delta_1 V^{\ddagger}$, but also of the volume contraction in the transition state due to secondary orbital interaction, $\Delta_s V^{\ddagger}$.[16,19] The value of $\Delta_s V^{\ddagger}$ is inevitably positive. While the importance of the secondary orbital interaction in [4+2] cycloaddition reactions seems to have been established, the degree of the interaction has scarcely been taken into consideration. When the value of $\Delta_s V^{\ddagger}$ is large, there is a possibility that the molal volume profile of the reaction has the minimum in Fig. 3. Hence, the value of $\Delta_s V^{\ddagger}$ must be estimated in order to discuss the position of the transition state.

Recently we reported that, in the reactions of cyclopentadiene with various dienophiles, the *exo*: *endo* product ratio is correlated to $\delta\Delta V^{\ddagger}$ (which is equal to $\Delta_s V^{\ddagger}$).[19] This correlation enables us to estimate the values of $\Delta_s V^{\ddagger}$ when *exo*: *endo* ratios are given. For most of the dienophiles $\Delta_s V^{\ddagger}$ was estimated to be negligible (0~1.0 cm^3/mol), while in the reactions with MA the estimated value attained nearly 5 cm^3/mol;[26] too large to be ignored. Hence, some of the observed $\Delta V^{\ddagger}$ values listed in Table 1 were corrected in order to give $\Delta V^{\ddagger}_{\text{corrected}}$, taking into account the provisionally assumed value of $\Delta_s V^{\ddagger}$, 4.0 cm^3/mol, for the reactions with MA.

In addition to the correction mentioned above, further revision was made. The use of the $\Delta V^{\ddagger}/\Delta V$ ratio as a parameter indicating the position of the transition state is more suitable than that of $\Delta V^{\ddagger}$ itself. The application of the $\Delta V^{\ddagger}/\Delta V$ parameter with regard to the activation free energy-activation volume relationship may cancel out any possible volume increase or decrease caused by subtle differences in the molecular structures of reagents and/or transition state species. Thus, the revised correlation of the activation free energy with $(\Delta V^{\ddagger}/\Delta V)_{\text{corrected}}$ is presented in Fig. 5. The correlation shown strongly supports the concept now under discussion.

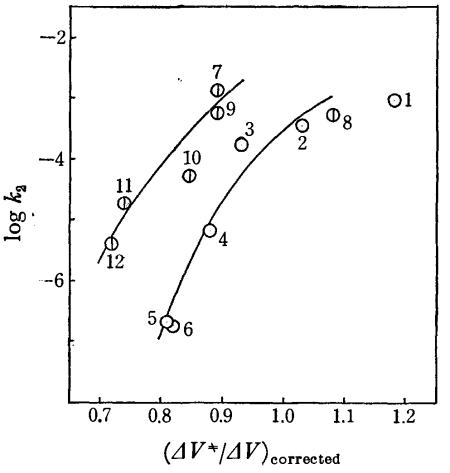

Fig. 5. Correlation of log k_2 with $\Delta V^{\ddagger}/\Delta V$ for the Diels-Alder reaction: numerals correspond to reaction numbers in Table 1; ○, acyclic diene; ⊕, cyclic diene.

However, this parameter should not be used if the solvation term ($\Delta_2 V^{\ddagger}$) is too large to be ignored. The reaction of methoxybutadiene with MA is typical; the activation volume of this reaction is abnormally negative and is dependent on the solvent (−32~−52 cm^3/mol).[16c] This contribution of the solvation term

can be estimated from the solvent dependence of $\Delta V^{\ddagger}/\Delta V$. The values of $\Delta V^{\ddagger}/\Delta V$ and $(\Delta V^{\ddagger}/\Delta V)_{corrected}$ are presented in Table 2 for the reactions of methoxybutadiene[16c] and isoprene[16b] with MA. The $\Delta V^{\ddagger}/\Delta V$ is solvent-dependent for the reaction of MA–methoxybutadiene, as expected, while that for the reaction of MA–isoprene is solvent-independent within the limits of experimental error. Actually, $(\Delta V^{\ddagger}/\Delta V)_{corrected}$ is anomalous for the former reaction, as is shown in Fig. 5 (point number 1). This anomaly is undoubtedly due to the highly dipolar transition state of the reaction.[16c] The other anomaly shown in Fig. 5 is the deviation of the reaction of cyclohexadiene-1,3 with MA (point number 8), which shows a rather larger $(\Delta V^{\ddagger}/\Delta V)_{corrected}$ value than expected. The reason for this is not yet fully understood. Possibly both the specificity of the solvent, dichloromethane (Table 2), and the geometric peculiarity of the reaction (a six-membered diene→bicyclo[2.2.2]-transition state) may be responsible for the observed anomaly.

Table 2. Solvent dependence of $\Delta V^{\ddagger}/\Delta V$ and $(\Delta V^{\ddagger}/\Delta V)_{corrected}$[a]

Solvent	Methoxybutadiene–MA	Isoprene–MA
Acetonitrile	0.99 (0.86)[a]	1.09 (0.97)[a]
Nitromethane	1.52 (1.38)	1.06 (0.93)
1,2-Dichloroethane	1.44 (1.30)	1.04 (0.93)
n-Butyl chloride	1.30 (1.18)	1.03 (0.92)[c]
Dimethyl carbonate	1.68 (1.55)	1.07 (0.96)[c]
Acetone	—	1.09 (0.98)
Dichloromethane	—	1.20 (1.07)
Zeroelectrostriction	1.18 (1.00)[b]	1.08 (0.97)

a) $(\Delta V^{\ddagger}/\Delta V)_{corrected}$ is given in parenthese. b) Estimated value from $\Delta V^{\ddagger}=-32$ cm³/mol and $\Delta V=-28$ cm³/mol. c) Calculated using ΔV in ethyl acetate.

In the reaction of isoprene with MA as well as in the other reactions under consideration, the solvation term may thus be thought to be negligible. Ideally, the value of $\Delta V^{\ddagger}/\Delta V$ at zeroelectrostriction should be referred to. However, the values of $\Delta V^{\ddagger}$ and ΔV at zeroelectrostriction are not so reliable.

The proposed reaction characteristics for the Diels-Alder reactions (Fig. 4) may allow us to scrutinize the selectivity-reactivity relationship of the reactions. The details will be reported elsewhere.[27]

Experimental

The NMR spectra were recorded on a JEOL PS-100 spectrometer, using TMS as the internal standard. The chemical shifts were expressed in δ-values. The analytical determination by glc was performed on a JEOL JGC-20K. The preparative glc was performed on a JEOL JGC-1100. The following stainless steel columns were used: A, 2m PEG 20M (5%); B, 1m Apiezon Grease L (5%); C, 1m PEG 20M (1%); D, 3m TCEP (7%); E, 2m Silicone QF-1 (7%).

Materials. 2,3-Dimethylbutadiene,[28] cyclopentadiene,[29] and 1,2,3,4-tetrachlorocyclopentadiene-1,3[30] were prepared by the reported procedures. The other dienophiles and solvents were commercial materials and were purified when necessary. The following Diels-Alder adducts were prepared by the usual methods: 4-carbomethoxy-2,3-dimethylcyclohexene-1, bp 114—115 °C/27 mmHg; 4-carbobutoxy-2,3-dimethylcyclohexene-1, bp 118—118.5 °C/5 mmHg; *trans*-4,5-dicarbomethoxy-2,3-dimethylcyclohexene-1, bp 131—132 °C/5 mmHg; 1,2-dimethylcyclohex-1-ene-4,5-dicarboxylic anhydride, mp 78—79 °C; *trans*-2,3-dicarbomethoxy-5-norbornene, bp 104—105 °C/4 mmHg. The *exo* and *endo* isomers of 2-carbomethoxy-5-norbornene were prepared by the reaction of cyclopentadiene with methyl acrylate and were separated by glc (column D); NMR spectrum, the *exo* isomer, 3.63 (CO_2CH_3); the *endo* isomer, 3.57 (CO_2CH_3). The *exo* and the *endo* isomers of 2-carbomethoxy-1,4,5,6-tetrachloro-5-norbornene were prepared by the reaction of 1,2,3,4-tetrachlorocyclopentadiene-1,3 with methyl acrylate and were separated by glc (column E); NMR spectrum, the *exo* isomer, 3.83 (CO_2CH_3); the *endo* isomer, 3.78 (CO_2CH_3). 2-Carbomethoxy-1,4,5,6,7,7-hexachloro-5-norbornene was prepared by the reaction of hexachlorocyclopentadiene with methyl acrylate; bp 140—145 °C/7 mmHg. The glc and NMR indicated the presence of a single product. NMR spectrum; 3.65 (CH), 2.60—2.76 (CH_2), 3.82 (CO_2CH_3).

High-Pressure Apparatus. The basic design of the pressure apparatus is essentially identical with that described by Whalley.[31] The high-pressure vessel was immersed in a thermostatted-bath, and the temperature was controlled within ±0.03 °C. The high-pressure hydroaulic liquid used was Silicon Oil KF-96 (200 cs, Shin-etsu Chem. Ind.).

Kinetics and Analysis. Stock solutions of a diene and a dienophile in *n*-butyl chloride were prepared and stored in a freezer. Aliquots were taken from the stock solutions and mixed for each kinetic run. The kinetic solution was transferred into a reaction vessel (20 cm³ glass syringe) and pressurized. Reactions were carried out at five fixed pressures (1, 300, 500, 700, 900 kg/cm²). Analysis was done by glc by means of a comparison of the peak areas or heights on a chromatogram. The initial concentrations of the dienes and the dienophiles, the column specifications and the internal standards for quantitative glc analyses are shown in Table 3.

Table 3. Data for kinetic measurement

Reaction No.[a]	Initial concentration (×10 M) Diene	Initial concentration (×10 M) Dienophile	Glc column[b]	Glc internal standard
2	1.28~2.88	1.36	B	*p*-bromo-*t*-butylbenzene
4	1.13	1.58~1.91	A	dimethyl benzylmalonate
5	4.89~5.31	8.82~11.0	A	ethyl phenylacetate
6	8.91~11.6	21.3~31.3	A	methyl phenylacetate
7	0.506	0.203~0.502	C	diethyl adipate
10	0.503	4.82~7.48	B	2,4-dichlorotoluene
11	2.33	2.20	C	2-carbomethoxy-1,4,5,6,7,7-hexachloro-5-norbornene
12	14.8~16.6	—	A	*p*-chlorotoluene

a) Reaction number cited corresponds to that in Table 1. b) See Experimental part.

Each reaction studied was cleanly second-order and gave only a single product or a mixture of *exo-endo* isomeric products. Although a small amount of a by-product (cyclopentadiene dimer) appeared in the reaction of cyclopentadiene with

methyl acrylate (reaction No. 10), the use of an excess of dienophile depressed the formation of this dimer. The second-order rate constants were calculated by the usual second-order rate expression.[32]

Partial Molal Volume. The technique employed for the determination of the partial molal volumes of liquid samples was the dilatometric method of Hyne and his coworkers.[33] For solid samples, the pycnometric method[34] was employed and calculations were made for the apparent partial molal volumes.

The present work has been supported in part by a Grant-in-aid for Scientific Research from the Ministry of Education.

12) In general, an activation volume of a particular reaction is considered to consist of the structural term ($\Delta_1 V^*$) and the solvation term ($\Delta_2 V^*$). The former represents an inherent volume change of reacting molecules resulting from changes in interatomic distances during an activation process, while the latter does a corresponding volume change due to interactions between solvent molecule(s) and a transition state species, see M. G. Evans and M. Polanyi, *Trans. Faraday Soc.*, **31**, 875 (1935). In the present instance, $\Delta_1 V^*$ is the dominant term because the solvent effect on the reaction is negligible except special cases (for example, the reaction of methoxybutadiene with maleic anhydride is a typical one, see text).

20) Although both ΔV^* and ln k are dependent on temperature, corrections by temperature coefficient was ignored because $(\partial \Delta V^*/\partial T)_P$ is unknown. However, as observed in the dimerizations of isoprene and of cyclopentadiene, the higher the temperature is, the more negative the activation volume becomes.[14] Accordingly the correlation trend shown in Fig. 2 will be, we believe, almost insensitive to temperature.
21) The equilibrium constant for isoprene was reported to be $K_{(cis/trans)}=0.03$ or less, see a) J. G. Aston, G. Szasz, H. W. Woolley, and F. G. Brickedde, *J. Chem. Phys.*, **14**, 67 (1946); b) W. B. Smith and J. L. Massingill, *J. Amer. Chem. Soc.*, **83**, 4301 (1961).

Reaction of Sulfilimine and Sulfonium Ylide with Hydroxide or Methoxide Ion in Methanol

Naomichi FURUKAWA, Toshiaki MASUDA, Masatoshi YAKUSHIJI, and Shigeru OAE

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received October 27, 1973)

The reactions of dialkyl and alkyl aryl *N*-*p*-tosylsulfilimines with hydroxide or methoxide in methanol afforded either *S*-substitution products or Pummerer type products or a mixture of both, their distribution being dependent on the structure of the sulfilimine. From the results of analyses, the mechanisms of the formation of these products are discussed. A similar alkaline methanolysis of sulfonium ylides was also investigated.

Cram and his co-workers investigated the hydrolysis of methyl *p*-tolyl *N*-*p*-tosylsulfilimine with sodium hydroxide in methanol to afford the corresponding sulfoxide in a high yield and suggested the reaction to proceed *via* the nucleophilic attack of hydroxide anion on *S*(III) atom.[1] We found that a similar alkaline treatment of cyclic *N*-*p*-tosylsulfilimines gave α-methoxysulfides as the main product without forming any detectable amount of the corresponding sulfoxides.[2] The marked difference in the mode of reaction by the change of the sulfilimine is of interest, and deserves further investigation with various sulfilimines in order to clarify the nature of the two reactions, the substitution on *S*(III) atom and the Pummerer type rearrangement. We have carried out the alkaline hydrolyses of various sulfilimines with both hydroxide and methoxide in methanol.

Results and Discussion

Reaction of Dialkyl or Alkyl Aryl N-p-*Tosylsulfilimines with Potassium Hydroxide in Methanol.* The reaction was carried out as follows: A mixture of a *N*-*p*-tosylsulfilimine with 20 mol excess of potassium hydroxide in methanol was kept for 24 hr at room temperature. The products were then isolated and identified by comparing their IR and NMR spectra with those of authentic samples. The yields of products are summarized in Table 1. The scheme of the reaction is as follows.

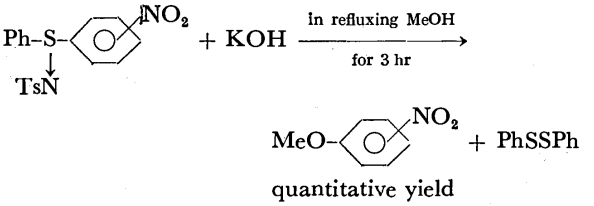
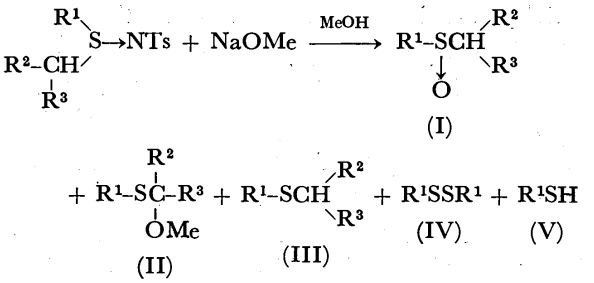
a) This reaction was carried out by refluxing methanol for 24 hr. b) A trace amount of benzaldehyde was detected.

Reaction of Diaryl N-p-*Tosylsulfilimines with Potassium Hydroxide in Methanol.* Diphenyl *N*-*p*-tosylsulfilimine did not react even under refluxing with its alkaline methanol solution for 48 hr. However, *o*- or *p*-nitrophenyl phenyl *N*-*p*-tosylsulfilimine gave *o*- or *p*-nitroanisole in a quantitative yield as shown below.



Reaction of Alkyl Phenyl N-p-*Tosylsulfilimines with Sodium Methoxide in Methanol.* The reactions of alkyl phenyl *N*-*p*-tosylsulfilimines with sodium methoxide were carried out in methanol at 40—50 °C for 20—35 hr. The distributions of products are summarized in Table 2.



The following results were obtained. 1) The treatment of dimethyl, methyl phenyl and cyclopropyl phenyl sulfilimines with potassium hydroxide in methanol gave

Table 2. Reaction of alkyl phenyl *N*-*p*-tosylsulfilimines with sodium methoxide in methanol

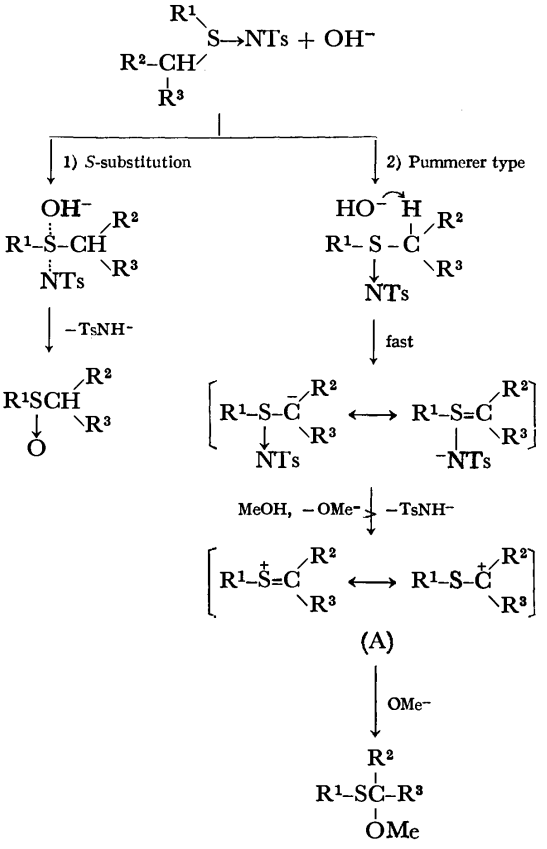
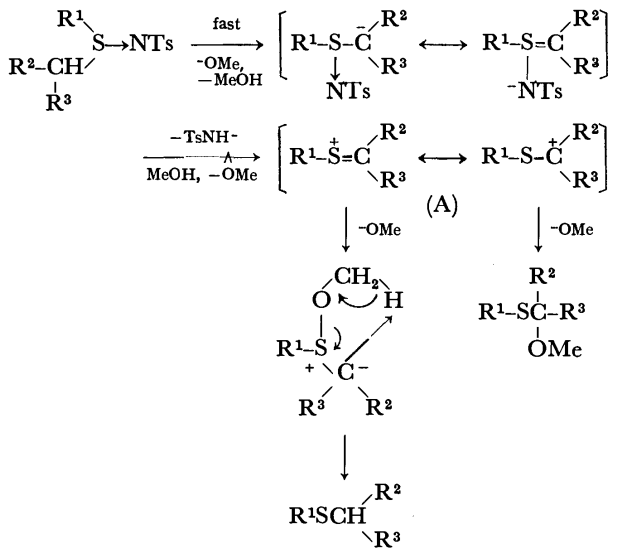
a) Phenyl vinyl sulfide was isolated in 5% yield. b) 42% sulfilimine was recovered. c) Benzaldehyde was obtained in 20% yield.

only the substitution products, *i.e.*, the corresponding sulfoxide. 2) A similar treatment of sulfilimines having α-ethyl, *n*-propyl or *i*-propyl groups gave both the sulfoxides and the Pummerer type rearranged products (α-methoxysulfides). The yield of the Pummerer type rearranged product increased in expense of the substitution product, the sulfoxide, with increasing bulkiness of alkyl substituents. 3) In the reactions with methoxide ion, however, the major products were the Pummerer type rearranged products and the reduced sulfides. 4) Diphenyl *N*-*p*-tosylsulfilimine did not react even under treatment with potassium hydroxide in refluxing methanol for 48 hr, while *o*- or *p*-nitrophenyl phenyl *N*-*p*-tosylsulfilimines reacted with potassium hydroxide readily affording unexpectedly either the *o*- or *p*-nitroanisole quantitatively. Thus, except for diaryl *N*-*p*-tosylsulfilimines, most sulfilimines react smoothly in alkaline methanol giving either the *S*(III)-substitution products or the Pummerer type rearrangement products or both. Both steric and electronic effects appear to control the reaction paths. In the case of nucleophilic attack on *S*(III) atom, *viz.*, route (1), the steric hindrance of alkyl group in the approach of hydroxide ion on *S*(III) atom plays an important role. Thus the yield of the sulfoxide in the series of alkyl phenyl sulfilimines, $\left(PhSCH(R^2)(NTs)R^3\right)$, falls in the order: Me(R^2,R^3; H,H)≫Et (R^2,R^3; H,Me)~*n*-Pr (R^2,R^3; H, Et)>*i*-Pr (R^2,R^3; Me,Me). This postulate also explains the higher reactivity of methyl phenyl sulfilimine as compared to cyclopropyl phenyl derivative and the lack of reactivity of diphenyl derivative. Since the Pummerer type rearrangement (2) is known to proceed *via* an E_1CB process the rate of the reaction depends on the stability of the postulated intermediate (A). Apparently (A) formed during the Pummerer rearrangement is stabilized mostly by the *S*(II) atom bonded to the α-carbon atom since the cyclopropylmethyl phenyl derivative afforded the corresponding cyclopropyl-α-methoxymethyl phenyl sulfide and not the ring enlargement or fission products. However the intermediary carbonium ion (A) could be stabilized further by the alkyl or aryl group attached to the α-carbon, thus yielding the Pummerer type products from alkyl phenyl *N*-*p*-tosylsulfilimines, $\left(PhSCH(R^2)(NTs)R^3\right)$, in the order: *i*-Pr ($R^2$,$R^3$; Me,Me)>$PhCH_2$ (R^2,R^3; H,Ph)~Et (R^2,R^3; H,Me)~*n*-Pr (R^2,R^3; H,Et)≫Me (R^2,R^3; H,H), which is in line with the order of ability to stabilize the carbonium ion by hyperconjugation.

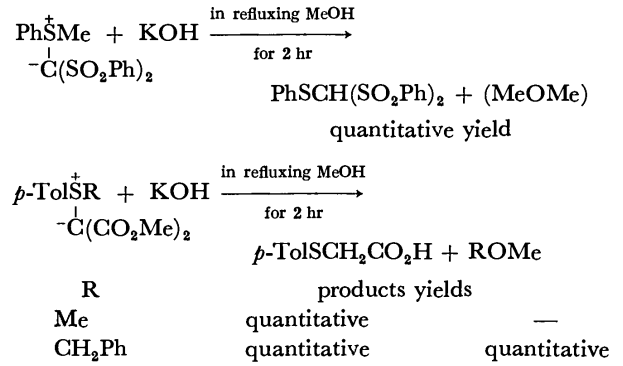


Apparently *o*- or *p*-nitroanisole is formed *via* an aromatic S_N reaction of the corresponding sulfilimine by the attack of methoxide anion on the phenyl carbon atom, with phenylsulfenamide as leaving group. When methoxide ion is used instead of hydroxide, the exchange of methoxide with NTs group might take place to form the alkoxy sulfonium salt from which both the Pummerer rearrangement and the reduction take place

analogously as in the case of alkoxy sulfonium salt[3] as shown below.



Reaction of Sulfonium Ylide with Potassium Hydroxide in Methanol. The hydrolysis of the sulfonium ylide with hydroxide proceeds *via* an entirely different route from that of the sulfilimine. When methyl *p*-tolyl or benzyl bis(methoxycarbonyl)sulfonium methylides or methyl phenyl bis(phenylsulfonyl)sulfonium methylide was refluxed with an excess potassium hydroxide in methanol, quantitative formation of *p*-toluenethioacetic acid or bis(phenylsulfonyl)methyl phenyl sulfide and benzyl methyl ether or dimethyl ether was observed, while the diphenyl derivative gave diphenyl sulfide in a poor yield.



R	products yields	
Me	quantitative	—
CH_2Ph	quantitative	quantitative

The mechanism completely differs from that of the corresponding sulfilimine, the attacking site by methoxide being the α-carbon atom in this case. Although the mechanisms of all these reactions are by no means unambiguously clarified, our results indicate that the reactions of trivalent sulfur compounds are very sensitive to the minor change in the structure of both the attached substituents on the trivalent sulfur atom and the attacking bases.

Experimental

Materials. Methanol was purified by the standard procedure. Potassium hydroxide was of special grade. Sodium methoxide, sulfides and disulfide were prepared by the usual procedures. α-Methoxysulfides were prepared by the reaction of the corresponding α-chlorosulfides[4] with sodium methoxide in methanol. Sulfoxides were prepared by treating the corresponding sulfides with hydrogen peroxide in acetic acid;[5] (PhS- ; bp 137—138 °C/1 mmHg).

p-Toluenethioacetic acid was synthesized by first dissolving *p*-toluenethiol in an excess of aqueous sodium hydroxide, into which was then added a slight excess of chloroacetic acid; mp 93—94 °C (lit,[6] 94.0—94.4 °C).

Preparation of Starting Materials. All the *N*-*p*-tosylsulfilimines were prepared as usual by the reaction of the corresponding sulfides with Chloramine-T.[7]

(PhS- ; mp 135.0—135.5 °C; Found: C, 60.11; H, 5.47; N, 4.36%. Calcd for $C_{16}H_{17}NS_2O_2$: C, 60.12; H, 5.33; N, 4.39%.)

(PhSCH$_2$- ; mp 117.5—118.0 °C; Found: C, 61.19; H, 5.82; N, 4.22%. Calcd for $C_{17}H_{19}NS_2O_2$: C, 61.22; H, 5.71; N, 4.20%.)

All the sulfonium ylides were synthesized by the reaction of the corresponding sulfides with diazo-compounds in the presence of copper sulfate catalyst.[8]

($PhS^{+}Me$; $^{-}C(SO_2Ph)_2$ decomp. 160.5—161.5 °C; Found: C, 57.14; H, 4.27%. Calcd for $C_{20}H_{18}O_4S_3$: C, 57.42; H, 4.31%.)

(*p*-Tol$S^{+}Me$; $^{-}C(CO_2Me)_2$ mp 137—138 °C) (*p*-Tol$S^{+}CH_2Ph$; $^{-}C(CO_2Me)_2$ mp 154—155 °C)

Reaction of Dialkyl or Alkyl Aryl N-p-*Tosylsulfilimines with Potassium Hydroxide or Sodium Methoxide in Methanol.* About 10 mmol of each of the *N*-*p*-tosylfulfilimines was reacted with 20 mol excess of potassium hydroxide or sodium methoxide in methanol (40 ml). The reaction mixture was then neutralized with a 10% aqueous hydrochloric acid and the products were extracted with chloroform except in the case of dialkyl derivatives. In the case of dialkyl derivatives, after the solvents were evaporated, the products were extracted from the residue with chloroform. The products obtained were separated by chromatography through a silica-gel packed column and identified by comparing their IR and NMR spectra with those of authentic samples. The yields and products are given in Tables 1 and 2, respectively. In all the reactions, the corresponding *p*-tosylamide was obtained quantitatively.

Reaction of o- *or* p-*Nitrophenyl Phenyl* N-p-*Tosylsulfilimine with Potassium Hydroxide in Methanol.* About 10 mmol of *o*- or *p*-nitrophenyl phenyl *N*-*p*-tosylsulfilimine was heated with 20 mol excess of potassium hydroxide in refluxing methanol for 3 hr. The reaction solution was then poured into a large amount of water and acidified with 10% aqueous hydrochloric acid and the products were extracted with chloroform. The products obtained were separated by column chromatography and identified by comparing their IR and NMR spectra with those of authentic samples. Yields of *o*- or *p*-nitroanisole, *p*-tosylamide and diphenyl disulfide were quantitative.

Reaction of Bis(methoxycarbonyl)sulfonium Methylides or Bis(phenylsulfonyl)sulfonium Methylide with Potassium Hydroxide in Methanol. About 20 mmol of each of the sulfonium ylides was heated with 20 mol excess of potassium hydroxide for 2 hr in refluxing methanol (80 ml). The reaction solution was then neutralized with 10% aqueous hydrochloric acid

and the products were separated by passing the chloroform extract through a silica-gel packed column. The products obtained were identified by comparing their IR and NMR spectra with those of authentic samples. In all the reactions yields of bis(phenylsulfonyl)methyl phenyl sulfide, *p*-toluenethioacetic acid and benzyl methyl ether were quantitative.

The Ionic Reaction in the Chlorophosphonation of Alkylbenzenes

Toshihiro OKADA, Yoshiki OKAMOTO, and Hiroshi SAKURAI

The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka 565

(Received December 17, 1973)

The chlorophosphonation of toluene, *p*-xylene, ethylbenzene, and diphenylmethane gave methyldiphenylmethanes; 2,4′,5-trimethyldiphenylmethane and ethyl-1,1-diphenylethanes; and *p*-benzyltriphenylmethane respectively as the main products. Isopropylbenzene gave α-methylstyrene, 4-methyl-2,4-diphenylpentene-1, 4-methyl-2,4-diphenylpentene-2, and 1,1,3-trimethyl-3-phenylindane, in addition to the ordinary chlorophosphonated products. Those diphenylmethane derivatives may be formed by the electrophilic attack of the benzylic cations, presumably resulting from electron transfer from the benzylic radicals to phosphorus trichloride with the participation of the oxygen or oxy radical, upon toluene, *p*-xylene, ethylbenzene, or diphenylmethane. α-Methylstyrene may be formed by the elimination of a proton from the intermediate 1,1-dimethylbenzyl cation, resulting from isopropylbenzene in a manner similar to that above. Diphenylpentene and phenylindane derivatives may be formed by the acid-catalyzed dimerization of α-methylstyrene.

Jensen and Noller[1] reported that, on chlorophosphonation, toluene gave only a 12.8% yield of benzylphosphonic acid, ethylbenzene gave 11% of 2-phenylethylphosphonic acid, and diphenylmethane gave 2% of diphenylmethylphosphonic acid. Isbell and Wadsworth[2] reported that isopropylbenzene failed to react at all. Also, in our previous investigation of the chlorophosphonation of *n*-alkylbenzene,[3] it was found that the yield of the α-substituted product was abnormally lower than that to be anticipated from the inductive effect alone, in comparison with other isomers.

In the present paper, the chlorophosphonation of alkylbenzenes has been investigated in order to elucidate the reason for this anomalous behavior in the reactivity of the benzylic C-H bond of alkylbenzene.

Results and Discussion

The chlorophosphonation was performed on each alkylbenzene for 3 hr in the temperature range of −15—0 °C, with a 5-fold mole excess of phosphorus trichloride, by the control of the flow rate of oxygen gas. The products were isolated by vacuum distillation after the slipping of the phosphorus oxychloride and unreacted material. The isolated products were esterified with ethanol–triethylamine, followed by analysis with glc.

Toluene gave methyldiphenylmethanes (I) and diethyl benzylphosphonate (II) in the ratio of 50.0: 1.0; the isomer distribution of I was found by glc analysis to consist of 43.6% *o*-, 5.8% *m*-, and 50.6% *p*-isomers. This isomer distribution was similar to that of the benzylation of toluene with benzyl chloride catalyzed with aluminum trichloride in nitromethane.[4] *p*-Xylene gave 2,4′,5-trimethyldiphenylmethane (III) and diethyl *p*-methylbenzylphosphonate (IV) in the ratio of 3.2: 1.0. Ethylbenzene gave ethyl-1,1-diphenylethane (V), diethyl 1-, and diethyl 2-phenylethylphosphonate in the ratio of 12.5: 1.0: 2.0. The isomer distribution of V consisted of 6.6% *o*-, 2.1% *m*-, and 91.3% *p*-isomers. Styrene could not be detected. Diphenylmethane gave *p*-benzyltriphenylmethane (VI) and a trace amount of diphenylmethylphosphonic dichloride. Isopropylbenzene gave 1,1,3-trimethyl-3-phenylindane (VII) and diethyl 2-phenylpropylphosphonate as the main products in the ratio of 0.7: 1.0. Trace amounts of α-methylstyrene (VIII), 4-methyl-2,4-diphenylpentene-1 (IX), 4-methyl-2,4-diphenylpentene-2 (X), and diethyl 1-methyl-1-phenylethylphosphonate were also obtained.

TABLE 1. EFFECT OF SOLVENT ON THE ISOMER DISTRIBUTIONS AND YIELDS OF DIMERS OF VIII

Solvent	Yield (%)	Products (mol%)		
		IX	X	VII
PCl_3	20.8[a]	89.8	9.9	0.3
$POCl_3$	54.1[a]	29.2	68.6	2.2
PCl_3+POCl_3	38.3[a]	31.4	68.2	0.4
$POCl_3+H_3PO_4$	quant.[b]	trace	trace	100

a) Isolated yield. b) By glc.

The dimerization of VIII might give VII, IX, and X with an acid-catalyzed reaction.[5] The isomer distributions of VII, IX, and X obtained by the dimerization of VIII and with the participation of phosphorus trichloride, phosphorus oxychloride, a mixture of phosphorus trichloride and phosphorus oxychloride, or phosphorus oxychloride containing a small amount of phosphoric acid are given in Table 1. The phosphorus trichloride-catalyzed dimerization of VIII gave IX predominantly, while phosphorus oxychloride gave X as the major product and IX as a minor product. On the other hand, when a small amount of protic acid was added to phosphorus oxychloride, VIII dimerized to give VII only. The isomer distribution of the dimers obtained in the chlorophosphonation of isopropyl benzene was similar to that obtained in the last case. This similarity suggests that the dimerization of VIII which occurs during the chlorophosphonation is catalyzed effectively with protic acid, resulting from the hydrolysis of phosphorus trichloride or phosphorus oxychloride with the moisture in the reaction mixtures.

Mechanism. Mayo, Durham, and Griggs[6] have presented good evidence for the following sequence in the chlorophosphonation of cyclohexane:

$$RH + Cl\cdot \longrightarrow R\cdot + HCl \quad (1)$$

$$R\cdot + PCl_3 \longrightarrow \dot{R}PCl_3 \quad (2)$$

$$R\dot{P}Cl_3 + O_2 \longrightarrow RPCl_3OO\cdot \quad (3)$$

$$RPCl_3OO\cdot + PCl_3 \longrightarrow RPOCl_2 + POCl_3 + Cl\cdot \quad (4)$$

$$RPCl_3OO\cdot + PCl_3 \longrightarrow R\cdot + 2POCl_3 \quad (5)$$

However, the formation of I, III, V, VI, and VIII can not be explained only in terms of the radical substitution or disproportionation of R· in reaction (1) or (5), because the isomer distribution of I or V implies that they are formed *via* the electrophilic attack of the benzylic cation on the aromatic nucleus.

The addition of a small amount of iodine, a radical scavenger, to the reaction mixture of toluene and phosphorus trichloride inhibited the formation of both I and II. Moreover, by the reaction of toluene with di-*t*-butyl peroxide at 110 °C, in the presence of an equivalent amount of phosphorus trichloride, I and II were given in the ratio of 5.0: 1.0 without any bibenzyl. These facts, therefore, suggest that the benzyl radical is involved as an intermediate in the process of the formation of I.

A possible mechanism to account for the formation of I can be proposed. The benzyl chloride formed by

$$R\cdot + O_2 \longrightarrow ROO\cdot \quad (6)$$

$$ROO\cdot + PCl_3 \longrightarrow RO\cdot + POCl_3 \quad (7)$$

$$RO\cdot + RH \longrightarrow ROH + R\cdot \quad (8)$$

$$ROH + PCl_3(POCl_3) \longrightarrow RCl + HP(O)Cl_2 \quad (9)$$

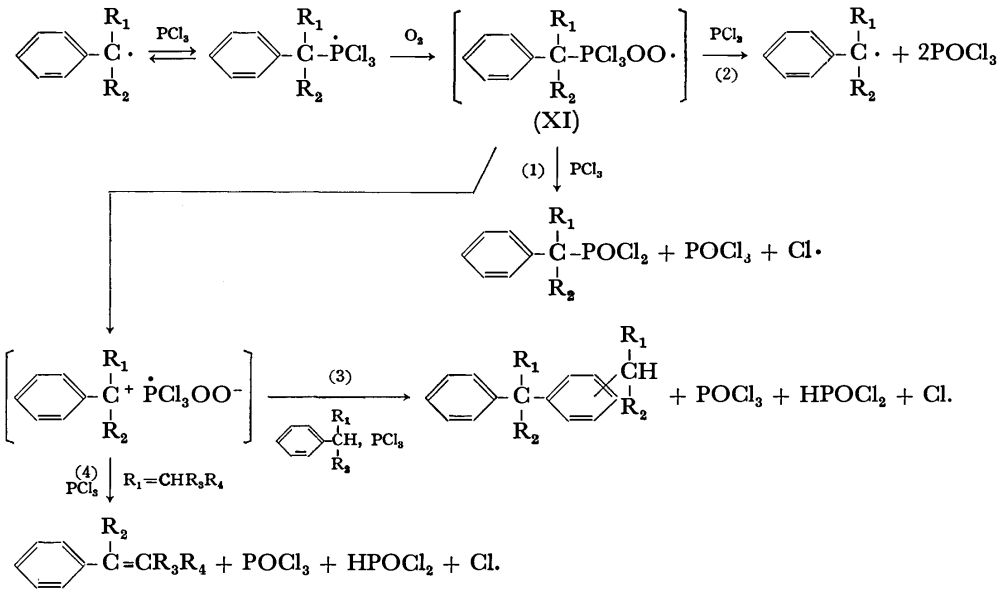
the sequence of radical reactions (6)—(8) and a successive ionic reaction (9),[6] may react with toluene by means of the catalytic action of phosphorus trichloride or phosphorus oxychloride as a Lewis acid, thus giving I. However, this possibility can be eliminated on the basis of the following two facts: benzyl chloride could not be detected in the reaction mixture and, after a mixture of benzyl chloride and toluene with phosphorus trichloride or phosphorus oxychloride had been allowed to stand for at least 24 hr at room temperature, no I could be detected in the mixture.

The UV-irradiation of a mixture of benzyl chloride and toluene with phosphorus trichloride under degassed conditions gave neither bibenzyl nor I, but small amounts of unidentified products, although the irradiation of the same mixture without phosphorus trichloride gave bibenzyl in an appreciable yield, indicating the formation of the benzyl radical. These findings suggest that the presence of oxygen or an oxy radical is also required for the formation of I.

When the temperature of the chlorophosphonation of toluene was raised from −15—0 °C to 65—75 °C, the combined yield of I and II was reduced to one-third. This negative temperature effect is not incompatible with the idea that a thermally unstable phosphoranyl intermediate radical may be present in this process.[20]

The formation of I from toluene, like the formation of III, V, VI, and VIII from the other alkylbenzenes, can be explained by the following scheme, Scheme 1.

The intermediate peroxide radical (XI) may react with phosphorus trichloride to give alkylphosphonic dichloride, phosphorus oxychloride, and atomic chlorine (Path 1) or the alkyl radical and two mol of phosphorus oxychloride (Path 2), as presented by Mayo *et al.*[6] Competing with these reactions, however, the radicals of a low ionization potential, such as the benzyl radical,[7] may transfer an electron to the phosphorus trichloride–oxygen complex, thus resulting in the benzylic cation or the ionic complex $[C_6H_5\overset{+}{C}R_1R_2\dot{P}Cl_3\text{-}OO^-]$. A subsequent ionic reaction of the benzylic cation with the alkylbenzenes may give I, III, V, or VI. Isopropylbenzene gave VIII and its dimers, IX, X, and VII, but not isopropyl-2,2-diphenylpropane, which would be derived from the electrophilic attack of the 1,1-dimethylbenzyl cation on isopropylbenzene. The formation of VIII may be explained by the elimination of a proton from the methyl groups of the 1,1-dimethylbenzyl cation. The dimerization of VIII gives IX, X, and VII by means of the catalytic action of phosphorus trichloride and phosphorus oxychloride con-



Scheme 1.

taining a small amount of acid. Ethylbenzene gave only V without the elimination of a proton from the 1-methylbenzyl cation. The difference in their behavior may result from differences in the stabilities or electrophilicities of their intermediate cations. Thus, Path 4 may be favorable for the more stable and less electrophilic 1,1-dimethylbenzyl cation, whilst the competing Path 3 may be favorable for the less stable and more electrophilic 1-methylbenzyl cation.

The mechanism proposed involves an intermediate complex, which then undergoes an ionic process to give the products. The formation of such similar complexes has been postulated for the reaction of benzoyl peroxide with tertiary amines or tertiary phosphine,[8] and for the inhibitation of the polymerization of acrylonitrile, vinyl chloride, or butyl acrylate with dimethylaniline.[9]

Recently, the formation of diphenylmethane derivatives by the thermal decomposition of benzoyl peroxide in toluene in the presence of boron trifluoride has also been reported.[10] In this case, a similar mechanism may be applied.

Experimental

All the boiling points are uncorrected. The NMR spectra were obtained at 100 MHz on a JNM-TS-100 spectrometer, with TMS as the internal reference. The mass spectra were obtained on a Hitachi RMU-6 or RMU-7 spectrometer with a direct inlet. The GC–MS were obtained on a Hitachi RMS-4 spectrometer. The gas-chromatographic analyses were done using a Shimadzu GC-3AF on a 3 m×3 mmϕ column packed with 5% Ucon LB 550X on Shimalite W, Mixed Nitrate on C-22,[11] or 10% Benton 34 on Neopack 1A. The preparative work was done using a Hitachi 023 on a 1 m×12 mmϕ column packed with 10% Benton 34 on Neopack 1A.

All the reagents used in this study were commercially available and were purified in all cases except that of di-*t*-butyl peroxide by distillation until found to be at least 99% pure by glc.

General Procedure of Chlorophosphonation. A mixture of alkylbenzene (0.2 mol) and phosphorus trichloride (1.0 mol) was placed in a reaction vessel equipped with a gas inlet and an outlet tube protected from moisture by a drying tube. Dry oxygen was bubbled into the mixture at a flow rate of 100 ml/min and at a temperature of −15—0 °C for 3 hr. After the removal of a large portion of the unreacted material and the phosphorus oxychloride, the residue was distilled *in vacuo*. The yields and boiling points of the products are given in Table 2.

Table 2. Yields of products in the chlorophosphonation of alkylbenzenes

Starting Material	Yield (g)	Bp °C/mmHg
Toluene	4.8	80—113/0.8
p-Xylene	7.8	96—121/1.0
Ethylbenzene	4.5	66— 86/0.1
Diphenylmethane	4.6	180/0.1
Isopropylbenzene	4.5	80—119/0.2

Analysis. The products were treated with ethanol-triethylamine, followed by distillation *in vacuo*, except for the products obtained from the reaction of diphenylmethane. The distillates were identified by a comparison of their retention times in glc with those of authentic samples, prepared by the methods to be described below. The products obtained from the reaction of diphenylmethane were identified with the data from the NMR and mass spectra of each component as follows; *p*-benzyltriphenylmethane; NMR(CCl_4): δ 3.85 (s, 2H, methylene), 5.40 (s, 1H, methine), 6.94 and 7.06 (19H, phenyl), MS: *m/e* 334 (M^+). Diphenylmethylphosphonic dichloride; NMR(CCl_4): δ 4.73 (d, 1H, J_{PCH} 20.0 Hz, methine), 7.30 (m, 10H, phenyl), MS: *m/e* 167 (M^+-121). Also, the two products, IX and X, obtained from the reaction of isopropylbenzene were identified with the data from the NMR on each component fractionated by a preparative glc and GC–MS as follows; 4-methyl-2,4-diphenylpentene-1 (IX); NMR(CCl_4): δ 1.20 (s, 6H, methyl), 2.80 (s, 2H, methylene), 4.75 (d, 1H, J 2.0 Hz, vinyl), 5.10 (d, 1H, J 2.0 Hz, vinyl), 7.16 (10H, phenyl), GC–MS: *m/e* 236 (M^+). 4-Methyl-2,4-diphenylpentene-2 (X); NMR(CCl_4): δ 1.21 (d, 3H, J 5.0 Hz, methyl), 1.44 (s, 6H, methyl), 6.00 (qui, 1H, J 5.0 Hz, vinyl), 7.13 (m, 10H, phenyl), GC–MS: *m/e* 236 (M^+).

Authentic Samples. The following diethyl alkylphosphonates were prepared by the Arbuzov reaction of alkyl bromides with triethyl phosphite,[12] or by the Michaelis-Becker reaction of alkyl bromides with diethyl sodium phosphite;[12] diethyl benzylphosphonate[13] (II bp 121—122 °C/3 mmHg), diethyl *p*-methylbenzylphosphonate[14] (IV bp 134—135 °C/3 mmHg), diethyl 1-phenylethylphosphonate[13] (bp 120—121 °C/0.7 mmHg), diethyl 2-phenylethylphosphonate[13] (bp 154—156 °C/6 mmHg), and diethyl 2-phenylpropylphosphonate (bp 120—122 °C/0.5 mmHg). Diethyl 1-methyl-1-phenylethylphosphonate[15] was prepared by the reaction of diethyl 1-lithio-1-phenylethylphosphonate with methyl iodide (bp 92—93 °C/0.1 mmHg). The diphenylmethane derivatives were prepared by the Friedel-Crafts reaction of alkylbenzenes with their corresponding α-chloro derivatives.[4] *m*- And *p*-isopropyl-2,2-diphenylpropane[16] were prepared by the Friedel-Crafts reaction of 2,2-diphenylpropane[17] with isopropyl alcohol (bp 96—99 °C/0.1 mmHg). 1,1,3-Trimethyl-3-phenylindane (VII) was prepared by the dimerization reaction of α-methylstyrene in the presence of sulfuric acid.

The Chlorophosphonation of Toluene in the Presence of Iodine. Three grams of iodine were added to a mixture of toluene (0.2 mol) and phosphorus trichloride (1.0 mol). The chlorophosphonation was then performed in the same manner as in the general procedure. Glc analysis showed no detectable amount of a product.

The Thermal Decomposition of Di-t-butyl Peroxide[18] in a Mixture of Toluene and Phosphorus Trichloride. A mixture of phosphorus trichloride (0.3 mol), toluene (0.3 mol), and di-*t*-butyl peroxide (1.0 mol) was refluxed for 5 hr. After the removal of a large portion of the unreacted material, the residue was treated with a solution of ethanol–triethylamine. Glc analysis showed I and II in the ratio of 5.0: 1.0; the isomer distribution of the former consisted of 45.1% *o*-, 5.9% *m*-, and 49.0% *p*-isomers. When a mixture of toluene and di-*t*-butyl peroxide was refluxed in the absence of phosphorus trichloride, only bibenzyl was obtained.

The Reaction of Benzyl Chloride and Toluene in the Presence of Phosphorus Trichloride or Phosphorus Oxychloride. A mixture of benzyl chloride (0.1 mol), toluene (0.1 mol), and phosphorus trichloride (1.0 mol) or phosphorus oxychloride (1.0 mol) was stirred under a nitrogen atmosphere at room temperature for 4.5 hr. Glc analysis showed no detectable amount of a product.

Photochemical Reaction of Benzyl Chloride in Toluene.[19] A mixture of toluene (4 g) and benzyl chloride (3 g) in a

Pyrex tube was irradiated with a high-pressure mercury arc at room temperature for 24 hr. The formation of bibenzyl alone was observed by glc. When phosphorus trichloride (7 g) was added to the mixture, and it was then irradiated in the same manner as above, neither bibenzyl nor I could be detected.

Dimerization Reaction of α-Methylstyrene. *a)*: A mixture of VIII (12 g) and phosphorus trichloride (13.7 g) was allowed to stand for 40 hr, protected from atmospheric moisture by a drying tube. After the removal of the VIII and the phosphorus trichloride by means of an aspirator, dimers were obtained by vacuum distillation (yield, 2.5 g; bp 86—98 °C/0.2 mmHg).

b): Phosphorus oxychloride (15 g) was used in place of phosphorus trichloride, and the reaction was carried out in a manner similar to that in *a)* (yield, 6.5 g; bp 84—98 °C/0.2 mmHg).

c): A mixture of phosphorus trichloride (7 g) and phosphorus oxychloride (7.5 g) was used in place of phosphorus trichloride, and the reaction was carried out in a manner similar to that in *a)* (yield, 4.5 g; bp 89—103 °C/0.5 mmHg).

d): A mixture of VIII (2 g), phosphorus oxychloride (60 g), and phosphoric acid (2 g) was allowed to stand for 15 hr. After the distillation of the phosphorus oxychloride, the solution was washed with water and extracted with ether. Glc analysis showed only VII.

Photochemical Reactions of Some 1-Aryl-1,2-propanediones[1)]

Yoshiro OGATA and Katsuhiko TAKAGI

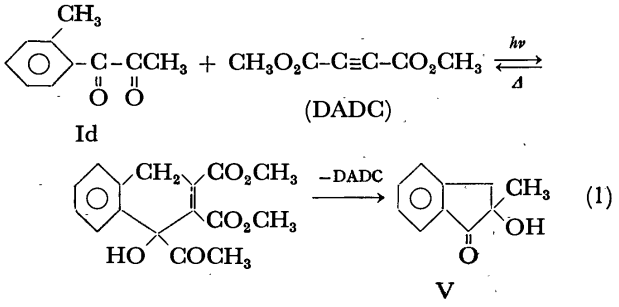
Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received January 7, 1974)

Irradiation of four 1-aryl-1,2-propanediones (Ia—Id) with over 300 nm light in 2-propanol gives reduction products identified to be the corresponding pinacols or hydrols formed by the reduction at the aroyl (but not acetyl) oxygen. The products from 1-(*o*-tolyl)-1,2-propanedione (Id) can also be accounted for by the initial hydrogen abstraction from *ortho* methyl by the aroyl carbonyl oxygen. Their photoreactivities are discussed as regards their electronic emission spectra and triplet configuration.

Sometimes one of the two carbonyls in unsymmetrical α-dicarbonyl compounds is selectively photoreduced,[2,3)] *e.g.*, unsymmetrical benzils are photoreduced at a carbonyl with a stronger electron-withdrawing group.[4)] The product is not always determined by the hydrogen abstraction with excited diketone, because the 1,2-hydrogen migration from the resulting ketyl radical being sometimes significant.[5,6)] Intramolecular H abstraction reactions might be utilized to see which of the two carbonyls really abstracts a H atom on the basis of sterically favorable proximity. The intramolecular H transfer is specific as revealed by the fact that the 1,5-shift predominates over the 1,6-shift, particularly in acyclic ketones which are photoreduced with 100% γ-H abstraction.[7)]

Cyclization of 1-(*o*-tolyl)-1,2-propanedione to 2-hydroxy-2-methylindanone (V) on irradiation has been reported by Bishop and Hamer.[8)] They preferred a mechanism *via* benzocyclobutanol to that *via* photoenol (VIII).[8b,c)] We have obtained some evidence for a six-membered transition state (1,5-shift) followed by 1,2-shift, *e.g.*, trapping of the intermediary enol(VII) with dimethyl acetylenedicarboxylate (DADC) as shown below.



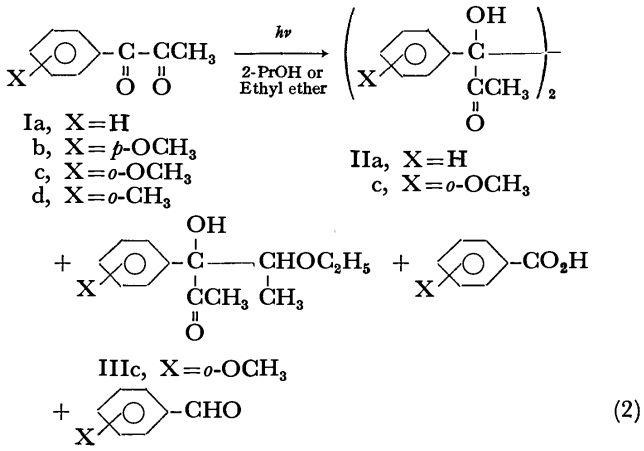
(1)

From their interest in the photoreduction behavior of alkyl aryl α-diketones, the authors present some results on the correlation of photoreactivity with electronic configuration.

Results and Discussion

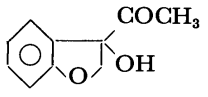
Irradiation of α-Diketones. 1-Aryl-1,2-propanediones (Ia—Id) were irradiated in dilute 2-propanol or ethyl ether with UV light filtered with Pyrex (>300 nm).

Ia was photoreduced at the benzoyl oxygen but not the acetyl oxygen. A reduction dimer, 1,2-diacetyl-1,2-diphenylethanediol (IIa, 10%) was obtained. The major product was benzoic acid (23%) which seems



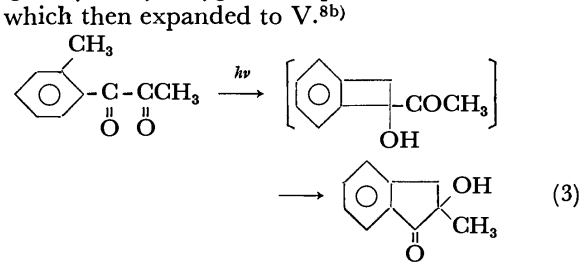
(2)

to be derived from benzoyl radical *via* photodecomposition. In the case of *p*-methoxy derivative (Ib), a complex mixture consisting of more than five components was obtained. The major product was *p*-anisaldehyde (*ca.* 40%) along with a small amount of *p*-anisic acid, all attempts for isolation of other components in a pure form being unsuccessful. The photodecomposition rate was *ca.* 5 times as slow as that of Ia. Photochemical behavior of Ic (*o*-OCH_3) is quite different from that of Ia and Ib. It is smoothly reduced in ether to a dimer (IIc, 550 mg) and a 1:1 adduct of ether (IIIc, 100 mg) along with a trace of *o*-anisic acid. The yield including all recovered materials becomes 90%. There is no product which is reduced at the acetyl oxygen or cyclized by the intramolecular reduction to benzofuran derivative (IV).



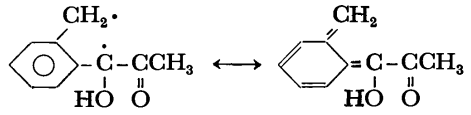
IV

Photolysis of 1-(o-Tolyl)-1,2-propanedione (Id). The photocyclization of Id to indanone (V) was reported by Bishop and Hamer, who assumed either a mechanism involving hydrogen abstraction of *o*-CH_3 hydrogen by acetyl oxygen or a presumed intermediate (VI) which then expanded to V.[8b)]



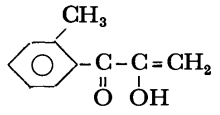
(3)

We postulated an alternative mechanism involving an enol intermediate for the photocyclization of Id on the basis of trapping of intermediary enol, VII.[9]



VII

The change of UV spectrum of Id in degassed cyclohexane on irradiation with 366 nm light (Fig. 1) illustrates the gradual disappearance of Id (λ_{max} 257 nm) with a simultaneous increase in V (λ_{max} 242 and 250 nm). The two isosbestic points at 253 and 297 nm indicate the stoichiometry for the conversion Id→V without accumulation of intermediates such as enols (VII and VIII).



VIII

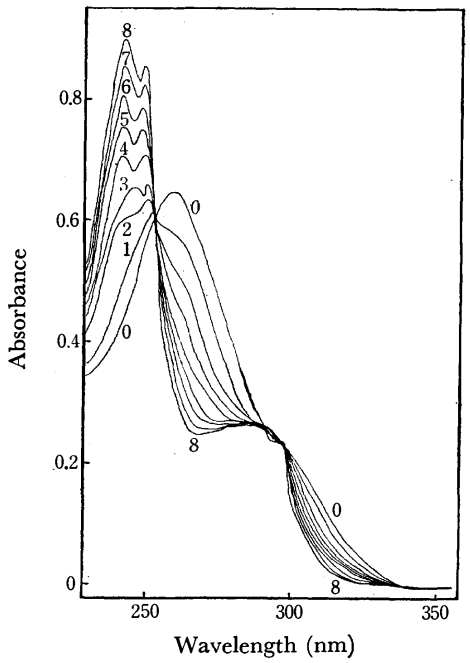


Fig. 1. UV absorption of 1-(*o*-tolyl)-1,2-propanedione in cyclohexane in a 1 cm square cell, degassed and sealed, followed by successive irradiation.
(0) Before irradiation, (1) after 30 s of irradiation, (2) after 60 s, (3) after 90 s, (4) after 135 s, (5) after 160 s, (6) after 200 s, (7) after 250 s, (8) after 300 s.

The quantum yields in various solvents for the disappearance of Id and the formation of V determined independently by glc and UV are given in Table 1.

If there is accumulation of enols (VII and/or VIII) liable to return to the starting diketone as evidenced with 1-phenyl-1,2-alkanedione,[10,11] quantum yields for the disappearance of Id estimated by means of glc at 180 °C (the injection temperature) would be lower than those by UV spectrometry at an ambient temperature. No appreciable difference can be seen between the

Table 1. Quantum yields for disappearance of Id and formation of V in various solvents[a]

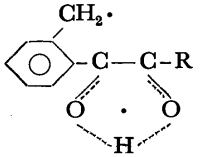
Solvent	Quantum yield for disappearance of Id	Quantum yield for formation of V
Ethyl ether	0.46 (0.44)	0.25
Cyclohexane	0.57 (0.57)	0.51
Benzene	0.62 (0.61)	0.54
Acetonitrile	0.53 (0.51)	0.42
Ethanol	0.66 (0.51)	0.43

a) Degassed solutions of *ca.* 10^{-2}M diketone were irradiated to 50—70% conversion by 366 nm light. Ferrioxalate actinometry was used. Estimation by glc technique using propiophenone as an internal standard. Values in brackets are estimated from the measurement of disappearance of α-diketone $n\pi^*$ absorption around 400 nm.

yields from glc and UV (Table 1), suggesting no accumulation of enol although there may be the enol of short life. The stoichiometry of the photocyclization of Id to V was also confirmed by similar quantum yields for the disappearance of Id to those for the formation of V. However, the value of the quantum yield (0.57 in cyclohexane) is small in view of the quantum efficiency of over 0.9 for the population of α-diketones at its lowest triplet. Thus, the efficiency for the intersystem crossing of S→T with benzil is known to be 0.92[12] and other aliphatic α-diketones have values 0.95—0.98.[13] Photoenolization might be expected to play a role for the triplet energy dissipation, since the emissive efficiency is generally *ca.* 0.1.[14]

α-Diketons with α-hydrogen undergo facile photoenolization followed by thermal decomposition, which tends to lower apparent yields. Variation in solvent polarity does not affect the efficiency of disappearance of Id and formation of V (Table 1). The solvent effect was also observed with 1-phenyl-1,2-alkanediones,[10,11] *i.e.*, quantum yields for disappearance of diketones tends to be slightly higher in wet acetonitrile than in benzene.

This is contrast to the Type II photoenolization and photocyclization of aromatic monoketones,[15] which are influenced by solvent polarity, especially by a hydrogen bonding on account of the suppression of reversal hydrogen shift from 1,4-biradical to the original ketone. However, since the hydrogen exchange with solvent is difficult for semidione radical IX, as judged by no incorporation of deuterium into V,[8a] the reformation of Id and formation of product V should be too fast to exchange the proton of the hydroxy group with solvent.



IX

The biradical seems to resist the hydrogen exchange by the intramolecular hydrogen bonding (IX).

Table 2. Absorption and emission spectra of α-diketones[a)]

Ar in Ar-COCOCH$_3$	abs λ_{max}^{EPA} (nm) (A)[b)]	abs λ_{max}^{IP} (nm)	phos λ_{max}^{EPA} (nm) (P)[c)]	phos λ_{max}^{IP} (nm)	$A-P$[d)] (cm^{-1})	ΔE_{ST}[f)] (cm^{-1})	E_T[e)] (kcal/mol)
	396	537	525	537	6300	1800	54.4

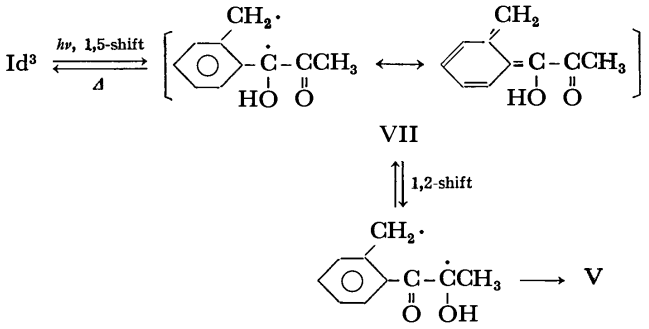
	382	400	508	540	5800	900	56.3

a) Absorption spectra were measured at room temperature and emission spectra at 77 K in EPA (ether-isopentane-alcohol, 5: 5: 2, in vol.) and IP (isopentane). b) A: absorption maximum in EPA (cm^{-1}). c) P: phosphorescence maximum in EPA (cm^{-1}). d) The energy difference between the absorption and phosphorescence maxima. e) Value obtained from phosphorescence maxima. f) The energy difference between the fluorescence and phosphorescence maxima in EPA.

The formation of V can reasonably be explained by the following Scheme.[9)]



Scheme 1.

However, an alternative direct 1,6-hydrogen shift can not completely be excluded.

Configuration of the Lowest Triplet State of α-Diketones. The configurational analysis of α-diketones in their excited states was performed in a similar way to that in our previous procedures.[4)] The results are compiled in Table 2.

Phosphorescence spectra of α-diketones generally show a broad peak; hence we make use of their emission maxima at the lowest triplet energies instead of their 0-0 bands. Their energy diagrams are illustrated in Fig. 2.

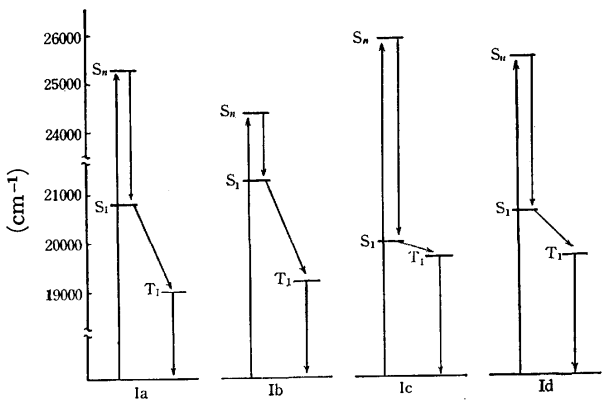


Fig. 2. Energy diagrams of α-diketones.

The $n\pi^*$ absorption maximum shifts hypsochromically (below 400 nm) as the dihedral angle between the planes of two carbonyl groups of α-diketone increases from 0 to 90°, and bathochromically (over 400 nm) as the angle increases from 90 to 180°.[16)]

Two carbonyls of 1-phenyl-1,2-propnedione (Ia) with its $n\pi^*$ at 396 nm is orthogonally twisted.[17)] The situation is the same with those for Ic and Id, since they have their $n\pi^*$ absorptions at 386 and 382 nm, respectively. An aromatic ring and a carbonyl attached to it tend to be coplanar because of the resonance between the groups. The large energy difference between the absorption and phosphorescence maxima (A–P) in EPA is ascribed to the recovery of coplanarity at the excited triplet.[17)] Judging from Table 2 and Fig. 2, the large value of (A–P) of Ic (6200 cm^{-1}) and Id (5800 cm^{-1}) similar to that of Ia (6300 cm^{-1}) seems to be due to the recovery of coplanarity of carbonyls. The coplanarity of carbonyls favors the hydrogen abstraction *via* a six-membered transition state in view of the proximity of *o*-methyl to benzoyl oxygen. α-(*o*-Tolyl)acetone, a monoketone analogue of Id, was found to yield the corresponding pinacol but not indenes.[9)] The reduction to pinacol in spite of the proximity of *ortho*-methyl to the acetyl oxygen is explained by the small ability of intramolecular hydrogen abstraction of acetyl oxygen *via* 1,6-shift.

The observed difference of photochemical behavior between Ib (*p*-OCH_3) and Ic (*o*-OCH_3) remains obscure. The trend where the *p*-methoxy substrate is easily photodecomposed was observed in the photolysis of *p*-methoxybenzil and *p*-methoxyacetophenone, *i.e.*, *p*-methoxybenzil is photodecomposed as easily as unsubstituted benzil, but the yield of the reduction is much lower,[4)] whereas, the *ortho*-substituted α-diketone, *o*-benzyloxyphenylglyoxalate, is photoreducible intramolecularly.[18a,b,c)] This difference in behavior of *p*- and *o*-methoxy-substrates can be explained by the difference in their lowest triplets, *i.e.*, $\pi\pi^*$ in the former and $n\pi^*$ in the latter. The lowest triplet levels for all these α-diketones (Ia—Id) have $n\pi^*$ character, since the phosphorescence maxima shift bathochromically with the change of solvent from EPA to isopentane (IP). Thus, the different behavior of Ic among Ia—Id should

be explained by the mixing of $n\pi^*$ triplet level with $\pi\pi^*$ or CT.

The energy difference between the lowest singlet and the triplet (ΔE_{ST}), a measure of the behavior in the intersystem crossing for singlet to triplet,[18d] seems to reflect their photochemical behavior since this type of carbonyl reduction occurs by way of triplet; *i.e.*, Ia (H) and Ib (p-OCH_3), which are more easily photodecomposed to acid and aldehyde, exhibit higher values of ΔE_{ST} ($>1800\ cm^{-1}$), while Ic (o-OCH_3) and Id (o-CH_3), which are mainly photoreduced, show a lower ΔE_{ST} ($<900\ cm^{-1}$). However, all these ΔE_{ST} are estimated to be within several kcal/mol which is negligible for a discussion of the intersystem crossing.

Experimental

All NMR spectra were taken in CCl_4 solution with TMS as an internal standard on a JEOL, C 60 HL. Mass spectra were recorded on a Hitachi RMS-4 at 70 eV ionizing voltage.

Materials. 1-Phenyl-1,2-propanedione (Ia) was prepared by oxidation of α-phenylacetone with selenium oxide.[19] 1-(p-Anisyl)-1,2-propanedione (Ib) was prepared by the reaction of *trans*-anetole with a mixture of mercuric oxide and mercuric acetate in aqueous acetic acid.[20] 1-(o-Anisyl)-1,2-propanedione (Ic): o-Methoxyisonitrosopropiophenone was prepared by reacting o-methoxypropiophenone with n-butyl nitrite passing through dry HCl, mp 133—134 °C (lit,[21] 132 °C). The oxime was converted by heating with aqueous H_2SO_4 to give a yellow liquid. It has IR band at 2830 (OCH_3), 1710 (aliph. C=O), 1660 (arom, C=O), and 760 cm^{-1} (*ortho* substituent); NMR: τ 2.2—3.2 (m, 4H, phenyl), 6.28 (s, 3H, OCH_3), and 7.69 (s, 3H, $COCH_3$). 1-(o-Tolyl)-1,2-propanedione (Id) was obtained by nitrosation of o-methylpropiophenone similarly to Ic, mp 106—108 °C, followed by conversion into the diketone by heating with H_2SO_4, bp 128—137 °C/20 mmHg.

Quantum Yields. A cyclohexane solution of *ca.* 10^{-4} and 10^{-2} M α-diketone in 1 cm square cells were degassed by three freeze-pump-thaw-cycles. Irradiation was carried out with a 300 W high-pressure mercury vapor lamp using a Corning color filter (7—51) to isolate 366 nm light. Ferrioxalate actinometry was used. Total light intensity on the 9×25 mm unmasked area of a reaction cell was estimated to be 2.1×10^{15} quanta/s.

Products from 1-Phenyl-1,2-propanedione (Ia). A 2-propanol solution (100 ml) of the diketone (700 mg) was irradiated for 6 hr until its original yellow color had disappeared, and the two products were collected by a column packed with silica gel. The first eluted product, mp 131.5—132 °C (lit,[22] mp 118.5 °C) (10% yield) was 1,2-diacetyl-1,2-diphenylethanediol (IIa). It has the following spectral properties: IR peak at 3450 (OH) and at 1700 cm^{-1} (aliph. C=O); NMR: τ 2.90 (m, 10H, phenyl), 4.52 (s, 2H, OH), 7.77 (s, 6H, $COCH_3$); Mass *m/e* 149 ($M^+/2$); UV: λ_{max}^{MeOH} 258—270 nm (an isolated phenyl ring). The second eluted product was identified to be benzoic acid (130 mg, 23%) from its IR data and mp.

Products from 1-(p-Anisyl)-1,2-propanedione (Ib). A 2-propanol solution (100 ml) of the diketone (1.01 g) was irradiated with over 300 nm light passing through a Pyrex filter; 64% of the starting diketone was recovered in spite of the long irradiation (24 hr). The glc analysis of the irradiated solution shows the presence of more than five products, in which p-anisaldehyde was a major product and confirmed by tlc, IR and UV. A small amount of p-anisic acid (5.4%) was detected.

Products from 1-(o-Anisyl)-1,2-propanedione (Ic). A dilute ethereal solution (120 ml) of the diketone (912 mg) was irradiated through a Pyrex filter to 90% conversion for 7 hr. Separation by column chromatography afforded three components. A major product was a pinacol (IIc, 550 mg); NMR: τ 3.0 (m, 8H, phenyl), 4.67 (s, 2H, OH), 6.34 (s, 6H, OCH_3), and 7.90 (s, 6H, $COCH_3$). The second product was a monoalcohol (IIIc, 100 mg); NMR: τ 3.0 (m, 7H, phenyl), 5.84 (s, 1H, OH), 6.25 (s, 3H, OCH_3), 6.74 (q, 2H, OCH_2CH_3), 8.00 (s, 3H, $COCH_3$), 8.78 (d, 3H, $OCH-CH_3$) and 9.05 (t, 3H, OCH_2CH_3). The NMR spectrum, however, did not clearly show the signal of ethoxy methine proton expected to appear at τ *ca.* 6.0 hidden by the signal of methoxy methyl and ethoxy methylene protons. The third product in a small amount was o-anisaldehyde on the basis of NMR: τ 2—3 (m, 4H, phenyl), 7.40 (s, 3H, methyl), and 0.03 (s, H, aldehyde).

Products from 1-(o-Tolyl)-1,2-propanedione (Id). A 2-propanol solution (120 ml) of the diketone (862 mg) was irradiated for 3 hr to complete the conversion and the three products were collected by a column packed with silica gel. The first eluate was the starting diketone (1.6%). The second eluate (12.6%) (mp 97—99 °C) was identified to be o-toluic acid, since it has the same spectra (IR and UV) as those of the authentic sample. The third eluate (mp 53.0—54.5 °C) was 2-hydroxy-2-methylindanone (V, 75%).[8a]

All preparative scale irradiation was conducted using UV light (>300 nm) from a high pressure mercury lamp (Halos HIP 300 W) in a Pyrex tube (ϕ 35×150 mm) under N_2 for 30 min prior to and during the irradiation.

Emission Studies. Emission studies were performed on a Hitachi MPF-2A Fluorescence Spectrophotometer with phosphorescence attachments. Fluorescence spectra were recorded at an ambient temperature using EPA (ether–isopentane–ethanol, 5:5:2 in volume) as a solvent and phosphorescence spectra were recorded at 77 K using the same solvent.

Nitration of Decamethylbiphenyl and 2,3,4,5,6-Pentamethyl-2′,3′,4′,5′,6′-pentachlorobiphenyl with Fuming Nitric Acid. Exclusive *Ortho* Orientation for the Side-chain Attack[1)]

Hitomi Suzuki, Osamu Yagiu, and Terukiyo Hanafusa

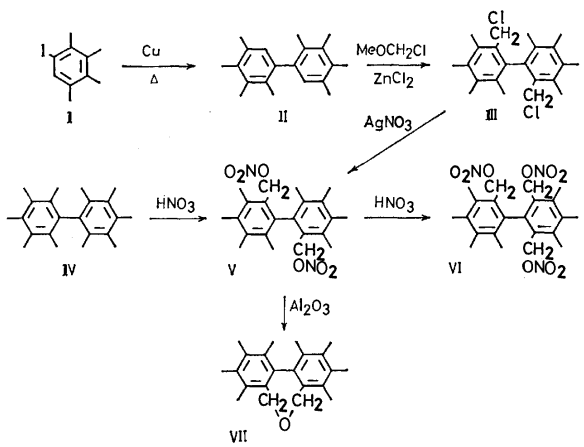
Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-sendamachi, Hiroshima 730

(Received February 6, 1974)

Products obtained by the reaction of the title compounds with fuming nitric acid in dichloromethane were investigated. Decamethylbiphenyl gave 6,6′-bis(nitrooxymethyl)-2,2′,3,3′,4,4′,5,5′-octamethylbiphenyl or 2,6,6′-tris(nitrooxymethyl)-2′,3,3′,4,4′,5,5′-heptamethylbiphenyl as the major product, depending on the amount of nitrating agent. 2,3,4,5,6-Pentamethyl-2′,3′,4′,5′,6′-pentachlorobiphenyl similarly gave 6-nitrooxymethyl-2,3,4,5-tetramethyl-2′,3′,4′,5′,6′-pentachlorobiphenyl or 2,6-bis(nitrooxymethyl)-3,4,5-trimethyl-2′,3′,4′,5′,6′-pentachlorobiphenyl. Some plausible reaction sequences for the exclusive *ortho* attack on the alkyl side-chains of biphenyl systems have been suggested.

On treatment with fuming nitric acid at low temperature, polymethylbenzenes and their derivatives undergo side-chain nitrooxylation to give benzyl nitrates in good yields. The reaction is characterized by a peculiar orientation of the products and high positional selectivity. Substitution will preferentially occur into the side-chain *ortho* to the electron-withdrawing groups and *meta* to the electron-releasing groups.[2)] For a facile nitrooxylation there should be a pair of methyl groups situated *para* one another. In order to clarify the mechanism of the reaction, studies were extended to the unusual nitration of the biphenyl systems. So far no report has appeared on the nitration of fully alkylated biphenyl systems.

Decamethylbiphenyl (IV) was treated with five molar proportions of fuming nitric acid (d=1.5) in dichloromethane below 0 °C to give a light brown paste, which upon recrystallization from ligroin yielded a crystalline solid melting at 142—144 °C as the only product (*ca.* 70% yield). The compound has a molecular formula of $C_{22}H_{28}N_2O_6$ and shows strong infrared absorptions due to $-ONO_2$ at 1632, 1275, and 854 cm^{-1}; ^1H NMR peaks at δ 1.82, 2.28, 2.30, and 5.08 with relative areas 3:3:6:2. The peak at higher field (δ 1.82) corresponds to two *ortho* methyl groups. Signals of the methylene protons appear at a considerably high field (δ 5.08) as compared to those of ordinary benzyl nitrates (δ 5.5—5.8).[3)] This can be interpreted by the structure 6,6′-bis(nitrooxymethyl)-2,2′,3,3′,4,4′,5,5′-octamethylbiphenyl (V) and suggests a configuration in which one phenyl ring lies in a plane nearly perpendicular to that of another ring, each *ortho* methyl and nitrooxymethyl group lying above the adjacent ring and subjected to a diamagnetic shielding effect. Its identity was confirmed by comparison with an authentic specimen prepared from prehnitene by the sequence shown in Scheme 1. The alternative synthesis was initiated by the Ullmann condensation of iodoprehnitene (I). The resulting 2,2′,3,3′,4,4′,5,5′-octamethylbiphenyl (II) was bis-chloromethylated with chloromethyl methyl ether in the presence of anhydrous zinc chloride. The chloride (III) so obtained was converted into V by treatment with silver nitrate in acetonitrile. The possibility of the concurrent formation of other isomeric nitrates in a significant amount was rule out by comparison of ^1H NMR spectra of the crude product with those of authentic 5,5′-bis(nitrooxymethyl)-2,2′,3,3′,4,4′,6,6′-octamethylbiphenyl (XV) and 4,4′-bis(nitrooxymethyl)-2,2′,3,3′,5,5′,6,6′-octamethylbiphenyl (XVI), obtained from iodoisodurene and iododurene, respectively, by a similar sequence to that in Scheme 1. No peak could be observed in the region δ 5.6—5.7, ascribed to the absorptions of *meta* and *para* nitrooxymethyl groups.



Scheme 1.

When the product mixture was placed on the top of an alumina column and eluted with light petroleum and diethyl ether, successively, large prisms with the composition $C_{22}H_{28}O$ (*m/e* 308) were obtained from the ether eluates in 42% yield. The compound exhibited ^1H NMR peaks at δ 2.04 (2 Me), 2.32 (4 Me), 2.40 (2 Me), 3.72 (2 CH, d; J_{gem}=12 Hz), and 4.82 (2 CH, d; J_{gem}=12 Hz); infrared band at 1036 cm^{-1} (C–O–C). These spectral data are consistent with the formulation of the product as 6,6′-(2-oxapropano)-2,2′,3,3′,4,4′,5,5′-octamethylbiphenyl (VII), which was obtained from V by the alumina-catalyzed ring closure during elution. A pair of *geminal* benzylic protons appear as a doublet

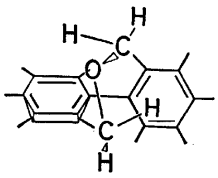


Fig. 1.

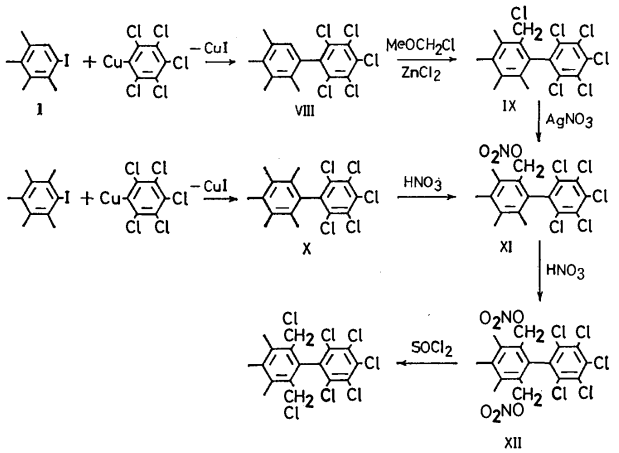
at a higher field (δ 3.72). This is ascribed to a greater diamagnetic shielding of the protons due to the induced ring current, suggesting the configuration shown in Fig. 1. Methylene signals of bisbenzyl ethers usually appear in the δ 4.6—4.9 region.[4]

With the use of a large excess of fuming nitric acid, the major isolable product was found to be 2,6,6′-tris(nitrooxymethyl)-2′,3,3′,4,4′,5,5′-heptamethylbiphenyl (VI), the structure of which was established by elemental analysis as well as by comparison of the spectra of related compounds. Isolation of VI as pure crystalline solid was difficult. Most of the product (80%) remained as non-crystallizable syrupy substance. This result is in contrast to the nitration of hexamethylbenzene under similar conditions to give predominantly 5,6-bis(nitrooxymethyl)-1,2,3,4-tetramethylbenzene.[5]

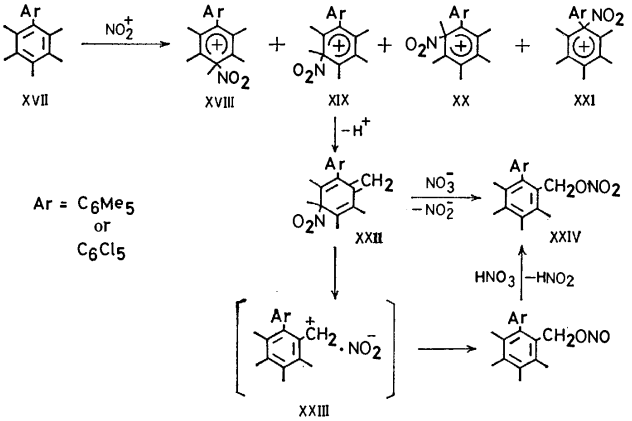
2,3,4,5,6-Pentamethyl-2′,3′,4′,5′,6′-pentachlorobiphenyl (X) was comparatively stable towards the action of cold fuming nitric acid in dichloromethane, but readily underwent side-chain nitrooxylation at room temperature to give a nitrate in 84% yield. The nitrate was identified as 6-nitrooxymethyl-2,3,4,5-tetramethyl-2′,3′,4′,5′,6′-pentachlorobiphenyl (XI) by direct comparison with the authentic sample prepared from 2,3,4,5-tetramethyl-2′,3′,4′,5′,6′-pentachlorobiphenyl (VIII) by chloromethylation to IX followed by treatment with silver nitrate in hot acetonitrile (Scheme 2).



Scheme 2.

When either X or XI was treated with a large excess of fuming nitric acid in an ice bath and the mixture was left to stand for several hours, the temperature of the system being allowed to gradually rise to room temperature, the only product was 2,6-bis(nitrooxymethyl)-3,4,5-trimethyl-2′,3′,4′,5′,6′-pentachlorobiphenyl (XII), which was obtained almost quantitatively and resisted further reaction even on prolonged contact with the nitrating agent. Proof of the symmetrical structure of XII was obtained from the ^{1}H NMR spectrum which contained the expected sharp bands at δ 2.37, 2.43, and 5.17 in a 3:6:4 ratio of intensities. Thus, irrespective of the electronic nature of substituent groups on the opposite ring, the side-chain substitutions in the polymethylated biphenyl systems are found to occur exclusively on the methyl groups adjacent to the phenyl-phenyl bond. The nitrooxymethyl group is a versatile unit, and the present reaction provides an attractive entry into some polysubstituted biphenyls with functionalized substituents at *ortho* positions.

The exclusive *ortho* orientation for the side-chain attack might be rationalized as follows: electrophilic attack of nitronium ion on biphenyl (XVII) can theoretically lead to a mixture of four benzenium ions (XVIII to XXI) (Scheme 3). Although the attack



Scheme 3.

of nitronium ion at C_4 will be most favored with unsubstituted biphenyl due to the electromeric diffusion of positive charge into the adjacent ring, the ion XVIII can not enjoy such stabilizing effect, because it exists in a non-planar configuration to minimize the steric interaction of four *ortho* substituents. Contribution of ions XX and XXI is supposed to be much less important, since the access of the nitronium ion to the ring positions C_1 and C_2 to form these ions would undergo considerable steric hindrance. Thus, ion XIX in which the charge is most effectively dissipated by three methyl groups seems to be the most favored intermediate ion, from which the proton release would occur preferentially on the methyl group bonded to the more positively polarized ring carbon at the 6-position, giving a methylene cyclohexadiene (XXII). Heterolytic scission of the carbon-nitrogen bond in XXII will form a benzyl cation-nitrite ion pair (XXIII); recombination at benzylic carbon atom *via* carbon-oxygen bond followed by oxidation will afford the nitrate (XXIV). A possible alternative mechanism for the conversion of XXII into XXIV involves the attachment of the nitrate ion to the terminal methylene carbon of XXII, redistribution of electrons to regain the aromatic system, and concurrent departure of the nitro group as an anion, leading to the formation of XXIV.[6] It is not clear which course is actually followed.

Experimental

All melting points were determined with a hot-stage apparatus and are uncorrected. Infrared spectra were obtained as Nujol on a Jasco 402G spectrophotometer. ^{1}H NMR measurements were carried out in deuteriochloroform solutions on a Varian T-60 spectrometer at probe temperatures against internal tetramethylsilane.

Decamethylbiphenyl (IV)[7] was prepared by the Ullmann reaction of iodopentamethylbenzene and purified by chro-

matography on alumina with light petroleum as an eluant. Mp 259—262 °C.

2,3,4,5,6-Pentamethyl-2',3',4',5',6'-pentachlorobiphenyl (X). A Grignard reagent was prepared from magnesium (1.3 g) and hexachlorobenzene (14 g) in tetrahydrofuran (40 ml). Cuprous iodide (9.6 g) was added to this solution, and the mixture was stirred for some hours at room temperature. Iodopentamethylbenzene (13.7 g) was then added and the reaction mixture was heated under reflux for 8 hr and poured into water. The insoluble solid was filtered off and extracted with benzene with a Soxlhet extractor. The extract was concentrated and passed over alumina to give pentachlorobenzene from light petroleum eluates and X (5.1 g; 25.7%) from benzene eluates. Mp 276—278 °C.

Found: C, 51.02; H, 3.70%. Calcd for $C_{17}H_{15}Cl_5$: C, 51.49; H, 3.81%.

2,3,4,5-Tetramethyl-2',3',4',5',6'-pentachlorobiphenyl (VIII) was prepared in a similar manner from iodoprehnitene (I). Mp 281—283 °C.

Authentic specimens of nitrooxymethyl compounds XIII, XIV, and IX were prepared by essentially the same procedure involving chloromethylation of the respective biphenyls with chloromethyl methyl ether, followed by treatment of the chlorides with silver nitrate in acetonitrile. Physical properties of a series of polysubstituted biphenyls prepared in the context of the present work are summarized in Table 1.

6,6'-Bis(chloromethyl)-2,2',3,3',4,4',5,5'-octamethylbiphenyl (III). A mixture of 2,2',3,3',4,4',5,5'-octamethylbiphenyl (II; 0.30 g),[8] chloromethyl methyl ether (3 g), and anhydrous zinc chloride (0.04 g) was heated with stirring at 40—50 °C for 1 hr, and then poured into water to give III (0.28 g; 68%), which was crystallized from ligroin in the form of fine needles, mp 205—206 °C.

Found: C, 72.46; H, 7.65%. Calcd for $C_{22}H_{28}Cl_2$: C, 72.72; H, 7.77%.

By a similar treatment, 2,2',3,3',4,4',6,6'-octamethylbiphenyl[9] was converted into *5,5'-bis(chloromethyl)-2,2',3,3',4,4',6,6'-octamethylbiphenyl (XIII)*, mp 211—213 °C; 2,2',3,3',5,5',6,6'-octamethylbiphenyl[10] and 2,3,4,5-tetramethyl-2',3',4',5',6'-pentachlorobiphenyl (VIII) were converted into *4,4'-bis(chloromethyl)-2,2',3,3',5,5',6,6'-octamethylbiphenyl (XIV)*, mp 246—247 °C, and *6-chloromethyl-2,3,4,5-tetramethyl-2',3',4',5',6'-pentachlorobiphenyl (IX)*, mp 265—268 °C, respectively. VIII required an extended reaction period to obtain satisfactory conversion into IX.

XIII: Found: C, 72.84; H, 7.62%. Calcd for $C_{22}H_{28}Cl_2$: C, 72.72; H, 7.77%.

XIV: Found: C, 72.68; H, 7.82%. Calcd for $C_{22}H_{28}Cl_2$: C, 72.72; H, 7.77%.

IX: Found: C, 47.21; H, 3.19%. Calcd for $C_{17}H_{14}Cl_6$: C, 47.37; H, 3.27%.

6,6'-Bis(nitrooxymethyl)-2,2',3,3',4,4',5,5'-octamethylbiphenyl (V). A warm solution of silver nitrate (0.75 g) in acetonitrile (20 ml) was added all at once with stirring to a hot solution of III (0.31 g) in the same solvent (30 ml). The mixture was stirred with heating for several hours, silver chloride being separated by filtration. Evaporation of the solvent *in vacuo*, followed by crystallization of the residue

XVI: Found: C, 63.48; H, 6.65%. Calcd for $C_{22}H_{28}N_2O_6$: C, 63.45; H, 6.78%.

XI: Found: C, 44.39; H, 3.12; N, 3.25%. Calcd for $C_{17}H_{14}Cl_5NO_3$: C, 44.62; H, 3.08; N, 3.06%.

Procedure for Nitration of Fully Substituted Biphenyls. A mixture of a biphenyl (IV or X; 0.005 mol) and dichloromethane (10 ml) was vigorously stirred and fuming nitric acid (d=1.5; 1.6 g) in the same solvent (5 ml) was added dropwise at −5 to 0 °C to give a dark brown solution. The mixture was allowed to stand at room temperature for several hours, during the course of which the initial dark color faded to light yellow. It was then poured into water and the organic layer was thoroughly washed with water. Evaporation of the solvent left a light brown paste (in the case of IV) or a white crystalline solid (in the case of X), which was inspected by IR, ^1H NMR, or thin-layer chromatography. Nitrates were obtained by crystallization of the crude product from a mixture of dichloromethane and light petroleum, and identified by their spectra and elemental analyses, or by direct comparison with the authentic specimens.

Chromatography on alumina of the crude nitration product obtained from IV gave unchanged material and nitrooxymethyl compounds from light petroleum eluates, and a cyclic ether VII (42%) from diethyl ether eluates. Recovery of nitrooxymethyl compounds was very unsatisfactory.

VI: Found: C, 56.29; H, 5.78; N, 8.59%. Calcd for $C_{22}H_{27}N_3O_9$: C, 55.34; H, 5.70; N, 8.80%.

IR: 1624, 1274, and 857 cm^{-1} ($-ONO_2$).

VII: Found: C, 85.47; H, 9.09%. Calcd for $C_{22}H_{28}O$: C, 85.66; H, 9.15%.

XI: Found: C, 44.52; H, 3.11; N, 3.08%. Calcd for $C_{17}H_{14}Cl_5NO_3$: C, 44.62; H, 3.08; N, 3.06%.

IR: 1632, 1277, and 855 cm^{-1} ($-ONO_2$).

XII: Found: C, 39.46; H, 2.55; N, 5.28%. Calcd for $C_{17}H_{13}Cl_5N_2O_6$: C, 39.37; H, 2.53; N, 5.40%.

IR: 1632, 1276, and 842 cm^{-1} ($-ONO_2$).

We are grateful to the Ministry of Education of Japan for financial support of this work.

Aromatic Nucleophilic Substitution. III.[1] Meisenheimer Complexes in the Reactions of 1-(*N*,*N*-Dialkylamino)-2,4-dinitronaphthalenes with Sodium Methoxide

Shizen SEKIGUCHI, Katsuo SHINOZAKI, Tetsuo HIROSE
Kohji MATSUI, and Kiyoshi SEKINE

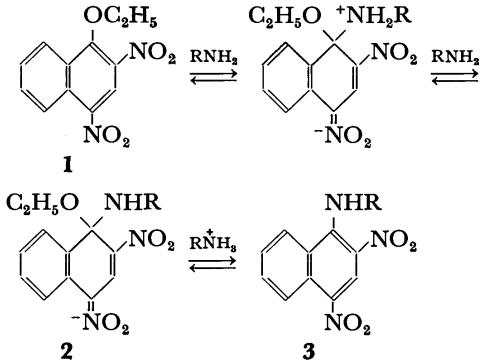
(Received February 6, 1974)

The intermediates in the reaction of 1-(*N*,*N*-dimethylamino)-2,4-dinitronaphthalene (**9**) with sodium methoxide have been studied in the mixtures of DMSO and CH_3OH. The NMR spectra of the equimolar mixture of **9** and sodium methoxide indicate that **9** and a 1,1-disubstituted Meisenheimer complex coexist immediately after mixing, and that nearly all **9** changed into the Meisenheimer complex 15 min after mixing. The addition of 2 mol of sodium methoxide to 1 mol of **9** gave no 1,1,3,3-tetrasubstituted 2,4-dinitronaphthalene Meisenheimer complex. 1-Piperidino- or 1-(*N*-methyl-*N*-*n*-butylamino)-2,4-dinitronaphthalene reacted with sodium methoxide to give a similar Meisenheimer complex.

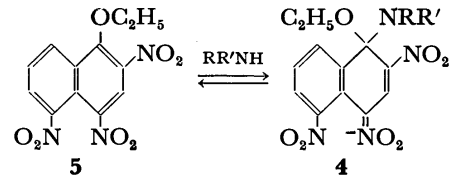
Many Meisenheimer complexes have been prepared by nucleophilic attack on polynitroaromatic compounds, the reactions being extensively studied and the results reviewed in detail.[2]

In the nucleophilic substitution reaction of 1-ethoxy-2,4-dinitronaphthalene (**1**) with primary amines, Orvik and Bunnett[3] confirmed the presence of the Meisenheimer complex (**2**, hereinafter referred to as σ complex) during the course of reaction by means of the kinetics and visible spectra as shown in Eq. (1). We reported on the presence of σ complexes (**4**) in the



(1)

reactions of **1** or 1-ethoxy-2,4,5-trinitronaphthalene (**5**) with secondary amines by NMR measurement:[1] Only

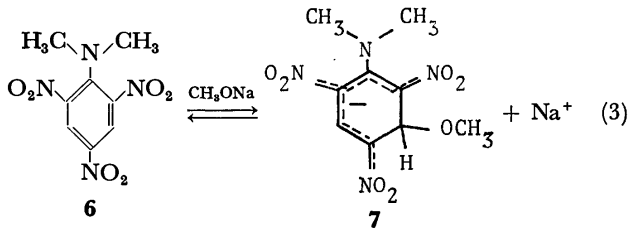


(2)

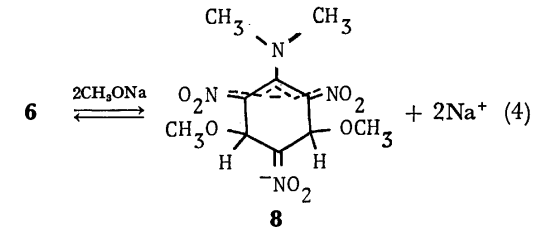
a few papers have appeared on the reactions of amino-substituted polynitromaromatic compounds with sodium or potassium alkoxides.

Crampton and Gold[4] reported that 1-(*N*,*N*-dimethylamino)-2,4,6-trinitrobenzene (**6**) reacted with CH_3ONa to give a 1,3-disubstituted Meisenheimer complex (**7**) and that addition of excess CH_3ONa produced dianion (**8**).

We have carried out the reactions of 1-(*N*,*N*-dialkylamino)-2,4-dinitronaphthalenes with CH_3ONa in DMSO–CH_3OH mixture and found that 1,1-disubstituted σ complexes were formed but no 1,3-disubstituted σ

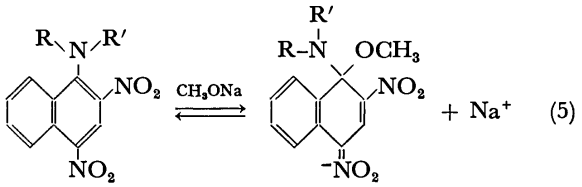


(3)



(4)

complex, and that the reactions give an easy method for the preparation of 1,1-disubstituted naphthalene σ complexes containing both an alkoxyl- and a dialkylamino groups at C-1:



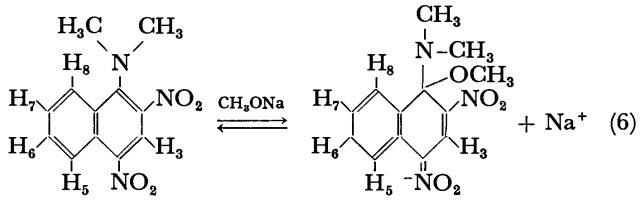
(5)

This paper reports on the presence of σ complexes in the reactions of 1-(*N*,*N*-dialkylamino)-2,4-dinitronaphthalenes with CH_3ONa.

Results and Discussion

*Reaction of 1-(*N,N*-Dimethylamino)-2,4-dinitronaphthalene (9) with Sodium Methoxide.* The addition of methanolic CH_3ONa to a solution of **9** in DMSO (**9** 2.19×10^{-5} mol/l, CH_3ONa 2.05×10^{-1} mol/l) gave a red species (λ_{max} 351, 264, and 518 nm). Not only the shape but also the positions and intensities of these bands are similar to those of 1,1-disubstituted polynitronaphthalene σ complexes.[1,2]

The NMR spectra of the reaction system are shown in Fig. 1. Immediately after methanolic CH_3ONa was added to **9** in DMSO (0.20 ml) (CH_3ONa 1.68×10^{-4}



9 **10**

mol, **9** 1.68×10^{-4} mol), to which a small amount of CH_3OH had been added so that the volume ratio (DMSO/CH_3OH) was 1.5, the H_3 band intensity of **9** (δ 8.61, Fig. 1A, 1B) decreased, and, at the same time,

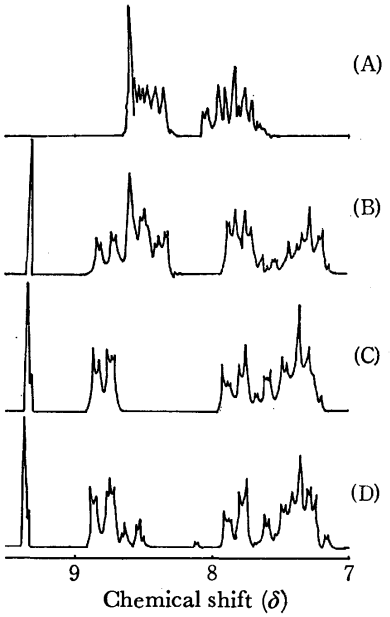


Fig. 1. NMR spectra relevant to the reaction of **9** with CH_3ONa: (A) **9** before addition of CH_3ONa; (B), (C), and (D) immediately, *ca.* 15 min, and 24 hr, respectively, after addition of CH_3ONa.

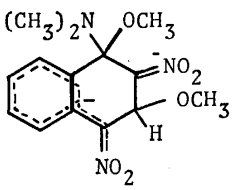
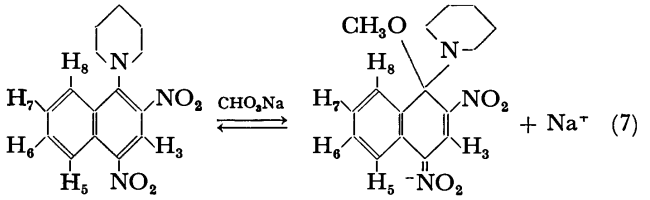
its band position was shifted to δ 9.32, attributed to H_3 of **10**.[1,4] A new multiplet appeared at δ 7.33, attributed to H_6 and H_7 of **10** (Fig. 1B).[1,4] The calculation of band intensity indicates the presence of the H_3 band of **9**, which overlaps the H_8 band (d, δ 8.79) of **10**. Thus, the spectrum (Fig. 1B) indicates that compounds **9** and **10** coexist in this reaction system. The bands at δ 8.45 (Table 1) disappeared 15 min after mixing (Figs. 1B and 1C). Even 1 hr after mixing, the spectrum of the system was the same as that in Fig. 1C. After 24 hr a part of **10** decomposed to **9** since bands attributed to **9** appeared (Fig. 1D).[5]



11

When two mol of CH_3ONa had been added to one mol of **9** under similar conditions, the same spectrum as that in Fig. 1C was obtained. In the case of **9**, therefore, no dianion such as **11**, which is similar in structure to **8**, was produced. When the solvent ratio was varied, the chemical shift of each proton band of **10** was substantially the same in both cases (Table 1). The results and the large shift of each proton band position in the conversion of **9** into **10** indicate that the intermediate in the reaction of **9** with CH_3ONa is not a charge transfer complex, but a σ one.[6-8]

Reaction of 1-Piperidino-2,4-dinitronaphthalene (12) with Sodium Methoxide. The addition of methanolic CH_3ONa to a solution of **12** in DMSO (**12** 2.39×10^{-5} mol/l, CH_3ONa 2.39×10^{-2} mol/l) gave a red species (λ_{max} 352, 361, and 517 nm). The spectrum was similar in shape, position and intensity to that of the complex in the reaction of **9** with CH_3ONa.



12 **13**

The NMR spectra of the reaction system are shown in Fig. 2[9] [**12** 1.83×10^{-4} mol, CH_3ONa 1.83×10^{-4} mol, DMSO/CH_3OH 0.62 ml (4.2/1)].

The time-dependent change of the spectrum of the reaction system differs from that in the reaction of **9** with CH_3ONa. Immediately after mixing, the H_3 bands of **12** and **13** appeared at δ 8.65 and 9.31, respectively (Figs. 2A and 2B). The H_8, H_5, and $H_{6,7}$ bands of **12** appeared at δ 8.78, 7.71, and 7.29, respectively, besides the bands of the aromatic protons of **12** (Fig. 2B). These results indicate that **12** and **13** coexist immediately after mixing. Twenty-four hours after mixing, nearly all **12** changed into **13** (Fig. 2C). Calculation of band intensity indicates that 43 hr after mixing a part of **13** decomposes to **12**.[5]

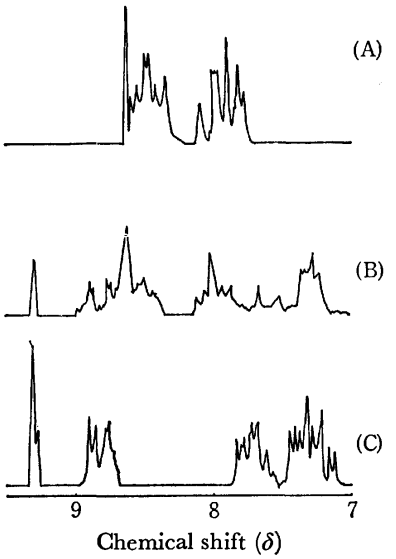


Fig. 2. NMR spectra relevant to the reaction of **12** with CH_3ONa: (A) **12** before addition of CH_3ONa; (B) and (C) immediately and 24 hr, respectively, after addition of CH_3ONa.

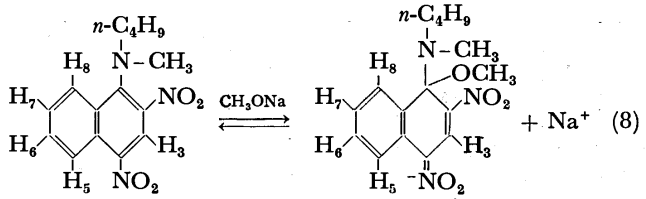
TABLE 1. RELEVANT NMR DATA

Compound	H_3	H_8	H_5	$H_{6,7}$	Solvent ratio $\frac{DMSO}{CH_3OH}$ (vol.)
9	8.61 (s)	8.45 (m)		7.85 (m)	DMSO[b]
10	9.32 (d)	8.79 (d)	7.79 (d)	7.33 (m)	1.5
	9.31 (d)	8.80 (d)	7.65 (d)	7.23 (m)	4.4
12	8.60 (s)	8.47 (d)		7.92 (m)	DMSO[b]
13	9.23 (s)	8.78 (d)	7.71 (m)	7.29 (m)	4.3
14	8.65 (s)	8.50 (m)		7.94 (m)	DMSO[b]
15	9.31 (s)	8.83 (m)	7.61 (m)[c]	7.21 (m)	4.5

a) Chemical shifts were described in δ values relative to TMS. b) NMR spectra were measured in DMSO only. c) The doublets were split into multiplets by long range coupling.

Reaction of 1-(N-Methyl-N-n-butylamino)-2,4-dinitronaphthalene (14) with Sodium Methoxide. As in the reaction of **9** or **12** with CH_3ONa, the addition of methanolic CH_3ONa to a solution of **14** in DMSO (**14**, 2.47×10^{-5} mol/l; CH_3ONa, 2.47×10^{-1} mol/l) gave a red species (λ_{max} 349, 364, and 516 nm). The spectrum was also similar to that obtained in the reaction of **9** or **12** with CH_3ONa.



14 **15**

The NMR spectra of the reaction system are shown in Fig. 3[9] [**14** 1.79×10^{-4} mol, CH_3ONa 1.79×10^{-4} mol, DMSO/CH_3OH 0.24 ml (4.5/1)]. Only the bands attributed to the aromatic protons of **15** appeared immediately after mixing (Figs. 3A and 3B). The spectrum did not substantially change 24 hr after mixing, but a part of **15** decomposed to **14** 43 hr after mixing (Fig. 3C).[5]

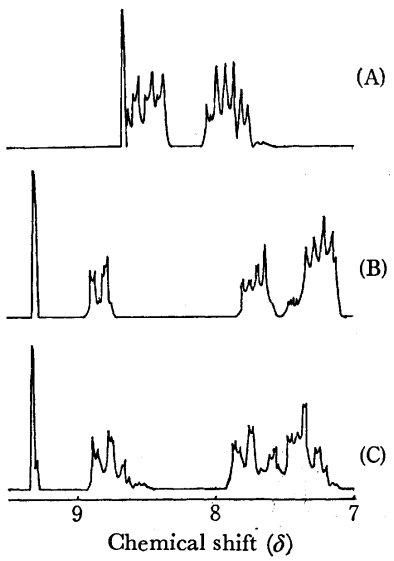


Fig. 3. NMR spectra relevant to the reaction of **14** with CH_3ONa: (A) **14** before addition of CH_3ONa; (B) and (C) immediately and 43 hr, respectively, after addition of CH_3ONa.

It is thus concluded that a 1,1-disubstituted naphthalene σ complex is formed in the reaction of 1-(*N,N*-dialkylamino)-2,4-dinitronaphthalene with CH_3ONa. Bunnett and Zahler[10] stated that the formation of an anion by the dissociation of a complex depends upon the stability of the anion: the ease of anion separation decreases in the order alkoxide ions>amide ions.

The fact that no nucleophilic substitution by methoxide ion took place confirms the interpretation of Bunnett and Zahler. For the sake of confirmation relevant NMR spectral data are included in Table 1.

Experimental

NMR spectra were recorded on a Varian A-60D spectrometer. Visible spectra were measured on a Hitachi-124 UV-VIS spectrophotometer. Compounds **9**, **12**, and **14** were prepared according to the method given previously.[1]

Base-induced Reactions of 2-Substituted 2-Bromodimedones

Tadahiro WAKUI, Yoshio OTSUJI, and Eiji IMOTO

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai-shi, Osaka 591

(Received February 12, 1974)

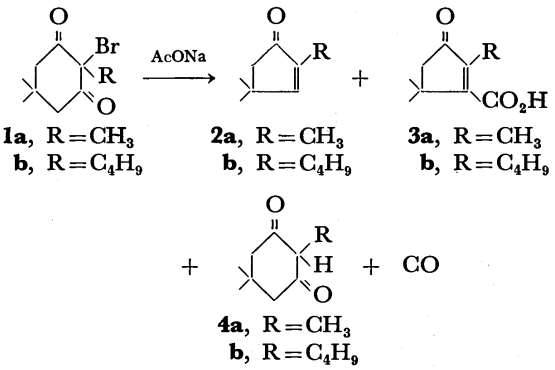
The reactions of 2-substituted 2-bromodimedones with various bases were studied. The behavior of the dimedones changed with the base and substituent attached to the dimedones. Treatment of 2-alkyl-2-bromodimedones (**1a** and **1b**) with a weak nucleophilic base such as sodium acetate afforded 2-alkyl-4,4-dimethyl-2-cyclopenten-1-ones (**2a** and **2b**), 2-alkyl-5,5-dimethyl-3-oxo-1-cyclopentene-1-carboxylic acids (**3a** and **3b**), 2-alkyl-5,5-dimethylcyclohexane-1,3-diones (**4a** and **4b**) and carbon monoxide. A similar treatment of 2,2-dibromodimedone (**7**) with the weak nucleophilic base gave 2,3-dibromo-4,4-dimethyl-2-cyclopenten-1-one (**8**), 2-bromo-5,5-dimethylcyclohexane-1,3,4-trione (**9**) and 2-bromodimedone (**10**). However, the reactions of **1a** and **7** with a strong nucleophilic base such as sodium ethoxide gave mainly the open-chain products, ethyl 3,3-dimethyl-5-oxoheptanoate (**5a**) and diethyl 3,3-dimethylglutarate (**11**). On treatment of **1a** with silver acetate, a debrominative dimerization occurred to produce the dimer **6**. The mechanisms of these reactions were discussed.

The preparation of substituted cyclopentenones has drawn considerable attention. One available method is the conversion of cyclohexane-1,3-dione derivatives into cyclopentenones. Spencer and co-workers[1,2] reported that the thermolysis of 2-acetoxy-2-alkylcyclohexane-1,3-diones gives carbon monoxide and 2-alkylcyclopentenones. However, an application of this method is limited because of the difficulty to prepare the acetoxydiones. Büchi and Egger[3] found that 2-chloro-2-(2-pentynyl)-cyclohexane-1,3-dione can be converted into 2-(2-pentynyl)-2-cyclopenten-1-one in an 80% yield upon treatment with sodium carbonate. Since 2-chlorocyclohexane-1,3-dione derivatives are readily accessible, this base-induced ring contraction seems to have a wide applicability, provided that the ring contraction is a general reaction. We recently found that the chemical behavior of 2-bromocyclohexane-1,3-diones varied remarkably with the nature of the base employed and also with the substituent attached to the diones. This paper deals with a systematic study on the reactions of 2-substituted 2-bromodimedones with various bases.

Results and Discussion

Reaction Products. The reactions of 2-substituted 2-bromodimedones with various bases were carried out in tetrahydrofuran (THF) or in ether, and the products were isolated and then characterized. The products isolated are summarized in Table 1.

The reaction of 2-bromo-2-methyldimedone (**1a**) with an equivalent of sodium acetate in THF under reflux afforded 2,5,5-trimethyl-2-cyclopenten-1-one (**2a**), 2,4,4-trimethyl-3-oxo-1-cyclopentene-1-carboxylic acid (**3a**) and 2-methyldimedone (**4a**). A similar reaction of 2-bromo-2-butyldimedone (**1b**) with sodium acetate gave the corresponding products, **2b**, **3b**, and **4b**. Evolution of CO was observed during the course of these reactions.



1a, R=CH_3 **2a**, R=CH_3 **3a**, R=CH_3
b, R=C_4H_9 **b**, R=C_4H_9 **b**, R=C_4H_9

4a, R=CH_3
b, R=C_4H_9

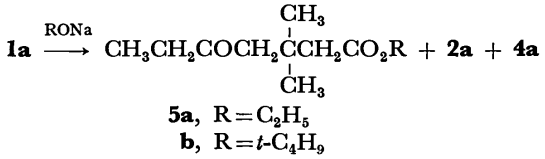
However, when **1a** was treated with two equivalents

Table 1. Reactions of 2-substituted 2-bromodimedones with bases in THF

Compd	Base	Reaction time, hr	Products (Yield, %)			
			Cyclopentenone	Cyclopentenone-carboxylic acid		Others
1a	AcONa	4	**2a** (21)	**3a** (37)		**4a** (7.5)
1b	AcONa	4	**2b** (35)	**3b** (15)		**4b** (5.3)
1a	C_2H_5ONa[a]	5	**3a** (5.6)		**5a** (64)	**4a** (9)
1a	*t*-C_4H_9ONa	5	**2a** (12)			**4a** (34)
1a	AcOAg	5	**2a** (17)	**3a** (10)	**6** (53)	**4a** (7.5)
1a	AcOAg	18	**2a** (19)	**3a** (3)	**6** (22)	**4a** (9)
7	AcONa	4	**8** (25)		**9** (16)	**10** (32)
7	Na_2CO_3	4	**8** (16)		**9** (10)	**10** (25)
7	$C_2H_5CO_2Na$	4	**8** (15)		**9** (13)	**10** (28)
7	C_2H_5ONa	5			**11** (38)	**10** (35)
7	AcOAg	5	**12** (24)			**10** (41)

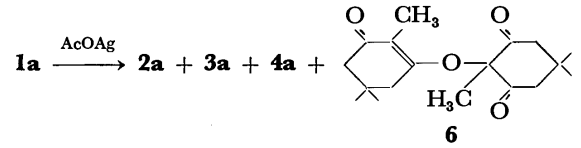
a) The reactions were carried out in ether instead of THF.

of sodium ethoxide, ethyl 3,3-dimethyl-5-oxoheptanoate (**5a**) was obtained as a major product along with small amounts of **2a** and **4a**.



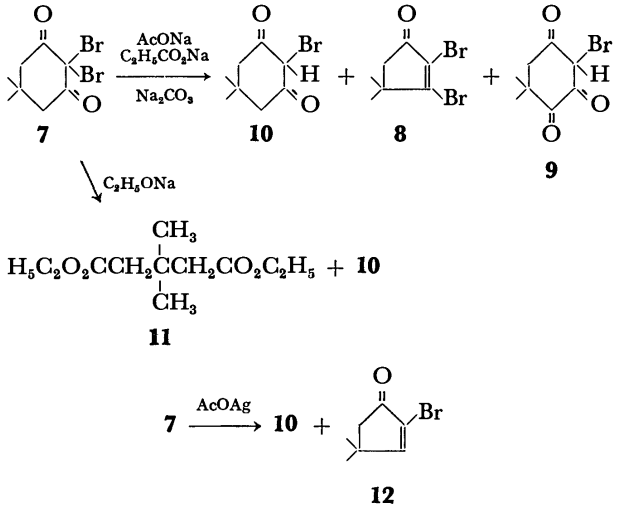
5a, R=C_2H_5
b, R=t-C_4H_9

Treatment of **1a** with an equivalent of sodium t-butoxide gave **2a** and **4a**, but t-butyl ester (**5b**) could not be isolated. The reaction of **1a** with an equivalent of silver acetate in THF yielded a small amount of a dimeric product (**6**) along with **2a**, **3a** and **4a**.



6

The reaction of 2,2-dibromodimedone (**7**) with various bases was then examined. Treatment of **7** with an equivalent of weak bases, such as sodium acetate, sodium propionate and sodium carbonate, in THF afforded 2-bromodimedone (**10**), 2,3-dibromo-4,4-dimethyl-2-cyclopenten-1-one (**8**) and 2-bromo-5,5-dimethylcyclohexane-1,3,4-trione (**9**). The reaction of **7** with two equivalents of sodium ethoxide in ether gave **10** and diethyl 3,3-dimethylglutarate (**11**). The reaction of **7** with an equivalent of silver acetate in THF yielded **10** and 2-bromo-4,4-dimethyl-2-cyclopenten-1-one (**12**).



11

12

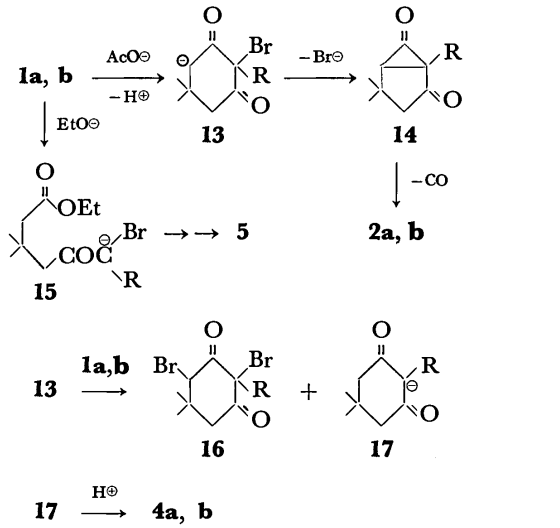
Determination of the Structures of the Products. The structures of the cyclopentenones **2a**, **2b**, **8**, and **12** were readily established from their IR and NMR spectra which exhibited absorptions and signals characteristic of the assigned structures (see Experimental): the IR and NMR spectral data of **2a** obtained in this investigation were identical with those reported.[1]

The structures of the cyclopetenonecarboxylic acids **3a** and **3b** were established by their IR, NMR, and UV spectra. The IR spectrum (KBr) of **3a** showed multiple absorptions characteristic of a carboxyl group at 3300—2500 cm^{-1}, carbonyl absorptions at 1710 and 1670 cm^{-1}, and an absorption due to the C=C bond at 1620 cm^{-1}. The NMR spectrum ($CDCl_3$–DMSO-d_6) of **3a** exhibited a singlet signal due to six protons of the two methyl groups at the 5-position at δ 1.34, and a singlet signal due to three protons of the methyl group at the 2-position at δ 1.88, a singlet signal due to two protons of the methylene function at the 4-position at δ 2.32, and a broad singlet signal due to one proton of the carboxyl group at the 1-position at δ 6.15. The UV spectrum of **3a** in 95% ethanol showed an absorption maximum at 243 nm (ε 9800), indicating that **3a** has a cyclopentenone skeleton.[4] These data are consistent with the structure assigned to **3a**. Similar spectral data were obtained for **3b**, confirming the assingned structure: the IR spectrum (KBr) showed absorptions at 3300—2600 (multiplet), 1710, 1680, and 1620 (C=C) cm^{-1}. The NMR spectrum (CCl_4) exhibited a singlet signal at δ 1.36 (six protons of the two methyl groups at the 5-position), multiplet signals at δ 0.8—2.3 (nine protons of the butyl group at the 2-position), a singlet signal at δ 2.32 (two protons of the methylene group at the 4-position) and a broad singlet signal centered at δ 9.1 (one proton of the carboxyl group at the 1-position). The UV spectrum in 95% ethanol showed an absorption maximum at 244 nm (ε 9300).

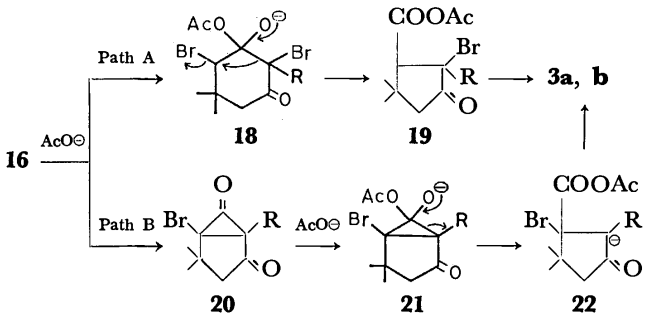
The IR and NMR spectral data of the dimer **6** obtained in this investigation were identical with those reported.[1] Additional evidence for the assigned structure was obtained from the fact that a mild treatment of **6** with aqueous hydrochloric acid afforded quantitatively 2-methyldimedone (**4a**). As a result of this chemical reaction, a fragment peak appeared at m/e 153 (corresponding to just a half of the molecule) in the mass spectrum. The structure of **9** was confirmed by a color reaction with ferric chloride, which demonstrated the enolizable property of the substance, and by the IR and NMR spectra. The structures of the esters **5a** and **11** were confirmed by comparison of the retention times in vpc with those of authentic samples.

Mechanistic Interpretation. From the results obtained we see that the kind and distribution of the products produced by the reactions of 2-bromodimedones with bases depend largely on the nature of the base as well as the substituent attached at the 2-position of dimedones.

The reactions of 2-alkyl-2-bromodimedones, **1a** and **1b**, with bases are discussed first. The yields of cyclopentenones **2a** and **2b** were high in the reactions with a weak nucleophilic base such as sodium acetate. The production of **2a** and **2b** was accompanied by the formation of cyclopentenonecarboxylic acids **3a** and **3b** and debrominated dimedones **4a** and **4b**. When **1a** was allowed to react with sodium ethoxide which possesses a relatively high nucleophilicity, an attack of ethoxide ion on a carbonyl carbon in the substrate predominated to produce mainly the open-chain product, **5**. The proposed mechanisms which qualitatively accomodate these results are represented in Schemes 1 and 2: since experimental difficulty in the separation of the products prevented a quantitative determination of the product distribution, the proposed



Scheme 1.



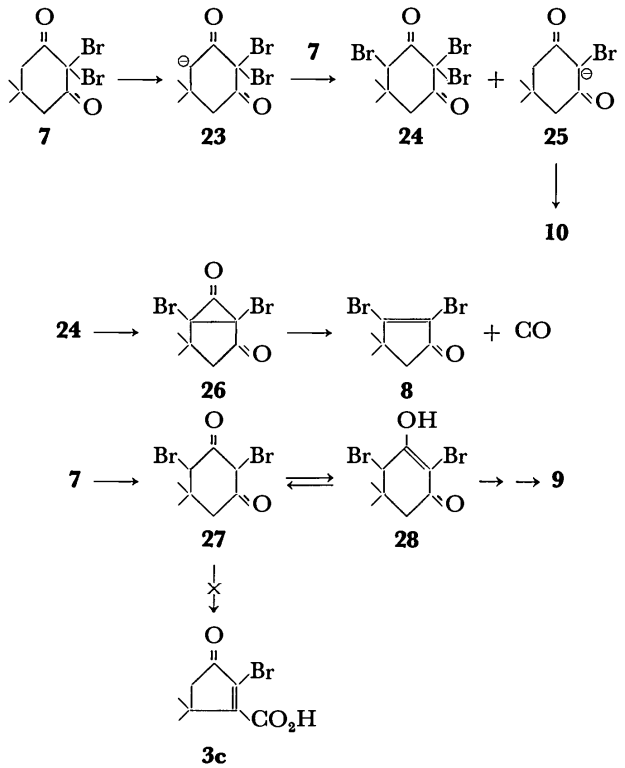
Scheme 2.

mechanisms might be inconsistent with the results given in Table 1.

A base of low nucleophilicity abstracts a proton from an active methylene group of **1a**, **b** to form carbanion **13**, which is then transformed into cyclopropanone intermediate **14** by elimination of bromide ion. The 1,3-elimination of hydrogen bromide of this sort has been postulated in the Favorskii rearrangement of α-bromoketones.[5] Decarbonylation from **14** affords the cyclopentenone **2a**, **b** (Scheme 1). The stabilized carbanion **13** would also react with **1a**, **b** to form the dibromide **16** and the carbanion **17** which on protonation yields **4a**, **b**. The transfer of bromonium ion from **1a**, **b** to **13** is possible, since bromine in **1a**, **b** is activated by the two adjacent carbonyl groups.

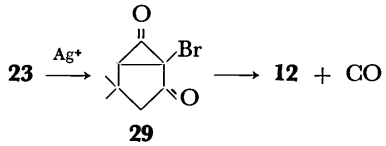
Two paths can be considered for the formation of **3a**, **b** (Scheme 2). Path A is a semibenzylic-type rearrangement[6] induced by an attack of base to the carbonyl carbon of **16** to form an intermediate **19** which is readily converted into **3a**, **b** by the dehydrobromination and the hydrolysis. Path B is the base-induced Favorskii-type rearrangement of **16** to produce **3a**, **b** through an intermediate **22**. We prefer path A to path B from the following considerations: (a) The reaction of **1a** with *t*-butoxide, which is a bulky strong base, exclusively affords **2a** without formation of **3a**. This result can be interpreted by assuming that a larger steric interaction between a substituent at the 2-position of **16** and base hinders an attack of the base on the carbonyl carbon of **16**. (b) If path B were to be taken, a compound produced by the decarbonylation from **20** should be obtained. However, such a product could not be isolated.

A possible mechanism for the reactions of **7** with weak bases is outlined in Scheme 3. In these reactions cyclohexane-1,3,4-trione (**9**) was obtained, but not 2-bromo-5,5-dimethyl-3-oxo-1-cyclopentene-1-carboxylic acid (**3c**, R=Br in **3**). This is understandable from the fact that 2-monosubstituted dimedone such as **27** which is a precursor of **3c** exists predominantly in the enol form such as **28**. The attack of weak bases on the enolized carbonyl carbon would be difficult. Consequently, the pathway leading to **3c** is prohibited, and **28** might be transformed into **9** through complex pathways involving oxidation.



Scheme 3.

An unusual reaction took place with the use of silver acetate. The reaction of **1a** with silver acetate gave the dimeric product **6**, whose yield increased with reaction time. However, the mechanism for the formation of **6** is yet uncertain. The reaction of **7** with silver acetate afforded the monobromocyclopentenone **12**. This may be accounted for by a strong affinity of silver ion to bromide ion, which promotes the formation of the cyclopropanone **29** from **23**.



Experimental

2-Bromo-2-methyldimedone (1a). Bromine (16.0 g, 0.1 mol) was added gradually to a stirred mixture of 15.4 g

(0.1 mol) of 2-methyldimedone (**4a**)[7] and 11.8 g (0.1 mol) of AcONa in 120 ml of $CHCl_3$–H_2O (6: 1) below 5 °C. The mixture was stirred for 1 hr, and the $CHCl_3$ layer was then separated. The aqueous layer was extracted with 50 ml of $CHCl_3$. The combined $CHCl_3$ solutions were dried (Na_2SO_4) and evaporated under reduced pressure. Recrystallization of the residue from $CHCl_3$–CCl_4 (1: 3) gave 19.5 g (84%) of **1a**; mp 102—104 °C. IR(KBr): 1720 and 1695 cm^{-1} (C=O). NMR($CDCl_3$) δ 1.12 (s, 6H, two CH_3's), 1.82 (s, 3H, CH_3–C(Br)–) and 2.70 (s, 4H, $-CH_2-C(Br)-CH_2-$).

Found: C, 46.52; H, 5.37%. Calcd for $C_9H_{12}O_2Br$: C, 46.37; H, 5.62%.

2-Bromo-2-butyldimedone (1b). Bromination of 2-butyldimedone[7] by a method similar to that described above gave **1b** in 78% yield; mp 97—99 °C; IR(KBr) 1710 and 1700 cm^{-1} (C=O).

Found: C, 52.46; H, 6.62%. Calcd for $C_{12}H_{19}O_2Br$: C, 52.38; H, 6.96%.

Reaction of 1a with AcONa. A mixture of 1.0 g (4.3 mmol) of **1a** and 0.37 g (4.5 mmol) of anhydrous AcONa in 60 ml of THF was refluxed for 4 hr. The reaction mixture was poured into water, neutralized with 1 M HCl, and extracted with two 30 ml portions of ether. The combined ether extracts were washed with 5% Na_2CO_3, dried and evaporated to leave an oil. Distillation of the oil gave 0.11 g (21%) of (**2a**); bp 160—165 °C. IR (film): 1700 (C=O) and 1640 cm^{-1} (C=C). NMR (CCl_4): δ 1.19 (s, 6H, two CH_3's at the 4-position), 1.65 (d, J=1 Hz, 3H, **CH_3**–C=CH–), 2.12 (s, 2H, –**CH_2**–), and 6.92 (q, J=1 Hz, 1H, **H**–C=C–CH_3).

Found: C, 77.68; H, 9.58%. Calcd for $C_8H_{12}O$: C, 77.38; H, 9.74%.

Chromatography of the oil on silica-gel with $CHCl_3$ gave 50 mg (5%) of unchanged **1a**.

The Na_2CO_3 solution was neutralized with 1 M HCl and extracted with ether. The extract was dried over Na_2SO_4, and evaporated. The residue was chromatographed on silica-gel with benzene–CCl_4 (1: 3). The earlier fractions gave 0.27 g (37%) of 5,5-dimethyl-2-methyl-3-oxo-1-cyclopentene-1-carboxylic acid (**3a**), which upon recrystallization from $CHCl_3$ afforded an analytical sample of mp 189—191 °C. Mass spectrum: *m/e* 168 (M^+), 140, 125, and 124.

Found: C, 64.53; H, 7.41%. Calcd for $C_9H_{12}O_3$: C, 64.27; H, 7.19%.

The latter fractions in the chromatography afforded 50 mg (7.5%) of **4a**, mp 160—162 °C (lit,[7] mp 162—163 °C).

Found: C, 70.33; H, 8.92%. Calcd for $C_9H_{14}O_2$: C, 70.10; H, 9.15%.

Reaction of 1b with AcONa. A mixture of 0.8 g (2.9 mmol) of **1b** and 0.25 g (3.0 mmol) of AcONa in 50 ml of THF was refluxed for 4 hr. The reaction mixture was worked up as described above and separated into two fractions. From the neutral fraction, an oil was obtained after evaporation of the ether. Distillation of the oil gave 0.17 g (35%) of 2-butyl-4,4-dimethyl-2-cyclopenten-1-one (**2b**); bp 65—70 °C/3 mmHg. IR (film): 1730 (C=O) and 1630 cm^{-1} (C=C). NMR (CCl_4): δ 1.20 (s, 6H, two CH_3's), 0.7—2.3 (m, 9H, $-CH_2CH_2CH_2CH_3$), 2.16 (s, 2H, –CO**CH_2**C(CH_3)–), and 6.97 (m, 1H, >C=C**H**–). Mass spectrum: *m/e* 166 (M^+), 151, 138, and 109.

Found: C, 79.41; H, 10.76%. Calcd for $C_{11}H_{18}O$: C, 79.47; H, 10.91%.

The oily material obtained from the Na_2CO_3-soluble fraction was triturated with ice-water. The solid thus precipitated was separated into 0.03 g (5.3%) of **4b**, mp 152—153 °C (lit,[7] mp 155 °C) and 0.09 g (15%) of 2-butyl-5,5-dimethyl-3-oxo-1-cyclopentene-1-carboxylic acid (**3b**) by fractional recrystallization from benzene–CCl_4 (1: 3). An analytical sample of **3b** was prepared by recrystallization from $CHCl_3$; mp 159—162 °C. Mass spectrum; *m/e* 210 (M^+), 182, 166, 153.

Found: C, 68.33; H, 8.98%. Calcd for $C_{12}H_{18}O_3$: C, 68.54; H, 8.63%.

Reaction of 1a with EtONa. A suspension of 1.0 g (4.3 mmol) of **1a** and 0.58 g (8.6 mmol) of EtONa in 100 ml of dry ether was heated under reflux for 5 hr. The reaction mixture was poured into 50 ml of water and neutralized with 1 M HCl, the ether layer then being separated. The aqueous layer was further extracted twice with 30 ml portions of ether. The ether solutions were combined, washed with 5% Na_2CO_3, dried over Na_2SO_4, and the ether was evaporated. The residual oil was distilled to give 0.47 g (64%) of ethyl 3,3-dimethyl-5-oxoheptanoate (**5a**); bp 73—75 °C/1 mmHg. IR (film): 1735 (sh) and 1730 cm^{-1} (C=O). NMR ($CDCl_3$): δ 1.13 (s, 6H, $(CH_3)_2$C–), 1.20 (t, J=6.0 Hz, 3H, –$COCH_2$–**CH_3**), 1.25 (t, J=7.0 Hz, 3H, –$COOCH_2$**CH_3**), 1.90 (s, 2H, –**CH_2**–), 2.40 (s, 2H, –**CH_2**–), 4.12 (q, J=6.0 Hz, 2H, –CO**CH_2**–CH_3), and 4.20 (q, J=7.0 Hz, 2H, –COO**CH_2**CH_3). Mass spectrum: *m/e* 200 (M^+), 172, 156, 146, 130, 87, 83, 43, and 29.

Found: C, 65.55; H, 9.82%. Calcd for $C_{11}H_{20}O_3$: C, 65.97; H, 10.07%.

Vpc analysis of the residual oil indicated that the oil contained 30 mg (5.6%) of 2,4,4-trimethyl-2-cyclopenten-1-one (**2a**). The aqueous Na_2CO_3 solution was neutralized with 1 M HCl, and extracted with ether. The ether extract was dried over Na_2SO_4 and evaporated. The residue was recrystallized from $CHCl_3$ to give 60 mg (9%) of **4a**.

Reaction of 1a with t-BuONa. A mixture of 0.8 g (3.4 mmol) of **1a** with 0.4 g (3.7 mmol) of *t*-BuONa in 50 ml of anhydrous THF was heated under reflux for 5 hr. The reaction mixture was poured into 40 ml of water, neutralized with 1 M HCl and then extracted with two 30 ml portions of ether. The ether extracts were washed with 5% Na_2CO_3, dried and evaporated to leave a tarry material which could not be purified. However, vpc analysis indicated that the tar contained 50 mg (12%) of **2a**. Work-up of the aqueous Na_2CO_3 solution gave 0.18 g (34%) of **4a**.

Reaction of 1a with AcOAg. A mixture of 1.0 g (4.3 mmol) of **1a** and 0.75 g (4.5 mmol) of AcOAg in 40 ml of THF was refluxed with stirring for 5 hr. The reaction mixture was separated into two fractions, *i.e.*, neutral and Na_2CO_3 soluble fractions, by a method similar to that described above. Fractional distillation of the oil obtained from the neutral fraction gave first 90 mg (17%) of **2a**. Trituration of the residue of this distillation gave the solid, which upon fractional recrystallizations from hexane–CCl_4 (5: 1) yielded 0.2 g (20% of unchanged **1a** and 0.06 g (5.3%) of the dimer (**6**).[1] Compound **6** melted at 168—169 °C. IR(KBr): 1725, 1710, 1635, and 1610 cm^{-1}. NMR ($CDCl_3$): δ 1.00—1.17 (m, 12H, four CH_3's), 1.60 (s, 3H, CH_3C(–)–O–), 1.75 (t, J=2 Hz, 3H, **CH_3**–C=C–CH_2–), 2.04 (q, J=2 Hz, 2H, –**CH_2**–C=C–CH_3), 2.23 (s, 2H, –C=C(CH_3)CO**CH_2**–), and 2.81 (m, 4H, two of –CO**CH_2**C(CH_3)$_2$–). Mass spectrum: *m/e* 153 (M—153, 30%), 151 (30), 136 (15), 125 (10), 109 (20), 98 (50), and 83 (100).

Found: C, 70.34; H, 8.52%. Calcd for $C_{18}H_{26}O_4$: C, 70.56; H, 8.55%.

Work-up of the Na_2CO_3 soluble fraction gave 0.07 g (10%) of **3a** and 0.05 g (7.5%) of **4a**.

When the reaction of 1.0 g (4.3 mmol) of **1a** with 0.75 g (4.5 mmol) of AcOAg was carried out for 18 hr, 0.1 g (19%) of **2a**, 0.02 g (3%) of **3a**, 0.27 g (22%) of **6** and 0.06 g (9%) of **4a** were isolated.

Hydrolysis of **6**. A solution of 0.1 g (0.3 mmol) of **6** in 30 ml of dioxane-water mixture (1: 1) containing 6 M HCl was heated at 80 °C for 3 hr, and then evaporated to dryness under reduced pressure. Recrystallization of the residue from $CHCl_3$ gave 0.09 g (90%) of **4a**.

2,2-Dibromodimedone (7). This compound was prepared by the bromination of dimedone with two equivalents of Br_2 in 77% yield; mp 144—145 °C, (lit,[8] mp 144—146 °C). IR(KBr): 1720 and 1730 cm^{-1}. NMR ($CDCl_3$): 1.05 (s, 6H), and 3.05 (s, 4H).

Found: C, 32.22; H, 3.45%. Calcd for $C_8H_{10}O_2Br_2$; C, 32.25; H, 3.38%.

Reaction of 7 with AcONa. A mixture of 1.5 g (5 mmol) of **7** and 0.45 g (5.5 mmol) of anhydrous AcONa in 60 ml of THF was stirred under reflux for 4 hr. The reaction mixture was separated into two fractions. An oily material obtained from the neutral fraction was chromatographed on silica-gel with hexane-CCl_4 (5: 1) to give 0.33 g (25%) of 2,3-dibromo-4,4-dimethyl-2-cyclopenten-1-one (**8**). An analytical sample of **8** was obtained by recrystallization from hexane; mp 85—86 °C. IR(KBr): 1702 (C=O), and 1570 cm^{-1} (C=C). NMR (CCl_4); δ 1.50 (s, 6H, two CH_3's at the 4-position) and 2.70 (s, 2H, $-CO\mathbf{CH_2}C(CH_3)_2-$). Mass spectrum: *m/e* 270, 268, 266 (1: 2: 1); 255, 253, 251 (1: 2: 1); 227, 225, 223 (1: 2: 1); 189, 187 (1: 1); 161, 159 (1: 1); 133, 131, (1: 1).

Found: C, 31.28; H, 2.98%. Calcd for $C_7H_8OBr_2$; C, 31.38; H, 3.01%.

Another oily material obtained from the Na_2CO_3 soluble fraction was partly solidified on being left to stand overnight in a refrigerator. The solid was separated by filtration and then recrystallized from CCl_4-$CHCl_3$ (2: 1) to give 0.35 g (32%) of **10**: mp 169—172 °C (lit,[8] mp 175—176 °C). IR (KBr): 1620 cm^{-1} (C=O).

Found: C, 43.62; H, 5.13%. Calcd for $C_8H_{11}O_2Br$: C, 43.86; H, 5.06%.

A mixture-melting point test of **10** with its authentic sample showed no depression. The filtrate was chromatographed on silica-gel with $CHCl_3$-CCl_4 (3: 1) to give 0.19 g (16%) of 2-bromo-5,5-dimethylcyclohexane-1,3,4-trione (**9**); mp 188—190 °C. IR(KBr): 3200, 1690, 1665, 1650, and 1620 cm^{-1}. NMR (DMSO-d_6): δ 1.16 (s, 6H, two CH_3's at the 5-position), 2.82 (s, 2H, $-CO\mathbf{CH_2}C(CH_3)_2-$) and 6.02—6.25 (broad s, 1H, $-CO-\mathbf{CH}Br-CO-$). Mass spectrum: *m/e* 234, 232 (1: 1), and 220, 218 (1: 1).

Found: C, 41.20; H, 3.66%. Calcd for $C_8H_9O_3Br$: C, 41.23; H, 3.89%.

Reaction of 7 with Na_2CO_3 and with C_2H_5COONa. The reactions were carried out under conditions similar to those described above. The isolated products are given Table 1.

Reaction of **7** *with EtONa*. A mixture of 1.5 g (5.0 mmol) of **7** and 0.68 g (10 mmol) of EtONa in 60 ml of dry ether was stirred at reflux temperature for 5 hr. The reaction mixture was separated into two fractions, *i.e.*, neutral and Na_2CO_3-soluble fractions. An oil obtained from the neutral fraction was distilled under reduced pressure to give 0.41 g (38%) of diethyl 3,3-dimethylglutarate (**11**); bp 82—84 °C/3 mmHg. IR (film); 1735 cm^{-1} (C=O). NMR (CCl_4): δ 1.08 (s, 6H, two CH_3's at the 3-position), 1.24 (t, J=7.0 Hz, 6H, two of $COOCH_2\mathbf{CH_3}$), 2.35 (s, 4H, CH_2's at the 2- and 4-positions), 4.12 (q, J=7.0 Hz, 4H, two of $COO\mathbf{CH_2}CH_3$).

Found: C, 61.37; H, 9.06%. Calcd for $C_{11}H_{20}O_4$: C, 61.11; H, 9.32%.

The retention time of **11** in vpc was the same as that of the authentic sample.[9] A solid obtained from the Na_2CO_3-soluble fraction was recrystallized from CCl_4-$CHCl_3$ (2: 1) to give 0.38 g (35%) of 2-bromodimedone (**10**).

Reaction of 7 with AcOAg. A mixture of 1.5 g (5 mmol) of **7** and 0.84 g (5 mmol) of AcOAg in 50 ml of THF was stirred at reflux temperature for 5 hr. The reaction mixture was separated into two fractions. An oily material obtained from the neutral fraction was chromatographed on silica-gel with CCl_4 to give 0.23 g (24%) of 2-bromo-4,4-dimethyl-2-cyclopenten-1-one (**12**), which upon recrystallization from hexane showed mp 67—68 °C. IR(KBr): 1710 (C-O) and 1585 cm^{-1}. NMR(CCl_4): δ 1.26 (s, 6H, two CH_3's at the 4-position), 2.27 (s, 2H, $-CO\mathbf{CH_2}C(CH_3)_2-$), and 7.42 (s, 1H, $-CBr=\mathbf{CH}-$). Mass spectrum: *m/e* 190, 188 (1: 1), 175, 173 (1: 1); 147, 145 (1: 1); 110.

Found: C, 44.43; H, 4.51%. Calcd for C_7H_9OBr: C, 44.47; H, 4.80%.

From the Na_2CO_3-soluble fraction, 0.45 g (41%) of **10** was obtained.

p-(3,4-Diphenyl-1,3-cyclopentadien-1-yl)phenyltropylium Perchlorate. An Intermediate in the Synthesis of [5.6.7]Quinarene System[1,2]

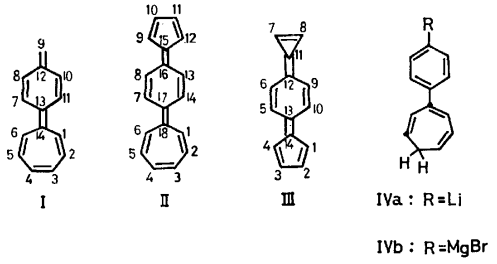
Kazuko TAKAHASHI, Shunsuke TAKENAKA,* Yoriko KIKUCHI, Kahei TAKASE, and Tetsuo NOZOE**

Department of Chemistry, Faculty of Science, Tohoku University, Aramaki-aza-Aoba, Sendai 980

(Received February 18, 1974)

Attempt was made to dehydrogenate *p*-(3,4-diphenyl-1,3-cyclopentadien-1-yl)phenyltropilidene, prepared by treating *p*-tropylphenyllithium or *p*-tropylphenylmagnesium bromide[3] with 3,4-diphenylcyclopent-2-enone, to 3″,4″-diphenyl-1-cycloheptatrienylidene-4-cyclopentadienylidene-2,5-cyclohexadiene, 10,11-diphenyl[5.6.7]quinarene. The resulting blue pigment showed spectral properties in line with those of *p*-(3,4-diphenyl-1,3-cyclopentadien-1-yl)phenyltropylium ion, [5.6.7]quinarenium ion, carrying a delocalized positive charge (VII′), but not those of expected cross-conjugated hydrocarbon.

The chemistry of fulvalene has been developed[4] and shown to be of greate theoretical interest.[5] The chemistry of polycyclic cross-conjugated π-systems such as I,[2,6] II or III having an inserted *p*-quinoid structure between the two dipole centers of heptafulvene, sesquifulvalene or calicene would also be of interest in connection with its aromatic nature. We have used the name "quinarene"[7] for the sake of convenience to designate this type of polycyclic cross-conjugated hydrocarbon possessing quinoid structure inserted between the two rings of fulvalene (fulvene) type structure. The ring size is shown in brackets; II being [5.6.7]-quinarene, III [3.6.5]quinarene and I [1.6.7]quinarene.[2] Numbering systems (I, II, III) are given for the structures.



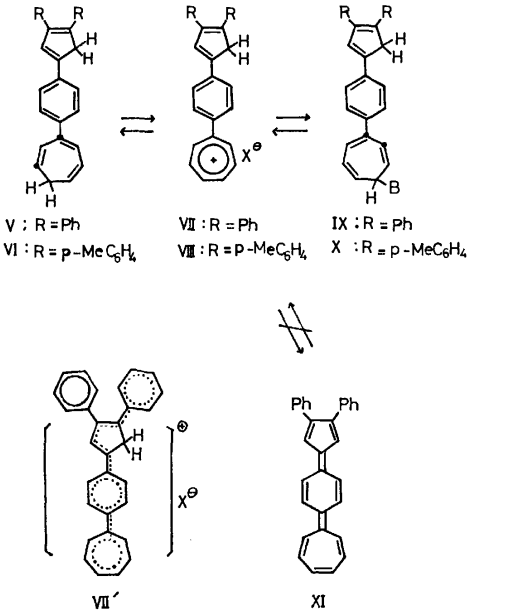


Chart 1.

PPP-type SCF-π-MO calculation[8] suggests that the quinarene (II) should have aromatic character (E_R/π) analogous to sesquifulvalene. In order to determine the ground-state properties of II, the synthesis of 10,11-diphenyl[5.6.7]quinarene (XI) was undertaken.

We reported on a convenient synthetic method of *p*-tropylphenylcarbinol derivative by the reaction of *p*-tropylphenyllithium (IVa) with alkyl or aryl ketones.[2] The reaction was developed for the synthesis of the compounds of type II.

Results and Discussion

Treatment of IVa or the corresponding Grignard reagent (IVb) with 1.7 mol equivalents of 3,4-diphenylcyclopent-2-enone[9] in ether at room temperature followed by hydrolysis with 2 M sulfuric acid gave yellow needles (V), mp 125—126 °C in 33.5% yield. V has no OH band in its IR spectrum and contains one additional singlet methylene proton resonance at 3.84 ppm besides a triplet (at 2.31 ppm) and a doublet (at 2.72 ppm) tropyl[3] methylene proton resonance in NMR spectrum, indicating that the dehydration of primarily formed carbinol had occurred to afford the hydrocarbon (V). V in dichloromethane was allowed to react with 2.5 mol equivalents of triphenylmethyl perchlorate resulting in an intensely blue solution, from which perchlorate VII was isolated as blue black needles in 88% yield. Di-*p*-tolyl derivative (VI), obtained by the treatment of IV with 3,4-di-*p*-tolylcyclopent-2-enone, also afforded blue black needles (VIII)[10] on reaction with triphenylmethyl salt. VII turned to the original tropilidene (V) on lithium aluminum hydride reduction in ether. Perchlorate (VII) was immediately converted into a yellow 3- and 2-aryl-7-ethoxytropilidene (IX: B=OEt) on treatment with sodium bicarbonate in the presence of ethanol, from which salts of the cation (VII) were regenerated by the action of acids such as hydrogen bromide, hydrogen chloride, trifluoroacetic acid, or perchloric acid. The chemical

a) Absorption maxima of dications formed by a protonation at the 5-membered ring of VII and VIII.

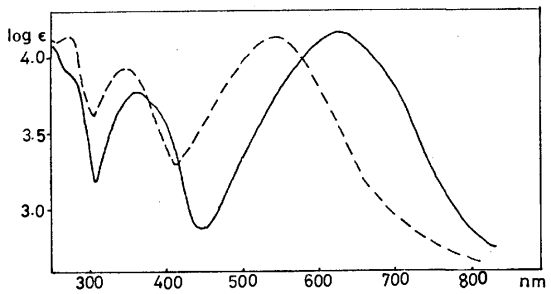

Fig. 1. Electronic absorption spectra of 10,11-diphenyl-[5.6.7]quinarenium ion (VII): (——) in $CHCl_3$, and (------) in CH_3CN.

properties as well as elemental composition of VII ($C_{30}H_{23}ClO_4$) were in line with the *p*-(3,4-diphenyl-1,3-cyclopentadien-1-yl)phenyltropylium ion structure.

However, there is some doubt as to the structure of pigment (VII), as seen from its electronic spectra. The longest wavelength absorption maximum of VII at 543—550 nm in such solvents as acetonitrile, acetic acid, or methanol–hydrochloric acid (violet solutions) shows a large bathochromic shift to 617—630 nm when the solvent is changed to chloroform, dichloromethane, or 9: 1 mixed solvent of chloroform and trifluoroacetic acid (blue solutions) (Table 1 and Fig. 1). The absorption maximum of VII at an extraordinary longer wavelength region of 630 nm is conspicuous as compared with the absorption maxima of phenyltropylium ion[11,12] at 385 nm and *p*-biphenylyltropylium ion at 415 nm. On the other hand, molecular orbital calculation for diphenyl derivative of [5.6.7]quinarene[8] using the variable bond length SCF-π-MO-CI procedure predicted the lowest singlet transition energies of XI to be 2.09 eV: f=2.96. The observed absorption maximum (630 nm) of VII and molecular orbital

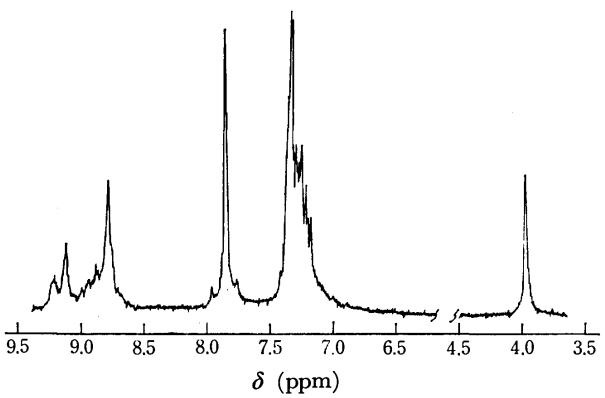

Fig. 2. NMR spectrum of 10,11-diphenyl[5.6.7]quinarenium ion (VII) in a 9: 1 mixture of $CHCl_3$ and CF_3CO_2H.

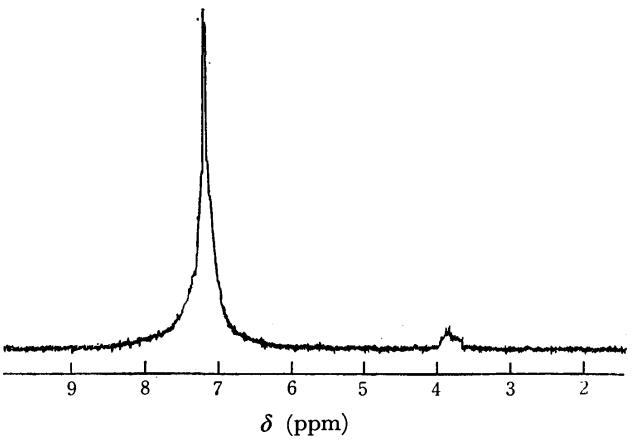

Fig. 3. NMR spectrum of 10,11-diphenyl[5.6.7]quinarenium ion (VII) in $CHCl_3$ at +30 °C.

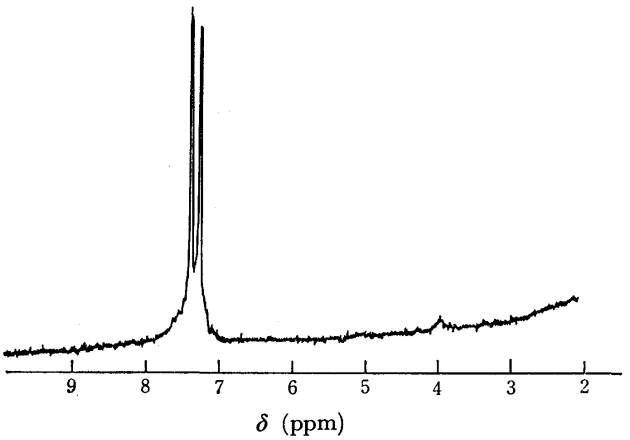

Fig. 4. NMR spectrum of 10,11-diphenyl[5.6.7]quinarenium ion (VII) in $CHCl_3$ at −30 °C.

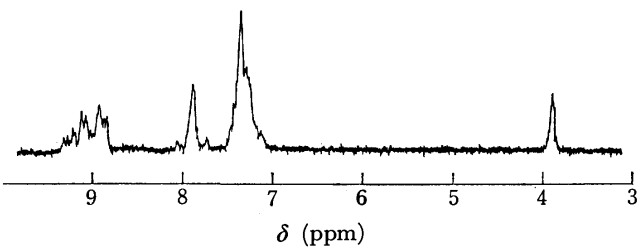

Fig. 5. NMR spectrum of 10,11-diphenyl[5.6.7]quinarenium ion (VII) in liq. SO_2.

calculation would be reasonable if cation (VII) is capable of existing as an equilibrium mixture with quinarene-type hydrocarbon (XI) in chloroform or dichloromethane solution.

NMR spectral studies of VII, however, exclude the possibility of the equilibrium. A deep blue solution of VII in chloroform containing 10% of trifluoroacetic acid shows a multiplet at 8.90 ppm (6H, tropylium ion), AB-type triplet at 7.80 ppm (4H, benzene ring), a multiplet at 7.20 ppm (11H, benzene ring and an olefinic proton of 5-membered ring) and a singlet at 3.96 ppm (2H, methylene), indicating that VII is the structure of the blue pigment (Fig. 2). In non-acidic, pure chloroform, the presumed equilibrium between VII and XI would favor deprotonated species XI. However, the solution showed a small and broad singlet at 3.9—4.0 ppm attributed to the methylene group of the 5-membered ring of VII, besides a broad peak at around 7.20 ppm, at +30 °C (Fig. 3), and two sharp peaks at −30 °C (Fig. 4) where all 7- and 6-membered ring protons appear together, no signal at lower field being observed. Moreover the solution of VII in liq. SO_2, having violet color (λ_{max} at 552 nm) analogous to the acetonitrile solution, showed a spectrum of Fig. 5 clearly attributable to the cation (VII).

TABLE 2. CALCULATED TRANSITION ENERGIES OF 10,11-DIPHENYL[5.6.7]QUINARENE (XI) AND 10,11-DIPHENYL [5.6.7]QUINARENIUM ION (VII) COMPARED WITH THE OBSERVED SPECTRUM OF VII IN CHLOROFORM

Calculated				Experimental
XI		VII		VII (X=ClO_4)
ΔE (eV)	f	ΔE (eV)	f	ΔE (eV) (logε)
2.00	0.004 (y)	2.02	0.79	2.02 (4.2)
2.08	0.008 (y)	2.52	0.008	
2.09	2.96 (z)	3.10	0.57	3.40 (4.0)
3.33	0.06 (z)	3.45	0.27	
3.81	0.00 (y)	3.60	0.003	

It was concluded that both violet- and blue-colored solutions contain a single species having structure VII excluding the presumed equilibrium with XI. The absorption maximum of VII at a longer wavelength region of 630—617 nm might be due to the contribution of structure VII′ carrying a delocalized positive charge all over the molecule. Prinzbach and his co-workers observed a similar bathochromic effect[13-15] of the conjugated acids XIII and XV as compared with the corresponding cross-conjugated hydrocarbons, sesquifulvalene (XII) and calicene (XIV). Jutz and Voithenleitner[16] presented further examples of the long conjugated tropylium ion derivatives (XVI), stating that XVI (n=3) and XVI (n=4) have absorption maximum at 592 nm in chloroform (539 nm in acetonitrile) and at 646 nm in chloroform (582 nm in acetonitrile), respectively. These values are in fair agreement with the spectral characteristics of VII, if the bathochromic effect of a benzene ring is equivalent to about 1½ ethylenic links.[17]

The calculated electronic spectral data of VII are summarized in Table 2, where the calculated values for VII, rather than those for XI, are in good agreement with the observed values. The deprotonation of VII with a base such as diisopropylamine or pyridine has not been successful so far.

Experimental

Mps and bps are uncorrected. The instruments used for spectral measurements are Shimadzu IR-27-G spectrophotometer (IR), Varian Associates A-60 and HA-100 spectrometers (NMR, TMS as internal standard) and Hitachi EPS-2U spectrometer (UV).

Preparation of 3-[p-(3,4-Diphenyl-1,3-cyclopentadien-1-yl)-phenyl]tropilidene (V). *a)* To a solution of *p*-tropylphenyllithium[1] (10.0 mmol) in ether (40 ml), prepared from *p*-tropyliodobenzene (4.0 g, 13.6 mmol) and *n*-butyllithium (30.0 mmol), was added dropwise a solution of 3,4-diphenylcyclopent-2-enone (2.58 g, 11.1 mmol) in ether (100 ml) with stirring at room temperature. After being stirred for 5 hr, the mixture was hydrolyzed with 2M-H_2SO_4 and extracted with ether. The combined organic solution was washed (satd. $NaHCO_3$ soln.), dried (Na_2SO_4), and concentrated. The residual yellow semi-solid was chromatographed on an alumina column with light petroleum-benzene as an eluent. The chromatographic fractions from light petroleum-benzene (1: 1) were recrystallized from ether to give V (1.29 g, 33.6%) as yellow needles, mp 125—126 °C; ν_{max} (KBr) 3050, 2930, 1600, 1500, 1440, 1370, 1200, 1070, 1030, 912, 891, 822, 759, 697 cm^{-1}; δ (CCl_4) 7.39 (4H, s, benzene), 7.26 (5H, s, benzene), 7.15 (5H, s, benzene), 6.96 (1H, s, 5-membered ring) 6.60—6.05 (3H, m, tropyl), 5.65—5.15 (2H, m, tropyl), 3.84 (2H, s, 5-membered methylene), 2.72 (4/5H, d, J=7.0 Hz, tropyl methylene), 2.31 (6/5H, t, J=6.8 Hz, tropyl methylene); λ_{max} ($CHCl_3$) nm (log ε) 303 (4.25), 375 (4.57). Found: C, 93.59; H, 6.56%. Calcd for $C_{30}H_{24}$: C, 93.71; H, 6.29%.

b) To a solution of *p*-tropylphenylmagnesium bromide[1] (7.7 mmol) in THF (25 ml), prepared from *p*-tropylbromobenzene (2.4 g, 9.7 mmol) and Mg-ribbon (1.236 g, 9.7 mmol), was added a solution of 3,4-diphenylcyclopent-2-enone (1.96 g, 8.4 mmol) in THF (30 ml) with stirring at room temperature. After being stirred for 5 hr, the mixture was worked up as above to give V (1.19 g, 31%).

Preparation of 4-Hydroxy-3,4-di(p-tolyl)-2-cyclopentenone. To a suspension of 4,4′-dimethylbenzil (12.5 g, 51.3 mmol) in acetone (10 ml) was added 33% NaOH solution (0.5 ml) and the red solution was stirred for 30 min at room temp. After addition of another NaOH solution (33%, 1.5 ml), the mixture was refluxed for 2 hr and then poured into hot water (50 ml). The crude product (10.3 g, 72.4%) which separated was washed with ether and recrystallized from benzene to give 4-hydroxy-3,4-di(*p*-tolyl)-2-cyclopentenone as colorless needles, mp 171 °C; ν_{max} (KBr) 3440, 2920, 1680, 1590, 1515, 1410, 1333, 1267, 1212, 1183, 1060, 980, 864, 831, 818, 734 cm^{-1}; δ ($CDCl_3$) 7.25 (8H, m, benzene), 6.56 (1H, s, 5-membered ring), 3.51 (1H, s, OH), 2.94, 2.79, (each 1H, AB-q, J=19.0 Hz); λ_{max} (MeOH) nm (log ε)

399 (4.40), 220 (4.37). Found: C, 81.64; H, 6.59%. Calcd for $C_{19}H_{18}O_2$: C, 81.98; H, 6.52%.

Preparation of 3,4-Di(p-tolyl)cyclopent-2-enone. To a warmed mixture (50 °C) of red phosphorus (3.4 g), 58% hydriodic acid (1.8 ml) and acetic acid (30 ml) was added 4-hydroxy-3,4-di(*p*-tolyl)-2-cyclopentenone (3.2 g, 11.5 mmol). The mixture was stirred for 2 hr at 80 °C and then filtered to remove phosphorus. The filtrate was added to cooled 10% $NaHSO_3$ solution and extracted with ether. After removal of the ether, the residue was distilled *in vacuo* affording the crude product (2.32 g, 76.8%), which was recrystallized to colorless needles, mp 109 °C; ν_{max} (KBr) 2950, 1680, 1590, 1510, 1270, 1190, 935, 813 cm^{-1}; δ ($CDCl_3$) 7.45, 7.12, (each 2H, J=8.2 Hz, benzene), 7.05 (4H, s, benzene), 6.72 (1H, d, J=1.5 Hz, 5-membered ring), 4.57 (1H, ddd, J=7.3, 2.5, 1.5 Hz, benzyl), 3.10 (1H, dd, J=18.5, 7.3 Hz, methylene), 2.37 (1H, dd, 18.5, 2.5 Hz, methylene), 2.29 (3H, s, methyl), 2.25 (3H, s, methyl); λ_{max} (MeOH) nm (log ε) 295 (4.31), 220 (4.18). Found: C, 86.91; H, 7.05%. Calcd for $C_{19}H_{18}O$: C, 86.98; H, 6.91%).

3-[p-(3,4-Di-p-tolyl-1,3-cyclopentadien-1-yl)phenyl]tropilidene (VI). To a solution of *p*-tropylphenyllithium[1] (5.0 mmol) in ether (20 ml) was added dropwise a solution of 3,4-di(*p*-tolyl)cyclopent-2-enone (1.57 g, 6.0 mmol) in ether (80 ml) with stirring at room temperature. After being stirred for 5 hr at the same temp., the resulting mixture was worked up as for V and the residual oil was chromatographed on silica gel column with 5% benzene in *n*-hexane as an eluent. The later chromatographic fraction was recrystallized from light petroleum to give VI (0.94 g, 45.5%) as pale yellow needles, mp 156 °C; ν_{max} (KBr) 3020, 1505, 810, 764, 718 cm^{-1}; δ (CCl_4) 7.37 (4H, s, benzene), 7.17—6.81 (8H, m, tolyl), 6.97 (1H, s, 5-membered ring), 6.46—6.05 (3H, m, tropyl), 5.60—5.18 (2H, m, tropyl), 3.73 (2H, s, 5-membered methylene), 2.68 (1/5H, d, J=7.0 Hz, tropyl methylene), 2.30 (9/5H, t, J=6.8 Hz, tropyl methylene), 2.26 (3H, s, methyl), 2.32 (3H, s, methyl); λ_{max} (MeOH) nm (log ε) 370 (4.51), 298 (4.22), 275 (4.19), 238 (4.35). Found: C, 93.43; H, 6.97%. Calcd for $C_{32}H_{28}$: C, 93.16; H, 6.84%.

p-(3,4-Diphenyl-1,3-cyclopentadien-1-yl)phenyltropylium Perchlorate (VII). To a solution of tropilidene (V) (0.20 g, 0.52 mmol) in dichloromethane (9 ml) was added triphenylmethyl perchlorate (0.45 g, 1.30 mmol) with stirring. After being stirred for 3 hr, the precipitate was filtered and washed with ether to give crude VII (0.22 g, 88%). Recrystallization from acetic acid gave blue black needles, mp>300 °C; ν_{max} (KBr) 3030, 1600, 1517, 1500, 1477, 1260, 1200, 1090, 917, 829, 758, 697 cm^{-1}; δ (10% CF_3CO_2D in $CDCl_3$) 9.25—8.70 (6H, m, tropylium), 7.77 (4H, s, benzene), 7.40—7.17 (10H, m, benzene), 3.98 (2H, s, methylene); λ_{max} ($CHCl_3$) nm (log ε) 617 (4.24), 363 (4.02), 276 sh (4.16). Found: C, 74.27; H, 4.97%. Calcd for $C_{30}H_{23}ClO_4$: C, 74.58; H, 4.85%.

p-(3,4-Di-p-tolyl-1,3-cyclopentadien-1-yl)phenyltropylium Perchlorate (VIII). Tropilidene (VI) (0.30 g, 0.73 mmol) in dichloromethane (5 ml) was treated with triphenylmethyl perchlorate (0.50 g, 1.46 mmol) as for VII to give crude VIII (0.25 g, 67.3%). Recrystallization from acetic acid afforded blue black needles, mp>300 °C; ν_{max} (KBr) 3003, 1590, 1508, 1490, 1260, 1200, 1090, 917, 813, 765 cm^{-1}: δ (10% CF_3CO_2D in $CDCl_3$) 9.34—8.77 (6H, m, tropylium), 7.84 (4H, s, benzene), 7.34—6.97 (8H, m, benzene), 3.90 (2H, s, methylene), 2.37 (3H, s, methyl), 2.31 (3H, s, methyl); λ_{max} ($CHCl_3$) nm (log ε) 640 (4.32), 371 (4.16), 281 (4.27). Found: C, 75.27; H, 5.44%. Calcd for $C_{32}H_{27}ClO_4$: C, 75.21; H, 5.33%.

Reduction of VII with Lithium Aluminum Hydride. To a suspension of tropylium ion (VII: X=BF_4) (0.10 g, 0.2 mmol) in ether (8 ml) was added dropwise a solution of $LiAlH_4$ (24.5 mg, 0.64 mmol) in ether (3 ml). The solution was stirred for 2 hr at room temperature. Water was then added to decompose the excess reagent and the precipitate was filtered. The precipitate and the filtrate were separately extracted with ether, and the combined extract was evaporated. The residue (82 mg) was chromatographed on a silica gel column and eluted with benzene(3%)-hexane. Yellow needles (30 mg, 37%) obtained showed IR spectrum identical with that of V.

Reaction of VII with Ethanol in the Presence of Sodium Bicarbonate. To a suspension of VII (0.10 g, 0.21 mmol) in chloroform (30 ml) and ethanol (3 ml) was added satd. $NaHCO_3$ soln. (30 ml). The mixture was then shaken vigorously and a yellow chloroform layer was separated, washed (satd. NaCl soln.) and dried (Na_2SO_4). Evaporation of the solvent gave IX: B=OEt (80 mg, 88%) as a yellow powder, mp 108—110 °C; ν_{max} (KBr) 3021, 2857, 1597, 1502, 1441, 1372, 1200, 1109, 912, 889, 820, 757, 696 cm^{-1}; δ ($CDCl_3$) 7.45 (4H, s, benzene), 7.25 (10H, m, benzene), 7.00 (1H, s, 5-membered ring), 6.70—6.05 (m, tropyl), 5.80—5.45 (m, tropyl), 3.85 (2H, s, 5-membered methylene), 3.65 (4/5H, q, J=6.9 Hz, ethyl), 3.51 (6/5H, q, J=6.9 Hz, ethyl), 3.50 (1H, m, methine), 1.26 (6/5H, t, ethyl), 1.23 (9/5H, t, ethyl); λ_{max} ($CHCl_3$) nm (log ε) 275 sh, 290 sh, 370 (4.27).

Reaction of VIII with Ethanol in the Presence of Sodium Bicarbonate. Tropylium perchlorate(VIII) (0.20 g, 0.39 mmol) in chloroform (50 ml) and ethanol (5 ml) was treated with $NaHCO_3$ as above to give X: B=OEt (0.16 g, 90%) as a yellow powder; δ (CCl_4) 7.37 (4H, s, benzene), 7.05 (9H, m, tolyl and 5-membered ring), 6.40—5.90 and 5.80—5.30 (5H, m, tropyl), 3.75 (2H, s, methylene), 3.62 (4/5H, q, J=6.9 Hz, ethyl), 3.58 (6/5H, q, J=6.9 Hz, ethyl), 3.50 (1H, m, methine), 2.32 and 2.16 (each 3H, tolyl methyl), 2.92 (6/5H, t, J=6.9 Hz, ethyl), 2.90 (9/5H, t, J=6.9 Hz, ethyl).

Reaction of IX with Hydrogen Bromide. Dry hydrogen bromide was introduced to a solution of IX: B=OEt (80 mg, 0.186 mmol) in benzene (5 ml). The blue black precipitate was then collected by filtration, washed (with benzene) and dried *in vacuo*, affording VII: X=Br (60 mg, 70.0%). Recrystallization from acetic acid gave blue needles, mp 180 °C (decomp.). Found: C, 77.23; H, 4.99%. Calcd for $C_{30}H_{23}Br$: C, 77.75; H, 5.00%.

Reaction of IX with Hydrogen Chloride. Dry hydrogen chloride was introduced to a solution of IX: B=OEt (100 mg, 0.23 mmol) in benzene (5 ml). The reaction mixture was worked up as above to give a blue black powder of VII:X=Cl (87 mg, 87%), which was recrystallized from acetic acid to give blue black needles, mp 150 °C (decomp.). Found: C, 85.38; H, 5.27%. Calcd for $C_{30}H_{23}Cl$: C, 86.00; H, 5.53%.

The authors express their hearty thanks to Professor T. Nakajima and Dr. H. Yamaguchi for the MO calculation. The work was carried out with financial support from the Ministry of Education and Sankyo Co., Ltd.

Studies on Cyclic Dipeptides. II.[1] Isomerization among *cyclo*-(-4-Hydroxyprolyl-4-hydroxyprolyl-)s and a Novel Conversion of D-*allo*-Hydroxyproline to L-Hydroxyproline[2]

Chikahiko EGUCHI and Akio KAKUTA

Central Research Laboratories, Ajinomoto Co., Inc., Suzuki-cho, Kawasaki-ku, Kawasaki 210

(Received March 26, 1974)

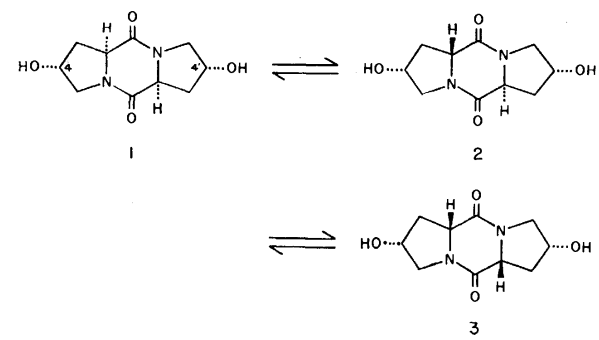
The isomerization among *c*-L-Hyp-L-Hyp (**1**), *c*-L-Hyp-D-*a*Hyp (**2**) and *c*-D-*a*Hyp-D-*a*Hyp (**3**) has been examined in ethanolic sodium ethoxide at 25—78 °C as well as in aqueous solutions at 75—250 °C. At equilibrium state, **1** was predominant and **2** was not found at all in the reaction mixture. By the use of this isomerization reaction and the difference of solubility between **1** and **3**, **3** could be converted almost quantitatively to **1**. The mixture of **1** and **3** was obtained in good yield directly from D-*a*Hyp or L-Hyp by heating in water or ethylene glycol. **1** was hydrolyzed quantitatively to L-Hyp by acid. Thus, L-Hyp was obtained with the yield of 59% from D-*a*Hyp by combination of preparation, isomerization and acid hydrolysis of cyclic dipeptide.

In our previous work,[1] we have determined the thermodynamic constants (K, $\Delta G°$, $\Delta H°$, and $\Delta S°$) of the *cis-trans* isomerization of cyclic dipeptides and found that, for *c*-Pro-Pro type of cyclic dipeptides, *e.g.*, *c*-Pro-Pro, *c*-Hyp-Hyp, only the *cis*-isomer occurs at equilibrium. This finding suggested a new method of obtaining L-Hyp from D-*a*Hyp, which involves an application of the isomerization reaction among *cyclo*(-4-hydroxyprolyl-4-hydroxyprolyl-)s. Our further study conducted on this suggestion is a subject of this paper.

So far, the interconversion between L-Hyp and D-*a*Hyp has been made by three methods: (A) heating an aqueous solution of the amino acid in the presence of excess barium hydroxide at 200 °C for several hours,[3] (B) treating the amino acid with excess acetic anhydride in refluxing glacial acetic acid,[4] and (c) heating an aqueous solution of the amino acid at 200 °C for 2 hr.[5] The method of obtaining L-Hyp from D-*a*Hyp is important to our new process to synthesize L-Hyp from D-Glu.[5] However, the reaction mixture at equilibrium state contained about 50% of L-Hyp in method (A), about 25% of L-Hyp in method (B), and about 55% of L-Hyp in method (C). Thus, it was not efficient to obtain L-Hyp from D-*a*Hyp by these methods. By our present method, on the other hand, the reaction mixture at equilibrium state contains about 97% of L-Hyp, therefore, L-Hyp is very easily obtained from D-*a*Hyp as will be described below.

Results and Discussion

Isomerization among c-L-*Hyp*-L-*Hyp* ***(1)***, c-L-*Hyp*-D-a*Hyp* ***(2)***, *and* c-D-a*Hyp*-D-a*Hyp* ***(3)***. The *cis-trans* isomerization among **1**, **2**, and **3** (Scheme 1) has been examined in 0.1 M ethanolic sodium ethoxide at three temperatures, 25, 50, and 78 °C. A part of the results is shown in Fig. 1. It was found that **2** is very rapidly isomerized to **1** and **3**. For example, when the isomerization was started from **2** at 25 °C, after only two min **2** was not found at all in the reaction mixture any more. Thus, under these conditions, the isomerization among *cis*-isomers (**1** and **3**) and *trans*-isomer (**2**) was actually equivalent to the isomerization between only two *cis*-isomers. The equilibrium constants (K) between **3** and **1** were determined at 25, 50, and 78 °C,



Scheme 1.

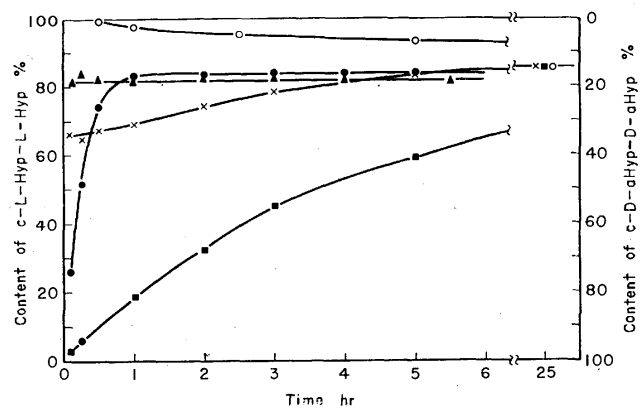


Fig. 1. Contents of *c*-L-Hyp-L-Hyp and *c*-D-*a*Hyp-D-*a*Hyp in the isomerization mixture in 0.1 M ethanolic sodium ethoxide: (○), **1** (starting material), 25 °C (reaction temperature); (×), **2**, 25 °C; (■), **3**, 25 °C; (●), **3**, 50 °C; (▲), **3**, 78 °C.

and then the thermodynamic constants ($\Delta H°$ and $\Delta S°$) of this isomerization were obtained by plotting $\log K$ against $1/T$ and by adopting the least-squares method. The results are summarized in Table 1.

Table 1. Thermodynamic constants for the equilibrium, *c*-D-*a*HYP-D-*a*HYP (**3**) ⇌ *c*-L-HYP-L-HYP (**1**)

$K_{298} = 5.94$	(85.6% of **1**)
$K_{323} = 5.10$	(83.6% of **1**)
$K_{351} = 4.43$	(81.6% of **1**)
$\Delta G_{323} = -1.04 \pm 0.01$ kcal/mol	
$\Delta H° = -1.15 \pm 0.2$ kcal/mol	
$\Delta S° = -0.29 \pm 0.3$ e.u.	

The conformation of the diketopiperazine (DKP) ring of **3** is probably similar to that of **1**, which is a boat form with C^{α}–C^{β} bond in the pyrrolidine ring setting at the quasi-equatorial position of the DKP ring.[1,6-8] The enthalpy difference between **1** and **3** is considered to be due to intramolecular dipole-dipole interactions. The vector sum of the dipole moments of two amide groups in the DKP ring is considered to be oriented along the perpendicular direction of the DKP ring. In **1**, both dipole moments of the C–O bonds on the two pyrrolidine rings are directed opposite to that of the amide groups. While, in **3**, the two C–O dipoles are oriented along the same direction with the net dipole of the amide groups.

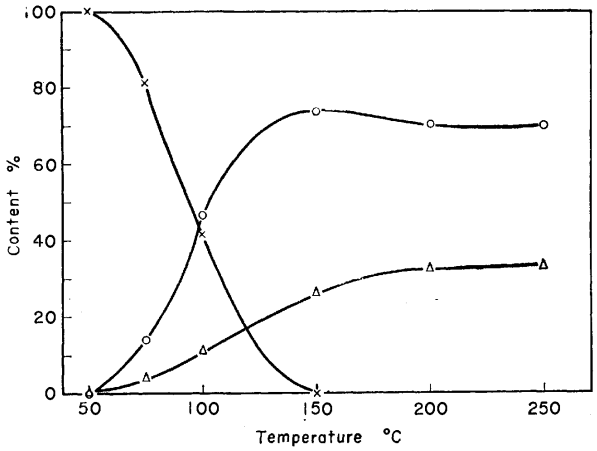

Fig. 2. Contents of *c*-L-Hyp-L-Hyp (○), *c*-L-Hyp-D-*a*Hyp (×), and *c*-D-*a*Hyp-D-*a*Hyp (△), in the isomerization mixture: starting material, 10% aqueous solution of **2**; heating time, 2 hr.

The isomerization experiment was also carried out in an aqueous solution in the temperature range of 75—250 °C. The results of the experiment in which the reaction was started from **2** are shown in Fig. 2. When an aqueous solution of **2** was heated for 2 hr at 150 °C, **2** was completely isomerized into a mixture of 74% of **1** and 26% of **3**. On the other hand, when an aqueous solution of **1** or **3** was heated, **2** was not found at all in the reaction mixture at any temperature. The equilibrium mixture at 250 °C contained 71% of **1** and 29% of **3**.

Almost Quantitative Conversion of 3 to 1. The solubility of **1** in ethanol or water is lower than that of **3**, so **1** and **3** are easily separated by fractional crystallization. Thus almost quantitative conversion of **3** to **1** may be accomplished by letting the isomerization reaction and the fractional crystallization proceed simultaneously in one vessel.

The compound, **3** (181 mg) was heated in 0.1 M ethanolic sodium ethoxide (2 ml) for 15 min at 78 °C, so that it was completely dissolved. The solution was cooled slowly to room temperature for 4 hr under stirring. The crystals thus produced were filtered, washed with absolute ethanol. The mother liquor was immediately neutralized with hydrochloric acid. The contents of **1** and **3** in the crystals, those in the washing solution and those in the mother liquor were analyzed by glc (Expt. No. 1 in Table 2). The crystals were shown to be pure **1** (78% yield). The ratio of **1** to **3** in the mother liquor was found to be equal to the ratio of the equilibrium at room temperature, so the equilibrium between **1** and **3** is considered to be established in the solution before the end of the reaction. As shown in Fig. 1, only about 83% of **3** would be able to be converted to **1** if only the equilibrium reaction between **1** and **3** at room temperature was used. However, 97% of **3** could, in fact, be converted to **1** in our experiment as shown in Table 2 (Expt. No. 1). These results show that the isomerization and the fractional crystallization simultaneously took place in practice.

A mixture of 58% of **3** and 42% of **1** in crystalline states could also be converted to 96% of **1** and 4% of **3** on the whole as shown in Table 2 (Expt. No. 2). During this experiment, which is different from the case of Expt. No. 1, there were always some amount of crystals remaining in the solution.

By this method, any mixture composed of **1**, **2**, and **3** would be converted almost quantitatively to **1** in one vessel.

One-step Preparation of Cyclic Dipeptide from the Amino Acid. A cyclic dipeptide is known to be prepared by heating the corresponding amino acid in ethylene glycol, however, no detailed examination has yet been made on the composition of the product, that is, the

Table 2. Conversion of *c*-D-*a*Hyp-D-*a*Hyp (**3**) to *c*-L-Hyp-L-Hyp (**1**)

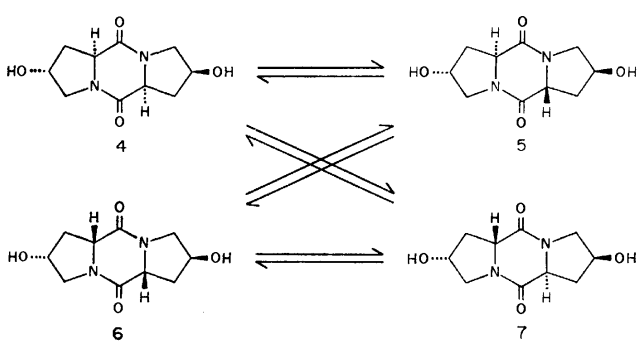
a) A: a 20—25% solution of amino acid in water was heated at 260—290°C for 4 hr. B: a 5—10% solution of amino acid in ethylene glycol was refluxed for 7—10 hr. b) The content was estimated by glc. c) A mixture of equal amounts of DL-Hyp and DL-*a*Hyp.

amounts of *cis*- and *trans*-isomers.[9,10] In the course of the present studies, it was found that cyclic dipeptides can be formed even in an aqueous solution (instead of ethylene glycol) directly from the amino acid at high temperature in good yield. We therefore examined, in the next step, the composition of *cis*- and *trans*-isomers in such products. The results are shown in Table 3 for the case of 4-hydroxyproline and proline heated in an aqueous solution or ethylene glycol.

The composition of cyclic dipeptides produced by heating an aqueous solution of L-Hyp or D-*a*Hyp was found to be equal to that in the equilibrium of the isomerization between **1** and **3** at the same temperature. Pure **1** was easily obtained by the recrystallization of these cyclic dipeptides mixture from ethanol or water.

When a mixture of equal amounts of DL-Hyp and DL-*a*Hyp was heated in an aqueous solution, only the *cis*-isomers were formed. This *cis*-isomer mixture contained 50% of racemic modification of **1** and **3**, and 50% of racemic modification of *c*-L-Hyp-L-*a*Hyp (**4**) as shown in Table 3. Therefore, three isomerization reactions, *i.e.*, the reaction shown in Scheme 1, the reaction among *c*-D-Hyp-D-Hyp (**8**), *c*-D-Hyp-L-*a*Hyp (**9**) and *c*-L-*a*Hyp-L-*a*Hyp (**10**) (the enantiomeric reaction of Scheme 1), and the reaction among *c*-L-Hyp-L-*a*Hyp (**4**), *c*-L-Hyp-D-Hyp (**5**), *c*-D-*a*Hyp-D-Hyp (**6**), and *c*-D-*a*Hyp-L-*a*Hyp (**7**) (Scheme 2), occurred and



Scheme 2.

independently reached the equilibrium without mutual intersection.

By refluxing in ethylene glycol, L-Pro was coverted to optically inactive *c*-Pro-Pro,[10] which was found in the present studies to be racemic form, *i.e.*, equimolar mixture of *c*-L-Pro-L-Pro (**11**) and *c*-D-Pro-D-Pro (**12**), but not to be *meso* form, *c*-L-Pro-D-Pro (**13**).

Acid Hydrolysis of Cyclic Dipeptides. In order to obtain L-Hyp from D-*a*Hyp through cyclic dipeptide, **1** should be hydrolyzed into L-Hyp in its last step. Therefore, it is desirable that no racemization takes place in this procedure. It was reported, however, that the amino acids produced by acid hydrolysis of cyclic dipeptides were in general partially racemized.[11,12] We therefore made a slightly more detailed examination on this point.

Table 4. Acid hydrolysis of cyclic dipeptides

Compd	Reaction condition[a]	Amino acid, %		
			Yield[b]	Degree of racemization[c]
1	A	L-Hyp	97.4	2.1
		D-*a*Hyp	2.1	
2	A	L-Hyp	52.6	52.1
		D-*a*Hyp	48.2	
3	A	L-Hyp	3.3	3.3[d]
		D-*a*Hyp	96.4	
11	A	Pro	101.9	3.1[e]
14[f]	B	Ala	99.4	1.9[e]
15[g]	C	Val	69.9	1.2[e]

a) A: a 5% solution of cyclic dipeptide in 6 M hydrochloric acid was heated for 14 hr at 110°C in an open vessel B: a 0.5% solution of cyclic dipeptide in 6 M hydrochloric acid was similarly heated. C: a 0.3% solution of cyclic dipeptide in 6 M hydrochloric acid was similarly heated in a closed vessel. b) The analyses were carried out by amino acid analyzer. c) [D]/[L+D]. d) [L]/[L+D]. e) The analyses were performed by the method of Halpern and Westley (Refs. 15 and 16). f) *c*-L-Ala-L-Ala (**14**). g) *c*-L-Val-L-Val (**15**).

The *c*-Pro-Pro type of cyclic dipeptides were hydrolyzed under acidic condition and then the degree of racemization during hydrolysis was examined. The results are shown in Table 4. When a solution of the cyclic dipeptide in 6 M hydrochloric acid was heated for 14 hr at 110 °C, the degree of racemization was about 2—3%. This value is not so much larger than that found for other peptides.[13,14] Therefore, cyclic dipeptides are not necessarily considered to be easily racemized under acidic condition. Pure L-Hyp was easily obtained by recrystallization of crude L-Hyp produced by hydrolysis of **1**.

Conversion of D-a*Hyp to* L-*Hyp.* On the basis of our examination so far described, it has now been made clear that, by combination of isomerization and hydrolysis of cyclic dipeptide, L-Hyp could be readily obtained from D-*a*Hyp or any mixture of D-*a*Hyp and L-Hyp. Actually L-Hyp was obtained in 59% yield from D-*a*Hyp by the procedures. Here, the preparation of cyclic dipeptides was made in an aqueous solution by heating and the isomerization was made

in ethanolic sodium ethoxide. L-Hyp was also very easily obtained in 50% yield from D-*a*Hyp by combination of preparation of cyclic dipeptides by heating in ethylene glycol and acid hydrolysis of cyclic dipeptides. These procedures have been also applied to the conversion of L-*a*Hyp to D-Hyp with practically the same yield in the conversion of D-*a*Hyp to L-Hyp, as expected.

Experimental

All melting points are uncorrected. IR spectra were recorded in KBr disk on a Jasco Model IR-S Infrared Spectrophotometer. NMR spectra were measured in DMSO-d_6 solution with a Varian Spectrometer T-60 using TMS as internal standard. Mass spectra were obtained using a Hitachi RMU-6E Mass Spectrometer. Optical rotations were measured with a Jasco Model DIP-SL automatic polarimeter. The thin layer chromatography (tlc) was carried out on Merck silica gel 60 using the following solvent systems: (A) chloroform: methanol: acetic acid: water=68: 28: 1: 3; (B) *n*-butanol: acetic acid: water=4: 1: 1. The analyses of amino acid were carried out using a Hitachi KLA-3B Automatic Amino Acid Analyzer (column size, 50×0.9 cm; resin, Hitachi Type 2612; column flow rate, 60 ml/hr; buffer, citrate (0.2 N) pH 3.25; temperature, 55 °C). Glc analyses were performed using a Hewlet Packard 402 High Efficiency Gas Chromatogram equipped with FID and a 4 ft×1/4 in. i.d. glass column packed with 5% QF-1 on Chromosorb G (AW-DMC), 80—100 mesh.

Preparation of Cyclic Dipeptides. The physical constants of *c-Pro-Pro* type of cyclic dipeptides are summarized in Table 5.

c-L-*Hyp*-L-*Hyp* (*1*) and *c*-L-*Pro*-L-*Pro* (*11*) were prepared by the method of Kapfammer and Matthes.[17] *c*-L-*Pro*-D-*Pro* (*13*) was prepared by the method of Siemion.[6]

c-L-*Hyp*-D-*aHyp* (*2*). A mixture of D-*allo*-hydroxyproline methyl ester hydrochloride (6.90 g, 39.0 mmol) and equimolar triethylamine in 30 ml of chloroform was added at −5 °C with vigorously stirring to a mixture of *N*-carbobenzoxy-L-hydroxyproline (10.1 g, 38.0 mmol), methyl chloroformate (4.10 g, 38.0 mmol) and equimolar triethylamine in 100 ml of chloroform. The mixture was stirred at 0 °C for 4 hr and washed with water, 2 M hydrochloric acid, water, saturated sodium bicarbonate and water. The chloroform solution was dried over sodium sulfate. Evaporation gave *N*-carbobenzoxy-L-hydroxyprolyl-D-*allo*-hydroxyproline methyl ester (4.90 g) in 33% yield as oil. This dipeptide ester was hydrogenated in methanol solution at atmospheric pressure in the presence of 10% Pd-C (50 mg) for 10 hr and the filtrate was evaporated. Water (10 ml) was added to the residue and the aqueous solution was passed through an ion exchange column carrying 5 ml of IR·120 resin (acid form) to remove substrates positive for ninhydrin test. The passed solution was decolorized with active charcoal and evaporated to dryness under

reduced pressure. The residue was recrystallized from ethanol–ether to give 1.22 g (5.40 mmol) of **2** in 43% yield from dipeptide ester: IR 3380 (OH), 1655 and 1625 (C=O) cm^{-1}; NMR δ 1.6—2.2 (4H), 3.40 (4H), 4.2—4.5 (4H) and 5.16 (2H).

c-L-*Hyp*-L-*aHyp* (**4**), *c*-L-*Hyp*-D-*Hyp* (**5**) and *c*-D-*aHyp*-L-*aHyp* (**7**) were prepared in a similar manner to that of **2**. **4**: IR 3350 (OH), 1632 and 1645 (C=O) cm^{-1}; NMR δ 1.9—2.4 (4H), 3.39 (4H), 4.2—4.6 (4H) and 5.10 (2H). **5**: IR 3334 (OH) and 1630 (C=O) cm^{-1}; NMR δ 1.8—2.2 (4H), 3.4 (4H), 4.0—4.5 (4H) and 5.22 (2H). **7**: IR 3390 (OH) and 1635 (C=O) cm^{-1}; NMR δ 1.5—2.0 (4H), 3.40 (4H), 4.0—4.6 (4H) and 5.20 (2H).

c-D-*aHyp*-D-*aHyp* (**3**). Thionyl chloride (5.45 g, 45.8 mmol) was added to a solution of D-*aHyp* (5.00 mg, 38.2 mmol) in 50 ml of methanol at —5 °C. The mixture was refluxed for 2 hr and evaporated under reduced pressure. Anhydrous ammonia was bubbled into a chloroform solution (50 ml) of the dried residue at 0 °C. After filtration of ammonium chloride, the filtrate was concentrated below 40 °C under reduced pressure. The resulting syrup was allowed to stand at room temperature for two weeks. Water (10 ml) was added and the aqueous solution was treated with IR-120 resin (acid form) and active charcoal in a similar manner to that of **2**. The residue was recrystallized from ethanol to give 3.67 g (16.2 mmol) of **3** in 85% yield: IR 3380 (OH) and 1645 (C=O) cm^{-1}; NMR δ 2.1—2.5 (4H), 3.35 (4H), 4.2—4.5 (4H) and 5.00 (2H); mass spectrum *m/e* 226 (M^+), 198, 140, 112 and 86. Differences among **1**—**10** were not found in mass spectra.

c-D-*Pro*-D-*Pro* (**12**) was prepared from D-Pro in a similar manner to that of **3**.

Racemic c-Pro-Pro. An equimolar mixture of **11** (0.219 g, 1.13 mmol) and **12** (0.219 g, 1.13 mmol) in ethanol was recrystallized to yield racemic *c*-Pro-Pro (0.277 g, 1.43 mmol, 63%).

Isomerization in 0.1 M Ethanolic Sodium Ethoxide. A solution of *c*-D-*a*Hyp-D-*a*Hyp (**3**) (50.0 mg, 0.221 mmol) in absolute ethanol (3.57 ml) was allowed to stand at 50.0±0.1 °C. The isomerization started immediately after 0.85 ml of 0.520 M ethanolic sodium ethoxide was poured into the solution. After 5 min, 0.44 ml of the solution was taken out and rapidly poured into 0.095 ml of 0.5 M hydrochloric acid. The slightly acidic solution was immediately evaporated to dryness under reduced pressure. The residue was further dried *in vacuo* over potasium hydroxide and was heated with *N,O*-bis(trimethylsilyl)acetamide (0.5 ml) and dry pyridine (0.5 ml) for 5 min at 80 °C. The mixture was injected directly into gas liquid chromatogram. The contents of **1**, **2** and **3** were analyzed. The mixture was composed of 26.1% of **1** and 73.9% of **3**. **2** was not detectable. The samplings were done at different times. The following results were obtained: 52.8% of **1** at 15 min, 74.3% of **1** at 30 min, 83.3% of **1** at 1 hr, 83.6% of **1** at 3 hr, 83.7% of **1** at 4 hr, 83.4% of **1** at 5 hr, and 83.6% of **1** at 8 hr. From the isomerization using **1** as a starting material, the following results were obtained at the same temperature: 83.6% of **1** at 3 hr, 83.7% of **1** at 4 hr, and 83.4% of **1** at 8 hr. The isomerizations were similarly carried out at 25.0±0.1 °C and 78.0±0.1 °C by use of **1**, **2** and **3**. The time required for reaching the equilibrium between **1** and **3** was about 20 hr at 25 °C, 2 hr at 50 °C and 0.5 hr at 78 °C.

Isomerization in Aqueous Solution. A solution of *c*-L-Hyp-D-*a*Hyp (**2**) (50 mg, 0.22 mmol) in water (0.5 ml) was sealed in a small glass tube and heated at 100 °C for 2 hr. The tube was immediately cooled and opened. One-eighth of the resulting clear solution was taken out and evaporated under reduced pressure. The residue was treated in a similar manner to that described in the isomerization in ethanolic sodium ethoxide. The product was composed of 46.8% of **1**, 42.0% of **2** and 11.2% of **3**. In a similar manner, the isomerizations were carried out at 50, 75, 100, 150, 200 and 250 °C by use of **1**, **2** and **3**.

Conversion of c-D-aHyp-D-aHyp (3) to c-L-Hyp-L-Hyp (1). The reaction condition and the results are shown in Table 2. The following results were obtained for the crystals in Table 2, Expt. No. 1: mp 243—245 °C; $[\alpha]_D^{25}$ −153.2° (*c* 1.00, H_2O); Found: C, 53.30; H, 6.32; N, 12.40; Na, 0.041%. Calcd for $C_{10}H_{14}O_4N_2$: C, 53.09; H, 6.24; N, 12.38%. The following analytical results were also obtained for the crystals in Table 2, Expt. No. 2: mp 245—247 °C; $[\alpha]_D^{28}$ −150.1° (*c* 1.00, H_2O).

Preparation of c-L-Hyp-L-Hyp (1) from D-aHyp. (*A*) A solution of D-*a*Hyp (15.0 g, 115 mmol) in water (80 ml) was heated at 250—270 °C for 4 hr. The mixture was passed through an ion exchange column carrying 15 ml of IR-120 resin (acid form) to remove substrates positive for ninhydrin test. The passed solution was decolorized with active charcoal and evaporated to dryness under reduced pressure. The residue was further dried *in vacuo* over phosphorus pentoxide. The residue weighed 11.6 g and, by the results of glc analyses, was composed of 72% of **1** and 28% of **3**. A solution of 10.0 g of the cyclic dipeptide mixture thus obtained in 0.1 M ethanolic sodium ethoxide (70.0 ml) was heated by stirring at 78 °C for 30 min. The solution was cooled by gently stirring to room temperature for 4 hr. The crystals thus produced were filtered, washed with cooled absolute ethanol and dried *in vacuo* to give 7.54 g (33.4 mmol) of **1** in 68% yield from D-*a*Hyp: mp 247—249 °C; $[\alpha]_D^{24}$ −152.0° (c 1.00, H_2O); Found: C, 53.08; H, 6.26: N, 12.34%. Calcd for $C_{10}H_{14}O_4N_2$: C, 53.09; H, 6.24; N, 12.38%.

(*B*) A solution of D-*a*Hyp (30.0 g, 229 mmol) in ethylene glycol (500 ml) was heated under refluxing for 10 hr. The mixture was evaporated under reduced pressure. Water (150 ml) was poured into the residue. The aqueous solution was similary treated with IR-120 resin and active charcoal, and evaporated. By the results of glc analyses, the residue contained 22.3 g (99 mmol, 87%) of cyclic dipeptides composed of 77% of **1** and 23% of **3**. This residue was recrystallized from water to give 14.8 g (65.5 mmol) of **1** in 57% yield: mp 248—249 °C; $[\alpha]_D^{28}$ −155.3° (c 1.00, H_2O); Found: C, 53.00; H, 6.26; N, 12.41%. Calcd for $C_{10}H_{14}O_4N_2$: C, 53.09; H, 6.24; N, 12.38%.

Preparation of c-D-Hyp-D-Hyp (8) from L-aHyp. A solution of L-*a*Hyp (7.85 g, 59.9 mmol) in water (70 ml) was heated at 270—290 °C for 2 hr and was similarly treated with IR-120 resin. By the results of glc analyses, the passed solution contained 5.89 g (26.1 mmol, 87%) of cyclic dipeptides composed of 71% of **8** and 29% of *c*-L-*aHyp*-L-*aHyp* (**10**). The passed solution was decolorized with active charcoal, concentrated and cooled. The crystals thus produced were filtered, washed with cold water and dried *in vacuo* to give 3.68 g (16.3 mmol) of **8** in 54% yield: mp 248—250 °C; $[\alpha]_D^{28}$ +153.9° (c 1.17, H_2O); Found: C, 53.09; H, 6.27; N, 12.49%. Calcd for $C_{10}H_{14}O_4N_2$: C, 53.09; H, 6.24; N, 12.38%. IR 3290 (OH), 1655 and 1635 (C=O) cm^{-1}. NMR δ 1.9—2.1 (4H). 3.32 (4H), 4.1—4.7 (4H) and 5.05 (2H).

Hydrolysis of c-L-Hyp-L-Hyp (1). A solution of **1** (5.00 g, 22.1 mmol) in 6 M hydrochloric acid (100 ml) was heated for 14 hr at 110 °C. The contents of amino acids in the mixture were analyzed by automatic amino acid analyzer. L-Hyp (5.65 g, 43.1 mmol, 97.4% yield) and D-*a*Hyp (0.12 g, 0.93 mmol, 2.1% yield) were formed. The mixture was evaporated under reduced pressure. The residue was dissolved in water (30 ml) and the aqueous solution was

applied to an ion exchange column carrying 100 ml of IR-120 resin (acid form). The resin was washed with water and the absorbed amino acids were eluted with 0.2 M ammonium hydroxide. The elute was decolorized with active charcoal and concentrated under reduced pressure. Ethanol was poured into the residue to yield precipitates. The precipitates were filtered, washed with ethanol and dried *in vacuo* to give 5.03 g (38.4 mmol) of L-Hyp in 87% yield: mp 276—277 °C; $[\alpha]_D^{29}$ —76.0° (c 1.01, H_2O); Found: C, 45.92; H, 6.75; N, 10.84%. Calcd for $C_5H_9O_3N$: C, 45.80; H, 6.92; N, 10.68%.

The authors wish to express their thanks to Prof. Masamichi Tsuboi and Prof. Naoki Inamoto in University of Tokyo for their valuable suggestions, and to Dr. Takehiko Ichikawa, Dr. Yuji Iwashita and Dr. Masatsune Kainosho for many helpful discussions.

A Photochemical Reaction of Lupan-3-one

Hiroshi HIROTA, Takahiko TSUYUKI, Yoshiaki TANAHASHI, and Takeyoshi TAKAHASHI

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received April 8, 1974)

Lupan-3-one (**5**) was irradiated in *n*-hexane under an argon atmosphere using a high pressure mercury lamp. Besides three seco compounds, namely 10α-(2-formylethyl)-5β-isopropenyl-des-A-lupane (**6**), 10α-(2-carboxyethyl)-5β-isopropyl-des-A-lupane (**8**), and 10α-(2-carboxyethyl)-5β-isopropenyl-des-A-lupane (**9**), two seco-nor compounds, 10α-(carboxymethyl)-5β-isopropyl-des-A-lupane (**7**) and lactone of 10α-(carboxymethyl)-5α-hydroxy-5β-isopropyl-des-A-lupane (**10**), have been isolated and their structures have been determined. NMR signals of **10** were examined using Eu(fod)$_3$-d_{27} as a shift reagent.

In previous papers[1] we reported the photochemical reaction of friedelin (**1**), in which seco-nor products such as 5α-ethyl-10β-(formylmethyl)-des-A-friedelane (**2**) and 10β-(carboxymethyl)-5α-ethyl-des-A-friedelane (**3**) were obtained as abnormal products together with a normal product, 10β-(2-carboxyethyl)-5α-ethyl-des-A-friedelane (**4**). In connection with this observation, a formation of seco-nor derivatives was examined in a photo-reaction of lupan-3-one (**5**), bearing a 3-oxo-4,4-dimethyl moiety in the A ring. We wish to describe the isolation and structure determination of compounds (**6**—**10**) which were obtained by the photolysis of lupan-3-one (**5**) in *n*-hexane. Among these products, the seco-acid (**8**) had been obtained in about 50% yield by the photolysis of **5** in a mixture of water and acetic acid.[2]

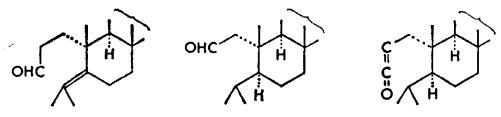
8 R=H 8a R=Me 9 R=H 9a R=Me 10

A solution of lupan-3-one (**5**) in *n*-hexane was irradiated at room temperature under an argon atmosphere for about 6.5 hr using a 100 W high pressure mercury lamp to give a complex reaction mixture, which was separated by silica gel column and thin layer chromatographies into hydrocarbon, aldehyde, ketone, lactone, and acid fractions.

From the aldehyde fraction, only one compound, $C_{30}H_{50}O$ (M^+ *m/e* 426) was isolated. This substance showed the presence of one olefinic methyl (δ 1.72), two olefinic protons (δ 4.65 and 4.85, each multiplet) and an aldehydic proton (δ 9.75, t, J=2 Hz) in NMR spectrum and exhibited characteristic IR absorption bands at 2720, 1735 (–CHO), 1640 and 895 cm^{-1} (–C=CH$_2$). Thus, the aldehyde was inferred to be 10α-(2-formylethyl)-5β-isopropenyl-des-A-lupane (**6**) and the structure was also supported by the fragmentation pattern of the mass spectrum.

The isolation of an unsaturated aldehyde with an isopropenyl group rather than an isopropylidene group in the photolysis of lupan-3-one (**5**) is unexpected. Since the well-documented photo-cleavage of cyclohexanones leads to a δ-unsaturated aldehyde by α-cleavage followed by transfer of a hydrogen atom from a δ-carbon (C-5 in the case of lupan-3-one (**5**)) *via* a six-membered ring transition state (reaction pathway "a"), the resulting unsaturated aldehyde from lupan-3-one (**5**) should be 10α-(2-formylethyl)-5-isopropylidene-des-A-lupane (**11**). The formation of the unsaturated aldehyde (**6**) with an isopropenyl moiety could be explained by α-cleavage of **5** followed by an abstraction of a hydrogen atom of $C_{(4)}$–CH_3 by the acyl radical through an eight-membered ring transition state (reaction pathway "b").[3] Although the occurrence of the reaction pathway "a" seems to be more likely than that of the path "b" in lupan-3-one (**5**), the aldehyde (**11**) was not obtained in the photolysate. However, the absence of the aldehyde (**11**) does not always mean that the path "a" did not occur at all,



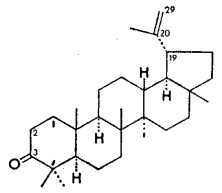
11 12 13

because the aldehyde (**11**) could further react photochemically or thermally.

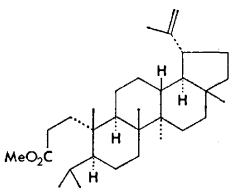
The ketone fraction was shown to be lupan-3-one (**5**) and the recovery was about 12%.

The carboxylic acid fraction showed three spots on tlc. A compound with the highest R_f value had molecular formula $C_{29}H_{50}O$, which was confirmed by high resolution mass spectrometry, and showed IR absorption band at 1705 cm^{-1}. This acid was converted into the methyl ester (IR 1740 cm^{-1}; NMR δ 3.64 ($-CO_2C\underline{H}_3$) and 2.37 (2H, s, $-\underset{|}{C}-C\underline{H}_2-CO_2CH_3$); M^+ *m/e* 444). From these findings, the original acid could be formulated as 10α-(carboxymethyl)-5β-isopropyl-des-A-lupane (**7**). This acid with one carbon atom less than lupan-3-one (**5**) is corresponding to the photochemically unusual carboxylic acid (**3**) obtained by the photochemical reaction of friedelin (**1**) in *n*-hexane. Although in the case of lupan-3-one (**5**), the seco-nor aldehyde (**12**) was not isolated, the formation of the acid (**7**) was explicable by the oxidation of the seco-nor aldehyde (**12**), which could be produced by the autoxidation of the ketene (**13**) during a subsequent separation work-up after the irradiation, as stated elsewhere.[1]

The remaining two carboxylic acids were converted into their methyl esters and separated by tlc. A methyl ester with higher R_f value was identical with an authentic specimen (**8a**), which was prepared by photochemical reaction of lup-20(29)-en-3-one (**14**) in methanol followed by hydrogenation. Thus, the original acid was identified to be 10α-(2-carboxyethyl)-5β-isopropyl-des-A-lupane (**8**) and the spectral data were identical with those of tetrahydrocanaric acid.[2]



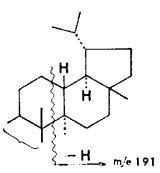
14



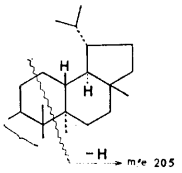
21

The other methyl ester with lower R_f value showed characteristic IR and NMR spectra due to an isopropenyl group. On hydrogenation, the methyl ester gave a saturated methyl ester, which was identical with 5β-isopropyl-10α-(2-methoxycarbonylethyl)-des-A-lupane (**8a**). The carboxylic acid, therefore, was formulated as 10α-(2-carboxyethyl)-5β-isopropenyl-des-A-lupane (**9**) and the formation could be explained by the oxidation of the unsaturated aldehyde (**6**) during work-up.

A lactone was isolated from the fraction between the ketone and the carboxylic acids by preparative tlc and recrystallized from chloroform-methanol. IR and NMR spectral data and the molecular formula, $C_{28}H_{48}O_2$, given by high resolution mass spectrometry, indicate the presence of a γ-lactone group with one carbon atom less than the original ketone (**5**). Fragment ions at *m/e* 191 ($C_{14}H_{23}$) and 205 ($C_{15}H_{25}$) correspond to species **15** and **16**, respectively, showing the presence of the intact rings D and E (and C).[4] The NMR spectrum showed the presence of an isolated methylene (δ 2.41, 2H, br.s) at the α-position to the carbonyl group and the absence of a hydrogen atom on the carbon atom adjacent to the ethereal oxygen atom.



15



16

NMR measurements using Eu(fod)$_3$-d_{27} as a shift reagent were applied in order to determine the structure of the lactone. The result was summarized in Fig. 1. A spectrum obtained in a mixture of Eu(fod)$_3$-d_{27} and the lactone in a molar ratio of 1.33: 1 in deuteriochloroform solution, was given in Fig. 2. In addition to the isopropyl group at C-19, the presence of a new isopropyl group was clearly shown. On irradiation of the signal around δ 5.3, two pairs of doublets due to two methyl protons (δ 3.54, J=7 Hz and δ 2.46, J=7 Hz) changed into two singlets. Judging from a large degree of the shift, one of the isopropyl groups must be located fairly near the carbonyl group. These observations suggest that the lactone could be represented by structure (**10**).

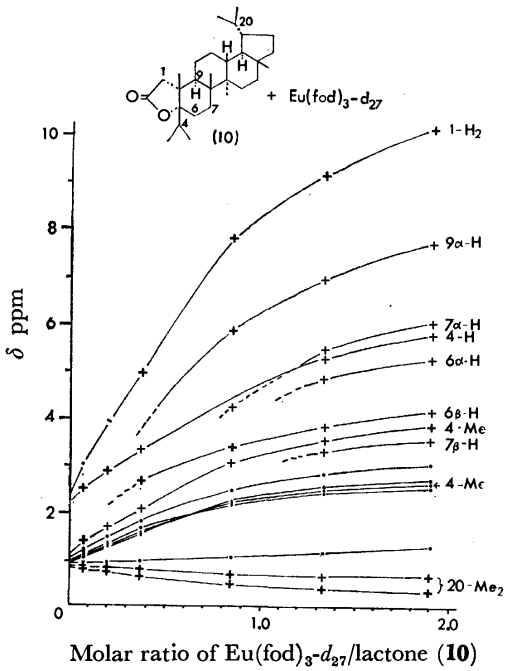


Fig. 1. Molar ratio of Eu(fod)$_3$-d_{27}/lactone (**10**) *vs.* chemical shift.

From the fact that two methylene protons adjacent to the carbonyl carbon were shifted with the largest slope and with nearly the same degree (see Figs. 1 and 2), it is considered that Eu(fod)$_3$-d_{27} is associated with the carbonyl group (and the ethereal oxygen) and located almost on a plane which bisects the methylene group at C-1. One proton (q, J=10.5 and 5.5 Hz) showing the second largest slope was assigned to 9α-(axial)-proton from the degree of shift (Figs. 1 and 2). These assignments, therefore, lead to the conclusion

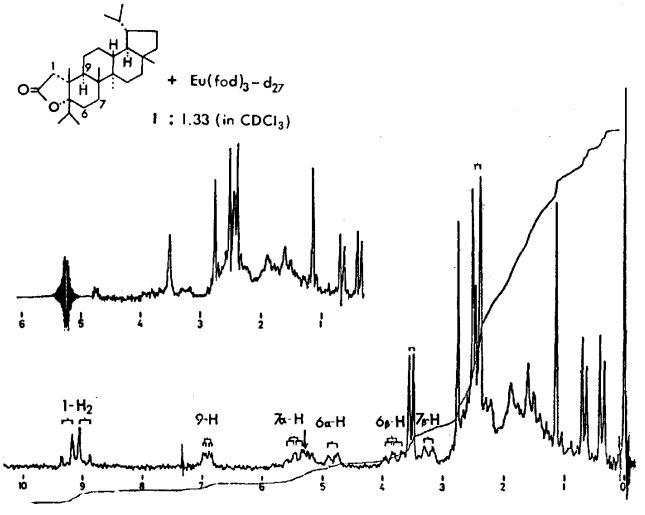

Fig. 2. NMR spectra.

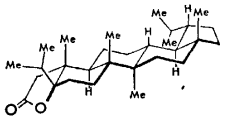
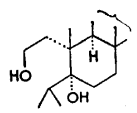
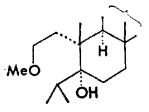
that the ring juncture A/B is *cis* and then the C-5 isopropyl group is situated in β-side. The other stereochemistries are not compatible with the spectral data including pseudo-contact shift experiments. For example, a proton at C-9 of a *trans*-lactone (a C-5 epimer of **10**) would scarecely suffer the induced paramagnetic shift. Thus, the conformation of the lactone molecule is established as **17**. This conformation (**17**) could also explain a small shift of two methyl protons of 19α-isopropyl group. The remaining four protons (7α-, 6α-, 6β-, and 7β-) at ring B, which showed fairly large shifts, could be assigned as shown in Fig. 2 from the degree of the pseudo-contact shift and from the results of decoupling experiments (Figs. 1 and 2).



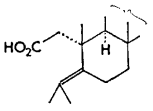
17



18



19



20

The lactone (**10**) was reduced with lithium aluminium hydride in tetrahydrofuran to the corresponding diol (**18**), which in turn was coverted into the monomethyl ether (**19**) with methyl iodide and silver oxide in dimethylformamide.[5] The spectral data of these two derivatives could be explicable by their proposed structures. These observations furnish further evidence for the presence of the lactone structure in **10**.

It is most likely that the lactone (**10**) may be derived from 10α-carboxymethyl-5-isopropylidene-des-A-lupane (**20**), which was undetectable in the photo-reaction products of lupan-3-one (**5**) in *n*-hexane, although the formation of the unsaturated seco-nor acid (**20**) could hardly be explained. The elucidation of the mechanism is under way.

Experimental

IR spectra were measured using a Hitachi EPI-G2 spectrometer. NMR spectra were taken on a Hitachi R-20B (60 MHz) or a JEOL-PS-100 spectrometer (100 MHz) in deuteriochloroform solution containing tetramethylsilane as an internal standard. High resolution mass spectra were measured using a Hitachi RMH-2 or RMU-7M mass spectrometer operating at 70 eV. Measurements of low resolution mass spectra were carried out using a Hitachi RMU-6-Tokugata mass spectrometer with a direct inlet system operating at 70 eV unless otherwise stated. Gas chromatographic (glc) analyses were performed on a Shimadzu gas chromatograph model GC-4APF. For column chromatography Wakogel C-200 (Wako Pure Chemical Industries) and Activated Alumina (mesh 200—300, Showa Chemical Co.) were used. Thin layer chromatography (tlc) was carried out on Kieselgel G (E. Merck, Darmstadt) in 0.25 mm thickness. All melting points were determined on a hot block and reported uncorrected.

n-Hexane (extra pure grade, Wako Pure Chemical Industries) was found to contain 2-methylpentane, 3-methylpentane, and methylcyclopentane, but no unsaturated hydrocarbons as impurities by GC-MS examination (column: DC-550, 1m; oven temperature 10 °C). Any coloration with concentrated sulfuric acid was not observed.

The purity of the starting material, lupan-3-one (**5**) was checked by glc (column: OV-1 (2%); 270 °C and OV-17 (2%), 300 °C), tlc, and MS. And the absence of any compound with one carbon atom less than lupan-3-one (**5**) was confirmed.

Photochemical Reaction of Lupan-3-one (5). Lupan-3-one (**5**; 500 mg) was dissolved completely in dry *n*-hexane (750 ml) and the solution in a Pyrex vessel was then irradiated for about 6.5 hr at room temperature using a 100 W high pressure mercury lamp under an argon atmosphere.

Isolation and Characterization of the Reaction Products. After the solvent was distilled off under reduced pressure, the reaction products were roughly separated by silica gel (100 g) column chromatography into hydrocarbon, aldehyde, ketone, lactone, and carboxylic acid fractions. Each fraction was further separated and purified by repetition of column and/or preparative thin layer chromatography.

Elution with petroleum ether gave a mixture (about 20 mg) of hydrocarbons, which showed more than three spots on tlc (10% $AgNO_3$-SiO_2). Further examination of the mixture was not effected.

Successive elution with petroleum ether–benzene (1: 1) afforded about 80 mg of a crude aldehyde (**6**). However, the aldehyde was so liable to decompose gradually in contact with air and rapidly on silica gel and alumina, that column chromatographic separations on silica gel and then on alumina could give only about 20 mg of the aldehyde (**6**).

Upon continued elution with benzene, a ketone (about 60 mg) was obtained, which was identified by direct comparison of the IR and MS data with those of the starting material, lupan-3-one (**5**).

Although further elution with benzene–ether (10: 1) was continued, good separation was not obtained. A mixture (about 180 mg) of γ-lactone (**10**), carboxylic acids (**7**), (**8**), and (**9**) and other unknown minor compounds was eluted at the same time. The main four compounds were recorded in their order of elution. Since it was difficult to separate these compounds completely, further separation was accompanied with a considerable extent of loss. Repetition of column and thin layer chromatographic separations, though

these methods were not so effective for the separation of the fraction obtained above, could afford about 20 mg of pure γ-lactone (**10**) and about 15 mg of pure seco-nor acid (**7**). A mixture of the remaining two carboxylic acids with the lowest and the second lowest R_f values was treated with diazomethane in ether to give a mixture of their methyl esters (**8a**) and (**9a**). The mixture was separated into **8a** and **9a**. Each weighed about 15—20 mg.

10α-(2-Formylethyl)-5β-isopropenyl-des-A-lupane (6): An amorphous solid, IR (KBr disk) 2720, 1735, 1640, and 895 cm^{-1}; NMR δ 1.72 (CH_2=Ç-C$\underline{H}_3$), 4.65, 4.85 (each m, C$\underline{H}_2$=Ç-), and 9.75 (t, J=2 Hz, -C$\underline{H}$O), 0.76, 0.82, 0.88, 0.95, 1.05, and 1.10 (other methyl protons); MS *m/e* (relative intensity %) 426 [3; $M^+(C_{30}H_{50}O)$], 411 [3; $(M-15)^+$], 383 [5; $(M-43)^+$], 369 [5; $(M-57)^+$], 345 [12; $(M-81)^+$], 327 [15; $(M-99)^+$], 231 (17), 205 (37), 191 (61), and 81 (100).

10α-(Carboxymethyl)-5β-isopropyl-des-A-lupane (7): An amorphous solid, IR (Nujol mull) 3400—2500 (br) and 1705 cm^{-1}; MW 430.3805, Calcd for $C_{29}H_{50}O_2$: 430.3808; MS *m/e* (%) 430 (13; M^+), 387 (16), 371 (6), 370 (4), 259 (8), 231 (10), 205 (16), 191 (31), and 95 (100).

5β-Isopropyl-10α-(methoxycarbonylmethyl)-des-A-lupane (7a): The above carboxylic acid (**7**; 15 mg) was treated with diazomethane and the methyl ester (**7a**; 12 mg) was obtained. An oil, IR (neat) 1740 cm^{-1}; NMR δ 2.37 (2**H**, s), 3.64 (3H, s), and other methyl protons; 0.75 (s), 0.83 (s), 0.91 (s), 1.05 (s), 0.75 (d, J=6.5 Hz), 0.82 (d, J=6.5 Hz), 0.84 (d, J=6.5 Hz), and 0.93 (d, J=6.5 Hz); MS *m/e* (%) 444 [23; $M^+(C_{30}H_{52}O_2)$], 401 (20), 371 (18), 370 (29), 205 (23), 191 (31), 178 (18), 177 (21), and 95 (100).

5β-Isopropyl-10α-(2-methoxycarbonylethyl)-des-A-lupane (8a): Mp 139—140 °C (recrystallized from chloroform-methanol); IR (KBr disk) 1745 cm^{-1}; MW 458.4130, Calcd for $C_{31}H_{54}O_2$: 458.4121; MS *m/e* (%) 458 (11; M^+), 443 (6), 415 (11), 371 (12), 253 (23), 231 (19), 209 (21), 205 (25), 191 (40), 137 (80), and 109 (100).

5β-Isopropenyl-10α-(2-methoxycarbonylethyl)-des-A-lupane (9a): An amorphous solid, IR (KBr disk) 1745, 1640, and 890 cm^{-1}; NMR δ 0.75 (3H, s), 0.76 (3H, d, J=7 Hz), 0.83 (3H, d, J=7 Hz), 0.84 (3H, s), 0.94 (3H, s), 1.08 (3H, s), 1.72 (3H, s), 2.25 (2H, m), 3.63 (3H, s), ~4.6 (1**H**, m), and ~4.8 (1H, m); MS *m/e* (%) 456 [5; $M^+(C_{31}H_{52}O_2)$], 441 (3), 425 (2), 413 (5), 375 (47), 369 (13), 231 (24), 205 (32), 191 (52), and 109 (100), (Ionization potential: 30 eV).

The methyl ester (**9a**; 10 mg) in methanol (30 ml) was hydrogenated in the presence of 10% palladium-carbon at room temperature overnight to afford **8a** quantitatively. This ester (**8a**) was identical (IR, NMR, and tlc) with a specimen mentioned above and also with an authentic specimen, prepared by photochemical reaction of lup-20(29)-en-3-one (**14**) in methanol followed by hydrogenation (*vide infra*).

Lactone of 10α-(Carboxymethyl)-5α-hydroxy-5β-isopropyl-des-A-lupane (10): A white crystal, mp 245—246 °C with sublimation; IR (KBr disk) 1775, 1455, 1390, 1385, 1375, 1280, 1245, 995, 950, and 945 cm^{-1}; MW 428.3652, Calcd for $C_{29}H_{48}O_2$: 428.3652; MS *m/e* (%; fragment composition, determined by high resolution mass spectrometry) 428 (2; $C_{29}H_{48}O_2$), 413 (3; $C_{28}H_{45}O_2$), 400 (1; $C_{28}H_{48}O$), 385 (95; $C_{26}H_{41}O_2$), 357 (24; $C_{25}H_{41}O$), 205 (15; $C_{15}H_{25}$), 191 (33; $C_{14}H_{23}$), and 69 (100; C_5H_9); NMR δ 0.77 (3H, d, J=7 Hz), 0.79 (3H, s), 0.87 (3H, d, J=7 Hz), 0.95 (3H, s), 1.03 (6H, d, J=7 Hz), 1.12 (3H, s), 1.16 (3H, s), and 2.41 (2H, br.s). The data using Eu(fod)$_3$-d_{27} were shown in Figs. 1 and 2.

Reduction of Lactone of 10α-Carboxymethyl-5α-hydroxy-5β-isopropyl-des-A-lupane (10) with Lithium Aluminium Hydride. A mixture of the lactone (**10**; 45 mg) and lithium aluminium hydride (about 30 mg, in large excess) in tetrahydrofuran (10 ml) was heated under reflux for 8.5 hr. Usual work-up gave a crystalline product, which was purified by preparative tlc to afford 5α-hydroxy-10α-(2-hydroxyethyl)-5β-isopropyl-des-A-lupane (**18**; 20 mg). Mp 221—222 °C (recrystallized from chloroform-methanol); IR (KBr disk) 3500—3150 (br), 1070, and 990 cm^{-1}; NMR (sparingly insoluble in $CDCl_3$) δ 3.4—3.8 (2H, m); MS (no molecular ion was observed at any of the measured ionization potential at 70, 25, and 20 eV.) *m/e* (%) 389 [7; $(M-43)^+$], 371 [100; $(M-43-18)^+$], 333 [24; $(M-99)^+$], 205 (22), 191 (40), and 111 (100).

Methylation of 5α-Hydroxy-10α-(2-hydroxyethyl)-5β-isopropyl-des-A-lupane (18). A mixture of the diol (**18**; 40 mg), methyl iodide (1 ml), silver oxide (200 mg) and dimethylformamide (5 ml) was stirred at room temperature for 21 hr. After usual treatment, 5α-hydroxy-5β-isopropyl-10α-(2-methoxyethyl)-des-A-lupane (**19**; 25 mg) was obtained by preparative tlc. Mp 168—169.5 °C (recrystallized from chloroform-methanol); IR (KBr disk) 3600—3300 (br), 1110, 1040, and 995 cm^{-1}; NMR δ 3.34 (3H, s), 4.12 (1H, br.s, O$\underline{H}$); MS (the molecular ion (*m/e* 446) was not observed at any of the measured ionization potential at 70, 20, and 15 eV.) *m/e* (%) 403 [10; $(M-43)^+$], 385 [4; $(M-43-18)^+$], 371 [100; $(M-43-33)^+$], 347 (26; $(M-99)^+$], 315 (27), 205 (26), and 191 (48); Found: C, 80.44; H, 12.29%. Calcd for $C_{30}H_{54}O_2$: C, 80.65; H, 12.18%.

Photochemical Reaction of Lup-20(29)-en-3-one (14) Followed by Hydrogenation. A solution of lup-20(29)-en-3-one (**14**; 400 mg) in methanol (700 ml) was irradiated using a 100 W high pressure mercury lamp under a nitrogen atmosphere for 16.5 hr at room temperature. After the solvent was removed, the reaction products were separated by silica gel column chromatography to afford 5β-isopropyl-10α-(2-methoxycarbonylethyl)-des-A-lup-20(29)-ene (**21**; about 100 mg) as a main product. IR (neat) 1750, 1645, and 890 cm^{-1}; NMR δ 3.65 (3H, s) and 4.50—4.75 (2H, m); MS *m/e* (%) 456 [43; M^+ ($C_{31}H_{52}O_2$)], 441 (22), 413 (16), 373 (9), 369 (30), 203 (77), and 189 (100).

Then, a mixture of the methyl ester (**21**; 40 mg) and 5% palladium-carbon (20 mg) in methanol was stirred under a hydrogen atmosphere at 50 °C for one day. After filtration, the reaction mixture was subjected to preparative tlc using a mixture of petroleum ether-benzene-chloroform (4:1:1) as an eluent. The main product (**8a**; 25 mg) was obtained as crystals.

The authors wish to thank Dr. Hiroshi Satoh and Dr. Yoshiaki Katoh of Naka Works, Hitachi Ltd. and Dr. Kazuyuki Aizawa of Department of Agricultural Chemistry, this University, for the measurements of high resolution mass spectra.

Sulfur-containing Polymers. XIII.[1] The Synthesis and Properties of Soluble Polydithiocarbamates

Norio KOBAYASHI, Akiko OSAWA, and Tamotsu FUJISAWA

Sagami Chemical Research Center, Nishi-Ohnuma, Sagamihara, Kanagawa 229

(Received April 15, 1974)

Polydithiocarbamates have been synthesized by the polycondensation of di-K or di-Na bisdithiocarbamates based on secondary diamines with bischloromethylated aromatics in *N,N*-dimethylformamide. The polymers obtained in good yields had inherent viscosities up to 0.66. The polymers derived from 1,3-di-4-piperidylpropane were soluble in organic solvents, such as dichloromethane and chloroform, and gave transparent, tough films from the solution. These polymers decomposed upon UV irradiation, with the liberation of carbon disulfide. The photopolymerization of methyl methacrylate in the presence of the polymer has also been studied.

The facile condensation of Na or K dithiocarbamates with alkyl halides is well known and has been extensively studied.[2] This reaction has been employed to introduce a dithiocarbamate side chain into polymers. Some of these polymers can serve as the backbone for photografting and as photosensitive resin.[3,4] However, the condensation reaction has not been extended to the preparation of high molecular-weight linear polymers. Although Zochniak has prepared polydithiocarbamates by the polycondensation of di-Na alkylene bisdithiocarbamates with bischloromethylated diphenyl ether, the polymers are insoluble in organic solvents.[5] This presents a major obstacle to the solution characterization of the products.

We have been interested in the polymers containing photosensitive groups in the main chain.[6-8] In the course of our studies, it was found that fairly high molecular-weight polydithiocarbamates (**3**) with good solubility characteristics can be prepared from di-K or di-Na bisdithiocarbamates based on secondary diamines (**1**) and bischloromethylated aromatics (**2**).[9] This paper will describe the synthesis and properties of the polydithiocarbamates. Their photochemical behavior will also be discussed in some detail.

Results and Discussion

Synthesis. The bisdithiocarbamate salts, **1**, were prepared from secondary diamines, carbon disulfide, and alkali metal hydroxides [Eq. (1)]. Their structures were confirmed as dibenzyl derivatives, (**4**) and (**5**). The polycondensation of **1** with **2** proceeds according to Eq. (2). The polymer formation was carried out by

a) Determined by a hot-stage microscope. b) Determined by DTA (heating rate 10 °C/min). c) Measured in methanesulfonic acid (0.5 g/100 ml, 30 °C). d) Measured in TCE (0.5 g/100 ml, 30 °C).

during the reaction was washed with water and methanol and dried at 50 °C under a vacuum. Using different combinations of **1** and **2**, a variety of different polymers with novel backbone structures were prepared. Table 1 contains a listing of these polymers, together with a partial compilation of their properties. Polymers were obtained in good yields regardless of the combinations of **1** and **2**. The inherent viscosities of the polymers ranged from 0.38 to 0.66, indicating that these polymers were of a fairly high molecular weight.

Other solvents, such as benzene–water, chloroform–water, and *sym*-tetrachloroethane (TCE), can also be used in the polycondensation; however, they usually give polymers with low inherent viscosities. The prominent feature of DMF may be attributed to its ability to increase the nucleophilicity of anions and to activate halogenated compounds by forming ionic complexes.[10]

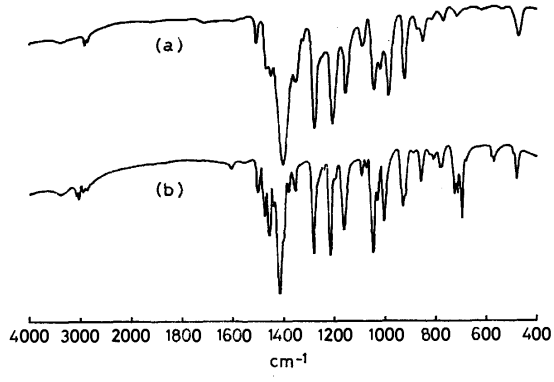

Fig. 1. The IR spectra of (a) polymer **3a** and (b) model compound **4** (KBr disks).

The polymers showed essentially the same results of elemental analyses as polydithiocarbamates. The IR spectra of the **3a**—**3e** polymers (piperazine polymers) were virtually identical and compared favorably with that of the corresponding model compound, **4** (Fig. 1). The bands at 1280, 990, and 930 cm^{-1} are characteristic of the dithiocarbamate group and are assigned to ν_{C-N}, $\nu_{C=S}$, and ν_{C-S}, respectively. It is interesting to note that the band at 1470 cm^{-1} due to the polar C–N partial double bond[11] is not so intense. On the other hand, the IR spectra of the **3f**—**3j** polymers (dipiperidylpropane polymers) and the model compound **5** displayed an intense absorption of $\nu_{C=N}$ at 1480 cm^{-1}. The NMR spectra provided further support for the assigned polymer structures; these polymers showed a triplet, centered at $\delta\sim3.1$ ($J=12$ Hz), for the four axial *N*-methylene protons, a broad signal centered at δ 5.1—5.2 for the four equatorial *N*-methylene protons, and a singlet at δ 4.5—4.6 for the four benzylic protons. As is shown in Fig. 2, the NMR spectrum of the **3f** polymer is quite similar to that of **5**.

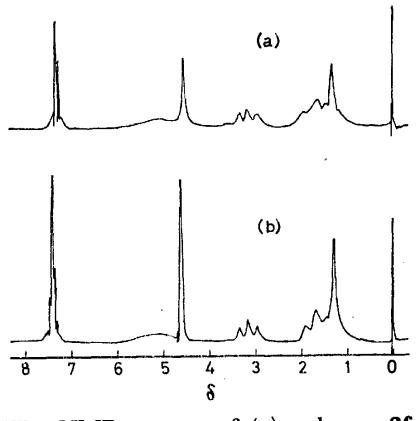

Fig. 2. The NMR spectra of (a) polymer **3f** and (b) model compound **5** ($CDCl_3$–TMS).

General Properties. The softening points of the piperidylpropane polymers lie below those of the corresponding piperazine polymers and tend to increase with an increase in the number of methyl substituents per unit. The introduction of symmetrical 1,4-phenylene ring structures into the polymer chain also increases the softening point. All the polymers decomposed on heating above 270 °C. The decomposition was exothermic, according to DTA.

The piperazine polymers were soluble in methanesulfonic acid and insoluble in organic solvents, whereas the dipiperidylpropane polymers were soluble in dichloromethane, chloroform, TCE, and *m*-cresol in addition to methanesulfonic acid, and the resulting polymer solutions gave transparent, tough films when cast upon a glass plate. This made possible an investigation of the photochemical properties of the polymers.

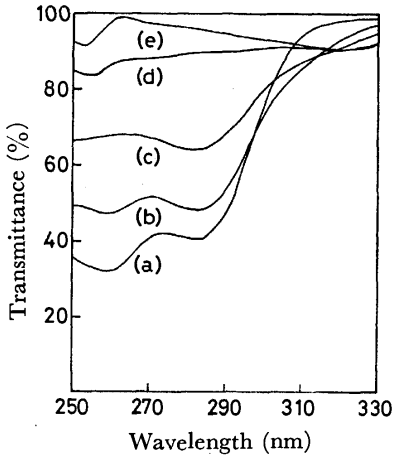

Fig. 3. UV spectral changes of polymer **3j** with irradiation in chloroform solution. Irradiation time; (a) 0, (b) 1, (c) 3, (d) 15, and (e) 110 min.

Photochemical Properties. When polymer films were exposed to the UV light from a 450 W high-pressure mercury lamp, they decomposed with a noticeable color change. The photolysis of the **3j** polymer was followed by means of the UV and IR spectra in an appropriate solvent. Figure 3 depicts the changes in the UV spectra on irradiation. The unirradiated sample showed two bands at 260 and 283 nm assignable to the S–C=S conjugation and the N–C=S conjugation, respectively.[12] These bands decreased in intensity with time and finally disappeared, while two new bands appeared. The band in the 252—255 nm range showed a shift to a shorter wavelength with continued exposure; it was unaccounted for. The band at approximately 320 nm coincided in position with that of carbon disulfide. The formation of carbon disulfide

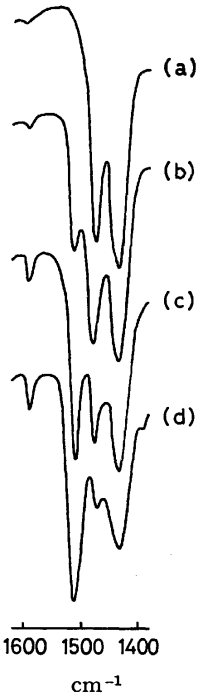

Fig. 4. IR spectral changes of polymer **3j** with irradiation in dichloromethane solution. Irradiation time; (a) 0, (b) 4, (c) 11, and (d) 25 hr.

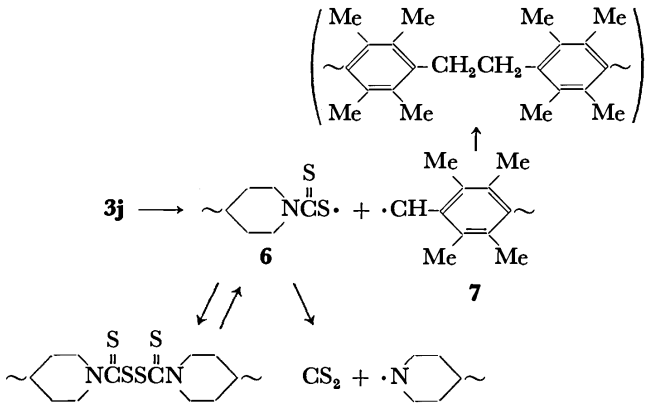
was confirmed by the IR spectra. As is shown in Fig. 4, a new band attributable to carbon disulfide appeared on irradiation at 1510 cm^{-1}. The intensity of the band increased with a decrease in the intensity of C=N band at 1480 cm^{-1}. From the spectral evidence and the precedents for the photolysis of non-polymeric analogues,[13,14] the following scheme for the photolysis of **3j** may be assumed:



The initial photochemical step involves the formation of a dithiocarbamoyl radical (**6**) and a benzyl radical (**7**). The former either dimerizes to a thiuram disulfide or dissociates to carbon disulfide and an amino radical.[15] The **7** radical may dimerize to give a bibenzyl derivative, but this point is not clear.

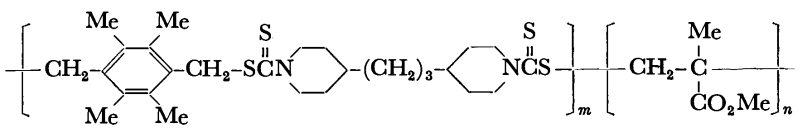
Photopolymerization of Methyl Methacrylate (MMA). In view of the above results and the known tendency of dithiocarbamate to initiate the photopolymerization of vinyl monomers,[3,13,16] we expected that a new type of block copolymers could be obtained by using the **3** polymer as the initiator of the vinyl polymerization. Chloroform solutions containing MMA and **3j** were irradiated in a Pyrex tube (frozen and vacuum sealed) at room temperature. A linear relationship was noticed between the polymer yield and the reaction time. The IR spectra of the polymers obtained were identical with that of poly MMA, but the UV spectra exhibited characteristic absorption of **3j** at 259 and 283 nm, showing that some units of **3j** were incorporated in the polymer. Table 2 shows the effect of **3j** on the polymerization of MMA, the polymerization time being 2 hr. The molecular weights of the polymers were determined viscometrically in toluene at 30 °C with the aid of the relation, $[\eta]=7.0\times10^{-5}\,M^{0.71}$, given by Stanley.[17] Compared to the polymerization without additives, the polymerization in the presence of **3j** gave a polymer with a lower molecular weight in higher yield. Thus, it may be concluded that **3j** functions not only as an initiator but also as a chain-transfer agent. A similar observation has been reported for benzyl diethyldithiocarbamate.[3] The ratio of the **3j** unit and the MMA unit in the polymer (m: n), as estimated on the basis of sulfur analysis, was 1: 64.[18] This means that each polymer molecule contains about 11 units of **3j**. Furthermore, the ratio of the durene unit and the MMA unit obtained from the NMR spectrum[19] was 1: 72. These values are indicative of the block character of the copolymer.

Experimental

Instrumentation. The following instruments were used in this study: a Hitachi EPI-G3 grating infrared spectrophotometer, a Varian T-60 NMR spectrometer, a Hitachi EPS-3 recording spectrophotometer, and an AGNE TGD-1500 thermal balance.

Materials. 2,5-Bis(chloromethyl)-*p*-xylene and 4,6-bis-(chloromethyl)-*m*-xylene were prepared by the reaction of the corresponding xylene with formaline and hydrochloric acid.

Table 2. Photopolymerization of MMA



MMA (mol/l)	**3j** (mol[a]/l)	Polymer Yield (%)	$[\eta]$[b]	MW $\times10^{-5}$	S anal. (%)	n/m[c]	m per molecule
2.83	0	1.0	0.60	3.47	—	—	—
2.83	9.6×10^{-3}	14.5	0.21	0.79	1.85	64	11.4

a) Based on recurring unit. b) Measured in toluene at 30 °C. c) Estimated from sulfur analysis.

2,5-Bis(chloromethyl)-*p*-xylene; mp 134 °C (lit,[20] mp 132—134 °C). 4,6-Bis(chloromethyl)-*m*-xylene; mp 98—99 °C (lit,[21] mp 99 °C). Piperazine, 1,3-(di-4-piperidyl)propane, α,α′-dichloro-*p*-xylene, -*m*-xylene, and 3,6-bis(chloromethyl)-durene were used as received. MMA was purified by distillation in the usual manner.[22]

Di-K Piperazine-N,N′-*biscarbodithioate (1a).* To a solution of 8.6 g of piperazine and 13.1 g of potassium hydroxide in 200 ml of ethanol was added dropwise a solution of 15.2 g of carbon disulfide in 40 ml of ether below 10 °C; the mixture was then stirred for 1 hr. The solid product was used for a subsequent reaction after one reprecipitation from water into acetone, followed by drying at 80 °C under a vacuum. The yield was 23.2 g.

Di-Na 1,3-Di-4-piperidylpropane-N,N′-*biscarbodithioate (1b).* To a stirred solution of 21.0 g of 1,3-(di-4-piperidyl)propane and 9.0 g of sodium hydroxide in 200 ml of ethanol was added dropwise a solution of 15.2 g of carbon disulfide in 40 ml of ether below 10 °C after which the mixture was stirred for 1 hr. The mixture was then filtered into a large volume of ether. The white precipitate was used for a subsequent reaction after one reprecipitation from ethanol into ether, followed by drying at 80 °C under a vacuum. The yield was 36.0 g.

Dibenzyl Piperazine-N,N′-*biscarbodithioate (4).* A solution of 6.28 g of **1a** in 150 ml of water was mixed with a solution of 5.07 g of benzyl chloride in 50 ml of chloroform. The mixture was stirred vigorously for 3 hr under reflux. The chloroform layer was then separated, washed with water, dried over anhydrous magnesium sulfate, and concentrated to give 7.85 g (94%) of **4**; mp 122—123 °C (from benzene-*n*-hexane). The IR spectrum is shown in Fig. 1.

NMR ($CDCl_3$); δ 4.33 (s, 8H), 4.70 (s, 4H), 7.48 (m, 10H).

Found: C, 57.42; H, 5.13; N, 6.59; S, 30.66%. Calcd for $C_{20}H_{22}N_2S_4$: C, 57.38; H, 5.30; N, 6.69; S, 30.63%.

Dibenzyl 1,3-(Di-4-piperidyl)propane-N,N′-*biscarbodithioate (5).* A mixture of 8.13 g of **1b**, 5.07 g of benzyl chloride, 150 ml of water, and 50 ml of chloroform was refluxed for 3 hr with vigorous stirring. From the reaction mixture, 10.4 g of an oily product was obtained after the same work-up as above. The product was treated with 100 ml of ether to give 8.90 g (82%) of **5**; mp 122—124 °C (from ethanol). The NMR spectrum is shown in Fig. 2.

Found: C, 64.40; H, 6.89; N, 5.17; S, 23.84%. Calcd for $C_{29}H_{38}N_2S_4$: C, 64.16; H, 7.06; N, 5.16; S, 23.62%.

Polycondensation. The polycondensation of **1** with **2** was carried out in DMF. The results are summarized in Table 1. The following is a typical example. A mixture of 2.03 g of **1b**, 1.16 g of 3,6-bis(chloromethyl)durene, and 30 ml of DMF was stirred for 1 hr at room temperature and then heated up to 110 °C over a 30 min period. The mixture was cooled and kneaded with 50 ml of methanol. The solvents were decanted. This treatment was repeated until the polymer solidified completely. The polymer was filtered with suction, washed with water and methanol, and dried at 50 °C under a vacuum. The yield of the **3j** polymer was 2.33 g (90%).

NMR ($CDCl_3$); δ 0.8—2.0 (m, 16H), 2.33 (s, 12H), 3.12 (t, J=12 Hz, 4H), 4.50 (s, 4H), ~5.1 (broad signal, 4H).

The polymer was purified by two reprecipitations from chloroform into methanol and was then used for analysis and photolysis.

Found: C, 62.35; H, 7.61; N, 5.25; S, 24.57%. Calcd for $(C_{27}H_{40}N_2S_4)_n$: C, 62.26; H, 7.74; N, 5.38; S, 24.62%.

Photolysis of 3j. Irradiations were carried out with a 450 W high-pressure mercury lamp (Ushio UM-452) centrally situated in a water-cooled Pyrex cold-finger. A chloroform solution of **3j** (1.1×10^{-5} mole-based on the repeating unit/l) was irradiated in a 1 cm quartz cell at a distance of 60 cm from the lamp. The UV spectral measurements were made immediately after the removal of the sample from the exposure unit. The results are shown in Fig. 3.

A dichloromethane solution of **3j** (*ca.* 6×10^{-3} mol-based on the repeating unit/l) was irradiated in a 0.1 mm NaCl closed cell at a distance of 20 cm from the UV lamp. The IR spectral changes around 1500 cm^{-1} are shown in Fig. 4.

Photopolymerization of MMA. A solution of 0.05 g of **3j** and 3 ml of MMA in 10 ml of chloroform was placed in a Pyrex tube, 2 cm in diameter. The tube was degassed under a vacuum by the usual freezing and thawing technique and then sealed. The tube was irradiated at a distance of 40 cm from the UV lamp. After a given interval the mixture was concentrated under reduced pressure, dissolved in acetone, and filtered into a large volume of methanol. The yield was calculated from the weight of the polymer obtained in the dry state. Viscosity measurements were made in toluene with a Ubbelohde viscometer at 30 °C. The IR spectra of the polymers were identical with that of poly MMA. The UV spectra exhibited the weak absorptions at 259 and 283 nm characteristic of **3j**.

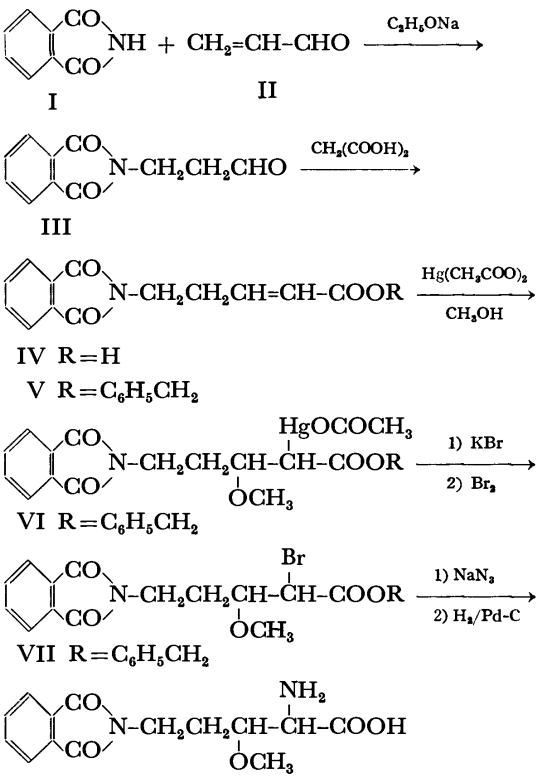
Chemical Studies on Tuberactinomycin. VII.[1] Synthesis of γ-Hydroxy-β-lysine[2]

Tateaki WAKAMIYA, Tadashi TESHIMA, Ichiro KUBOTA,*
Tetsuo SHIBA, and Takeo KANEKO**
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received June 7, 1974)

γ-Hydroxy-β-lysine is a new basic amino acid isolated from the hydrolyzates of antitubercular peptides, tuberactinomycin A and N. In order to confirm the structure and establish the stereochemistry of the amino acid, two diastereoisomers of γ-hydroxy-DL-β-lysine were synthesized by Arndt-Eistert synthesis *via* β-hydroxyornithine. Synthetic *erythro* and *threo* isomers were found to be identical spectroscopically and chromatographically with the corresponding forms obtained from the antibiotics respectively.

The isolation and the structural determination of γ-hydroxy-β-lysine in antitubercular peptides tuberactinomycin A and N[3] were reported in the previous paper.[4] Two different stereoisomers of the amino acid were obtained depending on acid reagent and reaction condition for the hydrolysis. The complete hydrolysis of the peptides by heating with hydrochloric acid gave *threo*-γ-hydroxy-β-lysine, while the partial hydrolysis with concentrated sulfuric acid at room temperature afforded the *erythro* isomer.[4] Our stereochemical investigation on *N,O*-acyl migration reaction of vicinal hydroxy amino acid revealed that the *threo* form of this amino acid was a genuine configuration in the intact molecules of tuberactinomycins, since the treatment with concentrated sulfuric acid caused an epimerization of the configuration at carbon atom carrying the hydroxyl group.[1,5] This paper presents a total synthesis of both isomers of the amino acid in order to confirm the conclusion of the structural and stereochemical studies.

In our synthetic plan, β-hydroxyornithine is required as an important intermediate which is subjected to the homologation to γ-hydroxy-β-lysine through Arndt-Eistert reaction. The synthesis of β-hydroxyornithine was carried out as follows (Scheme 1). Coupling of phthalimide with acrolein gave 3-phthaliminopropionaldehyde (III), which was then condensed with malonic acid to yield 5-phthalimino-2-pentenoic acid (IV).[6] Acid IV was esterified to benzyl ester V with benzyl alcohol and *p*-toluenesulfonic acid in benzene. From the coupling constant of 16 Hz for olefinic protons in its NMR spectrum, the benzyl ester V thus obtained was indicated to be a *trans* form. The ester V was allowed to react with mercuric acetate in methanol to give benzyl 2-acetoxymercuri-3-methoxy-5-phthaliminopentanoate (VI). A conversion of 2-acetoxymercuri compound VI to 2-bromomercuri derivative with potassium bromide followed by bromination gave benzyl 2-bromo-3-methoxy-5-phthaliminopentanoate (VII) in a good yield. A direct amination of VII in alkaline medium should be avoided in view of possible cleavage of phthalyl group to phthalamic acid derivative.[7] Since a substitution of phthalimino group into α-carbon atom of VII with potassium phthalimide failed, the compound VII was converted to an azide derivative with sodium azide in aqueous dimethylformamide and then hydrogenated to N^{δ}-phthalyl-β-methoxyornithine (VIII) using palladium on charcoal as a catalyst. The amino acid VIII thus obtained was a mixture of two diastereoisomers. One of them was easily crystallized as hydrochloride from ethanolic solution, while another isomer was crystallized as free base from the mother liquor on addition of triethylamine.



VIIIa, *erythro* as hydrochloride
b, *threo* as free base

Scheme 1.

In order to determine the configuration of these products, the NMR study for oxazolidone derivative of β-hydroxy-α-amino acid was applied.[8] Thus VIII was hydrolyzed to β-hydroxyornithine (IX) with hydrobromic acid in the presence of anisole. The amino acid IX was then benzyloxycarbonylated in aqueous sodium hydroxide solution to afford the oxazolidone

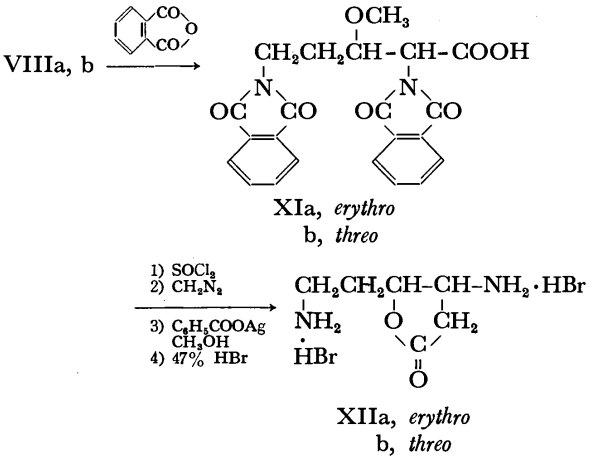


Scheme 3.

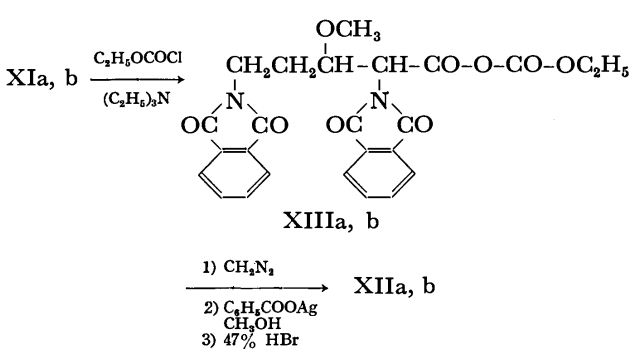
derivative X (Scheme 2). Oxazolidone compounds derived from β-hydroxy-α-amino acids may possess a fixed structure of nearly planar five-membered ring. Therefore, the coupling constants of *cis* and *trans* isomers will be distinguishable. In fact, the coupling constants of vicinal protons on the ring of several oxazolidone derivatives are converged at around 9 Hz in *cis* configurations and at 5 Hz in *trans* ones as far as tested.[8] Actually, the coupling constant between C-4 and C-5 protons was measured to be 9 Hz in Xa and 5 Hz in Xb. Consequently, the configurations of Xa and Xb were assigned to *cis* and *trans* forms which should have been derived from *erythro* and *threo* compounds respectively. Therefore, the configurations of VIIIa and VIIIb must be *erythro* and *threo* forms respectively. In general, a so-called hydroxymercuration, an addition reaction of mercuric acetate to an olefin in methanol, is known to proceed by *trans* addition preferentially.[9] However, since the following bromination induced racemization at α-carbon atom more or less,[9,10] the fact is not unreasonable that the product VII and hence VIII were mixtures of the diastereoisomers.

For Arndt-Eistert synthesis, each isomer of VIII was then phthalylated respectively to N^{α},N^{δ}-diphthalyl-β-methoxyornithine (XIa) (XIb) with phthalic anhydride either by fusion method or by heating in dioxane. Use of ethoxycarbonylphthalimide as phthalylation reagent[11] did not give satisfactory result, because of a possible cleavage of N^{δ}-phthalyl group to phthalamic acid derivative during the reaction under a basic condition.

According to the usual manner of Arndt-Eistert reaction, diphthalyl acid XI was converted to an acid chloride and then to diazoketone which was rearranged to N^{β},N^{ϵ}-diphthalyl-γ-methoxy-β-lysine methyl ester in methanol using silver benzoate. Without isolation of the ester, the product was immediately hydrolyzed with hydrobromic acid in the presence of anisole. Eventually, both desired isomers of γ-hydroxy-DL-β-lysine were obtained starting from VIIIa and VIIIb respectively as their lactone (XIIa) (XIIb) dihydrobromide (Scheme 3).

Since the configurations of the asymmetric carbon atoms are known to be maintained through Arndt-Eistert synthesis involving Wolff rearrangement reaction, the final product XIIa prepared from *erythro* compound XIa can be assigned to *erythro* form and XIIb from XIb to *threo* form. The lactone XIIa dihydrobromide synthesized here was completely identical with *erythro*-γ-hydroxy-L-β-lysine lactone dihydrobromide obtained by *N,O*-acyl migration with concentrated sulfuric acid from tuberactinomycin A and N, in IR, NMR spectra, thin-layer chromatogram, and paper electrophoresis. Another isomer XIIb was also identified with *threo*-γ-hydroxy-L-β-lysine lactone obtained from the hydrochloric acid hydrolyzates of tuberactinomycin A and N in all respects.

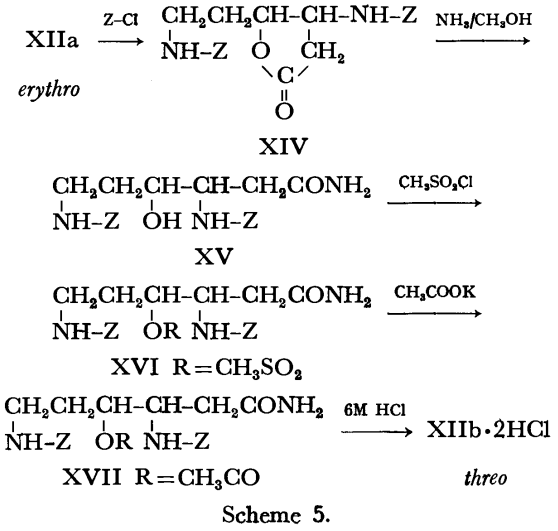
The synthesis of γ-hydroxy-β-lysine by the usual Arndt-Eistert reaction *via* acid chloride could not always give good yields. This defect seems to be due to an undesirable formation of chloroketone which may be produced from diazoketone and hydrogen chloride in the reaction course. Actually, mixed crystals composing of the diazoketone and the chloroketone was readily precipitated in the case of *erythro* compound and purification of the diazoketone by recrystallization of the mixed crystals was made extremely difficult. By this reason, an improved method for preparation of the diazoketone was attempted by application of mixed carbonic-carboxylic acid anhydride method.[12] This method afforded a satisfactory result in yield of the product compared with the acid chloride method (Scheme 4). However, partial racemization occurred through the reaction particularly in *threo* isomer. Therefore, for the preparation of *erythro*-γ-hydroxy-β-lysine, Arndt-Eistert synthesis *via* the mixed anhydride procedure serves as a fairly good synthetic process, though



Scheme 4.

the purification of the *threo*-isomer was shown to be difficult even after repetition of recrystallization. However, the mixed anhydride method could be improved for diazoketone synthesis, if a prevention of the partial racemization becomes feasible for instance by choice of protection of α-amino group or by use of an adequate amine like *N*-methylmorpholine in place of triethylamine.

In attempt of an interconversion of diastereoisomers of γ-hydroxy-β-lysine, an epimerization of γ-carbon atom of the amino acid was investigated. As shown in



Scheme 5.

Scheme 5, synthetic *erythro*-γ-hydroxy-DL-β-lysine lactone XIIa was benzyloxycarbonylated to N^{β},N^{ϵ}-dibenzyloxycarbonyl-*erythro*-γ-hydroxy-DL-β-lysine lactone (XIV) which was then converted to its amide XV. Otherwise, the reverse lactonization proceeded very easily when free hydroxy acid was attempted to be obtained. Hydroxyl group of the amide XV was mesylated with methanesulfonyl chloride in pyridine. When this *O*-mesyl compound XVI was treated with potassium acetate in absolute ethanol, substitution of acetoxyl group was accompanied by an inversion of the configuration on γ-carbon atom. Through hydrolysis of γ-acetoxy derivative XVII thus prepared with 6 M hydrochloric acid, *threo*-γ-hydroxy-DL-β-lysine lactone (XIIb) dihydrochloride was obtained. This conversion was also confirmed by identity of XIIb with natural *threo*-γ-hydroxy-L-β-lysine from the antibiotics on thin-layer chromatogram and IR spectra.

From the result of this synthetic study, not only the assignment of the chemical structure of the new natural amino acid in tuberactinomycins to γ-hydroxy-β-lysine, was assured, but also the relationship between the stereoisomers of the amino acid was clearly established.

Experimental

All melting points are uncorrected. The IR spectra were obtained in nujol mull with a Nihon Bunko IR-S spectrophotometer. The NMR spectra were obtained with a Varian T-60 spectrometer (60 MHz). Tetramethylsilane (TMS) was used as an internal reference in deuterochloroform and deuteromethanol solution, and as an external reference in the case of deuterium oxide solution. Thin-layer chromatography was carried out by the ascending method on silica gel G using a developing solvent of phenol–water–28% ammonium hydroxide (30: 10: 0.6). Paper electrophoresis was carried out at 750 volt and 10 mA for 1.5 hr on Toyo Roshi No. 51 filter paper using a buffer solution of pyridine–acetic acid–water (30: 4: 966).

Benzyl 5-Phthalimino-2-pentenoate (V). To a suspension of 5-phthalimino-2-pentenoic acid[6] (36.9 g, 0.150 mol) in 220 ml of benzene, there were added benzyl alcohol (26.0 g, 0.241 mol) and *p*-toluenesulfonic acid monohydrate (2.16 g, 11.4 mmol). The mixture was heated under reflux and the liberated water was removed azeotropically by means of Dean and Stark distilling receiver. After water had been no longer distilled off, the reaction mixture was permitted to cool to room temperature. Clear benzene solution was washed with sodium hydrogencarbonate solution and then water. Organic layer was dried over anhydrous sodium sulfate and evaporated *in vacuo*. Oily residue was triturated in petroleum ether under cooling to deposit crystals, yield 38.3 g (76%). Recrystallization from methanol gave prisms, mp 57—58 °C.

Found: C, 71.58; H, 5.20; N, 4.15%. Calcd for $C_{20}H_{17}O_4N$: C, 71.63; H, 5.11; N, 4.18%.

Benzyl 2-Bromo-3-methoxy-5-phthaliminopentanoate (VII). To a solution of V (63.0 g, 0.188 mol) in 500 ml of methanol, mercuric acetate (89.9 g, 0.282 mol) was added. The clear reaction mixture was stirred at room temperature for four days. The colorless crystals of 2-acetoxymercuri-3-methoxy derivative (VI) precipitated were filtered, yield 86.0 g. To the suspension of the above crystals VI in 500 ml of acetone, a solution of potassium bromide (41.8 g, 0.351 mol) in 75 ml of water was added on stirring. A clear solution thus obtained was concentrated *in vacuo*. A residue obtained was dissolved in water and then extracted with chloroform. The organic layer was dried over anhydrous sodium sulfate and concentrated to 200 ml *in vacuo*. To the chloroform solution containing 2-bromomercuri derivative a solution of bromine (28.0 g, 0.175 mol) in 50 ml of chloroform was added dropwise at 50 °C. The precipitate of mercuric bromide was filtered off and the filtrate was washed with aqueous sodium hydrogencarbonate and then water. It was dried over anhydrous sodium sulfate and concentrated *in vacuo*. Residual oil was triturated with petroleum ether to make powder, yield 66.1 g (78.7%). Recrystallization from benzene gave needles, mp 112—114 °C.

Found: C, 56.73; H, 4.55; N, 3.15; Br, 17.64%. Calcd for $C_{21}H_{20}O_5NBr$: C, 56.51; H, 4.52; N, 3.14; Br, 17.91%.

*N^{δ}-Phthalyl-β-methoxy-*DL*-ornithine (VIII).* To a suspension of sodium azide (24.5 g, 0.377 mol) in 60 ml of dimethylformamide and 20 ml of water, a solution of VII (11.2 g, 0.025 mol) in 20 ml of dimethylformamide was added dropwise at 50 °C for 30 min. The solution was stirred at the same temperature overnight. The reaction mixture was diluted with water, saturated with sodium chloride, and then extracted with ethyl acetate. The extract was dried over anhydrous sodium sulfate and evaporated *in vacuo*. Residual oil was dissolved in a mixture of 30 ml of methanol and 2 ml of concentrated hydrochloric acid. Catalytic hydrogenation was carried out by passing a slow stream of hydrogen gas through the above solution added with 5% palladium on charcoal as a catalyst until the IR absorption band of the azide group disappeared in the reaction mixture. After filtration of catalyst, the filtrate was concentrated *in vacuo*. The residue was dissolved in water and extracted with ether several times. Aqueous layer was again concentrated *in vacuo*, and the residue was dissolved in ethanol. An addition

of ether precipitated *erythro* isomer VIIIa as hydrochloride. Recrystallization from aqueous ethanol and ether gave needles, yield 1.30 g (15.8%), mp 221 °C (decomp.).

Found: C, 50.92; H, 5.37; N, 8.55; Cl, 11.12%. Calcd for $C_{14}H_{17}O_5N_2Cl$: C, 51.15; H, 5.21; N, 8.52; Cl, 10.79%.

The filtrate of VIIIa was concentrated *in vacuo* and the residue was dissolved in a small amount of ethanol. On addition of triethylamine and then ether to the solution, precipitate of a free amino acid was formed. It was filtered and washed with ethanol. Recrystallization from aqueous ethanol gave needles of *threo* isomer VIIIb, yield 1.10 g (15.1%), mp 214—215 °C (decomp.).

Found: C, 57.43; H, 5.53; N, 9.65%. Calcd for $C_{14}H_{16}O_5N_2$: C, 57.53; H, 5.52; N, 9.59%.

erythro-*β-Hydroxy*-DL-*ornithine Hydrobromide (IXa)*. A solution of VIIIa (1.00 g, 3.04 mmol) in 30 ml of 47% hydrobromic acid was heated under reflux in the presence of 15 ml of anisole for 20 hr. Hydrolyzate was extracted with benzene and aqueous layer was concentrated *in vacuo*. Crystalline residue was recrystallized from aqueous ethanol and ether, yield 0.46 g (66%). Recrystallization was repeated from aqueous ethanol for analysis, mp 230 °C (decomp.).

Found: C, 26.58; H, 5.85; N, 12.15; Br, 34.70%. Calcd for $C_5H_{13}O_3N_2Br$: C, 26.21; H, 5.72; N, 12.23; Br, 34.89%.

threo-*β-Hydroxy*-DL-*ornithine Hydrobromide (IXb)*. Hydrolysis of VIIIb (1.00 g, 3.42 mmol) was similarly carried out as for the *erythro* isomer to obtain IXb, yield 0.59 g (75%). Recrystallization from aqueous ethanol gave needles, mp 110—111 °C.

Found: C, 25.47; H, 6.02; N, 11.77; Br, 33.49%. Calcd for $C_5H_{13}O_3N_2Br \cdot 1/2H_2O$: C, 25.22; H, 5.92; N, 11.77; Br, 33.56%.

cis-*5-(2-Benzyloxycarbonylaminoethyl)-2-oxazolidone-4-carboxylic Acid (Xa)*. To a solution of IXa (0.28 g, 1.22 mmol) in 5 ml of 1 M sodium hydroxide, benzyloxycarbonyl chloride (0.50 g, 2.93 mmol) was added at 0 °C and the mixture was stirred for 30 min at the same temperature. After stirring at room temperature for 3 hr, the reaction mixture was extracted with ether and an aqueous layer was acidified with hydrochloric acid. Oily product formed was extracted with ethyl acetate and an organic layer was dried over anhydrous sodium sulfate. It was concentrated *in vacuo* to obtain the oily residue which was triturated with petroleum ether and then ether to yield crystals. Recrystallization from ethyl acetate and petroleum ether gave needles, yield 0.15 g (43.0%), mp 139—140 °C (decomp.). NMR: δ 4.33 (d, H-4, $J_{4-5}=9$ Hz).

Found: C, 54.63; H, 5.33; N, 8.98%. Calcd for $C_{14}H_{16}O_6N_2$: C, 54.54; H, 5.23; N, 9.09%.

trans-*5-(2-Benzyloxycarbonylaminoethyl)-2-oxazolidone-4-carboxylic Acid (Xb)*. *trans*-Oxazolidone derivative Xb was obtained from IXb (1.00 g, 4.37 mmol) as in the preparation of Xa, yield 0.80 g (59.0%). It was recrystallized from ethyl acetate and petroleum ether, mp 103—105 °C. NMR: δ 4.08 (d, H-4, $J_{4-5}=5$ Hz).

Found: C, 54.24; H, 5.30; N, 9.06%. Calcd for $C_{14}H_{16}O_6N_2$: C, 54.54; H, 5.23; N, 9.09%.

N^{α},N^{δ}-*Diphthalyl*-erythro-*β-methoxy*-DL-*ornithine (XIa)*. To a solution of VIIIa (1.00 g, 3.04 mmol) in methanol, triethylamine was added in excess and the mixture was concentrated *in vacuo*. Crystalline residue was suspended in anhydrous dioxane and phthalic anhydride (0.50 g, 3.38 mmol) was added. The suspension was refluxed at 130—135 °C for 30 hr, and then the clear solution was concentrated *in vacuo*. Residual oil was dissolved in sodium hydrogencarbonate solution and extracted with ethyl acetate. Aqueous layer was acidified with 6 M hydrochloric acid and extracted with ethyl acetate for several times. Ethyl acetate layer was washed with water and dried over anhydrous sodium sulfate. It was concentrated *in vacuo* and the oily residue was dissolved in a small amount of methanol. Crystals formed were filtered and recrystallized from methanol, yield 1.00 g (72.1%), mp 188—189 °C.

Found: C, 58.07; H, 4.82; N, 6.09%. Calcd for $C_{22}H_{18}O_7N_2 \cdot 2H_2O$: C, 57.64; H, 4.84; N, 6.11%.

After drying over phosphorus pentoxide at 80 °C for 36 hr under reduced pressure, elemental analysis was repeated.

Found: C, 62.13; H, 4.40; N, 6.67%. Calcd for $C_{22}H_{18}O_7N_2$: C, 62.56; H, 4.30; N, 6.63%.

N^{α},N^{δ}-*Diphthalyl*-threo-*β-methoxy*-DL-*ornithine (XIb)*. The mixture of VIIIb (1.00 g, 3.42 mmol) and phthalic anhydride (0.76 g, 5.13 mmol) was heated at 150—160 °C for 1 hr. The melting product was cooled to room temperature and the residue was treated with ether. Insoluble material was recrystallized from methanol, yield 1.03 g (71.3%), mp 214—215 °C.

Found: C, 62.43; H, 4.36; N, 6.58%.

Mixed Anhydride of N^{α},N^{δ}-*Diphthalyl*-erythro-*β-methoxy*-DL-*ornithine with Ethoxycarbonic Acid (XIIIa)*. To a solution of XIa (0.43 g, 1.02 mmol) in 5 ml of anhydrous dioxane and 10 ml of anhydrous ether, triethylamine (0.13 g, 1.29 mmol) and then ethoxycarbonyl chloride (0.12 g, 1.12 mmol) were added on ice cooling. After stirring for 30 min at 0 °C and then at room temperature for several hours, petroleum ether was added to the reaction mixture. Precipitate was filtered and washed rapidly with water. It was dried over phosphorus pentoxide in vacuum desiccator, yield 0.42 g (84.9%). Recrystallization from dioxane and petroleum ether gave needles, mp 160—161 °C.

Found: C, 60.50; H, 4.62; N, 5.57%. Calcd for $C_{25}H_{22}O_9N_2$: C, 60.73; H, 4.49; N, 5.67%.

Mixed Anhydride of N^{α},N^{δ}-*Diphthalyl*-threo-*β-methoxy-ornithine With Ethoxycarbonic Acid (XIIIb)*. To a solution of XIb (0.84 g, 1.99 mmol) in 4 ml of dimethylformamide, triethylamine (0.23 g, 2.28 mmol) and ethoxycarbonyl chloride (0.24 g, 2.20 mmol) were added under ice cooling. After stirring at 0 °C for 1 hr, 20 ml of anhydrous ether and 100 ml of petroleum ether were added. Precipitate formed was filtered and washed rapidly with water. It was dried over phosphorus pentoxide in vacuum desiccator, yield 0.76 g (78%). Recrystallization from ethyl acetate and petroleum ether gave prisms, mp 143—144 °C.

Found: C, 60.67; H, 4.56; N, 5.74%. Calcd for $C_{25}H_{22}O_9N_2$: C, 60.73; H, 4.49; N, 5.67%.

erythro-*γ-Hydroxy*-DL-*β-lysine Lactone Dihydrobromide (XIIa)*. *a)* via *Acid Chloride*: A solution of XIa (1.50 g, 3.55 mmol) in 15 ml of thionyl chloride was refluxed for 30 min. Thionyl chloride was thoroughly removed by evaporation *in vacuo* with anhydrous benzene. Residual oil was dried over sodium hydroxide in vacuum desiccator. Acid chloride thus obtained was dissolved in 70 ml of anhydrous benzene and added to a solution of diazomethane in ether on ice cooling for 2.5 hr. After stirring at room temperature for 3 hr, the reaction mixture was kept in a refrigerator. Pale yellow precipitate (0.90 g, 56%) obtained was suspended in methanol and a solution of silver benzoate (0.20 g, 0.87 mmol) in 1 ml of triethylamine was added. After stirring in the dark overnight, insoluble material was filtered off. Filtrate was concentrated *in vacuo* and oily residue was dissolved in ethyl acetate. Insoluble material formed again was filtered off and filtrate was washed with dilute hydrochloric acid and then water. Organic layer was dried over anhydrous sodium sulfate and concentrated *in vacuo*. Oily residue obtained was dissolved in 20 ml of 47% hydrobromic acid containing 7 ml

of anisole. It was heated under reflux for 20 hr. Aqueous layer was separated from organic layer and washed with benzene several times. Aqueous solution was concentrated *in vacuo* and the residue was crystallized from a small amount of ethanol. It was recrystallized from 94% ethanol and ether, yield 60 mg (9.7%), mp 217—219 °C (decomp.).

Found: C, 23.56; H, 4.67; N, 9.14; Br, 52.02%. Calcd for $C_6H_{14}O_2N_2Br_2$: C, 23.54; H, 4.61; N, 9.16; Br, 52.23%.

b) via *Mixed Anhydride*: A solution of XIIIa (1.07 g, 2.53 mmol) in 50 ml of anhydrous dioxane was added to a 0.1 mol solution of diazomethane in ether on ice cooling. After stirring at 0 °C for 6 hr and allowing to stand overnight at room temperature, the reaction mixture was concentrated *in vacuo* to obtain pale yellow oily residue of diazoketone in a quantitative yield. To a solution of the diazoketone in methanol, a solution of silver benzoate (0.10 g, 0.44 mmol) in triethylamine was added. Subsequent treatments were carried out as mentioned in a), yield 0.25 g (37.8%), mp 217—219 °C (decomp.).

threo-*γ-Hydroxy*-DL-*β-lysine Lactone Dihydrobromide (XIIb)*. *a)* via *Acid Chloride*: When the reaction of acid chloride of XIb and diazomethane was carried out at room temperature in a similar procedure to that in preparation of XIIa, crystalline diazoketone could not be isolated. Then the reaction mixture was warmed at 40 °C for removal of excess diazomethane and evaporated *in vacuo*. The oily residue thus obtained was immediately used for subsequent rearrangement and hydrolysis. From XIb (0.47 g, 1.11 mmol) 80 mg of *threo* isomer XIIb (23.5%) was obtained, mp 220—229 °C (decomp.).

Found: C, 23.64; H, 4.61; N, 9.19; Br, 52.12%. Calcd for $C_6H_{14}O_2N_2Br_2$: C, 23.54; H, 4.61; N, 9.16; Br, 52.23%.

b) via *Mixed Anhydride*: By mixed anhydride method as mentioned in the preparation of XIIa, *threo* isomer XIIb was obtained from XIIIb (0.65 g, 1.54 mmol), yield 0.14 g (34%). It was recrystallized from 94% ethanol and ether, mp 205—212 °C (decomp.).

N^{β},N^{ε}-*Dibenzyloxycarbonyl*-erythro-*γ-hydroxy*-DL-*β-lysine Lactone (XIV)*. To an aqueous solution of XIIa (0.11 g, 0.36 mmol), sodium carbonate (0.27 g, 2.55 mmol) and benzyloxycarbonyl chloride (0.15 g, 0.87 mmol) were added at 0 °C. After stirring at 0 °C for 30 min and then at room temperature for 4 hr, the reaction mixture was acidified with dilute hydrochloric acid. Oily product formed was extracted with ethyl acetate and organic layer was dried over anhydrous sodium sulfate. It was concentrated *in vacuo* and the residual oil was treated with petroleum ether. Finally, the oil was dissolved in ethyl acetate. Addition of petroleum ether yielded crystals, yield 95 mg (64%). Recrystallization from ethyl acetate and petroleum ether gave needles, mp 79—81 °C.

Found: C, 63.78; H, 5.89; N, 6.71%. Calcd for $C_{22}H_{24}O_6N_2$: C, 64.06; H, 5.87; N, 6.79%.

N^{β},N^{ε}-*Dibenzyloxycarbonyl*-erythro-*γ-hydroxy*-DL-*β-lysine Amide (XV)*. A solution of XIV (80 mg, 0.19 mmol) in methanol was saturated with ammonia. After keeping at room temperature in a pressure bottle for 3 days, methanol was evaporated *in vacuo* to obtain crystals, yield 80 mg (96%). Recrystallization from methanol gave needles, mp 197—198 °C.

Found: C, 61.69; H, 6.44; N, 9.69%. Calcd for $C_{22}H_{27}O_6N_3$: C, 61.52; H, 6.34; N, 9.79%.

N^{β},N^{ε}-*Dibenzyloxycarbonyl*-O-*methanesulfonyl*-erythro-*γ-hydroxy*-DL-*β-lysine Amide (XVI)*. To a suspension of XV (0.10 g, 0.23 mmol) in 2 ml of pyridine, methanesulfonyl chloride (0.10 g, 0.87 mmol) was added. After stirring overnight, the reaction mixture was poured into ice-cold water. The aqueous solution was saturated with sodium chloride and extracted with ethyl acetate. Organic layer was washed with saturated sodium chloride solution and dried over anhydrous sodium sulfate. It was concentrated *in vacuo* and the residual oil was purified by silica gel column chromatography. Elution with chloroform gave a pure mesylate XVI, yield 60 mg (51%). It was recrystallized from ethyl acetate and petroleum ether, mp 106—107 °C.

Found: C, 54.37; H, 5.72; N, 8.49; S, 6.65%. Calcd for $C_{23}H_{29}O_8N_3S$: C, 54.42; H, 5.76; N, 8.28; S, 6.32%.

Conversion of erythro *Amide (XVI) to* threo *Lactone (XIIb)*. To a solution of XVI (30 mg, 0.06 mmol) in anhydrous ethanol, potassium acetate (0.20 g, 2.04 mmol) was added. The reaction mixture was heated under reflux for 10 hr, and then concentrated *in vacuo*. The residue was dissolved in water and extracted with ethyl acetate. Organic layer was concentrated *in vacuo* after drying over anhydrous sodium sulfate. The oily residue obtained was hydrolyzed with 6 M hydrochloric acid. Hydrolyzate was extracted with ethyl acetate and aqueous layer was evaporated *in vacuo* to obtain crystals of XIIb, yield 5 mg (39%).

Nucleosides. XXI.[1] Preparative Routes to Nucleosides Derived from 4-Amino-4-deoxy-β-D-glucopyranose[2]

Frieder W. LICHTENTHALER, Peter Voss, and Gerd BAMBACH
Institut für Organische Chemie, Technische Hochschule Darmstadt, 61 Darmstadt, Germany
(Received January 14, 1974)

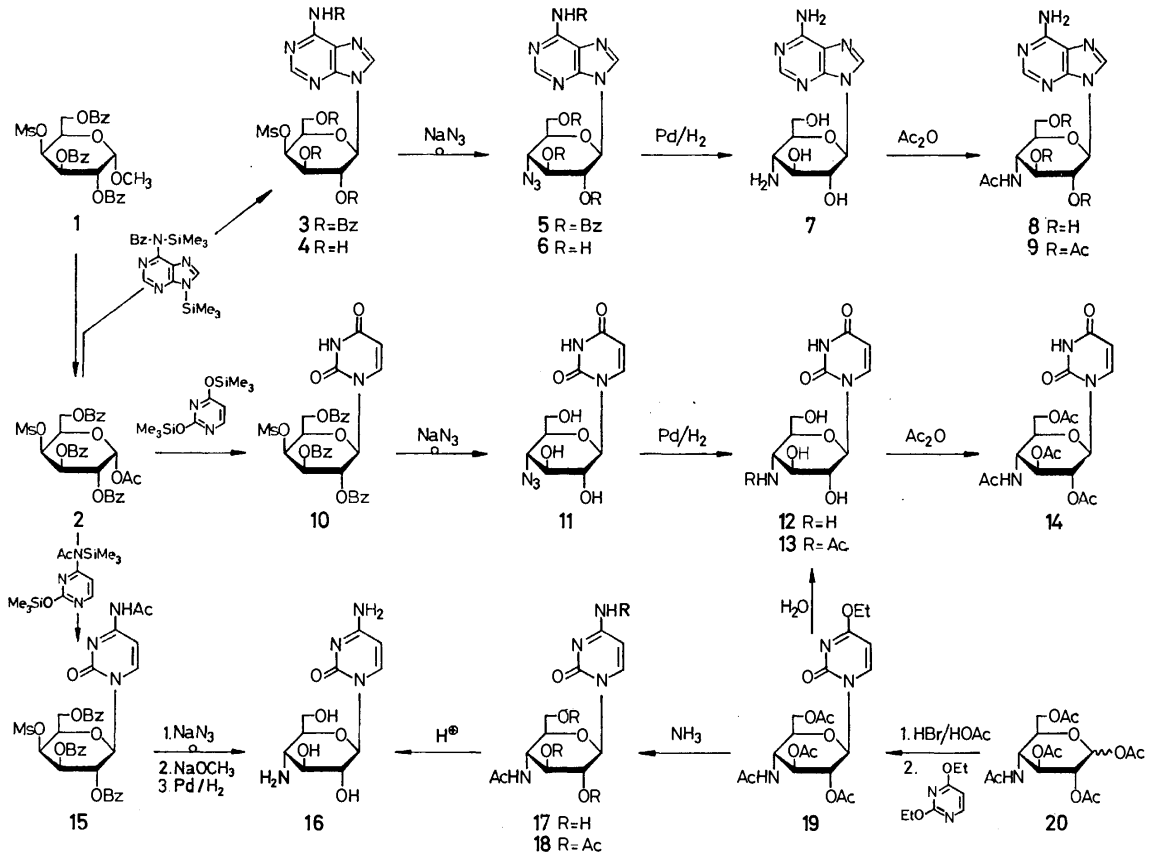
Four-step syntheses for the 4′-amino-4′-deoxy-β-D-glucopyranosyl nucleosides of adenine (**7**), uracil (**12**) and cytosine (**16**) from a readily accessible galactose derivative (**2**) are described, in overall yields of 41—47%. The reaction sequence, used, involved (i) stannic chloride catalyzed nucleosidations of **2** with the bis-trimethylsilyl derivatives of N^6-benzoyladenine, uracil and N^4-acetylcytosine, (ii) displacement of the 4′-sulfonyloxy groups in **3**, **10**, and **15** by azide, (iii) de-*O*-benzoylation and (iv) hydrogenation. An alternate route to **12** and **16**, comprising nucleosidation of tetraacetyl-4-acetamido-4-deoxy-D-glucopyranose (**20**) *via* the classical Hilbert-Johnson approach proved feasable, yet inferior with respect to yields and accessibility of educts. The structures and configurations assigned followed from the synthetic route as well as from spectroscopic data, particularly from the acetyl resonances of the peracetylated nucleosides **9**, **14**, and **18**, which are in excellent agreement with those of the respective glucosyl- and 3-acetamido-3-deoxy-glucosyl analogs (Table).

The aminoacyl-4-aminohexosyl-cytosine antibiotics gougerotin and blasticidin S, both elaborated by streptomyces species found in Japan,[3,4] have been the subject of intense chemical and biochemical investigations,[5] the main stimulus stemming from their inhibition of protein biosynthesis at the peptide chain elongation stage.[6] As a result, the structures of these antibiotics have been unequivocally established,[7] total synthesis for both have been advanced[16,17] and their structure-activity relationships have been assessed on the basis of the presently available structural analogs.[18] However, number and variety of the structural types being rather limited, these minimal functional group and spatial requirements for inhibition of transpeptidation[18] need to be further substantiated in order to elicit persuasive conclusions with respect to the molecular architecture of the ribosomal binding site. To provide this corroborative evidence, the synthesis of a systematic series of structural analogs, modified in nucleobase, aminosugar unit and aminoacid component, was deemed essential, which on biological evaluation are more likely to produce results of biological significance than previous studies, mainly directed towards the total syntheses of the natural products.[19] By consequence, synthetic work on purine and pyrimidine nucleosides derived from 4-amino-4-deoxy-hexoses was initiated.[15,20] In this paper, we present the results of our synthetic studies on 4′-amino-4′-deoxy-β-D-glucopyranosyl nucleosides, providing with the synthesis of **7** the first purine nucleoside in this series, as well as preparative procedures for the respective uracil (**12**) and cytosine nucleosides (**16**), that are alternate or considerably improved over those already known.[14,15,21]

Choice of Methods. Of the newer nucleosidation procedures available,[22] the most recently advanced[23] "Friedel-Crafts catalyzed trimethylsilyl procedure" was considered the most propitious for the preparation of pyrimidine as well as purine nucleosides[1] allowing utilization of a per-*O*-acyl-glycose rather than the 1-halide. As the sugar precursor to be nucleosidated, a suitably blocked derivative of 4-amino-4-deoxy-D-glucopyranose, *e.g.* its pentaacetate **20**, might be surmised to provide a very direct access to 4-aminoglucosyl nucleosides. However, whilst this approach can be realized as shown by the conversion of **20** to **19** (*vide infra*), it appears to be of limited general applicability for several reasons; *e.g.* the educt is encumbered by conceivable ring contraction to the pyrrolidinose form during nucleosidation and difficulties may arise in removing an *N*-acetyl group in purine nucleosides. Hence, a more suitable starting sugar for Friedel-Crafts catalyzed *N*-glycosidations was required and found in 1-*O*-acetyl-2,3,6-tri-*O*-benzoyl-4-*O*-mesyl-α-D-galactopyranose (**2**), readily accessible in crystalline form and good yield (79%) from its methyl glycoside **1**[24] by acetolysis in the presence of boron trifluoride-etherate.[25]

Adenine Nucleosides (3—9). When 1-*O*-acetyl-2,3,6-tri-*O*-benzoyl-4-*O*-mesyl-α-D-galactose (**2**) was allowed to react with a slight excess of *N*-benzoyl-*N*,9-bis(trimethylsilyl)adenine in the presence of stannic chloride (12 hr/60 °C in dichloroethane), the protected nucleoside **3** could be isolated by a simple workup procedure in reasonable yield (59%). Subsequent removal of the *O*- and *N*-benzoyl groups with sodium methoxide/methanol afforded the highly crystalline 4′-*O*-mesyl-derivative **4**. Of the two compounds, **3** and **4**, respectively, **3** was found to give a more uniform reaction mixture when subjected to azidolysis with sodium azide in hexamethyl phosphoric triamide (8 hr/80 °C). The protected azidonucleoside **5** formed in this way was directly debenzoylated, to afford in an overall yield (**3**→**6**) of 78% the 4′-azidoglucosyl-adenine **6**. Subsequent hydrogenation over 10% palladium on carbon proceeded smoothly to give in the form of colorless prisms the desired 4′-amino-4′-deoxy-β-D-glucopyranosyl-adenine (**7**)—the hitherto first purine nucleoside of a 4-aminohexose. It was further characterized by its 4′-acetamido derivative **8** as well as its peracetate **9**, each clearly exhibiting the NMR characteristics required for the *gluco*-configuration (*cf.* Table).

Of particular relevance in this context appears to be the overall yield for the four step reaction sequence **2**→**3**→**5**→**6**→**7**, which is 42%, and, hence, may be the method of choice for the preparation of other 4-amino-hexosyl-purines, should their synthesis be required.



Uracil Nucleosides (10—14). Whilst stannic chloride catalyzed nucleosidations of 1-*O*-acetyl-2,3,5-tri-*O*-benzoyl-D-ribofuranose with silylated pyrimidines may readily be performed at room temperature,[23] it was found advantageous to use somewhat more forcing conditions (12 hr, 60 °C) for the *N*-glycosidation of *O,O*-bis(trimethylsilyl)uracil with the hexose derivative **2**, particularly when performing the reaction on rather larger scale. In this way, a crystalline product was obtained in 83% yield, comprising according to tlc an approximate 10: 1 mixture of the *β*-nucleoside **10** and a second component, most probably the N^3-isomer. The latter, however, was readily removed by recrystallization to afford the protected galactosyl-uracil **10** in a yield of 71%. Displacement of the mesyloxy group in **10** by sodium azide in hexamethyl phosphoric triamide (5 hr, 80 °C) followed by de-*O*-benzoylation with sodium methoxide gave the 4'-azidoglucosyl nucleoside **11** (72%). The subsequent hydrogenation over 10% palladium on carbon readily afforded 4'-amino-4'-deoxy-*β*-D-glucosyl-uracil **12** (81%), which was further characterized by an amorphous *N*-acetate (**13**) and its crystalline tetraacetyl derivative **14**.

Prior to the availability of the "Friedel-Crafts catalyzed silyl procedure" we had followed another approach for the preparation of the pyrimidine nucleosides **13** and **18**,[15] which expectedly gave inferior results with respect to accessibility of the starting sugar and the yield in the nucleoside synthesis: nucleosidation of peracetylated 4-aminoglucosyl bromide *via* the classical Hilbert-Johnson procedure.[26] Accordingly, 4-acetamido-1,2,3,6-tetra-*O*-acetyl-4-deoxy-D-glucopyranose (**20**) in the form of a sirupy 9: 1 *α*/*β*-mixture,[27] was converted into the corresponding 1-bromo sugar by treatment with 40% hydrogen bromide in glacial acetic acid, which *in situ* was reacted with diethoxypyrimidine. The ethoxypyrimidinone nucleoside **19** was readily obtained from the reaction mixture, yet the yield was far from satisfactory (36%, based on **20**). The subsequent hydrolysis with methanolic hydrochloric acid, however, proceeded smoothly affording **13** in 84% yield.

In comparing the preparative utility of the three synthetic routes by which 4-aminoglucosyl-uracil now has been prepared, the four step conversion of **2** into **12** in a 41% overall yield appears to be an appreciable improvement over the alternate five step sequence from the much less accessible galactosyl-uracil (overall yield: 31%[21]). The classical Hilbert-Johnson approach **20**→**19**→**13**→**12**, however, is expectedly inferior to either one of the two others.

Cytosine Nucleosides (15—18). Whilst a conversion of galactoside **1** into nucleoside **15** *via* the glycosyl bromide of **1** and its condensation with N^4-acetylcytosine has already been described,[14] the high yield (95%) reported for the two steps was based on the pyrimidine precursor, and amounts to only 47% when based on the more precious sugar component. A superior procedure appears to be the nucleosidation of the acetolysis product of **1** with N^4,*O*-bis(trimethylsilyl)-N^4-acetylcytosine in the presence of stannic chloride (12 hr/60 °C in dichloroethane) affording crystalline **15** with a yield of 85% in the nucleosidation step **2**→**15** (62% from **1**). Since the conversion **15**→**16** is readily accomplished by the three step sequence azidolysis→deacetylation→hydrogenation,[14] 4'-amino-

4′-deoxy-β-D-glucosyl-cytosine can now be prepared from a readily accessible galactose derivative (**2**) in an overall yield of 47%.

An alternate route to **16**, elaborated earlier, proved to be of less preparative utility (21% overall yield): the classical Hilbert-Johnson nucleosidation of 4-amino-glucose peracetate (**20**→**19**) followed by aminolysis to **17** and de-*N*-acetylation (**17**→**16**). Nevertheless, a sample prepared in this way, which was subsequently *N*-acylated with BOC-blocked sarcosyl-seryl-azide[15] has provided the first biologically active analogue[31] of the nucleoside antibiotic gougerotin.

Structural and Configurational Assignments. Whilst the mode of preparation in itself provides conclusive proof for structure and configuration of the nucleosides described, corroborative evidence is readily derived from NMR data. However, except for the anomeric proton (*cf.* Table 1), the chemical shifts and coupling patterns of the pyranoid ring protons are not extractable from 60 MHz spectra without extensive decoupling. Much more conveniently, the configurations are ascertained by the chemical shifts of the acetyl resonances of per-acetylated nucleosides on the basis of the "acetyl resonance rule" elaborated for cyclitols,[32] hexopyranoses[33] and hexopyranosyl nucleosides.[33,34] As is apparent from the data collected in Table 1, neither one of the glucopyranosyl nucleosides (II—III), their 3′-amino-analogs (V—VII) or their 4′-amino counterparts (**9**, **14**, **18**, and **19**) exhibited signals attributable to an axially oriented acetoxy group (below τ 7.95 in DMSO-d_6). Equally distinct is the presence of an equatorial acetamido function in the 3′-aminoglucosyl nucleosides V—VII as well as their 4′-amino analogs, appearing as a signal in the τ 8.20—8.24 range, nicely separated from the others. Noteworthy is also the low field resonances for the cytosine nucleosides III and VI, originating from the N^4-acetyl group in the aglycon, as well as the highfield signals, at τ 8.30 and 8.31

Table 1. NMR-Data in DMSO-d_6 and rotations of peracetyl-β-D-glucopyranosyl-nucleosides

Kuwada, *Chem. Pharm. Bull.*, **16**, 944 (1965). h) J. Beranek, H. A. Friedman, K. A. Watanabe, and J. J. Fox, *J. Heterocycl. Chem.*, **2**, 188 (1965).

respectively, for the adenine derivatives VII and **9** (*cf.* Table 1). Those clearly arise from the 2'-acetoxy resonances, being in the range of diamagnetic shielding by the purine moiety, since similar upfield shifts have been observed for other purine nucleosides with an equatorial pyranoid 2'-acetoxy function.[33] In the pyrimidine nucleosides, this diamagnetic shielding is expectedly[33] lower, giving rise to resonances that are only shifted by approximately 0.1 ppm towards higher field (τ 8.08—8.14).

The results clearly demonstrate that examination of the acetyl resonances in DMSO-d_6 provides a reliable, convenient method for configurational assignments in the hexopyranosyl nucleoside field, when taking into consideration the predictable shielding effects by purine and pyrimidine nucleobases. Converse conclusions reached by Cushley *et al.*[35] have later been shown[36] invalid, being based, in part, on incorrect configurational assignments.

Whilst configuration and conformation of the sugar moiety may readily be elicited from NMR data, the orientation of nucleobase to the sugar is less clear. An attempt was made to obtain some, though admittedly limited information on this from the rotational values of the peracetylated nucleosides. Since replacement of an acetoxy by an acetamido group does not substantially affect rotations,[37] the sign and magnitude of the nucleosides in the Table 1 would be excepted to be at least very similar, if the sugar-nucleobase orientations are identical. However, as is clearly apparent from the data in the Table, they vary within too wide a range as to allow even limited conclusions on this matter.

Experimental

Melting points were determined on a Bock Monoskop, and are uncorrected. Spectra were recorded on Perkin-Elmer 125 (IR), Perkin-Elmer 137 (UV), and Varian A-60A (NMR) instruments.

Thin layer chromatography (tlc) on Kieselgel F_{254} plastic sheets (Merck, Darmstadt) was used throughout to monitor the reactions and to ascertain the purity of the products; developers employed (A) ethyl acetate–chloroform (1:1); (B) ethyl acetate–ethanol–water (15:2:1). The spots were visibilized by UV, by iodine vaporing, or by spraying with 80% aqueous sulfuric acid and charring at 110 °C for 5 min. Column chromatography was carried out on silica gel of 70—230 mesh ("Kieselgel 60", Merck, Darmstadt).

1-O-Acetyl-2,3,6-tri-O-benzoyl-4-O-mesyl-α-D-galactopyranose (2). To a solution of 30.0 g (51 mmol) of methyl 2,3,6-tri-*O*-benzoyl-4-*O*-mesyl-α-D-galactopyranoside (**1**)[28] in 600 ml of acetic anhydride 30 ml of BF_3–etherate in ether was added, and the mixture was heated to 60 °C for 12 hr, followed by gradually stirring into ice–water (3 l). After 2 hr, the solution was neutralized by careful addition of solid $NaHCO_3$, and subsequently extracted with two 500 ml portions of dichloromethane. The organic phase was dried over Na_2SO_4 and evaporated to dryness to yield a residue, which after charcoal treatment in methanol (500 ml), was recrystallized from the minimum amount of methanol: 24.2 g (79%), mp 143—144 °C; $[\alpha]_D^{20}$ +92° (*c* 1, $CHCl_3$); NMR ($CDCl_3$) τ 1.8—2.8 (m, 15, $3C_6H_5$), 3.35 (narrow [4 Hz] m, H-1), 4.12 (narrow m [4 Hz], H-2 and H-3), 4.41 (m [4 Hz], 1, H-4), 6.90 (s, 3, OMs), 7.83 (s, 3, OAc).

Found: C, 58.42; H, 4.63; S, 5.16%. Calcd for $C_{30}H_{28}O_{12}S$: C, 58.82; H, 4.61; S, 5.22%.

Adenine Nucleosides (3—9). 9-(2',3',6'-Tri-O-benzoyl-4'-O-mesyl-β-D-galactopyranosyl)-N⁶-benzoyladenine (3): To a solution of 3.0 g (4.9 mmol) of 4-*O*-mesylgalactose **2** in 1,2-dichloroethane (75 ml) was added 6 g of molecular sieve[38] and 1.5 ml of stannic chloride. After 30 min standing 2.0 g (5.2 mmol) of N^6-benzoyl-N^6,9-bis(trimethylsilyl)adenine[39,40] was added and the mixture was heated to 60 °C for 12 hr under careful exclusion of moisture. The molecular sieve was removed and the solution, after dilution with dichloromethane (75 ml), was extracted with aqueous sodium bicarbonate (2×100 ml) and washed with water (2×100 ml). Drying (Na_2SO_4) and evaporation to dryness followed by repeated reevaporations from methanol, left a sirup, which was crystallized by dissolving in benzene (120 ml), removal of some insoluble material, and gradual addition of cyclohexane (*ca.* 100 ml): 2.3 g (59%) of a colorless, amorphous product, uniform by tlc (A); $[\alpha]_D^{20}$ −17° (*c* 1, $CHCl_3$); NMR ($CDCl_3$) τ 1.26 and 1.52 (two 2 H-s, H-2 and H-8), 1.8—2.8 (broad m, 20, $4C_6H_5$), 3.65 (m, 2, H-1' and H-4'), 6.83 (s, 3, OMs).

Found: C, 60.45; H, 4.26; N, 8.83; S, 3.97%. Calcd for $C_{40}H_{33}N_5O_{11}S$: C, 60.67; H, 4.20; N, 8.85; S, 4.05%.

9-(4'-O-Mesyl-β-D-galactopyranosyl)adenine (4): To 1.0 g of tetrabenzoyl derivative **3** in methanol (20 ml) was added 1 ml of 5 M methanolic sodium methoxide with cooling, and the mixture was stored in a refrigerator overnight. The crystals, which had separated, were filtered off (0.35 g). From the mother liquor a second crop (0.1 g) was obtained by deionization with a strongly acidic ion exchange resin (Merck I), evaporation to dryness and trituration with little methanol. Both fractions were recrystallized from little water: 0.28 g (58%) of **4** as needles of mp 216—218 °C (decomp.); $[\alpha]_D^{20}$ +9° (*c* 0.6, H_2O); NMR (DMSO-d_6) τ 6.67 (s, 3, OMs).

Found: C, 37.97; H, 4.68; N, 18.49; S, 8.41%. Calcd for $C_{12}H_{17}N_5O_7S$: C, 38.30; H, 4.57; N, 18.66; S, 8.53%.

9-(4'-Azido-4'-deoxy-β-D-glucopyranosyl)adenine (6): To a solution of 10.0 g (12.6 mmol) of galacto-mesylate **3** in hexamethyl phosphoric acid triamide (50 ml) was added sodium azide (4.2 g, 5 molar equiv.) and the mixture was heated to 80 °C with vigorous stirring for 8 hr, followed by pouring into ice–water (2 l). The precipitate was collected, washed with water and subjected to treatment with activated carbon in methanol (150 ml). Evaporation to dryness, filtration with water and drying gave 9-(2',3',6'-tri-*O*-benzoyl-4'-azido 4'-deoxy-β-D-glucopyranosyl)-N^6-benzoyladenine (**5**) as an amorphous, colorless product (9.0 g), showing only traces of an impurity (tlc in A). Due to difficulties encountered in crystallization attempts from the usual solvents, the product was directly subjected to debenzoylation with sodium methoxide (4 ml of a 5 M methanolic solution) in methanol (100 ml) by storing for 24 hr at ambient temperature. Some product had crystallized and was isolated after standing overnight in a refrigerator: 2.60 g (60%) of mp 231—233 °C (decomp.). The mother liquor was deionized (Merck I resin) and evaporated to dryness *in vacuo* to give, from a concentrated methanolic solution, a second crop (0.77 g) Total yield on crude **6**: 3.37 g (78%); mp 229—231 (decomp.). For analytical data, a 200 mg portion was recrystallized from a small amount of water; mp 236—238 °C (decomp.); $[\alpha]_D^{20}$ +46° (*c* 1, dimethylformamide); IR (KBr) N_3 at 2100 cm^{-1}; NMR (DMSO-d_6 + D_2O) τ 1.84 and 1.99 (two 1 H-s, H-2 and H-8), 4.67 (d, 1, $J_{1,2}$=8.5 Hz, H-1').

Found: C, 39.00; H, 4.39; N, 32.98%. Calcd for $C_{11}H_{14}N_8O_4 \cdot H_2O$: C, 38.82; H, 4.74; N, 32.93%.

9-(4'-Amino-4'-deoxy-β-D-glucopyranosyl)adenine (7): To a

prehydrogenated suspension of 500 mg 10% Pd/C in water (100 ml) was added a solution of 2.0 g (6.3 mmol) of azido-nucleoside **6**, and the hydrogenation was continued. After 2 hr, tlc in B showing the absence of starting material, the catalyst was removed followed by concentration to dryness and several reevaporations from methanol, which induced crystallization: 1.70 g (90%) of **7**, crystallizing with 1 mol of methanol in colorless prisms, decomposing from 200 °C on, after sintering around 160 °C; $[\alpha]_D^{20}$ +12° (*c* 1, H_2O).

Found: C, 43.67; H, 6.00; N, 25.54. Calcd for $C_{11}H_{16}N_6O_4 \cdot CH_3OH$: C, 43.90; H, 6.14; N, 25.60%.

9-(4'-Acetamido-4'-deoxy-β-D-glucopyranosyl)adenine (8): To a stirred suspension of **7** (100 mg) in methanol (10 ml) was added 1 ml of acetic anhydride, giving gradually a clear solution. After 5 hr at room temperature (tlc in B showed the reaction to be complete), the mixture was evaporated to dryness followed by two reevaporations from ethanol. The residue was filtered with ethanol to give **7** as a hygroscopic (after drying over P_2O_5), solid product, containing 1 mol of acetic acid; NMR (D_2O) τ 1.63 and 1.83 (two 1 H-s, H-2 and H-8), 4.33 (d, 1, $J_{1',2'}$=9 Hz, H-1'), 7.86 (s, 3, acetic acid of crystallization), 7.91 (s, 3, NHAc).

Found: C, 44.94; H, 5.55; N, 21.39%. Calcd for $C_{13}H_{18}N_6O_5 \cdot CH_3COOH$: C, 45.22; H, 5.57; N, 21.10%.

9-(4'-Acetamido-2',4',6'-tri-O-acetyl-4'-deoxy-β-D-glucopyranosyl) adenine (9): To a pyridine solution (2 ml) of **8** (100 mg) was added 1 ml of acetic anhydride with cooling and stirring and the mixture was then kept at room temperature for 3 hr. Concentration to dryness *in vacuo* (finally 0.1 mm, bath temperature 25 °C), followed by reevaporations from water and ethanol–water (1: 1) gave a sirup which on trituration with ether solidified. Filtration afforded 100 mg (63%) of an amorphous product, uniform by tlc (in B); $[\alpha]_D^{20}$ +6° (*c* 1, $CHCl_3$); NMR (DMSO-d_6) τ 1.60 and 1.80 (two 1 H-s, H-2 and H-8), 2.00 (d, 1, J=8 Hz, 4'-NH), 2.71 (s, 2, 6-NH_2), 3.98 (d, 1, $J_{1',2'}$=9 Hz, H-1'), 4.25 (t, 1, $J_{1',2'}=J_{2',3'}$= 9 Hz, H-3'), 5.88 (m, 4, H-4', H-5', and 6'-CH_2), acetyl resonances *cf.* Table 1.

Found: C, 49.00; H, 5.56; N, 17.89%. Calcd for $C_{18}H_{24}N_6O_8$C: 49.14; H, 5.21; N, 18.10%.

Uracil Nucleosides. 1-(2',3',6'-Tri-O-benzoyl-4'-O-mesyl-β-D-galactopyranosyl)uracil (10): To a solution of 20.0 g (32.7 mmol) of 4-*O*-mesyl-galactose **2** in 1,2-dichlorethane was added 40 g of molecular sieve,[38] followed, after standing for 30 min, by the addition of stannic chloride (10 ml) and *O,O*-bis(trimethylsilyl)uracil[39,41] (11.0 g, 1.3 molar equiv.). The mixture was heated to 60 °C for 12 hr, and subsequently treated with saturated sodium bicarbonate solution (2×500 ml) and water (2×500 ml). The organic layer was dried (Na_2SO_4), concentrated to dryness and reevaporated twice from methanol. The residue was dissolved in hot ethanol (150 ml), from which it crystallized: 18.4 g of product, mp 189—190 °C, that, according to tlc in B, was contaminated with approximately 10% of another product (N^3-isomer) of lower R_f-value. The latter, being scarcely soluble in ethanol, was removed by one recrystallization from this solvent, affording 15.5 g (71%) of **10** as needles of mp 204—206 °C (lit,[21] 207—208 °C); UV (MeOH) and NMR data ($CDCl_3$) correlated well with those reported by Kondo and Goto[21] for their product, obtained by another route.

Found: C, 57.87; H, 4.19; N, 4.26; S, 4.71%. Calcd for $C_{12}H_{28}N_2O_{12}S$: C, 57.83; H, 4.25; N, 4.22; S, 4.82%.

1-(4'-Azido-4'-deoxy-β-D-glucopyranosyl)uracil (11): A mixture of 12.0 g (18 mmol) of mesyl-nucleoside **10**, 6.6 g (5 molar equiv.) of sodium azide and 45 ml of hexamethyl phosphoric triamide was stirred at 80—90 °C for 5 hr, followed by pouring into ice-water (1 l). The solid precipitate was filtered off, dried over P_2O_5 and directly subjected to de-*O*-benzoylation by dissolution in methanol (110 ml), containing 5 ml of 5 M methanolic sodium methoxide, and storage at room temperature overnight. The mixture was then deionized by a strongly acidic resin (Merck I) and evaporated to dryness, followed by several reevaorations from 1: 1 methanol–water, which induced crystallization. Filtration with methanol yielded 3.3 g (72%) of **11** as colorless crystals of mp 226—228 °C (decomp.); lit,[21]: 226 °C (decomp.).

1-(4'-Amino-4'-deoxy-β-D-glucopyranosyl)uracil (12): *A. Form Azidonucleoside 11 by Hydrogenation*:[42] To a prehydrogenated suspension of 500 mg 10% Pd/C in 1: 1 water–ethanol (100 ml) was added 2.0 g (6.8 mmol) of azide **11** in 20 ml of water, and the hydrogenation was continued. After 3 hr, tlc in B showing the absence of starting material, the catalyst was removed followed by evaporation to dryness *in vacuo*. Trituration of the residue with ethanol gave a crystalline product, which was filtered after standing in a refrigerator overnight: 1.52 g (81%) of colorless crystals, mp 241—243 °C (decomp.); mp, UV (MeOH), NMR (D_2O) and analytical data corresponded well with those reported for a product from another route.[21]

B. From 4'-Acetamido-nucleoside 13 by Deacetylation: A solution of sirupy **13** (680 mg, 2.15 mmol) in 4 M hydrochloric acid was refluxed for 3 hr, followed, after cooling down, by deionization with a strongly basic resin (Merck III), which was thoroughly washed on removal. The filtrate was subjected to charcoal treatment and subsequently evaporated to dryness, yielding a residue which crystallized on several reevaporations from ethanol. Filtration with ethanol and recrystallization from the same solvent gave 410 mg (65%) of **12** as colorless crystals, identical in all respects with the product described under A.

1-(4'-Acetamido-4'-deoxy-β-D-glucopyranosyl)uracil (13): *A. From Ethoxypyrimidinone-Nucleoside 20 by Hydrolysis*: A solution of 750 mg (1.5 mmol) of **20** in 8% methanolic hydrochloric acid (30 ml) was kept at ambient temperature for 24 hr followed by concentration *in vacuo* and repeated reevaporations of the residue from methanol. The yellowish sirup was purified on a silica gel column by elution with methanol to yield, after drying for 2 hr at 60 °C and 0.1 mm, 476 mg of amorphous **13** (84%), homogeneous by tlc (B), $[\alpha]_D^{23}$ +8° (*c* 1, CH_3OH); the product could not be crystallized from the usual solvents.

Found: C, 45.64; H, 5.52; N, 13.10%. Calcd for $C_{12}H_{17}N_3O_7$: C, 45.71; H, 5.44; N, 13.33%.

B. De-O-acetylation of Tetraacetate 14: To a solution of 440 mg (1 mmol) of **14** in methanol (15 ml) was added 0.2 ml of N methanolic sodium methoxide and the mixture was kept overnight at ambient temperature. Deionization with Dowex 50 (H^+) and concentration to dryness followed by repeated reevaporations from ethanol left a sirup, which was subjected to a small silica gel column and eluted with methanol. After evaporation to dryness *in vacuo* (finally 0.1 mm): 240 mg (76%) of **14** a colorless sirup, identical with respect to tlc (in B), IR and NMR data with the product described under A.

1-(4'-Acetamido-2',3',6'-tri-O-acetyl-4'-deoxy-β-D-glucopyranosyl)uracil (14): To aminoglucosyl-uracil **12** (430 mg, 1.5 mmol) in pyridine (10 ml) was added with stirring 4 ml of acetic anhydride. After 15 hr at ambient temperature, the clear solution was evaporated to dryness *in vacuo* (finally 0.1 mm) followed by coevaporations with water, water–ethanol (1: 1) and ethanol. The resulting sirup was dissolved in a small amount of methanol from which **14** crystallyzed gradually. Filtration after standing overnight in a refrigerator and drying at 60 °C/0.1 mm for 3 hr afforded 470 mg (68%) of

14 as colorless crystals of mp 260—263 °C (decomp.)[43]; $[\alpha]-$ +11° (*c* 1, CH_3OH); NMR (DMSO-d_6) τ 1.35 (s, 1, uracil-NH), 2.01 (broad d, 1, 4'-NH), 2.07 and 4.31 (two 1 H-d, $J_{5,6}$=8.5 Hz, H-5 and H-6), 4.15 (m, 1, H-1'), acetyl resonances *cf.* Table.

Found: C, 48.79; H, 5.15; N, 9.49%. Calcd for $C_{18}H_{23}N_3O_{10}$: C, 48.98; H, 5.25; N, 9.52%.

Treatment of *N*-acetyl derivative **13** with pyridine–acetic anhydride and processing of the mixture in a manner analogous to the one described above gave compound **14** in 74% yield.

*1-(4'-Acetamido-2',3',6'-tri-*O*-acetyl-4'-deoxy-β-*D*-glucopyranosyl)-4-ethoxypyrimidin-2-one (19)*: A solution of 2.30 g (5.9 mmol) of sirupy 1,2,3,6-tetra-*O*-acetyl-4-acetamido-4-deoxy-D-glucopyranose (**20**, α/β-ratio 9: 1)[27] in 40% HBr in glacial acetic acid (15 ml) was kept at ambient temperature for 3 hr. The mixture was then diluted with chloroform (200 ml) and extracted successively with cold water (2×100 ml), saturated sodium bicarbonate solution (2×100 ml) and water, followed by drying of the organic phase (Na_2SO_4). After filtration, the solution was added to 4.0 g (4 molar equiv.) of 2,4-diethoxypyrimidine and the solvent was removed *in vacuo*. The resulting mixture was then heated for 12 hr on a water-bath at 60 °C. After cooling down, *n*-hexane (200 ml) was added, resulting in a brownish precipitate. The hexane, containing the excessive diethoxypyrimidine, was removed by decantation, followed by another *n*-hexane extraction and discoloration of the residue in benzene solution with activated charcoal. Addition of *n*-hexane to the filtrate till beginning turbidity and standing in a refrigerator gave a first crop of crude **20**, successive further additions of *n*-hexane to the respective mother liquors a second and third. Recrystallization of the combined fractions by dissolution in the minimum amount of methanol and addition of water afforded 1.07 g (36%) of **20**, mp 118—120 °C (after sintering around 110 °C); $[\alpha]_D^{23}$ +46° (*c* 1, CH_3OH), +59° (*c* 1, $CHCl_3$); NMR (DMSO-d_6) τ 1.81 and 3.93 (two 1 H-d, $J_{5,6}$=7.5 Hz, H-5 and H-6), 2.10 (d, 1, $J_{4',NH}$=9 Hz, NH), 4.02 (m, 1, halfwidth 9 Hz, H-1'), 4.68 (m, 2, H-3' and H-2'), 5.63 and 8.71 (2H-q and 3H-t, J=7 Hz, OCH_2CH_3), 5.9 (m, 4, H-4', H-5', and 6'-CH_2), acetyl resonances *cf.* Table 1; acetyl resonances in $CDCl_3$ at τ 7.93, 7.97, 8.02, and 8.04.

Found: C, 50.99; H, 6.03; N, 8.90%. Calcd for $C_{20}H_{27}N_3O_{10}$: C, 51.17; H, 5.80; N, 8.95%.

*Cytosine-Nucleosides (15—18). 1-(2',3',6'-Tri-*O*-benzoyl-4-*O*-methanesulfonyl-β-*D*-galactopyranosyl)-*N*⁴-acetylcytosine (15)*: To a stirred solution of 4-*O*-mesyl-galactose **2** (4.8 g, 7.8 mmol) in sieve-dried 1,2-dichlorethane (150 ml) was added molecular sieve[38] (5 g), tin tetrachloride (2.4 ml), and, after 15 min, 1.65 g (1.1 molar equiv.) of N^4,*O*-bis(trimethylsilyl)-N^4-acetylcytosine,[39] and the mixture was kept in a bath at 60 °C for 12 hr. After dilution with 300 ml of 1,2-dichloroethane the solution was extracted with saturated sodium hydrogen carbonate (2×200 ml) followed by washing with water (2×200 ml). The organic phase was dried (Na_2SO_4), and evaporated to dryness *in vacuo*, yielding a solid mass that was filtered and thoroughly washed with ethanol: 4.7 g (85%) of **15** as colorless needles, mp 266—268 °C (decomp.) and $[\alpha]_D^{23}$ +38.6° (*c* 1, dimethylformamide). The product was identical with respect to tlc (in A), IR and NMR with a sample prepared by another route.[14]

*1-(4'-Acetamido-4'-deoxy-β-*D*-glucopyranosyl)cytosine (17)*: A solution of ethoxypyrimidinone-nucleoside **19** (2.70 g, 5.46 mmol) in methanol, saturated with ammonia (150 ml), was heated in a pressure bottle for 22 hr at 95 °C. After treatment with charcoal, the mixture was concentrated to dryness followed by several reevaporations from methanol. The solid residue was recrystallized from methanol: 1.13 g (66%) of **17** as colorless crystals of mp 290—292 °C (decomp.) and $[\alpha]_D^{23}$ +34° (*c* 1, H_2O). The product was identical with a sample prepared by *N*-acetylation of **16** with acetic anhydride in methanol, for which mp 317—319 °C (decomp.) and $[\alpha]_D^{26}$ +32° (*c* 1, H_2O) have been reported.[14]

*1-(4'-Amino-4'-deoxy-β-*D*-glucopyranosyl)cytosine (16)*: A solution of 4'-acetamido-nucleoside **17** (540 mg, 1.72 mmol) in 4 M hydrochloric acid was refluxed for 4 hr, followed, after cooling, by deionization with a strongly basic resin (Merck III), which was thoroughly washed on removal. The filtrate was subjected to charcoal treatment and then evaporated to dryness, giving a sirupous residue that gradually crystallized on repeated reevaporations from methanol. Recrystallization from the same solvent afforded 320 mg (69%) of **16** of mp 210 °C and $[\alpha]_D^{23}$ +15° (*c* 1, H_2O).

A sample prepared from mesylate **15** *via* azidolysis, deacylation and hydrogenation[14] had mp, UV, and IR data duplicating those above.

*1-(4'-Acetamido-2',3',6'-tri-*O*-acetyl-4'-deoxy-β-*D*-glucopyranosyl)-*N*⁴-acetylcytosine (18)*: *N*-Acetyl derivative **17** (1.0 g) in 1:1 pyridine–acetic anhydride (1:1) was kept overnight at ambient temperature, followed by evaporation to dryness *in vacuo* (finally 0.1 mm). Trituration of the residue with ethanol induced crystallization to give, after recrystallization from the same solvent 1.1 g (72%) of **18** as needles of mp 295 °C (decomp.); $[\alpha]_{23}^{D}$ +28.1° (*c* 1, dimethylformamide); lit.,[14] mp 293—294 °C; $[\alpha]_{25}^{D}$ +27°; NMR (DMSO-d_6) τ −0.84 (s, 1, N^4-H), 1.56 and 2.75, (two 1 H-d, $J_{5,6}$=7 Hz, H-6 and H-5), 2.18 (d, 1, $J_{4',NH}$=9 Hz, C-4'-NH), 3.90 (m, 1, H-1'), acetyl resonances *cf.* Table 1.

Grateful acknowledgment is made to the Deutsche Forschungsgemeinschaft and to the Fonds der Chemischen Industrie for persevering support of this research and to the Japan Society for the Promotion of Science for granting a visiting professorship (to F. W. L.) at Keio University, Yokohama, providing the quietude for writing this work.

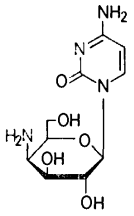
Nucleosides. XXII.[1] Pyrimidine Nucleosides of 4-Amino-4-deoxy-β-D-galactopyranose

Frieder W. LICHTENTHALER, Tamio UENO,[2] and Peter Voss
Institut für Organische Chemie, Technische Hochschule Darmstadt, 61 Darmstadt, Germany

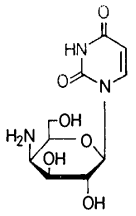
(Received January 14, 1974)

In a four step sequence from 1-*O*-acetyl-2,3,6-tri-*O*-benzoyl-4-*O*-mesyl-α-D-glucose (**4**), 4′-amino-4′-deoxy-β-D-galactosyl-cytosine (**1**) was synthesized, involving stannic chloride catalyzed nucleosidation with bis(trimethylsilyl)-N^4-acetyl-cytosine, azidolysis of the 4′-sulfonyloxy group, deblocking and reduction (overall yield: 48%). An alternate, though preparatively less satisfactory approach was used for the preparation of the uracil analogue **2**, which started from β-D-glucosyl-cytosine or uracil (**9** or **15**) and proceeded *via* standard blocking and deblocking reactions to the 4′-*O*-mesylglucosyl-uracil (**20**) and was concluded by azidolysis (**20**, **21**), removal of protecting groups and reduction. Structural and configurational assignments evolved from the mode of preparation as well as from spectroscopic data, most conveniently from the acetyl resonances of the peracetylated nucleosides **8** and **24**, which are in accord with those of their galactosyl and 3-acetamido-3-deoxy-galactosyl counterparts (Table).

Because of the unique structural features associated with the aminoacyl-aminohexosyl-cytosine group of antibiotics, considerable attention has been given to an assessment of their structure-activity relationships.[3] The variety of analogs modified in the carbohydrate portion being rather limited, it was of interest to evaluate analogs for their biological relevance, which have a "1,4-*cis*-arrangement" of nucleobase and amino-acid component, *i.e.* 4-aminogalacto-configuration in the sugar unit, rather than the 1,4-*trans*-disposition present in gougerotin and blasticidin S. We have, by consequence, initiated studies towards a preparatively satisfactory access to 4-amino-galactosyl-pyrimidine nucleosides **1** and **2**, the results being subject of this communication.



1



2

In design, the synthetic scheme was based upon the efficient preparation of 4-amino-4-deoxy-D-galactose and derivatives by a route involving direct displacement of a 4-mesyloxy group by azide ion in a suitably blocked D-glucose derivative.[4] Nevertheless, when utilizing this route for the preparation of 4-amino-galactosyl nucleosides, several synthetic possibilities remain with respect to the stage at which the aglycon is preferably introduced:

(i) Nucleoside synthesis with an *a priori* prepared 4-aminosugar derivative, *e.g.* with tetra-*O*-acetyl-4-acetamido-4-deoxy-D-galactopyranose by the fusion method or the Friedel-Crafts catalyzed silyl procedure.

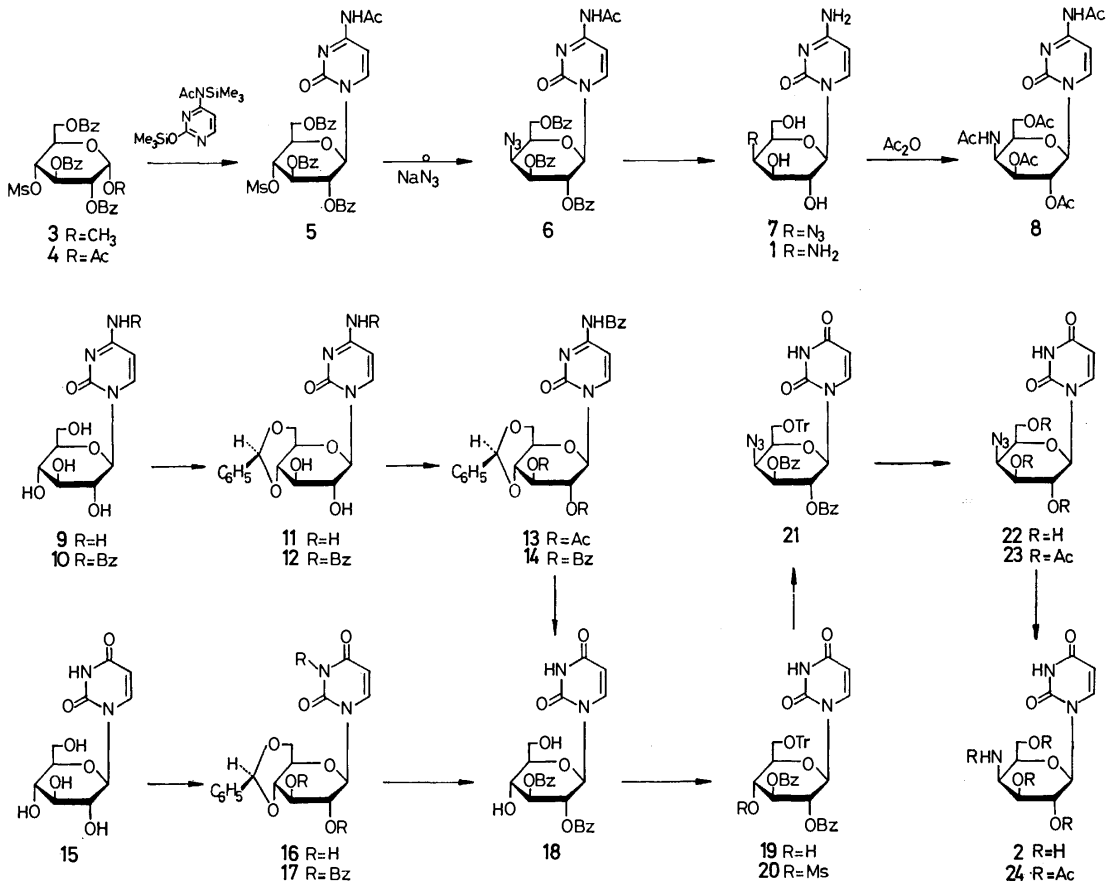
(ii) Nucleosidation at the outset, *e.g.* conversion of the respective glucopyranosyl nucleoside *via* a series of reactions into a suitably blocked 4′-*O*-mesylate followed by azidolysis, deblocking and reduction.

(iii) Introduction of the nucleobase at some intermediate stage, *e.g.* at that of a suitably blocked 4-*O*-mesyl-glucose.

Since certain preliminary experiments with the first approach, which might be surmised to be the most direct one, presented some preparative complications when employing the stannic chloride catalyzed silyl nucleosidation,[5,6] the second and third reaction path was deemed more appropriate and used for the preparation of **1** and **2**.

Cytosine Nucleosides. A 4-*O*-mesyl-glucose derivative suitable for nucleosidation *via* the Friedel-Crafts catalyzed silyl procedure[5,6] proved to be 1-*O*-acetyl-2,3,6-tri-*O*-benzoyl-4-*O*-mesyl-α-D-galactopyranose (**4**), obtained from its readily accessible methyl glycoside **3**[4] by boron trifluoride catalyzed acetolysis.[7] When reacted in dichloroethane with N^4-acetyl-bis(trimethylsilyl)-cytosine in the presence of stannic chloride (12 hr, 60 °C), crystalline nucleoside **5** was obtained in high yield (81%). The secondary C-4′-mesyloxy function in **5** was readily displaced by sodium azide in hexamethylphosphoric triamide (20 hr, 80 °C), to afford the blocked azidogalactosyl nucleoside. Subsequent de-*O*-benzoylation by methanolic ammonia to the free azido-nucleoside **7**, followed by hydrogenation over palladium-on-charcoal then yielded the desired 4′-amino-4′-deoxy-β-D-galactosyl-cytosine (**1**) as an analytically and chromatographically pure sirup, that could not be induced to crystallize, yet gave a crystalline tetraacetyl derivative (**8**). The yields in this four-step sequence from **4** *via* **5**, **6**, and **7** to **1** being consistently high, the overall yield amounts to a quite satisfactory 48%.

In addition, a number of new crystalline derivatives of β-D-glucopyranosylcytosine (**9**) were prepared and although they could not directly be utilized for the synthesis of **1** (yet of **2**, see below), are placed on record as readily accessible, preparatively useful intermediates. Thus, selective benzoylation of the N^4-amino function in the nucleobase was readily achieved by refluxing **9** with benzoic anhydride in methanol, to afford highly crystalline **10** in 74% yield, further characterized as its tetra-*O*-acetyl derivative. By treatment with benzaldehyde/zinc chloride, **9** as well as **10** were converted into their 4′,6′-*O*-benzylidene derivatives **11** and **12**, respectively, the conversion **9**→**11**, however, proceeding



rather sluggishly due to the low solubility of the educt in the reaction mixture. Subsequent acylation of **12** with acetic anhydride or benzoyl chloride in the presence of pyridine proceeded smoothly to afford the 2′,3′-di-*O*-acyl derivatives **13** and **14**. However, as expected from the ready hydrolytic deamination of N^4-acylated cytosine and cytidine derivatives,[8,9] a de-*O*-acetalization in benzylidene-nucleosides **11**—**14** cannot be achieved without concomitant removal of the benzoylamido-function to yield the respective uracil nucleosides. Thus, brief treatment of **14** with 80% acetic acid at 80—90 °C, gave in an 81% yield 2′,3′-di-*O*-benzoyl-β-D-glucosyluracil (**18**), identical with the same product prepared by another route (*cf.* below).

Uracil Nucleosides. In analogy to the efficacious four-step preparation of **1** from 4-*O*-mesyl-glucose (**4**), for a synthesis of 4-aminogalactosyluracil (**2**) the nucleosidation of **4** with bis(trimethylsilyl)uracil followed by introduction of the 4′-amino function must be considered to be the most appropriate and should be feasible without complications. Yet, prior to this, we had followed approach (ii) for a synthesis of **2**, comprising eight steps from readily accessible[10] β-D-glucopyranosyl-uracil (**15**). The conversion of **15** into its 2′,3′-di-*O*-benzoyl derivative (**18**) was readily accomplished by treatment with benzaldehyde/zinc chloride (to **16**), acylation with benzoyl chloride/pyridine to the N^3,2′,3′-tribenzoyl derivative **17** and deacetalization with 80% acetic acid (1 hr, 80 °C) to **18**, which was also obtained from the cytosine nucleoside **18** (*vide supra*). Subsequent tritylation of the primary hydroxyl function in **18**, followed by mesylation gave the key intermediate **20**, suitably blocked for an ensuing S_N2-displacement of its 4′-mesyloxy function by sodium azide in HMPT (20 hr, 90 °C). Deblocking in **21** by treatment with sodium methoxide/methanol and, subsequently, with 80% acetic acid afforded the free azidogalactosyl nucleoside **22**. Due to difficulties in crystallizing **22**, it was directly hydrogenated to yield 4′-aminogalactosyl-uracil (**2**) as an amorphous substance. The peracetyl derivatives of **22** and **2**, however, were obtained in crystalline, readily characterizable form, as was the case with all other intermediates in the conversion of **15** into **2** over eight steps. Not unexpected, though, the preparative utility of the reaction sequence **15**→**2** is considerably inferior to the four-step approach employed in the cytosine series for the synthesis of **1**.

Structural and Configurational Assignments. Since well-defined synthetic procedures have been used throughout as well as readily characterizable starting materials (**4**, **9**, and **15**, respectively), the structures and configurations of the newly synthesized nucleosides already follow from the mode of preparation. Sustaining evidence is furnished by NMR data, most conveniently from the acetyl resonances in $CDCl_3$ or DMSO-d_6 of the peracetylated nucleosides. As is clearly apparent from the empirical principles laid down in the "acetyl resonance rule",[11,12] hexopyranosyl nucleosides with axial *O*-acetyl substituents give a larger separation of signals in the 8 τ range than *e.g.* glucosyl derivatives[13] with an equatorial orientation of groups.

Table 1. Relevant NMR-data in DMSO-d_6 and $CDCl_3$, and rotations of peracetyl-β-D-galactopyranosylpyrimidines

a) Abbreviations used: U = uracilyl-1; U(O⁴-Et) = 4-ethoxypyrimidinonyl-1; C = cytosinyl-1; C(N⁴-Ac) = N^4-acetyl-cytosinyl-1. b) Except for some values in $CDCl_3$ (G. Bambach, Diplomarbeit, Techn. Hochschule Darmstadt, 1968) the NMR data for compounds I—VI are derived from Ref.[11] c) Observed as doublets with $J_{1',2'} = 8$—9 Hz. d) N^4-Acetyl resonance of the cytosine moiety. e) F.W. Lichtenthaler, G. Bambach, and P. Emig, *Chem. Ber.*, **102**, 1003 (1969). f) G. E. Hilbert, *J. Amer. Chem. Soc.*, **59**, 330 (1937). g) F. W. Lichtenthaler, G. Bambach, and U. Scheidegger, *Chem. Ber.*, **102**, 991 (1969).

In DMSO-d_6 and in $CDCl_3$, the peracetylated galactosyl-nucleosides I—IV as well as their 3′-aminoanalogs V[14] and VI show one distinct lowfield resonance in the 7.80—7.85 τ range (*cf.* Table), clearly attributable to the axial C-4′-acetoxy group. The 4′-aminogalactosyl-pyrimidines **8** and **24**, however, were expectedly devoid of a resonance within the axial range, since acetamido resonances of axial orientation fall together with those for equatorial and C-6′-signals.[11] Equally distinct is the presence of an equatorial acetamido function in 3′-aminogalactosyl nucleosides V and VI, appearing at τ 8.08 in $CDCl_3$, yet at 8.23 in DMSO-d_6, the separation from the equatorial acetoxy groups being larger by about 0.1 ppm in the more polar solvent, undoubtedly due to different solvation of the acetamido group. This solvent effect is also observed—yet in reverse direction—with the N^4-acetyl resonances of the cytosine nucleosides IV and **8**, exhibiting lowfield resonances at τ 7.88 in DMSO-d_6, yet at 7.73 and 7.71, resp., in $CDCl_3$. Worthy of note with all nucleosides in the Table 1 is also the appearance of an acetyl resonance in the upper equatorial range (τ 8.09—8.10 in DMSO-d_6) which is to be assigned to the respective 2′-acetoxy resonances, being in the range of diamagnetic shielding by the nucleobase.

The rotational values for the peracetylated nucleosides, which should be similar in sign and magnitude, if the sugar-nucleobase orientations are identical, show a considerably better conformity as their glucoanalogs.[13] Although farreaching conclusions may not be drawn therefrom, it is interesting to note that the ethoxypyrimidinone nucleosides II and VI have the highest rotational values (+59 and +87° in chloroform, *cf.* Table 1), whilst, curiously, the 4′-aminogalacto derivatives exhibit the lowest.

Experimental

Melting points were determined on a Bock Monoskop, and are uncorrected. Spectral measurements were effected with Perkin-Elmer 125 (IR), Perkin-Elmer 137 (UV), and Varian A-60A (NMR) instruments. Thin layer chromatography on Kieselgel F_{254} plastic sheets (Merck, Darmstadt) was used to monitor the reactions and to ascertain the purity of the reaction products; developers employed (A) benzene–ethyl acetate (4:1); (B) benzene–ethyl acetate–methanol (12:7:1); (C) ethyl acetate–ethanol–water (15:2:1). The spots were visivalized by UV light, by iodine vaporing or by spraying with 80% aqueous sulfuric acid and charring at 110 °C for 5 min. Column chromatography was carried out on silica gel 70—230 mesh ("Kieselgel 60", Merck,

Darmstadt).

1-O-Acetyl-2,3,6-tri-O-benzoyl-4-O-mesyl-α-D-glucopyranose (**4**). To a solution of 10.0 g (17 mmol) of methyl 2,3,6-tri-*O*-benzoyl-4-*O*-mesyl-α-D-glucopyranoside (3)[4] in acetic anhydride (200 ml) was added 20 ml of ethereal BF_3-etherate and the mixture was kept at 60 °C for 12 hr, followed by pouring into ice-water under vigorous stirring. The aqueous phase was decanted several times to be replaced by new ice-water. After 2 hr, chloroform (500 ml) was added and the organic phase was separated, dried over Na_2SO_4 and evaporated to dryness. The residue, after charcoal treatment in hot methanol (150 ml), was crystallized gradually on standing at ambient temperature and was collected after standing overnight in a refrigerator: 5.9 g (47%), mp 175—178 °C, after sintering from 150 °C on; $[\alpha]_D^{20}$ +126° (*c* 1, $CHCl_3$); NMR ($CDCl_3$) τ 3.40 (d, 1, $J_{1,2}$=3.5 Hz, H-1), 3.86 (t, 1, $J_{2,3}=J_{3,4}$=10 Hz, H-3), 4.53 (q, 1, J=3.5 Hz and 10 Hz, H-2), 4.77 (t, 1, $J_{3,4}=J_{4,5}$=10 Hz, H-4), 7.08 (s, 3, OMs), 7.84 (s, 3, OAc).

Found: C, 59.09; H, 4.63; S, 5.39%. Calcd for $C_{20}H_{28}O_{12}S$: C, 58.82; H, 4.61; S, 5.22.

Cytosine Nucleosides (1, 5—14). *N⁴-Acetyl-1-(2',3',6'-tri-O-benzoyl-4'-O-mesyl-β-D-glucopyranosyl)cytosine* (**5**): To a solution of 3.0 g (4.9 mmol) of mesylate **4** in 1,2-dichloroethane (100 ml) was added 6 g of molecular sieve,[18] stannous tetrachloride (1.5 ml) and, after 15 min, 1.65 (1.1 molar equiv.) of *N⁴,O*-bis(trimethylsilyl)-*N⁴*-acetyl-cytosine[19] and the mixture was heated to 60° for 12 hr. Subsequently, 750 ml of dichloromethane was added and the solution was extracted with two 200 ml portions of saturated $NaHCO_3$-solution,[20] followed by washing with water (2×200 ml). The organic phase was dried (Na_2SO_4), and evaporated to dryness *in vacuo*, to leave a crystalline residue which was filtered and thoroughly washed with ethanol: 2.8 g (81%) of crystals; mp 240—241 °C (decomp.); $[\alpha]_D^{20}$ +24° (*c* 1.2, dimethylformamide); uniform by tlc (D); λ_{max}^{MeOH} 233, 283, and 330 nm.

Found: C, 57.63; H, 4.48; N, 5.85; S, 5.46%. Calcd for $C_{34}H_{31}N_3O_{12}S$: C, 57.87; H, 4.43; N, 5.96; S, 5.54%.

N⁴-Acetyl-1-(4'-azido-2',3',6'-tri-O-benzoyl-4'-deoxy-β-D-galactopyranosyl)cytosine (**6**): A suspension of 2.3 g (3.1 mmol) of mesyl derivative **5** and sodium azide (1.0 g, 5 molar equiv.) in hexamethylphosphoric acid triamide (20 ml) was heated at 80 °C for 20 hr with vigorous stirring. The yellow mixture, containing some undissolved sodium azide, was poured into ice-water (100 ml), and the crystalline, colorless precipitate was filtered off: 1.8 g (88%) of the crude, chromatographically homogenous (tlc in A) product which was used for the ensuing reactions. A small amount was recrystallized from chloroform-methanol to give the analytical sample of mp 228 °C (decomp.) and $[\alpha]_D^{20}$ +121° (*c* 1, $CHCl_3$); NMR ($CDCl_3$) τ 0.33 (s, 1, NH), 2.0—3.0 (m, 17, H-5, H-6 and 3 C_6H_5); 3.77 (m, 1, H-1'), 8.13 (s, 3, NHAc).

Found: C, 60.65; H, 4.30; N, 12.75%. Calcd for $C_{33}H_{28}N_6O_9$: C, 60.74; H, 4.43; N, 12.87%.

1-(4'-Azido-4'-deoxy-β-D-galactopyranosyl)cytosine (**7**): To a suspension of **6** (1.6 g, 2.5 mmol, of crude product as described above) in methanol (20 ml) was added, with stirring, 0.1 ml of sodium methoxide solution, prepared from 1 g of sodium and 10 ml of methanol. A clear solution was not obtained, since product (**7**) started to precipitate immediately. After 3 hr stirring and standing overnight at ambient temperature, the precipitate was filtered (500 mg, 61%). Deionization of the filtrate and evaporation to dryness afforded a second crop (120 mg, 15%) of crude product, homogeneous by tlc (in C), which was used for hydrogenation (s. below).

A 150 mg portion was recrystallized from little methanol (standing for 1—2 days due to slow crystallization) to give the analytical sample of mp 180—182 °C (effervesc.); $[\alpha]_D^{20}$ −34° (*c* 1, H_2O); NMR (D_2O) τ 2.28 and 3.90 (two d, 1, $J_{5,6}$=7.5 Hz, H-6 and H-5), 4.36 (d, 1, $J_{1,2}$=8 Hz, H-1'), other protons give complex multiplets.

Found: C, 39.98; H, 5.00; N, 27.94%. Calcd for $C_{10}H_{14}N_6O_5$: C, 40.27; H, 4.73; N, 28.18%.

1-(4'-Amino-4'-deoxy-β-D-galactopyranosyl)cytosine (**1**): To a prehydrogenated suspension of 10% Pd/C (100 mg) in water (30 ml) was added 450 mg of crude azido-nucleoside **7**, and the hydrogenation was continued. After 2 hr, tlc (in C) showing the absence of starting material, the catalyst was removed and the filtrate was evaporated *in vacuo* (bath temperature below 25 °C) to give 380 mg (89%) of **1** as a sirup, that could not be induced to crystallization from the usual solvents. The analytical sample was dried at 0.1 mm for 12 hr.

Found: C, 43.95; H, 6.14; N, 20.14%. Calcd for $C_{10}H_{16}N_5O_5$: C, 44.11; H, 5.92; N, 20.58%.

N⁴-Acetyl-1-(4'-acetamido-2',3',6'-tri-O-acetyl-4'-deoxy-β-D-galactopyranosyl)cytosine (**8**): Sirupy **1** (250 mg) was refluxed for 30 min in 1:1 pyridine-acetic anhydride, followed by evaporation to dryness *in vacuo* (finally 0.1 mm). The remaining sirup was subjected to purification on a silica gel column (2×20 cm) with ethyl acetate. The residue, obtained after concentration of the eluate, was dissolved in ethyl acetate (3 ml) and precipitated by addition of ether: 380 mg (86%); mp 174—177 °C, after sintering from 165 °C on; $[\alpha]_D^{20}$ +16° (*c* 1, $CHCl_3$); NMR (DMSO-d_6) τ 0.87 (s, 1, cytosine-NH), 1.54 and 2.73 (two 1 H-d, $J_{5,6}$=7.5 Hz, H-6 and H-5); 1.86 (d, 1, $J_{4',NH}$=10 Hz, C-4'-NH), 3.91 (m, 1, H-1'), 4.63 (narrow (6 Hz) m, 2, H-2' and H-3'), 5.5 (broad m (25 Hz), 2, H-4' and H-5'), 5.95 (m, 2, CH_2), acetyl resonances *cf.* Table.

Found: C, 49.64; H, 5.27; N, 11.63%. Calcd for $C_{20}H_{26}N_4O_{10}$: C, 49.79; H, 5.39; N, 11.62%.

N⁴-Benzoyl-1-(β-D-glucopyranosyl)cytosine (**10**): To solution of 5.0 g (0.18 mol) of 1-(β-D-glucopyranosyl)cytosine (**9**)[22] in methanol (500 ml) was added 4.2 g (1 molar equiv.) of benzoic anhydride and the mixture was refluxed. After 1 and 3 hr, respectively, another molar equiv. of benzoic anhydride was added, followed by additional 4 hr of reflux. Filtration and evaporation to dryness *in vacuo* left a white residue, which was thoroughly extracted with ether for removal of benzoic acid and excessive benzoic anhydride. The ether-insoluble residue (3.2 g, mp 173—177 °C) was recrystallized twice from ethanol to yield 2.55 g (74%) of **10** as colorless prisms of mp 191—192 °C; $[\alpha]_D^{20}$ +28° (*c* 1, dimethylformamide).

Found: C, 54.06; H, 4.99; N, 11.12%. Calcd for $C_{17}H_{19}N_3O_7$: C, 54.11; H, 5.08; N, 11.14%.

N⁴-Benzoyl-1-(tetra-O-acetyl-β-D-glucopyranosyl)cytosine: A solution of 200 mg of **10** in 1:1 pyridine-acetic anhydride (10 ml) was kept at ambient temperature overnight followed by concentration to dryness and several reevaporations from ethanol. The solid residue was recrystallized from ethanol to give needles (150 mg, 52%) of mp 248—252 °C; NMR ($CDCl_3$) τ 7.93, 7.95, 8.01, and 8.03 for acetoxy resonances.

Found: C, 55.51; H, 4.94; N, 7.75%. Calcd for $C_{25}H_{27}N_3O_{11}$: C, 55.62; H, 4.99; N, 7.70%.

1-(4',6'-O-Benzylidene-β-D-glucopyranosyl)cytosine (**11**): Anhydrous zinc chloride (4.0 g) and 2.5 g (9.2 mmol) of glucosylcytosine (**9**) in 20 ml of benzaldehyde were stirred at ambient temperature until completely dissolved (5 days). The mixture was then stirred into ice-water (400 ml) and the crystalline product was filtered off. Recrystallization from methanol gave 1.4 g (42%) of **11**, decomposing from 270 °C on,

$[\alpha]_D^{20}$ −48° (*c* 1, $CHCl_3$).

Found: C, 56.43; H, 5.20; N, 11.60%. Calcd for $C_{17}H_{19}N_3O_6$: C, 56.50; H, 5.30; N, 11.63%.

N^4-*Benzoyl-1-(4′,6′-O-benzylidene-β-D-glucopyranosyl)cytosine* (**12**): A mixture of zinc chloride (1.2 g), **10** (1.2 g, 3.2 mmol) and benzaldehyde (12 ml) was stirred overnight at room temperature followed by pouring into ice-water (200 ml) with vigorous stirring. *n*-Hexane (200 ml) was added whereafter the product started to crystallize. Filtration, washing with cold ethanol and recrystallization from methanol afforded 850 mg (61%) of colorless prisms of mp 245—248 °C; $[\alpha]_D^{20}$ −11° (*c* 1, dimethylformamide).

Found: C, 61.86; H, 4.96; N, 9.01%. Calcd for $C_{24}H_{23}N_3O_7$: C, 61.93; H, 4.98; N, 9.03%.

N^4-*Benzoyl-1-(2′,3′-di-O-acetyl-4′,6′-O-benzylidene-β-D-glucopyranosyl)cytosine* (**13**): A solution of **12** (465 mg, 1 mmol) in 1:1 pyridin-acetic anhydride (10 ml) was kept for 2 hr at 80 °C and subsequently stirred into ice-water (150 ml). The crystalline solid was filtered off after 1 hr and recrystallized from ethanol: 360 mg (65%) of **13** as colorless needles; mp 262—264 °C; $[\alpha]_D^{20}$ −37° (*c* 1, $CHCl_3$).

Found: C, 60.98; H, 5.02; N, 7.62%. Calcd for $C_{28}H_{27}N_3O_9$: C, 61.20; H, 4.95; N, 7.65%.

N^4-*Benzoyl-1-(2′,3′-di-O-benzoyl-4′,6′-O-benzylidene-β-D-glucopyranosyl)cytosine* (**14**): Benzoyl chloride (2.0 ml) was added to 1.18 g (2.5 mmol) of **12** in pyridine (40 ml) and the mixture was heated to 80 °C for 6 hr. Since starting material could still be detected by tlc (in B), another 2.0 ml of benzoyl chloride was added followed by heating to 100 °C for 5 hr. The mixture was then evaporated to dryness *in vacuo* (finally 0.1 mm) and the residue was dissolved in chloroform (150 ml) followed by washings, successively, with 1 M NaOH, water, 2 M HCl and again water. Drying over Na_2SO_4 and removal of the solvent left a residue which was recrystallized from ethanol: 1.32 g of **14** as colorless prisms; mp 271—273 °C; $[\alpha]_D^{20}$ −26° (*c* 1, $CHCl_3$).

Found: C, 67.43; H, 4.92; N, 5.96%. Calcd for $C_{38}H_{31}N_3O_9$: C, 67.46; H, 5.06; N, 6.21%.

Uracil Nucleosides (**2**, **15**—**24**). *1-(4′,6′-O-Benzylidene-β-D-glucopyranosyl)uracil* (**16**): A suspension of 10.0 g (36.4 mmol) of 1-(β-D-glucopyranosyl)uracil (**15**)[10] and 11 g of freshly molten zinc chloride in 115 ml of benzaldehyde was shaken for 30 hr. The resulting clear solution was stirred into ice water (700 ml), from which was decanted after 1 hr of vigorous stirring. The viscous sirup was brought to crystallization by trituration with petroleum ether, filtered off and recrystallized from methanol: 4.5 g (72%) of **16** as colorless needles, uniform by tlc (C); mp 282—284 °C; $[\alpha]_D^{22}$ −10° (*c* 1, dimethylformamide).

Found: C, 56.54; H, 5.21; N, 7.85%. Calcd for $C_{17}H_{18}N_2O_7$: C, 56.35; H, 5.01; N, 7.73.

1-(2′,3′-Di-O-benzoyl-4′,6′-O-benzylidene-β-D-glucopyranosyl)-N^3-benzoyluracil (**17**): To a suspension of 9.2 g (25.4 mmol) of **17** in pyridine (360 ml) was added with cooling 30 ml of benzoyl chloride and the mixture was stirred at ambient temperature for 24 hr. After removal of pyridine by evaporation (1 mm, bath temperature 50 °C), the brownish residue was taken up in chloroform and washed, successively, with N sodium carbonate, water, 0.1 M hydrochloric acid, and water. Treatment with activated carbon, drying over Na_2SO_4 and removal of chloroform *in vacuo* left a residue, which crystallized on solution in little hot chloroform and addition of methanol. Recrystallization from methanol afforded 10.1 g (59%) of colorless prisms; mp 217—219 °C; $[\alpha]_D^{22}$ +3.7° (*c* 1, chloroform).

Found: C, 67.63; H, 4.42; N, 4.19%. Calcd for $C_{38}H_{30}N_2O_{10}$: C, 67.65; H, 4.48; N, 4.15%.

1-(2′,3′-Di-O-benzoyl-β-D-glucopyranosyl)uracil (**18**): *A. From* **17** *by Removal of* N-*Benzoyl and* O-*Benzylidene Groups*: A solution of **17** (9.15 g, 13.5 mmol) was refluxed in 80% aqueous acetic acid for 9 hr and the mixture was subsequently taken to dryness *in vacuo* (1 mm), followed by several reevaporations from ethanol-water to remove the benzaldehyde formed. The residue crystallized on trituration with ether and was recrystallized by dissolution in little hot ethanol and addition of ether until turbidity: 4.0 g (61%) of **18**; tlc in A; mp 158—161 °C; $[\alpha]_D^{22}$ +47° (*c* 1, ethanol); τ (DMSO-d_6) 1.9—2.8 (11H-m, H-6 and $2C_6H_5$), 3.91 (1H-d, J=8.5 Hz, H-1′).

Found: C, 60.01; H, 4.73; N, 5.89. Calcd for $C_{24}H_{22}N_2O_9$: C, 59.75; H, 4.60; N, 5.81%.

B. From Cytosine Nucleoside **14** *by Simultaneous De-O-benzylidenation and Hydrolytic Deamination*: A solution of **14** (1.60 g, 2.4 mmol) in 80% acetic acid (80 ml) was heated to 80—90 °C for 1 hr, and subsequently filtered upon addition of charcoal. Evaporation to dryness and trituration of the residue with ethanol gave a solid mass, which was filtered and recrystallized from ethanol-ether (as above), to yield 1.13 g (81%) of **18** as colorless needles, identical in mp, rotation, tlc (A) and IR data with the product obtained above.

1-(2′,3′-Di-O-benzoyl-6′-O-trityl-β-D-glucopyranosyl)uracil (**19**): To a solution of 1.82 g (3.7 mmol) of **18** in pyridine (30 ml) was added 4.0 g (4 molar equiv.) of trityl chloride[23] and the mixture was stirred for 3 days at ambient temperature. Filtration, evaporation to dryness followed by several reevaporations from ethanol-water gave a sirup, which was disolsved in chloroform. Washing with water, drying over Na_2SO_4 and evaporation *in vacuo* left a sirup, which was transfered to a silica gel column (2×20 cm) and eluted with chloroform until the effluent was free of UV active material.[24] The product (**19**) was then eluted with ethyl acetate, followed by evaporation of the eluate to dryness and trituration of the residue with methanol, which induced crystallization. Recrystallization from ethanol-*n*-hexane afforded 2.1 g (78%) of tlc pure (A) crystals of mp 171—173 °C and $[\alpha]_D^{25}$ +46° (*c* 1, $CHCl_3$).

Found: C, 71.16; H, 4.98; N, 4.10%. Calcd for $C_{43}H_{36}N_2O_9$: C, 71.26; H, 5.01; N, 3.87%.

1-(2′,3′-Di-O-benzoyl-4′-O-mesyl-6′-O-trityl-β-D-glucopyranosyl)uracil (**20**): To a solution of 1.90 g (2.6 mmol) of the trityl derivative **19** in pyridine (60 ml) was added under cooling (0 °C) 1.3 ml (7 molar equiv.) of methanesulfonyl chloride and the mixture was kept in a refrigerator (5 °C) for 24 hr, followed by stirring into ice-water (50 ml). The resulting precipitate was filtered off, washed with water and subjected to purification by chromatography on silica with chloroform. Removal of solvent from the eluate and recrystallization of the residue from ethanol-*n*-hexane gave 1.42 g (66%) of **20** as prisms of mp 152—154 °C; $[\alpha]_D^{25}$ +89° (*c* 1, $CHCl_3$).

Found: C, 65.53; H, 4.58; N, 3.38%. Calcd for $C_{44}H_{38}N_2O_{11}S$: C, 65.82; H, 4.47; N, 3.49%.

1-(4′-Azido-2′,3′-di-O-benzoyl-4′-deoxy-6′-O-trityl-β-D-galactopyranosyl)uracil (**21**): A mixture of 1.20 g (1.5 mmol) of mesylate **20** and 390 mg of sodium azide (4 molar equiv.) in hexamethyl phosphoric triamide (50 ml) was heated at 90 °C for 24 days, followed by evaporation to dryness *in vacuo* (1 Torr). The sirup was dissolved in ethyl acetate, which was repeatedly washed with water and dried over Na_2SO_4. Removal of the solvent, and purification of the sirup by chromatography on a silica gel column (2×20 cm) with chloroform. The residue obtained on evaporation to dryness of the appropriate eluate, crystallized on trituration with ethanol. Recrystallization from the same solvent yielded 0.88 g (78%) of **21** as colorless prisms; mp 226—227 °C; $[\alpha]_D^{25}$ −37° (*c* 1,

$CHCl_3$).

Found: C, 68.92; H, 4.75; N, 9.52%. Calcd for $C_{43}H_{35}N_5O_8$: C, 68.88; H, 4.71; N, 9.34%.

1-(4'-Azido-2',3',6'-tri-O-acetyl-4'-deoxy-β-D-galactopyranosyl)-uracil (23): To azidogalactoside **21** (750 mg, 1 mmol) in methanol (70 ml) was added 0.5 ml of 4% methanolic sodium methoxide, followed by storage in a refrigerator (5 °C) for 2 days. After neutralization with acetic acid, the mixture was taken to dryness *in vacuo* and the residual sirup was heated in 30 ml of 80% acetic acid for 1 hr (80 °C). Evaporation to dryness *in vacuo*, followed by several reevaporations from ethanol gave a sirup, which upon solution in water was extracted twice with ether. The aqueous phase was evaporated to dryness and the residual **22**, resisting crystallization, was refluxed in acetic anhydride (20 ml) containing potassium acetate (200 mg) for 2 hr. The dark solution was poured in water followed by several extractions with 1:1 chloroform–ethyl acetate. The combined extracts, after drying over Na_2SO_4, were taken to dryness and the solid mass remaining was recrystallized from ethanol, involving charcoal treatment: 285 mg (68%) of **23** as colorless crystals of mp 225—226 °C; $[\alpha]_D^{25}$ −40° (*c* 0.5, dimethylformamide), IR (KBr) cm^{-1} 2154; N_3; NMR (DMSO-d_6) τ −1.73 (broad s, 1, NH) 2.51 (d, 1, $J_{5,6}$=8.5 Hz, H-6), 4.04 (d, 1, $J_{1',2'}$=9.0 Hz, H-1'), 4.29 (d, 1, $J_{5,6}$=8.5 Hz, H-5), 4.36 (dd, 1, J=3 and 9 Hz, H-3'), 4.79 (t, 1, J=9 Hz, H-2'), 7.93, 7.97, and 8.06 (three 3H-s, acetyl resonances).

Found: C, 44.98; H, 4.55; N, 16.41%. Calcd for $C_{16}H_{19}N_5O_9$: C, 45.18; H, 4.50; N, 16.47%.

1-(4'-Amino-4'-deoxy-β-D-galactopyranosyl)uracil (2): To blocked azidogalactosyl-uracil **21** (800 mg, 1.1 mmol) in methanol (80 ml) was added 2 ml of N sodium methoxide/methanol. After being stood at 5 °C for 2 days, the mixture was neutralized with acetic acid followed by evaporation to dryness. After treatment with 80% acetic acid (30 ml) for 1 hr at 80 °C, to effect complete detrytilation, the mixture was evaporated to a sirup, which upon solution in water was extracted twice with ether for removal of methyl benzoate and tritanol. The aqueous layer was taken to dryness, repeatedly reevaporated from ethanol to yield a viscous sirup of **22**, not amenable to crystallization. It was dissolved in 1:1 methanol–water (50 ml) and added to a prehydrogenated suspension of Pd/C in water (200 mg in 20 ml). After 2 hr the hydrogen uptake was complete (tlc in C), the catalyst was filtered off and the filtrate taken to dryness. Solving the residue in warm ethanol (70—80 ml), removal of some insoluble material, and concentration to a volume of about 30 ml afforded after longer standing (1—2 day) 94 mg (67%) of **2** as an amorphous, hygroscopic, ninhydrin-positive product; another 25 mg was isolated by concentration of the mother liquor; mp 155—158 °C, $[\alpha]_D^{23}$ +45° (*c* 0.2, MeOH).

Found: C, 43.73; H, 5.70; N, 15.12. Calcd for $C_{10}H_{15}N_3O_6$: C, 43.96; H, 5.53; N, 15.38.

1-(4'-Acetamido-2',3',6'-tri-O-acetyl-4'-deoxy-β-D-galactopyranosyl)uracil (24): A solution of 200 mg of azidotriacetate **23** in 50 ml of methanol saturated with ammonia was stored in a refrigerator (5 °C) overnight, followed by evaporation to dryness and hydrogenation of the residue in water (50 ml) in the presence of Raney-Nickel T4 catalyst[25] (1 ml). After 2 hr, tlc (C) showing the absence of starting material, the catalyst was removed by filtration and the filtrate was evaporated to dryness *in vacuo*. *N*-Acetylation of the sirupous residue with acetic anhydride (0.5 ml) in 20 ml of methanol (5 hr, 25 °C) and evaporation to dryness with subsequent reevaporations from methanol afforded a sirup, pure by tlc (C), yet resistant to crystallization from the usual solvents.[26] Treatment with 1:1 pyridine–acetic anhydride (20 ml) for 12 hr at ambient temperature, removal of solvents *in vacuo* (finally 0.1 mm), yielded a sirup, which was dissolved in ethyl acetate and extracted with water (3×10 ml). The aqueous extracts were washed with ethyl acetate (2×10 ml) and the combined ethyl acetate solutions were evaporated to dryness. The remaining residue was applied to a silica gel column (2×20 cm) and first eluted with chloroform for removal of impurities, subsequently with ethyl acetate to yield the product. Evaporation of the eluate gave a sirup which crystallized on dissolution in little methanol and addition of benzene: 124 mg (59%) of crystals, pure by tlc (C); mp 165—168 °C after sintering from 145 °C on; $[\alpha]_D^{23}$ +14° (*c* 1, CH_3OH); NMR (DMSO-d_6) τ −1.36 (s, 1, uracil-NH), 1.90 and 4.22 (two d, 1, $J_{5,6}$=8.5 Hz, H-6 and H-5), 1.92 (d, 1, $J_{4',NH}$=9 Hz, C-4'-NH), 4.06 and 4.67 (two m, 1 and 2, ABX system for H-1' and H-2'/H-3'), 5.5 (m, 2, H-4' and H-5'), 6.00 (m, 2, 6'-CH_2); acetyl resonances *cf.* Table 1.

Found: C, 48.89; H, 5.18; N, 9.40%. Calcd for $C_{18}H_{23}N_3O_{10}$: C, 48.98; H, 5.25; N, 9.52%.

Conformational Analysis About N-N Bond by NMR Spectroscopy: *N'*-Sulphonyl Derivatives of *N*-Aminoimides of Anthracene-Citraconic Anhydride and Naphthalene-Maleic Anhydride Adducts

S. M. VERMA, O. SUBBA RAO, and K. O. P. SINHA
Department of Chemistry, Banaras Hindu University, Varanasi-221005, India
(Received February 4, 1974)

A series of *N',N'*-disulphonyl and *N'*-sulphonyl-*N'*-acetyl derivatives of *N*-amino-9,10-dihydroanthracene-9,10-*endo*-α-methyl-α,β-succinimide and *N*-amino-1,2,3,4-tetrahydro-1,4-etheno/ethano-naphthalene-2,3-*exo*/*endo*-dicarboximides with a benzo ring in the cage-moiety were prepared and their NMR spectra were studied. Shielding constants of the substituents provide evidence for the non-eclipsed conformations of the *N'*-substituents with the ring carbonyls. The preferred conformations of *N'*-sulphonyl-*N'*-acetyl derivatives are explained on steric grounds. In *N'*-tosyl-*N'*-acetyl derivatives the tosyl group takes up a fixed conformation about *N'*-SO_2 bond in which the aryl part of the tosyl group projects away from the cage-moiety.

Preferred conformations about N–N bond in systems of type I have been reported with the help of a cage-moiety which does not possess symmetry about the plane of the succinimidyl ring.[1-4] Nonplanar conformations about the N–N' bond in *N',N'*-diacetyl-*N*-amino-1,2,3,4-tetrahydro-1,4-etheno/ethano-naphthalene-2,3-*endo*/*exo*-dicarboximides have been used to assign *endo*/*exo*-configurations to the Diels-Alder adducts.[5] A study has been made of the steric and electronic effects of a sulphonyl substituent at the *exo*-cyclic nitrogen of the *N*-aminocamphorimide[6] leading to the synthesis and conformational study of a series of *N'*-sulphonyl derivatives of *N*-amino-9,10-dihydroanthracene-9,10-*endo*-α-methyl-α,β-succinimide (II) and *N*-amino-1,2,3,4-tetrahydro-1,4-ethano/etheno-naphthalene-2,3-*endo*/*exo*-dicarboximides (III and IV) with a cage benzo ring.

Torsional barriers to rotation about N–N bond ($\Delta G^{\ddagger}$ of the order of 23 kcal/mol) have been reported in *N',N'*-dimesyl and *N'*-mesyl-*N'*-acetyl-*N*-aminocamphorimides.[6] The NMR spectra of the compounds at 45 °C gave further support for the non-planar ground states in *N',N'*-disulphonyl and *N'*-sulphonyl-*N'*-acetyl-*N*-aminoimide systems. Variable temperature NMR spectra have provided evidence for some slow conformational changes in the molecule in solution. The general spectral pattern in nitrobenzene was similar to that observed in $CDCl_3$.

Results and Discussion

N',N'-Dimesyl Compounds (IIb and IIIc). The NMR spectra of compounds IIb and IIIc (Fig. 1) in $CDCl_3$ are similar and show two sharp singlets of equal

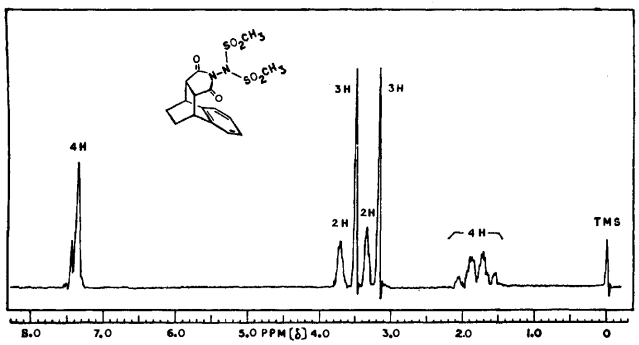

Fig. 1. 60 MHz NMR spectrum of *N',N'*-dimesyl-*N*-amino-1,2,3,4-tetrahydro-1,4-ethanonaphthalene-2,3-*endo*-dicarboximide (IIIc) in $CDCl_3$ at 45 °C.

a) The NMR spectra of all the compounds (Tables 1 and 2) were recorded in $CDCl_3$ except IIa which was recorded in pyridine and IIIb, IIIe, and IVb which were recorded in nitrobenzene. The total number of protons and the multiplicity of the bands are indicated in brackets. In case of multiplicity due to slow rotation, the ratio of the intensity of downfield to upfield and the separation in Hz are indicated. s=singlet, t=triplet, q=quartet, m=multiplet, ds=double singlet, nm=narrow multiplet, bs=broad singlet. TMS was used as internal reference.

a) Refer to footnote, Table 1.

intensity for the two mesyl groups with an internal chemical shift of 20 Hz. The other cage proton resonances are given in Tables 1 and 2. The spectra are temperature dependent and the two mesyl proton signals move closer as the temperature is raised.

The structure of the *exo*-cyclic trivalent nitrogen atom is assumed to be nearly planar, since the sulphonyl group is as efficient as a carbonyl group for the delocalization of the nitrogen lone-pair electrons.[7] The possibility of slow rotation about N′–SO_2 bond is discarded since the free rotation about this bond is possible with effective and continuous $p\pi$-$d\pi$ delocalization.[7,8] Hence, slow rotation about N–N′ bond could be the only possible explanation for the observed multiplicity.

Non-planar conformations about the N-N′ bond similar to tetraacyl hydrazines, could explain the large $\Delta\nu$=20 Hz between the two mesyl signals as compared to the $\Delta\nu$=5.7 Hz of *N*′,*N*′-dimesyl-*N*-aminocamphorimide.[6] In the proposed conformation (V and Fig. 1) the mesyl group *syn* to the cage-moiety is shielded by the cage benzo ring, whereas the mesyl group *anti* to the cage-moiety appears at the normal position. Non-bonding repulsions between the ring carbonyls and the sulphonyl groups and also some steric factors could make the N–N′ bond torsional barrier sufficiently high.

N′,N′-*Ditosyl Compounds (IIe, IIIf, and IVd).* The *N*′,*N*′-ditosyl compounds show, in their NMR spectra, a slightly broad singlet of 6H intensity near δ 2.50 for the two tosyl-methyl protons, whereas the monotosyl compounds show a sharp singlet (width at half height 1.5 Hz) for its tosyl methyl protons (Tables 1 and 2).

* The prefixes *endo* and *exo* are used in the sense that substituents on the same side of the bicyclo[2.2.2]octene ring as the benzene ring are *endo*, those on the other side are *exo*.

The broadness of the singlet (width at half height 3 Hz) observed for the two tosyl-methyl groups may be due to hindered rotation about the N–N′ bond. A preferred conformation about the N–N′ bond in these compounds could give two signals for the two tosyl-methyl groups as in *N′,N′*-dimesyl compounds IIb and IIIc, but the appearance of a broad singlet indicates that the two tosyl-methyl protons lie away from the effective magnetic zone of the cage-moiety.

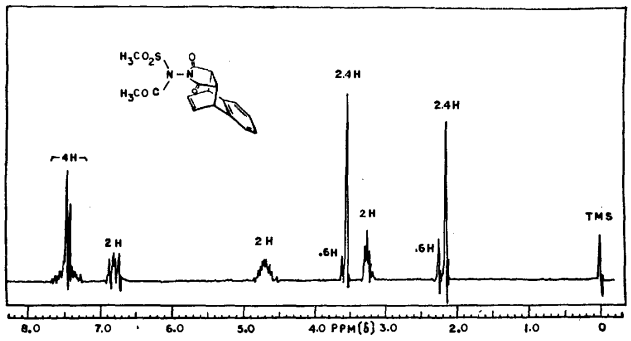

Fig. 2. 60 MHz NMR spectrum of N′-mesyl-N′-acetyl-N-amino-1,2,3,4-tetrahydro-1,4-ethylenonaphthalene-2,3-*exo*-dicarboximide (IVc) in $CDCl_3$ at 45 °C.

N′-Suphonyl-N′-acetyl Derivatives (IIc, IIf, IIId, IIIg, and IVc). The NMR spectrum of *N′*-mesyl-*N′*-acetyl compound (IVc) in $CDCl_3$ (Fig. 2) shows along with other normal resonances (Table 2), two singlets for mesyl protons and two singlets for acetyl protons.

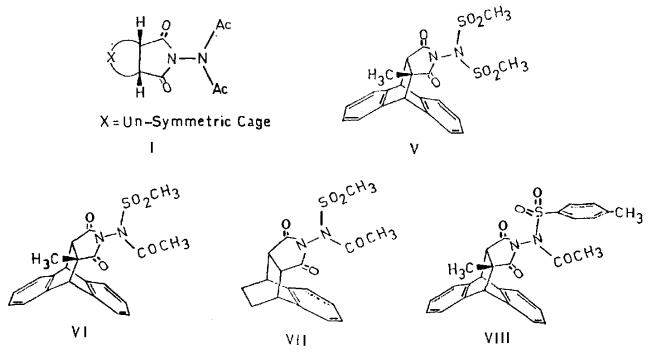
The splitting of the mesyl and acetyl proton signals in the spectrum indicates the possibility of two conformations due to the restricted rotation about the N–N′ bond. In the two different conformations the mesyl protons experience different magnetic environments and therefore, appear as a pair of singlets. The conformer in which the acetyl group lies *syn* to the cage-moiety, while the bulkier mesyl group lies *anti*, is predominant (Fig. 2).

Compounds IIc and IIId in $CDCl_3$ exhibit different patterns in their NMR spectra. Each compound shows a singlet of 3H intensity for the mesyl protons at a normal position ($\delta \approx 3.43$) and another singlet of 3H intensity for the acetyl protons at a shielded position ($\delta \approx 0.80$). As in the case of compound IVc, restricted rotation about N–N′ bond could also be expected in IIc and IIId. Appearance of the acetyl signal with 3H population at the shielded position indicates that the conformation (VI and VII) in which the acetyl group lies *syn* to the cage-moiety is preferred.

The NMR spectrum of each of the *N′*-tosyl-*N′*-acetyl compounds IIf and IIIg in $CDCl_3$ shows two sharp singlets, one for the tosyl-methyl protons and the other for the acetyl protons, along with other proton resonances (Tables 1 and 2).

The spectral features of these compounds are very much similar to *N′*-mesyl-*N′*-acetyl analogues IIc and IIId. They also take up preferred conformations of types VI and VII in which the less bulkier acetyl group is *syn* to the cage-benzo ring.

The tosyl group does not have any shielding effect on the cage-moiety protons. Shielding of the cage protons by the *N′*-benzoyl group has been reported in the case of *N′*-benzoyl-*N′*-acetyl derivatives of *N*-amino-[2.2.1]bicycloheptene-2,3-*endo*-dicarboximide[2] and *N*-aminocamphorimide.[6] This observation indicates that the aryl part of the tosyl group projects away from the cage-moiety (VIII).



Experimental

NMR spectra were recorded on a Varian A-60D spectrometer equipped with a variable temperature controller (Model No. V-6040). IR spectra were recorded for Nujol mulls on a Perkin-Elmer-257 spectrophotometer. NMR spectral data are given in Tables 1 and 2, and IR spectral data, melting points and elemental analyses of all the compounds in Table 3.

1,2,3,4-Tetrahydro-1,4-ethenonaphthalene-2,3-endo/exo-*dicasboxylic anhydrides* were obtained by the method of Takeda *et al.*[9] The *endo*-isomer on refluxing with hydrazine hydrate[10] (4 mol) in ethanol medium in the presence of animal charcoal gave the reduced product, 1,2,3,4-tetrahydro-1,4-ethanonaphthalene-2,3-*endo*-dicarboximide (IIIa). The *exo*-isomer was reacted with equimolecular amount of hydrazine hydrate in ethanol medium at room temperature to give the *N*-aminoimide (IVa). The two *N*-aminoimides were recrystallized from ethanol and gave benzal derivatives with benzaldehyde which showed a characteristic one proton singlet near δ 9.0.

*N′-Monomesyl and N′,N′-Dimesyl Derivatives of N-Amino-9,10-dihydroanthracene-9,10-*endo-*α-methyl-α,β-succinimide*[4] *and N-Amino-1,2,3,4-tetrahydro-1,4-ethanonaphthalene-2,3-*endo-*dicarboximide IIIa (IIa, IIb, IIIb, and IIIc).* The compounds were prepared by heating the corresponding *N*-aminoimide with mesyl chloride (2 mol) in the presence of pyridine on a water bath for about 2 hr. The reaction mixture was then washed with water, filtered, dried and recrystallized from a mixture of ethanol and ethyl acetate. The product thus obtained was a mixture of both *N′*-monomesyl and *N′,N′*-dimesyl derivatives. *N′,N′*-Dimesyl derivatives were soluble in cold chloroform and were separated from the mixture.

N′-Monomesyl Derivative (IVb). This was prepared by heating *N*-amino-1,2,3,4-tetrahydro-1,4-ethenonaphthalene-2,3-*exo*-dicarboximide (1 mol) with mesyl chloride (2 mol) in the presence of a few drops of pyridine on a water bath for about 2 hr. The product was recrystallized from ethanol and was found to be exclusively a monomesyl derivative.

N′-Mesyl-N′-acetyl Derivatives (IIc, IIId and IVc). The compounds were prepared by heating the corresponding *N′*-monomesyl derivative with acetic anhydride in the presence of pyridine on a water bath for 2—3 hr. The reaction mixture was then treated with water, filtered, dried and recrystallized from ethanol.

N′-Monotosyl-N-aminoimides (IId and IIIe). The compounds were prepared by heating equimolar amounts of *N*-aminoimide and tosyl chloride in the presence of pyridine on a water bath for about 2—3 hr and were recrystallized

Dielectric Studies of *ortho*- and *para*-Bromoanisoles and β-Bromophenetole in the Liquid State

Alpana GHATAK, Arati DAS, and Subir Kr. ROY

Optics Department, Indian Association for the Cultivation of Science, Calcutta 32, India

(Received February 8, 1974)

Complex dielectric permittivities in *ortho*- and *para*-bromoanisoles and β-bromophenetole in the liquid state have been measured in 1.6, 3.17, and 3.49 cm microwave regions at different temperatures. The dielectric data were analysed in terms of molecular and intramolecular relaxation times. The values of methoxy group relaxation times and its contribution to total polarization obtained in the liquid bromoanisoles have been compared to the corresponding values in dilute solutions reported in literatures. Activation energy for dielectric relaxation and viscous flow in all the cases have also been obtained in all the liquids.

From studies of dielectric relaxation in anisole and dimethoxy benzenes in the liquid state Vaughan *et al.*[1] reported that the relaxation time of methoxy group rotation τ_2 and its contribution C_2 to total polarization are about 3 ps at 20 °C and 0.2 respectively excepting in the case of *o*-dimethoxy benzene where $C_2=0.7$. Garg and Smyth[2] extended the investigation in liquid anisole at still higher frequency region and reported the similar values of τ_2 and C_2. These values of τ_2 and C_2 in anisole and *p*-dimethoxy benzene in dilute solutions reported by different workers[3-5] are found to be 7—9 ps at 20 °C and 0.7 respectively, while in *p*-bromoanisole in dilute solution though the τ_2 value is 9 ps at 20 °C, the C_2 is only 0.2 as reported by Farmer and Walker.[4] So it appears that the methoxy group relaxation time and its contribution C_2 in anisole or dimethoxy benzene in dilute solution are larger than their values in pure liquids. Garg and Smyth[2] suggested that the reduction in the contribution of C_2 of the methoxy group rotation from its value in solution to the liquid state might be due to some restraint in the C–O bond as a result the methoxy group rotation in anisole is not completely free but hindered.

It will be interesting to study how the methoxy group rotation τ_2 and its contribution C_2 in haloanisoles in the liquid state, compare with the corresponding values in dilute solutions published in literatures. The present paper reports the results of investigation on dielectric relaxation of *o*-bromo and *p*-bromoanisoles and β-bromophenetole in the liquid state together with a discussion of the results.

Experimental

Pure samples of *o*-bromoanisole, *p*-bromoanisole and β-bromophenetole were dried with fused calcium chloride and then subjected to fractional distillation. The proper fraction was then distilled under reduced pressure before use in the investigation. The experimental arrangement for measurement of dielectric permittivity ε', dielectric loss ε'', static dielectric constant ε_0, refractive index n_D, viscosity η, and density d at different temperatures were the same as described in an earlier paper.[6] The accuracy in the measurements of ε' and ε'' were about 2 and 5% respectively.

Results

The experimentally obtained values of ε' and ε'' at different wave lengths and at different temperatures together with ε_0 at 1 MHz at different temperatures are given in Table 1 and the viscosity η, density d and refractive index n_D at different temperatures are given in Table 2. Cole-Cole arc plots (some shown in Fig. 1) were drawn with the dielectric data. The high frequency dielectric constant ε_∞ and the distribution parameter α were obtained as usual from the arc plots. The large values of distribution parameter and also the nonlinear plots of ε' *vs.* $\varepsilon''\omega$ indicated the presence of more than one relaxation mechanism in all the liquids. The dielectric data were therefore analysed in terms of two relaxation processes by a straightforward analytical method developed by Kastha[7] and applied successfully by others.[8-10] The values of relaxation times for

molecular orientation τ_1 and group rotation τ_2 and weight factor C_1 for molecular orientation are included in Table 3. The activation energies for dielectric relaxation by molecular orientation $\Delta H\tau_1$ and group rotation $\Delta H\tau_2$ were obtained from the slopes of the straight line plots of log $T\tau$ *vs.* $1/T$ and the activation energy for viscous flow $\Delta H\eta$ were obtained from the graphs of log η *vs.* $1/T$. The values of $\Delta H\tau_1$, $\Delta H\tau_2$, and $\Delta H\eta$ are included in Table 3.

Discussion

It can be seen from Table 3 that the molecular and intramolecular relaxation times as also the distribution parameter α in all the liquids decrease with increase of temperature as is generally observed.

The value of molecular relaxation time τ_1=49 ps at 30 °C in *o*-bromoanisole appears much larger than the value of τ_1=33.7 ps at the same temperature in *p*-bromoanisole. But the reduced relaxation time τ_1/η of the two molecules are of the same order (≈23 ps) of magnitude, showing thereby that the two isomeric molecules are of the same size.

o-Bromoanisole. A comparison of molecular relaxation time τ_1 of *o*-bromoanisole and *o*-dimethoxy benzene both in the liquid state, shows that the molecular relaxation time $\tau_1 \simeq$49 ps at 30 °C in the former molecule obtained in the present investigation is almost the same as that of 48.5 ps at 25 °C in the latter reported by Vaughan *et al.*[1] This is consistent with the sizes of the two molecules.

The contribution of methoxy group rotation C_2 in *o*-bromoanisole in the liquid state is only about 0.37 as against the value 0.7 in the case of *o*-dimethoxy benzene in the liquid state. The former molecule having C–Br bond moment of about 1.55 D as against O-CH_3 bond moment of ≈1.3 D in the latter molecule, has total moment larger than the latter molecule. So the ratio of group moment component to the total moment which is a measure of C_2 is expected to be larger in the latter molecule.

The contribution of the methoxy group rotation C_2 in *o*-bromoanisole can be calculated from the consideration of total moment and methoxy group moment of the molecule. The O–CH_3 bond has a moment of about 1.3 D making an angle 55° with the direction of C–O bond in the benzene ring. The component of the O-CH_3 bond moment perpendicular to the direction of C–O bond, which is responsible for methoxy group rotation is

$$\mu_2 = 1.3\text{D} \times \sin 55° = 1.06\text{D}$$

and the total moment of the molecule μ_1 can be obtained by the vector sum of C–Br bond moment and component of O–CH_3 bond moment along the C–O axis and is given by

$$\begin{aligned}\mu_1^2 &= (1.55)^2 + (1.3\cos 55°)^2 \\ &\quad + 2 \times 1.55 \times 1.3 \cos 55° \cdot \cos 60° \\ &= 3.92 \\ \mu_1 &= 1.99\text{D}\end{aligned}$$

This value of 1.99 D agrees fairly well with the experimentally obtained value of 2.15 D.

Now $$C_2 = \left(\frac{\mu_2}{\mu_1}\right)^2 = \left(\frac{1.06}{1.99}\right)^2 = 0.30$$

So theoretically calculated value of C_2=0.30 compares reasonably well with the experimentally obtained value of C_2=0.37.

p-*Bromoanisole.* The value of molecular relaxation time τ_1=33.7 ps and group relaxation time τ_2=7.3 ps at 30 °C as also the contribution from methoxy group rotation C_2=0.15 obtained in the liquid *p*-bromoanisole, agree fairly well with the values of τ_1=31 ps τ_2=7 ps at 25 °C and C_2=0.2 in *p*-bromoanisole in dilute solution of *p*-xylene reported by Farmer and Walker.[4] The similarity in dielectric behaviour of *p*-bromoanisole in pure liquid and dilute solution suggests that the dipole-dipole interaction is not very effective in the liquid state of the molecule.

Comparison of the Relaxation Time of Methoxy Group Rotation in Pure Liquid and Dilute Solution. The relaxation time of methoxy group rotation in *o*-bromo- and *p*-bromoanisole in the liquid state obtained in the present investigation are of the same order of methoxy group rotation (7—9) ps reported in anisole and substituted anisoles in dilute solutions reported by Farmer and Walker[4] and Klages and Krauss[5] but larger than the value of about 3 ps of the methoxy group rotation in anisole and dimethoxy benzenes in liquid state reported by Vaughan *et al.*[1] and Garg and Smyth.[2] So it appears that the methoxy group rotation in molecules containing only methoxy group as substituent is less hindered in the liquid state than in anisole in dilute solution or in haloanisoles either in the liquid state or in solutions. This is supported by the fact that the activation energy of methoxy group rotation in anisole in liquid state as reported by Garg and Smyth[2] is only 1.5 kcal/mol which is much smaller than the value of 2.6 kcal/mol for methoxy group rotation in anisole in dilute solution in *p*-xylene calculated from the data of Farmer and Walker[4] and also from the values of 2.2—2.6 kcal/mol (Table 3) for methoxy group rotation in the bromo-anisoles in liquid state obtained in the present investigation.

The larger value of the methoxy group rotation of anisole in benzene or *p*-xylene solution than in the pure liquid may be due to the formation of a weak bond between the π-electron of the solvent molecule and hydrogen atom of the methoxy group. Similar bond formation in 1,2-dichloroethane and benzene has been reported by Chitoku and Higasi.[11]

β-Bromophenetole. The reduced molecular relaxation time τ_1/η of β-bromophenetole at 40 °C is about 14 ps which is smaller than the value τ_1/η=23 ps at 30 °C in bromoanisoles. Thus the β-bromophenetole molecule appears to be a little bit smaller than the molecules of bromoanisoles.

The group relaxation time τ_2=9.8 ps at 40 °C in this case is larger than the methoxy group rotation in anisole in dilute solution or haloanisoles in liquid state. This value of τ_2=9.8 ps at 40 °C is also larger than the relaxation time of ethoxy group rotation τ_2=4 ps at 40 °C in the liquid state reported by Bhattacharyya *et al.*[8] which is consistent with their sizes.

The contribution of group rotation C_2 here is only −0.32 as against the value of C_2=0.63 in ethoxy group rotation in phenetole. The substitution of Br-atom in the ethoxy group might increase hindrance and thus reduces the value of C_2 in the present case.

Activation Energy. The activation energy of dielectric relaxation by molecular orientation in all the liquids are of the same order (2.1 kcal/mol) and each is smaller than the corresponding activation energy for vicous flow as usually observed.

The activation energy for molecular relaxation $\Delta H\tau_1$=2.1 kcal/mol in *p*-bromoanisole in liquid state obtained in the present investigation is about the same as the value of $\Delta H\tau_1$=2.07 kcal/mol obtained for *p*-bromoanisole in dilute solution, calculated from the data of Farmer and Walker.[4] This shows that the dipolar interaction are almost the same in the liquid *p*-bromoanisole and its solution in *p*-xylene as mentioned earlier.

The activation energy of group rotation in the liquid ($\Delta H\tau_2$=2.2 kcal/mol) and in solution ($\Delta H\tau_2$=1.9 kcal/mol) calculated from the data of Farmer and Walker[4] are also compatible.

It can be seen from Table 2 that the values of n_D^2 in all the liquids are less than the respective values of ε_∞. This indicates the presence of a high frequency absorption region as suggested by Poley.[12] This 'Poley absorption' has been generally explained as due to torsional molecular librations in potential minima of fluctuating interaction field of the neighbouring molecules.[13]

The authors wish to express their sincere thanks to Dr. S. B. Roy for his guidance and to Professor G. S. Kastha for his keen interest.

Dye Sensitized Photo-oxidation of Diphenylamine

W. R. BANSAL, S. PURI, and K. S. SIDHU*
Physical Chemistry Laboratories, Punjabi University, Patiala, India

(Received October 22, 1973)

Synopsis. Evidence is presented to show that excited O_2 ($1\sum_g^+$, $1\Delta_g$) is an intermediate in the dye (methylene blue, rose bengal, eosin) sensitized oxidation of diphenylamine which yeilds *N*-phenyl-*p*-benzoquinonimine. The relative rates in different solvents are reported and a mechanism is suggested.

Evidence has been presented for the non-participation of O_2 ($^1\sum_g^+$ or $^1\Delta_g$) in the ketone or dye sensitized oxidation of a number of aliphatic amines and *N*-substituted anilines.[1-3] In the benzophenone sensitization of diphenylamine (DPA) diphenyl nitroxide formed through triplet DPA in the presence of oxygen is reported[4] while in the absence of oxygen 4-(*N*-phenylamino)-phenyl-diphenylmethanol has been identified.[5] Sensitization of DPA which is apparently quite complex[2] thus has appeared to fall in line with general mechanistic features of other similar amines. We report here the isolation of a unique product in its oxidation sensitized by methylene blue, rose bengal and eosin (all known for initiating reactions through their triplet states[6]) along with other kinetic features suggesting the participation of first excited singlet state of oxygen.

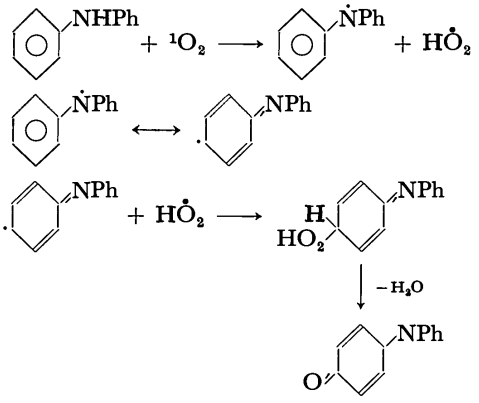
Experimental

All reagents were BDH grade and were purified by repeated crystallization and fractional distillation. The dyes had their maxima in spectrograde methanol in the visible at; methylene blue 645 nm; rose bengal 550 nm, eosin 515 nm. Photolysis assembly consisted of a white light bulb, a 320 nm cut off glass filter and a pyrex cell (50 mm dia × 10 mm) maintained at 26±2 °C in an air thermostat. Oxygen concentrations were varied by maintaining different partial pressures of it in the cell. Mixtures of dry nitrogen and oxygen at a total pressure of one atmosphere were used for the purpose. The reaction mixture after evaporation of the solvent was fractionated by column chromatography over alumina with benzene as eluent. The brown product after crystallization from petroleum ether was identified as *N*-phenyl-*p*-benzoquinonimine (PBQ) by mp 101—102 °C (reported 101.5 °C); identity of its IR in KBr with the reported spectrum and understandable NMR in CS_2.[7] PBQ on hydrolysis with 10^{-2} M HCl at 65 °C gave aniline and *p*-quinone which were identified by UV spectra after chromatographic separation. The product yields in these runs were kept between 2.4 and 3.0% in order to avoid any secondary products through secondary photolysis. In the kinetic runs the monitoring was done at 448 nm where PBQ has a maximum in alcohols with blank as reference on a Hilger and Watt spectrophotmeter.

Hydrogen peroxide was shown to have no reaction with DPA in alcohols at the concentrations examined. To solutions of hydrogen peroxide (0.3 M) in excess and DPA (0.05 M) in alcohol-water mixtures in the ratio 5: 1, varying amounts of NaOCl (0.2 M) were added dropwise from the burette. After the instantaneous reaction at 26 °C the reaction mixture was double diluted with water and extracted with ether. The ether layer was evaporated and column chromatographed. The yields were kept below 8.0% and no attempt was made to carry the reaction to completion because of the observed further oxidation of PBQ at larger concentrations. NaOCl alone gave a different mixture of products.

Results and Discussion

In the photolysis of 5.0×10^{-4} to 1.0×10^{-2} M of DPA with 3.0×10^{-5} to 7.5×10^{-4} M of the dye, time study and UV/visible spectra demonstrated PBQ to be a primary product. Unlike previous studies increase in oxygen concentration increased the extent of reaction.[3c] The relative reaction rates in different solvents were CH_3OH=1.00, C_2H_5OH=0.78, *iso*-C_3H_7OH=0.55, *n*-C_4H_9OH=0.69, CH_3CN=0.78, CH_3OH–H_2O(9: 1)=1.68, CH_3OH–H_2O(8: 2)=2.76, CH_3OH–H_2O(7: 3)=3.95. Viscosity effect decreasing the rates is apparent in alcohols. In isopropanol an additional decrease appears because of the availability of easily abstractable tertiary hydrogen. The effect of water cannot be a pure dielectric effect in view of the rate in acetonitrile. The life time of singlet oxygen is also less in water.[8] It appears, therefore, that water is stabilizing some of the intermediate radical species. A very likely course for the reaction is;



There exist the possibilities of (a) intial hydrogen abstraction from N–H by the triplet dye and (b) direct attack of singlet O_2 at the *para* position as proposed in the photo-oxidation of phenols.[9,10] However, both of these require a hydrogen abstraction by the inter-

* To whom correspondence be addressed.

mediate peroxy radical mechanisms and in view of the low concentration of the substrate as compared to the solvent and bond strengths of N–H and *tert*-C–H (in isopropanol)[11] the rate in isopropanol should be higher. On the contrary the rate is higher in methanol. Also H_2O_2 is a product which militates against these possibilities.

A specific search for tetraphenyl hydrazine did not detect it. This is evidence of the greater stability of the conjugated structure of the radical. The reaction sequence is helped by the resonance stabilization of the radical as expected.

To further substantiate the participation of singlet oxygen, these species were generated chemically by the well-known reaction of $NaOCl+H_2O_2$.[12,13] In alcohols with similar concentrations of DPA, PBQ was formed with parallel kinetic features (*cf.* effect of solvents).

It is thus established that excited $O_2(^1\Sigma_g^+, {}^1\Delta_g)$ is an intermediate in the dye sensitized oxidation of diphenyl amine which proceeds through hydrogen abstraction by $^1O_2$.

We thank UGC and CSIR for the award of fellowships (to W.R.B. and S.P.) and financial assistance. We also thank Regional Research Laboratory, Hyderabad for the NMR spectra.

The Crystal and Molecular Structure of Dimeric [3-(Salicylideneamino)-1-propanolato(2−)]copper(II)

Peter J. NASSIFF,* E. R. BOYKO, and Loren D. THOMPSON

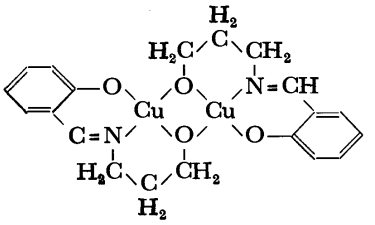
Contribution from the Department of Chemistry, Providence College, Providence, R. I., 02908 U.S.A.

(Received May 4, 1974)

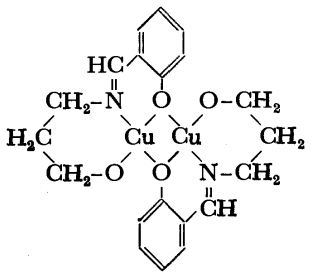
Synopsis. The crystal structure of dimeric[3-(salicylideneamino)-1-propanolato(2−)]copper(II) has been determined by X-ray diffraction. The two copper atoms are square planar with a separation of 3.021(4) Å and are bridged with aliphatic oxygens. The unusually low antiferromagnetism, explained by superexchange, has been correlated with the Cu-O-Cu angles of similar complexes.

Tridentate Schiff bases which contain an alcoholic side chain occasionally form 1 : 1 copper(II)-ligand complexes which have unusually low antiferromagnetic moments.[1,2] At room temperature the moments for these compounds lie between 0.3 and 0.7 BM, compared to the more usual values which are in the range 1.1 to 1.7 BM. The title compound, abbreviated $[Cu(3\text{-PrO}\cdot Sal)]_2$, is of this type; molecular weight measurements indicate a dimer.[1]

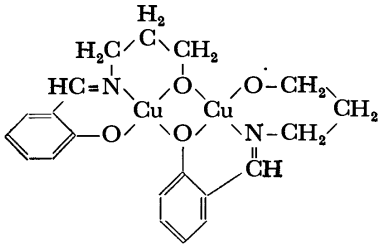
Three possible dimeric structures have been discussed in the literature.[3] These involve bridging with the aliphatic oxygens, I, bridging with the phenolic oxygens, II, or a combination of both, III. Infrared studies strongly favor structure I.[3] It is clear that a crystal structure determination is desirable, and this is the purpose of the present work.



I



II



III

Experimental

Bis[3-(Salicylideneamino)-1-propanolato(1-)]copper(II) was converted into $[Cu(3\text{-PrO}\cdot Sal)]_2$ by refluxing in DMF for 5 hr (52% yield). Violet crystals were crystallized from DMF. Found: Cu, 26.51; C, 50.02; H, 4.70; N, 6.50%.[4] Calcd for $Cu(C_{10}H_{11}NO_2)$: Cu, 26.40; C, 49.89; H, 4.60; N, 5.81%.

The smaller crystals were plates having a predominant (100) face, and examination under polarized light showed that extensive twinning occurs. A crystal of dimensions $0.5\times0.5\times0.1$ mm in which a small amount of twinning could be seen around the edges was mounted for X-ray investigation.

Crystal data: $Cu_2C_{20}H_{22}N_2O_4$; Monoclinic, space group $P2_1/c$, $a=9.018(5)$,[5] $b=10.810(4)$, $c=10.233(5)$ Å, $\beta=106.62(9)°$, $D_m=1.667$, $D_x=1.673$, $Z=2$, $F(000)=984$. Absorption for Ni-Kα radiation, 37.0 cm^{-1}.

Using Ni-Kα radiation, multiple-film equi-inclination Weissenberg photographs were taken for the layers *h0l* to *h5l*. Because of the twinning problem, the same crystal was then used to obtain the *hk*0 and *hll* zones. The intensities were visually estimated, and no corrections for absorption or extinction effects were made. Standard treatment of the data produced 860 observed independent structure factors.

Structure Determination

Space group considerations require the dimer to have a center of symmetry which coincides with one in tke unit cell. A Patterson synthesis produced the approximate location of the copper atom, and an electron density map was computed employing the signs determined from its coordinates. An outstanding feature of the map was a large peak in a position which would correspond to a bridging oxygen. Assuming that this was a bridging oxygen, and that the dimer for the most part was expected to be planar, the electron density map for the plane determined by the copper and oxygen positions and the center of symmetry of the dimer was calculated. The observed regions of high electron

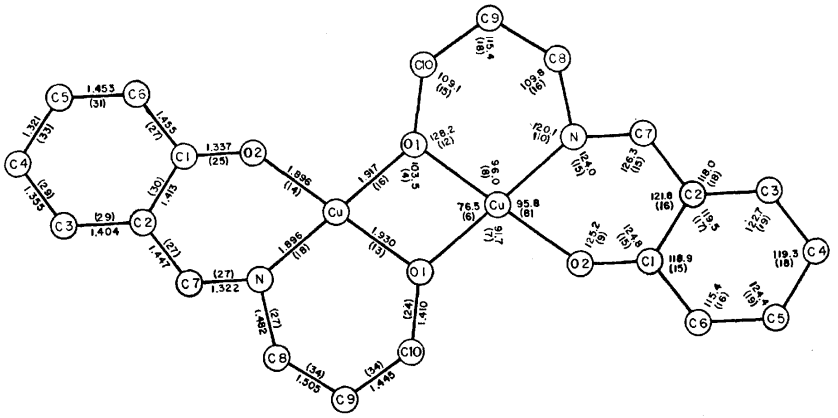

Fig. 1. Bond distances and bond angles of $[Cu(3\text{-}PrO\cdot Sal)]_2$.

density in this plane were interpreted on the basis of isomer I, and a full trial structure developed.

The structure was then refined by the block-diagonal least-squares technique with isotropic thermal parameters. After several cycles, 25 strong reflections with low Bragg angles had calculated structure factors well exceeding the observed values. These reflections were suspected of suffering from absorption or extinction effects and were removed from the refinement process which was then continued until convergence to an R value of 0.132. The R value for all observed structure factors was 0.136. An anisotropic treatment of the copper atom reduced R slightly and produced no significant shifts in the atomic coordinates. Consequently, the refinement process was considered complete. Table 1 lists the final atomic coordinates and thermal parameters.

Discussion

The bond distances and angles of the final structure are shown in Fig. 1; there are no short intermolecular contacts. The structure is that which has been proposed by Miners and Sinn on the basis of infrared studies.[3] The dimer may be considered to be approximately planar with the exception of C9 which is 0.72 Å out of the least-squared plane of the other atoms. A better description, however, is provided by the use of two planes which have a dihedral angle of 11°. The first plane is determined by the Cu, N, O1, C7, and C8 atoms and is restricted to go through the center of symmetry of the dimer at 0 0 1/2. The maximum deviation of the atoms used in the determination is 0.05 Å. Atoms C9 and C10 are out of this plane by 0.84 and 0.25 Å, respectively. The second plane is determined by atoms C1 through C6 and the phenolic oxygen, O2. The maximum deviation of those atoms from the plane is 0.02 Å. The two benzene rings are stepped with an interplanar distance of 0.50 Å.

Our results are compared in Table 2 with two previously reported copper(II) alkoxy-bridged dimer complexes with ligands prepared by the addition of acetylacetone to 2-amino-1-ethanol (EIA) and 3-amino-1-propanol (PIA).[6] It is seen that the Cu–Cu separations are similar.

The magnetic susceptibility of the series can be correlated with the Cu–O–Cu angle.[8] Relatively large Cu–Cu separations rule out direct interactions. Consequently the principal path for magnetic interaction is the mechanism of superexchange through the Cu–O–Cu bridge.[9] The values of the singlet-triplet energy level splitting, $2J$, may be calculated by using the Bleaney-Bowers equation for exchanged-coupled copper(II) dimers. With $g=2.10$ and $N\alpha=6\times10^{-5}$, the resulting values are listed in Table 2. The value of $2J$ for $[Cu(PIA)]_2$ is based only on the room temperature magnetic susceptibility. $[Cu(EIA)]_4$ is a tetramer and is considered magnetically normal. The values of $2J$ show the same trend as previously reported,[8] *i.e.*, an increasing negative $2J$ with increasing Cu–O–Cu bond angle.

Table 2. Magnetic and structural properties of alkoxy-bridged copper(II) dimers

Compound	Cu–Cu distance, Å	Cu–O–Cu angle	$2J$, cm^{-1}
$[Cu(EIA)]_4$[a]	3.006(8)	97.8(8)	0
$[Cu(3\text{-}PrO\cdot Sal)]_2$[b]	3.021(4)	103.5(4)	− 890[c]
$[Cu(PIA)]_2$[a]	3.026(6)	106.4(6)	−1100[d]

The Mechanism of the Reduction of Tosylhydrazones with B_2H_6 and with $NaBH_4$ in Aprotic Solvents

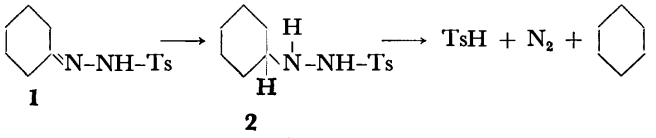
S. CACCHI, L. CAGLIOTI, and G. PAOLUCCI
Istituto Chimica Organica, Via Castro Laurenziano 9, Roma, Italy

(Received May 4, 1973)

Synopsis. Cyclohexanone tosylhydrazone was reduced with $NaBH_4$ and B_2H_6 in aprotic solvents; results indicate that the reduction affords cyclohexyl-tosylhydrazine or an equivalent organometallic adduct confirming the mechanism previously proposed by us in the case of $NaBH_4$ in protic solvents.

The reduction of tosylhydrazones of aldehydes and ketones with reducing hydrides such as B_2H_6, $LiAlH_4$ and $NaBH_4$[1] constitutes an efficient method for conversion of carbonyls to CH_2 under mild conditions. The reactions can be carried out in either protic ($NaBH_4$)[2,3] or aprotic solvents ($NaBH_4$, B_2H_6, and $LiAlH_4$).[2,4,5]

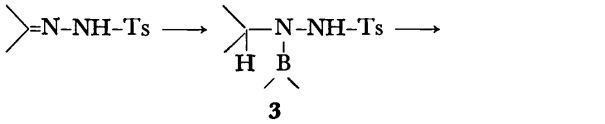
As far as the mechanism of the reaction is concerned, we have demonstrated[6] that in protic solvents the treatment of tosylhydrazones with $NaBH_4$ leads to tosylhydrazines followed by subsequent thermal decomposition to TsH, N_2 and Alkanes.



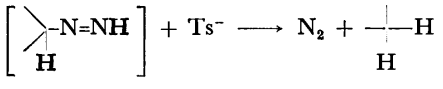
1 2

In aprotic solvents, it has been shown [4,8] that the reaction of tosylhydrazones with $LiAlH_4$ and B_2H_6 proceeds in two steps: reduction to an intermediate compound followed by decomposition of the intermediate.

The mode of action of $LiAlH_4$ and B_2H_6 towards C=N bonds,[9] and other considerations, induced us to postulate the formation of intermediary organometallic compounds, whose oxidation level is identical to that of a substituted tosylhydrazine. With B_2H_6 as reducing agent, this conclusion is well substantiated by the observation that no hydrogen is evolved during the first step of the reaction and that the intermediate compound contains all the theoretical nitrogen. The following mechanism[10] is proposed:



3



4

In order to complete our work, and to confirm our previous conclusions, this report presents results obtained upon reduction of cyclohexanone tosylhydrazone (**1**), with B_2H_6 and with $NaBH_4$ in aprotic solvents. Cyclohexanone tosylhydrazone (**1**) was chosen for study since the corresponding 1-cyclohexyl-2-tosylhydrazine (**2**) is well characterized and readily obtainable by reduction of **1** with $NaBH_4$ in protic solvents.[6]

From reduction of **1** with B_2H_6 in THF solution at room temperature, pure **2** in 55—60% yield was obtained.

These results substantiate the mechanism previously proposed for the reduction of tosylhydrazones with diborane: the reduction occurs at the C=N double bond to give an intermediate compound (**3**) which contains the fundamental skeleton of alkyltosylhydrazines.

Then, this intermediate decompose to alkanes *via* an unstable[7] alkyl diimide.

Compound **1** has been submitted to reduction with $NaBH_4$ in different aprotic solvents: ether–tetrahydrofuran (6: 1), 1,2-dimethoxyethane, diglyme and the course of the reaction was examined by thin layer chromatography. Compound **2** was isolated after reduction of **1** in ether–tetrahydrofuran (10—15%), 1,2-dimethoxyethane (50—55%) and diglyme (70—75%). The low yield in ether–tetrahydrofuran apparently results from the slow reduction rate in this solvent which allows decomposition of the intermediate (**2**).

The above results indicate that the reduction of **1** in aprotic solvent affords **2**, or an equivalent organometallic adduct that leads to the formation of **2** when treated with water or when subjected to thin layer chromatography.

However, when the action of the reducing agent is complete (excess hydride is neutralized by addition of acetone) the fundamental skeleton of **2** is present in the molecule. Thus the results obtained with B_2H_6 and $NaBH_4$ in aprotic solvents confirm our previous conclusions and are analogous to those observed with $NaBH_4$ in protic solvents.

Finally, it is noteworthy that the reduction of tosylhydrazones, at least with B_2H_6, and $NaBH_4$ in protic and aprotic solvents, leads to the formation of a substituted tosylhydrazines (or equivalent organometallic adducts (**3**)) as the first product. Subsequent elimination of Ts^- leads to the formation of an alkyl diimide (**4**), which decomposes rapidly to N_2 and alkane. One of the two hydrogens of the resulting CH_2 takes its origin from the reducing hydride, the second one from the NH originally present in the tosylhydrazone (B_2H_6 and $NaBH_4$) or from water added during the working up of the reaction mixture ($LiAlH_4$).

The experimental results reported by Djerassi and coworkers[11] are in perfect agreement with the mechanism proposed by us. With regard to the reaction pathway of tosylhydrazones with $NaBH_4$, a different mechanism has been suggested.[12] This mechanism is

in contrast with our experimental data and with our conclusions.

Experimental

1-Cyclohexyl-2-tosylhydrazine from Reduction of Cyclohexanone Tosylhydrazone with B_2H_6. A solution of compound **1** (1 g, 3.75 mmol) in diglyme (20 ml) was treated at room temperature with excess of B_2H_6 (5.5 mmol) in THF (5 ml). After 15 min, the mixture was poured into a large excess of water and the resulting precipitate was filtered. Compound **2** (850 mg) was obtained, mixed with variable amounts of boron-containing compounds. This material was treated three-four times with aqueous methanol in the cold and passed through a column of Kieselgel (10-fold) in CH_2Cl_2 solution to obtain pure **2** (55—60%) identified by comparison with an authentic sample.[6]

1-Cyclohexyl-2-tosylhydrazine from Reduction of Cyclohexanone Tosylhydrazone with $NaBH_4$. To a solution of **1** (1 g, 3.75 mmol) in diglyme (20 ml), 300 mg (7.94 mmol) of $NaBH_4$ were added and the solution was maintained at room temperature for 10 min. Acetone (20 ml) was added and then (30 s) H_2O (200 ml). The resulting precipitate of crude **2** (810 mg) was recrystallized from CH_2Cl_2–hexane to give **2** in 70—75% yield.

In a parallel experiment, 1 g of **1** in diglyme (20 ml) and 300 mg of $NaBH_4$ were mixed, and in a few seconds, acetone (20 ml) and H_2O (200 ml) were added to the solution. No **2** was obtained. When 1,2-dimethoxyethane was used as solvent, the reaction time was prolonged to 20 min in order to obtain a good yield.

We wish to thank C.N.R. for financial support (Contract N°72.00048.03).

Stereochemistry of Ionic Thiol Addition to Acetylenic Ketones

Mohamed Tawfik OMAR and Mohamed Nabih BASYOUNI

Chemistry Department, Faculty of Science, Ain Shams University, Abbassia, Cairo, Egypt

(Received September 4, 1973)

Synopsis. Piperidine-catalysed addition of thiols to benzoyl- and *p*-chlorobenzoyl-phenylacetylenes in benzene gave a mixture of (*E*)- and (*Z*)-1-aryl-3-arylthio-3-phenyl-2-propen-1-ones. However, in methanol or aqueous 1,4-dioxane only the (*Z*)-isomers were obtained. Configurational assignments to the isomers were based on NMR, UV, and IR spectroscopy.

Although the nucleophilic thiol addition to acetylenes[1-3] has been studied no reports seem to deal with such addition to acetylenic ketones. The present publication describes the nucleophilic addition of thiols to benzoyl- and *p*-chlorobenzoyl-phenylacetylenes. The work was undertaken primarily to elucidate the stereochemistry of the mono-adducts for such addition, and also to study the effect of solvents on these additions.

Piperidine-catalysed addition of *p*-bromophenyl thiol to benzoyl-Ia and *p*-chlorobenzoyl-Ib-phenylacetylenes in benzene gave a mixture of (*E*)*-1-aryl-3-*p*-bromophenylthio-3-phenyl-2-propen-1-ones IIa and IIb, and their (*Z*)*-isomers IIIa and IIIb, respectively. The ratio of the (*E*)- to the (*Z*)-isomers in both cases was about 1:3.

The structures of IIa and IIb and IIIa and IIIb were confirmed by analytical data, electronic and infrared spectra. Their configurational assignments were based primarily on electronic spectroscopy since the absorption maxima of III are shifted slightly towards the red with intensification when compared with the corresponding II isomers. This indicates that IIa and IIb have the (*E*)-configuration, whereas IIIa and IIIb have the (*Z*)-configuration. This is consistent with the *cis-trans* relationship[4] on the one hand and *cis-* and *trans-*chalcones[5] on the other. Further confirmation for these configurational assignments was gained from infrared spectroscopy. $\nu_{C=O}$ of the (*E*)-isomers II are at a relatively higher value than those of the corresponding (*Z*)-isomers III. The configurational assignments to IIa and IIIa were confirmed by studying their NMR spectra. This was based on the deshielding effect caused by a phenyl group on a *β-cis* olefinic proton relative to a *trans* proton,[6] a feature characteristic of a number of styrene derivatives.[7,8] According to our data (Table 1), no vinyl proton signal for IIIa can be observed; apparently, it is hidden in the multiplet of aromatic protons, and must acquire the (*Z*)-configuration.

Isomer IIIa was identical with the product obtained by treating *cis*-(H/Ph)-*β*-bromochalcone[9] with *p*-bromophenylthiolate at 0 °C. The authentic sample is the (*Z*)-isomer since similar reactions are known to proceed with retention of configuration.[10]

When the addition of *p*-bromophenyl thiol to Ia or Ib was conducted in methanol or aqueous 1,4-dioxan, only the (*Z*)-isomers III were obtained in a nearly quantitative yield.

The investigation was extended to include the addition of other thiols such as benzyl-, *p*-tolyl-, and phenylthiols to Ia and Ib. In the case of the two latter thiols, when the addition was conducted in benzene a mix-

a) $\tau(CDCl_3)$ 3.58 (1H, singlet), 2.2—2.8 (14H, multiplet).
b) $\tau(CDCl_3)$ 1.8—2.9 (15H, multiplet)

ture of (*E*)- and (*Z*)-isomers IIc—f and IIIc—f, respectively, was obtained; benzyl thiol, however, yielded only the (*Z*)-isomers IIIg and IIIh with either of the two ketones. In methanol or aqueous 1,4-dioxan, only the (*Z*)-isomers III were obtained in a nearly quantitative yield.

The structures of IIb—f and IIIb—h were confirmed by analytical data, electronic and infrared spectra. Their stereochemical configurations were established by analogy of their electronic spectra with those of IIa and IIIa, respectively. Furthermore, $\nu_{C=O}$ of the (*E*)-isomers are of a higher frequency than those of the (*Z*)-isomers.

h; Ar=benzyl, X=Cl

Experimental

All melting points are not corrected. Infrared and electronic spectra were measured on a Unicam SP 1200 spectrophotometer (KBr discs) and Beckmann DK 1 spectrophotometer (in methanol), respectively. NMR spectra (in $CDCl_2$) were determined on a Varian T 60 instrument using TMS as an internal reference. Light petroleum refers to the fraction of bp 60—80 °C, unless otherwise stated.

(E)-*IIa—f and* (Z)-*IIIa—h 1-Aryl-3-arylthio-3-phenyl-2-propen-1-ones.* To a solution of the ketone (0.004 mol) and phenyl-, *p*-tolyl-, *p*-bromophenyl, or benzyl-thiol (0.004 mol) in benzene (5 ml) was added two drops of piperidine and the solution was allowed to stand at room temperature overnight. Crystallization of the filtered solid products from benzene-light petroleum gave the (Z)-*Title compounds.* Evaporation of the mother-liquors at room temperature gave a solid residue which was fractionally crystallized from the same solvent to give an additional amount of the (*Z*)-isomers besides the (*E*)-*Title compounds.*

When methanol was used as a solvent, a quantitative yield of the (*Z*)-isomers was obtained immediately. However, in the case of aqueous 1,4-dioxan they were obtained after being left to stand overnight. The results are shown in Table 1.

(Z)-*IIIa.* To a cold solution (0 °C) of *cis*-(H/Ph)-*β*-bromo-chalcone[9] (0.5 g) in ethanol (10 ml) was added dropwise an alcoholic solution of sodium *p*-bromophenyl thiolate (0.4 g). After 1 hr at 0 °C the precipitated product was filtered off and crystallized from benzene–light petroleum to give (Z)-*3-p-bromophenylthio-1,3-diphenyl-2-propen-1-one* IIIa in yellow needles, mp 167—169 °C. Found: C, 63.9; H, 3.6; S, 8.2%. Calcd for $C_{21}H_{15}BrSO$: C, 63.8; H, 3.8; S, 8.1%.

Reaction of Methylcyclopentane and *n*-Hexane over Evaporated Platinum Film Catalysts

J. R. ANDERSON* and Kin'ya SHIMOMURA**
School of Physical Sciences, Flinders University, Adelaide, Australia

(Received June 8, 1973)

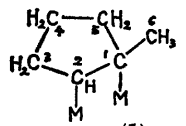
Synopsis. In the reaction of *n*-hexane and methylcyclopentane over polycrystalline platinum films evaporated in a ultrahigh vacuum condition, the initial distribution of reaction products varied with the reaction temperature and the hydrogen/hydrocarbon ratio. The effect of the reaction conditions was interpreted as depending on the possible reaction mechanisms cited.

Since hydrogenolysis of saturated hydrocarbons accompanied by skeletal isomerization over evaporated platinum films was first reported by Anderson and his collaborators, extensive studies have shown the reaction to involve a simple C–C bond shift or the use of an adsorbed carbocyclic intermediate.[1]

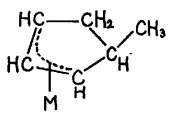
We have carried out the reaction of methylcyclopentane and *n*-hexane over unoriented platinum films evaporated in a ultrahigh vacuum in order to study the effect of the reaction conditions on the initial distribution of C_6 reaction products.

From methylcyclopentane, two classes of C_6 reaction products were obtained: (1) 2- and 3-methylpentane and *n*-hexane, (2) C_6 cyclic products (cyclohexane and benzene). The proportion of C_6 cyclic products decreased with increasing hydrogen/methylcyclopentane ratio, while this also caused the proportion of the methylpentanes to increase. Changing the reaction temperature from 240 to 310 °C caused a decrease in the proportion of the methylpentanes and an increase in that of *n*-hexane.

The possible existence of a diadsorbed σ-complex and an adsorbed π-complex (allyl type) in the reaction of saturated hydrocarbons has been suggested mechanistically.[2]



(1)

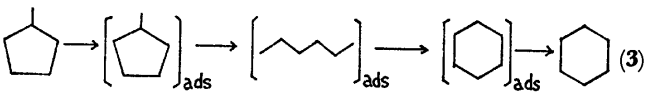


(2)

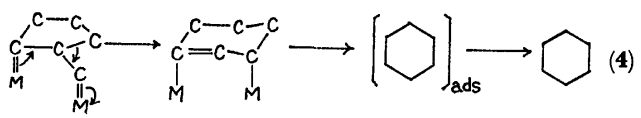
These intermediates in the hydrogenolysis of methylcyclopentane were also shown to occur over Al_2O_3-supported platinum catalysts.[3] In the present case, at a higher hydrogen ratio the probability of formation of (2) could be favoured since (2) requires only one free metal site, whereas (1) requires two sites and their geometrical distributions suitable for the structure and orientation of the methylcyclopentane molecule to be adsorbed in the positions C_1–C_2 and C_5–C_1 for *n*-hexane formation, on the surface covered predominantly with hydrogen.

The hydrogenolytic ring opening modes including diadsorbed species in the positions C_2–C_3, C_4–C_5, and C_3–C_4 for the formation of 2-methylpentane and 3-methylpentane, which might be compatible with the occurrence of (2), could also be taken into consideration in conjunction with the hydrogen/methylcyclopentane ratio. It has been proposed that the direction of hydrogenolysis of methylcyclopentane is determined by the correlation between the electron density distribution in the hydrocarbon molecule and the electron affinity of the metal atom or ion.[4] Hydrogen, chemisorbed over platinum, could exist in two forms—M^+–H^- and M^-–H_2^+ on the surface and an increased hydrogen coverage favours the proportion of hydrogen chemisorbed in the form of H_2^+.[5] This tendency could cause a decrease in the electron acceptability of platinum to increase the proportion of adsorption occurring at the positions C_2–C_3, C_4–C_5, and C_3–C_4 in conformity with the higher negative charge distribution in the methylcyclopentane molecule. However, this reaction mode does not appear dominant because the above-mentioned correlation between the electron distribution among these carbon atoms and the electronegativity of platinum is not reflected in the experimental result where the ratio of 2-methylpentane/3-methylpentane produced remains almost constant with changing ratio of hydrogen.

A possible mode of aromatization of methylcyclopentane which might alternatively occur has been presented.[6]



(3)



(4)

These mechanisms could probably take place in parallel with the formation of (1) and (2) for ring opening. The fact that at a higher hydrogen ratio the proportion of *n*-hexane and C_6 cyclic products showed a concurrent decrease suggests less preferential occurrence of (3) than (4), in which the formation of 1,3-diadsorbed intermediate would be suppressed at a higher hydrogen coverage on the surface to decrease ring enlargement by a bond-shift process *via* this intermediate.

Higher reaction temperatures apparently favour the formation of a diadsorbed σ-complex to produce *n*-hexane probably by reducing the covering effect of adsorbed hydrogen.

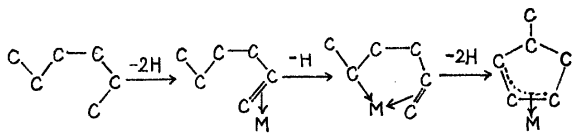
	310	7/1	1.69	6.7	0.6	1.9	trace	54.2	—	34.2	2.5

a) *i*-P, *n*-P: isopentanes, *n*-pentane, Cp: cyclopentane, 2- and 3-Mp: 2:-methylpentane plus 3-methylpentane, Mcp: methylcyclopentane, *n*-H: *n*-hexane, C_6 cyclics: cyclohexane plus benzene.
b) Reaction time: 35 min.

From *n*-hexane, three classes of C_6 products were obtained: (1) 2- and 3-methylpentane, (2) methylcyclopentane, (3) C_6 cyclic products. The proportion of methylcyclopentane increased with an increasing ratio of hydrogen/*n*-hexane, while this also caused the proportion of the methylpentanes to decrease. Increasing reaction temperature in the range 240—310 °C caused the proportion of C_6 cyclic products to increase and the proportion of methylpentanes and methylcyclopentane to decrease.

According to the proposed mechanism for the isomerization and dehydrocyclization of hexanes,[6] the first step of *n*-hexane could be expressed as



(5)

The results could be accounted for if the effect of increasing the hydrogen concentration strongly increases the rate of desorption of the π-allyl adsorbed C_5 species (*cf.* reaction (5)), and if this effect is more important than the effect of an increased hydrogen concentration on the rate of ring opening in the π-allyl adsorbed species.

It was found that the lower the hydrogen/*n*-hexane ratio in the reactant, the greater the tendency for the formation of lower molecular weight hydrogenolysis products. This was very pronounced when the reactant ratio was 1/1. This is probably because a low hydrogen/hydrocarbon ratio favours the retention of adsorbed hydrocarbon residues on the surface, so that a greater chance for carbon-carbon bond rupture occurs.

Aromatization of *n*-hexane could be explained by a proposed mechanism[7] which proceeds *via* a direct C_6 ring formation or a C_5 ring formation followed by enlargement to a C_6 ring by two-site adsorption. The experimental facts could be explained by a retardation of the third step in reaction scheme (3) with an increasing hydrogen/*n*-hexane ratio and by promotion of both the third and fourth steps in reaction scheme (3) with increasing reaction temperature.

Experimental

The reaction system is similar to the one reported previously,[8] which consists of a bakeable reaction system and a gas handling line. A platinum filament, made of 0.1 mm diameter platinum wire wound on 0.2 mm diameter tungsten wire of a hair-pin type, was pretreated for outgassing and melting, accompanied by a slight evaporation, at a heating electric current up to 7 A in a separate bell-jar system. After the filament was spot-welded in a Pyrex glass reaction vessel, evaporation was carried out within 10^{-9} Torr at 275 °C for about an hour. The reaction mixture of hydrogen, purified by a heated palladium thimble in a separate purification system, and hydrocarbon, evaporated from a liquid nitrogen-cooled trap in the gas handling line of 10^{-6} Torr, was made in a reservoir whose pressure was measured with a capsule dial gauge. The reactant and products were collected in a trap cooled with liquid nitrogen and analysed by gas chromatography.[9] The maximum extent of reaction 45 min after the introduction of a reaction mixture was about 3%.

Adsorption of Aniline Derivatives on Platinum Electrode in Aqueous Alkaline Solution

Yoshiharu MATSUDA,* Yukio ISHIKAWA, and Hideo TAMURA

*Department of Industrial Chemistry, Faculty of Engineering, Yamaguchi University, Tokiwadai, Ube 755
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita 565

(Received September 21, 1973)

Synopsis. In the adsorption of aniline derivatives on Pt electrode, a linear relation was observed between the chemical shift of the *m*- and *p*-amino protons and the inhibiting effect on the anodic oxidation of methanol. However, *o*-alkylanilines and chloroanilines showed deviations due to steric hindrance and strong interactions, respectively.

Earlier papers[1,2] pointed out that the adsorption phenomena in the electrode-solution interphase is possibly related to the overvoltage of the electrochemical reaction on the electrode. The influence of the structures of some organic compounds on the adsorption has also been reported[3,4] with reference to corrosion inhibitors. Cox and his co-workers[5] reported on the relationship between the NMR chemical shift of the amino protons of the aromatic inhibitors and the corrosion-inhibiting effect on iron in hydrochloric acid. Furthermore, some works[6-8] have referred to the inductive effects of the anchoring groups in organic compounds in connection with corrosion inhibition. The mechanism[3] of the adsorption of organic compounds containing nitrogen was investigated with reference to the iron in acids and with reference to the platinum in an aqueous alkaline solution.[9] Previous reports suggested a strong inhibition of chloro-substituted alkylamines[10,11] and allyl halides.[12]

The nitrogen atoms of organic amines and pyridine homologues can occupy anchoring positions on the adsorption on the platinum electrode in an aqueous alkaline solution, because of their strong electronegativity. However, the halogen atoms in organic compounds are also electronegative, and they may also be expected to occupy the anchoring positions. The purpose of this work is, then, to clarify the mechanism of the adsorption of the aniline derivatives on the platinum electrode in aqueous alkaline solution. The adsorption of the aniline derivatives on the electrode is estimated by measuring the influence on the peak current of the current-potential curves in the anodic oxidation of methanol.

Experimental

The sodium hydroxide, methanol, and aniline were guaranteed reagents by the Japanese Industrial Standards. The *m*- and *p*-chloroanilines, *o*-, *m*-, and *p*-methylanilines, *p*-ethylaniline, 2,4-dimethylaniline, *N*-methylaniline, and *N,N*-dimethylaniline were also guaranteed reagents, while the *o*-ethylaniline was an extra pure reagent made by the Wako Pure Chemical Ind. Co., Ltd. The purity of these reagents was detected by ascertaining one peak on the gas chromatograms. The carbon tetrachloride used in NMR measurements was a spectrometric-grade reagent made by the Nakarai Chemicals Co., Ltd.

The electrolytic cell and the instrument used for the potential sweep voltammetry were identical with those previously described.[13] The test electrode was a platinum plate with dimensions of $1\times1\times0.05$ cm^3; it was pretreated as in the previous work.[13] The electrolyte solution was deoxygenized by bubbling argon gas for 10 min before electrolysis.

The adsorption of aniline derivatives on the platinum electrode was estimated by measuring the influence of the peak current of methanol added to the electrolyte solution on the potential-current curves by single-sweep voltammetry.[13,14] The inhibition of the anodic oxidation of methanol as a measure of the adsorption was calculated by using Eq. (1):

Degree of the inhibiting eflect

$$= [(i_0-i)/i_0] \times 100\ (\%) \qquad (1)$$

where i_0 is the current on the electrode in the solution without the aniline derivatives and where i is that in the solution with the aniline derivatives. The NMR spectra of the aniline derivatives in carbon tetrachloride were measured on a JNM 3H-60 spectrometer (Nippon Denshi Co., Ltd.), with tetramethylsilane as the internal standard.

Results and Discussion

In the single-sweep voltammetry, the potential of the test electrode was initially maintained at −400 mV (*vs.* Hg/HgO/1 M KOH) for 15 min and was then swept anodically, at the rate of 100 mV/s, in aqueous solutions of potassium hydroxide containing aniline and methanol. The anodic current peaks were observed at about −140 mV on the current-potential curve for the aqueous solution of 1 M potassium hydroxide containing 0.5 mol/l methanol. These peaks were caused by the adsorption and electro-oxidation of methanol. This process was irreversible, and a linear relation was observed between the peak potentials and the logarithms of the potential sweep rate in the range from 0.001 to 0.4 V/s.

We also measured the influence of the concentration of aniline in 1 M aqueous potassium hydroxide containing 0.5 mol/l methanol on the degree of the inhibiting effect of the anodic oxidation of methanol, as is shown in Table 1. From these results, the proper concentration of the aniline derivatives for the test was determined to be 5×10^{-4} mol/l. The peak potential for the anodic oxidation of methanol was shifted in the anodic direction according to the addition of aniline; it was −85 mV (*vs.* Hg/HgO/1 M KOH) in an aqueous solution containing 1 M potassium hydroxide, 0.5 mol/l methanol, and 5×10^{-4} mol/l aniline. With regard to the accuracy of the inhibiting effect (percent), the standard deviation for five measurements was 1.3 percent in the solution cited above. However,

Table 1. Inhibiting effect of aniline on the anodic oxidation of methanol in aqueous potassium hydroxide. (concentration: 1 M KOH, 0.5 M CH_3OH), 25°C.

Concentration of aniline M	Inhibiting effect %
10^{-2}	95.5
5×10^{-3}	89.3
10^{-3}	85.0
5×10^{-4}	72.4
10^{-4}	64.0
5×10^{-5}	42.0
10^{-5}	33.1
5×10^{-6}	16.7
10^{-6}	8.8

these peak potentials were almost constant with the variation in the concentration of methanol in the range from 0.01 to 1 mol/l.

The mechanism of the adsorption of aniline derivatives on the platinum electrode is presumed to be related to the variation in the electron densities, and it probably has some relation with the chemical shift of the NMR spectra of these derivatives. For example, in these experiments, the chemical shifts of the amino protons of aniline and *p*-chloroaniline were observed at 6.69 and 6.61 ppm respectively. In this case, it was found from the spectra that the chemical shift of the amino protons was displayed at a field 0.08 ppm lower than that in aniline as a result of the introduction of the chloro-substituent. Similarly, the chemical shift of the amino proton of *p*-chloroaniline was in a lower magnetic field because of the strong electrophilicity of the chlorine atom. Figure 1 shows the relations between these chemical shifts of the amino protons of the aniline derivatives and the inhibiting effect on the anodic current of methanol in aqueous potassium hydroxide resulting from the adsorption of the derivatives on the electrode.

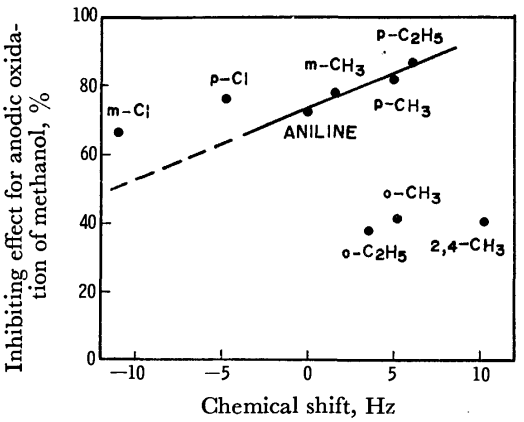

Fig. 1. Chemical shift of the amino protons of aniline derivatives plotted against the inhibition of the anodic oxidation of methanol. 25 °C.

As has been reported in previous reports,[5-9] the adsorption of the organic compounds containing nitrogen is related to the variation in the electron densities around the nitrogen atoms caused by the effects of resonance and hyperconjugation and by the inductive effect. In Fig. 1, a linear relation may be observed between the chemical shifts of the amino protons and the inhibiting effect of the anodic oxidation of methanol with regard to the *p*- and *m*-alkylanilines. However, the steric hindrance of the *o*-alkylanilines to the anchoring nitrogen atom gave large deviations from the linear relation shown in Fig. 1. In the case of the additions of 5×10^{-4} mol/l *N*-methylaniline and *N,N*-dimethylaniline, the inhibiting effects were 23.0 and 9.3% respectively. These low effects probably depend on the strong steric hindrance to nitrogen atoms in the molecules.

Furthermore, the deviations of the chloroanilines were observed in the direction opposite from that shown in Fig. 1; this phenomenon suggests some direct combination of the chlorine atom with the electrode. These results correspond with the previous experimental results [10-12] that the inhibiting effect of chlorinated alkylamines and allyl halides on the corrosion of iron is stronger than that of the corresponding alkylamines and allyl compounds.

The results suggest that there is a linear relation between the chemical shifts of the amino protons of *m*- and *p*-alkylanilines and the inhibiting effect of the aniline derivatives on the anodic oxidation of methanol on a platinum electrode in an aqueous alkaline solution, but *o*-alkylanilines and chloroanilines showed deviations from this relation. The anchoring site of these derivatives should be the nitrogen atom, but some steric hindrance was observed with the *o*-alkylanilines and some strong interactions were observed on *m*- and *p*-chloroanilines respectively.

The authors wish to express their thanks to Dr. Yoshiki Ohshiro for his helpful discussion and encouragement throughout the course of this work.

The Dissociation of Carbon Monoxide in an Induction-coupled Argon Plasma Jet

Yukio NISHIMURA,* Takeyoshi TAKENOUCHI,* and Wataru SAKAI**

*Research Institute of Industrial Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

**Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received October 2, 1973)

Synopsis. The major products were solid carbon, CO_2 and O_2. As the inside diameter of the probe decreased, the concentration of O_2 in the quenched gas increased and that of CO_2 decreased. The product distribution was independent of the argon-flow rate.

For many high-temperature chemical reactions, the distribution of the final products is determined by the quenching step. One of the techniques used to quench reacting high-temperature gas streams is placing them in contact with a cold wall[1-5] by, for example, passing them through a small-diameter, water-cooled tube. Baddour and Iwasyk have studied the reactions of elemental carbon with hydrogen above 2800 K, using this quenching method.[1] A similar method of quenching has been also applied to the synthesis of nitrogen fluorides[2] and of hydrogen cyanide.[3]

The present work, using small silica tube as a quenching apparatus, was undertaken in order to examine the effects of the operating conditions on the quenching conditions and on the distribution of the final products, when carbon monoxide was decomposed in the induction-coupled argon plasma jet at 1 atm.

Experimental

Materials. The argon used in this work was a high-purity cylinder gas (above 99.99% purity), while the carbon monoxide was commercially obtained from the Seitetsu Kagaku Co. (above 99.0% purity).

Apparatus and Procedures. The apparatus and procedures were similar to those used in previous papers.[6,7] Carbon monoxide was charged into the plasma jet counter-currently. The quenching of the decomposed products was done by means of small water-cooled silica tubes (which we shall hereafter name "probes"). The distance between the probe inlet and the induction coil was 0.5 cm. The mean temperature of the gas at the probe inlet was estimated by a method previously reported.[8] In this estimation, the hot gas was assumed to be composed of argon only, since it was difficult to ascertain precisely the composition of the hot gas at the probe inlet and since argon accounted for more than 93% of the hot gas under the conditions used in this work.

Results and Discussion

Table 1 shows the effects of the inside diameters of probes on the decomposition results and the mean temperatures of gas at the probe inlet. The major products are solid carbon, molecular oxygen, and carbon dioxide. Most of the carbonaceous species formed by the dissociation of carbon monoxide are transformed to solid carbon in the quenching step. As is clear from Table 1, the mean temperature of the gas at the probe inlet reaches 7500—8100 K; it is within the limits of experimental error independent of the inside diameter of the probe with a given outside diameter. Thermodynamic calculations of the carbon-oxygen system with a composition of C/O=1.0 at 1 atm have suggested that the partial pressures of molecular oxygen and carbon dioxide are less than 10^{-4} atm above 2500 K.[9] Therefore, it is certain that molecular oxygen and carbon dioxide are formed mainly in the quenching process. It is considered that the cooling rate in the probe with an inside diameter of 1 mm is greater than those in the other two probes.[4,8] Table 1 shows that, as the cooling rate increases, the amount of carbon dioxide formed decreases and that of molecular oxygen increases. Table 1 also shows that the conversion of carbon monoxide decreases with a lowering of cooling rate; this result suggests that the reproduction of carbon monoxide occurs in the quenching process.

Figure 1 shows the effects of the argon-flow rates on the conversions of carbon monoxide and the mean temperatures of gas at the probe inlet. Figures 2 and 3 indicate the variations in the quenched-gas compositions with the argon-flow rates. At a given power

(A) and (B): Conversion of CO at 4.62±0.02 kW and 8.65±0.02 kW, respectively.
(C) and (D): Mean temperature of gas at the probe inlet at 4.62±0.02 kW and 8.65±0.02 kW, respectively.

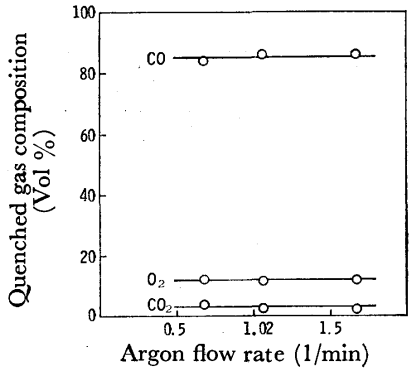

Fig. 2. Variation of quenched gas composition with argon flow rate at 4.62±0.02 kW (other conditions are the same as that of Fig. 1).

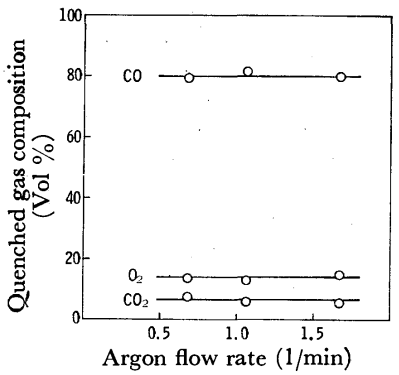

Fig. 3. Variation of quenched gas composition with argon flow rate at 8.65±0.02 kW (other conditions are the same as that of Fig. 1).

input, the mean temperature of the gas at the probe inlet becomes higher as the argon-flow rate increases, but the conversion of carbon monoxide and the composition of the quenched gas are almost independent of the argon-flow rate. It has been reported by Sundstrom and DeMichiell that the rate of quenching is greater at a higher mass flow rate in the case of the same initial gas temperature.[4] However, when the initial gas temperature is low at a given mass flow rate, it has been assumed that the decomposed products are cooled to the quenching temperature in a time shorter than when the initial gas temperature is high.[4,8] That is, when the argon-flow rate is increased, the increase in the rate of quenching is cancelled out by the rise of the initial gas temperature; apparently, then, the quenching temperature does not depend on the argon-flow rate. Therefore, it may be considered that the conversion of carbon monoxide and the composition of the quenched gas are almost independent of the argon-flow rate.

At a given argon-flow rate, as is clear from Figs. 2 and 3, both the conversion of carbon monoxide and the concentration of carbon dioxide in the quenched gas increase slightly with an increase in the power input. The mean temperature of gas at the probe inlet at 8.65 kW is higher than that at 4.62 kW. Thus, the situation in the quenching step is similar to that described above. However, one may say that, at a given argon flow rate, the dissociation of carbon monoxide at a high power input gives a quenched gas in which the concentration of carbon dioxide is higher than does the dissociation of carbon monoxide at a low power input.

The Crystal Structure of Tetraiodo-*p*-benzoquinone

Hayao KOBAYASHI, Takaaki DANNO, and Ichimin SHIROTANI*

Department of Chemistry, Faculty of Science, Toho University, Narashino, Chiba 275

**The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106*

(Received December 20, 1973)

Synopsis. The crystals of tetraiodo-*p*-benzoquinone-(iodanil) are monoclinic, with a space group of $P2_1/c$ and with $a=7.630(1)$, $b=5.268(1)$, $c=14.222(2)$ Å, $\beta=113.07(2)°$, and $Z=2$. The iodanil molecules are stacked to form columns along the b axis, with an interplanar distance of 3.694 Å.

The crystals of iodine molecules have been reported to be metallic under high pressure (>200 kbar).[1] On the other hand, those of tetraiodo-*p*-benzoquinone (iodanol) are still semiconductive up to 500 kbar. However, the pressure dependence of the electrical resistivity of the powder crystals of iodanil is quite large (10^{12} Ωcm at 1 bar and 10^{-1} Ωcm at 500 kbar[2]). Considering the simplicity of the molecular structure, such a large change in conductivity seems noteworthy.

The crystals of iodanil were subjected to X-ray structure analysis in order to obtain structural information.

Experimental

The iodanil was prepared by the reaction of bromanil with NaI and KI and was crystallized from an ethylacetate solution. The crystal data are; $C_6I_4O_2$, F.W. 611.7, monoclinic, $a=7.630(1)$, $b=5.268(1)$, $c=14.222(2)$ Å, $\beta=113.07(2)°$, $U=525.9$ Å^3, $D_x=3.862$ gcm^{-3}, $Z=2$, Space group $P2_1/c$. The intensities were collected on a Rigaku automated four-circle diffractometer with Mo$K\alpha$ radiation monochromated by a graphite crystal. The shape of the crystal used was parallelpiped, with dimensions of $0.17\times0.16\times0.09$ mm. The $\omega-2\theta$ scan technique was employed. Data were recorded for 1683 independent reflections up to $2\theta=60°$, of which 831 were observed.

Determination of the Structure and Discussion

The structure was solved by means of three-dimensional Patterson maps. The atomic parameters were refined by the block-diagonal least-squares method. The R-value was reduced to 0.069. The positional and thermal parameters are listed in Table 1.

TABLE 1. THE FINAL ATOMIC PARAMETERS AND THEIR ESTIMATED STANDARD DEVIATIONS ($\times10^4$)

	28	40	14	40	75	10	45	17	24
C(2)	1065	1576	822	163	182	34	−28	20	8
	30	40	14	45	74	11	48	18	25
C(3)	−785	1825	502	131	247	35	−10	22	10
	29	43	15	42	86	12	48	18	26

The iodanil molecules are stacked at equal intervals to form columns parallel to the b axis (Figs. 1a and 1b). The interplanar distance is 3.694 Å. Since no short contact can be observed, the intermolecular interaction between iodanil in the same column seems to be weak. The mode of overlapping is illustrated in Fig. 2. The least-squares plane of iodanil is:

$$-0.3000X-0.7060Y+0.6416Z=0.0,$$

where X, Y, and Z are coordinates (in Å) referred to the a, b, and c* crystal axes respectively. The deviations of atoms from this plane are:

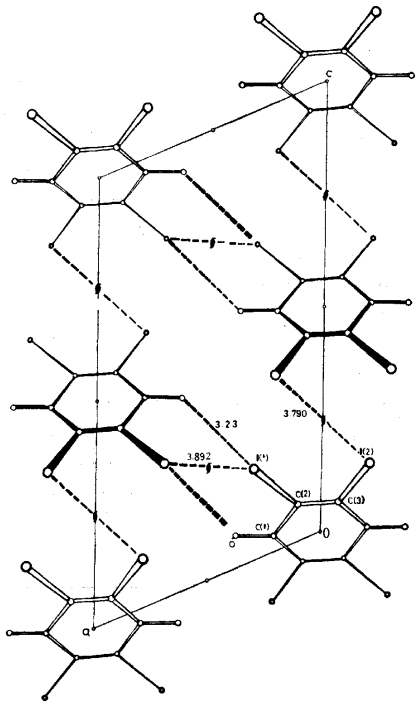

Fig. 1a. Projection of the structure along the b axis.

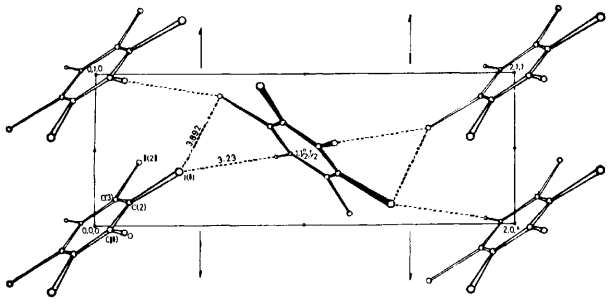

Fig. 1b. The structure viewed along [201].

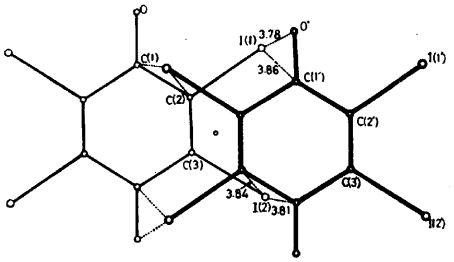

Fig. 2. Nearest-neighbour packing.

I(1), −0.019; I(2), 0.017; O, 0.025; C(1), 0.005; C(2), −0.003; C(3), 0.007 Å.

Few intermolecular short contacts are observed (Figs. 1a and 1b). The interatomic distances, which are shorter than the sum of the van der Waals radii, are as follows:

$I(1^{i})\cdots I(2^{ii})$, 3.790(3); $I(2^{i})\cdots I(1^{ii})$, 4.181(3); $I(1^{i})\cdots I(1^{iii})$, 3.892(4); $I(1^{i})\cdots O^{iii}$, 3.23(2) Å,

where the figures in parentheses are the standard deviations and where i, ii, and iii indicate the following equivalent positions:

i, x, y, z; ii, $-x, -0.5+y, 0.5-z$; iii, $1.0-x, 0.5+y, 0.5-z$.

The bond lengths and angles are given in Fig. 3; they show a strong quinoid character in iodanil. The mean bond length of C(1)–C(2) and C(1)–C(3′) is 1.50 Å (C(3′) is the atom associated with C(3) (Table 1) by a center of symmetry) and C(2)–C(3) is 1.31 Å. The corresponding values of chroranil are 1.490 and 1.344 Å respectively.[3] C(2)–I(1) (2.069 Å) is slightly longer than C(3)–I(2) (2.030 Å).

The visible absorption spectra of the vacuum-deposited thin films on quartz gave two broad maxima (330 and 380 mμ), wheras only one maximum (320 mμ) was observed in the spectra of the benzene solution (7×10^{-5} M). The infrared spectra showed that the C=O stretching frequencies in iodanil are 1665 and 1652 cm^{-1} in solution (carbon tetrachloride) and in a crystalline solid (KBr disks and Nujol mulls) respectively. For chloranil it is 1686 cm^{-1} in a chloroform solution and 1674 cm^{-1} in the crystalline state.[4] The magnitudes of the shift of the C=O stretching frequencies are almost equal to each other, while the shift is only 2 cm^{-1} in *p*-benzoquinone.[4] A crystal-structure analysis of chloranil has revealed that there is one unusually short contact between carbon and oxygen atoms (r(C···O)=2.85 Å).[4] In iodanil crystals O···I(1) is 0.32 Å shorter than the van der Waals radii (Figs. 1a and 1b), which may be noteworthy in this regard.

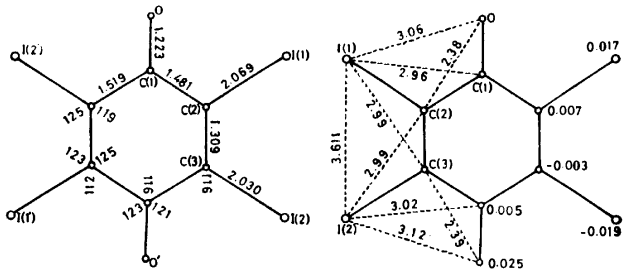

Fig. 3. Geometry of the iodanil molecule.
a) Bond lengths and angles, σ(C–I)=0.02 Å, σ(remaining bonds)=0.03 Å, σ(angle)=1.5—2.0 °.
b) Deviation from the best plane of iodanil and the values for some non-bonded distances.

The large electrical conductivity under high pressure indicates that the interatomic distances between adjacent molecules may be extremly reduced. The contact of O···I and I···I (Figs. 1 and 3) would be important for electric conduction. More information on molecular arrangement under high pressure would be desirable.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 47 (9), 2335—2336 (1974)

The Photosensitized Isomerization of 2-Butenes by Sensitizers Adsorbed on Porous Vycor Glass

Kiyoshi OTSUKA and Akira MORIKAWA

Department of Chemical Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received December 26, 1973)

Synopsis. The triplet-triplet energy transfer from ketones adsorbed on the Vycor glass to 2-butenes was rapid enough for us to neglect the transfer to the surface when the transfer is exothermic. Different photoisomerization mechanisms were suggested for different groups of sensitizers.

The photochemical behavior of electronically-excited molecules adsorbed on the solid surface is considerably different from that in the gas or solution phase.[1]

The photosensitized *cis-trans* isomerizations of olefins have been studied in detail in a homogeneous system; these studies have led to a considerable increase in our understanding of the triplet-triplet energy transfer mechanism.[2] However, the mechanism of the photoisomerization by the electronically-excited molecules adsorbed on the solid surface has not yet been well understood.

In this brief note, we intend to report on a study of the *cis-trans* photoisomerization of 2-butenes using various kinds of adsorbed molecules as sensitizers and to discuss the effect of the adsorption on the reaction.

Experimental

Adsorbent. A porous Vycor glass plate (30×9×1 mm, Corning 7930, surface area of 144 m²/g) used as an adsorbent is transparent in the ultraviolet region down to about 200 nm. Its transparency and large surface area are advantageous for the UV-spectra measurement of the adsorbed molecules and for the kinetic investigation of the sensitized isomerization. Prior to every run of the experiments, the glass was calcined with dried air in a reactor and degassed at 650 °C *in vacuo* for 2 hr.

Materials. The compounds used as sensitizers were extra pure reagents obtained from Tokyo Kasei Kogyo Co., Ltd., or Wako Pure Chemical Industries, Ltd. The sulfur dioxide was an anhydrous product of Matheson Chemical Co.

Procedure. The photoisomerization of 2-butenes was carried out using a closed gas-circulation apparatus capable of achieving a vacuum down to 10^{-6} Torr. Vycor glass plates on which sensitizers has been adsorbed with a coverage of 0.25 at most were irradiated by means of a Toshiba H-400-P medium-pressure mercury lamp. The light was filtered by passing it through a 1 cm path of water and one of the following glass filters: (1) Corning 7—54 (transparent 230—410 nm), (2) Toshiba UV-29 (transparent >270 nm), and (3) Toshiba UV-35 (transparent >320 nm). The choice of filter depends on the sensitizers used for exciting the molecules to their lowest singlet states. The adsorption of sensitizers and the photoisomerization of 2-butenes were carried out at room temperature.

Results and Discussion

The Vycor glass plate degassed at temperatures lower than 600 °C catalyzed the thermal isomerization of butenes, while it became negligible at 650 °C.

Upon irradiation, the adsorbed acetone, methylethyl ketone, pyrazine, acetophenone, biacetyl, nitrobenzene, and sulfur dioxide sensitized the photoisomerization of 2-butenes without any double-bond migration. Without irradiation, the isomerization did not occur on the Vycor glass where one of those compounds has been adsorbed; this was checked before and after carrying out the photosensitized isomerization. The adsorbed benzene, toluene, naphthalene, phenol, aniline, and *p*-dichlorobenzene could catalyze the *cis-trans* isomerization as well as the double-bond migration appreciably. However, irradiation increased the rate of *cis-trans* isomerization only.[3]

The simplest general scheme for a sensitized *cis-trans* photoisomerization over the solid surface is given by Eqs. (1)—(7), by analogy with the homogeneous reaction,[4] where $^0S(a)$, $^1S(a)$, and $^3S(a)$ are the adsorbed

$$^0S(a) \xrightarrow{h\nu} {}^1S(a) \quad (1)$$

$$^1S(a) \longrightarrow {}^0S(a) \quad (2)$$

$$^1S(a) \longrightarrow {}^3S(a) \quad (3)$$

$$^3S(a) \xrightarrow{\text{surface}} {}^0S(a) \quad (4)$$

$$^3S(a) + t\text{-}{}^0B(a) \longrightarrow {}^0S(a) + X^*(a) \quad (5)$$

$$^3S(a) + c\text{-}{}^0B(a) \longrightarrow {}^0S(a) + X^*(a) \quad (6)$$

$$X^*(a) \longrightarrow \alpha \cdot t\text{-}{}^0B(a) + (1-\alpha) \cdot c\text{-}{}^0B(a) \quad (7)$$

sensitizers in the ground, lowest singlet, and lowest triplet states respectively, and where c-$^0B(a)$ and t-$^0B(a)$ are adsorbed *cis-* and *trans*-2-butene in the ground states respectively. $X^*(a)$ represents an unspecified common intermediate which produces *trans*-2-butene with a probability of α.

Starting from 100% of *cis*-2-butene, the initial rate of *trans* isomer formation, R_0, can be written as follows;

$$R_0 = \alpha I_0 \phi_{isc} \cdot [c\text{-}{}^0B]/(k_4/k_6 + [c\text{-}{}^0B]) \quad (8)$$

where I_0 is the light intensity absorbed by a sensitizer on the Vycor glass, and where ϕ_{isc} is the quantum yield of intersystem crossing for the sensitizer. I, the relative light intensity adsorbed by a sensitizer, was calculated by the combination of the UV-absorption spectra of the adsorbed sensitizer with the radiative intensity distribution of the arc and the transmission of the combined filters. The relative quantum yields of *cis* to *trans* isomerization (R_0/I) for the sensitizers obtained at an initial *cis*-2-butene pressure of 50 Torr are plotted against the lowest triplet energies (E_T) of the sensitizers in Fig. 1.[5]

The relative quantum yields for ketones and pyrazine[6] increased sharply at an E_T value of about 77 kcal/mol, which is very close to that of 2-butenes.[11] This shows that the triplet-triplet energy-transfer mech-

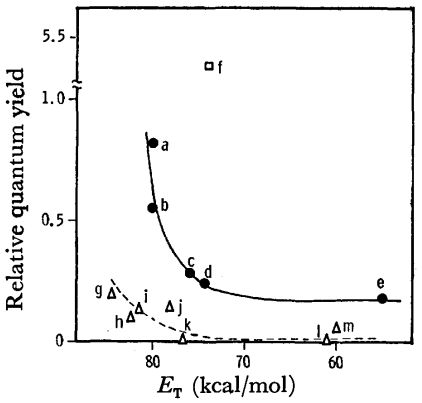

Fig. 1. The relative quantum yield as a function of the triplet energy of the sensitizers.
a, methyl-ethyl-ketone; b, acetone; c, pyrazine; d, acetophenone; e, biacetyl; f, sulfur dioxide; g, benzene; h, toluene; i, phenol; j, *p*-dichlorobenzene; k, aniline; l, naphthalene; m, nitrobenzene.

anism must be favored when the triplet state of a sensitizer has a higher energy than that of 2-butenes. In this case, X*(a) represents the adsorbed 2-butene in the triplet state.

It has been shown that the triplet-triplet energy transfer occurs upon every collision if the transfer is exothermic in the gas phase.[12] This is valid also for stilbene and piperylene in the solution phase.[4] On the solid surface, however, since adsorbed triplet molecules are always in contact with the surface, the energy dissipation to the surface, Eq. (4), may compete effectively with Eq. (5) or (6). To examine this, the pressure effect on the rates of photoisomerization was studied with acetone as a sensitizer. The relation between the initial rates of *trans*-2-butene formation and the pressures of *cis*-2-butene is shown in Fig. 2. The rates do not depend on the pressure. The coverage of adsorbed 2-butenes was confirmed to be less than unity when the pressure was lower than about 300 Torr. These results show that Reaction (6) is fast enough for us to neglect the (4) process in this case.

The fairly high isomerization yield for biacetyl, even though its triplet energy is as low as 54.9 kcal/mol,[13]

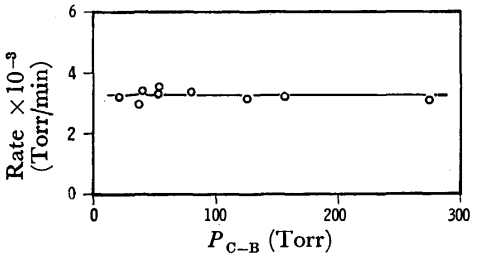

Fig. 2. The effect of pressure of *cis*-2-butene on the rate of photoisomerization.

implies that a different intermediate is produced. Presumably, the Schenck mechanism[14] predominates in this case.

Naphthalene, benzene, and its derivatives showed low quantum yields compared to those of ketones, as may be seen in Fig. 1. The correlation between the quantum yield and E_T is not so clear as that found for ketones. If the energy transfer from the excited singlet state to the surface occurs rapidly, the low isomerization yield may be attributed to the inefficient triplet formation of sensitizers.[15] On the other hand, if this process is not competitive with the intersystem crossing, it is conceivable that the low isomerization yield may be caused by a relatively faster triplet energy transfer to the surface than to 2-butenes.

The isomerization yield for sulfur dioxide was extremely high compared to those of the other compounds examined. A rough estimation of the absolute quantum yield gave about 5 for this compound. This high quantum yield suggests that the reaction proceeds *via* a chain mechanism.

Additional study is still needed before the role of adsorption can be clarified definitively for the above sensitized photoisomerization. However, we would like to stress that the mechanisms on the surface are quite different among the groups of sensitizers.

2) For a review see N. J. Turro, "Molecular Photochemistry," Benjamin, New York, (1967), p. 178.

3) Irradiation with the light of wavelength about 250 nm to the bare surface caused the isomerization to some extent, and its rate was proportional to the intensity of incident light. In the cases of benzene, toluene, phenol, and *p*-dichlorobenzene as sensitizers, the light of this wavelength region was included. However, more than 90% of incident light was absorbed by the sensitizers, and the contribution from the bare surface to the total reaction can be neglected.

The Molecular Structure of Boron Triiodide as Determined by Gas Electron Diffraction

Hironobu KAKUBARI,* Shigehiro KONAKA, and Masao KIMURA**
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received January 21, 1974)

Synopsis. The B–I distance of BI_3 was determined to be 2.118±0.005 Å. A modified Schomaker-Stevenson rule holds for the boron-halogen bond lengths of the boron trihalides except for the fluoride. The B–F distance is much shorter than the value predicted by the rule.

Previously one of the present authors (S.K.) and co-workers reported the molecular structures of BF_3,[1] BCl_3,[2] and BBr_3[3] as determined by gas-phase electron diffraction. The present note will report on the molecular structure of BI_3 as determined by the same method, aiming at a comparison of the boron–halogen bond distances.

The sample was obtained commercially and was purified by sublimation before use. Diffraction photographs were taken with a high-temperature nozzle under the following experimental conditions: camera length, 123.9 mm; accelerating voltage, about 42 kV; beam current, 0.06 μA; exposure time, 240 s; nozzle temperature, about 60 °C. The scale factor was determined by using the diffraction pattern of carbon disulfide. The data covered the $6<s<26$ Å^{-1} range.[4] The measurement of the scattering intensities and the reduction of the molecular intensities were carried out by our usual procedure.[5] Three plates were selected for analysis. The dots in Fig. 1 typify the observed molecular intensities.

The structure was determined by the least-squares method.[5] In the analysis, a planar equilibrium structure with D_{3h} symmetry was assumed. The B–I bond distance, which contributes little to the total intensity,

a) The B–I distance was calculated from the observed I···I distance. The errors represent the limits of error.

was constrained to have an r_a distance calculated from the I···I distance by taking the shrinkage effect into account.[6] The B–I mean-amplitude was fixed at the value evaluated at 60 °C, 0.059 Å, using the force filed proposed by Cyvin.[7] The Hartree-Fock and the Thomas-Fermi-Dirac elastic scattering factors for B and I respectively,[8] and the Thomas-Fermi inelastic scattering factors,[9] were used.[10] The interatomic distances thus derived are shown in Table 1. The I···I mean amplitude and the index of resolution were determined to be 0.078±0.006 Å and 0.63±0.05 respectively. The errors indicate the limits of error, which include both the random error and the systematic error due to the uncertainty in the scale factor. The corresponding theoretical intensity curve and the differences from the observed intensities are shown in Fig. 1. The observed index of resolution, 0.63, is unexpectedly small in our ordinary experimental experience,[11] and the I···I mean amplitude is smaller than the calculated value, 0.089 Å. One of the most probable causes of these discrepancies seems to be the extraneous background due to scattering from impurities produced by reactions with moisture, nozzle materials, and grease, and also by thermal decomposition during the loading and heating of the sample in the high-temperature nozzle. At a nozzle temperature of about 60 °C, HI and I_2 are thought to be the main impurities contributing to the background scattering. In order to examine the influence of these impurities on the results, the data were analyzed by assuming mixtures in various ratios of BI_3 and HI or I_2 by the use of known structures for the latter molecules.[12,13] In the cases of mixtures of BI_3 and I_2, the index of resolution increased with an increase in the amount of mixed I_2, becoming about unity in the case of a mixture of 50% I_2 in mole fraction. On the other hand, the standard deviations for the I···I distance and its mean amplitude increased approximately proportionally to the amount of mixed I_2 and became, for a 50% mixture, about three times as large as those in the case of pure BI_3. Those results indicate that no significant amount of I_2 is present in the sample gas. For mixtures of BI_3 and HI, the index of resolution increased linearly with an increase in the amount of HI, for instance, from 0.63 in the case of pure BI_3 to 0.96 in the case of a mixture containing 60% HI, while the other parameters and their standard deviations remained practically the same

** To whom correspondence should be addressed.

as the quoted results. The amount of HI mixing in the sample gas is not known. However, the injected gas can hardly be considered to contain 50% or more impurities. There seems to be another unknown background spreading over the inner scattering region. In any case, this extraneous scattering has no influence on the resulting I···I distance and its mean amplitude. The discrepancy between the experimental and calculated I···I mean amplitudes remains unexplained.

Table 2 compares the observed bond lengths, r_g, the sums of the covalent radii, r_B+r_X, the differences, $(r_B+r_X)-r_g$, and modified Schomaker-Stevenson correction terms proportional to the differences in electronegativity, $0.06|\chi_B-\chi_X|$, for boron trihalide molecules.[14] The observed B–X bond lengths, except for the fluoride, can be reproduced by this equation with a correction term for bond ionicity, while the B–F bond length is much shorter than the value predicted by the equation. This extra shortening of the B–F bond seems to reflect a larger amount of double-bond character in the B–F bond.[15]

The authors are grateful to Professor Takao Iijima for his helpful advice. The computation was carried out on the FACOM 230-60 of the Hokkaido University Computing Center.

(Received February 18, 1974)

Synopsis. The optically-active vibration was analyzed for the $NaNO_2$ crystal on the basis of a simple mechanical model. Force constants which interpret fairly well both the observed elastic constants and the vibrational frequencies of the optically-active modes were determined.

In connection with the phase-transition phenomena, many investigators have taken part in the determination of the elastic constants[1] and in the spectroscopic study[2] of the crystal. In the present work, the elastic constants and the eigenfrequencies of the optically-active modes were calculated using a simple mechanical model.

The space symmetry of the sodium nitrite crystal is Im2m in the ferroelectric phase, and the cell constants are a_0=3.569 Å, b_0=5.563 Å, and c_0=5.348 Å.[3] Since two formula units are present in this crystallographic cell, the original lattice vector, **a**, has been transformed into a conventional lattice vector, $\mathbf{a}'=(\mathbf{a}+\mathbf{b}+\mathbf{c})/2$, in order to obtain the primitive unit cell in the vibrational analysis.[2a] The vibrational analysis was performed on the basis of the GF-matrix method,[4] in which vibrationally-induced dynamical effects[5] are implicitly neglected. In addition to the ordinary potential parameters of the NO_2 group, thirteen short-range interaction parameters were taken into account, as is illustrated in Fig. 1.

The elastic constants were microscopically calculated by the method established by Shiro.[6] In order to obtain the best fit, the potential parameters were

refined by the least-squares method with reference to the observed elastic constants[1c] and the vibrational frequencies[2c] complementally.

The best set of force constants was determined to be as is shown in Table 1. The observed[1c] and calculated elastic constants are compared in Table 2. Obviously, the observed elastic constants other than the C_{31} are reproduced fairly well. The contribution (%) of the potential parameters to the calculated elastic constants is also listed in Table 2. It is difficult on the basis of this model only to explain the relatively small value of the observed C_{31}, since the C_{31} constant is found to be considerably coupled with the C_{11} and C_{21} constants.

a) Ref. 2(c). b) str, stretching; def, deformation; transl (a), translational(along the direction parallel to the a axis); rot (a), rotational (around the *a* axis).

The vibrational modes of the crystal have the following irreducible representations: $\Gamma=3A_1+A_2+2B_1+3B_2$. The calculated eigenfrequencies and the tentative assignments are given in Table 3. The observed frequencies cited here are the ones corrected by Tsuboi *et al.*[2c] to exclude conventionally the dynamical effects.[5] The simple Urey-Bradley force field has been found to give a somewhat poor agreement with the observed frequencies in a water-type molecule; therefore, we have introduced the correction term, p, between the stretching coordinates.[7] It is shown in Table 3 that the calculated frequencies reproduce the observed ones fairly well. Further investigations will, however, be required on the basis of some elaborated models, for a rigorous treatment is essential for the satisfactory explanation of the other dynamical properties.[2e] The degrees of the contribution of the potential parameters are considered to be independent of those from the elastic constants; therefore, the resulting force constants, which were obtained with reference to both properties complementally, seem to be reliable, at least in this idealized but simple model. The force constants obtained here may become a measure of the interatomic interactions due to repulsive forces.

The calculations were carried out on the TOSBAC 3400 TOPS 14 electronic computer at the Computing Center of Hiroshima University. The authors wish to express their thanks to Mr. Masaru Ohsaku of their laboratory for his useful suggestions.

Mössbauer Spectroscopic Studies of Iron(II) and Iron(III) 1-Nitroso-2-naphtholate Complexes

Mitsuko TAKADA* and Hirotoshi SANO**

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158

(Received May 2, 1974)

Synopsis. The anomalous Mössbauer parameters of iron(II) 1-nitroso-2-naphtholate complex are interpreted by assuming the presence of iron(III) and iron(II) complex species. Partial oxidation of iron(II) by 1-nitroso-2-naphthol is suggested.

Iron 1-nitroso-2-naphtholate complexes known in analytical chemistry are used as the dye "Naphthol Green Y".[1] However, there are not many structural studies on these complexes except for the work by Stukan *et al.*[2] on bis (1-nitroso-2-naphtholato)iron(II) by means of the Mössbauer effect. They reported that bis(1-nitroso-2-naphtholato)iron(II) shows a quadruplet in the Mössbauer spectrum. A component doublet of the spectrum has parameters similar to those for the spectrum of other planar iron complexes, while the quadrupole splitting of the second doublet is similar to that of high-spin iron(II) compounds, although the isomer shift is anomalously more negative than that of the latter. The reason for the appearance of a quadruplet has not so far been clarified.[3] Since no Mössbauer spectroscopic data have been given of tris-(1-nitroso-2-naphtholato)iron(III), we examined the Mössbauer spectroscopic character of these complexes.

Dark colored crystallites of tris(1-nitroso-2-naphtholato)iron(III) were prepared from iron(III) trichloride hexahydrate and 1-nitroso-2-naphthol both in ethanol or in acetic acid.[1] The products were identified as $Fe(C_{10}H_6NO_2)_3$ by elemental analysis. The molar magnetic susceptibility observed by the Gouy method was 2.09 ± 0.7 B.M. at room temperature, indicating low-spin ($S=1/2$) iron(III) state. Mössbauer spectra were measured against a ^{57}Co(Pt) source moving with constant acceleration at room temperature. A typical Mössbauer spectrum is shown in Fig. 1a. The isomer shift is 0.19 mm/s with respect to metallic iron, the quadrupole splitting being 2.12 mm/s at 78 K. The large quadrupole splitting suggests an octahedral structure with a peripheral configuration.

Optimum conditions for the preparation of a stoichiometric iron(II) 1-nitroso-2-naphtholate complex were studied.[4] An ethanol solution saturated with potassium 1-nitroso-2-naphtholate was prepared by adding a concentrated potassium hydroxide solution to an ethanol solution of 1-nitroso-2-naphthol. The mixture was allowed to stand for one day at room temperature. The resulting blue-green crystallites were filtered and washed with water and ethanol. All the procedures were carried out under nitrogen. Found: Fe, 8.67; C, 55.90; H, 3.53; N, 6.54%. Calcd for $KFe(C_{10}H_5NO_2)_3 2H_2O$: Fe, 8.63; C, 55.65; H, 3.43; N, 6.49%. Magnetic susceptibility measurements indicate that the compound is diamagnetic ($S=0$). A Mössbauer spectrum is shown in Fig. 1b. The isomer shift is 0.22 mm/s and the quadrupole splitting is 0.86 mm/s at 78 K. The fairly large quadrupole splitting suggests an octahedral structure with peripheral configuration as in tris(1-nitroso-2-naphtholato)iron(III).

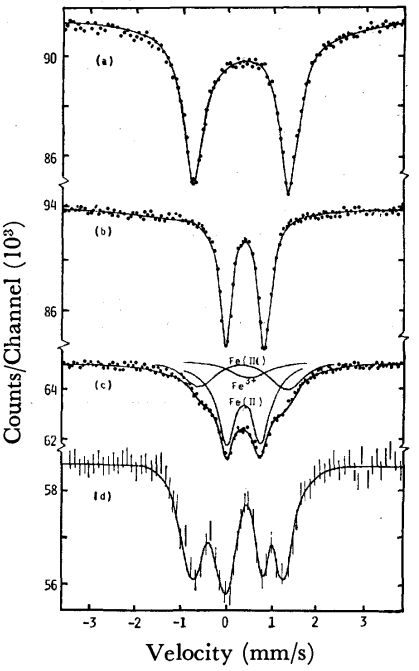

Fig. 1. Mössbauer spectra at 78 K of (a) tris(1-nitroso-2-naphtholato)iron(III), (b) potassium tris(1-nitroso-2-naphtholato)ferrate(II), (c) bis(1-nitroso-2-naphtholato)iron [containing iron(II) and iron(III) species]. (d) Spectrum of bis(1-nitroso-2-naphtholato)iron at 80 K, reproduced from Ref. 4.

The low values of isomer shift found in the tris-(1-nitroso-2-naphtholato)iron(III) and potassium tris(1-nitroso-2-naphtholato)ferrate(II) indicate the low-spin iron(III) and iron(II) states, respectively, which are consistent with the magnetic measurements. The results could be ascribed to the back-donation of non-bonding $3d_{t2g}$ electrons of iron to the π^* orbitals of the ligands through nitrogen and oxygen atoms.

Dark green crystallites were obtained by mixing iron(II) dichloride tetrahydrate and 1-nitroso-2-naphthol in a 1:2 mole ratio in ethanol under nitrogen. The elemental analysis gives a reproducible result, but always higher iron content as compared with the calculated value for $Fe(C_{10}H_6NO_2)_2H_2O$ and lower

* Present address: Japanese Patent Office, Kasumigaseki, Chiyoda-ku, Tokyo.

** To whom all correspondence should be addressed.

values for carbon and hydrogen. The apparent molar susceptibility was 3.70 B.M. at room temperature. The Mössbauer spectrum (Fig. 1c) could be decomposed into two doublets and a small singlet assigned to tris(1-nitroso-2-naphtholato)ferrate(II), tris(1-nitroso-2-naphtholato)iron(III), and high-spin iron(III) species, respectively. The results suggest that some iron(II) species are oxidized to iron(III) species probably by 1-nitroso-2-naphthol, as in the reaction of this reagent with cobalt(II) species,[5] giving tris(1-nitroso-2-naphtholato)iron(III) and some inorganic iron(III) species. The quadruplet consisting of two doublets seems similar to the spectrum reported by Stukan *et al.* in the values of isomer shift and quadrupole splitting.[2] Earlier data on some salicylaldehyde and salicylaldoxime iron(II) chelates[2,6] were found by De Vries *et al.* to be erroneous in the interpretation of Mössbauer parameters of what were believed to be pure iron(II) compounds.[7] The result on bis(1-nitroso-2-naphtholato)iron may also be interpreted by assuming oxidation of iron(II) species in the preparation of the material, since the obtained potassium tris(1-nitroso-2-naphtholato)ferrate(II) is stable in air at room temperature.

A part of this work was carried out at Ochanomizu University.

(Received October 8, 1973)

Synopsis. When alkali 4-hydroxyisophthalates are heated with phenol or alkali phenolates, *p*-hydroxybenzoic acid is formed from potassium salts and salicylic acid is formed from sodium salts preferentially.

Although the Kolbe-Schmidt reaction has long been studied from the synthetic point of view, the complete elucidation of this reaction mechanism has not yet been given and 4-hydroxyisophthalic acid (4-OIP) has been regarded as an unimportant by-product, because its yield was extremely poor.

In a preceding paper,[1] though, it was reported that 4-OIP was formed in a good yield when the rearrangement of monopotassium *o*-hydroxybenzoate (SA–K) to dipotassium *p*-hydroxybenzoate (POB–K_2) was investigated in detail by means of microthermal analyses.

4-OIP may be the dominant product which holds the key to the Kolbe-Schmidt reaction scheme. Therefore, the thermal behavior of 4-OIP under various conditions was examined.

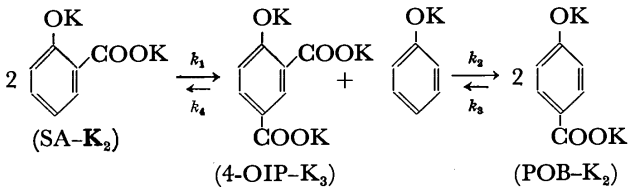
Experimental

Samples. The disodium, trisodium, dipotassium, and tripotassium 4-hydroxyisophthalates (4-OIP–Na_2, –Na_3, –K_2, and –K_3) were prepared as has been reported previously[1] from commercial 4-OIP (Tokyo Kasei Kogyo, Ltd.).

Methods. The reader should refer to the previous paper[1,2] for a description of the methods and the apparatus. When the experiment was carried out at increased pressures, a tubular resistance[3] was connected to the apparatus in order to maintain the sample vessel at 3.85 atm.

Results and Discussion

Rostron *et al.*[4] have proposed the following scheme for the reaction of 4-OIP–K_3 with potassium phenolate (PhOK),



This reaction was at first re-investigated by using a mixture of 4-OIP–K_3 and PhOK (4-OIP–K_3: PhOK = 1 : 1) at 300 °C under a N_2 atmosphere. As PhOK reacts with CO_2, this reaction in a CO_2 atmosphere was not examined.

The amount of evolved gases (PhOH+CO_2) leads to a decrease in the sample; this decrease was evaluated by subtracting the product's weight from the anhydrous sample's weight, as has been described in the previous paper.[1] PhOK is fairly stable in a N_2 atmosphere, even at elevated temperatures.

Table 1. Reactions of 4-OIP–K_3 with PhOK or PhOH at 300°C[a]

Atmospheric condition	Decrement[b] (%)	Purity[c] (%)	Composition of acids (mol%)		
			POB[d]	SA[e]	4-OIP[f]
With PhOK					
N_2 stream[g]	10.9	94.1	6	0	94
N_2 stream	13.2	89.1	16	16	68
N_2 3.85 atm[g]	10.0	90.0	3	0	97
N_2 3.85 atm	14.1	91.8	16	6	78
With PhOH					
N_2 stream	3.6[h]	94.2	22	18	60
N_2 3.85 atm	2.4[h]	83.3	41	14	45
CO_2 stream	3.1[h]	95.0	23	18	59
CO_2 3.85 atm	5.0[h]	80.7	32	13	55

a) Reaction period = 10 s (Raised the temperature continuously at the rate of 10°C/min from 30°C to the fixed temperature). b) (Decrease in weight/Original weight) × 100. c) [K salts of the total acid/(The product—PhOK)] × 100. d) *p*-Hydroxybenzoic acid. e) Salicylic acid. f) 4-Hydroxyisophthalic acid. g) The sample was sealed into a small Al vessel to suppress the evolution of gases. h) (Decrease in weight/Original weight of 4-OIP–K_3) × 100.

As is shown in Table 1, a mixture is converted into POB and SA with an increase in the decrement, regardless of the variation in the N_2 pressure. The rate of conversion decreases in this order: $k_2 > k_4$. The conversion of 4-OIP–K_3 is affected more remarkably in the presence of PhOH than in the presence of PhOK, as was revealed by the previous results.

On the bases of these results, we carried out the reaction of 4-OIP–K_3 with PhOH under N_2 and CO_2 (Table 1). As expected, the conversion took place more rapidly in the presence of PhOH and the yield of POB was higher than that of SA. 4-OIP–K_3 itself was very stable upon heating in the absence of PhOK or PhOH and was more stable than 4-OIP–K_2 at 300 °C, as is shown in Table 2.

It seems that the formation of a large amount of 4-OIP conflicts with the poor yield of 4-OIP obtained from the same reaction carried out in an autoclave.[5]

This can be explained as follows: the fair amounts of both 4-OIP–K_2 and –K_3 produced are consumed in their interaction with the PhOH which is simultaneously formed and can not be removed from an autoclave. Therefore, the reaction of 4-OIP–K_2 with PhOH was examined under N_2 or CO_2 (PhOH/4-OIP–K_2 = 1.2 mol/mol). The results are shown in Table 3.

The conversion of 4-OIP–K_2 into POB and SA was

h) (Decrease in weight/Original weight of 4-OIP-K_2) $\times 100$.

found to occur much more effectively in the presence of PhOH in a closed system than in the absence of PhOH. The reaction proceeded greatly and the 4-OIP-K_2 was almost completely converted into POB under increasing pressures. This suggests that a rather large quantity of PhOH remains in the reaction system and contributes to the formation of POB.

The reaction of 4-OIP-K_2 with PhOK instead of PhOH was carried out under N_2; the results are shown in Table 3. This reaction proceeded more rapidly than the reaction in the absence of PhOH (Table 2). Especially, the reaction with PhOK in a closed Al vessel resembled that with PhOH under the same conditions, but the compositions of the acids formed were different.

The thermal stabilities of 4-OIP-Na_2 and 4-OIP-Na_3 were examined at 320 °C (Table 2). 4-OIP-Na_2 was slightly more stable than 4-OIP-Na_3; this relation was the reverse of that of the corresponding potassium salts (4-OIP-K_2<4-OIP-K_3). The effects of the differences in atmosphere and pressure were hard to recognize in the conversion of both sodium salts into SA and POB.

Table 4. Reactions of both 4-OIP-Na_2 and 4-OIP-Na_3 with PhONa or PhOH at 340°C[a]

Reactant	Atmospheric condition	Decrement[b] (%)	Purity[c] (%)	Composition of acids (mol%) POB[d]	SA[e]	4-OIP[f]
4-OIP-Na_2	With PhONa[i]					
	N_2 3.85 atm[g]	24.0	85.3	9	45	46
	With PhOH[j]					
	N_2 3.85 atm[g]	21.8[h]	80.7	10	45	45
	CO_2 3.85atm[g]	20.9[h]	81.8	9	53	38

	With PhOH[j]					
	N_2 3.85 atm[g]	12.8[h]	68.5	12	43	45
	CO_2 3.85atm[g]	12.1[h]	75.0	10	55	35

a), b), c), d), e), f), g), h), See Table 1, and also c), h), See Tables 2 and 3 (K is replaced by Na).
i) PhONa/4-OIP-$Na_{2(3)}$ = 1.2 mol/mol. j) PhOH/4-OIP-$Na_{2(3)}$ = 1.6 mol/mol.

The results of the reaction of 4-OIP-Na_2 with PhOH or sodium phenolate (PhONa) and that of 4-OIP-Na_3 with PhOH or PhONa are shown in Table 4. As may be seen in Table 4, both 4-OIP-Na_2 and -Na_3 were markedly converted into SA in the presence of PhOH or PhONa at 340 °C under an elevated gaseous pressure.

In conclusion, the difference in the orientation between PhOK and PhONa in the Kolbe-Schmidt reaction—that is, at high temperatures PhOK and PhONa give POB and SA respectively—may be caused by the difference in the degree of conversion between 4-OIP-K_α and 4-OIP-Na_α (α=2, 3).

The author wishes to thank Dr. Manabu Senō, Tokyo University, for his advice and Dr. Tetsuro Seiyama, Kyushu University, for his encouragement.

The Synthesis of Methoxylated Aromatic Carotenoids

Nobuhisa OKUKADO

Department of Chemistry, Faculty of Science, Kyushu University, Higashi-ku, Fukuoka 812

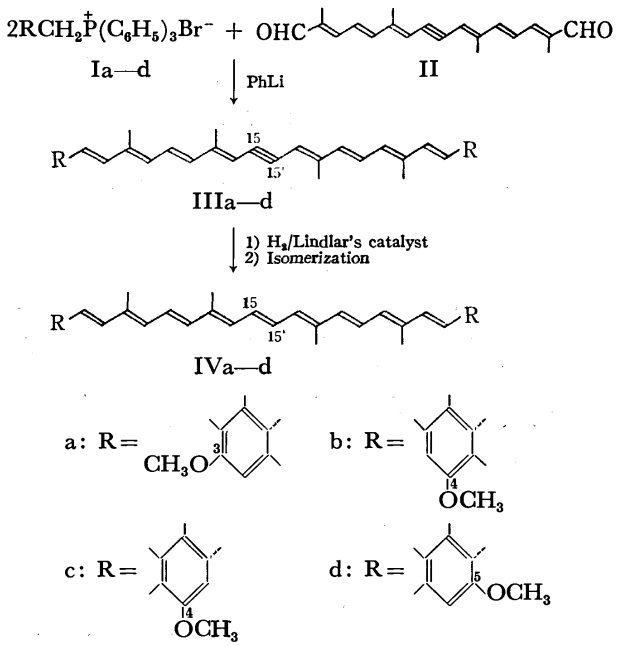
(Received December 21, 1973)

Synopsis. Four methoxylated aromatic carotenoid derivatives (IVa—d) were prepared by the condensations of the ylids derived from the phosphonium salts (Ia—d) with didehydrocrocetindial (II) followed by partial hydrogenation of the acetylenic bond.

Since aromatic carotenoid hydrocarbons had been isolated from a sea sponge "*Reniera japonica*",[1] the natural occurrence of aromatic carotenoids with oxygen functions such as hydroxyl or methoxy groups on their aryl end-groups has been expected. In fact, phenolic carotenoids were isolated from "*Streptmyces mediolani*" in 1969,[2] but the presence of pigments containing methoxylated aryl end-groups has not so far been reported. In this paper, the synthesis and characterization of 3,3'- and 4,4'-dimethoxyisorenieratene (IVa and IVb), 4,4'- and 5,5'-dimethoxyrenierapurpurin (IVc and IVd), and their 15,15'-didehydro compounds (IIIa—d) will be described.

Syntheses were carried out according to the $C_{10}+C_{20}+C_{10}$ building principle.[3] Wittig reactions of didehydrocrocetindial (II) with the appropriate methoxylated trimethylbenzylidenetriphenylphosphoranes prepared from the corresponding phosphonium salts (Ia—d) gave 15,15'-didehydro compounds (IIIa—d), which were then converted to all-*trans* pigments (IVa—d) by partial hydrogenation and isomerization during purification under diffused light.

The structures and configurations of IVa—d were ascertained by analytical and spectral studies, as is shown in Tables 1 and 2. The facts that IVa—d exhibited the highest UV λ_{max}, with a wavelength 21—23 nm longer and with a higher intensity than those of the corresponding 15,15'-didehydro compounds (IIIa—d), and that IVa—d did not show any *cis*-peak in their UV spectra evidently suggest that IVa—d has the all-*trans* configuration.[4] This was also supported by the IR spectra of IVa—d, which showed a sharp singlet at 962—965 cm^{-1} due to CH out-of-plane deformation vibrations.[5]



When the highest λ_{max} of IVa—d were compared with those of the parent non-substituted compounds, isorenieratene[1b] [IV, R=2,3,6-$(CH_3)_3C_6H_2$-, λ_{max}, 466 nm (C_6H_6)] and renierapurpurin[1c] [IV, R=2,3,4-$(CH_3)_3C_6H_2$-, λ_{max}, 486 nm (C_6H_6)], the bathochromic effect of methoxy groups was observed only in IVa, in which the substituents are located at *para* positions to the polyene chain. The IVd and IVb pigments, which contain methoxy groups at positions *ortho* or *meta* to the chain respectively, absorbed at a wavelength location 3—4 nm lower than the corresponding parent compounds. This apparently shows that the chromophore systems of these pigments are more distorted than those of the corresponding parent compounds because of the steric interference between the polyene chain

a) Besides the methyl signals described here, the NMR spectra of IIIa—d showed a singlet at δ 5.75—5.76 ppm assignable to 14,14'-protons and a complex multiplet in the region of δ 6.10—7.00 ppm due to the other olefinic and aromatic protons, but the spectra of IVa—d exhibited only a complex multiplet in the δ 6.10—7.00 ppm region due to all olefinic and aromatic protons. b) Values in parenthesis show number of methyl groups. c) The signal was overlapped with that of C-13, 13'-methyls.

and the newly-introduced substituents or because of the increase in the steric effect of 5,5'-standing methyl groups by the buttressing effect of 4,4'-standing methoxy groups. However, the methoxy groups at positions *meta* to the chain in IVc caused no appreciable change in the absorption maximum.

Experimental

All the melting points are uncorrected. The UV spectra were taken with a Hitachi EPS-3T spectrometer. The IR spectra were recorded from KBr pellets, using a Hitachi 215 infrared spectrometer. The NMR spectra were measured with a Hitachi R-22 spectrometer at 90 MHz, using tetramethylsilane as the internal standard.

Preparations of Methoxytrimethylbenzyltriphenylphosphonium Bromides (Ia—d). These were prepared from the corresponding benzyl alcohols[6] according to the method described by Cooper *et al.*[7] Ia, colorless prisms, mp 225 °C. Found: C, 68.82; H, 6.18%. Calcd for $C_{29}H_{30}BrOP$: C, 68.91; H, 5.98%. Ib, colorless prisms, mp 240 °C. Found: C, 68.56; H, 6.08%. Ic, colorless prisms, mp 229—230 °C. Found: C, 68.79; H, 5.88%. Id, colorless prisms, mp 249 °C. Found: C, 68.92; H, 6.22%.

Preparations of 15,15'-Didehydro Compounds (IIIa—d). A typical example is as follows: to a stirred suspension of phosphonium bromide (Ia, 1.5 g) in absolute ether (30 ml), was added an ethereal solution of phenyllithium (*ca.* 1 M, 5 ml) over a 5 min period under an atmosphere of nitrogen. The mixture was then stirred for 1 hr at room temperature, and methylene chloride (0.3 ml) was added to decompose the excess of phenyllithium. After 10 min, a solution of didehydrocrocetindial (II, 250 mg) in methylene chloride (15 ml) was added, and the mixture was stirred under reflux for 5 hr. The mixture was then diluted with methanol (70 ml) and allowed to stand overnight in an ice-box. The precipitate was subsequently collected; several recrystallizations from a mixture of methylene chloride and ethanol gave IIIa (280 mg) as orange prisms. The yields, melting points, elemental analyses, and UV, IR, and NMR spectral data of IIIa—d are given in Tables 1 and 2.

Preparations of All-trans Carotenoids (IVa—d). A typical example is as follows: IIIa (30 mg) was dissolved in toluene (45 ml) and hydrogenated at 25 °C in the presence of the Lindlar catalyst[8] (65 mg) and quinoline (0.3 ml) until a 1.2-molar equivalent of hydrogen (1.4 ml) was consumed. The catalyst was filtered and washed with benzene. The combined filtrate was concentrated under reduced pressure, petroleum benzine (20 ml) was added to the residue, and the mixture was allowed to stand overnight in an ice-box. The crystallized product was collected, and several recrystallizations from a mixture of chloroform and ethanol gave IVa (17 mg) as purple crystals. The yields, melting points, elemental analyses, and UV, IR, and NMR spectral data of IVa—d are given in Tables 1 and 2.

The author wishes to express his deep gratitude to Professor Masaru Yamaguchi and Professor Tamotsu Yoshino of this department for their many helpful discussions and suggestions during this work.

Organic Photochemical Reactions. XXII.[1] The Photoaddition of Methyl Pyruvate to Methyl-substituted Olefins

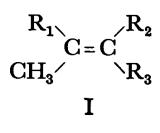
Kensuke SHIMA, Teruo KAWAMURA, and Koji TANABE

Department of Industrial Chemistry, Faculty of Engineering, Miyazaki University, Miyazaki 880

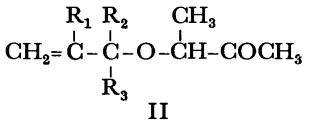
(Received January 21, 1974)

Synopsis. The irradiation of methyl pyruvate (III) and several methyl-substituted olefins (I) in acetonitrile gives allylic ethers (IV) as well as oxetanes (V) and alcohols (VI). Quenching studies suggest that IV and V are formed from the triplet state of methyl pyruvate, while VI is produced from the excited singlet state.

We have recently described a novel photoreaction in which biacetyl adds to methyl-substituted olefins, such as 2,3-dimethyl-2-butene (Ia), 2-methyl-2-butene (Ib), α-methylstyrene (Ic), and 2-ethoxypropene (Id), to afford allylic ethers (II).[2] We now find that the formation of allylic ethers is not confined to biacetyl, but is also applicable to methyl pyruvate (III), the simplest α-ketoester.[3]



I



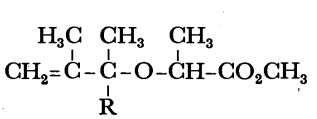
II

$CH_3COCO_2CH_3$

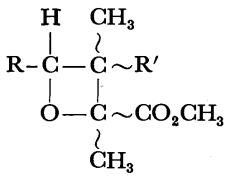
III

a, $R_1=R_2=R_3=CH_3$
b, $R_1=R_2=CH_3$, $R_3=H$
c, $R_1=C_6H_5$, $R_2=R_3=H$
d, $R_1=OC_2H_5$, $R_2=R_3=H$

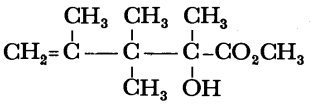
The irradiation of a solution of methyl pyruvate and 2,3-dimethyl-2-butene using a 300 W high-pressure mercury arc filtered through an *n*-hexane solution of naphthalene yielded IVa, VIa-1, and VIa-2. No detectable amounts of oxetanes were isolated in this photoreaction, as was the case with biacetyl and Ia. Furthermore, large amounts of alcohols (VIa-1 and VIa-2), the products expected from the hydrogen abstraction of Ia by excited III, were obtained. Similarly, the irradiation of methyl pyruvate and 2-methyl-2-butene gave IVb, Vb, and VIb. The major products from the irradiation of methyl pyruvate with α-methylstyrene and 2-ethoxypropene were the Vc and Vd oxetanes respectively. No detectable amounts of allylic ethers and alcohols were isolated in these reactions. These 1:1 adducts were isolated by preparative vpc and by distillation.



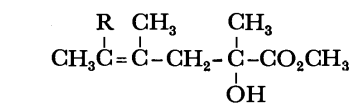
IVa, R=CH_3
IVb, R=H



Vb, R=R′=CH_3
Vc, R=H, R′=C_6H_5
Vd, R=H, R′=OC_2H_5



VIa-1



VIa-2, R=CH_3;
VIb, R=H

Table 1 shows the yields and ratios of oxetanes to allylic ethers for these reactions. The formation of IV and V is quenched by the presence of 1,3-cyclohexadiene or 2,3-dimethyl-1,3-butadiene. The Stern-Volmer plots are linear in benzene and acetonitrile.[4] On the other hand, the formation of VI is not quenched at all by large amounts of these triplet quenchers. From this observation, it is evident that VI is formed from an excited singlet state of methyl pyruvate. These results are very interesting because it has been reported that the rate of the hydrogen abstraction from an excited singlet carbonyl compound is slow.[5]

Table 1. Product yields in the photoreaction of III with Ia—Id

Olefin	Product yield, %			Ratio of V/IV
	IV	V	VI	
Ia	21	—	74	0 (0)
Ib	24	15	25	0.61 (0.41)
Ic	—	50, 27	—	(1.8)
Id	—	54, 46	—	(2.1)

Experimental

General. The NMR spectra were recorded on a Hitachi Perkin-Elmer R-20 or on a JEOL JNM-100 spectrometer in CCl_4. The infrared spectra were obtained on a JASCO IRA-1 infrared spectrophotometer. The mass spectra were obtained on a Hitachi Perkin-Elmer RMU-60 mass spectrometer. The vapor-phase chromatographic analyses were run on a Shimadzu gas chromatograph, GC-3BF or GC-2C.

The following materials were prepared by the previously-reported procedures: 2,3-dimethyl-2-butene (Ia),[6] 2-methyl-2-butene (Ib),[7] 2-ethoxypropene (Id),[8] methyl pyruvate (III),[9] 2,3-dimethyl-1,3-butadiene,[10] and 1,3-cyclohexadiene.[11]

Irradiation of Methyl Pyruvate (III) with 2,3-Dimethyl-2-butene (Ia). A solution of III (10.2 g) and Ia (8.4 g) in acetonitrile was irradiated for 120 hr using a 300 W high-pressure mercury arc filtered through an *n*-hexane solution of naphthalene under nitrogen at room temperature. Vpc (PEG 6000, 150 °C) showed the starting materials plus four products with a relative ratio of the peak areas of 21: 5: 29: 45. After the evaporation of the low-boiling fractions, a fraction boiling at 105—125 °C/30 mmHg (5.0 g) was collected; residues, 1.1 g. These products were separated by preparative vpc on a 3 m PEG 6000 column (140 °C).

The first component was identified as 1,1,2-trimethyl-2-propenyl 1′-carbomethoxyethyl ether (IVa): bp 82 °C/25

mmHg; *m/e* 186 (M^+), 171, 127, and 87 (base); IR 1755, 1640, and 1125 cm^{-1}; NMR δ 1.22 (3H, s), 1.25 (3H, d, $J=7$ Hz), 1.27 (3H, s), 1.73 (3H, s), 3.63 (3H, s), 3.80 (1H, q, $J=7$ Hz), and 4.89 (2H, m). Found: C, 64.19; H, 10.04%. Calcd for $C_{10}H_{18}O_3$: C, 64.49; H, 9.74%.

Due to its instability, the second component was neither isolated nor identified.

The third component was identified as methyl 2-hydroxy-2,3,3,4-tetramethyl-4-pentenoate (VIa—l): bp 101 °C/25 mmHg; *m/e* 186 (M^+), 168, 127, 104, and 43 (base); IR 3590, 1740, and 1640 cm^{-1}; NMR δ 1.14 (6H, s), 1.29 (3H, s), 1.76 (3H, s), 3.10 (1H, s, OH), 3.70 (3H, s), and 4.70—4.92 (2H, m). Found: C, 64.26; H, 9.58%. Calcd for $C_{10}H_{18}O_3$: C, 64.49; H, 9.74%.

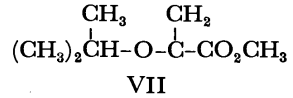
The fourth component was identified as methyl 2-hydroxy-2,4,5-trimethyl-4-hexenoate (VIa-2): bp 107 °C/22 mmHg; *m/e* 186 (M^+), 168, 127, 104, and 83 (base); IR 3530 and 1735 cm^{-1}; NMR δ 1.33 (3H, s), 1.64 (9H, s), 2.44 (2H, s), 2.99 (1H, s, OH), and 3.70 (3H, s). Found: C, 64.56; H, 9.72%. Calcd for $C_{10}H_{18}O_3$: C, 64.49; H, 9.74%.

Irradiation of Methyl Pyruvate (III) with 2-Methyl-2-butene (Ib). A mixture of III (10.2 g) and Ib (7.0 g) in acetonitrile was irradiated for 250 hr. After the removal of the unreacted materials, a fraction boiling at 83—99 °C/30 mmHg (7.6 g) was collected; residues, 4.0 g. Vpc analysis (PEG 6000, 120 °C) showed five products with a relative ratio of peak areas of 24: 27: 15: 25: 9. These products were separated by preparative vpc on a 3 m PEG 6000 column at 125 °C.

The first component was identified as 1,2-dimethyl-2-propenyl 1′-carbomethoxyethyl ether (IVb): bp 75 °C/19 mmHg; *m/e* 172; IR 1755, 1650, and 1120 cm^{-1}; NMR δ 1.20 (3H, d, $J=7$ Hz), 1.29 (3H, d, $J=7$ Hz), 1.70 (3H, s), 3.62 (3H, s), 3.85 (2H, q, $J=7$ Hz), and 4.60—4.88 (2H, m). Found: C, 62.67; H, 9.31%. Calcd for $C_9H_{16}O_3$: C, 62.76; H, 9.36%.

The second component proved to be an inseparable mixture of two products (areas, *ca.* 40: 60). The minor product was assumed to be VII from the NMR data of the hydrogenation product of this component. The structure of the major one has not yet been determined.

The third component was identified as 2,3,3,4-tetramethyl-2-carbomethoxyoxetane (Vb); bp 89 °C/23 mmHg; *m/e* 172; IR 1745 and 980 cm^{-1}; NMR δ 0.99 (3H, s), 1.12 (3H, s),



VII

1.16 (3H, d, $J=7$ Hz), 1.44 (3H, s), 3.67 (3H, s), and 4.34 (1H, q, $J=7$ Hz). Found: C, 62.60; H, 9.23%. Calcd for $C_9H_{16}O_3$: C, 62.76; H, 9.36%.

The fourth component was identified as VIb: bp 93 °C/20 mmHg; *m/e* 172; IR 3500 and 1735 cm^{-1}; NMR δ 1.32 (3H, s), 1.55—1.82 (6H, m), 2.16—2.46 (2H, m), 2.93 (1H, s, OH), 3.72 (3H, s), and 4.85—5.40 (1H, m). Found: C, 62.51; H, 9.34%. Calcd for $C_9H_{16}O_3$: C, 62.76; H, 9.36%.

The fifth component is an alcohol, but its exact structure remains undetermined.

Irradiation of Methyl Pyruvate (III) with α-Methylstyrene (Ic). After a 120 hr irradiation of a mixture of III (10.2 g) and Ic (23.6 g) in acetonitrile, a fraction boiling at 112—115 °C/4 mmHg (1.9 g) was obtained; residues, 0.9 g. The products were analyzed and separated by vpc using a 3 m Silicone DC 550 column at 190 °C. The relative ratio of the peak areas of the two major peaks was 27: 50.

The first component was identified as 2,*t*-3-dimethyl-2-carbomethoxy-3-phenyloxetane (Vc-1): bp 104 °C/4 mmHg; *m/e* 220; IR 1745 and 990 cm^{-1}; NMR δ 1.61 (3H, s), 1.64 (3H, s), 3.15 (3H, s), 4.20 (1H, d, $J=5$ Hz), 5.23 (1H, d, $J=5$ Hz), and 6.90—7.40 (5H, m). Found: C, 70.61; H, 7.50%. Calcd for $C_{13}H_{16}O_3$: C, 70.89; H, 7.32%.

The second component was identified as 2,*c*-3-dimethyl-2-carbomethoxy-3-phenyloxetane (Vc-2): mp 68.5—69 °C; IR 1750 and 982 cm^{-1}; NMR δ 1.27 (3H, s), 1.57 (3H, s), 3.83 (3H, s), 4.20 (1H, d, $J=5$ Hz), 4.96 (1H, d, $J=5$ Hz), and 7.05—7.35 (5H, m). Found: C, 70.65; H, 7.35%. Calcd for $C_{13}H_{16}O_3$: C, 70.89; H, 7.32%.

Irradiation of Methyl Pyruvate (III) with 2-Ethoxypropene (Id). A solution of III (10.2 g) and Id (8.6 g) in acetonitrile was irradiated for 300 hr. After the removal of the unreacted materials, a fraction boiling at 98—123 °C/15 mmHg (3.1 g) was collected; residue, 1.8 g. The vpc analysis (DNP, 3 m, 150 °C) of the distillate showed one major peak. The product, isolated by preparative vpc, was identified as a mixture of 2,*t*-3- and 2,*c*-3-dimethyl-2-carbomethoxy-3-ethoxyoxetane (Vd-1 and Vd-2) from the NMR spectra (ratios, *ca.* 6: 5): bp 103 °C/18 mmHg; NMR, Vd-1 δ 1.22 (3H, t, $J=7$ Hz), 1.41 (3H, s), 1.50 (3H, s), 3.46 (2H, q, $J=7$ Hz), 3.68 (3H, s), 4.07 (1H, d, $J=6$ Hz), and 4.36 (1H, d, $J=6$ Hz); Vd-2 δ 1.10 (3H, t, $J=7$ Hz), 1.46 (3H, s), 1.58 (3H, s), 3.37 (2H, q, $J=7$ Hz), 3.68 (3H, s), 4.07 (1H, d, $J=6$ Hz), and 4.62 (1H, d, $J=6$ Hz). Found: C, 57.19; H, 8.66%. Calcd for $C_9H_{16}O_4$: C, 57.43; H, 8.57%.

Functionalization of *trans*-Decalin. I. Synthesis of 1-Oxo-*trans*-decalin-4a, 6-carbolactone

Sigeru TORII, Tsuyosi KUNITOMI, and Tsutomu OKAMOTO

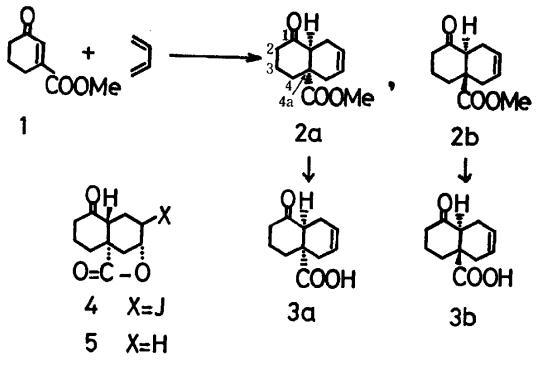
Department of Industrial Chemistry, School of Engineering, Okayama University, Okayama 700

(Received February 25, 1974)

Synopsis. The synthesis of 4a-carbomethoxy-*cis*- and *trans*-Δ^6-octalin-1-ones (**2a** and **2b**), 4a-carboxy-*trans*-Δ^6-octalin-1-one (**3b**), and 1-oxo-*trans*-decalin-4a,6-carbolactone (**5**) from the adduct of 3-carbomethoxy-2-cyclohexen-1-one with butadiene was described.

Although the combinations of some alicyclic β-methyl-α,β-unsaturated ketones with butadienes were unsuccessful,[1] alicyclic β-carbomethoxy-α,β-unsaturated ketone such as 3-carbomethoxy-2-cyclohexen-1-one (**1**) was found to be a reactive dienophile. A similar reaction has been observed in the β-carboxy-α-butenolide system.[2] Thus, the cycloaddition of **1** with butadiene was investigated as a means of preparing functionalized *trans*-decalins (**4** and **5**), which would provide a synthetic intermediate for the preparation of sesquiterpenoids. The starting compound (**1**)[3] was prepared from readily available 1-carbomethoxycyclohexene[4] by oxidation with selenium dioxide[3] followed by treatment with the Jones reagent[5] in dichloromethane.

The Diels-Alder reaction of **1** with butadiene at 130—140 °C in a sealed tube exclusively afforded the *cis* adduct (**2a**) in 55% yield. However, when the reaction was carried out above 155 °C, a mixture of *cis*- and *trans*-adducts (**2a** and **2b**) was obtained in a *ca.* 3:1 ratio. Hydrolysis of **2a** with a wet ethanolic potassium hydroxide solution gave the corresponding acids (**3a** and **3b**) in a 1:4 ratio. Separation of the *trans* isomer (**3b**), a white crystals, mp 138 °C, was performed by column chromatography on silica gel, followed by recrystallization from water. Reaction of **3b** with diazomethane provided a pure specimen of **2b**. During the course of recrystallization from hot water, isomerization of the *cis* isomer (**3a**) into **3b** took place. The structures of **2a** and **2b** were comfirmed by means of elemental analyses and spectral data. Their NMR spectra showed differences such as a three-proton singlet at δ 3.58 (*trans* isomer) and 3.65 (*cis* isomer), both due to the methyl ester protons, and also a two-proton broad singlet at δ 5.50 (*cis* isomer) and 5.58 (*trans* isomer).



Iodolactonization[6] of **3b** gave a lactone iodide (**4**) in 95% yield, mp 119 °C. Reduction of **4** with tri-*n*-butyltin hydride[7] afforded a keto lactone (**5**) in 80% yield, mp 104 °C. The structures of **4** and **5** were confirmed by their elemental analyses and spectral data. Characteristic carbonyl bands of **4** were seen at 1770 (iodolactone carbonyl) and 1708 (ketone carbonyl) cm^{-1}, whereas those of **5** appeared at 1762 (lactone carbonyl) and 1715 (ketone carbonyl) cm^{-1}, indicating that both decalin-1-ones have a γ-lactone function.

Experimental

All the melting points are uncorrected. The IR spectra were recorded on a Hitachi EPI-S2 spectrophotometer. The NMR spectra were observed with Hitachi R-24 and/or R-22 spectrometers. Mass spectral analyses were carried out on a Hitachi RMS-4 mass spectrometer, ionizing at the order of 70 eV.

3-Carbomethoxy-2-cyclohexen-1-one (1). A mixture of 3.33 g (30 mmol) of selenium dioxide and 3.50 g (25 mmol) of 1-carbomethoxy-1-cyclohexene[4] in 35 ml of dioxane was stirred at 70—80 °C for 18—20 hr and at 90 °C for 3 hr. The precipitate was filtered and washed with 20 ml of dichloromethane. The combined filtrates were concentrated in a rotary evaporator. The residue, a reddish-brown viscous oil, was taken up in ether–*n*-hexane (4:1). The mixture was stirred for some minutes, after which the organic layer was separated. Removal of the solvent gave crude 3-carbomethoxy-2-cyclohexen-1-ol. Without further purification, a solution of the crude alcohol in 50 ml of dichloromethane was treated with 12 ml of a chromic acid solution[5b] with vigorous stirring for 25 min under nitrogen atmosphere at 0 °C. After being left to stand for a few minutes, the organic layer was separated. The aqueous layer was washed with 30 ml of dichloromethane. The combined extracts were washed with water and dried (Na_2SO_4). The solvent was concentrated and the residue was taken up in ether and the insoluble material was filtered off. The filtrate was concentrated in a rotary evaporator to afford a brown oil. The crude oil was purified by column chromatography on silica gel with *n*-hexane–dichloromethane (2:1), which eluted 0.89 g (23%) of **1**; bp 126—128 °C/8 mmHg; IR (Neat) 1725 (ester C=O), 1685 (conj. ketone), 1628 (C=C) cm^{-1}; NMR (CCl_4) δ 1.97—2.71 (m, 6H, CH_2), 3.78 (s, 3H, CH_3O), 6.59 (m, 1H, HC=C). Found: C, 62.24; H, 6.53%. Calcd for $C_8H_{10}O_3$: C, 62.33; H, 6.54%.

4a-Carbomethoxy-cis-Δ^6-octalin-1-one (2a). A mixture of 462 mg (3.0 mmol) of 3-carbomethoxy-2-cyclohexenone (**1**), 1 mg of 2,5-di-*tert*-butylhydroquinone, and 1.35 ml of butadiene in 1 ml of benzene was charged in a sealed tube. The tube was allowed to stand in an oil bath at 130—140 °C for 3 day. The mixture was then poured into 15 ml of methanol. The precipitate was filtered and washed with methanol. The combined filtrates were concentrated in a rotary evaporator. The residue was purified by chromatography on a

silica gel column with dichloromethane-*n*-hexane (1:3), which eluted 343 mg (54.9%) of **2a**, mp 78.0—78.5 °C, bp 111—114 °C/1 mmHg; IR (Neat) 1725 (ester C=O), 1715 (ketone C=O) cm^{-1}; NMR ($CDCl_3$) δ 1.83—2.46 (m, 10H, CH_2), 3.00 (broad, d, 1H, CHC=O), 3.65 (s, 3H, CH_3O), 5.50 (broad s, 2H, HC=C); MS (*m/e*) 208 (M^+). Found: C, 69.20; H, 7.72%. Calcd for $C_{12}H_{16}O_3$: C, 69.21; H, 7.74%.

A mixture of *cis*- and *trans*-adducts (**2a** and **2b**) (3:1) was obtained when the sealed tube was heated above 155 °C for 3 day.

4a-Carboxy-trans-Δ^6-*octalin-1-one (3b)*. To a stirred solution of 112 mg (2.0 mmol) of potassium hydroxide in 1 ml of water was added a solution of 250 mg (1.2 mmol) of **2a** in 2 ml of ethanol. After stirring at room temperature for 15—20 hr, the solution was heated at 60 °C for 2 hr and then concentrated. The residual solution was acidified with 10% aqueous hydrogen chloride and extracted with chloroform. The extracts were washed with brine and dried (Na_2SO_4). Removal of the solvent gave 210 mg of crude acids (**3a** and **3b**) (*ca.* 1:4). The crude product was chromatographed over silica gel (Wako Gel C-200). Elution of the column with dichloromethane gave 80 mg of a mixture of **3a** and **3b** (*ca.* 1:1) as an oil. The following elution with dichloromethane-ethyl acetate (4:1) gave 110 mg (48% yield) of **3b** as a white crystals, mp 138.0 °C (from water); IR (Nujol) 3400—2500 (COOH), 1723 (C=O), 1682 (COOH) cm^{-1}; NMR ($CDCl_3$) δ 1.55—2.53 (m, 10H, CH_2), 2.66 (m, 1H, CHC=O), 5.69 (broad s, 2H, CH=C), 10.93 (s, 1H, COOH). Found: C, 68.20; H, 7.40%. Calcd for $C_{11}H_{14}O_3$: C, 68.02; H, 7.27%.

4a-Carbomethoxy-trans-Δ^6-*octalin-1-one (2b)*. Mp 71.5—73.0 °C, bp 83—86 °C/0.02 mmHg, obtained by treatment of **3b** with diazomethane: IR (Nujol) 1724 (ester C=O), 1712 (ketone C=O) cm^{-1}; NMR ($CDCl_3$) δ 1.67—2.67 (m, 10H, CH_2), 2.83 (m, 1H, CHC=O), 3.58 (s, 3H, CH_3O), 5.58 (broad s, 2H, HC=C). Found: C, 69.38; H, 7.89%. Calcd for $C_{12}H_{16}O_3$: C, 69.21; H, 7.74%.

1-Oxo-trans-*decalin-4a,6-carbolactone (5)*. To a stirred solution of 160 mg (0.82 mmol) of **3b** in 5 ml of 0.5 M aqueous sodium bicarbonate was added a mixture of 317 mg (1.25 mmol) of iodine and 1.33 g (8.0 mmol) of potassium iodide in 3 ml of water for 5 min under cooling in an ice-water bath. The flask was covered with a black napkin and stirring was continued for 24 hr at room temperature. The reaction mixture was extracted with ether. The extracts were washed with aqueous sodium thiosulfate and saturated aqueous sodium carbonate and dried (Na_2SO_4). Removal of the solvent gave 250 mg (95%) of the iodolactone (**4**), mp 119 °C, as a white crystal (from *n*-hexane-benzene, 2:3): IR (Nujol) 1770 (lactone C=O), 1708 (C=O) cm^{-1}; NMR ($CDCl_3$) δ 1.74—3.04 (m, 11H), 4.47—4.88 (m, 2H, HCI, HC–O). Found: C, 41.42; H, 4.15%. Calcd for $C_{11}H_{13}O_3I$: C, 41.27; H, 4.09%.

To a solution of 250 mg of **4** in 5 ml of dry benzene was added 450 mg (1.55 mmol) of tri-*n*-butyltin hydride dropwise with stirring for 5 min at 5 °C under nitrogen atmosphere. Stirring was continued for 48 hr at room temperature and the solvent was removed in a rotary evaporator to afford 128 mg (80% yield) of **5**, a columnar crystals, mp 104 °C (from benzene-*n*-hexane, 3:2): IR (Nujol) 1762 (γ-lactone C=O), 1710 (C=O) cm^{-1}; NMR ($CDCl_3$) δ 1.68—2.43 (m, 13H, CH_2, CH), 4.73 (t, 1H, HC–O); MS (*m/e*) 194 (M^+). Found: C, 68.25; H, 7.25%. Calcd for $C_{11}H_{14}O_3$: C, 68.02; H, 7.27%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 47 (9), 2351—2352 (1974)

The Diazo-coupling Reaction of Phenol in Organic Solvents. The Isomer Ratio

Hideo YAMADA, Yōji HASHIDA, Shizen SEKIGUCHI, and Kohji MATSUI

Department of Synthetic Chemistry, Faculty of Engineering, Gunma University, Tenjincho, Kiryu, Gunma 376

(Received March 11, 1974)

Synopsis. The *ortho*: *para*-ratios in the reaction of phenol with benzenediazonium fluoroborate have been investigated in organic solvents. It has been found that the *o*/*p* ratios in protic solvents were smaller than those in aprotic solvents. The results were interpreted in terms of the difference in solvation toward the phenolate ion.

In diazo-coupling reactions, it is known[1] that the ratio of the isomers depends upon various factors, such as the structures of the diazo and coupling components, the pH values of the media, the reaction temperatures, and the catalysts. In a previous paper,[2] we reported that the rate of the reaction of 2-naphthol with benzene diazonium salt was markedly affected by the solvent. Thus, in the diazo-coupling reaction of phenol, the isomer ratio can be expected also to be influenced by the solvents, as has been reported for the other aromatic electrophilic substitutions.[3,4] However, the effect of solvents on the isomer ratios has not been studied systematically in connection with this reaction. This paper will report the *ortho*: *para*-ratios for the diazo-coupling reactions of phenol with benzenediazonium salt in organic media.

Experimental

Materials. Commercial phenol and triethylamine were purified by distillation prior to use. The benzenediazonium fluoroborate was prepared by the usual method and were dried over phosphorus pentoxide.

Solvents. The solvents used were purified by the usual methods.[5]

Syntheses of Azo-compounds. The *p*-hydroxyazobenzene,[6] *o*-hydroxyazobenzene,[6] and 2,4-bis(phenylazo)phenol[7] were prepared by the usual procedure. Their purities were checked by observing their melting points, by elemental analyses, and by thin-layer chromatography. The optical properties of these azo-compounds are shown in Table 1.

TABLE 1. OPTICAL PROPERTIES OF AZO-COMPOUNDS

Azo-compound	Mp (°C)	λ_{max}(nm)	ε[a]
2-Hydroxyazobenzene	83—83.5	322	19100
4-Hydroxyazobenzene	154—155	346	25300
2,4-Bis(phenylzao)phenol	130—131	335	44700

a) In methanol.

Measurements of the Product Distributions. The product distributions were measured spectrophotometrically by the method described below. To 100 ml of a solution of phenol (0.471 g, 5×10^{-3} M) and triethylamine (1.52 g, 1.5×10^{-2} M) in an appropriate solvent, we added finely-powdered benzenediazonium fluoroborate (0.960 g, 5×10^{-3} M) at 0 °C. The reaction mixture was stirred for a few hours after the diazonium salt had been dissolved, and the reaction mixture was concentrated; then the azo-compounds thus produced were separated by silica gel thin-layer chromatography, using a mixture of *n*-hexane and acetone (20: 1, v/v) as the developing solvent. From the thin-layer chromatogram each azo-compound was extracted and diluted to a definite volume with methanol; its extinction was measured spectrophotometrically.

Results and Discussion

As has been reported[6] for the coupling reaction in water, phenol gave *o*-, *p*-, and 2,4-di-substituted[8] products even in the reactions in organic solvents. The product distributions in various solvents are given in Table 2.

TABLE 2. PRODUCT DISTRIBUTIONS FOR THE REACTION OF PHENOL WITH BENZENEDIAZONIUM FLUOROBORATE (0 °C)

No.	Solvent	(Molar comp. of) product (%)			
		o-	*p*-	2,4-di-	$o/p\times100$
1	Water	0.7	99.1	0.2	0.7
2	Methanol	1.2	97.5	1.3	1.2
3	Methanol[a]	1.4	98.3	0.3	1.4
4	2-Propanol	1.6	98.4	—[b]	1.7
5	Phenol	3.2	96.8	—[b]	3.3
6	*t*-Butanol	4.3	89.9	5.8	4.8
7	Acetone	3.2	93.1	3.6	3.5
8	Tetrahydrofuran	3.6	96.3	—[b]	3.8
9	Acetonitrile	3.8	91.5	4.7	4.2
10	Dimethylsulfoxide[c]	4.6	90.7	4.7	5.0
11	Nitromethane	4.7	93.1	2.2	5.0
12	Dioxane	5.2	93.2	1.6	5.6
13	Dimethylformamide	6.5	88.7	4.8	7.3
14	Pyridine	6.7	86.7	6.6	7.7

a) Pyridine was used as a base (see Experimental Section). b) The product ratio could not be measured by the method of T.L.C., because of the formation of unknown by-product. c) At 20 °C.

In diazo-coupling reactions, many examples are known[1] in which the isomer ratio depends upon the base used and upon its concentration. To examine the effect of bases on isomer ratios, the reaction was carried out in methanol in the presence of triethylamine and/or pyridine; however, these bases scarcely affected the *o*/*p* ratio at all (No. 2, 3).

As can be seen from Table 2, the solvents do have significant effects on the isomer ratio, even though every value of the *o*/*p* ratio is small: in pyridine and DMF, the yields of the *o*-isomer were greater than that in water by a factor of about ten. The solvents employed can be divided into two groups: the protic (No. 1—6)

and aprotic solvents (No. 7—14).

In the protic solvents, the *o*/*p* ratios were small; however, within a series of protic solvents with similar structures, the yield of the *o*-isomer increased with a decrease in the solvent polarity in this order: H_2O< MeOH<*i*-PrOH<*t*-BuOH.

On the contrary, in the aprotic solvents there was no significant correlation between the *o*/*p* ratio and the solvent polarity. However, as a whole, in the aprotic solvents higher yields of the *ortho*-substituted derivatives were obtained than in the protic solvents.

In the ordinary electrophilic substitutions of monosubstituted benzenes, many factors have been suggested[9] as affecting the *o*/*p* ratio; however, little is known about the effect of solvents on the isomer distribution. Therefore, it was of interest to consider the solvent effect on the isomer ratio in this reaction.

One of the most important factors of the solvent effect in this reaction is considered to be the influence on the reactivities of the reaction components by solvation. According to the selectivity relationship,[10] the difference in yields between *ortho*- and *para*-products is also assumed to increase as the reactivity of the reagent decreases;[11,12] this concept is consistent with the results described above. It was pointed out in a previous work[2] that, in the diazo-coupling reaction of 2-naphthol, the reactive species of the substrate is the naphtholate ion, even in organic solvents, and that the reaction is remarkably enhanced in dipolar aprotic solvents, presumably because of the decrease in the solvation of the naphtholate ion in these solvents.[2] A similar relation between the reactivities of the substrates and the kind of solvent is considered to hold for the reaction of phenol; therefore, the coupling reaction of benzenediazonium salt with phenol is considered to proceed more rapidly in dipolar aprotic solvents than in protic solvents. Therefore, the finding that, in this reaction, relatively high *o*/*p* ratios were obtained in the aprotic solvents is quite reasonable. Furthermore, the tendency for, in protic solvents, the *o*/*p* ratio to increase with a decrease in the solvent polarity may be ascribed to a decrease in solvation in the less polar solvent, which thus increases the reactivity of the phenolate ion. Thus, the increased reactivity of the phenolate ion leads to a decrease in selectivity.

On the other hand, it is also known[10] that the *o*/*p* ratio of the aromatic electrophilic substitution is governed by the steric effect of the substituents of the substrates. The change in the *o*/*p* ratio described above may be also explained by assuming that the steric effect of the $-O^-$ group varies with the solvents, as has been pointed out by several authors.[4,13] For example, the total bulkiness of the $-O^-$ group may be larger in protic solvents than in aprotic solvents, for the $-O^-$ group is considered to be strongly solvated in protic solvents by means of the general hydrogen-bonding. The bound solvent molecules would interfere with the *ortho*-substitution.

Either of the two concepts may explain our results satisfactorily, but it is difficult to conclude at present which of the effects plays the leading role; the isomer ratios are probably affected by the combined action of both the effects.

The Isomerization of Purine Nucleosides in a Dilute Alkaline Solution

Yoshihisa SUZUKI and Setsuko YATABE

Central Research Laboratories, Ajinomoto Co., Inc., Suzuki-cho, Kawasaki 210

(Received January 24, 1974)

A further study of the isomerization of inosine (**1a**) in a dilute alkaline solution has revealed the formation of α-pyranosyl isomer (**4a**) and its β-isomer (**3a**). Adenosine (**1b**) was isomerized at 130 °C for 12 hr at pH 10, giving α-furanosyl (**2b**) (2% yield), β-pyranosyl (**3b**) (11%), and the α-pyranosyl isomer (**4b**) (0.8%), respectively; 65% of the **1b** also remained. 9-β-D-Ribopyranosyl-6-mercaptopurine (**3c**) was prepared through this reaction from the corresponding β-furanoside (**1c**). Arabinosyl or xylosyl purine nucleosides were also isomerized, whereas neither 2′-deoxy nor 2′-substituted nucleoside showed any clear evidence of isomerization. In conclusion, the purine base and the 2′-hydroxyl anion are essential to the alkaline isomerization of nucleosides. By means of NMR, both **4a** and **4b** were found to have a 1C conformation, while **3a** and **3b** have a C1 conformation.

The isomerization of inosine (**1a**) in a dilute alkaline solution (pH 10), giving 9-β-D-ribopyranosyl hypoxanthine (**3a**), has been reported in the preceding paper.[1] This paper will describe the isolation of 9-α-D-ribopyranosyl hypoxanthine (**4a**) from the same mixture as that described in the preceding paper, and will further describe the isomerization of adenosine (**1b**) and other purine nucleosides under the standard conditions at 130 °C for 6 hr at pH 10 (Chart 1).

The action of alkali on some purine nucleosides was examined by Jones *et al.*[2] in 1 M NaOH at 100 °C for 1 hr; they found that **1a** was extremely stable under their conditions and that **1b** gave two degraded compounds (adenine and 4,5,6-triaminopyrimidine) and one deaminated nucleoside, **1a**. Garret and Mehta[3] examined the solvolysis of adenine nucleosides in 0.05—1.0 M NaOH at 60—80 °C and obtained similar products. Neither of these groups, however, found any isomerization. On the basis of what we found, it does not occur under their conditions (pH values over 13 and temperatures below 100 °C); a more diluted alkali and a temperature higher than 100 °C are essential for isomerization.

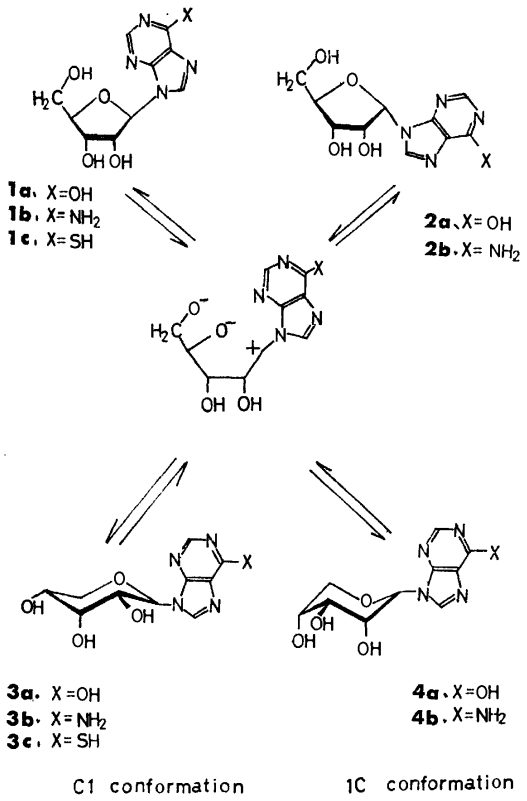

Chart 1.

The action of alkali on pyrimidine nucleosides was examined by Jones *et al.*[4] under the same conditions as with purine nucleosides; they found that thymidine is quite stable, that some amounts of urea and ammonia are formed from uridine, and that a considerable degree of deamination takes place for cytidine. These pyrimidine nucleosides did not show any clear evidence of isomerization even under the conditions where the isomerization of purine nucleosides takes place. On the other hand, an isomerization of an abnormal pyrimidine nucleoside, pseudouridine, was found in acid and in alkali by Chambers *et al.*[5]

Although both α- and β-pyranosyl anomers of pseudouridine were illustrated in the C1 form by Thomasz *et al.*,[6] the α-pyranosyl anomers of adenosine (**4b**) and **4a** were found to be in the 1C conformation, and their β-pyranosyl anomers, to be in the C1 form.

These alkaline isomerizations will be useful for the synthesis of various analogs of nucleic acid components.

Results and Discussion

Identification of 4a. Under the standard conditions, **1a** was treated in a KOH aqueous solution. The reaction mixture was fractionated by use of a column of Diaion SK1B-S, as is illustrated in Fig. 1. The I-1 and I-2 fractions are assignable to **3a** and **1a** respectively on the basis of our previous study.[1]

The I-4 fraction was found by means of tlc to be a mixture of hypoxanthine and 5-amino-1-β-D-ribofuranosyl-4-imidazolecarboxamide (AICA-riboside); this is consistent with our previous results. The new fraction, I-3, which was not clearly detected in the previous experiments,[1] was found to be a mixture of two other components: hypoxanthine and another compound which is similar to **1a** in its behavior in tlc and UV spectroscopy. The former is suspected to be a degraded product of the latter in the isolation procedure. The latter reacts with the orcinol reagent; therefore, its ribose moiety is intact. This compound was separated from hypoxanthine by means of the acetylation of the ribose moiety, followed by the extraction of the acetylated compound with dichlormethane and then deacetylation.

Table 1. The analytical data on the four isomers of 9-ribosyl adenine

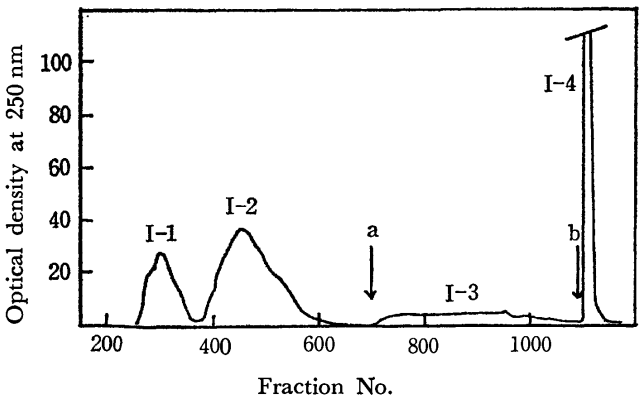

Fig. 1. The elution of UV-absorbing compounds contained in alkaline-treated inosine from the Diaion SK1B-S column with water followed 0.1 M NH_4Cl(a) and 0.1 M NH_4OH(b).
I-1 : 9-β-D-Ribopyranosyl hypoxanthine (**3a**).
I-2 : Inosine (**1a**).
I-3 : 9-α-D-Ribopyranosyl hypoxanthine (**4a**) and hypoxanthine.
I-4 : AICA-riboside and hypoxanthine.

The compound now in question has been found to be **4a** in the following way: On the thin-layer plate this compound gave a spot between those of **1a** and **3a**. On paper chromatography (PC), the acid hydrolysate gave one UV-absorbing spot (the R_f value agreed with that of authentic hypoxanthine), and also one positive spot with a periodate reagent (the R_f value agreed with that of authentic D-ribose). The UV spectrum was similar to that of **1a**, and after acid hydrolysis it came into accord with that of authentic hypoxanthine. These facts suggested that the compound was 9-α-D-ribosyl hypoxanthine. The optical rotation in water was −50°. Martinez *et al.*[7] reported the amounts of the optical rotation of four isomers of arabinosyl adenine. By comparison with their data, this compound was assumed to be α-pyranoside rather than α-furanoside because the latter is expected to have an opposite sign or at least a levorotatory value smaller than the −50° actually observed. The measurements of the NMR spectra supported this assumption. When the compound is acetylated, the signals in CD_3OD display the acetylation shifts for H-2′, 3′, and 4′. This fact means that three hydroxyl groups are attached, at C-2′, 3′, and 4′ respectively, and that the ribose ring has a pyranosyl structure. Signals appeared at 4.01 δ (J_{AB}=14 Hz, J_{AX}=2 Hz) and 4.28 δ (J_{AB}=14 Hz, J_{BX}=2 Hz), indicating that two protons of H-5′ and one proton of H-4′ are in the *gauche* relation around the C-4′—C-5′ bond. Thus, the pyranose ring was determined to have the 1C conformation. The small value of $J_{1'2'}$ (0—1 Hz) also explains well that the compound is the α-pyranoside in the 1C conformation.[8]

Thus, α-pyranoside of inosine has been found in the reaction mixture; therefore, the concomitant formation of α-furanoside is considered to be probable. However, this was not satisfactorily detected by the column chromatography. Presumably the amount is too small to be detected.

Identification of Four Isomers of Adenosine. **1b** was treated at 130 °C for 12 hr in a KOH aqueous solution whose pH was kept at 9—10. The reaction mixture gave three major spots on the thin-layer plate, as has been reported before.[1] They were suspected to be adenine, unreacted **1b**, and the β-pyranosyl isomer (**3b**) on the basis of the known results in the case of inosine. The reaction products were fractionated by a column of Dowex-1 with an eluting reagent of 25% methanol (Fig. 2). Four fractions were obtained, but adenine was not eluted from the column. Each of the four compounds from the four fractions were confirmed to be adenine nucleosides through some analytical tests such as orcinol reaction, UV spectrometry, and acid hydrolysis. The results of the individual identifications are summarized in Table 1 in comparison with the known data in the literature. In spite of a lack of available data on **4b** in the literature, the optical rotation datum of A-1 made it reasonable to identify it as **4b**, in comparison with the data on 9-D-arabinopyranosyl adenine.[1,7]

The conformations of the pyranosyl anomers (**3b** and **4b**) were determined on the basis of the chemical

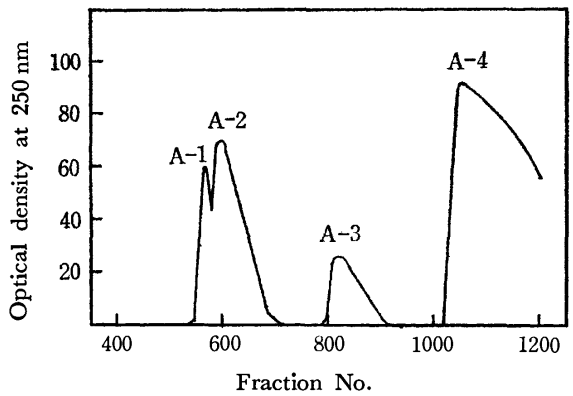

Fig. 2. The elution of UV-absorbing compounds contained in alkaline-treated adenosine from theD owex-1 column with 25% methanol.
A-1 : 9-α-D-Ribopyranosyl adenine (**4b**).
A-2 : 9-β-D-Ribopyranosyl adenine (**3b**).
A-3 : 9-α-D-Ribofuranosyl adenine (**2b**).
A-4 : 9-β-D-Ribofuranosyl adenine (adenosine, **1b**).

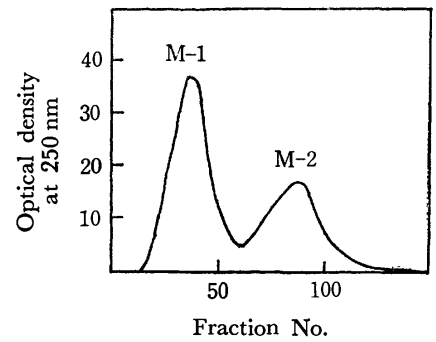

Fig. 3. The elution of UV-absorbing compounds contained in alkaline-treated 9-β-D-ribofuranosyl-6-mercaptopurine from the Dowex-50 W column with water.
M-1 : 9-β-D-ribopyranosyl-6-mercaptopurine (**3c**).
M-2 : 9-β-D-ribofuranosyl-6-mercaptopurine (**1c**).

shifts in the NMR spectra in DMSO-d_6. An NMR signal of **3b** attributable to the anomeric proton appears at 5.74 δ, and the coupling constant, $J_{1'2'}$, is found to be 8—9 Hz. Since such a large coupling constant could only be expected for an axial-axial interaction between the protons on C-1′ and C-2′, **3b** was unambigously identified as β-ribopyranoside in the C1 conformation as was determined by Pan *et al.*[12] On the other hand, the 1C conformation of **4b** was corroborated on the basis of the signals of two protons for H-5′ after acetylation. The H-5′ and H-4′ protons appear as ABX-type signals at 4.04 δ (J_{AB}= 14 Hz, J_{AX}=2 Hz) and 4.38 δ (J_{AB}=14 Hz, J_{BX}= 2 Hz).

Isolation of ***1a*** *from Alkaline-treated* ***3a***. The isomerization of **3a** to give **1a** was confirmed. The reaction mixture which was obtained by heating **3a** at 150 °C for 6 hr at pH 10 was subjected to column chromatography on a Dowex-50W column. Subsequent elution with 0.001 M NH_4Cl gave two UV-absorbing fractions; the first one is considered to be the unreacted starting material, and the second, **1a**. The crystals obtained from the latter fraction were identified as **1a** on the basis of the R_f value on the tlc and the X-ray diffraction pattern of its anhydrous α-crystal form.[13]

*Preparation of 9-β-D-Ribopyranosyl-6-mercaptopurine (**3c**).* **3c** was obtained through the isomerization of **1c**. The products were fractionated by column chromatography on a Dowex-50W column (Fig. 3). The two UV-absorbing fractions (M-1 and M-2) were obtained upon elution with water. The first was assigned to **3c**, and the second, to the original **1c**, on the basis of an analogy with the fractionation of alkaline-treated inosine. The mobilities of these two fractions on tlc supported these assignments. It is empirically established that the β-pyranosyl isomer shows a little less mobility than that of the corresponding β-furanosyl one on tlc and PC in the *n*-butanol–acetic acid–water (4 : 1 : 1) solvent system. From the M-1 fraction, needle crystals were obtained. The UV spectrum of this compound was found to be similar to that of **1c**. The results of elementary analysis and mass spectrometry after trimethylsililation were consistent with what would be expected for **3c**. An NMR signal of **3c** attributable to the anomeric proton appears at 5.62 δ, with a large coupling constant, $J_{1'2'}$, of 9 Hz; this can be explained unambigously by the fact that **3c** is β-pyranoside in the C1 conformation.

Alkaline Treatment of Various Nucleosides. Tables 2 and 3 summarize the reaction products of various nucleosides with alkali. All the reaction mixtures of adenosine, guanosine, and xantosine gave three major UV-absorbing spots on the chromatograms corresponding to the base, β-pyranoside, and unreacted β-furanoside. Usually too few of the α-isomers of these nucleosides were produced for their spots to be given clearly on the chromatograms.

1a and **1c** exhibit more complicated reactions. They are cloven at C-2 of the purine ring, giving 5-amino-4-imidazolecarboxamide (AICA) derivatives as has been reported in the previous paper. The AICA derivatives are detectable by means of the NBDF-reagent,[1] giving a purple-red color on the chromatogram. Isomerization was observed in competition with these degrading reactions. The substitution also took place in the case of **1c**, giving **1a**.

9-β-D-Arabinofuranosyl adenine and 9-β-D-xylofuranosyl hypoxanthine are also considered to isomerize in alkali in a way similar to that of purine ribonucleosides on the basis of the presence of a characteristic UV-absorbing spot located a little lower than that of the original furanoside on the chromatogram. A change in the sugar moiety from ribose to arabinose or from ribose to xylose of the purine nucleoside does not exert any significant effect on the isomerization.

However, the substitution of the sugar 2′-hydroxyl group serves to prevent the isomerization. 2′-*O*-Methyladenosine gave only adenine and no other UV-absorbing products under the same conditions as when adenosine gives its β-pyranoside. 2′-Deoxyinosine is hydrolyzed completely and gives a large amount of hypoxanthine and a small amount of a NBDF-reagent-positive compound. The latter is considered to be AICA-2′-deoxy-riboside from the fact that λ_{max} in 0.1

a) Treated in aq. KOH (pH 10) at 130 °C for 6 hr except uridine (12 hr), thymidine (13 hr), AICA-riboside (42 hr) and Ip-inosine (additional 11 hr at 160 °C at pH 10.5). b) UV-absorbing spots on tlc. Solvent system, *n*-butanol–acetic acid–water (4 : 1 : 1). c) See experimental section. d) Starting material remained. e) 2',3'-isopropylidene. f) Purple-red color development was observed with NBDF reagent.

M NaOH (267.5 nm) is similar to that of AICA-riboside (268 nm) and unlike that of AICA (278.5 nm) and from the fact that the presence of deoxysugar was proved by the method of Buchanan.[14] 2'-Deoxyguanosine was more stable than 2'-deoxyinosine, and no evidence of isomerization was observed. Some guanine and a trace amount of an unknown compound were obtained. 2',3'-Isopropylidene-inosine gave several spots (Table 3); however, none of them was considered to be responsible for the isomerization.

The isomerization was also significantly affected by a change in the base moiety from purine to pyrimidine or from purine to imidazole. Thymidine was found to be resistant against alkali, and even when the reaction period was prolonged up to 12 hr, no spot was observed except that of the starting material and a trace of thymine. Uridine was less resistant than thymidine; however, no UV-absorbing products could be detected except uracil. No effect was found even under more severe conditions (1 M KOH, 140 °C, 6 hr). In the case of cytidine, deamination followed by hydrolysis at the glycosyl bond was dominantly observed under the standard conditions, so that chromatography revealed three UV-abosorbing compounds corresponding to uridine, uracil, and cytidine. AICA-riboside was also resistant against alkali; even when it was reacted for 42 hr, the only reaction product was found to be AICA. The above four nucleosides showed no evidence of isomerization, even though the starting pH of the solution was changed from 10 to 8 or 12.

Reaction Mechanism. The available information concerning the alkaline isomerization of usual nucleosides is insufficient for us to determine clearly its reaction mechanism. One of the most important pieces of information is that the isomerization takes place only for 2'-hydroxypurine nucleosides. The C-2' hydroxyl group is known to be the most acidic hydroxyl group of the three OH groups in the ribofuranoside.

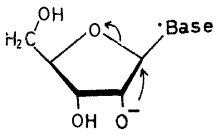

Chart 2. C-2′ Oxyanion participation of β-nucleoside for cleavage of sugar ring at C-1′.

It is supposed that the formation of the carbonium ion at C-1′ is facilitated by the anchimeric assistance[15] of an ionized hydroxyl group at C-2′, and that then the isomerization proceeds (Chart 2). The final equilibrium state of the four isomers and the rate of the reaction are not known.

Garret *et al.*[3] reported that adenosine and 2′-deoxyadenosine in an alkaline solution (pH higher than 13) have almost equal rates of hydrolysis at the glycosyl bond. Therefore, it may be supposed that the oxyanion participation affects only the cleavage of the sugar-ring bond at C-1′, while it does not affect that of the glycosyl bond.

The dissociation constant, pK_a, of the ribose moiety in nucleosides is approximately 12, and the isomerization in question is dependent on the pH of the solution. The optimum pH is between 7 and 12, about 10.[16] This pH range results from the competition among several parallel and sequential reactions, and outside this pH range these concomitant reactions occur in preference to isomerization. It has not been demonstrated whether or not the rate of isomerization would depend on the concentration of the hydroxyl ion, because parallel reactions, for example, hydrolysis, disturb the system.

It has not yet been explained why pyrimidine nucleosides do not isomerize, while purine nucleosides do.

Experimental

Materials and Equipment. The **1a**, **1b**, guanosine, and AICA-riboside used were commercial products of the Ajinomoto Co., Inc. The xantosine, uridine, cytidine, and 9-β-D-arabinofuranosyl adenine used were reagents of the Nutritional Biochem. Corp. The 2′-deoxyinosine and 2′-deoxyguanosine were obtained from Sigma Chemicals. The 2′,3′-isopropylideneinosine and 9-β-D-xylofuranosyl hypoxanthine were supplied by Dr. Akihiro Yamazaki of this department. The **3a** and **1c** were prepared according to the method described in the preceding paper[1] and according to the method of J. J. Fox *et al.*[17] respectively. The **1b** was methylated by the method of Martin *et al.*[18]; however, the separation of 2′-*O*-methyladenosine from the 3′-isomer by this method was unsatisfactory. It was, though, achieved with a method similar to that described by Gin *et al.*[19] The pHs of the solutions were measured at room temperature. The NMR spectra were recorded at 100 MHz with a Varian XL-100 spectrometer, using TMS as the internal standard. The melting points were measured by the use of a Yanagimoto MP-S2 apparatus and are uncorrected.

PC and Tlc. One-dimensional ascending PC on Toyo-Roshi No. 51A for quantitative analysis, and tlc on DC-Fertigplatten Cellulose F for qualitative analysis, were both carried out in the *n*-butanol–acetic acid–water (4 : 1 : 1) solvent system. Whichever chromatography was used, paper or thin-layer, similar R_f values were obtained for the same compounds. A paper or a plate was thrice developed if necessary to separate the components completely on the chromatogram. The components of the reaction mixture were detected on the paper or plate by two methods: (a) absorption in UV light, and (b) color development with a NBDF reagent[1] for the detection of diazotizable amines.

Conditions of Alkaline Treatment. The compound was dissolved in aq. KOH (1.5—4 g/dl), and the pH was adjusted to 10. Unless otherwise stated, a solution was heated at 130 °C for 6 hr in a sealed stainless steel tube on an oil bath. Adenosine and AICA-riboside were reacted for 12 hr and 42 hr respectively. The tube was removed from an oil bath after 2—3 hr, and the decreased pH of the solution was corrected to 10. The pH was corrected two times 2 hr and 6 hr after heating for adenosine and six times, at six-hour intervals, for AICA-riboside. Guanosine was subjected to further heating for 4 hr at 140 °C in addition to that under the standard conditions. In the cases of some nucleosides, several different conditions were also employed where the initial pH of the solution was changed. Two solutions (pH 9.6 and 11.3) of AICA-riboside were heated at 130 °C for 42 hr, and two solutions (pH 8.6 and 11.5) of cytidine, at 130 °C for 6 hr. Uridine was heated at 140 °C for 6 hr in 1 M KOH.

Determination of the Yields of the Products. Samples of the reaction mixtures were made up to appropriate volumes with water and submitted to PC. The spots of the samples and available authentic references, which were developed on the same paper with the samples, were cut off, together with their appropriate blanks, and eluted in 0.1 M HCl. The optical density of the eluent at the wavelength of the maximum absorption of each component was measured. The percentage of the remaining original material and the products, which were obviously identified as known compounds by means of the R_f values and UV spectra, were calculated from the optical density of the spots of the samples, which were compared with that of each authentic standard reference. The percentages of the products were converted into those of the original compound by the use of the equivalent mole ratio. The yields in Tables 2 and 3 were obtained by this procedure except in the cases of **4a**, **2b**, and **4b**. The yields of these three compounds were roughly calculated from the optical density of the individual fraction, and the molar extinction coefficients were assumed to be 12,000. The recovery yields of **1a** and **1b** were corrected by the subtraction of the above yields of **4a** and **2b** respectively because they are not separable on PC.

*Isolation of **4a**.* **1a** (5 g) was dissolved in 125 ml of 0.2 M KOH and heated at 130 °C for 2 hr. A few drops of 1M KOH were added to correct the pH of the solution to 10.0. After the reaction had been continued for another 4 hr, the mixture was made acid (pH 2) with conc. HCl and applied to a column (28 cm × 3 cm) of Diaion SK1B-S (H-form, 50—100 mesh). The column was eluted with 7 l of water. Each 20-ml fraction was collected. The first and second UV-absorbing peaks were obtained within 7 l. When an eluting reagent was changed to 3.9 l of 0.1 M NH_4Cl, a third peak was obtained. It was composed of two components on tlc, the one was hypoxanthine (R_f 0.35), and the other, a compound closely resembling inosine (R_f 0.22). A fourth, obtained by the use of an eluting reagent of 0.1 M ammonia, was a mixture of hypoxanthine and AICA-riboside (R_f 0.31). The fractions between No. 718 and No. 1,080 in the third peak were collected, neutralized with 1 M NaOH, and concentrated *in vacuo*. The resultant solution was applied to a column (30 cm × 0.7 cm) of granular activated carbon (Tsurumi-Coal GVA-80) in order to eliminate

inorganic salts passing through the column. The column was then eluted with a solvent mixture (1 : 1) of ethanol and 20% aq. ammonia. The eluate was concentrated *in vacuo* to dryness. The residue was dissolved in a small portion of pyridine and added to the same volume of acetic anhydride for acetylation. After refluxing for 1 hr, the solution was allowed to stand for 30 min at room temperature. To the solution some portion of ethanol was added and then it was evaporated *in vacuo*. The addition of ethanol to the solution and the evaporation of the resultant mixture were repeated several times, and finally it was evaporated to dryness. The residue was extracted with CH_2Cl_2, and the extract was evaporated to dryness, giving an acetylated compound. This compound was dissolved into ammonia-saturated methanol for deacetylation. The solution was then allowed to stand overnight and concentrated *in vacuo* to dryness. The resultant solid was extracted with $CHCl_3$ in order to remove the acetamide. The remaining solid was dried for analysis. (a) R_f on tlc. (thrice-developed) 0.39, for control inosine 0.43 and β-pyranoside 0.33. (b) UV_{max}; 249.2 nm in 0.1 M HCl, 248.2 nm in H_2O, and 253.9 nm in 0.1 M NaOH, for control, inosine corresponds to 249.9 nm, 249.2 nm and 254.5 nm respectively. (c) Components of acid hydrolysate: The compound was refluxed for 1.5 hr in 4 M H_2SO_4 followed by neutralization with $Ba(OH)_2$ and filtration of the resultant $BaSO_4$. UV_{max}; the values of 249.5 nm, in 0.1 M HCl and 264.5 nm in 0.1 M NaOH agreed with those of hypoxanthine. PC; an UV-absorbing spot, R_f 0.35 (hypoxanthine). A positive spot with a periodate reagent, R_f 0.33 (D-ribose). (d) Optical rotation. $[\alpha]_D^{20}$ −50° (c, 0.2, water). (e) NMR. (DMSO-d_6) δ 8.09 (H-2), 8.32 (H-8), 5.75 (H-1′, d, $J_{1'2'}$=0—1 Hz), 3.7—4.0 (broad, m); the acetylated compound (CD_3OD), δ 4.01 (J_{AB}=14 Hz, J_{AX}=2 Hz) and 4.28 (J_{AB}=14 Hz, J_{BX}=2 Hz) for two protons of H-5′.

Four Isomers of Adenosine. **1b** (5 g) was dissolved in 120 ml of 0.005 M KOH at 60 °C and heated in a sealed tube at 130 °C for 2 hr. The pH of the solution varied from 10.0 to 9.4 during the reaction period. A few drops of 1 M KOH were added to correct the pH to 10.0, and then the reaction was continued for another 4 hr. The pH of the solution decreased again to 8.9. After the pH adjustment, the reaction was continued for 6 hr more. When the reaction mixture was submitted to tlc, three major UV-absorbing spots were obtained (R_f 0.56, 0.46, 0.32). Then the reaction mixture was neutralized with conc. HCl and submitted to a column (36 cm×3 cm) of Dowex-1, X-4, (OH-form, 200—400 mesh). The column was eluted with 25% (w/v) methanol. Each 4-ml fraction was collected. Four UV-absorbing fractions were obtained. The first fraction (from No. 551 to No. 580), the second (from No. 581 to No. 700), the third (from No. 795 to No. 910), and the fourth (from No. 1,011 to No. 1,200) were severally concentrated to dryness *in vacuo*, and the residues were recrystallized from water. Two of them (A-1 and A-3) were finally crystallized from ethanol. The results of the analysis are summarized in Table 1. Pieces of the four compounds were individually hydrolyzed in 6 M HCl at 80 °C for 1 hr. The four hydrolysates all showed, on PC, one UV-absorbing spot (R_f 0.56) (adenine) and one positive spot (R_f 0.33) with a periodate reagent (D-ribose). NMR: Compound A-**1** (DMSO-d_6), δ 8.18(H-2), 8.39(H-8), 7.26(NH_2-6), 5.79(H-1′, d, J_{AB}=14 Hz); an acetylated compound ($CDCl_3$), δ 4.04 (J_{AB}=14 Hz, J_{AX}=2 Hz) and 4.38(J_{AB}=14 Hz, J_{BX}=2 Hz) for two protons of H-5′.

*Isomerization of **3a**.* **3a** (10 g) was dissolved in 250 ml of 0.15 M KOH to give a solution with a pH of 10. When the solution was heated at 150 °C for 3 hr, the decreased pH (8.4) of the solution was corrected to 10 with 13 ml of 1 M KOH. After further heating for 3 hr, the reaction mixture was acidified to pH 4 with 1 M HCl and submitted to a column (53 cm×3.1 cm) of Dowex 50W X-4 (H-form, 100—200 mesh). The column was washed with 2 l of water, and then eluted with 0.001 M NH_4Cl. Each 20-ml fraction was collected. The first UV-absorbing fraction was obtained from No. 260 to No. 370, and the second, from No. 450 to No. 590. The latter fraction was concentrated *in vacuo* until 3 ml and cooled for crystallization overnight. Subsequent recrystallization from water gave 50 mg (dried in a desiccator) of needle crystals. PC: R_f 0.23. UV_{max}: 250 nm in 0.1 M HCl, 249 nm in H_2O, 254 nm in 0.1 M NaOH. The X-ray (Cu$K\alpha$) diffraction pattern: α-form of inosine.[12]

*Preparation of **3c**.* To 50 ml of 0.01 M KOH, **1c** (1 g) was added and the pH was adjusted to 10.2 with a few drops of 1 M KOH. The solution was heated in a sealed tube at 130 °C for 6 hr. The reaction mixture was neutralized with 1 M HCl, concentrated *in vacuo* to 10 ml, and submitted to a column (40 cm×1.3 cm) of Dowex-50W (H-form, 50—100 mesh). The column was eluted with 1.6 l of water. Each 10-ml fraction was collected. The first and second UV-absorbing peaks appeared from No. 20 to No. 60 and from No. 61 to No. 110 respectively. The first fractions were concentrated *in vacuo* until 2 ml and then allowed to stand in an ice box overnight for crystallization. The precipitated crystals were filtered and recrystallized from water. Needle crystals were thus obtained (47 mg). Found: C, 41.90; H, 4.32; N, 19.56%; Calcd for $C_{10}H_{12}N_4O_4S \cdot 0.2\,H_2O$: C, 42.25; H, 4.23; N, 19.72%. Mp 232—233 °C. UV_{max}; 317.5 nm at pH 7. Mass: M^+ 500 (trimethylsililated). NMR (DMSO-d_6): δ 5.62 (H-1′, d, $J_{1',2'}$=9.0 Hz), 1.14 (SH-6).

We wish to thank Dr. Masatsune Kainosho and Dr. Akihiro Yamazaki in this department for their valuable suggestions. We are also indebted to Professor Dr. Masamichi Tsuboi of Tokyo University for reading the manuscript.

Alkylation of Phenols. II. The Selective Formation of Thymol from *m*-Cresol and Propylene with a γ-Alumina Catalyst

Masahiro NITTA, Kazuo AOMURA, and Katsumi YAMAGUCHI

Faculty of Engineering, Hokkaido University, Sapporo 060

(Received February 16, 1974)

The alkylation of *m*-cresol with propylene was carried out over a γ-alumina catalyst in a flow system under atmospheric pressure. It was found that the composition of the thymol mixture thus obtained was greatly *ortho*-rich. It was also observed that the catalytic activity varied with the temperature and the atmosphere for the calcination of the catalyst, whereas the selectivity for thymol formation was almost constant at about 90% at the reaction temperature of 250 °C. It has been established that thymol can be obtained selectively by vapor-phase alkylation over a commercial γ-alumina catalyst under appropriate reaction conditions. Furthermore, the active sites of γ-alumina for this reaction were investigated by the poisoning technique with acids and bases. It was suggested that, for the alkylation, the Lewis-acid sites (surface aluminum) and the adjacent acid sites (surface hydroxyl) are necessary. The mechanism of the alkylation on those sites is also discussed.

In the first part of this series the present authors reported their results on the vapor-phase alkylation of *m*-cresol with propylene over supported metal sulfate catalysts.[1] It was shown that the activity of the catalyst depended on the catalyst acidity, and that the selectivity of the catalyst for thymol formation seemed to be affected by the surface structure of the catalyst. However, experimental research to obtain thymol in higher yields has been required, because thymol is the raw material of an important perfumery, menthol.

On the other hand, it is well known that γ-Al_2O_3 has acidity[2-5] and promotes the reaction of phenol with alcohols;[6,7] recently the structure and orientation of phenols chemisorbed on γ-Al_2O_3 have been reported.[8] No method of synthesizing thymol using this catalyst is found in the literature. It is, therefore, of particular interest to examine the activity and selectivity of γ-Al_2O_3 for the said reaction.

The present paper will describe the results on the γ-Al_2O_3 catalyst, which shows quite a good thymol selectivity. Descriptions will also be given of the active sites of the catalyst for the alkylation, as well as discussions of the reaction mechanism.

Experimental

Materials. Commercial *m*-cresol was vacuum-distilled under an atmosphere of nitrogen; the purity was estimated to be over 99.5% by means of gas chromatography. Propylene, with a purity of over 99%, was obtained from the Mitsubishi Petrochemical Co., Ltd.

Catalyst. AE-11-type γ-Al_2O_3 obtained from the Nishio Industries Co., Ltd., was used. The alumina was pellected, crushed, and sized in 10—20 mesh, and then it was heat-treated before reaction at a temperature between 250 and 900 °C for 3 hr in an atmosphere of nitrogen, oxygen, hydrogen, or air. When the calcination temperature was below 500 °C, the catalyst was heated in a glass tube reactor, while when it was above 500 °C, it was calcined in a crucible in the air.

Analysis. The liquid products obtained were analyzed by gas chromatography (GC) and identified by a comparison of their chromatograms with those of authentic samples. The conditions for the analysis have been described in a previous report (Part I).[1] The analysis of the gaseous products was done by another GC with a column containing DMF on Chromosorb AW (8 m, 0 °C).

Measurement of the Surface Properties. The surface acidity of the catalyst was determined by the usual titration method with *n*-butylamine and Hammett indicators and by the color change of *p*-phenylenediamine.[9] The specific surface area of the catalyst was measured by the BET method using the N_2 adsorbate. The X-ray powder diffraction patterns of the catalyst was taken using filtered copper $K\alpha$ radiation.

Apparatus and Procedure. The same continuous-flow apparatus as has been described in Part I was used. The reaction was carried out in the same manner as has been described in Part I. In the experiments to investigate the poisoning effect of the acid or base agent, the reagent was introduced into the catalyst bed before the reaction. After the injection, the carrier gas was made to flow for 30 min; the alkylation reaction was then carried out.

The activity of the catalyst was expressed in terms of the conversion of *m*-cresol; it was taken at the highest conversion, which usually occurred after 1 or 2 hr of process time.

The selectivity of the catalyst defined as below did not change with the process time, except at the start of the reaction:

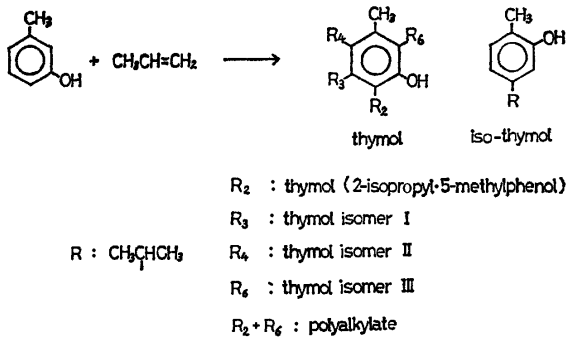
$$\text{Selectivity} = \frac{\text{thymol}}{(\text{thymol isomers}) - (\text{unknown})} \times 100 \ (\%)$$

Results and Discussion

The material balance of the reaction of *m*-cresol and propylene was first investigated at the reaction temperature of 250 °C using γ-Al_2O_3 calcined at 300 °C in an N_2 stream. Over 90% of the reacted propylene was obtained in the form of alkylates. All of the *m*-cresol was recovered in the liquid product. Some of the lost propylene would be consumed by the polymerization and cracking to produce other hydrocarbons. Practically, propane was detected in the exhaust gas. The products obtained in this alkylation, except at higher reaction temperatures, are as follows:

The influence of *iso*-thymol on the results below 300 °C could be neglected because its amount almost held constant at about 2% of all the alkylates. There was also an unknown peak at the end of the gas chromatogram; it was estimated to be a polyalkylate (U) such as 2,6-diisopropyl-5-methylphenol. The amount of U did not exceed 10%* of all the alkylates.

* We assumed the relative mole sensitivity of U to be the same as that (0.78) of thymol isomers to *m*-cresol.



Both the methyl and hydroxyl groups in benzene nuclei are known to have a *para*/*ortho* orientation effect; most of the products may be, therefore, considered to be *ortho* and *para* isomers with respect to the hydroxyl of *m*-cresol. In the present case, however, the *ortho* alkylates, *i.e.*, thymol and III, were formed in much excess, as will be shown below (Fig. 1).

The catalytic activity changes gradually with the process time, as is shown in Fig. 1. This method of activity change is similar to that observed in the alkylation by zeolite catalysts,[10,11] but not in that by metal sulfate catalysts.[1] This may be due to the existence of an induction period and the catalyst aging.

Surprisingly, in many runs, the selectivity of the γ-Al_2O_3 catalyst for thymol formation had the high value of about 90%, much more than that of the metal sulfate catalyst.[1] In the case of the liquid-phase reaction using a protonic acid catalyst or the Friedel-Crafts catalyst, the thymol selectivity is about 70%.[12]** In addition, those catalysts have the disadvantage of the corrosion of reaction facilities. In this process, the problem does not exist. It can, consequently, be accepted that γ-Al_2O_3 is the most suitable catalyst for the selective formation of thymol.

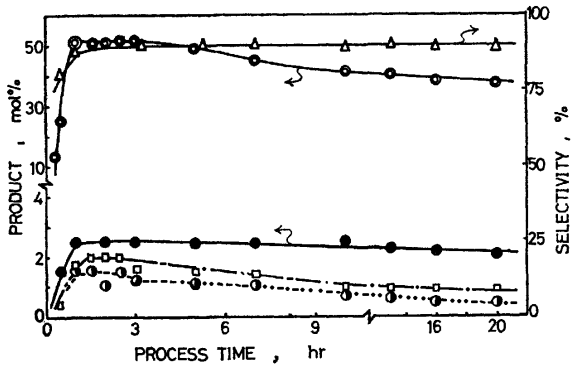


Fig 1. Activity and selectivity changes with process time.
Conditions: W/F=19.5 g·hr/mol, reaction temp=250 °C, propylene/*m*-cresol=1.0 mol/mol. Catalyst: γ-Al_2O_3 calcined at 300 °C. ◎: thymol, ◑: I, □: II, ●: III, △: thymol selectivity.

** Kolka *et al.* have obtained *o*-alkylphenol selectively in the presence of aluminum phenoxide-type catalyst in liquid phase.[13] For example, in the reaction of phenol and ethylene, 2-ethylphenol and 2,6-diethylphenol selectivities were 68% and 29% respectively (using the same selectivity as we defined here).

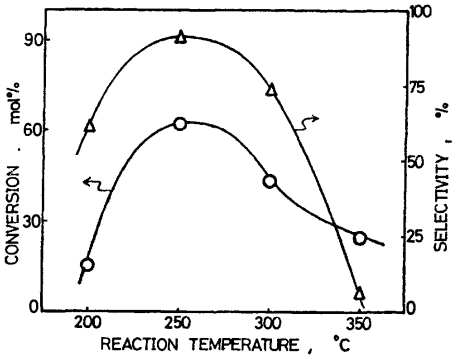

Fig. 2. Effect of reaction temperature on conversion and selectivity.
Conditions: W/F=19.5 g·hr/mol, propylene/*m*-cresol=1.0, calcination temp=400 °C.
○: conversion of *m*-cresol, △: thymol selectivity.

The effects of the reaction conditions on the catalytic activity and selectivity were investigated in detail using the γ-Al_2O_3 calcined at 300 and 400 °C. Furthermore, the active sites and reaction mechanism were discussed.

Effect of the Reaction Temperature. The effect of the reaction temperature on the selectivity of thymol formation was investigated with the γ-Al_2O_3 calcined at 400 °C under a constant contact time (W/F) and a constant mole ratio of reactants. The results are shown in Fig. 2. The optimal reaction temperature was 250 °C. At temperatures higher than 250 °C, the conversion of *m*-cresol decreased with the rise in the temperature. This is attributed to a side reaction, such as the polymerization of the alkylating agent. Further, the selectivity of thymol formation also decreased suddenly because of the formation of many unknowns in addition to U. Many of the unknwons may be alkylates with secondary alkylating agents which are produced by the above side reactions of propylene, or transalkylates. However, the amount of the unknwons was below 10%, as is shown by the single symbol in the right top of Fig. 3.

Figure 3 shows the relation between the reaction temperature and the product distribution. The increase in *iso*-thymol at higher temperatures indicates the occurrence of isomerization or disproportionation.

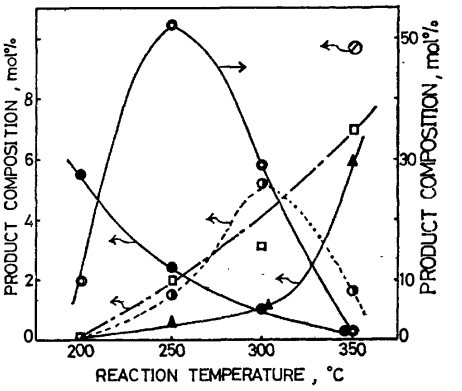

Fig. 3. Relation between reaction temperature and product composition.
Conditions are the same as in Fig. 2.
▲: *iso*-thymol, other symbols are defined in Fig. 1.

Thymol isomer III seems to be unstable energetically and transforms into other thymol isomers at higher temperatures.

Effect of the Contact Time. As an indication of contact time, we used W/F, defined as follows:

$$W/F = \frac{\text{catalyst weight (g)}}{\text{feed rate of reactants (mol/hr)}}$$

The effect of W/F on the convresion of *m*-cresol and on the thymol formation are presented in Fig. 4. The largest conversion was obtained at $W/F \approx 40$. Above this W/F value, there was no noticeable change in the conversion or in the selectivity. The thymol selectivity was constant; it was maintained at a high value of 90% except at low contact times.

At low contact times, thymol and III were formed predominantly and the formation of I and II was very small. With higher contact times, however, the formation of III decreased, while those of thymol, I and II increased. Finally, at $W/F > 20$ the yield of thymol became almost constant. The isomerization of thymol (cyclohexane solution) was carried out using a nitrogen carrier instead of propylene under the same conditions as the alkylation. The resulting products were *m*-cresol, isopropylphenol, I and II, and the unknowns including U. It is, consequently, almost certain that the isomerization and the disproportionation of thymol and III take place during the reaction. It was difficult to estimate the equilibrium composition of thymol isomers in the present experiment because of the unknowns produced.

Effect of Mole Ratio of Reactants. The conversion of *m*-cresol increased with the increase in propylene in the reactant mixture, as is shown in Fig. 5. The thymol selectivity did not change with the mole ratio of propylene to *m*-cresol, whereas *iso*-thymol and U increased. From the standpoint of selective thymol formation, the optimal mole ratio is 1.0.

From these results, the reaction conditions were so chosen that the conversion was large and the thymol selectivity was the highest. The optimal conditions

Reaction temperature=250 °C

Propylene/*m*-cresol=1.0 (mol/mol)

Further investigations of the active sites of the catalyst have been made under the above conditions.

Catalyst Activation. In general, the activity of solid oxide catalysts changes appreciably with the conditions for activating the catalyst—for example, the calcination temperature and the calcination atmosphere. Therefore, the activity and selectivity of γ-Al_2O_3 have been investigated over a wide range of calcination temperatures between 250 and 900 °C. The results are shown in Fig. 6. Thymol was produced selectively on every catalyst calcined between 250—900 °C. No anomalous product distribution was observed over 250—900 °C, but the activity changed appreciably. For the catalyst calcined at 250 °C, the low activity may be due to the incomplete desorption of materials, such as CO_2 and H_2O, which covered the active sites on the catalyst surface. The results of the physical-property measurements for the catalyst calcined at 900 °C re-

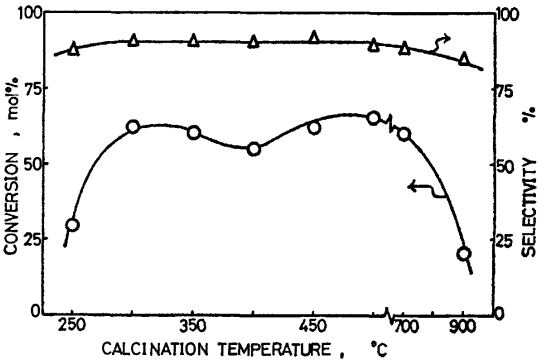

Fig. 6. Activity and selectivity of γ-Al_2O_3 catalyst calcined at various temperatures.

vealed that the crystal form of alumina changed from the γ to the θ type and that the surface area decreased from 154 to 84 m^2/g. These facts suggest that the differences in the surface structure among aluminas of different calcination temperatures may sensitively result in the differences in the nature of active sites. Such an effect of the calcination temperature on the surface properties of alumina has also been found in studies of the acidity.[5,14] Therefore, the activity changes with the calcination temperatures may be related to the acidity of the catalyst.

The influence of the calcination atmosphere was next examined. The results are summarized in Table 1. It was found that the catalytic activity of γ-Al_2O_3 varied with the change in the calcination atmosphere. In particular, the activity almost completely disappeared on calcining at 300 °C in an oxygen stream. The activity decrease due to the calcination in the air can apparently be explained by the influence of oxygen in the air. However, the comparison of the X-ray diffraction patterns and the surface area gave little information about the differences in the crystal form of the catalyst calcined in N_2, O_2, H_2, and air. When the catalyst was recalcined at 250 °C for 1 hr in a nitrogen stream after having been calcined at 300 °C for 3 hr in an oxygen stream, the catalytic activity and selectivity were restored to the standard level of N_2 calcination. It may, therefore, be considered that, on the sample calcined in oxygen, the adsorbed oxygen molecules would cover the active sites for alkylation.

Effect of Acid and Base Addition. It has been shown that, in addition to acid sites, basic sites exist on the surface of alumina.[15] By masking either acidic sites or basic sites it is possible to discern which sites are effective in the isopropylation of *m*-cresol. Before the reaction various acid and base reagents were added to the catalyst in the reaction system at 250 °C and their effects were examined. The results are shown in Table 2. Neither the activity nor the selectivity was changed by the addition of acidic reagents. On the other hand, basic reagents poisoned the catalyst. With the increase in the strength (pK_a value) of the added base the activity fell. Aniline, which is a weaker base, has little effect on the activity. This implies that a weak poison adsorbs reversibly on alumina; that is, the reactant molecules replace the preadsorbed poison molecules. On the contrary, the catalyst was completely deactivated by the addition of stronger bases, such as benzylamine and *n*-butylamine. The alkylation activity decreased with the increase in the amount of the base added, and the depressed activity was restored little with the process time. Therefore, the strong bases are considered to be irreversible poisons. The catalyst partially poisoned with a strong base produced only *ortho* alkylates, *i. e.*, thymol and III (60 mol% and 40 mol% respectively), though the conversion was low. Consequently, it may be concluded that the active sites promoting the isopropylation of *m*-cresol are mainly the acid sites on the γ-Al_2O_3 catalyst.

Catalyst Acidity. It is possible to confirm the existence of the Lewis-type acid sites on γ-Al_2O_3 by means of the coloration of *p*-phenylenediamine. The observed dark violet coloration of this reagent on the alumina indicates the presence of electron-acceptor sites (Lewis-acid sites in the most general sense), because its color is based on the cation radical formed from the reagent.[9] It is supposed that γ-Al_2O_3 also has weak Brönsted-type acid sites.[3] From the above results, a correlation can be expected to be seen between the activity and the acidity of each catalyst. We then tried to determine the total amount of the surface acid sites using the method of amine titration

Table 2. Effect of the addition of acidic and basic reagents

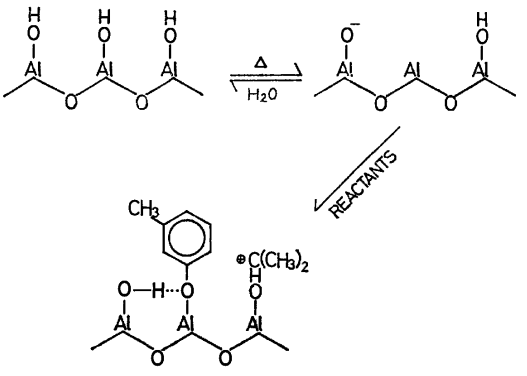
with the Hammett indicators. However, it was very difficult to determine accurately the acidity by this method, because the catalysts were very sensitive to moisture in cooling after the calcination and in the weighing of the sample. It was, therefore, impossible to find a direct correlation between the acidity and the activity.

General Discussion

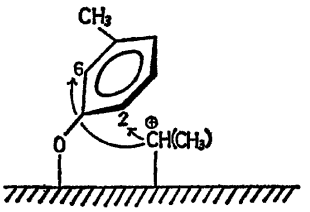
The experimental results showed that the γ-Al_2O_3 catalyst used in the present work has a considerably high selectivity for thymol formation. This seems to suggest that there are some merits of the orientation effect of reactants on the γ-Al_2O_3 surface, at least under the present experimental conditions. Thus, the model for the surface sites on alumina and that for the adsorbed state of *m*-cresol, both proposed by Medema,[5] Peri,[2,3] and Taylor,[8] can favorably be used to discuss the active sites and the reaction mechanism in the present work.

Small numbers of aluminum ions exposed to the surface as a result of the condensation of surface hydroxyl groups form L acid sites on the calcined γ-Al_2O_3. In addition, small numbers of hydroxyl ions of several types persist on the alumina surface even after the calcination at high temperatures; they form B acid sites. Taylor *et al.* showed that phenols form a strongly chemisorbed aluminum phenoxide on γ-Al_2O_3 at 300 °C. They concluded that the cresol molecule is oriented with its aromatic ring almost coplanar with the surface, but is tilted upward so that the *para* position is further from the surface than the *ortho* position. On the other hand, Cvetanovic *et al.*[16] have shown that there are two different sites on the alumina surface for the chemisorption of olefin. They considered that this is an intrinsic property of alumina catalysts. Further, they have suggested that one of the two types of adsorption sites may be Brönsted-type acid centers, and that olefin molecules adsorbed on the sites of this type could transform so as to have the character of chemisorbed carbonium ions.

Based on the above-mentioned surface models proposed by the previous workers and the results of the present work, the alkylation of *m*-cresol with propylene over γ-Al_2O_3 can be pictured as follows:



That is, if *m*-cresol is adsorbed on the L acid sites and if propylene is adsorbed on the neighboring B acid sites, most of the isopropylcarbonium ions will subsequently attack the *ortho* positions (2 and 6 in the following picture) of the adsorbed *m*-cresol, because these positions are closer to the surface.



However, the attack on the 6-position must be subjected to steric hindrance by the methyl group of the adsorbed *m*-cresol. Consequently, propylene may add preferably to the 2-position, and thymol is formed selectively. Kolka also explained the high selectivity of the liquid-phase *ortho* alkylation in terms of the intermediate formation of aluminum phenoxide.[13]

The poisoning action of a strong base appears to be closely related to the irreversible adsorption on active sites. The bonding of the base with aluminum or hydroxyl is much stronger because the nitrogen atom in the base molecule is more basic than the oxygen atom in the *m*-cresol molecule or the double bond in the propylene molecule.

Reactions in the Adsorbed Layer: Hydrogenation of Acetone on Nickel Catalysts

Hisashi MIYATA, Mitsuhiko MINOBE,* and Yutaka KUBOKAWA

Department of Applied Chemitsry, University of Osaka Prefecture, Mozu-Umemachi, Sakai, Osaka 591

(Received November 26, 1973)

The hydrogenation of acetone adsorbed and the dehydrogenation of isopropanol adsorbed on silica-supported nickel catalyst have been studied by following the changes of hydrogen pressure and the reaction products as well as the IR spectra of adsorbed species. It was found that the formation of isopropanol proceeds *via* a precursor composed of acetone and hydrogen. The activation energies of hydrogenation of acetone adsorbed and of dehydrogenation of isopropanol adsorbed were 11—13 and 4—8 kcal/mol, respectively. The activation energy of the desorption was 13 kcal/mol for isopropanol and 19 kcal/mol for acetone. From the results the potential energy change during the hydrogenation of acetone was determined.

Although a number of investigations have been made on the hydrogenation of acetone on nickel catalysts, in most cases the nature of the adsorbed species on the catalysts as well as the energy relation for the reaction was deduced on the basis of the kinetics of the reaction. They can be elucidated more precisely by measurements of the hydrogenation of adsorbed acetone. Work along this line was carried out[1-3] with some decomposition reactions. As an extension of this work, hydrogenation of acetone adsorbed on nickel catalyst has been investigated by an infrared technique as well as by the analysis of reaction products.

Experimental

Materials. The 15 wt% Ni-SiO_2 catalyst was prepared by impregnation of silica gel (30—50 mesh) with an aqueous solution of $Ni(NO_3)_2 \cdot 6H_2O$. The supported salt was dried at 100 °C and heated at 400 °C in the air. The catalyst samples were reduced in 100 Torr hydrogen at 400 °C for 60 hr and degassed at the same temperature for 3 hr. The equilibrium amount of hydrogen adsorbed after the reduction was 1.8 cm^3/g at 0 °C and 20 Torr hydrogen. For spectroscopic experiments, Aerosil (Degussa) supporting 6.5 wt% nickel was prepared by impregnation with a nickel nitrate solution. The slurry was dried at 100 °C in the air and heated in a vacuum at 300 °C. The silica-salt mixture was pressed into a disk of 20 mm diameter. Before adsorption of acetone, the disk was heated in hydrogen at 350 °C for 6 hr and degassed at the same temperature.

Acetone and isopropanol (Tokyo Chemical Industry) were dried in a vacuum over a degassed molecular sieve, degassed by freeze-pump-thaw cycles and stored over the molecular sieve. Cylinder hydrogen was purified by diffusing through an electrically heated palladium thimble.

Apparatus and Procedures. A closed circulation system, equipped with Töpler pump and a mercury diffusion pump, was used for desorption experiments. The rate of hydrogen uptake by the catalyst adsorbed acetone was determined manometrically. The experiments of dehydrogenation of isopropanol adsorbed were carried out as follows: Using either liquid N_2 traps or a Töpler pump and a diffusion pump, the desorbed amounts of hydrogen as well as of condensable gases such as acetone, isopropanol, and propane were determined as a function of time, the rate of desorption being obtained. Details were described previously.[1-4] During the rate measurements the temperature of the catalyst was lowered abruptly and the temperature dependence of the rates at the same amount adsorbed was obtained. The desorption products were analyzed by gas-chromatography with the use of a column with 3 m silica gel or 2 m molecular sieve for methane and hydrogen and with a 2 m PEG 1500 column for the other products. Similar desorption experiments were carried out under circulation of hydrogen over the catalyst. In this case the desorption system was kept shut and only the condensable desorption products were analyzed.

The IR cell was the same as that used previously.[5] All the spectra were recorded at room temperature with a Hitachi EPI-G2 grating infrared spectrophotometer with a spectral slit width 2.8 cm^{-1} at 1000 cm^{-1}.

Results and Discussion

Hydrogenation of Acetone Adsorbed. The IR spectra of acetone adsorbed on the nickel catalyst at 25 °C showed bands at 1700 cm^{-1} (ν(C=O)), 1420, 1370 ($\delta(CH_3)$), and also around 3000 cm^{-1} (ν(CH)).[6] When hydrogen was admitted into the catalyst with adsorbed acetone at room temperature, the spectra changed gradually, hydrogen uptake occurring simultaneously. With increasing time of contact with hydrogen, the band due to the carbonyl group became

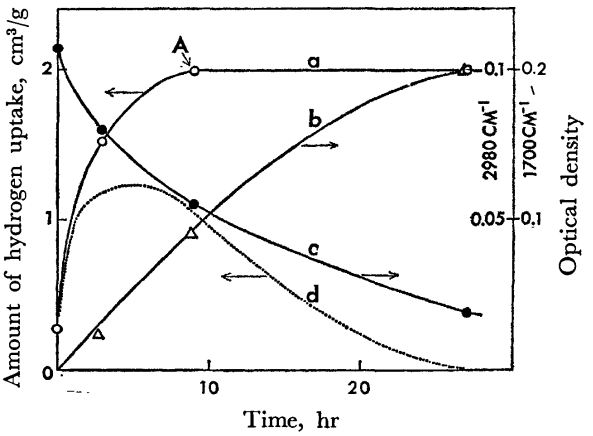

Fig. 1. Changes in the intensities of the bands and in the amount of hydrogen uptake: (a) amount of hydrogen uptake; (b) band intensity at 2980 cm^{-1}; (c) band intensity at 1700 cm^{-1}; (d) amount of the precursor. The amount of acetone adsorbed at 25 °C and hydrogen pressure were 1.75 cm^3/g and 20 Torr, respectively.

* Present address: Chemical Planning Department, Kyowa Hakko Kogyo Co., Ohtemachi, Chiyoda-ku, Tokyo 100

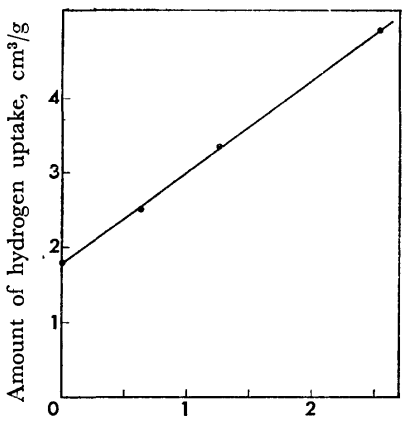

Fig. 2. Hydrogen uptake by the acetone-covered surface. Temp, 20 °C. The amount of catalyst and the equilibrium pressure of hydrogen were 6.67 g and 20 Torr, respectively.

weak, while a new band at 2980 cm^{-1} was intensified. The new band is attributable to ν(CH) of isopropanol.[7] The results are shown in Fig. 1. After 8 hr the amount of hydrogen uptake appears to attain a saturation value, while the intensities of the bands at 1700 and 2980 cm^{-1} still change. Such a phenomenon suggests that during the hydrogenation of acetone adsorbed, hydrogen adsorption of a certain type takes place to form an intermediate. In other words, the formation of isopropanol proceeds *via* a precursor composed of acetone and hydrogen. The amount of hydrogen uptake at the saturation (point A, Fig. 1) increased with increasing amount of acetone adsorbed. The increase in the amount of hydrogen uptake is 1.2 times as much as the amount of acetone adsorbed (Fig. 2).[8] Such a constant ratio suggests the formation of the precursor. A similar phenomenon was reported by Akhtar and Tompkins[9] who suggested that on the Pt surface containing adradicals such as $-NH_2$, -OH, and $-CH_3$, hydrogen is molecularly adsorbed on the adradicals (possibly by H-bonding). It was found that the intensity of the band at 2980 cm^{-1} was proportional to the amount of adsorbed isopropanol in the range 0.6—1.5 cm^3/g.[10] Assuming that the amount of hydrogen uptake at the saturation corresponds to the intensity of the band observed at 2980 cm^{-1} after 25 hr, it is possible to estimate the amount of the precursor which has a maximum (curve d, in Fig. 1).

It can be seen that an instantaneous hydrogen uptake is followed by a slow uptake. Taking account of the practical absence of hydrogen uptake without adsorbed acetone, it is concluded that the instantaneous uptake is due to the hydrogen adsorption between acetone molecules[12] and the slow uptake to the formation of isopropanol as well as of the precursor. The activation energy of the slow hydrogen uptake increased from 11 to 13 kcal/mol with the progress of uptake in the range 0.3—0.8 of the fraction of hydrogenated acetone. The rate of hydrogen uptake varied in proportion to the square root of hydrogen pressure in the range 20—100 Torr.

Dehydrogenation of Isopropanol Adsorbed. In order to obtain information on the energy changes for the dehydrogenation of isopropanol, the following experiments were carried out. After the hydrogenation of adsorbed acetone at 0 °C was completed, hydrogen was removed from the reaction vessel. The temperature of the catalyst was then raised stepwise to 20, 50, and 100 °C. The products are shown in Table 1. In the temperature range below 50 °C the hydrogen evolved amounted to 80% of the total hydrogen uptake, while a negligible evolution was observed for acetone as well as isopropanol. This suggests that acetone as well as isopropanol is adsorbed more strongly than hydrogen.

The rates of evolution of hydrogen were measured at 20 and 0 °C with various amounts of isopropanol adsorbed. The value of E for the hydrogen evolution (Rate$\propto\exp(-E/RT)$) increased from 4 to 8 kcal/mol with increasing fraction of dehydrogenated isopropanol from 0.1 to 0.3. It appears that the rate of dehydrogenation of isopropanol adsorbed is equal to the evolution rate of hydrogen, since the observed rate of hydrogen evolution was much larger than that for the catalyst with only adsorbed hydrogen.

In order to obtain energetic information on the hydrogenation of acetone, the dehydrogenation of isopropanol adsorbed was carried out in the presence of hydrogen circulating over the catalyst. The results of experiments in which the temperature of the catalyst was raised stepwise are shown in Fig. 3. Evolution of acetone as well as isopropanol began at 50 °C, showing a maximum at 100 °C and then decreased. Figure 4 shows the results of experiments at a constant temperature. The evolution rate of the products decreased with a decrease in the amount of isopropanol adsorbed. Dependence of the rate of evolution of the products upon hydrogen pressure was determined by abruptly changing the pressure during the course

Table 1. Dehydrogenation of isopropanol adsorbed

Temp range °C	Products,[a] $cm^3/g\times10^2$						Remaining amount,[b] cm^3/g	
	A	IPA	C_3H_8	CH_4	H_2O	H_2	A	H_2

0— 20	0.45	1.17	—	—	0.27	121.2	2.50	2.73
20— 50	18.4	3.87	0.30	4.68	1.89	190.2	2.25	0.748
50—100	86.2	0.35	1.39	33.6	7.32	158.8	1.26	—

a) A, Acetone; IPA, isopropanol. The temperature of the catalyst was kept constant for 2 hr at each step of temperature rise. b) The remaining amount is expressed as acetone+H_2, *e.g.*, at 0 °C isopropanol remained 2.51 and hydrogen 1.45 cm^3/g. Above 50 °C most of the hydrogen formed arises from the decomposition of acetone adsorbed.

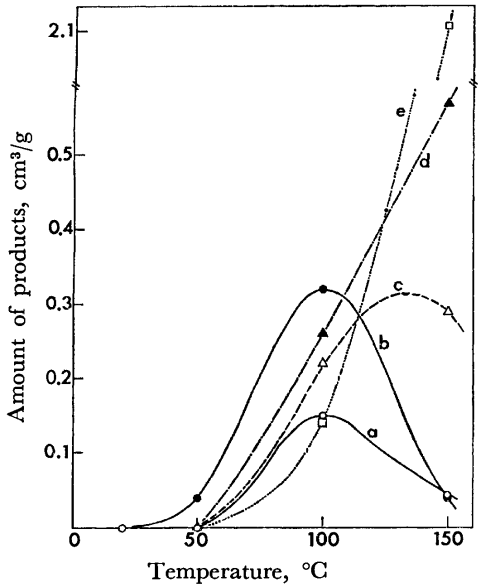

Fig. 3. Dehydrogenation of isopropanol adsorbed: (a) acetone; (b) isopropanol; (c) propane; (d) water; (e) methane. The amount of acetone adsorbed at 0 °C and hydrogen pressure were 2.51 cm³/g and 20 Torr, respectively.

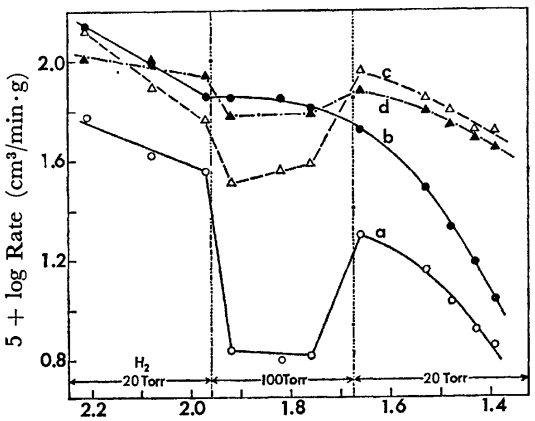

Fig. 4. Dehydrogenation of isopropanol adsorbed at 100 °C. Symbols are the same as for Fig. 3.

of dehydrogenation. The rate of evolution of acetone changes inversely proportional to P_H, while that of isopropanol is independent of P_H (Fig. 4).

The temperature dependence of the rate of evolution for isopropanol and for acetone was determined from the results shown in Fig. 5. The values of E at 1.95 cm³/g of the amount of isopropanol adsorbed are calculated to be 26.8 for acetone and 13.3 kcal/mol for isopropanol. Another experiment at 4.2 cm³/g of the amount of isopropanol adsorbed gave the activation energies 22.5 and 13.3 kcal/mol, respectively. It is seen that the value of E for acetone evolution changes with the remaining amount of isopropanol but that for isopropanol is nearly constant.

Dependence of the rates of evolution of the products upon the amount of isopropanol adsorbed was examined over a wide range of adsorbed amounts. The rate of evolution of propane changes slightly with

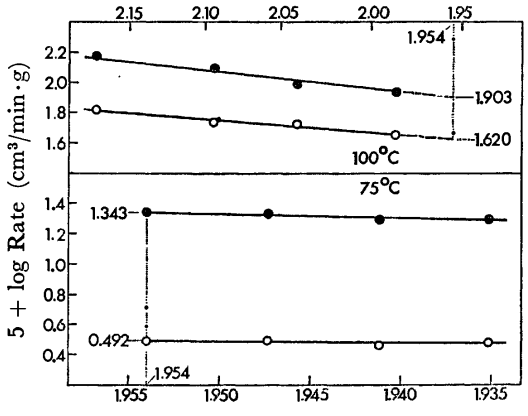

Fig. 5. Change in the rates of evolution of the products with temperature. During the measurements the temperature was changed abruptly from 100 to 75 °C, the rates at 1.954 cm³/g being compared. Hydrogen pressure, 20 Torr. Symbols are the same as for Fig. 3.

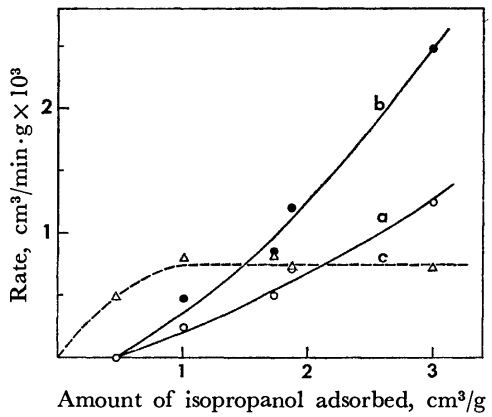

Fig. 6. Change in the rates of evolution of the products with the amount of isopropanol adsorbed. Symbols are the same as for Fig. 3. The temperature and hydrogen pressure were 100 °C and 20 Torr, respectively.

increasing amount adsorbed, while that of isopropanol markedly increases (Fig. 6). Such a behavior suggests that propane is formed from a strongly adsorbed species.

Potential Energy Change During the Hydrogenation of Acetone. Taking into account the results given in Table 1 and Fig. 1, it seems that the hydrogen uptake by the catalyst with adsorbed acetone and its reverse reaction, *i.e.*, hydrogenation of acetone adsorbed and dehydrogenation of isopropanol adsorbed[13] are much faster than the desorption of acetone as well as isopropanol at around 100 °C, where the dehydrogenation experiments were carried out. It appears that the equilibrium is established for the dehydrogenation and its reverse reaction. Since hydrogen is adsorbed between the acetone molecules, it would be expected that the acetone adsorption is independent of hydrogen adsorption. Hence

$$k_4\theta_A\theta_H'^2 = k_{-4}\theta_{IPA}(1-\theta_H')^2, \quad (1)$$

where $\theta_H'=1$ corresponds to a saturated amount of hydrogen adsorbed between acetone molecules; the rate constants refer to the following steps:

$$\begin{array}{ccccc} A(g) & & H_2(g) & & IPA(g) \\ k_1\uparrow & & k_2\uparrow\downarrow k_{-2} & & k_3\uparrow \\ A(a) & + & 2H(a) & \underset{k_{-4}}{\overset{k_4}{\rightleftharpoons}} & IPA(a) \end{array}$$

where A, H_2, and IPA represent acetone, hydrogen, and isopropanol, respectively. Since adsorption equilibrium is established for hydrogen, we have

$$k_{-2}P_H(1-\theta_H')^2 = k_2\theta_H'^2, \quad K = k_{-2}/k_2 \tag{2}$$

Substitution of equation (2) into equation (1) gives

$$\theta_A = k_{-4}\theta_{IPA}/k_1KP_H. \tag{3}$$

Hence, the evolution rates of isopropanol and acetone, R_{IPA} and R_A, are given by

$$R_{IPA} = k_3\theta_{IPA} \tag{4}$$

$$R_A = k_1\theta_A = k_1k_{-4}\theta_{IPA}/k_4KP_H. \tag{5}$$

In the case where θ_{IPA} is independent of hydrogen pressure, R_{IPA} becomes independent of P_H and R_A inversely proportional to P_H, in agreement with the results described above. Such a pressure independence of θ_{IPA} suggests that during the experiments such as shown in Fig. 6 the values of $\theta_{IPA}/(\theta_A+\theta_{IPA})$ are always close to unity, although θ_{IPA} as well as θ_A decrease with progress of the reaction. The pressure dependence of R_A as well as R_{IPA} would support the assumption that equilibrium is established for the hydrogenation and dehydrogenation reaction.

According to Eqs. (4) and (5), the temperature dependence of k_3 and k_1k_{-4}/k_4K is the same as that of R_{IPA} and R_A, which are 13.3 (E_3) and 22.5—26.8 kcal/mol (E_A), respectively. When Eqs. (4) and (5) hold, the value of R_{IPA}/R_A should be constant at a constant hydrogen pressure, irrespective of the amount of isopropanol adsorbed. Such a prediction was confirmed by experiments (Fig. 6, $R_{IPA}/R_A=1.98$ at 20 Torr hydrogen). The activation energy (E_4) of 11—13 kcal/mol for the hydrogen uptake corresponds to the temperature dependence of k_4. The activation energy (E_{-4}) of 4—8 kcal/mol for the evolution of hydrogen from isopropanol adsorbed corresponds to the temperature dependence of k_{-4}. Schuit and Reijen[14] investigated the adsorption isotherms of hydrogen on a silica supported nickel catalyst similar to the one we used. By applying their results to the present system, the coverage of hydrogen during the course of dehydrogenation of isopropanol at 100 °C and 20 Torr hydrogen is estimated at 0.7. Their results show that the heat of adsorption at $\theta=0.7$ is 16 kcal/mol.[15] Thus the temperature dependence (E_2) of K is estimated as -16 kcal/mol. From the relationship $E_A=E_1+E_{-4}-E_4-E_2$, the value of E_1 for k_1 can be calculated. The values of E_4 and E_{-4} vary with the progress of dehydrogenation. $E_4=12$ and $E_{-4}=4$ are obtained from the values at the fraction of hydrogenated acetone of 0.8. Combining these values with $E_A=27$, the value of E_1 for k_1 is obtained as 19 kcal/mol. Figure 7 shows the energy values as the change of potential energy during the course of reaction. The activation energies of adsorption of acetone, hydrogen, and isopropanol are neglected.

Strictly speaking, Fig. 7 is valid only in the case where the fraction of hydrogenated acetone is 0.8. In the case where the fraction of hydrogenated acetone is small, it is expected that the value of E_{-4} becomes larger than 8, although other quantities such as E_1, E_3, and E_4 do not change a great deal.

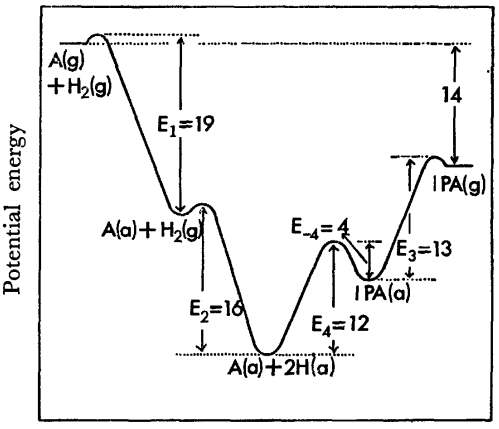

Fig. 7. Potential energy diagram for acetone hydrogenation. Figures indicate the potential energy in kcal/mol. The amount of isopropanol adsorbed and hydrogen pressure were 2.0 cm³/g and 20 Torr, respectively.

15) In the presence of acetone adsorbed, θ appears to differ from 0.7. According to Schuit and Reijen,[14] the heat of adsorption does not change markedly with coverage. It seems unlikely, therefore, that the above conclusion is affected seriously by a different θ value.

The Magnetic Properties of Verdazyl Free Radicals. VI. ESR Studies of Pairs and Triads† of the Symmetrical Triphenylverdazyl Radical in the 1,3,5-Triphenylbenzene Matrix

Nagao AZUMA, Hiroaki OHYA-NISHIGUCHI, Jun YAMAUCHI*, Kazuo MUKAI**, and Yasuo DEGUCHI

(Received February 22, 1974)

Single-crystal ESR studies have been carried out on symmetrical triphenylverdazyl (TPV) doped in a diamagnetic 1,3,5-triphenylbenzene (TPB) crystal at room temperature. There have appeared seven pairs of fine-structure absorptions in addition to the hyperfine splittings. Three out of the seven pairs have been assigned as zero-field splittings due to radical pairs, while the other three pairs have been identified as from radical triads. The six fine structure tensors have been determined through the angular variation of the resonance-field separations. The structures of the pairs and triads of TPV were discussed on the basis of the fine structure tensors, the crystal structures of TPB and TPV, and the spin distribution in the radical molecule, assuming that the unit cell of the mixed crystal with the radical concentration of less than 11.1% is identical with that of the host crystal, TPB. Within the limits of the X-ray examination, this assumption was found to be reliable. It was found that the molecular planes in each species are almost parallel to the *bc*-plane and that all the *C*-phenyl rings lie in the *c*-direction.

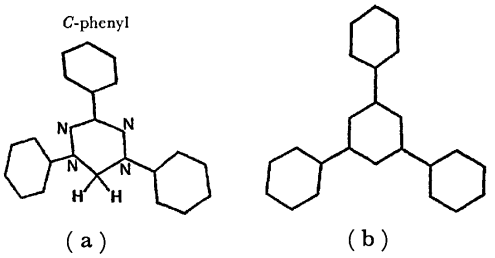
Recently, the present authors have reported the temperature dependence of the ESR linewidth, the *g*-value shift, and the magnetic susceptibility of the powdered sample of symmetrical triphenylverdazyl (TPV) and have concluded from these data, the crystal structure, and the spin distribution that this radical solid is subjected to the magnetic phase-transition from the short-range ordered state to the long-range ordered one at about 1.7 K.[1,2] In order to clarify the magnetic properties of the TPV solid in more detail, single-crystal experiments are highly desirable. For this investigation, it would be a reasonable step to study the magnetic behavior of the radical pair or triad of TPV, since they are magnetic unit systems containing interacting spins. However, it is difficult in general to investigate precisely the magnetic dipolar and exchange interactions of the radical pair in the solid of the stable neutral radical at any temperature, because of the above interactions between the given two spins and the surrounding spins, which cause the work to be desperately complicated. In the rather fortunate case in which the species is defined well by some evidence, one can study the spin-spin interactions in the radical pair by making a certain portion of the radical diluted in a suitable diamagnetic crystal. This method is different from that employed in the case of the thermally-excited triplets[3] or the radical pairs caused by the irradiation.[4,5] In fact, the dilution method was applied to nitroxide radicals which possess a fairly localized electron spin.[6,7]

On the other hand, Wiersma and Kommandeur have pointed out that even a *D*-parameter depends largely upon the magnitude of the spin delocalization.[4] Therefore, it is also of particular interest to study the dipolar coupling tensor of a radical pair with delocalized spins and, in turn, to compare the tensor with that expected for the hypothetical radical pair with localized spins. The TPV radical not only has a delocalized spin,[1] by which its enormous stability can be understood, but its molecular structure is also well known,[8] so that this radical is an adequate example for the study of the effect of the spin delocalization on the magnetic properties.

By the way, the spin structure or the interaction between the spins and the lattice in the ordered state of TPV solid has not yet been made clear. For the purpose of clarifying this spin-lattice interaction, the study of the anisotropic dipolar interactions in the radical pair of TPV, its derivatives,[9] and its analogues[10] may be a possible approach, for the dipolar interaction Hamiltonian contains the scalar product of the spin and the vector distance, while the single-spin vector in the monoradical molecule has little interaction with the vector distance.

This paper will describe mainly the fine-structure tensors of the TPV radical pairs in the 1,3,5-triphenylbenzene (TPB) matrix in order to present the fundamental data for the above-mentioned studies as well as the investigation of these magnetic entities themselves. Besides, the possible TPV radical triads will also be discussed on the basis of the radical concentration, the ESR signal intensity, and the crystal structures of TPB and TPV.

The Crystal Structures of TPB and TPV. These structures were investigated by Farag[11] and Williams[8] respectively; they are shown in Figs. 1 and 2. It should be remarked that the molecular geometry of TPV is similar to that of TPB: Each configuration



(a) (b)

Fig. 1. Molecular structures of the TPV radical (a)[8] and diamagnetic TPB matrix (b).[11]

† "Triad" means a three-membered radical cluster in which the exchange interaction energy should be much less than that of the ordinary chemical bond. We will refer to it as a "radical triad" in this text.

of the three substituted phenyl rings of both the compounds is antipropellar in the crystalline state. Some molecular flexibility of the compounds may be encountered because of the bending and twisting freedom about the bonds connecting with the rigid ring systems. Furthermore, it should be noted that the large and intense diffused X-ray spots corresponding to thermal vibrations affecting the (200) planes of TPB signify that all the bonds in these planes are stronger than those normal to them[11] and that the elastic constant along the *a*-direction, which is almost normal to the molecular planes, as may be seen from Fig. 2, is naturally smaller than the others.[12] This fact may be favorable to accommodate the guest molecule, TPV, with a molecular thickness slightly different from that of the host molecule, TPB. In the meantime, Kuhn and Trischmann have reported a Debye-Scherrer X-ray photograph with sharp lines from the equi-molecular mixed crystal of TPB and TPV,[13] which may indicate a uniform mono-phase crystal. Therefore, it is expected, in the low-concentration region, that the guest molecules, TPV, can be doped substitutionally in the host, TPB, crystal without any drastical crystal distortion, as will be described in detail in a later section. Thus, the TPV molecules in the TPB matrix will be able to form radical pairs and triads with certain concentrations.

TPB is an orthorhombic crystal with the crystal parameters of $a=7.47$, $b=19.66$, $c=11.19$ Å, and $z=4$; the space group is $Pna2_1$.[11] The molecules inclined from the *bc*-plane by $\pm 11°$ are stacked face-to-face and form two zigzag chains along the *a*-axis. The chains are related to each other by the twofold screw axis parallel to the *c*-axis. Since the interchain distance is longer than 10 Å, not only the nearest-neighboring but also the second-nearest-neighboring molecules can be found in the same chain, separated by 4.90 and 7.47 Å respectively. For the present purpose, it is safe to confine our consideration to one chain. The angle in the zigzag chain, which is bisected by the *bc*-plane, is about 100°, so that the radical pairs in the chain can be expected to be related to each other by the plane of symmetry parallel to the *bc*-plane. The most probable direction of the N-N bonds in the radical pair has been considered to be parallel to the *ac*-plane if the local symmetry around the radical pair is the same as that of the host crystal, since the crystal distortion of that orientation would be the smallest among those of the three possible orientations. The above arguments would also hold in the case of the radical triads.

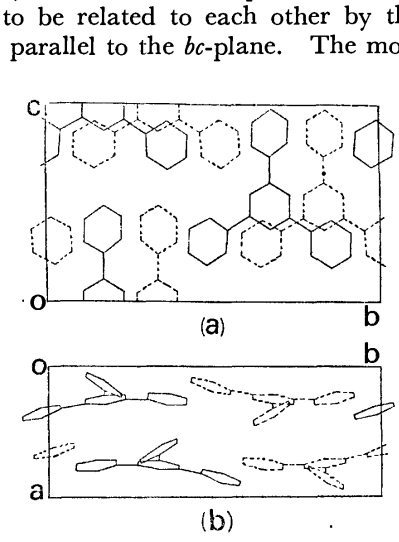

Fig. 2. Molecular packing of the host crystal, TPB.[11] (a) and (b) were projected along the crystallographic *a*- and *c*-axis, respectively.

Experimental

The TPV prepared by the method of Kuhn and Trischmann[13] was identified by the melting point, by studying the ESR spectrum in a solution, and by elementary analysis. The values obtained were in good agreement with those in the literature.[13] Commercial TPB was recrystallized from an ethereal solution; the results of the elementary analysis were satisfactory. The TPV and TPB (3 : 7 in weight) were dissolved together in an ether solvent and then slowly evaporated under nitrogen gas, thus giving small crystals. Then, the sample crystals of a suitable size were recrystallized again from the ethereal solution under a nitrogen gas flow for three days. Judging from the elementary analysis for carbon and nitrogen, the sample crystals contained TPV of 11.1% (Found: C, 92.15; N, 2.10%). More diluted crystals and reference crystals of pure TPB were also prepared by the same procedure.

The mixed and reference crystals were compared with each other, observing their crystal forms and cleavages, measuring their interfacial angles, and by the polarizing microscope technique. The X-ray diffraction spectra of the powdered samples were also compared with each other in the region from 7 to 40 degrees in 2θ, using Cu$K\alpha$ radiation.

The crystals used in the ESR measurements were mounted on the end of a synthesized polymer rod in various orientations by means of the goniometer. The ESR spectra about each of three mutually-perpendicular axes were obtained at room temperature by rotation at 5° intervals, using a JEOLCO JES-ME3X X-band spectrometer, equipped with a 100 kHz field modulation for the first derivatives and with an 80 Hz one for the second derivatives. The magnetic field was calibrated by the hyperfine splittings of Mn^{2+} in MgO.

The powdered sample containing 11.1% TPV exhibited the ESR absorptions characteristic of the randomly-oriented triplets. The half-field absorptions ($g=4$, $\Delta m_s=\pm 2$) were also observed in the powdered sample with a radical concentration of 11.1%, but no $\Delta m_s=\pm 2$ absorption was detected in the more diluted sample with a radical concentration of less than 3%.

Results and Spectral Analyses

Crystallography. When we compared the mixed crystals with the reference TPB crystals, no difference between them was detected, except for their colors, within the limits of our experimental error. This fact clearly indicates that the unit cell of the mixed crystal is identical macroscopically with that of the host crystal. Using the polarizing microscope, the samples were identified as single crystals. The sample crystal was of a trigonal form elongated along the *a*-axis and also showed an imperfect cleavage normal to that axis.[11] The faces parallel to the *a*-axis were (011) and (01$\bar{1}$) planes, and the interfacial angle was 59 degrees.

The mixed crystal with a radical concentration of less than 3% was studied by means of the ESR

technique in order to clarify the orientation of the TPV molecules. For the rotation about the *a*-axis, the crystal exhibited a symmetrical single line with the small angular dependent peak-to-peak width of 12 gauss. For the rotation about the *b*- and *c*-axis, the resonance lines varied with the rotation of the crystal; the maximum number of the lines was 18, at which the over-all width of the resonance field spread to about 100 gauss. On the other hand, the ESR spectrum of TPV in solution gave nine lines with the hyperfine coupling constant of 6 gauss due to the almost-equivalent four nitrogen nuclei. These facts indicate that the angular dependent lines are attributable to the hyperfine splittings due to the nitrogen nuclei in the isolated radical, and that no radical oligomer has any significant population. It may also reasonably be deduced that this fairly planar π-radical can occupy at least two sites and that its molecular plane is nearly parallel to the *bc*-plane.

ESR Spectra. Figure 3 shows some typical ESR spectra of the 11.1% single crystal. The intense central peak in Fig. 3(A) and nine sharp peaks in Fig. 3(B) are due to the hyperfine interactions of the isolated radicals. Each of the absorption pairs with the resonance-field separation of d_{I} and d_{I}' in Fig. 3(A) is results from two differently-oriented species. The fine structure lines in Fig. 3(B) are broader than those in Fig. 3(A). Their linewidths, proportional to the over-all width of the central lines, are probably due to the hyperfine structure broadening, which indicates that the orientation of the molecules in the pairs and triads of TPV is similar to that of the isolated radicals.

The angular variations of the observed splittings denoted by d_{I}, d_{II}, *etc.* in Fig. 3 are shown in Fig. 4. The rectangular coordinate system a'b'c' was chosen so as to avoid the overlap of the spectral lines in the orthorhombic crystal system *abc*. The relationship between the two right-hand systems is given by the following equation:

$$\begin{bmatrix} a \\ b \\ c \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & \cos\alpha & -\sin\alpha \\ 0 & \sin\alpha & \cos\alpha \end{bmatrix} \begin{bmatrix} a' \\ b' \\ c' \end{bmatrix}, \quad \alpha = -59.2^\circ \qquad (1)$$

where α is the angle measured from the *b*- to the b'-axis, equalling the interfacial angle between (011) and (01$\bar{1}$) planes.

Spectral Analysis of the Triplet. Under the conditions of (I) $g\beta H \gg |D|$, $|E|$ and (II) small *g*-anisotropy, the zero-field splittings of the triplet species can be analyzed by the approximate method described by Itoh.[14] Recently, this method has been successfully employed by Takizawa *et al.*[6] in the case of a radical pair in a matrix. The (I) assumption is considered to be valid in the present case, because the maximum value of the zero-field parameters is estimated to be less than 300 gauss from the angular variation of the splittings shown in Fig. 4. On the other hand, the *g*-values of the organic free radicals are usually almost isotropic and close to the free electron *g*-value. In fact, the *g*-value of TPV is found to be almost isotropic and to be very close to 2.0033. Therefore, the second assumption (II) is also reliable in the present case. We

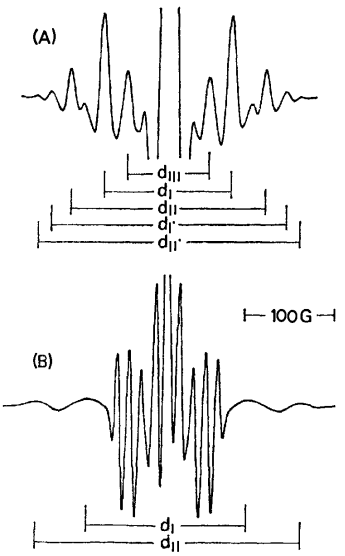

Fig. 3. Tracings of the ESR spectra from a single crystal of the diluted TPV radical. (A) *c*//**H**, the second derivative; (B) *a*//**H**, the second derivative.

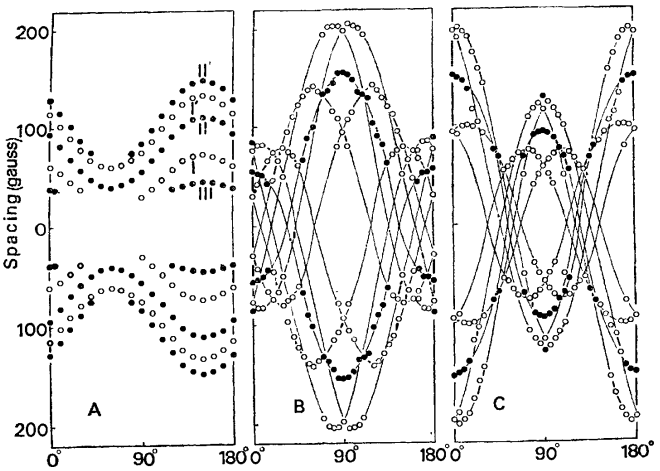

Fig. 4. Angular variations of the resonance-field separations. The numbers on the *abscissa* indicate the rotation angles. The separation, *d*, is represented by the term of *spacing*. The number of *zero* on the *ordinate* corresponds to the central field of the pairing resonance field. A, B, and C were obtained by rotations about the a'-, b'-, and c'-axis, respectively.

can thus introduce the following spin Hamiltonian:

$$\mathrm{H} = g\beta\mathbf{S}\cdot\mathbf{H} + \mathbf{S}\cdot\tilde{\mathbf{D}}\cdot\mathbf{S}, \qquad (2)$$

where $\mathbf{S}=\mathbf{S}_1+\mathbf{S}_2$, and where the subscripts 1 and 2 indicate the respective radicals forming the radical pair. The other symbols have the usual meanings. The second term in Eq. (2) is the perturbing Hamiltonian. The second-order perturbation theory gives the following resonance-field separation of the doublet splitting in the case of a-axis rotation:

$$\begin{aligned} d &= 3(g_e/g)(D'_{zz}) \\ &= 3(g_e/g)(D'_{bb}\cos^2\theta + D'_{bc}\sin 2\theta + D'_{cc}\sin^2\theta) \text{ (gauss)}, \end{aligned} \qquad (3)$$

where g_e is the free electron *g*-value and where D'_{ij}

	∓22.7	0.0043	1.0000	0.0015	

a) The alignment of the principal values is; D_{ZZ}, D_{XX}, and D_{YY}. The values were measured in gauss. Experimental errors in the values from I_a to I_b' were ±2.0 gauss. As for II′, an approximation which was described in the text was made. b) Experimental errors in directions were ±2°. c) The parameters were represented by an absolute value (in gauss).

(i,j=a, b, c) is the ij-component of the dipolar coupling tensor, $\tilde{\mathbf{D}}$, defined by the abc-system. The θ angle is measured from the b-axis to the external field, $\mathbf{H}$. For the rotation about the other two axes, the separation, d, is also described by Eq. (3) with the cyclic replacement of the subscripts. By applying the least-squares method to Eq. (3), the components of the dipolar coupling tensor can be completely determined by means of the abc-system. Then, the resulting tensor is diagonalized, giving the principal values and their directions. The zero-field parameters are given by:

$$D = 3D_{ZZ}/2 = D_{ZZ} - (D_{XX}+D_{YY})/2,$$
$$E = (D_{XX}-D_{YY})/2, \tag{4}$$

where D_{KK} (K=X, Y, Z) represents the principal value. The results of the analysis are shown in Table 1.

Spectral Analysis of the Quartet. One can analyze the spectra due to the quartet state by the procedure employed in the case of the triplet state. As is well known, the spin Hamiltonian is given by Eq. (2), but $\mathbf{S}=\mathbf{S}_1+\mathbf{S}_2+\mathbf{S}_3$, where the subscripts show the radicals in the radical triad. By employing the assumptions introduced in the last section and the second-order perturbation theory, the energy levels in terms of the Zeeman coordinate system, xyz, are obtained:

$$E(\pm 3/2) = (\pm 3/2)g\beta H + \varepsilon \pm \gamma,$$
$$E(\pm 1/2) = (\pm 1/2)g\beta H + \varepsilon' \pm \gamma',$$

where:

$$\varepsilon = (3/4)(3D_{zz}+D_{xx}+D_{yy}),$$
$$\varepsilon' = (1/4)\{D_{zz}+7(D_{xx}+D_{yy})\},$$
$$\gamma = \{24(D_{zx}^2+D_{yz}^2)+3(D_{xx}-D_{yy})^2+12D_{xy}^2\}/8g_e\beta H,$$
$$\gamma' = \{-24(D_{zx}^2+D_{yz}^2)+3(D_{xx}-D_{yy})^2+12D_{xy}^2\}/8g_e\beta H.$$

For the $\Delta m_s=\pm 1$ transition, the three resonance fields are given by:

$$H(1/2-3/2) = (g_e/g)(H_o-\delta-\delta'),$$
$$H(-1/2-1/2) = (g_e/g)(H_o+\delta'') = (g_e/g)H_o(1+\delta''/H_o), \tag{5}$$
$$H(-3/2--1/2) = (g_e/g)(H_o+\delta-\delta'),$$

where:

$$\delta = 2D'_{zz} - (D'_{xx}+D'_{yy}),$$
$$\delta' = 6(D'_{zx}^2 + D'_{yz}^2)/H_o,$$
$$\delta'' = (3/4)\{8(D'_{zx}^2+D'_{yz}^2) - (D'_{xx}-D'_{yy})^2 - 4D'_{xy}^2\}/H_o, \tag{6}$$

and where H_o stands for the resonance field of the free electron. The resonance-field separation, d, is as follows:

$$d = H(-3/2--1/2) - H(1/2-3/2)$$
$$= 2(g_e/g)(2D'_{zz}-D'_{xx}-D'_{yy})$$
$$= 6(g_e/g)D'_{zz}, \tag{7}$$

where we used this relationship: $D'_{xx}+D'_{yy}+D'_{zz}=0$. The $\tilde{\mathbf{D}}_{xyz}$-tensor in terms of the Zeeman coordinate system is represented by means of the $\tilde{\mathbf{D}}_{abc}$-tensor, which is defined by the rectangular coordinate system fixed in a crystal, using a unitary matrix, $\tilde{\mathbf{U}}$:

$$\tilde{\mathbf{D}}_{xyz} = \tilde{\mathbf{U}}^{-1}\cdot\tilde{\mathbf{D}}_{abc}\cdot\tilde{\mathbf{U}}. \tag{8}$$

When the crystal is rotated about the a-axis which coincides with the y-axis, and when the external field, $\mathbf{H}$, makes an angle, θ, with the b-axis, $\tilde{\mathbf{U}}$ is represented by:

$$\tilde{\mathbf{U}} = \begin{bmatrix} 0 & 1 & 0 \\ -\sin\theta & 0 & \cos\theta \\ \cos\theta & 0 & \sin\theta \end{bmatrix}. \tag{9}$$

By using Eqs. (7)—(9), d is given by:

$$d = 6(g_e/g)(D'_{bb}\cos^2\theta + D'_{bc}\sin 2\theta + D'_{cc}\sin^2\theta). \tag{10}$$

Eq. (10) is similar to Eq. (3) used in the case of the triplet. Therefore, we can analyze the spectra due to the quartet state using Eq. (10), to which the same procedure as that employed in the last section is applied.

As for the (−1/2—1/2) transition, let us put the second-order term given by Eq. (6) on the far right-hand side in Eq. (5). The δ''/H_o ratio is estimated roughly to be 1/100 at most in the case of H_o=3000, D=200 gauss, and $|E|<|D|$, so that the angular variation of the absorption is restricted within ±30 gauss from the central resonance field. Hence, the absorption is hard to detect in the radical triad in a matrix because of its overlap with the much more intense absorptions due to the isolated radicals.

The results of the analysis are also shown in Table 1, in which the indices from I to II′ correspond to the same subscripts and to the indices in Figs. 3 and 4 respectively. The subscripts, a and b, stand for the

sites occupied by the radical oligomers. The directions obtained in the a'b'c'-system were transformed to those with respect to the orthorhombic one, *abc*, by using Eq. (1). In the case of the zero-field splitting, II', we could measure $d_{II'}$ only in two directions about the b'-axis and in only one about the c'-axis because of the quite weak absorption intensities in addition to the broader linewidths. However, the following approximation was taken based on the angular variations of the other splittings as well as the $d_{II'}$ obtained: the absorption lines of II' are overlapped with those of I_a' and I_b', at least in the vicinity of each summit in Figs. 4-B and 4-C. The directions obtained by such an approximation may be more reliable than the principal values.

Discussion

Discrimination of Radical Triad from Radical Pair. In the chain containing the radical molecules with a moderate concentration, **c**, the probabilities making the radical triad, the radical pair, and the isolated radical are $3\mathbf{c}^3(1-\mathbf{c})^2$, $2\mathbf{c}^2(1-\mathbf{c})^2$, and $\mathbf{c}(1-\mathbf{c})^2$ respectively. When **c** is 0.11, the ratios of the triad to the isolated radical and to the pair give 0.036 and 0.165 respectively. Therefore, the observation of the radical triad is possible by the usual ESR technique, using a rather bulky single crystal with a suitable radical concentration. The observed intensity ratio, $\Sigma I_{triad}/\Sigma I_{pair}$, is about 0.12 after the correction for the absorption from the (−1/2—1/2) transition. This value is quite close to the calculated one, provided that the signal intensities are proportional to the concentrations of the species along with a common proportionality constant.†† This result supports our assignment of the radical oligomers. Other evidence for the identification will be discussed later.*

Structure of the Radical Pair. The $\tilde{\mathbf{D}}$-tensors of I_a and I_b satisfy the aforementioned symmetry within the limits of experimental error. The angles between the *a*-axis and each z-axis in these radical pairs are both 31°, which is close to the angle of 40° deduced from the intrachain angle of the host crystal. The $\tilde{\mathbf{D}}$-tensors, I_a and I_b, can, therefore, be attributed to the radical pairs which are formed from the TPV molecules located as nearest-neighbors to each other in the host crystal. On the other hand, the x-axis coincides approximately with the *c*-axis. This implies that one of the substituted phenyl rings is almost in the *c*-direction; this is consistent with the crystal structure of TPB, in view of the molecular geometry of TPV. However, we can not definitely decide the orientation of the *C*-phenyl rings (see Fig. 1) on the basis of the $\tilde{\mathbf{D}}$-tensor alone, as will be discussed in later section.

The *D*-parameter of II is the same as those of I_a and I_b, but the three principal axes coincide with the orthorhombic crystal axes within the limits of experimental error. The absorption intensity ratio of I_{II}/I_{I_a} is about 3/4. These results were reproduced using another sample of a (1 : 4) mixture, so this species is an intrinsic radical pair in the TPV-TPB system. The structure of this radical pair, based on the $\tilde{\mathbf{D}}$-tensor, is as follows: both of the molecular planes in this pair are parallel to the *bc*-plane, and the *C*-phenyl rings are in the *c*-direction; the second molecule is just above the first molecule, the distance between them being about *a*/2. This structure implies that the molecules in this pair have; (i) a planar geometry or (ii) a plane of symmetry. The first possibility, (i), is alternative evidence for the planar geometry of the TPV molecule, although Williams has revealed it by means of X-ray diffraction.[8] As for the second possibility, (ii), we would like to present the following facts: the symmetrically-substituted verdazyls seem to possess a plane of symmetry in their crystalline state.** In fact, TPV itself has a pseudo- or almost-mirror plane.[8]***

Radical Triad. The $\tilde{\mathbf{D}}$-tensors of I_a' and I_b' in Table 1 have the same symmetry as that of the tensors of I_a and I_b within the limits of experimental error. The *a*-axis and each of the z-axes in the former make angles of 10°, which is one-third of that in the latter. The above results suggest that the $\tilde{\mathbf{D}}$-tensors of I_a' and I_b' ought to be attributed to the radical triads. If it were not for the radical triad, one should presume another radical pair with an intermolecular distance less than that of the pair, I_a, without the third radical molecule on either side of the latter pair causing the deformation of the pair. A similar comment can be made on the I_b and II radical pairs. On the other hand, the directions of the $\tilde{\mathbf{D}}$-tensor, II', are also similar to those of the tensor, II. The tensor of II' can also be attributed to the radical triad for the same reason. All the results may be consistent with the structures of the radical triads proposed in Fig. 5; each triad is formed by adding one radical molecule to each aforementioned radical pair to the position obtained by the *a*-transla-

†† When both the electron-spin-exchange interactions in the radical oligomers are antiferromagnetic, and when a linear alignment of the spins in the radical triad is taken, the more reasonable signal intensity ratio, I_{triad}/I_{pair} $(=r)$, can be given by:

$$r = 3\mathbf{c}^3(1-\mathbf{c})^2\chi_q\{2\mathbf{c}^2(1-\mathbf{c})^2\chi_t\}^{-1}$$
$$= 15\mathbf{c}\{3+\exp(2|J_t|/kT)\}[8\{2+\exp(3|J_q|/2kT)+\exp(5|J_q|/2kT)\}]^{-1},$$

where χ_q and χ_t are the magnetic susceptibilities due to the quartet and triplet states respectively. J_q and J_t stand for the exchange integrals in the radical triad and the pair respectively. *T* and *k* have the usual meanings. When one puts $\mathbf{c}=0.11$, $T=300$ K, and $-J_q/k=-J_t/k=10$, 50, 100 K into the equation, the ratios give 0.203, 0.189, and 0.172 respectively. The exchange integrals, $|J/k|$'s, in the present radical oligomers are supposed to be from ten to a few score degrees. Therefore, the approximation ($r=3\mathbf{c}^3(1-\mathbf{c})^2/2\mathbf{c}^2(1-\mathbf{c})^2$ $(=0.165$ for $\mathbf{c}=0.11)$) mentioned in the text is considered to be a tolerable one.

* The possibility of the observation of the radical tetrad was not discussed, because the ratio of the tetrad to the triad is about 1/10.

** Two symmetrical verdazyls have a plane of symmetry (Ref. 15).

*** Note that Fig. 1(a) was not projected along the normal of the molecular plane.

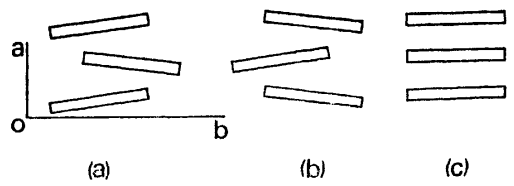

Fig. 5. Schematic drawings of chemical structures of the proposed radical triads projected along the *c*-axis. (a), (b), and (c) correspond to the radical triads I_a', I_b', and II', respectively. Oblongs stand for the sections of the idealized molecular planes.

tion of that occupied by the first molecule in the pair.

The absorption-intensity ratio, $I_{II'}/(I_{I_a'}+I_{I_b'})$, is very close to the $I_{II}/(I_{I_a}+I_{I_b})$ ratio. This suggests the following mechanism for the formation of the radical oligomer in the TPV-TPB system. There are two types of positions occupied by the first radical molecule; (A) one is one of the four general positions determined originally by the host molecules in the unit cell, and (B) the other is a special one. The positions occupied by one kind of radical oligomer are all of the same type, that is, A-A or B-B and A-A-A or B-B-B for the radical pairs and triads respectively. This mechanism also may explain the observation of only three $\tilde{\mathbf{D}}$-tensors for the radical triads. The letters correspond to the subscripts in Table 1. On the basis of the above consideration, we expect that the B-B-B type stacking may be a meta-stable packing of the host and the guest molecules. Actually, a molecular packing very similar to this type has been found in the 1,3,5-triphenyl-6-methylverdazyl crystal.[15]

The spin multiplicity of the fine structure defined by the resonance-field separation, d_{III}, is not clear at present, although the signal intensity can be explained well b assuming a radical triad containing one TPB molecule in its structure rather than presuming a second-nearest-neighboring radical pair.

$\tilde{D}$-Tensor Calculation with Spin Densities. The calculation of the dipolar coupling tensors of the proposed radical pairs is made in order to clarify the orientation of the *C*-phenyl rings in the pairs and in order to examine the effect of the spin delocalization on the $\tilde{\mathbf{D}}$-tensor. The parameters, *D* and *E*, of radical pairs have already been calculated by several authors[4,16] on the basis of the molecular orbital theory. Although the present method is essentially the same as theirs, the principal values and their directions are both obtained by our method. The spin Hamiltonian which is considered to be valid for the radical pair is given by:

$$H_D = \sum_{i,j} g^2\beta^2\rho_i\rho_j\{\mathbf{S}_1\cdot\mathbf{S}_2/r_{ij}^3 - 3(\mathbf{S}_1\cdot\mathbf{r}_{ij})(\mathbf{S}_2\cdot\mathbf{r}_{ij})/r_{ij}^5\}, \quad (11)$$

where ρ_i and ρ_j are the π-spin densities on the *i* atom in the first molecule, 1, and on the *j* atom in the second molecule, 2, and where $\mathbf{r}_{ij}$ is the vector distance connecting *i* to *j*. The Hamiltonian, Eq. (11), is rewritten in a matrix form by means of the total spin, $\mathbf{S}=\mathbf{S}_1+\mathbf{S}_2$:

$$H_D = \mathbf{S}\cdot\tilde{\mathbf{D}}\cdot\mathbf{S},$$

where the symmetrical tensor is:

$$\tilde{\mathbf{D}} = \begin{bmatrix} D_{xx} & D_{xy} & D_{xz} \\ D_{xy} & D_{yy} & D_{yz} \\ D_{xz} & D_{yz} & D_{zz} \end{bmatrix}, \quad (12)$$

and where:

$$D_{mm} = (1/2)g^2\beta^2\sum_{i,j}\rho_i\rho_j(r_{ij}^2-3m_{ij}^2)/r_{ij}^5, \quad (m=x, y, z),$$

$$D_{mn} = (1/2)g^2\beta^2\sum_{i,j}\rho_i\rho_j(-3m_{ij}n_{ij})/r_{ij}^5,$$

$$(m, n=x, y, z; \text{ but } m\neq n).$$

The $\tilde{\mathbf{D}}$-tensor given by Eq. (12) can be calculated in an arbitrary rectangular coordinate system if the structure of the radical pair and the spin distribution are known, followed by diagonalization. However, we use an alternative method in which the Zeeman system is employed and in which only the *zz*-component is used:

$$D'_{zz} = (1/2)g\beta\sum_{i,j}\rho_i\rho_j(r_{ij}^2-3z_{ij}^2)/r_{ij}^5$$

$$= (1/2)g\beta\sum_{i,j}\rho_i\rho_j(1-3\cos^2\theta_{ij})/r_{ij}^3, \quad (13)$$

where θ_{ij} is the angle between the vector, $\mathbf{r}_{ij}$, and an applied field, $\mathbf{H}$. Putting Eq. (13) into Eq. (3), we obtain:

$$d = (3/2)g_e\beta\sum_{i,j}\rho_i\rho_j(1-3\cos^2\theta_{ij})/r_{ij}^3, \quad (14)$$

By employing Eq. (14), the diagonalized $\tilde{\mathbf{D}}$-tensor is obtained by the procedure described in the section on spectral analyses.

The results of the calculation are shown in Table 2, together with the directions of the *C*-phenyl rings. When the calculation was carried out, the spin densities were taken from Ref. 1. The vector distances were deduced from the host crystal for the I_1 and I_2 radical pairs. As for the II_1 and II_2 pairs, the distances have been estimated from the structures in which the first molecules are the same as those in the I_1 and I_2 pairs, while the second molecules are obtained by the *a*/2-translation of the first molecules. In the table, the $\tilde{\mathbf{D}}$-tensor of I_a in Table 1 is close to the I_1 rather than to the I_2. This result suggests that the *C*-phenyl rings in the I_a and I_b radical pairs are in the *c*-direction, which is consistent with our expectation. II_1 also explains II; this indicates again the orientation of the *C*-phenyl rings in the radical pair of II along the *c*-axis. The discrepancy between the observed and the calculated $\tilde{\mathbf{D}}$-tensors depends mainly on the difference between the true and the presumed vector distances. However, the results of the calculation may not only support our assignment of the radical pairs with the proposed structure, but also suggest that the $\tilde{\mathbf{D}}$-tensors due to the proposed radical triads can not be explained by assuming the radical pairs with *C*-phenyl rings differently oriented from those in the I_a, I_b, and II pairs.

In order to compare the *D*-parameters observed and calculated above with that expected from a point-spin approach, we estimated the latter to be 240 gauss by using the relation: $D=(3/2)g\beta/r^3$.[17] On the other hand, the *D*-parameters observed and calculated by our method are 150 and 130 gauss respectively. This

Electronic Spectra of Perylene Crystals

Jiro TANAKA, Tohru KISHI, and Masashi TANAKA
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464
(Received March 20, 1974)

The electronic absorption and emission spectra of α and β forms of perylene have been investigated. The low-temperature spectra have been studied with the (001) plane, and a detailed vibrational analysis is presented. The reflection measurements with the (001) plane and the (110) or (1$\bar{1}$0) plane are carried out, and the Kramers-Kronig transformation is carried out in order to obtain the absorption coefficient. The results present reasonable evidence for the existence of the intermolecular CT transition in the 27000 cm^{-1} region. The emission spectra at 4.2 K present several novel features of the mechanism of a monomer-like emission of the α-crystal.

Since the absorption and fluorescence of perylene have been investigated on two crystalline forms of perylene,[1] many papers have apperared on this and related problems.[2-6] Detailed spectroscopic investigations of this system will still be of great value, because they will provide a unique chance to examine the conditions of the excimer formation in molecular crystals.[7] The intermolecular CT band between the same entity in a neat crystal is still a problem of dispute[8]; however, the CT band of 9,10-dichloroanthracene[9] has recently been confirmed by the electroreflectance experiment of Abbi and Hanson.[10]

In the present paper, we will report a further spectroscopic investigation of perylene crystals by using somewhat elaborate methods. First, the low-temperature absorption spectra at 1.6 K and 4.2 K of the α and β forms of perylene are measured by the transmission method, using a medium spectrograph. Then, the crystalline reflection spectra are recorded and the Kramers-Krnoig transformation is used to calculate the absorption spectra. By the latter method the spectra along a different crystalline direction which has not been measured in the previous paper can be obtained, and further discussions of the CT state and of hypochromism are presented. The emission spectra at 4.2 K are also photographed, and the Stokes shifts of fluorescence are discussed in connection with the crystal structure and intermolecular interactions.

Experimental

The perylene used was a product of Theodor Schuchardt of W. Germany. It was recrystallized, and then further purification was carried out by means of column chromatography. The α crystal for the transmission measurement was obtained by a sublimation method, and it was not difficult to obtain crystals about 5 mm × 5 mm with a thickness of less than 1 μ. The thin crystal of the β form was rather difficult to obtain, but it could be grown from a solution of 90% benzene and 10% toluene. For the transmission measurement the crystal was polished with benzene until it showed retardation of about 300 mμ of a yellow colour. The crystals for the absorption measurement at a low temperature were mounted between thin quartz disks and then covered with a black mask with a pin-hole. The light penetrated through the pin-hole, with a diameter of less than 1 mm, and the pin-hole was placed on the uniformly thick part of the crystal. The crystals were placed in the holder in the direction in which the polarization effect of the grating spectrograph was not serious. The holder was then placed in the double quartz Dewar vessel and immersed in liquid helium.

The set-up of apparatus for absorption and emission measurements is shown in Fig. 1. The spectrograph used was a Shimadzu GE-100 apparatus, with a Bausch-Lomb grating of dispersion of 8.3 Å/mm. The light source for the absorption measurement was a tungsten lamp containing iodine of 100 W. A high-pressure mercury lamp of 250 W combined with a Toshiba DV-1 filter was used for the excitation of fluorescence. The fluorescence was either photographed by means of the spectrograph or was photo-electrically recorded by means of a Carl-Zeiss spectrofluorometer. For the measurement at 1.6 K, the helium Dewar was pumped out and the temperature was measured by means of the vapour pressure of helium.

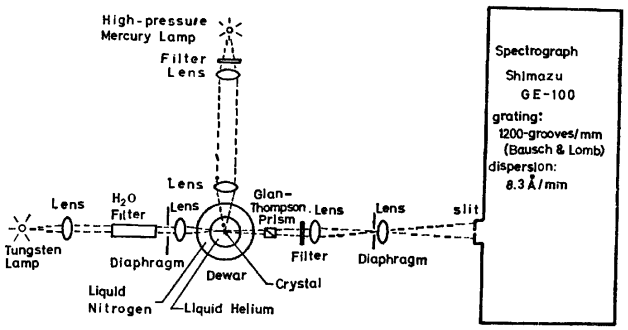

Fig. 1. The optical system for spectral measurement.

The reflection spectra are recorded with (001) and (110) or (1$\bar{1}$0) planes of α and β forms by means of a system which will be described in a separate paper.[11] Although the transmission measurements are confined along the a- and b-axes of α and β crystals, the reflection data are obtained with the other direction, perpendicular to the ab plane.

Results and Discussion

Low-temperature Absorption Spectra of α-Perylene. The low-temperature absorption spectra of the α-crystal at 1.6 K show clear vibrational structures in the beginning of the band series. The absorption band along the b-axis shows a particularly close resemblance to that of the solution (Fig. 2), while the band shape and intensities are greatly changed along the a-axis (Fig. 3). The 0–0 band origins are certainly confirmed along the a- and b-axes, and the Davydov splitting is determined as 820 cm^{-1}. The band systems are assigned with reference to the solution band system as is shown in Table 1. The band width is much broader along the a-axis, and the width of the 0–0 band at 1.6 K was 300 cm^{-1} for the a-axis and 190 cm^{-1} for the b-axis. The width in the *n*-hexane solution was smaller than 10 cm^{-1}, which may be a typical pattern

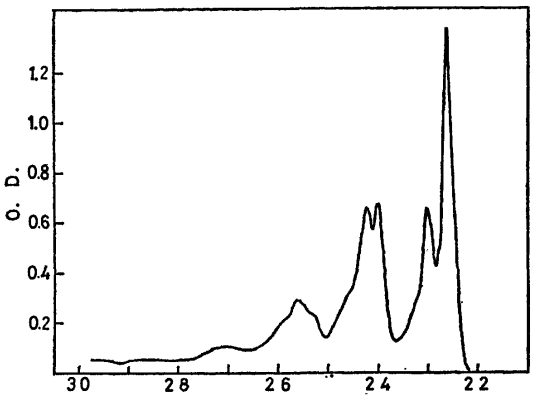

Fig. 2. Absorption bands of perylene in EPA solution at 77 K.

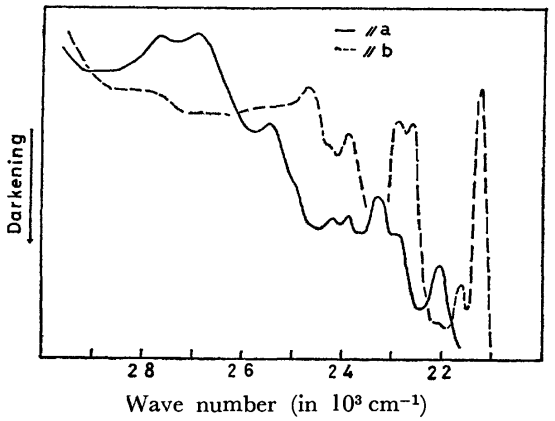

Fig. 3. Polarized absorption spectra of α crystal at 1.6 K.

of the Shpolskii effect.[12] At higher vibrational levels the band widths are much broader for the a- and b-axes; this may be induced by the effect of other types of transitions near-by or overlapping.

Above 26000 cm^{-1} the band becomes very broad and it may be supposed that the band in this region is composed of transitions of a different character rather than of vibrational progressions of a unique electronic origin. The intermolecular CT transition, which has been suspected because of its weak intensity, is found in this spectra in the 26500—29000 cm^{-1} region. There have been several discussions of the presence of the CT band, because only a weak and broad band was found at room temperature in an earlier paper.[1] One of the criticisms of the CT mechanism is based on the calculation of the vibronic structure of the coupled dimer,[3,4] but the broad character of the band at very low temperatures can not be reasonably explained by this mechanism because each vibronic band is clearly resolved in the 21000—25000 cm^{-1} region. Therefore, the overlapping of the intermolecular CT band and the vibrational progressions of the first $^1B_{2u}$-type transition seem the most reasonable explanations of the anomalous

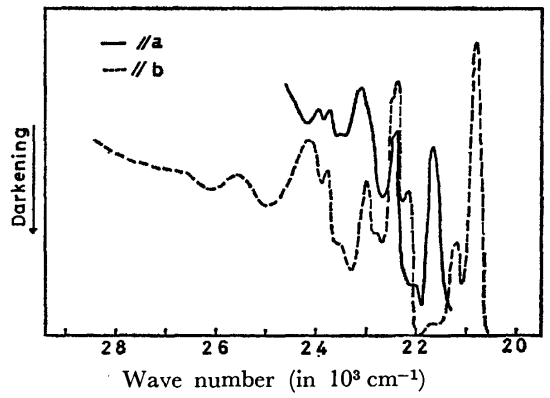

Fig. 4. Polarized absorption spectra of β crystal at 1.6 K.

band shape.

Low-temperature Absorption Spectra of β-Perylene. The spectra photographed at 1.6 K with the (001) plane are shown in Fig. 4. The 0–0 band origin and the details of the vibrational structures were clearly resolved. The Davydov splitting is 830 cm^{-1}, of nearly the same magnitude as the α crystal. In an earlier paper[1] a much larger value was assigned for this splitting, but it should be corrected because the 0–0 band origin has now been clearly confirmed.

The vibrational progressions of the b-axis spectra are nicely correlated with the solution spectra, since the band shape is nearly regular. On the other hand, the band shape is rather anomalous along the a-axis, and the band width for the a-axis is broader than for the b-axis. For instance, the half-width of the 0–0 band is 290 cm^{-1} for the a-axis and 180 cm^{-1} for the b-axis. The pattern of vibrational progression along the a-axis is also modified from the solution band. There are several reasons for this change; one is the change in Franck-Condon factors from the free molecule to the molecule in the crystal, which means that the vibrational mode in the excited state involves a significant anisotropy. Another possible effect may be due to the CT transition or band-to-band transition along the direction of the stacking of the molecule. Although the intensities of these transitions may be quite small, they may be influential upon the a-axis band in causing hypochromism or broadening. In this respect, several weak humps around the 28000—31000 cm^{-1} region may be suspected as CT bands, because these bands were enhanced under high pressures.[13]

Two more characteristics of the low-temperature spectra of the α and β crystals are that the Davydov splitting for higher vibrational progressions are rather small, while the band splitting is not proportional to the intensity of each vibronic band. The assignment of band splitting with higher levels was rather difficult; it appears thereby that the intramolecular vibrational coupling is much stronger than the excitonic interaction between adjacent molecules in the crystalline lattice. At any rate, the weak coupling scheme must be used to analyse the perylene crystalline spectra rather than the intermediate or strong coupling, because the band splittings were found at all vibronic levels.

Reflection Spectra of α and β Perylene. The reflection measurement has several advantages over the transmission method; for instance, the thick crystal can be used to determine the polarization direction with more than two crystalline faces, and the intensity of a very strong band can be determined rather accurately.

The reflectivities of the α and β forms are shown in Figs. 5 and 6. The Kramers-Kronig transform of the reflectivity gave the absorption spectra shown in Figs. 7 and 8. The spectra are taken with the (001) and ($\bar{1}$10) planes of the α crystal and with the (001) and (110) planes of the β crystal. Although the direction perpendicular to the (001) plane is not exactly coincident with the c-axis, it is in nearly the same direction. The spectra show several interesting properties which have not been recognized in earlier transmission measurements on the (001) plane.

The first absorption region of the α crystal, at 20000—28000 cm^{-1}, can be recorded for all three directions.

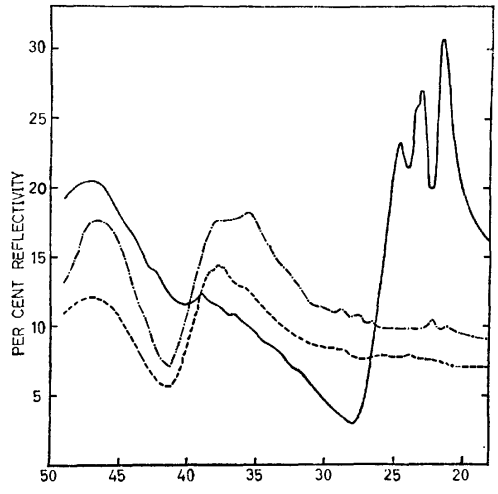

Fig. 5. Reflectivity of α crystal at room temperature.

—— a-axis, —·— b-axis, —— c-axis.

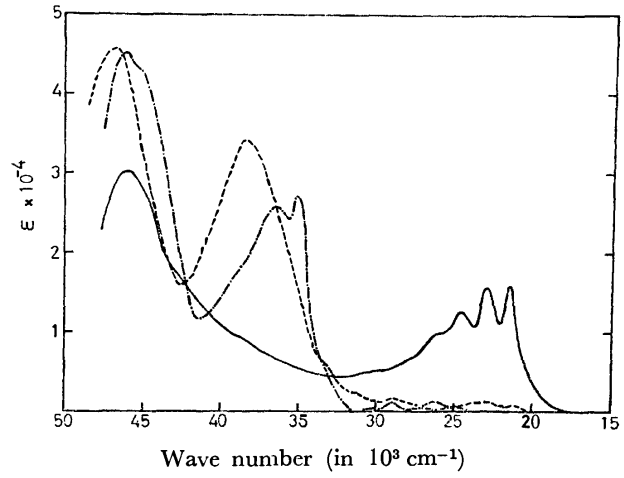

Fig. 8. Absorption spectra of β crystal at room temperature.
—— a-axis, —·— b-axis, —— c-axis.

It is quite interesting that the spectrum along the c-axis is nearly in agreement with the powder state spectra in KBr disk measured by Offen and Beardslee;[13] this result is reasonable since the intensity is strongest along this axis. The absorption curves obtained by reflection for the $^1B_2$ and the CT bands of the a- and b-axes were not accurate enough as compared with the transmission results. The c-axis spectrum of the β-crystals shows vibrational progressions which resemble those of the solution spectra; this may imply that the whole band in this region is of a unique character. On the other hand, the c-axis band of the α crystal is in marked contrast; there the vibrational progressions higher than 23500 cm^{-1} are greatly changed from their regular shape.

Theoretically, the energy levels of a molecular crystal should conform to the group theoretical splitting, and the levels must be the same for the a- and c-axes bands in a monoclinic crystal. Therefore, the band positions should be coincident for the a- and c-axes if the same electronic transition is involved. Actually, this prediction is almost in accord with the first several vibronic levels when we compare the band positions of the a-axis obtained by the transmission method with the c-axis band based on the reflection data. Moreover, the band shape of the c-axis spectrum is in accord with neither the a-axis spectrum nor the theoretical curve of Witkowskii *et al.*[4]

On the other hand, a similar change in band shape has been observed in the case of the mixing of the CT state with the molecular exciton state. The CT transition may cause such an anomaly; for instance, the c-axis band of 9,10-dichloroanthracene is changed from the regular band shape in solution. In this crystal, the CT transition with the out-of-plane polarization has been found along the particular crystalline direction (a-axis);[9] the presence of such a CT state influences the shape of the in-plane transitions along the c-axis. Therefore, the marked change in the α perylene spectra along the c-axis in this range may be regarded as another token of this type of mixing, indicating the existence of the CT transition in the 26000—28000 cm^{-1} region of the a-axis. The enhancement of the 25000 cm^{-1} band of α perylene under high pressure has been reasonably explained by the CT mechanism.[13]

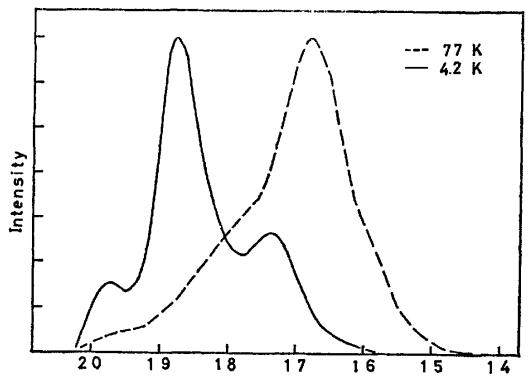
Direct evidence for the existence of the CT state with the (001)-plane reflection spectra was rather difficult to obtain because of the weak intensity of the bands along the a-axis. In spite of this difficulty, though, several weak bands were observed with the a- and b-axes of the α and β-form crystals in this region. It may be said that the detection of a weak CT transition is rather difficult by the reflection method unless the crystal structure is mostly favoured; a negative result with dibenzoselenophene[14] may be understood by this reasoning.

The second absorption region at 33000—42000 cm^{-1} is due to the short-axis polarized transition of the $^1B_{3u}$ type, and the absorption shape is different for the α and β crystals. The absorption spectra transformed from the reflection data for the α form gave a pattern similar to that of the transmission result, but the β form spectrum was somewhat different from the earlier transmission result. Along the a-axis band of the β crystal, a vibrational progression resembling that of the solution was observed. A Davydov splitting of the same sign and magnitude as the calculated value given in the previous paper was found with the β crystal.

The higher energy transition in the 44000—53000 cm^{-1} region in a solution is confirmed to be composed of several long- and short-axes polarized bands. This was also found by Fuke, Kaya, and Nagakura[15] independently.

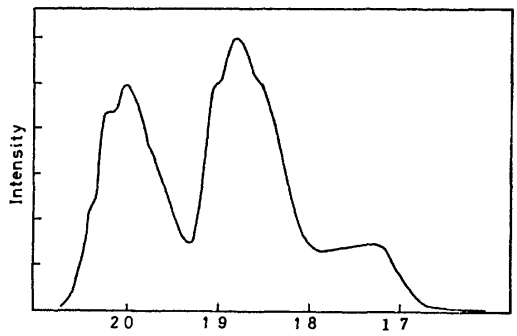
In the light of the present results, it is quite interesting that the dimer spectra in a rigid solution found by Ferguson[3] showed a band shape similar to that of the a-axis band of the α crystal. Since the average of intensities with three crystalline axes is more or less the same as that of the solution spectrum, it appears that the dimer or its aggregates in a rigid solution may have a much more symmetrical or specific structure than in crystals, because the hypochromism and the anomaly of the band shape is rather pronounced.

Fluorescence Spectra of α and β Perylene. At 4.2 K the excimer fluorescence of the α form does not appear; instead, a monomer-like emission is observed. In an earlier investigation the effect of the re-absorption of the crystalline surface on the shape of the fluorescence



Wave number (in 10^3 cm^{-1})

Fig. 9. Emission spectra of α crystal at 4.2 K.



Wave number (in 10^3 cm^{-1})

Fig. 10. Emission spectra of β crystal at 4.2 K.

was not properly taken into account;[5] therefore, a detailed band analysis is undertaken in this study. The fluorescence spectra of α and β perylene are illustrated in Figs. 9 and 10, where the results at 4.2 K are presented. No essential difference in spectra were found at 1.6 K and 4.2 K. The spectra are recorded on a Carl-Zeiss fluorometer.

In the photograph of β emission at 1.6 K, very sharp lines are observed, and the 0–0 band origin is assigned at 20517 cm^{-1}. The vibrational progressions are tabulated in Table 2, together with the values found in a solution. The Stokes shift in a solution is only 30 cm^{-1}, while the corresponding value for the β crystal is 293 cm^{-1}.

The α-form emission at 77 K shows the peak of the excimer band at 16850 cm^{-1}, but weak components at 19000—20000 cm^{-1} are also observed. Inoue *et al.*[6] showed, by time-resolving spectroscopy, that these results are due to a monomer-like emission.

The photographs at 4.2 K and 1.6 K show only broad emission bands, situated at 19800, 18750, and 17400 cm^{-1}. The band origin was not clearly ascertained since no fine structure could be detected at the beginning of the first band. The Stokes shift was estimated as about 1000—1400 cm^{-1}, significantly larger than that of the β crystal.

It has been suggested in an earlier paper[1] that the intermolecular approach of two molecules in the excited state is essential for the excimer formation. This point seems to be substantiated by the following investigations. At 4.2 K in the α crystal, the excimer emission is absent, but there still remains a significant red

Table 2. Sharp emission lines of β-perylene crystal

β-Crystal (cm^{-1})	$\Delta\nu$	*n*-Hexane solution[12] $\Delta\nu$
20517	(0)	0
20496	(−21)	
20473	(−44)	
20408	(−109)	
20333	(−184)

20145	(−372)	
19389	(−1128)	−1104
19314	(−1203)	
19283	(−1234)	
19212	(−1305)	−1298
19144	(−1373)	−1375
18939	(−1577)	−1578

shift of the emission band. The shift is certainly larger than the monomer emission band of the β crystal. This may imply that the levels in the α crystal are split by the excitonic interaction at the distance of the ground-state configuration or that the shift of the level is accompanied by a slight distortion of the structure. The lower energy level will be forbidden in a strict D_{2h} symmetry, but the band is actually observed to the red of the 0–0 absorption band; this may suggest a deformation of the paired molecule from the parallel arrangement. In other words, the intermolecular interaction is much larger for the α-form than for the β-form even at 4.2 K.

The emission spectrum of the perylene dimer[3] in a rigid solution is reported to have a maximum at 18280 cm^{-1}, and the band shape at 20 K is composed of the excimer type and a monomer-like band of the α crystal. The crystalline bands are 500 cm^{-1} higher in energy than that found for the dimer. This finding suggests that the excitonic and charge-resonance interaction will be easier for the dimer in a rigid solution than in crystals.

In the earlier paper the monomer-like emission of the α-form at 4.2 K was simply called a monomer band, and it was considered it was nearly the same in character as the β-form emission band. As a matter of fact, the level is significantly shifted; therefore, the previous interpretation of this level must be revised so as to involve a different character rather than the Franck-Condon excitonic state.

Recently Inoue *et al.*[6] claimed that the excimer formation from the Franck-Condon excited state competes with the process of the relaxation to a monomer-like emission level. The discrimination of the monomer-like emissive level of the α crystal from the Franck-Condon excited level will be important for any further analysis of the excimer process.

The red shift of the excimer emission of the α-form at 77 K may be estimated to be as large as 9000 cm^{-1} if we take the origin of the CT band at 26000 cm^{-1}. Therefore, such a large shift can be explained only when the distortion of molecules in the excited state is allowed to move to a closer distance than in a crystal

at 4.2 K[1,16] where the interaction of the charge-resonance state with the excitonic state will be very much larger than for the above-mentioned deformed configuration.

Concluding Remarks. The existence of the CT state in neat molecular crystals is a problem of interest, and evidence of such a state obtained by an accurate spectral study has been presented for perylene crystals. The polymorphism of the crystal has been shown to be of great help for such an investigation. Although the reflection method in crystalline spectroscopy is very powerful, its limitation for weak transitions has been presented. The combination of reflection with the transmission method will give the most reliable results in determining the polarization character. The investigation of the CT state in neat molecular crystals will still be a challenging problem, and the critical condition for observing such a band must be sought in further studies.

Although the geometry of the excimer state is still not known, it has been found that the shape and position of the emission band are greatly dependent on the relative orientation of molecules in the crystal. Further investigation will elucidate the structure of the excimer state in a crystal or in a fluid solution.

Microwave Spectrum, Structure and Dipole Moment of Ethanethiol. I. *Trans* Isomer

Michiro HAYASHI, Hisae IMAISHI, and Kazunori KUWADA
Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-sendamachi, Hiroshima 730
(Received December 10, 1973)

The microwave spectra of *trans*-ethanethiol and its isotopic species were measured. The r_s structure of the *trans* isomer was determined from the observed moments of inertia. The *trans* isomer has a symmetrical CH_3 group, the parameters for the CH_2SH part of the molecule being approximately equal to those of methanethiol. The C-C bond length, found to be 1.529±0.006 Å, is close to that of propane. The angle α(CCS), obtained as 108°34′ ±19′, is much smaller than that of analogous molecules. Discussion is given for this anomalously small α(CCS) angle. From the Stark shifts, the dipole moment of the *trans* isomer was determined to be $\mu_a = 1.058 \pm 0.023$, $\mu_b = 1.146 \pm 0.002$ and $\mu_{total} = 1.560 \pm 0.032$ D, an angle of 28°46′ being made with the bisector of the α(CSH) angle inclining towards the ethyl group. Since the dipole moment of methanethiol makes an angle of 18°30′ with the bisector of the α(CSH) angle, the increase of the angle with the bisector for ethanethiol was concluded to arise from the induction moment of the ethyl group. A brief description is given for the spectra due to the *gauche* isomer.

From an interest in the internal rotation of completely asymmetric molecules, we investigated the microwave spectra of ethanethiol. The rotational spectra of ethanethiol might be influenced by two modes of internal rotation, one relating to the CH_3 group and the other to the SH group. If the barrier to the internal rotation of the SH group is sufficiently high, the rotational isomers can be observed. Actually we could observe two groups of strong spectra belonging to the ground states of the *trans* and *gauche* isomers, as well as several groups of weak spectra belonging to the vibrationally excited states.

Kadzhar, Abbasov, and Imanov[1] reported on the microwave spectra of two isotopic species of *trans*-ethanethiol. Schmidt and Quade[2] studied the normal species of *trans*-ethanethiol.

A part of our studies on the microwave spectra of ethanethiol, was reported[3] but publication of details was postponed until the spectra of a sufficient number of isotopic species necessary for determining the r_s structure of *trans*-ethanethiol were obtained.

As regards the *gauche* isomer, several strong spectra with Stark effects characteristic of the *a*-type *R* brnach transitions were observed for the normal and seven deuterated species. For the normal and CH_3CD_2SH species, the transitions of types $(J+1)_{1J+1} \leftarrow J_{1J}$ and $(J+1)_{1J} \leftarrow J_{1J-1}$ exhibited doublet structures with several MHz spacings, each component of the doublet having identical Stark shifts. The transitions of types $(J+1)_{0J+1} \leftarrow J_{0J}$, $(J+1)_{2J} \leftarrow J_{2J-1}$ and $(J+1)_{2J-1} \leftarrow J_{2J-2}$ were observed as singlets. For the CH_3CH_2SD and two of the CH_3CHDSH species, all the *a*-type transitions were observed as singlets.

For the CH_2DCH_2SH species, there are two different molecular forms expected for the *trans* isomer, (designated as *s*-CH_2DCH_2SH and *a*-CH_2DCH_2SH species, where "*s*-" and "*a*-" refer to the symmetric and asymmetric forms, respectively, with respect to the molecular plane). There are three different molecular forms expected for the *gauche* isomer, one of which corresponds to the *s*-CH_2DCH_2SH species for the *trans* isomer and the other two to the *a*-CH_2DCH_2SH species.

For these three CH_2DCH_2SH species for the *gauche* isomer, similar doublet structures were observed for the species corresponding to the *s*-CH_2DCH_2SH species of the *trans* isomer, while only singlets were observed for the other two species corresponding to the *a*-CH_2DCH_2SH species of the *trans* isomer.

The splittings of the transitions vanish for the CH_3CH_2SD species whose reduced moment of inertia around the internal rotation axis of the SH group increases, and only the singlets were observed for the species expected to have non-equivalent *gauche* minima of the internal rotation potential. Thus these spectra can be confirmed to belong to the *gauche* isomer and the doublet structures can be considered to arise from the tunnelling effect through the barrier between two *gauche* minima.

For the four species having non-equivalent *gauche* minima, the *c*-type *Q* and *R* branch transitions could also be assigned.

For the other four species, the rotational constant *A* cannot be obtained from the *a*-type transition frequencies alone since the *gauche* isomer is still a nearly symmetric top molecule. Splittings of the transitions prevent an accurate determination of the *B* and *C* rotational constants unless a theoretical analysis of the internal rotation is carried out.

In the present paper, we deal with the r_s structure and the dipole moment of the *trans* isomer alone.

Experimental

Commercial normal species of ethanethiol was purified by gas chromatography. CH_3CH_2SD was prepared from sodium ethanethiolate and D_2O.[4] CH_2DCH_2SH, CH_3CHDSH and CH_3CD_2SH were prepared from the corresponding S-ethyl thiuronium bromides prepared from CH_2DCH_2Br, CH_3CHDBr and CH_3CD_2Br, respectively, with thiourea.[5]

The spectra of ^{34}S and ^{13}C species were measured with a sample of ethanethiol containing these species in natural isotopic abundance.

Measurements were carried out in the frequency region 8.4—34 GHz with conventional Stark modulation spectrometers with 100 kHz square- and sine-wave modulation. The $2_{12} \leftarrow 1_{01}$ transition appearing around 42500 MHz was also measured for four of the isotopic species. Measurements were usually made on an oscilloscope at dry ice temperature, a strip-chart recorder being used for the measurements for ^{34}S and ^{13}C species.

Rotational Spectra of the *Trans* Isomer

Spectra belonging to the *trans* isomer of ethanethiol were observed as singlets, indicating that the barrier to the internal rotation of the CH_3 group is relatively high. Both *a*- and *b*-type transitions could be easily assigned, for the normal and deuterated species (Table 1). For ^{34}S and two ^{13}C species, most of the *a*-type transitions were obscured under strong spectra of the normal species since the measurements were made in natural abundance. In order to ascertain the present assignments, the measurements were extended to the $2_{12}\leftarrow1_{01}$ transitions around 42500 MHz which exhibited characteristic Stark patterns.

As the influence of the centrifugal distortion seems to be small, the rotational constants were determined by a least-squares analysis from all the observed frequencies (Table 1) so as to fit a modified rigid rotor expression which includes only the $D_J[J(J+1)]^2$ term of the centrifugal distortion formula. The rotational constants and the moments of inertia are shown in Tables 2 and 3, respectively.

The quantities ΔP_c shown in the table are quite reasonable for all the isotopic species,[6] confirming the present assignments of transitions.

a) Conversion factor is 505376 MHz·amu·Å². Figures in parentheses indicate the uncertainty attached to the last significant figures estimated from 2.5 times the standard deviations. Only the effect of uncertainty in measured frequencies is taken into account. b) $\delta = I_{obsd} - I_{calcd}$. I_{calcd} is calculated on the basis of the structure shown in Table 4. c) $P_c = (I_a + I_b - I_c)/2$. d) $\Delta P_c = (P_c)_{isotopic} - (P_c)_{parent}$.

The r_s Structure of the *Trans* Isomer

Our data are sufficient to determine the r_s coordinates of all the atoms in the *trans* isomer by the substitution method. The *trans* isomer possesses a plane of symmetry perpendicular to the *c*-axis, so that the isotopic substitution of an atom in this plane would leave $P_c(=(I_a + I_b - I_c)/2)$ unaltered if the molecule is rigid. If such were the case, one of the three moments of inertia of the isotopic species would be calculated from the other two. Any two of the three moments of inertia would be sufficient for calculation of the x_a and x_b coordinates of the atom by the following specialized Kraitchman equation for the in-plane atom.

$$\left.\begin{aligned} |x_a| &= [(\Delta I_b/\mu)(1+\Delta I_a/(I_a{}^0 - I_b{}^0))]^{1/2} \\ |x_b| &= [(\Delta I_a/\mu)(1+\Delta I_b/(I_b{}^0 - I_a{}^0))]^{1/2} \\ |x_c| &= 0 \\ \Delta I_g &= I_g - I_g{}^0,\ \mu = \Delta m M/(M+\Delta m) \end{aligned}\right\} \quad (1)$$

where M is the molecular weight of the parent species, Δm is the mass increment of the substituted atom in the isotopic species and $I_g{}^0$ and I_g indicate the g-th moment of inertia for the parent and isotopic species, respectively.

However, since isotopic substitution of such an atom usually alters P_c slightly, the computed coordinates will depend on which pair of moments is used, or whether all three moments are used in the Kraitchman equation.

In order to check the dependence of the computed coordinates on the choice of the moments, the following five different cases were compared. a) All the three moments were used equally in the following general Kraitchman equation.

$$\left.\begin{aligned} |x_a| &= [(\Delta P_a/\mu)(1+\Delta P_b/(I_a{}^0 - I_b{}^0))(1+\Delta P_c/(I_a{}^0 - I_c{}^0))]^{1/2} \\ |x_b| &= [(\Delta P_b/\mu)(1+\Delta P_c/(I_b{}^0 - I_c{}^0))(1+\Delta P_a/(I_b{}^0 - I_a{}^0))]^{1/2} \\ |x_c| &= [(\Delta P_c/\mu)(1+\Delta P_a/(I_c{}^0 - I_a{}^0))(1+\Delta P_b/(I_c{}^0 - I_b{}^0))]^{1/2} \\ P_a &= (-I_a + I_b + I_c)/2,\ P_b = (I_a - I_b + I_c)/2 \\ P_c &= (I_a + I_b - I_c)/2,\ \Delta P_g = P_g - P_g{}^0,\ \text{g=a, b and c} \end{aligned}\right\} \quad (2)$$

where $P_g{}^0$ and P_g indicate the quantities P_g for the parent and isotopic species, respectively. In this case the x_c coordinate, which should be zero from the symmetry, can also be calculated if $\Delta P_c > 0$, but will be disregarded. b) All the three moments were used but ΔP_c was set to zero. c) ΔI_a and ΔI_b were used in the specialized Kraitchman equation (1). d) ΔI_c and ΔI_b were used assuming $\Delta P_c = 0$. e) ΔI_a and ΔI_c were used assuming $\Delta P_c = 0$.

The coordinates calculated in the five cases were in good agreement with each other for the two C atoms and the S atom within estimated uncertainty of the observed moments of inertia. Therefore, the averages of the five values were used for the r_s coordinates of these atoms.

However, the difference in the coordinate values for the five cases was found to exceed the estimated experimental uncertainty for the hydrogen atom in the SH group and for the in-plane hydrogen atom (H_s) in the CH_3 group. Since $\Delta P_c > 0$, the apparent x_c coordinates in case a) can be calculated for these atoms. They are 0.130 and 0.107 Å, respectively, and indicate the serious influence of the zero point energy contribution to the coordinates of these atoms.

Since the x_b coordinate of H_s is small, the serious influence of the zero point energy is not surprising and makes it impossible to calculate from the expreimental data for this coordinate. Then, this coordinate is considered to be better determined from other coordinates by the use of some special assumptions such as the first moment equation and so on.

However, even for the x_a coordinate of H_s and the x_a and x_b coordinates of the hydrogen atom in the SH group which are not so small and for which the solutions of the Kraitchman equation can be regarded to be reliable, the half differences between the largest and smallest values of the coordinates for the five cases $(|x_{max}| - |x_{mix}|)/2$ are calculated to be 0.00219, 0.00447 and 0.00565 Å, respectively, while the uncertainties are 0.00114, 0.00174 and 0.00324 Å, respectively. The structural parameters such as r(SH), α(CSH), $r(CH_s)$, $\alpha(CCH_s)$ and $\alpha(H_aCH_s)$, which are related to these coordinates will then strongly depend on the choice of the moments of inertia.

The same situation was reported for ethyl choride[7] by Schwendeman and Jacobs, and for propane[8] by Lide. Taking the above into account, case a) was used for the r_s coordinate of the hydrogen atom in

Table 4. Atom coordinates (Å)[a] and the structural parameters of *trans*-ethanethiol

a) Figures in parentheses are 99% reliability intervals attached to the last significant figures.

the SH group and the x_a coordinate of the H_s atom. The x_b coordinate of the H_s atom was then determined from the first moment equation.

As for the hydrogen in the CH_2 group, two independent sets of r_s coordinates are available from the observed moments of inertia for CH_3CHDSH and CH_3CD_2SH species.

For the substituted atom in CH_3CD_2SH species whose coordinates satisfy relations $(x_a)_1=(x_a)_2$, $(x_b)_1=(x_b)_2$ and $(x_c)_1=-(x_c)_2$, where 1 and 2 designate the substituted atom number, the Kraitchman equation can be written as

$$\left.\begin{aligned} |x_a| &= [(\Delta P_a/\mu)(1+\Delta P_b/(I_a^0-I_b^0))]^{1/2} \\ |x_b| &= [(\Delta P_b/\mu)(1+\Delta P_a/(I_b^0-I_a^0))]^{1/2} \\ |x_c| &= [\Delta P_c/2\Delta m]^{1/2},\ \mu=2\Delta mM/(M+2\Delta m) \end{aligned}\right\} \quad (3)$$

Actually, the two sets of computed coordinates were found to be in good agreement within experimental uncertainty in spite of the expected large difference of the zero point energy contributions between the two species. The averages of the two sets of the coordinate values were then used for the r_s coordinates of this atom.

Since no other isotopic species useful for determining the coordinates of the H_a atom in the CH_3 group is available at present, the influence of the zero point energy to these coordinates cannot be evaluated from a unique solution of the general Kraitchman equation (2) alone.

Coordinates of the atoms and structural parameters are given in Table 4.

It is seen that a slightly asymmetric CH_3 structure was obtained from the above procedures though it is within the range of uncertainties for the structural parameters.

Completion of the determination of the structure of *trans*-ethanethiol is of interest since it is desirable to know to what extent the structure correlations found in the analogous molecules are applicable.

Comparison of the structural parameters of the CH_2SH part of *trans*-ethanethiol with those of methanethiol[9] reveals that r(SC) remains unchanged between them, while those of both ethane- and methanethiol are definitely greater than that of dimethyl sulfide (1.802±0.002 Å).[10]

r(SH) and α(CSH) of ethanethiol are essentially equal to those of methanethiol within experimental error.

A comparison of the structural parameters of the CH_2 part of the molecule with those of ethyl halides,[7,11] propane[8] and ethylsilane[12] is given in Table 5.

r(CC) of ethanethiol has a value between that of ethylsilane and those of ethyl chloride and bromide, being roughly equal to that of propane.

The value 108°34′ obtained for α(SCC) of ethanethiol is abnormally small compared with the value for α(XCC) (X=Cl, Br, Si and C) of analogous molecules, for which they are always larger than tetrahedral. On the other hand, the value 108°54′ obtained for α(HCH) is smaller than tetrahedral.

The following angular constraint can be imposed on sp^3 hybrids for the present case if each hybrid is orthonormal or localized.[13] That is, the α(HCH) angle should be larger than tetrahedral if the α(XCC) angle is smaller than tetrahedral.

This is approximately valid for CH_3CH_2X molecules except *trans*-ethanethiol (Table 5). On the other hand, though this rule is valid for the α(HCC) and α(HCX) angles of all the molecules listed, the α(HCX) angle of *trans*-ethanethiol is the largest, except that of propane for which these two angles should be equal for the sake of symmetry.

This anomalous feature found in *trans*-ethanethiol can be easily explained if the ethyl group is tilted in the molecular plane towards the lone pair electrons of the S atom.

When the tilt angle is assumed to be equal to that of methanethiol and of dimethyl sulfide (2°30′), the α(CCS) and α(HCS) angles of ethanethiol are considered to contain contributions in amounts of −2°30′ and +1°15′ respectively. In order to compare these angles with those of other molecules having the non-tilted ethyl group, the corrected angle values should be used.

	1	−4.420(0.5)	−4.342	50→ 120

$\mu_{total}=1.560$ D (0.032), $\mu_a=1.058$ D (0.023), $\mu_b=1.146$ D (0.022)

a) Figures in parentheses indicate the uncertainty calculated from 2.5 times the standard deviations.

They are 108°34′+2°30′=111°4′ and 109°26′−1°15′=108°11′ for α(CCS) and α(HCS), respectively, which are plausible as values expected from angles of similar molecules.

Dipole Moment

The electric dipole moment and its components for the parent species were quantitatively determined by Stark-effect measurements of eight *a*- and *b*-type rotational transitions. Two Stark components of different M values could be resolved for some of the transitions. Before and after the measurements, the electric field was calibrated using the OCS molecule as a standard.[14] The results are given in Table 6.

Since the molecule is a slightly asymmetric top having a relatively large μ_a dipole component, some transitions used for the Stark-effect measurements exhibit fast Stark shifts due to the first-order effect. On the other hand, in the relatively higher range of applied field strength, the frequency shift $\Delta\nu$ changes linearly against the squares of the field strength E^2 within experimental error for all the transitions used, so that the fourth-order effect[15] might not be noticeable. Analysis of the present Stark-effect measurements is possible by the usual second-order perturbation treatment with the appropriate first-order corrections,[16] but the method by direct diagonalization of the energy matrices[17] was used in order to make calculation with an electronic computer easier. As the J quantum number for the transitions used is at most 2, the energy matrices were truncated at $J=4$ after confirming that the truncation error was negligible.

The theoretical Stark coefficients are shown in Table 6 where $\Delta\nu/E^2$ is the value at the field strength 200 V/cm. Agreement is very good for both *a*- and *b*-type transitions.

The obtained dipole moments are $\mu_a=1.058\pm0.023$, $\mu_b=1.146\pm0.022$ and $\mu_{total}=1.560\pm0.032$ D.

The dipole moment of *trans*-ethanethiol determined by microwave spectroscopy can be compared with the value 1.33 D obtained by dielectric constant measurement[18] in the gaseous state. The reported values for methanethiol by microwave spectroscopy and dielectric constant measurement are 1.532 D[9] and 1.26 D,[19] respectively. The values obtained by the former measurement are larger for both molecules,

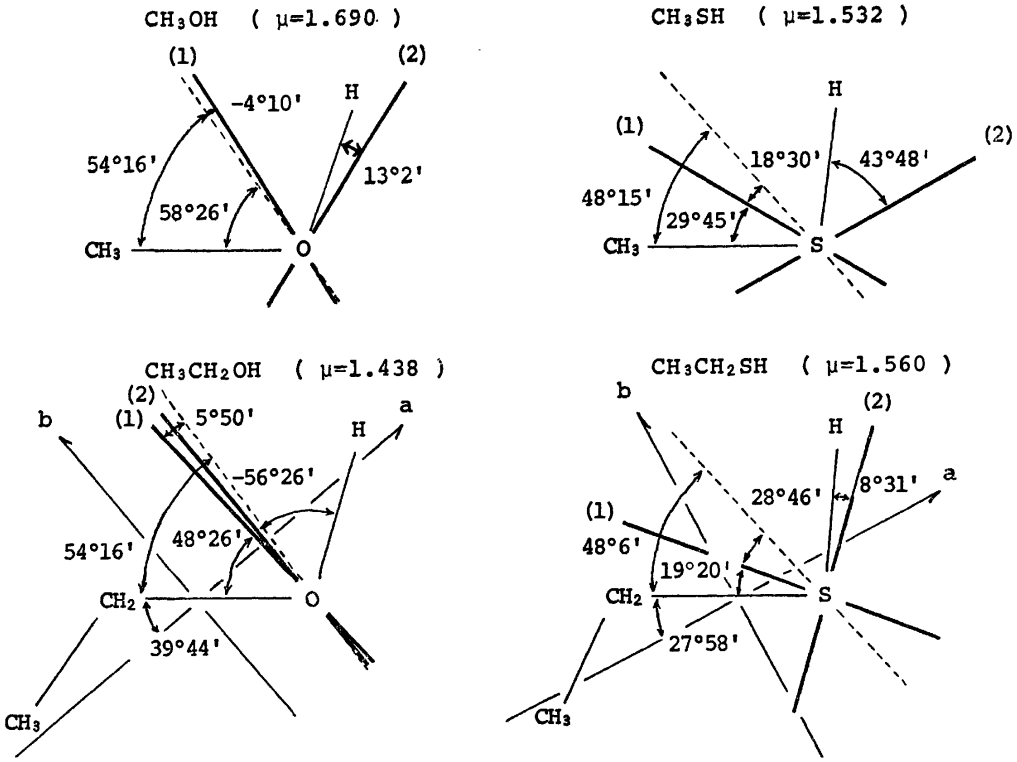

Fig. 1. Directions of the dipole moments for CH_3SH, CH_3CH_2SH, CH_3OH, and CH_3CH_2OH.
—— Direction of the dipole moment.
---- Bisector of the angle CXH, X=O, S.
←— The principal inertial axis.

From the dipole components obtained, the dipole moment of *trans*-ethanethiol is inclined by either 47°18′ or 132°42′ against the *a*-principal inertial axis (Fig. 1). Usually the direction of the dipole moment can be determined uniquely if a comparison is made between the isotopic species. However, for *trans*-ethanethiol, the rotation of the principal axes due to the isotopic substitution is estimated to be too small when compared with the experimental error limit for the available isotopic species.

In order to find the correct direction of the dipole moment, a comparison was made between methanethiol, ethanethiol, methanol[20] and ethanol.[21] The reported values of the CXH angles of these molecules are 96°30′ 96°13′, 108°32′ and 108°32′, respectively. The possible directions of the dipole moment in the molecule are designated as (1) and (2) in Fig. 1, the dotted line indicating the bisector of the CXH angle.

The CS and CO bonds are found to make angles of 27°58′ and 39°44′, respectively, with the *a*-axis for *trans*-ethanethiol and ethanol from the structure analysis. Direction (1) then makes angles of 29°45′, 19°20′, 58°26′ and 48°26′ with the CX bonds of methanethiol, ethanethiol, methanol and ethanol, respectively, which correspond to the angles 17°30′, 28°46′, −4°10′ and 5°50′ against the bisectors, respectively.

Direction (2) makes angles of 43°48′, 8°31′, 13°2′ and −56°26′ with the XH bonds, respectively. A regularity can be found for direction (1) in the angles with the CX bonds and with the bisectors of the CXH angles. No such regularity can be found for direction (2). Since both of the two possible directions for ethanol are almost parallel to the bisector of the COH angle, this strongly suggests that the correct direction of the dipole moments for this series of molecules can be regarded as (1) which is more parallel to the bisector of the CXH angle than (2).

The angle between the dipole moment and the bisector of the CXH angle increases by about 10° when the methyl group is replaced by the ethyl group for both mercaptan and alcohol. The dipole moments of the present series are considered to consist of the C–X and X–H bond moments and the moment along the bisector of the CXH angle which is produced by the long pair electrons on the atom X. The directions of these moments are considered to be from H to X for the X–H bond moment, from C to X for the C–X bond moment and from X to the outside of the CXH angle for the lone pair moment. Thus, if the lone pair moment and the X–H bond moment remain unchanged on replacement of the alkyl group, the above change in direction of the dipole moment indicates that the apparent C–X bond moment increases as the methyl group is replaced by the ethyl group. This is similar to the so-called inductive effect for the case of alkyl halides.[22]

If the X–H and lone pair moments between methane- and ethanethiol and between methanol and ethanol are assumed to be equal, the C–X bond moments of the ethyl group are calculated to be larger than those of the methyl group by about 0.36 and 0.33 D, re-

spectively.

The authors would like to thank Dr. Chi Matsumura and Dr. Harutoshi Takeo, Government Chemical Industrial Research Institute, for the use of their spectrometer and for their kind assistance in measuring the spectra due to the ^{13}C and ^{34}S species of ethanethiol.

The Ion-exchange Behavior of Some Cations on Crystalline Zirconium Phosphate

Yoshitsugu HASEGAWA* and Isao TOMITA

Department of Chemistry, Faculty of Science, Tokyo Kyoiku University, Bunkyo-ku, Tokyo 112

(Received January 30, 1974)

The distribution coefficients of Ag^+, Tl^+, K^+, NH_4^+, Mg^{2+}, Ca^{2+}, Sr^{2+}, Ba^{2+}, Co^{2+}, Zn^{2+}, Y^{3+}, and Ce^{3+} have been determined on a crystalline zirconium phosphate ion-exchanger in chloride solution media, and the affinity sequences are presented. pH titration curves and X-ray powder diffraction data were obtained for calcium and barium ions. The ion-exchange capacity of the exchanger for barium ions was found to be 4.4 meq/g, but the X-ray powder patterns were rather unusual as compared to those of other ions studied previously.

Extensive investigations have been made of the crystalline zirconium phosphate ion-exchanger, $Zr(HPO_4)_2 \cdot H_2O$ (c-ZrP). Studies of the exchanger at lower loadings have mainly been concerned with the distribution coefficients (K_d) of alkali metal ions and their pH dependence.[1,2] In the first half of the present study, the measurement of K_d values was extended to monovalent cations, such as Ag^+, K^+, Tl^+, and NH_4^+, alkaline earth cations, and some polyvalent cations such as Co^{2+}, Zn^{2+}, Y^{3+}, and Ce^{3+}.

On the other hand, studies of the ion-exchange at higher loadings include pH titrations on the exchanger for alkali or alkaline earth metal ions and X-ray studies of cation-replaced exchangers as well as of the original hydrogen-form.[3-7] With regard to the uptake of alkaline earth metal ions onto c-ZrP, Clearfield and Smith have shown that strontium ions can be sorbed, but barium ions are not taken up from acidic media.[4] Harvie and Nancollas have given the pH titration curve for calcium-hydrogen exchange.[5] Dyer *et al.* have reported that the barium form of c-ZrP was prepared.[6] Further, Alberti *et al.* have shown that hydrolysis starts at a 10% conversion of barium ions.[7]

In the second half of this paper, the results of detailed examination of the pH titration curves for barium ions as well as of the X-ray diffraction patterns of the metal ion-replaced solid are given.

Experimental

The crystalline zirconium phosphate (c-ZrP) was prepared by refluxing a gelatinous precipitate in 6.7M phosphoric acid for 120 hr, as has been reported previously.[2] The resulting crystalline solid was an extremely fine powder, and after drying it was made into tablets under a pressure of about 4200 Kg/cm^2 and then sieved to a grain size of 100—200 mesh.

Distribution Coefficients. The batch distribution coefficients were measured at 25 °C by equilibrating a weighed amount of c-ZrP with known volumes of suitable solutions, followed by analysis of the supernatant liquid. The ratio of volume to the solid weight was usually 100 ml/g.

For all the metal concentrations studied, the exchange reaction attained to equilibrium within 6 hr. The determination of the batch distribution coefficients was made after the reaction mixtures had been shaken for at least 24 hr.

Chemical analyses included the use of such radioisotopes as ^{110m}Ag, ^{133}Ba, ^{89}Sr, ^{60}Co, ^{65}Zn, ^{90}Y, and ^{144}Ce as isotopic tracers. The yttrium-90 tracer was prepared from its parent, ^{90}Sr, using the c-ZrP column as an example of the practical application of the exchanger. For the determinations of potassium, magnesium, and calcium, atomic-absorption photometry was employed. The thallium and ammonium were determined colorimetrically by the use of rhodamine B[8] and the Nessler reagent[9] respectively.

For some cations, the values of the distribution coefficients were determined as a function of the acidity.

pH Titration. A 250 mg portion of c-ZrP was placed in contact at 25 °C with 50 ml of a solution $CaCl_2 + Ca(OH)_2$. The ratio of chloride to hydroxide was varied for each run, keeping the total calcium concentration at 0.1 N. After equilibration, the pH of the supernatant was measured with a glass electrode. Since the solubility of calcium hydroxide is rather low, the amount of hydroxide used was limited up to about 6 meq/g of c-ZrP. The experiment with the barium solution was performed in a similar way. In this case, the barium-ion content in the supernatant was determined by EDTA titration. The solid phase obtained at the neutralization point was analyzed for Zr, P, and Ba.

X-Ray Powder Diffraction. The X-ray powder patterns of the exchangers taken during the titration were obtained with Ni filtered copper X-rays using a Geigerflex (Rigaku Denki Co., Ltd.).

Results and Discussion

Affinity series. Table 1 gives the values of the distribution coefficients, K_d, for several ions on the hydrogen-form of c-ZrP. For Zn^{2+} ions, the initial pH of the solution was set at 4.12 in order to suppress hydrolysis. The sorption of monovalent cations increases in the following order:

$$Ag^+ < NH_4^+ < K^+ \simeq Tl^+$$

As compared with the affinity of these ions on a gelatinous zirconium phosphate,[10] less sorption of silver ion is found. The affinity increases with an increase in the crystal radii except for the ammonium ion.

For alkaline earth cations, the sequence is as follows:

$$Mg^{2+} < Sr^{2+} < Ca^{2+} < Ba^{2+}$$

The series of these ions on a gel has been reported by Amphlett *et al.*[10]:

$$Mg^{2+} < Ca^{2+},\ Sr^{2+} < Ba^{2+}$$

Separation factors calculated from the $\alpha_{M_1}^{M_2} = K_d(M_2)/K_d(M_1)$ relation are rather constant and give a value of about 1.46 for a pair of adjacent alkaline earth cations in the sequence.

TABLE 1. DISTRIBUTION COEFFICIENTS (K_d values) FOR CATIONS WITH INITIAL CONCENTRATION OF 1×10^{-3} N

ion	pH of solution		K_d
	initial	final	
Ag^+	5.10	3.68	30
NH_4^+	5.30	3.11	63
K^+	5.85	3.07	94
Tl^+	5.20	3.51	110
Mg^{2+}	5.50	3.01	90
Ca^{2+}	5.55	3.00	190
Sr^{2+}	5.88	3.00	130
Ba^{2+}	5.85	2.97	280
Co^{2+}	5.60	2.93	230
Zn^{2+}	4.12	2.94	340
Y^{3+}	5.35	2.96	$\sim5.7\times10^3$
Ce^{3+}	5.30	3.39	$\sim3.6\times10^4$

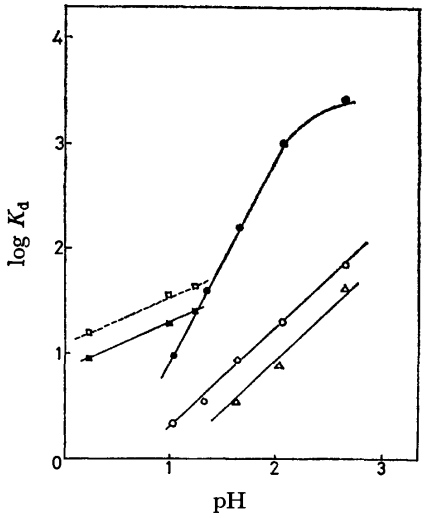

Fig. 1. Distribution coefficients for some cations on c-ZrP at different acidities
○: Ba^{2+}, △: Co^{2+}, ●: Ce^{3+}, ■: Rb^+, □: Cs^+
(total metal ion concentration is 1.0×10^{-3} N)

For other polyvalent cations, the K_d values increase in the order shown in Table 1:

$$Co^{2+} < Zn^{2+} < Y^{3+} < Ce^{3+}$$

This sequence is identical with that reported by Ahrland *et al.* for a gelatinous zirconium phosphate.[11]

When the values of K_d are plotted as a function of pH, straight lines are obtained (see below). Hence, the affinity sequences obtained may hold in the acidic media.

One of the possible factors which determine the distribution coefficients on the crystalline zirconium phosphate ion-exchanger might be the formation of a stable, less soluble phosphate of polyvalent cations.

In Figs. 1 and 2, the logarithmic values of the distribution coefficients are plotted against the pH. In the cases of Ba^{2+} and Co^{2+} ions whose concentrations are 1×10^{-3} N in the initial solutions, straight lines with a slope of nearly unity were obtained. For Ce^{3+}, the slope was about 2 up to the pH value of 2, beyond

this point a serious deviation from the straight line resulted. For the metal-ion concentrations of 1.0×10^{-5} N, the log K_d *vs.* pH plots again exhibit straight lines for these ions, with slopes of somewhat higher values for each case. The slopes are certainly correlated with the charge of the sorbed cations, but no quantitative explanation can be made on the basis of the data given here, because they were not based upon the constant loading of exchanging ions along the curves.[12,13]

pH Titrations. The results of the pH titrations for Ca^{2+} and Ba^{2+} are given in Fig. 3. The titration curve for Ca^{2+} agreed with those given by Harvie and Nancollas and by Alberti *et al.*[5,7]

In the barium titration, the dependence of the pH of a supernatant on the time was determined at three different compositions (see Fig. 4). It is inferred that the neutralization reaction proceeds in two steps: that is, at an earlier stage the reaction takes place on a surface of the exchanger, and then the diffusion of the cations into the exchanger proceeds gradually. Under those experimental conditions, it took about four days to reach equilibrium. In Fig. 3 the titration curves at different reaction times and the barium-ion contents in the exchanger calculated from those in the supernatants of 6-day sample are shown. The titration curves show that the ion-exchange capacity of c-ZrP for barium ions is equal to 4.4 meq/g (corresponding to 66% of the total exchange capacity) and that the reaction time between 50 and 66% of exchange is quite long.

Beyond 66% of exchange, the exchanger itself is hydrolyzed and the phosphates of barium and zirconium hydroxide are precipitated.

The exchanger at 66% of exchange was stored on a saturated sodium chloride solution, then placed in contact with *ca.* 1 N hydrochloric acid and warmed on a water bath for two days. After cooling, the suspension was centrifuged. The barium ions in the supernatant were analyzed by EDTA titration, and the zirconium and phosphate were analyzed as has been described previously.[14] Found: Zr 22.2%, PO_4^{3-} 42.3%, Ba^{2+} 20.4 and H_2O 10.3% (weight loss at 120 °C). These data correspond to the $ZrBa_{0.67}H_{0.67}(PO_4)_2 \cdot 2.39H_2O$ formula. The barium content is lower than that calculated from the supernatant in the pH titration. This suggests that the barium ion is held strongly in the exchanger. The phosphate ion was not detected in the supernatant.

X-Ray Studies. X-Ray powder patterns of the exchanger at different titration stages are shown in Fig. 5. The first reflection of c-ZrP was detectable in the diffractograms up to a 5 meq/g addition of OH^-. In the diffraction patterns of the ignited exchanger, the peaks of zirconium pyrophosphate resulting from c-ZrP were found up to 5 meq/g. Moreover, exchanger at 10 meq/g showed the peaks to be those of zirconium oxide.

In conclusion, in 0~66% of exchange, the mixture of c-ZrP and its barium form, and at 66% of exchange the $ZrBa_{0.67}H_{0.67}(PO_4)_2 \cdot nH_2O$ phase was present, while beyond 67% of exchange the complex mixtures including the hydrolysis product were present.

The crystalline zirconium phosphate is known to have a layered structure and to contain a zeolitic cavity between the layers, and the expansion of the interlayer distance is caused by an uptake of cations.[15,16] According to Clearfield *et al.* the opening to the cavity permits only the cations with a 2.6Å diameter to diffuse into the crystal lattice unless c-ZrP swells considerably. Hence, the ionic radius of sorbed cations has a significant effect on the ion-exchange capacity of c-ZrP. However, as has been shown above, the ion-exchange capacity for barium ions is equal to 4.4 meq/g, which is equal to that for lithium and ammonium ions.[14,17]

In Table 2, the interplanar spacing (*d* values) of the Ca^{2+} and Ba^{2+} ion-replaced exchangers are shown. For the Ca^{2+} ion-replaced exchanger, an increase in the interlayer distance (7.6→10.05Å) was observed, as had been expected from the previous works. On the

other hand, for the Ba^{2+} ion-replaced exchanger, no change in the interlayer distance was observed.

The above results should be further considered in terms of the behavior of hydrated water molecule during exchange; an investigation along this line is needed. It should be worthwhile, also, to mention how much the press treatment influences the exchange behavior.

The authors wish to express their sincere thanks to Professor Kozo Nagashima of Tokyo Kyoiku University for his valuable suggestions and constant encouragement throughout this work. They also wish to express their gratitude to Professor Shuji Abe of Tokyo University of Agriculture and Technology for his ready permission for use of the university facilities.

Metal Complexes of Amino Acids. VI.[1] μ-L-Aspartato and μ-L-Glutamato Complexes of Cobalt(III)

Takaji YASUI, Hiroshi KAWAGUCHI, Zenjiro KANDA, and Tomoharu AMA

Faculty of Arts and Sciences, Kochi University, Asakura, Kochi 780

(Received June 20, 1974)

Some binuclear and trinuclear complexes containing μ-L-aminocarboxylato ligands, $(+)_D$- and $(-)_D$-$[en_2Co(OCOCH(NH_2)(CH_2)_nCOO)Co(OH_2)en_2](ClO_4)_4$, $(+)_D$-$[en_2Co(OCOCH(NH_2)(CH_2)_nCOO)Co(NH_3)_5](ClO_4)_4$, and $(+)_D$- and $(-)_D$-$[en_2Co\{(OCOCH(NH_2)(CH_2)_nCOO)Co\ en_2\}_2](ClO_4)_5$ ($n=1$ for L-aspartato and $n=2$ for L-glutamato), have been newly prepared. The structure and vicinal CD effect of these complexes were discussed on the basis of their absorption, ^{13}C NMR and CD spectra data. Their geometrical structures were assigned as *cis* to the μ-L-aminocarboxylato-OH_2 binuclear complexes (with respect to the β-COO or γ-COO end of μ-aminocarboxylato bridge and the aquo ligand), and as *trans* to the di-μ-L-aminocarboxylato trinuclear complexes (with respect to the β-COO or γ-COO ends of two μ-aminocarboxylato bridges).

In the previous paper[1] we reported the study on the formation and preparations of the binuclear and trinuclear complexes containing μ-aminocarboxylato ligand, $[(NH_3)_5Co(OCORNH_2)Co\ NO_2(acac)_2]ClO_4$ and $[en_2Co\{(OCORNH_2)Co\ NO_2(acac)_2\}_2]ClO_4$. In these complexes the μ-aminocarboxylato ligand is the bidentate which bridged two cobalt(III) ions with the COO and NH_2 ends.

In the present paper, the preparations of some new binuclear and trinuclear complexes containing L-aspartato or L-glutamato as the μ-aminocarboxylato ligand are reported. The complexes isolated are characterized on the basis of their elemental analyses, visible and ultraviolet absorption, CD, and ^{13}C NMR spectra.

Experimental

Preparation of Starting Materials—L-Aspartato and L-Glutamato-bis(ethylenediamine)cobalt(III) Complexes. $(+)_D$-$[Co(L\text{-}asp)en_2]ClO_4\cdot 2H_2O$, $(-)_D$-$[Co(L\text{-}asp)en_2]ClO_4\cdot H_2O$, $(+)_D$- and $(-)_D$-$[Co(L\text{-}glu)en_2]ClO_4$ were prepared and separated by the same method as that of Legg and Steele.[2] Elemental analyses and $[\alpha]_D$ values of these complexes are listed in Table 1.

Preparation and Separation of μ-L-Aspartato Binuclear Complexes—$(+)_D$-$[en_2Co(L\text{-}asp)Co(OH_2)en_2](ClO_4)_4\cdot H_2O$ (abbreviation: $(+)_D$-μ-L-asp-OH_2). An aqueous solution containing 1.78 g (0.004 mol) of $(+)_D$-$[Co(L\text{-}asp)en_2]ClO_4\cdot 2H_2O$ ($[\alpha]_D=+445°$) and 3.10 g (0.006 mol) of $[Co(OH_2)_2en_2](ClO_4)_3$ in 40 ml of water was gradually evaporated almost to dryness at 50—55 °C on a water-bath. The residue was dissolved in 15—20 ml of water, and the solution was repeatedly evaporated to dryness. The final residue was dissolved in about 100 ml of water and then the solution was loaded on a SP-Sephadex cation-exchange column (C-25, Na-form, 3.6 cm × 70 cm). The red band adsorbed was developed with 0.1—0.3 N aqueous solution of $NaClO_4$. Each band which splitted from the red band was eluted in the order of orange-yellow ($[Co(L\text{-}asp)en_2]^+$), orange ($[Co(L\text{-}aspH)en_2]^{2+}$), pinkish-red ($[Co(OH_2)_2en_2]^{3+}$), and orange (μ-L-asp-$OH_2$ binuclear complex ion) bands. The latest orange eluate was concentrated by using a vacuum evaporator at 35—40 °C, and the deposited $NaClO_4$ was filtered off. After repeating the evaporation of the solution and the removal of $NaClO_4$, finally the solution was completely dried, and a large amount of absolute ethanol was added to the residue. The complex which remained as orange powder was collected by filtration and washed with absolute ethanol and then ether. Recrystallization of the complex was carried out by adding a small amount of $NaClO_4$ and ethanol to a concentrated solution and by allowing to stand the mixture in a refrigerator overnight. The complex deposited as reddish-orange crystals was filtered, washed with ethanol and then ether, and dried in a vacuum desiccator at room temperature. The yield was about 0.7 g. The complex obtained was readily soluble in water, and sparingly soluble in methanol and acetone, but insoluble in ethanol and ether.

$(-)_D$-$[en_2Co(L\text{-}asp)Co(OH_2)en_2](ClO_4)_4\cdot H_2O$. This complex was prepared by the same method as used for the $(+)_D$-isomer, except for using $(-)_D$-$[Co(L\text{-}asp)en_2]ClO_4\cdot 2H_2O$ ($[\alpha]_D=-315°$) instead of $(+)_D$-$[Co(L\text{-}asp)en_2]ClO_4\cdot H_2O$.

$(+)_D$-$[en_2Co(L\text{-}asp)Co(NH_3)_5](ClO_4)_4\cdot H_2O$ (abbr.: $(+)_D$-μ-L-asp-NH_3). To an aqueous solution containing 2.25 g (0.005 mol) of $(+)_D$-$[Co(L\text{-}asp)en_2]ClO_4\cdot 2H_2O$ ($[\alpha]_D=+445°$) in 10 ml of water was added 2.4 g (0.005 mol) of $[Co(NH_3)_5(OH_2)](ClO_4)_3\cdot H_2O$, and the mixture was gradually evaporated almost to dryness at 50—55 °C on a water-bath. The residue was dissolved in 10 ml of water, and the solution was evaporated again. The final residue was dissolved in 10 ml of water, and the solution was loaded on a SP-Sephadex cation-exchange column (C-25, Na-form, 3.6 cm × 70 cm). The adsorbed band splitted into five bands in sweeping with 0.3 N aqueous solution of $NaClO_4$. The eluate from the third band was concentrated to about 5 ml by using a vacuum evaporator at 35—40 °C, and a large amount of ethanol was added to the concentrated solution. The μ-L-aspartato binuclear complex which deposited as a pinkish-orange powder was filtered, and washed with a mixture of water–methanol (1 : 3) mixture, methanol and then ether. Recrystallization was carried out by adding a small amount of methanol to the concentrated solution and by keeping in a refrigerator overnight. The pinkish-orange complex was obtained as needle crystals. The yield was 1.2 g.

Preparation and Separation of μ-L-Glutamato Binuclear Complexes—$(+)_D$-$[en_2Co(L\text{-}glu)Co(OH_2)en_2](ClO_4)_4\cdot 2H_2O$ (abbr.: $(+)_D$-μ-L-glu-OH_2). This complex was obtained by a procedure similar to that of the $(+)_D$-μ-L-aspartato binuclear complexes, except for using 2.3 g (0.0045 mol) of $[Co(OH_2)_2en_2](ClO_4)_3$ and 1.27 g (0.003 mol) of $(+)_D$-$[Co(L\text{-}glu)en_2]ClO_4$ ($[\alpha]_D=+348°$) instead of $(+)_D$-$[Co(L\text{-}asp)en_2]ClO_4\cdot 2H_2O$. The yield was about 0.8 g. The reddish-orange complex was readily soluble in water, sparingly soluble in methanol and acetone, but insoluble in ethanol and ether.

$(-)_D$-$[en_2Co(L\text{-}glu)Co(OH_2)en_2](ClO_4)_4\cdot 2H_2O$. This $(-)_D$-isomer was obtained by the same procedure as that for $(+)_D$-isomer, except for using $(-)_D$-$[Co(L\text{-}glu)en_2]ClO_4$ in-

stead of $(+)_D$-[Co(L-glu)en_2]ClO_4.

$(+)_D$-[en_2Co(L-glu)Co(NH_3)$_5$](ClO_4)$_4\cdot H_2O$ (abbr.: $(+)_D$-μ-L-glu-NH_3). To an aqueous solution containing 2.4 g (0.005 mol) of [Co(NH_3)$_5$(OH_2)](ClO_4)$_3\cdot H_2O$ in 20 ml of warm water was added 2.12 g (0.005 mol) of $(+)_D$-[Co(L-glu)en_2]ClO_4 ($[\alpha]_D=+348°$). The solution was gradually evaporated to dryness at 60—65 °C on a water-bath. The residue was dissolved in 5—10 ml of water, and the solution was evaporated again. This procedure was repeated six or seven more times. Finally the residue was dissolved in 100 ml of warm water, and the solution was loaded on a SP-Sephadex cation-exchange column (C-25, Na-form, 3.6 cm × 70 cm). The elution and the isolation of the complex were performed by the same way as the case of $(+)_D$-[en_2Co(L-asp)Co(NH_3)$_5$](ClO_4)$_4\cdot H_2O$. The crude complex obtained was recrystallized from a minimum amount of water by adding a small amount of ethanol to the concentrated solution and by keeping in a refrigerator overnight. The yield was 0.2 g.

Preparations and Separations of Di-μ-L-aspartato and -L-glutamato Trinuclear Complexes—$(+)_D$-[en_2Co{(L-asp)Co en_2}$_2$](ClO_4)$_5\cdot 5H_2O$ (abbr.: di-μ-L-asp). To an aqueous solution of 0.82 g (0.006 mol) of [Co(OH_2)$_2$$en_2$]($ClO_4$)$_3$ containing in 20—30 ml of water was added 1.31 g (0.003 mol) of $(+)_D$-[Co(L-asp)en_2]$ClO_4\cdot 2H_2O$ ($[\alpha]_D=+445°$). The solution was evaporated to dryness at over 80 °C on a steam-bath. The residue was dissolved in about 10 ml of water and evaporated again. This procedure was repeated two more times. Finally the residue was dissolved in 50 ml of water, and the solution was loaded on a SP-Sephadex cation-exchange column (C-25, Na-form, 3.6 cm × 50 cm), and the adsorbed band was developed with 0.1—0.3 N aqueous solution of $NaClO_4$. Each band splitted was eluted in the order of orange-yellow ([Co(L-asp)en_2]$^+$), orange ([Co(L-aspH)en_2]$^{2+}$), pinkish-red ([Co(OH_2)$_2$$en_2$]$^{3+}$), pinkish-red ([$en_2$Co(L-asp)Co($OH_2$)$en_2$]$^{4+}$), and reddish-orange (di-μ-L-asp trinuclear complex ion) bands. The latest eluate was concentrated by using a vacuum evaporator and the deposited $NaClO_4$ was filtered off. After repeating the procedure of the evaporation of the solution and the removal of an excess of $NaClO_4$, finally the solution was completely evaporated to dryness, and a large amount of methanol was added to the residue until the deposited $NaClO_4$ disappeared. The reddish-orange complex deposited as needle crystals was filtered and washed with methanol and then acetone. Recrystallization was carried out from a minimum amount of warm water by adding a few drops of saturated solution of $NaClO_4$, and by keeping in a refrigerator for 2—3 hours. The yield was 1.1 g.

$(-)_D$-[en_2Co{(L-asp)Co en_2}$_2$](ClO_4)$_5\cdot 5H_2O$. The $(-)_D$-isomer was prepared by the same method as used for the $(+)_D$-isomer.

$(+)_D$- and $(-)_D$-[en_2Co{(L-glu)Co en_2}$_2$](ClO_4)$_5\cdot nH_2O$ (n= 4 and 5 for $(+)_D$- and $(-)_D$-isomers) (abbr.: $(+)_D$- and $(-)_D$- di-μ-L-glu). These complexes were prepared by a similar way to that used for the $(+)_D$-di-μ-L-asp trinuclear complex, except for using 1.03 g (0.002 mol) of [Co(OH_2)$_2$-en_2](ClO_4)$_3$ and 1.70 g (0.004 mol) of $(+)_D$-[Co(L-glu)en_2]-ClO_4 ($[\alpha]_D=+348°$)/and $(-)_D$-[Co(L-glu)en_2]ClO_4 ($[\alpha]_D=-409°$) instead of $(+)_D$-[Co(L-asp)en_2]$ClO_4\cdot 2H_2O$. The reddish-orange complexes were obtained as needle crystals. The yields were about 0.7 g.

Measurements. The absorption spectra were obtained by using a Hitachi Model EDS-3T spectrophotometer. The CD measurements were made by a JASCO Model ORD/UV-5 spectrophotometer with CD attachment. The ^{13}C NMR spectra were recorded on a JEOL MH-100 spectrometer with pulsed Fourier transform/proton noise-decoupled mode. The samples used for the ^{13}C NMR measurements were converted perchlorate to the chloride to obtained higher solubility in D_2O. An external benzene was used as a standard signal.

The chemical shifts (ppm) in the figures are shown by adopting chemical shift of benzene down field of 128.50 ppm from that of TMS.[3]

Results and Discussion

Elemental analyses and CD data for the μ-L-amino-carboxylato binuclear and trinuclear complexes are listed in Table 1.

Absorption Spectra. The absorption curves of the L-asp mononuclear ([Co(L-asp)en_2]$^+$), μ-L-asp binuclear and di-μ-L-asp trinuclear complexes are shown in Fig. 1. In Figs. 2, 4 and 5, the residual absorption curves for the μ-L-asp-OH_2 and μ-L-asp-NH_3 binuclear complexes, and di-μ-L-asp trinuclear complex are shown. The absorption spectra of these complexes indicate almost analogous absorption curve each other, although their intensities are different (Fig. 1). However, the residual curve for the trinuclear complex (Fig. 5) shows quite different behavior from those for the binuclear complexes (Figs. 2 and 4), and consists of two splitted bands in the first band region. Such split for the trinuclear complex coincides with the absorption behavior which generally appears in the *trans(O)*-[Co O_2N_4] type complexes.[4,5] Therefore, it can be concluded that the di-μ-L-asp trinuclear complex obtained in the present study takes the *trans(O)* structure with respect

to the two β-carboxyl groups of the μ-L-aspartato ligands, as shown in Fig. 3. On the other hand, the residual curve for the μ-L-asp-OH_2 binuclear complex does not indicate such splitted band as observed for the trinuclear complex. In addition the first and second band maxima (502 and 358 nm) in the residual curve appear at the positions corresponding to the *cis(O)*-[Co O_2N_4] type complexes.[5,6] Therefore, it is reasonable to conclude that this binuclear complex takes the *cis* structure with respect to the β-carboxyl group of the μ-L-aspartato and the coordinated OH_2 (Fig. 6). The same conclusions can also be obtained for the corresponding μ-L-glutamato complexes.

Circular Dichroism Spectra. Gillard *et al.* prepared the $(+)_D$- and $(-)_D$-$[Co(L\text{-glu})en_2]ClO_4$ by the reaction between $[Co\ CO_3en_2]ClO_4$ and L-glutamic acid, and showed that the $(+)_D$-isomer produces more preferentially than the $(-)_D$-isomer.[7,8] They have also determined that the absolute configutation of the $(+)_D$-isomer is Λ-form by the X-ray analysis.[9]

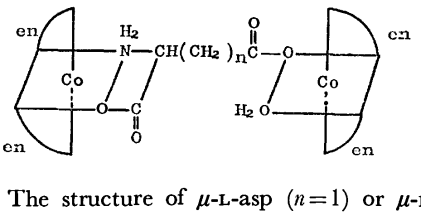

Fig. 6. The structure of μ-L-asp ($n=1$) or μ-L-glu ($n=2$) binuclear complex.

Recently, Buckingham *et al.* have demonstrated from the kinetical and thermodynamical studies that there is no substantial preference for the formation of one diastereomer relative to the other in the $[Co(L\text{-glu})en_2]^+$ complex ion.[10] The complete separation of the $(+)_D$- and $(-)_D$-isomers of L-aspartato-bis(ethylenediamine)-cobalt(III) complexes was performed by Legg *et al.*,[2,11] and Kojima and Shibata.[12]

The CD curves of the mononuclear, binuclear and trinuclear L-aspartato complexes are shown in Figs. 1, 2, 4 and 5, and those of L-glutamato complexes are shown in Fig. 7. The absolute configurations of the mononuclear complexes for the $(+)_D$- and $(-)_D$-isomers are assigned respectively as Λ- and Δ-form from the sign of the main CD band in the first band region (in Fig. 1).[13] The μ-L-asp binuclear and di-μ-L-asp trinuclear complexes indicate the CD curves of similar type to those of the L-asp mononuclear complexes. This suggests that the CD bands of these binuclear and trinuclear complexes arise from the contributional CD effect of the mononuclear complex. The same discussion can also be made for the L-glutamato complexes.

The residual CD curves which were obtained by subtracting the CD curve of the mononuclear complex from that of each binuclear and trinuclear complex are shown in Figs. 2, 4, 5 and 7. These residual curves mean that the CD band of the mononuclear complex is intensified by the coordination of another cobalt(III) complex ion to the free β- or γ-carboxyl group of the

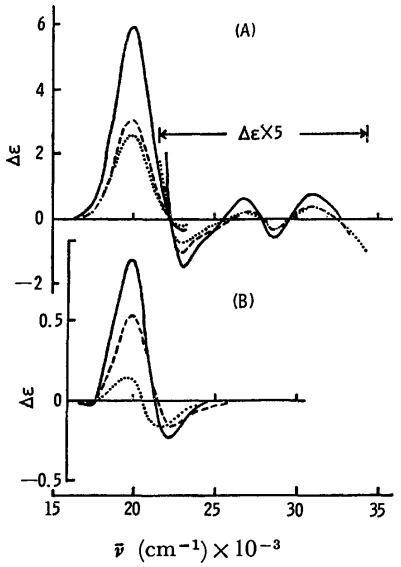

Fig. 7. CD and its residual curves for $(+)_D$-μ-L-glu complexes.
(A) (1) ·····, $[en_2Co(L\text{-}glu)Co(NH_3)_5]^{4+}$; (2) ----, $[en_2Co(L\text{-}glu)Co(OH_2)en_2]^{4+}$; (3) ——, $[en_2Co\{(L\text{-}glu)Co\ en_2\}_2]^{5+}$. (B) ·····, (1)—$\{(+)_D\text{-}[Co(L\text{-}glu)\text{-}en_2]^+\}$; ----, (2)—$\{(+)_D\text{-}[Co(L\text{-}glu)en_2]^+\}$; ——, (3)—$\{(+)_D\text{-}[Co(L\text{-}glu)en_2]^+\}$.

former complex, and that no configurational change of the original mononuclear complex occurs in the preparing process of the binuclear and trinuclear complexes. The almost symmetrical curves of the main CD bands for the $(+)_D$- and $(-)_D$-isomers of the binuclear and trinuclear complexes with μ-L-aspartato also support the complete retention of the configuration in the original mononuclear complex.

The intensities of these residual CD bands increase in the order of the μ-L-aa-NH_3, μ-L-aa-OH_2 binuclear and di-μ-L-aa trinuclear complexes. The residual CD band of the μ-L-aa-OH_2 binuclear complex indicates lower intensity of about half as compared with that of the trinuclear complex. This suggests that the former complex consists of the equivalent mixture of the two diastereomers (Λ(L)-Λ and Λ(L)-Δ).

^{13}C Nuclear Magnetic Resonance Spectra. The ^{13}C NMR patterns of some $(+)_D$-L-aspartato complexes are shown in Fig. 8. Two kinds of resonance signals which appear in the low magnetic field (176.55—186.98 ppm) correspond to the carbon atoms of the two carboxyl groups (α- and β-carboxyl groups) in the L-aspartato. Of these signals, the ones at the lower field side exhibit hardly change in chemical shift, but the ones at the higher field side do the considerable different chemical shift among the mononuclear and μ-L-asp complexes. The change of the chemical shift in the carboxyl group can be related to the change of its chemical environment. Quirt *et al.* have demonstrated from the pH titration study for the various amino acids that the carbon resonance of the carboxyl group indicates large shift with pH change.[11] The signal of 179.32 ppm in the $(+)_D$-$[Co(L\text{-}asp)en_2]^+$ ion shifts to higher field side (176.55 ppm) when its solution was acidified with D_2SO_4, and contrarily to lower field side (183.83 and 184.43 ppm) in the binuclear and

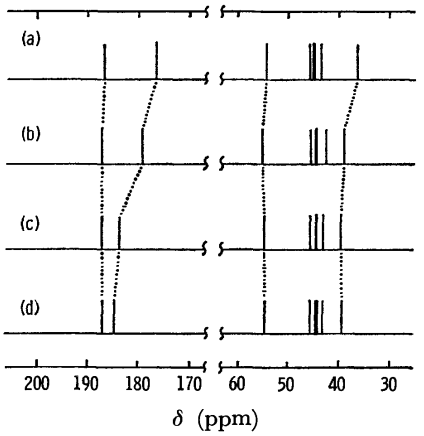

Fig. 8. ^{13}C NMR patterns of $(+)_D$-L-asp complexes in D_2O: (a) $[Co(L\text{-}aspD)en_2]^{2+}$ (acidified with D_2SO_4), (b) $[Co(L\text{-}asp)en_2]^+$, (c) $[en_2Co(L\text{-}asp)Co(NH_3)_5]^{4+}$, (d) $[en_2Co\{(L\text{-}asp)Co\ en_2\}_2]^{5+}$.

trinuclear complexes. The former shift can be related to the protonation of the free β-carboxyl group and the latter ones to the coordination of the β-carboxyl group to the cobalt(III) ion. The signals at the lower field side exhibit nearly constant chemical shift (186.74—187.35 ppm) for all the L-aspartato complexes. This result suggests that these signals can be assigned to the carbon atoms of the α-carboxyl groups which take the same coordination form in these complexes.

The carbon signals of methin and methylene of L-aspartato, and of ethylenediamine appear at the positions of about 55, 36—40, and 43—46 ppm, respectively. The change of the chemical shift is also observed in the methylene carbon of the protonated mononuclear complex. More detailed discussion relating to the ^{13}C NMR of these complexes will be made in the successive study.

Layered Compounds. XVIII[1]. Synthesis of a Paracyclophane Containing the 1,2,3,4,5-Hexapentaene Group and the Stereochemistry of Its Formation

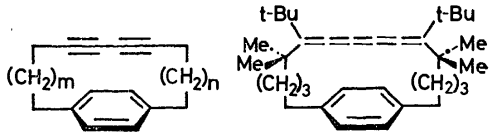
Taichi NEGI, Takahiro KANEDA, Hiroshi MIZUNO, Toshihiro TOYODA, Yoshiteru SAKATA, and Soichi MISUMI

The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka 565

(Received September 28, 1973)

Novel cyclic 1,2,3,4,5-hexapentaene compounds were synthesized from cyclic diyne-diol IX *via* diallene-dibromide X in order to study transannular electronic interaction. A diallene-dibromide Xc-I obtained from a diyne-diol isomer IXc-I was debrominated with active zinc to give cyclic hexapentaene IIc, whereas the other diallene-dibromide Xc-II derived from the second diyne-diol isomer IXc-II was not. The X-ray crystallographic analysis of the dibromide Xc-I was then carried out, and the *s-trans* structure was assigned to the dibromide. On the basis of this result, the stereochemistry of the transformation from diyne-diol to the hexapentaene group was discussed. The electronic spectrum of a cyclophane IIa containing the hexapentaene group showed a transannular π-electronic interaction between the benzene ring and the hexapentaene group, unlike those of the other hexapentaene derivatives, IIc and XV.

In the previous paper we reported that the electronic spectra of [*m.n*]paracyclophadiynes (I) show remarkable transannular interaction between the benzene nucleus and the diacetylenic unit as the numbers of the bridge methylene chains, *m* and *n*, decrease.[2] However, the absorption band of the diacetylene unit is partially submerged into the strong short-wavelength band of the benzene chromophore. Accordingly, the spectra have been mainly interpreted in terms of the long-wavelength band of the latter chromophore. For the clearer elucidation of the transannular electronic interaction between two different chromophores, a distinct observation of the absorption bands due to both chromophores is desirable. For that purpose, we have undertaken to study a paracyclophane IIa containing a benzene nucleus and a 1,2,3,4,5-hexapentaene group which shows a characteristic, strong absorption band in a longer wavelength region than that of the former chromophore.[3]



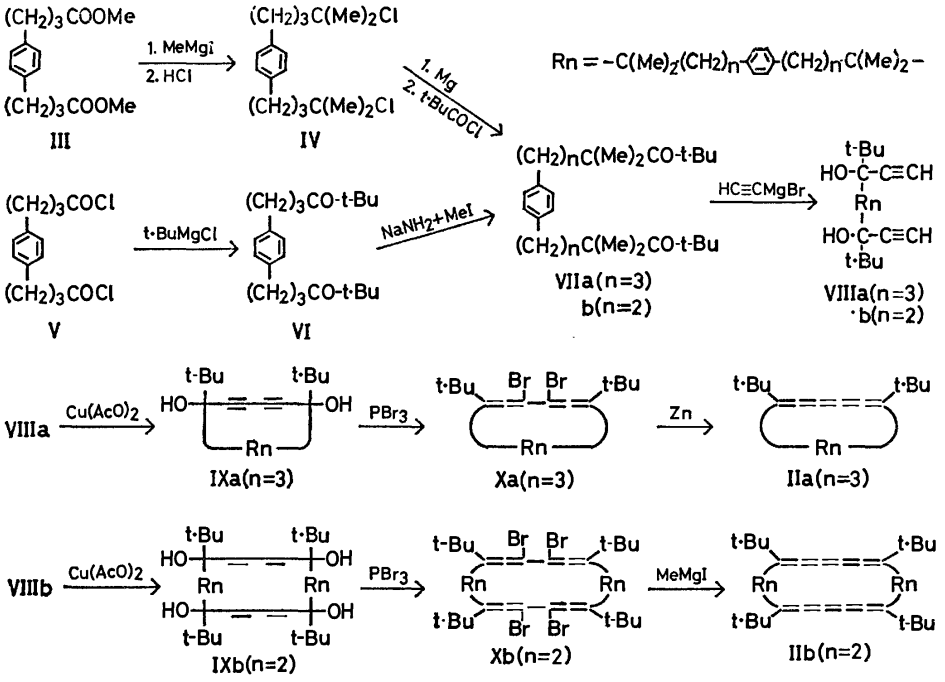
I IIa

The present paper deals with the syntheses and properties of IIa and related compounds and discusses stereochemical process concerning the formation of the 1,2,3,4,5-hexapentaene group from 2,4-butadiyne-1,6-diol derivatives *via* an intermediate diallene-dibromide like X. Three cumulenic compounds, IIa, IIb, and IIc, are the first cyclic 1,2,3,4,5-hexapentaene derivatives except for some annulenes having a formal hexapentaene group.[4]

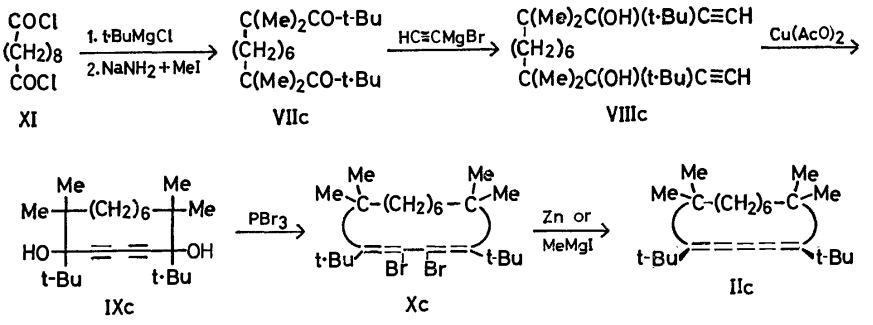
Results and Discussion

Synthesis. The syntheses of the cyclic hexapentaenes IIa, IIb, and IIc, are outlined in Schemes 1 and 2. By the reaction of the bis-Grignard compound of the dichloride IV with pivaloyl chloride in the presence of copper powder and cuprous chloride,[5] a diketone VIIa was obtained in a low yield (14%), along with a large amount of olefinic compounds. The syntheses of the diketones VIIb and VIIc were achieved *via* two steps from acid chlorides V and XI respectively. Thus, two diketones, VI and 2,2,13,13-tetramethyl-3,12-tetradecanedione, which were obtained from V and XI in 87 and 65% yields respectively, were subjected to methylation with sodium amide and methyl iodide to give VIIb and VIIc in 53 and 37% yields respectively. This methylation process needs to be repeated to give good yields of VII. The reaction of the highly-branched diketone VII with ethynylmagnesium bromide[6] was barely completed after 7—10 days at 35 °C to afford a 68—80% yield of a diyne-diol VIII. Such a slow reaction is obviously caused by the bulkiness around the α-carbon atoms adjacent to the carbonyl group, because an unbranched ketone XVI gives a 61% yield of a diyne-diol XVII even under the mild conditions of room temperature for 4 hr. The intramolecular oxidative coupling reaction of the diyne-diol VIII was carried out by the use of a high-dilution technique to give cyclic monomers, IXa and IXc, in 13 and 32% yields respectively.[7] On the other hand, the oxidative coupling of VIIIb afforded a cyclic dimer IXb (34% yield) in place of the cyclic monomer, probably because of internal steric hindrance in the monomer. By column chromatography with silica gel, each of the cyclic monomers IXa and IXc were separated into two isomers, a meso and a racemic, distinguishable by means of the IR spectra.

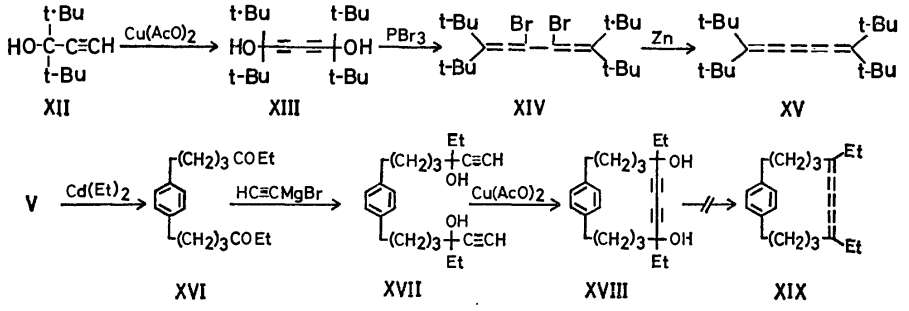
Both isomers of IXc, the first-eluted one IXc-I and the second-eluted one IXc-II, were individually treated with phosphorus tribromide[8a] to derive diallene-dibromides Xc-I and Xc-II respectively. By the debromination of Xc-I with active zinc powder,[8a] followed by chromatography with neutral alumina, a cyclic hexapentaene IIc was obtained as pale greenish yellow crystals in a 71% yield, whereas the same treatment of Xc-II gave no product with a spectrum characteristic of the hexapentaene group. On the other hand, upon debromination reaction with methylmagnesium iodide,[8b] both Xc-I and Xc-II afforded the desired compound IIc. This reaction sequence from the diyne-diol IXc to IIc is of particular interest with regard to the stereochemistry in the reaction mechanism, which will be discussed below.



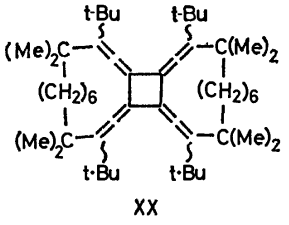
Scheme 1.



Scheme 2.



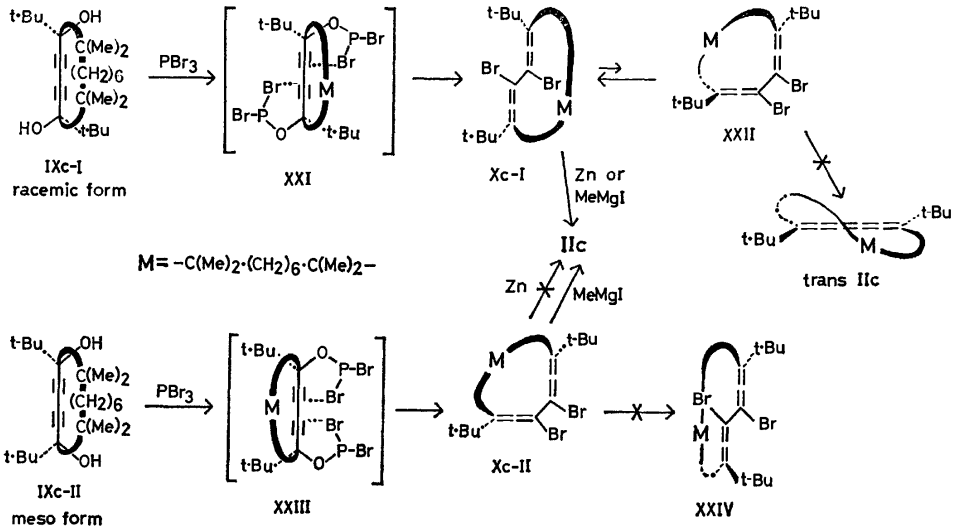
Scheme 3.



XX

Upon melting (146—147 °C), IIc immediately solidified to give white crystals with a mp of 280—282 °C. On the basis of the elemental analysis, the mass spectrum, and the UV spectrum of tetrakis(di-*tert*-butylvinylidene)cyclobutane,[8c] this product is assumed to be a dimer XX, the configuration of which has not yet been determined.

The debromination of diallene-dibromide Xa obtained in a 62% yield through the same treatment of IXa as in the case of IXc, was carried out by the active zinc method above-stated to give the desired cyclic hexapentaene IIa as a greenish yellow oil. Also, by debromination with methylmagnesium iodide, the



Scheme 4.

tetraallene-tetrabromide Xb derived from IXb gave a cyclic bishexapentaene IIb as greenish yellow crystals, which showed an electronic spectrum characteristic of the hexapentaene group. Tetra-*tert*-butyl-1,2,3,4,5-hexapentaene XV[8c] was prepared *via* the synthetic route shown in Scheme 3 for spectral reference.

In preliminary experiments, the preparation of a simpler cyclic hexapentaene XIX from XVIII was attempted by the following methods: 1) phosphorus diiodide,[9] 2) phosphorus tribromide in pyridine,[10] 3) phosphorus tribromide followed by active zinc, 4) stannous chloride-hydrogen chloride,[11] and 5) methylmagnesium bromide, but all the methods failed to give XIX.

Crystal Structure of Diallene-dibromide Xc-I. The diallene-dibromide Xc-I obtained from the first-eluted diyne-diol IXc-I is considered as an important key substance for clarifying the reaction mechanism for the well-known formation of the hexapentaene group from the diyne-diol derivative, as will be described below. In order to determine the geometrical structure of Xc-I and then to elucidate the stereochemical course of the formation of the hexapentaene IIc, X-ray crystallographic analysis was carried out.

The diallene-dibromide Xc-I was crystallized from ethyl acetate as colorless columns.

Crystal data: $C_{26}H_{42}Br_2$, Mol wt=514.4, triclinic, $a=9.662$, $b=16.761$, $c=8.306$ Å; $\alpha=88.12°$, $\beta=92.30°$, $\gamma=92.73°$; $V=1341.9$ Å^3; $D_m=1.267$, $D_x=1.273$ gcm^{-3}; $Z=2$, Space group $P\bar{1}$.

The crystal selected for data collection was of the approximate dimensions of $0.13\times0.10\times0.23$ mm and was mounted with the c-axis coincident to the ϕ-axis of the goniostat. The intensity data were collected with $2\theta<55°$ on a fully-automatic Hilger four-circle diffractometer using Zr-filtered Mo-Kα radiation and the ω-2θ scan technique. The intensities of 1863 independent reflections were recorded as observed. However, when the intensity of a standard reflection, $\bar{5}1\bar{1}$, was measured every 10 reflections, an obvious decay was discernible. Accordingly, the intensities of the observed reflections were corrected with the Lorentz and polarization factors after a decay correction corresponding to the decay curve of the $\bar{5}1\bar{1}$ reflection. No absorption corrections were made.

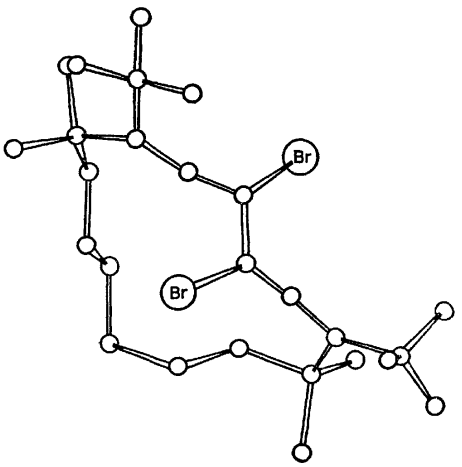


Fig. 1. Crystal structure of diallene-dibromide Xc-I.

A three-dimensional Patterson synthesis was first computed, and the positions of the bromine atoms were deduced. All the carbon atoms were revealed after successive Fourier synthesis. Although the structure of this dibromide was partially disordered, the essential features of the molecule are shown in Fig. 1 with a final R index of 0.113. The figure clearly shows that the two bromine atoms are positioned in the manner of the *s-trans* form around the sp^2-sp^2 single bond and that the two *tert*-butyl groups are in the *cis* configuration with respect to the plane containing the two bromine atoms.

All the calculations were performed on a NEAC-700 computer at the Computation Center of Osaka University by the use of the following programs: PSSFR-5* and HBLS-IV.**

* T. Sakurai, The Universal Crystallographic Computing System (I), p. 18, The Crystallographic Society of Japan, 1967.

Stereochemical Aspect of the Formation of Hexapentaene. The stereochemistry of the reaction sequence from cyclic diyne-diol IXc to cyclic hexapentaene IIc is given in Scheme 4. The bromination of IXc with phosphorus tribromide is presumed to proceed in a stereospecific manner *via* a bis-dibromophosphite ester, XXI or XXIII, as a cyclic transition state,[13] since the halogenation of acetylenic alcohol with thionyl chloride[12] or phosphorus tribromide[13] has been well established or illustrated to follow the S_Ni' mechanism.

Thus, *s-trans*-diallene-dibromide Xc-I should be derived from the racemic form of the diyne-diol IXc-I *via* the bis-dibromophosphite ester XXI, whereas its *s-cis* conformer XXII seems to be hardly producible at all, for it is considerably strained, according to an examination with the Stuart-Briegleb molecular model. Similarly, the *s-cis*-dibromide Xc-II should be formed from the meso form of the diyne-diol IXc-II through the bis-dibromophosphite ester XXIII, and the corresponding *s-trans* conformer XXIV can not be yielded because of its highly strained system.***

As is shown in Fig. 1, X-ray crystallographic analysis assigned the *s-trans* structure of Xc-I to the diallene-dibromide which was obtained from the first-eluted diyne-diol IXc-I. Accordingly, this result demonstrates that the diyne-diol IXc-I is of the racemic form, whereas the second-eluted diyne-diol IXc-II must be of the meso form. Since *trans*-IIc, in which two *t*-butyl groups are bonded in the *trans* form to the hexapentaene group, can not at all expect to exist because of the short bridged chain, the debromination product IIc should have the *cis* configuration. Consequently, the fact that IIc is obtained from Xc-I by debromination with zinc powder, but not from Xc-II, clearly indicates that the debromination proceeds through the *trans* elimination mechanism. On the other hand, the debromination with methylmagnesium iodide might proceed by a mechanism other than E2 elimination, because both Xc-I and Xc-II afforded IIc by the reaction.

Electronic Spectra. Figure 2 records the electronic spectra of cyclic hexapentaenes as well as that of an open-chain analogue, tetra-*t*-butylhexapentaene XV. The spectrum of IIc is very similar to that of the reference compound XV. On the other hand, the hexapentaene cyclophane IIa shows a red shift of the longest wavelength band by 8 nm than the corresponding band of IIc, besides a slight change of the bands in the 220—270 nm region. A Stuart-Briegleb molecular model demonstrates that both cyclic hexapentaenes, IIc and IIa, are strainless and in similar steric environments around the hexapentaene group. Accordingly, it may be concluded that the red shift of the longest wavelength band of IIa is caused by transannular π-electronic interaction between the benzene ring and the 1,2,3,4,5-hexapentaene group. The longest wavelength bands of cyclic bis-hexapentaene IIb appear near the band positions of IIc, hence, such an interaction is hardly discernible.

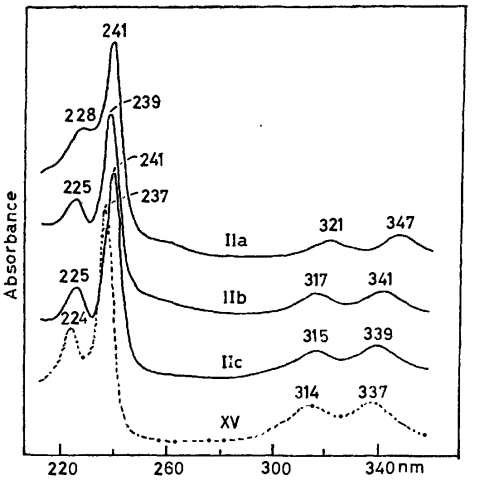

Fig. 2. Electronic spectra of cyclic cumulenes and tetra-*t*-butyl hexapentaene in ether.

Experimental

The melting points are uncorrected. The UV, IR, NMR, and mass spectra were measured on a Hitachi EPS-3T autorecording spectrophotometer, a Hitachi EPI-G2 spectrometer a Hitachi R-20 spectrometer, and a Hitachi RMU-7 spectrometer respectively.

p-*Bis(4-hydroxy-4-methylpentyl)benzene.* Into a solution of methylmagnesium iodide, prepared from magnesium (14 g, 0.58 mol) and methyl iodide (81 g, 0.57 mol) in 300 ml of ether, a solution of the diester III[14] (20 g, 0.072 mol) in 100 ml of ether was added over a period of 1.5 hr with stirring at reflux. The mixture was refluxed for 2 hr with stirring and then poured into a dilute sulfuric acid. The diol thus precipitated was collected, washed well with water, and dried. The filtrate was extracted with ether, followed by the usual work-up. After removing the solvent, the residue was chromatographed on 50 g of silica gel, using ether-petroleum ether (2 : 3) as an eluent, to yield white crystals. The total yield of the desired diol was 18 g (90%).

For analysis, a small amount of the sample was recrystallized from toluene to yield white crystals, mp 121—122 °C. Found: C, 77.73; H, 10.92%; Mol wt, 278 (mass spectrometry). Calcd for $C_{18}H_{30}O_2$: C, 77.65; H, 10.86%; Mol wt, 278. IR (KBr disk): 3280, 1510, 1190, and 826 cm^{-1}. NMR ($CDCl_3$), δ: 7.07 (s, 4H), 2.59 (t, 4H), 1.65~1.5 (m, 8H), 1.32 (s, 2H), and 1.20 ppm (s, 12H).

p-*Bis(4-Chloro-4-methylpentyl)benzene (IV).* Into an ice-cooled mixture of the above diol (52 g), 100 ml of methanol, and 2 l of petroleum ether, a current of hydrogen chloride was passed for 6 hr with stirring. The upper organic layer of the mixture was then separated, washed with concd sulfuric acid, and allowed to stand overnight over sodium carbonate. The subsequent concentration of the solution gave colorless plates (44 g, 75%).

For analysis, a small amount of the sample was recrystallized from petroleun ether to yield colorless plates, mp 49—51 °C. Found: C, 68.44; H, 9.18; Cl, 22.42%. Calcd for $C_{18}H_{28}Cl_2$: C, 68.56; H, 8.95; Cl, 22.49%.

p-*Bis (4,4,6,6-tetramethyl-5-oxoheptyl)benzene (VIIa).* To magnesium (0.60 g, 0.025 mol) in 50 ml of dry ether, a solution of the dichloride IV (4.0 g, 0.013 mol) in 50 ml of ether was added dropwise in a 1.5 hr period with stirring under a nitrogen atmosphere. A mixture of copper powder

*** Although the diallene-dibromides are also considered to yield by a "two-step mechanism" through a monodibromophosphite ester as a cyclic transition state, one may reach stereochemically the same result.

(1.5 g), cuprous chloride (2.4 g), freshly-prepared pivaloyl chloride (2.7 g, 0.022 mol), and 100 ml of ether in an alternative flask was cooled in an ice-salt bath, and into the mixture the above Grignard solution, filtered through glass-wool, was added dropwise over a period of 1 hr with vigorous stirring under a nitrogen atmosphere. Stirring was then continued for 4 hr at room temperature, after which the reaction mixture was poured into a dilute hydrochloric acid and the organic layer was separated. The aqueous layer was extracted with ether. The combined etherial solution was washed successively with dilute hydrochloric acid, a sodium bicarbonate solution, and water, and then dried over magnesium sulfate. After the solvent had been removed, the residue was chromatographed on 50 g of alumina, using ether–petroleum ether (1 : 3) as an eluent, to yield a colorless solid (0.63 g, 14% based on pivaloyl chloride).

For analysis a small amount of the sample was recrystallized from petroleum ether to yield colorless plates, mp 66—67 °C. Found: C, 80.95; H, 11.27%; Mol wt, 414 (mass spectrometry). Calcd for $C_{28}H_{46}O_2$: C, 81.10; H, 11.18%; Mol wt, 414. IR (KBr disk): 1674 cm^{-1} (C=O).

p-Bis (5-t-butyl)-5-hydroxy-4,4-dimethyl-6-heptynyl) benzene (VIIIa). To a solution of ethynylmagnesium bromide,[6] prepared from magnesium (31 g, 1.3 mol), ethyl bromide (140 g, 1.3 mol), and 1 l of dry tetrahydrofuran, a solution of the diketone VIIa (5.0 g, 0.012 mol) in 100 ml of tetrahydrofuran was added dropwise over a period of 30 min. The mixture was stirred for a week at 30—35 °C with the passage through of a slow stream of acetylene. After the addition of dilute sulfuric acid and salting-out, the mixture was extracted with ether. The ether extract was washed successively with dilute sulfuric acid, a sodium bicarbonate solution, and water, and then dried over magnesium sulfate. After the solvent had been removed, the residue was chromatographed on 120 g of silica gel, using ether–petroleum ether (1 : 4), to give a colorless oil (3.8 g, 68%); IR (neat), 3560 (OH) and 3305 cm^{-1} (C≡CH); NMR (CCl_4), δ: 7.00 (s, 4H), 2.5 (m, 4H), 2.33 (s, 2H), 1.8—1.5 (m, 10H), and 1.15 and 1.09 ppm (d, 30 H).

5,10-Di-t-butyl-4,4,11,11-tetramethyl-6,8-[14]paracyclophadiyne-5,10-diol (IXa). The intramolecular oxidative coupling of the bisethynyl compound VIIIa was accomplished in a manner similar to that previously reported.[2b] Into a mixture of 30 g of anhydrous cupric acetate and 1.5 l of pyridine, a solution of VIIIa (3.0 g) in 2 l of oxygen-free ether was added dropwise over a period of three days at 50 °C with vigorous stirring under a nitrogen atmosphere. After the addition, the reaction was continued for another day. The reaction mixture was then poured into a cold dilute sulfuric acid, and the organic layer was separated. The aqueous layer was extracted with ether, and the combined ethereal solution was washed well with dilute sulfuric acid, a sodium bicarbonate solution, and water successively, and dried over anhydrous magnesium sulfate. The solvent were removed under reduced pressure, and the residue was chromatographed on 120 g of silica gel to yield two compounds.

The first compound (230 mg, 7.7%) was eluted with ether–petroleum ether (1 : 2). It was confirmed to be the cyclic monomer IXa-I. For analysis, a small amount of the sample was recrystallized from carbon tetrachloride–petroleum ether, colorless needles, mp 161 °C. Found: C, 82.52; H, 10.76%. Mol wt, 464 (mass spectrometry). Calcd for $C_{32}H_{48}O_2$: C, 82.70; H, 10.41%. Mol wt, 464. UV (cyclohexane): λ_{max} 214, 220, 225, 247, 260, 265, 268, and 274 nm. IR (KBr disk): 3580, 3470, 1511, 1393, 1384, 1367, 1290, 1220, 1205, 1069, 1051, 980, 927, and 800 cm^{-1}.

The second substance (170 mg, 5.7%) was eluted with ether–petroleum ether (1 : 1). It was confirmed to be the cyclic monomer IXa-II. For analysis, a small amount of the sample was recrystallized from carbon tetrachloride–petroleum ether, white crystals, mp 175.5—176 °C. Found: C, 82.85; H, 10.64%; Mol wt, 464 (mass spectrometry). UV (cyclohexane): λ_{max} 214, 221, 226, 247, 260, 265, 267, and 273 nm. IR (KBr disk): 3570, 3480, 1506, 1385, 1366, 1297, 1227, 1208, 1195, 1124, 1074, 1053, 1040, 1006, 998, 983, 932, 884, and 803 cm^{-1}.

7,8-Dibromo-5,10-di-t-butyl-4,4,11,11-tetramethyl-5,6,8,9-[14]-paracyclophatetraene (Xa). A mixture of the diyne-diol IXa (100 mg, 0.22 mmol), phosphorus tribromide (1 g, 3.7 mmol), and 50 ml of dry benzene was stirred at 50 °C for 3 hr under a nitrogen atmosphere. The reaction mixture was then poured into ice–water and extracted with ether. The ethereal solution was washed successively with dilute hydrochloric acid, a sodium carbonate solution, and water, and then dried over anhydrous magnesium sulfate in a dark and cold room. The solvent was removed under reduced pressure, and the residue was recrystallized from chloroform–methanol to yield a white solid (93 mg, 62%).

For analysis, a small amount of the sample was recrystallized from chloroform–methanol, white crystals, mp 145—146 °C. Found: C, 65.16; H, 7.61%; Mol wt, 590 (mass spectrometry). Calcd for $C_{32}H_{46}Br_2$: C, 65.08; H, 7.85%; Mol wt, 590. UV (cyclohexane): λ_{max} 232 nm (ε 45300).* IR (KBr disk): 1938, 1510, 840, 685, and 654 cm^{-1}.

5,10-Di-t-butyl-4,4,11,11-tetramethyl-5,6,7,8,9-[14]paracyclophapentaene (IIa). A mixture of diallene-dibromide Xa (50 mg, 0.085 mmol) and 5 g of active zinc powder[8a] in 50 ml of dry ether was stirred for three days at room temperature under a nitrogen atmosphere. The reaction mixture was filtered through a short column of silica gel to remove the zinc under a nitrogen atmosphere. The filtrate was then concentrated under reduced pressure, and the residue was chromatographed on 20 g of silica gel, using petroleum ether as an eluent and under a nitrogen atmosphere, to give a greenish yellow oil; MS (*m/e*), 430 (M^+), 373 (M−Bu-*t*) and 316 (M−2Bu-*t*); NMR (CCl_4), δ: 6.90 (s, 4H), 2.7—2.4 (m, 4H), 1.4 (m, 8H), and 1.27 and 1.25 ppm (d, 30H); UV: Fig. 2.

2,2,13,13-Tetramethyl-3,12-tetradecanedione. A mixture of freshly-prepared acid chloride XI (30 g, 0.13 mol), copper powder (25 g), cuprous chloride (50 g), and 300 ml of dry eth r was cooled in an ice-salt bath. Into the mixture a solution of *tert*-butylmagnesium chloride, prepared from magnesium (12 g, 0.49 mol) and *tert*-butyl chloride (45 g, 0.49 mol) in 300 ml of dry ether, was added dropwise over a period of 6 hr with vigorous stirring. Stirring was continued overnight at room temperature. Water was added to decompose the excess of the Grignard reagent, and the mixture was poured into dilute hydrochloric acid and then extracted with ether, followed by the usual work-up. After the solvent had been removed, the residue was chromatographed on 120 g of silica gel, using 5% ether–petroleum ether as an eluent, to yield colorless crystals (23 g, 65%).

For analysis, a small amount of the sample was recrystallized from *n*-hexane, colorless needles, mp 24—25 °C (lit,[15] bp 178—182 °C/1 mmHg). Found: C, 76.27; H, 12.46%. Calcd for $C_{18}H_{34}O_2$: 76.54; H, 12.13%. IR(neat): 1705 cm^{-1} (C=O).

2,2,4,4,11,11,13,13-Octamethyl-3,12-tetradecanedione (VIIc). A mixture of the above diketone (28 g, 0.099 mol) and sodium

* In the previous paper (Ref. 3) this value was erroneously reported as 45.3×10^4.

amide (40 g, 1.0 mol) in 300 ml of benzene was refluxed for 24 hr. To the cold mixture, methyl iodide (210 g, 1.5 mol) was added for 1 hr, after which the mixture was refluxed for 3 hr with stirring. Methanol was added to decompose the excess sodium amide, after which the reaction mixture was poured into dilute hydrochloric acid and extracted with ether, followed by the usual work-up. After the solvent had been removed, the residue was subjected to the above treatment for exhaustive methylation once again. The resulting product, obtained by removing the solvent, was chromatographed on 200 g of neutral alumina, using ether-petroleum ether (1 : 4) as an eluent, to yield white crystals (12 g, 37%).

For analysis, a small amount of the sample was recrystallized from *n*-hexane, colorless plates, mp 40—41 °C. Found: C, 77.91; H, 12.70%; Mol wt, 338 (mass spectrometry). Calcd for $C_{22}H_{42}O_2$: C, 78.04; H, 12.50%; Mol wt, 338. IR (KBr disk): 1670 cm^{-1} (C=O).

*3,12-Di-*t*-butyl-4,4,11,11-tetramethyl-1,13-tetradecadiyne-3,12-diol (VIIIc).* The ethynylation of the diketone VIIc was accomplished in a manner similar to that described for the preparation of VIIIa. From 11 g of the diketone VIIc we obtained 10 g (79%) of the diyne-diol VIIIc as a colorless oil after chromatography on 150 g of silica gel, using ether-petroleum ether (1 : 9); IR (neat), 3490 (OH) and 3310 cm^{-1} (C≡CH); NMR (CCl_4), δ: 2.34 (s, 2H) and 1.8—1.1 ppm (m, 44H: 1.75 (s), 1.3 (m), 1.18 (s), and 1.10 (s)).

*5,14-Di-*t*-butyl-6,6,13,13-tetramethyl-1,3-cyclotetradecadiyne-5,14-diol (IXc).* The intramolecular oxidative coupling of VIIIc was accomplished in a manner similar to that described for that of VIIIa except for the following conditions: anhydrous cupric acetate, 60 g; VIIIc, 5.0 g; reaction temperature, 60 °C; dropping period, five days. The residue obtained by removing the solvent was chromatographed on 200 g of silica gel to yield two compounds.

The first compound (980 mg, 20% yield) was eluted with ether-petroleum ether (1 : 20); it was the cyclic monomer IXc-I (racemic isomer). For analysis, a small amount of the sample was recrystallized from carbon tetrachloride, colorless needles, mp 202 °C (dec, in sealed tube). Found: C, 80.15; H, 11.67%; Mol wt, 388 (mass spectrometry). Calcd for $C_{26}H_{44}O_2$: C, 80.35; H, 11.41%; Mol wt, 388. UV (cyclohexane): λ_{max} 225, 236, 248, and 261 nm. IR (KBr disk): 3583, 1395, 1385, 1367, 1287, 1253, 1222, 1202, 1063, 1036, 1006, 980, and 925 cm^{-1}.

The second substance (620 mg, 12%) was eluted with ether-petroleum ether (1 : 9); it was the cyclic monomer IXc-II (*meso* isomer). For analysis, a small amount of the sample was recrystallized from carbon tetrachloride, white crystals, mp 142—143 °C. Found: C, 80.30; H, 11.58%; Mol wt, 388 (mass spectrometry). UV (cyclohexane): λ_{max} 224, 235, 248, and 261 nm. IR (KBr disk): 3580, 3450, 1392, 1382, 1370, 1288, 1220, 1205, 1082, 1043, 1005, 975, and 937 cm^{-1}.

*3,4-Dibromo-1,6-di-*t*-butyl-7,7,14,14-tetramethyl-1,2,4,5-cyclotetradecatetraene (Xc).* The bromination of diyne-diol IXc was accomplished in a manner similar to that described in the case of IXa.

From the first-eluted diyne-diol IXc-I (3.0 g, 7.7 mmol), phosphorus tribromide (10 g, 37 mmol), and 50 ml of dry benzene, we obtained 1.7 g (43%) of diallene-dibromide Xc-I as white crystals after chromatography on 30 g of silica gel using *n*-hexane. For analysis, a small amount of the sample was recrystallized from carbon tetrachloride-methanol, white crystals, mp 132—134 °C. Found: C, 60.73; H, 8.46; Br, 31.22%; Mol wt, 514 (mass spectrometry). Calcd for $C_{26}H_{42}Br_2$: C, 60.70; H, 8.23; Br, 31.07%; Mol wt, 514. UV (cyclohexane): λ_{max} 231 nm (ε 38700). NMR (CCl_4), δ: 1.28 and 1.37 ppm. IR (KBr): 1950, 1928, 1364, 1222, 1205, 1158, 974, 685, and 653 cm^{-1}.

From the second-eluted diyne-diol IXc-II (3.0 g), diallene-dibromide Xc-II was obtained by the method described above, white crystals, mp 134—135 °C (from carbon tetrachloride-methanol). Found: C, 60.89; H, 8.48; Br, 31.42%. UV(cyclohexane): λ_{max} 231 nm (ε 41700). NMR (CCl_4), δ: 1.28 and 1.38 ppm. IR (KBr): 1950, 1925, 1363, 1221, 1204, 1156, 972, 685, and 653 cm^{-1}.

*1,6-Di-*t*-butyl-7,7,14,14-tetramethyl-1,2,3,4,5-cyclotetradecapentaene (IIc). Debromination with Active Zinc*: The debromination of Xc was accomplished in a manner similar to that described for the preparation of IIa. From Xc-I (200 mg), active zinc powder (5 g), and 80 ml of dry ether, cyclic hexapentaene IIc was obtained by chromatography on 10 g of neutral alumina, using petroleum ether under a nitrogen atmosphere, as pale greenish yellow plates (98 mg, 71%), mp 146—147 °C. MS (*m/e*): 354 (M^+), 297 (M−Bu-*t*), and 240 (M−2Bu-*t*). NMR (CCl_4), δ: 1.45—1.2 ppm (m). UV: Fig. 2.

Diallene-dibromide Xc-II was treated with active zinc under conditions as like those described above as possible. However, no spectral evidence characteristic of IIc was observed.

Debromination with Methylmagnesium Iodide: To a solution of Xc-I (83 mg) in 25 ml of dry ether, we added a solution of methylmagnesium iodide, prepared from magnesium (6 g) and methyl iodide (35 g) in 100 ml of ether; the mixture was then stirred overnight at room temperature under nitrogen atmosphere. After the decomposition of the excess of the Grignard reagent with a saturated ammonium chloride solution, the mixture was extracted with ether and dried over anhydrous sodium sulfate. The etherial solution obtained by passing the mixture through a short column of silica gel under nitrogen showed the λ_{max}'s characteristic of IIc.

Similarly, Xc-II gave the same results upon the same treatment.

p-Bis(5,5-dimethyl-4-oxohexyl)benzene (VI). The alkylation of V was accomplished in a manner similar to that described for the preparation of 2,2,13,13-tetramethyl-3,12-tetradecanedione. From 20 g of fresh acid chloride V, which had been prepared from *p*-bis(3-carboxypropyl)benzene,[14] we obtained 20 g (87%) of the diketone VI as colorless crystals after chromatography on 150 g of silica gel using ether-petroleum ether (1 : 9).

For analysis, a small amount of the sample was recrystallized from petroleum ether, white crystals, mp 45—46 °C. Found: C, 79.85; H, 10.44%. Calcd for $C_{22}H_{34}O_2$: C, 79.95; H, 10.37%. IR (KBr disk): 1675 cm^{-1} (C=O).

p-Bis(3,3,5,5-tetramethyl-4-oxohexyl)benzene (VIIb). The methylation of the above diketone was accomplished in a manner similar to that described for the preparation of VIIc. From 15 g of the diketone VI we obtained 9.4 g (53%) of the diketone VIIb as colorless crystals after chromatography on 100 g of silica gel using ether-petroleum ether (1 : 4).

For analysis, a small amount of the sample was recrystallized from *n*-hexane, colorless needles, mp 79—80 °C. Found: C, 80.56; H, 11.25%; Mol wt, 386 (mass spectrometry). Calcd for $C_{26}H_{42}O_2$: C, 80.77; H, 10.95%; Mol wt, 386. IR (KBr disk): 1660 cm^{-1} (C=O).

*p-Bis(4-*t*-butyl-4-hydroxy-3,3-dimethyl-5-hexynyl)benzene (VIIIb).* The ethynylation of the diketone VIIb was accomplished in a manner similar to that described for the preparation of VIIIa. From 9 g of the diketone VIIb we obtained 8.2 g (80%) of the diyne-diol VIIIb as a colorless solid (mp 63—65 °C) after chromatography on 150 g of silica gel using ether-petroleum ether (1 : 9); IR (KBr disk):

3250 (OH) and 3300 cm^{-1} (C≡CH); NMR (CCl_4), δ: 6.97 (s, 4H), 2.8—2.4 (m, 4H), 2.37 (s, 2H), 2.1—1.6 (m, 6H), and 1.20 ppm (s, 30H).

Oxidative Coupling of VIIIb. The oxidative coupling of VIIIb was accomplished in a manner similar to that described for the case of VIIIa except for the following conditions: anhydrous cupric acetate, 40 g; VIIIb, 3.0 g; dropping period, seven days. The residue obtained by removing the solvent was chromatographed on 120 g of silica gel, using ether-*n*-hexane (1 : 1), to yield the cyclic dimer IXb as white crystals (1.0 g, 33%). For analysis, a small amount of the sample was recrystallized from carbon tetrachloride, colorless fine crystals, mp 240—241 °C. Found: C, 82.23; H, 10.40%; Mol wt, 865 (osmometry). Calcd for $C_{60}H_{88}O_4$: 82.51; H, 10.16%; Mol wt, 873. UV(cyclohexane): λ_{max} 214, 220, 224, 248, 260, 265, 268, and 274 nm.

Tetraallene-tetrabromide Xb. The bromination of XIb was accomplished in a manner similar to that described for the preparation of Xa except for the use of benzene-chloroform (10 : 1) as a solvent. From 200 mg of IXb, 97 mg (38%) of tetraallene-tetrabromide Xb was obtained as fine white crystals, mp 204—205 °C (from chloroform-methanol). Mol wt, Found: 1092 (osmometry). Calcd for $C_{60}H_{84}Br_4$: 1124. UV (cyclohexane): λ_{max} 222 and 231 nm. IR (KBr disk): 1924 cm^{-1} (C=C=C).

Cyclic Bis-hexapentaene IIb. The debromination of tetraallene-tetrabromide Xb with methylmagnesium iodide was accomplished in a manner similar to that described for the case of Xc. From 200 mg of Xb, 54 mg (58%) of cyclic bis-hexapentaene IIb was obtained as greenish yellow crystals, which showed a negative Beilstein's test and which were decomposed in the range of 180—200 °C, after chromatography on 10 g of neutral alumina using ether-petroleum ether (1 : 9). The UV spectrum of IIb is shown in Fig. 2.

3,8-Di-t-butyl-2,2,9,9-tetramethyl-4,6-decadiyne-3,8-diol (XIII). A mixture of di-*tert*-butyl ethynyl carbinol[16] (XII) (10 g) and anhydrous cupric acetate (30 g) in 400 ml of pyridine was stirred for 24 hr at 50 °C under a nitrogen atmosphere. The reaction mixture was poured into cooled dilute sulfuric acid and extracted with ether, followed by the usual work-up. The residue obtained by removing the solvent was chromatographed on silica gel using petroleum ether-ether (5 : 1) to yield 6.8 g (69%) of pale yellow crystals.

For analysis, a small amount of the sample was recrystallized from *n*-pentane-carbon tetrachloride, white crystals, mp 166 °C. Found: C, 78.83; H, 11.66%. Calcd for $C_{22}H_{38}O_2$: C, 78.98; H, 11.45%. IR (KBr disk): 3480 cm^{-1} (OH). NMR ($CDCl_3$), δ: 1.90 (s, 2H) and 1.17 ppm (s, 36H).

5,6-Dibromo-3,8-di-t-butyl-2,2,9,9-tetramethyl-3,4,6,7-decatetraene (XIV). The bromination of the diyne-diol XIII was accomplished in a manner similar to that described for the preparation of Xa. From 6 g of XIII, 85 g of phosphorus tribromide, and 100 ml of benzene we obtained 5.2 g (63%) of diallene-dibromide XIV as a white solid after recrystallization from chloroform-methanol. The further recrystallization of this solid gave white plates, mp 232—233 °C (sealed tube). Found: C, 57.53; H, 8.23; Br, 34.38%. Calcd for $C_{22}H_{36}Br_2$: C, 57.40; H, 7.88; Br, 34.72%. IR (KBr disk): 1937 cm^{-1} (C=C=C). UV (cyclohexane): λ_{max} 231 nm (ε 43500). NMR ($CDCl_3$), δ: 1.27 ppm (s).

1,1,6,6-Tetra-t-butylhexapentaene (XV). The debromination of XIV with active zinc was accomplished in a manner similar to that described for the case of Xa. From XIV (200 mg) and active zinc powder (3 g), 81 mg (62%) of the hexapentaene XV was obtained as yellow crystals, mp 182—184 °C (lit,[8c] mp 188—189 °C). NMR (CCl_4), δ: 1.29 ppm (s) (lit,[8c] 1.28 ppm (s) in $CDCl_3$). The UV spectrum of XV is shown in Fig. 2.

p-Bis(4-oxohexyl)benzene (XVI). A suspension of diethylcadmium,[17] prepared from magnesium (3.9 g, 0.16 mol), ethyl bromide (18 g, 0.17 mol), cadmium chloride (24 g, 0.13 mol), and 150 ml of ether, was cooled in an ice-salt bath. Into the mixture a solution of freshly-prepared acid chloride V (5.5 g, 0.019 mol) in 50 ml of benzene was added dropwise over a period of 20 min with vigorous stirring. The mixture was stirred for an hour and then for a further hour at room temperature. After the addition of dilute sulfuric acid and extraction with ether, followed by the usual work-up, the residue obtained by removing the solvent was chromatographed on 40 g of silica gel, using ether-petroleum ether (1 : 4), to give colorless needles (3.9 g, 74% from V).

For analysis, a small amount of the sample was recrystallized from carbon tetrachloride, colorless needles, mp 36—37 °C. Found: C, 78.82; H, 9.65%. Calcd for $C_{18}H_{26}O_2$: C, 78.79; H, 9.55%.

p-Bis(4-ethyl-4-hydroxy-5-hexynyl)benzene (XVII). The ethynylation of the diketone XVI was accomplished in a manner similar to that described for the preparation of VIIIa, but in this case the completion of the reaction required 4 hr. From 2.5 g of the diketone XVI, 1.8 g (61%) of the diynediol XVII was obtained as a pale yellow oil after chromatography on 50 g of silica gel using ether-petroleum ether (1 : 2), NMR (CCl_4), δ: 7.00 (s, 4H), 2.58 (t, J=7 Hz, 4H), 2.25 (s, 2H), 1.97 (s, 2H), 1.9—1.4 (m, 12H), and 0.98 (t, J=7 Hz, 6H).

4,9-Diethyl-5,7-[12]paracyclophadiyne-4,9-diol (XVIII). The intramolecular oxidative coupling of XVII was accomplished in a method similar to that described for the case of VIIIa except for the following conditions: XVII, 2.9 g; reaction temperature, 40 °C; dropping period, 4 days. The residue obtained by removing the solvent was chromatographed on 80 g of silica gel to yield two compounds.

The first compound (500 mg, 17%) was eluted with ether-petroleum ether (1 : 4), it was the cyclic monomer XVIII-I; colorless crystals (from carbon tetrachloride-petroleum ether), mp 155—156.5 °C. Mol wt, Found: 324 (mass spectrometry). Calcd for $C_{22}H_{28}O_2$: 324. UV (cyclohexane): λ_{max} 214, 221, 225, 250, 259, 266, and 273 nm. NMR ($CDCl_3$), δ: 7.12 (s, 4H), 2.7—2.5 (m, 4H), 2.1—1.4 (m, 14H), 1.60 (q, J=7 Hz), and 0.98 ppm (t, J=7 Hz, 6H). IR (KBr disk): 3340 cm^{-1} (OH).

The second substance (520 mg, 18%) was eluted with ether-petroleum ether (2 : 3); it was the cyclic monomer XVIII-II, white fine crystals (from carbon tetrachloride-petroleum ether), mp 156—158 °C. Mol wt, 324 (mass spectrometry). UV (cyclohexane): λ_{max} 214, 220, 225, 245, 259, 264, and 273 nm. NMR ($CDCl_3$), δ: 7.11 (s, 4H), 2.7—2.5 (m, 4H), 2.1—1.4 (m, 14H), 1.61 (q, J=7 H_2), and 0.97 ppm (t, J=7 Hz, 6H). IR (KBr disk): 3540, 3400, and 3340 cm^{-1} (OH).

The authors are greatly indebted to Dr. Hirozo Koyama of the Shionogi Research Laboratory, Shionogi & Co., Ltd., for X-ray crystallographic analysis, to Mr. Takuzo Fujino and Mr. Tsuneyo Shishido for microanalyses, and to Mr. Yoshio Takai for his NMR measurements. This research is supported by a grant-in-aid of the Ministry of Education, to which the authors' thanks are due.

Reaction of Chlorohydrocarbons. VI. Co-pyrolysis of Chloroethanes and Methanol on Activated Alumina

Kiyonori SHINODA

Toyama Technical College, Hongo, Toyama-shi, 930

(Received December 21, 1973)

Co-pyrolysis of chloroethanes and methanol on activated alumina was carried out in order to elucidate the reaction mechanism. The reaction rate was of first order in chloroethanes in the presence of excess methanol. A linear free energy relationship was found to exist between the reactivities of chloroethanes (at 230 °C) and Taft's σ^* constants. ρ^* values for reactions of RCH_3, RCH_2Cl and $RCHCl_2$ series were 0.24, 0.45 and 0.70, respectively. It could be assumed that a β-hydrogen of chloroethanes was abstracted by the nucleophilic attack of methanol, chlorine being removed at the same time. *E*2 reaction seems to dominate in co-pyrolysis of chloroethanes and methanol on activated alumina.

Chloroethylenes and methyl chloride are formed by co-pyrolysis of 1,1,2-trichloroethane and methanol on activated alumina.[1] Andrussow and Edler[2] reported that in the co-pyrolysis of 1,1,2,2-tetrachloroethane and methanol on activated alumina the reaction proceeds according to the following equation.

$$CHCl_2CHCl_2 + CH_3OH \rightarrow CHCl{:}CCl_2 + CH_3Cl + H_2O$$

Dehydrochlorination of 1,1,2-trichloroethane at high temperature is unfavorable for the formation of 1,1-dichloroethylene.[3] Elimination of hydrogen chloride from 1,1,2-trichloroethane on solid acids such as activated alumina, has a poor selectivity for 1,1-dichloroethylene.[4,5] In contrast, the 1,1/1,2 ratio in co-pyrolysis of 1,1,2-trichloroethane and methanol amounted to several times as high as that of ordinary pyrolysis.[1] Another merit of the reaction is that the dehydrochlorination of chloroethanes can proceed at a lower temperature.

The present investigation was undertaken to study co-pyrolysis of several different chloroethanes and methanol on activated alumina with a conventional flow type reactor. The relation between the molecular structure and the rate of the dehydrochlorination is discussed.

Experimental

Reagents. 1,1-Dichloroethane, 1,2-dichloroethane, 1,1,2-trichloroethane and 1,1,2,2-tetrachloroethane (Wako Pure Chemicals Co.) were of reagent grade and were used without further purification. 1,1,1-Trichloroethane was washed several times with water, and then dried with calcium chloride and fractionated. Pentachloroethane and 1,1,1,2-tetrachloroethane were prepared by the chlorination of trichloroethylene and 1,1,1-trichloroethane in the presence of ferric chloride as a catalyst, washed with aqueous sodium carbonate solution and then with water, and fractionally distilled; bp 161.5 °C for pentachloroethane and 129—130 °C for 1,1,1,2-tetrachloroethane.

Catalyst. 0.4 cm pellets of activated alumina (KH-A24, Sumitomo Chemical Co.) with surface area 200 m^2/g and 0.2% Na_2O content were used.

Apparatus. A flow type reaction system was used. A Pyrex reaction vessel, tube of length *ca.* 30 cm and diameter 2.6 cm was heated in a vertical electric furnace. The evaporator, a glass tube, was placed in an electrically wound vertical furnace. The reaction temperature was measured with a Chromel-Alumel thermocouple in a thermowell placed in the catalyst bed.

Procedure. 20 g of catalyst was placed in the middle of the reactor, the bed being supported by necking the reactor tube. The catalyst was heated in the air at 350 °C for 3 to 5 hr. While the reaction temperature was regulated, nitrogen gas was passed over the catalyst. A mixture of chloroethanes and methanol was then fed into the evaporator with a microfeeder and preheated to 200°C, the vapor being passed to the reactor. The time factor (W/F: g·hr/g-mol) was varied by adjusting the feed rate of each chlorinated ethane (F: g-mol/hr), the weight of the catalyst (W : g) being kept constant. The product gas stream entered a cooler and condensed in a water-ice trap. Organic products were separated from the water with a separating funnel.

Gas-chromatographic analyses were performed with a GC-5 type apparatus from Shimadzu Seisakusho. The column was Silicone DC 550 on Celite.

Results

Co-pyrolysis of chloroethanes and methanol on activated alumina proceeded as follows.

$$C_2H_{6-n}Cl_n + CH_3OH \rightarrow C_2H_{5-n}Cl_{n-1} + CH_3Cl + H_2O$$

The side reaction products were dimethyl ether and a dechlorinated product. Dimethyl ether was formed by the dehydration of methanol on the surface of activated alumina. The dechlorinated product was formed by the pyrolysis of higher chlorinated derivatives such as 1,1,1,2-tetrachloroethane and pentachloroethane. Hydrogen chloride was formed in a trace amount. Dimethyl ether and methyl chloride were not determined. In all runs, two chloroethanes were competitively pyrolyzed in order to check the balance of the volatile products such as vinyl chloride.

1,1-Dichloroethane and 1,1,1,2-tetrachloroethane were mixed with methanol at the mole ratio 0.107 : 0.142 : 1.00. W/F values were 305 and 403 for 1,1-dichloroethane and 1,1,1,2-tetrachloroethane, respectively. All other experiments were carried out with the chloroethanes to methanol mole ratio 0.5 : 0.5 : 3.0.

The design equation[6] for a catalytic flow reactor can be written as

$$W/F = \int_0^x dx/r \qquad (1)$$

The reaction rate r is of first order in each chloroethane. r is a function of conversion since the concentration of chlorinated ethane varies with conversion.

The final equation[7] is

$$\frac{W}{F} = \frac{2.303}{k} \times \log \frac{n_0}{n_0 - x} \qquad (2)$$

where n_0 is the initial concentration of chlorinated ethane and x is the amount of chlorinated ethylene formed.

The plots of $\log k$ against $1/T$ gave straight lines (Fig. 1). From the slopes of the straight lines, the activation energies for the dehydrochlorination of 1,1-dichloroethane and 1,1,1,2-tetrachloroethane were calculated to be 9100 and 12000 cal, respectively. In the case of 1,1,1,2-tetrachloroethane dechlorination, exchange of chlorine with hydrogen, took place besides the

TABLE 1. REACTION RATE CONSTANTS

Reaction type	Reaction rate constant (g-mol/g·hr)	Entropy of activation (cal/deg.)
$CH_3CHCl_2 \rightarrow CH_2 : CHCl$	$k_1 = 9.47 \exp(-9060/RT)$	−55.13
$CH_2ClCH_2Cl \rightarrow 1/2\,CH_2 : CHCl$	$k_2 = 7.36 \times 10^3 \exp(-17900/RT)$	−41.89
$CH_3CCl_3 \rightarrow CH_2 : CCl_2$	$k_3 = 3.38 \times 10^2 \exp(-12200/RT)$	−48.02
$CH_2ClCHCl_2 \rightarrow CH_2 : CCl_2$	$k_4 = 1.00 \times 10^5 \exp(-20200/RT)$	−36.71
$CH_2ClCHCl_2 \rightarrow CHCl : CHCl$	$k_5 = 1.67 \times 10^4 \exp(-18600/RT)$	−40.28
$CH_2ClCCl_3 \rightarrow CHCl : CCl_2$	$k_6 = 1.08 \times 10^2 \exp(-12000/RT)$	−50.30
$CH_2ClCCl_3 \rightarrow CH_2 : CCl_2$	$k_7 = 1.33 \times 10^2 \exp(-14000/RT)$	−49.88
$CHCl_2CHCl_2 \rightarrow 1/2\,CHCl : CCl_2$	$k_8 = 4.69 \times 10^4 \exp(-17600/RT)$	−38.23
$CHCl_2CCl_3 \rightarrow CCl_2 : CCl_2$	$k_9 = 2.30 \times 10 \exp(-9230/RT)$	−53.37
$CHCl_2CCl_3 \rightarrow CHCl : CCl_2$	$k_{10} = 1.58 \exp(-9700/RT)$	−58.69

elimination of hydrogen chloride. The rate of dechlorination was found to be smaller than that of dehydrochlorination.

The effect of the temperature on co-pyrolysis of 1,2-dichloroethane and 1,1,2,2-tetrachloroethane is shown in Fig. 2. The values indicated by symbol ○ were obtained from co-pyrolysis of 1,1,2-trichloroethane and 1,1,2,2-tetrachloroethane to confirm the reproducibility of the experiment. We see that the dehydrochlorination rate of 1,1,2,2-tetrachloroethane is greater than that of 1,2-dichloroethane. However, the activation energies showed no difference under the experimental conditions within the limits of error.

Figure 3 shows the Arrhenius plots of co-pyrolysis of 1,1,1-trichloroethane and pentachloroethane. Dechlorination of pentachloroethane took place concurrently with dehydrochlorination to some extent. The activation energies for the dehydrochlorination of 1,1,1-trichloroethane and pentachloroethane were 12200 and 9200 cal, respectively.

The Arrhenius plots for the competitive pyrolysis of 1,1,2-trichloroethane and 1,1,2,2-tetrachloroethane are shown in Fig. 4. The dehydrochlorinated products of 1,1,2-trichloroethane are 1,1-dichloroethylene, *cis*- and *trans*-1,2-dichloroethylene. The rate constant k_5 was a sum of the rates of the formation of *cis*- and *trans*-dichloroethylene. The ratio of 1,1-dichloroethylene to 1,2-dichloroethylene amounted to several times as high as that in ordinary pyrolysis.[1] However, the rate constants of the dehydrochlorination of 1,1,2-trichloroethane were considerably smaller than that of 1,1,2,2-tetrachloroethane. Activation energies for the formation of 1,1-dichloroethylene and 1,2-dichloroethylene were calculated from the slopes to be 20200 and 18600 cal, respectively.

Discussion

The reaction rate constants were obtained by means of the activation energies and intercepts of Arrhenius plots (Table 1). Since the reactivity seemed to be affected by the polar nature of the substituent, Taft's equation was applied to this heterogeneous catalysis.

$$\log k/k_0 = \rho^*\sigma^* \qquad (3)$$

where k/k_0 is the relative rate constant with respect to standard reaction (1,2-dichloroethane in this case),

TABLE 2. RELATIVE REACTIVITIES FOR CO-PYROLYSIS OF CHLOROETHANES AND METHANOL ON ACTIVATED ALUMINA AT 230 °C

Reaction site	Substituent	Relative reactivity
$-CH_3$	$-CCl_3$	13.71
	$-CHCl_2$	9.34
$-CH_2Cl$	$-CCl_3$	5.49
	$-CHCl_2$	1.14
	$-CH_2Cl$	1.00 (Standard)
$-CHCl_2$	$-CCl_3$	19.06
	$-CHCl_2$	8.90
	$-CH_2Cl$	1.46

●: $-CH_3$, ○: $-CH_2Cl$, ⓓ: $-CHCl_2$

and σ^* represents the alkyl substituent parameter which is a measure of the inductive effect.[8] Rate constants at 230 °C were calculated from the equations in Table 1. The relative reactivities obtained in the competitive co-pyrolysis of chloroethanes and methanol on activated alumina are given in Table 2. A linear free energy relationship was found to exist between the reactivities of chloroethanes and Taft's σ^* constants (Fig. 5). Values of ρ^* were calculated by the method

of least squares. ρ^* values for reactions of RCH_3, RCH_2Cl and $RCHCl_2$ series were 0.24, 0.45 and 0.70, respectively.

For the photochlorination and chlorine-sensitized photooxidation of chloroethanes, ρ^* values were negative, indicating an electrophilic reaction mechanism.[9-11] On the other hand, positive ρ^* values were observed for co-pyrolysis of chloroethanes and methanol on activated alumina.

For the formation of ethers from alcohols over alumina catalysts, Knözinger and Bühl observed a positive ρ^* value.[12] Adsorption of alcohol molecules on basic sites of alumina by hydrogen bonding through the hydrogen of the hydroxyl group generates incipient alkoxide anions.[13] Thus, it was suggested that a β-hydrogen of chloroethanes was abstracted by the nucleophilic attack of methanol, chlorine being removed at the same time. For example, the reaction scheme in the case of 1,1,2-trichloroethane can be given by the following equations.

$$CH_3OH \xrightarrow{\text{basic sites of alumina}} CH_3O^{\ominus} + H^{\oplus}$$

$$CH_3O^{\ominus} + \underset{\beta}{CHCl_2}\underset{\alpha}{CH_2Cl} \rightarrow \left[CH_3O^{\delta\ominus}\cdots H \quad H \;\; Cl{-}C{=}C{-}H \;\; Cl \quad Cl^{\delta\ominus} \right]$$

$$CH_3OH + CCl_2 : CH_2 + Cl^{\ominus}$$

$$H^{\oplus} + Cl^{\ominus} \rightarrow HCl$$

$$CH_3OH + HCl \xrightarrow{\text{activated alumina}} CH_3Cl + H_2O$$

Dechlorination occurred considerably with the pyrolyses of 1,1,1,2-tetrachloroethane and pentachloroethane. The acid sites of alumina seemed to play an important role in the elimination reaction. The reaction could proceed according to *E*1 on the acid sites and *E*2 on the basic sites of the catalysts. It was found that *E*2 reaction dominated in the co-pyrolysis of chloroethanes and methanol on activated alumina.

Effects of Substituents on the Formation of Acetals of 4-Substituted 1,3-Indandiones

Kazuo SAKANE, Yoshio OTSUJI, and Eiji IMOTO

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai-shi, Osaka 591

(Received February 22, 1974)

Treatment of 4-nitro-1,3-indandione (**1**) with an equivalent of ethylene glycol in benzene in the presence of *p*-toluenesulfonic acid afforded 4-nitro-1,3-indandione-1-ethylene acetal (**2**), 3-ethylene acetal (**3**) and 1,3-bis-ethylene acetal (**4**). Kinetic studies revealed that **2** is a kinetically preferred product and **3** is a thermodynamically preferred product. However, the reaction of 4-acetamido-1,3-indandione (**5**) with ethylene glycol under similar conditions gave 4-acetamido-1,3-indandione-1-ethylene acetal (**6**) as a product both kinetically and thermodynamically controlled. Thioacetalization of **1** with an equivalent of 1,2-ethanedithiol afforded selectively 4-nitro-1,3-indandione-1-ethylene thioacetal (**9**).

The regioselective preparation of an acetal of polycarbonyl compounds is in general difficult.[1] From the need of monoacetals of 4-substituted 1,3-indandiones for our synthetic studies of azaacenaphthene derivatives, we studied the acetalization of 4-substituted 1,3-indandiones and found that the keto groups, where the acetalization takes place, are largely influenced by the substituents attached and alcohols used. The results are summarized and the mechanisms of the reactions are discussed in the present paper.

Results and Discussion

Reactions and Mechanisms. Treatment of 4-nitro-1,3-indandione (**1**) with an equivalent of ethylene glycol in benzene in the presence of *p*-toluenesulfonic acid afforded a mixture of 4-nitro-1,3-indandione-1-ethylene acetal (**2**), 4-nitro-1,3-indandione-3-ethylene acetal (**3**) and 4-nitro-1,3-indandione-1,3-bisethylene acetal (**4**). The reaction of **1** with a large excess of ethylene glycol under similar conditions gave only **4**. Products **2**, **3** and **4** were isolated by repeated fractional recrystallization.

5; X= NHAc 6; X=NHAc 7; X=NHAc 8; X= NHAc

The yields of **2**, **3** and **4** varied with reaction time when the reaction of **1** with an equivalent of ethylene glycol was carried out in benzene in the presence of *p*-toluenesulfonic acid. The yields of **2**, **3** and **4** were determined by vpc analysis of the reaction mixture at appropriate time intervals.[2] The results are shown in Fig. 1. At an initial stage of the reaction, the yield of **2** was higher than that of **3**. Aftre a while, however, the situation was reversed and finally the yields of **2**, **3** and **4** approached constant values.

When **2** was refluxed in benzene in the presence of *p*-toluenesulfonic acid without ethylene glycol, **3** and **4** were obtained. A similar treatment of **3** yielded **2** and **4**. Variation of the yields of the products with reaction time for these reactions were followed by vpc analyses of the reaction mixtures. The results are shown in Figs. 2 and 3. The results indicate that the rate of disappearance of **2** is greater than that of **3**, and that **3** and **4** are produced from **2** at almost equal rates. The rates of formation of **2** and **4** from **3** are also almost equal.

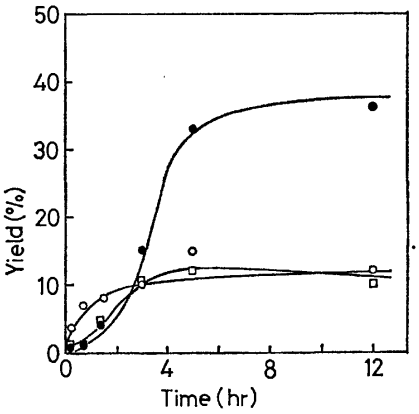

Fig. 1. Variation of the yields of the products with reaction time in the acid-catalyzed acetalization of **1** with ethylene glycol. A mixture of 5.7 g (0.03 mol) of **1**, 1.8 g (0.03 mol) of ethylene glycol and 0.3 g of *p*-TsOH·H_2O in 300 ml of benzene was refluxed. ○: **2**, ●: **3**, □: **4**.

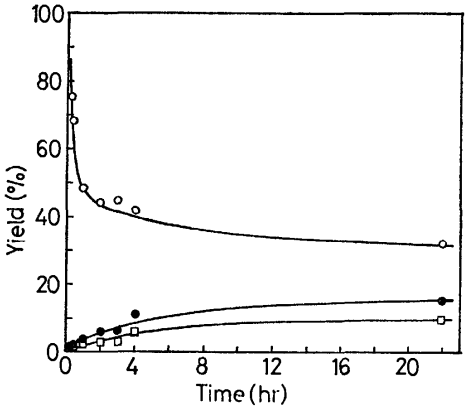

Fig. 2. Variation of the yields of the products with reaction time in the acid-catalyzed reaction of **2**. A mixture of 12.2 mg (0.052 mmol) of **2** and 1.0 mg of *p*-TsOH·H_2O in 1.0 ml of benzene was refluxed. ○: **2**, ●: **3**, □: **4**.

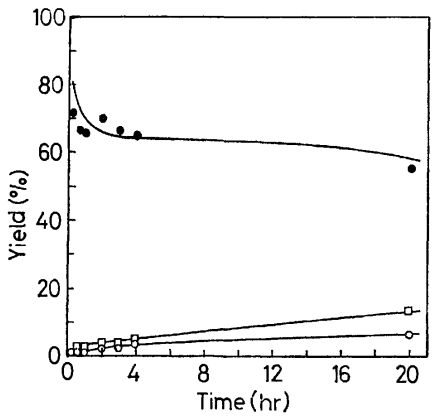

Fig. 3. Variation of the yields of the products with reaction time in the acid-catalyzed reaction of **3**. A mixture of 11.1 mg (0.047 mmol) of **3** and 1.0 mg of *p*-TsOH·H_2O in 1.0 ml of benzene was refluxed.
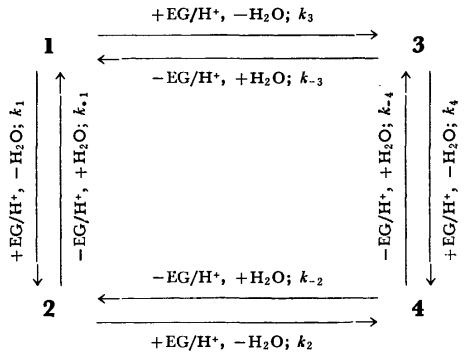
○: **2**, ●: **3**, □: **4**.

The results may be accounted for by assuming that the acid-catalyzed acetalization of **1** with ethylene glycol proceeds through the pathways represented in Scheme 1.[3] Since $k_1 > k_3$, the formation of **2** is favored over that of **3** at the initial stage of acetalization.



Scheme 1.

However, as a result of $k_{-1} > k_{-3}$ the yield of **3** becomes higher than that of **2** after a prolonged reaction, indicating that **3** is a thermodynamically controlled product; **3** is thermodynamically more stable than **2**.

As another example of acetalization, we studied the acid-catalyzed acetalization of 4-acetamido-1,3-indandione (**5**) with ethylene glycol. Treatment of **5** with an equivalent of ethylene glycol in benzene in the presence of *p*-toluenesulfonic acid gave 4-acetamido-1,3-indandione-1-ethylene acetal (**6**), accompanied by a black material which could not be purified. In this reaction, 3-ethylene acetal (**7**) and 1,3-bisethylene acetal (**8**) were not detected. Variation of the yield of **6** with reaction time is shown in Fig. 4. Treatment of **7** in benzene in the presence of *p*-toluenesulfonic acid afforded **5** and **6**. Variation of the yields of **5** and **6** with reaction time is shown in Fig. 5. The results suggest that **6** is a product which is both kinetically and thermodynamically preferable in the acetalization of **5**. The results also indicate that the acetal formation of 1,3-indandiones is strongly influenced by the substituents attached to the benzene ring in the diones; an

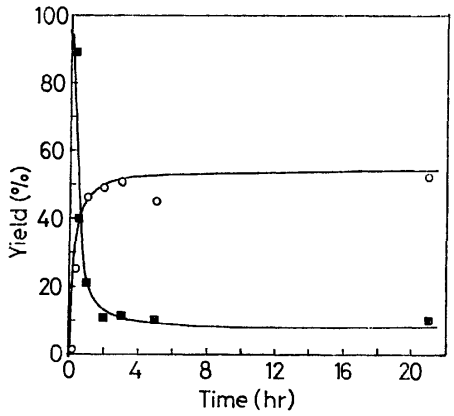


Fig. 4. Variation of the yields of the products with reaction time in the acid-catalyzed acetalization of **5**. A mixture of 50.9 mg (0.25 mmol) of **5**, 35.3 mg (0.57 mmol) of ethylene glycol and 5.3 mg of *p*-TsOH·H_2O in 5.0 ml of benzene was refluxed.

electron-withdrawing substituent such as a nitro group at the 4-position stabilizes 3-ethylene acetal, but an electron-releasing substituent at the same position stabilizes 1-ethylene acetal.[4] However, it must be borne in mind that in a kinetical sense, the carbonyl group at the 1-position is more reactive than the carbonyl group at the 3-position, irrespective of the nature of substituents.[5]

In contrast to ethylene acetals, ethylene thioacetals are relatively stable under the conditions of their formation; they are not easily hydrolyzed by mineral acids. Consequently, in the case of thioacetals, a predominant formation of the kinetically controlled products is to be expected: *i.e.*, thioacetalization of **1** would yield selectively 4-nitro-1,3-indandione-1-ethylene thioacetal (**9**). The reaction of **1** with an equivalent of 1,2-ethanedithiol in acetic acid in the presence of *p*-toluenesulfonic acid gave **9** in a 36% yield along with a small amount (1% yield) of 4-nitro-1,3-indandione-1,3-bisethylene thioacetal (**10**), but no 3-ethylene thioacetal (**11**). The reaction of **1** with a large excess

of 1,2-ethanedithiol gave only **10**. A high regioselectivity of this reaction may in part be attributed to a bulkiness of sulfur atoms besides an inherent high reactivity of the carbonyl group at the 1-position.

Characterization of the Products. The structures of the products were established by the sepctral properties and chemical modifications whereby the products can be interrelated. The relevant IR and NMR spectral data of compounds **1**—**9** and 4-acetamido-1,3-indandione-1-ethylene thioacetal (**12**) are listed in Table 1.

The 4-acetamido derivatives **5**, **7** and **8** were prepared respectively from the corresponding 4-nitro derivatives, **1**, **3** and **4**. Catalytic reduction of **1**, **3** and **4** over a Raney nickel to the corresponding amino derivatives followed by acetylation led to the formation of **5**, **7** and **8**, respectively. Compound **6** was obtained by the acetalization of **5**. The catalytic reduction of **9** over a Raney nickel gave 4-amino-1,3-indandione-1-ethylene thioacetal which was acetylated to yield **12**.

Let us compare the spectral properties of the 4-nitro derivatives with those of the corresponding 4-acetamido derivatives. The carbonyl band in the IR spectrum of 4-nitro-1-ethylene acetal **2** appeared at higher wavenumber than that of 4-acetamido-1-ethylene acetal **6** by 50 cm^{-1}. A similar shift of the carbonyl band was observed in a comparison of 4-nitro-1-ethylene thioacetal **9** with 4-acetamido-1-ethylene thioacetal **12**; *i.e.*, the carbonyl band of **9** appeared at higher wavenumber than that of **12** by 32 cm^{-1}. In contrast, the carbonyl band of 4-nitro-3-ethylene acetal **3** appeared at a wave number almost the same as that of 4-acetamido-3-ethylene acetal **7**.

Another difference in spectral properties between the 1-ethylene acetal (or the 1-ethylene thioacetal) and the 3-ethylene acetal was observed in the NMR spectra. For 1-ethylene acetal **6** and 1-ethylene thioacetal **12**, the signal due to the NH proton appeared at δ 10—11 ppm. On the other hand, the same signals appeared at higher fields, *i.e.*, δ 8—9 ppm, for 3-ethylene acetal **7** and 1,3-bisethylene acetal **8**. All these spectral properties can be interpreted by assuming that an intramolecular interaction exists between the NH and carbonyl groups in 4-acetamido-1-ethylene acetals and 4-acetamido-1-ethylene thioacetal.

Table 1. Spectral properties

Compd	νC=O (cm^{-1})	Compd	νC=O	NH (ppm)
1	1740 1710	**5**	1740 1705	10.08— 10.40
2	1740	**6**	1690	10.07— 10.70
3	1725	**7**	1722	8.03— 8.31
4	—	**8**	—	8.25— 8.90
9	1730	**12**	1698	10.14— 10.54

The chemistry and spectral properties described above are consistent with the assigned structures. Further evidence for the structure assignment was provided by the fact that 5-azaacenaphthene derivatives were synthesized from **2** and **9**.[6]

Experimental

Vpc analyses were carried out on a 063 Hitachi gas chromatograph with a column packed with 30% Silicone-grease on Celite 545 and tlc analyses with Wakogel B5.

4-Nitro-1,3-indandione-1-ethylene Acetal (2). A mixture of 1.9 g (0.01 mol) of 4-nitro-1,3-indandione (**1**),[7] 5.0 g (0.08 mol) of ethylene glycol and 0.1 g of *p*-toluenesulfonic acid monohydrate (*p*-TsOH·H_2O) in 75 ml of benzene was heated under reflux in a Dean-Stark trap for 2 hr, water formed during the reaction being continuously removed. The reaction mixture was then washed with two 20 ml portions of 5% Na_2CO_3. The aqueous layer was extracted with two 30 ml portions of benzene. All the benzene solutions were combined, washed twice with 100 ml of water, dried (Na_2SO_4) and then evaporated. The oily residue was recrystallized from $CHCl_3$–CCl_4 to yield 0.55 g (23%) of the crude **2**. Repeated fractional recrystallization from $CHCl_3$–CCl_4 gave an analytical sample of **2** as white crystals, mp 142—143 °C. IR (KBr): 1740 (C=O), 1539 (NO_2), and 1361 cm^{-1} (NO_2). NMR ($CDCl_3$): δ 3.04 (s, 2H, $-CO-CH_2C(O-)_2$), 4.12—4.50 (m, 4H, $-OCH_2CH_2O-$), and 7.92 ppm (s, 3H, aromatic H); Mass: *m/e* 235 (M^+), 219, 205, 192, 177, 161, 147, and 133.

Found: C, 56.22; H, 3.78; N, 5.88%. Calcd for $C_{11}H_9NO_5$: C, 56.17; H, 3.86; N, 5.96%.

4-Nitro-1,3-indandione-3-ethylene Acetal (3). A mixture of 5.7 g (0.03 mol) of **1**, 1.8 g (0.03 mol) of ethylene glycol and 0.3 g of *p*-TsOH·H_2O in 240 ml of benzene was heated under reflux in a Dean-Stark trap for 24 hr. The reaction mixture was worked up as described above. From the benzene solution, 5.3 g (76%) of crude **3** was obtained. Repeated fractional recrystallization from ethanol gave an analytical sample of **3** as white crystals, mp 134—136 °C. IR(KBr): 1725 (C=O), 1540 and 1362 cm^{-1} (NO_2). NMR ($CDCl_3$): δ 2.95 (s, 2H, $-COCH_2C(O-)_2$), 4.00—4.50 (m, 4H, $-OCH_2-CH_2O-$), and 7.52—8.30 ppm (m, 2H, aromatic H). Mass: *m/e* 235 (M^+), 207, 192, 175, 167, 161, 159, 149, 147, 145, 133, and 113.

Found: C, 55.98; H, 3.70; N, 5.92%. Calcd for $C_{11}H_9NO_5$: C, 56.17; H, 3.86; N, 5.96%.

Upon acidification of the Na_2CO_3 solution, 0.95 g (17%) of crude **1** was recovered.

4-Nitro-1,3-indandione-1,3-bisethylene Acetal (4). A mixture of 5.7 g (0.03 mol) of **1**, 7.2 g (0.12 mol) of ethylene glycol and 0.3 g of *p*-TsOH·H_2O in 200 ml of benzene was heated under reflux in a Dean-Stark trap for 48 hr. The reaction mixture was worked up as described above. Recrystallization of the residue obtained after evaporation of benzene from CCl_4–hexane gave 5.7 g (69%) of **4** as light pink crystals; mp 78—80 °C. IR (KBr): 1535 cm^{-1} (NO_2), no absorption appearing at the carbonyl region. NMR ($CDCl_3$): δ 2.49 (s, 2H, $(-O)_2CCH_2C(O-)_2$), 3.94—4.50 (m, 8H, two of

$-OCH_2CH_2O-$), 7.38—7.64 (m, 2H, aromatic H), and 7.75 ppm (dd, $J=6.4$ and 3.0 Hz, 1H, aromatic H). Mass: *m/e* 279 (M^+), 262, 249, 233, 207, 191, 177, 162, 161, 147 and 133.

Found: C, 55.95; H, 4.46; N, 4.89%. Calcd for $C_{13}H_{13}NO_6$: C, 55.91; H, 4.70; N, 5.02%.

4-Amino-1,3-indandione. A suspension of 3.8 g (0.02 mol) of **1** and *ca.* 10 g of a W-1 Raney nickel in 340 ml of ethanol was hydrogenated under atmospheric pressure at room temperature for 8 hr. The catalyst was separated and washed thoroughly with ethanol. The filtrate was evaporated to give a deep yellow solid. Recrystallization of the solid from ethanol gave 1.0 g (30%) of the amino compound as yellow needles; mp 203—205 °C. IR (KBr): 3455, 3340 (NH_2), 1720, 1685 (C=O), and 1620 cm^{-1}.

Found: C, 67.27; H, 4.30; N, 8.67%. Calcd for $C_9H_7NO_2$: C, 67.07; H, 4.38; N, 8.69%.

4-Acetamido-1,3-indandione (5). A solution of 100 mg (0.62 mmol) of 4-amino-1,3-indandione in 2 ml of acetic anhydride was heated at 80 °C for a few minutes. Evaporation of the solvent gave a dark brown oil. Recrystallization of the oil from CCl_4 gave 60 mg (55%) of **5** as yellow plates; mp 120—124 °C. IR (KBr): 3310 (NH), 1740, 1705, 1690 (C=O), and 1600 cm^{-1}. NMR ($CDCl_3$): δ 2.29 (s, 3H, $-COCH_3$), 3.28 (s, 2H, $-COCH_2CO-$), 7.58 (dd, $J=7.2$ and 1.7 Hz, 1H, aromatic H), 7.80 (t, $J=7.2$ Hz, 1H, aromatic H), 8.91 (dd, $J=7.2$ and 1.7 Hz, 1H, aromatic H), and 10.08—10.40 ppm (m, 1H, NH). Mass: *m/e* 203 (M^+), 161, 133, 87, and 43.

Found: C, 65.15; H, 4.22; N, 6.83%. Calcd for $C_{11}H_9NO_3$: C, 65.02; H, 4.46; N, 6.89%.

4-Acetamido-1,3-indandione-1-ethylene Acetal (6). A mixture of 0.5 g (2.5 mmol) of **5**, 0.6 g (8.1 mmol) of ethylene glycol, and 30 mg of *p*-TsOH·H_2O in 50 ml of benzene was heated under reflux in a Dean-Stark trap for 10 hr. The reaction mixture was worked up by a method similar to that for **2**. Recrystallization of the product from CCl_4-hexane gave 0.1 g (16%) of **6** as yellow crystals; mp 145—147 °C. IR(KBr): 3310 (NH), 1690 (C=O), 1610, and 1540 cm^{-1}. NMR ($CDCl_3$): δ 2.23 (s, 3H, $-COCH_3$), 2.97 (s, 2H, $-COCH_2C<^{O-}_{O-}$), 4.15—4.40 (m, 4H, $-OCH_2CH_2O-$), 7.25 (d, $J=7.7$ Hz, 1H, aromatic H), 7.65 (t, $J=7.7$ Hz, 1H, aromatic H), and 8.58 ppm (d, $J=7.7$ Hz, 1H, aromatic H). Mass: *m/e* 247 (M^+), 205, 177, 162, 149, 133, and 120.

Found: C, 62.85; H, 5.11; N, 5.87%. Calcd for $C_{13}H_{13}NO_4$: C, 63.15; H, 5.30; N, 5.67%.

4-Amino-1,3-indandione-3-ethylene Acetal. A suspension of 2.35 g (0.01 mol) of **3** was hydrogenated on a W-1 Raney nickel in 100 ml of dioxane over 3 hr. The crude product was recrystallized from $CHCl_3$–hexane to give yellow needles; mp 132—135 °C. IR(KBr): 3440, 3350 (NH_2), 1705 (C=O), and 1620 cm^{-1}. NMR($CDCl_3$): δ 2.79 (s, 2H, $-COCH_2C<^{O-}_{O-}$), 3.90—4.62 (m, 4H, $-OCH_2CH_2O-$), 6.77 (dd, $J=6.9$ and 2.1 Hz, 1H, aromatic H), and 6.91—7.42 ppm (m, 2H, aromatic H).

Found: C, 64.65; H, 5.50; N, 7.02%. Calcd for $C_{11}H_{11}NO_3$: C, 64.38; H, 5.40; N, 6.83%.

4-Acetamido-1,3-indandione-3-ethylene Acetal (7). A solution of 410 mg (2.0 mmol) of 4-amino-1,3-indandione-3-ethylene acetal in 10 ml of dry tetrahydrofuran (THF) was added to a stirred mixture of 300 mg (3.8 mmol) of acetyl chloride and 5 ml of pyridine in 5 ml of dry THF under cooling in an ice-water bath. The mixture was stirred at room temperature for 0.5 hr and then poured into 100 ml of water. The aqueous mixture was extracted with three 200 ml portions of CH_2Cl_2. The extract was washed with two 30 ml portions of water, dried over Na_2SO_4 and evaporated. Recrystallization of the solid from ethanol gave **7** as white needles quantitatively; mp 162—165 °C. IR(KBr) 3345 (NH), 1722, 1690 (C=O), and 1600 cm^{-1}. NMR ($CDCl_3$): δ 2.17 (s, 3H, $-COCH_3$), 2.83 (s, 2H, $-COCH_2C<^{O-}_{O-}$), 4.07—4.41 (m, 4H, $-OCH_2CH_2O-$), 7.42—7.61 (m, 2H, aromatic H), 8.00—8.30 (m, 1H, NH), and 8.69 ppm (dd, $J=5.8$ and 2.9 Hz, 1H, aromatic H). Mass: *m/e* 247 (M^+), 204, 188, 174, 162, 161, 149, 133, and 120.

Found: C, 62.98; H, 5.19; N, 5.58%. Calcd for $C_{13}H_{13}NO_4$: C, 63.15; H, 5.30; N, 5.67%.

4-Amino-1,3-indandione-1,3-bisethylene Acetal. A suspension of 2.8 g (0.01 mmol) of **4** was hydrogenated on a W-1 Raney nickel in 100 ml of dioxane over 7 hr. Recrystallization of the crude product from CCl_4-hexane gave 2.5 g (quantitative) of the amino compound as yellow needles; mp 132—134 °C. IR(KBr) 3100—3600 (NH_2) and 1620 cm^{-1}.

Found: C, 62.88; H, 5.82; N, 5.90%. Calcd for $C_{13}H_{15}NO_4$: C, 62.64; H, 6.07; N, 5.62%.

4-Acetamido-1,3-indandione-1,3-bisethylene Acetal (8). Acetylation of 4-amino-1,3-indandione-1,3-bisethylene acetal with acetyl chloride in the presence of pyridine in dry THF yielded crude **8**, which upon recrystallization from ethanol–$CHCl_3$ gave a pure sample as pale yellow crystals in 70% yield; mp 210 °C. IR(KBr): 3380 (NH), 1692 (C=O), and 1610 cm^{-1}. NMR ($CDCl_3$) δ 2.16 (s, 3H, $-COCH_3$), 2.53 (s, 2H, $-O>CCH_2C<^{O-}_{O-}$), 4.10—4.50 (m, 8H, $-OCH_2-CH_2O-$), 7.30 (t, $J=7.4$ Hz, 1H, aromatic H), 7.64 (d, $J=7.4$ Hz, 1H, aromatic H), and 8.25—8.92 ppm (m, 2H, NH plus aromatic H). Mass: *m/e* 291 (M^+), 263, 248, 247, 232, 219, 206, 205, and 191.

Found: C, 61.77; H, 5.75; N, 4.79%. Calcd for $C_{15}H_{17}NO_5$: C, 61.85; H, 5.88; N, 4.81%.

4-Nitro-1,3-indandione-1-ethylene Thioacetal (9). To a solution of 3.8 g (0.02 mol) of **1** in 140 ml of AcOH were added 1.9 g (0.02 mol) of 1,2-ethanedithiol and 2.0 g (0.01 mol) of *p*-TsOH·H_2O. The mixture was allowed to stand at room temperature overnight. Filtration of the mixture gave 60 mg (1%) of 4-nitro-1,3-indandione-1,3-bisethylene thioacetal (**10**), mp 202—205 °C, which showed no depression in the mixed melting-point test with the product obtained by the reaction of **1** with an excess 1,2-ethanedithiol. The filtrate was poured into 300 ml of water and extracted with three 50 ml portions of CH_2Cl_2. The extract was washed successively with two 300 ml portions of water, two 100 ml portions of 5% NaOH and two 200 ml portions of water. The CH_2Cl_2 solution was dried over Na_2SO_4 and then evaporated to give 2.7 g (51%) of crude monothioacetal **9**. The tlc analysis of this crude product indicated that the product consists of only **9**. Recrystallization from $CHCl_3$-hexane gave 1.9 g (36%) of **9** as pure yellow needles; mp 117—119 °C. IR (KBr): 1730 (C=O), 1530, and 1360 cm^{-1} (NO_2). NMR ($CDCl_3$): δ 3.48 (s, 2H, $-COCH_2C<^{S-}_{S-}$), 3.63 (m, 4H, $-SCH_2CH_2S-$), and 7.60—8.17 ppm (m, 3H, aromatic H).

Found: C, 49.32; H, 3.29; N, 5.03%. Calcd for $C_{11}H_9NO_3S_2$: C, 49.44; H, 3.40; N, 5.24%.

Upon acidification of the NaOH solution, 1.3 g (34%) of **1** was recovered.

4-Nitro-1,3-indandione-1,3-bisethylene Thioacetal (10). A mixture of 1.9 g (0.01 mol) of **1** and 10 ml of BF_3-etherate in 70 ml of AcOH was maintained at room temperature

overnight. The resulting solid was filtered, washed with water and then dried to give **10** as greenish yellow solid quantitatively; mp 205—207 °C. IR(KBr): 1520 and 1355 cm^{-1} (NO_2).

Found: C, 45.56; H, 3.78; N, 3.83%. Calcd for $C_{13}H_{13}NO_2S_4$: C, 45.49; H, 3.82; N, 4.08%.

4-Amino-1,3-indandione-1-ethylene Thioacetal. A suspension of 5.34 g (0.02 mol) of **9** was hydrogenated over a W-I Raney nickel in 100 ml of dioxane under atmospheric pressure at room temperature for 3 hr. The catalyst was removed by filtration. Evaporation of the filtrate left a yellow oil which was chromatographed on a neutral alumina. Elution with $CHCl_3$ gave 3.5 g (73%) of the amino compound as a pale yellow oil. IR (film): 3450, 3340 (NH_2), and 1670 cm^{-1} (C=O). The oil solidified upon distillation under reduced pressure; bp 200—210 °C/0.4 mmHg. Recrystallization from CCl_4–hexane gave an analytical sample as yellow needles; mp 94—99 °C.

Found: C, 55.56; H, 4.58; N, 5.77%. Calcd for $C_{11}H_{11}NOS_2$: C, 55.70; H, 4.64; N, 5.91%.

*4-Acetamido-1,3-indandione-1-ethylene Thioacetal (**12**).* Crude 4-amino-1,3-indandione-1-ethylene thioacetal was heated with excess Ac_2O on a water bath for 1 hr. After removal of AcOH and excess Ac_2O under reduced pressure, the residue was recrystallized from ethanol to yield **12** as light brown needles in 70% yield, mp 128—130 °C. IR (KBr): 3210—3280 (NH), 1698, and 1675 cm^{-1} (C=O). NMR ($CDCl_3$): δ 2.24 (s, 3H, $-COCH_3$), 3.49 (s, 2H, $-COCH_2-\overset{1}{C}<^{S-}_{S-}$), 3.62 (bs, 4H, $-SCH_2CH_2S-$), 7.50 (dd, $J=7.2$ and 1.7 Hz, 1H, aromatic H), 7.63 (t, $J=7.2$ Hz, 1H, aromatic H), and 10.14—10.54 ppm (m, 1H, NH).

Found: C, 55.71; H, 4.87; N, 5.12%. Calcd for $C_{13}H_{13}NO_2S_2$: C, 55.91; H, 4.70; N, 5.02%.

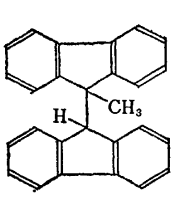
(Received March 5, 1974)

Several 9-methyltriptycene derivatives have been synthesized and the PMR spectra examined at low temperatures. The compounds which have a methoxy or a methyl group at a peri position showed only broadening of methyl signals, whereas those with a chlorine at a peri position and another substituent at some other peri position showed a splitting of methyl signals. The compounds which have a halogen atom at a peri position are the intermediary cases in a sense that they show separation of the signal into two with 1 : 2 relative intensities but fail to show fine splittings. Activation parameters for the rotation were obtained by total line shape analysis. Substituent effects have been discussed.

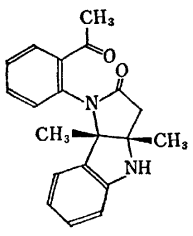
Many studies have been made on restricted rotation about carbon-carbon single bonds by means of the variable temperature technique of high resolution NMR spectroscopy.[2] However, this method is only applicable to the 10^0-10^3 s^{-1} rates of exchange, and little is known about the rates of restricted rotation of methyl groups whose barriers to rotation are in the range 3.0 (ethane)—4.3 (neopentane) kcal/mol.[3] In order to detect the slow rotation of methyl groups of this kind, the temperature has to be so lowered that technical difficulties arise.

There are two cases as regards the restricted rotation of a methyl group, one of which is 9-methyl-9,9'-bifluorenyl (**1**) which shows line-broadening of the methyl at low temperatures as reported by Bartle *et al.*[4] Dave and Warnhoff observed a similar phenomenon with quaternary methyl groups of compound **2** and claimed that it must be attributed to the slow rotation of the methyl groups.[5] However, the observations deal only with line-broadening and lack a basis for claiming the restricted rotation. No report has appeared to show further evidence for the restricted rotation of methyl groups.[6] If the rotation of a methyl group is frozen, an ABC or AB_2 type signal is expected depending upon the substituent of the neighboring carbon. The situation is clear when Newman projections (**4** and **5**) are drawn. In the intermediary cases, a methyl group should show an unsymmetrical signal, since differences in chemical shifts between A and B and C are generally not the same.

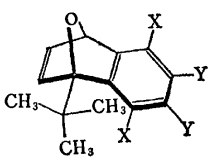
Recently we were able to observe an unsymmetrical methyl signal at −133 °C with compound **3** and attributed it to the slow rotation of the methyl group on the NMR time scale.[7] We looked for examples showing distinct splitting of a methyl signal. Probable examples were 9-methyltriptycene derivatives,



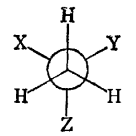
(**1**)



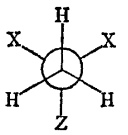
(**2**)



(**3**)



(**4**) ABC Type



(**5**) AB_2 Type

since 9-*t*-butyltriptycene type compounds are known to possess extremely high barriers to rotation about the C_9–C_{Bu} bond,[8] and 9-chloromethyltriptycene has been reported to have a high barrier to internal rotation.[9]

Results and Discussion

9-Methyl-1,2,3,4-tetrachlorotriptycene (**8**) was prepared by treating 9-methylanthracene with tetrachlorobenzyne and its PMR spectrum was examined at low temperature. The compound gave no signals with fine structure even at −95 °C, though separation of the methyl signal into two with 2 : 1 relative intensities was observed. The results sugest that the methyl group rotates slowly enough to show different chemical shifts of two kinds of protons but the rotation is too fast to show fine splittings. It was thought that increasing the steric hindrance by introducing another substituent to another ring might increase the barrier.

9-Methyl-1,2,3,4,5,6,7,8-octachlorotriptycene (**10**) was similarly prepared. Its methyl signal showed a clear AB_2 type splitting at −65.4 °C and below, suggesting that the rotation in question is really slow on the

NMR time scale. The results imply that the substituents at peri positions play an important role in determining the rates of rotation. Various types of substituted 9-methyltriptycenes were prepared in order to obtain information on the effect of substituents at peri positions.

The methyl signals can be classified into three cases: (a) only line-broadening at low temperature, (b) separation of a methyl signal into two broad signals with relative intensities 1 : 2, and (c) appearance of a clear AB_2 type signal. Compounds **6** and **7** with one substituent other than a halogen atom at a peri position belong to (a), **8** and **9** with one halogen atom at a peri position to (b) and **10**, **11**, and **12** with a substituent at a peri position in addition to a halogen atom at another peri position to (c). Figure 1 shows the temperature-dependent PMR spectra of **6**, **8**, and **11** as typical examples.

The effect of a peri-substituent is important. The factor determining the barrier might not be van der Waals radius only: a methyl group which has a larger van der Waals radius than a chlorine seems to effect a smaller barrier. In order to discuss this point, exact knowledge of kinetic parameters or the chemical shift difference is necessary, because, if the latter is small, the coalescence temperature is low.

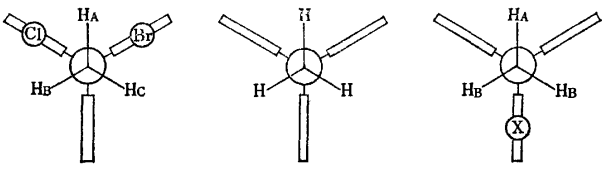
TABLE 1. PMR PARAMETERS OF METHYL PROTONS OF COMPOUNDS **8**—**12**

Compound	δ_A	δ_B	δ_C	$\delta_B-\delta_A$	J_{AB}
8	2.23	3.02	—	0.79	—
9	2.20	3.09	—	0.89	—
10	2.78	3.89	—	1.11	−12.6
11	2.71	4.07	—	1.36	−12.6[a]
12	2.72	2.82	3.53	—	−12

a) Assumed value.

The chemical shifts of protons of methyl groups were obtained with the use of LAOCOON MBYH program[10] for compounds **8**—**12**. The results are shown in Table 1. Since the difference in chemical shifts of protons B and C in compound **11**, as shown in a Newman projection **13**, was considered to be very small, the line shape was treated as an AB_2 pattern. The coupling constants were also obtained when possible. They are also given in Table 1. It was not possible to obtain geminal coupling constants of methyl protons in compounds **8** and **9**, since they showed no signal splitting. We could obtain three chemical shifts for the methyl protons of compound **12**, but estimation of the geminal coupling constants was difficult: the spectral lines were broad even at −90 °C due to the slow rotation taking place and further lowering of temperature caused precipitation.

Chemical shifts of methyl protons of compounds **6** and **7** could not be obtained by computation since they showed symmetrical signals, although broad, even at the lowest temperature attained (−90 °C). Thus the chemical shifts were estimated by making the following simple assumption. A chemical shift of the methyl group of 9-methyltriptycene in carbon disulfide is known to be δ 2.25. Since three protons



(**13**) (**14**) (**15**)

are located in the identical environment (**14**), it follows that the chemical shift of each proton should also be δ 2.25. If we extend this discussion to the substituted triptycenes in questions, the observed

Table 2. Calculated chemical shifts of methyl protons of compounds **6** and **7**

Compound	δ_{obs}[a)]	δ_A	δ_B	$\delta_B-\delta_A$
9-methyltriptycene	2.25	2.25	2.25	0
6	2.50	2.25	2.63	0.38
7	2.53	2.25	2.67	0.42

a) in CS_2 solution

chemical shift is the average of two identical chemical shifts of protons (H_B in **15**) in the neighborhood of the peri-substituent and a proton (H_A in **15**) far from the substituent. Since H_A is far from the substituent, we may tentatively assume that the chemical shift of H_A is very close to that of protons in 9-methyltriptycene, δ 2.25. Since the observed value is the weighted mean, we can calculate the chemical shift of H_B. The values thus obtained are given in Table 2.

The validity of the above assumption should be checked by seeing whether the assumption is valid for other compounds such as **8** and **9** whose chemical shifts of protons far from the substituents are δ 2.23 and 2.20, respectively (Table 1). Since these values agree with those obtained by the assumption to the extent of two significant digits, the assumption could be taken as valid for semi-quantitative discussion.

Comparison of the chemical shift differences ($\delta_B-\delta_A$) in Tables 1 and 2 shows that those compounds which exhibited line separation or splitting have larger values than those which showed only line broadening. The large difference in chemical shift caused by the halogen atom is one reason that we could detect the frozen rotation of the methyl group in compound **10**. We were lucky in a sense that a compound with a large difference in chemical shift of methyl protons was chosen as the first example.

We should know the activation parameters to discuss the substituent effect, since the difference in the chemical shift between compounds is not common. The observed line shapes were simulated by putting the parameters in Table 1 into INVERS EX II program. Some computed spectra are shown in Fig. 1 to demonstrate the agreement with the observed. The rate constants thus obtained were plotted against $1/T$. Linearity holds and activation energies are obtained. Substitution of these data into Eyring's equation affords kinetic parameters shown in Table 3.

Various kinetic parameters are used, depending upon the authors, for discussion of the barrier to rotation. We believe that the Arrhenius activation energy is the most appropriate for comparison since it is obtainable from the experimental results.

Activation energies can be classified into three categories, as in the case of the spectra. From the chemical shift difference of two kinds of protons and the fact that the signal at −90 °C was still symmetrical, *i.e.* −90 °C is still above the coalescence temperature, free energy of activation seems to be less than 8 kcal/mol for compounds **6** and **7**.[11] Thus compounds **6** and **7** form group (a) with a barrier less than 8 kcal/mol, compounds **8** and **9** form another group (b) with a barrier 9—10 kcal/mol, and **10**, **11**, and **12** form a third group (c) with a barrier greater than 12 kcal/mol.

As regards group (a), a comparison of the heights of signals at low temperature is possible to some extent. Since the difference in chemical shift of methyl protons in compounds **6** and **7** is almost the same, the coalescence temperature of the methyl protons should be higher for a compound having a higher barrier than one with a lower barrier. Though no coalescence was observed, it is reasonable to assume that the coalescence temperature is reflected in the height or the half-band width of signals: a broader signal is a reflection of a higher coalescence temperature. Since the half-height widths for **6** and **7** are 12 and 5 Hz at −90 °C, respectively, and relative heights are 1 : 1.4, the methyl compound (**7**) seems to possess lower barrier to rotation than the methoxy compound (**6**).

From the above discussion, effectiveness of substituents in monosubstituted methyltriptycenes for raising the barrier would be in the order

$$Br > Cl > OCH_3 > CH_3$$

This is in line with the van der Waals radii except for the methyl. Butterssing effects may be incorporated in chloro (**8**) and bromo (**9**) compounds, but the barrier in compound **7** is much smaller than expected.

This apparent reversal of the sequence could be explained by considering either one of the following factors or both. 1) Attractive interactions may exist between atoms having lone pair electrons and the methyl group at the 9-position, functioning to lower the ground state level for rotation and raising the barrier to rotation. This cannot be expected between two methyl groups, as in compound **7**. 2) The shape of a halogen atom might be considered spherically symmetrical, whereas a methyl group is tetrapodal. In compound **8**, the relation between the chlorine atom and the methyl group at the transition state of rotation does not differ from that at the ground state, whereas the situation is not the same for compound **7**. Two methyl groups, in a heavily compressed state such as in compound **7**, could not take a conformation in which a hydrogen atom in one methyl group can squeeze in the apertures made by two hydrogen atoms of

Table 3. Activation parameters for rotation of methyl groups (25 °C)

Compound	E_a (kcal/mol)	$\Delta H^{\neq}$ (kcal/mol)	$\Delta S^{\neq}$ (eu)	$\Delta G^{\neq}$ (kcal/mol)
8	9.2±0.4	8.6±0.4	−5.9±2.1	10.3±1.0
9	10.2±0.4	9.6±0.4	−2.1±2.0	10.2±1.0
10	14.1±0.6	13.5±0.6	9.8±3.0	10.6±1.0
11	13.0±0.3	12.4±0.3	3.4±1.3	11.4±0.6
12	12.7±0.3	12.1±0.3	3.0±1.4	11.2±0.7

another methyl. Thus the relation of the two methyls in space could be considered as a pair of gears. In the process where the methyl gear at position 9 rotates

ground state transition state

to reach the transition state, another methyl gear should rotate as well.[12] It is thus considered that effective van der Waals radius of the methyl group in heavily compressed cases is far less than the normal methyl and rather close to that of a carbon atom.

The barrier to rotation in compounds which carry substituents at two peri positions showed a tendency similar to that observed above, *viz.*, methyl compound (**12**) shows a lower barrier to rotation than the halogen compounds (**10** and **11**). The bromo compound (**11**) shows a lower barrier to rotation than that of the chloro compound (**10**). It is difficult to account for this from a mere consideration of the transition state. We attribute this to the rise of the ground state level due to the large size of the bromine atom.

Experimental

Syntheses. *1,2,3,4-Tetrachloro-9-methylanthracene.* To a vigorously stirred solution of methylmagnesium iodide, prepared from 7.1 g (0.05 mol) of methyl iodide and 1.3 g (0.053 mol) of magnesium, was added 13.2 g (0.04 mol) of 1,2,3,4-tetrachloroanthrone[13] at 0 °C. The reaction mixture was heated with stirring for 2 hr and cooled. The mixture was treated with concentrated hydrochloric acid and the organic layer separated. After drying the ethereal solution over sodium sulfate, the solvent was evaporated and the residue chromatographed on alumina. Elution with hexane followed by recrystallization from chloroform yielded pure yellow product, mp 171—172 °C, yield being 61% based on the anthrone. Found: C, 54.42; H, 2.40; Cl, 43.20%. Calcd for $C_{15}H_8Cl_4$: C, 54.59; H, 2.44; Cl, 42.97%. NMR ($CDCl_3$, δ): 3.27 (3H, s), 7.0—8.4 (4H, m), 8.67 (1H, s).

*1,4-Dimethoxy-9-methyltriptycene (**6**).* To a vigorously stirred solution of 3.47 g (0.02 mol) of 1-chloro-2,5-dimethoxybenzene and 1.92 g (0.01 mol) of 9-methylanthracene[14] in 20 ml of dry benzene was added a suspension of *ca.* 2 g (0.02 mol) of phenylsodium[15] in 20 ml of dry benzene over a period of 30 min under nitrogen. After being stirred for 5 hr below 20 °C, the reaction mixture was treated as above to give 1.97 g (60%) of colorless crystals, mp 238—239 °C, after recrystallization from benzene. Found: C, 84.09; H, 5.86%. Calcd for $C_{23}H_{20}O_2$: C, 84.12; H, 6.14%. NMR ($CDCl_3$-CS_2, δ): 2.50 (3H, s), 3.63 (3H, s), 3.72 (3H, s), 5.72 (1H, s), 6.37 (2H, s), 6.8—7.4 (8H, m).

*1,4,9-Trimethyltriptycene (**7**).* To a refluxing solution of 3.11 g (0.03 mol) of butyl nitrite and 2.20 g (0.01 mol) of 1,4,9-trimethylanthracene[16] in 20 ml of methylene chloride was added with stirring a solution of 1.78 g (0.013 mol) of anthranilic acid in 30 ml of purified acetone over a period of 3 hr. The reaction mixture was heated for 3 hr, cooled and evaporated *in vacuo*. The residue was taken up in hexane, washed with aqueous sodium bicarbonate and then with aqueous sodium chloride, and dried over sodium sulfate. After evaporation of the solvent, the residue was chromatographed on alumina. Elution with hexane afforded 2.16 g (73%) of pure **7**, mp 245—246 °C, after recrystallization from chloroform-methanol. Found: C, 93.40; H, 6.50%. Calcd for $C_{23}H_{20}$: C, 93.20; H, 6.80%. NMR ($CDCl_3$, δ): 2.48 (3H, s), 2.52 (3H, s), 2.60 (3H, s), 5.63 (1H, s), 6.6—7.5 (10H, m). The signal at 2.60 was assigned to 9-methyl protons since the signal showed line-broadening at low temperature.

*1,2,3,4-Tetrachloro-9-methyltriptycene (**8**),* mp 276 °C, was similarly prepared by treating 9-methylanthracene and butyl nitrite in methylene chloride with tetrachloroanthranilic acid[17] in purified acetone. The yield was 65%. Found: C, 62.16; H, 2.79; Cl, 34.99%. Calcd for $C_{21}H_{12}Cl_4$: C, 62.10; H, 2.98; Cl, 34.92%. NMR ($CDCl_3$, δ): 2.73 (3H, s), 6.03 (1H, s), 6.9—7.5 (8H, m).

*1,2,3,4-Tetrabromo-9-methyltriptycene (**9**),* mp 302 °C, was similarly prepared by treating 9-methylanthracene and butyl nitrite in methylene chloride with tetrabromoanthranilic acid[18] in purified acetone. The yield was 52%. Found: C, 43.52; H, 2.09; Br, 55.12%. Calcd for $C_{21}H_{12}Br_4$: C, 43.19; H, 2.07; Br, 54.74%. NMR ($CDCl_3$, δ): 2.75 (3H, s), 6.10 (1H, s), 6.9—7.6 (8H, m).

*1,2,3,4,5,6,7,8-Octachloro-9-methyltriptycene (**10**),* mp > 300°C, was prepared by treating 1,2,3,4-tetrachloro-9-methylanthracene and butyl nitrite in methylene chloride with tetrachloroanthranilic acid in purified acetone. The yield was 45%. Found: C, 46.57; H, 1.22; Cl, 52.06%. Calcd for $C_{21}H_8Cl_8$: C, 46.37; H, 1.48; Cl, 52.14%. NMR ($CDCl_3$, δ): 3.17 (3H, s), 6.75 (1H, s), 7.0—7.7 (4H, m).

*1,2,3,4-Tetrabromo-5,6,7,8-tetrachloro-9-methyltriptycene (**11**),* mp > 300 °C, was prepared by treating 1,2,3,4-tetrachloro-9-methylanthracene and butyl nitrite in methylene chloride with tetrabromoanthranilic acid in pure acetone. The yield was 35%. Although it was not possible to obtain satisfactory analytical data for this compound, probably because of poor combustibility, it gave no signals attributable to impurities in the PMR spectrum. The mass spectrum showed a peak at *m/e* 722 which corresponded to the molecular ion. NMR ($CDCl_3$, δ): 3.13 (3H, s), 6.78 (1H, s), 7.0—7.7 (4H, m).

*1,2,3,4-Tetrachloro-5,8,9-trimethyltriptycene (**12**),* mp 250.5—251.5 °C, was similarly prepared from 1,4,9-trimethylanthracene, butyl nitrite and tetrachloroanthranilic acid, the yield being 55%. Found: C, 63.56; H, 3.98; Cl, 32.48%. Calcd for $C_{23}H_{16}Cl_4$: C, 63.62; H, 3.71; Cl, 32.66%. NMR $CDCl_3$, δ): 2.53 (3H, s), 2.62 (3H, s), 2.98 (3H, s), 6.03 (1H, s), 6.65 and 6.75 (2H, AB quartet), 6.9—7.6 (4H, m). The signal at δ 2.98 was assigned to 9-methyl protons because of its broadening and splitting at low temperatures.

PMR Measurement and Calculation. PMR spectra at various temperatures were recorded on a Varian HA-100D spectrometer operating at 100 MHz by the usual field sweep method. In every case TMS was used as an internal reference and a lock signal. Compounds were dissolved in $CDCl_3$-CS_2 to make up *ca.* 3% solutions. The temperature was read by the method reported previously.[19] Calculations in spectral analysis and line shape analysis were performed with a FACOM 270/30 computer.

PMR Spectral Analysis. The chemical shifts and coupling constants of methyl protons were determined by computation using the LAOCOON MBYH program.[10] The line position of each signal was determined with a frequency counter. The analysis for compounds **10** and **11** was performed by assuming the spectral patterns to be of AB_2 type and spin coupling constant J_{AB} equal to J_{BB}. The rms errors

estimated were about 0.08 Hz, the calculated spectra agreeing with the observed ones. Spectral analysis of compound **12** was difficult since the signals due to the 9-methyl group were obscured by the aromatic methyl signals at the tail part of the higher field. However, when the coupling constants (J_{AB} and J_{BB}) were assumed to be -12.6 Hz, the spectra obtained agreed. Calculation of the PMR parameters for compounds **8** and **9** were performed by trial and error, taking the chemical shift as a variable and assuming geminal coupling constants to be -12.6 Hz.

Total Line Shape Analysis. The line shape analysis of temperature-dependent spectra of methyl protons was performed by the density matrix method, since the protons couple with each other. The principle of evaluation of density matrix equations to determine the rotational rates has been described.[20] Rotation of the methyl group corresponds to the exchange of three proton spins. The methyl group can rotate in two directions, clockwise and counter-clockwise. If one spin can exchange with two spins at different positions, the density matrix in general becomes very complex.[21-23] In the three spin system, two 9×9 dimension matrices and one 27×27 dimension matrix must be treated, making computation time-consuming. In the case of the rotation of a methyl group, however, the three spins are all protons, the transition probability in clockwise and counter-clockwise directions is the same, and the two mean life-times are also the same. Thus the damping term is not $(\boldsymbol{R}\rho\boldsymbol{R}-\rho)/\tau$ but

$$\frac{\boldsymbol{R}'\rho\boldsymbol{R}+\boldsymbol{R}\rho\boldsymbol{R}'-2\rho}{2\tau}$$

where $\boldsymbol{R}$ and $\boldsymbol{R}'$ are the exchange operators in the clockwise and counter-clockwise rotations, respectively, ρ is the density matrix operator, and τ the mean life time. The total density matrix equation is then

$$\frac{\mathrm{d}\rho}{\mathrm{d}t}=\frac{\boldsymbol{R}'\rho\boldsymbol{R}+\boldsymbol{R}\rho\boldsymbol{R}'-2\rho}{2\tau}+\frac{i}{\hbar}[\rho,\mathscr{H}]$$

By means of this equation, the coefficient matrix of the density operators for the three spin system can be divided into two 3×3 dimension matrices and one 9×9 dimension matrix, greatly reducing the calculation time.

A computer program was written along this line. For the calculation of theoretical spectra, chemical shifts and coupling constants as determined by spectral analysis were used. Natural line width was included in the calculation, taking advantage of the line width of bridge-head methine protons. The rates of rotation of methyl groups were determined by iteration method or visual fitting of the calculated spectra with the observed at various temperatures. Agreement between the theoretical and experimental spectra was excellent.

Reactivity of *exo*- and *endo*-Tricyclo[3.2.1.$0^{2,4}$]octan-8-ylidenes and 7-Norbornenylidene

Shun-Ichi MURAHASHI,* Kazuo OKUMURA, Yusuke MAEDA, Akio SONODA, and Ichiro MORITANI

Department of Chemistry, Faculty of Engineering Science, Osaka University, Machikaneyama, Toyonaka, Osaka, 560

(Received March 9, 1974)

endo-Tricyclo[3.2.1.$0^{2,4}$]octan-8-ylidene (**2**) generated by the thermolysis of sodium salt of *endo*-tricyclo[3.2.1.$0^{2,4}$]octan-8-one tosylhydrazone (**5**) gave toluene (3.9%), cyclohepta-1,4-diene(**6**, 14%), cyclohepta-1,3-diene(**7**, 3.5%), bicyclo[3.3.0]octa-1,6-diene(**8**, 4.8%), bicyclo[3.3.0]octa-1,7-diene(**9**, 9.0%), and *endo*-tricyclo[3.2.1.$0^{2,4}$]-octane (**10**, 21%). In sharp contrast, *exo*-tricyclo[3.2.1.$0^{2,4}$]oct-8-ylidene (**1**) gave toluene (1.5%) and tricyclo-[5.1.$0^{2,3}$.$0^{1,7}$]oct-5-ene (**14**, 57%). The results indicate significant homoconjugative interaction between the p-orbital of the divalent carbon and the symmetric Walsh orbital of the cyclopropane. This is in line with the results of 7-norbornenylidene (**3**) in which the interaction between the divalent carbon and the carbon-carbon double bond stabilizes the nonclassical methylene. Thermolysis of sodium salt of 7-norbornenone tosylhydrazone (**18**) gave rise to cyclohexa-1,3-diene (3%), norbornene (6%), toluene (5%), spiro[2.4]hepta-4,6-diene (**19**, 10%), and bicyclo[3.2.0]hepta-1,6-diene (**21**, 56%).

Moss and Whittle reported the intramolecular reaction of 7-norbornanylidene to give norbornane (11 %), tricyclo[3.2.0.$0^{2,7}$]heptane (9.5%) and bicyclo[3.2.0]hept-1-ene (52%), and suggested the carbene to have normal geometry and a triplet ground state.[1] In constrast, Fisch and Pierce[2] reported bicyclo[3.3.1]-non-2-en-9-ylidene to be a singlet stabilized nonclassical methylene[3] with interaction between the carbenic bridge and the p-orbital of the double bond. In connection with this, the reactions of *exo*- and *endo*-tricyclo[3.2.1.$0^{2,4}$]octan-8-ylidene (**1** and **2**, respectively) and 7-norbornenylidene (**3**) are of interest, since significant homoconjugative interaction between the p-orbital of the divalent carbon and the symmetric Walsh orbital of the cyclopropane ring or the carbon-carbon double bond can be expected. Related cyclopropyl or olefinic homoconjugative participation at the developing carbonium ion center has been demonstrated,[4] kinetic results as well as extended Hückel calculations[5] on 8-tricyclo[3.2.1.$0^{2,4}$]octenyl cation indicating primary stabilization of the bridge cation from interaction with the cyclopropane ring rather than the double bond.[4]

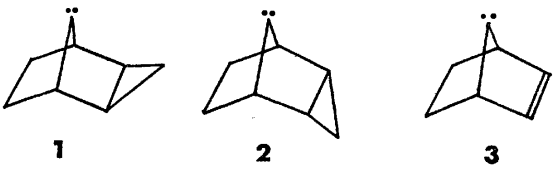

Fig. 1.

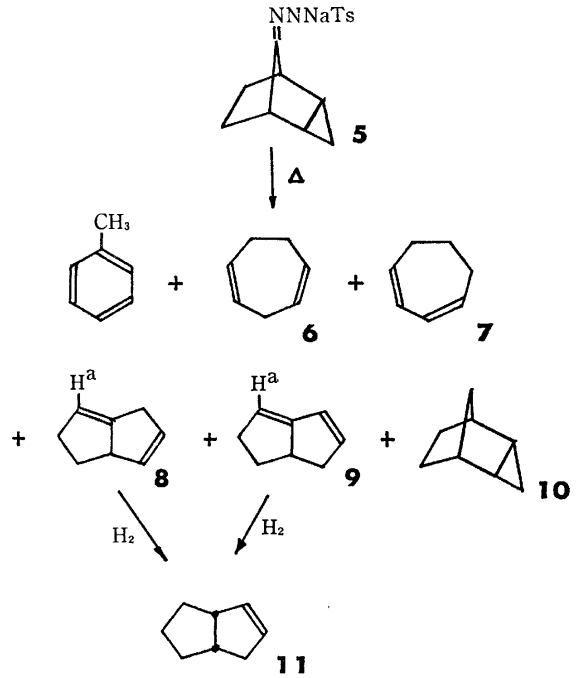
Results on the chemistry of **1** and **2** were reported by Freeman *et al.*[6] A report was made on results differing to some extent but clearly demonstrating the presence of tris-homocyclopropenyl interaction in *endo*-carbene **2**.[7] We also report results on carbene **3**, prepared from sodium salt. Moss *et al.* initially prepared it by thermolysis of lithium salt.[8] The overlapping of the vacant p-orbital of the divalent carbon with the p-orbital of the carbon-carbon double bond could be expected to stabilize sp^2 hybrid of the singlet state as in norbornenyl cation.[9]

Results and Discussion

endo-Tricyclo[3.2.1.$0^{2,4}$]octan-8-one tosylhydrazone (**4**) was converted into sodium salt **5** by treatment with sodium hydride in THF. Salt **5**, dried at 130° *in vacuo*, was placed in a flask connected with a trap cooled at 77 °K. The flask was promptly immersed into an oil-bath which had been preheated at 180°. The volatile products (65% yield) were collected in the receiver, and subjected to careful vpc analyses. The pyrolysate was revealed to consist of six hydrocarbons as shown in Scheme 1. The first, second, third, and fifth components were readily assigned to toluene (6.9%), cyclohepta-1,4-diene (**6**, 25%),[10] cyclohepta-1,3-diene(**7**, 6.3%),[10] and *endo*-tricyclo[3.2.1.$0^{2,4}$]octane (**10**, 38%),[11] respectively, by comparison of their IR NMR and mass spectra, and the retention times with those of an authentic sample. Both fourth and fifth components are highly unstable olefins, and their mass spectra show the molecular peak at *m/e* 106. The NMR spectrum of the former component (8.6%) shows the vinyl proton resonances at δ 5.42 (multiplet, H^a)[12] and 5.75 (broad singlet, 2H) as well as signals due to

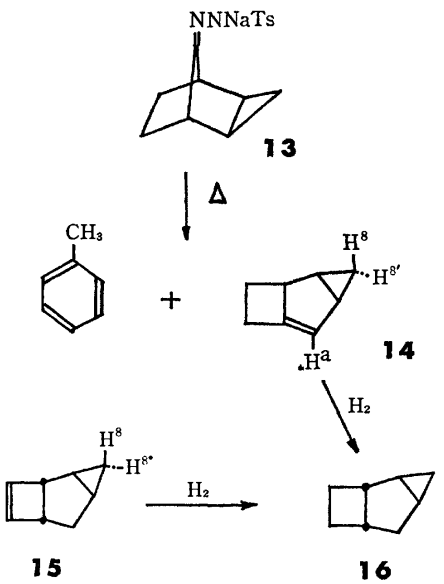


Scheme 1.

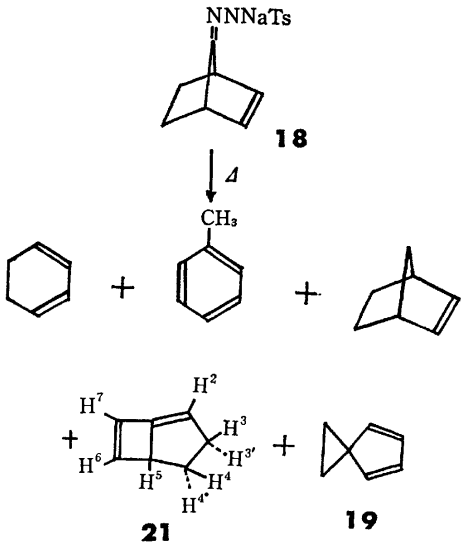
the methine proton at 3.45 (multiplet, H), double allylic protons at 2.77 (multiplet, 2H), the allylic protons at 2.34 (multiplet, 2H), and the methylene protons at 1.46 (triplet-doublet, 2H). The UV spectrum shows $\lambda_{max}^{n\text{-hexane}}$ 218 nm, indicating its non-conjugated olefin structure. Careful hydrogenation over palladium in carbon tetrachloride gave *cis*-bicyclo[3.3.0]oct-2-ene (**11**).[13] Thus, the structure was assigned to bicyclo-[3.3.0]octa-1,6-diene(**8**). On the other hand, the NMR spectrum of the fifth component (16% yield) shows signals arising from the vinyl protons at δ 5.27 (multiplet, H^a) and 6.23 (singlet, 2H), the methine proton at 3.0 (multiplet, H), the allylic protons at 2.83—1.89 (multiplet, 4H), and the methylene protons at 1.49 (triplet-doublet, 2H). The UV spectrum shows $\lambda_{max}^{n\text{-hexane}}$ 246 nm, indicating the existence of a conjugated diene moiety. Its hydrogenation gave **11** again. Thus, the structure was assigned to bicyclo[3.3.0]oct-1,7-diene (**9**).[14]

A similar vacuum pyrolysis of sodium salt **13** derived from *exo*-tricyclo[3.2.1.$0^{2,4}$]octan-8-one tosylhydrazone (**12**) gave hydrocarbons (60% yield), consisting of extremely unstable tricyclo[5.1.$0^{2,5}$.$0^{1,7}$]oct-5-ene (**14**, 95.5%) and toluene (2.5%). The NMR spectrum of **14** displays multiplets at δ 5.13 (vinyl proton, H^a), 3.0—2.4 (allylic and methine, 3H), 2.3—1.5 (cyclopropyl and methylene, 4H), 1.15—0.92 and 0.55—0.35 (cyclopropyl, 1H each). Careful hydrogenation of **14** at −30——20 °C over palladium black in carbon tetrachloride caused absorption of one equivalent of hydrogen to yield *trans*-tricyclo[5.1.$0^{2,5}$.$0^{1,7}$]octane (**15**), which was identical with a sample independently prepared by hydrogenation of *trans*-tricyclo[5.1.$0^{2,5}$,$0^{1,7}$]-oct-3-ene (**16**)[15] over palladium black in methanol. The molecular ion in the mass spectrum was found at *m/e* 108. The NMR spectrum consisted of three multiplets at δ 2.93—1.14 (10H), 0.64—0.24 (1H), and −0.22——0.46 (1H).

Pyrolysis of sodium salt **18** derived from 7-norbornenone tosylhydrazone (**17**) at 180° gave hydrocarbons



Scheme 2.



Scheme 3.

(80% yield),[16] which by careful vpc analyses was found to consist of five components in the ratio 3.7 : 8.0 : 70 : 5.7 : 12. The first, second, and fourth components were assigned to 1,3-cyclohexadiene, norbornene, and toluene, respectively, by comparison of their spectral data and the vpc retention times with those of the corresponding authentic sample. The structure of the fifth component was assigned to spiro[2.4]hepta-4,6-diene (**19**) by spectral comparison with an authentic sample.[17] For the sake of confirmation, **19** was converted into the TCNE adduct **20**. The NMR spectrum (acetone-d_6) includes signals due to the vinyl protons at δ 6.85 (triplet, 2H), the bridge protons at 3.88 (triplet, 2H), and the cyclopropyl protons at 1.05 (A_2X_2, 4H). The structure of the third, very unstable component was confirmed as follows. Hydrogenation over Pd-sponge gave bicyclo[3.2.0]pentane, which was identical with a sample prepared by hydrogenation of bicyclo[3.2.0]-hepta-2,6-diene.[18] The mass spectrum showed a molecular peak at *m/e* 92. The presence of three vinyl protons was indicated by the NMR spectrum (δ 6.67 doublet, 6.36 triplet, and 4.92 quartet). Thus, structure **21** or **22** can be considered. Double irradiation experiments showed that H_2 (δ 4.92) is not coupled to the vinyl protons, either H^6 (6.36) or H^7 (6.67), and coupled to methylene protons (H^3 and $H^{3'}$). This confirms the structure of bicyclo[3.2.0]hepta-1,6-diene (**21**) as the third component of the volatile products. Treatment of **21** with tetracyanoethylene at −78° gave rise to the TCNE-adduct, 8,8,9,9-tetracyanotricyclo[5.2.$0^{1,4}$.$0^{1,7}$]oct-2-ene (**23**). The structure of the adduct was firmly established by analysis of the IR (2260 cm^{-1}, C≡N), mass (*m/e* 220), and NMR spectra. The 100 MHz NMR spectrum ($CDCl_3$) showed absorption at δ 6.47 (H^3, doublet-doublet), 6.21 (H^2, doublet), 3.87 (H^7, multiplet), 3.63 (H^4, multiplet), 2.55 (H^5, $H^{5'}$, multiplet 2.30, and 1.80 (H^6, $H^{6'}$, multiplet). Double irradiation experiments showed that H^7 was coupled to H^6 and $H^{6'}$. Control experiments showed that norbornene, **19** and **21** are stable under the pyrolysis conditions in the presence of so-

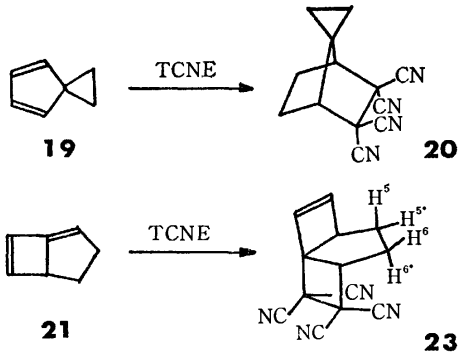


Fig. 2.

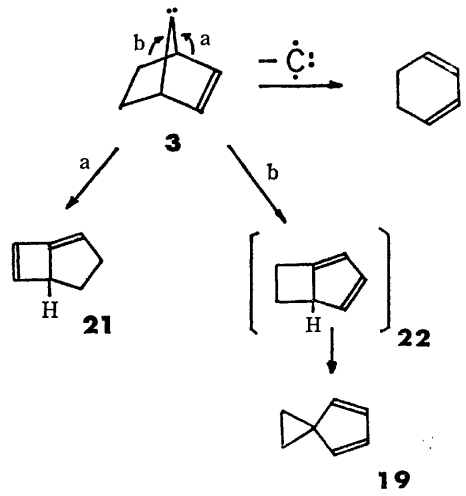
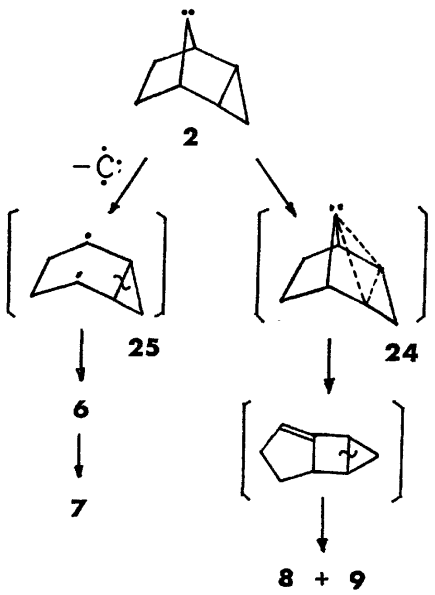
dium p-toluenesulfinate. When the pyrolysate left to stand at −20 °C, the diene **19** polymerized gradually, but other products remained unchanged.

The products of vacuum pyrolyses of **5**, **13**, and **18** are explained reasonably by assuming the intermediacy of free carbene.[1,2] However, the pyrolysis products of either **5** or **13** are different from those derived from decomposition of **5** and **13** prepared with sodium methoxide in diglyme.[6] Thus, tetracyclo[3.3.0^{2,8}.0^{4,6}]-octane, which is the main product of decomposition of **5** in diglyme, could not be detected among the products of the vacuum pyrolysis of **5**. Under the conditions of thermolysis in diglyme, two major reaction routes, a carbonium ion pathway as well as a carbene pathway, can be involved. Carbon-hydrogen and carbon-skelton rearrangements can be derived from a highly energetic cation.[19] Thus, no real chemical discrepancy between **1** and **2** can be pointed out. A favorable pathway of the reaction of **2** affording **6**—**10** can be envisioned as shown in Scheme 4. Dienes **8** and **9** can be formed by bond cleavage between C-1 and C-7 of a highly strained intermediate **24** derived from symmetrical interaction of the olefin-like cyclopropyl ring orbitals with the p-orbital of the divalent carbon. This resembles the behavior of bicyclo[3.3.1]nonen-9-ylidene[2] and indicates the nonclassical stabilization[3] of carbene **2**. It is noteworthy that tricyclo[5.1.0^{2,5}.0^{1,7}]oct-5-ene and its derivatives which can be formed *via* the 1,2-alkyl shift could not be detected among the products. Cycloheptadiene **6** can stem from cycloreversion[10] of **2** *via* the biradical intermediate **25**, accompanied by the release of a singlet carbon atom C_1. Analogous fragmentation and release of carbon atom were observed in quadricyclanylidene[20] and **3** forming cyclohexa-1,3-diene as a product. Diene **7** is an isomerization product of diene **6**.[10] Compound **10** is a hydrogen-abstraction product of carbene **2**, as norbornene arises from carbene **3**. The products from carbene **3** can be rationalized by Scheme 5. Diene **21** would arise *via* the 1,2-rearrangement (a) and diene **19** *via* the 1,2-rearrangement (b) followed by 1,5-sigmatropic rearrangement.[21] Preference of the formation of **21** to that of **19** indicates that **21** would arise fulfillment of the carbene π-bond interaction. The 1,2-rearrangement (a) of **3** finds analogies in carbonium ion chemistry.[9] It is noteworthy that the 1,3-insertion product, tricyclo[4.1.0.0^{3,7}]hept-4-ene[22] could not be detected among the reaction products;



Scheme 5.



Scheme 4.

considerable 1,3-insertion products were obtained in the reaction of norbornanylidene.[1] This also suggests the presence of the carbene-π bond interaction in carbene **3**.

In sharp contrast, in the *exo*-carbene **1**, no participation of the cyclopropane ring can be observed to stabilize the carbenic center. The result was analogous to that of norbornanylidene which is suggested to have normal geometry and a triplet ground state.[1] Migration of C-7 (**26**) affording **14** is an exclusive pathway, which is presumably ascribed to steric reason.

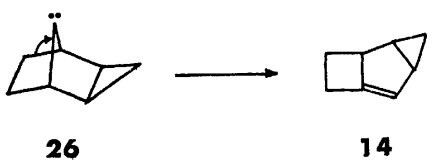


Fig. 3.

In brief, the presence of significant homoconjugative interaction between the p-orbital of the divalent carbon and either the symmetric Walsh orbital of the cyclopropane ring or the p-orbital of the carbon-carbon double bond can be demonstrated by comparative studies of the chemical reactivities of the carbenes **1**—**3** and norbornanylidene.

Experimental

All melting points are uncorrected. Infrared spectra were determined with a Hitachi 215 spectrometer, and NMR spectra with JNM-4H-100 with the use of internal tetramethylsilane. Mass spectra were taken on a Hitachi RSM-4 mass spectrometer. Vpc analyses were carried out on YANACO-550T and JEOL-20K.

endo-*Tricyclo[3.2.1.0^{2,4}]octan-8-one.*[11] Hydrolysis of 8,8-dimethoxy-*endo*-tricyclo[3.2.1.0^{2,4}]octane [bp 84°/9 mm Hg; NMR (CCl_4) δ 3.25 (s, 3H), 3.15 (s, 3H), 2.03 (m, 2H), and 1.72—0.56 (m, 8H)], with 3 M $HClO_4$ solution gave the ketone in 67% yield. IR (liquid film) 1760 cm^{-1} (C=O).

endo-*Tricyclo[3.2.1.0^{2,4}]octan-8-one* p-*Touenesulfonylhydrazone (4).* A mixture of *p*-toluenesulfonylhydrazine (2.1 g, 11 mmol) and the ketone (1.1 g, 8.6 mmole) in ethanol (55 ml) was stirred for 40 min at 65°C. Evaporation of ethanol, followed by washing with ether and methanol gave pure tosylhydrazone (2.4 g, 94%): mp 171.5—172 °C (decomp); IR (Nujol mull) 3210 (N-H), 1685 (s), 1600(s), 1350(s), 1314(s), 1180(s), 1095(m), 980(s), and 925(s) cm^{-1}; NMR ($CDCl_3$) δ 7.77 (AX, J=8 Hz, 2H), 7.24 (AX, J=8 Hz, 2H), 2.42 (broad s, 3H), and 1.8—0.6 (m, 10H).

Pyrolysis of the Sodium Salt (5) of endo-*Tricyclo[3.2.1.0^{2,4}]octan-8-one* p-*Touenesulfonylhydrazone (4).* To a suspension of sodium hydride (1 g, 21 mmol) prewashed with dry THF (10 ml) in a 200 ml-round flask was added a solution of tosylhydrazone **4** (5 g, 17 mmol) in THF (105 ml). The mixture was stirred under nitrogen until the evolution of hydrogen ceased. Evaporation of THF gave white powder. Further removal of THF under reduced pressure at 130 °C gave sodium salt **5**. The flask was bridged with glass tubing to a trap cooled at 77 K under reduced pressure (2 mmHg), when the salt was immersed into an oil bath preheated at 180 °C, spontaneous decomposition occurred to give the pyrolysate (1 g, 56%) in the trap. The pyrolysate was subjected to the vpc analysis (KF-96, injection temp 105 °C, detector temp 130 °C, colomun temp 60 °C). The vpc showed that six components were existent in the reaction mixture in the ratio 7 : 25 : 6 : 9 : 16 : 38, which was uncorrected for vpc detector response. The retention times of these products are 6, 11, 12, 16, 19, and 21 min, respectively. The first component was assigned to toluene, the second to cyclohepta-1,4-diene (**6**) [Mass *m/e* 94; NMR (CCl_4) δ 5.95—5.12 (m, 4H), 3.00—2.70 (m, 2H), and 2.35—2.14 (m, 4H); IR (liquid film) 1660 cm^{-1} (C=C)], the third to cyclohepta-1,3-diene (**7**) [Mass *m/e* 94; NMR (CCl_4) 5.84—6.65 (broad s, 4H) 2.55—2.16 (m, 4H), and 2.10—1.61 (m, 2H)], the sixth to *endo*-tricyclo[3.2.1.0^{2,4}]octane (**10**) [Mass *m/e* 108; IR (liquid film) 3080(m), 3030(s), 3015(s), 2960(s), 2880(s), 1480(m), 1455(m), 1440(m), 1315(s) 1250(w), 1175(w), 1150(w), 1120(m), 1075(w), 1040(m), 1015(w), 1000(m), 920(w), 900(w), 860(w), and 720(s) cm^{-1}]. Each product was collected by preparative vpc (KF-96, 20%, 6m). The extremely unstable fourth component collected in a receiver at —78° was assigned to bicyclo[3.3.0]oct-1,6-diene (**8**) according to the following data. Mass *m/e* 106; NMR (CCl_4) δ 5.54—5.32 (m, H), 5.81—5.70 (broad s, 2H), 3.75—3.27 (broad m, H), 2.87—2.71 (m, 2H), 2.62—2.12 (m, 2H), and 1.46 (d-t, $J_{H^4H^5}$=8 Hz, $J_{H^3H^4}$=10 Hz, 2H). Hydrogenation of the sample collected by vpc over palladium in carbon tetrachloride afforded a sample containing two products. Preative vpc (Ucon oil 20%, 2m, colomun temp 75 °C) of the main component gave *cis*-bicyclo[3.3.0]-oct-2-ene in a 65% yield. Mass *m/e* 108; NMR (CCl_4) δ 5.44 (m, 2H), 3.37—2.88 (m, H), 2.88—2.60 (m, H), 2.60—2.28 (m, H), 2.28—1.97 (m, H), and 1.97—0.71 (m, 6H). The minor product, mass *m/e* 106, was tentatively assigned to *cis*-bicyclo[3.3.0]oct-2,6-diene, which was probably derived from **8** *via* palladium induced 1,3-hydride site.[23] The fifth extremely unstable component was assigned to bicyclo-[3.3.0]oct-1,7-diene (**9**), [Mass *m/e* 106; NMR (CCl_4) δ 5.40—5.20 (m, H), 6.23 (broad s, 2H), 3.38—2.62 (broad m, H), 2.83—1.89 (m, 4H), and 1.49 (t-d, $J_{H^3H^4}$=11 Hz, $J_{H^4H^5}$=8 Hz, 2H)]. Hydrogenation over palladium-charcoal (5%) in carbon tetrachloride followed by preparative vpc gave *cis*-bicyclo[3.3.0]oct-2-ene in 69% yield along with *cis*-bicyclo[3.3.0]oct-2,7-diene, since hydrogenation of **8** gave the same product.

exo-*Tricyclo[3.2.1.0^{2,4}]octan-8-one.* To a suspension of Zn(Cu) (36 g) in dry ether (200 ml) was added freshly distilled methylene iodide (2 g) with stirring. To the mixture was added a solution of 7,7-dimethoxynorbornene(20 g) and and methylene iodide (80 g) with rigorous stirring at reflux for 1 hr. After stirring for 1 hr, a solution of 0.5 M HCl and ice was added. The usual work-up followed by distillation gave a mixture (10.2 g, 67—75°C/30 mmHg), which contained norbornen-7-one (8%), an unidentified product (16%), *exo*-tricyclo[3.2.1.0^{2,4}]octan-8-one (70%), and *exo*-8,8-dimethoxy-tricyclo[3.2.1.0^{2,4}]octane (6%). Mass *m/e* 168; IR (CCl_4 (liquid film) 3100 and 1020 cm^{-1} (cyclopropyl C-H); NMR (CCl_4) δ 3.03 (s, 6H), 2.06 (broad s, 2H), 1.7 (m, 2H), 1.30—1.15 (m, 4H), and 0.75 (m, 2H). Found: C, 71.28; H, 9.95%. Calcd for $C_{10}H_{16}O_2$: C, 71.39; H, 9.95%. Further fine distillation gave pure *exo*-tricyclo[3.2.1.0^{2,4}]octan-8-one (bp 75 °C/30 mmHg) in 32% yield. Mass *m/e* 122; IR (liquid film) 1775 cm^{-1} (C=O); NMR (CCl_4) δ 1.98 (broad s, 2H), 1.77 (broad s, 4H), 1.16 (d-d, $J_{H^2H^3}$=3.4 Hz, $J_{H^2H^{3'}}$=6.9 0.50 (d-t, $J_{H^3H^{3'}}$=6,9 Hz, $J_{H^2H^{3'}}$=6.9 Hz, H$^{3'}$), and 0.14 (d-t, $J_{H^3H^{3'}}$=6.9 Hz, $J_{H^2H^3}$=3.4 Hz, H^3). Found: C, 78.68; H, 8.36%. Calcd for $C_8H_{12}O$: C, 78.65; H, 8.23%. *exo*-8,8-Dimethoxytricyclo[3.2.1.0^{2,4}]octane can be quantitatively converted into the ketone on treatment with a small amount of acetic acid at ambient temperature for 8 hr.

exo-*Tricyclo[3.2.1.0^{2,4}]octan-8-one* p-*Touenesulfonylhydrazone (12).* *p*-Toluenesulfonylhydrazine (6 g, 32 mmol) was dissolved in a minimum amount of dry methanol, and *exo*-tricyclo[3.2.1.0^{2,4}]octan-8-one (4 g, 33 mmol) was added. The mixture was stirred under reflux for 30 hr. On standing, a precipitated colorless solid was collected by filtration. Recrystallization from methanol gave **12** (5 g, 53%). [Mp 165—166°; IR (Nujol mull) 3330 cm^{-1} (N-H); NMR (acetone-d_6) δ 7.88 (AX, J=9 Hz, 2H), 7.51 (AX, J=9 Hz, 2H), 3.2 (broad s, H), 2.45 (s, 3H), 2.3 (broad s, 2H), 1.6 (broad s, 4H), 1.05—0.95 (m, 2H), 0.16 (d-t, $J_{H^2H^3}$=6.55 Hz, $J_{H^3H^{3'}}$=6.7 Hz, H^3), and —0.33 (d-t, $J_{H^3H^{3'}}$=6.7 Hz, $J_{H^2H^{3'}}$=3.5 Hz, H$^{3'}$). Found: C, 62.16; H, 6.13; N, 9.76; S, 11.21%. Calcd for $C_{15}H_{18}N_2O_2S$: C, 62.04; H, 6.25; N, 9.65; S, 11.04%].

Pyrolysis of the Sodium Salt (13) of exo-*Tricyclo[3.2.1.0^{2,4}]octan-8-one* p-*Touenesulfonylhydrazone (12).* Vacuum pyrolysis of salt **13** prepared from sodium hydride (0.7 g, 15 mmol) and **12** (3.2 g, 11 mmol) gave the pyrolysate (0.7 g, 60%) in a cold trap. Vpc analysis (KF-96, 20%, 2m, 80 °C) showed that three components were contained in the ratio 2.5 : 2.2 : 95.3. The first component was assigned to toluene,

but the second component could not be identified. Preparative vpc (Ucon oil, 20%, 2m, 50 °C) gave an analytical sample of the extremely unstable third component, assigned to tricyclo[5.1.$0^{2,5}$.$0^{1,7}$]oct-5-ene (**14**) according to the following spectral data. Mass *m/e* 106, NMR(CCl_4) (at −20 °C) δ 5.20—5.08 (m, H), 3.00—2.40 (m, 3H), 2.30—1.50 (m, 4H), 1.03 (d-t, $J_{H^1H^8}=4.05$ Hz, $J_{H^8H^{8'}}=4.05$ Hz, H^8), and 0.44 (d-t, $J_{H^1H^8}=8.3$ Hz, $J_{H^8H^{8'}}=4.05$ Hz, $H^{8'}$)]. Hydrogenation **14** over palladium black at −30—20 °C in carbon tetrachloride gave tricyclo[5.1.$0^{2,5}$.$0^{1,7}$]octane (**15**), [Mass *m/e* 108; (CCl_4) 3080(m), 3045(m), 2950(s), 2875(s), 1730(w), 1460(m), 1380(w), 1338(w), 1300(w), 1250(w), 1120(w), 1080(w), 1030 (w), 1005(w), 980(w), 830(w), 810(m), 790(w), and 730(w); NMR (CCl_4) δ 2.93—1.14 (m, 10H), 0.43 (d-t, $J_{H^8H^{8'}}=$ 4.2 Hz, $J_{H^1H^8}=8.4$ Hz, H^8), and −0.34 (d-t, $J_{H^8H^{8'}}=4.2$ Hz, $J_{H^1H^{8'}}=4.2$ Hz, $H^{8'}$)], which was independently synthesized by hydrogenation of *trans*-tricyclo[5.1.$0^{2,5}$.$0^{1,7}$]oct-3-ene (98 mg) over palladium black in methanol.

7-Norbornenone p-*Toluenesulfonylhydrazone* (***17***). 7-Norbornenone was prepared by the method of Gassman and Rape[24] from 7,7-dimethoxybicyclo[2.2.1]hept-2-ene, [Bp 64.5 —65.5 °C/30 mmHg, IR (liquid film) 1860, 1790, and 1780 cm^{-1} (C=O); NMR (CCl_4) δ 0.9—2.5 (m, 4H), 2.75 (q, 2H), 6.5(t, $J=2.5$ Hz, 2H)]. A solution of *p*-toluenesulfonylhydrazine (2.2 g, 12 mmol) and 7-norbornenone (1.3 g, 12 mmole) in methanol (30 ml) was stirred at ambient temperature for 1 hr. Precipitated white crystals were collected and recrystallized from methanol to give **11** (2.7 g, 82%). [Mp 159—160 °C (decomp); IR (Nujol mull) 3230 (N-H), 1720(s), 1600(s), 1460(s), 1330(s), 1290(m), 1170(s), 1090(s), 1018(s), and 930(s). NMR (acetone-d_6) δ 7.73 (AX, $J=8$ Hz, 2H), 7.35 (AX, $J=8$ Hz, 2H), 6.55 (t, $J=2$ Hz, 2H), 3.6(m, 1H), 2.65—2.8 (m, 2H), 2.38(s, 3H), 1.6— 2.0 (m, 2H), and 1.0—1.3 (m, 2H). Found: C, 60.57; H, 5.96; N, 10.01%. Calcd for $C_{14}H_{16}N_2SO_2$: C, 60.85; H, 5.84; N, 10.13%].

Pyrolysis of the Sodium Salt (***18***) *of 7-Norbornenone* p-*Toluenesulfonylhydrazone* (***17***). Vacuum pyrolysis of salt **18** prepared from tosylhydrazone **17** (7.68 g, 28 mmol) and sodium hydride (0.16 g) gave volatile products (2 g) in the trap. Vpc analyses (di-*n*-decyl phthalate 2 m, column temp 60 °C, detecter temp 135 °C, injection temp 130 °C) showed that five components were contained in the reaction mixture in the ratio 1.0 : 2.2 : 19 : 1.5 : 3.3. The first component was assigned to 1,3-cyclohexadiene, the second to norbornadiene, and fourth to toluene. These compounds were collected by preparative vpc, and their structures were determined by comparison with those of authentic samples. The fifth component was assigned to spiro-[2.4]heptadiene-(**19**) which was identified by comparison of their NMR spec trum with that of an authentic sample. NMR (CCl_4) δ 7.45 (m, 2H), 6.05—5.75 (m, 2H), 1.52 (s, 4H); Mass *m/e* (species %) 92 (M^+, 100), 91 (M^+-1, 215), 65 ($M^+ + 1 - C_2H_4$, 37), 63($M^+ - C_5H_5$, 15). For confirmation of the stractural assignment, **19** was converted into the TCNE adduct. To a solution of tetracyanoethylene (692 mg, 5.4 mmol) in THF (20 ml) was added **19** (500 mg, 5.4 mmol) with stirring. After being stirred for 1 hr, precipitated white crystals were collected by filtration. Recrystallization from THF gave the adduct **20** (1.1 g, 90%). [Mp 217 °C (decomp); NMR (acetone-d_6) δ 6.85 (t, $J=2.5$ Hz, 2H), 3.88 (t, $J=2.5$ Hz, 2H), and 1.05 (A_2X_2, $\Delta\nu/J$ 2, 4H). Mass *m/e* 220(M^+). Found: C, 70.61; H, 3.70; N, 25.50%. Calcd for $C_{13}H_{18}N_4$: C, 70.89; H, 3.66; N, 25.44%]. The fourth component, highly polymerizable even at −20 °C, was assigned to bicyclo[3.2.0]hept-1,6-diene (**21**) as follows. Hydrogenation of a sample collected by vpc palladium-sponge in ether at −30° gave rise to bicyclo[3.2.0]heptane. Mass *m/e* 96; NMR (CCl_4) δ 2.7 (m, 2H), 2.4—1.7 (m, 4H), and 1.6— 1.2 (m, 6H). The NMR spectrum was identical with that of the sample prepared by hydrogenation of bicyclo[3.2.0]-hept-2,6-diene. Mass *m/e* (species, %) 92 (M^+, 100), 91($M^+ - 1$, 360), 73(620), 72(1900), 71(1000), 58(400), and 57(2900); NMR (CS_2, −60 °C) δ 6.67 (d, $J=1.5$ Hz, H^7), 6.36 (t, $J=2$ Hz, H^6), 4.92 (q, H^2), 3.6—3.0 (m, H^5), and 3.0—1.0 (m, 4H). To a solution of the pyrolysate in THF was added a solution of TCNE in THF at −60°. White crystalline material precipitated was collected and recrystallized from THF and acetone to give pure 8,8,9,9-tetracyanotricyclo[5.2.0]oct-2-ene (**23**). [Mp 154—155°; IR (Nujol mull) 2260(m), 1310(m), 1305(s), 1280(m), 1195(m), 1150(m), 905(m), 800(m), 785(s), 760(s), and 700(m) cm^{-1}; NMR($CDCl_3$) δ 6.47 (d-d, $J_{H^1H^2}=3$ Hz, H^2), 6.21(d, H^1), 3.87(d, H^8), 3.63 (m, H^3), 2.55(m. H^4, H^5), and 2.30 and 1.89(m, H^6, H^7). Found: C, 70.70; H, 3.70%. Calcd for $C_{13}H_8N_4$: C, 70.89; H, 3.66%].

Photolysis of the Sodium Salt (***18***) *of* p-*Toluenesulfonylhydrazone* (***17***). A solution of sodium salt (**18**, 30 mg) in THF (10 ml) was irradiated at −78 °C with a high pressure mercury arc for various periods of time with and without Pyrex filter. Aliquots were withdrawn periodically and examined by vpc.

The One-electron Reduction of Carbonium Ions. VII. A Kinetic Study of the Reduction of the Aryl- and *n*-Alkyl-substituted Tropylium Ions with Cr(II)

Kunio OKAMOTO, Koichi KOMATSU, Masami FUJIMORI, and Sumio YASUDA

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received March 13, 1974)

A series of substituted phenyltropylium (I) and *n*-alkyltropylium ions (II) has been synthesized, and the kinetic measurements for the one-electron reduction of these ions have been carried out with Cr(II) in 10% HCl at 25 °C. A linear correlation is observed between the log k_2 values, for I (X-C_6H_4-$C_7H_6^+$, X=*p*-OH, *p*-OCH_3, *p*-CH_3, H, *p*-Cl, *p*-Br, *p*-CN, *m*-OCH_3) and for II (C_nH_{2n+1}-$C_7H_6^+$, $n=0$, 1—6), and the transition energy of the charge-transfer band of these ions, with pyrene as a donor. In addition, the values of log k_2 for I exhibit a good linear free-energy relationship with pK_{R^+} and also with the σ-value ($\rho=+1.31$), but not with σ^+. The *n*-alkyl group is shown to diminish the reducibility of the tropylium ion, and a slight alternation effect of the length of the *n*-alkyl chain on the k_2's is observed.

In previous papers of this series, we have reported on the chromous-ion reduction of some substituted tropylium[1a,b] and cyclopropenium ions.[1c] It was demonstrated that the reducibility of these carbonium ions depends mainly on the electron affinity of the respective cations and that it is also linearly correlated with their pK_{R^+} values.

In the present study, first, we have investigated the effect of substituents on the reducibility of the phenyltropylium ion. The problem with regard to the nature and extent of the electronic effect exerted by phenyl substituents upon the electronic state of a tropylium ring has aroused much interest[2,3] especially when it has been assumed that the plane of the phenyl ring makes a considerable dihedral angle with the seven-membered ring in the phenyltropylium system. Thus, Jutz and Voithenleitner[2] have synthesized a series of aryltropylium ions and discussed their pK_{R^+}'s and electronic spectra; Schuster and his coworkers[3] have carried out the HMO calculation of the various aryltropylium ions and compared the results with their electronic and NMR spectra. However, no systematic study of the chemical reactivity of aryltropylium ions seems yet to have been reported.

Secondly, we have also synthesized a series of *n*-alkyltropylium ions and examined the effect of the alkyl-chain length upon the properties and reducibility of these ions.

Results and Discussion

The salts of the aryltropylium ions (Ia—f, h·Y^-) were prepared according to the method of Jutz and Voithenleitner.[2] *p*-Cyanophenyltropylium perchlorate (Ig·ClO_4^-) is a new compound; it was synthesized by hydride abstraction from 7-(*p*-cyanophenyl)-1,3,5-cycloheptatriene, which in turn has been prepared from 7-(*p*-aminophenyl)-1,3,5-cycloheptatriene by the use of the Sandmeyer reaction.

	X	Y

Ig	*p*-CN	ClO_4
Ih	*m*-OCH_3	ClO_4

The perchlorates of the *n*-alkyltropylium ions (II: C_nH_{2n+1}-$C_7H_6^+\cdot ClO_4^-$; $n=1-6$, 8, 12) were prepared, in part ($n=3,4,5,6,8$) for the first time, in a similar manner from 7-alkyl-1,3,5-cycloheptatrienes, which had themselves been synthesized by the reaction of alkylmagnesium bromides with 7-ethoxy-1,3,5-cycloheptatriene. The spectral and analytical data for II are listed in Table 1. It is of interest to note that the change in the mp's of these salts with the increase in the alkyl-chain length exhibits a tendency similar to that of *n*-alkylbenzenes, as is shown in Fig. 1.

The I and II ions are all readily soluble and quite stable in such polar solvents as acetonitrile and aqueous HCl except for II ($n=8,12$), which is hardly soluble in aqueous HCl (10%), though it dissolves rather more readily in a non-polar solvent, benzene.[4] Thus, the one-electron reduction was carried out for I and II ($n=1-6$) with Cr(II) in 10% HCl and for II ($n=8,12$) with zinc powder in acetonitrile. The respec-

tive tropylium ions gave the dimers of each substituted tropyl radical, *i.e.*, x,x'-disubstituted bitropyl, in almost quantitative yields without the formation of any by-product. The NMR spectra of the products indicated a typical pattern for a cycloheptatrienyl system, together with the signals corresponding to each substituents, in a manner similar to one that has previously been reported.[1b] The analytical and ultraviolet spectral data are shown in Table 4 (see Experimental).

A previous mechanistic study[5] indicated that the chromous ion (0.01—0.02 g-ion/l) in 10% HCl (2.9 M) is co-ordinated with the chloride ion and that, therefore, the one-electron reduction of the carbonium ion in this solvent would proceed effectively by way of the chloride-ion bridging between the two reagents. Thus, the kinetic measurements for the chromous-ion reduction of I and II (n=3—6) were carried out in 10% HCl, by the use of the flow method described previously,[5] to give the results listed in Table 2.

It has already been shown that the transition energy for the charge-transfer band observed between carbonium ions and a given electron donor (*e.g.*, pyrene) is correlated with the relative electron affinity of those cations[6] and also with the log k_2 for the chromous-ion reduction.[1] The I and II ions were also found to exhibit a charge-transfer band ($\nu_{C.T.max}$) with pyrene as the standard electron donor (Table 3); the correlation between log k_2 and the values of $\nu_{C.T.max}$ is reasonably good (Fig. 2) and seems to support the previous assumption[1] that the reducibility of these ions with Cr(II) can be regarded as a relative criterion of the electron affinity of the carbonium ion in solution.

With respect to the aryltropylium ions, I, the reducibility (log k_2) is also linearly related to the pK_{R^+} values, measured spectrophotometrically in 23% ethanol (Table 3), as is shown in Fig. 3. The electron-with-

a) Ref. 1b.

drawing substituents accelerate the reaction rate, whereas the electron-donating groups decelerate it. Thus, the Hammett plot, shown in Fig. 4, gave a positive ρ-value (+1.31). The application of the σ-value[7] gave a better linear correlation (correlation coefficient, 0.980) than that of the σ^+-value[8] (correlation coefficient 0.815) as the substituent constant. This would imply that the *para*-substituent on the phenyl group does not

exert a strong conjugative effect across the phenyl group upon the tropylium ring in either the ground or transition state, in accord with the assumption that the phenyltropylium ion can not be coplanar, but the planes of phenyl and tropylium rings are twisted more than 45°.[2,3,9]

The results of the reduction of *n*-alkyltropylium ions, II, indicated that the introduction of the alkyl group into the tropylium ring brings about a decrease in the reducibility of the cation. The chain length of the *n*-alkyl substituent was found to have no remarkable effect upon the reducibility, but a slight alternation of $\log k_2$ is observed with the increase in the carbon number of the *n*-alkyl chain. A similar alternating effect is sometimes observed in the case of S_N2 reactions of *n*-alkyl halides.[10]

Experimental[11]

Materials. All the reagents employed were of a reagent-grade quality except when otherwise noted. The acetonitrile and ethyl acetate were refluxed and distilled over phosphorus pentoxide; acetonitrile, bp 81.5—81.7 °C; ethyl acetate, bp 77.0—77.4 °C. The 1,2-dichloroethane for the measurement of the charge-transfer band was dried and distilled over calcium chloride: bp 83.0—83.5 °C.

Aryltropylium ions, Ia-f, h, were prepared according to the method of Jutz and Voithenleitner.[2]

7-(p-Cyanophenyl)-1,3,5-cycloheptatriene was synthesized from 7-(*p*-aminophenyl)-1,3,5-cycloheptatriene[2] by reference to the preparation of *p*-tolunitrile reported by Clarke and Read[12] as follows. Into 25 ml of 20% HCl we dissolved 10.0 g (54.6 mmol) of 7-(*p*-aminophenyl)-1,3,5-cycloheptatriene by vigorous stirring at 60 °C for 10 min. To this turbid solution there was then slowly added, with ice-cooling,

a solution of 3.9 g (57 mmol) of sodium nitrite in 20 ml of water over a 5-min period with magnetic stirring. The mixture was subsequently stirred at 0 °C for 1.5 hr to give a dark brown solution, which was then neutralized with *ca.* 7 g of sodium carbonate. On the other hand, 60 ml of an aqueous solution of cuprous cyanide was prepared by the reaction of 8.8 g (180 mmol) of sodium cyanide with the aqueous solution of cuprous chloride which had been obtained from 1.72 g (68.9 mmol) of $CuSO_4 \cdot 5H_2O$ and 4.5 g (77 mmol) of NaCl upon the action of 3.6 g (35 mmol) of $NaHSO_3$ and 2.4 g (60 mmol) of NaOH in an aqueous medium. Into a stirred mixture of 50 ml of benzene-ether (4 : 1) and 60 ml of an aqueous solution of cuprous cyanide, a dark brown solution of the diazonium salt was added over a 30-min period with ice-cooling. The mixture was stirred at 0 °C for 40 min, at room temperature for 4 hr, and finally at 60 °C for 30 min. The mixture was then extracted with benzene and worked up in the usual way to give 6.1 g of a viscous, dark red oil, which was chromatographed over 130 g of silica gel (Nakarai, No. II-A, 100—200 mesh). From the fractions eluted with benzene we isolated, by the use of preparative tlc over silica gel (Merck, Kieselgel PF_{254}) with the same eluent, 1.070 g (5.54 mmol) of crude 7-(*p*-cyanophenyl)-1,3,5-cycloheptatriene, which was then further purified by vacuum distillation to give white crystals; 10.1% yield; bp 135 °C (bath tempreature)/0.05 mmHg; mp 68.5—73.8 °C; NMR, τ_{CCl_4} 2.5 (m, 4H, phenyl protons), 3.4 (t, 2H, $H^{3,4}$), 3.8 (m, 2H, $H^{2,5}$), 4.8 (d of d, 2H, $H^{1,6}$)), 7.2 (t, 1H, H^7).

Found: C, 87.13; H, 5.50%. Calcd for $C_{14}H_{11}N$: C, 87.01; H, 5.74%.

p-*Cyanophenyltropylium perchlorate (Ig·ClO_4^-)* was synthesized by the following procedures. To a solution of 0.735 g (3.85 mmol) of 7-(*p*-cyanophenyl)-1,3,5-cycloheptatriene in 2.4 ml of acetonitrile, we added 1.30 g (3.79 mmol) of triphenylmethyl perchlorate. The mixture was stirred at 60 °C for 15 min and at 80 °C for 3 min to give a dark red solution. Then, 25 ml of ethyl acetate was added and the solution was cooled to 0 °C. The glittering crystals which separated out were collected, washed successively with ethyl acetate and dry ether, and dried under reduced pressure to afford 1.021 g (3.50 mmol) of Ig·ClO_4^- as yellowish brown crystals; 92.4% yield. The crystals were then further recrystallized from acetonitrile-ethyl acetate; mp 212.5—212.8 °C (dec); ν_{max}^{KBr} 1090 (ClO_4^-), 1480 ($-C_7H_6^+$), 2240 cm^{-1} (–CN); $\lambda_{max}^{10\% HCl}$ 228.5 (ε, 33900), 270.5 (18200), 349 nm (17400); NMR, τ_{CF_3COOH} 0.6 (m, 6H, tropylium ring protons), 1.9 (s, 4H, phenyl protons).

Found: C, 57.66; H, 3.27%. Calcd for $C_{14}H_{10}NClO_4$: C, 57.64; H, 3.46%.

The 7-n-alkyl-1,3,5-cycloheptatrienes were prepared by the reaction of 7-ethoxy-1,3,5-cycloheptatriene with *n*-alkylmagnesium bromides following the procedures reported previously.[1b]

The Alkyltropylium perchlorates (II, n=3—6, 8, 12) were synthesized by hydride abstraction from the corresponding alkylcycloheptatrienes, following a previously-reported[1b] method. The melting points and ultraviolet-spectral and analytical data are given in Table 1.

One-electron Reduction of the Substituted Tropylium Ions. The Chromous-ion Reduction of Ia-h and II (n=3—6). Details of the procedures will be described below for the reduction of the *p*-chlorophenyltropylium ion (Ie) as a representative case. To a magnetically-stirred solution of 0.209 g (0.692 mmol) of Ie·ClO_4^- in 70 ml of 10% HCl, we added 3.5 ml (3.5 mmol) of a 1M solution of chromous chloride in 10% HCl by the use of a hypodermic syringe under an atmosphere of nitrogen. The solution was stirred for 5 min at room temperature, and then extracted with *n*-hexane and worked up in the usual way to give 0.140 g (0.347 mmol) of x,x'-di(*p*-chlorophenyl)bitropyl (x,x'-di(*p*-chlorophenyl)biscyclohepta-2,4,6-trien-1-yl) as a partially-solidified viscous oil; 100.3% yield; NMR, τ_{CDCl_3} 2.6 (m, 4H, phenyl protons), 3.1—3.5 (m, 3H, H^{3-6}), 4.4 (m, 2H, $H^{2,7}$), 7.8 (m, 1H, H^1). The chromous-ion reductions of Ia—d, If—h, and II (*n*= 3—6) were carried out in the same way to give the dimers in yields of 100—106%.

The Zinc Reduction of II (n=8, 12). To a magnetically-stirred solution of 0.0374 g (0.104 mmol) of *n*-dodecyltropylium perchlorate, II·ClO_4^- (*n*=12), in 2.1 ml of acetonitrile, there was added 0.0713 g (1.09 mg-atom) of zinc powder in a stream of nitrogen, after which the mixture was stirred for 10 min at room temperature. After the filtration of the reaction mixture, a 5-ml portion of water was added to the filtrate, which was then extracted with *n*-hexane and worked up in the usual way to give 0.0303 g (0.0582 mmol) of x,x'-di-*n*-dodecylbitropyl as a viscous oil; 106% yield; NMR, τ_{CCl_4} 3.4—4.1 (m, 3H, H^{3-6}), 4.9 (m, 2H, $H^{2,7}$), 7.9 (br, 3H, H^1 and $\rangle C-CH_2-$), 8.8 (s, 20H, $-(CH_2)_{10}-$), 9.2 (t, 3H, $-CH_3$). The zinc reduction of II (*n*=8) was conducted in the same

way to give the dimer in a 95.0% yield.

The Analysis of the Di-substituted Bitropyls. The elemental analysis and ultraviolet spectroscopy were performed in the reduction products of Ic—h and II ($n=3$—6, 8, 12), which had been purified by preparative tlc over silica gel (Merck, Kieselgel PF_{254}). The results are listed in Table 4. In the cases of Ia and Ib, the reduction products were not stable enough for purification by tlc. Therefore, they were transformed to x,x'-di(*p*-methoxyphenyl)biscycloheptyl as follows and then analyzed. First, 0.548 g (1.49 mmol) of crude x,x'-di(*p*-hydroxyphenyl)bitropyl was catalytically hydrogenated over 1.0 g of palladium carbon (Nakarai, 5%) in 30 ml of dry methanol to give 0.320 g (0.845 mmol) of x,x'-di(*p*-hydroxyphenyl)biscycloheptyl; 56.7% yield. Then, 0.180 g (0.476 mmol) of the biscycloheptyl was methylated with 0.20 g (1.6 mmol) of dimethyl sulfate in alkaline aqueous ethanol, by reference to the method reported by Vyas and Shah.[13] The subsequent purification of the crude product by the use of preparative tlc afforded 0.102 g (0.251 mmol) of x,x'-di(*p*-methoxyphenyl)biscycloheptyl as a colorless oil; 52.7% yield; NMR, τ_{CCl_4} 3.2 (q, 8H, phenyl protons), 6.3 (s, 6H, methoxy), 7.5 (br, 4H, methine), 8.3 (br, 20H, methylene).

Found: C, 82.69; H, 9.37%. Calcd for $C_{28}H_{38}O_2$: C, 82.71; H, 9.42%.

The reduction product of Ib was also hydrogenated in the same way to give x,x'-di(*p*-methoxyphenyl)biscycloheptyl, which showed an infrared spectrum identical with that of the authentic sample described above.

Kinetic Measurements. The reaction rate of the chromous-ion reduction was measured in 10% HCl at 25.0± 0.2 °C by the use of a flow method reported previously.[5] The products were determined by ultraviolet spectroscopy, using the characteristic bands listed in Table 4.

Measurements of the Charge-transfer Bands with Pyrene. The charge-transfer spectrum was measured in 1,2-dichloroethane as has been reported previously.[1b] The concentrations of pyrene and of the tropylium salts were 0.2 M and 2×10^{-3} M respectively. Precautions were taken so that the sample solution was shielded from the room light, and the spectrum was measured immediately after the preparation of the sample.

Determination of pK_{R^+}*'s.* The previously-described spectrophotometric method[1b] was followed for the determination of pK_{R^+}'s for I in 23% ethanol. As for the cations, II, the pK_{R^+} values could not be measured because of the decomposition of II in an aqueous solution with pH> 1.

The One-electron Reduction of Carbonium Ions. VIII. The Reducibility of Hetero-substituted Tropylium Ions as Measured by the Competitive Reduction Method with Zinc Powder

Kunio OKAMOTO, Koichi KOMATSU, and Osamu SAKAGUCHI

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received March 13, 1974)

A series of hetero-substituted tropylium salts ($X\text{-}C_7H_6^+ \cdot Y^-$), including three new compounds, have been synthesized. Their relative reactivities in one-electron reductions with zinc powder have been determined by the use of a competitive-reaction method, which gave the following reactivity sequence: $CH_3O\text{-}C_7H_6^+$ ($k_{rel.}=0.0295$), $t\text{-}C_4H_9\text{-}C_7H_6^+$ (0.146), $CH_3S\text{-}C_7H_6^+$ (0.255), $C_7H_7^+$ (1.00), $C_6H_5\text{-}C_7H_6^+$ (2.50), $(C_6H_5)_3Si\text{-}C_7H_6^+$ (7.50), $Cl\text{-}C_7H_6^+$ (16.8), $CH_3OCO\text{-}C_7H_6^+$ (35.7), $NC\text{-}C_7H_6^+$ (163). The values of log $k_{rel.}$ for the $t\text{-}C_4H_9$-, H-, and $C_6H_5\text{-}C_7H_6^+$ ions exhibit a good linear relationship with those of log k_2 in the chromous-ion reduction. A linear correlation is also observed between log $k_{rel.}$ and the transition energy for the charge-transfer band of the respective cations, with pyrene as a donor. A plot of log $k_{rel.}$ against σ_p (for the ring substituent, X) gives a greater ρ-value (+4.0) than in the case of $X\text{-}C_6H_4\text{-}C_7H_6^+$ (+1.31), reflecting the influence of the direct substitution on the tropylium ring.

In earlier publications,[1] we have demonstrated that the "one-electron" reducibility (log k_2) for some of the substituted tropylium and cyclopropenium ions in the chromous-ion reduction is linearly correlated with the electron affinity, which was estimated from the transition energy for the charge-transfer bands of the respective cations, with pyrene as the donor. Also, with respect to substituted phenyltropylium ions, the existence of the Hammett linear free-energy relationship was demonstrated.[1d] We were, therefore, encouraged to extend these studies to the tropylium ions with a variety of hetero-substituents which are directly bonded to the seven-membered ring.

However, the previous method of the chromous-ion reduction is not applicable to the hetero-substituted tropylium ions because of the instability of these cations in "aqueous" media. Furthermore, acetonitrile, in which these cations are stable, is not a good solvent for chromous ion. Hence, we have attempted to estimate the relative reducibility of these substituted tropylium ions by the use of a competitive heterogeneous reduction with zinc powder in "anhydrous" acetonitrile. The use of zinc powder as a one-electron reductant for the carbonium ions has been well documented[2] since the first observation of the zinc reduction of the tropylium ion to give bitropyl reported by Doering and Knox.[2a] In addition, the formation of the radical species (tropyl radical) in the course of the zinc reduction of the tropylium ion has been proved by the radical-trapping technique.[3]

In this paper, the correlation of the reducibility of the hetero-substituted tropylium ions with the electron affinity and the substituent effect on the rates of reduction will be discussed by the use of the relative reduction rates as measured by the competitive-reduction method.

Results and Discussion

Syntheses of the Hetero-substituted Tropylium Ions. Among the perchlorates of the hetero-substituted tropylium ions, I-VIII, those of the chloro-[4] (III), methoxy[5] (VI), diethylamino-[6] (VII), and *t*-butylamino-[6] (VIII) derivatives were prepared according to the literatures. The cyano- (I), carbomethoxy-(II) and methylthiotropylium[4] (V) perchlorates were synthesized by hydride abstraction from the corresponding 3-substituted 1,3,5-cycloheptatrienes, which had been obtained from the 7-substituted derivatives[7] by thermal isomerization. The triphenylsilyltropylium perchlorate (IV) was synthesized in the same way from 7-triphenylsilyl-1,3,5-cycloheptatriene, which had itself been obtained by the reaction of 7-ethoxy-1,3,5-cycloheptatriene with triphenylsilyllithium.[8] Among these salts, I,[9] II, and IV are new compounds.

Previously, we have observed a homolytic dissociation of 7-triphenylmethyl-1,3,5-cycloheptatriene into the tropyl (cycloheptatrienyl) and triphenylmethyl radicals by means of ESR measurements at 60—95 °C.[10] Larrabee[11] has found that 7-triphenylstannic-1,3,5-cycloheptatriene undergoes a similar thermal cleavage at 160 °C and also reported on the fluxional behavior of the triphenylstannic group around the seven-membered ring on the basis of NMR measurements at 0—139 °C. The ease of these homolytic cleavages may be attributed to the considerable resonance-stabilization of the "symmetrical" tropyl radical.[12] However, in spite of the close similarity of the structure, 7-triphenylsilyl-1,3,5-cycloheptatriene does not exhibit such behavior. It does not show any evidence of bitropyl formation when heated at 200 °C, indicating the resistance of the C-Si bond to homolytic dissociation.

Competitive Reductions. First, the one-electron reduction of each single cation with an excess (twenty-fold of the theoretical amount) of zinc powder was

carried out in acetonitrile for ten minutes. An almost quantitative formation of the x,x'-disubstituted bitropyl was confirmed, except for the aminotropylium ions, VII and VIII, which were not reduced, but were recovered unchanged under these conditions. This indicates the exceptional stability due to electron donation by the amino group. The analytical and spectral data for x,x'-disubstituted bitropyls are tabulated in Table 2 (see Experimental).

Then, the competitive reduction was conducted as follows. Each pair of equal amounts of cations (R_A^+, R_B^+) was subjected to a competitive reduction in acetonitrile at 25 °C with zinc powder 1/4~1/2 of the theoretical amount required for the complete reduction of a single cation. The mixture of the coupling products of the radicals formed from both cations (R_A–R_A, R_A–R_B, R_B–R_B) was then extracted. The yield of each radical was determined from the weight of the coupling-product mixture and by NMR analysis.[13] In each case, the material balance of the reduction was found to be 90—105% from the UV analysis of the unchanged cation. When we assume the first-order dependence of the reaction rate on the cation concentration, the ratio of rate constants for the competing cations is expressed by the following equation:[14]

$$k_A/k_B=\log([R_A^+]/[R_A^+]_0)/\log([R_B^+]/[R_B^+]_0)$$

where $[R_A^+]_0$ and $[R_B^+]_0$ denote the initial concentrations of the R_A^+ and R_B^+ cations respectively. The application of this equation to the present case was justified by the linearity of the plot of $\log([R_A^+]/[R_A^+]_0)$ against $\log([R_B^+]/[R_B^+]_0)$ through the point of origin, with regard to each cation pair, as is shown in Figs. 1 and 2. From the slope of each straight line, the relative rate constant ($k_{rel.}$) for the zinc reduction of each cation was determined. The results are listed in Table 1, together with the charge-transfer maxima (*vide infra*) of the respective cations.

In order to compare the results obtained by the present method ($k_{rel.}$) with that determined from the homogeneous chromous-ion reduction (k_2), $\log k_{rel.}$ was plotted against $\log k_2$. A linear correlation with the slope of 0.98 has been observed, as is shown in Fig. 3. This result clearly indicates that, in spite of the heterogeneous condition, the present method gives reasonably correct relative values for the reducibility inherent in the carbonium ions.

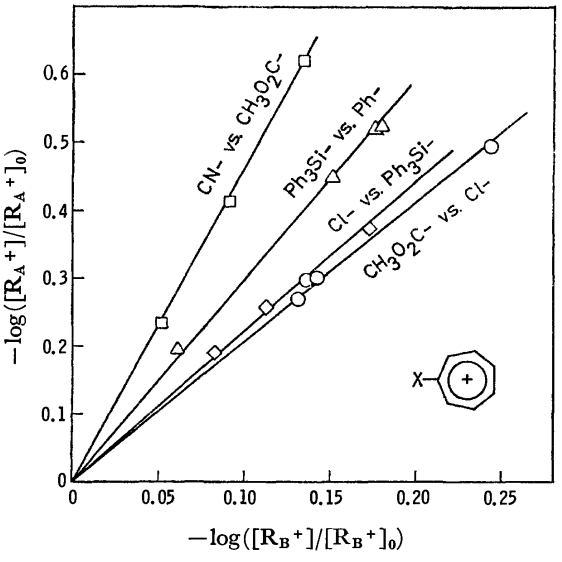

Fig. 1. Plot of $-\log([R_A^+]/[R_A^+]_0)$ *vs.* $-\log([R_B^+]/[R_B^+]_0)$ for the competitive reduction of NC–, CH_3OCO–, Cl–, $(C_6H_5)_3Si$–, and C_6H_5–$C_7H_6^+$ with Zn in CH_3CN at 25 °C.

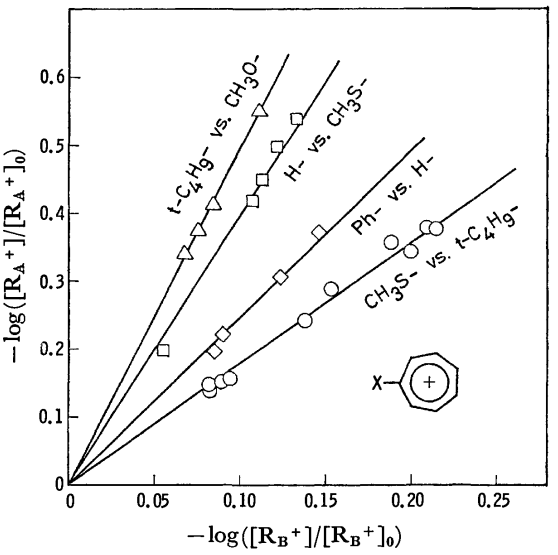

Fig. 2. Plot of $-\log([R_A^+]/[R_A^+]_0)$ *vs.* $-\log([R_B^+]/[R_B^+]_0)$ for the competitive reduction of C_6H_5–, H–, CH_3S–, *t*-C_4H_9–, and CH_3O–$C_7H_6^+$ with Zn in CH_3CN at 25 °C.

Table 1. Relative rate constants for the zinc reduction of hetero-substituted tropylium ions and absorptions of their charge-transfer spectra

Substituent	$k_{rel.}$[a]	log $k_{rel.}$	C. T. band[b]	
			λ_{max} nm	ν_{max} 10^4 cm^{-1}
CH_3O–	0.0295	−1.530	480	2.083
t-C_4H_9–	0.146	−0.836	508	1.969
CH_3S–	0.255	−0.594	510	1.961

C_6H_5–	2.50	0.398	543	1.842
$(C_6H_5)_3Si$–	7.50	0.875	555	1.802
Cl–	16.8	1.225	580	1.724
CH_3OCO–	35.7	1.552	610	1.639
NC–	163	2.212	680	1.471

a) Determined by the competitive reduction in acetonitrile at 25 °C. b) Measured in 1,2-dichloroethane with pyrene as a donor.

The Correlation of log $k_{rel.}$ with the Charge-transfer Energy. In order to examine the correlation of the reducibility with the electron affinity, the values of log $k_{rel.}$ were plotted against the wave number corresponding to the maximum absorption at the charge-transfer spectrum (ν_{max}, see Table 1) of each substituted tropylium ion, with pyrene as the standard electron donor. A good linear correlation was obtained, as is shown in Fig. 4. Since, for a given donor molecule,

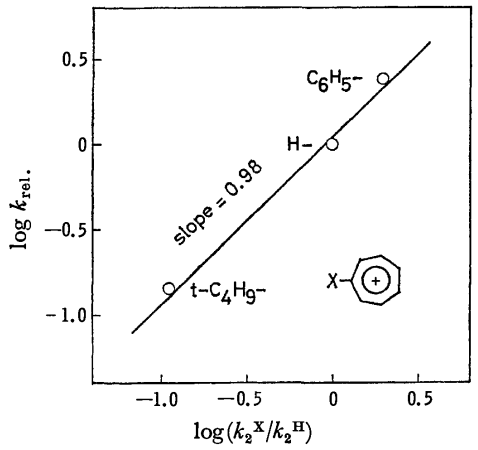

Fig. 3. Plot of $\log k_{rel.}$ measured by the competitive reduction *vs.* $\log(k_2^X/k_2^H)$ determined by the chromous-ion reduction.

the ν_{max} for the charge-transfer spectrum of a series of acceptors should correlate with the electron affinity of the acceptors,[15] this correlation (Fig. 4) clearly indicates that the reducibility of these cations is essentially regulated by the electron affinity inherent in the cation itself. Thus, the correlation[1] which holds for the alkyl- and aryl-substituted tropylium and cyclopropenium series has been successfully extended to a series of hetero-substituted tropylium ions.

The Correlation of log $k_{rel.}$ with Hammett's σ_p. The variation in the reactivity of substituted tropylium ions obviously reflects the influence of the electronic stabilization or destabilization caused by these substituents. In order to compare the substituent effect with that observed in the case of substituted phenyltropylium ions, the values of $\log k_{rel.}$ were plotted against Hammett's σ_p[16] (Fig. 5). The one-electron reducibility of the substituted tropylium ion thus measured is considered to be an average of the reactivity of the seven individual carbon atoms in the ring toward the reductant. Hence, the use of a single σ_p constant, though it includes both resonance and inductive electronic effects, may not be explicitly called for. This is perhaps one of the causes of the scatters in Fig. 5.[17] Thus, although we can not avoid such

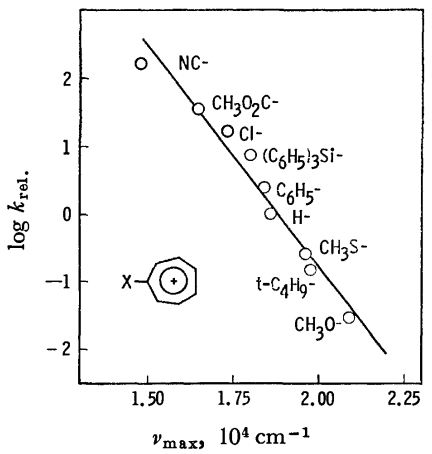

Fig. 4. Plot of $\log k_{rel.}$ *vs.* ν_{max} of the charge-transfer spectra.

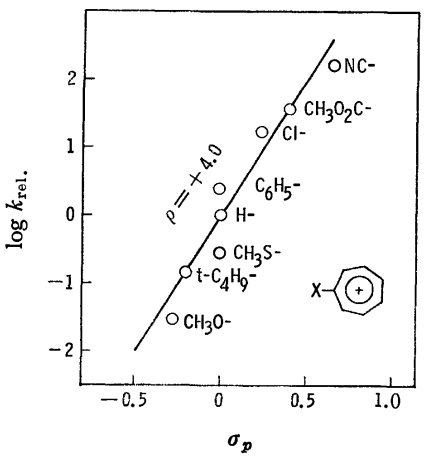

Fig. 5. Plot of $\log k_{rel.}$ *vs.* Hammett's σ_p.

a theoretical ambiguity, if we express the sensitivity to the substituent effect with the ρ-value it will amount to about +4.0. The increase in ρ-value, compared with that obtained in the case of a substituted phenyltropylium system (+1.31),[1d] is evidently caused by the direct transmission of the electronic effect of the substituent to the tropylium ring.

Experimental[18]

Materials. All the reagents employed were of a reagent-grade quality. The acetonitrile and ethyl acetate were refluxed and distilled over phosphorus pentoxide; acetonitrile, bp 80.5—81.1 °C; ethyl acetate, bp 75.5—76.5 °C. The carbon tetrachloride, chloroform and 1,2-dichloroethane were refluxed and distilled over calcium chloride; carbon tetrachloride, bp 75.0—75.5 °C; chloroform, bp 60.0—60.3 °C; 1,2-dichloroethane, bp 83.0—83.5 °C. The tetrahydrofuran (THF) was distilled over lithium aluminum hydride; bp 66.0—66.4 °C.

The chloro-[4] (III), methoxy-[5] (VI), diethylamino-[6] (VII), and *t*-butylamino-[6] (VIII) tropylium perchlorates were prepared by the methods reported in the literature; III, mp 175.0—176.0 °C (lit, mp 172—173 °C[4]), $\lambda_{max}^{CH_3CN}$ 232 nm (ε, 37200), 308 nm (9100) (lit, $\lambda_{max}^{CH_3CN}$ 232 nm (log ε, 4.57), 308 nm (3.96)[4]); VI, mp 107.0—107.5 °C (lit, mp 107 °C[5]), $\lambda_{max}^{CH_3CN}$ 232 nm (ε, 34700), 313 nm (11000) (lit, $\lambda_{max}^{CH_3CN}$ 232 nm (log ε, 4.54) 313 nm (4.04)[4]); VII, mp 68.0—72.0 °C (lit, mp 75—76 °C,[6]), $\lambda_{max}^{CH_3CN}$ 241 nm (ε, 20000) 335 nm (16300) (lit, $\lambda_{max}^{CH_3CN}$ 241 nm (log ε, 4.30), 335 nm (4.21)[6]); VIII, mp 111.5—112.0 °C (lit, mp 112—113 °C[6]), $\lambda_{max}^{CH_3CN}$ 239 nm (ε, 18400), 242.5 nm (18400), 333 nm (13000) (lit, $\lambda_{max}^{CH_3CN}$ 237 nm (log ε, 4.35), 330 nm (4.18)[6]).

The phenyl- (IX) and unsubstituted (X) tropylium fluoroborates and *t*-butyltropylium perchlorate (XI) were prepared by previously-reported methods.[1b]

Synthesis of Cyanotropylium Perchlorate (I). 7-Cyano-1,3,5-cycloheptatriene[2a] was heated in an evacuated ampoule at 175 °C for 1.5 hr and distilled under reduced pressure to give a mixture of 3- and 1-cyano-1,3,5-cycloheptatrienes; bp 86.5—90.0 °C/5 mmHg. To a solution of 3.498 g (29.8 mmol) of an isomeric mixture of cyanocycloheptatrienes in 7.7 ml of acetonitrile, we added 10.231 g (29.8 mmol) of triphenylmethyl (trityl) perchlorate. The mixture was magnetically stirred at 60 °C for 1 hr and then at 80 °C for 5 min; most of the crystals of trityl perchlorate thereby disappeared and the mixture turned dark red. After the addition of 26 ml of ethyl acetate, the mixture was cooled to 0 °C.

The pale yellow crystals that separated out were collected by filtration, washed successively with ethyl acetate and ether, and dried *in vacuo* to give 4.885 g (22.7 mmol) of I; 76.2% yield. For the analyses, I was purified by recrystallization from acetonitrile–ethyl acetate; mp 158.0 °C (decomposition with violent explosion); $\lambda_{max}^{CH_3CN}$ 293 nm (ε, 6610), 298 nm (6450); ν_{max}^{KBr} 3020, 2220, 1630, 1595, 1525, 1480, 1440, 1380, 1150—1080, 955, 940, 870, 740 cm^{-1}; NMR, τ_{CF_3COOH} 0.4 (s, tropylium ring protons).

Found: C, 44.34; H, 2.81%. Calcd for $C_8H_6NClO_4$: C, 44.57; H, 2.81%.

Synthesis of Carbomethoxytropylium Perchlorate (II). 7-Carbomethoxy-1,3,5-cycloheptatriene[7] was thermally isomerized at 175 °C for 1.5 hr to give a mixture of 3- and 1-carbomethoxy-1,3,5-cycloheptatrienes; bp 74.0—77.0 °C/3 mmHg. In 6.4 ml of acetonitrile, 3.509 g (23.4 mmol) of a mixture of carbomethoxycycloheptatrienes was allowed to react with 8.012 g (23.3 mmol) of trityl perchlorate with magnetic stirring at 60 °C for 6 min; the trityl salt disappeared almost instantaneously when the mixture was heated, and instead pale yellow crystals separated. After the addition of 24 ml of ethyl acetate, the mixture was cooled to 0 °C and then filtered to give 5.427 g (21.8 mmol) of II as pale yellow crystals; 93.4% yield; mp 143.0—143.3 °C (after recrystallization from acetonitrile–ethyl acetate); $\lambda_{max}^{CH_3CN}$ 225.5 nm (ε, 43000), 286 nm (4660); ν_{max}^{KBr} 3015, 2960, 1730, 1615, 1480, 1440, 1370, 1350, 1290, 1270, 1250, 1150—1070, 970, 940, 925, 870, 805, 760, 740, 680 cm^{-1}; NMR, τ_{CF_3COOH} 0.0 (m, 2H, tropylium ring protons), 0.5 (m, 4H, tropylium ring protons), 5.7 (s, 3H, methyl protons).

Found: C, 43.21; H, 3.58%. Calcd for $C_9H_9ClO_6$: C, 43.48; H, 3.65%.

Synthesis of Methylthiotropylium Perchlorate (V). To a magnetically-stirred solution of 10.356 g (58.1 mmol) of tropylium fluoroborate in 110 ml of 0.1 M HCl, we added 9.5 g of a 30% methanolic solution of methanethiol (58.7 mmol); a slightly exothermic reaction then took place, and the solution turned yellow. After stirring for 20 min at room temperature, the turbid solution was extracted with three 100-ml portions of ether, washed with 10% NaCl, and dried over $MgSO_4$. The ethereal solution, after evaporation and distillation, gave 4.309 g (31.2 mmol) of 7-methylthio-1,3,5-cycloheptatriene as a pale yellow oil; 53.6% yield; bp 74 °C/5 mmHg; NMR, τ_{CCl_4} 3.5 (t, 2H, $H^{3,4}$), 3.9 (m, 2H, $H^{2,5}$), 4.7 (d of d, 2H, $H^{1,6}$), 6.9 (t, 1H, H^7), 7.9 (s, 3H, methyl protons).

Found: C, 69.72; H, 7.42%. Calcd for $C_8H_{10}S$: C, 69.51; H, 7.29%.

A solution of 2.092 g (15.1 mmol) of the isomeric mixture of methylthiocycloheptatrienes (bp, 50.0—61.0 °C/4 mmHg), obtained by the thermal isomerization described above, in 10 ml of acetonitrile was added to a magnetically-stirred suspension of 5.205 g (15.2 mmol) of trityl perchlorate in 10 ml of acetonitrile over a 2-min period at room temperature. During the addition, the reaction temperature rose from 22.5 °C to 30.0 °C and all the trityl salt dissolved to give a dark red solution. After stirring for 15 min at room temperature, 100 ml of ethyl acetate was added and the mixture was cooled to 0 °C. The yellow crystals that thus separated out were collected, washed, and dried as has been described above to give 2.860 g (12.1 mmol) of V: 80.0% yield; mp 114.0—115.0 °C (lit, mp 114—115 °C[4]); $\lambda_{max}^{CH_3CN}$ 219.5 nm (ε, 23300), 260 nm (17000), 380 nm (19800) (lit, $\lambda_{max}^{CH_3CN}$ 258 nm (ε, 14800), 378 nm (17400)[4]); ν_{max}^{KBr} 3010, 2910, 1615, 1600, 1510, 1470, 1430, 1420(sh), 1370, 1325, 1280, 1235, 1225, 1120—1040, 845, 740 cm^{-1}.

Synthesis of 7-Triphenylsilyl-1,3,5-cycloheptatriene. To a stirred solution of 5.791 g (45.9 mmol) of 7-ethoxy-1,3,5-cycloheptatriene in 20 ml of THF, we added 130 ml of a THF solution of triphenylsilyllithium, prepared from 15.0 g (51.0 mmol) of triphenylsilyl chloride and 1.40 g (0.202 g-atom) of lithium according to the method of Gilman *et al.*,[8] by the use of a hypodermic syringe over a 25-min period at room temperature; the reaction temperature rose from 25.0 °C to 35.0 °C, and the dark reddish brown color of triphenylsilyllithium, which was, at the beginning, instantaneously discharged upon addition to the ethoxycycloheptatriene solution, began to remain during the course of addition. The dark brown mixture with white precipitates was stirred at room temperature for 2.5 hr and then left to stand overnight. Then, 150 ml of 10% HCl was cautiously added and the mixture was worked up in the usual way to give 17.5 g of a partially-solidified yellowish oil, from which, upon recrystallization from benzene, 0.451 g (0.836 mmol) of hexaphenyldisilane was separated as white crystals; mp 355—360 °C (lit, mp 361—362 °C[8]); the IR spectrum was identical with that of the authentic sample. The mother liquor was concentrated *in vacuo*, and the residual solid, upon recrystallization from ethanol, gave 3.338 g (9.53 mmol) of 7-triphenylsilyl-1,3,5-cycloheptatriene as white crystals; this compound begins to melt at 152 °C, but at 155 °C another solid, presumably the 3-triphenylsilyl isomer, appears, which eventually melts at 178 °C; NMR, τ_{CCl_4} 2.6 (m, 15H, phenyl protons), 3.4 (t, 2H, $H^{3,4}$), 3.7 (m, 2H, $H^{2,5}$), 4.8 (d of d, 2H, $H^{1,6}$), 8.2 (t, 1H, H^7).

Found: C, 85.48; H, 6.07%. Calcd for $C_{25}H_{22}Si$: C, 85.66; H, 6.33%.

The filtrate of the recrystallization, upon evaporation, gave 12.260 g of a yellowish solid, which was then chromatographed over 310 g of silica gel (Nakarai, No. II-A, 100—200 mesh). From the fractions eluted with *n*-hexane–benzene (9 : 1—6 : 1) we obtained a mixture of 0.163 g (0.898 mmol) of bitropyl and 0.340 g (0.131 mmol) of triphenylsilane; the composition was determined by the NMR analysis. From the fractions eluted with *n*-hexane–benzene(3 : 1) we isolated 4.654 g (13.3 mmol) of 7-triphenylsilyl-1,3,5-cycloheptatriene, whereas the following fractions, when eluted with *n*-hexane–benzene(2 : 1), gave 0.657 g (1.22 mmol) of hexaphenyldisilane after recrystallization from chloroform. In addition, the fractions eluted with benzene–ether (1 : 1) afforded 3.364 g (12.2 mmol) of triphenylsilanol after recrystallization from benzene; mp 152—155 °C (lit, mp 153—155 °C[8]).

Thus, the yields of each isolated product may be summarized as follows: bitropyl, 3.9%; 7-triphenylsilyl-1,3,5-cycloheptatriene, 47.5%; the tropylium ion, 21.2% (as determined from the UV spectrum of the aqueous layer); hexaphenyldisilane, 4.8% (based on triphenylsilyl chloride); triphenylsilane, 2.6% (*vide supra*); triphenylsilanol, 24.1% (*vide supra*).

7-Triphenylsilyl-1,3,5-cycloheptatriene was sealed in a Pyrex tube under a vacuum and heated at 200 °C for 30 min. The tlc analysis of the recovered sample indicated the presence of an isomeric mixture of triphenylsilylcycloheptatrienes, but no spot corresponding to bitropyl was detected.

Synthesis of Triphenylsilyltropylium Perchlorate (IV). 7-Triphenylsilyl-1,3,5-cycloheptatriene was thermally isomerized at 150 °C for 5 hr to give 3-triphenylsilyl-1,3,5-cycloheptatriene; NMR, τ_{CCl_4} 2.6 (m, 15H, phenyl protons), 3.1 (d, 1H, H^4), 3.7 (m, 2H, $H^{2,5}$), 4.5 (m, 2H, $H^{1,6}$), 7.7 (t, 2H, H^7). A suspension of 0.638 g (1.82 mmol) of the triphenylsilylcycloheptatriene and 0.634 g (1.85 mmol) of trityl perchlorate in 10 ml of acetonitrile was magnetically stirred at 55 °C for 30 min and then at 80 °C for 5 min to give a dark red solution. After the addition of 100 ml of ethyl acetate, the solution was cooled to 0 °C. The glittering, brownish

crystals that separated out were collected in the usual way to give 0.702 g (1.57 mmol) of IV; 86.0% yield. Recrystallization from acetonitrile–ethyl acetate gave a mp of 188.0 °C (decomposition with explosion); $\lambda_{max}^{CH_3CN}$ 218 nm (ε, 65000), 265 nm (sh) (6960), 271.5 nm (6800), 281 nm (6500); λ_{max}^{KBr} 3080, 3050, 3020, 1590, 1485, 1440(sh), 1430, 1380, 1265, 1240, 1190, 1160, 1120—1070, 1030, 1000, 940, 870, 750, 745(sh), 715, 700, 680 cm^{-1}; NMR, τ_{CH_3COOH} 0.5—0.8 (m, 6H, tropylium ring protons), 2.5 (s, 15H, phenyl protons).

Found: C, 66.80; H, 4.52%. Calcd for $C_{25}H_{21}SiClO_4$: C, 66.88; H, 4.72%.

Synthesis of Phenyl-d_5-tropylium Perchlorate (IX'). For the purpose of product analysis in the competitive reduction of IV and IX (*vide infra*), the phenyl-d_5 derivative of IX was synthesized from bromobenzene-d_5,[19] following the methods used for the preparation of IX;[1b] mp 152.0—153.0 °C (dec) (lit, mp for IX 151.0—152.0 °C[1b]); ν_{max}^{KBr} 3020, 3000, 2950, 2270, 2080, 1630, 1600, 1520, 1480, 1440, 1430, 1380, 1315, 1283, 1273, 1240, 1200, 1130—1000, 880, 860, 845, 830, 800, 790, 740 cm^{-1}; NMR, τ_{CF_3COOH} 0.6—0.9 (m, tropylium ring protons).

One-electron Reduction of the Substituted Tropylium Ions with Zinc Powder. To a magnetically-stirred solution of 0.500 g (2.01 mmol) of II in 20 ml of acetonitrile, we added 1.315 g (20.1 mg-atom) of zinc powder. The mixture was stirred for 10 min at room temperature under an atmosphere of nitrogen. The excessive zinc was then filtered off, and 40 ml of carbon tetrachloride and 40 ml of water were added to the filtrate, which was then worked up in the usual way to give 0.317 g (1.06 mmol) of x,x'-dicarbomethoxybitropyl as a viscous oil; 105.6% yield; NMR, τ_{CCl_4} 2.2—4.7 (m, 10H, olefinic ring protons), 6.1 and 6.2 (s, 6H, methyl), 8.0 (br, 2H, methine).

The Reductions of I, III, IV, V, VI, IX, and XI were carried out in the same way to give the disubstituted bitropyls in yields of 91—108%. The UV spectra and the results of the elemental analyses of all the products are tabulated in Table 2.

Under the same reaction conditions, 0.0557 g (0.239 mmol) of VII was allowed to react with 0.160 g (2.46 mg-atom) of zinc powder in 2 ml of acetonitrile. After filtration, 20 ml of ether was added to the filtrate and the white precipitates that separated were collected in the usual way to give 0.0503 g (0.216 mmol) of unchanged VII; 90.4% recovery. The ethereal filtrate gave 0.0015 g of an unidentified oily substance. An attempted reduction of VIII, with the same procedures, also resulted in a 106% recovery of VIII.

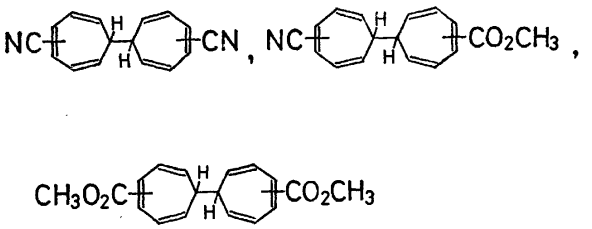
a) As for the data for diphenyl-, di-*t*-butyl-, and unsubstituted bitropyls, see Ref. 1b.

Competitive Reductions. With respect to the competitive reduction of the I, II, III, IV, IX, and X cations the details of the procedures may be illustrated by the following description of a representative run for the competition of I and II. Into a 25-ml, four-necked flask equipped with a thermometer, a magnetic-stirring bar, and a nitrogen inlet and outlet, which had been immersed in a water bath thermostated at 25.0 °C, there was stirred a solution of 0.108 g (0.502 mmol) of I and 0.125 g (0.503 mmol) of II in 5.0 ml of acetonitrile. To this solution we then added 0.0169 g (0.259 mg-atom) of zinc powder, and the mixture was stirred under a nitrogen atmosphere for 10 min. The reaction appeared to be very fast, completing in less than 1 min, as indicated by the rapid disappearance of the zinc powder. The solution was evaporated under reduced pressure to give an oily solid, which was then extracted in five portions with 25 ml of carbon tetrachloride. The carbon tetrachloride solution was washed with three 35-ml portions of water, dried over $MgSO_4$, and evaporated to give 0.0626 g of a colorless oil, which was then analyzed by means of NMR as follows: regarding the product oil as a mixture of substituted bitropyls such as,



the molar ratio of the cyano- and carbomethoxytropyl groups was determined to be 3.32 : 1.00 from the relative values of the integrated intensities (average of 5 measurements) for the signals corresponding to the methyl protons and the total olefinic ring protons (H^{2-7}). From this molar ratio and the weight of the product mixture, the radical yield was calculated to be 77.2% for the reduction of I and 23.3% for the reduction of II. On the other hand, the residual solid from the carbon-tetrachloride extraction was dissolved in acetonitrile and subjected to UV analysis. The amounts of the unchanged cations, I and II, were determined to be 0.116 mmol (23.1% recovery) and 0.373 mmol (74.2% recovery) respectively by the use of the absorbance and the molar extinction coefficient of each cation at the wave lengths corresponding to the maximum absorptions of the individual cations, assuming the additivity of the absorbance of the respective cations at each wavelength. The results of the competitive reduction were treated as has been described above. For the competition of IV and IX, the phenyl-d_5 derivative (IX')[20] was employed instead of IX itself, so that the NMR analysis of the product ratio became more accurate by integrating the signals for phenyl protons which came from IV and the total of the olefinic ring protons.

With respect to the V, VI, X, and XI cations, exactly the same method was adopted except for the following procedures: after the reaction, 20 ml of 10% HCl was added to the reaction mixture, after which the products were extracted with ether, worked up, and analyzed as has been described above, while the unchanged cations were determined by UV analyses of the acidic aqueous layer.

The validity of the analytical methods described above is verified by the fairly good material balance (90—105%) obtained in each case.

Measurements of the Charge-transfer Bands with Pyrene. The charge-transfer spectra were measured in 1,2-dichloroethane as has been reported previously.[1b] The concentrations of the donor (pyrene) and of the acceptor (the substituted tropylium ion) were 0.1 M and 1×10^{-3} M respectively. The previously-described[1d] precautions were taken against the light, and the spectra were measured immediately after the preparation of the sample solution.

16) The values of σ_p were cited from D. H. McDaniel and H. C. Brown, *J. Org. Chem.*, **23**, 420 (1958), except that for $-CO_2CH_3$, which was cited from H. van Bekkum, P. E. Verkade, and B. M. Wepster, *Rec. Trav. Chim.*, **78**, 815 (1959).

17) When log $k_{rel.}$ is plotted against Brown's σ_p^+ (H. C. Brown and Y. Okamoto, *J. Amer. Chem. Soc.*, **80**, 4979 (1958)), the correlation is worse than that in Fig. 5. This may be a reflection of the fact that the extent of conjugation of the substituent with the seven-membered ring is not changed so much throughout the reaction path from the tropylium ion to the tropyl radical, whereas, from the definition, σ_p^+ is applicable to those reactions in which the conjugative interaction of the carbonium-ion center with the substituent arises and develops during the course from the ground state to the intermediate.

18) The melting points and boiling points are uncorrected. The elemental analyses were performed by the Microanalytical Center, Kyoto University, Kyoto. The infrared and ultraviolet spectra were recorded on a Hitachi model 215 and Shimadzu model UV-50M spectrometers repsectively. The NMR spectra were taken with a Hitachi model R-24 spectrometer with tetramethylsilane as the internal standard.

19) Bromobenzene-d_5 was prepared by bromination of benzene-d_6 (99.6%, CEA, France), according to the method of L. Gatterman and F. H. Wieland, "Die Praxis des organischen Chemikers," Walter de Gruyter & Co., Berlin (1961), p. 95.

20) The reducibility of IX′ was examined also by the use of the chromous-ion reduction method. It was indicated that the reducibility of IX was not affected by deuteration of the phenyl ring.

Synthetic Photochemistry. IV.[1] The Reaction of Betaines with Singlet Oxygen

Hitoshi TAKESHITA, Akira MORI, and Shumei OHTA

Research Institute of Industrial Science, Kyushu University, Hakozaki, Fukuoka 812

(Received March 14, 1974)

Singlet oxygen was allowed to react with three 3-hydroxypyridine derivatives, I, II, and III, in order to investigate its general behavior toward dipolar substrates. The occurrence of an easy C=C cleavage process to give furanones (V and XI) through the dioxetones was a characteristic feature. In addition, maleimides (IV and IX), oxamates (VIII, XII and XIV), and a carbamate (XIII) were isolated as highly oxidized products.

During the course of our studies of the photosensitized oxygenation of vinyl cyclopropane derivatives, we have noticed an indication which could better be interpreted in terms of the involvement of a dipolar intermediate in the formation of dioxetanes.[2]

Therefore, it seemed that it would be worthwhile to study the reaction with dipolar substrates, like betaines, to observe the structural effect on the dipolar intermediate. In addition, there seems to have been no report on the reaction of singlet oxygen with a betaine derivative, although there have been some reports on the photooxidation of a few related compounds. For example, the photooxidation of an indenone epoxide[3] or an epoxycyclopentenone[4] has been shown to give the products corresponding to that of pyrilium 3-oxide on oxygen, probably by a reaction of photo-excited substrates and ground-state oxygen; furthermore, the photooxidation of a thiopyrilium salt[5] gave several products, but the substrate was shown to be inert against singlet oxygen. In this paper, we would like to describe the results of the reaction of singlet oxygen carried out in both an aprotic solvent(chloroform) and a protic solvent(ethanol) with *N*-meth lp ridinium 3-oxide (I), *N*-benzylpyridinium 3-oxide(II) and their parent compound, 3-hydroxypyridine(III).

Results and Discussion

Oxidation of N-*Methylpyridinium 3-Oxide.* When a chloroform solution of I was irradiated by means of a 500-W tungsten lamp under an oxygen stream with catalytic amounts of methylene blue, two products, IV and V, were obtained in yields of 3.8 and 26% respectively. IV was identified as *N*-methylmaleimide,[6] while the structure of V was deduced as follows: The NMR spectrum [$\delta^{35°C}_{CDCl_3}$: 2.71(3H, s), 6.1—7.3 (3H, m) and 8.36 (1H, s) for Va; 2.79(3H, s), 6.1—7.3(3H, m) and 8.20(1H, s) for Vb; (a : b=2 : 1). $\delta^{35°C}_{(CD_3)_2SO}$: 2.5(3H, s), 6.49(1H, dd, J=6, 2 Hz), 6.65 (1H, t, J=2 Hz), 7.66(1H, dd, J=6 2 Hz) and 8.39 (1H, s) for Va; 2.70(3H, s), and 8.22(1H, s) for Vb, (a : b=5 : 1)] indicated the existence of a pair of stereoisomers and was characteristic of a formamide derivative;[7] in addition, the lactonic carbonyl frequencies in the IR spectrum were in the range for γ-butenolides. Thus, V is 5-(*N*-methylformamido)-2(5*H*)-furanone. The NMR at higher temperature showed the coalescence of the each signal due to the respective components [$\delta^{150°C}_{(CD_3)_2SO}$: 2.68(3H, s), 6.45 (1H, dd, J=6, 2 Hz), 6.62(1H, t, J=2 Hz), 7.56 (1H, dd, J=6, 2 Hz), and 8.28(1H, s)].

When the irradiations were performed in an ethanol solution, the products were different from those described above. The mixture was fractionated by silica-gel column chromatography to give four products, 3-hydroxy-*N*-methyl-α-pyridone (VI),[8] diethyl maleate, (VIIa), diethyl fumarate (VIIb), and ethyl *N*-methyloxamate (VIII).[9] Thus a solvent dependence on the product formation is observed.

Oxidation of N-*Benzylpyridinium 3-Oxide.* A chloroform solution of *N*-benzylpyridinium 3-Oxide (II) was similarly irradiated by means of a tungsten lamp. The reaction in this case was faster than that of I. From the mixture, *N*-benzylmaleimide (IX, 1%),[6] *N*-benzylformamide (X, 12%),[10] and 5-(*N*-benzylformamido)-2(5*H*)-furanone (XI, 9.3%) were isolated. IX and X were identical with authentic specimens prepared independently. XI again revealed a presence of a stereoisomeric pair of compounds in NMR at room temperature [δ_{CDCl_3}: 4.13(1H, d, J=16 Hz), 4.87 (1H, d, J=16 Hz), 6.0—7.3(3H, m), 7.27 (5H, br.), and 8.64 (1H, s) for XIa; 4.17(1H, d, J=16 Hz), 4.50(1H, d, J=16 Hz), 6.0—7.13(3H, m), 7.27 (5H, br.) and 8.40(1H, s) for XIb(a : b=2 : 1)] and coalescence at higher temperatures.

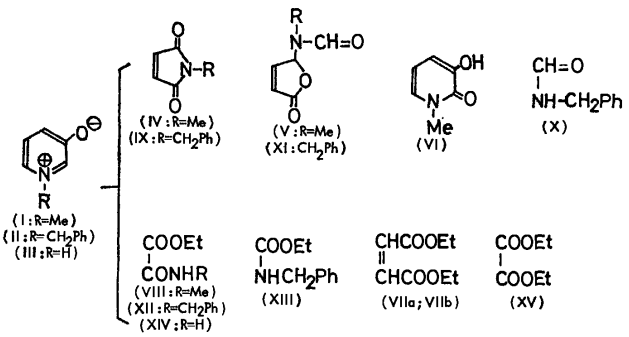

Chart 1.

The high-resolution mass spectrum of XI also supported the deduction of its structure; *i.e.*, the base peak was shown to correspond to $C_8H_8ON^+$, appearing at 134.06178 (Calcd: 134.06059), and arose from a cleavage of its C_5-N bond.

The oxidation of II in an ethanolic solution proceeded similarly to give the above three substances(2%, 21% and 14% yields respectively), together with two additional products, ethyl *N*-benzyloxamate(XII, 5.3%)[11] and ethyl *N*-benzylcarbamate(XIII, 8.7%),[12] which were identified by a direct comparison with an authentic specimen.

The Oxidation of 3-Hydroxypyridine(III). III is formally expressed in two tautomeric forms, IIIa and

IIIb, as has been illustrated.[13] Therefore, its behavior in reaction to singlet oxygen will be of interest in comparison with I and III. No oxidation in a chloroform solution has occurred; after irradiation for 160 hr, most of the starting material was recovered.

On the other hand, the oxidation performed in ethanol at 10—15 °C was shown to give diethyl maleate (VIIa), ethyl oxamate(XIV), and diethyl oxalate(XV) in low yields.

On the Pathways of Product Formations. As one sees, various types of products were formed. A technical difficulty in the isolation work-up of the products and the low yields almost throughout the reaction prevents detailed discussion; however, some of the interesting features should be noted.

Since a number of indoles and other chemiluminescent heterocycles has been shown to yield cleavage products by the action of ground-state oxygen, with the involvement of the intermediary dioxetanes formed *via* peroxy anions,[14] we have examined the reaction in the dark; no reaction with I and II has taken place. Therefore, the present C=C cleavage process must be solely photochemical, and the reactive species in the oxidation may be supposed to be the singlet oxygen, as in other dye-sensitized (by visible-light) photooxygenations.

The occurrence of the C=C cleavage process in both aprotic and protic solvents can be interpreted in terms of dioxetane formation, but the present "dipolar dioxetanes" might behave somewhat differently from those produced of ordinary substrates. The following explanation is based on this conception.

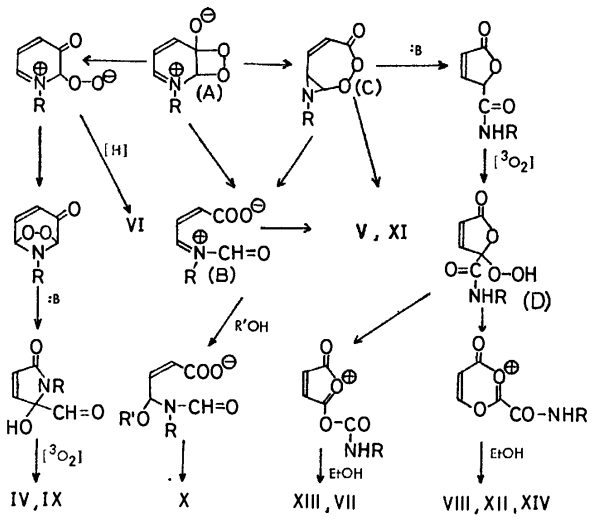

Chart 2.

The dioxetane (**A**), other than its ordinary fragmentation to **B**, can internally neutralize the separate charges by a rearrangement to **C**; it could equally possible be transformed into **B**. Once formed as a transient species, **B** could cause a lactonization (by an intramolecular path) or could form an amido-ether and an amido-alcohol (by an intermolecular path); the latter, derived by the addition of water, a trace of which should be present in the system, is thought to be responsible for the production of X. Since none of the maleimides (IV and IV), being stable under further reaction conditions, was converted into diethyl maleate (VIIa), their formation involves an independent path. Furthermore, the formamides (V and XI) were experimentally shown to be precursors of neither carbamate (XIII) nor oxamates (VIII, XII and XIV); hydroxy-α-pyridone, VI, was also shown to be inert under its formation conditions. Thus, among the remaining possibilities, we prefer to propose the formation of oxamates and maleate by a Baeyer-Villiger-type rearrangement of **D**, as a common intermediate which is probably formed by an action of the ground state oxygen. Further study along this line will be reported in the future.

Experimental

Photooxidation of N-*Methylpyridinium 3-Oxide (I).* a) I (2.0 g) was dissolved in chloroform (50 ml) and irradiated by means of a 500-W tungsten lamp in the presence of methylene blue under an oxygen stream for 73 hr at 10—15 °C. Then, after the removal of the solvent and the dye, the mixture was fractionated by silica-gel column chromatography to give IV (colorless crystals, 77 mg) (mp 92—94 °C (lit,[8] 90—92 °C)) and V (a colorless liquid, 674 mg) (Found: C, 50.90; H, 5.31; N, 10.46%. Calcd for $C_6H_7O_3N$: C, 51.06; H, 5.00; N, 9.93%. *ν*: 1800, 1770 and 1690 cm^{-1}).

b) I (5.05 g) was dissolved in ethanol (80 ml) and similarly irradiated at 0—5 °C. The silica-gel column chromatography of the mixture afforded VI (207 mg) as colorless needles (mp 134—134.5 °C (lit,[8] 130—131 °C)), found identical with an authentic sample by IR, NMR, and mixed-mp comparisons.

c) I (5.11 g) was irradiated in ethanol (80 ml) at 10—15 °C. A mixture of the products was then fractionated by silica-gel column chromatography to give VIIa (83 mg), VIIb (76 mg), and VIII (184 mg) (*δ* : 1.38(3H, t), 2.94 (3H, d, J=5.5 Hz), 4.34 (2H, q)). These three were found identical with independently-prepared samples by the IR and NMR spectral comparisons as well as by glc analysis.

Preparation of N-*Benzylpyridinium 3-Oxide (II).* III (10 g and benzyl chloride (13.3 g) were dissolved in *n*-propanol and refluxed for 8 hr. The mixture was then neutralized by passing it through anion-exchange resin (Amberlite IRA 401) to give hygroscopic crystals, (14.5 g, 74%), which gave the crystalline picrate (mp 185—187 °C (Found: C, 51.91; H, 3.29; N, 13.50%. Calcd for $C_{18}H_{14}O_8N_4$: C, 52.18; H, 3.41; N, 13.52%)).

Photooxidation of N-*Benzylpyridinium 3-Oxide (II).* a) II (2 g) was dissolved in chloroform (50 ml) and similarly irradiated. A mixture of the products was separated by silica-gel column chromotography to give IX (17 mg, colorless plates) (mp 71—72 °C (lit,[6] 67.7 °C) (*δ*: 4.60 (2H, s), 6.62 (2H, s), 7.25 (5H, s)) and X (180 mg, colorless needles) (mp 62—63 °C (lit,[10] 60—61 °C) (*δ*: 4.25(2H, d, J=7 8.15 (1H, s))), as identified by direct comparisons with independently-prepared samples (mixed-mp, IR and NMR spectra, and glc). The latter fraction of the chromatography yielded a colorless oil (220 mg) which was deduced to be XI (Found: mol. wt.=217.0781 (M^+). Calcd for $C_{12}H_{11}O_3N$: 217.0789. $\delta^{25°C}_{(CD_3)_2SO}$: 8.29(1H, s) for XIa and 8.60(1H, s) for XIb (a : b=1 : 6). $\delta^{100°C}_{(CD_3)_2SO}$: 8.55(1H, s). *ν*: 1800, 1700, 1620, and 1500 cm^{-1}).

b) Similarly, II (118 mg) was oxidized in ethanol at 10—15 °C to give IX (43 mg), X(300 mg), XI(330 mg), and

XII (118 mg, colorless needles) (mp 47—48 °C (lit,[11] 46—47 °C) (δ: 1.38(3H, t), 4.34(2H, q), 4.51(2H, d, J=6.2 Hz), ~1.3(1H, br.), and 7.32(5H, s))), (which was identified by means of a mixed-mp test as well as by spectral comparisons with an authentic sample), and XIII (172 mg, a colorless oil) (δ: 1.23(3H, t), 4.15(2H, q), 4.35(2H, q, J=6.2 Hz), 5.0(1H, br.), and 7.30(5H, s)), which was identical with an authentic sample (IR and MNR analysis).

Photooxidation of 3-Hydroxypyridine (III). III (1.0 g) was dissolved in ethanol (50 ml) and similarly irradiated at 10—15 °C. After 67 hr, the resulting mixture was chromatographed through a silica-gel column to give VIIa (17 mg), XIV (28 mg), and XV (25 mg). They were all found to be identical with authentic samples by IR and NMR spectral comparisons as well as by glc analysis.

Attempted Transformation of IV and IX under the Reaction Conditions. Authentic IV (200 mg) and IX (140 mg) were separately dissolved in ethanol (each 80 ml) and irradiated for 48 hr at room temperature under an oxygen stream with methylene blue. By the usual subsequent work-up, IV and IX were recovered quantitatively.

Further Oxidation of VI in an Ethanol Solution. VI (510 mg) was irradiated for 16 hr under an oxygen stream. Despite extensive fractionation by silica-gel column chromatography, no isolable product was obtained.

Further Oxidation of XI in Ethanol. XI (170 mg) was dissolved in ethanol (50 ml) and was irradiated for 21 hr under conditions similar to those of its formation. A careful fractionation of the reaction mixture by silica-gel column chromatography gave only the recovered XI quantitatively.

Attempted Autooxidation of I. I (500 mg) was dissolved in chloroform or ethanol, into which an oxygen stream was introduced for 84 hr at room temperature (with or without Methylene Blue). By a work-up similar to the one described above, unreacted I was recovered in a quantitative yield.

We wish to thank The Ministry of Education for its financial support.

Chemistry of α-Haloaldehyde. VI.* Reaction of 2-Chloro-2-methylpropanal with Benzoylacetonitrile in the Presence of Potassium Carbonate

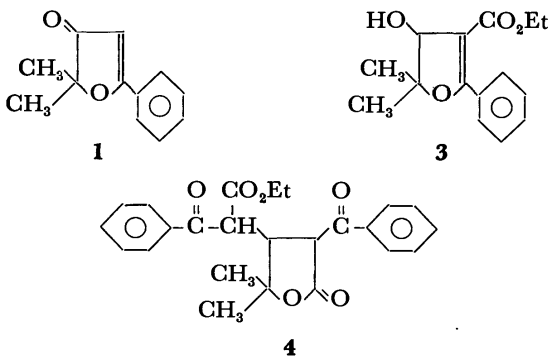
Akira TAKEDA, Sadao TSUBOI, and Takashi SAKAI

Department of Synthetics Chemistry, School of Engineering, Okayama University, Tsushima, Okayama 700

(Received March 30, 1974)

The reaction of 2-chloro-2-methylpropanal with benzoylacetonitrile in aqueous K_2CO_3 has been studied. When 2-chloro-2-methylpropanal was added to a stirred suspension of benzoylacetonitrile in aqueous K_2CO_3, 2-hydroxy-3,3-dimethyl-4-cyano-5-phenyl-2,3-dihydrofuran (**7**) was obtained. The oxidation of **7** with CrO_3 gave α,α-dimethyl-β-cyano-γ-phenyl-$\Delta^{\beta,\gamma}$-butenolide (**8**). When benzoylacetonitrile was added to a suspension of 2-chloro-2-methylpropanal in aqueous K_2CO_3 stirred beforehand for 60 min, the reaction proceeded in a different manner to give the enol tautomer (**9b**) of 2,4-dibenzoyl-3-(α-hydroxyisopropyl)glutaronitrile (**9a**) at room temperature, and 2,2-dimethyl-3-(α-carbaminophenacyl)-4-cyano-5-phenyl-2,3-dihydrofuran (**11**) at 80—90 °C. The alkaline hydrolysis of the nitrile **9** conducted at 70 °C also afforded the amide **11**. The nitrile **9** eliminated one mol of benzoylacetonitrile on treatment with H_2SO_4 to afford 2,2-dimethyl-3-hydroxy-4-cyano-5-phenyl-2,3-dihydrofuran (**12**). Chromic acid oxidation of **12** gave 2,2-dimethyl-3-oxo-4-cyano-5-phenyl-2,3-dihydrofuran (**14**), which can be derived from bullatenone in two steps. Structures of compounds **11**, **12**, and **14**, which all possess 2,2-dimethyl-4-cyano-5-phenyl-2,3-dihydrofuran ring, have been confirmed and well correlated by both chemical transformations and spectral data.

The synthesis of bullatenone (2,2-dimethyl-3-oxo-5-phenyl-2,3-dihydrofuran) (**1**) has been carried out.[1,2] Studies on the reaction of 2-halo-2-methylpropanal (**2**)[3,4] with active methylene compounds show that in contrast to reactions under nonaqueous conditions, undergoing S_N2-type substitution at the α carbon of **2**, the enolate anion attacks the carbonyl carbon of **2** in aqueous media. It was thought that the base-catalyzed condensation of **2** with ethyl benzoylacetate in an aqueous solution of K_2CO_3 might turn out to be a new route for obtaining 3-hydroxydihydrofuran **3**, which is expected to be readily oxidized to bullatenone. However, it gave only α-benzoyl-β-benzoylethoxycarbonylmethyl-γ-butyrolactone (**4**).[4] It appears that the extraordinarily facile lactonization of the aldol-type product interrupted the formation of **3**. Such a breakdown could be evaded by starting from benzoylacetonitrile (**5**) in place of ester, since the aldol-type product in this case is incapable of lactonization. We report the result of the title reaction conducted under several basic conditions in aqueous media. Structural assignments were made based on spectral data and microanalysis.



1 **3** **4**

Results and Discussion

When 2-chloro-2-methylpropanal (**2a**) was added to a stirred suspension of benzoylacetonitrile (**5**) in an aqueous solution of K_2CO_3, 2-hydroxy-3,3-dimethyl-4-cyano-5-phenyl-2,3-dihydrofuran (**7**) was obtained in a 72% yield. This indicates that a nucleophilic substitution occurred at the α carbon of **2a** to give the 1,4-dioxo compound **6** as an intermediate, which immediately tautomerized to the cyclic hemiacetal **7**. Compound **7** is more stable against heating as compared with the corresponding ester and resists ring-opening on distillation.[5] The oxidation of **7** with CrO_3 gave α,α-dimethyl-β-cyano-γ-phenyl-$\Delta^{\beta,\gamma}$-butenolide (**8**) in an 81% yield. NMR spectrum ($CDCl_3$) of **8** showed a simple pattern exhibiting a singlet at δ 1.55 ppm due to α,α-dimethyl protons and a multiplet (5H) at δ 7.2—8.0 ppm due to phenyl protons. Its IR spectrum showed characteristic bands at 2240 and 1830 cm^{-1} due to β-cyano-$\Delta^{\beta,\gamma}$-butenolide structure. The reaction sequence of the formation of compounds **7** and **8** is shown in Scheme 1.

The reaction proceeded quite differently when nitrile **5** was added to a suspension of **2a** in an aqueous solution of K_2CO_3, which was stirred beforehand for at least 60 min (Scheme 2). The reaction carried out in this way at room temperature gave the enol tautomer of 2,4-dibenzoyl-3-(α-hydroxyisopropyl)glutaro-

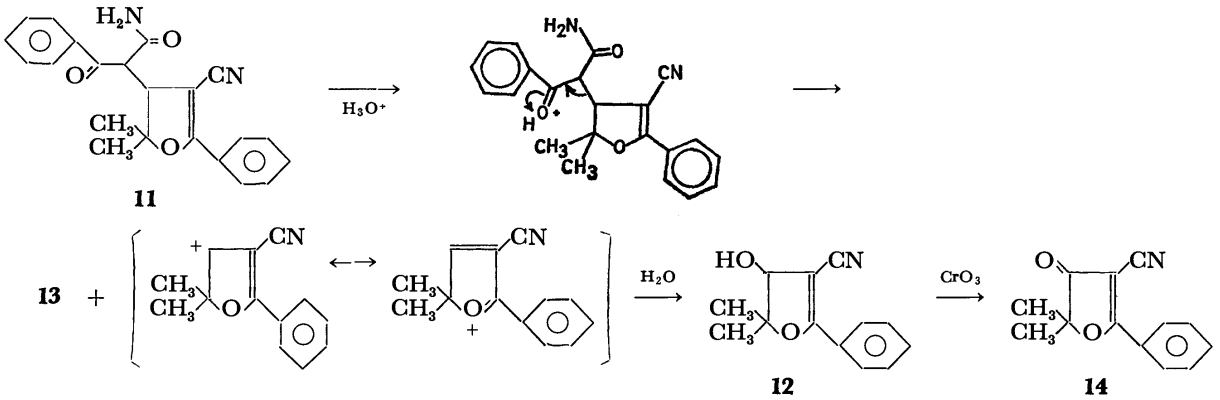
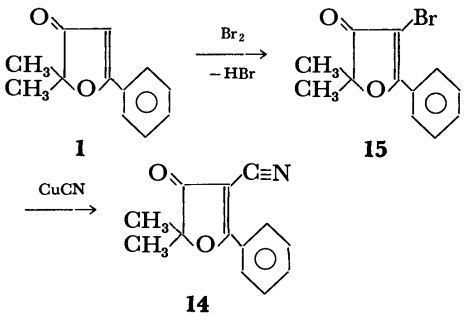


Scheme 3.

nitrile (**9**) in an 81% yield, whereas a similar reaction conducted at 80—90 °C afforded 2,2-dimethyl-3-(α-carbaminophenacyl)-4-cyano-5-phenyl-2,3-dihydrofuran (**11**) in a 48% yield together with a small amount of α-benzoyl-γ,γ-dimethyl-$\Delta^{\alpha,\beta}$-butenolide (11%).[5] NMR spectrum [$(CD_3)_2SO$] of the nitrile **9** exhibited two doublets at δ 3.11 and 4.21 ppm (1H each, J= 13 Hz, β-methine proton and α-methine proton), and singlets at 3.20 and 11.8 ppm (1H each, 2 OH), respectively. These signals indicate that one of two benzoyl groups of **9** has been enolized, since otherwise a more complex pattern due to three methine protons coupled to each other should be observed. On the other hand, NMR spectrum [$(CD_3)_2SO$] of the amide **11** showed two singlets at δ 1.01 and 1.40 ppm due to 2,2-dimethyl protons, and one singlet at δ 3.30 ppm due to amide protons. Signals due to two methine protons of this compound appeared at δ 5.02 ppm (d, 1H, J=11 Hz, β-methine proton) and 5.38 ppm (d, 1H, J=11 Hz, α-methine proton), respectively. The amide **11** can be prepared also by treating **9** with an aqueous solution of K_2CO_3 at 70 °C in an 88% yield. Since **9** does not show any tendency to cyclize to dihydrofuran structure, compound **11** is thought to be derived from amide **10**, which was produced from **9** by the saponification of its cyano group.

Treatment of **9** with concentrated H_2SO_4 caused elimination to yield 2,2-dimethyl-3-hydroxy-4-cyano-5-phenyl-2,3-dihydrofuran (**12**) and benzoylacetamide (**13**) in 69% and 78% yields, respectively. A probable mechanism of this acid-catalyzed elimination is given in Scheme 3. The chromic acid oxidation of **12** afforded 2,2-dimethyl-3-oxo-4-cyano-5-phenyl-2,3-dihydrofuran (**14**). This ketone has been prepared by an alternative way starting from bullatenone (**1**). The direct bromination of **1** gave 2,2-dimethyl-3-oxo-4-bromo-5-phenyl-2,3-dihydrofuran (**15**) in good yield (91%). The treatment of **15** with CuCN afforded **14** in a 24% yield.



It is assumed that 2-hydroxy-2-methylpropanal (**2b**) acts as the real substrate of the reaction when nitrile **5** was added to **2a** treated beforehand with an aqueous solution of K_2CO_3, since 2-halo-2-methylpropanal promptly undergoes displacement of halogen to give **2b**.[6] The fact that the reaction of **2b** and **5** carried out at 60 °C in an aqueous solution of K_2CO_3 also gave **11** in a 55% yield supports the assumption.

Experimental

General. Melting points and boiling points are uncorrected. The infrared spectra were recorded on a Hitachi EPI-S2 model spectrophotometer. NMR spectra (60 MHz) were taken on a Hitachi R-24 model spectrometer, and MS spectra were obtained on a Hitachi RMS-4 model mass spectrometer. Analytical thin layer chromatography (tlc) was carried out using silica gel GF_{254} (E. Merck AG, Darmstadt). Preparative tlc was carried out on silica gel PF_{254} (E. Merck AG). Microanalyses were carried out by Mr. Eiichiro Amano of our laboratory. Starting materials such as 2-chloro-2-methylpropanal (**2a**),[7] 2-hydroxy-2-methylpropanal (**2b**)[8] were prepared by the procedures in literature.

2-Hydroxy-3,3-dimethyl-4-cyano-5-phenyl-2,3-dihydrofuran (7). To a solution of 4.8 g (0.0345 mol) of potassium carbonate in 12 ml of water was added 5 g (0.035 mol) of **5** at room temperature. To the resulting mixture was added 3.3 g (0.031 mol) of **2a** with ice bath cooling. The mixture was stirred at room temperature for 2 hr, and then at 60 °C for 3 hr. It was poured into a large amount of water and extracted with ether. The ethereal extract was washed several times with water and dried over Na_2SO_4. Removal of the solvent left 7 g of a brown oil which, on distillation, gave 4.8 g (72%) of **7**: bp 144—148 °C/0.16 mmHg; mp 75—76 °C (petroleum ether–benzene–ethanol); IR (nujol) 3420 (OH), 2200 (CN), 1615 (C=C), 1600 and 1575 cm^{-1} (benzene C=C); NMR ($CDCl_3$) δ 1.30 (s, 6H, $2CH_3$), 4.35 (broad s, 1H, OH), 5.60 (s, 1H, >CH(OH)), 7.26—8.02 (m, 5H, C_6H_5); MS (70 eV) *m/e* (rel. intensity) 215 (14, M^+), 200 (8, M^+-CH_3), 186 (43), 172 (9), 154 (14), 105 (100, PhCO), 77 (74, C_6H_5). Found: C, 72.59; H, 6.05; N, 6.81%. Calcd for $C_{13}H_{13}NO_2$: C, 72.54; H, 6.09; N, 6.51%.

α,α-Dimethyl-β-cyano-γ-phenyl-$\Delta^{\beta,\gamma}$-butenolide (8). To a mixed solution of 0.62 g (0.0029 mol) of **7** in 5 ml of aqueous 50% acetic acid was added 0.32 g (0.0032 mol) of chromium trioxide in several portions, with moderate cooling. The mixture was stirred for 2.5 hr at room temperature. The reaction mixture was diluted with 5 ml of water and then extracted with ether. The ethereal extract was washed with water and dried over Na_2SO_4. Removal of the solvent left 0.50 g (81%) of **8**: mp 95—95.5 °C (petroleum ether–benzene); IR (neat) 2240 (CN), 1830 (lactone C=O), 1640 cm^{-1} (conjugated C=C); NMR (CCl_4) δ 1.55 (s, 6H, $2CH_3$), 7.20—8.00 (m, 5H, C_6H_5); MS (70 eV) *m/e* (rel. intensity) 213 (50, M^+), 198 (85, M^+-CH_3), 184 (40, $M^+-C_2H_5$), 171 (34), 157 (8), 143 (8), 122 (31), 105 (100, PhCO), 77 (87, C_6H_5).

Found: C, 73.41; H, 5.08; N, 6.61%. Calcd for $C_{13}H_{11}NO_2$: C, 73.23; H, 5.20; N, 6.57%.

Enol Tautomer (9b) of 2,4-Dibenzoyl-3-(α-hydroxyisopropyl)-glutaronitrile (9a). To a solution of 2.5 g (0.017 mol) of potassium carbonate in 10 ml of water was added 1.85 g (0.017 mol) of **2a**. After the mixture was stirred for 1 hr at room temperature, 4.0 g (0.028 mol) of **5** was added and the stirring was continued for 17 hr. The semisolid material separated was collected by filtration and washed with 10% HCl and with ether successively to give 2.4 g (81%) of **9b**, white crystal: mp 178—178.5 °C (acetone); IR (KBr) 3300 (broad, OH), 2980, 2200 (CN), 1700 (m, C=O), 1630 (s, C=C, C=O), 1600 (w), 1350, 1240, 1050, 765, 700 cm^{-1}; NMR [$(CD_3)_2SO$] δ 1.33 (s, 3H, CH_3), 1.57 (s, 3H, CH_3), 3.11 (d, 1H, J=13 Hz, β-methine proton), 3.20 (broad s, 1H, OH), 4.21 (d, 1H, J=13 Hz, α-methine proton), 7.10—7.83 (m, 10H, $2C_6H_5$), 11.80 (broad s, 1H, enolic OH); MS (70 eV) *m/e* (rel. intensity) 343 (0.1), 342 (0.1). 317 (0.2), 302 (0.2), 198 (3), 197 (2.6), 172 (4.4), 149 (9), 145 (5), 122 (4), 105 (100, PhCO), 77 (79, C_6H_5).

Found: C, 73.39; H, 5.88; N, 7.47%. Calcd for $C_{22}H_{20}N_2O_3$: C, 73.32; H, 5.59; N, 7.77%.

2,2-Dimethyl-3-(α-carbaminophenacyl)-4-cyano-5-phenyl-2,3-dihydrofuran (11). (a) From 2a and 5. A mixed solution of **2a** (0.107 g, 0.001 mol) and potassium carbonate (0.138 g, 0.001 mol) in 1 ml of water was stirred for 30 min at room temperature. To the resulting suspension was added 0.145 g (0.001 mol) of benzoylacetonitrile. After being stirred at room temperature for 2 hr and at 80—90 °C for an additional 3 hr, the mixture was acidified with 10% HCl. After addition of a small amount of ether, the precipitated crystals of **11** (0.0445 g, 25%) were collected by filtration: mp 230 °C (THF); IR (KBr) 3450 (sharp, NH_2), 2230 (w, CN), 1685 (s, C=O), 1640 (m, C=C), 1604 and 1584 (benzene ring), 780, 700 cm^{-1}; NMR [$(CD_3)_2SO$] δ 1.01 (s, 3H, CH_3), 1.40 (s, 3H, CH_3), 3.30 (s, 2H, $CONH_2$), 5.02 (d, 1H, J=11 Hz, β-methine proton), 5.38 (d, 1H, J=11 Hz, α-methine proton), 7.30—8.30 (m, 10H, $2C_6H_5$); MS (70 eV) *m/e* (rel. intensity) 343 (0.2), 317 (3), 302 (8), 197 (3), 195 (6), 122 (33), 105 (100, C_6H_5CO), 77 (67, C_6H_5).

Found: C, 73.50; H, 5.63; N, 7.67%. Calcd for $C_{22}H_{20}N_2O_3$: C, 73.32; H, 5.59; N, 7.77%.

Tlc analysis (*n*-hexane : acetone, 1 : 1) of the residue (0.077 g) recovered from the filtrate showed three spots at R_f values 0.48, 0.57, and 0.66 (content ratio in wt, 12 : 42 : 23). Component with R_f value 0.57 and that with R_f value 0.66 were identified as **11** (23%)[9] and α-benzoyl-γ,γ-dimethyl-$\Delta^{\alpha,\beta}$-butenolide[5] (11% yield), respectively, by the identities of the spectral data with those of authentic samples.

(b) From 9b. A mixed solution of **9b** (0.067 g, 0.19 mmol) and potassium carbonate (0.068 g, 0.49 mmol) in water (1 ml) was stirred for 3 hr at 70 °C. After being acidified with 10% HCl, the mixture was extracted with ether. White crystals (0.031 g) precipitated were collected and identified as **11** by comparison of its IR spectrum with that of an authentic sample. From the ethereal layer, additional amount (0.040 g) of crude product with 70% purity by tlc analysis (*n*-hexane : acetone, 1 : 1) was obtained, total yield 88%.

(c) From 2b and 5. To a solution of 0.106 g (0.76 mmol) of potassium carbonate in 0.45 ml of water was added 0.11 g (0.76 mmol) of **5**. After the mixture was stirred for 1 hr, 0.081 g (0.76 mmol) of **2b** was added. It was stirred at room temperature for 2 hr, and at 60—65 °C for 3 hr, and then acidified with dilute HCl. The crude product was collected and washed with ether to give 0.15 g (55%) of **11**: mp 230 °C (acetone).

2,2-Dimethyl-3-hydroxy-4-cyano-5-phenyl-2,3-dihydrofuran (12). The nitrile **9** (0.24 g, 0.67 mmol) was dissolved in 6 ml of concd H_2SO_4. After being allowed to stand for one day at room temperature, the solution was poured into 50 ml of ice-water. The organic layer was extracted with ether and dried over $MgSO_4$. After removal of the solvent, residual semisolid (0.018 g) was obtained. Tlc analysis (*n*-hexane : acetone, 2 : 1) of this solid showed two spots at R_f values 0.07 and 0.26 (content ratio in wt, 44 : 56). Component with R_f value 0.07 was collected by preparative tlc and iden-

tified as benzoylacetamide (**13**), 78% recovery: mp 111—112 °C (acetone) (lit,[10] mp 112—113 °C). IR and NMR spectra were identical with those of the authentic sample obtained by the treatment of benzoylacetonitrile with concd H_2SO_4: IR (KBr) 3400 and 3170 (NH and enolic OH), 1670 and 1630 (C=O), 1595 and 1575 (benzene C=C), 1390, 800, 760, 690 cm^{-1}: NMR[11] [$(CD_3)_2SO$] δ 2.85 (broad s, NH_2), 3.99 (s, $-CH_2CO$), 5.88 (s, enolic >C=CH–), 7.30—8.18 (m, C_6H_5), 15.10 (broad s, enolic OH).

Component with R_f value 0.26 collected by preparative tlc was microdistilled at 150 °C under 0.05 mmHg with a bath, and identified as **12**, yield 69%: IR (neat) 3450 (OH), 2200 (CN), 1625 (C=C), 1575 (benzene C=C), 1495, 1115, 1070, 875, 820, 780, 695 cm^{-1}; NMR [$(CD_3)_2C=O$] δ 1.43 (s, 3H, CH_3), 1.50 (s, 3H, CH_3), 4.71 (d, 1H, J=8 Hz, OH), 4.85 (d, 1H, J=8 Hz, >CHOH), 7.40—8.10 (m, 5H, C_6H_5); MS (70 eV) *m/e* (rel. intensity) 215 (40, M^+), 188 (34), 156 (26), 141 (40), 128 (50), 105 (100), 77 (78), 59 (68).

Found: C, 72.70; H, 6.33; N, 6.31%. Calcd for $C_{13}H_{13}NO_2$: C, 72.54; H, 6.09; N, 6.51%.

*2,2-Dimethyl-3-oxo-4-cyano-5-phenyl-2,3-dihydrofuran (**14**).* *(a) From **12**.* To a mixture of 0.1 ml of 70% acetic acid and 0.04 g (0.4 mmol) of chromium trioxide was added 0.042 g (0.2 mmol) of **12** in several portions at 0 °C. The mixture was stirred for 2 hr at room temperature and then for 1 hr at 60 °C. The mixture was poured into 1 ml of water and the organic layer was extracted with ether, washed with water, and dried over $MgSO_4$. After removal of the solvent, 0.022 g of the residual oil was obtained. Tlc analysis (*n*-hexane : acetone, 2 : 1) of this oil showed two spots at R_f values 0.3 and 0.5 (content ratio in wt, 1 : 3). The component of R_f value 0.5 collected by preparative tlc was recrystallized from the mixed solvent of *n*-hexane and ether to give 0.017 g (40%) of **14**: mp 122—124 °C; IR (KBr) 2200 (CN), 1705 (C=O), 1590 (benzene ring), 1560 (C=C), 1395, 1215, 900 (C–O), 765 and 695 cm^{-1} (monosubstituted benzene); NMR ($CDCl_3$) δ 1.57 (s, 6H, $2CH_3$), 7.40—8.45 (m, 5H, C_6H_5); MS (70 eV) *m/e* (rel. intensity) 213 (22, M^+), 149 (10), 127 (100), 105 (11, C_6H_5CO), 77 (11, C_6H_5).

Found: C, 72.85; H, 5.28; N, 6.86%. Calcd for $C_{13}H_{11}NO_2$: C, 73.23; H, 5.20; N, 6.57%.

*(b) Synthesis from 2,2-Dimethyl-3-oxo-4-bromo-5-phenyl-2,3-dihydrofuran (**15**).* In a hood, a stirred suspension of 0.18 g (0.66 mmol) of **15** and 0.069 g (0.76 mmol) of cuprous cyanide in 1 ml of dry DMF was heated at 80 °C for 4 hr, and finally at 150 °C for 20 min. A solution of 2 g of ferric chloride in 4 ml of 5% HCl was added to the reaction mixture, which was then stirred for 20 min at 60 °C to decompose the complex. Ethereal extract of the organic layer was washed with water and dried over $MgSO_4$. After removal of the solvent, 0.146 g of a solid was obtained. Tlc analysis (*n*-hexane : acetone, 2 : 1) of this solid showed the presence of two spots at R_f values 0.42 and 0.49. Preparative tlc of the component with the R_f value 0.42 gave 0.034 g (24%) of a crystal, which was identified as **14** by comparison of IR spectrum with that of the authentic sample. The component with the R_f value 0.49 was collected similarly and identified as **15**.

*2,2-Dimethyl-3-oxo-4-bromo-5-phenyl-2,3-dihydrofuran (**15**).* To a stirred suspension of 0.38 g (2 mmol) of **1**[1] in 2 ml of water was added 0.51 g (3.2 mmol) of bromine dropwise at 80 °C. The mixture was stirred for 15 min at 90 °C. Removal of the solvent left 0.49 g (91%) of **15**: mp 66—67 °C (*n*-hexane): IR (KBr) 1700 (C=O), 1602 and 1583 (benzene ring), 1559 cm^{-1} (C=C); NMR ($CDCl_3$) δ 1.51 (s, 6H, $2CH_3$), 7.40—8.30 (m, 5H, C_6H_5); MS (70 eV) *m/e* (rel. intensity) 266 (68, M^+, 1Br), 187 (8, M^+-Br), 180 (22, $C_6H_5C{-}CBr$, 1Br), 129 (100, $C_6H_5C=C=C=O$).

Found: C, 53.97; H, 3.96%. Calcd for $C_{12}H_{11}O_2Br$: C, 53.95; H, 4.31%.

Reactions of Aryliminotriphenylphosphoranes with Sulfenes

Takayuki KAWASHIMA and Naoki INAMOTO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received May 9, 1974)

Aryliminotriphenylphosphoranes reacted with methanesulfonyl, ethanesulfonyl and α-toluenesulfonyl chlorides in the presence of triethylamine to give 1 : 2 adducts [α-(*N*-alkanesulfonyl-*N*-arylsulfamoyl)alkylidenephosphoranes] and the decomposition products, instead of 1 : 1 adducts [α-(*N*-arylsulfamoyl)alkylidenephosphoranes). They were obtained under ice-cooling, the structure being of betaine type. In the case of methanesulfonyl chloride, isomeric 1 : 2 adduct [α-(*N*-arylsulfamoyl)methanesulfonylmethylenephosphorane] was also obtained. 2-Propanesulfonyl chloride gave *N*-triphenylphosphonio-*N*-arylsulfamate instead of expected adduct. In the absence of triethylamine, α-(*N*-arylsulfamoyl)alkyltriphenylphosphonium chlorides were obtained in good yields. Possible mechanisms of these reactions have been discussed.

In a previous paper,[1] we reported that reactions of arylimino- and acylmethylenetriphenylphosphoranes with benzenediazonium-2-carboxylate take place in a different manner. Ito *et al.*[2] reported the formation of alkanesulfonylmethylenephosphoranes (1 : 1 adduct) and episulfones or the decomposition products (*i.e.*, olefins) in the reactions of alkylidenephosphoranes with sulfene (CH_2=SO_2). Hamid and Trippett[3] obtained a similar 1 : 1 adduct in the reaction with phenylsulfene.

We have carried out the reactions of aryliminophosphoranes with sulfenes in order to compare them with reactions of alkylidenephosphoranes. Slightly different results were obtained.

Reactions with Unsubstituted Sulfene. When aryliminotriphenylphosphoranes (**1**) were allowed to react with two equivalents of sulfene generated from methanesulfonyl chloride (**2a**) and triethylamine at room temperature, *N*-aryl-*N*-methanesulfonylsulfamoylmethylenetriphenylphosphoranes (**3**), α-(*N*-arylsulfamoyl)-methanesulfonylmethylenetriphenylphosphoranes (**4**), which is an isomer of **3**, and triphenylphosphoniomethanesulfonate (**5**) were obtained in the yields shown in the following chart.

$$Ph_3P{=}N\text{-}Ar + 2\,MeSO_2Cl + 2\,Et_3N \rightarrow$$
1 **2a**

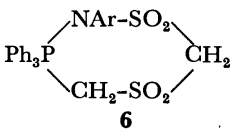
a, Ar=Ph
b, Ar=*p*-MeC_6H_4

$$Ph_3P{=}CHSO_2NAr\text{-}SO_2Me + Ph_3P{=}C(SO_2Me)SO_2NHAr + Ph_3\overset{+}{P}CH_2SO_3^-$$

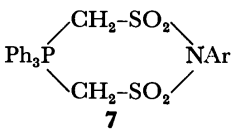
	3	**4**	**5**
a	54%	38%	6%
b	38%	33%	16%

The structures of **3**, **4** and **5** were determined by elemental analyses, IR, NMR and MS spectra.

The NMR spectrum of **3a** showed a singlet peak at δ 3.20 ($MeSO_2$) and a doublet at δ 3.45 (J_{PCH} 12 Hz, disappeared by D_2O). The ^{31}P-NMR spectrum of **3b** exhibited a signal at δ_p −14.4 ppm (from 85% H_3PO_4 as an external standard). The data support the phosphorane structure (**3**), ruling out the exclusively cyclic structures **6** and **7**.



6



7

The IR spectra of **4** showed an NH absorption band at about 3300 cm^{-1}.

The structures are also supported by the following reactions. By chromatography on silica gel, **3a** was partially hydrolyzed to triphenylphosphine oxide (**8**) and bis(methanesulfonyl)anilide (**9**), mp 195—196 °C, which was in agreement with that of an authentic sample prepared from aniline and excess of **2a**. Reaction of **3b** with *p*-nitrobenzaldehyde gave the corresponding olefin (**10**) and **8** in 38 and 41% yields, respectively.

p-$NO_2C_6H_4$-CH=CH-SO_2-N(SO_2Me)-C_6H_4Me-*p*

10

The presence of NH group in **4b** was confirmed by *N*-methylation to the *N*-methyl derivative (**11**).

$Ph_3P{=}C(SO_2Me)\text{-}SO_2NMe\text{-}C_6H_4Me\text{-}p$

11

The spectral data and melting point of **5** were in agreement with those of an authentic sample prepared from methylenetriphenylphosphorane with sulfur trioxide according to the method of Nesmeyanov *et al.*[4]

Equimolar reaction of **1a** and sulfene also gave 1 : 2 adducts (**3a** and **4a**) at room temperature, but a 1 : 1 adduct (**12a**) by slow addition of **2a** under cooling with ice. However, **12a** could not be obtained in a pure state, because of easy hydrolysis in solution to **8** and methanesulfonylanilide (**13a**).

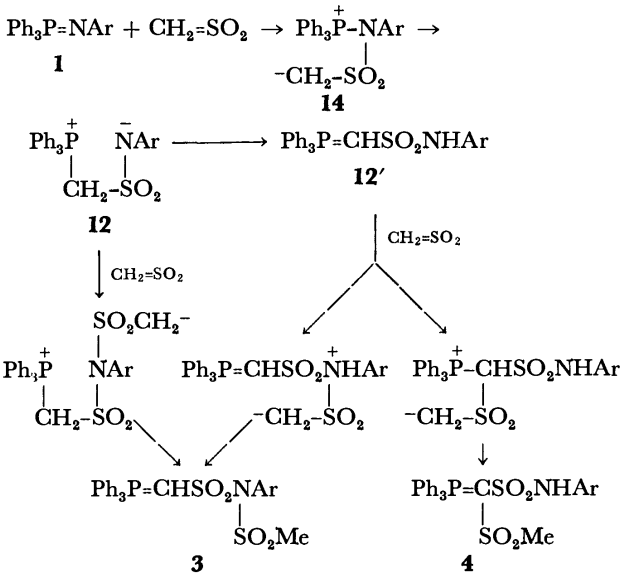
The MS spectrum of **12a** showed a parent peak at *m/e* 431. The absence of NH absorption band in the IR spectrum and the presence of a broad singlet at δ 4.30 (2H) in the NMR spectrum supported the betaine structure (**12a**) rather than a phosphorane structure (**12'a**).

$$Ph_3P{=}NPh + CH_2{=}SO_2 \rightarrow Ph_3\overset{+}{P}\text{-}\overset{-}{C}H_2SO_2NPh \xrightarrow{H_2O}$$
1a **12a**

$$Ph_3PO + MeSO_2NHPh \qquad Ph_3P{=}CHSO_2NHPh$$
8 **13a** **12'a**

Crude **12a** was allowed to react with sulfene to give 1 : 2 adducts **3a** and **4a** in 38 and 26% yields, respectively. The ratio of yield of **3a** to that of **4a** is 1.46, which is nearly equal to that in the above-mentioned 1 : 2 molar reaction (1.42). This indicates that **12a** is regarded as an intermediate in the formation of **3a** and **4a**.

Thus, the following mechanism is suggested.



The first step is supported by the fact that benzoyliminophosphorane did not react with sulfenes, because of the low electron density on the nitrogen atom.

On the other hand, the ratio of yield of **3b** to that of **4b** was 1.15 in the case of **1b**. This value was inconsistent with an expectation (above 1.42) on the basis of the presence of electron-donating methyl group, but the yield of **5** from **1b** was larger than that from **1a**. It is thus suggested that **5** is formed by the hydrolysis of **3b** during the treatment.

No nucleophilic attack of the carbanion center in **14** on the nitrogen atom gave triphenylphosphine and thiaziridine 1,1-dioxide or Schiff's base. This is a different case from that of alkylidenephosphoranes having no α-hydrogen,[2] and might be attributed to a greater stabilization of betaine (**12**) than that of carbon analogues, because of more electronegative nitrogen.

Reactions with Monosubstituted Sulfenes. Reaction of **1b** with phenylsulfene, generated from α-toluenesulfonyl chloride (**2b**) and triethylamine, gave 1 : 2 adduct (**3c**) and a betaine (**15c**) in 26 and 44% yields, respectively. Chromatography of the residue gave α-toluenesulfonyl-*p*-toluidide (**13c**) and **8** in 66 and 24% yields, respectively.

$$\underset{\mathbf{1}}{Ph_3P{=}NAr} + 2\,RCH_2SO_2Cl + 2\,Et_3N \rightarrow \underset{\mathbf{2}}{}$$

a, Ar=Ph b, R=Ph
b, Ar=*p*-MeC_6H_4 c, R=Me

$$Ph_3P{=}CR{-}SO_2NAr{-}SO_2CH_2R + RCH_2SO_2NHAr$$
$$\mathbf{3} \qquad\qquad \mathbf{13}$$

c, Ar=*p*-MeC_6H_4, R=Ph;
d, Ar=Ph, R=Me

$$+\ Ph_3\overset{+}{P}{-}CHR{-}SO_3^- + Ph_3PO$$
$$\mathbf{15} \qquad\quad \mathbf{8}$$

c, R=Ph

Betaine (**15c**) precipitated from the filtrate on standing was insoluble in usual organic solvents, suggesting that it was formed during the treatment. Formation of **13c** and **8** also suggests that these compounds are hydrolyzed products of **3c**.

Thus, **3b** was heated in aqueous ethanol as a model compound, but was recovered unchanged. When hydrogen chloride gas was bubbled into **3b** in chloroform, **5** and **13b** (R=H, Ar=*p*-MeC_6H_4) were obtained almost quantitatively. Thus, it seems reasonable to consider that **5** or **15** and **13** are formed by acid-catalyzed hydrolysis of **3**, where acid is probably sulfonic acid produced during treatment. The first step is considered to be protonation at the α-carbon of **3b**, because the NMR spectrum of **3b** containing hydrogen chloride gas showed a doublet (δ 6.20, J_{PCH} 12 Hz) assignable to α-methylene protons of the corresponding phosphonium chloride, which is hydrolyzed easily because of the presence of positively charged phosphorus atom.

In the case of reaction of **1a** with methylsulfene, only 1 : 2 adduct (**3d**) was obtained in 34% yield as an identified product.

Reaction with Disubstituted Sulfene. Reactions of dimethylsulfene as a disubstituted sulfene with **1a** and **1b** gave only *N*-triphenylphosphonio-*N*-phenylsulfamate (**16a**) and -*N*-*p*-tolylsulfamate (**16b**) in 45 and 44% yields, respectively, as identified products.

$$\underset{\mathbf{1}}{Ph_3P{=}NAr} + Me_2C{=}SO_2 \rightarrow \underset{\mathbf{16}}{Ph_3\overset{+}{P}{-}NAr{-}SO_3^-}$$

a, Ar=Ph; b, Ar=*p*-MeC_6H_4

The structures were determined by elemental analyses, IR, ^1H- and ^{31}P-NMR spectra. The ^1H-NMR spectrum of **16b** showed A_2B_2 spin system (J 8.4 Hz) for four aromatic protons of *p*-tolyl group. The ^{31}P-NMR spectrum of **16a** showed a signal at δ_p −39 ppm, which is nearly equal to that of anilinotriphenylphosphonium chloride (δ_p −34 ppm[5]). However, **16** was stable against alkaline hydrolysis.

For the preparation of **16a**, **1a** was allowed to react with sulfur trioxide, but an isomeric betaine (**17**) was obtained in 58% yield. The alkaline hydrolysis gave sodium sulfanilate and **8**.

$$\underset{}{Ph_3P{=}NPh} + SO_3 \rightarrow \underset{\mathbf{17}}{Ph_3\overset{+}{P}{-}NHC_6H_4{-}SO_3^-{-}p}$$

The formation mechanism of **16** is obscure.

Reactions with Sulfonyl Chlorides in the Absence of Base. In the absence of triethylamine, reactions of iminophosphoranes (**1a,b**) with sulfonyl chlorides (**2a—c**) gave α-(*N*-arylsulfamoyl)alkyltriphenylphosphonium chlorides (**18**) in quantitative yields except for the case of **18c** (40% yield).

$$\underset{\mathbf{1}}{Ph_3P{=}NAr} + \underset{\mathbf{2}}{RCH_2SO_2Cl}$$

a, Ar=Ph a, R=H
b, Ar=*p*-MeC_6H_4 b, R=Ph

$$\underset{\mathbf{19}}{Ph_3\overset{+}{P}{-}NAr{-}SO_2CH_2R\ Cl^-}$$

$$\longrightarrow \underset{\textbf{18}}{Ph_3\overset{+}{P}\text{-}CHRSO_2NHAr\ Cl^-}$$

a, Ar=Ph, R=H
b, Ar=Ph, R=Ph
c, Ar=Ph, R=Me
d, Ar=*p*-MeC_6H_4, R=H

The spectral data showed evidence that these products have structure **18** instead of the expected structure **19**[6] which was synthesized from triphenylphosphine and the corresponding *N*-chloroamide. Their IR spectra showed very broad NH absorption bands at 2700—2810 cm^{-1}, and their NMR spectra exhibited signals due to methine or methylene protons coupling with phosphorus nucleus.

Reaction of **1a** with **2b** gave **18b** and anilinotriphenylphosphonium chloride in 46 and 28% yields, respectively, under conditions similar to those in the case of **2a**. Thus, the reaction mechanism is considered to be as follows.

$$\underset{\textbf{1}}{Ph_3P{=}NAr} + \underset{\textbf{2}}{RCH_2SO_2Cl} \rightarrow Ph_3\overset{+}{P}\text{-}NHAr\ Cl^- + RCH{=}SO_2$$

$$RCH{=}SO_2 \overset{\textbf{1}}{\rightarrow} Ph_3\overset{+}{P}\text{-}\overset{-}{C}HRSO_2NAr \rightarrow \underset{\textbf{20}}{Ph_3P{=}CRSO_2NHAr}$$

$$\textbf{20} + Ph_3\overset{+}{P}NHAr\ Cl^- \rightleftharpoons \underset{\textbf{18}\quad a,\ Ar=Ph;\quad b,\ Ar=p\text{-}MeC_6H_4}{Ph_3\overset{+}{P}\text{-}CHRSO_2NHAr\ Cl^-} + \textbf{1}$$

Namely, **1** acts also as a base to generate sulfenes from **2**. In the case of **2b**, the basicity of the phosphorane (**20**) is weak because of α-phenyl group and attainment of the equilibrium in the last step becomes slow.

These reactions are the first example of reaction of aryliminophosphoranes with sulfonyl chlorides and may be synthetically useful because of high yield and easy treatment.

Experimental

All melting and boiling points were uncorrected. IR and MS spectra were measured with a Hitachi EPI-G2 spectrophotometer and a Hitachi RMU-6L mass spectrometer, respectively. ^{1}H-NMR spectra were measured with Hitachi R-20B, R-24 and R-22 spectrometers using TMS as an internal standard. ^{31}P-NMR spectra were measured with Hitachi R-20-R-204-P and R-20B-R-204-PB spectrometers using 85% phosphoric acid as an external standard.

Materials. Aryliminotriphenylphosphoranes were prepared by the method of Horner and Oediger[7]: phenylimino- (**1a**), mp 128—131 °C, and *p*-tolyliminotriphenylphosphoranes (**1b**), mp 133—136 °C.

Methanesulfonyl, α-toluenesulfonyl and 2-propanesulfonyl chlorides were prepared by the procedures given in literature: methanesulfonyl,[8] bp 154—158 °C, α-toluenesulfonyl,[9] mp 92 °C, and 2-propanesulfonyl chlorides,[10] bp 80 °C/20 mmHg. Commercial ethanesulfonyl chloride and triethylamine were used without further purification.

*Reactions of Methanesulfonyl Chloride (**2a**) in the Presence of Triethylamine. a) With Phenyliminotriphenylphosphorane (**1a**)*: To **1a** (3.53 g, 10.0 mmol) and triethylamine (2.06 g, 20.3 mmol) in benzene (150 ml) was added dropwise **2a** (2.30 g, 20.2 mmol) in benzene (5 ml) with stirring at room temperature and the mixture was stirred overnight. The resulting precipitates were thoroughly washed with water and recrystallized from acetone to give **3a** (2.75 g, 54%), mp 198—199 °C(dec). IR (KBr): 1340, 1310 (*as*-SO_2), 1150 and 1130 cm^{-1} (*s*-SO_2); NMR ($CDCl_3$): δ 3.20 (s, 3H, SO_2Me), 3.45 (d, J_{PCH} 12 Hz, 1H, P=CH–, disappeared by D_2O), 7.0—7.2 (m, 5H, NPh), and 7.4—7.8 (m, 15H, Ph_3P).

Found: C, 61.42; H, 4.48; N, 2.82; S, 12.82%. Calcd for $C_{26}H_{24}NO_4PS_2$: C, 61.28; H, 4.75; N, 2.75; S, 12.58%.

Concentration of the mother liquor in the above recrystallization gave **4a**, mp 215—216 °C (dec) (from MeOH), yield 0.87 g. IR (KBr): 3300 (NH), 1335, 1285 (*as*-SO_2), 1150 and 1120 cm^{-1} (*s*-SO_2); NMR ($CDCl_3$): δ 2.98 (s, 3H, SO_2Me), 7.22 (s, 5H, NPh), and 7.38—7.73 (m, 15H, Ph_3P). No signal due to NH proton could be detected. HDO signal (1H) appeared at δ 4.65 by addition of D_2O.

Found: C, 61.28; H, 4.66; N, 2.59; S, 12.50%. Calcd for $C_{26}H_{24}NO_4PS_2$: C, 61.28; H, 4.75; N, 2.75; S, 12.58%.

From the filtrate of the reaction mixture, **5** precipitated on standing, mp 290—291 °C (from EtOH), yield 0.20 g (6%). IR (KBr): 1255 and 1240 cm^{-1} (SO_3^-); NMR (DMSO-d_6): δ 5.20 (d, J_{PCH} 13 Hz, 2H, CH_2), and 7.7—8.0 (m, 15H, Ph_3P).

Found: C, 63.97; H, 4.53; S, 9.06%; mol wt (Rast), 332. Calcd for $C_{19}H_{17}O_3PS$: C, 64.03; H, 4.81; S, 9.00%; mol wt, 356.

From the above filtrate, 1.07 g of **4a** was further obtained. Thus, the total yield of **4a** was 38%.

*b) With p-tolyliminotriphenylphosphorane (**1b**)*: A similar reaction using **1b** (5.50 g, 15 mmol), Et_3N (3.23 g, 32 mmol), and **2a** (3.65 g, 32 mmol) in benzene (200 ml) gave **3b** (3.00 g, 38%), **4b** (2.60 g, 33%), and **5** (0.86 g, 16%).

3b: mp 188—189 °C (dec) (from acetone); IR (KBr): 1340, 1300 (*as*-SO_2), 1160 and 1130 cm^{-1} (*s*-SO_2); ^{1}H-NMR ($CDCl_3$): δ 2.76 (s, 3H, C_6H_4Me), 3.21 (s, 3H, SO_2Me), 3.49 (d, J_{PCH} 12 Hz, 1H, P=CH–), 6.94 (s, 4H, C_6H_4Me), and 7.4—7.8 (m, 15H, Ph_3P); ^{31}P-NMR (DMF): δ_p −14.4 ppm; MS: *m/e* 523 (M^+).

Found: C, 61.65; H, 4.86; N, 2.38; S, 12.08%. Calcd for $C_{27}H_{26}NO_4PS_2$: C, 61.95; H, 4.95; N, 2.68; S, 12.24%.

4b: mp 194—195 °C (dec) (from benzene); IR (KBr): 3260 (NH), 1320, 1290 (*as*-SO_2), 1135 and 1125 cm^{-1} (*s*-SO_2); NMR ($CDCl_3$): δ 2.32 (s, 3H, C_6H_4Me), 2.95 (s, 3H, SO_2Me), 7.10 (m, 4H, C_6H_4), and 7.3—7.8 (m, 15H, Ph_3P). Signal due to NH proton was obscure.

Found: C, 62.19; H, 4.65; N, 2.82; S, 12.28%. Calcd for $C_{27}H_{26}NO_4PS_2$: C, 61.95; H, 4.95; N, 2.68; S, 12.24%.

*Reaction of **1b** with α-Toluenesulfonyl Chloride (**2b**) in the Presence of Triethylamine.* To a solution of **1b** (4.40 g, 12.0 mmol) and Et_3N (2.54 g, 25.2 mmol) in benzene (200 ml) was added dropwise **2b** (5.01 g, 25.8 mmol) in benzene (100 ml) and the mixture was stirred for 10 hr at room temperature. The resulting precipitates were washed with water and recrystallized from acetonitrile and then acetone to give **3c** (2.12 g, 26%), mp 177 °C (dec). IR (KBr): 1350, 1265 (*as*-SO_2), 1190 and 1165 cm^{-1} (*s*-SO_2); NMR ($CDCl_3$): δ 2.05 (s, 3H, C_6H_4Me), 4.30 (s, 2H, SO_2CH_2), 6.60 (s, 4H, NC_6H_4Me), and 6.8—8.0 (m, 25H, 5Ph).

Found: C, 69.41; H, 4.83; N, 1.77; S, 9.75%. Calcd for $C_{39}H_{34}NO_4PS_2$: C, 69.31; H, 5.07; N, 2.07; S, 9.49%.

On being left to stand the filtrate gave **15c** (2.26 g, 44%), mp 280—282 °C (dec) (from acetonitrile). IR (KBr): 1250 and 1230 cm^{-1} (SO_3^-); NMR (DMSO-d_6): δ 6.70 (d, J_{PCH} 14 Hz, 1H, CH), 7.3—7.5 (m, 5H, CHPh), and 7.6—8.0 (m, 15H, Ph_3P).

An analytically pure sample could not be obtained, but

the structure was supported by the spectral data.

The filtrate was chromatographed on silica gel. Elution with benzene, benzene-ether and ethyl acetate-ethanol gave unchanged **2b** (0.40 g), **13c** (2.07 g, 66%), mp 113—114 °C (from EtOH) (lit,[11] 113 °C), and **8** (0.81 g, 24%), mp 153 °C (lit,[12] 156 °C), respectively.

*Reaction of **1a** with Ethanesulfonyl Chloride (**2c**) in the Presence Triethylamine.* Triethylamine (1.97 g, 18.3 mmol), **1a** (3.07 g, 8.7 mmol) and **2c** (2.48 g, 18.3 mmol) in benzene (100 ml) were allowed to react in a similar way, except for cooling with ice. The resulting precipitates were mainly triethylamine hydrochloride. After the solvent was removed from the filtrate, the residue was treated with ethanol to precipitate **3d**, mp 178 °C (from benzene), yield 1.58 g (34%). IR (KBr): 1335, 1300 (*as*-SO_2), 1160 and 1150 cm^{-1} (*s*-SO_2); NMR ($CDCl_3$): δ 1.41 (t, J 8 Hz, 3H, $SO_2CH_2CH_3$), 1.84 (d, J_{PCCH} 12 Hz, 3H, =CMe), 3.65 (q, J 8 Hz, 2H, SO_2CH_2), and 7.3—7.6 (m, 20H, Ph).

Found: C, 62.82; H, 5.46; N, 2.57; S, 12.18%. Calcd for $C_{28}H_{28}NO_4PS_2$: C, 62.55; H, 5.25; N, 2.61; S, 11.93%.

*Reaction of 2-Propanesulfonyl Chloride in the Presence of Triethylamine. a) With **1a**:* To a solution of **1a** (3.54 g, 10 mmol) and triethylamine (2.10 g, 20.8 mmol) in benzene (100 ml) was added dropwise 2-propanesulfonyl chloride (2.87 g, 20.1 mmol) in benzene (5 ml), and the mixture was stirred for two days. The resulting triethylamine hydrochloride (2.08 g, 71%) was filtered off and the filtrate was evaporated. After addition of benzene, recrystallization of the insoluble part from ethanol gave **16a** (1.94 g, 45%), mp 178—180 °C. IR (KBr): 1270 cm^{-1} (SO_3^-); ^{31}P-NMR (DMF): δ_p −39 ppm.

Found: C, 66.45; H, 4.61; N, 3.13; S, 7.68%. Calcd for $C_{24}H_{20}NO_3PS$: C, 66.50; H, 4.65; N, 3.23; S, 7.40%.

*b) With **1b**:* Triethylamine (2 ml), **1b** (1.84 g, 5.01 mmol) and the chloride (1.44 g, 10.1 mmol) were allowed to react in benzene in a similar manner.

16b: yield 1.00 g (44%); mp 181—182 °C (from EtOH); IR (KBr): 1275 cm^{-1} (SO_3^-); NMR (DMSO-d_6): δ 2.16 (s, 3H, C_6H_4Me), 6.90, 7.04, 7.17, 7.30, (A_2B_2, J 8.4 Hz, 4H, C_6H_4Me), and 7.5—8.1 (m, 15H, Ph_3P).

Found: C, 67.02; H, 5.00; N, 3.21; S, 7.30%. Calcd for $C_{25}H_{22}NO_3PS$: C, 67.10; H, 4.90; N, 3.13; S, 7.17%.

*Equimolar Reaction of **1a** with Sulfene.* To a solution of **1a** (3.51 g, 9.95 mmol) and triethylamine (1.5 ml) in benzene (100 ml) was added dropwise **2a** (1.14 g, 10.0 mmol) in benzene (10 ml) with stirring under cooling with ice and the mixture was stirred for 4 hr. The resulting precipitates were washed with water and dried quickly over phosphorus pentoxide to give **12a** (4.27 g, 99.5%). IR (KBr): 1290, 1255, 1165, and 1140 cm^{-1} (SO_2); NMR ($CDCl_3$): δ 2.90 (s, 0.6H, impurity, $PhNHSO_2Me$), 4.30 (broad s, 2H, P-CH_2SO_2, disappeared by D_2O), 7.1 (s, 5H, NPh), and 7.5—7.9 (m, 15H, Ph_3P); MS: *m/e* 431 (M^+). Addition of D_2O resulted in increase of the signal at 2.90.

The pure sample could not be obtained, because of easy hydrolysis in solution by moisture to **8** and **13a**. Thus, it was used for reactions without further purification.

*Reaction of **12a**. a) With Hydrogen Chloride*: Into a solution of **12a** (1.66 g, 3.86 mmol) in absolute methanol (50 ml) was bubbled dry hydrogen chloride for 1 hr. The solvent was removed *in vacuo* and the residue was chromatographed on silica gel. Elution with chloroform-methanol (15 : 1) gave *N*-phenylsulfamoylmethylenetriphenylphosphonium chloride (1.07 g, 60%). The compound was recrystallized from ethanol. The spectra and melting point were in agreement with those of the sample obtained from **1a** and **2a**.

b) With Sulfene: To a suspension of **12a** (1.04 g, 2.4 mmol) and triethylamine (0.5 ml) in benzene (50 ml) was added dropwise **2a** (0.275 g, 2.4 mmol) in benzene (5 ml) and the mixture was stirred overnight. Washing of the resulting precipitates with water gave 0.30 g (0.59 mmol) of **3a**. Removal of the solvent from the filtrate and addition of ethanol afforded 0.49 g of precipitates, which were found to be a mixture of **3a** and **4a** by thin layer chromatography (tlc) and NMR spectrum. On the basis of the signal areas of methanesulfonyl protons in the NMR spectrum, the ratio of **3a** (δ 3.20) to **4a** (δ 2.98) was calculated to be 35/65. Thus, the total yields of **3a** and **4a** were 38 (0.47 g) and 26% (0.32 g), respectively.

*Wittig Reaction of **3b** with p-Nitrobenzaldehyde.* A mixture of **3b** (0.587 g, 1.12 mmol) and *p*-nitrobenzaldehyde (0.175 g, 1.15 mmol) in *o*-dichlorobenzene (50 ml) was heated at 150 °C for 32 hr under nitrogen. After filtration of precipitates and removal of the solvent from the filtrate, the residue was chromatographed on alumina. Fractions eluted with chloroform-benzene(3 : 5) gave 0.167 g (0.42 mmol, 38%) of **10**, mp 233—235 °C (from EtOH). IR (KBr): 1620 (C=C) 1510, 1370 (NO_2), 1350, 1330 (*as*-SO_2), 1160 and 1110 cm^{-1} (*s*-SO_2); NMR (DMSO-d_6): δ 2.35 (s, 3H, C_6H_4Me), 3.56 (s, 3H, SO_2Me), 7.32 (s, 4H, NC_6H_4Me), 7.71, 7.75 (2H), and 8.2—8.4 (m, 4H, $C_6H_4NO_2$); MS: *m/e* 396 (M^+).

Found: C, 48.78; H, 4.05; N, 6.81; S, 15.88%. Calcd for $C_{16}H_{16}N_2O_6S_2$: C, 48.48; H, 4.07; N, 7.07; S, 16.18%.

Elution with chloroform gave 0.129 g (0.46 mmol, 41%) of **8**.

*Methylation of **4b**.* Sodium hydride (45 mg) was added to a solution of **4b** (0.492 g, 0.94 mmol) in benzene (50 ml) and the mixture was stirred at room temperature for 1 hr. After addition of methyl iodide (1 ml), the mixture was refluxed overnight. After evaporation, the residue was washed with water and recrystallized from ethanol to give 0.345 g (68%) of **11**, mp 232—234 °C. IR (KBr): 1330, 1280 (*as*-SO_2), 1140 and 1120 cm^{-1} (*s*-SO_2); NMR ($CDCl_3$): δ 2.30 (s, 3H, C_6H_4Me), 2.95 (s, 3H, NMe), 3.30 (s, 3H, SO_2Me), 7.0—7.15 (m, 4H, C_6H_4Me), and 7.3—7.8 (m, 15H, Ph_3P); MS: *m/e* 537 (M^+).

Found: C, 62.29; H, 4.96; N, 2.43; S, 11.87%. Calcd for $C_{28}H_{28}NO_4PS_2$: C, 62.55; H, 5.25; N, 2.61; S, 11.93%.

*Preparation of **5**.* To a suspension of methyltriphenylphosphonium bromide (18 g, 50.4 mmol) in dioxane (80 ml) was added sodium hydride (1.5 g) under nitrogen, and the mixture was stirred for 1 hr. Filtration of sodium bromide and unchanged materials under nitrogen gave a solution of methylenetriphenylphosphorane. The solution was added dropwise to a suspension of sulfur trioxide-dioxane adduct[13] (14 g) in dioxane (80 ml) under nitrogen. The dioxane layer was separated off and the viscous liquid was chromatographed on silica gel. Elution with chloroform-methanol (15 : 1) gave 1 g (6%) of **5**, mp 290—291 °C (from EtOH).

*Reaction of **1a** with Sulfur Trioxide.* To a suspension of sulfur trioxide-dioxane adduct (10 g) in dichloromethane (30 ml) was added dropwise **1a** (8.39 g, 23.5 mmol) in dichloromethane (10 ml) and the mixture was stirred for 3 hr at room temperature. The resulting precipitates were recrystallized from methanol quickly, because of hygroscopic material, to give 5.955 g (58.4%) of **17** mp 276 °C (dec). IR (KBr): 2700 (NH) and 1230 cm^{-1} (SO_3^-); NMR ($HOCH_2CH_2OH$): 3.26, 3.40 (2H, half part of A_2B_2), 3.90, 4.0—4.6 (17H), and 4.70 ppm (broad s, 1H, NH), in low field from methylene signal of ethylene glycol.

Found: C, 66.54; H, 4.66; N, 3.07%. Calcd for $C_{24}H_{20}NO_3PS$: C, 66.50; H, 4.65; N, 3.23%.

*Hydrolysis of **3b**.* Into a solution of **3b** (0.53 g, 1.0 mmol) in chloroform (40 ml) was bubbled hydrogen chloride gas for 2 hr. After evaporation, the residue was chromatographed on silica gel to give **13b**, mp 101—102 °C (from EtOH) (lit,[14] 102.5 °C) with chloroform-methanol (19 : 1) and **5** with chloroform-methanol (5 : 1) almost quantitatively.

*Reactions of **1** with Sulfonyl Chloride (**2**) in the Absence of Triethylamine. a) Reaction of **1a** with **2a**:* A solution of **2a** (2.29 g, 2.01 mmol) in benzene (10 ml) was added dropwise to a solution of **1a** (7.05 g, 20.0 mmol) in benzene (100 ml) at room temperature under stirring and the mixture was stirred for 1 hr. The resulting precipitates were identified as **18a**, mp 122—124 °C (from acetone). Yield, quantitative. IR (KBr): 2700 (NH), 1350 and 1170 cm^{-1} (SO_2); NMR ($CDCl_3$): δ 5.86 (d, J_{PCH} 12 Hz, 2H, PCH_2SO_2), 7.15—8.0 (m, 20H, 4Ph), and 12.7 (very broad s, 1H, NH).

Found: C, 64.11; H, 5.17; N, 2.69; S, 6.93%. Calcd for $C_{25}H_{23}ClNO_2PS$: C, 64.17; H, 4.95; N, 2.99; S, 6.85%.

To **18a** (1.125 g, 24 mmol) in dichloromethane (50 ml) was added an excess of triethylamine, and the reaction mixture was subjected to silica gel dry column chromatography with ether after being stirred for 10 hr. Extraction of a part of R_f 0.6—0.8 with ether and recrystallization from ethanol gave 0.29 g (71%) of **13a**, mp 102 °C (lit,[14] 100.5 °C). Extraction of a part of R_f 0.2—0.5 with ethyl acetate gave 0.515 g (97%) of **8**.

*b) Reaction of **1a** with **2b**.* 1) A mixture of **1a** (3.56 g, 10.1 mmol) and **2b** (1.96 g, 10.3 mmol) was allowed to react similarly to give 3.83 g of precipitates. A part of the precipitates (1.60 g) was chromatographed on silica gel. Elution with chloroform-methanol (79 : 1) gave 1.07 g (46%) of **18b**, mp 150—151 °C (from ethanol-ether). IR (KBr): 2800 (NH), 1350 and 1160 cm^{-1} (SO_2); NMR ($CDCl_3$): δ 6.7—8.0 (m, 25H, 5Ph), 8.65 (d, J_{PCH} 16 Hz, 1H, P-CH-Ph), and 10.8 (very broad s, 1H, NH).

Found: C, 68.49; H, 4.86; N, 2.67; S, 5.99; Cl, 6.74%. Calcd for $C_{31}H_{27}ClNO_2PS$: C, 68.44; H, 5.00; N, 2.57; S, 5.89; Cl, 6.52%.

Elution of chloroform-methanol (3 : 1) gave 0.51 g (28%) of anilinotriphenylphosphonium chloride, mp 229—233 °C (lit,[15] 230—233 °C).

2) **1a** (3.55 g, 10.1 mmol) and **2b** (1.88 g, 9.87 mmol) were reacted in benzene (100 ml) for 3 days at room temperature to give **18b**, mp 150—151 °C, as precipitates quantitatively.

*Reactions of **1a** and **2c**.* **1a** (3.57 g, 10.1 mmol) and **2c** (1.31 g, 10.2 mmol) in benzene were allowed to react as in the case of **2a**. **18c** was obtained as precipitates, 1.97 g (40%), mp 180—185 °C (dec) (from acetone). IR (KBr): 2810 (NH), 1355 and 1170 cm^{-1} (SO_2); NMR ($CDCl_3$): δ 1.50 (d d, J_{PCCH} 18, J_{HH} 6 Hz, 3H, P-CHMe), 7.0—7.3 (m, 3H), 7.5—8.3 (m, 18H), and 11.75 (very broad s, 1H, NH). On addition of D_2O, the signal at δ 11.75 disappeared and double doublets at 1.50 changed to a doublet (J 18 Hz). Signal at 7.5—8.3 changed the peak area to 17H, indicating an overlap with methine proton.

Found: C, 64.81; H, 5.06; N, 2.71%. Calcd for $C_{26}H_{25}ClNO_2PS$: C, 64.79; H, 5.23; N, 2.91%.

*Reaction of **1b** and **2a**.* **1b** (3.657 g, 10.0 mmol) was allowed to react with **2a** (1.43 g, 9.98 mmol) as in the case of **2a** to afford **18d**, mp 166.7—168 °C (from acetone), quantitatively. IR (KBr): 2810 (NH), 1345 and 1165 cm^{-1} (SO_2); NMR ($CDCl_3$): δ 2.30 (s, 3H, C_6H_4Me), 5.91 (d, J_{PCH} 12 Hz, 2H, PCH_2SO_2), 7.01, 7.16, 7.50 (centered at 7.33) (A_2B_2, J 9 Hz, 3H, NC_6H_4Me), 7.6—8.2 (m, 16H, 3Ph and CH), and 10.57 (broad s, 1H, NH).

Found: C, 64.74; H, 5.31; N, 2.62%. Calcd for $C_{26}H_{25}ClNO_2PS$: C, 64.79; H, 5.19; N, 2.91%.

Metal Phosphinylides and Phosphinothioylides. I. Formation of Metal Diphenylphosphinylides and Diphenylphosphinothioylides and the Reactions with Some Organic Halides and Aldehydes

Tateki Emoto, Hideyuki Gomi, Masaaki Yoshifuji, Renji Okazaki, and Naoki Inamoto

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received May 14, 1974)

Lithium diphenylphosphinylide or diphenylphosphinothioylide ([Ph_2PX]Li; X=O, S), prepared from diphenylphosphine oxide or sulfide and *n*-butyllithium, reacted with methyl iodide, acetaldehyde and benzaldehyde to give the corresponding phosphine oxides or sulfides in good yields, indicating the formation of C–P bond. Formation of [Ph_2PS]MgCl from diphenylphosphinothioyl chloride (**1**) and magnesium was confirmed by the similar reactions. When **1** was allowed to react with magnesium or sodium for a long time, diphenylphosphides ([Ph_2P]-M) were produced by desulfurization, together with [Ph_2PS]M (M=MgCl, Na). Reaction of **1** with [Ph_2PS]M gave tetraphenyldiphosphine disulfide through formation of P-P bond, while diphenylphosphinyl chloride and [Ph_2PO]M reacted through formation of P–O bond. The difference has been explained by soft-hard-acid-base concept.

Tetraphenyldiphosphine disulfide is prepared by the reaction of diphenylphosphinothioyl chloride (**1**) with an alkyl Grignard reagent. The reaction mechanism has been considered as follows.[1)]

$$\underset{\mathbf{1}}{Ph_2P(S)Cl} + RMgBr \longrightarrow \underset{\mathbf{2'}}{Ph_2P(S)MgBr} + RCl$$

$$\mathbf{2'} + \mathbf{1} \longrightarrow Ph_2P(S)\text{-}P(S)Ph_2 + MgClBr \qquad (1)$$

Phosphinothioylmagnesium bromide (**2'**) has been assumed as the intermediate,[1)] but there is no report on the direct formation of phosphinothioylmagnesium chloride (**2**) from **1** and magnesium. There are several reports[2,3)] on formation of metal diphenylphosphinylides by reaction of dialkyl phosphite with excess amounts of phenylmagnesium bromide[2)] and by reaction of diphenylphosphinyl chloride with sodium or magnesium.[3)]

Metal diphenylphosphinylides and diphenylphosphinothioylides have two reaction centers, that is, the phosphorus and the oxygen or sulfur atoms.

$$Ph_2P(X)\text{-}M \rightleftharpoons Ph_2P\text{-}X\text{-}M \qquad [X=O, S]$$

In this paper, such compounds are represented as [Ph_2PX]M. It has been reported that metal derivatives (M=Li, Na, K, MgCl) of dialkyl phosphites exist as $(RO)_2P$–O–M from the ^{31}P-NMR data.[4)] ^{31}P-NMR measurements of [Ph_2PX]M are under investigation and will be reported in the near future.

This paper describes formation of **2** and other metal diphenylphosphinothioylides by metallation of diphenylphosphine sulfide (**3b**) and by reaction of some metals with **1**, and comparison of their reactions with those of metal diphenylphosphinylides prepared by similar methods.

First, lithium derivatives (**4**) were prepared from diphenylphosphine oxide (**3a**) or sulfide (**3b**) and *n*-butyllithium in tetrahydrofuran (THF) at 0 °C.

$$\underset{\mathbf{3}}{Ph_2P(X)H} + n\text{-}Bu\text{-}Li \longrightarrow \underset{\mathbf{4}}{[Ph_2PX]Li}$$

a, X=O; b, X=S

Reactions of **4a** with methyl iodide, acetaldehyde and benzaldehyde gave methyldiphenylphosphine oxide (**5a**) (93%), α-hydroxyethyldiphenylphosphine oxide (**6a**) (95%), and α-hydroxybenzyldiphenylphosphine oxide (**7a**) (63%), respectively. Similar reactions of **4b** gave the corresponding sulfides (**5b, 6b** and **7b**) in 66, 81 and 63% yields, respectively.

In the case of reaction of **4b** with methyl iodide, methyl diphenylphosphinothionite could not be detected in the crude reaction mixture by means of NMR.

$$\underset{\mathbf{4}}{[Ph_2PX]Li} \xrightarrow{MeI} \underset{\mathbf{5}}{Ph_2P(X)Me}$$

$$\xrightarrow{RCHO} Ph_2P(X)CHOH\text{-}R$$

a, X=O
b, X=S

6, R=Me; **7**, R=Ph

In all cases, the reaction center seems to be the phosphorus atom.

Reactions of **1** with magnesium was carried out to prepare **2**. An equimolar mixture of **1** and magnesium was refluxed for 1 hr in THF. Treatment of the reaction mixture with water gave **3b** in 37% yield, indicating the formation of **2**.

Grignard-type reagent (**2**), prepared under the same condition, reacted with benzyl chloride, benzaldehyde and **1** to give benzyldiphenylphosphine sulfide (**8**), **7b** and tetraphenyldiphosphine disulfide (**9**) in 44, 31 and 36% yields, respectively. Formation of **9** from **1** and **2** supported the reaction (1).

$$\underset{\mathbf{1}}{Ph_2P(S)Cl} + Mg \xrightarrow[\text{refl. THF}]{1\text{ hr}} \underset{\mathbf{2}}{[Ph_2PS]MgCl}$$

$$\underset{\mathbf{3b}}{Ph_2P(S)H} \xleftarrow{H_2O} \underset{\mathbf{2}}{[Ph_2PS]MgCl} \xrightarrow[\mathbf{1}]{PhCHO} \underset{\mathbf{7b}}{Ph_2P(S)CHPh\text{-}OH}$$

$$\underset{\mathbf{8}}{Ph_2P(S)CH_2Ph} \xleftarrow{PhCH_2Cl} \qquad \longrightarrow \underset{\mathbf{9}}{Ph_2P(S)\text{-}P(S)Ph_2}$$

From the above results, it is expected that yields of **2** were below 50% under the above condition. Then, two equivalents of magnesium were used and the mixture was refluxed for 8—10 hr. Hydrolysis of the reaction mixture gave **3b** in only 0.6% yield, and produced **3a** and diphenylphosphinic acid in 77 and 14% yields, respectively, indicating the formation of $[Ph_2P]MgCl$ by desulfurization.

$$Ph_2P(S)Cl\ (\mathbf{1}) + 2\,Mg \xrightarrow[\text{refl. THF}]{\text{8—10 hr}} [Ph_2PS]MgCl + [Ph_2P]MgCl$$

$[Ph_2PS]MgCl \xrightarrow{H_2O} Ph_2P(S)H$ (**3b**)

$[Ph_2P]MgCl \xrightarrow{H_2O} Ph_2PH \xrightarrow{O_2} Ph_2P(O)H$ (**3a**) $\xrightarrow{O_2} Ph_2P(O)OH$

The formation of **3a** and diphenylphosphinic acid is attributed to successive oxidation of diphenylphosphine initially formed during treatment.

The desulfurization was also indicated by formation of **7a** (7.5%) and **7b** (18%) in reaction with benzaldehyde.

Reaction of **1** with excess amounts of sodium in toluene for 115 hr at room temperature gave **9** (3.8%) and diphenylphosphinic acid (30%) after hydrolysis. The formation of the latter also indicates occurrence of desulfurization.

$$Ph_2P(S)Cl\ (\mathbf{1}) + Na \xrightarrow[\text{in PhMe}]{\text{115 hr, r. t.}} [Ph_2PS]Na + [Ph_2P]Na$$

$[Ph_2PS]Na \xrightarrow{1} Ph_2P(S)\text{-}P(S)Ph_2$ (**9**)

$[Ph_2P]Na \xrightarrow{H_2O} \xrightarrow{O_2} Ph_2P(O)OH$

From the above results, it is suggested that reaction of **1** with the corresponding metal derivative ($[Ph_2PS]$-M) gives diphosphine disulfide, indicating the formation of P(S)-P(S) bond.

Reaction of diphenylphosphinyl chloride (**10**) with twice molar amounts of sodium was carried out in refluxed toluene for 5 hr. The resulting precipitates contained sodium diphenylphosphinylide (**11**) from result of hydrolysis, and reacted with **10** to give diphenylphosphinic acid in 55% yield.

$$Ph_2P(O)Cl\ (\mathbf{10}) + 2\,Na \rightarrow [Ph_2PO]Na\ (\mathbf{11}) \xrightarrow{\mathbf{10}} (Ph_2P(O)\text{-}OPPh_2)\ (\mathbf{12})$$

$$\xrightarrow{O_2} (Ph_2P(O)\text{-}O\text{-}P(O)Ph_2)\ (\mathbf{13}) \xrightarrow{H_2O} 2\,Ph_2P(O)OH$$

In this case, the crude product was found to contain diphenylphosphinic diphenylphosphonous anhydride (**12**) by IR and mass spectra. Therefore, the formation of diphenylphosphinic acid is attributed to oxidation[5] and hydrolysis of **12** during isolation and purification, because diphenylphosphinic anhydride (**13**) undergoes hydrolysis easily.[6]

Thus reaction of **10** with the corresponding metal derivative ($[Ph_2PO]M$) was found to afford the product through the formation of P–O–P(O) bond.

The difference in the reactions of $[Ph_2PX]M$ with $Ph_2P(X)Cl$ may be explicable in terms of soft-hard-acid-base.[7] The phosphorus and oxygen atoms of $[Ph_2PO]M$ are soft and hard, respectively, and the phosphorus atom of **10** is hard.[8] Thus, in the reaction of **11** with **10**, P–O–P(O) bond is formed. The phosphorus and sulfur atoms of $[Ph_2PS]M$ and also the phosphorus atom of **1** are all soft,[8] and moreover, tervalent phosphorus atom is more nucleophilic than sulfide anion.[9] Therefore, in the reaction of **2** with **1**, P(S)–P(S) bond is formed.

The following reactions support this consideration.[5,10]

$$Ph_2P(O)H \xrightarrow{Ph_2PCl} Ph_2P(O)\text{-}PPh_2\ ^{10)}$$

$$Ph_2P(O)H \xrightarrow[\mathbf{10},\ Et_3N]{Et_3N} Ph_2P\text{-}OP(O)Ph_2\ ^{5)}$$

One possible mechanism of desulfurization in preparation of $[Ph_2PS]M$ may be disproportionation as follows, because the reaction of **1** with magnesium in THF at 150 °C gave a small amount of diphenylphosphinodithioic acid.[11]

$$2[Ph_2PS]^- \longrightarrow Ph_2P^- + Ph_2P(S)S^-$$

In the preparation of $[Ph_2PS]M$ from **1** and metal, desulfurization took place by using excess amounts of metal or by heating for a long time. Therefore, the best method to prepare $[Ph_2PS]M$ is that from **3b** through hydrogen-metal exchange reaction, because of homogeneous and rapid reaction.

Experimental

All melting and boiling points are uncorrected. The IR spectra were recorded on Hitachi EPI-G2 spectrophotometer, NMR spectra were measured with Hitachi R-24 and R-20B spectrometers using TMS as an internal standard, and ^{31}P-NMR spectra were measured with a Hitachi R-20B spectrometer equipped with a phosphorus measurement unit R-204-PB (24.3 Hz) using 85% phosphoric acid as an external standard. Mass spectra were determined with Hitachi RMU-6L mass spectrometer. All reactions were carried out under nitrogen.

Materials. The following materials were prepared by the methods reported in the literature: diphenylphosphinothioyl chloride,[12] bp 155—157 °C/0.3 mmHg; diphenylphosphinyl chloride,[13] bp 155 °C/0.1 mmHg; diphenylphosphine sulfide,[14] mp 93—94 °C; diphenylphosphine oxide,[15] mp 45—48 °C. *n*-Butyllithium was used as 15% *n*-hexane solution.

*Reactions of Lithium Diphenylphosphinylide (**4a**).* *a) With Methyl Iodide*: A solution of **4a** prepared from diphenylphosphine oxide (**3a**) (2.66 g, 13.2 mmol) and *n*-butyllithium (13.2 mmol) in THF (50 ml) was stirred with methyl iodide (2.00 g, 14.0 mmol) in THF (10 ml) for 2.5 hr. After removal of THF, the residue was treated with water, and extracted with ether. After removal of ether from the dried extract, crude methyldiphenylphosphine oxide (**5a**) was recrystallized from *n*-hexane-benzene, mp 113.5—115 °C (lit,[16] 113—114 °C), yield 2.66 g (93%). NMR ($CDCl_3$): δ 2.02 (d, J_{PCH} 13.6 Hz, 3H, Me) and 7.3—8.0 (m, 10H, 2Ph); δ_P ($CHCl_3$): −29.7 ppm.

b) With Acetaldehyde: A solution of **4a** prepared from **3a** (2.11 g, 10.4 mmol) and *n*-butyllithium (11 mmol) in THF (60 ml) was stirred with acetaldehyde (0.66 g, 14.9 mmol) for 2 hr. Similar work-up gave α-hydroxyethyldiphenylphosphine oxide (**6a**) (2.54 g, 95%), mp 131—132 °C (from benzene). IR (KBr): 3150 (OH) and 1170 cm^{-1} (P=O); NMR ($CDCl_3$): δ 1.38 (d d, J_{PCCH} 15.4, J_{HH} 7.2 Hz, 3H, Me), 4.57 (q, J_{PCH} *ca.* 0 Hz, 1H, CH), 5.02 (s, 1H, OH), and 7.3—8.1 (m, 10H, 2Ph); δ_P ($CHCl_3$): −32.9 ppm.

Found: C, 68.31; H, 6.00%. Calcd for $C_{14}C_{15}O_2P$: C, 68.29; H, 6.14%.

c) With Benzaldehyde: A solution of **4a** prepared from **3a** (1.98 g, 9.4 mmol) and *n*-butyllithium (10.4 mmol) in THF (40 ml) was refluxed with benzaldehyde (1.7 g, 16 mmol) in THF (15 ml) for 1.5 hr. The reaction mixture was poured into a mixture of ice and hydrochloric acid, and ether was added. Evaporation of the ethereal layer gave α-hydroxybenzyldiphenylphosphine oxide (**7a**) (1.9 g, 63%), mp 172—174 °C (from ethanol) (lit,[3a] 176 °C). δ_P (DMF): −26.9 ppm.

*Reactions of Lithium Diphenylphosphinothioylide (**4b**).* *a) With Methyl Iodide*: To a solution of diphenylphosphine sulfide (**3b**) (5.01 g, 23 mmol) in THF (50 ml) was added dropwise *n*-butyllithium (24 mmol) in hexane under ice-cooling with stirring over 30 min. The mixture was stirred at room temperature for 30 min. To the solution was added dropwise 3.47 g (24.4 mmol) of methyl iodide in 10 ml of THF with stirring under ice-cooling, and the mixture was stirred for 2 hr at room temperature. After removal of THF, the residue was treated with water, and extracted with ether. Removal of the ether from the dried extract gave oily material. The NMR spectrum was quite the same with that of the distillate (**5b**), bp 170—171 °C/1 mmHg (lit,[17] 181 °C/1.5 mmHg), yield 3.52 g (66%). NMR (CCl_4): δ 2.07 (d, J_{PCH} 13.6 Hz, 3H, Me) and 7.2—8.0 (m, 10H, 2Ph); δ_P ($CHCl_3$): −35.9 ppm.

b) With Acetaldehyde: To a solution of **4b** prepared from **3b** (4.01 g, 18.4 mmol) in THF (50 ml) and *n*-butyllithium (19 mmol), acetaldehyde (0.83 g, 19 mmol) was added dropwise at room temperature and the mixture was stirred for 2 hr. Similar work-up gave oily materials, which solidified on standing to give **6b**, mp 84—86 °C (from *n*-hexane-ether), yield 3.91 g (81%). IR (KBr): 3300 (OH) and 590 cm^{-1} (P=S); NMR ($CDCl_3$): δ 1.30 (d d, J_{PCCH} 17, J_{HH} 7.2 Hz, 3H, Me), 2.87 (s, 1H, OH), 4.72 (d q, J_{PCH} 2.6, J_{HH} 7.2 Hz, 1H, CH), and 7.3—8.2 (m, 10H, 2Ph); δ_P ($CHCl_3$): −49.0 ppm.

Found: C, 64.16; H, 5.57%. Calcd for $C_{14}H_{15}OPS$: 64.10; H, 5.77%.

c) With Benzaldehyde: A solution of **4b** prepared from **3b** (2.14 g, 9.8 mmol) and *n*-butyllithium (10 mmol) in THF (50 ml) was stirred with benzaldehyde (1.78 g, 16.8 mmol) for 20 hr. Similar work-up gave colorless crystals, which were recrystallized from carbon tetrachloride to give **7b**, mp 121—122.5 °C, yield 1.99 g (63%). IR (KBr): 3250 (OH) and 610 cm^{-1} (P=S); NMR ($CDCl_3$); δ 3.92 (s, 1H, OH), 5.54 (d, J_{PCH} 1.8 Hz, 1H, CH), and 6.8—8.15 (m, 15H, 3Ph); δ_P ($CHCl_3$): −52.3 ppm.

Found: C, 70.39; H, 5.30; S, 9.95%. Calcd for $C_{19}H_{17}OPS$: C, 70.35; H, 5.29; S, 9.88%.

*Preparation of Diphenylphosphinothioylmagnesium Chloride (**2**) and the Hydrolysis.* *a) Shorter Reaction Time*: A mixture of diphenylphosphinothioyl chloride (**1**) (5.1 g, 20 mmol) and magnesium turnings (0.73 g, 30 mg atom) in THF (100 ml) was heated under reflux for 1 hr. The reaction mixture was decanted and the solution was evaporated *in vacuo*. After addition of ether to the residue, 10% aqueous ammonium chloride was poured into the ether solution, and the ether was removed from the dried ethereal layer. The residual oily material was crystallized with acetonitrile to give **3b** (1.6 g, 37%), mp 93—94 °C (lit,[14] 95—97 °C).

b) Longer Reaction Time: A mixture of **1** (4.5 g, 18 mmol) and magnesium turnings (875 mg, 36 mg atom) in THF (50 ml) was heated under reflux with vigorous stirring for 10 hr. Remaining magnesium (0.14 g, 6 mg atom) was removed by decantation and the solution was evaporated. The residue was dissolved in 50 ml of benzene and a small amount of water was added. The benzene layer was dried and removal of the benzene gave oily material, which was crystallized with ether to give diphenylphosphinic acid (0.56 g, 14%), mp 190—191 °C (lit,[18] 194 °C). After evaporation of the filtrate the residue was chromatographed on silica gel with dichloromethane to afford 2.8 g (77%) of **3a**, mp 46—48 °C (lit,[15] 51—54 °C), and 22 mg (0.6%) of **3b**, mp 92—93 °C.

*Reactions of **2**.* *a) With Benzyl Chloride*: A solution of **2** was prepared from **1** (5.1 g, 20 mmol), magnesium (0.5 g, 20 mg atom) and THF (60 ml) under a condition of shorter reaction time described above. To the solution was added benzyl chloride (2.6 g, 21 mmol) in THF (10 ml) at room temperature. After stirring for 20 min, the mixture was heated under reflux for 2 hr. After removal of THF, the residual oil dissolved in dichloromethane was dried with anhydrous sodium sulfate. After removal of the dichloromethane, the residual oil was mixed with a small amount of ethanol to precipitate benzyldiphenylphosphine sulfide (**8**) (2.7 g, 44%), mp 160—161 °C (from ethanol) (lit,[19] 162—163 °C).

b) With Benzaldehyde: 1) To a solution of **2** prepared by the same method described in a), was added dropwise benzaldehyde (2.12 g, 20 mmol) in THF (15 ml) at room temperature. After stirring for 1 hr, the mixture was heated gradually and then refluxed for 10 min. THF was removed, the residue was treated with 10% aqueous ammonium chloride, and extracted with dichloromethane. After evaporation of the dried extract, the residue was recrystallized from 2-propanol to give **7b** (2.0 g, 31%), mp 113—114 °C, which was identified by the IR spectrum.

2) A mixture of **1** (5.1 g, 20 mmol), magnesium (0.97 g, 40 mg atom) in 100 ml of THF was refluxed for 8 hr. After decantation, to the solution was added dropwise 2.1 g (20 mmol) of benzaldehyde in 10 ml of THF at room temperature, and the mixture was refluxed for 2 hr. The residue, which was obtained by a similar treatment to that described in 1), gave colorless crystals by addition of ether. The crystals were recrystallized from ethanol to give pure **7a** (0.49 g, 7.5%), mp 173—175 °C (lit,[3a] 176 °C). Standing of the ethereal filtrate gave 1.1 g (18%) of **7b**.

*c) With Diphenylphosphinothioyl Chloride (**1**)*: A mixture of **1** (7.9 g, 31 mmol), magnesium (0.82 g, 34 mg atom) and THF (60 ml) was refluxed for 1 hr. To the solution was added dropwise **1** (7.7 g, 30 mmol) in THF (40 ml) at room temperature. The mixture was refluxed for 6 hr. After filtration of magnesium chloride and removal of THF from the filtrate, the residual semi-solid was washed twice with water and extracted with dichloromethane. Removal of dichloromethane from the extract gave oily material, which crystallized by addition of a small amount of ethanol. The crystals were recrystallized from acetone-ethanol (9 : 1) to give **9** (4.7 g, 36%), mp 165—167 °C (lit,[20] 168.5 °C).

*Reaction of **1** with Sodium.* A solution of **1** (1.7 g, 6.8 mmol) in toluene (10 ml) was added dropwise to sodium (1.2 g, 52 mg atom) in toluene (10 ml) at room temperature, the mixture was stirred for 115 hr and poured into water,

The organic layer was evaporated after drying. Extraction with a small amount of acetonitrile gave diphenylphosphinic acid (4.4 g, 30%), mp 188—190 °C, as insoluble material. The acetonitrile solution gave a solid after evaporation. Recrystallization from ether gave **9** (56 mg, 3.8%), mp 167—168.5 °C.

*Reaction of Sodium Diphenylphosphinylide with Diphenylphosphinyl Chloride. (**10**).* To a suspension of sodium (0.97 g, 42 mg atom) in toluene (50 ml) was added dropwise **10** (4.9 g, 21 mmol) in toluene (50 ml), and the mixture was refluxed for 5 hr. Precipitates thus obtained were filtered off under nitrogen. Hydrolysis of a small amount of the precipitates gave **3a**. To a suspension of the dry precipitates (1.2 g), which contain an equimolar amount of sodium chloride, in xylene (25 ml) was added dropwise **10** (1.0 g, 4.2 mmol) in xylene (25 ml) at room temperature, and the mixture was refluxed for 12 hr. Treatment of the reaction mixture with water gave insoluble solid, which was identified as diphenylphosphinic acid (1.0 g, 55%) by IR. Evaporation of the organic layer gave white solid, which was found to be diphenylphosphinic acid mainly by IR. The IR spectrum showed a band at 960 cm^{-1} (P-O-P). The mass spectrum also showed the absence of tetraphenyldiphosphine dioxide (M^+, *m/e* 402) and the presence of diphenylphosphinic anhydride (M^+, *m/e* 418).

Metal Phosphinylides and Phosphinothioylides. II.[1] Effects of Metals on the Reactions of [Ph_2PX]M with Benzaldehyde and *p*-Benzoquinone

Koshiro GODA, Hideyuki GOMI, Masaaki YOSHIFUJI, and Naoki INAMOTO

(Received May 14, 1974)

Reactions of [Ph_2PO]M with benzaldehyde gave benzyl benzoate and benzyldiphenylphosphine oxide (**3**) in the case of M=Na, **3**, α-hydroxybenzyldiphenylphosphine oxide, benzyl alcohol, benzoin and benzil in the case of M=MgCl, and **3** in the case of M=ZnCl. Reactions of [Ph_2PX]M with *p*-benzoquinone gave 2,5-dihydroxyphenyldiphenylphosphine oxide or sulfide and *p*-hydroxyphenyl diphenylphosphinate in the cases X=O, S and M=Li, MgCl, Al, and 1,4-phenylene bis(diphenylphosphinate) or bis(diphenylphosphinothioate) in the cases X=O, S and M=FeCl. The reaction mechanisms have been discussed.

The formation of [Ph_2PX]M (X=O, S; M=Li, Na, MgCl) was reported in the preceding paper,[1] reactions of [Ph_2PO]Li or [Ph_2PS]M (M=Li, MgCl) with benzaldehyde giving α-hydroxybenzyldiphenylphosphine oxide or sulfide in good yields.

This paper describes the effects of metals on reactions of [Ph_2PO]M with benzaldehyde, and those on the reactions of [Ph_2PX]M (X=O, S) with *p*-benzoquinone.

Reactions with Benzaldehyde. When sodium diphenylphosphinylide (**2a**) prepared from diphenylphosphinyl chloride (**1a**) and two equivalents of sodium in tetrahydrofuran (THF) was allowed to react with benzaldehyde for 24 hr at room temperature and then for 2 hr at the refluxing temperature, benzyl benzoate (65%) and benzyldiphenylphosphine oxide (**3**) (7%) were obtained, instead of α-hydroxybenzyldiphenylphosphine oxide (**4**).

$$\underset{\mathbf{1a}}{Ph_2P(O)Cl} + 2\,Na \rightarrow \underset{\mathbf{2a}}{[Ph_2PO]Na} \xrightarrow{PhCHO} Ph_2P(O)CH_2Ph + PhCO_2CH_2Ph$$

3

A similar reaction of diphenylphosphinylmagnesium chloride (**5a**) with benzaldehyde gave **4** in only 6% yield, together with **3** (1%), benzyl alcohol (30%), benzoin (5%) and benzil (9%).

$$\underset{\mathbf{5a}}{[Ph_2PO]MgCl} + PhCHO \rightarrow \mathbf{3} + \underset{\mathbf{4}}{Ph_2P(O)CHPh\text{-}OH} + PhCH_2OH + PhCOCHOHPh + PhCOCOPh$$

The reaction of diphenylphosphinylzinc chloride (**6a**) with benzaldehyde gave only 8% of **3** as an isolated product.

Formation of **3** is explicable by the deoxygenation of intermediate anion (**7**) by diphenylphosphinylide anion as follows.

$$[Ph_2PO]^- + PhCHO \rightleftharpoons \underset{\mathbf{7}}{Ph_2P(O)CHPh\text{-}O^-} \xrightarrow{[Ph_2PO]^-} Ph_2P(O)O^- + \underset{\mathbf{8}}{Ph_2P(O)\bar{C}HPh} \xrightarrow{H^+} \mathbf{3}$$

The driving force may be due to the formation of stabilized anion (**8**).

In the case of **5a**, **3** was formed in a trace amount, the normal product (**4**) being also obtained. The result is attributable to the fact that the concentration of free anion (**7**) in this case was lower than that in the case of **2a**, due to the formation of the covalent magnesium derivative of **7**.

The formation of benzyl alcohol and benzoate is explained by an intermolecular hydride shift from **7** to benzaldehyde to give benzyloxide anion and benzoyldiphenylphosphine oxide (**9**). The mechanism is analogous to that in the Cannizzaro reaction.

$$\underset{\mathbf{7}}{Ph_2P(O)CHPh\text{-}O^-} + PhCHO \rightarrow \underset{\mathbf{9}}{Ph_2P(O)COPh} + PhCH_2O^- \xrightarrow{H^+} [Ph_2PO]^- + PhCOOCH_2Ph \quad PhCH_2OH$$

In the case of **5a** benzyl alcohol is produced due to a low concentration of free benzyloxide anion. However, in the case of **2a**, benzyl benzoate is formed through attack of free benzyloxide anion on the carbon atom of the carbonyl group in **9**, since diphenylphosphinylide anion is considered to be a good leaving group on the basis of the following decomposition.[2]

$$Ph_2P(O)CH_2OH \xrightarrow{OH^-} Ph_2P(O)CH_2O^- \rightarrow [Ph_2PO]^- + CH_2O$$

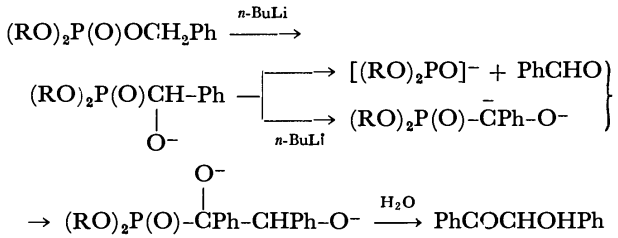
The formation of benzoin is considered to be analogous to benzoin condensation, indicating that diphenylphosphinylide anion behaves in a similar way to that of cyanide anion.

$$\underset{\mathbf{7}}{PhCH(O^-)\text{-}PPh_2} \rightarrow \underset{\mathbf{10}}{Ph\text{-}\bar{C}(HO)\text{-}PPh_2} \xrightarrow{PhCHO} PhC(OH)\text{-}CHPh\text{-}O^- \rightarrow Ph\text{-}C(O^-)\text{-}CHPh\text{-}OH \rightarrow PhCOCHOHPh + [Ph_2PO]^-$$

Benzil is formed through an attack of the anion (**10**) on the carbonyl carbon atom of **9**.

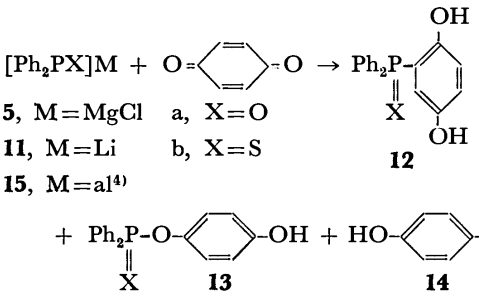
$$\underset{\mathbf{10}}{Ph\text{-}\bar{C}(OH)\text{-}P(O)Ph_2} + \underset{\mathbf{9}}{PhCOP(O)Ph_2} \rightarrow PhC(OH)\text{—}CPh\text{-}O^- \rightarrow PhC(OH)\text{-}COPh + [Ph_2PO]^- \rightarrow Ph\text{-}C(O^-)\text{-}COPh \rightarrow PhCOCOPh + [Ph_2PO]^-$$

An analogous formation of benzoin has recently been reported.[3]



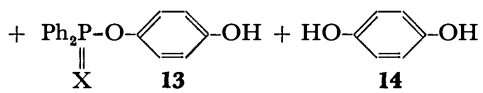
In conclusion, since the formation of **7** is reversible, long reaction time results in the formation of several abnormal products. The products depend on the extent of ionic character of the initial addition product (**7**), which depends on metal in $[Ph_2PO]M$.

Reactions with p-*Benzoquinone.* Reactions of $[Ph_2PX]M$ (X=O, S) with *p*-benzoquinone were carried out at room temperature in THF.



5, M=MgCl a, X=O
11, M=Li b, X=S
15, M=al[4]

12



13 **14**

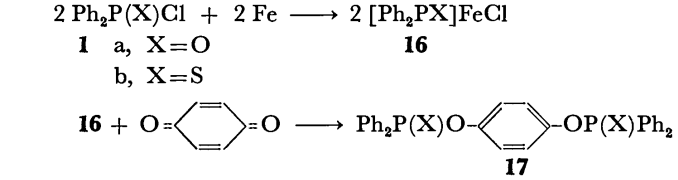
The reaction of lithium diphenylphosphinylide (**11a**) gave 2,5-dihydroxyphenyldiphenylphosphine oxide (**12a**) (20%), *p*-hydroxyphenyl diphenylphosphinate (**13a**) (18%) and hydroquinone (**14**) (33%).

The reaction of **5a** gave 17% of **12a**, 17% of **14**, and 8% of magnesium diphenylphosphinate.

The reaction of **15a** gave 8% of **13a**, 20% of **14** and compounds containing aluminum as the main product. A similar reaction of **15b** gave 9% of **13a** and similar aluminum-containing products as main products. The formation of **13a** indicates desulfurization during the course of the preparation of **15b**.[1] The above aluminum-containing compounds are considered to be a mixture of aluminum chelate of **12** and aluminum diphenylphosphinate, but attempts to isolate **12** were unsuccessful.

Reaction of **11b** gave also 30% of **12b**.

A reaction mixture of diphenylphosphinyl (**1a**) or diphenylphosphinothioyl chloride (**1b**) with reduced iron powder in THF reacted with *p*-benzoquinone to give 1,4-phenylene bis(diphenylphosphinate) (**17a**) or bis(diphenylphosphinothioate) (**17b**) by considerably fast reaction in 78 or 79% yield, respectively.



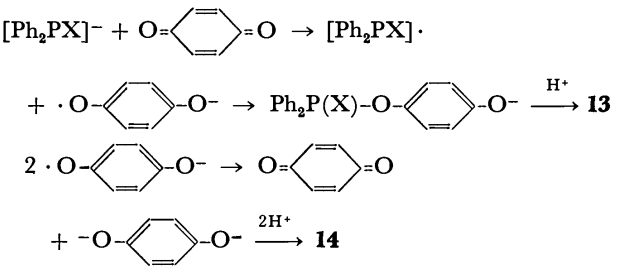
1 a, X=O b, X=S **16**

17

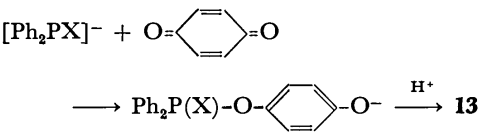
Solutions of **16** were pale green and the ^{1}H-NMR spectra could be measured without difficulty. Thus, the iron atom in **16** is considered to be bivalent.

Compounds **12** are considered to be formed through a nucleophilic addition to quinone nucleus, since diphenylphosphine oxide and sulfide give **12a**[5] and **12b** with *p*-benzoquinone, respectively. It is noteworthy that **12b** is formed in a better yield in the absence of any base than in the presence of base, isolation being very easy.

The formation of **13** and **14** is considered to be due to electron transfer mechanism.



However, the following direct addition to the oxygen atom of quinone cannot be ruled out for the formation of **13**.



Since **16** did not react with benzyl chloride, acetaldehyde, diethyl disulfide, olefins, dienes, and naphthalene, it does not have an anionic character and does not generate free radicals under similar conditions.

Moreover, **16a** reacted with air to give iron diphenylphosphinate, which gave diphenylphosphinic acid after alkaline hydrolysis. It is suggested that the reactions proceed through an coordinate complex between **16** and quinone in a homolytic fashion without formation of free radicals.

Experimental

All melting and boiling points are uncorrected. IR and mass spectra were measured with a Hitachi EPI-G2 spectrophotometer and a Hitachi RMU-6L mass spectrometer, respectively. ^{1}H-NMR spectra were measured with Hitachi R-20B and R-24 spectrometers, using TMS as an internal standard. ^{31}P-NMR spectra were measured with Hitachi R-20-R-204-P and R-20B-R-204-PB spectrometers, using 85% phosphoric acid as an external standard.

Starting materials were prepared as described previously.[1] All the reactions were carried out under nitrogen.

Reactions of Benzaldehyde. *a) With* $[Ph_2PO]Na$ *(**2a**)*: A solution of **2a** was prepared from 2.27 g (9.6 mmol) of diphenylphosphinyl chloride (**1a**) and 0.47 g (20 mg atom) of sodium metal in 14 ml of THF at room temperature for 24 hr. To the filtrate was added 2.39 g (23 mmol) of benzaldehyde. The mixture was stirred for 24 hr at room temperature and then refluxed for 2 hr. The reaction mixture was poured into water and extracted with ether. The dried extract was evaporated and the residue was separated by dry column chromatography (DCC) on silica gel with ether to give 0.187 g (7%) of benzyldiphenylphosphine oxide (**3**) and 1.55 g (65%) of benzyl benzoate which was identified by the IR spectrum.

3: mp 190—192 °C (from ethanol) (lit,[6] 192—193 °C); NMR ($CDCl_3$): δ 3.6 (d, J_{PCH} 13.8 Hz, 2H, PCH_2), 7.15 (s, 5H, Ph), and 7.35—7.9 (m, 10H, 2Ph).

*b) With $[Ph_2PO]MgCl$ (**5a**)*: A mixture of 2.97 g (12.6 mmol) of **1a** and 0.568 mg (23.7 mg atom) of magnesium in THF (32 ml) was stirred at room temperature for 1 hr and then refluxed for 1 hr. To the filtrate was added 2.13 g (20 mmol) of benzaldehyde and the mixture was treated similarly. Separation by DCC gave 0.64 g (30%) of benzyl alcohol, 0.112 g (5%) of benzoin, 0.197 g (9%) of benzil, which were identified by the IR spectra, 0.227 g (6%) of α-hydroxybenzyldiphenylphosphine oxide, mp 172—174 °C (lit,[2b] 176 °C), and 34 mg (1%) of **3**, mp 190—192 °C, which were identified by the IR and NMR spectra.

*c) With $[Ph_2PO]ZnCl$ (**6a**)*: A mixture of 1.47 g (6.2 mmol) of **1a** and 0.954 g (15 mg atom) of zinc dust in 15 ml of THF was stirred at room temperature for 24 hr. To the solution was added 2.32 g (22 mmol) of benzaldehyde. The mixture was stirred for 24 hr at room temperature and then refluxed for 2 hr. After removal of unchanged zinc dust and THF, the residue was crystallized to give 0.813 g (60%) of diphenylphosphinic acid and 0.149 g (8%) of **3**, successively.

Reactions of p-*Benzoquinone.* *a) With $[Ph_2PO]Li$ (**11a**)*: A solution of **11a** was prepared from 1.53 g (6.5 mmol) of **1a** and 0.19 g (27 mg atom) of lithium metal in 15 ml of THF by stirring for 3 hr at room temperature and then heating for 1 hr, and decanted under nitrogen. To the solution was added 0.562 g (5.2 mmol) of *p*-benzoquinone in 15 ml of THF and the mixture was allowed to stand overnight. The resulting blue solution was poured into water, acidified with 2M hydrochloric acid, and extracted with chloroform and ethyl acetate, successively. The ethyl acetate extracts gave 0.19 g (33%) of hydroquinone (**14**) after evaporation, which was identified by comparison of IR and tlc with those of an authentic sample. The chloroform extracts were chromatographed on silica gel with chloroform to give two crystalline compounds. One was recrystallized twice from 95% ethanol to give **12a**, mp 218—220 °C, yield 0.341 g (20%). IR (KBr): 3150 (OH) and 1140 cm^{-1} (P=O); Mass: *m/e* 310 (M^+).

Found: C, 69.93; H, 5.06%. Calcd for $C_{18}H_{15}O_3P$: C, 69.67; H, 4.87%.

The other was recrystallized from benzene-methanol to give **13a**, mp 190—192 °C, yield 0.267 g (18%); IR (KBr): 3200 (OH) and 1218 cm^{-1} (P=O); NMR ($CDCl_3$): δ 6.75 (q, *J* 9 Hz, 4H) and 7.4—8.2 (m, 10H).

Found: C, 69.92; H, 4.85%. Calcd for $C_{18}H_{15}O_3P$: C, 69.67; H, 4.87%.

*b) With $[Ph_2PO]MgCl$ (**5a**)*: A solution of **5a**, prepared from 1.50 g (6.3 mmol) of **1a** and 0.257 g (11 mg atom) of magnesium in 15 ml of THF, was added to 0.545 g (5 mmol) of *p*-benzoquinone in THF (15 ml) and stirred for 14 hr at room temperature. The resulting greenish precipitates turned brown in the air. The precipitates were added to 2 M hydrochloric acid, but were not completely soluble. A small amount of methanol was then added for complete dissolution and the reaction mixture was treated with DCC on silica gel with ether. Each fraction was extracted with methanol to give 0.342 g (17%) of **12a**, 94 mg (17%) of **14**, mp 172—173 °C (identified by tlc and IR), and 0.124 g (8%) of magnesium salt, mp>300 °C, which was dissolved in 10% NaOH solution and neutralized with hydrochloric acid to give diphenylphosphinic acid after extraction with chloroform.

*c) With $[Ph_2PO]al$ (**15a**)*: A solution of **15a**, prepared from 1.65 g (7.0 mmol) of **1a**, 0.263 g (9.7 mg atom) of aluminum foil and 54 mg (0.2 mmol) of mercuric chloride in 15 ml of THF by heating for 6 hr, was added to 0.932 g (8.6 mmol) of *p*-benzoquinone in 15 ml of THF. The reaction mixture was chromatographed on silica gel after filtration to give 0.134 g (8%) of **13a** and 0.183 g (20%) of **14**. The precipitates (1.33 g) contained aluminum which was difficult to remove.

*d) With $[Ph_2PS]al$ (**15b**)*: A solution of **15b**, prepared from 1.89 g (7.5 mmol) of **1b**, 0.435 g (16 mg atom) of aluminum foil and 54 mg (0.2 mmol) of mercuric chloride in 15 ml of THF by heating for 3 hr, was added to 0.693 g (6.4 mmol) of *p*-benzoquinone in 15 ml of THF, and stirred for 15 hr at room temperature. After filtration of precipitates, the filtrate was chromatographed to give 47 mg (0.4 mmol) of recovered quinone and 0.221 g (9%) of **13a**. The precipitates (1.26 g) contained aluminum.

e) With Diphenylphosphine Sulfide: A mixture of 1.64 g (7.5 mmol) of the sulfide and 0.97 g (9.0 mmol) of *p*-benzoquinone in 50 ml of THF was stirred for one day at room temperature. After evaporation, a dark brown tarry substance was subjected to DCC on silica gel with chloroform to afford 1.71 g (70%) of **12b**, which was further purified by column chromatography on alumina with ethanol and recrystallized from ethanol-*n*-hexane, mp 148—149 °C. IR (KBr): 3320, 3275 (OH), and 640 cm^{-1} (P=S); NMR ($CDCl_3$): δ 6.12 (s, 1H, OH), 6.22 (d, J_{PCCH} 14.4 Hz, 1H), 6.8—6.9 (m, 2H), 7.2—7.85 (m, 10H, 2Ph), and 9.07 (s, 1H, OH); δ_p ($CHCl_3$): −37.2 ppm; Mass: *m/e* 326 (M^+).

Found: C, 66.30; H, 4.59%. Calcd for $C_{18}H_{15}O_2PS$: C, 66.25; H, 4.63%.

*f) With $[Ph_2PS]Li$ (**11b**)*: To a solution of **11b** prepared from diphenylphosphine sulfide (1.44 g, 6.6 mmol) in THF (50 ml) and *n*-butyllithium (7.7 mmol) was added dropwise 0.81 g (7.5 mmol) of *p*-benzoquinone in 20 ml of THF with stirring, and the mixture was stirred for one day at room temperature. After removal of THF, the residue was treated with 2 M hydrochloric acid, and extracted with chloroform. Removal of the chloroform from the dried extract gave a tarry product, which was subjected to column chromatography with ethyl acetate to give 0.646 g (30%) of **12b**. Crude **12b** was purified by DCC on silica gel with ether and recrystallized from chloroform-*n*-hexane, mp 155—157 °C. The NMR, IR, and mass spectral data were identical with those of a sample obtained in *e*).

*g) With $[Ph_2PO]FeCl$ (**16a**)*: A mixture of 1.48 g (6.3 mmol) of **1a** and 0.30 g (5.4 mg atom) of reduced iron powder in 15 ml of THF was stirred overnight. To the solution was added 0.338 g (3.1 mmol) of *p*-benzoquinone in 15 ml of THF and stirred for 30 min at room temperature. The resulting precipitates were filtered off. The filtrate was again filtered through alumina to remove diphenylphosphinic acid and the filtrate was evaporated. The residue was treated with ether. Insoluble part (**17a**) was recrystallized from 2-propanol, mp 210—212 °C, yield 1.24 g (78%). IR (KBr): 1235 (P=O), 1180 (Ph–O), and 920 cm^{-1} (P–O); NMR ($CDCl_3$): δ 7.25 (s, 4H) and 7.5—8.2 (m, 20H); δ_p ($CHCl_3$): −30.5 ppm.

Found: C, 70.38; H, 4.58%. Calcd for $C_{30}H_{24}O_4P_2$: C, 70.56; H, 4.74%.

The precipitates (0.287 g) were insoluble in organic solvents. When the precipitates were dissolved in 10% NaOH solution and neutralized with hydrochloric acid, diphenylphosphinic acid was obtained.

*h) With $[Ph_2PS]FeCl$ (**16b**)*: A reaction mixture of 1.55 g (6.1 mmol) of **1b** and 0.270 g (4.7 mg atom) of reduced iron powder in 15 ml of THF was added to 0.254 g (2.3 mmol) of quinone in 15 ml of THF and 1.00 g (79%) of **17b** was obtained, mp 220—221 °C (from 2-propanol). IR (KBr): 1170 (C–O), 1120 (P–Ph), 900 (P–O), and 550 cm^{-1} (P=S); NMR ($CDCl_3$): δ 6.9 (s, 4H) and 7.35—8.2 (m, 20H).

Found: C, 66.20; H, 4.22%. Calcd for $C_{30}H_{24}O_2P_2S_2$: C, 66.41; H, 4.46%.

Anomeric Effect in Sulfur Heterocycles Carrying Sulfur Substituents[1]

Michinori Ōki, Tadashi Sugawara, and Hiizu Iwamura
Department of Chemistry, Faculty of Science, The University of Tokyo, Tokyo 113
(Received July 4, 1974)

Conformational analysis of 1,3,5-trithiane derivatives with sulfur-substituents was carried out with the aid of PMR spectra at various temperatures. 2-Phenylthio-1,3,5-trithiane exhibited the strong anomeric effect whereas 2-phenylthiothiane the moderate. This enhanced anomeric effect in trithiane derivatives was attributed to both the stabilization of the axial form and the destabilization of the equatorial form. *cis*-2,4-Bis(phenylthio)-1,3,5-trithiane was found to possess a diaxial conformation to a fair extent in support of the presence of the strong anomeric effect. Equilibration between *cis* and *trans* forms of 2,4-bis(phenylthio)-1,3,5-trithiane was carried out to show that the *trans* form was more stable than the *cis*. The barrier to inversion of *trans*-2,4-bis(phenylthio)-1,3,5-trithiane was obtained as *ca.* 11 kcal/mol.

Since the discovery of the fact, by Lemieux *et al.*,[2] that pyranose derivatives possessing such substituents as alkoxy, acyloxy, or halogen at 2-position prefer the substituent-axial conformation, the phenomenon has drawn attention of many investigators. This phenomenon is in sharp contrast with the free energy difference in cyclohexane derivatives in which the substituent equatorial conformation predominates. The effect which favors the axial conformation in pyranose and analogous sulfur systems has been recognized as the anomeric effect.

Whereas many reports have been published on this effect in oxane and 1,3-dioxane derivatives,[3] there has been only one report on the anomeric effect in sulfur analogs.[4] Since we have observed strong anomeric effect in benzoyloxy derivatives of thiane and analogs,[5] it must be of interest to see the effect in sulfur-substituted thiane and trithiane.

As to the conformational energy of sulfur-substituents, there are two factors to be considered. These are the bond length and the van der Waals radius. Comparison of these factors with the oxygen compound indicates that a longer C–S distance (1.81 Å) than that of the C–O (1.43 Å) tends to lessen and a larger van der Waals radius of sulfur (1.85 Å) than that of oxygen (1.40 Å) tends to enlarge the 1,3-diaxial interaction. As a consequence, the conformational free energy diference for the SH group (0.9 kcal/mol) is only a little larger than that for the OH (0.7 kcal/mol) in cyclohexane series.[6] There is another factor to be considered in sulfur heterocycles. The larger bond distance of the C–S may lessen the 1,3-diaxial interaction.

This paper reports discovery of strong anomeric effect in trithiane derivatives, compares the effect with another sulfur heterocycle, and discusses equilibria of disubstituted compounds.

Results and Discussion

Monosubstituted 1,3,5-Trithianes. Methylene and methine part of PMR spectra of 2-phenylthio-1,3,5-trithiane (**1**) in $CDCl_3$–CS_2 (1 : 1 v/v) both at room temperature and at −83 °C are shown in Fig. 1. At room temperature, methine and methylene signals are seen at δ 5.35, and 3.73 and 4.80, respectively, whereas at −83 °C, a pair of methine signals at δ 5.46, and 5.10, and a pair of AB signals (δ 3.55 and 5.15, J=14.4 Hz; δ 3.91 and 4.40, J=14.4 Hz) are found. The results must be interpreted on a basis that, while the exchange between two conformations is too fast at room temperature, that at −83 °C is slow enough to detect the respective conformations by means of NMR technique. The integrated intensities of these signals show that the population ratio of these isomers is 8.2±0.2.

The spectral features of the more stable isomer are showing up of the methine signal at lower field than the unstable conformer and larger difference in chemical shifts of the A and B protons. Indeed, the difference in chemical shifts of the AB signals amounts to 1.60 ppm and is much larger than that of 1,3,5-trithiane in $CDCl_3$ at −70 °C (0.75 ppm). In contrast to this feature, the difference in chemical shifts of AB signals of the less stable isomer is only 0.45 ppm which is a little smaller than the corresponding value of trithiane. These spectral features of two conformers should be clues to assign the conformation.

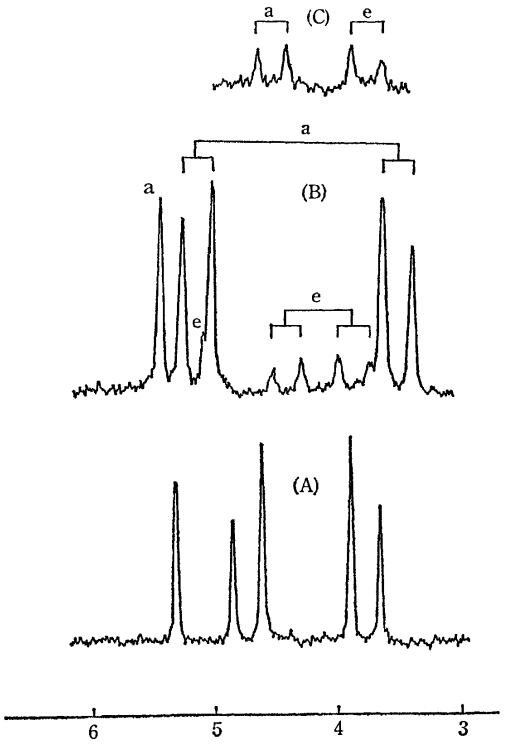

Fig. 1. PMR spectra of 2-phenylthio-1,3,5-trithiane [(A) at 34 °C and (B) at −83 °C] and that of 1,3,5-trithiane [(C) at −70 °C] in $CDCl_3$–CS_2 (1 : 1).

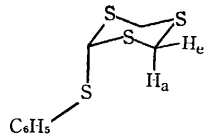
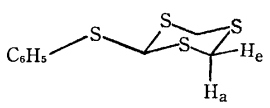
Higher field doublets of the respective AB signals may be assigned to the equatorial proton because equatorial protons are known to give a higher field signal than the axial in trimethyltrithianes.[7] Since 1,3,5-trithiane shows AB signals at δ 3.76 and 4.51 with coupling constant of 14.7 Hz, the equatorial proton of the more populated isomer shows a little up-field shift from the trithiane itself, whereas the axial proton a large low-field shift. As the difference in structure between 1,3,5-trithiane and **1**, the presence of phenylthio group instead of hydrogen can be taken as a major one. Since phenyl is a bulky group, it will not reside above the trithiane ring as one of the possible conformations of phenylthio-axial conformer requests: an assumption that conformations like **1a** only exist becomes a good approximation in the present discussion. Then a major factor which determines the chemical shifts of equatorial and axial protons in the axial isomer is the presence of an axial C–S bond. Likewise, in the phenylthio-equatorial conformer, the C–S bond exerts the major factor for determining the chemical shifts of the axial and equatorial protons. While three conformations are made by the rotation about the C_{ph}–S bond in this case, the phenyl group is located so distantly from the protons in question that its effect may be neglected.



(**1a**)

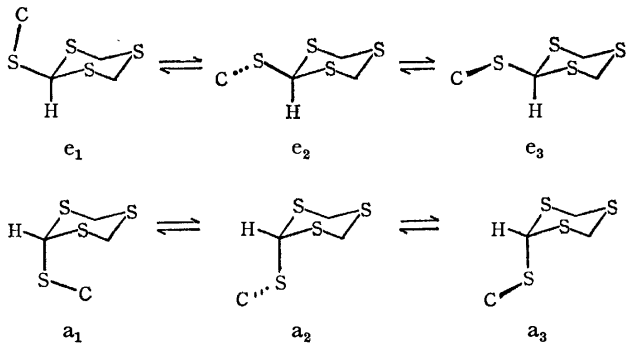


(**1e**)

Consideration of the standard molecular structure, the bond anisotropy of the C–S bond, and McConnell equation[8] reveals that, if there is an axial C–S bond, the axial proton (H_a) at 3-position from the C–S should be strongly deshielded, whereas the equatorial proton (H_e) should be relatively unaffected. Consequently, an increase in chemical shift difference is expected for the methylene protons from that of trithiane. This tendency compares with the observed value of an increase by 0.85 ppm. On the other hand, if there is an equatorial C–S bond, H_e should be unaffected whereas H_a should shift to the higher field slightly. As a consequence, the chemical shift difference should decrease slightly from that of trithiane. This tendency compares with the observed one of a decrease by 0.30 ppm. Thus the more stable isomer must be assigned to phenylthio-axial isomer (**1a**) and the less stable isomer to phenylthio-equatorial isomer (**1e**).

Above assignment is supported by the following fact. When the PMR spectrum of **1** is taken as a CD_3COCD_3 solution at −83 °C, population of the conformer which shows the smaller chemical shift difference increases and the ratio becomes 1.6±0.2 in favor of the isomer which gives larger chemical shift difference. These results indicate that the more polar form is the one which shows less chemical shift difference between protons of the AB type. Since the direction of the dipole in thioethers is known to be that of the lone pairs,[9] compound **1** is considered to be more polar if it takes the phenylthio-equatorial conformation (**1e**).[3] Then a conclusion is drawn that **1a** conformation is more stable and is consistent with that drawn by consideration of the chemical shift difference of the AB protons.

It may be argued that, because of the anisotropy of the C–S bond, the equatorial methine proton at the foot of the phenylthio group should appear at the higher magentic field than the axial, as are the other trithiane protons.[7] The following consideration, however, could give rationale to the apparent reversal of the chemical shifts of axial-equatorial methine protons.



Three stable conformations (e_1, e_2, and e_3) made by the rotation about the S–$C_{trithiane}$ bond of the phenylthio-equatorial conformations may be considered. From the steric grounds, none of these conformations is very unstable and these contribute to a fair extent. On the other hand, the phenylthio-axial form includes other apparently stable conformations (a_1, a_2, and a_3) produced by the rotation about the S–$C_{trithiane}$ bond. As discussed earlier, however, a_1 conformation is considered to be unstable because of the steric effect of the phenyl group and contributes to a very limited extent, if any. Consideration of the dipole moments of the respective conformers reveals that e_1 is the least polar among the phenylthio-equatorial conformations and that there is no appreciable difference in polarity among the phenylthio-axial conformations. Thus, in non-polar media such as those we are discussing here, the e_1 form is the most populated species among **1e**, whereas the a_1 form will have scarce contribution.[10]

A plausible assumption is again that the chemical shift of the methine proton is mainly determined by the bond anisotropy of the C–S bond. Considered the bond anisotropy of the C–S bond, conformers e_2, e_3, a_2, and a_3 are the ones in which the methine proton suffers from the deshielding, whereas the methine proton in conformation e_1 and a_1 is relatively shielded. Then the phenylthio-equatorial form which exists mainly as e_1 should give the methine proton signal at the relatively high field, compared with the phenylthio-axial form which exists mainly as a_2 and a_3.

One may wonder why the apparently abnormal chemical shift of equatorial protons at the foot of the phenylthio group is not attributed to the effect of the phenyl group. However, that this is not the case is understood when the case of 2-methylthio-1,3,5-trithiane (**2**) is taken into account. This compound in $CDCl_3$–CS_2 showed a single peak for the methine proton

at δ 4.95 and a quartet for the methylene protons (δ 4.63 and 3.73, J=14.5 Hz), which split into a pair of singlets (δ 5.05 and 4.95) and a pair of quartets (δ 3.51 and 5.07, J=14.4 Hz; δ 3.99 and 4.45, J=14.4 Hz), respectively, at −83 °C. The ratio of integrated intensities was 3.0±0.2 in favor of the conformer which showed a large chemical shift difference between A and B protons of the AB quartet. The stable isomer may be assigned to the methylthio-axial conformer (**2a**) from the same ground as discussed earlier. This assignment is supported by a fact that the population ratio of these isomers is reduced to 1.1±0.1 when the spectrum is measured with CD_3COCD_3 solution at −83 °C; the less stable form is apparently more polar than the stable.[3] Taking this assignment into account, the axial proton at the foot of methylthio group is at the higher magnetic field than the equatorial.

(**2e**) (**2a**)

After the establishment of the assignment of conformations, determination of the difference in conformational energies will be worthy of study. The conformational energy may be obtained by applying the following equations and obtaining equilibrium constants (K) at various temperatures.

$$\Delta\delta_{obs} = N_a\Delta\delta_a + N_e\Delta\delta_e \quad (1)$$

$$K = \frac{N_e}{N_a} \quad (2)$$

where $\Delta\delta_{obs}$ is the observed chemical shift difference between A and B protons of the AB type after coalescence, $\Delta\delta_a$ and $\Delta\delta_e$ are those of axial and equatorial conformers, respectively, and N_a and N_e are the mole fractions of axial and equatorial conformers, respectively. A similar treatment would have been possible for the methine protons at 2-position, if the heavy overlap with the strong signal were not present. In order to make Eq. (1) valid, the chemical shift of each isomer should not vary at various temperatures. Measurements at various temperatures after splitting of the signals were thus carried out and the results are listed in Table 1. It will be seen that the chemical shift differences between −68 °C and −85 °C are essentially the same. The same tendency may be extended up to room temperature.* The chemical shift differences after coalescence of the two sets of AB signals are also listed in Table 1.

By the averaging process above the coalescence temperature, an equatorial proton of one conformer is converted to an axial proton of the other. Therefore the sign of $\Delta\delta_a$ and $\Delta\delta_e$ must be different. In the actual calculations $\Delta\delta_a$ was taken as positive and $\Delta\delta_e$ negative. The equilibrium constans thus obtained are shown in Table 1. From these data, ΔH and ΔS for the equilibrium **1a**⇌**1e** in $CDCl_3$–CS_2 were obtained as 1.3±0.1 kcal/mol and 3.0±0.5 eu, respectively. The conformational energy in acetone-d_6 can be obtained in the same manner: ΔH=0.4±0.1 kcal/mol and ΔS=1.0±0.3 eu. It can be pointed out that

* This method of determination of thermodynamic parameters can be checked by extrapolating the population ratio to low temperatures. The calculated value is 7.7±0.5 at −83 °C and this compares favorably with the observed ratio of 8.2±0.2

Table 3. Chemical shift difference between two methylene protons of *cis*-2,4-bis(phenylthio)-1,3,5-trithiane at various temperatures and equilibrium constants for the equilibrium **3aa**⇌**3bb** (1 : 1 $CDCl_3$-CS_2)

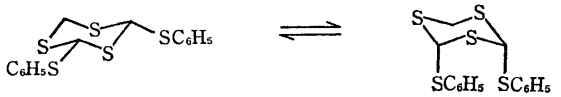
T°C	51	46.5	32	29	14	−6	−83
$\Delta\delta$ ppm	0.21	0.20	0.19	0.17	0.16	0.16	a 1.60
							e 0.27
K	0.34	0.33	0.32	0.30	0.29	0.29	0.3[a]

a) Obtained by direct integration.

ΔH is reduced by 0.9 kcal/mol in acetone-d_6, and this change can be attributed largely to the fact that conformer **1e** is stabilized in a high dielectric medium on the electric ground.

Similar treatment was made for 2-methylthio-1,3,5-trithiane. The results are listed in Table 2, which produce ΔH and ΔS, for the equilibrium **2a**⇌**2e** in $CDCl_3$–CS_2, of 0.9±0.1 kcal/mol and 1.0±0.5 eu, respectively. These parameters in acetone-d_6 are 0.1± 0.1 kcal/mol and 0.2±0.2 eu, respectively. Stabilization, to a large extent, of the polar conformer is observed again.

Disubstituted 1,3,5-Trithianes. Since the anomeric effect in 2-phenylthio-1,3,5-trithiane has been found to be fairly large, it will be interesting to see the effect of substitution by one more phenylthio group in 1,3,5-trithiane system. If 2,4-bis(phenylthio)-1,3,5-trithiane has a *cis* configuration, it will assume either a diequatorial (**3ee**) or a diaxial (**3aa**) conformation. In cyclohexane series, the diequatorial form is overwhelming because of a severe 1,3-*syn*-diaxial interaction, whereas the diequatorial form in 1,3,5-trithiane system is disfavored by the anomeric effect. The PMR spectrum of *cis*-2,4-bis(phenylthio)-1,3,5-trithiane (**3**) in $CDCl_3$–CS_2 showed a single peak for methine protons at δ 5.10 and a quartet for methylene protons at δ 3.98 and 4.17, J being 14.4 Hz. On cooling the solution



(**3ee**) (**3aa**)

down to −83 °C, however, the spectrum changed to show a pair of singlets at δ 4.92 and 5.38 and two sets of AB quartets (δ 3.88 and 4.15, J=14.4 Hz; δ 3.62 and 5.22, J=14.4 Hz). The results are best interpreted by assuming that the inversion of the ring is fast at room temperature but frozen at −83 °C on the PMR time scale to show the signals of both isomers (**3ee** and **3aa**) separately. The population ratio as determined by the integrated intensity was 3.2±0.3. From an analogy of the discussion given in the part of 2-phenylthio-1,3,5-trithiane, it will be natural to assume that an isomer which has two axial phenylthio groups should give further separation of the chemical shifts of the AB protons, because two C–S bonds are inserted axially. On the contrary, an isomer which has two equatorial phenylthio groups should show smaller separation of the chemical shifts than **1e**. Thus the isomer which gives $\Delta\delta$ of 1.60 ppm is assigned to **3aa** and the other to **3ee**, $\Delta\delta$ for the latter being 0.27 ppm. Then the diequatorial form **3ee** is favored over the diaxial form **3aa**. The chemical shifts and intensities of the methine protons at 2-position are consistent with this assignment: the signal at higher magnetic field is more intense than that at the lower field.

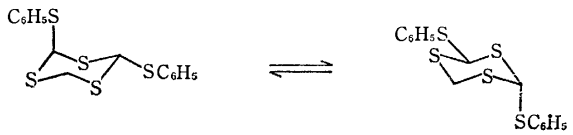
The change in population of **3ee** and **3aa** at various temperatures is tabulated in Table 3. The enthalpy change and entropy change for the equilibrium **3aa**⇌ **3ee** are estimated to be −0.2±0.1 kcal/mol and +1.0± 0.1 eu, respectively, from these results. Thus composition of **3** at 34 °C is 24.5% **3aa** and 75.5% **3ee**.

It is rather surprising to see that the diaxial form exists to a fair extent in **3**, in view of the results obtained with cyclohexane derivatives. In the cyclohexane series, a substituent of RS type generally shows the free energy difference of *ca.* 0.8 kcal/mol at room temperature, the equatorial form being favored.[6] Existence of 1,3-diaxial conformer **3aa** to a fair extent must then be a reflection of the strong anomeric effect and lessened 1,3-diaxial interaction because of the long distance of C–S bonds in this compound.

Barrier to Inversion of trans-*2,4-Bis(phenylthio)-1,3,5-trithiane.* It may be argued that the ring conformation of 1,3,5-trithiane with a phenylthio axial substituent might be altered from the normal chair as in the case of multisubstituted 1,3-dithiane series.[11] However, this possibility may not be taken as a serious one for the following reason.

Since it is well known that the inversion barrier of the six-membered rings is not largely affected by substituents if the ring structure is not deformed from the normal chair,[12] estimation of the inversion barrier of the system in question must lead help in diagnosing the ring conformation.

trans-2,4-Bis(phenylthio)-1,3,5-trithiane (**4**) was used for the investigation, because this compound should give easier analysis due to the high degree of symmetry. While **4** showed sharp singlets due to methylene (δ 4.37) and methine (δ 5.62) protons at 34 °C, the former split to two singlets (δ 5.52 and 5.69)** and the latter



(**4**) (**4'**)

** The signal at the lower field is assigned to the axial, because the signal at the higher magnetic field is broader probably owing to the long range coupling. This anomaly, compared with other methine protons at the foot of phenylthio group in compounds examined here, may be attributed to the presence of an axial C–S bond at 3-position from the proton.

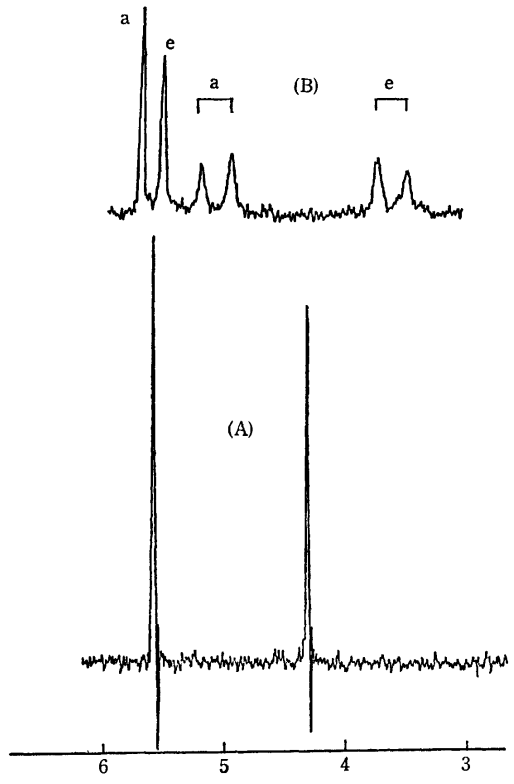


Fig. 2. PMR spectra of *trans*-1,3-bis(phenylthio)-1,3,5-trithiane in $CDCl_3$-CS_2 (1 : 1): (A) at 34 °C and (B) at −80 °C.

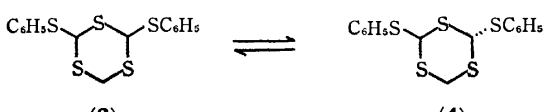
changed to an AB quartet (δ 3.70 and 5.09, J=15 Hz) at −80 °C. The methine protons showed coalesence of the signals at −61 °C, whereas the methylene protons at −46 °C. The free energy of activation for inversion was calculated to be 10.4 and 11.1 kcal/mol from methine and methylene protons, respectively, by putting these results into the following equations. Equation (3) was applied for the methine proton and Eq. (4) for the methylene protons. These data are in good agreement with the barrier (11.0 kcal/mol) to inversion of 1,3,5-trithiane.[13]

$$\Delta G_C^{*} = 4.57\ T_C(9.97+\log_{10} T_C/\Delta\nu) \quad (3)[14]$$

$$\Delta G_C^{*} = 4.57\ T_C(9.97+\log_{10} T_C/\sqrt{\Delta\nu^2+6J_{AB}{}^2}) \quad (4)[15]$$

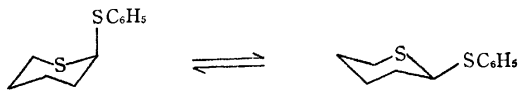
cis-trans *Equilibration of 2,4-Bis(phenylthio)-1,3,5-trithiane.* In view of the fact that 1,3-diaxial form is present to a fair extent in *cis*-2,4-bis(phenylthio)-1,3,5-trithiane (**4**), equilibration between the *cis* and *trans* isomers of **4** will clear another aspect of the conformational energies of the phenylthio group in trithiane. In the *cis* isomer, both phenylthio groups will be either axial or equatorial, whereas one of the phenylthio groups is equatorial and the other axial in the *trans*.



(**3**) (**4**)

The equilibration is carried out by heating the *cis*-isomer in $CDCl_3$ at 80 °C in the presence of benzoic acid as a catalyst. Equilibrium constant was obtained as 3.2 in favor of the *trans*. The same ratio of *cis* and *trans* isomers was obtained also by starting from the *trans*-isomer. Since the *trans* form has two degenerate conformations **4** and **4'**, these conformations must contribute to the same degree and the contributions are calculated to be 38% each. On the other hand, the equilibrium constant for **3aa**⇌**3ee** at 80 °C is calculated as 0.37 by using the thermodynamic parameters derived as before. Thus the equilibrium mixture of 2,4-bis(phenylthio)-1,3,5-trithiane at 80 °C must consist of 6% **3aa**, 18% **3ee**, 38% **4** and 38% **4'**. Although detailed discussion on the conformational and configurational equilibrium of *cis* and *trans* compounds is difficult because of the presence of many factors, the preference of the trans compound clearly indicates the presence of strong anomeric effect.

2-Phenylthiothiane. In order to discuss the strength of anomeric effect in 1,3,5-trithiane derivatives, conformational analysis of 2-phenylthiothiane (**5**) will afford the useful information. Thus study on this compound was undertaken. Compound **5** in $CDCl_3$ shows a near double doublet signal (J=7.5 and 3.0 Hz) for the methine proton at 2-position in the PMR spectrum at 34 °C to indicate that the phenylthio equatorial isomer exists to at least some extent. This result is in accordance with those obtained by Zefirov *et al.*[4] who reported that 2-phenylthiothiane exists as a mixture of 45% **5a** and 55% **5e** from the shapes of methine proton signals.



(**5a**) (**5e**)

On cooling the solution, the methine proton signal broadened considerably at −80 °C and was split into two peaks at −100 °C: one peak is a near triplet centered at δ 4.26 and the other an apparent double doublet centered at δ 3.89. The assignment is straightforward: the near triplet signal and the double doublet are assigned to **5a** and **5e**, respectively.[16] The relative intensity is 1.8±0.2 to 1 in favor of **5a**. From these data ΔH and ΔS are calculated as 0.2±0.1 kcal/mol and 0.4±0.2 eu, respectively. The results indicate that the axial isomer is more stable in terms of enthalpy but, because of unfavorable entropy change probably due to the steric effect in one of the rotational isomers, the equatorial isomer contributes to a fair extent at relatively high temperatures: 44% at 34 °C.

Comparison of the Anomeric Effect in Various Compounds. Three main factors are usually cited for the appearance of the anomeric effect. They are dipole-dipole interactions of the polar bonds,[17] repulsive lone-pair-lone-pair interactions of the heteroatoms,[18] and the resonance effect which involves overlap between the p-orbitals of the heteroatom and the back lobe of the orbital involved in forming the axial polar bond.[19] These three factors operate favorably in axial isomers but not in the equatorial.

It is quite natural to consider that these factors are enhanced when heteroatoms reside on both sides of the axial polar bond and these must cause the enhanced anomeric effect in 1,3,5-trithiane, compared with

thiane derivatives. There are reports which contradict this idea: the anomeric effect in 2-methoxy-1,3-dioxane is smaller than that in 2-methoxyoxane.[3] However, the phenomenon was later attributed to the puckering of 1,3-dioxane ring[20] and the short distance in 1,3-*syn*-axial interaction because the C–O bond is shorter than the C–C.[10]

Striking enhancement of the anomeric effect is observed by going from thiane to trithiane. This observation may be attributed to the destabilization of the equatorial form and/or the stabilization of the axial form in trithiane derivatives. In the axial form of 1,3,5-trithiane derivatives, the energy level may not be so high as that of the corresponding thiane derivatives because the 1,3-diaxial interaction is lessened to a considerable extent owing to the longer distance of the C–S bonds and a somewhat flattened conformation of trithiane.[21] In the equatorial form of 2-phenylthiothiane, the repulsive interaction between lone pairs of electrons belonging to two sulfur atoms in the ring and the substituent may be relieved to some extent by increasing the torsion angle about the C_{ring}–C_{subst} bond. However, this mode of relief is not possible for the trithiane derivative: the relief of repulsive interaction with one sulfur atom by increasing the torsion angle necessarily increases the repulsive interaction with another sulfur. Thus both factors seem to enhance the anomeric effect in trithianes.

Experimental

PMR Measurement. The PMR spectra were recorded on a Hitachi R 20B spectrometer equipped with a temperature variation accessory. Temperature was read by the chemical shift difference of methyl and hydroxy protons of methanol at the low temperature and those of ethylene glycol at room temperature or above.

*2-Phenylthio-1,3,5-trithiane (**1**)*, mp 123.0—123.5 °C, was prepared from 2-benzoyloxy-1,3,5-trithiane and benzenethiol as reported previously.[5]

*2-Methylthio-1,3,5-trithiane (**2**).* A solution of 2 g (9 mmol) of 2-benzoyloxy-1,3,5-trithiane[5] and 1.5 g (30 mmol) of methanethiol in 30 ml of chloroform was heated for 5 hr in a reaction vessel equipped with a Dry Ice condenser. Benzoic acid produced during the reaction was removed by passing the solution through a potassium carbonate layer and the solvent was evaporated to give crude products (95 %). Recrystallization from carbon tetrachloride–chloroform (1 : 1 v/v) gave a pure compound, mp 94—95 °C. Found: C, 26.27; H, 4.20%. Calcd for $C_4H_8S_4$: C, 26.06; H, 4.37%. PMR ($CDCl_3$, δ): 2.21 (s, 3H), 3.73 and 4.63 (q, 4H), 4.95 (s, 1H).

*2,4-Bis(phenylthio)-1,3,5-trithianes (**3** and **4**).* A solution of 4 g (0.01 mol) of *cis*-2,4-dibenzoyloxy-1,3,5-trithiane[5] and 3 g (0.03 mol) of benzenethiol in 50 ml of benzene was refluxed for 3 hr. Removal of benzoic acid followed by evaporation of the solvent gave an isomeric mixture of bis-(phenylthio) derivatives (95%). They were separated by chromatography on neutral alumina.

Elution with hexane–benzene(7 : 3) afforded the trans isomer which was purified by recrystallization from carbon tetrachloride, mp 97—99 °C. Found: C, 51.03; H, 3.82; 45.04%. Calcd for $C_{15}H_{14}S_5$: C, 50.80; H, 3.98; S, 45.21%. PMR ($CDCl_3$, δ): 4.33 (2, 2H), 5.61 (s, 2H), 7.2—7.6 (m, 10H).

Elution with benzene afforded the crude *cis* isomer which was purified by rechromatography. Found: C, 51.07; H, 4.39%. Calcd for $C_{15}H_{14}S_5$: C, 50.80; H, 3.98%. PMR ($CDCl_3$, δ): 4.03 and 4.18 (q, 2H), 5.09 (s, 2H), 7.2—7.6 (m, 10H).

Equilibration of cis- *and* trans-*2,4-bis(phenylthio)-1,3,5-trithianes.* A solution of 60 mg (0.16 mmol) of **3** and 50 mg (0.4 mmol) of benzoic acid in 0.4 ml of deuteriochloroform was heated in a sealed NMR sample tube at 80 °C. The process of equilibration could be monitored by the careful integration of methine proton signals of the respective isomers. It took 10 hr to reach the equilibrium.

The same equilibrium mixture was obtained by starting from the *trans* isomer (**4**). It took 20 hr to reach the equilibrium.

Die Rolle des Oxydationseffekts bei der Lithentwicklung

Tsuneo SUGA

Forschungslaboratorium der Konishiroku Photoindustrie AG, Hino-shi, Sakura-machi 1, Tokio 191

(Eingegangen am 4. März 1974)

Als Fortsetzung früherer Mitteilungen,[1,2] in welchen der Autor auf die oxydative Wirkung der Oxydationsprodukte des Hydrochinons bei der Lithentwicklung hinwies, wurde hier der Oxydationseffekt eingehender untersucht und der Mechanismus der Lithentwicklung diskutiert, obwohl einige Arbeiten[3-6] keinen Oxydationseffekt vertreten. Die Lithentwicklung hat eine beträchtliche Induktionsperiode, in der man keine Schwärzung bemerken kann. Durch physikalische Entwicklung, die der chemischen Entwicklung und dem Fixieren nachfolgte, bemerkte man eine sichtbare Schwärzung. Diese Versuchsmethode führte zu folgenden Ergebnissen. Während der Induktionsperiode konnte man das Wachstum von Entwicklungskeimen experimentell finden. Der Oxydationseffekt angesammelter Oxydationsprodukte auf die Entwicklungskeime wurde im Entwicklungsverlauf nach der Induktionsperiode als wirksam betrachtet. Während der Induktionsperiode wurde aber eine Oxydation der Entwicklungskeime durch die diffundierenden Oxydationsprodukte als Saumeffekt beobachtet. Durch die Feststellung des Oxydationseffekts ist die Folgerung über den Mechanismus der Lithentwicklung die gleiche wie in früheren Arbeiten, kann aber ausführlicher beschrieben werden.

Der Lithentwickler ist bekanntlich ein Hydrochinon-Alkali-Entwickler mit einer niedrigen Konzentration von Sulfitionen, bei dessen Behandlung ein Lithfilm einen bildscharfen Litheffekt zeigt. Zum Mechanismus der Lithentwicklung wurden bisher verschiedene Hypothesen[2] vorgeschlagen, von denen die auf einer Entwicklungsaktivität der Oxydationsprodukte des Hydrochinons beruhende besonders unterstützt werden kann. In früheren Arbeiten[1,2] weist der Autor auf die Wichtigkeit des Oxydationseffekts der Oxydationsprodukte sowie deren Beschleunigungseffekt über den Mechanismus der Lithentwicklung hin. Eine Reihe von gegenteiligen Arbeiten,[3-6] die keinen Oxydationseffekt bei der Lithentwicklung mitteilen, sind bis heute erschienen: Zwicky[3] fand keine Oxydation des latenten Bildkeimes durch die Phenidon-Hydrochinon-Entwicklung nach der Lithentwicklung. Die Versuche von Okutsu, Sakai und Iwano,[4,6] die den Einfluß der diffundierenden Oxydationsprodukte auf eine andere Emulsionsschicht suchten, zeigten keinen Oxydationseffekt. Die elektronenmikroskopischen Beobachtungen von Shiozawa und Sakai[5] zeigten ebenso keine Oxydation der Entwicklungskeime.

In der vorliengenden Arbeit wurde der Oxydationseffekt eingehender als früher untersucht, indem der Beschleunigungseffekt berichtet wurde.[2] In Zusammenfassung der Ergebnisse wurde eine Hypothese über den Mechanismus der Lithentwicklung diskutiert.

Experimentelles

Emulsion und chemische Entwicklung. Eine Chlorbromsilber-Emulsion, die 30 Mol% AgBr betrug und schwefelsensibilisiert wurde, wurde auf eine Unterlage gegossen. Für die chemische Entwicklung bei 20 °C dienten ein normaler Lithentwickler und dieser Lithentwickler mit Natriumsulfit. Einzelheiten der Materialien und der Versuchsdurchführung wurden in früherer Arbeit[2] beschrieben.

Physikalische Entwicklung. Die Probefilme, die zuerst chemisch entwickelt, fixiert und gewässert wurden, wurden dann in der Lüppo-Cramerschen Lösung 60 Sekunden bei 20°C physikalisch entwickelt. Sie enthielt pro Liter 10 g Metol (*N*-Monomethyl-*p*-aminophenolsulfat), 100 g Zitronensäure, 10 g Natriumzitrat und außerdem 10 g Silbernitrat, die kurz vor der Behandlung zugesetzt wurden.

Ergebnisse und Diskussion

Hydrochinonentwicklung hat eine ausgeprägte Induktionsperiode bis zur ersten sichtbaren Silberabscheidung, die in diesem Versuch etwa 45 Sekunden dauerte. Gegenwart von Sulfit verhindert bekanntlich die Bildung der Oxydationsprodukte des Hydrochinons unter Bildung von Hydrochinonsulfonsäure. Die Wirkung des Sulfites auf den Entwicklungsverlauf nach der Induktionsperiode wurde heir untersucht. Abb. 1 schildert den Einfluß der Sulfitkonzentration von 0, 10 und 30 g/l auf die Form der Schwärzungskurven von 60 und 90 Sekunden chemisch entwickelter Probefilme. Durch steigende Sulfitzusätze rückte der Fuß der Schwärzungskurven vor, indem er eine weiche Gradation zeigte. Die Ursache dafür wurde in voriger Arbeit[2] auf die oxydative Wirkung der Oxydationsprodukte mit Hilfe von Br^-- und H^+-Ionen zurückgeführt.

Innerhalb der Induktionsperiode kann man elektronenmikroskopisch die kleinsten Entwicklungskeime an Körnern beobachten. Pontius *et al.*[7] fanden elektronenmikroskopisch, daß sich die Entwicklungskeime ungefähr beim Endpunkt der Induktionsperiode in sichtbare fadenförmige Silberteilchen verändern. Von den Ent-

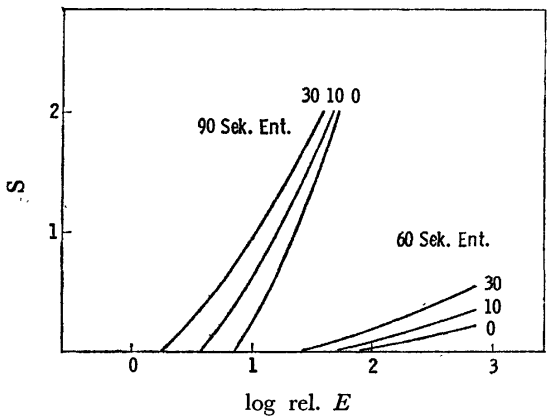

Abb. 1. Einfluß des Sulfites auf Lithentwicklungsvorgang nach der Induktionsperiode. Die Filme wurden 60 und 90 Sekunden bei Anwesenheit von 0, 10 und 30 g Natriumsulfit/l chemisch entwickelt.

rechts: Lithentwickler + 30 g Natriumsulfit/l

wicklungskeimen während der Induktionsperiode nimmt man an, daß sie als physikalische Entwicklungskeime wirken. Nach Vorob'eva und Svirilov[8] beträgt die minimale Größe der Keime für die physikalische Entwicklung etwa 35 Å. Die Versuche, deren Engebnisse in Abb. 2 dargestellt sind, wurden folgendermaßen durchgeführt. Die belichteten Filmstreifen wurden kurze Zeit chemisch entwickelt, fixiert und gewässert, wobei man fast keine Schwärzung bemerkte. Hier sollen die Keime von der Lösungsphase umgeben werden. Bei der nachfolgenden physikalischen Entwicklung entstand eine Schwärzung, die sich mit der Lichtmengenzunahme erhöhte. In dieser Schicht beobachtete man elektronenmikroskopisch die kugelförmigen Silberteilchen. Abb. 2 zeigt Schwärzungskurven der physikalischen Entwicklung von Filmstreifen, die zunächst 15 und 30 Sekunden chemisch entwickelt worden waren. Daraus ist ersichtlich, daß sich mit zunehmender chemischer Entwicklungsdauer die Abscheidungsmenge des Silbers bei der physikalischen Entwicklung erhöhte. Diese Tatsache zeigt, daß sich die unsichtbaren Entwicklungskeime während der Induktionsperiode bei der Hydrochinonentwicklung vergrößern. Wie aus Abb. 2 ersichtlich ist, hatte Sulfit einen geringen Einfluß auf das Keimwachstum im Anfangsstadium der Lithentwicklung, während es im Entwicklungsverlauf nach der Induktionsperiode sehr wirksam war. Daher ist anzunehmen, daß sich die Oxydationsprodukte im Entwicklungsverlauf nach der Induktionsperiode wesentlich auf die Keime auswirken. Die Ursache dafür ist vermutlich ein Vorkommen von geringen Mengen an Oxydationsprodukten zu Beginn der Entwicklung oder eine irreversible Reaktion der Oxydationsprodukte mit Gelatine. Dieses Resultat entspricht dem von Charkoudian *et al.*,[9] die beobachteten, daß keine Spur von Semichinon im Anfangsstadium der Lithentwicklung durch ESR-Messungen vorkam.

An der entwickelten Grenzlinie zwischen schwächer und stärker belichteten Filmflächen bemerkt man eine Schwärzungserniedrigung, wie sie auch als Saumeffekt bezeichnet wird. Im Fall der Lithentwicklung nach der Induktionsperiode wurde schon mitgeteilt,[2] daß die Ursache hierfür auf die oxydative Wirkung der aus den stärker belichteten Stellen diffundierenden Oxydationsprodukte zurückgeführt werden kann. In der vorliegenden Arbeit wurde der Saumeffekt im Laufe der Induktionsperiode, in welcher sich die unsichtbaren Entwicklungskeime vergrößern, untersucht. Die nach der früheren Methode[2] unterschiedlich belichteten Filmflächen wurden 80 Sekunden chemisch entwickelt, wobei sich eine Schwärzung auf der stärker belichteten Fläche befand, jedoch keine auf der schwächer belichteten. Die Schicht wurde dann physikalisch entwickelt, um eine Schwärzung auf der schwächer belichteten Fläche hervorzubringen. Die mikrodensitometrischen Schwärzungsverteilungen zwischen beiden Flächen sind in Abb. 3 dargestellt. Im Fall der Lithentwicklung ist eine merkliche Schwärzungserniedrigung an der Grenze erkennbar, die sich durch Zusatz von Sulfit erheblich verringerte. Auf Grund dieser Tatsachen kann man folgern, daß im Anfangsstadium der Lithentwicklung die von Stellen hoher Schwärzung herausdiffundierenden Oxydationsprodukte auf die Bildkeime der schwächerer Belichtung oxydativ einwirken, um das Wachstum der Keime bei der Entwicklung zurückzuhalten, oder um die Keime zum Abbau zu führen. Dies entspricht einer Oxydation der Bildkeime, deren Möglichkeit aus Messungen von Redoxpotentialen der latenten Bildkeime und der umliegenden Lösung bereits gedeutet wurde.[2] Der exakte Nachweis, ob es sich um eine oxydative Hemmung der Entwicklung oder um einen Abbau von Keimen handelt, ist experimentell schwierig und nicht so bedeutungsvoll für den Mechanismus der Lithentwicklung. Eine vollständige Erklärung der Lithentwicklung ist noch nicht ausreichend, aber eine Hypothese dafür soll mit Hilfe der neuen Ergebnisse ausführlicher als früher wie folgt beschrieben werden. Im Anfangsstadium der Lithentwicklung ist das Wachstum der Entwicklungskeime elektronenmikroskopisch zu beobachten. Die entstandenen Oxydationsprodukte wirken sich währenddessen auf die Keime wenig aus. Im fortgeschritteneren Entwicklungsstadium während der Induktionsperiode sammeln sich die Oxydationsprodukte bei Abwesenheit von Sulfit an, so daß sie auf die Keime

zuerst oxydativ einwirken, um das Auswachsen zum sichtbaren Silber zu hemmen. Diese oxydative Hemmung im Entwicklungsverlauf nach der Induktionsperiode ist wahrscheinlich an den schwächer belichteten Stellen besonders stark. Die Keime an den stärker belichteten Stellen widerstehen der Oxydation und werden weiter entwickelt, wo eine Menge Oxydationsprodukte entstehen, und diffundieren einigen Abstand zu den benachbarten Körnern, in denen die stärker belichteten Bildkeime durch die Herabsetzung der Ladungsschranke beschleunigend entwickelt werden, und die schwächer belichteten durch die oxydative Hemmung oder durch den oxydativen Abbau hemmend entwickelt werden. Die Lithentwicklung gehört einem komplizierten Entwicklungssystem an, in dem die Oxydationsprodukte gleichzeitig zwei Rollen spielen, d.h. die Entwicklung zu beschleunigen und sie oxydativ zu hemmen, oder die Keime oxydativ abzubauen. Eine einheitliche Deutung, wie man sie bisher angenommen hat, wäre für die Diskussion der Lithentwicklung nicht ausreichend.

Obwohl einige Untersuchungen[3-6] keinen Oxydationseffekt bei der Lithentwicklung bemerken, wurde eine Oxydation der Entwicklungskeime durch Versuch bestätigt, was zur Vorstellung der Lithentwicklung von großer Bedeutung ist. Aus dieser Bestätigung des Oxydationseffekts kommt man auch diesmal mit Berücksichtigung der vorigen Ergebnisse der Emulsionseigenschaften[2] im Lithentwickler über die Entstehung des Litheffekts folgendermaßen zu derselben Erklärung wie zuvor:[1,2] Der Litheffekt ist abhängig von der Entwickelbarkeit der stärker belichteten Bildkeime und von der Oxydierbarkeit der schwächer belichteten. Eine richtige Balance dieser beiden Faktoren ist für einen guten Litheffekt wichtig.

Herrn Prof. Dr. K. Honda von der Universität Tokio möchte ich herzlichst für die Diskussion danken.

The Methylation of Phenol and the Decomposition of Methanol on ZnO-Fe_2O_3 Catalyst

Takeshi KOTANIGAWA

Government Industrial Development Laboratory Hokkaido, Higashi-Tsukisamu, Toyohiraku, Sapporo 061-01

(Received March 23, 1974)

As a result of a series of studies, ZnO-Fe_2O_3 catalysts have been shown to promote the selective methylation (k_1) of phenol at the ortho position and also to promote the decomposition of methanol (k_2). The activation energies were determined to be 22±2 kcal/mol for the methylation and 27±3 kcal/mol for the decomposition. The selectivity factor ($S=k_1/k_2$) of the simultaneous reaction was determined for five types of catalysts in order to estimate the most favorable catalyst for the methylation. The selectivity factor of these catalysts decrease with the rise in the calcination temperature. For example, the S on the catalysts calcined at 500 °C is approximately at unity but the S on the catalysts calcined at 800 °C is at about 0.4. These results suggest that the calcination using the present catalysts should be controlled at a low temperature.

In the vapor-phase reaction on a solid catalyst, the selectivity for a desired product is said to be enormously affected by the pore structure of the catalyst.[1,2] However, there have been few experimental studies treating the effects of the pore structure on the selectivity for a desired reaction. Weisz *et al.*, however, reported the effects of pore sizes in the cracking of cyclohexane on a chromia-alumina catalyst.[3] Further, they reported the relations between the pore sizes and the selectivity for the dehydration of *iso*-butyl alcohol and *n*-butyl alcohol on a calcium alumino-silicate.[4]

The present author previously demonstrated that ZnO-Fe_2O_3 catalysts promoted the selective methylation of phenol at the ortho position and that it simultaneously promoted the decomposition of methanol.[5] Further, the relations between the preparative methods and the pore structures of the ZnO-Fe_2O_3 catalysts were studied.[6] In this paper, the present author will, therefore, discuss the relations between the preparative methods of the ZnO-Fe_2O_3 and the selectivity of the methylation of phenol to the decomposition of methanol on five types of ZnO-Fe_2O_3 catalysts.

Experimental

Apparatus and Reaction Conditions. A conventional flow-type reaction apparatus (reactor : Pyrex glass, 18 mm, i.d.) was used. A mixture of 1 mol of phenol and 5 mol of methanol was introduced into the vaporizer. The reaction vapors were carried with nitrogen gas onto the catalyst bed. The partial pressures of the phenol, methanol, and nitrogen gas in the reaction system were 0.105 atm, 0.515 atm, and 0.38 atm respectively. The time factor, W/F, was changed from 6 to 36 g-cat.h/mol-feed, and the reaction temperature was selected between 300 °C and 400 °C.

Analysis of the Reaction Products. The contents of the reaction products were quantitatively analyzed by means of gas chromatography. In the packed columns for gas chromatography, silicon oil DC 550 was used for analyzing aromatics, porapak Q was used for analyzing water and methanol in liquid products, and active charcoal was used for analyzing gaseous products.

Catalysts. The catalysts were prepared by the procedures reported in the previous paper.[6] These catalysts were analyzed as ZnO-$ZnFe_2O_4$ by means of X-ray analysis ($FeK\alpha$ radiation). All the experimental data were obtained using catalysts with particle sizes of 0.75 mm (average, 0.5—1.0 mm).

Results and Discussion

The physical properties of the catalysts are summarized in Table 1. These catalysts possess micropores of about 20 Å in addition to macropores (Table 1).

The reaction between phenol and methanol was carried out at 375 °C. The time factor was 14.4 g-cat. h/mol-feed, and the catalysts in the calcination at 500 °C were used. The results of the reaction are shown in Tables 2a and 2b. As may be seen in Tables 2a and 2b, the catalysts selectively catalyze the methylation at the ortho position of phenol and simultaneously catalyze the decomposition of methanol. In order to

Methanol converted, mol%	27.3	26.8	52.8	28.0	43.7
Selectivity, %[b]					
Methylation	12.8	16.8	17.4	17.0	18.9
Decomposition	87.2	83.2	82.6	83.2	80.9

a) Defined by (mol of *o*-cresol or 2,6-xylenol per mol of converted phenol). b) Defined by (mol of methyl group in products or gaseous products per mol of converted methanol).

Table 2b. Compositions of gaseous products in the reaction between phenol and methanol over various catalysts

Catalyst symbol	A-5	B-5	C-5	D-5	E-5
Carbon dioxide, mol%	16.5	20.6	17.4	18.0	17.5
Hydrogen, mol%	56.4	51.6	60.8	58.9	59.7
Methane, mol%	23.9	20.9	12.3	14.5	15.2
Carbon monoxide, mol%	8.1	6.8	9.5	8.6	7.6

confirm the above results, the reaction between 2,6-xylenol and methanol was carried out on a (A-6) catalyst under the same reaction conditions. The experimental results showed that no methylphenol was produced. However, it was shown that methanol decomposed to form gaseous products similar to those shown in Table 2b. Therefore, it may be concluded that the overall reaction is a composite of the following two reactions:

$$\text{Phenol} + \text{Methanol} \xrightarrow{k_1} \begin{cases} o\text{-Cresol} \\ 2,6\text{-Xylenol} \end{cases} \quad (1)$$

$$\text{Methanol} \xrightarrow{k_2} \text{Gaseous products} \quad (2)$$

Phenol is consecutively consumed by Reaction (1), but methanol is consumed by Reactions (1) and (2).

In order to obtain available information on the preparative method of the most favorable catalyst, estimations of the individual rate constants were undertaken. For this purpose, the effects of the intraparticle diffusion on the observed rate should be clarified. The relation between the particle size and the activity of catalyst is shown in Fig. 1. The figure indicates that the effect of intraparticle diffusion is negligible. On the basis of this experimental result, the catalysts used for measuring the rate constant were crushed and sieved from 0.5 mm to 1.0 mm size.

The rate of the methylation was found to obey the following equation:

$$-\ln(1-f_p) = k_1(W/F) \quad (3)$$

where f_p is the conversion of phenol.

However, as methanol is consumed by both methylation and decomposition, the rate of Reaction (2) should be expressed by the net conversion (f_m) of the decomposition of methanol. Therefore, the rate of the decomposition satisfies the following equation:

$$-\ln(1-f_m) = k_2(W/F) \quad (4)$$

Arrhenius plots of k_1 and k_2 are given in Fig. 2, and the activation energies are summarized in Table 3.

The data summarized in Table 4 indicate that the activities of the catalysts used were not directly proportional to the surface area. Further, it may be suggested on the basis of Table 4 that the difference in the activities of these catalysts arises from the different starting materials and the various calcination tem-

peratures. For example, although the (B) and (D) catalysts were both prepared from the one starting material of zinc carbonate (Table 1) and have nearly equal pore radii, the activities show a considerable difference, even at the same calcination temperature. The difference in the activities of the (B) and (D) catalysts may, therefore, be attributed to the difference in the starting material because the (B) catalyst was prepared from ferric oxide as the other starting material, while the (D) catalyst was prepared from ferric hydroxide. Moreover, the difference in the activities of the catalysts prepared from the same starting materials may be attributed to the difference in the calcination temperature. That is, the degree of the decrease in the rate of the methylation becomes considerably larger with the rise in the calcination temperature of the catalyst, while that of the decomposition is not so large.

These facts seem to indicate that the difference in the intrinsic activity of the catalysts resulted from the differences in the preparative method and in the calcination temperature.

According to Wheeler,[2] when the effects of the intraparticle diffusion is negligible, the selectivity factor (S) in a simultaneous reaction is defined as follows:

$$S = k_1/k_2 \qquad (5)$$

Since the rate constants in Table 4 were determined under negligible intraparticle diffusion, Eq. (5) was reasonably used for the estimation of the most favorable

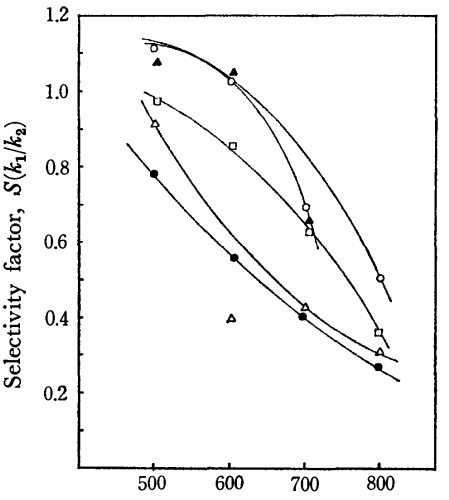

Fig. 3. Relations between the selectivity factor and the calcination temperature.
△: A, □: B, ○: C, ●: D, ▲: E.

catalyst. The effects of the calcination temperature on the selectivity factor are shown in Fig. 3. The Figure shows that the selectivity factor is considerably affected not only by the calcination temperature, but also by the preparative methods. The selectivity factors of the (A) and (D) catalysts (S_a and S_d) decrease considerably with the rise in the calcination temperature, but S_b and S_c are comparatively stable at temperatures below 600 °C. Although the decrease in the selectivity factor occurs with the disappearance of the active sites for the methylation and/or creation of the active sites for the decomposition, it may be said on the basis of Table 4 that when the calcination temperature is higher, the concentration of the active sites for the methylation is smaller.

Thus, it was concluded that the ZnO-Fe_2O_3 catalyst should be prepared at a low temperature. Further, it can be said that the catalysts for the methylation are effective in this order: (C), (E)>(B)>(D),(A).

The author is grateful to Mr. Mitsuyoshi Yamamoto for his assistance in the experiments.

The Stability of Inosine in Acid and in Alkali

Yoshihisa SUZUKI

Central Research Laboratories, Ajinomoto Co., Inc., Suzuki-cho, Kawasaki 210

(Received November 30, 1973)

The rate constants of the decrease in inosine at several temperatures between 50 °C and 140 °C in water were determined over the pH range from 1 to 13. They can be expressed as a sum of four simultaneous bimolecular reactions. Their thermodynamic parameters were obtained.

For the industrial isolation of inosine from the fermentation broth, information about the stability of inosine in acid and in alkali is of importance to developing the process design for the maximum yield. The kinetics of the hydrolysis of some purine nucleosides,[1-4] such as adenosine and guanosine has been reported in a limited pH range, and that for psicofuranine,[5] over the whole pH range. However, no studies concerning inosine have been reported in the literature. The present paper deals with the pH profile of the rates of the decrease in inosine at several temperatures, and with the pH dependence on the yields of the products.

Experimental

Material and Equipment. The inosine used was a commercial product of the Ajinomoto Co., Inc. The pH of the solution was measured at room temperature with a Toa Dempa HM-5A pH meter. The UV absorbance was measured with a Hitachi spectrophotometer, Model 139.

Paper Chromatography (PC). One-dimensional ascending PC was carried out on Toyo-Roshi No. 51A, the following two solvent systems being used: Solvent A, *n*-butanol–acetic acid–water (4 : 1 : 1); Solvent B, distilled *i*-butyric acid–*n*-butanol–28% ammonia aq.–water (36 : 30 : 3 : 31). The papers were developed three times if necessary for the complete separation of the components on the chromatogram. The components of the reaction mixture were detected on the paper by means of UV absorption. Usually standard solutions of inosine and hypoxanthine(H) were spotted with the reaction mixture. Several spots corresponding with the products including the remaining inosine and the standards were cut off, together with their appropriate blanks, and eluted with 0.1 M HCl, and the absorbances of the eluates were measured at 250 nm. The concentration of each component in the reaction mixture was calculated from the absorbance compared with that of each standard reference. The standard solution of 9-*β*-D-ribopyranosyl hypoxanthine (Y) used was that of inosine because of their similarity. The absorbance of the spot corresponding with 5-amino-1-*β*-D-ribofuranosyl-4-imidazolecarboxamide(X) was corrected in terms of inosine by the use of their molecular extinction coefficients.

Acid Hydrolysis. Inosine was dissolved(3 w/v%) in aq. HCl with a definite concentration, and 25 ml of the resulting solution was sealed in a glass ampoule or a stainless steel tube. It was kept for a definite period on an oil-bath at a constant temperature. The resultant solution was diluted with water to 100 ml and analyzed by means of PC in Solvent A. Table 1 lists the conditions. A steel tube was used for each run over 100 °C and a glass ampoule for each below 80 °C except that a steel tube was used for No. 6 (at 70 °C).

Degradation in Neutral Buffer Solutions. The method used was the same as that to be described with alkaline degradation except that the solvents were phosphate buffer solutions. Table 2 lists the conditions. The following buffer solutions were used: B-1, B-2, B-3, M/2 KH_2PO_4-M/2 Na_2HPO_4 (95 : 5), (30 : 60), (5 : 95); B-4, B-5, M/15 KH_2PO_4-M/15 Na_2HPO_4 (90 : 10 , (40 : 60 .

Alkaline Degradation. Inosine was degraded in the same manner as has been described above in the case of acid hydrolysis except that the solvent was aq. NaOH instead of HCl and except that a steel tube was used throughout all the runs. Table 3 lists the conditions. The chromatogram in Solvent A with three-times development was exhibited in the preceding paper.[6] The spot corresponding with inosine(R_f 0.52) tends to be contaminated with an unknown pale-red spot (R_f 0.55), while that corresponding with Y(R_f 0.43) is not. Therefore, the amount of Y was determined by the use of the chromatogram in Solvent A. The chromatogram in Solvent B with two-times development indicates a clear separation of a pale-red spot(R_f 0.64) from that o:

inosine(R_f 0.55), whereas the mobility of Y is the same as that of inosine. Then, the total amounts of inosine and Y were determined by the use of the chromatogram in Solvent B; the subsequent subtraction of the amount of Y determined before gave that of inosine. The amounts of H and X were determined by means of PC in Solvent A.

Results and Discussion

Inosine (I) degrades in an acid solution, giving hypoxanthine (H) and D-ribose. On the other hand, in an alkaline solution a significant amount of a ring-opened or isomerized product, such as 5-amino-1-β-D-ribofuranosyl-4-imidazolecarboxamide (X) or 9-β-D-ribopyranosyl hypoxanthine (Y), is concomitantly produced, as has been described previously[6] (Chart 1). However, apparent first-order linear plots were obtained for the acid-catalyzed degradation, and even for the alkaline treatment.

Rates of the Decrease in Inosine. Tables 1, 2 and 3 show the conditions and observed first-order rate constants (k) corresponding to the regions for acid, for a neutral solution, and for alkali. A variation in the pH during the degradation was usually observed, and it was larger under alkaline conditions than in acid,

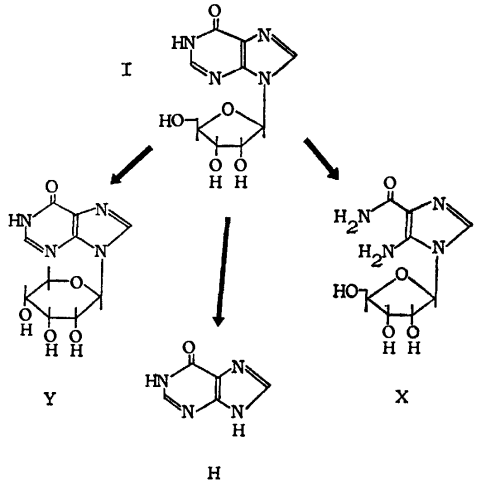

Chart 1

The longer the reaction time, the larger the variation in the pH. This variation, however, had a significant effect on the first-order rate constants. This is the reason why there are some differences in the rate constants in the corresponding experimental runs in Tables 2 and 3; for instance, between Experimental Runs No. 29a and No. 29b in Table 3 there is some difference in rate constant (16.2—11.8) resulting from the difference in the final pH (7.9—7.4). Such a variation in pH can be explained in terms of the production of considerable acid substances; for example, formic acid is released when inosine is cloven at C-2 in dilute alkali, giving X.

The observed first-order rate constant, k, at a constant pH was determined by the linear plots given by Eq. (2), which is derived from Eq. (1):

$$-d[I]/dt = k[I] \quad (1)$$

$$\ln([I_s]/[I]) = kt \quad (2)$$

where $[I_s]$ is the initial concentration of inosine and where [I] is its concentration after a certain time, t.

Figure 1 shows the profile of the overall rates of the decreases in inosine at several tempreatures. The rate is linearly dependent on the hydrogen-ion concentration in the 1—5 pH range, decreasing with an increase in the pH to a minimum of 6—7 and then

a) Rate constants for specific hydrogen ion catalysis to uncharged species (k_1), for specific hydrogen ion catalysis to mono-anionic species (k_2), for water catalysis to mono-anionic species (k_3) and for hydroxyl ion catalysis to anionic species (k_4).

increasing with an increase in the pH in the pH range of 8—9. It is insensitive to the pH in the region pH of 10—12 and then seems to increase again with an increase in the pH. This profile is similar to that obtained for aspirin by Edwards[7] with the exceptions, that the minimum of the rate constant is in the neutral region and that has a smaller value. As will be shown below, the profile of this curve can be explained in terms of four bimolecular simultaneous reactions composed of those between uncharged inosine and hydrogen ions, anionic inosine and hydrogen ions, anionic inosine and water molecules, and anionic inosine and hydroxyl ions.

It is known that the acid-catalyzed hydrolysis of nucleosides giving nucleic bases and sugars can be explained in terms of a bimolecular reaction between nucleosides and hydrogen ions.[2] The mechanism of the reaction has also been discussed.[2] A decrease in the inosine in the acid solution in the present study can be simply explained by this reaction.

In the pH range of 1—5 plots of log k *vs.* pH show a linear relation with a slope of unity (Fig. 1), and the rates of the hydrogen ion-catalyzed reactions are given by Eq. (3):

$$-d[I]/dt = k[I] = k_1[H^+][I^\circ] \quad (3)$$

where k_1 is the catalytic rate constant for a specific hydrogen-ion catalysis and where $[I^\circ]$ is the concentration of the uncharged species of inosine, being equal to the total inosine [I] in this pH range. The intercepts, log k_1, at the several temperatures derived from the acid branch in Fig. 1 are given as k_1 in Table 4.

The Arrhenius plots according to the classical relation of the specific rate constant, k or k_1, are given by:

$$k_1 = A \cdot \exp(-E_a/RT) \quad (4)$$

The plots of log k_1 *vs.* $1/T$ were linear, and the activation energy, E_a and the frequency factor, A, were determined as is shown in Table 5 using Eq. (4), where R is 2 $cal \cdot deg^{-1} \cdot mol^{-1}$ and where T is $(273+t)$K.

In the pH region over 6 the dissociation of inosine to the anion (pK_a 8.75[8]) must be taken into consideration; that is,

$$[I^\circ] \rightleftharpoons [I^-] + [H^+] \quad (5)$$

$$[I^-]/[I^\circ] = K_a/[H^+] \quad (6)$$

$$[I] = [I^\circ] + [I^-] \quad (7)$$

where $[I^-]$ is the concentration of anionic inosine and where K_a is the ionization constant of the equilibrium given in Eq. (5). The plots of log k *vs.* pH in this region are not linear. However, a ready explanation can be found for this curve by employing other terms, including a water-catalytic reaction independent of both hydrogen and hydroxyl ions, in addition to a usual hydrogen-ion- or hydroxyl-ion-catalyzed reaction for anionic inosine. Such a solvent attack on a degradable species is known to be frequently acceptable. The observed rate expression in this region is given by Eq. (8):

$$-d[I]/dt = k[I] = k_2[H^+][I^-] + k_3[H_2O][I^-] + k_4[OH^-][I^-] \quad (8)$$

where k_2 and k_4 are the catalytic rate constants for hydrogen-ion and hydroxyl-ion catalysis respectively and where k_3 is that for water catalysis.

The isomerization or ring-cleavage is observed in this region besides usual hydrolysis, and three main UV-absorbing reaction products, illustrated in Chart 1, were found, along with several minor products, as has been described in a previous paper.[6] However, these three main reaction products seem not to correspond simply with the above three bimolecular reactions. This problem will be briefly discussed later. The complete mechanisms of these three reactions will be clarified in the future. In spite of the above uncertainty, Eq. (8) is useful in estimating the stability of inosine over a wide pH range with a view to obtaining information about the decrease in a marked compound.

The rate constants over the whole pH range can be expressed by a sum by Eq. (3) and Eq. (8). This resultant equation may be rearranged by the use of Eq. (6) and Eq. (7) as follows:

$$k = \frac{k_1[H^+]}{1+K_a/[H^+]} + \frac{k_2[H^+]+K_3[H_2O]+k_4[OH^-]}{1+[H^+]/K_a} \quad (9)$$

The term including k_1 predominates over the others below pH 5, the term including k_2 does so at pH 6—7, k_3 does so at pH 8—12, and k_4, over pH 13.

The k_3 value is easily obtained from the apparent first-order rate constant, k, by the use of Eq. (9) at pH 11, where k is completely independent of the pH (Fig. 1) and where the other three terms are negligible. The Arrhenius plots for k_3 are also easily obtained by the use of Eq. (4). The determination of k_2 and k_4 were not so simple because of the considerable influence from the other terms. They were obtained so as to fit with the observed values of the total rate constants, k, by the use of Eq. (9). The activational energy and the frequency factor for them were also obtained so as to get the best fit with the experimental data. These are summarized in Tables 4 and 5, where K_a is 1.8×10^{-9}.

The curves in Fig. 1 were drawn by the use of Eq. (9) and the constants in Tables 4 and 5; they show a good agreement with the observed values. The ioniza-

4	28.6	2.8×10^{15}

a) Correspond to k_i (i=1—4).

tion of inosine for the cation and the dianion has little effect on the present study because their pK_a values are estimated[9)] to be 1.2 and 12.3 respectively. However, some disturbances are probable at both ends of our pH range; especially at the end of the alkaline region it is necessary to assume that [I$^-$] includes the dianion. It may be supposed that Eq. (9) gives a somewhat larger value if it is applied in the pH region below 1.

When the rate constants for acid hydrolysis are compared with those of guanosine as measured by Zoltewicz *et al.*,[3)] inosine is found to be hydrolyzed about 2 times faster than guanosine at 100 °C in the 1—4 pH range. This is consistent with our previous estimation[10)] that inosine would be hydrolyzed faster than guanosine in a weak acid, while it would be hydrolyzed slower in a strong acid.

Yields of Products. In the acid region the decrease in the mole amount of inosine was equal to amount of H produced, and no side-reaction was observed. On the other hand, in the alkaline region three major UV-absorbing products, H, X and Y, were obtained. The sum of these three products and the inosine remaining was often below 100% when a long reaction time was employed. This indicates the presence of other parallel or sequential degradations.

The representative pH dependences of the three major UV-absorbing products are exhibited in Fig. 2 in the case of 120 °C, corresponding to Experimental Runs No. 29—32. There is an optimum near pH 10 for the production of X and Y, while H increases with an increase in the pH. These convex curves for X and Y correspond with that calculated from the percentage for the mono-anionic species of inosine, as is shown in Fig. 2. The rate-determining term near pH 10 in Eq. (9) included k_5; this term represents a bimolecular reaction between the mono-anionic inosine and the water molecule. Therefore, the rate-determining step of such a reaction that produces X or Y must involve the attack of water on the mono-anionic inosine.

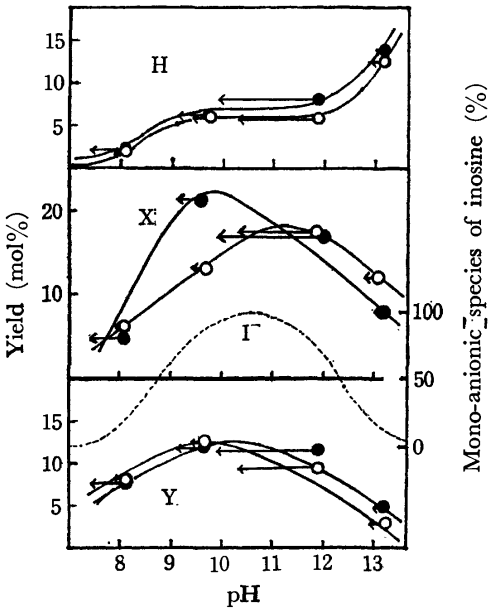

Fig. 2. Yields of UV-absorbing products at 120 °C, and a calculated curve of the development of mono-anionic inosine.

The Reaction of α-Olefins and Epoxyalkanes with the Dimethyl Sulfide–Sulfur Trioxide Complex

Masuzo NAGAYAMA, Osamu OKUMURA, Katsumi YAGUCHI, and Akira MORI

Central Research Laboratories, Lion Fat & Oil Co., Ltd., Hirai, Edogawa-ku, Tokyo 132

(Received March 2, 1974)

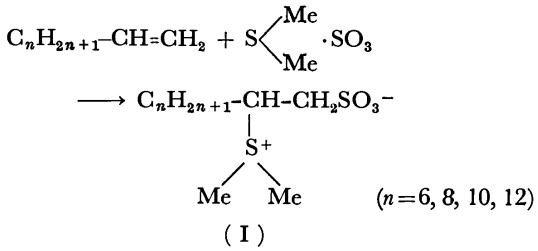
2-Dimethylsulfonioalkane-1-sulfonates were formed by the reaction of α-olefins with the dimethyl sulfide-sulfur trioxide complex. The treatment of these products with alkali gave Δ^1-alkene-1-sulfonates quantitatively. In the reaction between 1,2-epoxyalkanes and the dimethyl sulfide-sulfur trioxide complex, 1-dimethylsulfoniomethyl-1-alkyl sulfate was formed exclusively. 1-Dimethylsulfonio-1-alkenes were quantitatively formed upon the treatment of these products with alkali. The chemical structures of these compounds have been established, and the reaction routes were discussed.

The reaction product from an α-olefin with sulfur trioxide *i.e.*, an α-olefin sulfonate, is considered to be the base material of a new anionic surface-active agent, and a mechanism for the reaction has been proposed.[1,2]

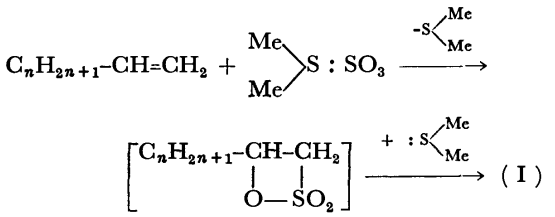
Furthermore, numerous reports have been published on the chemistry of sulfonation using sulfur trioxide-Lewis base complexes.[3,4] We have now obtained some interesting results when the dimethyl sulfide-sulfur trioxide complex was used as the sulfonating agent in the sulfonation of α-olefins and epoxyalkanes; we will report those results in this paper.

Results and Discussion

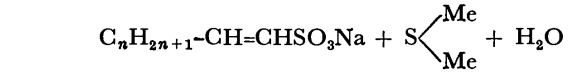
Reaction of α-Olefins with the Dimethyl Sulfide-Sulfur Trioxide Complex. Many studies have been carried out on the reaction between olefins and the sulfur trioxide-dioxane complex, particularly by Bordwell *et al.*[5-7] They considered that the zwitter ion was the initial sulfonation intermediate of this reaction; however, the zwitter ion has not actually been isolated. On the other hand we have ourselves proposed a new reaction mechanism in a previous paper.[4] An α-olefin was reacted with the sulfur trioxide-dimethyl sulfide complex, in ethylene dichloride at room temperature, to give a 2-dimethyl-sulfonioalkane-1-sulfonate (I) in a high yield. The structure of the product was established by IR and NMR spectroscopy.



Sulfonium sulfonate internal salts have been synthesized either by the alkylation of mercaptoalkane sulfonates or by the addition of alkyl sulfides to sultones.[8] In the previous report, we established that the initial product of the reaction of α-olefin with sulfur trioxide is a β-sultone,[4] which immediately undergoes ring-opening by means of a nucleophilic reagent. It appears likely that the β-sultone is first formed in the present reaction also, and that it then reacts with dimethyl sulfide.



In fact, we confirmed that the reaction between C_{12}-β-sultone, prepared by the previous method,[1] and dimethyl sulfide proceeds more rapidly than the reaction between the olefin itself and dimethyl sulfide. Also, in the former case the same 2-dimethylsulfoniododecane sulfonate internal salt was obtained in an excellent yield. Consequently, it may be considered that the formation of β-sultone is the rate-determining step. These internal salts decomposed easily with alkali to form Δ^1-alkene-1-sulfonates quantitatively.



It is apparent that the α-hydrogen has become highly activated by both dimethylsulfonium and sulfonyloxy groups. The decomposed product was identified by means of the NMR spectra.

The decomposition rate was measured using a pH stat. It was dependent on the pH above 6, and consequently, this amphoteric surface active agent is unsuitable for use on the alkaline side. It was confirmed by NMR spectroscopy that the Δ^1-octene-1-sulfonate in the product obtained from 1-octene was a mixture of 61% *trans*-form and 39% *cis*-form, and this finding suggests that the alkaline decomposition proceeds by means of competitive E_2 and E_{1cb} processes.

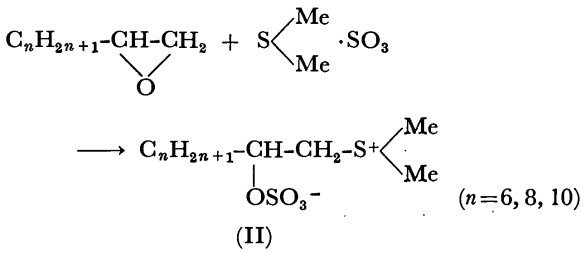
From olefins of a shorter chain length, similar sulfonation and alkaline decomposition products were obtained, as is shown in Table 1. From this table, a rather clear correlation between the yields and the electron-donating power of the alkyl groups of the olefins can be observed.

Reaction of Epoxyalkanes with the Dimethyl Sulfide-Sulfur Trioxide Complex. An epoxyalkane reacted with the dimethyl sulfide-sulfur trioxide complex in ethylene dichloride to give a 1-dimethylsulfoniomethyl-1-alkyl sulfate(II) quantitatively. The structure of the product was established by IR and NMR spectroscopy.

TABLE 1. REACTION PRODUCTS OF LOWER OLEFINS WITH DIMETHYL SULFIDE-SULFUR TRIOXIDE COMPLEX

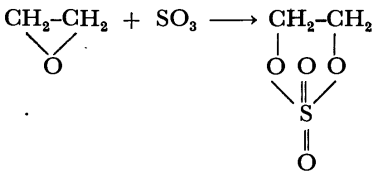
Olefin	Product	Yield %	Found % C	Found % H	Calcd % C	Calcd % H	Alkaline decomposed product
1-Butene	C_2H_5-CH-$CH_2SO_3^-$ (S+, CH_3, CH_3)	48	36.35	7.19	36.34	7.12	C_2H_5-CH=$CHSO_3Na$
Isobutene	CH_3, CH_3-C(H)-$CH_2SO_3^-$ (S+, CH_3, CH_3)	67	36.31	7.25	36.34	7.12	CH_3, CH_3-C=$CHSO_3Na$
Propylene	CH_3-CH-$CH_2SO_3^-$ (S+, CH_3, CH_3)	76	32.76	6.74	32.59	6.56	CH_3-CH=$CHSO_3Na$
Ethylene	CH_2-$CH_2SO_3^-$ [a] (S+, CH_3, CH_3)	trace	—	—	28.22	5.92	CH_2=$CHSO_3Na$

a) This product was not isolated, but identified by NMR spectrum, in reaction solution.

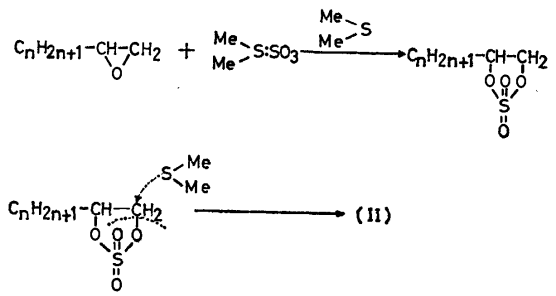


(II) (n=6, 8, 10)

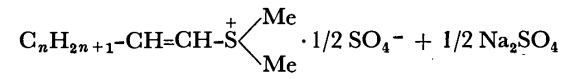
G. E. Ham has reported that SO_3 is inserted into ethylene oxide to form ethylene sulfate.[9]



Therefore, the mechanism of this reaction may be considered to involve the initial formation of alkyl-substituted ethylene sulfate, followed by ring-opening by means of S_N2 process with dimethyl sulfide.



The 1-dimethylsulfoniomethyl-1-alkyl sulfate (II) can be easily decomposed in an alkaline medium to form Δ^1-alkenesulfonium salt quantitatively.



In this case, it was also confirmed by NMR spectroscopy that the decomposed product was a mixture of 70% *trans*-form and 30% *cis*-form for n=6. The decomposition rate was measured similarly with a pH stat. It was dependent upon the pH. For example, the decomposition rate constant (at pH=9.0) is 0.0599 min^{-1}, about 80 times larger than that of the sulfonium-sulfonate (I) type mentioned above.

Ethylene oxide reacted similarly with the dimethyl sulfide-sulfur trioxide complex quantitatively.

As well as with dimethyl sulfide, the reaction also proceeded with methyl ethyl sulfide and diethyl sulfide. However, the expected products were not obtained with ethyl hexyl sulfide, suggesting that a steric effect may be an important factor in this reaction.

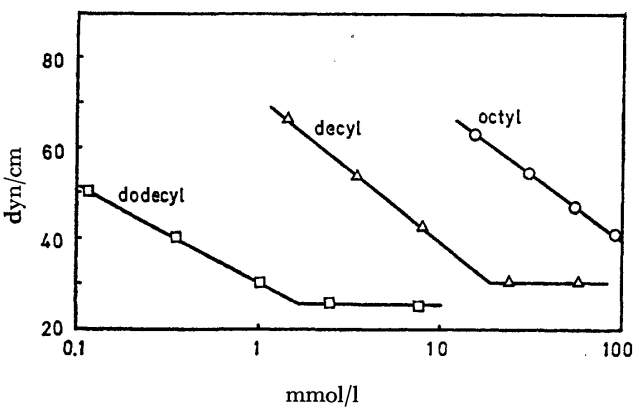


Fig. 1. Surface tension *versus* concentration of 1-dimethylsulfoniomethyl 1-alkyl (octyl, dodecyl) sulfate at 70 °C.

Surface-active Properties. 2-Dimethylsulfonioalkane-1-sulfonates have superior surface-active properties; Compound (I) with $n=8$ has an optimum surface activity, and its critical micelle concentration is 28 mmol/l and $\gamma_{cmc}=30$ dyn/cm. Its wetting power is 11 s at 25 °C, 40 mmol/l and its forming height is 170 mm at 25 °C, 40 mmol/l.

1-Dimethylsulfoniomethyl-1-alkyl sulfates (II) also show good surface activities. The correlation between their concentrations and surface tensions is shown in Fig. 1.

Experimental

Materials. The sulfur trioxide (liquid and stabilized, manufactured by the Nisso Kinzoku Co.) was used after distillation. The C_{10}–C_{16} olefins (manufactured by the Gulf Oil Co.) were purified by distillation. The C_8—C_{14} epoxyalkanes were prepared according to the method of Swern.[10] The ethylene, propylene, 1-butene, and isobutene (manufactured by the Wako Junyaku Co.) were used as received.

Reaction of α-Olefins with the Dimethyl Sulfide-Sulfur Trioxide Complex. The case of 1-dodecene will be described as a typical example. Dimethyl sulfide (0.6 M) was dissolved in 100 g of ethylene dichloride, and the mixture was cooled to −10 °C. When 0.5 M of sulfur trioxide, dissolved in 50 g of ethylene dichloride, was stirred, drop by drop, into the dimethyl sulfide solution, a white precipitate of dimethyl sulfide-sulfur trioxide complex was formed, with the evolution of heat. When 0.6 M of 1-dodecene was added to the reaction mixture, the reaction solution became transparent. A white precipitate was gradually formed while the reaction temperature was maintained at 55 °C for 3 hr. The product was cooled to 0 °C, filtered, and then recrystallized from ethanol. The yield was 52% on the basis of the sulfur trioxide. Found: C, 53.79; H, 9.60; S, 20.4%; Calcd for $C_{14}H_{30}S_2O_3$: C, 54.15; H, 9.74; S, 20.7%. IR (KBr-disk); 1200 ($\nu_{S=O}$) cm^{-1}, 1045 ($\nu_{S=O}$) cm^{-1}. NMR; 7.05 (s, 6H, $CH_3\rangle\overset{+}{S}-$), 6.63 (d, 2H, $-CH_2SO_3^-$), 6.20 (m, 1H, $\rangle CH-\overset{+}{S}\langle$).

Reaction of the C_{12} β-Sultone with Dimethyl Sulfide-Sulfur Trioxide Complex. C_{12} β-sultone (0.1 M), prepared by the previous method,[1] was dissolved in ethylene dichloride (100 g). To this solution, dimethyl sulfide (0.11 M) was added at 0 °C, and the mixture was stirred for 2 hr, a white precipitate was gradually formed, filtered and then recrystallized from ethanol. 26.4 g (85% yield) of 2-dimethylsulfoniododecane-1-sulfonate were thus obtained.

Reaction of the Epoxyalkanes with Dimethyl Sulfide-Sulfur Trioxide Complex. The following procedure for the reaction with 1,2-epoxydodecane is typical. The dimethyl sulfide-sulfur trioxide complex was prepared by the method described above. To one equivalent of this complex, we added equivalents of 1,2-epoxydodecane. A white precipitate was formed when the reaction product was aged at 45 °C for 25 hr. The reaction product was filtered and recrystallized from ethanol. The yield was 85% on the basis of the sulfur trioxide. Found: C, 51.74; H, 9.26; S, 19.7%: Calcd for $C_{14}H_{30}S_2O_4$: C, 51.50; H, 9.26; S, 19.6%. IR (KBr-disk); 1300, 1250, 1100 ($\nu_{S=O}$) cm^{-1}. NMR; 5.30 (m, 1H, $CH-OSO_3^-$), 7.02 (s, 6H, $-\overset{+}{S}\langle^{CH_3}_{CH_3}$), 6.33 (d, 2H, $-CH_2\overset{+}{S}\langle$).

Ethylene oxide was treated similarly to give 1-dimethylsulfonio ethane-2-sulfate in a 96% yield.

Measurements of Sulface-active Properties. The surface-active properties were measured by the JIS K-3362 method.

Measurements of the Decomposition Rates. The decomposition rate was measured at a given pH value in a pH stat(manufactured by the Toa Electronic Co., Model HS-1B). The amount of decomposed substances were calculated from those of the sodium hydroxide required to counterbalance the decrease in the pH with the progress of the reaction. The initial concentration of the substrate was 0.509 mmol/l; solvent, water; temperature, 48 °C; pH, 4.0—11.0.

Phosphorimetric Investigation of Triplet-Triplet Energy Transfer in Fluid Solution

Takeshi TAKEMURA, Masayuki AIKAWA, and Hiroaki BABA

Division of Chemistry, Research Institute of Applied Electricity, Hokkaido University, Sapporo 060

(Received March 29, 1974)

The mechanism of triplet-triplet (T-T) energy transfer in fluid solution has been studied by means of phosphorimetry in the temperature range 0—60 °C with acetophenone as energy donor, 1,4-dibromonaphthalene as acceptor and isooctane, isopentane or carbon tetrachloride as solvent. From the temperature dependence of the energy transfer, α and k_{dif} could be evaluated separately, k_{dif} denoting the diffusion-controlled rate constant for the encounter of donor and acceptor molecules and αk_{dif} corresponds to the rate constant for the overall energy transfer reaction. The α values are 0.28 at 25 °C in isopentane and 0.43 at 21 °C in isooctane, indicating that the T-T energy transfer process is not strictly diffusion-controlled. The k_{dif} values are nearly equal to those predicted by a modified Debye equation.

In a previous paper,[1] it was suggested by means of laser pulse photolysis that the triplet-triplet (T–T) energy transfer process is not strictly diffusion controlled in fluid solution. The overall T-T energy transfer rate constant k_t can be expressed as $k_t=\alpha k_{dif}$, where k_{dif} is the diffusion-controlled rate constant. We calculated k_{dif} from the standard Debye equation,

$$k_{dif} = 8RT/3000\eta \quad (1)$$

and obtained an α value smaller than unity.

Since the study by Porter and Wilkinson,[2] considerable attention has been given to whether the T-T energy transfer is diffusion controlled or not.[1–9] In most cases, the question was discussed through a comparison of k_t with k_{dif} which was predicted either by Eq. (1) or by a slightly modified Debye equation, *i. e.*,

$$k_{dif} = 8RT/2000\eta \quad (2)$$

However, we cannot place much reliance on the results because of the assumptions involved in the evaluation of k_{dif}.

We have examined the mechanism of T-T energy transfer in a fluid solution without resort to theoretical prediction. The experiment was carried out with the aid of the donor and acceptor phosphorescence emissions observed in fluid solution. Since it is generally difficult to detect phosphorescence in a fluid solution, most studies on T-T energy transfer have been made by means of T-T absorption or analysis of photochemical products. However, in the former method the first order rate constant for triplet decay is difficult to determine, because an exciting flash of very high intensity is used; the latter method is not suitable for obtaining direct information on the energy transfer process.

Acetophenone was chosen as the energy donor and 1,4-dibromonaphthalene as acceptor, isooctane, isopentane and carbon tetrachloride being used as solvents. We utilized the fact that both acetophenone and 1,4-dibromonaphthalene show phosphorescence with an appreciable intensity even in a fluid solvent provided that the solvent is fully degassed.[1,10–12]

Experimental

Reagents of Wako Pure Chemical Industries, Osaka were used. Acetophenone was purified by high-vacuum distillation, and 1,4-dibromonaphthalene (DBN) by vacuum sublimation. Spectro-grade isooctane and carbon tetrachloride were used without further purification. Isopentane was passed through a silica gel column.

The sample solutions consisted of acetophenone of a constant concentration (1.0×10^{-2} M) and DBN of varying concentrations (10^{-5}—10^{-4} M), with isooctane, isopentane or carbon tetrachloride as solvent. Each of these solutions was degassed repeatedly (7 or 8 times) by freeze-thaw cycles until the phosphorescence intensity of acetophenone reached a maximum. A representative example of the effect of degassing on the phosphorescence intensity is shown in Fig. 1, in which the phosphorescence intensity of DBN in isooctane is plotted against the number of freeze-thaw cycles.

The phosphorescence spectra were measured at various temperatures between 0° and 60 °C with a Hitachi MPF-2A fluorescence spectrophotometer equipped with a temperature-controlled water bath. The donor phosphorescence spectra were corrected for spectral sensitivity of a monochromator-photomultiplier system using quinine sulfate and β-naphthol as standards. The donor phosphorescence quantum yields were determined by comparing the corrected phosphorescence spectra with a corrected fluorescence spectrum of quinine sulfate in 0.5 M sulfuric acid, which has a fluorescence quantum yield of 0.51. The acceptor phosphorescence spectra were uncorrected because of large correction errors involved over the insensitive spectral region of the photomultiplier. Thus, the relative intensities of the peak were used in the acceptor phosphorescence analysis.

The phosphorescence decay was measured by means of the second harmonic of a giant pulse ruby laser[1] or a xenon flash for excitation.

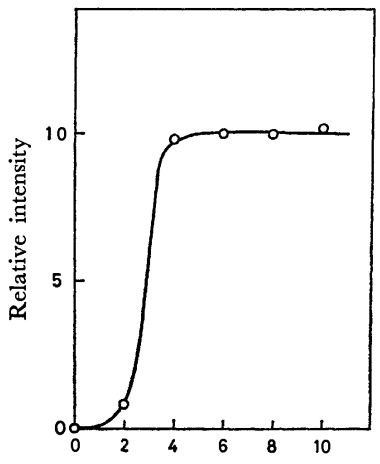

Fig. 1. Effect of degassing on the phosphorescence intensity of DBN in isooctane at room temperature.

Results

Changes in the phosphorescence spectrum of the acetophenone-1,4-dibromonaphthalene (DBN) system in isooctane at 25 °C caused by the increase of the concentration of DBN are shown in Fig. 2. In the absence of acetophenone no phosphorescence emission was observed from DBN upon excitation at 340 nm, which was adopted as the excitation wavelength throughout the T-T energy transfer experiments. The spectral changes are therefore regarded as due to the T-T energy transfer from acetophenone to DBN. Similar spectral changes were observed in isopentane and carbon tetrachloride at various temperatures (0—60 °C).

The Stern-Volmer plots for the quenching of the phosphorescence of acetophenone by DBN in isooctane at different temperatures are shown in Fig. 3, where ϕ_D^0 and ϕ_D are the quantum yields of the donor phosphorescence in the absence and presence of the acceptor, respectively, $[^1A]_0$ being the initial concentration of the acceptor in its ground state. The plot is linear for any temperature, the slope increasing with decreasing temperature. Stern-Volmer plots of essentially the same nature are obtained on changing the solvent from isooctane to isopentane or carbon tetrachloride (Figs. 4 and 5).

Under our experimental conditions of a weak excitation intensity and a low acceptor concentration, the reaction scheme involving the T-T energy transfer may be expressed as

$$^1D \longrightarrow {}^3D^* \tag{3a}$$

$$^3D^* \longrightarrow {}^1D \qquad k_1 \tag{3b}$$

$$^3D^* + {}^1A \longrightarrow (^3D^*...{}^1A) \qquad k_{dif} \tag{3c}$$

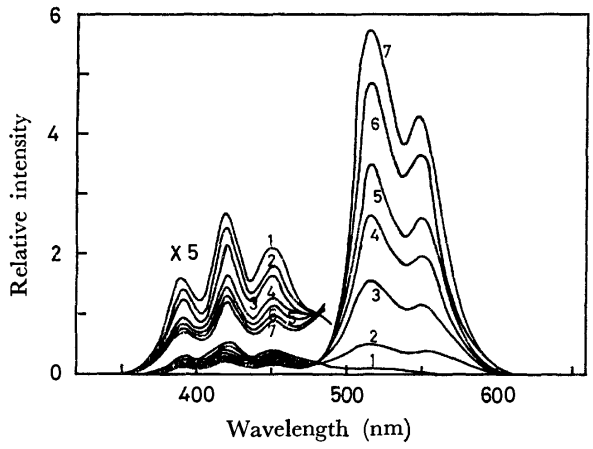

Fig. 2. Phosphorescence spectra (uncorrected for instrument response) of acetophenone-DBN system obtained by excitation at 340 nm in isooctane at 25 °C. The concentrations of DBN: (1) 0; (2) 0.12×10^{-4} M; (3) 0.25×10^{-4} M; (4) 0.74×10^{-4} M; (5) 0.98×10^{-4} M; (6) 1.23×10^{-4} M; (7) 1.47×10^{-4} M.

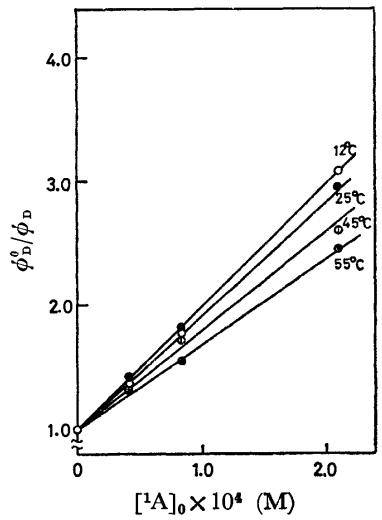

Fig. 4. Stern-Volmer plots for the quenching of the phosphorescence of acetophenone by DBN in isopentane at different temperatures between 12 and 55 °C.

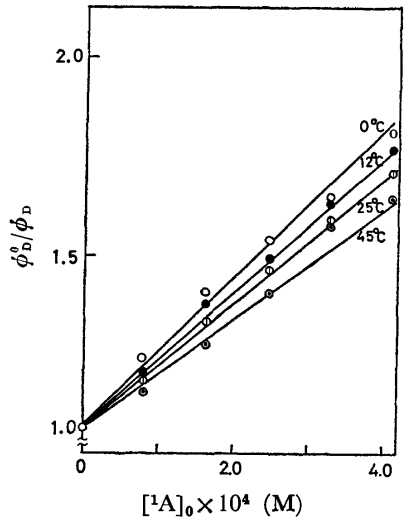

Fig. 5. Stern-Volmer plots for the quenching of the phosphorescence of acetophenone by DBN in carbon tetrachloride at different temperatures between 0 and 45 °C.

$$(^3D^*...^1A) \longrightarrow {}^3D^* + {}^1A \qquad k_{-dif} \qquad (3d)$$

$$(^3D^*...^1A) \longrightarrow (^1D...^1A) \qquad k_1' \qquad (3e)$$

$$(^3D^*...^1A) \longrightarrow (^1D...^3A^*) \qquad k_{et} \qquad (3f)$$

$$(^1D...^3A^*) \longrightarrow {}^1D + {}^3A^* \qquad (3g)$$

$$^3A^* \longrightarrow {}^1A \qquad (3h)$$

where $^3D^*$, ^1D and $^3A^*$, ^1A represent the excited triplet and ground singlet states of donor (D) and acceptor (A), respectively and k_1 and k_1' denote the sums of all unimolecular decay processes including both radiative and nonradiative transitions. The process expressed by (3c) corresponds to the encounter of a donor molecule in the triplet state and an acceptor molecule in the ground state; process (3d) represents the dissociation of the encounter complex, and (3f) the energy transfer from the donor to the acceptor.

We are here concerned with photostationary conditions. Since the concentrations of the encounter complexes ($^3D^*\cdots{}^1A$) and ($^1D\cdots{}^3A^*$) are considered to be very small as compared with those of the "free" triplet species $^3D^*$ and $^3A^*$, respectively, we can regard the donor and acceptor phosphorescence emissions as due exclusively to the free species. Furthermore, we may safely assume that $k_1' \ll k_{et}$. Thus it follows from the above reaction scheme that

$$\phi_D^0/\phi_D = 1 + \alpha k_{dif}\tau_0[^1A]_0 \qquad (4)$$

with

$$\alpha = \frac{k_{et}}{k_{-dif}+k_{et}} \qquad (4')$$

where $\tau_0(=1/k_1)$ is the phosphorescence lifetime of the donor in the absence of acceptor. α represents the probability that energy transfer occurs during the lifetime of the encounter complex. Equation (4) is compatible with the linear relations between ϕ_D^0/ϕ_D and $[^1A]_0$ (Figs. 3—5). Thus, from the slopes of the straight lines in these figures, the values of $\alpha k_{dif}\tau_0$ can be obtained for each temperature. The results given in Table 1 show that the quantity $\alpha k_{dif}\tau_0$ depends on the temperature.

TABLE 1. VALUES OF $\alpha k_{dif}\tau_0$ AT VARIOUS TEMPERATURES IN DIFFERENT SOLVENTS

Solvent	$\alpha k_{dif}\tau_0 \times 10^{-4}$, M^{-1}				
Isopentane		1.0 (12 °C)	0.9 (25 °C)	0.8 (40 °C)	0.7 (55 °C)
Isooctane	2.0 (0 °C)	1.5 (21 °C)	1.3[a] (25 °C)	1.2 (46 °C)	0.9 (65 °C)
Carbon tetrachloride	0.20 (0 °C)	0.18 (12 °C)	0.17 (25 °C)	0.16[a] (25 °C)	0.15 (45 °C)

a) Obtained from the sensitized acceptor phosphorescence.

Let us examine the spectral data concerning the sensitized acceptor phosphorescence. It can be shown that the following equation is derived from the reaction scheme:

$$\frac{1}{\phi_A} = \frac{1}{\theta}\left(1+\frac{1}{\alpha k_{dif}\tau_0[^1A]_0}\right) \qquad (5)$$

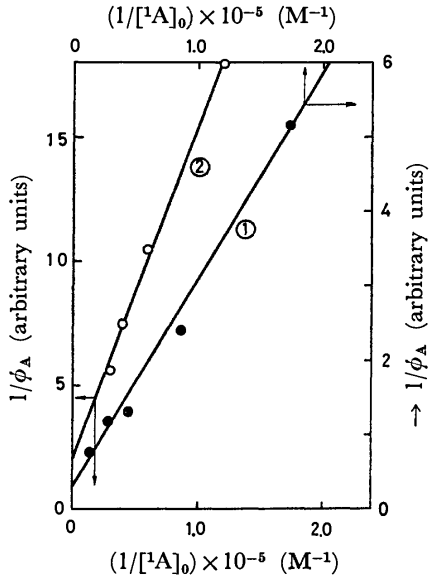

Fig. 6. Plots of $1/\phi_A$ *vs.* $1/[^1A]_0$ for acetophenone-DBN system in isooctane (1) and in carbon tetrachloride (2) at 25 °C.

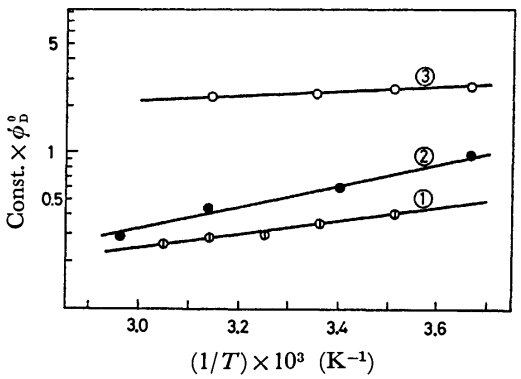

Fig. 7. Temperature dependence of ϕ_D^0 in various solvents: (1) isopentane, (2) isooctane; (3) carbon tetrachloride.

TABLE 2. DATA FOR THE DONOR PHOSPHORESCENCE IN THE ABSENCE OF THE ACCEPTOR IN VARIOUS SOLVENTS, AND THE VALUES OF ΔE_{flow} AND η OF THE SOLVENTS

Solvent	$\phi_D^0 \times 10^{4}$[a]	$\tau_0 \times 10^{6}$[a] s	ΔE kcal/mol	ΔE_{flow} kcal/mol	η[b] cP
Isopentane	0.95	0.63	1.8	1.5	0.225
Isooctane	2.7	1.6	2.8	2.1	0.504
Carbon tetrachloride	5.1		0.9	2.6	0.969

a) At 25 °C. b) At 20 °C, taken from Ref. 21.

where ϕ_A is the quantum yield of the sensitized acceptor phosphorescence and θ the fraction of triplet acceptor molecules which phosphoresce. Plots of $1/\phi_A$ against $1/[^1A]_0$ in isooctane and carbon tetrachloride at 25 °C give straight lines (Fig. 6). From the intercepts and slopes of these lines, we can obtain the values of $\alpha k_{dif}\tau_0$. The values were found to be in good agreement with those obtained from the quenching of the donor phosphorescence (*cf.* Table 1). This indicates

that the reaction scheme involving processes (3a)—(3h) describes satisfactorily the T-T energy transfer phenomenon in fluid solution.

Figure 7 shows the temperature dependence of ϕ_D^0. In each of the solvents a linear relation is found between log ϕ_D^0 and $1/T$.

Lifetimes of the donor phosphorescence at 25 °C in the absence of the acceptor are given in Table 2. The phosphorescence decay was found to be exponential in all the solvents.

Discussion

Evaluation of α and k_{dif}. Although we have obtained the values of $\alpha k_{dif}\tau_0$ at various temperatures from the slopes of the Stern-Volmer plots (Table 1), it is necessary to evaluate α and k_{dif} separately in order to establish whether the T-T energy transfer process is diffusion-controlled or not in a fluid solution.

On reference to Eq. (4') the changes in slope of the Stern-Volmer plots caused by temperature change are expressed as

$$y(T) = \frac{k_{et}}{k_{et}+k_{-dif}} k_{dif}\tau_0 \tag{6}$$

which is rewritten as

$$\frac{k_{dif}\tau_0 - y(T)}{y(T)} = \frac{k_{-dif}}{k_{et}} \tag{7}$$

We examine here the temperature dependence of the quantum yield of the donor phosphorescence in the absence of the acceptor, ϕ_D^0. From the fact that the phosphoressence decay is exponential, the donor lifetime τ_0 as defined in Eq. (4) is expressed in the form

$$\tau_0 = 1/(k_r+k_q),$$

where k_r denotes the rate constant for the radiative transition in the donor molecule, and k_q the sum of the rate constants for unimolecular and pseudo-unimolecular quenching processes of the donor; the latter quenching process might be caused by solvent molecules and by some quenching impurities. The quantum yield ϕ_D^0 is expressed in the form

$$\phi_D^0 = \phi_{ISC} k_r \tau_0 = \text{Const.} \times \tau_0,$$

where ϕ_{ISC} is the intersystem crossing quantum yield of the donor.

In a fluid solution, it can safely be assumed that $k_r \ll k_q$, so that $\tau_0 = 1/k_q$. In addition, it is recognized that the quenching constant k_q has a diffusion-controlled character.[13] Therefore k_q can be written as

$$k_q = \text{Const.} \times \exp(-\Delta E/RT) \tag{8}$$

where ΔE is an activation energy. Thus, ϕ_D^0 has the form

$$\phi_D^0 = \text{Const.} \times \exp(\Delta E/RT)$$

The foregoing considerations are supported by the fact that a linear relation exists between log ϕ_D^0 and $1/T$ in each of the solvents (Fig. 7). From the slopes of the straight lines, ΔE values are calculated to be 1.8, 2.8, and 0.9 kcal/mol, respectively, in isopentane, isooctane, and carbon tetrachloride as solvents. These values are approximately equal to the activation energies of flow, ΔE_{flow}, for the solvents except for the value in carbon tetrachloride. The data for ΔE and ΔE_{flow} are given in Table 2.

In view of these results we may assume that in a hydrocarbon solvent ΔE agrees with ΔE_{flow}. Thus it follows from Eq. (8) that $k_{dif}\tau_0$ is independent of temperature, since $k_q = 1/\tau_0$ and k_{dif} can be expressed as Const. $\times \exp(-\Delta E_{flow}/RT)$. The difference between the values of ΔE and ΔE_{flow} for carbon tetrachloride as a solvent cannot be explained from the present experimental data alone. It might be due to such a specific effect as an external heavy-atom effect of the solvent on the donor phosphorescence.

Let us now return to Eq. (7). k_{-dif} should show the same temperature dependence as k_{dif}. On the other hand, for the donor-acceptor pair under study, k_{et} would not appreciably vary with temperature. The right-hand side of Eq. (7) can then be written as

$$\frac{k_{-dif}}{k_{et}} = C \exp\left(-\frac{B}{RT}\right) \tag{9}$$

where C and B are constants. Even if k_{et} depends on temperature, Eq. (9) holds provided that k_{et} is assumed to be expressed by an Arrhenius type equation. Substitution of Eq. (9) into Eq. (7) gives

$$\frac{A-y(T)}{y(T)} = C \exp\left(-\frac{B}{RT}\right) \tag{10}$$

where A stands for $k_{dif}\tau_0$. If an appropriate value is inserted into A, a polt of $\log\{[A-y(T)]/y(T)\}$ against $1/T$ should yield a straight line.

Figure 8 shows the plots in question for different A values. It is seen that, when A equals 3.5×10^4 M^{-1} (the solid line), the plot gives a striaght line for acetophenone–DBN system in isooctane; from the slope of the line B is found to be 3.5 kcal/mol. A similar treatment of the same system in isopentane leads to $A=3.2\times10^4$ M^{-1} and $B=2.2$ kcal/mol.

By the use of $A(\equiv k_{dif}\tau_0)$ thus determined the values of α are immediately obtained (*cf.* Table 1), with the results shown in Table 3. It is seen that α is definitely smaller than unity. This shows that the T-T energy transfer is not diffusion-controlled under the present experimental conditions. Furthermore, α is found to decrease with increasing temperature. The lowering of the solvent viscosity accompanied by temperature

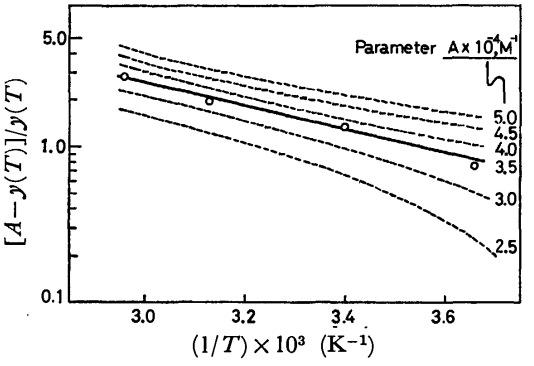

Fig. 8. Plots of $\log[A-y(T)]/y(T)$ *vs.* $1/T$ in isooctane solvent for different values of parameter A.

Table 3. Values of α at various temperatures in isopentane and isooctane

Solvent	α			
Isopentane	0.31 (12 °C)	0.28 (25 °C)	0.25 (40 °C)	0.21 (55 °C)
Isooctane	0.57 (0 °C)	0.43 (21 °C)	0.34 (46 °C)	0.26 (65 °C)

rise will increase the value of k_{-dif}, leaving k_{et} essentially unchanged. This causes a decrease in magnitude of α, since α is expressed as $1/(1+k_{-dif}/k_{et})$. In contrast, as temperature decreases, or the solvent viscosity increases, α becomes larger and tends to approach unity, so that the T-T transfer is reduced to a diffusion-controlled process. These statements are in agreement with the previous observations that T-T energy transfer is diffusion-controlled in solvents of relatively high viscosity,[3] but in less viscous solvents it is not strictly diffusion-controlled.[1,4]

Using the value of τ_0 shown in Table 2, we obtain $k_{dif}=5.1\times10^{10}$ M^{-1} s^{-1} in isopentane and 2.2×10^{10} M^{-1} s^{-1} in isooctane at 25 °C. These values differ from the k_{dif} values derived from the standard Debye equation (1), but agree well with the corresponding values predicted by the modified Debye equation (2). This is consistent with the results obtained by Osborne and Porter for T-T energy transfer in viscous solution.[3]

Estimation of k_{et}. From Smoluchowski's theory of the diffusion-controlled process,[14] the rate constant for the encounter of donor and acceptor molecules is given by[15-17]

$$k_{dif} = \frac{4\pi R_0 DN}{1000} \tag{11}$$

where R_0 is the sum of the radii of the donor and acceptor molecules in the encounter complex, D the sum of their respective diffusion coefficients D_d and D_a, and N is Avogadro's number. In this equation the transient term is neglected, since it is very small under present conditions of phosphorescence measurement.

The value $D=D_d+D_a$ was determined with the aid of the following relations:

$$\begin{aligned} D_d &= TC_d/\eta \\ D_a &= TC_a/\eta \end{aligned} \tag{12}$$

where C_d and C_a each are assumed to be a constant common to hydrocarbon solvents.[17] The C values, found in the literature,[18,19] for benzoic acid in toluene and for 1-bromonaphthalene in benzene were used, respectively, as C_d for acetophenone in isooctane and C_a for DBN in the same solvent.

By inserting the values of D determined in this way and k_{dif} obtained before into Eq. (11), R_0 in isooctane is calculated to be about 9 Å. The mean of the donor and acceptor radii ($R_0/2$) is somewhat greater than the mean of the radii estimated from the molar volumes of the donor and acceptor (3 Å).

On the basis of random-walk theory,[15,16] Wagner and Kochea gave the following relation:[4]

$$\frac{1-\alpha}{\alpha} = \frac{k_{-dif}}{k_{et}} = \frac{\xi}{k_{et}}\cdot k_{dif} \tag{13}$$

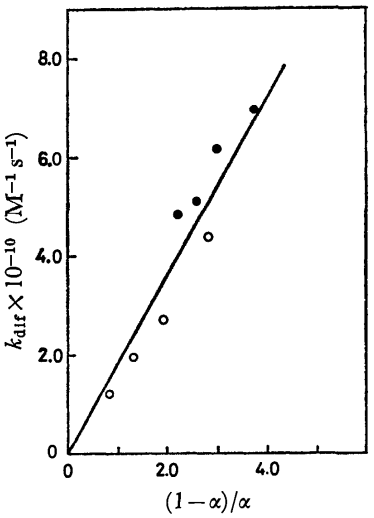

Fig. 9. Plots of k_{dif} *vs.* $(1-\alpha)/\alpha$: ○, in isooctane; ●, in isopentane.

with

$$\xi = \frac{3000}{2\pi NR_0^3} \tag{14}$$

The plot of k_{dif} against $(1-\alpha)/\alpha$ was found to give a straight line (Fig. 9). The value of k_{et}/ξ is determined to be 1.8×10^{10} M^{-1} s^{-1} from the slope of the line. By inserting the R_0 value into Eq. (14) ξ is found to be 1.1 M. We thus immediately obtain $k_{et}=2.0\times10^{10}$ s^{-1}. This k_{et} value, which corresponds to $R_0=9$ Å, is smaller by a factor of 10 than the value obtained in a mixed crystal.[20] This discrepancy may be understood by noting that the rate of T-T energy transfer should vary with the distance between donor and acceptor molecules,[22] and that the distance concerned is greater in the solution than in the mixed crystal.

The Formation and Collapse of Mixed Monolayer of Triolein and Tricaprylin

Masayuki NAKAGAKI and Noriaki FUNASAKI*

Faculty of Pharmaceutical Sciences, Kyoto University, Sakyo-ku, Kyoto 606

(Received May 8, 1974)

The surface pressure-area curves of mixed monolayers of triolein and tricaprylin and the equilibrium spreading pressures of these liquid mixtures were measured at 25 °C. The surface pressures of the monolayers of the pure components, triolein and tricaprylin, did not vary when the monolayer was compressed below its collapse area, but the surface pressure of their mixed monolayers increased with the compression; the surface pressure at a zero area agreed well with the value of the equilibrium spreading pressure. From the two curves, the one representing the relation between the collapse pressure and the composition of the mixed monolayer, and the other representing the relation between the equilibrium spreading pressure and the composition of the liquid mixture, the compositions of the mixed monolayer and the liquid mixture coexisting in the equilibrium were obtained. Consequently, it was found that the component whose collapse pressure was lower was richer in the liquid mixture than in the mixed monolayer, while the other component, whose collapse pressure was higher, was poorer in the liquid mixture than in the mixed monolayer. It was concluded, on the basis of the phase rule and thermodynamics for a plane interface, that triolein and tricaprylin form a regular mixture in the monolayer as well as in a liquid.

Studies of the processes by which a lipid mixture forms a monolayer and a mixed monolayer collapses to deposit a lipid mixture on the water-air interface are important in that the biological membrane contains the lipid mixture as one of its main components. Theoretical and experimental studies have been reported of the collapse pressure of mixed monolayers[1-3] and the equilibrium spreading pressure of mixed crystals.[4]

In a previous paper,[5] the compositions of the monolayer and the solid, which is in equilibrium with the former, have been studied for the binary system of triglyceride and cholesterol, and the miscibility of these components in the monolayer state and the solid state has been discussed on the basis of the two-dimensional phase rule. Moreover, the overcompression of the monolayer has been discussed. The state of the monolayer and the solid in equilibrium could not, however, be explained thoroughly, because these mixtures were solids, so the rate was quite low to arrive at an equilibrium between a monolayer and a solid.

In this paper, the equilibrium spreading pressure and the collapse pressure for the binary system of triolein and tricaprylin were measured, because these substances are liquid at room temperature and are practically insoluble in water.

Experimental

The triolein and tricaprylin were purchased from the Sigma Chemical Company and were stored at −25 °C. The water and chloroform were twice distilled. A mixture of triolein and tricaprylin was produced by evaporating the solvent from a chloroform solution in which the triolein and tricaprylin had been completely mixed. The triolein and tricaprylin were miscible in the liquid state in any proportion examined. When about 20 mg of this liquid mixture was dropped onto a clean aqueous surface with an area of about 60 cm², the surface pressure immediately increased, reaching a constant value after a while. This surface pressure was determined as the equilibrium spreading pressure, F_e, and it was measured at various compositions of mixtures of triolein and tricaprylin. On the other hand, the mixed monolayer of triolein and tricaprylin was spread from their chloroform solution and the pressure-area curve of the mixed monolayer was determined. The surface pressure was measured at 25±0.1 °C using a surface through equipped with a vertical-type surface balance described previously.[6]

Results

Pressure-Area Curve. The surface pressure-area curves of mixed monolayers of triolein and tricaprylin are shown at various mole fractions of tricaprylin, x_c, in Fig. 1. The kink points shown by arrows in this figure indicate that the monolayers begin to collapse at these points. Therefore, the pressures and the areas of these points are the collapse pressure, F_c, and the collapse area, A_c, respectively. At surface pressures lower than the collapse pressure, the pressure-area curves of the monolayers of triolein (shown by open circles in Fig. 1) and tricaprylin (shown by closed circles) were examined to see whether or not they fit the following equation presented by Jura and Harkins:[7]

* Present address: Kyoto College of Pharmacy, 5-Nakauchi-cho, Misasagi Yamashina, Higashiyama-ku, Kyoto 607,

$$F = -\alpha \log A + \beta A + \gamma \quad (1)$$

It has been found that these curves can be represented by Eq. (1), with $\alpha=500$ dyn/cm, $\beta=1.57$ dyn molec./cm Å^2, and $\gamma=856.53$ dyn/cm for the triolein monolayer, and with $\alpha=400$ dyn/cm, $\beta=1.290$ dyn molec./cm Å^2, and $\gamma=679.64$ dyn/cm for the tricaprylin monolayer, respectively. It has, therefore, been concluded that the monolayer of each component is in the state of the liquid expanded film. At the area below their collapse areas (shown by arrows), the surface pressure of monolayers of the pure components, triolein and tricaprylin, are kept constant, but those of their mixed monolayers increase with the decrease in the area.

Equilibrium Spreading Pressure and Collapse Pressure. The equilibrium spreading pressure was determined as the time-independent surface pressure exerted when a excess of a liquid mixture of triolein and tricaprylin was dropped onto the clean aqueous surface. In the case of the mixture of triolein and tricaprylin with the molar ratio of 1 : 2, for example, the surface pressure increased rapidly when a drop of the mixture was placed on the surface, thereafter reaching a constant value, as is shown in Fig. 2. Moreover, when the film in this state was compressed to some extent at the time shown by an arrow, the pressure increased slightly, but it returned immediately to its original value. This is the equilibrium spreading pressure, F_e, at the composition of the liquid mixture. Thus, the relation between the equilibrium spreading pressure and the mole fraction of tricaprylin, x_c^b, in the liquid mixture was obtained; it is shown in Fig. 3 by closed circles. The relation between the collapse pressure, F_c, obtained from Fig. 1 and the mole fraction of tricaprylin, x_c^s, in the mixed monolayer is also shown in Fig. 3 by open circles.

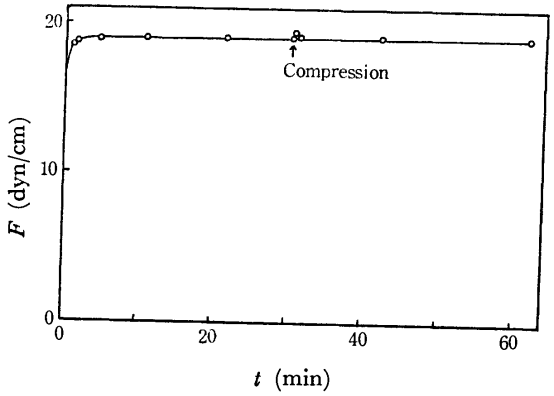

Fig. 2. The change of surface pressure with elapsed time in existence of the liquid mixture of triolein and tricaprylin (1 : 2).

- - - Curve calculated from Eq. (10) and Eq. (11) with $B^b=B^s=0$. -·-·- Curve calculated from Eq. (10) and Eq. (11) with $B^b=0.78$ kcal/mol and $B^s=1.13$ kcal/mol.

For the monolayers of both the pure components, triolein and tricaprylin, the collapse pressure was in good agreement with the equilibrium spreading pressure. For mixtures, however, the equilibrium spreading pressure varied continuously with the composition of the liquid mixtures, while the collapse pressure also varied with the composition of the mixed monolayer. The two curves, $F_e-x_c^b$ and $F_c-x_c^s$, did not agreed with each other, suggesting that the compositions of the liquid droplet and the monolayer are different from each other.

Discussion

Equilibrium Spreading Pressure and Collapse Pressure. Figure 3 shows the relation between the composition of a liquid mixture and that of the mixed monolayer coexisting at a given surface pressure. If a horizontal line is drawn at a given surface pressure in Fig. 3, the intersections of this line with the curve of the equilibrium spreading pressure (drawn through closed circles) and with the curve of the collapse pressure (drawn through open circles) give the mole fractions of tricaprylin in the liquid mixture and the mixed monolayer respectively. Therefore, it is found that tricaprylin, whose equilibrium spreading pressure is higher, is richer in the mixed monolayer than in the liquid mixture, while triolein, whose equilibrium spreading pressure is lower, is richer in the liquid mixture than in the mixed monolayer.

The facts in Fig. 3 show that both the equilibrium spreading pressure and the collapse pressure vary continuously, meaning that these components are miscible both in a liquid and in a monolayer. This can be concluded from the following. According to the phase rule for a plane interface,[8] the number of degrees of freedom for the surface phase, ω, is given by the Eq. (2):

$$\omega = c - \varphi - (\psi - s) + 2 \quad (2)$$

where c is the number of components, φ is the number of the bulk phases, ψ is the number of the interface phases, and s is the number of types of interfaces. When G, W and L designate air, water, and the liquid mixture of triolein and tricaprylin respectively, $c=4$, $\varphi=3$(G,W,L), $s=3$ (G/W, G/L, L/W), and $\psi=3$ (one phase at each interface). Then, ω is equal to the 3 from Eq. (2). As the temperature and pressure are

constant under the experimental conditions used in this study, it may be concluded that one more freedom is left. Therefore, the surface pressure can be varied continuously while the compositions of the liquid mixture and the mixed monolayer are fixed for each value of the surface pressure. This is the case when triolein and tricaprylin are miscible both in a liquid and in a monolayer. On the other hand, when both components are immiscible in either the liquid state or the monolayer state, the equilibrium spreading pressure or the collapse pressure must take a constant value, independent of the composition of the liquid mixture or of the mixed monolayer. This has been described in detail in a previous paper.[5]

The Pressure-Area Curve of the Monolayer in Equilibrium with Liquid Droplets. The interrelation between the pressure-area curve (Fig. 1) and the curves of the equilibrium spreading pressure and collapse pressure (Fig. 3) is illustrated schematically in Fig. 4. The left figure (a) of Fig. 4 corresponds to Fig. 3, while the NKLMP and NHIJP curves represent the equilibrium spreading pressure and the collapse pressure respectively. The right figure (b) of Fig. 4 corresponds to Fig. 1, while the BCDE curve represents the pressure-area curve of the mixed monolayer, whose mole fraction is x_2. In Fig. 4(b), the relation between the collapse pressure, F_c, and the collapse area, A_c, is given by the chained line, which is so drawn that it passes through the kink-points indicated by arrows in Fig. 1.

When the mixed monolayer at the mole fraction of x_2 is compressed along the BC curve, the monoalyer starts collapsing at the C point. At this point, it may be seen from Fig. 4(a) that the mixed monolayer at the mole fraction of x_2 coexists with a trace of the liquid mixture at the mole fraction of x_2^K. If the surface pressure is now increased further, the concentration of the 2 component (more stable against collapse) in the monolayer is increased by separating the liquid mixture further. At a certain point, *e.g.*, D in Fig. 4(b), the mixed monolayer of the composition of x_2^I and the liquid mixture of the composition of x_2^L coexist at the molar ratio of $(x_2-x_2^L)$ to $(x_2^I-x_2)$, as may easily be seen from Fig. 4(a). Finally, at the E point in Fig. 4(b), the liquid mixture of the composition of x_2 coexists with a trace of the mixed monolayer of the composition of x_2^J, as may be seen in Fig. 4(a). Since the area occupied by the liquid mixture is negligible, the mean molecular area at the E point, A^E, is obviously zero and the surface pressure in this state is the equilibrium spreading pressure of the liquid mixture whose composition is x_2.

Now, the CDE curve of Fig. 4(b) can be drawn theoretically as follows by calculating the area, A^D, corresponding to the point, D, at which the mixed monolayer of the surface pressure, F^D, coexists with the liquid mixture. The area actually occupied by one molecule in the monolayer is A^G, but only a fraction, $(x_2-x_2^L)/(x_2^I-x_2^L)$, of the initially-spread molecules remains in the monolayer. Since the area occupied by the liquid deposit can be neglected, the area divided by the total number of initially-spread molecules, A^D, is given by the following Eq. (3):

$$A^D = \frac{x_2-x_2^L}{x_2^I-x_2^L} \times A^G \tag{3}$$

The relation between the values of A^D calculated from Eq. (3) and various surface pressure values is shown by dotted lines in Fig. 1 as a function of the x_2 parameter, which is the mole fraction of the 2 component in the initially-spread monolayer. The calculated curves (dotted lines) are in good agreement with the curves obtained experimentally (solid lines).

Thermodynamic Treatment. The equilibrium between the mixed monolayer and the liquid mixture will be discussed here thermodynamically. Because the chemical potentials of the components, 1 and 2, in the liquid mixture are equal to those in the mixed monolayer in the equilibrium, the following two equations can be written according to Joos[9]:

$$\mu_1^{ob} + kT\ln\gamma_1^b x_1^b = \mu_1^{os} + kT\ln\gamma_1^s x_1^s + F\bar{A}_1 \tag{4}$$

$$\mu_2^{ob} + kT\ln\gamma_2^b x_2^b = \mu_2^{os} + kT\ln\gamma_2^s x_2^s + F\bar{A}_2 \tag{5}$$

where μ^0 is the standard chemical potential, γ is the activity coefficient, x is the mole fraction, and $\bar{A}$ is the partial molecular area. The superscripts, b and s, indicate the liquid mixture and the mixed monolayer respectively, while the subscripts, 1 and 2, indicate the components, 1 and 2 respectively. For one-component systems,

$$\mu_1^{ob} = \mu_1^{os} + F_{1c}A_{1c} \tag{6}$$

is derived for the 1 component from Eq. (4), with $x_1^b = x_1^s = 1$, and $\gamma_1^b = \gamma_1^s = 1$, while

$$\mu_2^{ob} = \mu_2^{os} + F_{2c}A_{2c} \tag{7}$$

is derived for the 2 component from Eq. (5). Assuming that the theory of regular solution applies to both the liquid mixture and the mixed monolayer, the activity coefficients can be replaced by using the following equations, which contain the B^b and B^s constants:

$$kT\ln\gamma_1^b = B^b(x_2^b)^2, \qquad kT\ln\gamma_1^s = B^s(x_2^s)^2 \tag{8}$$

$$kT\ln\gamma_2^b = B^b(x_1^b)^2, \qquad kT\ln\gamma_2^s = B^s(x_1^s)^2 \tag{9}$$

The substitution of these relations into Eqs. (4) and (5) yields:

$$kT\ln x_1^b + B^b(x_2^b)^2 + F_{1c}A_{1c} = kT\ln x_1^s + B^s(x_2^s)^2 + F\bar{A}_1 \tag{10}$$

and:

$$kT\ln x_2^b + B^b(x_1^b)^2 + F_{2c}A_{2c} = kT\ln x_2^s + B^s(x_1^s)^2 + F\bar{A}_2 \tag{11}$$

Therefore, the relation between x^s and x^b can be obtained by solving Eqs. (10) and (11) simultaneously, if the value of the partial molecular area, $\bar{A}$, is known as a function of the surface pressure, F, and if the values of the parameters, B, are assumed properly. If the values of the parameters, B^b and B^s, are assumed properly, the only unknown quantities in Eqs. (10) and (11) are x^s and x^b at a given surface pressure. The values of the partial molecular area, $\bar{A}$, should be obtained by drawing a tangent on the curve representing the relation between the mean area, A, and the mole fraction, x^s, of the monolayer at a given surface pressure. When A

was plotted against x^s on the basis of the data given in Fig. 1, a linear relationship between them was found to hold within the limits of experimental error. It was, therefore, concluded that the partial molecular area, $\bar{A}$, is equal to the molecular area of the pure component. For triolein, whose collapse pressure is relatively low, the following equation, previously presented, was used to obtain the value of the molecular area, by extrapolation, for a surface pressure higher than its collapse pressure:

$$F = -500 \log A + 1.547 A + 856.53. \quad (12)$$

When both B^b and B^s are set equal to zero, the values of x^s and x^b, as calculated from Eqs. (10) and (11), are as shown by dotted lines in Fig. 3. In this case, γ_1^s, γ_1^b, γ_2^s, and γ_2^b are all equal to one, according to Eqs. (8) and (9): their solutions are ideal both in the liquid mixture and in the mixed monolayer. They are considerably different from the experimental values. Next, when x^s and x^b are calculated from Eqs. (10) and (11) with $B^b = 0.78$ kcal/mol and $B^s = 1.13$ kcal/mol, the calculated results are as shown by chained lines in Fig. 3. These chained lines are fairly closed to the experimentally-found values. Therefore, it may be concluded that the mixture of triolein and tricaprylin can be treated like the regular solutions both in the liquid and in the monolayer states.

Fourier Analysis of AC Polarography. Elimination of Non-Faradaic Effects and Determination of Kinetic Parameters for Cd(II)-Na_2SO_4 System

Michio HIROTA, Yoshio UMEZAWA, Hiroyuki KOJIMA,* and Shizuo FUJIWARA

Department of Chemistry, Faculty of Science, University of Tokyo, Hongo, Tokyo 113

(Received March 7, 1974)

The on-line Fourier analysis of the AC polarographic current was found to give accurate results for electrode kinetics provided that the compensation of the *iR* drop and of the non-faradaic current was attained: The *iR* drop was compensated by a *positive feedback technique*. The charging current was cancelled by addition of a *pseudo-charging current*, inverse in phase to the former. Both the phase angles and amplitudes of the fundamental and second harmonic AC responses for the system of Pb(II) in 1M $NaClO_4$ ($[H^+]=12$ mM) agreed with theoretical prediction. As an illustration, the kinetic parameters of Cd(II)-1 N Na_2SO_4 system have been determined to be $k_s=(0.20\pm0.03)$ cm/s and $\alpha=0.30$ $(0.27<0.30<0.35)$ from the second harmonic AC polarogram.

The on-line Fourier analysis of instantaneuos AC polarographic currents enable us to determine simultaneously the amplitudes and phase angles of the fundamental and second harmonic responses.[1] However, since no instrumental compensation of the *iR* drop and the non-faradaic current(charging current) was made, the values obtained showed significant departure from those predicted theoretically. Thus, it was necessary to improve the instrument in order to eliminate the *iR* drop and the non-faradaic current. The cell resistance decreases the intensity and shifts the phase angle of AC polarographic current, and the large capacitive current reduces the precision of the analog-to-digital(A/D) conversion of small faradaic currents.

In the present study, a simple circuit has been adopted in order to compensate the charging current due to double layer capacity. A *positive feedback technique*[2-4] was employed for compensation of the *iR* drop. The results for typical chemical systems are presented to show the applicability of the apparatus.

Experimental

Apparatus and Procedure. A block diagram of the apparatus is given in Fig. 1. It is similar to the one previously described[1] except for the addition of circuits of compensation for the *iR* drop and the charging current. An oscillator (Model SY-118, NF Circuit Design Block) was used. A frequency counter(Model 5326B, Yokogawa-Hewlett-Packard) was used as a trigger generator. A sinusoidal AC potential with small amplitude was superposed on the DC potential applied to the electrode. A dropping mercury electrode (DME) was used with a reference electrode (saturated calomel electrode(SCE), Yanagimoto Model MRP). The polarographic current was sampled during a single drop life and stored in the computer with an 8 bit A/D converter(JRA-5 of JEOLCO), which was connected to the potentiostat. The Fourier transformation was performed after the DC component of the polarographic current had been largely eliminated by shifting the zero level.

Compensation for Charging Current and iR Drop. The charging current was nearly compensated with the aid of a *pseudo-charging current*, inverse in phase to the charging current. It was supplied from the common signal source (oscillator) through the phase inverter and differential circuit, the output of this circuit thus being inverse in phase to the charging current. It was then added to the polarographic current at the amplifier. The amplitude of the output of the differential circuit was proportional to the frequency of the input AC potentials in the range 20 Hz~3 kHz. In order to stabilize the circuit, a resistance was connected in series with the input of the differential circuit. Figure 2 shows the effect of the compensation for the charging current of the Cd(II)-1 N Na_2SO_4 system. At a potential where the faradaic current was negligible, the amplitude of the pseudo-charging current was adjusted to minimize the observed polarographic current. When the *iR* drop is effectively compensated, the second harmonic response is not influenced by the charging current. The amplitude of the charging current varies with DC potentials at which polarographic currents are measured and with the area of the DME, which makes it difficult to completely eliminate the charging current at all potential regions. It is therefore desirable for measurement of the second harmonic AC current for the charging current to be eliminated in major part, in order to retain accuracy and precision of A/D conversion and digital calculations. For the measurement of the fundamental harmonic response, the present method of charging current compensation only lowers the base line of the capacitive component.

The *iR* drop compensation was fulfilled by the use of the positive feedback circuit reported by Smith and his co-

workers:[2-4] The same amount of voltage as that of the *iR* drop was returned from the current follower to the adder *via* the variable resistance (Fig. 1). The small capacitances (C1, C2, C3=100 pF) were used to stabilize the circuit.

Measurement. The amplitude of the AC potential (ΔE) superposed on the DC potential was 5 mV or 15 mV, the frequency being adjusted to 27.9 or 173.6 Hz. The A/D converter began to sample 16 cycles of the AC polarographic current in 8 bit digital form 3.44 s after the time when the new drop started growing. The sampling method was similar to that reported previously.[5] The Fourier transformation was performed with a Fast Fourier Transform (FFT) program. The flow rate of mercury was 0.67 mg/s at the mercury column height of 40 cm. All the measurements were carried out at (25.0±0.5) °C. A computer simulation was performed using a HITAC 8800/8700 system at the Computer Centre, The University of Tokyo. A FORTRAN program from D. E. Smith was used to calculate the theoretical curves of the fundamental and the second harmonic responses.

All chemicals used were of analytical reagent grade. Water was distilled after deionization.

Results and Discussion

Figure 3 shows the reversible fundamental and second harmonic AC polarograms of Pb(II)–1M $NaClO_4$ ([H^+]=12 mM) system, where the tracings of the original instantaneous AC currents are also demonstrated for the sake of comparison.[6] The frequency and amplitude of the AC potential in this case were 27.9 Hz and 5 mV, respectively. The magnitude of resistance of the feedback for the *iR* drop was determined at the DC potential(arrow, Fig. 3(B)) so that the phase angle of the second harmonic response was made equal to the theoretical value.[7]* The solid lines indicate the reversible theoretical curves for the fundamental and the second harmonic responses which were calculated according to the expanding plane model by the following equations.

$$I(\omega t)=\frac{n^2F^2AC_0^*(\omega D_0)^{1/2}(\Delta E)}{4RT\cosh^2(j/2)}\sin(\omega t+\pi/4) \quad (1)$$

$$I(2\omega t)=\frac{n^3F^3AC_0^*(2\omega D_0)^{1/2}(\Delta E)^2\sinh(j/2)}{(4RT)^2\cosh^3(j/2)}\sin(2\omega t-\pi/4) \quad (2)$$

$$j=\frac{nF}{RT}(E_{DC}-E^r_{1/2}) \quad (3)$$

where $I(\omega t)$ and $I(2\omega t)$ represent the fundamental and the second harmonic AC currents, respectively. The other notations have their usual meanings.[1] D_0 was obtained experimentally from the average diffusion current by means of the Ilkovič equation. The electrode area A was obtained by

$$A=0.85\,m^{2/3}t^{2/3} \quad (4)$$

where m is the flow rate of mercury, t the drop time calculated from

$$t=(\text{waiting time})+\frac{(\text{sampling time})}{2} \quad (5)$$

where the waiting time was the quiescent time from the beginning of the drop growth to the data sampling, the sampling time being the time interval of the data sampling. The waiting time and sampling time were made to be 3.44 s and 0.57 s, respectively, so that 16 cycles of AC polarographic current were stored in the memory during the course of sampling time.

The cathodic peak of the second harmonic AC wave was higher than that of the anodic one, the peak intensity of the fundamental harmonic AC wave being slightly higher than that of the theoretical one (Fig. 3). The results are interpreted to be due to the effect of the spherical diffusion in which the reduced form is soluble in the DME.[8,9]

Departure of phase angles from theoretical values was less than ±1° in the regions (E_p±0.4) V for the fundamental harmonic AC polarogram, where E_p is the peak potential, and (E_p±0.1) V for the second harmonic AC polarogram. The results suggest that the circuit for the *iR* drop compensation works satisfactorily.

The effect of the amplitude of the applied AC potential was also examined. With the increase of amplitude of AC potential up to 15 mV, the half-width of the fundamental and the peak-to-peak separation of the second harmonic AC polarogram exceeded the theoretical values by 10%.

It is thus concluded that the apparatus can be used to obtain accurate values for the kinetic parameters of the electrode reactions.

* Cell resistance in the absence of the feedback circuit can be easily calculated from the measured vector components of the admittance for the electrolyte solution without depolarizer. However, this operation is less accurate than that mentioned above.

$n=2$, $D_0=0.84\times10^{-5}$ cm²/s, $D_r=1.6\times10^{-5}$ cm²/s, $A=0.015$ cm², $\Delta E=5$ mV, frequency=173.6 Hz.

Figure 4 shows the second harmonic AC polarogram for the Cd(II)–1 N Na_2SO_4 system. The frequency and amplitude of the AC potential were 173.6 Hz and 5 mV, respectively. The kinetic parameters for this system were found to be (0.20±0.03) cm/s for k_s and 0.30(0.27 <0.30<0.35) for α by computer simulation.[7] The diffusion coefficient of the reduced form was taken from the works of Furman *et al.*[10] The solid lines (I—III) are theoretical curves calculated from the expanding plane model. Curve IV was calculated considering the effect of spherical diffusion at the stationary electrode[11] on curve I. The kinetic parameters for Cd(II)–1 N Na_2SO_4 system are in good agreement with those obtained by the phase-sensitive AC polarographic method.[4,11-13]

We are grateful to Dr. M. Nishiyama and Mr. K. Hayashida of Yanagimoto MFG. Co., Ltd. for their helpful discussions and advice concerning the construction of the apparatus.

A Polarographic Study of the Dissociation Reactions of the Ethylenediaminemonoacetatocobalt(II) (Co(II)-EDMA) and Ethylenediaminediacetatonickel(II) (Ni(II)-EDDA) Complexes

Mutsuo KODAMA

Department of Chemistry, College of General Education, Hirosaki University, Bunkyo, Hirosaki, Aomori 036

(Received March 20, 1974)

The rates and the mechanisms of the dissociation reactions of the Co(II)-EDMA complex in a phosphate buffer solution and the Ni(II)-EDDA complex in an ethylenediaminediacetate solution were studied by analyzing their kinetic waves by means of conventional DC polarography. The dissociation of the Co(II)-EDMA complex gave this rate law: $-d[Co(II)\text{-}EDMA]/dt=k_p\cdot[Co(edma)^+]\cdot[H_2PO_4]^-$. On the other hand, the dissociation of the Ni(II)-EDDA complex was found to proceed through a reaction mechanism which involves ligandolysis, corresponding to this rate law: $-d[Ni(edda)^0]/dt=k_0\times[Ni(edda)^0]$. On the basis of the relative rate constant, the detailed reaction mechanism was discussed. In the dissociation of the Co(II)-EDMA complex, the phosphate anion acts just as a proton donor. In the case of the Ni(II)-EDDA complex, the ligandolysis of the coordinated water has a profound effect on the dissociation rate of the $edda^{2-}$ anion from the nickel(II) ion.

Previously,[1] the present author determined the detailed dissociation mechanisms of the aspartate, iminodiacetate, and 2,2′-ethylenedioxydi(ethylamine)-*N*,*N*,*N*′,*N*′-tetraacetate complexes of cobalt(II) by studying the nature of the kinetic waves they gave. The Co(II)-EDMA complex in a phosphate buffer solution and the Ni(II)-EDDA complex in an ethylenediaminediacetate (EDDA) solution also gave kinetic waves due to their dissociations at the electrode surface. In this paper, the present author will study their dissociation reactions by examining the nature of the kinetic waves. The effect of the phosphate anion on the dissociation of the Co(II)-EDMA complex, and that of the ligandolysis of the coordinated water on the dissociation rate of Ni(II)-EDDA complex, will also be discussed.

Experimental

Reagents. The procedure used to prepare the standard nickel(II) and cobalt(II) nitrate solutions was described previously.[2] The preparation and purification of the acid form of EDMA were also given in a previous paper.[3] All the other chemicals used were of analytical reagent-grades and were used without further purification.

Apparatus and Experimental Procedures. All the polarographs used for the measurement of the DC current-voltage curves have been described previously.[2] The characteristic feature of the DME used in this study has also been described previously.[4] All the other apparatus and the experimental procedures employed have also been described previously.[2] The ionic strength of the sample solution was adjusted to 0.30 by adding an appropriate amount of pure sodium perchlorate. For the Co(II)-EDMA system, a phosphate buffer solution was used. In the case of the Ni(II)-EDDA system, no buffer reagent was used, because the sample solutions always contained a large excess of uncomplexed EDDA and had a sufficient buffer capacity ($5.40<pH<7.20$).

Results and Discussion

The Co(II)-EDMA complex in a phosphate buffer solution containing an excess of ethylenediaminemonoacetate (EDMA) gave a single wave which is kinetically-controlled in nature. From the effects of the solution pH and the concentration of the uncomplexed EDMA, $[X]_f$, on the limiting current, i_k, the kinetic wave can be ascribed to the dissociation of the Co(II)-EDMA complex at the electrode surface. As in the case of the aminopolycarboxylate complexes of cobalt(II),[1] the reaction mechanism was investigated with the aid of the relation employed by Koryta in his polarographic study of the dissociation of the nitrilotriacetate complex of cadmium(II).[5] As is shown by the results in Fig. 1, at given concentrations of uncomplexed EDMA, $[X]_f$, and phosphate, $[P]_f$, the plot of $i_k/(i_d-i_k)$ against $[H^+]\cdot(\alpha_H)_X^{1/2}/(\alpha_H)_P^{1/2}\cdot(1+K_2\cdot[X]_f/(\alpha_H)_X)$ invariably gave a linear relation passing through the point of origin. Furthermore, the plot of $i_k/(i_d-i_k)$ against $[H^+]\cdot(\alpha_H)_X^{1/2}/(\alpha_H)_P^{1/2}\cdot(1+K_2\cdot[X]_f/(\alpha_H)_X)\cdot[X]_f^{1/2}$ also gave a straight line passing through the point of origin (Fig. 1). Here, $(\alpha_H)_X$ and $(\alpha_H)_P$

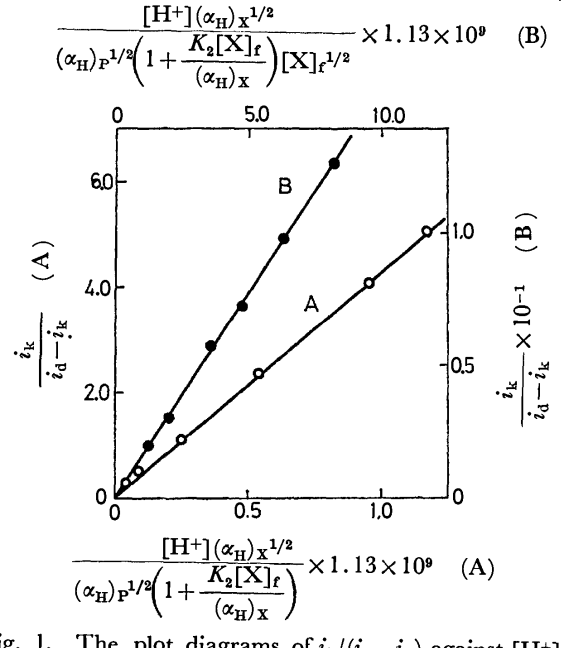

Fig. 1. The plot diagrams of $i_k/(i_d-i_k)$ against $[H^+]\cdot(\alpha_H)_X^{1/2}/(\alpha_H)_P^{1/2}\cdot(1+K_2\cdot[X]_f/(\alpha_H)_X)$ (A) and of that against $[H^+]\cdot(\alpha_H)_X^{1/2}/(\alpha_H)_P^{1/2}\cdot(1+K_2\cdot[X]_f/(\alpha_H)_X)\cdot[X]_f^{1/2}$ (B)
$\mu=0.3$, 25 °C
$[Co(II)]=0.74$ mM, $[P]_f=47.3$ M
(A) $[edma]_f=46.3$ mM
The pH ranged from 7.00 to 8.00.
(B) $[edma]_f$ ranged from 15 to 6.0 mM

Table 1. The phosphate anion effect on the $i_k/(i_d-i_k)$ ratio
$\mu=0.30$, 25 °C, pH=7.38
$[edma]_f=46.3$ mM, $[Co(II)]=0.74$ mM

$[P]_f$, mM	$\frac{i_k}{i_d-i_k}$	$\frac{i_k}{i_d-i_k}\cdot\frac{1}{[P]_f^{1/2}}$
46.3	2.36	11.0
92.6	3.35	10.9
138.9	4.10	11.0

are the (α_H) values of EDMA[6] and phosphoric acid respectively, and K_2, the second successive formation constant of the Co(II)-EDMA complex. When the other experimental conditions are kept constant, the $i_k/(i_d-i_k)$ value divided by $[P]_f^{1/2}$ was almost independent of the concentration of phosphate, $[P]_f$, (Table 1). Taking into consideration the fact that the cobalt(II) ions do not form a stable complex with the phosphate anion under the usual experimental conditions, the above facts suggest that the following reaction mechanism may operate for the kinetic wave of the Co(II)-EDMA system:

$$CoX_2^0 = CoX^+ + X^- \quad \text{in a rapid equilibrium}$$

$$CoX^+ + H_2PO_4^- \overset{k_p}{=} Co^{2+} + HX^0 + HPO_4^{2-} \quad \text{rate-determining step}$$

$$Co^{2+} + Hg + 2e^- = Co(Hg)$$

$$X^- = edma^-$$

corresponding to Relation (1):

$$\frac{i_k}{i_d-i_k}=0.886\cdot\sqrt{\frac{k_p\cdot t\cdot[H^+]^2\cdot(\alpha_H)_X\cdot[P]_f}{K_{CoX}\cdot(\alpha_H)_P\cdot K_2^P\cdot K_3^P\cdot[X]_f}}\,\frac{1}{1+\dfrac{K_2\cdot[X]_f}{(\alpha_H)_X}} \quad (1)$$

where K_{CoX} ($10^{8.30}$) is the formation constant of the 1 : 1-ratio Co(II)-EDMA complex and K_2^P and K_3^P, the second and third dissociation constants of phosphoric acid.[7] The k_p value was determined from the slope of straight line (A) given in Fig. 1; it is listed in Table 2. This value agreed well with that determined from the slope of the straight line (B) in Fig. 1, lending strong support to the above explanation.

Table 2. Dissociation rate constants
$\mu=0.30$, 25 °C

System	Rata constant
Co(II)-EDMA	$k_p=10^{8.33}$ ($M^{-1}s^{-1}$)
Ni(II)-EDDA	$k_o=10^{9.0}$ (s^{-1})

In the case of the Ni(II)-EDDA complex, the plot of $i_k/(i_d-i_k)$ against $(\alpha_H)_X^{1/2}[H^+]^{-1/2}$ (at a given concentration of uncomplexed EDDA, $[X]_f$) or $(\alpha_H)_X^{1/2}/[H^+]^{1/2}\cdot[X]_f^{1/2}$ yielded a straight line passing through the point of origin (Fig. 2). Here, $(\alpha_H)_X$ means the (α_H) value of EDDA. Since the $edda^{2-}$ anion forms only a 1 : 1-ratio complex with the nickel(II) ion, the above finding evidently implies that the reaction mechanism for the kinetic wave of the Ni(II)-EDDA system can be formulated as,

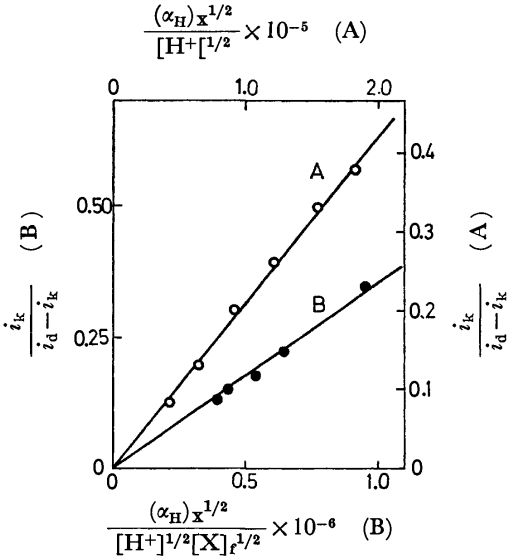

Fig. 2. The plot diagrams of $i_k/(i_d-i_k)$ against $(\alpha_H)_X^{1/2}/[H^+]^{1/2}$ (A) and of that against $(\alpha_H)_X^{1/2}/[H^+]^{1/2}\cdot[X]_f^{1/2}$ (B)
$\mu=0.30$, 25 °C
$[Ni(II)]=1.0$ mM
(A) $[edda]_f=30$ mM
The pH ranged from 5.20 to 6.50.
(B) $[edda]_f$ ranged from 10 to 50 mM.

$$NiX^0 \overset{k_0}{=} Ni(OH)^+ + HX^- \quad \text{rate-determining step}$$

$$Ni(OH)^+ + Hg + 2e^- = Ni(Hg) + OH^-$$

corresponding to Relation (2):

$$\frac{i_k}{i_d-i_k}=0.886\cdot\sqrt{\frac{k_0\cdot t\cdot(\alpha_H)_X\cdot K_{Ni(OH)}\cdot K_W}{K_{NiX}\cdot[H^+]\cdot[X]_f}} \quad (2)$$

where $K_{Ni(OH)}$ and K_{NiX}[7] are, respectively, the formation constants of the 1 : 1-ratio Ni(II)-OH and -EDDA complexes and K_w,[7] the ion product of water. The k_0 values estimated from the slopes of the straight lines, (A) and (B), in Fig. 2 agreed well with each other. This aggrement also supports the reaction mechanism proposed above. The $K_{Ni(OH)}$ value used in the estimation of k_0 was evaluated with the aid of this relation: $\log K_{Ni(OH)}=pK_w-pK^*$.[7]

Previously,[6] the present author reported that the Ni(II)-EDMA complex dissociates through the ethylenediamine-reaction intermediate. Since the cobalt(II) complex shows a kinetic behavior similar to that of the nickel(II) complex, it is not unreasonable to consider that the cobalt(II)-EDMA complex also dissociates through the ethylenediamine-reaction intermediate, by analogy with this. If the cobalt(II)-EDMA complex dissociates through the ethylenediamine-recation intermediate, the dissociation rate constant should be 10.0. This value was calculated by using the relation: $k=k_{rds}\cdot K_{Co\text{-}En}\cdot K_{st}\cdot K_{elec}/K_{CoX}$[6] and the k_{rds} estimated from the dissociation rate constant of a 1 : 1-ratio cobalt(II)-ammine complex[8] by making the correction for the rotational barrier around to C–N or C–C bond.[9] Here, $K_{Co\text{-}En}$ means the formation constant of a 1 : 1-ratio cobalt(II)-ethylenediamine complex. The observed rate constant, k_p, was $10^{7.30}$ times larger than that calculated. Previously,[10] Tanaka *et al.* determined

the rate constants of direct and proton-assisted dissociations of the cobalt(II)-EDTA complex. The rate constant for the proton-assisted dissociation is about $10^{7.0}$ times larger than that for the direct dissociation. Therefore, in view of the fact that the pK_2 value of EDMA is nearly identical with the pK_3 value of EDTA,[7] the fact that the k_0 value is $10^{7.30}$ times larger than the rate constant calculated on the basis of a simple ethylenediamine mechanism means that the $H_2PO_4^-$ anion acts just as a proton donor in the dissociation of the cobalt(II)-EDMA complex. This is also in full accord with the fact that the cobalt(II) ions do not form a stable complex with a phosphate anion.

The formation rate constant, k_f, of the 1 : 1-ratio Ni(II)-EDDA complex from $Ni(OH)^+$ and the $Hedda^-$ anion was estimated to be $10^{3.84}$ by employing the $k_f/k_0=K_{NIX}\cdot K_2/K_w\cdot K_{NI(OH)}$ relation, and the k_0 value of $10^{9.0}$. This value is nearly identical with the characteristic water-exchange rate of the aquo nickel(II) ion.[11] Since the outer-sphere association constant for the $Ni(OH)^+$—$Hedda^-$ system approximated by the Fuoss equation[12] is nearly equal to unity, the above fact means that the formation reaction of the 1 : 1-ratio complex, $Ni(edda)^0$, from $Ni(OH)^+$ and the $Hedda^-$ anion proceeds through a reaction mechanism in which the outer-sphere association between $Ni(OH)^+$ and $Hedda^-$ and the proton transfer from $Hedda^-$ to $Ni(OH)^+$ to give Ni^{2+} proceed verys rapidly; then, the slow dissociation of the coordinated water molecule from the nickel(II) ion is followed by the rapid formation of the Ni(II)-EDDA bond. The k_0 value determined in this study is much larger than the rate constant estimated on the basis of a simple ethylenediamine-reaction intermediate. This suggests that the ligandolysis of the coordinated water plays an important role in determining the dissociation rate of the nickel(II)-EDDA complex. That is to say, the hydroxide anion and the proton formed upon the dissociation of the coordinated water will effectively assist the dissociation of the $edda^{2-}$ anion from the nickel(II).

Glass Formation in Multicomponent Phosphate Systems Containing TiO_2

Akira KISHIOKA, Masanori HABA,* and Michio AMAGASA

Department of Chemistry, Faculty of Science and Technology, Sophia University, Kioicho, Chiyoda-ku, Tokyo 102

(Received March 30, 1974)

Glass formation was investigated in the Na_2O-TiO_2-P_2O_5, K_2O-TiO_2-P_2O_5, BaO-TiO_2-P_2O_5, Na_2O-BaO-P_2O_5, and Na_2O-BaO-TiO_2-P_2O_5 systems. In the Na_2O-TiO_2-P_2O_5 system, glass containing up to 45.5 mol% TiO_2 was found to be formed at the composition of $Na_2O/P_2O_5=1$, whereas in the K_2O-TiO_2-P_2O_5 system the glass formation was observed in a narrow region along the composition of $K_2O/P_2O_5=1$ in a three-component diagram. In the BaO-TiO_2-P_2O_5 system, only the glass containing about 10 mol% TiO_2 as a maximum was obtained. In the Na_2O-BaO-TiO_2-P_2O_5 system, the region of glass formation extended with an increase of Na_2O up to 30 mol%. These results suggested that a certain amount of Na_2O is necessary for the formation of glass containing a large amount of TiO_2 in the presence of BaO. The three-component diagrams of the Na_2O-TiO_2-P_2O_5 and Na_2O-BaO-P_2O_5 systems indicated that the most favorable amount of Na_2O for the glass formation in this four-component system is 27 to 28 mol%.

The region for glass formation in a three-component diagram is determined by the role of cations in the glass structure. The conditions and the region for glass formation in ternary systems of borate, silicate, germanate, and tellurite have been studied in detail by Imaoka *et al.*[1,2] However, there have been few investigations of glass formation in multicomponent phosphate systems of three or more components. From the studies of three-component diagram for glass formation in these multicomponent systems, one may be able to get some information on the role of cations, especially of such intermediate ions as Ti^{4+}, in the glass structure. It may also be worthwhile to determine the most favorable conditions for the glass formation in multicomponent phosphate systems.

In this work, the regions for glass formation in the three-component diagrams were determined for three kinds of phosphate systems containing TiO_2—the Na_2O–TiO_2–P_2O_5, K_2O–TiO_2–P_2O_5, and BaO–TiO_2–P_2O_5 systems. Based on the results of these ternary phosphate systems containing TiO_2 and that of the Na_2O–BaO–P_2O_5 system, the conditions for the formation of the glasses containing maximum amounts of TiO_2 and BaO were investigated for the four-component system of Na_2O–BaO–TiO_2–P_2O_5.

Experimental

Preparation of Glass. The raw materials used were sodium dihydrogenphosphate dihydrate, sodium triphosphate, anhydrous sodium carbonate, potassium dihydrogenphosphate, anhydrous potassium carbonate, barium carbonate, titanium dioxide, and orthophosphoric acid (85%). All the chemicals except sodium triphosphate were of a reagent grade. Commercial reagent-grade sodium triphosphate was purified before use by recrystallization and dehydration. Mixtures of from two to four kinds of the raw materials were placed in platinum evaporating dishes. For the batch of Na_2O/P_2O_5 or $K_2O/P_2O_5=1$ in the Na_2O–P_2O_5 or K_2O–P_2O_5 two-component system, $NaH_2PO_4\cdot 2H_2O$ or KH_2PO_4 was used respectively. All the batches were about 15 g in weight.

Samples were heated in a Siliconit electric furnace BSH-1530 (Siliconit Konetsukogyo Co.) equipped with a platinum platinum-rhodium thermocouple with an automatic thermoelectric regulator. It took about 5 hr to heat them up to 1350 °C, and this temperature was kept for 1 hr. The melt was quenched by pressing with copper plate cooled with water. In the batches containing TiO_2 with more than 50 mol% P_2O_5, except for the composition in which the homogeneous glass was formed, the crystalline material was separated out in the melt. The homogeneity of the glass formed was immediately observed by the naked eye and under a microscope or a polarizing microscope. No phase separation of the melt itself was found in any of the systems.

The phosphate glass usually contains a small amount of water in its structure when prepared by dehydration and condensation.[3,4] In addition, the composition of the glass is varied by the loss of P_2O_5 during the heating, it depends on the conditions of preparation.[3] In the Na_2O-BaO-P_2O_5 system, the amount of the volatillization loss of P_2O_5 was in the range from 3.3 to 14.0 mol%. Taking these facts into account, all the diagrams for the glass formation were expressed in terms of the batch composition.

Examination of Chemical Durability. Glass grains (0.25—1 mm) of about 0.5 g were weighed and each portion was placed in a 100-ml Erlenmeyer flask. Then 25 ml of water, 25 ml of 35% HCl, and 25 ml of 10% NaOH were added separately into each flask, and they were stoppered. After having been shaken at speed of 80 strokes per minute in the thermostat at 25 °C for 1 hr, the weight loss (%) of each sample was determined.

Results and Discussion

The experimental results for the glass-forming region in each system are given in Figs. 1, 3, and 5—11. Figures 7—11 show the glass-forming region in the Na_2O–BaO–TiO_2–P_2O_5 four-component system. In the systems containing TiO_2, the glasses were colored purple or brown due to the titanium ion reduced. The chemical durabilities of the Na_2O–TiO_2–P_2O_5 and K_2O–TiO_2–P_2O_5 glasses are shown in Figs. 2 and 4.

Na_2O–TiO_2–P_2O_5 System (Fig. 1). A slight amount of glass was obtained in the system with more than 50 mol% P_2O_5. However, glass with a large amount of TiO_2 was obtained by decreasing the amount of P_2O_5 to less than 50 mol%. It may be seen in Fig. 1 that the system containing Na_2O and P_2O_5 in the ratio of unity is most favorable for formation of the glass with a high TiO_2 content. This fact may possibly be interpreted by associating the increase in the glass-forming ability of the Ti^{4+} ion with the ring-opening polymerization of sodium trimetaphosphate ($Na_3P_3O_9$).[5] The composition of the glass containing a maximal

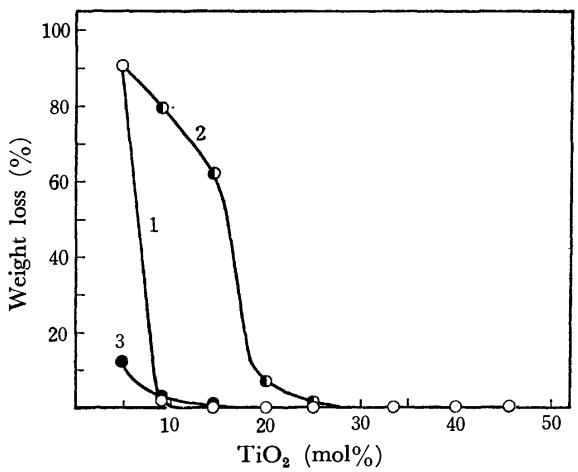

Fig. 2. Chemical durability of Na_2O-TiO_2-P_2O_5 glass ($Na_2O/P_2O_5=1$)
1 : water, 2 : 35% HCl, 3 : 10% NaOH.

quantity of TiO_2 is Na_2O: 27.3, TiO_2: 45.5, and P_2O_5: 27.3 mol%.

Figure 2 shows that the chemical durability of the glass is very much increased by increasing the amount of TiO_2. The glass containing more than 20 mol% TiO_2 is insoluble or only slightly soluble in either water, 35% HCl, or 10% NaOH.

K_2O-TiO_2-P_2O_5 System (Fig. 3). With respect to more than 50 mol% P_2O_5, the region of glass formation of this system is similar to that of the Na_2O-TiO_2-P_2O_5 system. As is shown with arrow marks in Fig. 3, the region of glass formation in the composition along the line of $K_2O/P_2O_5=1$ is narrow. This is a marked difference from the Na_2O-TiO_2-P_2O_5 system, it may be interpreted in terms of the formation of straight-chain molecules of potassium metaphosphate.[6]

Rao[7,8] reported a formation of glass in the K_2O-TiO_2 system. Under the experimental conditions in the present work, however, no homogeneous glass was obtained in the same system.

In the A and B regions in Fig. 3, the maximum concentrations of TiO_2 were about 38 mol% and 35 mol% respectively. The coloration in the glass was observed in only the A region. As is shown in Fig. 4,

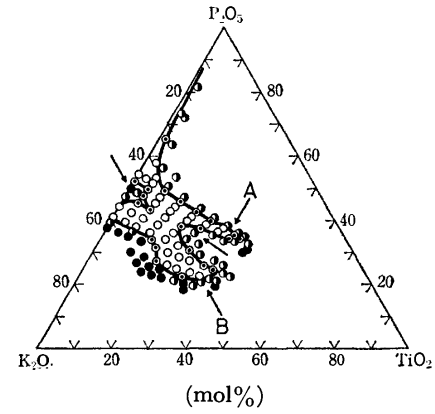

Fig. 3. Glass-forming region in K_2O-TiO_2-P_2O_5 system.
A; Region obtained the glass containing TiO_2 in the largest quantity in $K_2O/P_2O_5<1$
B: Region obtained the glass containing TiO_2 in the largest quantity in $K_2O/P_2O_5>1$

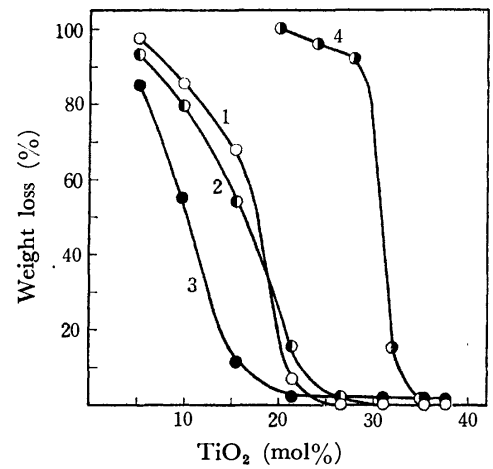

Fig. 4. Chemical durability of K_2O-TiO_2-P_2O_5 glass.
1: $K_2O/P_2O_5=0.83$, water, 2: $K_2O/P_2O_5=0.83$ 35% HCl, 3: $K_2O/P_2O_5=0.83$, 10% NaOH, 4: $K_2O/P_2O_5=1.67$, water.

the increase in the chemical durability of the glass formed in the system of K_2O-TiO_2-P_2O_5 was also observed with an increase in the TiO_2 content, as in the case of the NaO_2-TiO_2-P_2O_5 system

According to RaO,[7] the Ti^{4+} ion is able to act as a network former in silicate glass. The -P-O-Ti- linkage is probably formed in the phosphate glass. It seems that the increase in the chemical durability of the glass containing a large amount of TiO_2 results from the formation of such a linkage.

BaO-TiO_2-P_2O_5 System (Fig. 5). The homogeneous glass was obtained in the BaO-P_2O_5 system containing BaO up to approximately 58 mol%, but only about 10 mol% TiO_2 could be introduced in this glass at a maximum. This is very different from the glass formation in the NaO-TiO_2-P_2O_5 and K_2O-TiO_2-P_2O_5 systems (Figs. 1 and 3).

According to Kordes *et al.*,[9] the BaO-P_2O_5 glass is classified as a "normal glass" among the binary glasses of alkaline earth oxides and P_2O_5, and the Ba^{2+} ion has been regarded as a network modifier. However, the

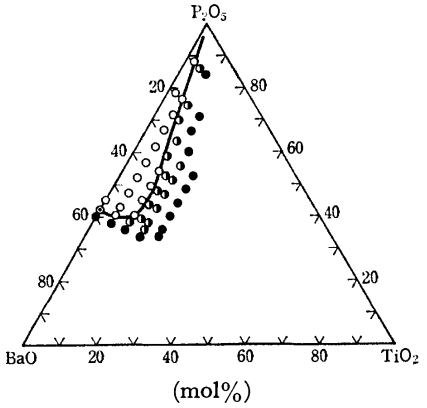

Fig. 5. Glass-forming region in BaO-TiO_2-P_2O_5 system.

electrostatic bond strength of the divalent Ba^{2+} ion, *i.e.*, the ratio of the charge number of the ion to its coordination number, is larger than that of the univalent Na^+ or K^+ ion. Thus it seems that BaO stabilizes the glass structure much more than Na_2O or K_2O in the phosphate glasses. The maximum content of TiO_2 in the Na_2O–TiO_2–P_2O_5 glass was found to be 45.5 mol% at $Na_2O/P_2O_5=1$, but that in the BaO–TiO_2–P_2O_5 glass only about 10 mol% at $BaO/P_2O_5=1$ (Figs. 1 and 5). The Ba^{2+} ion probably interferes with the introduction of the tetravalent Ti^{4+} ion into the glass structure.

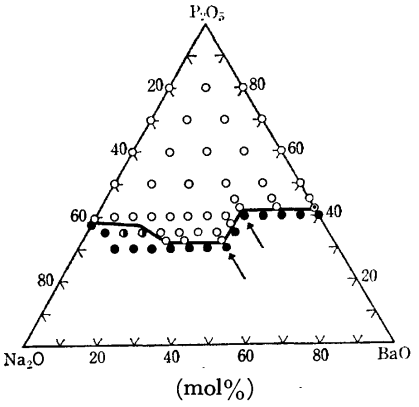

Fig. 6. Glass-forming region in Na_2O-BaO-P_2O_5 system.

Na_2O–BaO–P_2O_5 System (Fig. 6). This system consists of two kinds of network modifiers (Na_2O and BaO) and a network former (P_2O_5).

As is shown in Fig. 6, the glass is obtained over a considerably wide region. The lower limit of the P_2O_5 content in the glass formation is approximately 32 mol%. From the boundary curve in Fig. 6, it is known that the P_2O_5 content is constant in the regions of the Na_2O contents up to 20 mol%, 30—40 mol%, and 50—60 mol%, whereas the BaO content is constant in the region of 20 to 30 mol% Na_2O.

This shape of the boundary curve may possibly be interpreted as follows: the boundary of glass formation may be determined by the difference in the action between Na^+ and Ba^{2+} ions in the glass structure at the glass-forming limit. Thus, the increase in the Na_2O contents from 20 up to 30 mol% along the boundary (arrow marks in Fig. 6) seems to be the result of a break in the –P-O-P- linkage rather than of the substitution of the Ba^{2+} ion by the Na^+ ion. In the glass-forming boundary, the Ti^{4+} ion may be introduced quite easily into this glass when the Na_2O content is 20—30 mol%.

Na_2O–BaO–TiO_2–P_2O_5 System (Figs. 7—11). In order to observe the effect of Na_2O on the glass forma-

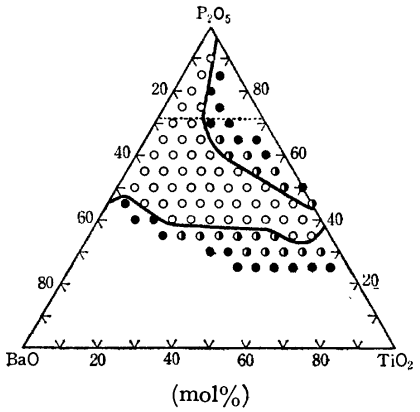

Fig. 9. Glass-forming region in Na_2O-BaO-TiO_2-P_2O_5 system containing 30 mol% Na_2O (dotted line represents P_2O_5 content is 50 mol%).

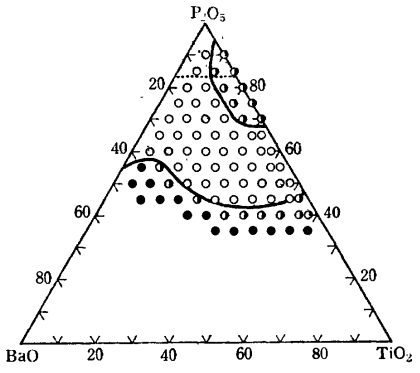

Fig. 10. Glass-forming region in Na_2O-BaO-TiO_2-P_2O_5 system containing 40 mol% Na_2O (dotted line represents P_2O_5 content is 50 mol%).

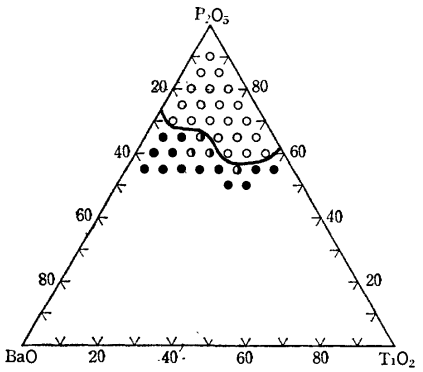

Fig. 11. Glass-forming region in Na_2O-BaO-TiO_2-P_2O_5 system containing 50 mol% Na_2O.

tion in the Na_2O–BaO–TiO_2–P_2O_5 system, the glass-forming region was studied for batches with different Na_2O contents (10, 20, 30, 40 and 50 mol%).

The results are shown in Figs. 7—11. The region in which the glass containing TiO_2 is formed extends up to 30 mol% of Na_2O. The decrease in the P_2O_5 content causes an increase in the TiO_2 content and a decrease in the BaO content in the glass. In addition, the tendency of the glass-forming region to be extended was observed in the system of up to 30 mol% Na_2O along with the compositions of the P_2O_5 contents of 27—28 mol%. The Ti^{4+} ion seems to be introduced easily into the glass structure at this amount of P_2O_5. The P_2O_5 content corresponds to the lower limit of the P_2O_5 contents in the Na_2O–TiO_2–P_2O_5 system (about 27 mol%). The glass-forming region in the Na_2O–BaO–TiO_2–P_2O_5 system (Figs. 7—11) extends to the boundary line in the Na_2O-TiO_2-P_2O_5 system (Fig. 1) when the Na_2O content is 27—28 mol%.

These results suggest that a certain amount of Na_2O is necessary for the formation of the glass containing a large amount of TiO_2 in the presence of BaO. This amount is probably in the range from 27 to 28 mol% Na_2O. Thus, it may be concluded that the Ti^{4+} ion is easily introduced into the glass when both Na_2O and P_2O_5 are 27—28 mol%; $Na_2O/P_2O_5 \approx 1$. These results also support the interpretation of the boundary of glass formation in the Na_2O–BaO–P_2O_5 system (Fig. 6).

The authors wish to thank Professor Hiroshi Fukutomi of the Tokyo Institute of Technology, and Associate Professor Koh Sakamoto of Kanazawa University, for their helpful advice

Properties and Configuration of Manganese(II), Cobalt(II), Nickel(II), Copper(II) and Zinc(II) Chelates of Acetoacetylferrocene

Hiromu IMAI and Tadamasa ŌTA*

Faculty of Engineering, Kansai University, Senriyama, Suita-shi, Osaka 564

(Received April 2, 1974)

Physical and chemical properties of manganese(II), cobalt(II), nickel(II), copper(II) and zinc(II) chelates of acetoacetylferrocene were investigated. The solubility decreased in the order $CHCl_3 > CH_2Cl_2 > C_6H_5Cl > C_6H_4(CH_3)_2 > C_6H_6$, the chelates being more soluble in pyridine. It was found from magnetic data that the configuration is octahedral for the aquo or pyridine adduct of manganese(II), cobalt(II) and nickel(II) chelates, square planar for anhydride of copper(II) chelate, distorted octahedral for its pyridine adduct, and quasi-tetrahedral for the anhydride of manganese(II) chelate. The d-d transition of electronic spectra was analysed by O_h symmetry for cobalt(II) and nickel(II) chelates, and by C_{2h} symmetry for copper(II) chelate. Assignment of the d-d transition for manganese(II) chelate was difficult.

It is of interest to investigate the behavior and properties of the chelates of acetoacetylferrocene ($C_5H_5FeC_5H_4COCH_2COCH_3$) in which the terminal methyl group in pentane-2,4-dione is replaced by a bulky ferrocenyl group. The bidentate ligand has been reported by several workers,[1-4] some of the first transition metal chelates being synthesized.[1-3] However, the properties and configuration of the chelates do not seem to have been reported. We wish to report on the solubility of the manganese(II), cobalt(II), nickel(II), copper(II) and zinc(II) chelates, and the configuration and assignment of the ligand field band of each chelate in the organic solvent and in the solid state.

Experimental

Synthesis of Ligand. The ligand was synthesized by the procedure described previously.[1]

Preparation of Chelates. Each chelate of manganese(II), cobalt(II), nickel(II), copper(II) and zinc(II) was prepared by the procedure reported previously.[1] The chelate obtained was dissolved in chloroform, and the filtrate was evaporated to a small volume under reduced pressure at room temperature. The chelate precipitated immediately on addition of four-fold petroleum ether to the concentrated solution. After being cooled overnight at about 0 °C, the precipitate was filtered, and washed thoroughly with petroleum ether.

Preparation of Pyridine Adduct. A solution obtained by dissolving 0.5 g of the chelate in 50 ml of pyridine was evaporated to about 10 ml under reduced pressure at room temperature. The pyridine adduct precipitated on addition of 40 ml of petroleum ether was filtered after being cooled overnight at about 0 °C, and washed thoroughly with petroleum ether.

Solubility Measurements. Excess chelate was added to 50 ml of various organic solvents which was warmed to 50 °C, and dissolved thoroughly. The resulting solution was allowed to stand at 25±0.1 °C for 3 hr, and then filtered. A 25 ml portion pipetted from this solution was evaporated completely under reduced pressure at room temperature. The solubility was measured by weighing the precipitated chelate.

Spectral Measurements. Solid reflectance spectra were measured with a Shimadzu QR-50 spectrophotometer with a diffuse reflectance attachment. Absorption spectra in ultraviolet and visible regions were measured with the same instrument. Infrared absorption spectra were measured with a Shimadzu IR-27G spectrophotometer on KBr pellets.

Molecular Weight Measurements. Molecular weights of the chelates were determined with a Shibayama recording cryoscope in bromoform, nitrobenzene, dioxane and dimethyl sulfoxide.

Magnetic Moment Measurements. The magnetic moment of the chelates in the solid state or in the organic solvent was measured by the Gouy method at room tempreature.

Results and Discussion

Solubility. The solubility of chelates reported[1] was determined in various organic solvents of different polarity. The results are given in Table 1.

Solubility decreases in the order $CHCl_3 > CH_2Cl_2 > C_6H_5Cl > C_6H_4(CH_3)_2 > C_6H_6$, which is in line with the decrease of polarity of solvent. All chelates, besides those given in Table 1, are soluble in pyridine, slightly soluble in methanol, ethanol and acetone, and almost insoluble in petroleum ether.

Composition of Chelates. It has been reported that the composition of the chelates (Table 1) is 2 : 1, other chelates except copper chelate being the bisaquo adduct.[1] When such chelates were recrystallized with a mixture of chloroform-petroleum ether, a change in color was recognized in manganese and zinc chelates. The results of elemental analysis and molecular weight determination are given in Table 2.

It was found that the water molecules coordinated to manganese and zinc chelates are dehydrated more easily than the bisaquo adduct of cobalt and nickel chelates.

The molecular weight agreed with the calculated one of the monomeric structure for other chelates except nickel. The molecular weight of the nickel chelate varies with the polarity of solvent, and has been found to be a monomer in bromoform (0.99D) or nitrobenzene (3.99D), and a dimer in dioxane (0.45D).

It is well known that bis(pentane-2,4-dionato)nickel(II) anhydride in the solid state has a trimeric structure, in which nickel(II) ion is octahedrally coordinated.[5] However, when a terminal methyl group in pentane-2,4-dione is replaced by a bulky ferrocenyl group, the steric hindrance among the substituents seems to prevent trimerization. Thus, the bisaquo adduct of the nickel chelate in a solvent such as dioxane

with a low polarity is suggested to be similar in structure to the dimeric octahedral structure of bis(1,5-dialkyl-2,4-pentanediono)nickel(II) monohydrate.[6]

The results of elemental analysis and molecular weight measurement of the pyridine adducts are given in Table 3.

From the composition of the pyridine adducts, they were recognized to be monomeric in the solvents used. Thus, when the chelates (Table 2) were isolated from pyridine solution, the hexa-coordinate chelates of $ML_2\cdot 2py$ type were obtained from the bisaquo adduct of the cobalt chelate by ligand exchange reaction, and from the anhydride of the manganese, copper and zinc chelates by coordination of pyridine molecules. It is of interest that $NiL_2\cdot py\cdot H_2O$ chelate, in which one water molecule was replaced by a pyridine molecule, is obtained from the bisaquo adduct of the nickel chelate.

A black-brown bispyridine adduct of CuL_2 turned gradually golden brown on exposure to the air, while

other pyridine adducts were stable under the same conditions.

The presence of pyridine molecules in such chelates is also confirmed by IR spectra (Fig. 1).

The absorption bands assignable to pyridine are observed in the spectra of the adducts. Thus, the absorption of $\nu_{C=C}$ on the pyridine ring is observed at about 1595 cm^{-1}, but that of $\nu_{C=N}$ could not be confirmed because of the overlapping with the strong absorption band of the chelates $\nu_{C=O}$ appearing at about 1570 cm^{-1}. There is a tendency that the absorption of $\nu_{C=O}$ shifts slightly towards the low wave number side by the coordination of pyridine. The absorption of ring vibration and δ_{CH} of adjacent hydrogen on pyridine were recognized at about 1135, 750 and 695 cm^{-1}. The absorption of ν_{M-O} of the pyridine adduct shifted to the low wave number side in comparison with that of the anhydrous or hydrous chelates as follow; from 426 cm^{-1} to 418 cm^{-1} for $MnL_2 \cdot 2py$, from 419 cm^{-1} to 415 cm^{-1} for $CoL_2 \cdot 2py$, from 422 cm^{-1} to 418 cm^{-1} for $NiL_2 \cdot py \cdot H_2O$, from 450 cm^{-1} to 445 cm^{-1} for $CuL_2 \cdot 2py$ and from 438 cm^{-1} to 422 cm^{-1} for $ZnL_2 \cdot 2py$.

Magnetic Moments. The magnetic moments of each chelate measured in the solid state or in pyridine are given in Table 4.

a) Manganese Chelate: The magnetic moment of 5.94 BM in the solid state of $MnL_2 \cdot 2H_2O$ agreed with 6.02 BM of bis(pentane-2,4-dionato)manganese(II) dihydrate,[7] and also with 5.92 BM of the theoretical spin-only moment which indicates the octahedral structure of a high-spin type. As the moment of 5.52 BM in pyridine is close to 5.64 BM in the solid state of $MnL_2 \cdot 2py$, the bisaquo adduct is thought to change into the pyridine adduct in pyridine solution. The moment of 4.32 BM in the solid state of MnL_2 anhydride showed a slightly higher value than the theoretical value of n=3, being close to 4.55 BM of phthalocyanine manganese(II) chelate which is considered to have a quasi-tetrahedral structure rather than a square planar one.[8] In contrast, the anhydride in pyridine showed a moment of 5.79 BM which corresponds to that of $MnL_2 \cdot 2py$. From the above results, MnL_2 anhydride, which is considered to have a quasi-tetrahedral structure, has been found to change into an octahedral structure by the coordination of two pyridine molecules in pyridine.

b) Cobalt and Nickel Chelates: The magnetic moment of 4.75—4.89 BM in the solid state or in pyridine of $CoL_2 \cdot 2H_2O$, and in the solid state of $CoL_2 \cdot 2py$ is in the range 4.4—5.6 BM of all cobalt(II) complexes which indicates the octahedral structure. $NiL_2 \cdot 2H_2O$ in the solid state or in pyridine, and $NiL_2 \cdot py \cdot H_2O$ in the solid state showed a moment of 3.50 and 3.64 BM, respectively. The bisaquo adduct of the nickel chelate in chloroform also showed a moment of 3.50 BM. The values were slightly higher than 3.2 BM of bis(pentane-2,4-dionato)nickel(II) dihydrate[9] and 3.32 BM of hexaamminenickel(II) chloride[10] which have octahedral structures. Thus, the aquo or pyridine adduct of the cobalt and nickel chelates were found to have the octahedral structure.

c) Copper Chelate: The magnetic moment in the solid state of CuL_2 showed a higher value than the

Values in parentheses are the wave numbers of shoulder absorptions. a) The following values were the most suitable for electron repulsion parameter B: 860 cm^{-1} for aquo adduct and 840 cm^{-1} for pyridine adduct of cobalt chelate; 850 cm^{-1} for aquo adduct and 730 cm^{-1} for pyridine adduct of nickel chelate.

theoretical spin-only moment of 1.73 BM, being in the range 1.9—2.0 BM of all copper(II) complexes which indicates the tetra-coordinate square planar structure. As the value of CuL_2 in pyridine agrees with 2.10 BM in the solid state of $CuL_2 \cdot 2py$, it is suggested that CuL_2 in pyridine changes into the distorted octahedral structure by the coordination of two pyridine molecules to the central copper(II) ion in planar on both side along z axis.

Electronic Spectra. The absorption bands of each chelate in 20—40 kcm^{-1} region are given in Table 5.

Two bands of 31—33 kcm^{-1} and 21—22 kcm^{-1} are due to the chelated carbonyl group and the charge transfer between cyclopentadienyl-iron atom, respectively. The former in benzene shifted slightly to the low wave number side than that in chloroform, and the latter, to the high wave number side. The wave numbers of both bands for the pyridine adduct were practically unchanged as compared with those of the corresponding anhydrous or hydrous chelate.

The absorption spectra in chloroform or pyridine, and the diffuse reflectance spectra of solid state in 8—20 kcm^{-1} region are shown in Fig. 2. Assignment of ligand field bands is given in Table 6.

a) Manganese Chelate: The very weak band at about 9 kcm^{-1} was observed in the spectra of MnL_2 in chloroform and in the solid state. The spectral pattern of the anhydride chelate in pyridine is close to that of bisaquo adduct measured in chloroform or pyridine (not given in Fig. 2(1)). Such spectral change is due to the formation of $MnL_2 \cdot 2py$. Although the structure of the anhydride and bisaquo or bispyridine adduct of this chelate was presumed from the magnetic data, the assignment of ligand field band was difficult.

b) Cobalt and Nickel Chelates: The spectra of the bisaquo adduct of cobalt and nickel chelates are very much similar to each other, and show a shoulder at 13—16 kcm^{-1}. The absorption or reflectance band of about 9 kcm^{-1} observed on spectra of both chelates in chloroform or in the solid state shifts about 10 kcm^{-1} in pyridine. The electronic spectra of both chelates confirmed to have an O_h symmetry from the magnetic data were analysed from the Tanabe-Sugano diagram[11] for d^7 and d^8 configurations with the use of the measured

Complexes: (1) MnL_2, (2) $CoL_2 \cdot 2H_2O$, (3) $NiL_2 \cdot 2H_2O$, (4) CuL_2, L: $FcCOCHCOCH_3$, ——: $CHCl_3$, ----: py, ——: Solid state

Table 7. β values

Complexes	B_0[a] cm^{-1}	β $(B/B_0)\%$
$CoL_2 \cdot 2H_2O$	1120	77
$CoL_2 \cdot 2py$	1120	75
$NiL_2 \cdot 2H_2O$	1080	79
$NiL_2 \cdot py \cdot H_2O$	1080	68

a) B. N. Figgis, "Introduction to Ligand Field," Interscience Publishers, New York (1966), p. 52.

crystal field stabilization energy 10 Dq of both chelates and the electron repulsion parameter B (Table 6). The wave number of ligand field bands measured is very close to the values obtained from this diagram, each band can be assigned as shown in Table 6. In order to investigate the partial covalent bonding in the coordination bond of both chelates from the above results, the B parameters were compared with the B_0 parameter of free ion of cobalt(II) and nickel(II).

The degree of covalent bonding $(1-\beta)$ for both chelates is estimated to be 20—30% from the results given inTable 7.

c) Copper Chelate: The absorption bands of CuL_2 in pyridine appeared at 15.0 and 10.5 kcm^{-1}. The sharp band of the former corresponds to the shoulder observed at 13—16 kcm^{-1} in chloroform and in the solid state, and the shoulder of the latter suggests the formation of a pyridine adduct which has a distorted octahedral structure. Although the transition of absorption bands for bis(pentane-2,4-dioato)copper(II) was assigned to D_{4h}[12-14] or D_{2h}[15] symmetry, it is considered that the C_{2h} symmetry used by Allene[16] is better for the chelate with a ligand such as acetoacetylferrocene (Table 6).

d) Zinc Chelate: Since all zinc(II) complexes have a tetrahedral or octahedral structure, ZnL_2 or $ZnL_2 \cdot 2H_2O$ might also have such structures.

Solvent Extraction Studies of the Hydrolysis of Antimony(III) in Tracer Concentrations

Hitoshi SHOJI,* Hisao MABUCHI, and Nobufusa SAITO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received June 14, 1974)

The hydrolysis of antimony(III) ions was investigated through solvent extraction with dithizone-carbon tetrachloride solutions. In a 3 M (H, Na)ClO_4 solution, a tracer concentration of antimony(III) ($<10^{-8}$ M) was found in the form of a monovalent cation, $Sb(OH)_2^+$ or SbO^+, and a neutral species, $Sb(OH)_3$ or SbO(OH). The former is predominant in strongly acidic media, while the latter becomes abundant in the weakly acidic-to-neutral region. One of the constants of successive hydrolysis, $K_1=[Sb(OH)_2^+][Sb(OH)_3]^{-1}[H^+]^{-1}$, was calculated from the distribution ratios, giving the result: $\log K_1=1.23_6\pm0.06$. The chemical composition of the extracted species was estimated to be $Sb(HDz)_3$.

Antimony, with its typical amphoteric character, is located on the border between the metal and non-metal regions in the periodic table. Since both antimony(III) and antimony(V) ions easily hydrolyze in an aqueous solution, it is difficult to keep macro amounts of antimony ions stationary in any solution except in highly acidic media. For this reason, relatively little fundamental information is available on the chemical species of antimony in aqueous solutions, especially on their stability constants. In earlier works,[1-12] the solubility measurement was the main tool for studying these problems with some exceptions—for example, spectrophotometry, potentiometry, the measurement of diffusion coefficients, and the chemical analysis of precipitates. Since these techniques necessitated the use of macro amounts of antimony, there was always some ambiguity about the formation of polymerized species whose chemical composition is hard to determine.

We investigated the hydrolysis of antimony(III) through solvent extraction with dithizone, using radioactive tracers. Some reports suggest the reaction of antimony(III) ions with dithizone,[13-15] but no quantitative treatment of this reaction has ever been given. Our preliminary experiment showed that dithizone extracts antimony(III) in the form of dithizonate and that it is very suitable for the present research because of its rather high extractability and good reproducibility.

Experimental

Water. Tap water was deionized with a mono-bed-type ion exchanger and then distilled in an all-glass distilling apparatus.

Perchloric Acid. A G.R.-grade reagent was diluted with distilled water and purified with a dithiozone-carbon tetrachloride solution.

Sodium Perchlorate Solution. The solution was prepared from G.R.-grade sodium carbonate and the purified perchloric acid. After the reagents had been mixed, the resulting solution was purified by filtration, crystallization, and dithizone extraction.

Acetic Acid. G.R.-grade glacial acetic acid was diluted with distilled water. The dilute solution was purified by dithizone extraction.

Ammonia Water. G.R.-grade ammonia water was distilled and absorbed in distilled water.

Carbon Tetrachloride. A G.R.-grade reagent was distilled in an all-glass distilling apparatus, and a fraction with a boiling temperature of 76—78 °C was taken.

Dithizone Solution. The Merck product was purified according to the method by E. B. Sandell.[16] The purity of the dithizone in carbon tetrachloride was checked spectrophotometrically by examining the ratio of the optical density at 620 mμ to that at 450 mμ.[17]

Radioactive Tracers. Two kinds of radioactive antimony(III) tracers were prepared.

a) Sb-125: Carrier-free isotope was purchased from the Oak Ridge National Laboratory, U.S.A. Further purification was carried out to exclude a trace amount of tin, the target element of Sb-125 production, by extraction with isopropyl ether and anion ion-exchange chromatography.[18] The purified Sb(III)-125 was stocked in a carbon tetrachloirde solution of dithizone. The concentration of non-radioactive antimony in this solution was found by neutron-activation analysis to be below 10^{-8} M. This tracer was employed to study the behaviour of the tracer amount of antimony.

b) Mixture of Sb-122 and Sb-124: This mixture was produced through the neutron irradiation of antimony in the JRR-1 reactor at the Japan Atomic Energy Research Institute. The irradiated, highly pure antimony metal was dissolved in *aqua regia*, evaporated to dryness, redissolved in 3 M HCl, and finally purified by dithizone extraction to remove other interfering metal ions. After reduction with SO_2, the trivalent antimony was extracted with a dithizone solution. It was then back-extracted and stocked as a perchloric acid solution.

Measurement of the Distribution Ratio. In the case of a tracer amount of antimony, the stocked organic solution of Sb-125 was added to a carbon tetrachloride solution of dithizone. The organic phase thus prepared was mixed with a solution of (H, Na)ClO_4 and was then shaken at 25±0.5 °C until the partition equilibrium was attained. In the case of macro amounts of antimony, the purified antimony containing the radio-nuclides was initially in various acidities of perchloric acid. A fresh carbon tetrachloride solution of dithizone was added to the aqueous phase and was shaken in a way similar to that in the case of the tracer amount of antimony.

In both cases, after the equilibrium had been attained, an equal volume of each phase was pipetted into a test tube and subjected to the measurement of the γ-activity. Another portion of the aqueous phase was used for the measurement of the hydrogen ion concentration. The distribution ratio, D, is given by the radioactivity of the organic phase divided by that of the aqueous phase.

Measurement of Hydrogen Ion Concentration. As for acidic media (pH<2), the hydrogen ion concentration was deter-

* Present address: Department of Chemistry, Faculty of Science, Tokyo Kyoiku University, Otsuka, Bunkyo-ku, Tokyo 112.

mined by the titration method. In other cases it was determined by potentiometry. The emf measurement was carried out using a pH meter (Radiometer PHM-4 type) with a glass electrode at 25±0.5 °C as soon as possible after shaking. As reference solutions, mixtures of 0.01 M $HClO_4$ and $(x-0.01)$ M $NaClO_4$ were prepared for the x M (H, Na)ClO_4 solution series ($-\log [H^+]=2.00$).

Measurement of Radioactivity. A well-type NaI(Tl) scintillation counter was used. For Sb-125, the sum of γ-rays whose energies are higher than 200 keV was taken in order to eliminate the daughter Te-125m activity. For the mixture of Sb-122 and Sb-124, the total γ-rays were counted.

Results

(1) Time Necessary for the Partition Equilibrium. As is shown in Fig. 1, the partition of antimony(III) between two phases reaches equilibrium within five minutes. This proved to be true under any conditions, independent of the acidity, the concentration of antimony (up to 2×10^{-4} M), the concentration of dithizone, and the phase to which antimony was added initially.

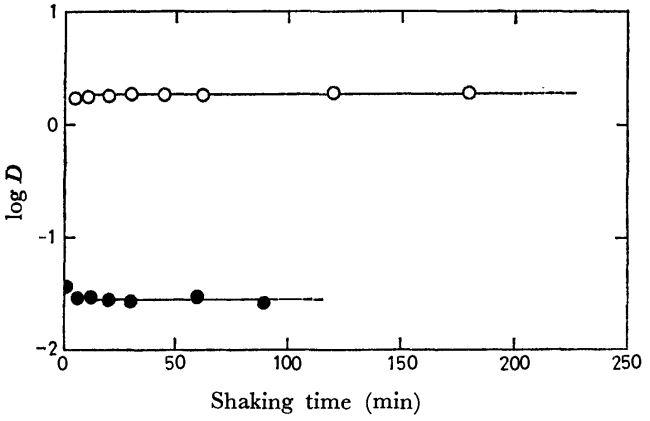

Fig. 1. The effect of shaking time on the distribution ratio in the back-extraction. ●: $[H^+]$ in the aqueous phase of 3.0 M (H, Na)ClO_4=1.5 M, $[H_2Dz]_{org}=2.5\times10^{-4}$ M. ○: $-\log [H^+]$ in the aqueous phase of 3.0 M (H, Na)ClO_4=3.5, $[H_2Dz]_{org}=3.1\times10^{-4}$ M.

(2) Effect of Acetate Buffer Solution. In the weakly acidic region ($-\log [H^+]>2$), an acetate buffer solution was employed for the adjustment of the hydrogen ion concentration in the aqueous phase. In order to study the effect of the acetate buffer on the distribution ratio, we varied the concentration of the acetate buffer from 3.0 to 0.008 M in the region of $-\log [H^+]=4-5$, where the distribution ratio is practically independent of $-\log [H^+]$. The results in the region are shown in Fig. 2. It may be seen that acetate concentrations less than 0.1 M have no effect on the distribution ratio.

(3) Dependence of the Distribution Ratio on the Antimony Concentration. Figure 3 shows the distribution ratios measured as a function of the antimony concentration in the tracer-amount region ($<10^{-8}$ M). No effect of the antimony concentration was observed for either 3.0 M perchloric acid media or a 3.0 M (H, Na)ClO_4 solution of $-\log [H^+]=4.6-4.8$. This

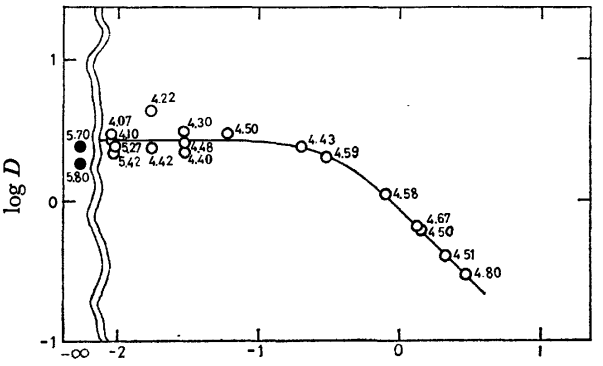

Fig. 2. The dependence of the distribution ratio on the total concentration of acetate buffer added. Each numerical value shows $-\log [H^+]$ in the aqueous phase after the equilibrium. ●: Without any acetate. The concentration of total salts was kept constant (3.0 M) by adding sodium perchlorate. $[H_2Dz]_{org}=3.0\times10^{-4}$ M.

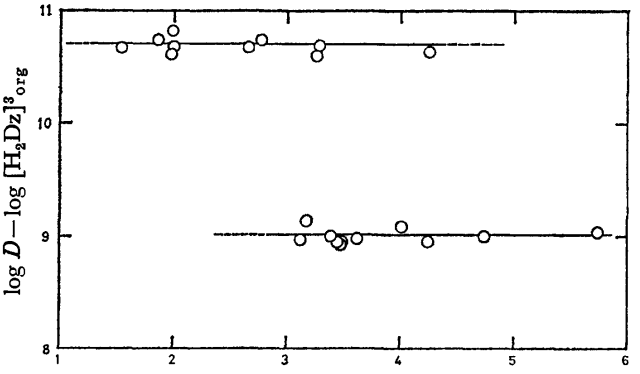

Fig. 3. The dependence of the distribution ratio on the tracer concentration of antimony(III) in the aqueous phase after the equilibrium. Upper group: $-\log [H^+]$ in the aqueous phase of 3.0 M (H, Na)-ClO_4=4.6−4.8. Lower group: Aqueous phase - - - 3.0 M $HClO_4$.

suggests that there is no difference in the polymerization number between the antimony species in the aqueous phase and those in the organic phase. Since it is improbable that any polymerized species are kept stable in both phases over such a wide range of antimony concentrations, we may safely assume that the monomers are the main species involved in the solvent extraction of tracer concentrations of antimony.

In the case of the 2×10^{-4} M antimony solution, the distribution ratio for the 0.5 M perchloric acid medium agreed well with that of the tracer amount of antimony, while a slightly higher value was obtained for the 0.06 M perchloric acid medium.

(4) Dependence of the Distribution Ratio on the Dithizone Concentration in the Organic Phase. The distribution ratio, D, was measured as a function of the dithizone concentration under various conditions. The results are shown in Figs. 4 and 5. From the figures we see that the slope of $\log D$ *versus* $\log [H_2Dz]_{org}$ is 3 in all cases, independent of the acid and antimony concentrations, where "H_2Dz" represents a neutral

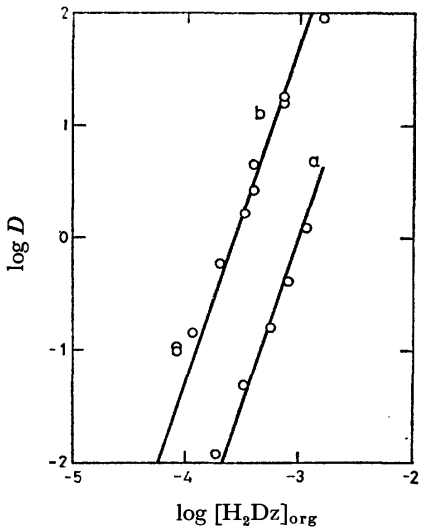

Fig. 4. The dependence of the distribution ratio on the concentration of dithizone in the organic phase. Tracer amount of antimony was used with Sb-125 as the tracer. a: Aqueous phase - - - 3.0 M $HClO_4$. b: $-\log[H^+]$ in the aqueous phase of 3.0 M (H, Na)ClO_4=4.2.

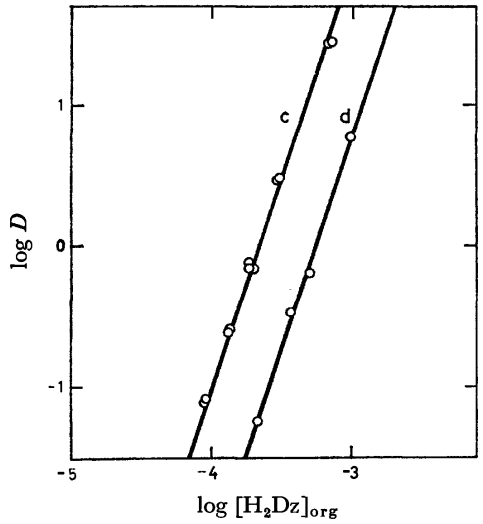

Fig. 5. The dependence of the distribution ratio on the concentration of dithizone in the organic phase. The initial concentration of antimony(III) in the aqueous phase was 2×10^{-4} M. Sb-124 was used as the tracer. c: Aqueous phase - - - 0.06 M $HClO_4$. d: Aqueous phase - - - 0.5 M $HClO_4$.

dithizone molecule.

The distribution ratio, D, is expressed as follows:

$$D=\frac{\sum_m[Sb(OH)_{3-m}(HDz)_m]_{org}}{\sum_p\sum_q[Sb(OH)_p(HDz)_q{}^{3-p-q}]}=\frac{\sum_m\{\bar{K}_m[Sb(OH)_3][H_2Dz]^m{}_{org}\}}{\sum_p\sum_q\{K_{p,q}[Sb(OH)_p{}^{3-p}][H^+]^{-q}[H_2Dz]^q{}_{org}\}},$$

where

$$\bar{K}_m=\frac{[Sb(OH)_{3-m}(HDz)_m]_{org}}{[Sb(OH)_3][H_2Dz]^m{}_{org}}$$

for this reaction:

$$Sb(OH)_3+m\cdot H_2Dz(org)=Sb(OH)_{3-m}(HDz)_m(org)+m\cdot H_2O,$$

and where

$$K_{p,q}=\frac{[Sb(OH)_p(HDz)_q{}^{3-p-q}][H^+]^q}{[Sb(OH)_p{}^{3-p}][H_2Dz]^q{}_{org}}$$

for this reaction:

$$Sb(OH)_p{}^{3-p}+q\cdot H_2Dz(org)=Sb(OH)_p(HDz)_q{}^{3-p-q}+q\cdot H^+.$$

In general, the slope of log D *versus* log $[H_2Dz]_{org}$, or that of $\partial\log D/\partial\log[H_2Dz]_{org}$, indicates the difference in the average number of monovalent dithizonate ions (HDz^-) attached to an antimony atom between the organic phase and the aqueous phase. The extracted species must be electrically neutral. It is generally accepted that the coordination number of antimony(III) is 4 or 6.[19-29] Therefore, we can reasonably assume that it does not exceed 6. Since HDz^- is a bidentate ligand, our results shown in Figs. 4 and 5 lead to the conclusion that only one kind of antimony species, *i.e.*, $Sb(HDz)_3$, exists in the organic phase without any adduct formation, and that the concentration of the Sb(III)-(HDz^-) complex species is negligibly low in the aqueous phase. Thus, D may be simplified as follows;

$$D=\frac{[Sb(HDz)_3]_{org}}{\sum_{n=0}^{6}[Sb(OH)_n{}^{3-n}]}=\frac{\bar{K}_3[Sb(OH)_3][H_2Dz]^3{}_{org}}{\sum_{n=0}^{6}[Sb(OH)_n{}^{3-n}]}$$

where

$$\bar{K}_3=\frac{[Sb(HDz)_3]_{org}}{[Sb(OH)_3][H_2Dz]^3{}_{org}}.$$

(5) Dependence of the Distribution Ratio on the Hydrogen Ion Concentration. In Fig. 6, we plot log $(D/[H_2Dz]^3{}_{org})$ for a tracer amount of antiomny as a function of $-\log[H^+]$. The slope is +1 for $-\log[H^+]<1$ and 0 for $-\log[H^+]=3-6$.

The distribution ratio of the previous section is expressed in terms of hydrolysis constants as follows:

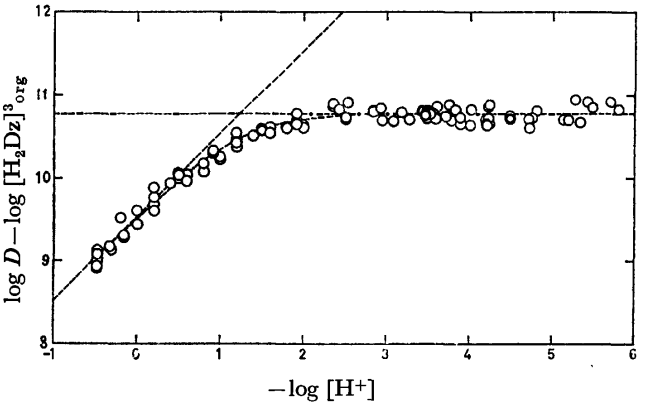

Fig. 6. The dependence of the distribution ratio on the hydrogen ion concentration. Aqueous phase - - - 3.0 M (H, Na)ClO_4. The best fitted theoretical curve based on the refined two constants is shown together with its two asymptotes.

$$D = \frac{\overline{K_3}[H_2Dz]^3_{org}}{\sum_{i=1}^{3}(K_i[H^+]^i)+1+\sum_{j=1}^{3}(K_j'[H^+]^{-j})}$$

where

$$K_i = \frac{[Sb(OH)_{3-i}^{i+}]}{[Sb(OH)_3][H^+]^i}$$

and

$$K_j' = \frac{[Sb(OH)_{3+j}^{j-}][H^+]^j}{[Sb(OH)_3]} .$$

The plot of log $(D/[H_2Dz]^3_{org})$ *versus* $-\log [H^+]$ in Fig. 6 indicates the presence of a neutral species, $Sb(OH)_3$ (or SbO(OH)), in the region of the long plateau and of a monovalent cation, $Sb(OH)_2^+$ (or SbO^+), in the acidic region where the slope is $+1$. Thus, the equation may be written in a simplified form for the present case:

$$\frac{D}{[H_2Dz]^3_{org}} = \frac{\overline{K_3}}{K_1[H^+]+1} ,$$

where

$$K_1 = \frac{[Sb(OH)_2^+]}{[Sb(OH)_3][H^+]} ;$$

(6) Estimation of the $\overline{K_3}$ and K_1 Constants. The approximate values of a set of $\overline{K_3}$ and K_1 constants were obtained by the graphical curve fitting method.[30,31]

We found:

$$\log \overline{K_3} = 10.77$$
$$\log K_1 = 1.25 .$$

These values were refined through computer work using a program based on a modified least-squares method.

The refined values are:

$$\log \overline{K_3} = 10.77_5 \pm 0.03$$
$$\log K_1 = 1.23_6 \pm 0.06 ,$$

where the uncertainties mean 3σ.

(7) Effect of Perchlorate and Chloride Ions. From Fig. 7, we can see that the distribution ratios at 0.1 M (H, Na)ClO_4 do not differ from those at 3.0 M (H, Na)ClO_4 over the range of $-\log [H^+]=1-4$. It can safely be said that perchlorate ions do not form any complex compounds with antimony(III), as is generally believed.

As for chloride ions, very little effect is seen in the region where $-\log [H^+]$ is nearly 4.5 (Fig. 8), while the effect is remarkable in the acidic media, as is shown in Fig. 9. Our preliminary experiment showed that the extraction behavior of the Sb(III)-Cl^-–H_2Dz system is very complicated and needs to be carefully studied. The details of this kind of investigation will be reported in a separate paper.

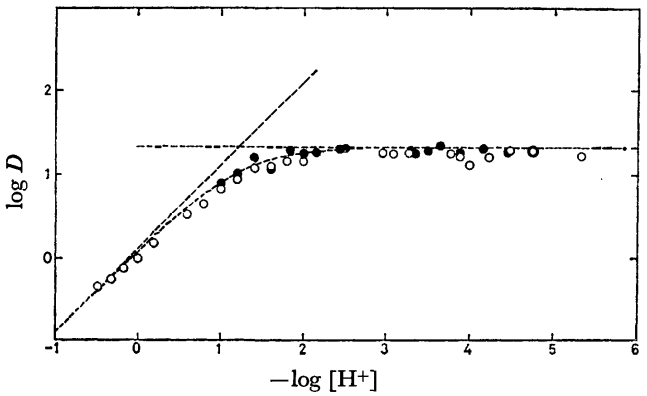

Fig. 7. The influence of the concentration of (H, Na)-ClO_4 media on the distribution ratio. ●: 0.1 M (H, Na)ClO_4. ○: 3.0 M (H, Na)ClO_4. $[H_2Dz]_{org}$ $=7.1\times10^{-4}$ M. The best fitted theoretical curve for all the data involving those other than presented here is shown together with its two asymptotes.

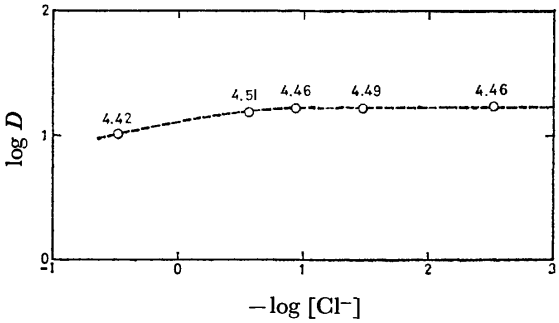

Fig. 8. The dependence of the distribution ratio on the concentration of the chloride ion. $[H_2Dz]_{org}=$ 7.1×10^{-4} M. The numerical data show $-\log [H^+]$ in the aqueous phase of 3.0 M (H, Na)(Cl, ClO_4).

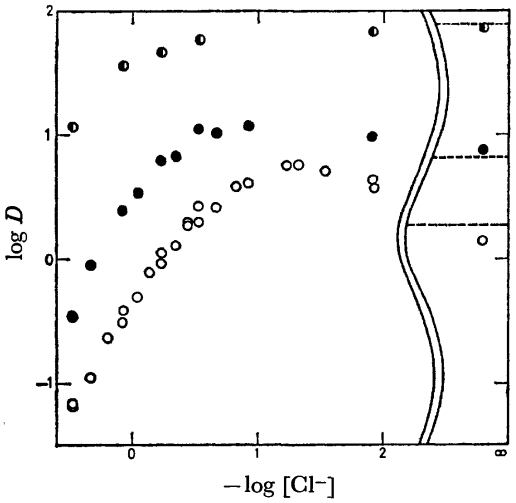

Fig. 9. The dependence of the distribution ratio on the concentration of the chloride ion. $[H_2Dz]_{org}=$ 1.16×10^{-3} M. At the right side, the experimental points (as circles) and the calculated values using the refined constants (as broken lines) are also shown on the case without the chloride ion.

Discussion

In acidic and neutral aqueous solutions, a tracer concentration of antimony(III) was found to be present as a monovalent cation and a neutral species of mono-nuclear antimony. The former is predominant in acidic solutions, while the latter is abundant in the

weakly acidic and neutral regions. These results agree with the observations by Schuhmann,[1] Gayer *et al.*,[4] Faucherre,[5] Pitman *et al.*,[6] and Mishra *et al.*,[11] who studied the solubility of macro amounts of antimony(III) oxide, the equilibrium potential of antimony metal–water system, or spectrometry.

The divalent and trivalent cation of antimony(III) could not be detected in the present investigation. The hydrolysis constants given by Kasper from his solubility measurements suggest the existence of the divalent cation in the acidic region.[3] Jander and Hartmann describe the possibility of the coexistence of a small amount of the trivalent cation and the predominant monovalent one in the perchloric acid solution judging from the results of their high-voltage ionophoresis and diffusion studies.[9] Dawson *et al.* have also reported the existence of the trivalent cation together with the monovalent one in perchloric acid media on the basis of a solvent-extraction study using phenylfluorone.[10] Our present results did not confirm these observations.

The value of the hydrolysis constant, K_1, obtained in the present investigation ($\log K_1 = 1.23_6 \pm 0.06$) falls in the range of three published data: 1.59,[4] 1.42,[11] and 0.87.[6] Kasper's value ($\log K_1 = 11.8$) seems to be too large.[3]

No evidence of the existence of polymerized species was found in the aqueous media investigated for the concentrations of antimony(III) below 10^{-8} M. According to Jander and Hartmann, no soluble, polymerized species were observed in the solution from 16 M sodium hydroxide to 11 M perchloric acid for the antimony concentrations of 10^{-6}—10^{-5} M in the acidic, 0.4×10^{-6} M in the neutral, and 10^{-6}—10^{-3} M in the alkaline region.[9] Dawson *et al.* report that the polymerization of antimony(III) ions occurs in 0.4—4 M perchloric acid solutions with antimony concentrations greater than 1×10^{-4} M.[10] For the alkaline solution of antimony(III), Jander and Hartmann report the existence of only one species, very likely a hydrated monomer SbO_2^-, in a sodium hydroxide solution with a 10^{-6}—10^{-3} M antimony concentration (up to 9 M sodium hydroxide),[9] while Scholder and Merbeth describe a polymerized species, $Sb_6O_{10}^{2-}$, in a 2.5—8.3 M sodium hydroxide solution with a 10^{-2}—10^{-1} M antimony concentration, $Sb_4O_7^{2-}$ in a 8.3—16.1 M sodium hydroxide solution with a 10^{-1} M order of antimony, and SbO_2^- in a strongly alkaline solution with a 10^{-1} M order of antimony.[8] Meites and Schlossel report that antimony(III) ions exist in the forms of $Sb(OH)_4^-$ and $Sb_2O(OH)_4$ in a $(1-5)\times10^{-1}$ M sodium hydroxide solution of 2×10^{-5}—1×10^{-2} M antimony.[12]

Using the data of the present work and the literature,[32-40] we can compare the monomeric chemical species in aqueous media in the absence of special complexing anions among the ions with the oxidation number of +3 of nitrogen-group elements. The comparison is shown in Fig. 10. A similar comparison is made, in Fig. 11, between antimony(III) and antimony(V), using the constants from this work and the literature.[6,41] From these figures we see a regularity on hydrolysis as a function of the charge density.

It may be noted that the distribution ratio for the Sb(III)–H_2Dz system is independent of the total ion

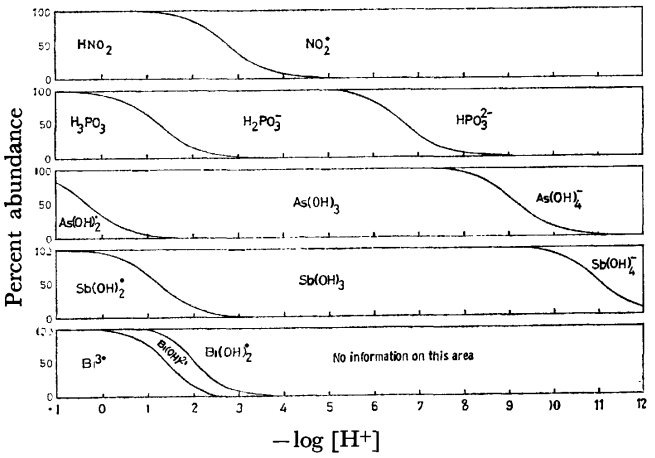

Fig. 10. Variation of the monomeric chemical species of the trivalent ion of the nitrogen group with the change of $-\log[H^+]$ value in the aqueous solution without any special complexing ligands.

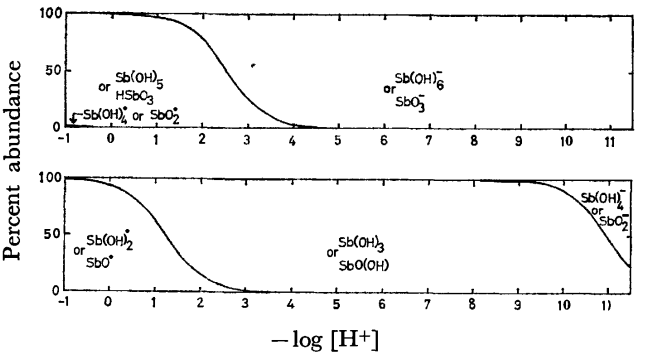

Fig. 11. The chemical species of the antimony(V) and antimony(III) ion in the aqueous solution without any special complexing ligands. Upper: Antimony(V). Lower: Antimony(III).

concentration, as is shown in Fig. 7. Sekine reports the presence of some effect in the case of the Zn-Amberlite LA-1 system.[42] Our results indicate that the number of hydrating water molecules is the same in both phases, or that the change in the water concentration is compensated for by the change in the activity coefficients of the chemical species involved.

In conclusion, it was found that antimony is one of the so-called dithizone metals[43] whose dithizonate has a stoichiometric composition of $Sb(HDz)_3$. The formation constant and one of the hydrolysis constants were obtained.

The authors are very grateful to Professor Tatsuya Sekine of the Science University of Tokyo for his valuable suggestions, especially with regard to the potentiometric measurements. The authors are also thankful to Professor Nagao Ikeda of Tokyo Kyoiku University for his kind support of this work. The authors wish to express their thanks to Professor Yukiyoshi Sasaki for his helpful suggestions, to Dr. Isao Okada for his valuable discussions, and to Dr. Shizu Tonomura and her colleagues in the Institute of Physical and Chemical Research for the absorptiometric measurements.

Calculations were carried out on the HITAC 5020

computer at the Computation Center of the University of Tokyo.

Intramolecular Hydrogen Bonding and Conformations of α,α-Dialkyl- and α-Alkyl-o-methoxybenzyl Alcohols

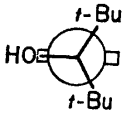
Akihiko YAMASHITA, Katsuo HARA, Shigeko AIZAWA, and Minoru HIROTA*

Department of Applied Chemistry, Faculty of Engineering, Yokohama National University, Minami-ku, Yokohama 233

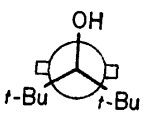
(Received January 18, 1974)

The stable conformations of α-alkyl- and α,α-dialkyl-o-methoxybenzyl alcohols were deduced by measurement of their infrared and PMR spectra. Population of these conformations was estimated from the intensities of the O-H stretching bands of the free and the hydrogen-bonded species. The O-H chemical shifts at infinite dilution (δ^{∞}_{OH}) of the free and the hydrogen-bonded species were determined by plotting the δ^{∞}_{OH} values against population obtained from the infrared spectra. An anomalous behavior was observed with the α-alkyl-α-*t*-butyl alcohols, which might be due to a buttressing effect.

α,α-Di-*t*-butylbenzyl alcohol consists of a highly overcrowded molecule in which the rotation of the di-*t*-butylhydroxymethyl group around the $C_{sp^3}-C_{sp^2}$ bond is so slow as to make it possible to observe the hydrogen atoms of the 2 and 6 positions of the aromatic nucleus separately by PMR measurement.[1,2] This suggests that conformer I or a similar one predominates over conformer II.



(I)



(II)

In relation to studies on the accelerating effect of the methoxy group upon the Grignard reaction between *o*-methoxyphenylmagnesium bromide and crowded ketones,[3] the conformations of the α,α-dialkyl-*o*-methoxybenzyl alcohols obtained were investigated by means of infrared and PMR spectroscopic measurements.

The two bulky *t*-butyl groups are expected to force the hydroxyl group nearer to the oxygen atom of the methoxy group than those of the unhindered dialkyl- and monoalkyl-benzyl alcohols in conformation I, causing a larger hydrogen bond shift of the O–H stretching absorption and a low field shift of the O-H proton signal.

Experimental

Preparation of Materials. All the α,α-dialkyl- and α-monoalkyl-benzyl alcohols were prepared by the addition of *o*-methoxyphenylmagnesium bromide to the corresponding ketones in tetrahydrofuran under nitrogen atmosphere. Some of the alcohols are new compounds and identified by elementary analyses, infrared and PMR spectra. The physical constants and the results of elementary analysis are given in Table 1.

Results and Discussion

The O-H stretching frequencies and molar absorptivities of α,α-dialkyl-*o*-methoxybenzyl alcohols[4] are given in Table 2, together with those of the monoalkyl substituted ones. A typical spectrum is illustrated in Fig. 1.

* To whom correspondences should be addressed.

The strength of the O-H···O hydrogen bond in these alcohols can be evaluated from the hydrogen bond shift $\Delta\nu$. The $\Delta\nu$ values are correlated with the length of hydrogen bond H···O by the following equation in which d is the H···O distance in cm.[5]

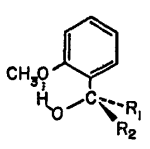
a) Molar absorptivity in $l \cdot mol^{-1} \cdot cm^{-1}$.

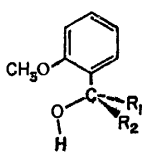
$$\Delta\nu = \frac{250 \times 10^{-8}}{d} - 74$$

The larger $\Delta\nu$ value indicates that the stronger hydrogen bond exists in the methoxy-alcohol. Except for the case of *t*-butyl substituted ones, the $\Delta\nu$ value increases with the increase in the bulkiness of the alkyl group, indicating that the hydrogen bond is stronger when the α-alkyl groups are bulkier.** However, the population of hydrogen-bonded species is not proportional to the bulkiness of the substituent.

The free O–H bands of the tertiary alcohols of this class generally lie near 3620 cm^{-1}, and the O–H bands arising from the O–H···π hydrogen-bonded forms are located near 3600 cm^{-1}.[6,7] Thus, the higher frequency band might be assigned to the free hydroxyl group and the lower frequency one to the O–H···O hydrogen-bonded hydroxyl group, at least with the *o*-methoxybenzyl alcohols without *t*-butyl substituent at the α-position. No absorption band due to O–H···π interaction could be detected. The O–H···π hydrogen-bonded conformation might be rather unfavorable. This conclusion is apparently contrary to the findings on benzyl alcohols without *o*-methoxy substituent.[6,7] However, it can be rationalized in the following way. α,α-Dialkyl-*o*-methoxybenzyl alcohols exist as the equilibrium mixture of the hydrogen-bonded and the free O–O *syn-periplanar* conformer represented by III and IV, respectively. Thus, the II′ conformation of the

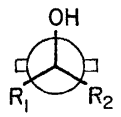


(III)

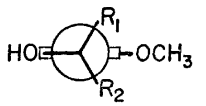


(IV)

o-methoxy-alcohols is by far less stable than the corresponding conformation of the parent benzyl alcohols due to the steric repulsion between the α-alkyl (R_1 in II′) and the *o*-methoxy groups. Thus, its contribution to the conformational equilibrium is not predominant. It is not certain whether IV or IV′ conformation gives rise to the free O–H absorption. However, the O–O *syn-periplanar* conformation IV seems somewhat less crowded when both of two substituents (R_1 and R_2) are alkyl groups. This is true especially when the alkyl groups are isopropyl and *t*-butyl.

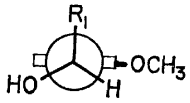


(II′)



(IV′)

In the alcohols of α-monoalkyl series (Compounds 1—4), the proportion of the hydrogen-bonded species is lower even when the alkyl group is *t*-butyl. In these molecules, the H_α-OCH_3 *syn-periplanar* conformation V might be a stable conformation, since the benzyl hydrogen atom is much less bulkier than the alkyl substituent in the dialkyl series. This conformation would have a free O–H stretching absorption, if the bulkiest alkyl group occupies a position nearly perpendicular to the aromatic nucleus as shown in V.



(V)

If we assume that the O–H chemical shift at infinite dilution δ^{∞}_{OH} is not affected by the nature of the alkyl substituent, the observed chemical shift (δ^{∞}_{OH}) should be linear with respect to the percentage of the hydrogen-bonded species. Hence, the chemical shift (δ^{∞}_{OH}) of the O–H···O hydrogen-bonded species and the free species might be obtained by extrapolating the observed δ^{∞}_{OH} *vs.* percentage plot. The O–H chemical

** The hydrogen-bonded O–H frequencies of the *t*-butyl substituted derivatives are lower than those of the other alcohols investigated, but the $\Delta\nu$ values are smaller because of their lower free O–H frequencies.

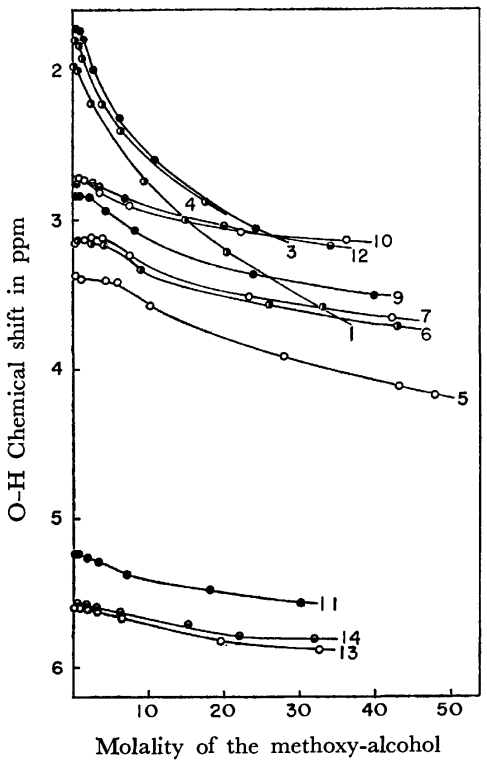


Fig. 2. The concentration dependence of the O-H chemical shifts of the *o*-methoxybenzyl alcohols.

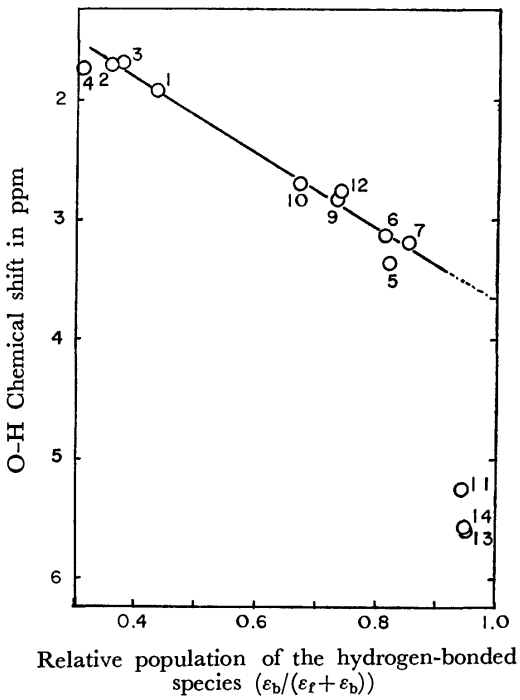

Fig. 3. The O-H chemical shift (δ^{∞}_{OH}) *vs.* the population of the hydrogen-bonded species $(\varepsilon_b/(\varepsilon_f+\varepsilon_b))$ plot.

values for the methoxy-benzyl alcohols were obtained from the O–H chemical shift *vs.* molality plot (Fig. 2) by extrapolating the δ^{∞}_{OH} values to zero concentrations. The δ^{∞}_{OH} values should be weighted mean values of the δ^{∞}_{OH}'s of the free and the intramolecularly hydrogen-bonded species of the alcohols. The proportion of the hydrogen-bonded species in these methoxy-alcohols, in turn, was estimated from the infrared spectral data. Thus, the intensity ratio $\varepsilon_b/(\varepsilon_f+\varepsilon_b)$ is taken as a measure for the proportion of the hydrogen-bonded species. Strictly speaking, the integrated intensities for the free and the hydrogen-bonded species should be estimated first, and the proportion should be derived with these values. However, the total molar absorptivity $(\varepsilon_f+\varepsilon_b)$ is constant through the series of alcohols without *t*-butyl group. Thus, the ratio $\varepsilon_b/(\varepsilon_f+\varepsilon_b)$ might be a suitable measure for the abundance of the intramolecularly hydrogen-bonded species. The plot δ^{∞}_{OH} *vs.* $\varepsilon_b/(\varepsilon_f+\varepsilon_b)$ is illustrated in Fig. 3 for the alcohols given in Table 2. Because of the broadening of the O–H signal in PMR spectra at lower concentrations, the δ^{∞}_{OH} value for α-methyl-α-*t*-butyl-*o*-methoxybenzyl alcohol could not be determined. The extrapolation gives the δ^{∞}_{OH} values for the free and the hydrogen-bonded species to be 0.63 ppm and 3.67 ppm, respectively. The δ^{∞}_{OH} value for the free form is lower than those reported by Ōki and Iwamura[8] for benzyl alcohols. The lower δ^{∞}_{OH} value can be interpreted by conformation IV in which the hydroxyl proton lies in the plane of the aromatic nucleus, opposite to the methoxy oxygen atom.

The plots of the alkyl-*t*-butyl alcohols (11, 13 and 14 in Fig. 3) deviate to the lower fields in the δ_{OH} scale from the line obtained by the mean square calculation excluding the plots of the *t*-butyl derivatives. The anomalous behavior of the *t*-butyl derivatives can be attributed to the buttressing effect which bends the aromatic carbon-benzyl carbon bond towards the methoxy group and forces the hydroxyl and methoxy oxygen atoms to approach closer than normal. Lowering of the free O–H frequencies in the *t*-butyl derivatives was not observed with α,α-di-*t*-butylbenzyl alcohol, and is peculiar to *o*-methoxybenzyl alcohols. The O–H···π interaction would not appear to be persistent in these alcohols carrying bulky alkyl groups. The lower O–H frequencies in overcrowded molecules have been observed in several cases.[9,10] Anet and Bavin[9] reported a similar frequency shift with some alcohols. However, the reason for it remains still unclarified.

The authors are grateful to Prof. M. Ōki, the University of Tokyo, for his valuable advice.

Reactions of Organoboranes with Ferric Chloride and Thiocyanate. Convenient Syntheses of Alkyl Chlorides and Thiocyanates from Olefins *via* Hydroboration

Akira ARASE, Yuzuru MASUDA, and Akira SUZUKI*

Kitami Institute of Technology, Kitami, Hokkaido 090

**Department of Applied Chemistry, Faculty of Engineering, Hokkaido University, Sapporo 060*

(Received March 13, 1974)

The reactions of trialkylboranes with ferric chloride and thiocyanate in an aqueous tetrahydrofuran solution give the corresponding alkyl chlorides and thiocyanates in good yields. It was found that two equivalents of ferric salts per alkyl group of organoborane are required, and not only the first alkyl group of trialkylborane but other alkyl groups are also used.

Many reports have appeared on new applications of organoboranes to the synthesis of various organic compounds.[1] Alkyl halide synthesis has also been reported. For example, the reaction of organoboranes with *N*-chlorodialkylamines gives the corresponding alkyl chlorides in 30—53% yields based on trialkylboranes.[2]

It was shown that concurrent polar and radical processes occur to give amine and alkyl chlorides, respectively, as follows.[3]

$$R_3B + R_2NCl \begin{cases} \xrightarrow{\text{polar}} RNR_2 + R_2BCl \\ \xrightarrow{\text{radical}} RCl + R_2BNR_2 \end{cases} \quad (1)$$

However, this reaction is unsuitable for efficient preparation of alkyl chlorides, since the four products are formed in approximately equal yields.

On the other hand, alkyl bromides and iodides are produced readily *via* organoboranes. For instance, the reaction of organoboranes with bromine in dichloromethane gives the corresponding alkyl bromides in yields exceeding 80% based on R_3B.[4,5] Treatment of trialkylboranes with bromine in the presence of sodium methoxide also gives the corresponding alkyl bromides in excellent yields,[6] the three alkyl groups in trialkylborane being almost consumed by the reaction.

Organoboranes similarly react with iodine in the presence of base to produce alkyl iodides in relatively good yields.[7] Alkyl iodides are synthesized by the reaction of organoboranes with allylic or benzylic iodides in tetrahydrofuran in the presence of air.[8]

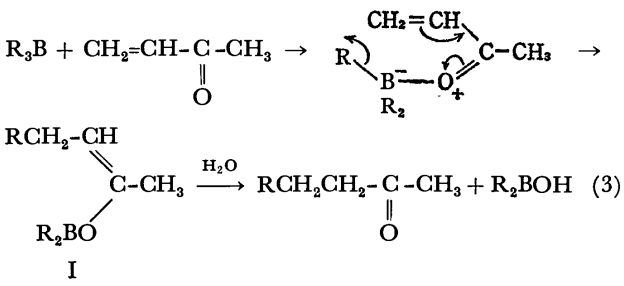
Lane reported an interesting synthetic procedure for alkyl chlorides and bromides by the reaction between trialkylboranes and cupric halides in 43—92% yields based upon R_3B:[9]

$$R_3B + 2CuX_2 \rightarrow RX + R_2BOH + Cu_2X_2 + HX \quad (2)$$
$$(X=Br, Cl)$$

During the course of studies on oxygen-induced addition reactions of organoboranes with α,β-unsaturated carbonyl compound,[10] it was found that the above reactions are enhanced in the presence of the Fenton reagent (hydrogen peroxide–ferrous sulfate),[11] and that when ferrous chloride is used instead of sulfate in the Fenton reagent, alkyl chlorides are obtained in high yield from the corresponding organoboranes.[12] We wish to report herewith our results, since they differ from and have certain advantages over those given by Lane.[9]

Results and Discussion

Reaction of Trialkylboranes with Fenton Reagent (Ferrous Chloride–Hydrogen Peroxide). It was reported that organoboranes react smoothly with methyl vinyl ketone through a co-ordination process.[10a]



I

In the absence of water or other protonolyzing species, the reaction product seemed to be enol borinate (I). Actually, such an intermediate was found to be readily isolated by distillation under reduced pressure.[13] Intermediate (I) was rapidly hydrolyzed to ketone by addition of water. However, the mechanism (Eq. 3) was later revised and it was reported that the reaction should proceed through a radical-chain mechanism.[10] Brown and Kabalka[14] confirmed that oxygen acts as a powerful radical initiator.

In connection with this work, we examined the reactions with α,β-unsaturated ketones in the presence of hydrogen peroxide–iron salt (Fenton reagent), since the reagent is known to form hydroxy radicals and could be considered to act as a radical initiator. Tricyclohexylborane was treated with crotonaldehyde in aqueous tetrahydrofuran in the presence of hydrogen peroxide–ferrous chloride at 40 °C. The reaction mixture was analyzed by glpc. It was found that the expected 4-methyl-4-cyclohexylbutyraldehyde was obtained in 91% yield, based on the organoborane, in addition to which cyclohexyl chloride was also produced in 70% yield.[12] We have attempted to find the synthetic procedure of alkyl chlorides. The results of representative reactions are summarized in Table 1.

It was found that more than one single alkyl group in trialkylborane seem to be involved in this reaction, contrary to general aspects of the organoborane reaction, in which only one alkyl group is used as the alkyl source.

Reaction of Trialkylboranes with Ferric Chloride. In

Table 1. Reaction[a] of trialkylboranes with ferrous chloride-hydrogen peroxide

R_3B from olefin	Reaction time, hr	Product	Yield,[b] %
1-Hexene	48	1-Chlorohexane	168[c] (153)[d]
		2-Chlorohexane	15[c] (9)[d]
Cyclohexene	24	Chlorocyclohexane	183[c] (156)[d]
Cyclooctene	48	Chlorocyclooctane	180[c]

a) Carried out at 55 °C by using R_3B (8 mmol), $FeCl_2$ (48 mmol) and H_2O_2 (48 mmol). b) Based on the trialkylborane, R_3B used. c) Determined by glpc. d) Isolated by distillation.

Table 2. Reaction[a] of trialkylboranes with ferric chloride

R_3B from olefin	Reaction time, hr	Product	Yield,[b] %
1-Pentene	24	1-Chloropentane	177[c] (144)[d]

the reaction of organoboranes with ferrous chloride-hydrogen peroxide, color change was observed. The brown color due to ferric ion gradually turned pale yellowish green, suggesting the reduction of Fe^{3+} ion to Fe^{2+} ion. Thus we examined the direct reaction between trialkylboranes and ferric chloride. The reaction proceeded smoothly. The results are given in Table 2. In the case of tricyclohexylborane, cyclohexyl chloride was obtained in a 219% yield based on tricyclohexylborane, indicating that not only the first and second alkyl groups in R_3B but also a part of the third alkyl group takes part in the reaction.

Table 4. Stoichiometric study of the reaction[a] of tricyclohexylborane with ferric chloride

$FeCl_3$, mmol	Product	Yield,[b] mmol (%)[c]
2.0	0.9	(11)
4.0	1.9	(24)
8.0	3.9	(49)
16.0	7.4	(93)
48.0	17.4	(219)

a) Carried out at 55 °C for 48 hr by using 8 mmol of tricyclohexylborane. b) Determined by glpc. c) Based on tricyclohexylborane.

Reaction of Trialkylboranes with Other Metal Halides. Other metal halides, including manganese chloride, cobalt chloride, cuprous chloride, cupric chloride, stannic chloride, mercuric chloride, ferrous bromide, cuprous bromide and cupric bromide, were examined as regards their activities in the reactions. Cuprous chloride-hydrogen peroxide, cupric chloride, cuprous bromide-hydrogen peroxide and cupric bromide were found to be powerful reactants. The results of the reactions of typical organoboranes with cupric chloride and bromide are summarized in Table 3.

Stoichiometric Study on the Reaction of Tricyclohexylborane with Ferric Chloride. In order to clarify stoichiometry in the reaction, we carried out reactions using tricyclohexylborane with various amounts of ferric chloride. The results are given in Table 4. We see that the use of two equivalents of ferric chloride for each equivalent of tricyclohexylboranes gave rise to an almost quantitative conversion of a single alkyl group into cyclohexyl chloride. Consequently, the reaction is considered to obey stoichiometry (Eq. 4), as pointed out by Lane[9] and Ainley and Challenger.[15] It was also observed that the use of 48 mmol of ferric chloride for 8 mmol of tricyclohexylborane gives 17.4 mmol of the product. Lane reported that a single alkyl group of a trialkylborane is converted into the corresponding alkyl halide in a reasonable length of time. However, our results demonstrate that not only the first alkyl group of the organoborane but also the second and third cyclohexyl groups react with ferric chloride (Eq. 5)

$$R_3B + 2FeCl_3 + H_2O \longrightarrow RCl + R_2BOH + 2FeCl_2 + HCl \quad (4)$$

$$R_3B + 6FeCl_3 + 3H_2O \longrightarrow 3RCl + B(OH)_3 + 6FeCl_2 + 3HCl \quad (5)$$

No mechanistic investigation was carried out for the reaction. However, the mechanism through an alkyl radical from organoborane by an electron transfer reduction of metal salts, proposed by Lane,[9] is apparently reasonable.

Reaction of Trialkylboranes with Ferric Thiocyanate. We attempted to extend the reaction to synthesize alkyl thiocyanates by using metal thiocyanates, instead of metal halides. Although potassium and cupric thiocyanates did not react smoothly with such trialkylboranes, the reaction with ferric thiocyanate gave the

corresponding alkyl thiocyanates in good yields. When a mixture of ferric ammonium sulfate (6 equiv. to each organoborane) and potassium thiocyanate (18 equiv.) in water was gradually added to a solution of tricyclohexylborane in tetrahydrofuran and refluxed for 24 hr, formation of a mixture of cyclohexyl thiocyanate and cyclohexyl isothiocyanate was shown by glpc in yields of 200% and 15%, respectively, based on R_3B. Representative results of the reaction are summarized in Table 5. In the preparative scale experiments 4, 7 and 9, the products were readily separated by extraction with petroleum ether, followed by distillation.

Experimental

Materials. Commercial 1-pentene, 1-hexene, 1-octene, cyclohexene and cyclooctene were dried over Molecular Sieve-5A, and 30%-hydrogen peroxide, metal halides and thiocyanates(Wako Chemical Co.) were used. Ferrous chloride was used after analysis by the usual *o*-phenanthroline method.

Reaction between Trialkylboranes and Metal Halides. The following procedure for the preparation of cyclohexyl chloride is representative. A dry 50-ml flask equipped with a magnetic stirring bar, septum inlet and reflux condenser was flushed with nitrogen. The flask was charged under nitrogen with 8 mmol of tricyclohexylborane in 5 ml of dry THF and 48 mmol of ferric chloride in 10 ml of water. The reaction mixture was stirred at 55 °C for 48 hr. After the completion of the reaction, the lower aqueous layer was separated and extracted with ether. The combined upper layer and extracts were washed with saturated aqueous sodium chloride solution, and finally analyzed by glpc, demonstrating that cyclohexyl chloride was obtained in a yield of 219% based on tricyclohexylborane.

All the products were confirmed either by comparison with authentic samples or examination of analytical and spectral data in accordance with assigned structures.

Reaction of Trialkylboranes with Ferric Thiocyanate. The following procedure is representative. A 100-ml flask, fitted with the same equipment as mentioned above, was charged with 8.5 mmol of the tri-2-butylborane obtained by hydroboration of 2-butene with diborane. To the solution was slowly added 8 ml (51 mmol) of aqueous solution of ferric ammonium sulfate and 40 ml (153 mmol) of aqueous solution of potassium thiocyanate. The mixture was refluxed at 55 °C for 24 hr under stirring. After cooling, the reaction mixture was extracted with petroleum ether several times. The combined extracts were washed with water and dried over anhydrous magnesium sulfate, and then distilled at 93 °C under 66 mmHg. Thus, 17.0 mmol (200%) of 2-butyl thiocyanate were obtained in a pure state. All the products were identified by direct comparison with authentic samples.

Preparation of 1,7-Disubstituted Indan Derivatives and Their Application to the Synthesis of Tricyclic Heterocyclic Compounds

Kazuo SAKANE, Shinichi ODA, Eiichi HARUKI, Yoshio OTSUJI, and Eiji IMOTO

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai-shi, Osaka 591

(Received March 22, 1974)

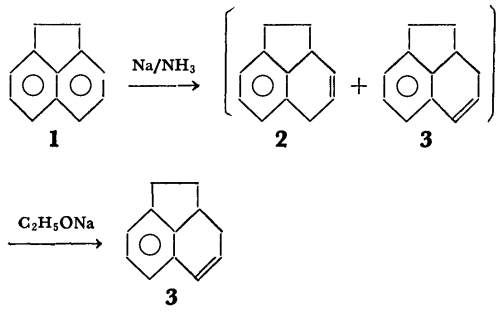
The Birch reduction of acenaphthene (**1**) followed by treatment of the reduction product with sodium ethoxide gave 2a,3-dihydroacenaphthene (**3**). The oxidation of **3** with hydrogen peroxide gave 2a,3,4,5-tetrahydroacenaphthene-4,5-diol (**5**). Further oxidation of **5** afforded various 1,7-disubstituted indan derivatives including 7-carboxyindan-1-acetic acid (**7**). Two tricyclic *N*-heterocyclic compounds, 3,3a-dihydrocyclopent[*de*]quinolin-2(1*H*)-one (**13**) and 3,3a-dihydrocyclopent[*de*]isoquinolin-1(2*H*)-one (**17**), were synthesized from **7**.

1,7-Disubstituted indan derivatives might be useful synthetic intermediates, since they can be converted into compounds of various structures. Rapoport and Pasky[1] synthesized the fused tricyclic compounds containing one six- and two five-membered rings, utilizing 1,7-disubstituted indan derivatives as key intermediates. However, their method of preparation involved a lengthy route starting from indene.

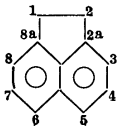
In this paper, we describe an alternative method for the preparation of 1,7-disubstituted indan derivatives and their application to the synthesis of tricyclic *N*-heterocycles, very rare type of compounds. Our method involves the Birch reduction of acenaphthene and an oxidative cleavage of the reduction product as key steps.

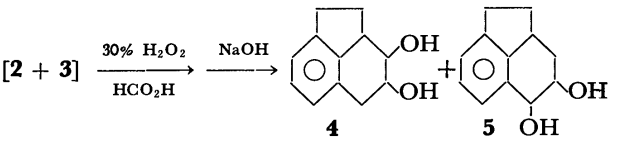
Results and Discussion

Preparation of 1,7-Disubstituted Indan Derivatives. The reduction of acenaphthene (**1**)* with calcium hexammine in ether and with a large excess of sodium in liquid ammonia gave 2a,3,4,5-tetrahydroacenaphthene.[2,3] However, we found that the Birch reduction of **1** by use of 2.3—2.4 molar equivalents of sodium in liquid ammonia afforded a mixture of 2a,5-dihydro- and 2a,3-dihydroacenaphthene (**2** and **3**) in a 90% yield. Treatment of the mixture with sodium ethoxide in ethanol gave **3** practically in a pure state. That the product obtained by the Birch reduction of **1** consists of a mixture of **2** and **3** is suggested from the fact that treatment of the reduction product with

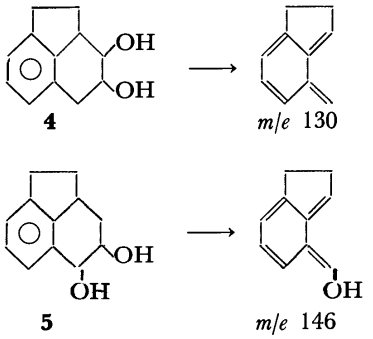


* The numbering system used for acenaphthene (**1**) is shown in the formula.

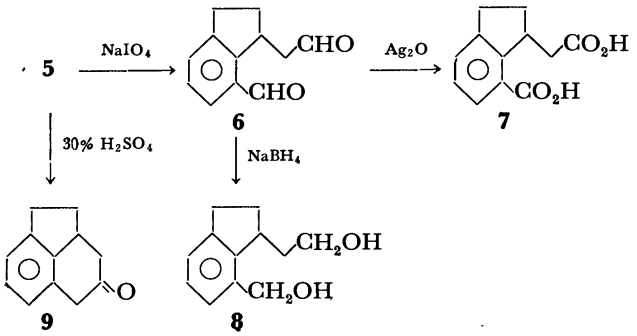




hydrogen peroxide in formic acid followed by hydrolysis gave a mixture of 2a,3,4,5-tetrahydroacenaphthene-3,4-diol (**4**) and 2a,3,4,5-tetrahydroacenaphthene-4,5-diol (**5**) which were separated by repeated recrystallization. The hydrogen peroxide oxidation of a pure sample of **3** afforded **5** in a 70% yield. The structures of **4** and **5** were confirmed by the fragmentation patterns in their mass spectra, which show the base peaks at *m/e* 130 and 146, respectively. These ions could be formed by the retro-Diels-Alder cleavage of the compounds, corresponding respectively to the loss of $C_2H_4O_2$ and C_2H_4O fragments.

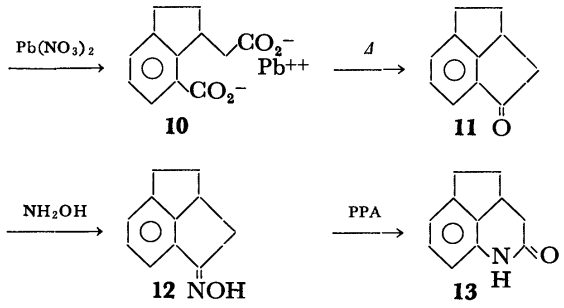


The oxidation of **5** with sodium metaperiodate in an aqueous ethanol gave 7-formylindan-1-acetaldehyde (**6**) in an 86% yield. The IR spectrum (film) of **6** showed carbonyl absorptions at 1690 and 1720 cm^{-1}. Its NMR spectrum (CCl_4) showed a multiplet at δ 9.9 due to an aliphatic aldehyde proton and a singlet at δ 10.2 due to an aromatic aldehyde proton. Treatment



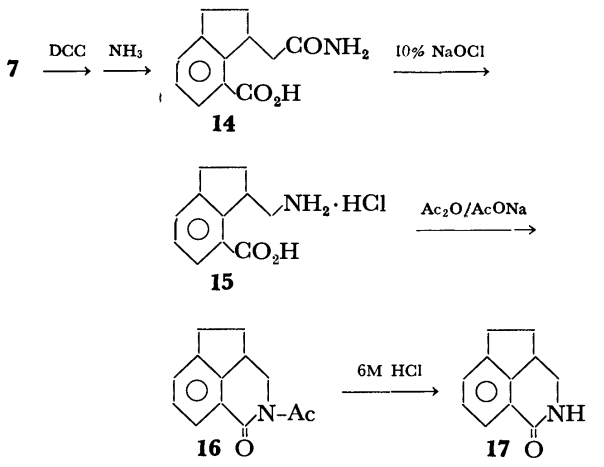
of **6** with silver oxide gave 7-carboxyindan-1-acetic acid (**7**) in an 88% yield. The dicarboxylic acid **7** has been synthesized starting from indene.[1] The reduction of **6** with sodium borohydride gave 1-(2-hydroxyethyl)-7-hydroxymethylindan (**8**) in a 78% yield. When **5** was refluxed in 30% sulfuric acid, 2a, 3,4,5-tetrahydroacenaphthen-4-one (**9**) was obtained in a 58% yield. IR spectrum (KBr) of **9** showed a carbonyl absorption at 1710 cm^{-1} and its NMR spectrum a singlet at δ 3.38 attributable to two methylene protons at C-5.

Synthesis of Heterocyclic Compounds. By the method of Rapoport and Pasky,[1] **7** was converted into 2,2a-dihydro-1-oxo-1H-cyclopent[*cd*]indene (**11**) *via* the lead salt (**10**). The transformation of **11** to its oxime **12**, followed by treatment with polyphosphoric acid



(PPA) afforded 3,3a-dihydrocyclopent[*de*]quinolin-2(1*H*)-one (**13**) in a 28% yield. The IR spectrum (KBr) of **13** showed absorptions at 3200, 1690 and 1630 cm^{-1} due to the amide group. The heterocyclic compound **13** was synthesized by Fuson and Veazey[4] from β-(*o*-nitrophenyl)glutaric acid. The melting point of **13** we obtained was in good agreement with theirs.[4]

We attempted to synthesize 3,3a-dihydrocyclopent-[*de*]isoquinolin-1(2*H*)-one (**17**), a structural isomer of **13**.



Treatment of **7** with *N,N'*-dicyclohexylcarbodiimide (DCC) followed by the addition of concentrated aqueous ammonia gave 7-carboxyindan-1-acetamide (**14**) in a 70% yield. The Hofmann rearrangement of **14** was carried out by use of sodium hypochlorite in an aqueous sodium hydroxide. Acidification of the rearranged product gave 7-carboxyindan-1-methylamine hydrochloride (**15**) which could not be purified. Treatment of the crude **15** with acetic anhydride containing sodium acetate afforded 2-acetyl-3,3a-dihydrocyclopent[*de*]isoquinolin-1(2*H*)-one (**16**) in a good yield. The IR spectrum (KBr) of **16** showed an amidecarbonyl absorption at 1690 cm^{-1} and no absorptions due to NH group, its NMR spectrum (CCl_4) a sharp singlet at δ 2.47 due to three methyl protons of the acetyl group, and its mass spectrum the parent peak at *m/e* 215. Hydrolysis of **16** with 6M hydrochloric acid gave a mixture of **17** (37%) and **15** (32%). The IR spectrum (KBr) of **17** showed absorptions characteristic of the amide group at 3200, 1670 and 1590 cm^{-1}, and its mass spectrum the parent peak at *m/e* 173.

Experimental

Birch Reduction of Acenaphthene (1). A solution of 40 g (0.26 mol) of **1** in 150 ml of dry ether was added rapidly to a stirred solution of 14 g (0.61 mol) of sodium in 400 ml of liquid ammonia at −70 °C, and the mixture was stirred for 3 hr at the same temperature. Excess ammonium chloride was added to this mixture, and ammonia was then evaporated at room temperature. Water and then ether were added to the residue. The ether layer was separated, washed with water, dried over Na_2SO_4, and then evaporated. The residual oil was distilled to yield 37 g of a pale yellow oil consisting of a mixture of **3** and **4**, bp 58—59 °C/0.15 mmHg. IR(film): 3020, 2940, 2840, 1600, 1460, 1435, 800, 760, 715, and 690 cm^{-1}. NMR(CCl_4): δ 1.3—2.0(1H, m), 2.1—2.7(2H, m), 2.7—3.1(2H, m), 3.0—3.5(2H, m), 5.7—6.1(1.6H, m), 6.5 (0.4H, dd, J= 10.0 and 3.0 Hz), and 6.65—7.15 ppm(3H, m).

2a,3-Dihydroacenaphthene (3). A solution of sodium ethoxide was prepared by adding 34.5 g (1.5 g-atom) of sodium to 500 ml of absolute ethanol. To this was added 46.8 g of the Birch reduction product, and the mixture was refluxed for 3 hr under nitrogen atmosphere. Most of the ethanol was removed, and then ice-water was added to the residue. The resulting mixture was extracted with ether. The ether solution was dried over Na_2SO_4 and evaporated. Distillation of the residue gave 42.1 g of **3** as a colorless oil, bp 73—74 °C/0.5 mmHg. The yield of **3** from **1** was 81%. IR(film): 3030, 2940, 2840, 1630, 1600, 1480, 1460, 1435, 800, 790, 750, and 690 cm^{-1}. NMR(CCl_4): δ 1.3—2.0 (2H, m, CH_2 at C-3), 2.1—2.7 (2H, m, CH_2 at C-2), 2.7—3.0(2H, m, CH_2 at C-1), 3.0—3.5(1H, m, CH at C-2a), 5.9(1H, bd, J= 10.0 Hz, vinyl proton at C-4), 6.5(1H, dd, J= 10.0 and 3.0 Hz, vinyl proton at C-5), and 6.65—7.15 ppm(3H, m, aromatic H).

2a,3,4,5-Tetrahedroacenaphthene-4,5-diol (5). To a stirred mixture of 30 g (0.19 mol) of **3** in 12 ml of 95% HCO_2H was added 26.5 g of 30% H_2O_2 at 20—25 °C. The reaction mixture was stirred for 1 hr at the same temperature, poured into 500ml of water, then extracted with $CHCl_3$. The $CHCl_3$ solution was washed with 10% $NaHCO_3$ solution, dried over Na_2SO_4, then evaporated to give a white solid. Since its IR spectrum(KBr) showed a carbonyl absorption due to the ester group at 1700 cm^{-1}, the solid was subjected to hydrolysis. To a stirred solution of the solid in 100ml of ethanol was added 65 ml of 20% NaOH solution under ice-cooling. The mixture was stirred for 5 hr at room temperature and diluted with 500 ml of water. The resulting brown solid was filtered, washed thoroughly with water to give 26 g (71%) of **5**. Recrystallization from benzene-ethanol gave pure **5** as white crystals, mp 138—139 °C. IR(KBr): 3320 cm^{-1}(OH). NMR($(CD_3)_2CO$): δ 1.3—1.9(2H, m), 2.65—3.0(2H, m), 3.0—3.5(1H, m), 3.85—4.3(3H, m), 4.55(1H, dd, J=5.6 and 3.1 Hz), and 7.2 ppm(3H, bs). Mass: *m/e* 190(M^+).

Found: C, 75.54; H, 7.58%. Calcd for $C_{12}H_{14}O_2$: C, 75.76; H, 7.42%.

Hydrogen Peroxide Oxidation of the Birch Reduction Product. The Birch reduction product (30 g) was treated with H_2O_2-HCO_2H and then with NaOH solution in the same manner as described above. The resulting mixture was extracted with $CHCl_3$. The extract was washed with water, dried over Na_2SO_4 and evaporated to give a brown viscous oil which was solidified upon treatment with CCl_4. The solid was collected by filtration to give 11.5 g of crude **4**, mp 130—137 °C. The crude **4** was recrystallized from benzene to give an analytical sample, mp 139—141 °C. IR(KBr): 3350 cm^{-1}(OH). NMR($(CD_3)_2CO$): δ 2.55—3.05(4H, m), 3.28(1H, m), 3.62(1H, m), 3.84—4.4(3H, m), and 6.75—7.15 ppm(3H, m). Mass: *m/e* 190(M^+).

Found: C, 75.62; H, 7.46%. Calcd for $C_{12}H_{14}O_2$: C, 75.76; H, 7.42%.

The CCl_4 filtrate was evaporated to give a brown viscous oil. Distillation of this oil gave yellow viscous oil of bp 140—150 °C/0.2 mmHg, which upon trituration with benzene yielded a white solid. The solid was recrystallized from $CHCl_3$ to give **5** as white crystals, mp 138—140 °C.

7-Formylindan-1-acetaldehyde (6). A soluiton of 12.8 g (0.06 mol) of sodium metaperiodate in 200 ml of water was added over 30 min to a stirred solution of 9.5 g (0.05 mol) of **5** in 200 ml of ethanol at 15—20 °C. Stirring was continued for 20 hr at room temperature, and most of the ethanol was evaporated under reduced pressure at room temperature. The resulting yellow oil was diluted with water, and extracted with CH_2Cl_2. The extract was washed with water, dried over Na_2SO_4 and evaporated. The resulting oil was distilled to afford 8.1 g (86%) of **6** as a colorless oil, bp 117—119 °C/0.3 mmHg, which upon standing in a refrigerator gave a white solid. IR(film): 1720(C=O) and 1690 cm^{-1}(C=O). NMR(CCl_4): δ 1.7—2.75(4H, m), 2.75—3.3(2H, m), 4.0—4.6(1H, m, CH at C-1), 7.3—7.9(3H, m, aromatic H), 9.9 (1H, m, aliphatic CHO), and 10.2 ppm(1H, s, aromatic CHO).

Found: C, 76.49; H, 6.57%. Calcd for $C_{12}H_{12}O_2$: C, 76.57; H, 6.43%.

The semicarbazone of **6** was prepared by the usual method and recrystallized from ethanol-water, mp 200—202 °C(decomp.).

Found: C, 55.71; H, 6.18; N, 28.04%. Calcd for $C_{14}H_{18}N_6O_2$: C, 55.61; H, 6.00; N, 27.80%.

7-Carboxyindan-1-acetic Acid (7). A solution of 210 ml of 1M NaOH solution was added over 30 min to a stirred mixture of 4.3 g (0.023 mol) of **6** and 17.6 g(0.134 mol) of $AgNO_3$ in 100 ml of 50% aqueous ethanol under cooling with an ice-water bath. After stirring for 30 min, air was passed into the stirred reaction mixture for 6 hr at room temperature. A black solid was separated by decantation and washed several times with 5% NaOH solution. All the aqueous solutions were combined and washed with ether. The aqueous solution was acidified with 6 M HCl to give a white solid which was separated, washed with water, and dried *in vacuo* to yield 4.6 g (88%) of **7**, mp 178—181 °C. An analytical sample of **7** was obtained by recrystallization from water-ethanol, mp 181—184 °C (lit,[1] mp 190—191 °C). IR(KBr): 3600—2500(OH), 1690(C=O), and 1670 cm^{-1} (C=O).

Found: C, 66.01; H, 5.31%. Calcd for $C_{12}H_{12}O_4$: C, 65.44; H, 5.49%.

1-(2-Hydroxyethyl)-7-hydroxymethylindan (8). To a solution of 500 mg(2.66 mmol) of **6** in 10 ml of ethanol was added 76 mg(2.0 mmol) of $NaBH_4$, and the reaction mixture was stirred at room temperature for 2 hr. The solvent was evaporated under reduced pressure, and the colorless viscous residue was added to ice-water and then extracted with CH_2Cl_2. The extract was washed with water, dried over Na_2SO_4, and evaporated to give a colorless viscous oil, which upon scratching with a spatula solidified to yield 400 mg (79%) of crude **8**. The crude solid was recrystallized from CCl_4 to yield white crystals, mp 54—56 °C. IR(KBr): 3200 cm^{-1} (OH). NMR($CDCl_3$): δ 1.3—2.3(4H, m), 2.6—3.0(2H, m), 3.0—3.4(1H, m), 3.55(2H, t, J=6.2 Hz, $-CH_2\mathbf{CH_2}OH$), 3.95(2H, bs, two of OH), 4.55(2H, s, Ar–$\mathbf{CH_2}OH$), and 7.05 ppm(3H, bs, aromatic H).

Found: C, 74.75; H, 8.36%. Calcd for $C_{12}H_{16}O_2$: C, 74.97; H, 8.39%.

2a,3,4,5-Tetrahydroacenaphthen-4-one (9). A mixture of 1.9 g (0.01 mol) of **5** and 200 ml of 30% aqueous H_2SO_4 was refluxed for 2 hr, cooled to room temperature, and then diluted with 150 ml of ice-water. The aqueous solution was extracted with ether, and the extract was washed with water, dried over Na_2SO_4, and evaporated. The resulting brown solid was sublimed at 100 °C under 0.5 mmHg to give 1.0 g (58%) of **9** as a white solid, mp 48—51 °C. IR(KBr): 1710 cm^{-1} (C=O). NMR(CCl_4): δ 1.2—3.3(7H, m), 3.38(2H, s, CH_2 at C-5), and 6.75—7.3 ppm(3H, m, aromatic H).

The oxime of **9** was prepared in the usual manner and purified by recrystallization from cyclohexane, mp 129—131 °C.

Found: C, 77.10; H, 6.95; N, 7.51%. Calcd for $C_{12}H_{13}NO$: C, 76.97; H, 7.00; N, 7.48%.

2,2a-Dihydro-1-oxo-1H-cyclopent[cd]*indene (11).* This was prepared from **7** *via* its lead salt (**10**) by the method of Rapoport and Pasky,[1] mp 59—61 °C (lit.[1] mp 63 °C).

2,2a-Dihydro-1-hydroxyimino-1H-cyclopent[cd]*indene (12).* This was prepared from 1.5 g (22 mmol) of hydroxylamine hydrochloride and 590 mg (3.7 mmol) of **11** by the usual method. The yield of **12** was quantitative. A pure sample was obtained by recrystallization from water-ethanol, mp 130—132 °C. IR(KBr): 1660 cm^{-1} (C=N).

Found: C, 76.04; H, 6.43; N, 8.08%. Calcd for $C_{11}H_{11}NO$: C, 76.27; H, 6.40; N, 8.09%.

3,3a-Dihydrocyclopent[de]*quinolin-2(1H)-one (13).* Polyphosphoric acid (PPA) was prepared by stirring a mixture of 12 g of 85% H_3PO_4 and 16 g of P_2O_5 at 130—140 °C for 2 hr, and then 1.8 g (14 mmol) of **12** was added at 80—100 °C. The reaction mixture was stirred at the same temperature for 15 min and then chilled. Ice-water was added to the reaction mixture until PPA was dissolved. The resulting solid was collected by filtration and recrystallized from *n*-hexane-$CHCl_3$ to give 500 mg (28%) of **13**, mp 163—164 °C (lit,[4] mp 163—164 °C). IR(KBr): 3200, 1690, 1630, 1605, 1490, 1330, and 770 cm^{-1}. NMR($CDCl_3$): δ 1.4—3.1(6H, m), 3.1—3.6(1H, 6.5—7.1(3H, m, aromatic H), and 9.1—9.5 ppm(1H, bs, NH).

Found: C, 76.33; H, 6.47; N, 8.04%. Calcd for $C_{11}H_{11}NO$: C, 76.27; H, 6.40; N, 8.09%.

7-Carboxyindan-1-acetamide (14). To a solution of 1.05 g (5.4 mmol) of *N,N'*-dicyclohexylcarbodiimide in 15 ml of dry dioxane was added 1.0 g (4.5 mmol) of **7**. The reaction mixture was allowed to stand at room temperature for 1.5 hr. The resulting *N,N'*-dicyclohexylurea was removed by filtration and the filtrate was evaporated under reduced pressure to give a pale yellow viscous oil; its IR spectrum showed absorptions characteristic of an acid anhydride at 1790 and 1720 cm^{-1}. A concentrated aqueous ammonia (30 ml) was added to the acid anhydride under ice-cooling. The mixture was allowed to stand at room temperature for 3 hr, warmed on a water bath for 30 min, and then extracted with CH_2Cl_2. The aqueous solution was acidified with concentrated HCl. The resulting solid was collected by filtra-

tion, washed with water and dried to give 700 mg(70%) of crude **14**, mp 194—200 °C. An analytical sample was obtained recrystallization from ethanol, mp 209—212 °C. IR(KBr): 3400, 3200, 1690, and 1650 cm^{-1}.

Found: C, 65.85; H, 6.08; N, 6.44%. Calcd for $C_{12}H_{13}NO_3$: C, 65.74; H, 5.98; N, 6.39%.

*7-Carboxyindan-1-methylamine Hydrochloride (**15**).* To a solution of 2.2 g (0.01 mol) of **14** in 30 ml of 10% aqueous NaOH solution was added 9.7 g of 10% aqueous sodium hypochlorite solution at room temperature. The reaction mixture was stirred at room temperature for 15 min, at 55 °C for 1 hr, and at 70—80 °C for 30 min. It was then washed with CH_2Cl_2. The aqueous solution was acidified to pH 1.0 with concentrated HCl. The acidified solution was again washed with CH_2Cl_2, and the resulting brown solid was collected by filtration. When the filtrate was concentrated to one-half its initial volume, a second crop of the solid was obtained. All the solids were combined and used without further purification for the preparation of **16**. The solids thus obtained weighed 2.1 g and decomposed at 230—240 °C. IR(KBr): 3100—2500, 1680, and 1630 cm^{-1}.

2-Acetyl-3,3a-dihydrocyclopent[de]*isoquinolin-1(2H)-one (**16**).* A mixture of 1.5 g of crude **15**, 900 mg of anhydrous AcONa, and 5 ml of Ac_2O was refluxed for 20 min. A large excess of 10% NaOH solution was added to the cooled mixture. The resulting mixture was heated for 15 min, and then extracted with ether. The ether extract was washed with $NaHCO_3$ solution, dried over Na_2SO_4, then evaporated to give 1.0 g (70%) of a pale yellow solid. Recrystallization of the solid from methanol-water gave an analytical sample of **15**, mp 74—76 °C. IR(KBr): 1690, 1600, 1370, 1300, 1235, 1225, and 755 cm^{-1}. NMR(CCl_4): δ 1.4—2.0(1H, m), 2.2—2.8(1H, m), 2.47(3H, s), 2.8—3.6(4H, m), 4.9(1H, dd, J= 10.0 and 4.0 Hz), and 7.1—7.8 ppm(3H, m). Mass: *m/e* 215(M^+).

Found: C, 72.49; H, 6.16; N, 6.46%. Calcd for $C_{13}H_{13}NO_2$: C, 72.54; H, 6.09; N, 6.51%.

3,3a-Dihydrocyclopent[de]*isoquinolin-1(2H)-one (**17**).* A mixture of 1.0 g (4.6 mmol) of **16** and 50 ml of 6 M HCl was refluxed for 2 hr, and then extracted with $CHCl_3$. During this operation a white solid appeared and was collected by filtration to yield 350 mg (32%) of **15**.

The $CHCl_3$ solution was washed with water, dried over Na_2SO_4, and then evaporated to give 300 mg (37%) of a brown solid. The solid was recrystallized from *n*-hexane–$CHCl_3$ to give **17** as white crystals, mp 150—152 °C. IR (KBr): 3200, 1670, 1610, 1595, 1490, 1400, 1350, 1320, 800, and 760 cm^{-1}. Mass: *m/e* 173(M^+).

Found: C, 76.37; H, 6.60; N, 8.05%. Calcd for $C_{11}H_{11}NO$: C, 76.27; H, 6.40; N, 8.09%.

(Received April 10, 1974)

A New synthesis of 2-hydroxy-3-methyl-2-cyclohexen-1-one (Ia), a flavor component of coffee aroma, is described. The selenium dioxide oxidation of ethyl 1-methyl-2-oxocyclohexanecarboxylate (IIa) gave α-diketone (IIIa), which was then hydrolyzed and decarboxylated to afford Ia. The treatment of IIa with cupric chloride in 50% acetic acid also yielded Ia. The dimethyl sulfoxide oxidation of ethyl 3-bromo-1-methyl-2-oxocyclohexanecarboxylate (IV) afforded IIIa, along with 3-bromo-6-ethoxycarbonyl-2-hydroxy-6-methyl-2-cyclohexen-1-one (V). The halogenation of IIa produced dihalogeno ketoesters (VIa) (VIIa), which also yielded Ia in a pure state by means of a direct acidic hydrolysis or by a two-step hydrolysis using morpholine. Other allied compounds are also described.

A number of alkyl-substituted cyclic α-diketones possessing a characteristic caramel flavor is known.[2] 2-Hydroxy-3-methyl-2-cyclohexen-1-one (Ia) has been identified in coffee aroma[3] and is one of the degradation products of fructose.[4] Ia has been synthesized in low yields by a variety of methods.[5]

We have previously reported the synthesis of 3-methyl-2-cyclopenten-2-ol-1-one.[6] In this paper, these studies will be extended to the synthesis of 3-alkyl-2-hydroxy-2-cyclohexen-1-ones (I) from ethyl 1-alkyl-2-oxocyclohexanecarboxylate (II) as starting materials.

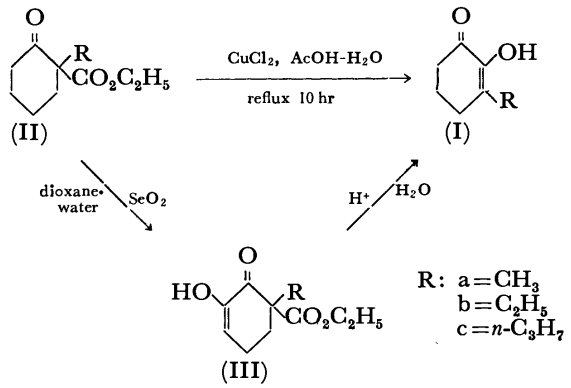
Ethyl 1-methyl-2-oxocyclohexanecarboxylate (IIa) can readily be prepared by the alkylation of ethyl 2-oxocyclohexanecarboxylate[7] with methyl iodide.[8a] Under the same conditions, the alkylation of ethyl 2-oxocyclohexanecarboxylate with ethyl or n-propyl iodide gave the corresponding II in a low yield. However, in the presence of dimethyl formamide, the enolate of the ketoester was easily alkylated to give (IIb) and (IIc), both in good yields.

The infrared spectrum of the compound II in the 6 μ region is unusual in that it consists of an unresolved envelope of absorption bands (see Experimental section), of which peaks at the normal ketone frequency (1710 cm^{-1}) but which has poorly-defined shoulders at higher frequencies (1720 and 1740 cm^{-1}). This implies that ethoxycarbonyl groups exist as mixtures of equatorial and axial conformers.[8b]

We have examined the following oxidations of II, using the key precursors of I: (1) selenium dioxide oxidation, (2) cupric chloride oxidation, (3) α-geminal halogenation, and (4) the DMSO oxidation of ethyl 3-bromo-1-methyl-2-oxocyclohexanecarboxylate (IV), which is easily obtained from IIa.

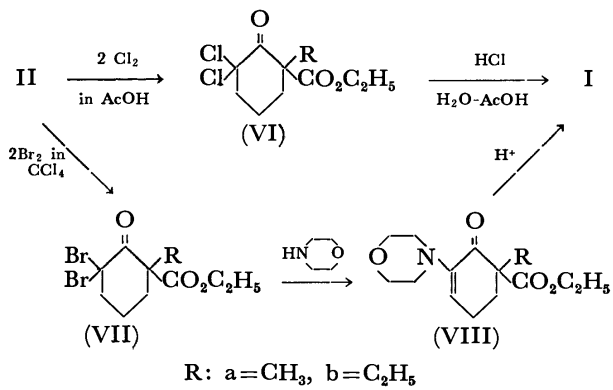
When IIa was refluxed with excess selenium dioxide in aqueous dioxane for 22 hr, 6-ethoxycarbonyl-2-hydroxy-6-methyl-2-cyclohexen-1-one (IIIa) was obtained in a 40% yield. Similarly, (IIIb) was also obtained from the ketoester IIb.

Compound IIIa could be readily converted into Ia (62.7%) by refluxing with 4M hydrochloric acid. The structure of Ia was assigned on the basis of its NMR, infrared, and ultraviolet spectra and the results of an elemental analysis. The NMR spectrum suggested that Ia was 100% enolized and that Ia exist as geometrical isomers, for we observed the methylene protons in the ethoxycarbonyl group showing two quartets (δ 4.15 and 4.17 ppm) in equal quantities.



On the other hand, Compound Ia was also obtained directly in a rather low yield by the refluxing of IIa with cupric chloride in 50% aqueous acetic acid.

The gem-dihalogeno group α to the carbonyl of II seemed to be an attractive possibility as the ketone precursor.[9] Indeed, IIa was easily chlorinated in acetic acid at 40—45° in a high yield and was easily brominated in carbon tetrachloride to give the corresponding ethyl 1-alkyl-3,3-dihalogeno-2-oxocyclohexanecarboxylates, (VI) (VII).



The NMR spectrum of VII in the region of the methylene protons in the ethoxycarbonyl group at an ordinary temperature peaks with two kinds of quartets (δ 4.15 and 4.17 ppm) equal in quantity. These two kinds of quartets are seemed due to axial and equatorial ethoxycarbonyl groups.

The dichloro ketoester (VIa) could be converted to Ia by hydrolysis and by subsequent decarboxylation.

When VIa was refluxed with dilute hydrochloric acid containing acetic acid, Ia was obtained in a 48% yield.

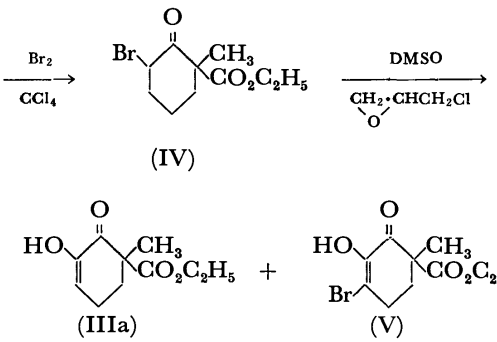
However, the direct acidic or basic hydrolysis of the dibromo ketoester (VIIa) gave mainly tarry materials; Ia was isolated in only a low yield.

On the other hand, the treatment of VIIa with morpholine,[10] followed by acidic hydrolysis, afforded Ia in a 59% yield.

Although the geminal dihalogeno compound has been shown to give the corresponding dimorpholino derivative upon treatment with morpholine,[10] an intermediate, ketoenamine (VIII), was isolated in this reaction in a 56% yield. The structure of VIII was assigned on the basis of its NMR, IR, and UV spectra and on the results of an elementary analysis.

The IR spectrum showed a conjugated double-bond absorption at 1620 cm^{-1}, and the NMR spectrum indicated the vinyl proton as a triplet (J=3.7 Hz) at δ 5.57 ppm.

The bromination of the IIa ketoester with an equimolar amount of bromine in carbon tetrachloride gave ethyl 3-bromo-1-methyl-2-oxocyclohexanecarboxylate (IV) in a good yield.



(IV)

(IIIa) (V)

The dimethyl sulfoxide oxidation of IV in the presence of epichlorohydrin as a scavenger for hydrogen bromide provided the enolate of α-diketone (IIIa), together with 3-bromo-6-ethoxycarbonyl-2-hydroxy-6-methyl-2-cyclohexen-1-one (V). The latter compound, V, seemed to be derived from the IIIa and bromine formed *in situ*.

This reaction contrasts with the fact that the DMSO oxidation of 2-bromo-5-ethoxycarbonyl-5-methylcyclopentanone in the presence of epichlorohydrin yielded 5-ethoxycarbonyl-2-hydroxy-5-methyl-2-cyclopenten-1-one exclusively.[6] Investigations are continuing into the DMSO oxidation of alicyclic α-haloketones.

Experimental

All the melting points and boiling points are uncorrected. The infrared spectra were recorded with a Hitachi Model EPI-S2 spectrophotometer, while the ultraviolet spectra were recorded with a Hitachi Model EPS-3T spectrophotometer. The NMR spectra were obtained on a JEOL Model C-60H spectrometer, with tetramethylsilane as the internal reference.

Materials. *Ethyl 2-oxocyclohexanecarboxylate* was prepared from cyclohexanone by the procedure of Synder.[7] *Ethyl 1-methyl-2-oxocyclohexanecarboxylate* was prepared by the method of Kötz.[8a]

Ethyl 1-Ethyl-2-oxocyclohexanecarboxylate (IIb). To a stirred suspension of sodium hydride (9.6 g, 0.2 mol as a 50% suspension in oil) in 300 ml of toluene, 34 g (0.2 mol) of ethyl 2-oxocyclohexanecarboxylate was added at 25°C, after which the mixture was stirred for 30 min. After the complete formation of the sodium salt, 10 ml of dimethyl formamide[11] and 34.3 g (0.22 mol) of ethyl iodide were dropped in at 25—30°C over a period of 15 min. The mixture was then refluxed with stirring for 3 hr. After cooling, the mixture was poured into 200 ml of water and the organic layer was separated. The water layer was extracted with ether, and the extract was combined with the organic layer. After washing with water and drying with magnesium sulfate, the solvent was distilled off. The residual oil (46 g) was distilled to give 33.3 g (84%) of IIb; bp 130—132°C/19 mmHg, n_D^{20}=1.4578. IR(neat): 1740, 1720 (C=O ester), 1710 (C=O) cm^{-1}. NMR(CCl_4): δ 0.80(3H, t, 7.0 Hz), 1.30 (3H, t, 7.0 Hz), 1.5—2.7 (10H, m), 4.18(2H, q, 7.0 Hz). Found: C, 66.77; H, 9.32%. Calcd for $C_{11}H_{18}O_3$: C, 66.64; H, 9.15%.

Ethyl 1-n-Propyl-2-oxocyclohexanecarboxylate (IIc). IIc was prepared according to the IIb procedure described above. Instead of ethyl iodide, *n*-propyl iodide (37.4 g (0.22 mol)) was used to give 35.2 g (83%) of IIc: bp 135—137 °C/14 mmHg, n_D^{20}=1.4573. IR(neat): 1740, 1720 (C=O ester), 1710 (C=O) cm^{-1}. NMR(CCl_4): δ *ca.* 0.95(3H, t, 7.0 Hz), 1.28 (3H, t, 7.0 Hz), 1.5—2.7(12H, m), 4.22(2H, q, 7.0 Hz). Found: C, 68.09; H, 9.89%. Calcd for $C_{12}H_{20}O_3$: C, 67.89; H, 9.50%.

6-Ethoxycarbonyl-2-hydroxy-6-methyl-2-cyclohexen-1-one (IIIa). A mixture of dioxane (100 ml), water (33 ml), selenium dioxide (4.4 g (0.04 mol)), and 3.68 g (0.02 mol) of IIa was stirred under reflux for 22 hr. After cooling, the deposited selenium was filtered off, the solvent was removed at reduced pressure, and the residue was extracted with ether. After drying, the ether was distilled and the resulting oil was distilled to give the crude product, IIIa: bp 92—106 °C/0.3 mmHg. Redistillation yielded 1.6 g (40%) of IIIa; bp 99—100 °C/0.3 mmHg. IR(neat): 3400 (O–H), 1730, 1680 (C=O), 1635 cm^{-1} (C=C). NMR(CCl_4): δ 1.25(3H, t, 7.0 Hz), 1.38(3H, s), 2.0—2.6(4H, m), 4.15 and 4.17(2H, q, 7.0 Hz), 6.0(1H, broad s), 6.55(1H, t, 3.0 Hz). UV max (EtOH): 283 nm (ε=8930). Found: C, 61.23; H, 7.23%. Calcd for $C_{10}H_{14}O_4$: C, 60.59; H, 7.12%.

6-Ethoxycarbonyl-6-ethyl-2-hydroxy-2-cyclohexen-1-one (IIIb). The preparation of IIIb was carried out according to the IIIa procedure described above. A mixture of dioxane (100 ml), water (33 ml), selenium dioxide (8.8 g(0.08 mol)), and IIb (8.0 g (0.04 mol)) was refluxed for 45 hr. A working-up of the reaction mixture yielded 3.0 g (35.4%) of IIIb: bp 110—111 °C/0.6 mmHg. IR(neat): 3400 (O–H), 1730, 1680 (C=O), 1635 cm^{-1} (C=C). NMR(CCl_4): δ 0.89(3H, t, 7.0 Hz), 1.23(3H, t, 7.0 Hz), 1.5—2.7(6H, m), 4.17 and 4.19(2H, q, 7.0 Hz), 6.10(1H, s), 6.75(1H, t, 3.0 Hz). UV-max(EtOH): 262 nm (ε=6390). Found: C, 61.93; H, 7.69%. Calcd for $C_{11}H_{16}O_4$: C, 62.25; H, 7.60%.

Ethyl 3,3-Dichloro-1-methyl-2-oxocyclohexanecarboxylate (VIa). Into a stirred solution of 9.2 g (0.05 mol) of IIa in 55 ml of acetic acid, chlorine(7.8 g(0.11 mol)) was bubbled at 45—50 °C over a period of 1 hr, and then the mixture was stirred for 2 hr (a vpc of the aliquot indicated a complete conversion to the dichlorinated material). The subsequent evaporation of the solvent gave a pale yellow liquid which was distilled to afford 12.5 g (99%) of VIa; bp 111—112 °C/0.45 mmHg, which was solidified in a cool place, mp 31—32 °C (petroleum ether). IR(KBr): 1730 (C=O), 1237 (C–O–C), 790 cm^{-1} (C–Cl). NMR(CCl_4): δ 1.24(3H, t, 7.0 Hz), 1.35(3H, t,

7.0 Hz), 1.5—2.9(6H, m), 4.05 and 4.07(2H, q, 7.0 Hz). Found: C, 47.22; H, 5.65; Cl, 28.16%. Calcd for $C_{10}H_{14}Cl_2O_3$: C, 47.45; H, 5.57; Cl, 28.01%.

Ethyl 3,3-Dibromo-1-methyl-2-oxocyclohexanecarboxylate (VIIa). Into a solution of 18.4 g (0.1 mol) of IIa in carbon tetrachloride (190 ml), we stirred a solution of 35.2 g(0.22 mol) of bromine in 10 ml of carbon tetrachloride at room temperature over a period of 50 min; the mixture was then warmed at 40—45 °C for 3 hr. The mixture was subsequently poured into 300 ml of ice–water, and the organic layer was washed with aqueous sodium bicarbonate and saturated aqueous sodium chloride. After drying and the removal of the solvent, the distillation of the residual pale yellow oil gave 31.6 g (92.4%) of VIIa; bp 130—131 °C/0.3 mmHg. The distillate solidified spontaneously, and recrystallization from petroleum ether afforded VIIa as colorless needles; mp 52 °C. IR(KBr): 1740, 1725 cm^{-1} (C=O); NMR(CCl_4): δ 1.30(3H, t, 7.0 Hz), 1.41(3H, s), 1.6—3.0(6H, m), 4.14 and 4.16(2H, q, 7.0 Hz). Found: C, 35.29; H, 4.18; Br, 46.54% Calcd for $C_{10}H_{14}Br_2O_3$: C, 35.12; H, 4.13; Br, 46.73%.

Ethyl 3,3-Dibromo-1-ethyl-2-oxocyclohexanecarboxylate (VIIb). The preparation of VIIb was carried out according to the procedure VIIa described above. From 9.9 g (0.05 mol) of IIb and 17.6 g (0.11 mol) of bromine, 16.5 g (93%) of VIIb were obtained; bp 138—142 °C/0.4 mmHg, mp 46—46.5 °C (petroleum ether). IR(KBr): 1730, 1715 cm^{-1} (C=O); NMR(CCl_4): δ 0.80(3H, t, 7.0 Hz), 1.30(3H, t, 7.0 Hz), 1.6—2.9(8H, m), 4.14 and 4.16 (2H, q, 7.0 Hz). Found: C, 37.63; H, 4.70%. Calcd for $C_{11}H_{16}Br_2O_3$: C, 37.11; H, 4.53%.

6-Ethoxycarbonyl-6-methyl-2-morpholino-2-cyclohexen-1-one (VIII). Into (17.4 g (0.2 mol) of morpholine, we stirred drop by drop, 6.8 g (0.02 mol) of VIIa. The mixture was then stirred at 35—40 °C for 3 hr. The removal of morpholine under reduced pressure yielded white crystals and orange oils. The crystals were filtered, washed with ether, and recrystallized from ethanol to give 6.4 g (94%) of morpholine hydrobromide; mp 201—202 °C (lit,[12] mp 202 °C). The filtrate was washed with water and dried over magnesium sulfate. After the removal of the ether, the residual oil was chromatographed on a silica gel column. Elution with benzene-ethanol (10 : 1) yielded 3.6 g (56.1%) of VIII: $n_D^{20}=1.5069$. IR(neat): 1725, 1690 (C=O), 1620 cm^{-1} (C=C); NMR(CCl_4): δ 1.20 (3H, t, 7.0 Hz), 1.24(3H, s), *ca.* 1.75 (2H, m), *ca.* 2.52 (6H, m), *ca.* 3.60(4H, m), 4.10(2H, q, 7.0 Hz), 5.57 (1H, t, 3.7 Hz); UVmax(EtOH): 301 nm ($\varepsilon=2710$). Found: N, 5.46%. Calcd for $C_{14}H_{21}NO_4$: N, 5.24%.

2-Hydroxy-3-methyl-2-cyclohexen-1-one (Ia). *a)*: A mixture of 1.5 g of IIIa and 20 ml of 4M-hydrochloric acid was heated with stirring for 4 hr. After cooling, the mixture was saturated with ammonium chloride and extracted with ether. The extract was dried and evaporated to dryness, giving a viscous oil which was solidified by standing in the cool box. Recrystallization from petroleum ether gave 0.60 g (62.7%) of Ia as colorless needles; mp 62—63 °C. (lit,[5d] mp 63 °C). IR(KBr): 3410(O–H), 1670 (C=O). 1645 cm^{-1}(C=C); NMR (CCl_4): δ 1.85(3H, s), 2.00(2H, m), 2.31(2H, m), 2.42(2H, m), 5.90(1H, s); UVmax(EtOH): 275 nm ($\varepsilon=10200$). Found: C, 67.06; H, 8.30%. Calcd for $C_7H_{10}O_2$: C, 66.65; H, 7.99%.

b): Into 17.4 g(0.2 mol) of morpholine, we stirred 6.8 g (0.02 mol) of VIIa, drop by drop. The mixture was then stirred at 35—40 °C for 3 hr. The subsequent evaporation of the excess morpholine yielded white crystals and orange oils. After the filtration of the crystals, the filtrate (5.0 g) was stirred with a 4M-hydrochloric acid solution for 1 hr at room temperature. A further 20 ml of conc. hydrochloric acid was added to the mixture, after which it was refluxed for 10 hr. Working up in a manner similar to that described above yielded 1.50 g (59.5%) of Ia; bp 70—80 °C/4 mmHg, mp 62 °C.

c): A mixture of 4.7 g (25.6 mmol) of IIa, 10.8 g(63.4 mmol) of cupric chloride, 40 ml of water, and 40 ml of acetic acid was stirred under reflux for 10 hr. After the copper compound has been filtered off, the solvent was removed under reduced pressure and extracted with ether. After drying and the removal of the ether, the distillation of the residual oil gave a pale yellow liquid (bp 80—90 °C/3 mmHg), parts of which solidified upon standing in a cool box. The precipitated crystals were separated, and recrystallization from petroleum ether gave 0.40 g (12.4%) of Ia; mp 60—62 °C.

d): A mixture of 6.3 g (25 mmol) of VIa, 50 ml of 5% hydrochloric acid, and 20 ml of acetic acid was refluxed with stirring for 46 hr. After cooling, the mixture was saturated with ammonium chloride and extracted with ether. After drying, the evaporation of the ether gave a viscous oil (3.8 g) which was subsequently distilled to give 1.50 g (47.6%) of Ia (bp 63—65 °C/3 mmHg), which was spontaneously solidified; mp 62—63 °C.

3-Ethyl-2-hydroxy-2-cyclohexen-1-one (Ib). *a)*: A mixture of 2.0 g of IIIb, 26 ml of 3M hydrochloric acid, and 8 ml of ethanol was refluxed with stirring for 20 hr., After cooling, a black oil was filtered off and the filtrate was extracted with chloroform. After the filtrate has been dried over magnesium sulfate, the evaporation of the solvent yielded a crude oil (0.60 g). The residual oil was distilled to give 0.40 g (30%) of Ib; bp 75—80 °C/6 mmHg; mp 29—30 °C (lit,[13] mp 29.5 °C). IR(KBr): 3410(O–H), 1670(C=O), 1650 cm^{-1} (C=C); NMR(CCl_4): δ 1.03(3H, t, 7.3 Hz), 1.6—2.7(8H, m), 5.89(1H, s); UVmax(EtOH): 276 nm ($\varepsilon=10800$). Found: C, 68.45; H, 8.57%. Calcd for $C_8H_{12}O_2$: C, 68.55; H, 8.63%.

b): Ib was prepared according to Procedure Ia Method *b)*, as described above. From 26.1 g (0.3 mol) of morpholine and 10.7 g (0.03 mol) of VIIb, we obtained 9.5 g of crude VIIIb, which was then hydrolyzed and decarbethoxylated to give 0.75 g (18%) of Ib; mp 29—30 °C. The infrared spectrum and the other chemical properties were identical with those of Ib presented above.

Ethyl 3-Bromo-1-methyl-2-oxocyclohexanecarboxylate (IV). To a stirred solution of 12.9 g (0.07 mol) of IIa in 140 ml of carbon tetrachloride, we added a solution of 11.5 g (0.072 mol) of bromine in 10 ml of carbon tetrachloride at 10 °C over a period of 80 min, and then we stirred the mixture for 5 hr. The resulting mixture was poured into water, and the organic layer was washed with aqueous sodium bicarbonate and aqueous sodium chloride. After drying and the removal of the solvent, the distillation of the residual oil gave 16.2 g (88.1%) of IV: bp 115—116 °C/1.2 mmHg. IR(neat) 1730, 1712 (C=O), 1260, 1160, 1024 cm^{-1} (C–O–C); NMR(CCl_4): δ 1.28(3H, t, 7.0 Hz), 1.32(3H, s), 1.6—2.7(6H, m), 4.23(2H, q, 7.0 Hz), 4.5—5.0(1H, m). Found: C, 45.61; H, 5.78; Br, 30.12%. Calcd for $C_{10}H_{15}BrO_3$: C, 45.64; H, 5.75; Br, 30.36%.

The Dimethyl Sulfoxide Oxidation of IV. A mixture of 10.5 g (0.04 mol) of IV, 3.7 g (0.04 mol) of epichlorohydrin, and 100 ml of DMSO was stirred at 69—72 °C for 8 hr. Then the DMSO was removed from the reaction mixture under reduced pressure, and the resulting oil was distilled to give 4.2 g (61%) of 1-bromo-3-chloro-2-propanol [bp 55—64 °C/0.7 mmHg, lit,[14] bp 92 °C/20 mmHg] and 6.6 g of an oil [bp 105—112 °C/0.7 mmHg]. The fractional distillation of the latter oil gave 2.0 g (25%) of IIIa [bp 105—108 °C/0.7

mmHg] and 3.5 g (33%) of V (bp 115—125 °C/0.7 mmHg), which was solidified spontaneously, subsequent recrystallization from petroleum ether afforded V as colorless crystals (mp 80—81 °C). IR(KBr): 3420 (O-H), 1715, 1675(C=O), 1640 cm^{-1}(C=C); NMR($CDCl_3$): δ 1.24(3H, t, 7.3 Hz), 1.44(3H, s), 1.70—3.0(4H, m), 4.16(2H, q, 7.3 Hz), 6.34(1H, s); UV_{max}(EtOH): 282.5 nm (ε=10200). Found: C, 43.84; H, 4.89%. Calcd for $C_{10}H_{13}BrO_4$: C, 43.34; H, 4.73%.

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606

(Received May 1, 1974)

The reactions of norbornadiene in amine by the use of nickel, palladium and rhodium complexes have been studied in the presence of protic acid. A catalytic system of $Ni(COD)_2$ (**1**)-n-Bu_3P gives a mixture of 5-*exo*-(*o*-tolyl)-2-norbornene (**3**) and 5-*exo*-(*N*-amino)-2-norbornene (**4**). Bis(triphenylphosphine)(maleic anhydride)-palladium (**5**) gives 3-(*N*-amino)nortricyclene (**6**). Dichlorotetrakis(cyclooctene)dirhodium (**10**) gives a [2+4] cycloaddition product (**11**). All these reactions mechanisms are discussed from the point of view of an acid-promoted reaction on low-valent transition metal complexes.

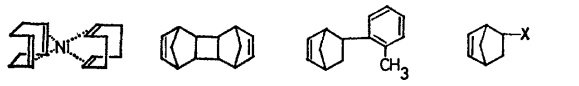
The amination or telomerization of 1,3-dienes is of interest from the points of view of both synthetic chemistry and mechanistic study. It has been clarified that controlled amounts of some protic acids enhanced the reactions remarkably.[1] However, the transition metal-catalyzed addition of an amine to olefin or homo-conjugated diene has so far been lacking. Norbornadiene is here employed as the diolefinic substrate in order to determine whether or not the anchimeric participation of one double bond might result in a transition metal-catalyzed addition of amine similar to that observed for 1,3-dienes, if the amination is possible.

On the other hand, the dimerization of norbornadiene by transition metals has been extensively studied.[2] The normal products in an aprotic solvent are [2+2] or [4+2] cycloaddition compounds. Previous work in this laboratory has shown a novel dimerization of norbornadiene by some nickel catalysts in an amine, giving 5-*exo*-(*o*-tolyl)-2-norbornene as the major product.[3] This reaction is also explicable in terms of an acid-promoted dimerization on a zerovalent nickel complex. Consequently, we expected that the amination and the dimerization might occur competitively. It appeared to us that the reaction patterns can, to a great extent, be altered mainly by adjusting the acidity of the catalytic system or by controlling the amount of protic acid added. Accordingly, we undertook a study of the effect of added acid on the reaction. This paper will be concerned with a systematic investigation of the reactions of norbornadiene by several nickel-, palladium-, and rhodium complexes.

Results and Discussion

The polymerization of norbornadiene catalyzed by low-valent nickel or palladium complexes proceeded rapidly in an alcohol, but in an amine no appreciable polymerization occurred. The use of amine as a solvent was favorable for the reaction of norbornadiene. Consequently, under these conditions the dimerization and the amination occurred competitively when trifluoroacetic acid was added. Among the amines used, cyclic amines such as morpholine and piperidine gave the best results. Accordingly, these amines were used.

Nickel Catalysts. Bis(1,5-cyclooctadiene)nickel (**1**) was used in the presence of tri-*n*-butylphosphine. The reaction in morpholine or piperidine proceeded smoothly at 90 °C. Without trifluoroacetic acid, only the [2+2]cycloaddition compound (**2**) was formed in a *ca.* 60% yield.



1 **2** **3** **4**

a: X=N O

b: X=N

A striking change in the reaction occurred when a small amount of trifluoroacetic acid (1 equiv. to Ni) was added to the system. The product (**2**) was no longer formed; instead 5-*exo*-(*o*-tolyl)-2-norbornene (**3**) was obtained as the sole dimeric product, accompanied by a small amount of 5-*exo*-(*N*-amino)-2-norbornene (**4**). The identifications of the products were based on the mass, infrared-, and NMR-spectra. The *endo* proton on the C-5 atom of **4** can couple only with two neighboring protons on the C-6 carbon atom, not with the bridge-head, giving a double doublet at 8.0 τ for **4a**. The spectral data of **3** have been reported previously.[3]

The further addition of the acid prevented the formation of **3**, but promoted that of **4**. These results are graphically shown in Fig. 1.

This reaction pattern is explicable in terms of a mechanism similar to that proposed in the dimerization

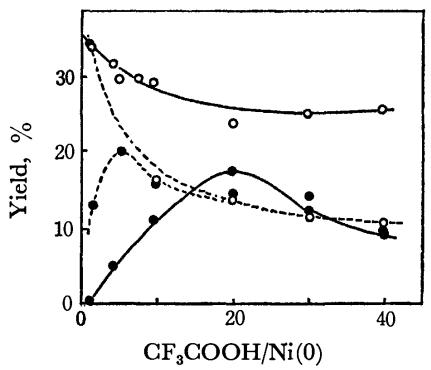


Fig. 1. Effect of [CF_3COOH] on the reaction by Ni at 90 °C.
(○), 5-*exo*-(*o*-Tolyl)-2-norbornene; (●), 5-*exo*-(N-amino)-2-norbornene.
(——), in morpholine; (·····), in piperidine.
Conditions: [$Ni(COD)_2$]=0.05 mmol, [n-Bu_3P]=0.2 mmol, [norbornadiene]=2 mmol; amine, 0.4 ml; 15 hr.

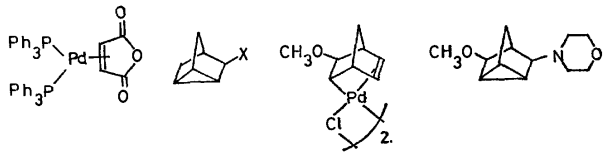
and amination of 1,3-dienes; a large amount of the added acid prevents the homolytic coupling of norbornadiene on the ligand-containing zerovalent nickel NiL_x, because the reaction of protic acid with the zerovalent nickel complex lies in the following equilibrium:[4]

$$HX + NiL_x \rightleftharpoons [HNiL_x]^+X^- \quad (1)$$

On the other hand, the first step in the amination appears to involve a metal-hydride initiated mechanism; metal-hydride adds to one of the carbon-carbon double bonds of norbornadiene. A similar reaction scheme was established in the reaction of 1,3-diene, which proceeds through a π-allyl intermediate.

It has already been reported in a previous paper[3] that the dimerization of norbornadiene in amine by the $(n\text{-}Bu_3P)_2NiBr_2$–$NaBH_4$ (1 : 1) system gives 5-*exo*-(*o*-tolyl)-2-norbornene. In this case, only the dimer was obtained, no appreciable amount of the reaction product of amine with norbornadiene being formed. The present results (Fig. 1) are consistent with the previous results, because the mixture of $(n\text{-}Bu_3P)_2NiBr_2$–$NaBH_4$ (1 : 1) is considered to give a system consisting of zerovalent nickel and an equimolar amount of hydrogen bromide (that is, the HX/Ni(0) ratio is unity); thus, the major product of the previous study is 5-*exo*-(*o*-tolyl)-2-norbornene.

Palladium Catalyst. Bis(triphenylphosphine)(maleic anhydride)palladium was effective in the reaction of norbornadiene with amines. The most marked difference in the catalysis between the palladium and nickel complexes lies in the reaction product. No dimeric product was formed; 3-(*N*-amino)nortricyclene was the sole reaction product. In this case, however, a higher temperature, 110 °C, was favorable for the desired reaction. The product was identified as



5 6 7 8

a: X= 
b: X= 
follows; the infrared spectrum has strong absorptions at 3080 and 805 cm^{-1} due to its nortricyclyl structure,[5] and no absorption due to olefinic protons is observed in its NMR spectrum.

In this catalytic system, trifluoroacetic acid plays an important role. No obvious reaction occurs without the added acid (Fig. 2). The added acid has a promoting effect on the formation of a palladium hydride. The equilibrium of Eq. 1 is applicable to the palladium complex also. However, in this case the equilibrium is considered to lie far to the right. This assumption is consistent with the fact that stable metal hydrides of the platinum group can be isolated.[6] Consequently, the coupling of norbornadiene no longer occurs on the palladium complex, but the reaction of the hydride

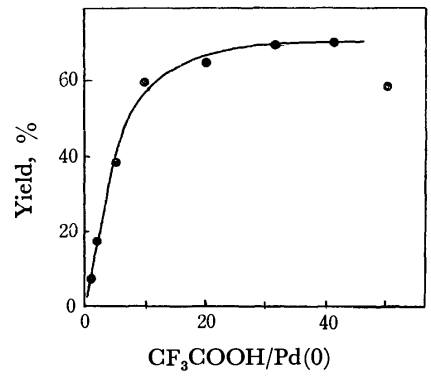


Fig. 2. Effect of [CF_3COOH] on the reaction by Pd at 110 °C.
Conditions: $Pd(PPh_3)_2(C_4H_2O_3)$, 0.015 mmol; norbornadiene, 2 mmol; piperidine, 0.4 ml; 5 hr.

with norbornadiene predominates; thus, a nortricyclyl palladium intermediate is formed. The addition of a large amount of the acid resulted in the formation of polymeric products. It is noteworthy that an acid-base reaction between the added acid and amine occurs competitively with the reaction of Eq. 1. Therefore, as the co-catalyst a quaternary ammonium salt such as piperidine hydrochloride can be used instead of the acid. However, its efficiency was far lower.

The stereochemistry of this amination is interesting to study. Complex **7**[7] was prepared for this purpose. When the pale-yellow complex **7** was added to morpholine, the complex turned black immediately. The gas-chromatographic analysis showed a single component(**8**). The presence of the infrared bands at 800 and 820 cm^{-1} indicated the formation of a derivative of nortricyclene. The chemical shift of the proton at C-5 (the carbomethoxy-bearing carbon) is very close to that of 3-carbomethoxynortricyclene.[8] From the spectral data, it may be concluded that the environment of the proton at the C-5 atom is not influenced by introducing the amino group at the C-3 atom. This fact indicates that the amino group is located in an *exo* configuration with respect to the methylene bridge. This stereochemistry suggests that the reaction of the amino group occurs in the opposite direction from the palladium atom. The reaction mechanism of this model compound seems to be applicable to the acid-promoted catalytic reaction with **5**. The only difference lies in the point that the intermediate in the catalytic reaction has a hydrogen atom instead of the methoxy group at the C-5 atom.

Rhodium Catalyst. As has been described above, the metal-hydride is an active species in the amination. From this point of view, hydridocarbonyltris(triphenylphosphine)rhodium (**9**) was used. However, the hydride was too stable to catalyze the amination.

$HRh(CO)(PPh_3)_3$ $[RhCl(C_8H_{14})_2]_2$ 
9 **10** **11**

The catalytic activity of dichlorotetrakis(cyclooctene)dirhodium (**10**) was low in reaction to the amination or

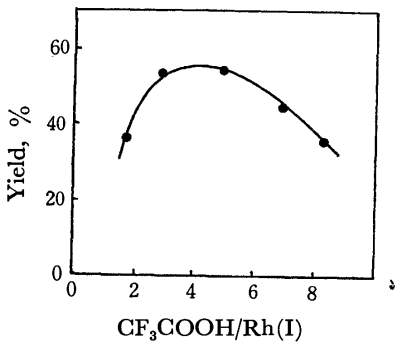

Fig. 3. Effect of [CF_3COOH] on the reaction by Rh at 110 °C.
Conditions: [$RhCl(COE)_2]_2$, 0.02 mmol; norbornadiene, 5.4 mmol; 8 hr.

dimerization in the presence of tri-*n*-butylphosphine and trifluoroacetic acid, and **4** was obtained in a low yield, accompanied by a small amount of the hydrogenation product of **4**. In the absence of the phosphine, however, **10** showed a specific activity for the formation of **11**. The identification of **11** was done by comparing its NMR spectrum with the reported one.[9] As is shown in Fig. 3, the yield was also influenced by the presence of acid. The maximum yield was realized when 4 equivalents of trifluoroacetic acid to **10** were added to the system. This catalytic system is characteristic in the point that **11** is selectively formed. The ordinary rhodium catalyst gives a mixture of dimers,[14] and the selectivity of **11** is not so high as in the present case. In this dimerization, the presence of amine has no effect on the reaction.

Experimental

Materials. Bis(1,5-cyclooctadiene)nickel,[10] dichlorobis(6-methoxybicyclo[2.1.1]hept-2-ene)dipalladium,[7] and bis(triphenylphosphine)(maleic anhydride)palladium,[11] hydridocarboxyltris(triphenylphosphine)rhodium,[12] and dichlorotetrakis(cyclooctene)dirhodium[13] were prepared according to the reported methods. Amines and norbornadiene were dried by the usual methods and, if necessary, distilled under an atmosphere of argon and stored over a Molecular Sieve 3 Å. Commercially-available trifluoroacetic acid and *n*-butylphosphine were used without further purification. Gas-chromatographic analyses were carried out on a Silicone DC 550 column on Celite 545 (3m, 150 °C), using tetralin as the internal standard.

Catalytic Reaction with Nickel Complex. All the reactions were carried out under an argon atmosphere in a sealed glass tube.

A. Without the Acid. In a glass tube (8 mm in diameter), 0.05 mmol of bis(1,5-cyclooctadiene)nickel was placed under an argon atmosphere, and then 0.2 mmol of Bu_3P, 0.4 ml of morpholine and 0.2 ml (2 mmol) of norbornadiene were added (in this order). The tube was sealed with a flame and heated without agitation at 90 °C for 15 hr. Subsequent gas-chromatographic analysis showed that the dimer (**2**) was formed in a 60% yield.

B. With the Acid. The following procedure is illustrative. To 0.05 mmol of $Ni(COD)_2$ in the glass tube was added 0.4 ml of morpholine containing 0.25 mmol (variable, as is shown in Fig. 1) of trifluoroacetic acid, 0.2 mmol of *n*-Bu_3P, and 0.2 ml of norbornadiene. The tube was sealed and heated without agitation at 90 °C for 15 hr. Subsequent gas-chromatographic analysis showed the formation of 5-*exo*-(*o*-tolyl)-2-norbornene, **3** (in a 30% yield) and **2**-*exo*-(*N*-morpholino)-2-norbornene, **4a** (in a 20% yield). The products were separated by gas-chromatography. The identification was based on the infrared, NMR, and mass spectra. The NMR spectrum ($CDCl_3$) showed peaks at 3.9, 4.1, (quartet), and 8.0 τ (double doublet). The yields under other conditions are shown graphically in Fig. 1.

*Catalytic Reactions with Palladium Complex (**5**).* The procedure was similar to those described above. The results are shown in Fig. 2. The infrared spectrum of **6a** showed strong absorptions at 800 and 810 cm^{-1} due to the nortricyclyl framework. The NMR spectrum ($CDCl_3$) showed multiplets centered at 8.0 (1H), 8.4 (1H), 8.9(1H), 8.2(2H), and 9.8 τ (4H).

*Reaction of **7** with Morpholine.* To 0.55 g (1 mmol) of **7** we added 4 ml of morpholine. The yellow complex, **7** immediately turned black. The solution was then stirred at room temperature for 5 hr. Subsequent gas-chromatographic analysis showed the formation of **8** in a 45% yield. The NMR spectrum has singlets at 8.7 (3H), 8.4 (1H), 8.0 (2H), and 6.6 τ (3H of methoxy group) and two multiplets centered at 7.7(4H, of morpholine) and 6.3 τ (4H of morpholine). The mass spectrum has a peak due to the molecular ion at *m/e* 209.

*Catalytic Reaction of the Rhodium Complex (**10**).* The reaction was carried out such as has been described above. The reaction conditions are shown in Fig. 3. The identification of the product (**11**) was based on the NMR spectrum.[9]

A New Method of Preparing Flavones

Akira KASAHARA, Taeko IZUMI, and Masatoshi OOSHIMA

Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa, Yamagata 992

(Received May 8, 1974)

The reaction of the sodium salt of 2′-hydroxychalcones with palladium(II) salt led to the formation of flavones, accompanied by a small amount of flavanones. The reaction proceeds *via* a phenoxypalladation, followed by the elimination of a hydridopalladium(II).

In the presence of palladium(II) salt, the reaction of the oxygen nucleophile with the carbon-carbon double bond has received wide attention.[1] Hosokawa *et al.*[2] have recently reported that the reaction of the sodium salt of 2-allylphenol with dichlorobis(benzonitrile) palladium in refluxing benzene proceeds *via* an intramolecular phenoxypalladation and gives 2-methylbenzofuran in a 31% yield. Independently of their work, we wish now to report that flavones (**1**) can be prepared in a high yield by the reaction of the sodium salt of 2′-hydroxychalcones (**2**) with lithium chloropalladite in a polar solvent, such as acetonitrile or ethanol. On the other hand, numerous reports of the synthesis of **1** have appeared in literature.[3] No direct cyclization of **2** into **1** is, however, known with the exception of the reaction of **2** with selenium dioxide in amyl alcohol or in xylene (the yields are not very good).[4]

Results and Discussion

At room temperature, the sodium salt of **2** was treated with lithium chloropalladite or with palladium(II) acetate in a polar solvent, such as acetonitrile or ethanol, to produce **1**, accompanied by a small amount of flavanone (**3**). For example, the reaction of 2′-hydroxychalcone (**2a**) with lithium chloropalladite in acetonitrile resulted in the formation of flavone (**1a**) (yield=75%) and flavanone (**3a**) (yield=6%). Similarly, 6-methoxy- and 7-methoxyflavone (**1d** and **1e**) were synthesized from the corresponding 2′-hydroxychalcones (**2d** and **2e** respectively). The reactions carried out are summarized in Table 1, and the usual conversions of **2** in the range of 40—90% were obtained. On the other hand, the reaction of **2a** with a combination of the palladium(II) catalyst and the copper(II) chloride co-catalyst gave **1a** (yield=62%) and **3a** (yield=16%). In the conversion of **2** to **1** with palladium(II) salt, no formation of the five-membered-ring product [benzylidenebenzofuran-3(2H)-one] was observed.

Usually, the addition of oxygen nucleophile to the carbon-carbon double bond of the olefin-palladium complex proceeds by the attack at the double bond on the side opposite from that facing the metal.[5] In addition, Henry *et al.*[6] have recently reported that the oxidation of deuterated cyclohexene by a mixture of palladium(II) chloride and copper(II) chloride in acetic acid gave products which were consistent with a *trans* acetoxypalladation, followed by a *cis* palladium(II)-hydride elimination. The reaction of **2** with palladium(II) salt, therefore, involves an intramolecular *trans* phenoxypalladation, followed by a *cis* palladium(II)-hydride elimination. On the other hand, the formation of **3** proceeds *via* a base-catalyzed cyclization of **2**.

Experimental

Materials. All the melting points are uncorrected. The following compounds were synthesized by the methods described in the literature: 2′-hydroxychalcone (**2a**),[7] 2′-hydroxy-4-methoxychalcone (**2b**),[8] 2′-hydroxy-3,4-methylenedioxychalcone (**2c**),[9] 2′-hydroxy-5′-methoxychalcone (**2d**),[10] 2′-hydroxy-4′-methoxychalcone (**2e**),[11] 2′-hydroxy-4,4′-dimethoxychalcone (**2f**),[12] and 2′-hydroxy-4,5′-dimethoxychalcone (**2g**).[13]

General Procedure for the Preparation of 1. A solution of 10 mmol of **2** in benzene (20 ml) was stirred with 10 mmol of sodium methoxide for 5 min at room temperature. To the mixture, lithium chloropalladite or palladium(II) acetate (10 mmol in 70 ml of solvent) was then added, after which the mixture was stirred at reaction temperature. After the resulting mixture had been filtered to remove the precipitated palladium metal, the filtrate was evaporated to dryness *in vacuo* to remove the solvent. The residue was poured into water and extracted with chloroform. The chloroform solution was washed with water, and then dried over anhydrous magnesium sulfate. After the evaporation of the solvent, the products were isolated by column chromatograph on silica gel. The first elution with benzene afforded the unreacted starting material (**2**), while the second elution and recrystallization from ethanol afforded the respective flavanones (**3**). Further elution with benzene-chloroform

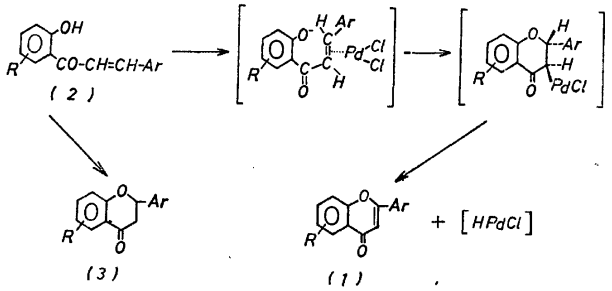

Fig. 1.

and recrystallization from benzene or ethanol afforded the respective flavones (**1**). The structures of the products were confirmed by mixed-melting-point determination with an authentic sample and by the observation of the IR and NMR spectra. The results are summarized in Table 1.

The authors would like to express their deep thanks to Mr. Hajime Baba of Yamagata University for his kind offering of the authentic samples, and to the Kawaken Fine Chemical Co., Ltd., for a gift of palladium chloride.

A New Synthesis of α,β-Unsaturated Carboxylic Esters. The Condensation of Ethyl Lithiotrimethylsilylacetate with Carbonyl Compounds

Hiroaki TAGUCHI, Katsuichi SHIMOJI, Hisashi YAMAMOTO, and Hitosi NOZAKI

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto 606

(Received May 27, 1974)

The key step of the title synthesis involves the conversion of ethyl trimethylsilylacetate to the corresponding enolate, **1**, by treatment with lithium dicyclohexylamide in tetrahydrofuran at −78 °C. The condensation of **1** with aldehydes and ketones proceeds smoothly to afford the desired two carbon homologated unsaturated esters in excellent yields. The new process is extended with success to readily-enolizable carbonyl compounds and also to chalcone, which gives no trace of the Michael adduct in the present reaction.

In the conversion of carbonyl compounds to two carbon-homologated α,β-unsaturated carboxylic esters, the most frequently used method is that of Emmons-Wadsworth-Horner olefin synthesis involving the phosphonate carbanions.[1] However, this method has certain limitations with such carbonyl compounds as highly-hindered or readily-enolizable ketones, which are often inert to this type of carbanion,[2] and also with enones which are susceptible to the Michael addition.[1f]

The present paper will be concerned with a new method for the above transformation using ethyl lithiotrimethylsilylacetate, **1**, which affords α,β-unsaturated carboxylic esters, **2**, exclusively in high yields.

1 **2**

This method is based upon a recent development in silicon-substituted carbanion chemistry, the Peterson olefin synthesis.[3] It should be noted, however, that the polarization of the silicon-carbon bond gives rise to a slight anionic character of the carbon, which is much intensified by the directly-attached electron-withdrawing carbonyl group. Ethyl trimethylsilylacetate and similar compounds containing such a $SiCH_2CO$ moiety have been known to undergo a facile heterolysis of the silicon to the carbon bond with diluted acids, alkalis, or even with ethanol.[4] The activation of the silicon-carbon bond by the ester substituent allows condensations in the presence of a basic catalyst to yield β-trimethylsiloxycarboxylate.[5] The previously-proposed mechanism involving ethyl sodiotrimethylsilylacetate has been questioned, and the intermediacy of ethyl sodioacetate has been proposed, the base attack occurring on the silicon atom under the Si–CH_2–bond heterolysis to form an ester enolate ion.[6]

Rathke has prepared lithium ester enolates by treating the corresponding esters with lithium *N*-isopropylcyclohexylamide or lithium bis(trimethylsilyl)amide.[7] This method utilizing the highly-hindered lithium amide has also been successfully applied to the formation of the desired lithium ester enolate, **1**.

The treatment of ethyl trimethylsilylacetate with lithium dicyclohexylamide was performed in dry tetrahydrofuran at −78 °C for 10 min. The quenching of the resulting anion, **1**, with water, followed by gas-liquid partition chromatography (glpc) yielded a 95% recovery of the starting ester. The formation of the **1** anion was further verified by the transformation of carbonyl compounds to the two carbon homologated carboxylic esters in the yields summarized in Table 1.

Table 1. Conversion of carbonyl compounds into **2** using ethyl lithiotrimethylsilylacetate

R^1–CO–R^2	Yield of **2** (%)[a),b)]	Bp bath temp	*E*—*Z* ratio
Benzaldehyde	84	126 °C (2 mmHg)	3 : 1—9 : 1[c,e)]
Nonanal	81	148 °C (2 mmHg)	1 : 1[d)]
Cyclohexanone	95	132 °C (15 mmHg)	—
Cyclododecanone	94	155 °C (2 mmHg)	—
Cyclopentanone	81	120 °C (15 mmHg)	—
Chalcone	86	176 °C (0.5 mmHg)	7 : 3[d,g)]
Acetophenone	63	140 °C (4 mmHg)	2 : 1[d)]
Pinacolone	21	116 °C (12 mmHg)	[f)]
β-Ionone	82	150 °C (3 mmHg)	3 : 2[d)]

a) All products were characterized by spectroscopic methods and elemental analyses. b) Yields are based on material isolated by chromatography. c) Isomer ratio was variable according to the reaction condition. d) Determined by isolation ratio. e) Determined by glpc. f) The *Z* isomer was undetectable by NMR assay. g) The *E* configuration of C(4)—C(5) double bond is retained.

In Wittig-type reactions, cyclopentanone often fails to give the desired products because of its high degree of enolization.[2a,c] Proton-transfer reaction may occur faster than carbonyl addition, with the consequent risk of the isomerization of the resulting α,β-unsaturated esters and/or condensation reactions of the ketone enolate. Nevertheless, we obtain exclusively ethyl cyclopentylideneacetate in a good yield. The reaction mixture must be quenched at −25 °C in this case; otherwise, an appreciable amount (as high as 10%) of the isomerized, endo-olefinic β,γ-unsaturated ester is detected by NMR assay.

As expected, however, the condensation of lithium enolate, **1**, with highly-hindered pinacolone gave a poor yield of the desired adduct.

Few examples of the Wittig-Horner reaction of α,β-unsaturated ketones have been recorded. Only chalcone is known to react with the phosphonate carbanions to give a Michael and/or a Wittig-Horner product in low yields.[1f] We found that the lithium enolate, **1**, gave solely the expected normal product, ethyl 3,5-diphenylpenta-2,4-dienoate.

β-Ionylideneacetate is one of the important intermediates in the synthesis of vitamin A and its analogs.[8] The lithium enolate, **1**, proved to react with β-ionone smoothly to give the trienic ester.

In those instances where the formation of both *cis* and *trans* esters were possible, the isomer ratios are as given in Table 1. The stereochemistry was assigned on the basis of the NMR data; the shift values of the vinylic protons were diagnostic (for details, see the Experimental section).[10]

Experimental

The IR spectra were determined on a Shimadzu IR-27-G spectrometer; the UV spectra, on a Shimadzu MPS-50-L spectrometer; the mass spectra, on a Hitachi RMU-6L mass spectrometer; the glpc analyses, on a Yanagimoto GCG-550F, and the NMR spectra, on a JEOL C-60-H or Varian EM-360 spectrometer. The chemical shifts are given in δ, with TMS as the internal standard. The analyses were carried out by Mrs. Kiyoko Fujimoto, Prof. Kawanisi's Laboratory and by the staff at the Elemental Analyses Center of Kyoto University. All the experiments were carried out under an atmosphere of dry nitrogen, by preparative thin-layer chromatography (plc) on silica gel PF-254 plates(Merck) with benzene as an eluent, and by preparative column chromatography on silica gel Wakogel C-100 (Wako).

Preparation of Ethyl Trimethylsilylacetate. Ethyl trimethylsilylacetate was prepared by the method of Fessenden[9] in a 71% yield after distillation; bp 65 °C (68 mmHg).

*Generation of Ethyl Lithiotrimethylsilylacetate (**1**).* Dicyclohexylamine (365 mg, 2.00 mmol) was dissolved in dry tetrahydrofuran (10 ml). The solution was then cooled to −78 °C and treated with *n*-butyllithium dissolved in hexane (1.35 ml of 1.50 M solution). After it has been stirred for 15 min, a solution of ethyl trimethylsilylacetate (320 mg, 2.00 mmol) in dry tetrahydrofuran (1.0 ml) was added, drop by drop, at −78 °C, and the resulting solution was stirred at the same temperature for 10 min before the subsequent treatments to be described below.

*Quenching of Lithium Enolate, **1**, with Water.* A solution of **1** prepared from 320 mg (2.00 mmol) of ethyl trimethylsilylacetate was simply quenched with water at −78 °C. A subsequent glpc analysis of the organic layer with tetralin as an internal standard indicated a 95% recovery of the starting ethyl trimethylsilylacetate.

*Condensation of Lithium Enolate, **1**, with Aldehydes.* To a solution of **1** (1.20 mmol), a solution of the respective aldehyde (1.00 mmol) in dry tetrahydrofuran (1.0 ml) was added, drop by drop, at −78 °C. The reaction mixture was stirred at −78 °C for 1 hr, at −25 °C for 1 hr, and finally at 25 °C for 1 hr. Finely-ground sodium bisulfate monohydrate (0.22 g) was then added, and the mixture was stirred for 10 min. The solid was filtered off, and water was added to the filtrate. This solution was extracted with three 5-ml portions of ethyl acetate. The extracts were combined, dried, and evaporated *in vacuo* to yield an oily product, which was subsequently purified by plc.

*Ethyl (*E*) and (*Z*)-Cinnamate* were prepared from lithium enolate, **1** (1.20 mmol), and benzaldehyde (108 mg, 1.00 mmol). The crude product was purified by plc, thus furnishing 147 mg (84%) of ethyl cinnamate ((*E*) : (*Z*)=8 : 1). The isomers were separated on a 75 cm×3 mm 5% SE 30 on Chromosorb W column at 120 °C.

*Ethyl (*E*) and (*Z*)-2-Undecenoate* were prepared from **1** and nonanal (142 mg, 1.00 mmol). The resulting oil was chromatographed on a silica-gel thin-layer plate. The first band contained ethyl (*Z*)-2-undecenoate (51 mg, 24%): IR (neat) 1724, 1646, 1470, 1418, 1186, 1040, 822 cm^{-1}; NMR ($CDCl_3$) δ 0.68—1.04 (m, 3H), 1.05—1.75 (m, 12H), 1.24 (t, J=7, 3H), 2.57 (br d, 2H), 4.06 (q, J=7, 2H), 5.62 (d, J=9.3, 1H), 6.05 (d, J=9.3 Hz, t, J=6.3 Hz, 1H); mass *m/e* (%) 212 (17), 183 (3), 169 (32), 127 (81), 115 (32), 101 (28), 99 (100), 88 (42), 81 (42), 77 (33), 69 (39), 55 (72). The second band was ethyl (*E*)-2-undecenoate (128 mg, 58%): IR (neat) 1724, 1656, 1470, 1270, 1185, 1047, 985 cm^{-1}; NMR ($CDCl_3$) δ 0.70—1.08 (m, 3H), 1.09—1.85 (m, 12H), 1.28 (t, J=7 Hz, 3H), 2.18 (br t, 2H), 4.18 (q, J=7 Hz, 2H), 5.74 (d, J=15 Hz, 1H), 6.86 (t, J=7 Hz, d, J=15 Hz, 1H); mass *m/e* (%) 212 (2), 185 (3), 183 (2), 167 (42), 127 (8), 125 (33), 115 (20), 101 (71), 99 (34), 88 (44), 73 (64), 69 (47), 55 (100). (Found: C, 73.7; H, 11.4%).

*Condensation of Lithium Enolate, **1**, with Ketones.* To a solution of **1** (2.00 mmol), a solution of ketone (1.00 mmol) in dry tetrahydrofuran (1.0 ml) was added, drop by drop, at −78 °C. The resulting mixture was stirred at −78 °C for 1 hr, at −25 °C for 1 hr, and finally at 25 °C for 1 hr. Finely-ground sodium bisulfate monohydrate (0.40 g) was then added, and the mixture was stirred for 10 min. A subsequent work-up yielded an oil, which was purified by silica-gel chromatography, with benzene (plc) or hexane (column) as the eluent.

Ethyl Cyclododecylidenaecetate was prepared from **1** (20.0 mmol) and cyclododecanone (1.82 g, 10.0 mmol). The crude product was chromatographed over a 100-g silica gel column, thus furnishing 2.36 g (94%) of ethyl cyclododecylideneacetate as a colorless semisolid; bp 155 °C (bath temp, 2 mmHg); IR (neat) 1720, 1644, 1468, 1444, 1170, 1150, 1036 cm^{-1}; NMR (CCl_4) δ 1.24 (t, J=7 Hz, 3H), 1.20—2.00 (m, 18H), 2.21 (br t, J=7 Hz, 2H), 2.71 (br t, J=7 Hz, 2H), 4.06 (q, J=7 Hz, 2H), 5.63 (br s, 1H); mass *m/e* (%) 252 (27), 207 (36), 164 (60), 128 (100). (Found: C, 75.9; H, 11.1%).

Ethyl Cyclohexylideneacetate was prepared from **1** (2.00 mmol) and cyclohexanone (98.0 mg, 1.00 mmol). The liquid thus obtained was purified by plc thus furnishing 159 mg (95%) of ethyl cyclohexylideneacetate as an oil.

Ethyl cyclopentylideneacetate was prepared from cyclopentanone (84 mg, 1.00 mmol), the reaction being quenched by the addition of water at −25 °C. The liquid thus obtained was purified by plc, thus furnishing 125 mg (81%) of ethyl cyclopentylideneacetate as an oil: IR (neat) 1718, 1655, 1377, 1250, 1205, 1125, 1045, 860 cm^{-1}; NMR (CCl_4) δ 1.23 (t, J=7 Hz, 3H), 1.50—2.03 (m, 4H), 2.10—3.07 (m, 4H), 4.10 (q, J=7 Hz, 2H), 5.70 (s, 1H); mass *m/e* (%) 154 (88), 140 (50), 126 (80), 109 (100), 97 (32), 81 (85), 79 (64), 67 (96); Found: C, 70.3; H, 9.20%. Calcd for $C_9H_{14}O_2$: C, 70.1; H, 9.15%.

*Ethyl 3,5-Diphenylpenta-(2*E*,4*E*) and (2*Z*,4*E*)-dienoate* were prepared from **1** (2 mmol) and chalcone (108 mg, 1.00 mmol). The crude oil was purified by plc. The first band contained ethyl 3,5-diphenylpenta-(2*Z*,4*E*)-dienoate (72 mg, 26%): IR (neat) 1715, 1610, 1588, 1275, 1230, 1155, 1100, 1034, 964, 753, 690 cm^{-1}; NMR (CCl_4) δ 1.30 (t, J=7 Hz, 3H), 4.26 (q, J=7 Hz, 2H), 5.90 (s, 1H), 6.44 (d, J=16 Hz, 1H), 7.35 (d, J=16 Hz, 1H), 7.36 (m, 10H); UV λ_{max}^{EtOH} 314 nm (ε 833); mass *m/e* (%) 278 (18), 249 (3), 233 (11), 205 (100), 190 (8), 178 (6), 165(4), 137 (9), 105 (6), 101 (9), 91 (9), 89 (7), 77 (13). The second band was ethyl 3,5-diphenylpenta-(2*E*,4*E*)-dienoate (168 mg, 60%): IR (neat) 1712, 1610, 1590, 1275, 1230, 1155, 1100, 1034, 965, 753, 690 cm^{-1}; NMR (CCl_4) δ 1.04 (t, J=8 Hz, 3H), 4.02 (q, J=8 Hz, 2H), 6.06 (s, 1H), 6.33 (d, J=14 Hz, 1H) 7.04 (d, J=14 Hz,

1H), 7.30 (m, 10H); UV λ_{max}^{EtOH} 316 nm (ε 716); mass *m/e* (%) 278 (15), 249 (4), 233 (10), 205 (100), 190 (9), 178 (7), 165 (5), 127 (12), 115 (5), 101 (11), 91 (10), 89 (10), 77 (18).

Ethyl (E) and (Z)-3-Phenyl-2-butenoate were prepared from **1** (4 mmol) and acetophenone (240 mg, 2.00 mmol). The crude mixture was chromatographed on a silica-gel plate. The first band consisted of ethyl (*E*)-3-phenyl-2-butenoate (165 mg, 43%): IR (neat) 1710, 1628, 1447, 1346, 1273, 1170, 1044, 870, 767, 696 cm^{-1}; NMR ($CDCl_3$) δ 1.27 (t, J=7 Hz, 3H), 2.52 (d, J=2 Hz, 3H), 4.13 (q, J=7 Hz, 2H), 6.02 (m, 1H), 7.30 (m, 5H); mass *m/e* (%) 190 (63), 175 (4), 161 (32), 145 (100), 115 (56), 101 (10), 91 (28). The second band was ethyl (*Z*)-3-phenyl-2-butenoate (74 mg, 20%): IR (neat) 1715, 1640, 1443, 1375, 1230, 1160, 1045, 857, 768, 700 cm^{-1}; NMR ($CDCl_3$) δ 1.05 (t, J=7 Hz, 3H), 2.12 (d, J=2 Hz, 3H), 3.90 (q, J=7, 2H), 5.71 (m, 1H), 7.15 (m, 5H); mass *m/e* (%) 190 (68), 161 (40), 145 (100), 115 (70), 105 (17), 91 (30). A mixture of the (E) and (Z) isomers was analyzed. Found: C, 75.6; H, 7.52%. Calcd for $C_{12}H_{14}O_2$: C, 75.8; H, 7.42%.

Ethyl 3,4,4-Trimethyl-2-pentenoate was prepared from **1** (4.00 mmol) and pinacolone (200 mg, 2.00 mmol). The crude liquid was purified by plc, thus furnishing 67 mg (21%) of ethyl (*E*)-3,4,4-trimethyl-2-pentenoate: IR (neat) 1717, 1636, 1263, 1180, 1122, 1054, 868 cm^{-1}; NMR ($CDCl_3$) δ 1.10 (s, 9H), 1.23 (t, J=7, 3H), 2.08 (d, J=1, 3H), 4.00 q, J=7, 2H), 5.53 (d, J=1, 1H): mass *m/e* (%) 170 (20), 155 (66), 127 (54), 125 (70), 109 (50), 97 (100), 83 (36), 81 (36), 69 (31), 57 (36), 55 (74). Found: C, 70.7; H, 10.9%. Calcd for $C_{10}H_{18}O_2$: C, 70.5; H, 10.7%.

Ethyl (E) and (Z)-β-Ionylideneacetate were prepared from **1** (4.00 mmol) and β-ionone (384 mg, 2.00 mmol). The crude oil was purified by plc, thus furnishing 430 mg (82%) of ethyl β-ionylideneacetate ((*E*) : (*Z*)=3 : 2). The isomers were separated on a 75 cm×3 mm 5% SE 30 on Chromosorb W column at 170°. The first peak was ethyl (*Z*)-β-ionylideneacetate: IR (neat) 1710, 1610, 1450, 1376, 1230, 1155, 1053, 983, 842 cm^{-1}; NMR (CCl_4) δ 1.06 (s, 6H), 1.24 (t, J=7 Hz, 3H), 1.43—2.60 (m, 6H), 1.75 (s, 3H), 2.00 (s, 3H), 4.05 (q, J=7, 2H), 5.50 (br s, 1H), 6.42 (d, J=16 Hz, 1H), 7.52 (d, J=16 Hz, 1H); mass *m/e* (%) 262 (38), 247 (16), 233 (8), 217 (20), 201 (20), 189 (24), 173 (40), 159 (32), 133 (52), 119 (100), 105 (40), 91 (32). The second peak was ethyl (*E*)-β-ionylideneacetate: IR (neat) 1710, 1605, 1443, 1366, 1236, 1154, 1047, 970 cm^{-1}; NMR (CCl_4) δ 1.02 (s, 6H), 1.25 (t, J=7 Hz, 3H), 1.44—2.85 (m, 6H), 1.54 (s, 3H), 1.68 (s, 3H), 2.33 (s, 3H), 4.06 (q, J=7 Hz, 2H), 5.62 (br s, 1H), 6.00 (d, J=16 Hz, 1H), 6.43 (d, J=16 Hz, 1H); mass *m/e* (%) 262 (26), 247 (10), 233 (5), 217 (15), 201 (15), 189 (15), 173 (33), 159 (32), 133 (46), 119 (100), 105 (34), 91 (25). A mixture of the (*E*) and (*Z*) isomers was analyzed. Found: C, 78.1; H, 10.1%. Calcd for $C_{17}H_{26}O_2$: C, 77.8; H, 10.0%.

X-Ray Photoelectron Spectroscopic Study of the Reaction of Evaporated Iron, Nickel, and Palladium with Nitric Oxide

Kosaku KISHI and Shigero IKEDA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received December 14, 1973)

The reaction of the evaporated iron, nickel, and palladium with NO was investigated by X-ray photoelectron spectroscopy. On both iron and nickel larger part of NO dissociates to give two or more N(1s) and O(1s) photoelectron peaks which are ascribable to the surface oxide, nitride, and NO species. The proportion of these species is estimated roughly from the intensity ratios of the N(1s) and O(1s) peaks at 15 NO: 65 O: 20 N (iron) and 7 NO: 65 O: 28 N (nickel) when the metals are exposed to 5 Torr of NO gasfor 1 s, and 35 NO: 55 O: 10 N (iron) and 10 NO: 75 O: 15 N (nickel) when exposed to 10 Torr of NO for 10 min. On palladium the N(1s) for chemisorbed NO is observed. The N(1s) binding energies of the surface NO are compared with the N(1s) binding energies and the infrared NO frequencies of the corresponding transition metal nitrosyls.

The NO molecule has one electron in an antibonding π orbital and, in transition metal nitrosyls, bonds to a metal atom at various electronic states.[1] Two limiting species are linearly coordinated NO^+ and angularly coordinated (bent) NO^-. Chemisorbed NO on transition metals is expected to take various bonding and electronic structures. An electronic structure of NO has a significant resemblance to and yet a difference from CO and O_2 whose chemisorption has been widely investigated.

Infrared studies of NO adsorption on transition metals have been reported by Terenin and Roev,[2] Dunken and Hobert,[3] and Blyholder and Allen.[4] Two or more bands of NO stretching were observed for chemisorbed NO. These bands have been assigned to structures described as ionic, covalent, or coordinative[2] and discussed on correlating their frequencies to the extent of π back-bonding to NO.[4] Sachtler[5] has reported that NO partially dissociates on nickel and both chemisorbed NO and oxygen exist on the surface.

In the present paper, X-ray photoelectron spectroscopy (ESCA) is applied to observe the reaction of evaporated iron, nickel, and palladium in order to characterize the surface species and to check an existence of surface nitride.

Experimental

Metals were evaporated onto a stainless steel plate at 10^{-6} Torr as described elsewhere.[6] The evaporated metal film was exposed to the gas to be studied at room temperature after about 10 s from evaporation. After evacuation of the gas for 5 min, photoelectron spectra of the surface species formed were recorded. During the spectral measurement, the vacuum was maintained at 10^{-7} Torr.

NO gas was obtained from Takachiho Kagaku Kogyo.

Spectra were recorded in 0.1 eV steps on a KES-X2001 (Kokusai Electric Co.) electron spectrometer using Al$K\alpha$ (for nickel and palladium) and Mg$K\alpha$ (for iron) X-radiation. The binding energy reference is the Fermi level which is taken as the inflection point of the low-energy edge of the 4d band of palladium according to Baer *et al.*[7]

Results

When evaporated iron was exposed to NO at a pressure of 5 Torr for about 1 s, the broad N(1s) peaks were observed at the binding energies of 396.6 and 400.7 eV (Fig. 1-a). Both minimum and maximum counting rates (counts/5 s) are shown in parentheses in the figures. The O(1s) peaks were at 530.0 and around 533.0 eV (Fig. 2-a). The Fe($2p_{3/2}$) were at 707.0 and around 709.8 eV (Fig. 3-a). The chemical shift of the latter peak is about 2.8 eV from the former which is due to metallic iron.

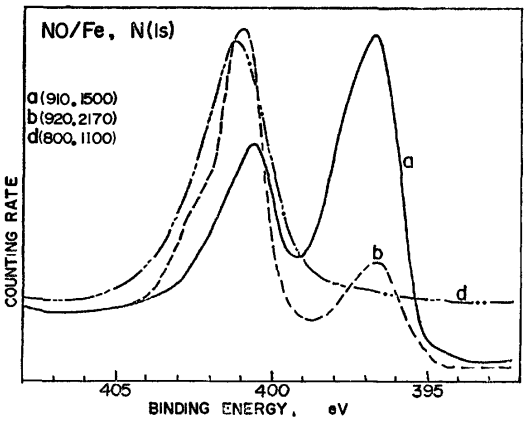

Fig. 1. N(1s) peaks from evaporated iron exposed to (a) 5 Torr of NO for about 1 s, (b) 10 Torr of NO for 10 min, (d) 10 Torr of NO for 10 min after exposure to 20 Torr of air for 5 min.

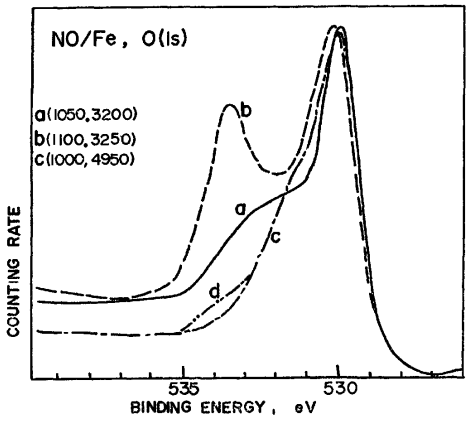

Fig. 2. O(1s) peaks from evaporated iron exposed to (a) 5 Torr of NO for about 1 s, (b) 10 Torr of NO for 10 min, (c) 20 Torr of air for 5 min, (d) 10 Torr of NO for 10 min after c.

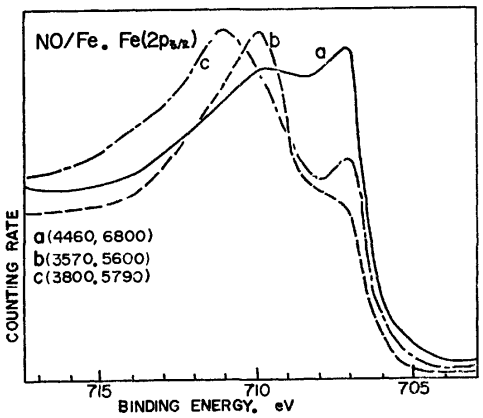

Fig. 3. $Fe(2p_{3/2})$ peaks from evaporated iron exposed to (a) 5 Torr of NO for about 1 s, (b) 10 Torr of NO for 10 min, (c) 20 Torr of air for 5 min.

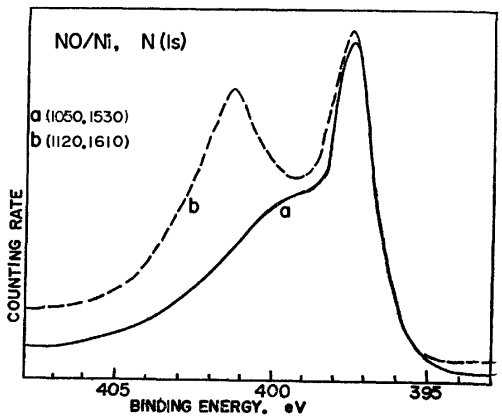

Fig. 4. N(1s) peaks from evaporated nickel exposed to (a) 5 Torr of NO for about 1 s, (b) 10 Torr of NO for 10 min.

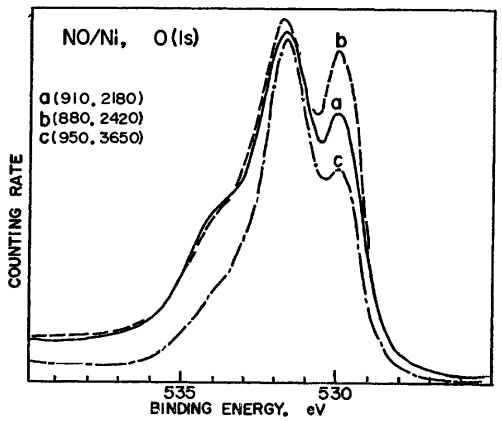

Fig. 5. O(1 s) peaks from evaporated nickel exposed to (a) 5 Torr of NO for about 1 s, (b) 10 Torr of NO for 10 min, (c) 20 Torr of air for 5 min.

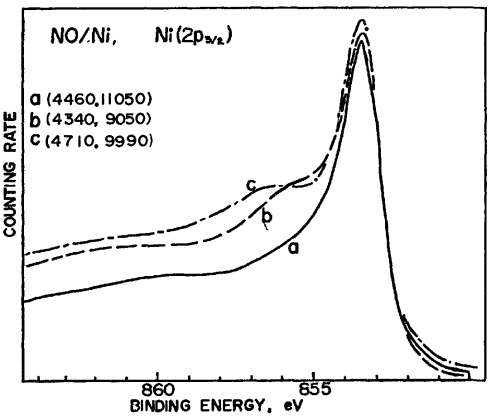

Fig. 6. $Ni(2p_{3/2})$ peaks from evaported nickel exposed to (a) 5 Torr of NO for about 1 s, (b) 10 Torr of NO for 10 min, (c) 20 Torr of air for 5 min.

Spectra b of Figs. 1 to 3 were recorded after evaporated iron was exposed to NO at a pressure of 10 Torr for 10 min. The N(1s) peaks are at 396.6 and 401.0 eV with a shoulder around 402.5 eV. The peak at 401.0 eV and the shoulder decreased in intensity with time during the spectral measurement while the 396.6 eV peak not at all. For example, the original 401.0 eV peak was depressed to one thirds after 1 hr. The N(1s), O(1s), and metal peaks (Figs. 1 to 3 for iron and 4 to 6 nickel) were recorded in this order within 1 hr. The 401.0 eV peak is considerably stronger in intensity than the 400.7 eV peak in Fig. 1-a. The O(1s) peaks are at 530.2 and 533.5 eV. The $Fe(2p_{3/2})$ peaks are at 707.0 and 710.0 eV. The 707.0 eV peak due to metallic iron is further depressed from that of spectrum a.

Spectra c of Figs. 2 and 3 were recorded after evaporated iron was exposed to air at a pressure of 20 Torr for 5 min. The intense O(1s) peak was observed at 530.0 eV with a shoulder around 531.7 eV. The $Fe(2p_{3/2})$ of oxidized iron shows a chemical shift of 4.0 eV from metallic iron which is 1.0 eV larger than when iron was exposed to NO. This surface oxide was subsequently exposed to NO at a pressure of 10 Torr for 10 min and spectra of Figs. 1 and 2 were recorded. The N(1s) electrons give only one broad peak at 401.3 eV and a weak O(1s) peak appeared at 533.7 eV. The above spectral data of N(1s) peaks are summarized in Table 1 with infrared data. The corresponding data of various compounds are also listed.

Spectra a of Figs. 4 to 6 were recorded after evaporated nickel was exposed to NO at a pressure of 5 Torr for about 1s. The N(1s) peaks are at 397.6 and around 400.2 eV. The O(1s) peaks are at 530.1, 531.7, and 533.3 eV. The $Ni(2p_{3/2})$ spectrum shows a peak at 853.5 eV due to metallic nickel and broad enhancement of intensity in the region from 854.8 to 859.5 eV as compared with the spectrum of unreacted nickel.

Spectra b of Figs. 4 to 6 were recorded after evaporated nickel was exposed to NO at a pressure of 10 Torr for 10 min. The N(1s) peaks are at 397.6 and 401.3 eV. Three O(1s) peaks are at the same binding energies as those in spectrum a. A shifted $Ni(2p_{3/2})$ peak is clearly shown at 855.9 eV; 2.4 eV from metallic nickel.

Spectra c of Figs. 5 and 6 were observed after evaporated nickel was exposed to air at a pressure of 20 Torr for 5 min. The binding energies of three O(1s) peaks are the same as those of spectra a and b. The chemical shift of $Ni(2p_{3/2})$ peak of oxidized nickel

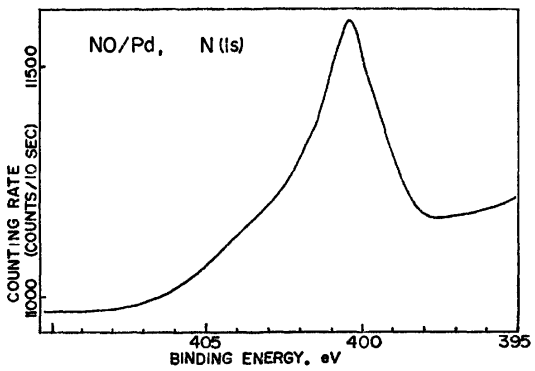

Fig. 7. N(1s) peaks from evaporated palladium exposed to 10 Torr of NO for 10 min.

is larger by 0.5 eV than that obtained when nickel was exposed to NO. After this surface oxide was subsequently exposed to NO at a pressure of 10 Torr for 10 min, no N(1s) peak could be detected even after counting the photoelectrons for 10 s/channel.

Figure 7 shows the N(1s) spectrum when evaporated palladium was exposed to NO at a pressure of 10 Torr for 10 min. The peak is at 400.4 eV and a very weak shoulder around 403.5 eV. The Pd 3d spectrum was the same in shape as that for unreacted palladium and no new peak was observed. The Pd($3p_{3/2}$) electrons give a strong peak at 532.7 eV and make the O(1s) peaks indistinct. The shape of Pd($3p_{3/2}$) peak is almost the same as that for unreacted palladium; indicating a low counting rate for O(1s) peaks.

When evaporated palladium was exposed to NO at a pressure of 5 Torr for about 1 s, the intensity of N(1s) peak at 400.4 eV was two thirds of that in Fig. 7 and the 403.5-eV shoulder could not be detected.

Discussion

The results for evaporated iron, nickel, and palladium reacted with NO show two or more N(1s) peaks (Table 1). The binding energy of N(1s) in NO_3^- or NO_2^- of $NaNO_3$(407.4 eV), $NaNO_2$ (404.1 eV), or of their transition metal compounds is much larger[8] than that obtained from the reaction of NO with the metals except the 403.5-eV peak in case of palladium. The N(1s) peaks from 400.2 to 402.5 eV for the surface species correspond in binding energy well with those in transition metal nitrosyls whose binding energies lie between 399.6 and 403.3 eV[8,9] and these peaks are, therefore, assigned to surface NO species.[10] The decrease in intensities of these peaks during spectra measurement is due to NO desorption occurred probably by evacuation or ejected electrons on the surface.

The N(1s) peaks at 396.6 eV for iron and 397.6 eV for nickel are smaller by 2.0 eV or more than that of NO^- in the metal nitrosyls. These peaks are reasonably assigned to the surface nitride since the N(1s) binding energies of VN and CrN are 397.2 and 396.6 eV, respectively.[8] The dissociation of NO on nickel has been reported.[4,5] The above results indicate that the dissociated nitrogen are in part present in the surface compounds on iron and nickel without recombining nitrogen molecule. From the N(1s) binding energies, the nitride-nitrogen is likely to be more ionic (negative) on iron than on nickel. This is similar to that the main oxygen species is smaller by 1.7 eV in binding energy of O(1s) peak (namely, more negative) on iron than on nickel when exposed to air. The absence of the nitride peak in case of palladium shows quite different reactivity to NO from nickel and indicates less stability of nitride or oxide on palladium surface at room temperature.

When iron and nickel were exposed to NO, the strongest O(1s) peak is at 530.0 eV in case of iron (Fig. 2) and at 531.7 eV in case of nickel (Fig. 5); being with the same binding energy as that obtained when each evaporated metal was exposed to air. In case of nickel exposed to air, the 531.7-eV peak does not correspond to the O(1s) of NiO (530.0 eV) and has been assigned to the surface oxide[11] or Ni_2O_3.[12] These facts also indicate that a large amount of oxygen anions are present on iron and nickel as a result of the dissociative reaction of NO.

When iron was preoxidized by air, the N(1s) due to

Table 1. Nitrogen 1s binding energies and NO stretching frequencies

Samples		N(1s) B. E., eV	ν(NO), cm^{-1}

a) NO exposure; 5 Torr for 1s. b) NO exposure; 10 Torr for 10 min.

the nitride could not be detected (Fig. 1-d). This indicates that the NO dissociation is effective on metal surfaces but not on the surface oxides.

The O(1s) peak at 533.5 eV in case b of Fig. 2 shows a fairly strong intensity and, under this reaction condition, the N(1s) peak at 401.0 eV is quite strong (case b of Fig. 1). Moreover, a weak O(1s) peak appeared at 533.7 eV (d of Fig. 2) with the appearance of the N(1s) peak at 401.3 eV (d of Fig. 1) when preoxidized iron surface was exposed to NO. These results indicate that the O(1s) at 533.5 eV and the N(1s) at 401.0 eV come from the same NO species. This is also affirmed by the counting rate ratio of the O(1s) and N(1s) peaks. The ratio of O(1s) peak to N(1s) peak in $NaNO_3$ is namely 1.2 per atom. In cases b of Figs. 1 and 2, the ratio is 1.25 for the O(1s) at 533.5 eV to the N(1s) at 401.0 eV.

In case of nickel, the O(1s) peak at 533.5 eV appears even when evaporated nickel was exposed to air (c of Fig. 5). This weak peak has been proposed as atomic oxygen adsorbed on nickel.[12]

In cases of iron, the ratio of NO to oxygen anion is derived approximately as 0.23 (case a) and 0.64 (case b), respectively, from the intensity ratio of the O(1s) peaks around 533 eV to the one at 530.0 eV of Fig. 2. This indicates that the initial reaction of NO with iron is, in larger part, the dissociative. Also from the intensity ratios of the N(1s) at 396.6 eV was the O(1s) at 530.0 eV in Figs. 1 and 2 and the counting ratio, 1.2, of O(1s) to N(1s), roughly 1/3 (case a) and 1/5 (case b) of nitrogen atoms formed by NO dissociation are estimated to remain on iron surface without recombining into molecular nitrogen. In other words, the proportion of the surface species is roughly, 15 NO: 65 O: 20 N in case a and 35 NO: 55 O: 10 N in case b.

In case of nickel, the corresponding values are roughly 7 : 65 : 28 (case a) and 10 : 75 : 15 (case b) which were estimated from the intensity ratio of the N(1s) at 400.2 eV (case a) or 401.3 eV (case b) for NO, the O(1s) at 530.1 eV plus the O(1s) at 531.7 eV for O, and the N(1s) at 397.6 eV for N.

When evaporated iron was exposed to air at a pressure of 20 Torr for 5 s, iron surface was oxidized nearly to Fe(III) as evidenced by the chemical shift, 4.0 eV, for Fe ($2p_{3/2}$) peak (Fig. 3-c) since that of Fe_2O_3 is 4.2 eV.[6] In case b of Fig. 3, the iron surface was oxidized by exposure to NO approximately to the same depth as in case c as shown by the similar intensity ratio of the two Fe($2p_{3/2}$) peaks which come from unreacted and oxidized iron in both cases. However, the chemical shift in case b is 3.0 eV and smaller by 1.0 eV than that in case c. This indicates that the iron atom on the surface is with higher electron densities in case b than in case c.

In case of nickel, the chemical shift of Ni($2p_{3/2}$) is also smaller when exposed to NO (2.4 eV in Fig. 6-b) than when exposed to air (2.9 eV in c). This also indicates that a surface nickel atom is with higher electron densities when reacted with NO than when oxidized with air.

Blyholder and Allen[4] have explained variations in NO stretching frequencies of the chemisorbed NO by the amount of charge in the second lowest π orbital of the Ni-N-O system, antibonding for the N-O bond but bonding for the Ni–N bond, which is depending on the number of metal atoms around the metal atom to which the chemisorbed NO is bound. In cases of iron and nickel, however, the surface oxygen and nitrogen anion as ligands are expected to take more important role in variations of NO stretching frequencies when considering the present photoelectron data, namely, the extent of surface oxidation and the proportions NO, O, and N on the surfaces. In $\{RuCl(NO)_2[P(C_6H_5)_3]_2\}PF_6$ complex, two different types of nitrosyls are bonded to the same metal atom;[13] linear equatorial nitrosyl (N(1s): 402.6 eV,[9] NO str. freq.: 1845 cm^{-1} [13]) and apical bent nitrosyl (400.2 eV, 1687 cm^{-1}). The surface compounds on the metal which have mixed ligands (NO, O, N) will also have various coordination geometries, coordination numbers, and electronic states. The metal atom surrounded by larger number of oxygen or nitrogen anions, especially oxygen, draws electrons from the NO to larger extent and gives higher binding energy of N(1s) peak and higher frequency of NO band as discussed below. Among the metal nitrosyls, bent nitrosyls (formally NO^-) generally show low binding energy of N(1s) peak and linear nitrosyls (NO^+) can show either low or high binding energy peak depending on the extent of π back-bonding from the metal.[9] The N(1s) binding energies are expected to be correlated with NO stretching frequencies in metal nitrosyls since the high positive charge on NO means less electrons on the orbital which is antibonding for the NO bond and, consequently, higher NO frequency. Such but rough correlations have been reported for many nitrosyl complexes.[9] For the iron complexes listed in Table 1, a good correlation is shown between the N(1s) binding energies and the NO stretching frequencies. The NO groups have been concluded to have relatively high positive charges in the upper two complexes and negative charges in the fourth complex. For the surface NO groups, the N(1s) of 401.0 eV and the NO str. freq. of 1720 cm^{-1} [4] correspond to the 401.2 eV[9] and the 1760-cm^{-1} [14] for $[Fe(NO)(diars)_2](ClO_4)_2$ and the 402.5 eV and the 1810-cm^{-1} to the 402.9 eV and the 1865 cm^{-1} [15] for $[FeCl(NO)(diars)](ClO_4)_2$. This means that the positive charges on NO groups increase and, namely, the π back donation to the NO decrease as NO oxidizes iron surface to larger extent as a result of dissociative reaction and the surface NO species increase in number.

The intensity of 401.0-eV peak is stronger than that of the 402.5 eV peak in case b of Fig. 1 while the the intensity of the 1720-cm^{-1} band is weaker than that of the 1810-cm^{-1} band for evaporated iron particles in an oil exposed to 10 Torr for NO 1 hr.[4] In the experiment by Terenin,[2] the 1805-cm^{-1} band shows approximately the same intensity as the 1735-cm^{-1} band for dispersed iron on alumina exposed to 20 Torr NO. This may suggest that the infrared bands were obtained the sample which was oxidized to larger extent by the dissociative reaction of NO and was bonded by larger number of NO species than the present photoelectron peaks were. The *trans*-[FeCl-

$(NO)(diars)_2](ClO_4)_2$ underwent decomposition in the X-ray beam, as evidenced by a gradual growth of a 400.4 eV peak at the expense of the 402.9 eV peak.[9] Such phenomenon also explains the intense 401.0 eV peak for the surface NO species.

The N(1s) binding energy for the chemisorbed NO on nickel is 400.2 eV (case a) and 401.3 eV (case b). The former value is near to that in $NiCl(NO)[P(C_6H_5)_3]_2$ (399.8 eV) and $Ni(N_3)(NO)[P(C_6H_5)_3]_2$ (399.6 eV,[9] Ni-N-O angle: 152.7°[16]). The NO frequency in $NiX(NO)[P(C_6H_5)_3]_2$ (X=Br, I) is 1735 cm^{-1}.[17] The weak 1735-cm^{-1} band for chemisorbed NO[2] seems to correspond to the surface NO species giving 400.2 eV peak. The low binding energy of N(1s) suggests a small negative charge on the surface NO. 401.3 eV peak in case b indicates less electron donation to NO from the nickel atom at higher oxidation state and is presumably associated with the NO giving the 1840-cm^{-1} band[4] (or 1850-cm^{-1} band[2]).

The low binding energy of N(1s) peak (400.4 eV) in case of palladium suggests that the surface NO groups bond to the palladium atom at very low oxidation state. This is in accord with the facts that the intense O(1s) peak was absent and no new peak for O (3d) due to oxidized palladium was detected. The surface NO may have small negative charge on it. Strongly chemisorbed NO on palladium supported on silica gives bands at 1845 and 1765 cm^{-1}.[3] However, the correspondence of the photoelectron peaks with the infrared bands is uncertain at present.

The authors wish to thank for the Ministry of Education for the financial support granted for this research.

Far Infrared Spectra and Internal Rotation of Ethyl Fluoride and Deuterated Species

Hiromu SUGETA, Yoshio ADACHI, and Tatsuo MIYAZAWA*

Institute for Protein Research, Osaka University, Yamada-kami, Suita, Osaka 565

(Received January 12, 1974)

Far infrared spectra were measured of ethyl fluoride CH_3CH_2F and deuterated species CH_3CD_2F, CD_3CH_2F, and CD_3CD_2F in the gaseous state. The potential barriers hindering the internal rotation were calculated with various models. Possibly because of isotope effects on structure relaxations due to torsional motion and to zero-point motion of other vibrational modes, the observed potential barriers are slightly different among isotopic molecules; the threefold barrier is lowered on the deuteration of the methyl group. The absorption intensities of the four isotopic species were also measured. The intensity of the torsional vibration of the methyl group is nearly doubled on deuteration of the methyl group but is reduced on deuteration of the methylene group. The observed intensity ratios among isotopic species were in good agreement with the ratios calculated with the intensity theory of our previous study.

In our previous study, infrared absorption intensities of torsion-rotation transitions of molecules with symmetric internal rotor were theoretically derived on the basis of torsion-rotation interactions and useful applications were discussed on absolute intensities, orientations of dipole transition moments, band types and deuteration effects.[1] According to the theory, the integrated absorption intensity of the internal-rotation vibration of methyl group [$-CH_3$] was expected to be nearly doubled on the deuteration of the methyl group [$-CD_3$].[1] In the present study, the far infrared spectra of deuterated ethyl fluoride [CH_3CD_2F, CD_3CH_2F, and CD_3CD_2F] were measured for the first time as well as ethyl fluoride [CH_3CH_2F], and experimental integrated intensities were compared with theoretical intensities.

As for the internal rotation of methyl groups, a number of data on barrier heights were accumulated by microwave spectroscopy[2] and far infrared spectroscopy.[3] The internal rotation barrier of ethyl fluoride [CH_3CH_2F] was previously determined as 3306 cal/mol (1156 cm^{-1}) by Herschbach with the microwave absorption spectroscopy.[4] The far infrared spectra of CH_3CH_2F were measured by Sage and Klemperer[5] and by Kinumaki and Kozuka,[6] and potential-barrier coefficients were estimated[5] as $V_3=1165$ and $V_6=-5$ cm^{-1}. In the present study, the internal-rotation potential for the four isotopic molecules were studied with various model calculations.

Experimental

The samples of ethyl fluoride [CH_3CH_2F] and deuterated species [CH_3CD_2F, CD_3CH_2F, and CD_3CD_2F] were prepared through tosyl esters from corresponding ethanols by the method of Edgell and Parts.[7] Ethanol [CH_3CH_2OH] and the perdeuterated species [CD_3CD_2OD] were obtained from commercial sources. The ethanol with the deuterated methylene group [CH_3CD_2OH] was prepared by the reduction of acetyl chloride with lithium aluminum deuteride. The ethanol with the deuterated methyl group [CD_3CH_2OH] was prepared by the reduction of CD_3COOD with lithium aluminum hydride. The samples for spectroscopic observations were dried over phosphorous pentoxide just before measurements.

Far infrared spectra were measured with a Hitachi FIS-3 Far Infrared Spectrophotometer and a 10 cm gas cell with polyethylene windows. The spectral slit width was 2—3 cm^{-1} and the frequency accuracy was estimated to be about ±0.5 cm^{-1}. The peak frequencies were calibrated with the absorption lines of water vapor.[8] The far infrared spectra observed for the four isotopic species are shown in Fig. 1. Mid infrared spectra were measured with a Hitachi Model-225 Infrared Spectrophotometer and a 10 cm gas cell with cesium iodide windows (gas pressure, 10 Torr). The infrared bands due to the C–H and/or C–D stretching vibrations of the four isotopic species are shown in Fig. 2.

Results on Peak Frequencies

The observed frequencies and assignments of internal-rotation transitions of ethyl fluorides are given in Table 1. The fundamental band ($1\leftarrow0$ transition) and two hot bands ($2\leftarrow1$ and $3\leftarrow2$ transitions) were observed for CH_3CH_2F and for CH_3CD_2F, while for CD_3CH_2F and CD_3CD_2F the fundamental band ($1\leftarrow0$) and three hot bands ($2\leftarrow1$, $3\leftarrow2$, and $4\leftarrow3$) were observed. The peak frequencies observed for CH_3CH_2F agreed with the values reported by Sage and Klemperer[5] within ±0.5 cm^{-1} but were slightly lower (by 0.6—1.3 cm^{-1}) than the values reported by Kinumaki and Kozuka.[6]

As for the symmetry index (σ) of the internal-rotation wave functions of ethyl fluoride, the selection rule of the infrared absorption allows $A_1\leftrightarrow A_2$ and $E\leftrightarrow E$ transitions for the vibrational transition $\Delta v=1$.[1,3] Accordingly, in principle, two peaks are expected for each transition $\Delta v=1$. However, in the present study, splitting into two peaks was not observed (Table 1). The $4A_1\leftrightarrow3A_2$ transition[5,6] and $4E\leftrightarrow3E$ transition[6] of CH_3CH_2F were not observed either, with the present experimental conditions.

Successive separations of hot bands usually increase with decreasing peak frequencies, although systematically anomalous cases have also been observed.[9] As shown in Table 1, for the four isotopic molecules of ethyl fluoride, systematic anomaly was not observed but for CD_3CH_2F some irregularity was found in successive separations of hot bands.

Internal Rotation Potential

The Hamiltonian for the internal rotation of a rigid

methyl group with respect to a rigid frame may be written as[10,11]

$$H = Fp_\alpha^2 + V_3(1-\cos 3\alpha)/2 + V_6(1-\cos 6\alpha)/2 + \cdots \quad (1)$$

where α is the internal-rotation angle ($\alpha=0$ for the staggered form), V_3 and V_6 are the threefold and sixfold barriers in the Fourier expansion of the potential energy, and F is equal to one-half of the inverse reduced moment of inertia. The F values for the four isotopic molecules were calculated, as given in Table 1, from molecular structure parameters reported by Nygaard.[12]

Calculation-I. In the rigid-top-rigid-frame model, the potential function may be taken common for all the isotopic molecules. In the first approximation, the threefold barrier (V_3) was taken into account but the sixfold barrier (V_6) was neglected. With the F values

a) The separation (cm^{-1}) between the observed frequencies. b) Calculated from the structure of Ref. 12.

of Table 1, the potential barrier V_3 of ethyl fluoride molecule was calculated by the method of least squares, with reference to the observed transitions of the four isotopic species. Equal weight was given to each of the observed transitions in the least-squares treatment. Since splitting of the $A_1 \leftrightarrow A_2$ and $E \leftrightarrow E$ transitions was not observed in the present experimental conditions, the calculated transition frequencies were taken as the weighted average of the calculated $A_1 \leftrightarrow A_2$ (weight=1) and $E \leftrightarrow E$ (weight=2) transition frequencies.

The potential barrier was thus obtained as $V_3=1142$ cm^{-1}. The torsional frequencies calculated with this barrier are given in Table 2, together with deviations from the observed values. The calculated frequencies agree fairly well with the observed frequencies, although there are systematic deviations greater than experimental errors; the frequencies calculated for CH_3CH_2F or CH_3CD_2F molecules with the CH_3 group are lower than the observed frequencies whereas the frequencies calculated for CD_3CH_2F or CD_3CD_2F molecules with the CD_3 group are higher than the observed frequencies.

Calculation II. The sixfold barrier (V_6) as well as the threefold barrier (V_3) were taken common for all the isotopic molecules. These barriers were thus calculated as $V_3=1152\pm8$ and $V_6=-6\pm4$ cm^{-1}, with reference to the observed frequencies of the four isotopic molecules. The method of least squares was used in similar manners as Calculation-I, although the V_6 term was treated with the second-order perturbation method.

Calculated transition frequencies agreed with observed frequencies, slightly better than the results of Calculation-I. However, the systematic deviations for the CH_3- and CD_3-groups were little reduced.

Calculation-III. The use of common potential function for the isotopic molecules of ethyl fluoride results in systematic frequency deviations for the CH_3- and CD_3-groups. Accordingly, potential barriers were then calculated for each isotopic molecules, where the F values of Table 1 were used.

In Calculation-III, the three-fold barrier was taken into account but the sixfold barrier was neglected. For each isotopic molecule, the value of V_3 was calculated, as shown in Table 3, by the method of least squares. The V_3 values calculated for the CH_3- group are higher than those calculated for the CD_3- group. Agreements between the calculated and observed frequencies were much improved as compared with the case of Calcula-

a) Errors are standard deviations (cm^{-1}) calculated by the method of least squares. b) $\delta=\nu_{calcd}-\nu_{obsd}$. c) Root-mean-squared deviation.

tion-I.

Calculation-IV. The sixfold barrier (V_6) as well as the threefold barrier (V_3) were calculated, as shown in Table 3, for each isotopic molecule by the method of least squares. The V_3 values calculated for the CH_3-group were systematically higher (by 30—35 cm^{-1}) than those calculated for the CD_3-group. The systematic variations of the calculated V_3 values possibly indicate the isotope effects on structure relaxations due to torsional motion and to zero-point motion of other vibrational modes.

For each isotopic molecule of ethyl fluoride, the agreements between the calculated and observed frequencies were improved, by the incorporation of the V_6 term, as compared with the case of Calculation-III. However, for the molecule of CD_3CH_2F, there are some noticeable frequency deviations for the 2←1 and 3←2 transitions. These deviations are due to the irregularity of successive separation of hot bands (Table 1). One of the origins for this irregularity may be ascribed to the Fermi resonance interaction between the second excited state of the torsional vibration and the first excited state of the skeletal C-C-F bending vibration. For the isotopic molecules of CH_3CH_2F, CH_3CD_2F, CD_3CH_2F, and CD_3CD_2F, the separations between the second excited torsional level and the ground level were calculated as 467.9, 459.0, 361.9, and 352.1 cm^{-1}, from the observed torsional transitions (Table 1). On the other hand, the separations between the first excited bending level and ground level were observed as the infrared bands[13] at 415, 409, 370, and 364 cm^{-1}. Accordingly, the separation between the second excited torsional level and the first excited bending level is smallest for CD_3CH_2F and some Fermi resonance effect may in fact be expected between these levels.

Calculation-V. The second excited torsional levels are perturbed by Fermi resonances whereas the first excited torsional levels are practically free from Fermi resonance interactions. Accordingly, from the observed fundamental transitions (1←0), the threefold barrier was calculated, as shown in Table 3, for each of the four isotopic molecules. The threefold barriers of the CH_3- group were calculated to be higher than those of the CD_3- group.

Calculation-VI. In Calculations III—V, the F values (Table 1) obtained by the microwave analyses[12] were used and the potential barriers were calculated for each isotopic molecule. Instead, the transition frequencies of the four isotopic molecules may also be reproduced by the least-square adjustments of F values for the four isotopic molecules and a common value of V_3. As shown in Table 4, the value of V_3 (1172± 14 cm^{-1}) thus calculated is higher than those of the Calculations-I—II whereas the values of F thus calculated are smaller than the F values from the microwave analyses. The attempt of determining the value of V_6 as well as V_3 and F values was not successful because of ill conditions for the least-squares adjustments.

Calculation-VII. The results of Calculations-I—VI imply that actual internal-rotation modes are accompanied with relaxations of the structures of the rotor and/or frame. Theoretical methods on non-rigid models were derived for the interpretation of microwave spectra by Kivelson[14] and by Kirtman.[15]

In the present study, however, the empirical method by Ewig and Harris[16] was used for the interpretation of the far infrared spectra of ethyl fluorides.

The Hamiltonian for the internal rotation of a molecule with structure relaxations may be written in a one-dimensional approximation as,

$$H = p_\alpha F(\alpha) p_\alpha + V_3(1-\cos 3\alpha)/2 + V_6(1-\cos 6\alpha)/2 + \cdots \quad (2)$$

where $F(\alpha)$ is a function of the internal-rotation angle α (for the rigid model of Eq. (1), F is independent of α). The function $F(\alpha)$ may be evaluated with an *a priori* knowledge or an assumption on the molecular

a) The values of $\bar{F}$ and $\bar{V}_3$ are given in the unit of cm^{-1}.

dynamics of the internal-rotation and other vibrational modes. The Hamiltonian in Eq. (2) may be transformed to the reduced θ representation,[16,17]

$$H=\bar{F}p_\theta^2+\bar{V}_3(1-\cos 3\theta)/2+\bar{V}_6(1-\cos 6\theta)/2+\cdots \quad (3)$$

on the basis of the following transformations.

$$\bar{F}^{-1/2}=(1/2\pi)\int_0^{2\pi}F(\alpha)^{-1/2}\,d\alpha \quad (4)$$

$$\theta=\bar{F}^{1/2}\int_0^{\alpha}F(\alpha')^{-1/2}\,d\alpha' \quad (5)$$

Here $\bar{F}$ is a constant independent of θ, and the transformation from α to θ is nonlinear. The angle θ has the same boundary condition as the internal-rotation angle α. The potential function $[\bar{V}(\theta)]$ of Eq. (3) is different from the potential function $[V(\alpha)]$ of Eq. (2), but these functions $\bar{V}(\theta)$ and $V(\alpha)$ have the same symmetry, same boundary condition, and same heights of the maxima and minima.[16,17]

For the four isotopic molecules of ethyl fluoride, sufficient knowledges were not available for evaluating the functions $F(\alpha)$. Therefore, the Hamiltonian H of Eq. (3) was used for determining empirically the kinetic-energy parameter $\bar{F}$ and the potential coefficients $\bar{V}_3$ and $\bar{V}_6$.

With Eq. (3), the values of $\bar{F}$ and $\bar{V}_3$ were calculated for each isotopic molecule, by the method of least squares, with reference to the observed transition frequencies. The $\bar{V}_6$ and higher terms were neglected. The calculated results are given in Table 5. Calculated transition frequencies agreed satisfactorily with observed frequencies. However, for the molecule of CD_3CH_2F, the frequency agreements were little improved, as compared with the case of Calculation-IV, possibly because of the limitation imposed by the effect of Fermi resonance.

As compared with the F values of the rigid model (Table 1), the $\bar{F}$ values calculated with Calculation-VII were smaller for the molecules of CH_3CH_2F, CH_3CD_2F, and CD_3CH_2F but larger for the molecule of CD_3CD_2F. Furthermore, as compared with the V_3 values of Calculation-III (Table 3), the $\bar{V}_3$ values calculated with Calculation-VII were higher for the molecules of CH_3CH_2F, CH_3CD_2F, and CD_3CH_2F but lower for the molecule of CD_3CD_2F. However, systematic deuteration effects were observed on the $\bar{V}_3$ values of the four isotopic molecules; the $\bar{V}_3$ values were lowered by deuteration of the methyl group ($\sim50\ cm^{-1}$) and also by the deuteration of the methylene group ($\sim40\ cm^{-1}$). The attempt of determining the value of $\bar{V}_6$ as well as

$\bar{V}_3$ and $\bar{F}$ was not successful because of ill conditions for the least-squares refinements.

Isotope Effects on Absorption Intensities of Torsional Bands

The absorption intensity of a torsional band may be calculated from molecular structure parameters and molecular dipole moment, with the theory previously reported by Sugeta and Miyazawa.[1] According to this theory, the molar integrated absorption intensity of the torsional transition ($\Delta v=1$) may be expressed as,

$$\int\alpha(\nu)\mathrm{d}\nu=\frac{N}{z}\frac{8\pi^3}{3h^2c}\times 4F^2|\boldsymbol{\mu}\times\boldsymbol{\rho}|^2\sum_{v,\sigma}[\exp(-E_{v,\sigma}/kT) -\exp(-E_{v+1,\sigma}/kT)]\times\frac{|\langle v+1,\sigma|p_\alpha|v,\sigma\rangle|^2}{E_{v+1,\sigma}-E_{v,\sigma}} \quad (6)$$

where v and σ are the vibrational quantum number and symmetry index, $E_{v,\sigma}$, is the eigenvalue of the state $v\sigma$, p_α is the angular momentum operator of the internal rotor along its symmetry axis, z is the partition function, N is the Avogadro number, and $\boldsymbol{\mu}$ is the dipole moment vector. The vector $\boldsymbol{\rho}$ is given by the moment of inertia of the internal rotor (I_α), the moment of inertia of the entire molecule (I_a, I_b, I_c), and the direction cosines of the internal-rotation axis (λ_a, λ_b, λ_c),

$$\tilde{\boldsymbol{\rho}}=[\lambda_aI_\alpha/I_a \quad \lambda_bI_\alpha/I_b \quad \lambda_cI_\alpha/I_c] \quad (7)$$

For the high-barrier harmonic approximation, Eq. (6) may be simplified as,[1]

$$\int\alpha(\nu)\mathrm{d}\nu\simeq(8\pi^3N/3h^2c)F|(\boldsymbol{\mu}\times\boldsymbol{\rho})|^2 \quad (8)$$

The theoretical absorption intensities of the torsional bands of the four isotopic species of ethyl fluoride were calculated, by the use of the molecular structure parameters[12] and dipole moment.[18] The results of Calculation-I were used for the intensity calculations. The theoretical intensities calculated with Eq. (6) are given for the four isotopic molecules in Table 6, where the summations in Eq. (6) were made up to the 4←3 transitions for CH_3CH_2F and CH_3CD_2F and up to the 6←5 transitions for CD_3CH_2F and CD_3CD_2F.

Table 6. Integrated absorption intensities[a] (and ratios[b]) of torsional bands of ethyl fluorides

CD_3CD_2F	2.7_5	1.3_5	4.09	1.12	4.32	1.10

a) In unit of $cm^{-2}\cdot atm^{-1}$, at 300 K. b) Relative to CH_3CH_2F. c) Calculated with Eq. (6). d) Calculated with Eq. (8).

On the deuteration of the methyl group, the theoretical intensities are nearly doubled (1.7—1.8 times), as discussed previously. This intensity enhancement is due to the twofold increase in the magnitude of the $\boldsymbol{\rho}$ vector, overcoming the decrease (to about one-half) in the F values. On the other hand, the theoretical intensities are reduced (to 0.6—0.7 times) on the deuteration of the methylene group. This intensity reduction is ascribed to the decrease in the magnitude of the $\boldsymbol{\rho}$ vector and in the F values.

The experimental absorption intensities were measured for the four isotopic species of ethyl fluoride and are given in Table 6. Experimental errors in the integrated intensities were estimated to be about 20%. In the far-infrared region, experimental determinations of absolute intensities were difficult with the present instrumental conditions, and accordingly the relative intensities among the four isotopic molecules were also calculated as shown in Table 6.

The experimental intensities were lower than the theoretical intensities [from Eq. (6)], because of instrumental limitations. However, as for the relative intensities among the four isotopic molecules, observed intensity ratios agreed fairly well with experimental intensity ratios. In particular, the observed changes of the absorption intensities on deuteration of the methyl group and methylene group confirmed the validity of the intensity theory previously reported.[1]

Theoretical values of the integrated absorption intensities of the torsional bands were also calculated with the high-barrier harmonic approximation [Eq. (8)]. As shown in Table 6, the intensity values calculated with Eq. (8) are appreciably higher than the values calculated with Eq. (6). Accordingly, for calculations of the absolute intensity values, Eq. (6) rather than Eq. (8) is to be used. However, the theoretical intensity ratios calculated with Eq. (8) agree closely with the ratios calculated with Eq. (6). With this harmonic approximation, evaluations of $F|(\boldsymbol{\mu}\times\boldsymbol{\rho})|^2$ in Eq. (8) are sufficient for calculating theoretical intensity ratios.

Discussion

For studying the effects of adjustable parameters (F, V_3, and V_6) on torsional transition frequencies, Jacobian elements have been calculated. For lower transitions, the values of $\delta\nu/\delta V_3$ are nearly constant so that a small increment in V_3 results in uniform shifts of transition frequencies. On the other hand, the values of $\delta\nu/\delta V_6$ significantly decrease for higher transitions so that a small increment in V_6 results in nonuniform shifts of transition frequencies. It may be remarked that the absolute values of $\delta\nu/\delta V_6$ are minimum for the 3←2 transitions of the CH_3 group and for the 4←3 or 5←4 transitions of the CD_3 group. These higher-transition frequencies are little subjected to the effect of the sixfold barriers, as noticed previously by Fateley and Miller.[19] The values of $\delta\nu/\delta F$ also decrease for higher transitions and an increment in F results in nonuniform shifts of transition frequencies.

In the present study on the four isotopic molecules of ethyl fluoride, systematic deviations between the observed and calculated frequencies were found in Calculations-I—II; the transition frequencies calculated for the molecules of CH_3CH_2F and CH_3CD_2F with the CH_3- group are lower than the observed frequencies whereas the frequencies calculated for the molecules of CD_3CH_2F and CD_3CD_2F with the CD_3-

group are higher than the observed frequencies. In Calculations-III—V, systematic variations among the barrier heights of isotopic molecules were found; the threefold barriers were lowered on the deuteration of the methyl group (from CH_3CH_2F to CD_3CH_2F and from CH_3CD_2F to CD_3CD_2F). In Calculation-VI, systematic variations among the apparent F values of isotopic molecules were found. Finally in Calculation-VII, systematic variations of the $\overline{V}_3$ values were also found; the $\overline{V}_3$ values were lowered by the deuteration of the methyl group and also by the deuteration of the methylene group. All these results indicate that the observed potential barriers hindering the internal rotation are slightly but definitely different among isotopic molecules, because of the structure relaxations due to torsional motion and to zero-point motion of other modes. This effect of deuteration on potential barriers of the methyl groups has also been found for other molecules.[20]

Recently some comments were made[16,21-23] on the physical meaning and spectroscopic determination of the V_6 terms of the internal-rotation potential and the 3α-dependent term of $F(\alpha)$ in Eq. (2).

$$F(\alpha) = F_0 + F_3 \cos 3\alpha + \cdots \quad (9)$$

In the least-squares refinements with reference to the observed transition frequencies,[16,22,23] the values of $4F_0V_6+F_3V_3$ may be estimated but the values of V_6 and F_3 may not be determined independent of each other. In the present non-rigid model of Calculation-VII, however, the internal-rotation angle α is transformed into the angle θ so that $\overline{F}$ is independent of θ and 3θ-dependent term vanishes [$\overline{F}_3=0$]. Then, the values of $\overline{F}$, $\overline{V}_3$, $\overline{V}_6$,$\cdots$in Eq. (3) may well be calculated by the method of least squares, if observed data of transition frequencies were sufficiently available.

In Calculation-VII, transition-frequency data of the present experimental study were not sufficient for the least-square adjustment of the three parameters $\overline{F}$, $\overline{V}_3$ and $\overline{V}_6$. For the molecule of CH_3CH_2F, the 4E←3E and 4A←3A transitions were observed by Kinumaki and Kozuka,[6] although their frequencies for lower transitions were systematically higher than those of the present study. These 4E←3E and 4A←3A transition frequencies were added to the present data of the 1←0, 2←1, and 3←2 transition frequencies, and the parameters $\overline{F}$, $\overline{V}_3$, and $\overline{V}_6$ were determined, as shown in Table 7, for the molecule of CH_3CH_2F. On the other hand, model calculations were made for the molecules of CD_3CH_2F and CD_3CD_2F, and it was found that the experimental data on the fundamental (1←0) through 5A←4A and 5E←4E or more preferably 6E←5E and 6A←5A transitions were required for calculating reliable values of $\overline{F}$, $\overline{V}_3$ and $\overline{V}_6$.

Table 7. Calculated frequencies and deviations (cm^{-1}) of torsional transitions of CH_3CH_2F.[a]

4E←3E	189.6[b]	188.9	−0.7
4A←3A	178.4[b]	178.5	0.1

a) $\overline{F}=6.576\pm0.128\ cm^{-1}$, $\overline{V}_3=1168.4\pm7.5\ cm^{-1}$, $\overline{V}_6=-18.4\pm6.4\ cm^{-1}$, and rmsd$=0.7\ cm^{-1}$. b) Ref. 6.

After the present study was completed, high resolution far-infrared spectrum of C_2H_5F was reported by Tuazon *et al.*[24] and the dependence of the potential parameters V_3 and V_6 on changes in selected values of F was discussed.

Conclusion

In the present study, several types of calculations with various models were made for analyzing the far infrared spectra and for calculating potential barrier coefficients of the four isotopic molecules of ethyl fluoride, All those calculations indicate that the observed potential barriers hindering the internal rotation are slightly different among isotopic molecules, because of the small coupling between the internal-rotation mode and other vibrational modes. For more detailed determinations of the potential barriers, however, it is desirable to observe weak far-infrared bands due to transitions between higher excited torsional states and to analyze microwave spectra of higher excited torsional states.

It has been established that the absorption intensities of C–H stretching vibrations are reduced to about one half on deuteration. In the present study, the absorption intensities of the C–H stretching vibrations of ethyl fluoride were in fact found to decrease, as shown Fig. 2, on deuteration of the methyl and/or methylene group. On the other hand, it has been anticipated theoretically[1] that the absorption intensity of the torsional vibration of the CH_3 group is nearly doubled on deuteration of the methyl group but is reduced on deuteration of the methylene group. In the present study, the absorption intensity ratios of the torsional bands of the four isotopic molecules were in fact found to agree closely with the theoretical ratios, confirming the intensity theory previously derived.

Numerical calculations of the present study were carried out with a NEAC 2200—700 computer of Osaka University.

Infrared Absorption Intensities of *trans*- and *cis*-Dichloroethylene

Kazutoshi TANABE and Shinnosuke SAËKI

National Chemical Laboratory for Industry, Honmachi, Shibuya-ku, Tokyo 151

(Received January 14, 1974)

Infrared absorption intensities of *trans*- and *cis*-dichloroethylene were measured in the vapor phase, and interpreted in terms of intensity parameters common to the isomers. In order to obtain L matrices, force constants common to the isomers were determined so as to attain the best fit between the observed and calculated frequencies of CHCl=CHCl, CDCl=CDCl and CHCl=CDCl. Using the L matrices thus obtained, intensity parameters were determined so as to attain the best fit between the observed and calculated intensities of CHCl=CHCl. As a result, the observed frequencies and intensities were satisfactorily represented in terms of the force constants and the intensity parameters common to the isomers.

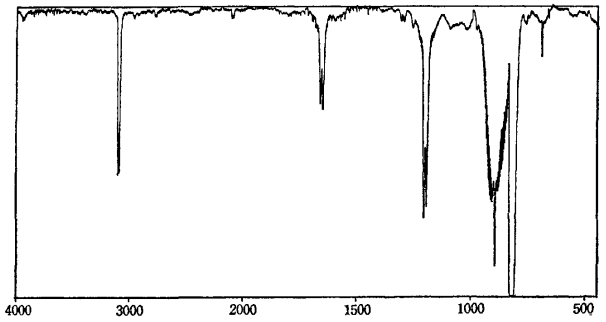
In our serial studies on rotational isomerism,[1-3] the energy differences between the rotational isomers were evaluated by applying the absolute intensity method. This is quite a unique method, not requiring any temperature variation in experiment, hence it may give a very reliable value for an energy difference. But it has a great disadvantage that intensity parameters are assumed to be transferable between the rotational isomers concerned. The validity of this assumption can by no means be confirmed by any direct method.

In our serial studies on infrared absorption intensities,[4-6] intensity data were interpreted in terms of intensity parameters common to some molecular groups or molecular series. At least as far as the molecular series treated so far are concerned, it was concluded that intensity parameters are transferable among some molecular groups.

In this investigation, in order to confirm the transferability of intensity parameters in molecules containing double bonds, infrared absorption intensities of *trans*- and *cis*-dichloroethylene CHCl=CHCl measured in the vapor phase have been interpreted in terms of intensity parameters assumed as transferable between the isomeric molecules.

Experimental

Infrared absorption intensities of fundamental bands of *trans*- and *cis*-dichloroethylene CHCl=CHCl were measured in the vapor phase using Perkin-Elmer Model 421 grating spectrophotometer combined with a digital recorder.[7] The vapor phase spectra recorded are shown in Figs. 1(a) and 1(b). The commercial material of the extra pure grade was used without further purification. The observed spectrum of *trans* isomer shows that it contains at most 1% of *cis* isomer.



Wave number (cm^{-1})

Fig. 1(a). Vapor phase spectrum of *trans*-dichloroethylene.

Gas cells 5 or 10 cm thick with KBr or polyethylene windows were used, and measurements were made at least ten times at different sample pressures ranging from 5 to 100 mmHg. Since vibration-rotation fine structures were observed for some absorption bands, dry air was introduced as foreign gas into gas cells in order to pressurize up to 1 atm, and absolute band intensities were evaluated by applying the Wilson-Wells extrapolation technique. The plots of intensities against pressures for some absorption bands are shown in Fig. 2.

In order to integrate absorbance curves for obtaining absolute band intensities, encoded paper tapes punched out from the digital recorder were processed by using a FACOM

Model 270—30 electronic computer system. For the absorption bands below 500 cm^{-1}, the digital recording was not available, and their absorption intensities were estimated by using a planimeter.

Other experimental conditions for the intensity measurement are the same as described in our previous papers.[1-7]

Results and Discussion

The absolute intensities of fundamental bands of *trans*- and *cis*-dichloroethylene CHCl=CHCl measured in the vapor phase are listed in Table 1 with experimental errors. Although several papers were published on the vibrational frequencies of dichloroethylene, the absorption intensities for these isomeric molecules have received little attention.

Shimozawa and Wilson[8] measured the infrared absorption intensities of several fundamental bands of *trans*- and *cis*-dichloroethylene in carbon tetrachloride or carbon disulfide solution, and evaluated the gaseous band intensities by applying the Polo-Wilson's equation. The values estimated by them are in rather good accordance with the intensities obtained in this study, except for the ν_{10} band of *trans* isomer.

Dervil[9] measured the infrared absorption intensities of the *trans* ν_{11} and *cis* ν_{10} bands of dichloroethylene in hexane or carbon disulfide solution. The gaseous

a) $\delta\nu = \nu_{calcd} - \nu_{obsd}$.

intensities estimated from her values by applying the Polo-Wilson's equation agree well with the present results. Hence the observed intensity data obtained in this study can be considered as reliable enough for the intensity computation.

In order to interpret these intensity data, it is necessary to obtain L matrices by the normal mode analysis. Concerning the vibrational frequencies of dichloroethylene, Bernstein *et al.*[10,11] pointed out the errors for the band assignments made by Wu,[12,13] Trumpy,[14] Herzberg,[15] or Pitzer *et al.*,[16] and reported the correct band assignment for *trans*- and *cis*-dichloroethylene CHCl=CHCl, CDCl=CDCl and CHCl=CDCl. However, the determination of force constants in dichloroethylene has received little attention, except for the out-of-plane vibrations studied by Pitzer *et al.*[16] or Dowling.[17]

In order to obtain L matrices as accurate as possible, force constants have been determined by the least-squares method so as to attain the best fit between the observed and calculated frequencies of *trans*- and *cis*-dichloroethylene CHCl=CHCl, CDCl=CDCl and CHCl=CDCl. Twenty force constants based on the internal coordinates given in Table 2 have been assumed as common to the *trans* and *cis* isomer, and their values have been refined from total seventy-two frequency data. As for the torsional coordinate, not τ(Cl–C–C–Cl), but the coordinate of the internal rotation type has been taken.

Previous authors pointed out that for substituted ethane or ethylene, it is necessary to introduce the *trans* interaction constant. Such an interaction constant may be required in the present case. However, since in this study, we examine whether we can explain the observed frequencies and intensities in terms of the force constants and the intensity parameters common to the isomeric molecules, the *trans* interaction constant has not been taken into account, and the determination of the common force constants has been carried out.

Converged values and standard deviations of the force constants are listed in Table 3, and the calculated normal frequencies are compared in Table 4 with the observed fundamental frequencies. The agreement between the observed and calculated frequencies is satisfactory on the whole, and the converged values of the force constants are all quite acceptable as compared with those of related molecules. A rather good agreement between the observed and calculated frequencies for the CCH bending vibrations may suggest that the *trans* interaction constant takes less significant role in representing the normal frequencies of dichloroethylene. Thus the L matrices obtained by this normal mode analysis can be considered as suitable enough for the intensity computation described below.

Using the L matrix data thus obtained, the intensity data given in Table 1 have been interpreted in terms of intensity parameters on the basis of the Gribov's valence-optical theory.[18,19] As for the intensity parameters for interpreting the intensity data of *trans*- and *cis*-dichloroethylene, the following assumption has been

TABLE 5. CONVERGED VALUES AND STANDARD DEVIATIONS OF INTENSITY PARAMETERS
(Unit : D, or D/Å)

μ_{CH}	0.80(0.01)
μ_{CCl}	−0.29(0.01)
$\delta\mu_{CH}/\delta r_{CH}$	0.14(0.04)
$\delta\mu_{CH}/\delta r_{CCl}$	−1.00(0.41)
$\delta\mu_{CH}/\delta\alpha_{CCH}$	0.12(0.05)
$\delta\mu_{CH}/\delta\beta_{CCCl}$	0.52(0.23)
$\delta\mu_{CCCl}/\delta r_{CCl}$	−3.57(0.21)
$\delta\mu_{CCCl}/\delta r_{CH}$	0.26(0.02)
$\delta\mu_{CCl}/\delta r_{CC}$	0.14(0.26)
$\delta\mu_{CCl}/\delta\beta_{CCCl}$	−0.26(0.14)
$\delta\mu_{CCCl}/\delta\alpha_{CCH}$	−0.28(0.07)

taken. That is, only bond moment derivatives have been taken where the bond moments and the internal coordinates are associated with the same carbon atoms, and the other bond moment derivatives have all been neglected.

The intensity parameters based on this assumption, as listed in Table 5, have been considered to take equal values between the *trans* and *cis* isomers, that is, they have been assumed as transferable. The values of these parameters have been refined by the least-squares method so as to attain the best fit between the observed and calculated band intensities and molecular dipole moment. Converged values and standard deviations of the intensity parameters are given in Table 5, and the calculated band intensities are compared in Table 1 with the observed intensities.

The agreement between the observed and calculated band intensities is rather satisfactory except for the ν_9 band of *cis*-dichloroethylene. The average difference between the calculated and observed intensities is about four times larger than the expreimental errors of the observed intensities. The accordance to such an extent is acceptable, taking into account the assumptions placed on the determination of the intensity parameters.

The converged values of the intensity parameters listed in Table 5 are all acceptable as compared with those of related molecules treated previously. Moreover, the determined values of the bond moments μ_{CH} and μ_{CCl} can well explain the observed molecular dipole moment of *cis*-dichloroethylene measured in the gaseous state ($\mu_{obsd}=1.90$ D, $\mu_{calcd}=1.899$ D). However, a comment has to be made on the values of μ_{CH} and μ_{CCl}.

In the case of chlorinated methanes[4,5] or ethanes,[6] μ_{CH} was converged to the values near 0.5 D, while μ_{CCl} was converged to −1.0 D. On the other hand, in the present case, μ_{CH} is relatively large, but the absolute value of μ_{CCl} is fairly small. The value of μ_{CH} is in rather good agreement with the one for ethylene (0.7 D).[20] The small value of μ_{CCl} might suggest that the non-bonded electron cloud on chlorine atoms in dichloroethylene may be attracted into π-electron cloud of the double bond.[21] Such a result will be confirmed by a quantum-chemical approach such as a CNDO technique.

In conclusion, the transferability of the intensity parameters in dichloroethylene may confirm that intensity parameters might be transferable in related molecules, and thus the absolute intensity method may reasonably be applied to the determination of an energy difference between the rotational isomers.

The Polymorphism of Inosine. II. The Measurement of Solubilities in Water

Yoshihisa SUZUKI

Central Research Laboratories, Ajinomoto Co., Inc., Suzuki-cho, Kawasaki 210

(Received February 20, 1974)

The solubilities of anhydrous inosine crystals in the α-form and in the β-form in water were determined in the temperature range between 20 °C and 60 °C. The results may be formulated as follows:

α-form $\log S = 0.0190\,t - 0.065$

β-form $\log S = 0.0198\,t - 0.161$

These data indicate that the β-crystals are more stable than the α-crystals over the whole temperature range examined. However, the difference in solubility is too small to induce the transition without seed crystals in the β-form, so that the α-crystals themselves are practically stable in water. The rate of the transition from the α-form to the β-form varies in proportion to the amount of the seed β-crystals. At low temperatures the dihydrate form of inosine is more stable than both of these two anhydrous forms. The solubility may be formulated as follows:

dihydrate-form $\log S = 0.0314\,t - 0.276$

The polymorphism of anhydrous inosine crystals was briefly presented in the preceding paper.[1] The crystals in an orthorhombic system are called α-form, and those in a monoclinic system, β-form. The solubility data of inosine in water were reported for the α-form.[2] This paper will describe the solubilities in the two forms and the transition from the α-form to the β-form.

Experimental

Material. The inosine used was of a commercial A-grade of the Ajinomoto Co., Inc.

Preparation of the Crystals. *Inosine Dihydrate*: The commercial inosine was recrystallized in water at 5 °C.

Inosine Anhydrous in the α-Form: The commercial inosine was recrystallized in water at 40 °C. *Inosine Anhydrous in the β-Form*: The commercial inosine was recrystallized in water at 40 °C in the presence of the seed crystals in the β-form. The seed crystals were obtained as follows: the commercial inosine (1.2 g) was dissolved in a 70% (w/w) dimethyl sulfoxide solution (10 ml), after which the wall of the glass vessel was scraped with a glass rod at room temperature until the β-crystals has been nucleated.

Solubility Measurement. A sufficient amount of the crystals was mixed with water to make a slurry in tightly-capped glass bottles. The equilibrium was achieved by tumbling the bottles at a constant temperature (±0.2 °C) for 16 hr. The supernatant clear solutions were sampled with a cotton-filtered pipet, weighed, diluted to appropriate volumes, and submitted to the measurement of the UV absorbance in 0.1 M HCl at 250 nm. The concentrations of the inosine were calculated from the molar extinction coefficient of 11800 under the above conditions. The residues were filtered and examined by means of the X-ray powder diffraction method in order to confirm the crystal form of the solid phase.

α-β Transition in Water. *Analysis*: For a brief quantitative analysis of the mixture of the two forms, the relative peak heights of the X-ray diffraction patterns were compared. The intensity of the 8.37 Å line (I_α) and that of 7.59 Å line (I_β) were measured. The β-form content was defined as $\{I_\beta/(I_\alpha+I_\beta)\}\times 100\%$. The calibration curve was almost linear. *In the Presence of the Seed Crystals*: Inosine crystals in the α-form (10 g) were added to 100 ml of water to make a slurry at room temperature. About three grams of inosine were dissolved, and seven grams remained undissolved. After the inosine crystals in the β-form (0.7 g or 1.4 g) had been added, the slurry was tumbled on a shaker at 30 °C. The suspended residues were sampled at successive intervals for X-ray examination. *In the Absence of the Seed Crystals*: Inosine crystals in the α-form (100 g) were added to 100 ml of water. After the resultant slurry had been vigorously stirred at 95 °C for 24 hr, the residue was examined by means of the X-ray diffraction method.

α-β Transition on the Drying of the Dihydrate Crystals. The dihydrate crystals of inosine were dried in air at 60 °C overnight with a little portion of the seed crystals in the β-form or without them. The resultant crystals were examined by means of X-ray analysis.

Results and Discussion

Table 1 shows the solubilities of inosine in water. The logarithms of the solubilities are linear to the temperature and are expressed as follows:

$$\text{α-form:}\quad \log S = 0.0190\,t - 0.065 \qquad (1)$$

$$\text{β-form:}\quad \log S = 0.0198\,t - 0.161 \qquad (2)$$

where S represents the gram weight of inosine per 100 g of water and where t is the temperature (°C). These results show that inosine in the β-form is less soluble than that in the α-form, and that, therefore, the β-form is more stable than the α-form. Accordingly, it can be expected that the α-crystals will be transformed into the β-crystals in water. However, the difference in solubility between them is too small to induce the transition without the seed crystals in the β-form, so that the α-crystals themselves are practically stable in water. During the measurement of the solubility, the transition of the crystals in the residue was not observed. As two lines, represented by Eq. (1) and Eq. (2), cross at nearly 120 °C, the stability may be reversed beyond that temperature.

At low temperatures the dihydrate form of inosine is more stable than either of the two anhydrous forms. On the assumption that the same linear relation between log S and t as in Eq. (1) or Eq. (2) holds good, the solubility of the dihydrate form is expressed from the data in Table 1 as follows:

$$\text{dihydrate-form:}\quad \log S = 0.0314\,t - 0.276 \qquad (3)$$

Table 1. Solubilities of inosine in water[a)]

Temp. (°C)	S (g/100 g water)

		β-Form	α-Form
0	0.52	—	—
10	1.10	—	—
20	—	1.75	2.14
30	—	2.71	3.29
40	—	4.20	4.72
50	—	6.73	7.79
60	—	10.5	11.8

a) Average of two measurements with deviations within ±5% except for the data at 30 °C and 40 °C which are single. b) Solubilities are expressed in terms of anhydride.

where S represents the gram weight of inosine in terms of anhydride per 100 g of water. Two cross-points are obtained, the one formed by the two lines derived from Eq. (1) and Eq. (3), and the other, from those derived from Eq. (2) and Eq. (3). They represent the transition temperatures from the dihydrate-form to the α-form, and from the dihydrate-form to the β-form, respectively. The former is estimated to be about 17 °C, and the latter, about 10 °C. The dihydrate-form is stable below these temperatures.

The transition from the α-form to the β-form was observed when some seed β-crystals were added to a slurry of the α-crystals in water. The rate is in proportion to the amount of the seed β-crystals. When the amount of the seed β-crystals added was 20% of the amount of the α-crystals in the slurry, the transition was observed to begin a little after 1 hr, to be about half completed after 4 hr, and to be over completely within 20 hr. A slower rate was observed when the seed crystals were decreased to 10%. In this case, the transition was slightly observed after 6 hr, and it took 40 hr for the complete conversion. On the other hand, in the absence of the seed β-crystals a slurry of the α-crystals did not show any transformation, not even at 95 °C after 24 hr.

The addition of the seed β-crystals also has a significant influence on the drying of the dihydrate crystals in air. When the dihydrate crystals are dried in air with heating, they lose the water of crystallization with ease, giving anhydrous crystals in the α-form. However, they give the crystals in the β-form when some seed crystals in the β-form are mixed in before heating.

Inosine crystallizes usually in the α-form from an aqueous solution; this fact is consistent with the law of successive reactions proposed by Ostwald. However, the crystals in the β-form were found to be often directly obtainable from about a 70%(w/w) dimethyl sulfoxide solution without the seed β-crystals. Since the solubility gap between the two forms causes the transition, any difference in the solubility between them in a 70% dimethyl sulfoxide solution must be larger than that in water. This will be discussed in the next paper.

The author wishes to thank Mr. Takashi Sato for his technical assistance.

Polymorphism of Inosine. III. The Equilibrium for the Inosine–Dimethyl Sulfoxide–Water System

Yoshihisa SUZUKI and Kentaro HARA

Central Research Laboratories, Ajinomoto Co., Inc., Suzuki-cho, Kawasaki 210

(Received March 1, 1974)

The phase diagram for the inosine–dimethyl sulfoxide–water system was determined at 30 °C. Inosine in the α-form is more soluble than that in the β-form in aqueous DMSO. The difference in the solubilities between the two forms is small when the concentration of DMSO is below 50%. However, it becomes several times larger in 70% DMSO than in water. This is the reason why inosine in the β-form is often obtainable with ease from 70% DMSO in the absence of seed β-crystals, while it is with difficulty obtained only from water. When the concentration of DMSO becomes higher than 82%, a new solid phase is obtained. It consists of inosine with two mol of DMSO of crystallization. Inosine in the β-form is also obtainable with ease through the decomposition of these new crystals.

Inosine is usually crystallized in the α-form from water; only when some seed crystals in the β-form are present it is crystallized in the β-form. However, the crystals in the β-form are directly obtained without seed crystals when inosine is crystallized from 70% (w/w) aqueous dimethyl sulfoxide (DMSO) at 30 °C.[1] In order to explain the above fact, the equilibrium for the inosine–DMSO–water system was studied. There is a datum on the solubility of inosine in pure DMSO at 30 °C by Rosenthal.[2]

Results and Discussion

Figure 1 shows the phase diagram for the inosine–DMSO–water system at 30 °C, and in Fig. 2 the details are plotted with the experimental data in terms of the solubility of inosine per 100 g of aqueous DMSO.

The solubility of inosine in the α-form in aqueous DMSO is higher than that in the β-form over the whole range. Consequently, β-crystals are more stable than α-crystals in aqueous DMSO, as is the case in water. However, a notable distinction was found between the aqueous DMSO system and the water system. It is the difference in the solubility between the two forms. It increases with an increase in the DMSO, with a steep ascent beyond 50% DMSO, while it is small and constant below 50%. In 75% DMSO it reaches about six times that in water. This large difference in the solubility is sufficient to cause the quick transition from the α-form to the β-form without any seed crystals. This is the reason why inosine is crystallized in the β-form from the 70% DMSO solution, whereas it is crystallized in the α-form from water.

In high concentration of DMSO near 80%, a new solid phase was obtained. It was found to be inosine, with two mol of DMSO of crystallization. It appears consecutively on the line of the β-crystal phase, as is shown in the figures. The composition of the critical point is DMSO : water : inosine=75.0 : 16.1 : 8.9(Point A in Fig. 2). When the concentration of DMSO is higher than that value, the new solid phase is most stable.

These inosine crystals with the DMSO of crystallization are incongruent and are decomposed by pure water. This property suggests another new method for the direct preparation of β-crystals. When these new crystals are treated with a small portion of water or aqueous DMSO (below 80%), they are transformed into inosine anhydrous crystals in the β-form. It has been pointed out that there is a region where the new crystals are less soluble than α-crystals and more solu-

ble than β-crystals. This region is shown between Point A and Point B in Fig. 2. When the new crystals are dissolved in this region, the β-crystals will be preferentially nucleated.

These new crystals are unstable in air and are gradually changed into β-crystals within a few days at room temperature, probably because of the influence of the humidity in the air. This transition of crystals in air is accelerated on heating.

Table 1 shows the X-ray powder diffraction data of these new crystals. It is of interest that inosine can be crystallized with two mol of DMSO of crystallization, while it is crystallized with the same moles of water of crystallization, and that DMSO is able to combine with inosine at room temperature, while water does so only at low temperatures.[1]

The solubility of inosine in pure DMSO reported by Rosenthal agreed with that for inosine in the α-form. However, it is obvious that the equilibrium is unstable and that inosine-dimethylsulfoxidate will be crystallized with a faint stimulation.

Experimental

Materials. The inosine used, of a commercial A-grade, was obtained from the Ajinomoto Co., Inc. The DMSO was of a reagent grade; its water content was checked by Karl Fischer titration.

Preparation of the Crystals. Inosine anhydrous crystals in the α-form and in the β-form were prepared according to the method reported in the preceding paper.[1] Inosine-dimethylsulfoxidate crystals were obtained as follows: inosine (12 g) was dissolved in DMSO (98%, 50 ml) with heating, after which mixture was stirred for two days at room temperature. The precipitated prism crystals were filtered, washed with ether, and analyzed immediately. Yield, 12 g; mp 88—89 °C. Found: C, 39.31; H, 5.69; N, 13.41%. Calcd for $C_{10}H_{12}N_4O_5\cdot(C_2H_6OS)_2$: C, 39.61; H, 5.70; N, 13.26%. Inosine content calculated from the optical density (250 nm in 0.1 M HCl) compared with the standard inosine, 64.0% (theoretical, 63.3%).

Solubility Measurements. A sufficient amount of the crystals selected among inosine-dimethylsulfoxidate and inosine in the α-form and in the β-form were mixed with aqueous DMSO to make a slurry in tightly-capped glass bottles. The equilibria were achieved by tumbling the bottles for 16 hr at 30 °C. Then, the mixtures were filtered by means of a glass filter. The UV absorbances at 250 nm in 0.1 M HCl were measured for the filtrates and the residues. The inosine contents were calculated from the molar extinction coefficient defined as 11,800 under the above conditions. The UV absorbances due to DMSO are negligible compared with those of inosine. The water contents in the solution phase were determined by Karl Fischer titration. The DMSO was determined by means of the difference. The residues on a filter were examined by the X-ray powder diffraction method in order to identify the crystal form.[3]

Decomposition of Inosine-dimethylsulfoxidate. (a) Inosine-dimethysulfoxidate (25 g) was added to aqueous DMSO (70%, 100 ml) to make a slurry. After the mixture had been shaken for 5 hr, it was left to stand overnight. The crystals suspended were filtered and identified by the X-ray method. (β-Form). (b) The crystals of inosine-dimethylsulfoxidate were precipitated according to the method described above. Immediately after the crystals had been removed from the mother liquor with a filter, they were washed with ether and left to stand in air for 3 hr at room temperature. Then, they are dried for 1 hr at 90 °C. They were identified by means of the X-ray method (β-Form).

The authors wish to thank Mr. Kunio Konno for his technical assistance.

The Equilibria for the Inosine–Calcium Hydroxide–Water and Inosine–Strontium Hydroxide–Water Systems

Yoshihisa SUZUKI and Yasuichi NOMURA

Central Research Laboratories, Ajinomoto Co., Inc., Suzuki-cho, Kawasaki 210

(Received March 1, 1974)

Solubility data have been obtained for the inosine-$Ca(OH)_2$-H_2O and inosine-$Sr(OH)_2$-H_2O systems at 10 °C. Three different solid phases of the calcium salt of inosine were found in the former system. The first is the normal hemi-calcium salt, $(inosine)_2 \cdot Ca \cdot 2H_2O$; the second, an abnormal salt, $(inosine)_3 \cdot Ca \cdot 3H_2O$, and the third, another abnormal salt, $(inosine)_4 \cdot Ca \cdot 9H_2O$. The former two salts have stable regions in the system, while the last one does not. The system including $Sr(OH)_2$ is simple, and no other salt-formation was found except for that of normal hemi-strontium salt, $(inosine)_2 \cdot Sr \cdot 2H_2O$. The X-ray powder diffraction data of the above four salts are given. The solubilities of the two normal hemi-alkaline-earth-metal salts of inosine in water were determined at 10—60 °C and formulated as follows:

$$\text{Ca-salt, } \log S = 0.00406 \cdot t - 0.4725$$

$$\text{Sr-salt, } \log S = 0.00551 \cdot t - 0.4116$$

where S represents the gram weight of anhydrous salt per 100 g of water.

In order to contribute to the process design of the separation or the purification of inosine, the two systems were examined and the solubility data for some alkaline-earth metal salts of inosine were obtained. No information has been found in the literature.

Results and Discussion

The results of the determination for the systems are presented in Tables 1 and 2, along with the experimental conditions. The mole ratio for the salt-formation between inosine and alkaline-earth metal is expected to be 2 : 1, in view of the acid-base valence. However, the system including calcium hydroxide is complicated because of the formation of two additional abnormal calcium salts of inosine besides the normal salt expected. One of them is estimated to be composed of three mol of inosine per mol of calcium atom with three mol of water of crystallization, and the other, of four mol of inosine per mol of calcium atom with nine mol of water. Their crystal habits are both feathery and fine-needle-like, thus hindering the precise determination of the water of crystallization. The above two abnormal salts of inosine can be explained as molecular compounds between the normal salts and free inosine. The former salt has a stable region in the system, while the latter does not and is metastable through-out the range. Their X-ray powder diffraction patterns are

shown in Table 3; they are characteristic enough to enable us to distinguish these crystals from other crystals.

The system including strontium hydroxide is simple, and no other salt-formation was found except the normal hemi-strontium salt of inosine.

The normal hemi-calcium salt and hemi-strontium salt of inosine possess stable regions in the systems. They are both obtained in the mono-hydrate form with respect to one mol of inosine and a half of the alkaline-earth metal. Their X-ray powder diffraction patterns are similar (Table 4), and it may be supposed that they have almost the same crystal structure except for the unit-cell dimensions, which are controlled by the atomic size of the alkaline-earth metal. The crystal appearances are also similar, both being fine hard pillars.

Table 5. Solubilities of normal alkaline-earth metal salts of inosine in water

Temp. (°C)	S (g anhydrous salt/100 g water)	
	$(Inosine)_2$·Ca·$2H_2O$	$(Inosine)_2$·Sr·$2H_2O$
10	0.364	0.430
30	0.458	0.590
40	—	0.664
50	0.530	—
60	—	0.801

Table 5 shows the solubilities of these two normal hemi-alkaline-earth-metal salts of inosine in water. Each logarithm of the solubility is linear to the temperature; they are expressed as follows:

$$\text{Ca-salt} : \log S = 0.00406 \cdot t - 0.4725$$

$$\text{Sr-salt} : \log S = 0.00551 \cdot t - 0.4116$$

where S is the gram weight of anhydrous salt per 100 g of water. The solubility-behavior of these two salts is similar. They are less soluble than free inosine.[1]

The two phase diagrams plotted with the data in Tables 1 and 2 are roughly similar figures in spite of the difference in the salt-formation. This is confirmed when they are superimposed with the same co-ordinates. The inosine-contents in solution give nearly equal minima when the mole ratio of inosine and alkaline-earth metal is 2 : 1. They both gradually increase with an increase in the alkaline-earth metal hydroxide content from that point. They both also show a steep descent with an increase in the alkaline-earth metal hydroxide content from a point where the inosine and alkaline-earth metal salts of inosine share the solid phase. The solubilities of calcium- and strontium-hydroxide in water increase at the same slope with an increase in the addition of inosine.

On the other hand, there is one remarkable difference between these two systems. The solubility of inosine in water always begins to increase with an increase in the strontium hydroxide content. However, two cases are possible in the system concerning calcium hydroxide:

in the one case the addition of calcium hydroxide to a saturated aqueous solution of inosine causes an increase in the solubility of inosine, while in the other case it causes a decrease. These two cases are incompatible while the same solid phase (inosine dihydrate) is present in the system. A different solubility is acceptable when different solid phases (calcium salt of inosine, B and C in Table 1) appear in the system. Actually a decrease in the solubility is observed when calcium hydroxide is added to a saturated aqueous solution of inosine, because a decrease in the solubility produces a stable calcium salt of inosine, whereas an increase of that produces a metastable calcium salt.

Experimental

Materials. The inosine used, of a commercial A-grade, was obtained from the Ajinomoto Co., Inc.; the other materials were of a reagent grade.

Analysis. The inosine was determined with UV-absorbance at 250 nm in 0.1 M HCl, using the molar extinction coefficient of 11,800 under the above conditions. The calcium was determined by EDTA-titration with a BT indicator and strontium by displacement titration with EDTA-Mg, using BT. The chlorine was checked by the Volhard method. The X-ray powder diffraction patterns (CuK_α) were used for the identification of the solid phase in equilibrium. The degree of hydration of the crystals was determined by Karl Fischer titration.

Preparation of the Crystals. Normal Calcium Salt of Inosine (A): Two solutions were prepared; one was inosine (26.8 g) in 1/12 M NaOH (1.2 l), and the other, $CaCl_2 \cdot 2H_2O$ (7.35 g) in water (10 ml). The latter solution was gradually stirred into the former solution at 40 °C. After the subsequent mixture had been cooled to room temperature, the precipitated needle crystals were filtered and dried in air. Mp 265 °C (colored), 290—295 °C (decomp. with bubbling). Found: Ca, 6.78; H_2O, 5.33; Cl, 0.00%; $\varepsilon_{250\,nm}$ in 0.1 M HCl, 10,370. Calcd for $(C_{10}H_{11}N_4O_5)_2 \cdot Ca \cdot 2H_2O$: Ca, 6.56; H_2O, 5.90; Cl, 0%; ε, 10,370. *Abnormal Calcium Salt of Inosine (B)*: Two solutions were prepared; one was inosine (20.1 g) in 1/6 M NaOH (300 ml), and the other, $CaCl_2 \cdot 2H_2O$ (3.68 g) in water (5 ml). The latter solution was gradually stirred into the former at 60 °C. After the mixture had been stirred for 30 min at that temperature, the precipitated crystals were filtered and dried in air. Mp 249—51 °C (decomp. with darkening). Found: Ca, 4.50; H_2O, 6.61%; $\varepsilon_{250\,nm}$ in 0.1 M HCl, 10,590. Calcd for $(C_{10}H_{11}N_4O_5)_2 \cdot C_{10}H_{12}N_4O_5 \cdot Ca \cdot 3H_2O$: Ca, 4.77; H_2O, 6.03%; ε, 10,400.

Abnormal Calcium Salt of Inosine (C): Finely powdered $Ca(OH)_2$ (0.17 g) was dissolved in cold water (100 ml), and then inosine (3.4 g) was stirred into this solution at 5—10 °C. When a few fine crystals appeared, they were quickly filtered and dried in air. Mp 146 °C(began to melt), 156 °C(half-melted), and 164—167 °C(decomp. keeping white). Found: Ca, 3.22; H_2O, 12.59%: $\varepsilon_{250\,nm}$ in 0.1 M HCl, 9,940. Calcd for $(C_{10}H_{11}N_4O_5)_2 \cdot (C_{10}H_{12}N_4O_5)_2 \cdot Ca \cdot 9H_2O$: Ca, 13.5; H_2O; 12.74%; ε, 9,760. *Normal Strontium Salt of Inosine* In water (500 ml), $Sr(OH)_2 \cdot 8H_2O$(21.3 g) was dissolved at 60 °C, and then powdered inosine crystals (43 g) were stirred into this solution. After the mixture had been kept for 30 min at 60 °C, the precipitated crystals were filtered and dried in air. Mp 326—8 °C(decomp. with darkening and bubbling). Found: Sr, 13.3; H_2O, 5.3%; $\varepsilon_{250\,nm}$ in 0.1 M HCl, 9.680. Calcd for $(C_{10}H_{11}N_4O_5)_2 \cdot Sr \cdot 2H_2O$: Sr, 13.3; H_2O, 5.5%; ε, 9.620.

Determination of Equilibria. Definite amounts (see Tables 1 and 2) of materials selected from among inosine, its calcium salts and $Ca(OH)_2$, or inosine, its strontium salts and $Sr(OH)_2 \cdot 8H_2O$ were added to water (50 ml) in tightly-capped glass bottles. The equilibrium was achieved by tumbling the bottles for 16 hr on a water bath at 10 °C. Then, the mixtures were quickly filtered with a glass filter, and the solution and the solid were submitted to analysis.

Solubility Measurements of Normal Alkaline-earth Metal Salts of Inosine. A sufficient amount of normal calcuim- or strontium-salt of inosine was added to water in a tightly-capped glass bottle, and the bottle was tumbled for 16 hr at a constant temperature(10—60 °C). Then the mixture was quickly filtered, and the UV absorbance of the filtrate was measured. The residue was checked by X-ray analysis.

The authors wish to thank Mr. Takashi Sato for his technical assistance.

A Study of the Inosine–Sodium Hydroxide–Water and Inosine–Potassium Hydroxide–Water Systems

Yoshihisa SUZUKI and Tadao TOKI

Central Research Laboratories, Ajinomoto Co., Inc., Suzuki-cho, Kawasaki 210

(Received March 27, 1974)

Solubility data have been obtained for the inosine-NaOH-H_2O and inosine-KOH-H_2O systems at 30 °C. Two different solid phases of the potassium salt of inosine ($C_{10}H_{11}N_4O_5 \cdot K \cdot H_2O$ and $C_{10}H_{11.5}N_4O_5 \cdot 0.5\,K \cdot 0.5\,H_2O$) were found in the latter system, while only one solid phase of the sodium salt of inosine ($C_{10}H_{11}N_4O_5 \cdot Na \cdot 2.5\,H_2O$) was found in the former system. The hemi-potassium salt of inosine is incongruent and is decomposed by pure water, whereas the mono-alkaline-metal salts are stable. The solubilities of the two mono-alkaline-metal salts of inosine in water were determined at 0—50 °C and formulated as follows:

$$\text{Na-salt, } \log S = 0.01359 \cdot t + 0.3997$$

$$\text{K-salt, } \log S = 0.00733 \cdot t + 1.6513$$

where S represents the gram weight of the anhydrous salt per 100 g of water. The X-ray powder diffraction data of the above three salts are given.

The equilibrium for the inosine—alkaline-earth metal hydroxide—water system was reported in the preceding paper.[1] This paper will describe the results for the inosine—alkaline metal hydroxide—water system. The solubilities of the alkaline metal salts of inosine in water were also determined.[2]

Results and Discussion

Table 1 shows the composition data in the solution phase for the inosine—sodium hydroxide—water system at 30 °C. The solubility of inosine increases linearly with an increase in the amount of sodium hydroxide until its mono-sodium salt is precipitated, and then it decreases with a steep slope until the mole ratio of inosine and sodium ion in the solution phase reaches 1 : 1. Thereafter, it increases again.

Table 2 shows the composition data in the solution phase and in the solid phase for the inosine—potassium hydroxide—water system at 30 °C. The solubility of inosine also increases with an increase in the quantity of potassium hydroxide with a slope nearly equal to that of sodium hydroxide until its mono-potassium salt is precipitated; thereafter it decreases a little until the mole ratio of inosine and potassium ion in the solution phase reaches about 2 : 3. Then, it increases again. However, on the way to the point where the mono-potassium salt begins to be precipitated, there is a clear region where the hemi-potassium salt of inosine is precipitated. Such a region is not found in the sodium hydroxide system.

The composition of the hemi-potassium salt of inosine can be explained as a molecular compound between one mole of the mono-potassium salt of inosine and one mole of free inosine. This salt is incongruent and is decomposed by pure water, because the region where this salt is stably present does not include the line on which the mole ratio of the inosine and the

potassium ion is 1 : (1/2).

On the other hand, the two mono-alkali-metal salts are stable in water. Table 3 shows the solubilities of these salts in water at 0—50 °C. Each logarithm of the solubility is linear to the temperature and is expressed as follows:

sodium-salt: $\log S = 0.01359 \cdot t + 0.3997$

potassium-salt: $\log S = 0.00733 \cdot t + 1.6513$

where S represents the gram weight of the salts per 100 g of water in terms of anhydride. No change in the solid phase was observed in the temperature range examined.

It is of interest that the alkaline metal salts of inosine examined in the present study show no similarity among each other with respect to solubility behavior and crystal structure, while the alkaline-earth metal salts of inosine do.[1] The solubility of the mono-potassium salt and that of the mono-sodium salt are quite different from each other. The former is ten times more soluble in water than the latter. On the other hand, the hemi-calcium salt and the hemi-strontium salt give solubilities nearly equal below a decimal point.[1] The hemi-alkaline-earth metal salts are both monohydrates, and their X-ray diffraction patterns are similar.[1] On the other hand, the mono-sodium salt possesses two and a half moles of water of crystallization, while mono-potassium salt possesses one mol of that; moreover, the X-ray diffraction patterns shown in Table 4 also indicate no resemblance.

There is another large difference between the two phase diagrams plotted with the data in Tables 1 and 2 in the mole ratios of inosine and alkaline metal ion at the point where mono-alkaline-metal salt begins to be precipitated. The ratios are 1 : 0.54 for the sodium hydroxide system and 1 : 0.98 for the potassium hydroxide system respectively. Because the latter value is very close to 1 : 1, it sometimes seems as if the mono-potassium salt of inosine were incongruent and were decomposed by pure water, especially when the salt possesses an impure composition.

Experimental

Materials. The inosine (α-form)[3] used was of a commercial A-grade of the Ajinomoto Co., Inc.,; the other materials were of a reagent grade.

Analysis. The inosine was determined by means of the UV absorbance at 250 nm in 0.1 M HCl using the molar extinction coefficient of 11,800 under the above conditions. The alkaline metal hydroxide was determined by titration with standard sulfuric acid, using a methyl red-bromcresol green indicator. The X-ray powder diffraction patterns (CuK_α) were used for the identification of the solid phase in equilibrium. The degree of hydration of the crystals was determined by Karl Fischer titration.

Preparation of the Crystals. *Mono-sodium Salt of Inosine*: Inosine (26.8 g) was dissolved in 1/2 M NaOH (200 ml) at 60 °C; then the solution was cooled at 10 °C. Precipitated thick prism crystals were filtered out and dried in air. Yield, 13 g; mp 198—202 °C. Found: Na, 6.90; H_2O, 13.5%; $\varepsilon_{250\,nm}$ in 0.1 M HCl, 9,450. Calcd for $C_{10}H_{11}N_4O_5 \cdot Na \cdot 2(1/2)H_2O$: Na, 6.87; H_2O, 13.4% ε, 9,440. *Mono-potassium Salt of Inosine*: Inosine (145 g) was dissolved in 22% aqueous KOH (180 g), and the solution was allowed to stand at 50 °C overnight with the addition of seed crystals. The seed crystals had previously been obtained by the rapid cooling of a little portion of that solution. The precipitated long prism crystals were filtered out, washed with 80% ethanol, and dried at 100 °C for 5 hr. Yield, 14 g; mp 163—6 °C. Found: K, 12.18; H_2O, 5.66%; $\varepsilon_{250\,nm}$ in 0.1 M HCl, 9,760. Calcd for $C_{10}H_{11}N_4O_5 \cdot K \cdot H_2O$: K, 12.06; H_2O, 5.55%; ε, 9,810. *Hemi-potassium Salt of Inosine*: Inosine (200 g) was dissolved at 80 °C in 12% aqueous KOH (240 g), after which the mixture was filtered with a glass filter in order to obtain a clear solution. When it was cooled to 50 °C, a very small amount of seed crystals was added; the mixture was then left to stand for two days at 50 °C. The seed crystals had previously been obtained by the rapid cooling of a little portion of that solution. The precipitated needle crystals were quickly filtered out, sandwiched between filter paper with pressure in order to remove the mother liquor completely, and then dried for 5 hr at 100 °C. Yield, 30 g; mp 172—5 °C. Found: K, 6.86; H_2O, 3.41%; $\varepsilon_{250\,nm}$ in 0.1 M HCl, 10,430. Calcd for $C_{10}H_{12}N_4O_5 \cdot C_{10}H_{11}N_4O_5 \cdot K \cdot H_2O$: K, 6.60; H_2O, 3.04%; ε, 10,660.

Determination of Equilibria. The equilibria were usually approached by dissolving the crystals in water or aqueous alkaline hydroxide at a constant temperature. In a few cases they were approached by cooling the supersaturated solution. The details in Table 1 show that the equilibria at 30 °C were approached by dissolving inosine in the α-form (Runs No. 1,3,7 and 11), by dissolving sodium salt of inosine

(No. 9,10 and 12—15), by dissolving the above two materials (No. 8), and by cooling the supersaturated solutions (No. 2,4,6 and 7). The supersaturated solutions were prepared by dissolving inosine in aqueous NaOH at 60 °C. Those in Table 2 show the results obtained by dissolving inosine in the α-form (Runs No. 1—3 and 5), by dissolving the hemi-potassium salt of inosine (No. 6), by dissolving the above two materials (No. 4), by dissolving the mono-potassium salt of inosine (No. 8—13), and by dissolving both hemi- and mono-potassium salts (No. 7). Those in Table 3 show the results obtained by dissolving the alkaline metal salts of inosine in water at a constant temperature (0—50 °C). It took 16 hr for the equilibrium to be reached by tumbling the bottles holding the mixture on a water bath at a constant temperature. The mixture in the bottles was quickly filtered with a glass filter, and the solutions and the residues were submitted to analysis.

The authors wish to thank Mr. Sukehiro Yamazaki for his technical assistance.

The Thermodynamic Properties of Tetraalkylammonium Halides in Acetone*

Masahiro IMURA, Hiroyasu NOMURA, Fumio KAWAIZUMI and Yutaka MIYAHARA

Department of Chemical Engineering, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya-shi 464

(Received April 1, 1974)

The vapor-pressure depressions of solutions of four tetraalkylammonium halides in acetone were determined by means of a vapor-pressure osmometer. The experimental results were discussed by analyzing the relationship between the $h(=1000 \ln a_1/M_1m+1)$ function and the concentration. The following conclusions are obtained: tetraalkylammonium salts are dissociated in acetone, and the thermodynamic behavior of the dissociated species is described by the Debye-Hückel-Onsager limiting formula with sufficient accuracy, where the undissociated species are assumed to behave ideally.

Except for $(n\text{-Bu})_4\text{NCl}$, the dissociation constants determined by the present work are in good agreement with those found in the literature, which were determined conductometrically.

In our previous papers,[1,2] we presented the results of our thermodynamic study of solutions of various strong electrolytes in such solvents as acetone, methanol, ethanol, ethyl methyl ketone, and *N,N*-dimethylformamide. The activities of solvents in these solutions were determined by vapor-pressure osmometry, and the unusual behavior of the activity coefficients of solutes in the vicinity of infinite dilution derived from those of solvents was ascribed to existence of an association or a dissociation equilibrium.

In the present paper, the results of a similar study of solutions of a series of tetraalkylammonium salts in acetone will be presented.

Theoretical

In vapor-pressure osmometry, the activity of a solvent in the solutions, a_1, is related to the change in electrical resistance, Δr, of the thermistor by the following equation:

$$\Delta r = \frac{BrR}{\Delta H} \ln a_1 = K_e \ln a_1 \qquad (1)$$

where B is the thermistor-constant; r, the electrical resistance of the thermistor; R, the gas constant, and ΔH, the enthalpy change in the evaporation of the pure solvent. The proportional constant, K_e, is determined by measurement with a standard substance, the activity of which is known.

If the dissolved salt, MX, is dissociated into the ions, M^+ and X^-, as:

$$MX \rightleftharpoons M^+ + X^- \qquad (2)$$

the activities of undissociated salt and ions are related to the activity of the solvent by the Gibbs-Duhem equation as:

$$N_1 d\ln a_1 + m_2 d\ln a_2 + m_3 d\ln a_3 + m_4 d\ln a_4 = 0 \qquad (3)$$

where a_2, a_3, and a_4 are the activities of MX, M^+, and X^- respectively, N_1 is the mole-number of the solvent $(=1000/M_1)$, and m_2, m_3, and m_4 are the molalities of MX, M^+, and X^- respectively.

In order to calculate the activity of the solute from that of the solvent by using the Gibbs-Duhem equation, a function, h, defined as:

$$h = \frac{1000 \ln a_1}{M_1 m} + 1 \qquad (4)$$

is usually used. Here, m is the molal concentration of the added solute. The apparent activity of the added solute a_2', is given by the integration of h as:

$$\ln \frac{a_2'}{m} = -h - \int_0^m \frac{h}{m} dm \qquad (5)$$

The unusual behavior of the h/m function of strong electrolytes in organic solvents at an infinite dilution has been fully discussed in our previous papers.[1,2]

Experimental

The lowering of the vapor pressure of a solution was measured by means of a vapor-pressure osmometer, Hitachi-Perkin-meter, Type 115. When the concentrations of the solutions were in the range from *ca.* 1×10^{-3} to 30×10^{-3} mol/kg. solvent, the reading of the meter became stable within 5 min after the solution was dropped. As the standard substance for the determination of the K_e constant, a standard sample of benzyl supplied by Nissei Sangyo Co., Ltd., was used. The tetraalkylammonium salts used were $(n\text{-Pr})_4\text{NI}$, $(n\text{-Bu})_4\text{NCl}$, $(n\text{-Bu})_4\text{NI}$, and $(n\text{-Bu})_4\text{NBr}$. The former three were supplied by Nakarai Chemicals Co., Ltd., and the last one, by Tokyo Kasei Co., Ltd. The guaranteed pure-grade reagents were used without further purification. The acetone, solvent, used was obtained by drying and distilling the guaranteed pure-grade commercial product by the usual method. The measuring temperatures were 40.3 °C for all samples and furthermore, 43.8 and 33.3 °C for benzyl and $(n\text{-Bu})_4\text{NI}$.

Results and Discussion

As an illustration, the plots of Δr against m for $(n\text{-Bu})_4\text{NI}$ and benzyl, the standard sample, at the temperatures of 33.0, 40.3, and 43.8 °C are shown in Fig. 1. As may clearly be seen in Fig. 1, the plots of $(n\text{-Bu})_4\text{NI}$ do not fall on the straight lines of benzyl, the activity coefficient of which is believed to be unity. As has been reported in the previous paper,[1] Eq. (1) holds true under the conditions of thermodynamic equilibrium. The value of K_e empirically obtainable is, however, that of the steady state, which we will designate as K_s hereafter. The K_s/K_e ratio was examined for benzyl, the standard sample. K_e was obtained from the data of the heat of vaporization of the solvent, ΔH, and the noted value of the thermistor-constant, B. The results are shown in Table 1. As may be seen in Table 1, the values of the K_s/K_e ratio are nearly constant at these temperatures. On the basis of these

results, we assume that present results can be used as the thermodynamic standard values at all temperatures.

As has been reported in the previous papers,[1,2] the plots of h/m against m show the existence of dissociation when $\lim_{m\to0} h/m=-\infty$ and of association when $\lim_{m\to0} h/m=+\infty$. The plots of h/m *vs.* m are, however, not adequate for the curve-fitting to determine the activity coefficients, since the errors become larger when m approaches zero. In the present paper, therefore, the plots of h *vs.* m are used for this purpose.

In Fig. 2, the plots of h against m at 40.3 °C are shown. The value of h is, as may be seen in Figs. 2 and 3 in the $-1\leq h\leq0$ range, which shows the existence of a dissociation equilibrium.

According to the Gibbs-Duhem equation, the behavior of h at low concentrations may be formulated on the basis of the following assumptions:

(I) There exists neither dissociation nor association, and the activity coefficient of the solute is unity over all the concentration range. Then:

$$\ln a_1 = -\frac{m}{N_1} \tag{6}$$

and

$$\lim_{m\to0} h = 0 \tag{7}$$

(II) There exists a dissociation equilibrium. The activity coefficients of MX, M^+, and X^-, γ_2, γ_3, and

● benzil, ■ $(n\text{-Bu})_4\text{NBr}$, △ $(n\text{-Bu})_4\text{NCl}$
▲ $(n\text{-Bu})_4\text{NI}$ ○ $(n\text{-Pr})_4\text{NI}$

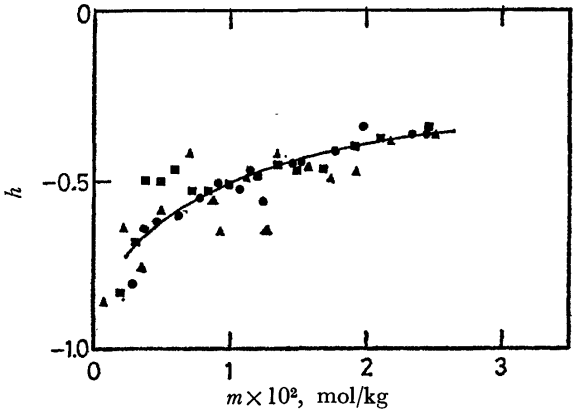

Fig. 3. Relationships between h and the concentration for $(n\text{-Bu})_4\text{NI}$ at three different tempertures.
■ at 43.8 °C, ▲ at 40.3 °C, ● at 33.3 °C

γ_4, are all unity. Then (see Appendix)

$$h = \frac{K-\sqrt{K^2+2mK}}{2m} \tag{8}$$

and:

$$\lim_{m\to0} h = -1 \tag{9}$$

where K represents a dissociation constant.

(III) The activity coefficient of MX, γ_2, is unity, while those of the dissociated ions, γ_3 and γ_4, obey the Debye-Hückel-Onsager limiting formula. Then (see Appendix):

$$h = \frac{1}{m}\left\{m_4 - \frac{2A(\sqrt{m_4})^3}{3}\sigma(x)\right\} \tag{10}$$

$$\sigma(x) = \frac{1}{x^3}\left\{(1+x)-2\ln(1+x)-\frac{1}{(1+x)}\right\} \tag{11}$$

$$x = Ba_0\sqrt{m} \tag{12}$$

$$m_4 = \frac{-K+\sqrt{K^2+4mK\gamma_\pm^2}}{2\gamma_\pm^2} \tag{13}$$

$$\ln\gamma_\pm = -\frac{A|Z_1Z_2|\sqrt{m_4}}{1+Ba_0\sqrt{m_4}} \tag{14}$$

(IV) The activity coefficient of the undissociated

molecule, γ_2, is also not unity. Then (see Appendix):

$$h = \frac{1}{m}\left\{\frac{1}{2}\beta_2 m_2^2 - \frac{2}{3}\beta_3 m_2^3 - m_4 + \frac{2A(\sqrt{m_4})^3}{3}\sigma(x)\right\} \quad (15)$$

$$\ln \gamma_2 = -\beta_2 m_2 + \beta_3 m_2^2 + \cdots \quad (16)$$

$$m_2 = m - m_4 \quad (17)$$

As may clearly be seen in Fig. 2, the (I) assumption is not satisfied in the present results. Most strictly speaking, the behavior of the solutes in solution must be analyzed on the basis of the (IV) assumption. In the present work, however, in order to determine the dissociation equilibrium constant, the curve-fitting was attempted by using Eq. (8) or (9) because of the difficulties in calculation and the obscurities of the parameters in Eq. (15) in their physical meanings. The calculations were carried out by means of a computer, HITAC 10. The calculated values of the dissociation constants obtained from either Eq. (8) or (10) are shown in Tables 2 and 3. The numerical values of a_0 appearing in Eqs. (12) and (14) are those of Evans *et al.*[3] obtained from the electric conductivity measurements. Table 4 shows the means errors for the h function, $|h_{exp}-h_{theor}|$.

Table 2. Dissociation constants K in acetone at 40.3 °C

	Eq. (8)	Eq. (10)
$(n\text{-Bu})_4$NCl	6.4×10^{-4}	5.5×10^{-4}
$(n\text{-Bu})_4$NBr	6.2×10^{-3}	4.5×10^{-3}
$(n\text{-Bu})_4$NI	5.6×10^{-3}	4.0×10^{-3}
$(n\text{-Pr})_4$NI	6.8×10^{-3}	4.4×10^{-3}

Table 3. Dissociation constants K of $(n\text{-Bu})_4$NI in acetone

	Eq. (8)	Eq. (10)
33.3 °C	5.4×10^{-3}	3.9×10^{-3}
40.3 °C	5.6×10^{-3}	4.0×10^{-3}
43.8 °C	4.6×10^{-3}	3.3×10^{-3}

Table 4. Mean errors for the h function ($=|h_{exp}-h_{theor}|$) in acetone at 40.3 °C

	Eq. (8)	Eq. (10)
$(n\text{-Bu})_4$NCl	0.042	0.041
$(n\text{-Bu})_4$NBr	0.053	0.048
$(n\text{-Bu})_4$NI	0.064	0.060
$(n\text{-Pr})_4$NI	0.032	0.030

As may be seen in Tables 2, 3, and 4, Eqs. (8) and (10) showed almost no significant difference in the values of the equilibrium constant and of h. Therefore, it can not be decided from the present results whether the activity coefficient of the undissociated molecule is unity or not.

Table 5 compares our values of the dissociation constant obtained from Eq. (10) and those found in the literature[4,5] obtained from the electric conductivity measurements. The agreement among them is satisfactory except for $(n\text{-Bu})_4$NCl.

Table 5. Comparison of the dissociation constants K by the present work with those by the conductometry

	Present work	Kraus *et al.*[4,5]	Evans *et al.*[3]
$(n\text{-Bu})_4$NCl	0.55×10^{-3}	2.28×10^{-3}	2.33×10^{-3}
$(n\text{-Bu})_4$NBr	4.5×10^{-3}	3.29×10^{-3}	3.51×10^{-3}
$(n\text{-Bu})_4$NI	4.0×10^{-3}	6.48×10^{-3}	6.45×10^{-3}
$(n\text{-Pr})_4$NI	4.4×10^{-3}	4.98×10^{-3}	5.75×10^{-3}

In the above comparison, the following two points were taken in consideration. First: in the electric conductivity measurements reported in the literature,[4,5] the concentration was given in terms of molarity, whereas that in our present result in terms of molality. The effect of this difference in the concentration on the final result is, however, considered not to be significant. Second: in Table 5, the measuring temperature of our present data is 40.3 °C, while that of the conductivity measurements is 25 °C. The effect of these temperature differences is also not taken into account since the temperature dependence of the equilibrium constant of the tetraalkylammonium salts in methanol reported by Kay *et al.*[6] is not very large.

Conclusion

Tetraalkylammonium salts dissolved in acetone are dissociated. The equilibrium constant of dissociation was determined on the assumption that the behavior of dissociated ions is represented by the Debye-Hückel-Onsager limiting formula. The extraordinarily small value in the equilibrium constant of $(n\text{-Bu})_4$NCl can not be explained at present.

Appendix

Derivation of Eq. (8): In the case of the (II) assumption, $a_2=m_2$, $a_3=m_3$, and $a_4=m_4$ as well as $m=m_2+m_4$ and $m_3=m_4$. The substitution of these relations into Eq. (3) gives, after integration:

$$\ln a_1 = -\frac{1}{N_1}(m+m_4) \quad (1a)$$

On the other hand, from the equation of the dissociation constant:

$$K = \frac{m\alpha^2}{1-\alpha} = \frac{m_4^2}{m-m_4} \quad (2a)$$

we obtain this relation:

$$m_4 = \frac{-K+\sqrt{K^2+4mK}}{2} \tag{3a}$$

On combining Eqs. (1a) and (3a) with Eq. (4), we obtain Eq. (8).

Derivation of Eq. (10): In the case of the (III) assumption, Eq. (3) reduces to:

$$N_1 \mathrm{d} \ln a_1 + \mathrm{d}m_2 + 2\mathrm{d}m_4 + 2m_4 \mathrm{d} \ln \gamma_\pm = 0 \tag{4a}$$

where $\gamma_\pm = (\gamma_3\gamma_4)^{1/2}$.

By substituting Eq. (13) in Eq. (4a) and intergrating the equation, we obtain:

$$\ln a_1 = -\frac{1}{N_1}\left\{m_2+2m_4-\frac{2A(\sqrt{m_4})^3}{3}\sigma(x)\right\} \tag{5a}$$

On combining Eq. (5a) with Eq. (4), we obtain Eq. (10).

Derivation of Eq. (15): we assume, for the activity coefficient, Eq. (16). Calculations similar to those for the derivation of Eq. (9) leads us to Eq. (15).

Photoelectron Spectra of Substituted Benzenes

Tsunetoshi KOBAYASHI and Saburo NAGAKURA

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato, Tokyo 106

(Received April 25, 1974)

Photoelectron spectra were measured in the region between 6 and 21 eV for aniline, *N,N*-dimethylaniline, phenol, anisole, benzonitrile, acetophenone, nitrobenzene, and their methyl derivatives. The observed spectra were interpreted in terms of their MO's obtained by the CNDO/2 and EHMO methods, the methyl-substituent effect and the steric hindrance effect being considered. Both effects are essential for the reliable assignment of the observed photoelectron spectra. We found a general tendency that the interaction of the doubly degenerate highest occupied orbitals (e_{1g}) of the benzene ring with the highest occupied orbital of a substituent group is important for the interpretation of the observed lower energy (7~12 eV) bands. The only exceptional case is the nitrobenzenes in which the lowest vacant orbital of the substituent group is rather close to the highest occupied orbitals of the benzene ring and the interaction between them is important. The effects of the substituent groups upon the observed photoelectron spectra are classified into four types.

Photoelectron spectroscopy[1] developed in recent years gives direct information about occupied molecular orbital energies and is expected to be a useful tool to investigate the effect of substituent groups upon the electronic structures of parent hydrocarbons.

We have studied photoelectron spectra (PES) of various kinds of substituted benzenes and have already published the results of styrene and its methyl derivatives.[2] Steric hindrance of the α- or *ortho*-methyl group was found to have great effect on the PES of methyl-substituted styrenes, and the relation between the higher occupied π-orbital energies of styrene and the twist angle of the vinyl group was discussed from both experimental and theoretical points of view. Furthermore, some preliminary reports have been published on the PES of aniline, *N,N*-dimethylaniline, nitrobenzene, and their methyl derivatives.[3,4]

In this paper we intend to discuss systematically our results of PES obtained hitherto with substituted benzenes; phenol, anisole, benzonitrile, acetophenone, and their methyl derivatives being newly treated in addition to the molecules studied in the preliminary reports.[3,4] Main purposes of the present study are as follows: 1) to make assignments of lower energy bands in the PES of the substituted benzenes under consideration as reliably as possible, orbital energies calculated by the CNDO and EHMO methods and the effect of methyl-substituent group being considered; 2) to interpret systematically the observed PES in terms of the interaction between substituent groups and the benzene ring; 3) to clarify the correlation between the observed PES and the steric hindrance of methyl-substituent groups.

Baker *et al.*[5] measured the PES of aniline, *N,N*-dimethylaniline, *p*-toluidine, *N,N*-dimethyl-*p*-toluidine, phenol, and anisole with a relatively low-resolution magnetic deflection type photoelectron spectrometer. Thereafter, several works[6-11] on the PES of some of the compounds studied here have been published. They are discussed in comparison with our results in later parts of this paper.

Experimental and Calculation

2,4-Dimethylanisole and 2,6-dimethylanisole were synthesized according to Ref. 12 and isolated by column chromatography. All the samples were purified in usual ways and their purities were checked with the aid of gas chromatograms and NMR spectra.

The PES of these compounds were recorded on a JASCO model PE-1 photoelectron spectrometer and a newly constructed photoelectron spectrometer[2] with a sample inlet system which can be heated, if necessary, up to *ca.* 140 °C. HeI resonance line of 584 Å was used as excitation source and Xe gas as the internal standard for the calibration.

The CNDO/2[13] and the EHMO[14] calculations of these compounds were carried out by a FACOM 270—30 and a FACOM 230—60 computer at the Institute of Physical and Chemical Research. The geometrical structure of *N,N*-dimethylaniline was taken from Ref. 15 and the geometrical structures of the other compounds were taken from Refs. 16 and 17 or assumed based on the data given in these references.

Results and Discussion

Anilines. The PES of aniline, *o*-, *m*-, and *p*-toluidines, *N,N*-dimethylaniline, and *N,N*-dimethyl-*o*-, *m*-, and *p*-toluidines are shown in Fig. 1. The vertical ionization potentials, $I_v(J)$, of these compounds were obtained from the observed PES and are summarized in Table 1.

As is seen in Fig. 1 and Table 1, these aromatic amines commonly show three lower energy bands in the region from 7 eV to 11 eV. They are assigned to the ionizations from three π MO's, b_1 (like), a_2 (like), and b_1 (like),[3] which are caused by the interaction among the highest occupied doubly degenerate π orbitals, e_{1g}(S) and e_{1g}(A), (9.23 eV) of the ring and the lone pair (n) orbital of the corresponding alkylamine (9.7 eV[18] for methylamine and 8.5 eV[18] for trimethylamine). As is clearly seen in Fig. 2 which shows schematically the orbitals concerned, the first and third highest occupied π MO's are delocalized over both benzene ring and amino nitrogen atom, while the second highest occupied π MO is localized on the benzene ring. This assignment is supported by the fact that the first and third bands of aniline and toluidines shift much more by *N,N*-dimethylation than their second bands.

The shifts, $\Delta I_v(J)$ (J=1,2....), of the lowest three vertical ionization potentials of aniline and *N,N*-dimethylaniline by *o*-, *m*-, and *p*-methyl substitutions

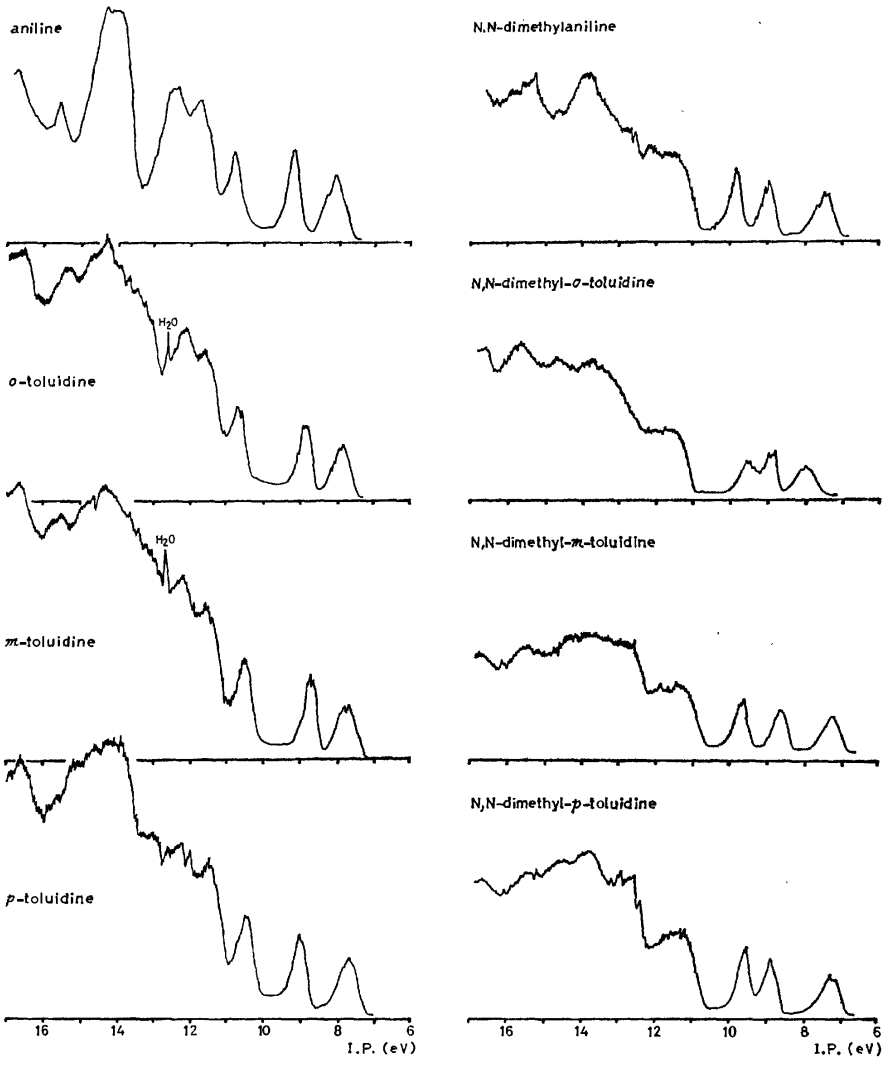

Fig. 1. Photoelectron spectra of anilines.

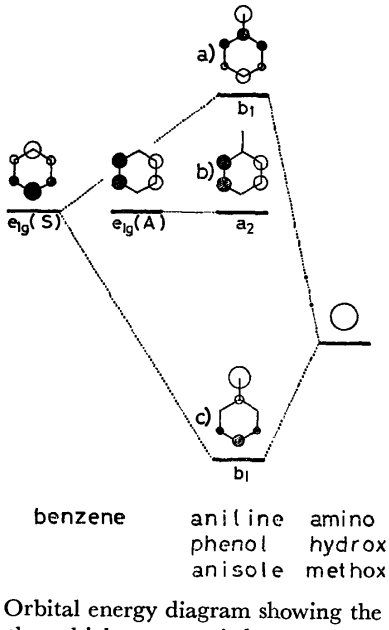

Fig. 2. Orbital energy diagram showing the correlation of the three highest occupied π orbitals of aniline (phenol or anisole) with the benzene e_{1g} π orbitals and a substituent lone pair orbital.

can be estimated by the aid of the following equation derived by the first-order perturbation theory.[19]

$$-\Delta I_v(J) = 0.0528 + 1.0110 \sum_{\zeta} (3C_{J\zeta}^2 + C_{J\tau}^2 + C_{J\tau'}^2)/3 \quad (1)$$

Here ζ denotes the position of methyl substitution, and τ and τ' the positions of the nearest neighbours to ζ. C_{Jk} is the coefficient of the k-th AO in the J-th π MO obtained by the CNDO/2 method. The vertical ionization potentials of methyl substituted anilines and *N,N*-dimethylanilines were estimated by considering those of the parent compounds and the $\Delta I_v(J)$ values thus obtained. The results are listed in Table 1 (in the parentheses).

As is seen in Table 1, the estimated values agree rather well with the observed ones except for the case of *N,N*-dimethyl-*o*-toluidine in which the estimated values of the first and third ionization potentials are smaller by 0.73 eV and greater by 0.17 eV than the corresponding observed ones, respectively, and, therefore, the estimated splitting between them (2.49 eV) is much larger than the observed value (1.59 eV). It is known[20-23] that the dimethylamino group of *N,N*-dimethyl-*o*-toluidine is twisted from the benzene ring

plane by the steric hindrance effect of the *o*-methyl group. This twisting decreases the conjugation between the e_{1g}(S)-like π orbital of benzene ring and the nitrogen n orbital and, therefore, decreases the splitting between the first and third I_v's of *N,N*-dimethyl-*o*-toluidine.

In the preliminary report,[3] we estimated the lowest three I_v's of the hypothetical *N,N*-dimethyl-*o*-toluidine with no steric hindrance effect to be 7.41~7.48 eV, 8.69 eV, and 9.85~9.86 eV by adding the correction terms due to *N,N*-dimethylation to the corresponding values of *o*-toluidine. The splitting between the first and third ionization potentials thus obtained, 2.37—2.45 eV, is in good agreement with the value estimated with the aid of Eq. (1), 2.49 eV.

Concerning aniline, the splitting between the first and second bands is smaller than that between the second and third bands. The reverse is the case for *N,N*-dimethylaniline. This indicates that in the case of aniline, as is shown in Fig. 2, the benzene ring e_{1g} π orbitals are higher than the amino group n orbital, while, in the case of *N,N*-dimethylaniline, the relative height of both orbitals is reversed. This reversal is caused by the increase in the n orbital energy of the amino group by *N,N*-dimethylation. This means that the highest occupied and third highest occupied MO's of aniline are mainly contributed by e_{1g}(S) orbital of the ring and the n orbital on the nitrogen atom, respectively, while the reverse is the case for *N,N*-dimethylaniline. This is supported qualitatively by the CNDO/2 calculation.

The correlation diagram for the orbital energies of these aromatic amines obtained on the assumption of $\varepsilon=-I_v$ (Koopmans' theorem[24]) has already been shown in Fig. 1 of Ref. 3.

The PES of aniline, *N,N*-dimethylaniline, *o*-toluidine and *N,N*-dimethyl-*o*-toluidine have recently been reported by Maier and Turner[11] and their assignment of the three lower energy bands is consistent with that given in our preliminary report[3] and in the present paper.

Phenols and Anisoles. The PES of phenol, *o*-, *m*-, and *p*-cresols, 2,4- and 2,6-dimethylphenols, anisole, *o*-, *m*-, and *p*-methylanisoles, and 2,4- and 2,6-dimethylanisoles are shown in Fig. 3, and the observed $I_v(J)$'s of these compounds are summarized in Table 2.

Phenols and anisoles commonly show three lower energy bands in the region between 8 eV and 11.5 eV. This region corresponds to the ionization from the benzene e_{1g}(S) and e_{1g}(A) orbitals and from the n orbital on the oxygen atom of methanol (10.96 eV)[25] or methyl ether (10.04 eV).[26] Therefore, the lower three energy bands of phenols or anisoles are mainly related to the MO's caused by the interaction of the e_{1g}(S) and e_{1g}(A) orbitals of the ring with the oxygen

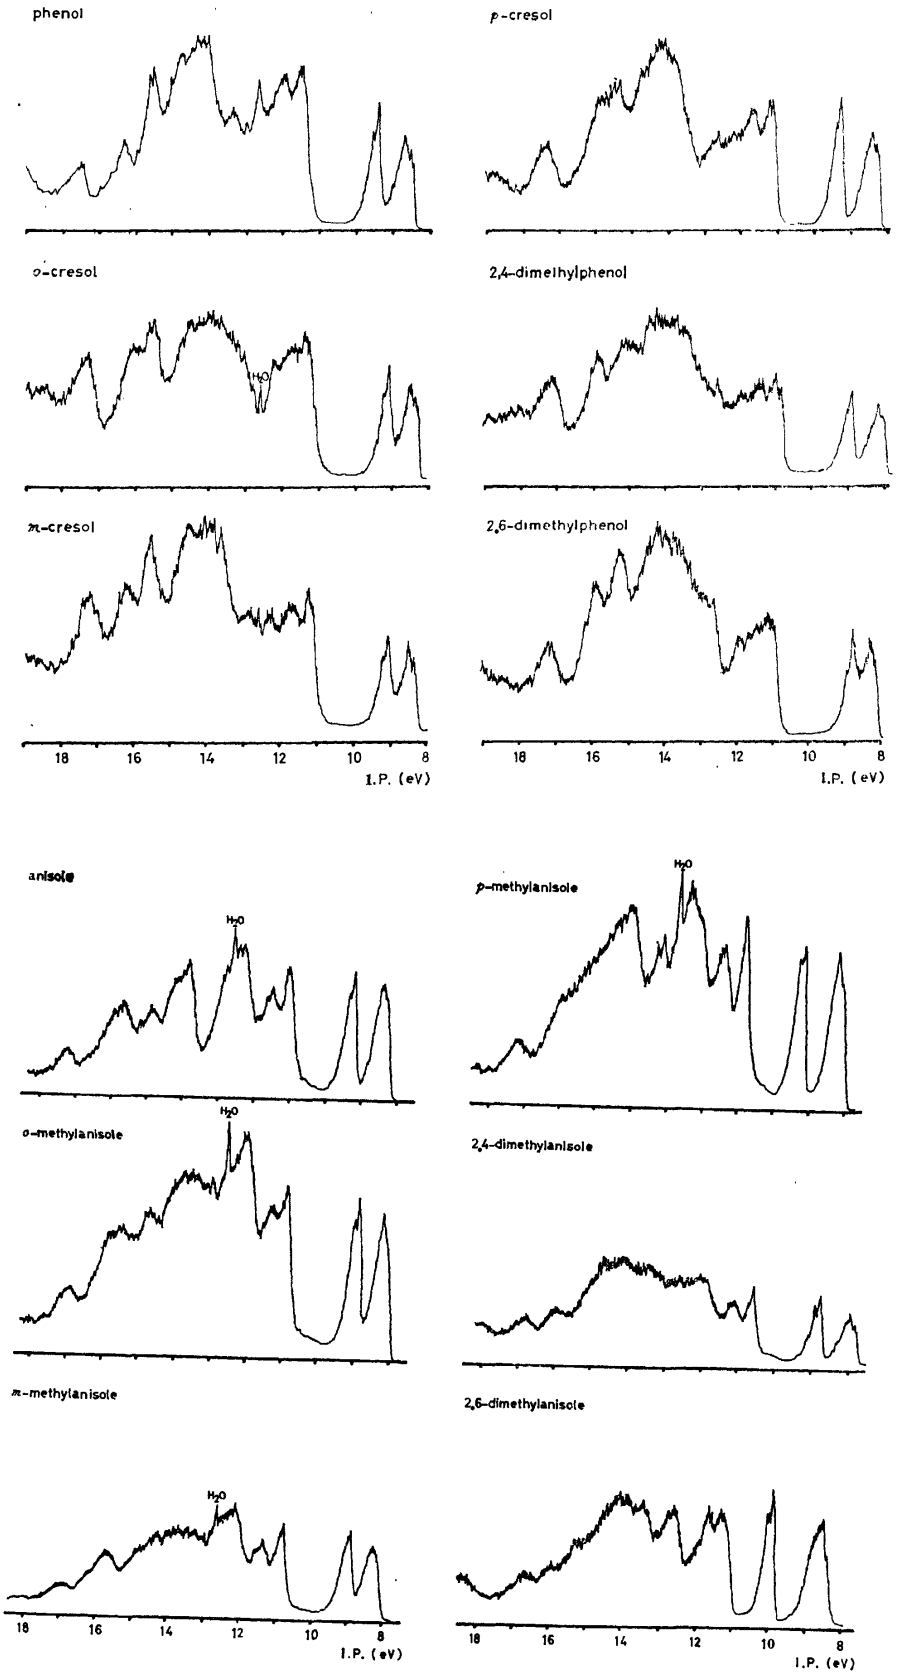

Fig. 3. Photoelectron spectra of phenols and anisoles.

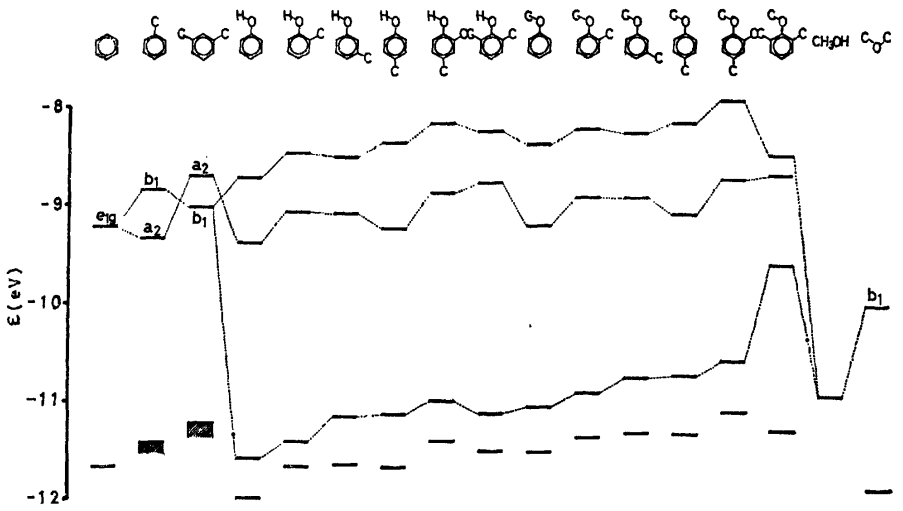

Fig. 4. Orbital energy diagram for the higher occupied orbitals of phenols and anisoles.

n orbital as schematically shown in Fig. 2. This qualitative scheme is supported by the CNDO/2 calculation. The observed orbital energy diagram estimated according to Koopmans' theorem[24] is shown in Fig. 4.

Now let us consider methyl substituent effects on the PES of phenol and anisole. The lowest three ionization potentials of some methyl substituted phenols and anisoles were estimated by two methods: one of them is to estimate the substituent effect by the aid of Eq. (1) and the other is to derive the ionization potentials of dimethyl derivatives from those of monomethyl derivatives and the parent molecules by assuming the additivity of the methyl substituent effect. The vertical ionization potentials of the methyl derivatives estimated by the aid of both methods are summarized in Table 2 (in the parentheses and the square brackets).

As is clearly seen in Table 2, the lowest three ionization potentials estimated by both methods are in good agreement with the observed values except for the case of 2,6-dimethylanisole. In particular, the agreement is better for the values estimated by the additivity rule.

The lowest and third lowest ionization potentials estimated by both methods for 2,6-dimethylanisole show large discrepancies from the observed values. The estimated values are for the planar molecule; in actuality, however, the methoxyl group of this molecule is considered to be twisted by around 90°[27,28] from the benzene ring plane because of the steric hindrance effect of the two *o*-methyl groups. This twisting decreases the conjugation between the ring π orbital and the oxygen n orbital. This is the reason why the observed lowest and third lowest ionization potentials are larger and smaller, respectively, compared with the corresponding values estimated for the hypothetical planar molecule.

The difference between the first and second ionization potentials is smaller for both phenol and anisole than that between the second and third ionization potentials. This is similar to the situation found for aniline and indicates that the highest occupied orbitals of phenol and anisole are mainly contributed by the ring e_{1g}(S) orbital.

The PES of phenol, *o*-cresol, 2,6-dimethylphenol, anisole, *o*-methylanisole and 2,6-dimethylanisole were reported recently by Maier and Turner.[11] The PES

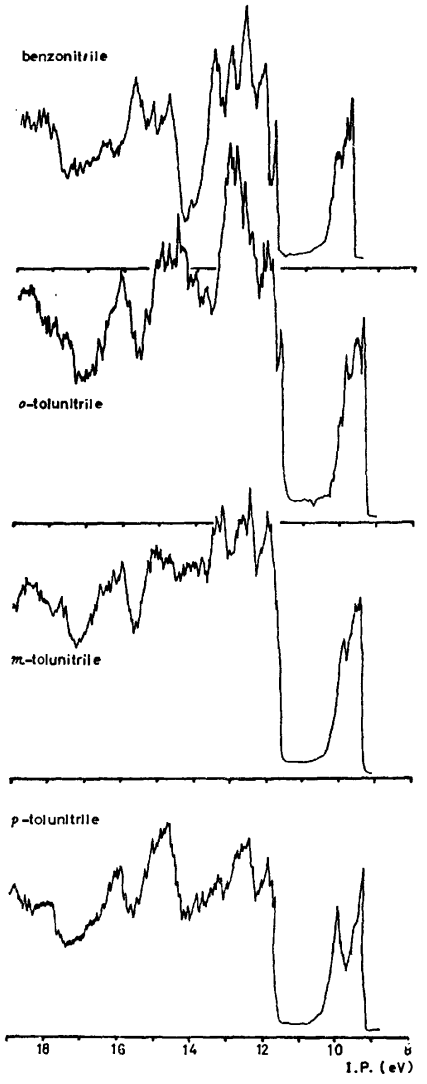

Fig. 5. Photoelectron spectra of benzonitriles.

of 2,6-dimethylanisole reported by them, however, is slightly different from ours: in their spectrum, the first band is too strong compared with the third band and an additional band appears around 9.20 eV. This additional band could not be observed for our sample which was purified by column chromatography and the purity of which was checked with gas chromatography and NMR spectrum. This band may be due to some impurities.

Benzonitriles. The PES of benzonitrile and *o*-, *m*-, and *p*-tolunitriles are shown in Fig. 5. The observed $I_v(J)$'s of benzonitriles are summarized in Table 3.

TABLE 3. VERTICAL IONIZATION POTENTIALS ($I_v(J)$ IN eV) OF BENZONITRILE AND ITS METHYL DERIVATIVES, AND ACETONITRILE[a)]

	$I_v(J)$ (eV)			
J	1	2	3	4
Benzonitrile	9.72	10.14	11.84	12.11
o-Tolunitrile	9.38 (9.49)	9.84 (9.75)	11.62	12.01 (12.01)
m-Tolunitrile	9.40 (9.51)	9.83 (9.75)	11.69	11.95 (11.91)
p-Tolunitrile	9.33 (9.39)	9.97 (9.92)	11.68	11.90 (11.83)
Acetonitrile[b)]	12.21	13.14		

a) See footnote a) for Table 1. b) Ref. 1.

According to the CNDO/2 and EHMO calculations, the occupied orbitals of benzonitrile are located in the following orders from the top, respectively: $b_1\pi$, $b_2\sigma$, $a_1\sigma$, $a_2\pi$.... and $a_2\pi$, $b_1\pi$, $a_1\sigma$, $b_2\sigma$..... Judging from the fact that the $e_{1g}(S)$ and $e_{1g}(A)$ orbitals of benzene are located at 9.23 eV while the highest occupied orbital of acetonitrile at 12.21 eV, we may safely assign the first and second bands of benzonitrile to two π($b_1\pi$ and $a_2\pi$) MO's mainly localized on the benzene ring.

Figure 6 shows the orbital energies determined from the observed ionization potentials by the aid of Koopmans' theorem.[24)] The observed first ionization potentials of *o*- and *m*-tolunitriles are similar to each other, but are larger than the corresponding value of *p*-tolunitrile. Furthermore, the second ionization potentials of *o*- and *m*-tolunitriles are smaller than that of the *p*-isomer. This tendency can be reproduced by the use of Eq. (1) on the assumption that the highest occupied π MO of benzonitrile is b_1 and the second one a_2. The ionization potentials obtained thus for *o*-, *m*-, and *p*-tolunitriles are in good agreement with the observed values as is shown in Table 3. Therefore the first and second bands of benzonitrile may be assigned to the ionizations from the $b_1\pi$ and $a_2\pi$ orbitals, respectively.

From the fact that the $b_1\pi$ orbital caused by the mixing with appropriate orbitals of the cyano group is located above the $a_2\pi$ orbital localized on the benzene ring, it is revealed that the highest occupied doubly degenerate orbitals of the ring interact more strongly with higher occupied orbitals of the cyano group than with lower vacant orbitals of the group. This scheme

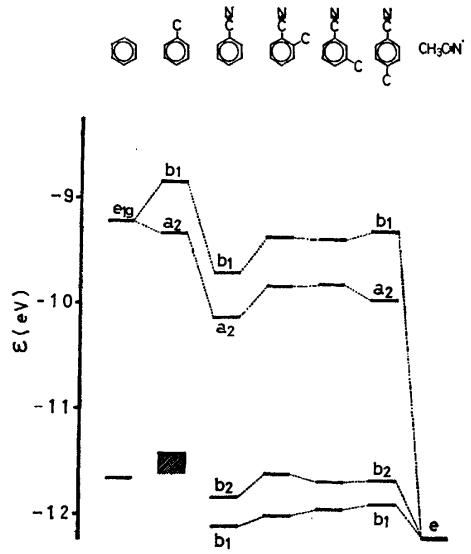

Fig. 6. Orbital energy diagram for the higher occupied orbitals of benzonitriles.

TABLE 4. VERTICAL IONIZATION POTENTIALS ($I_v(J)$ IN eV) OF ACETOPHENONE, *o*-, *m*-, AND *p*-METHYLACETOPHENONES, AND ACETONE[a)]

	$I_v(J)$ (eV)			
J	1	2	3	4
Acetophenone	9.37	9.55	9.77	11.91

p-Methylacetophenone	9.12 ((9.16))	9.36	9.56 ((9.60))	11.65
Acetone[b)]	9.72	12.6	13.4	13.9

a) The values in the double parentheses denote the ionization potentials estimated from the I_v data of acetophenone and benzonitriles on the assumption that the methyl-substitution effect upon the π orbitals of acetophenone is equal to that of benzonitrile. b) Ref. 29.

on the orbital interaction for benzonitrile is the same as for aniline, phenol, and anisole. There is a difference, however, between benzonitrile and aniline or phenol in the point that the first ionization potential of benzonitrile is greater than that of benzene, while the reverse is the case for aniline and phenol. This is due to the difference in the charge density on the benzene ring; the electron density on the ring is reduced by the electron-accepting group like the cyano group and is increased by the electron-donating group like amino or hydroxyl group.

Benzonitriles show commonly two sharp bands around 11.7~12.1 eV and this region is for the doubly degenerate π orbitals of the cyano group (for example, acetonitrile: 12.21 eV[1)]). Judging from the above assignment of the lowest energy band of benzonitrile, the higher energy band of the two sharp bands around 12 eV (the fourth lowest energy band) is due to the b_1-like π MO constructed by the bonding combination

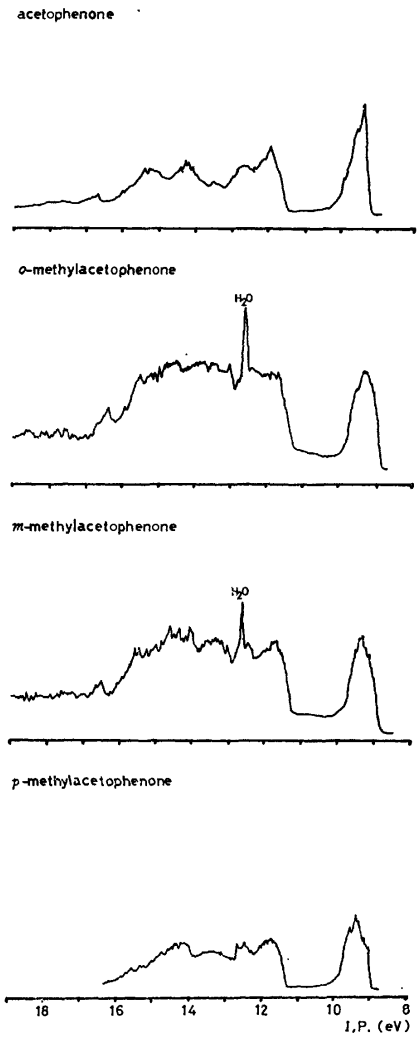

Fig. 7. Photoelectron spectra of acetophenones.

of the cyano group out-of-plane occupied π orbital and the ring e_{1g}(S)-type π orbital, and the other band (the third lowest energy band) is assigned to the ionization from the cyano group in-plane π orbital. The observed methyl-substitution effect on the former band supports this assignment; as is clearly seen in Table 3, the fourth ionization potentials of *o*-, *m*-, and *p*-tolunitriles estimated with the aid of Eq. (1) (the values in the parentheses in Table 3) are in excellent agreement with the observed values.

The PES of benzonitrile was recently assigned by Rabalais and Colton[9] on the basis of INDO and CNDO calculations, the assignment of the four lower energy bands being consistent with ours.

Acetophenones. The PES of acetophenone and *o*-, *m*-, and *p*-methylacetophenones are shown in Fig. 7. Their vertical ionization potentials are summarized in Table 4. Acetophenone has overlapped bands in the region of 9.3—9.8 eV. This region corresponds to the benzene e_{1g} orbital bands (9.23 eV) and the acetyl n orbital band (for example, acetone: 9.72 eV[29]). Therefore, it is quite natural to assign the overlapped bands to the acetyl n orbital and the benzene ring e_{1g}(S) and e_{1g}(A) orbitals perturbed by acetyl group π orbitals. The CNDO/2 calculation gives the following

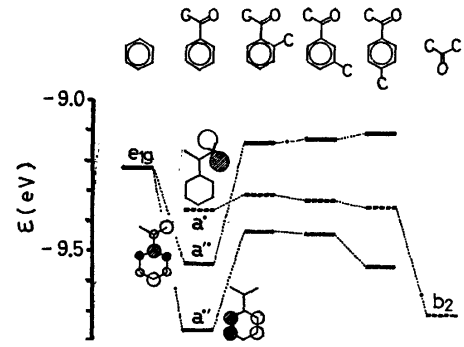

Fig. 8. Orbital energy diagram for the higher occupied orbitals of acetophenones.

order for the higher occupied orbitals of acetophenone: from the top, n, π, σ, and π. This order, however, is quite improbable in the point that the σ band is expected to appear in the 9.3—9.8 eV region.

Since the lowest energy peak at 9.37 eV is rather sharp, it is reasonable to assign this band to the acetyl n orbital. The second (9.55 eV) and third (9.77 eV) bands of acetophenone, which are due to the ionizations from π orbitals, change by the methyl substitution on the *o*-, *m*-, and *p*-positions with the same tendency as the first and second bands of benzonitrile, respectively. Therefore, by an analogy with the case of benzonitrile, the order of the π orbitals of acetophenone can be determined as shown in Fig. 8: namely, the π orbital localized on the ring (a″) is lower than the π orbital (a″) caused by the interaction of the ring π orbital with the highest occupied π orbital of the acetyl group.

Next, let us turn to the *o*-, *m*-, and *p*-methylacetophenones. The vertical ionization potentials from their π orbitals were estimated from the π $I_v(J)$ data of acetophenone and the benzonitriles on the assumption that the methyl-substitution effect upon the π orbitals of acetophenone is equal to that of benzonitrile: the results are given in Table 4 (in the double parentheses). The estimated values are in good agreement with the observed values for *o*-, *m*-, and *p*-methylacetophenones. It may be noticed that the a″ orbital of acetophenone is greatly pushed up by the methyl substitution while the a′ orbital is rather insensitive. Consequently, the highest and second highest occupied orbitals of acetophenone are reversed for the methyl substituted acetophenones. This is supported by the fact that the observed second ionization potentials of *o*-, *m*-, and *p*-methylacetophenones are almost constant and are close to the first ionization potential of acetophenone. The fact that these n ionization potentials are smaller than the corresponding value of acetone (9.72 eV) may be interpreted in terms of the electron migration from the benzene ring to the acetyl group and therefore the imcrement in the negative charge on the group.

Finally the orbital energy diagram estimated according to Koopmans' theorem[24] is shown in Fig. 8.

Nitrobenzenes. The PES of nitrobenzene, *o*-, *m*-, and *p*-nitrotoluenes, 2,4- and 2,6-dimethylnitrobenzenes, 2,4,6-trimethylnitrobenzene, and nitromethane are shown in Fig. 9. The vertical ionization potentials are summarized in Table 5. The correlation diagram

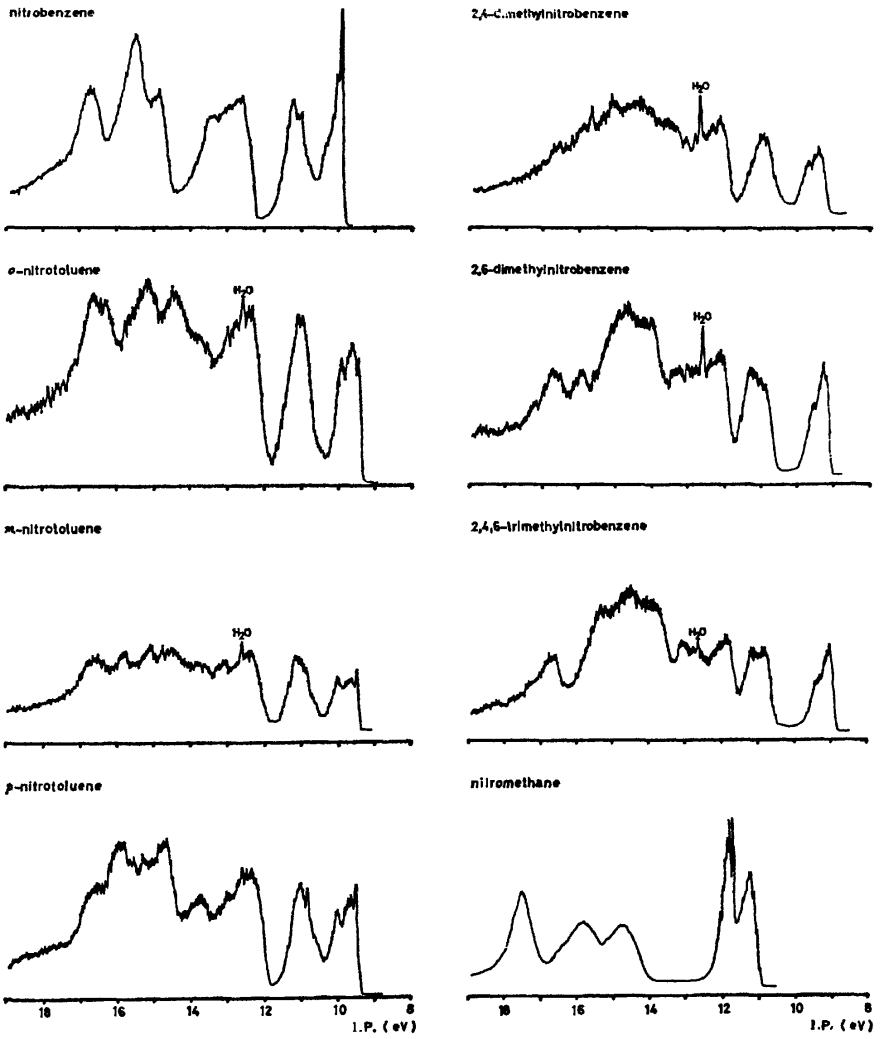

Fig. 9. Photoelectron spectra of nitrobenzenes and nitromethane.

Table 5. Vertical ionization potentials ($I_v(J)$ in eV) of nitrobenzene, its methyl derivatives, and nitromethane

	$I_v(J)$ (eV)				
J	1	2	3	4	5
Nitrobenzene	9.93	10.32	11.01	11.23	12.65
o-Nitrotoluene	9.63	9.90	10.98	11.09	12.43
m-Nitrotoluene	9.48	10.03	10.90	11.08	12.42
p-Nitrotoluene	9.52	10.01	10.84	11.01	12.36
2,4-Dimethyl-nitrobenzene	9.36	9.65	10.89		12.07
2,6-Dimethyl-nitrobenzene	9.17	9.57	10.87	11.20	12.10
2,4,6-Trimethyl-nitrobenzene	9.01	9.32	10.86	11.08	11.84
Nitromethane	11.29	11.71	14.76	15.80	17.49

for the orbital energies of these compounds obtained on the assumption $\varepsilon = -I_v(J)$ (Koopmans' theorem[24]) is shown in Fig. 10.

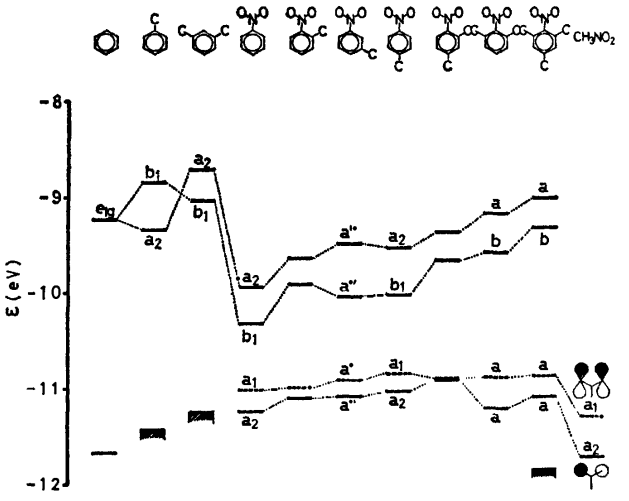

Fig. 10. Orbital energy diagram for the higher occupied orbitals of nitrobenzenes.

According to the EHMO calculation, the first and second bands can be correlated, respectively, with the $a_2\pi$ orbital corresponding to the e_{1g}(A) type π orbital of benzene and with the $b_1\pi$ orbital constructed by the combination of the lowest unoccupied orbital of the nitro group and the highest occupied e_{1g}(S) orbital of the benzene ring. These orbitals are schematically shown in Fig. 11. The prediction derived by the first-order perturbation theory on the basis of this assignment

can well explain the observed tendency shown in Fig. 10 that the difference between the first two vertical ionization potentials is larger for *m*-nitrotoluene than for *p*-nitrotoluene and is larger for 2,6-dimethylnitrobenzene than for 2,4,6-trimethylnitrobenzene.

It may be emphasized that in the case of nitrobenzenes the first band corresponds to a_2 (like) π orbital mainly localized on the benzene ring and the second band corresponds to the b_1 (like) π orbital, while the reverse is the case for the other molecules treated in the present paper. This characteristic of nitrobenzenes is due to the fact that the mixing of the ring $e_{1g}(S)$ orbital with the lowest vacant π orbital of the nitro group is predominant for nitrobenzenes, while, in the other cases, the occupied group π orbitals of the substituents mix more significantly with the benzene $e_{1g}(S)$-(like) orbital rather than the vacant group π orbital of the substituents.

From the spectral shape and the INDO calculation, Rabalais[8] assigned the first two bands of nitrobenzene to the $b_1\pi$ and $a_2\pi$ orbitals, respectively, but from the above discussion our assignment seems to be more reasonable.

Nitrobenzene and its methyl derivatives have commonly two bands in the range between 10.5 and 11.5 eV; lower energy bands around 10.9 eV and higher energy ones around 11.1 eV. From their positions and relative intensities, they are correlated with the 11.29 eV and 11.71 eV bands of nitromethane.[30] The third band of nitrobenzene at 11.01 eV is insensitive to the methyl substitution on the benzene ring and may be assigned to the a_1n orbital which is the nonbonding orbital in plane (see Fig. 11). The fourth band of nitrobenzene correlated with the 11.71 eV band of nitromethane is rather sensitive to the methyl substitution on a carbon atom of the benzene ring and may be due to the $a_2\pi$ orbital shown in Fig. 11. Further details of the assignment on the bands in the 10.5—12.0 eV region observed with nitromethane, nitrobenzene and its methyl derivatives are not described here, since they have been described in the previous paper[4]. Our assignments of the third and fourth bands are consistent with those by Rabalais.[8]

According to the first-order perturbation theory the splitting between the first two vertical ionization potentials of *o*-nitrotoluene should be similar to that of *m*-isomer. In reality, however, the former is significantly smaller than the latter. This abnormal result is easily understood if one remembers that in the case of *o*-isomer the conjugation between the benzene e_{1g}-like orbitals and the nitro group π orbitals is diminished by the twisting of the nitro group from the benzene ring plane: this twisting of $\sim 40°$ is caused by the steric hindrance of the *o*-methyl group.[4,31-40]

The second I_v of 2,4-dimethylnitrobenzene should be greater than that of 2,6-dimethylnitrobenzene according to the first-order perturbation theory but the reverse tendency was observed. This is also explained by the decreasing conjugation between the benzene $e_{1g}(S)$-like π orbital and the b_1 type vacant π orbital of the nitro group because of the additional twisting[40] of the nitro group from the benzene ring plane caused by the presence of two *o*-methyl groups.

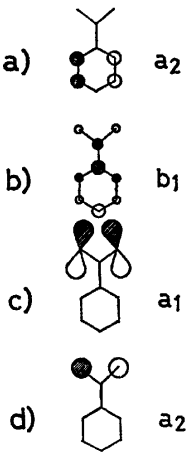

Fig. 11. Schematic representation of the higher occupied molecular orbitals of nitrobenzene.

TABLE 6. CLASSIFICATION OF SUBSTITUENT GROUPS

Character of substituent group	Case	Character of the H.O.[a]	Example
Electron donating	1	Mainly n	$-N(CH_3)_2$
	2	Mainly $e_{1g}(S)\pi$	$-NH_2$, $-OH$, $-OCH_3$
Electron accepting	3	$e_{1g}(S)\pi+S\pi$ (occupied)	$-CN$, $-COCH_3$
	4	$e_{1g}(A)\pi$	$-NO_2$

a) H.O. means the highest occupied orbital of a substituted benzene molecule, n the highest occupied nonbonding orbital of an electron-donating group, and $S\pi$(occupied) the highest occupied π orbital of an electron-accepting group.

PES of Substituted Benzenes and Classification of Substituent Groups. From the above discussion on the PES of substituted benzenes, the substituent groups under consideration can be classified into four categories as shown in Table 6.

Substituted benzenes with such electron-donating groups as OH, OCH_3, NH_2, and $N(CH_3)_2$ have lower first ionization potentials than benzene, because of the increasing electron density on the benzene ring. These substituent groups are divided into two cases, cases 1 and 2, in terms of the nature of the highest occupied MO's of substituted benzenes which are mainly constructed by the mixing of the highest occupied ($e_{1g}(S)$) MO of the ring with the highest occupied n orbital of the substituent group. Two cases are separated by the relative height of the e_{1g} MO to the n orbital. In case 1, the latter is located above the former and the highest occupied and third highest occupied MO's of the substituted benzenes are mainly contributed by the n orbital and the $e_{1g}(S)$ MO, respectively. In case 2, the reverse is the case concerning the relative height of the e_{1g} MO to the n orbital and also concerning the nature of the highest occupied and third highest occupied MO's.

Substituted benzenes with such electron-accepting groups as CN, $COCH_3$, and NO_2 have larger first π ionization potentials than benzene, because of the

decreasing electron density on the ring. From the consideration of the nature of their highest occupied π MO's, the electron-accepting groups are divided into two cases, cases 3 and 4.

In case 3, the highest occupied $e_{1g}(S)$ MO of the ring interacts mainly with the occupied π orbital of the substituent group and, therefore, both orbitals contribute to the highest occupied π orbital of the substituted benzene molecule. On the other hand, in case 4, the $e_{1g}(S)$ MO of the ring interacts mainly with the lowest vacant π orbital of the substituent group and the MO of the substituted benzene molecule obtained by this interaction is the second highest occupied MO: the highest occupied MO in this case is of the ring $e_{1g}(A)$ type.

The authors wish to thank Mr. Katsuyuki Yokota for his skillful assistance in the preparation of 2,4- and 2,6-dimethylanisoles. Their thanks are also due to Mr. H. Matsumoto, Japan Spectroscopic Co. for his kindness in putting the Jasco Model PE-1 spectrometer at their disposal at the initial stage of the present study.

Formation of Long-Lived Highly-Excited States of H, C, and N Atoms by Low-Energy Electron Impact on CH_3CN

Takemasa SHIBATA, Tsutomu FUKUYAMA, and Kozo KUCHITSU

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received May 8, 1974)

Long-lived excited states of hydrogen, carbon and nitrogen atoms (H**, C** and N**) produced by the electron bombardment of CH_3CN in the energy range from 20 to 100 eV were detected as H^+, C^+ and N^+ ions as a result of collisions with H_2O. The appearance potential of H^+ was observed to be about 3 eV lower than the threshold energy for He^+ formed from He** with H_2O (about 24.6 eV). The C^+ threshold energy was about the same as that for He^+, while that for N^+ appeared to be a few eV higher. This suggests that the H** species is mainly responsible for the formation of CH_3CN^- due to the electron bombardment of CH_3CN observed by Sugiura and Arakawa, at least in the energy region below the He** threshold energy.

Since the formation of long-lived highly-excited Rydberg states of atoms by electron impact was first observed by Čermák and Herman,[1] a number of investigations have been made on the formation mechanism and on the collision of such atoms with molecules.[2–6] The following three types of ionization processes of highly excited atoms (A**) in collisions with molecules (B or BC) are known:

$$A^{**} + B \longrightarrow A^+ + B + e \quad (1)$$

$$A^{**} + B \longrightarrow A^+ + B^- \quad (2)$$

$$A^{**} + BC \longrightarrow A^+ + B + C^- \quad (3)$$

The cross sections of these reactions have been estimated theoretically by Matsuzawa[7–9] and compared with experimental results.[4]

Recently, Sugiura and Arakawa[10] have observed the formation of a negative ion, CH_3CN^-, in a mixture of CH_3CN vapor and various rare gases by electron impact. They ascribed the formation of this ion to the reactions:

$$e + A \longrightarrow A^{**} + e \quad (4)$$

$$A^{**} + CH_3CN \longrightarrow A^+ + CH_3CN^-, \quad (5)$$

where A represents a He, Ne, Ar or Kr atom. This is an example of a reaction of type (2). Furthermore, they found that the CH_3CN^- ion was also produced from pure CH_3CN and that the CH_3CN^- intensity exhibited a second-order dependence with the gas pressure. Hence, they considered that the negative ion formation was due to the reactions:

$$e + CH_3CN \longrightarrow Y^{**} + Z + e \quad (6)$$

$$Y^{**} + CH_3CN \longrightarrow Y^+ + CH_3CN^-, \quad (7)$$

where Y** denotes an excited neutral fragment formed by the excitation of the electron to a high Rydberg state. The appearance threshold of CH_3CN^- was estimated to be 23.2±0.5 eV.

In the present study, the formation of the highly excited atoms, H**, C** and N**, from CH_3CN by the bombardment of electrons of 20—100 eV is reported. Among the three excited species, H** appeared at the lowest electron impact energy, while C** had nearly the same threshold energy as that of He**.

Experimental

The apparatus, which was described previously,[11,12] was evacuated to 2×10^{-6} Torr. The CH_3CN vapor was introduced into the excitation region (Fig. 1) through a multichannel orifice M and was subjected to electron impact. The total pressure of the vapor at the source S_1 was about 0.3 Torr. The filament was heated by a dc current of 6A operated at 5 V, and the electrons produced were accelerated by a voltage of from 20 to 100 V which was applied between the filament (measured at the low potential end) and electrode 3 in Fig. 1. The electron current measured at electrode 1 was 10—300 μA. The excited neutral species were separated from the accompanying ions by electrostatic potentials and were allowed to collide with the target H_2O molecules in the collision chamber C. The pressure of the H_2O target gas measured at the source S_2 was about 1 Torr. The ions produced in the collision chamber were measured by a quadrupole mass filter. The sample gas pressures were measured by oil manometers and Pirani gauges. In addition to H_2O, CH_3CN and CH_3OH were also used as target molecules.

The energy spread of the electrons was estimated to be a few eV. The energy scale was calibrated by measuring the He^+ ions formed under similar conditions from He**, *i.e.*, produced by the reactions:

$$e + He \longrightarrow He^{**} + e \quad (8)$$

$$He^{**} + H_2O \longrightarrow He^+ + H_2O + e \quad (9)$$

The appearance potential of He^+ formed from He** was assumed to be nearly equal to the inoization potential of He^+, 24.6 eV.[13]

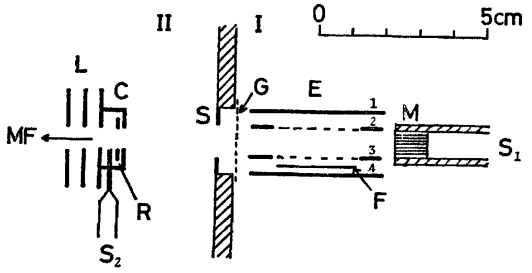

Fig. 1. Apparatus composed of Section I for producing long-lived highly-excited atoms by electron impact and section II, in which a collision chamber C and a mass filter MF are installed.
I: S_1, source of reactant molecules (CH_3CN); M, multichannel orifice; E, electron gun; F, tungsten filament; 1, electron trapping electrode; 2 and 3, exciting region; 4, repeller electrode; G, grid; S, slit. II: S_2, source of target molecule (H_2O); R, ion repeller electrode; L, ion lens system.

Results

The mass spectrum shown in Fig. 2 was obtained with H_2O as the target gas. Since the present study is concerned with the formation and ionization of H**, C** and N**, observed molecular ions, H_2O^+ *etc.*, were not analyzed in detail. The intensities of the H^+, C^+ and N^+ were found to be proportional to the electron current. In Fig. 3 the ion intensities divided by the electron currents are plotted as a function of the accelerating voltage. The intensities of H^+ and N^+ increased monotonically with increasing voltage, while the C^+ intensity curve had a shoulder at about 45 eV. The dependence of the H^+, C^+ and He^+ intensities on the electron accelerating voltage in the threshold region is shown in Fig. 4. The H^+ threshold appears to be about 3 eV lower than that for He^+, while the appearance potential of C^+ is nearly equal to the He^+ threshold.

The dependence of the ion intensities on the pressure of the target H_2O is shown in Fig. 5. The intensity I varies with the pressure p as

$$I \propto p \exp(-cp) \qquad (10)$$

This is demonstrated in Fig. 6, where $\log(I/p)$ values depend linearly on the gas pressure p. As discussed in Refs. 11 and 12, the behavior expressed by Eq. (10) can be accounted for as a result of the attenuation of the highly-excited atoms by collision with H_2O mole-

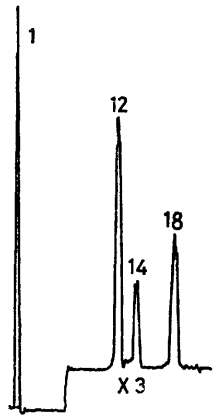

Fig. 2. Mass spectrum of the ions produced by collisions of highly-excited species from CH_3CN with H_2O. Electron accelerating voltage: 60 V, electron trap current: 200 μA, pressures of CH_3CN and H_2O: 0.13 and 0.4 Torr, respectively.

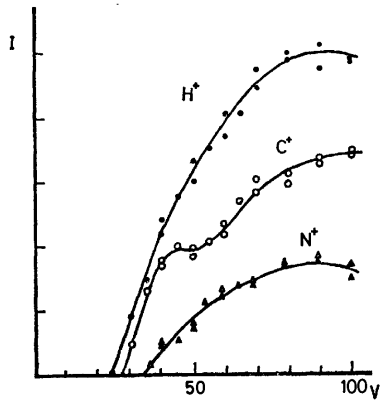

Fig. 3. Intensities of ions (in arbitrary units) divided by the electron trap current obtained for different electron accelerating voltages.

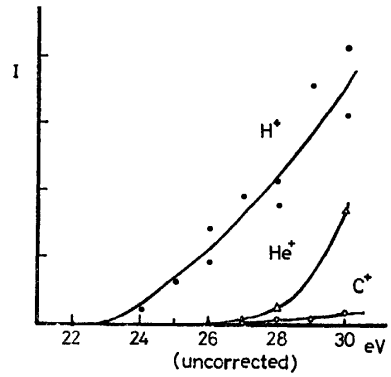

Fig. 4. Ion intensities (in arbitrary units) in the vicinity of threshold obtained for different electron bombardment energies.

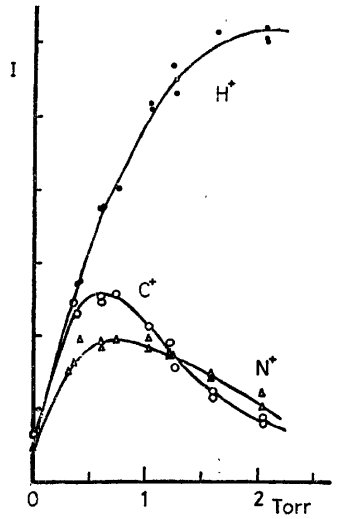

Fig. 5. Intensities of ions (in arbitrary units) plotted for different pressures of H_2O measured at S_2.

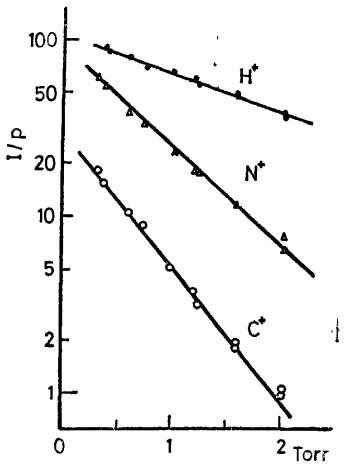

Fig. 6. Intensities of H^+, C^+ and N^+ displayed in Fig. 5 divided by the pressure p of H_2O measured at S_2 and plotted on a logarithmic scale as a function of p.

cules. The ion intensities do not tend to zero in the absence of target molecules, as shown in Fig. 5. This shows that the excited species can be ionized by collisions not only with the target gas but also with residual gases and/or the surface of the electrodes. The ion intensity varies with the pressure of the projectile molecule CH_3CN in a similar manner.

Ionization processes of the highly-excited atoms H**, C** and N** producing H^+, C^+ and N^+, respectively, were also observed when CH_3CN or CH_3OH was used as a target gas. The variations of the ion intensity, I, on the electron current and on the electron accelerating voltage were similar to those observed with H_2O as the target gas. The relation between I and the gas pressure p was also that given in Eq. (10).

Discussion

The uncorrected thresholds of H^+ and C^+ shown in Fig. 4 are shifted by about -1.4 eV with reference to that of He^+, as described in Experimental section, and compared with the appearance threshold of CH_3CN^- observed by Sugiura and Arakawa.[10] One can conclude that the essential part of the Y** species which they assumed in reactions (6) and (7) is H** at least in the range below the threshold of He**, since this species seems to be the only reactive species formed in this electron energy range. The C** and N** species can also contribute to molecular negative-ion formation at higher electron energies.

The threshold energy for H^+, which was thus estimated to be about 21.5 eV with a range of uncertainty of about 1.5 eV, seems to differ slightly from that for CH_3CN^- reported by Sugiura and Arakawa, 23.2 ± 0.5 eV; however, a more precise description of the threshold behavior requires a further critical experiment.

The shoulder appearing in the efficiency curve of C** suggests that the curve is composed of two separate efficiency curves which correspond to the C** species arising from the methyl and the nitrile carbon atoms in CH_3CN.

The authors are indebted to Drs. Toshio Sugiura and Kazuo Arakawa for helpful discussions and to Dr. Walter Shearer-Izumi for his critical reading of the manuscript.

Spectroscopic Studies on Some Ketimines

R. ABU-EITTAH and M. M. HAMED
Department of Chemistry, Faculty of Science, University of Cairo, Giza, Egypt
(Received June 20, 1973)

The electronic absorption spectra of some ketimines have been investigated using different solvents. Assignment of the obtained transitions was attempted. The *N*-substituted ketimines did not show a discrete band for the n—π^* transition as was obtained with the unsubstituted molecules. Molecular orbital calculations were carried out using the PPP variant of the SCF-MO theory. Agreement between the calculated and experimental transition energies was satisfactory.

The spectra of the ketimines are rarely found in the literature, though the spectra of the related compounds, anils or Schiff's bases, are common.[1] Kaplan[2] reported the spectra of some 4-alkyldiphenylketimine hydrochlorides. It was found that the unconjugated azomethine chromophore absorbs at higher energy than the corresponding carbonyl and thiocarbonyl chromophores.[3] The n→π^* transition for the >C=N– group is allowed but is symmetry forbidden for the carbonyls and thiocarbonyls.

Ultraviolet spectra of *N*-(diphenylmethylene) aniline were reported in different solvents.[4] The spectra of benzanils were found to be, essentially, a superposition of the spectra of the corresponding benzal and aniline parts of the molecule,[5] the azomethine group acted as an electron acceptor when linked to a phenyl group at its end.

Alexander *et al.*[6] investigated the solvent effects on the absorption spectra of *o*-, *m*-, and *p*-hydroxybenzylidenimines. Ebara[7] showed that the spectra of benzylideneanilines cannot be explained adopting the stilbene-type planar structure.

Different studies on some ketimines as ESR,[8] rate of hydrolysis,[9] complex formation with Cu(II) ion[10] and infrared spectra[11,12] are reported in the literature. Semi-empirical molecular orbital calculations were carried out on benzalaniline and some imines.[13,14]

In this work the spectroscopic behaviour of a series of ketimines, including halo and nitro ketimines, is investigated. Bands were assigned to transitions characteristic of specific chromophores in the molecules. To be more accurate, the extended PPP method of the SCF-MO theory was used to compute the energy of the lowest π→π^* transition.

Experimental

Solvents. Methanol and cyclohexane were purified by the conventional methods found in the literature.[15]

Compounds. 1,1-Diphenylmethylenimine was prepared by Grignard reaction between freshly distilled bromobenzene and phenylcyanide, where the complex was decomposed by absolute methanol.[16] The product was purified by vacuum distillation, n_D^{19} 1.6191. The other ketimines were prepared by condensing benzophenone and the corresponding aniline derivative till the calculated volume of water was collected.[17] Compounds were purified by repetitive crystallization. The compounds prepared were: *N*-(diphenylmethylene)aniline; *N*-(diphenylmethylene)-*ortho*-, *meta*-, and *para*-chloroanilines; *N*-(diphenylmethylene)-*p*-bromoaniline; *N*-(diphenylmethylene)-*ortho*-, *meta*-, and *para*-nitroanilines; *N*-(diphenylmethylene) *p*-methoxyaniline.

Melting points corresponded well to values reported in literature.

Apparatus. Spectra were scanned on a Beckmann DK-1 spectrophotometer using 1.0 cm fused silica cells.

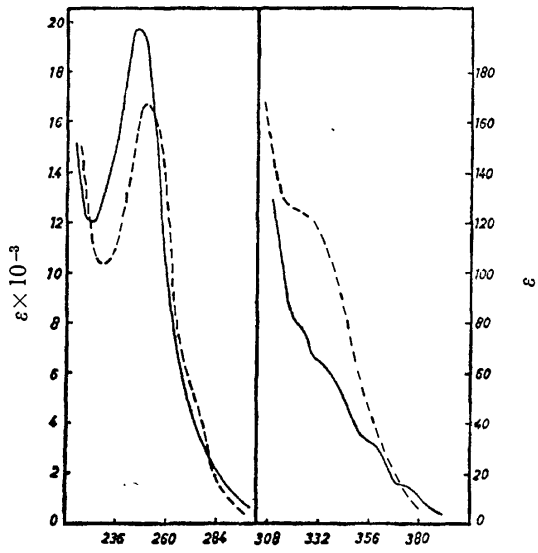

Fig. 1. Absorption spectra of 1,1-diphenylmethylenimine at room temperature.
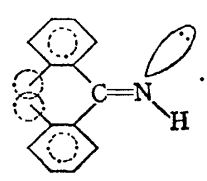
—— in cyclohexane, ---- in methyl alcohol

Results and Discussion

Electronic Absorption Spectra. 1,1-Diphenylmethylenimine, N-*Phenyl and* p-*Methoxy Derivatives*: Figure 1 shows the absorption spectra of 1,1-diphenylmethylenimine (a) in polar and non-polar solvents. The extent of molecular coplanarity will be clearly reflected in its spectrum. If the distortion is maximum *i.e.*, the two benzene nuclei are perpendicular, the spectrum will be similar to that of *N*-benzylimine whereas if the distortion is slight the spectrum will be different than that of *N*-benzylimine. In benzophenone Jones[18] calculated 30° as the angle between the planes of the



(a)

two benzene rings.

1,1-Diphenylmethylenimine is "π" isoelectronic with 1,1-diphenylethylene *i.e.* the $\pi \rightarrow \pi^*$ transitions of both compounds are expected to be energetically comparable. Korver[19] assigned the 260 nm band of 1,1-diphenylethylene to "styrene-conjugation" and the band around 230 nm to "phenyl-phenyl" interaction. Styrene[20] has O→O transition at ~290 nm, the blue shift of the O→O transition of 1,1-diphenylethylene is a result of steric hindrance.

The spectrum of 1,1-diphenylmethylenimine shows a weak shoulder (ε_{max}=65 in cyclohexane and 120 in methyl alcohol) at 332 nm in cyclohexane and at 323 nm in alcohol. The band shows a blue-shift in a polar solvent, and characteristic vibrational structures which are blurred in methanol, thus it may be assigned to an $n \rightarrow \pi^*$ transition. It was shown that 1,1-diphenylmethylenimine forms an n-σ charge transfer complex with iodine[21] which also supports this assignment.

In the UV region, 1,1-diphenylmethylenimine shows an intense assymetric band, with λ_{max} at 245 nm and a shoulder ~270 nm. The long wavelength shoulder is assigned to a transition corresponding to the $^1b_{2u} \leftarrow {}^1a_{1g}$ transition of benzene whereas the intense band is assigned to an intramolecular charge transfer transition. The donor site is a benzene nucleus, conjugated with the "π" system of the azomethine group, and the acceptor site is a free π-molecular orbital on the azomethine group. Evidences supporting this assignment will follow. The above way of transitions assignment is an approximate one, since with it, one is bisecting the same molecule to discrete chromophores. However, this approximation is not a crude one, especially if the separate chromophores are not coplanar.

Figure 2 shows the spectra of *N*-(diphenylmethylene)-aniline (b). The position and intensity of band maxima, in Figs. 1 and 2, are very much comparable. This

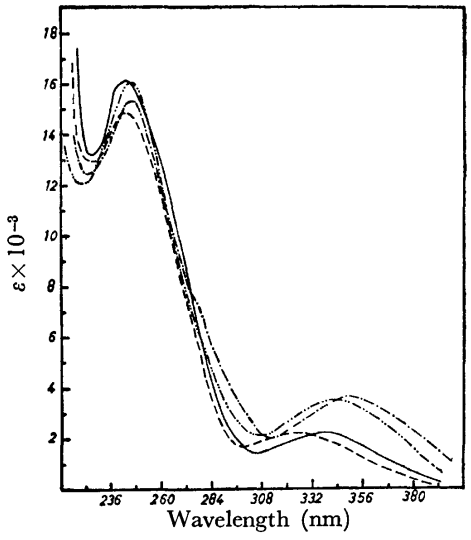


Fig. 2. Absorption spectra of *N*-(diphenylmethylene)-aniline.
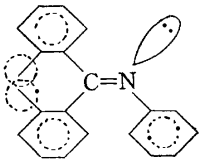
—— in cyclohexane, ----- in methyl alcohol *N*-(diphenylmethylene)-*p*-methoxyaniline
-·-·- in cyclohexane, -·-·-·- in methyl alcohol at room temperature



(b)

indicates that the π system of the *N*-phenyl ring is not conjugated with the π system of the >C=N– group and may be conjugated with "n" electrons on the nitrogen atom. If this is so, an $n \rightarrow \pi^*$ transition may overlap with the $\pi \rightarrow \pi^*$ band. The bands shown in Fig. 2 are all $\pi \rightarrow \pi^*$ transitions, the 338 nm band may correspond to the intense "a" band of stilbene.[22] The significant reduction of intensity is attributed to the non-coplanarity of the molecule. The 242 nm is assigned to an intramolecular charge transfer transition.

To confirm the above results, the spectra of *N*-(diphenylmethylene) *p*-methoxyaniline were investigated (Fig. 2). If "π" conjugation extends over the whole molecule, the $-OCH_3$ group will perturb all the π—π^* transitions, otherwise it will merely perturb the transitions localized on the benzene nucleus attached to it. Investigation of Fig. 2 indicates that the long wavelength band has been significantly red shifted and intensified on substitution by the $-OCH_3$ group whereas perturbation of the other transitions (at ~270 and 245 nm) is only slight. These results confirm that: the long wavelength transition is localized over the *N*-phenyl ring the "π" system of which is not in the same plane as the "π" system of the azomethine group. This is also confirmed by the fact that the band, ~245 nm, assigned to a charge transfer transition was not perturbed by $-OCH_3$ substitution. That is to say, the donor site is the same before and after $-OCH_3$ substitution. Anisole is of lower ionization potential than benzene, and if it were the donor, the energy of the charge transfer band would have been lowered than its value when benzene is the donor. In *N*-(diphenylmethylene) *p*-methoxyaniline, the anisole nucleus is not the donor, since its "π" system is not in the same plane as that of the acceptor site (C=N–). In Table 1 the values of the band maxima, molar extinction coefficient and oscillator strengths for the above molecules are given.

Halogenated Ketimines: Figure 3 shows the absorption spectra of *N*-(diphenylmethylene) *o*-chloroaniline in addition to the *meta* and *para* derivatives in cyclohexane. When the spectra were scanned in methanol, the long wavelength transition was slightly blue-shifted whereas the ~245 nm transition was red-shifted. The spectra are very much similar to those given in Figs. 1 and 2 indicating that the same types of electronic transitions are occurring. Chlorine substitution in the *N*-phenyl ring perturbed, mainly, the long wavelength transtion. This behaviour was also encountered with $-OCH_3$ substitution. Bands of the halogenated ketimines are assigned in a way similar to that of the previously studied ketimines. Bands of the *o*-chloro derivative are of lower intensity than those of the other, halo derivatives owing to steric hindrance in the former.

To confirm the above results the spectra of *N*-(diphenylmethylene) *p*-bromoaniline were studied (Fig. 3). Spectra of the *p*-chloro and *p*-bromo derivatives are very similar, yet one notices that though ionization potential of chlorobenzene differs from that of bromobenzene the band (248 nm) assigned to a charge transfer transition has the same λ_{max} for the two compounds. This indicates that the donor site is a benzene nucleus rather than the bromo or chlorobenzene nuclei. Rationalization of this point was given before. Numerical values of band maxima, molar extinction coefficients and oscillator strengths (Gaussian analysis was made to clarify the shape of the band and estimate its half width) of the absorption bands of halogenated derivatives are given in Table 2.

Nitroketimines: To investigate fairly the spectral properties of ketimines, the spectra of the nitro derivatives were studied. Figure 4 shows the spectrum of *N*-(diphenylmethylene) *o*-nitroaniline which is quite similar to that of *N*-(diphenylmethylene) aniline. This indicates that "π" conjugation does not extend over the >C=N– group and the nitrobenzene nucleus. Here again the nitro group, mainly, perturbed the long wavelength transition. The spectra of *p*-nitroketimine (Fig. 4) indicate many overlapping bands. More than one charge transfer transition can be obtained with this molecule and this reflects the large solvent effect on its spectra. In fact, *p*-nitroaniline possesses a symmetric charge transfer transition with an energy of 3.9 eV. The *p*-nitroketimine has a shoulder at —340 nm (3.6 eV), which appears more clearly in cyclo-

hexane, could very well be assigned to a charge transfer transition.

Figure 4 shows that the *ortho-* and *meta*-nitroketimines have similar spectra to each other which differ from that of the *para*-isomer. Moreover, the *para*-isomer has its first absorption maximum at a higher energy than those of the *ortho-* and *meta*-derivatives. The same results are found on investigating the spectra of nitroanilines. Resonance theory predicts that the *ortho-* and *para*-isomers should have similar spectra that differ from that of the *meta*-isomer. Godfrey and Murrell[23] calculated the energies of the first four transitions for *ortho-*, *meta-*, and *para*-nitroanilines using the localized-orbital model. Transitions were differentiated to locally-excited and charge-transfer ones. They found that the amino group *para-* to the nitro-group lowers the energy of the first charge transfer state but will have no effect on the energy of the second charge transfer state. On the other hand an amino-group *ortho-* or *meta-* to the nitro-group lowers the energy of the second charge transfer state three times as it does to the first charge transfer state. This goes along with experimental results.

The spectra of nitroketimines are comparable to those of nitroanilines and the lone pair of electrons on the nitrogen azomethine group will play the same role as that of the amino group in nitroanilines. Similarity of the spectra of the *ortho-* and *meta*-nitroketimines and their deviation from that of the *para* isomer are due to the lowering of the energy of the charge transfer states to different extents in the different isomers.

Localized-orbital model bisects the molecule to discrete chromophores, namely donor and acceptor,transition energies are better computed when the molecule is treated as one unit. Molecular orbital calculations were performed on 1,1-diphenylmethylenimine using the PPP[24] variant of the SCF-MO theory to investigate correspondence between the theoretical and experimental values of the energy of the first transition and to investigate how far the coplanarity of the molecule is distorted. The computed value of the energy of the first transition was found to be 4.2 eV (experimental value is 4.4 eV). The semi-empirical method of calculation accounted satisfactorily for the transition energy and showed that coplanarity of the molecule is not highly distorted. Table 3 gives the values of band maxima for the studied nitro derivatives.

Polarographic Behavior of Glycol Dimercaptoacetate

R. S SAXENA and S. K. BHATIA
Department of Chemistry, Malaviya Regional Engineering College, Jaipur, India
(Received November 20, 1973)

Polarographic behaviour of glycol dimercaptoacetate has been studied in 25% ethanol at d.m.e. in the pH range 1.56—11.56 in presence of 0.1 M KNO_3. In the acidic media, the current-voltage curves consist of three waves; a prewave due to the adsorption of anodic reaction product at the mercury drop surface, main anodic wave due to the electroxidation of -SH groups and a third wave at more positive potential due to the insoluble film formation on the electrode surface whose solubility depends on pH of the solution. In the alkaline media only two waves, a prewave and the main anodic wave, are observed. The effects of various factors such as different buffer, Hg-pressure, temperature, ethanol and depolarizer concentrations on the wave characteristics have been investigated. The electrode reaction is irreversible at higher pH but in acid media it is reversible and diffusion controlled involving a two electron transfer process, with the formation of $\begin{matrix}H_2COOCCH_2\text{-}S\\ \quad\quad\quad\

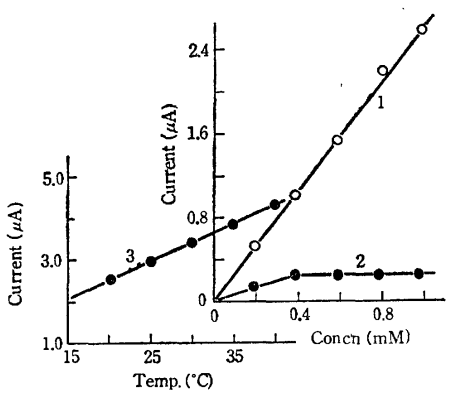

Fig. 2. Curve 1: Plot of i_d *vs.* [GDA], Curve 2: Plot of i_1 *vs.* [GDA], Curve 3: Plot of i_d *vs.* Temp.

the prewave, i_1, increases with [GDA] up to 0.4 mM above which it remains almost constant while i_2, i_3, and i_d vary linearly with [GDA] (0.2 to 1 mM). The mean values of diffusion current constant ($I=i_d/cm^{2/3}\cdot t^{1/6}$) and diffusion coefficient are 3.406 μA/mM/l/$mg^{2/3}\cdot s^{-1/2}$ and 6.60×10^{-6} cm^2/s respectively. These observations substantiate the diffusion controlled nature of the waves.

The total diffusion current (i_d) decreases with increase in ethanol percentage passing through a minimum in between 40—50% and then increases but the nature of the main wave remains the same.

Effect of $HgCl_2$ on Main Anodic Wave. Solutions containing GDA and $HgCl_2$ in proportions of 1:0, 1:0.5, and 1:1 were prepared. The insoluble mercury complex was removed by filtration and the filtrates were polarographed under identical conditions. In presence of increasing amounts of $HgCl_2$ the main anodic wave with decreased wave height was obtained; it disappeared completely, when GDA and $HgCl_2$ was present in 1:1 ratio. This shows the formation of 1:1 complex of GDA with Hg(II).

Mechanism of the Electrode Reaction. The electrooxidation of GDA (referred here as $R(SH)_2$) may involve (A) the formation of a disulphide, a four electron transfer Process (1) and (B) the formation of a mercuric-complex, a two electron transfer Process (2)

$$2R(SH)_2 \rightleftharpoons R\begin{<}S\text{-}S\\S\text{-}S\end{>}R + 4H^+ + 4e^- \quad (1)$$

$$R(SH)_2 + Hg \rightleftharpoons R\begin{<}S\\S\end{>}Hg + 2H^+ + 2e \quad (2)$$

Then the potential at every point on the wave should be given by

$$E = \text{Const.} - \frac{RT}{4F}\ln\frac{(i_d-i)^2}{i} \quad \text{(for reaction A)} \quad (3)$$

and

$$E = \text{Const.} - \frac{RT}{2F}\ln\frac{i_d-i}{i} \quad \text{(for reaction B)} \quad (4)$$

If the formation of a disulphide is involved (1), then the plot of $-E_{de}$ *vs.* $\log(i_d-i)^2/i$ should yield a straight line with slope 0.059/4 V. On the other hand, if Reaction (2) is involved, the plot of $-E_{de}$ *vs.* $\log i_d-i/i$ gives a straight line having a slope of 0.059/2 V.

It is observed that only the analysis corresponding to Eq. (4) yields a straight line with a slope of 0.031 V close enough to the theoretical slope of 0.029 V. Furthermore, it was found that the $E_{1/2}$ of the main wave was independent of [GDA]. This constancy of $E_{1/2}$ is characteristic of Eq. (4) and not of Eq. (3). This analysis indicates that the anodic reaction of GDA at d.m.e. occurs according to (2) and not to the formation of a disulphide.

If the reaction is reversible, then the mercury in the mercuric-GDA complex should be reversibly reducible at d.m.e. But on the contrary, the preceding experiments on the effect of added $HgCl_2$ show that the final product of the electrode reaction is an insoluble complex of mercury. It may, therefore, be concluded that the anodic wave is due to the formation of mercurous mercaptide $R\begin{<}S\text{-}Hg\\S\text{-}Hg\end{>}$ (soluble compound) which is unstable and changes into more stable mercuric complex and Hg.

$$R\begin{<}S\text{-}Hg\\S\text{-}Hg\end{>} \longrightarrow R\begin{<}S\\S\end{>}Hg + Hg$$

Adsorption Prewave. A steep depression in *E-t* curve was obtained for 1.0 mM GDA and 0.1 M KNO_3 at pH 4.80 in the potential range where the prewave appeared, showing the strong adsorption of the electrolysis product at d.m.e. A general theoretical treatment of adsorption waves (prewave) at the d.m.e. was first described by Brdicka who gave the expression for the average limiting current of the adsorption wave i_p.[9]

$$i_p = 0.85nFZm^{2/3}t^{-1/3} \quad (5)$$

in which i_p is expressed in ampere, Z is the maximum number of moles adsorbed per cm^2, m is the rate of mercury flow in g/s, t is the droptime in s, n and F have their usual significance. From Eq. (5), $Z=6.83\times10^{-10}$ mol/cm^2 *i.e.* 4.12×10^{14} molecule/cm^2 which corresponds to an area of 24.29 $Å^2$ per adsorbed molecule. Adsorption coefficient (ω) and molar adsorption energy (ϕ) are 1.445×10^4 and 31.2 kcal/g·mol, respectively, which are evaluated from the following equations:

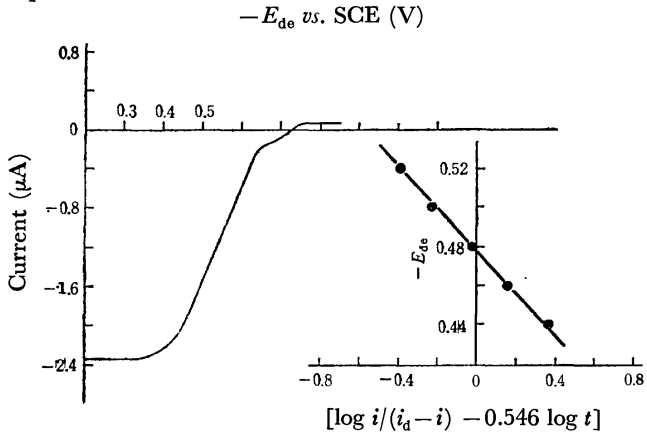

Fig. 3. (a) Polarograms for 1.0 mM GDA at pH= 11.56 (recorded by measureing current at the end of the drop life). (b) Plot of $-E_{de}$ *vs.* [log $i/(i_d-i)$ −0.546 log t]

$$\omega = \frac{2}{C_a} \exp \frac{n\Delta EF}{RT} \quad (6)$$

$$\phi = n\Delta EF + RT \ln \frac{2}{C_a V} \quad (7)$$

Where ΔE stands for the difference in half-wave potentials of the prewave and the main wave at concentration C_a at which adsorption and diffusion currents are equal and V is the molar volume of the particles.

Kinetic Parameters. The values of kinetic parameters are calculated at pH 11.56 from Koutecky's treatment[10] as extended by Meites and Israel.[11] For an irreversible anodic wave it follows:

$$E_{de} = -0.2412 + \frac{0.05915}{(1-\alpha)n} \log \frac{1.349K^{\circ}_{b.h}}{D_o^{1/2}} + \frac{0.0542}{(1-\alpha)n}\left[\log \frac{i}{i_d - i} - 0.546 \log t\right] \quad (8)$$

and

$$E^{\circ}_{1/2} = -0.2412 + \frac{0.05915}{(1-\alpha)n} \log \frac{1.349K^{\circ}_{b.h}}{D_o^{1/2}} \quad (9)$$

The plot of $[\log i/(i_d - i) - 0.546 \log t]$ *vs.* $-E_{de}$ yields a straight line (Fig. 3) whose slope is equated to $0.0542/(1-\alpha)n$ and the value of α is found to be 0.76. The intercept ($E^{\circ}_{1/2}$), obtained from the same plot, is substituted in Eq. (9) and the value of $K_{b,h}{}^{\circ}$ is calculated to be 2.6×10^{-9} cm/s.

The authors are thankful to C.S.I.R., New Delhi for the grant of a research fellowship to one of them (S.K.B.) and to Prof. R. M. Advani, Principal, for providing research facilities.

The Chemistry of α, *N*-Hydroxyamino Acids

Afzal AHMAD

Department of Chemistry, University of Islamabad, P.O. Box No. 1090, Islamabad, Pakistan

(Received February 4, 1974)

α,*N*-Hydroxyamino acids have been shown to be unstable compounds. They disproportionate into corresponding α-amino acids and α-oximino acids below pH 7. This has been suggested to be a general reaction in all mono-substituted hydroxylamines.

The chemistry of naturally occurring α-amino acids is well established and their biochemical importance is fully understood. Not enough is known, however, about the chemical behaviour of analogous *N*-hydroxyamino acids, which are now found to be present as parts of several natural products.[1-7]

During the course of investigations on the mechanisms of α-amino acid oxidation it was felt necessary to study the chemistry of α,*N*-hydroxyamino acids because of the conflicting reports in the available literature. They have been reported as weak acids without any significant basic properties,[2] and also as compounds giving acidic reaction in aqueous medium.[8] They are also described as amphoteric substances with isoelectric points between pH 6 and 7.[9] With ninhydrin they are reported to give yellow colors,[7] but have also been claimed to give blue or purple colors just like α-amino acids.[9]

Reasons for these discrepancies have now been determined. When α,*N*-hydroxyamino acids are paper chromatographed using the organic layer of *n*-butanol: acetic acid: water (40: 10: 50) as the irrigation solvent and the chromatograms developed with ninhydrin reagent, purple spots with long comet like tails appeared. The R_f values of these spots were found identical with those of the corresponding α-amino acids. When the chromatograms were sprayed with ammoniacal $AgNO_3$ or with triphenyltetrazolium chloride under appropriate conditions, only α,*N*-hydroxyaminopropionic acid and α,*N*-hydroxyaminoisobutyric acid were faintly detected, as black or pink spots. The R_f values of these two hydroxyamino acids were higher than those of the corresponding α-amino acids.

The appearance of long purple streaks on chromatograms and the partial or complete disappearance of α,*N*-hydroxyamino acids, strongly suggested that it was not the α,*N*-hydroxyamino acids which gave blue or purple colours with ninhydrin as reported, but that α,*N*-hydroxyamino acids had been spontaneously transformed to the corresponding α-amino acids during the process of chromatography. The complete identity of the R_f values of the ninhydrin positive products derived from α,*N*-hydroxyamino acids with authentic samples of the corresponding α-amino acids confirmed this transformation. The R_f values of α,*N*-hydroxyamino acids, of α-amino acids derived from the corresponding α,*N*-hydroxyamino acids on the chromatographic paper and of authentic α-amino acids are listed in Table 1. We have now been successful in separating α-amino acids as by-products of the syntheses of α,*N*-hydroxyamino acids.

Since the chromatographic solvent mixture did not contain any reducing agent, the formation of α-amino

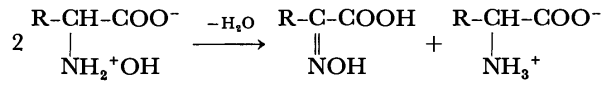

Fig. 1

acids from the corresponding α,*N*-hydroxyamino acids could most easily be explained by taking into consideration the possibility of a disproportionation reaction. The second product, therefore, could either be the corresponding α-nitroso acid or α-oximino acid formed by tautomerization of the nitroso compound (Fig. 1). The presence of α-oximino acids and of blue nitroso compounds on acid hydrolysis of α,*N*-hydroxyamino nitriles have now been demonstrated. The essential requirement of the disproportionation of α,*N*-hydroxyamino acids would be the formation of equimolar quantities of the corresponding α-amino acids and α-oximino acids. Confirmation of this fact came from the quantitative study.

α-Oximino acids, one of the products of disproportionation, have been shown to be unstable compounds in aqueous solutions, especially at higher temperatures and below pH 7. They decompose spontaneously to give lower homologous corresponding nitriles and CO_2[10]

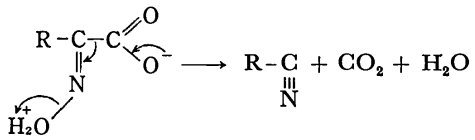

Fig. 2

(Fig. 2). Also since pK_2 ($-N^+H_2OH \rightleftharpoons -NHOH + H^+$) of an α,*N*-hydroxyamino acid is approximately 6 and that of the corresponding α-amino acid is 3—4 p*K* units higher, it is possible to titrate potentiometrically, a mixture of the two acids with standard alkali to a pH 7.5, which represents a complete titration of hydroxyamonium group of an α,*N*-hydroxyamino acid, whereas at this pH the ammonium group of the amino acid does not react with alkali at all. On addition of formaldehyde at pH 7.5, the pK_2 of the amino acid is sufficiently depressed to make possible the titration of the remaining α-amino acid with a reasonable sharp end point at pH 8.8. One such titration of a mixture of α,*N*-hydroxyaminopropionic acid and the corresponding α-amino acid (alanine) is shown in Fig. 3.

When known amounts of α,*N*-hydroxyamino acids were refluxed in aqueous solution under nitrogen atmosphere, corresponding α-amino acids and α-oximino

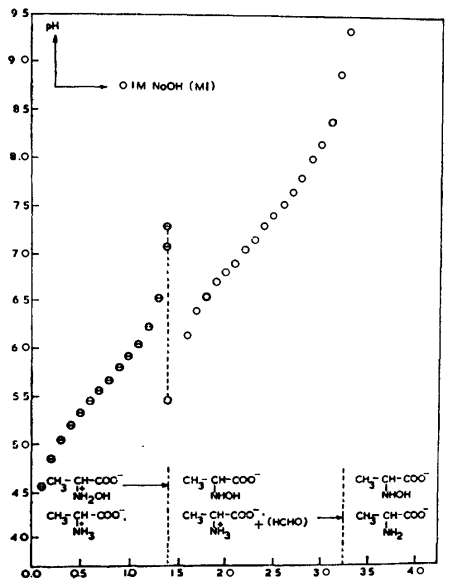

Fig. 3.

acids were obtained as primary products. Under these conditions α-oximino acids were decomposed to give lower nitriles and CO_2. With the exception of α,*N*-hydroxyamino-β-phenylpropionic acid and α,*N*-hydroxyaminoisovaleric acid, all other α,*N*-hydroxyamino acids gave almost equimolar yields of CO_2 (determined as $BaCO_3$) and the corresponding α-amino acids (Table 2). In general, yields of both α-amino acids and CO_2 were than theoretically expected on the basis of 100% disproportionation of the disappeared α,*N*-hydroxyamino acids. In the case of α,*N*-hydroxyaminophenylpropionic acid, the amount of CO_2 evolved was 43% more and phenylalanine formed was 49% less than expected on theoretical consideration based on 100% disproportionation. These differences were perhaps due to some other modes of decomposition in addition to disproportionation.

Since 5 out of 7 α,*N*-hydroxyamino acids studied gave almost equimolar quantities of CO_2 and the corresponding α-amino acids, it is reasonable to infer that two molecules of an α,*N*-hydroxyamino acid undergo mutual oxidation and reduction to give the corresponding α-amino acid and α-oximino acid as the primary products.

To explain the disproportionation, two mechanisms based on hydride shifts may be considered. Both are essentially alike as in one case nitrogen-linked hydrogen

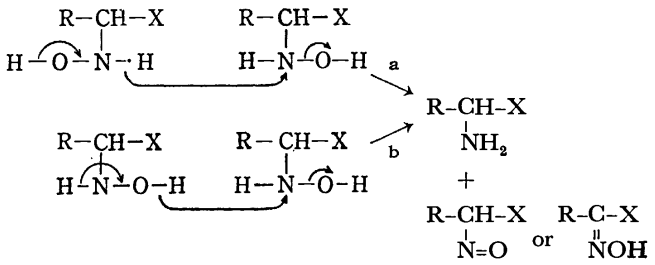
a) Percentage of theoretical on the basis of (50/50) disproportionation of the reacted HAA. b) Percentage of theoretical on the basis of quantitative decomposition of α-oximino acid to nitrile and CO_2.

of one molecule of hydroxyamino compound shifts to the nitrogen of the other molecule of hydroxyamino compound as a hydride ion, whereas in the second case a hydrogen from the oxygen rather than the nitrogen of one molecule shifts to nitrogen of the other. (Scheme 1).



Scheme 1

The mechanism (b) seems to be more likely since -OH·····N and N-H·····O; types of hydrogen bonding have been shown to be preferential in solid hydroxylamine.[11]

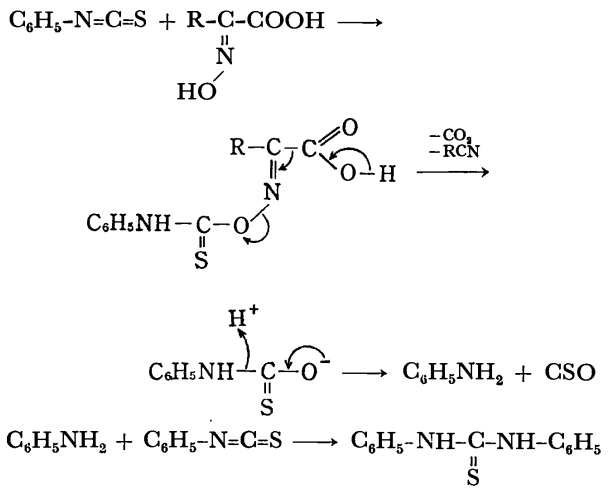
It is now clear that the products obtained by Neelakantan and Hartung[9] and regarded as α,N-hydroxyamino acids and which were described as ninhydrin positive, reducing and amphoteric, were in fact mixtures containing α,N-hydroxyamino, α-amino and α-oximino acids. The reaction products were not carefully analyzed and their true nature was overlooked by them.

When α,N-hydroxyamino-β-phenylpropionic acid was synthesized, a small quantity of α-oximino-β-phenylpropionic acid was actually crystallized out from the reaction mixture. Similarly α-oximino acids in small amounts were found amongst the products of acid hydrolyzates of other α,N-hydroxyamino nitriles. A part of α-oximino acids was possibly lost by decomposition to lower homologous nitriles and CO_2 under the conditions. Amino acids were also found in every case. They were isolated by column chromatography of the crude mixtures by making use of cation and anion exchange resins.

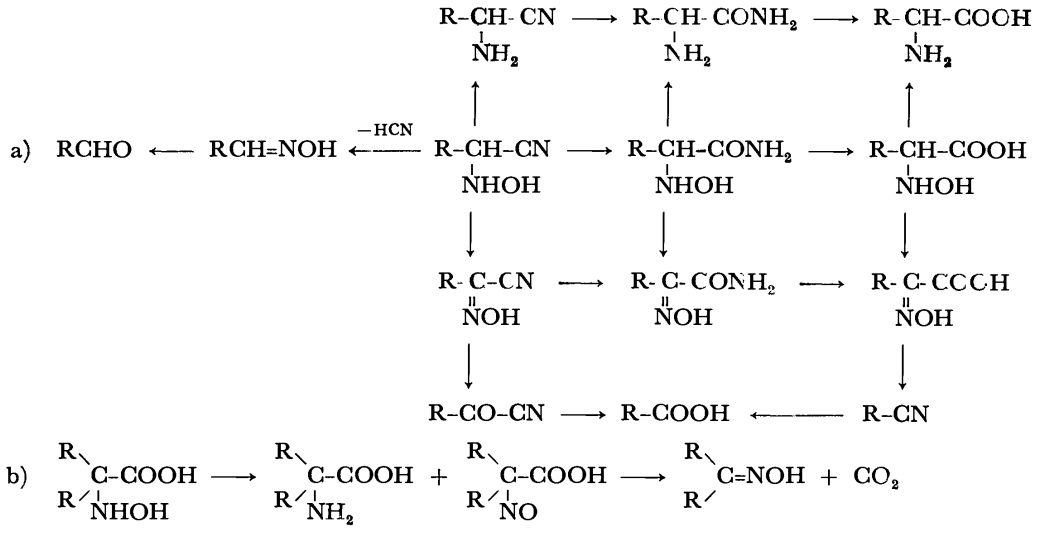
It has now become possible to offer an explanation for the formation of α-amino acid, α-oximino acid, the lower homologous aldehydes and nitriles and the corresponding aliphatic acids as by-products of acid hydrolysis of α,N-hydroxyamino nitriles to give α,N-hydroxyamino acids. This is shown in Scheme 2. Two molecules of α,N-hydroxyamino compound undergo mutual oxidation and reduction to give one molecule each of an α-amino compound and an α-oximino compound. In case of α,N-hydroxyaminoisobutyronitrile and 1-hydroxyamino-1-cyanocyclohexane, which do not possess any hydrogen on α-carbon atoms, similar changes take place but instead of α-oximino compounds, blue nitroso compounds are generated which undergo gradual decomposition.[12]

It has also been observed that all α-oximino acids are quantitatively decomposed to give diphenylthiourea and CO_2 when refluxed for one minute with phenylisothiocyanate in benzene solution or when kept for one week at 40 °C. The possible mechanism of this reaction is shown in Scheme 3.

Analogous experiments with α,N-hydroxyamino acids, contrary to the earlier report,[9] failed to give any diphenylthiourea. But when the reflux time was increased to 5 min or more, a small quantity of diphenyl-



Scheme 3



Scheme 2

thiourea did separate along with a major portion of another unidentified high melting product. It is likely that diphenylthiourea is formed from α-oximino acid which might have been produced by disproportionation of α,*N*-hydroxyamino acid. α,*N*-Hydroxyamino acids prepared by Neelakantan and Hartung yielding diphenylthiourea gives a further evidence in support of our observation that these products were in fact mixtures.

Treatment of α-halo acids with excess hydroxylamine gives rise to α-oximino acids.[13] With equimolar amounts of hydroxylamine, α,*N*-hydroxyamino acids are obtained in 50% yields.[2] The formation of α-oximino acids from α-halo acids and hydroxylamine, a reaction whose oddity has hitherto been ignored can now be explained on the basis of a disproportionation. It is now almost certain that hydroxyamino acid is a primary product which either disproportionates to give the corresponding α-amino acid and α-oximino acid or undergoes oxidation by a second molecule of hydroxylamine which is reduced to ammonia (Fig. 4).

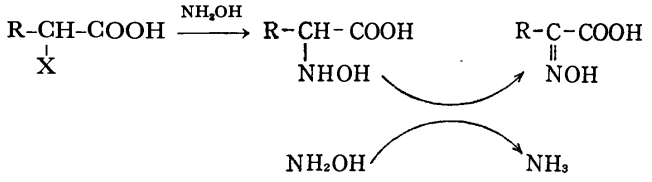


Fig. 4

It is interesting to note that not only α,*N*-hydroxyamino acids, but also hydroxylamine itself, and *N*-methyl and *N*-ethyl hydroxylamines have been reported to decompose in such a fashion[14] to give products whose origin can now be explained easily on the basis of a disproportionation reaction. *N*-Phenylhydroxylamine also gives products compatible with this interpretation.[15]

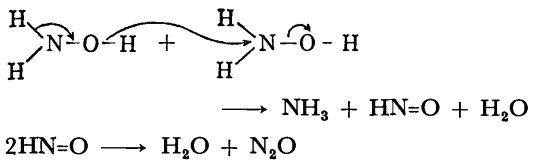

Fig. 5

Hydroxylamine when heated decomposes to give nitrous oxide, ammonia and water. The formation of these products can be explained in the following manner (Fig. 5). *N*-Methylhydroxylamine when distilled in the presence of alkali decomposes to give methylamine, ammonia and formic acid. *N*-Ethylamine under similar conditions gives ethylamine, acetic acid, acetaldehyde and ammonia (Fig. 6).

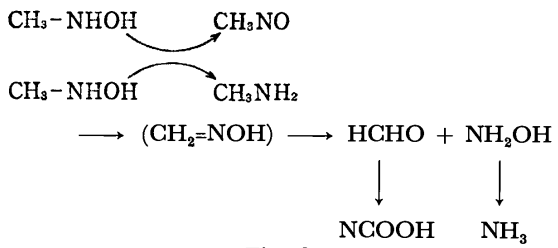

Fig. 6

It is therefore not difficult to infer that not only α,*N*-hydroxyamino acids but also other mono-*N*-substituted hydroxylamines are capable of undergoing disproportionation reactions. This likelihood is at present under investigation and the results will be communicated in a following publication.

Experimental

α,N-*Hydroxyamino Acids.*[16] Six α,*N*-hydroxyamino acids namely (α,*N*-hydroxyaminopropionic acid, α,*N*-hydroxyaminobutyric acid, α,*N*-hydroxyaminoisobutyric acid, α,*N*-hydroxyaminovaleric acid, α,*N*-hydroxyaminoisovaleric acid and 1-hydroxyaminocyclohexane-1-carboxylic acid) were prepared from the corresponding α,*N*-hydroxyaminonitriles by hydrolysis with concentrated hydrochloric acid.[7,9,17,18] When any one of α,*N*-hydroxyaminopropionitrile, α,*N*-hydroxyaminobutyronitrile, α,*N*-hydroxyaminovaleronitrile and α,*N*-hydroxyaminoisovaleronitrile was refluxed with concentrated hydrochloric acid for 5 hr, the reaction mixture was found to contain not only the expected α,*N*-hydroxyamino acid but also the corresponding α-amino acid, α-oximino acid, the lower homologous aldehyde and aliphatic acid. The aldehyde, the aliphatic acid and the oximino acid were separated by ether extraction of the acidic reaction mixture and the α,*N*-hydroxyamino acid was separated from the corresponding α-amino acid by cation and anion exchange resins. The quantity of oximino acid obtained was generally low but increased when the reaction mixture was allowed to stand at room temperature for a longer period before ether extraction.

α,N-*Hydroxyamino-β-phenylpropionic Acid.* α,*N*-Hydroxyamino-β-phenylpropionic acid was obtained from diethylbenzylmalonate.[19] Freshly cut sodium metal (2.3 g, 0.1 mol) was dissolved in absolute ethanol (150 ml) and diethylbenzylmalonate (25.0 g, 0.1 mol) was added, with cooling and stirring. Nitric oxide (generated by dropping conc. H_2SO_4 into a saturated aqueous solution of $NaNO_2$) was bubbled through the ethanolic reaction mixture for one hour. The yellow reaction product was kept overnight at 35 °C and then ethanol removed by evaporating at room temperature under reduced pressure to give a pale yellow slurry which was mixed with 20% aqueous NaOH (60 ml) and kept at 35 °C for 24 hr. The alkaline solution was then extracted with ether to remove any unchanged malonic ester. The solution was then acidified at 5 °C with 30% HCl, resulting in the separation of an oily product, which was extracted into ether. On removal of ether and warming the oily residue with concd HCl (50 ml) for 5 min, phenylpyruvic acid oxime (0.8 g), melting at 169—170 °C (decomp.) crystallized out. This was filtered off, and the filtrate evaporated to dryness. The residue was taken in water (20 ml) and treated with charcoal. The pale yellow clear solution obtained was passed through a column of cation exchange resin (Dowex 50W-X4, 200—400 mesh, H^+ form). After washing the column with water, the products were displaced with 2% aqueous ammonia. The effluent was collected into three fractions a, b, and c. The fraction (a) was strongly reducing towards ammoniacal $AgNO_3$. On evaporation to dryness at room temperature and reduced pressure this fraction yielded α,*N*-hydroxyamino-β-phenylpropionic acid (2.8 g, 15.5%), melting at 159 °C (decomp.) and identical in all respects with an authentic specimen.

The second fraction (b) on evaporation to dryness gave a mixture of α,*N*-hydroxyamino-β-phenylpropionic acid and phenylalanine. The third fraction (c) gave a strong ninhydrin positive reaction and on evaporation to dryness yeilded

phenylalanine (0.13 g), melting at 270..272 °C (decomp.), whose infrared spectrum was identical with an authentic specimen.

Paper Chromatography of α,N-Hydroxyamino Acids. Paper chromatography was carried out by the descending technique on 40 cm long Whatman No. 1 papers. One dimensional runs were performed using the organic layer of *n*-butanol: acetic acid: water (40: 10: 50 by volume) mixture as the solvent. The chromatograms were dried at 35 °C for 16 hr. α-Amino acids formed were detected by the conventional ninhydrin reagent. Reducing α,*N*-hydroxyamino acids were visualized either by spraying with ammoniacal $AgNO_3$ (1.0 g $AgNO_3$ in 100 ml water containing 15 ml 10 M ammonia), when α,*N*-hydroxyamino acids appeared as black spots or by spraying with a solution of triphenyltetrazolium chloride.[16] The dried chromatograms were first sprayed with 0.1% triphenyltetrazolium chloride in *n*-butanol saturated with water, dried once again, and resprayed lightly with a solution containing aqueous NaOH (10 M NaOH (10 ml)+ 95% ethanol (40 ml)+*n*-butanol (50 ml)). The presence of α,*N*-hydroxyamino acids was indicated by the immediate production of pink spots. The R_f values of α-amino acids were compared with those of markers of authentic samples applied to the same papers (Table 1).

Estimation of α-Amino Acid and the Corresponding α,N-Hydroxyamino Acid in the Presence of Each Other. A solution containing α,*N*-hydroxyaminopropionic acid (15.0 mg) and alanine (15.0 mg) in water (2 ml) in a 10 ml beaker, stirred by gently bubbling nitrogen gas, was potentiometrically titrated with 0.1 M NaOH. When the pH of the solution had reached to pH 7.5, the amount of alkali added corresponded to the quantity of the α,*N*-hydroxyaminopropionic acid. At this point 30% aqueous HCHO (1.0 ml), previously titrated with alkali to pH 7.5 was added, and the titration resumed with 0.1 M NaOH until pH rose to pH 8.8. The amount of alkali used in the second titration corresponded to the amount of alanine in the mixture. The plot of pH *versus* alkali added during the titration is shown in Fig. 3. Analogous results were obtained when other pairs of α-amino acids and the corresponding α,*N*-hydroxyamino acids were titrated in the same manner.

Disproportionation of α,N-Hydroxyamino Acids into Corresponding α-Amino Acids and α-Oximino Acids. The α,*N*-hydroxyamino acid (36 to 55 mg) was taken in water (10 ml) in a 25 ml two neck flask, supplied with water cooled condenser and a gas inlet. Nitrogen gas was passed first through a $Ba(OH)_2$ trap and then bubbled through the reaction mixture. CO_2 obtained by the decomposition of α-oximino acid was collected as $BaCO_3$ in a trap containing saturated $Ba(OH)_2$ solution and the reaction train was linked to a further baryta trap. All disproportionation experiments were conducted at reflux temperature over a period of 24 hr. $BaCO_3$ was carefully filtered off, washed with water and methanol before drying to a constant weight. From the weight of $BaCO_3$, the amount of α-oximino acid formed in the course of the reaction was determined.

The aqueous solution in the reaction flask was titrated potentiometrically against 0.1 M NaOH to pH 7.5. This titre was used to calculate the amount of unreacted α,*N*-hydroxyamino acid. At pH 7.5, 30% aqueous HCHO (2 ml, previously adjusted to pH 7.5 with NaOH) was added and the titration carried to pH 8.8. This second titre was taken as a measure of the amount of α-amino acid formed. Results are summarized in Table 2.

Reaction of α,N-Hydroxyamino-β-phenylpropionic Acid with Hydroxylamine. α,*N*-Hydroxyamino-β-phenylpropionic acid (1.0 g, 0.0055 mol) was dissolved in 5% aqueous NaOH (50 ml) containing $NH_2OH \cdot HCl$ (0.385 g, 0.0055 mol) and heated under reflux in a 100 ml reaction flask provided with a gas inlet and a water cooled condenser. Nitrogen gas was bubbled through the reaction mixture and the evolved ammonia was carried along with the nitrogen stream into a trap containing 0.1 M HCl (50 ml). After 12 hr the heating was discontinued and the acid solution in the trap was evaporated to dryness under reduced pressure to give ammonium chloride (0.2649, 91%). The alkaline solution in the reaction flask was cooled in ice and acidified with dil. H_2SO_4. A white material was precipitated out which on filtration, drying and recrystallization from dry benzene, was found identical with phenylpyruvic acid oxime (0.47 g, 46.8%).

Similar results were obtained when α,*N*-hydroxyamino-β-phenylpropionic acid was replaced by other α,*N*-hydroxyamino acids.

Reaction of α,N-Hydroxyamino Acid with Phenylisothiocyanate. α,*N*-Hydroxyaminobutyric acid (1.2 g, 0.01 mol) in dry benzene (50 ml) was mixed with freshly distilled phenylisothiocyanate (2 ml). After keeping at 40 °C for one week there was no sign of any reaction and α,*N*-hydroxyaminobutyric acid was separated unchanged. When the reaction was conducted at the reflux temperature for more than 5 min and the products analyzed, a less than 5% yield of diphenylthiourea was isolated along with an undetermined high melting white substance. Analogous results were obtained when other α,*N*-hydroxyamino acids were employed. α-Oximino acids, when treated with phenylisothiocyanate under identical conditions, almost quantitative yields of diphenylthiourea were obtained.

The author is grateful to Professor I. D. Spenser for helpful discussion during the course of this work.

Application of Chemical Reactions of Thin-Layer Chromatoplates. III.* Monoterpenes

M. EL-GARBY YOUNES** and A. MOKHTAR

Department of Chemistry, Faculty of Science, University of Assiut, Assiut, Egypt, A.R.E.

(Received February 15, 1974)

Some characteristic reactions of monoterpenoids were carried out on inert thin-layer chromatoplates under controlled conditions and the products of the reactions were compared with the expected substances on the same chromatogram. The reactions performed were: acetylation at 40 °C on silica gel and on alumina plates, saponification on silica gel and on alumina chromatoplates, benzoylation at 0 °C, dehydration with thionyl chloride, oxidation with chromium trioxide in acetic acid and in dry pyridine, formation of 2,4-dinitrophenylhydrazone derivatives, chloride formation, reduction with lithium aluminium hydride, reaction of *p*-toluenesulphonyl chloride with some monoterpene alcohols and a modified Clemmensen reaction on monoterpene ketones.

In the field of natural products the chromatoplate technique is used in detecting the components of natural mixtures and giving information useful for subsequent resolution of the mixtures on chromatographic columns. The technique is also used in following up the course of chemical reactions to its end point and consequently, a chemical reaction can be performed for the optimal length of the time and an improved yield of the end product could be obtained. The natural product chemist knows that, the amount of the material available for investigation and preparation of a derivative may be too minute to enable a conventional reaction in a conventional apparatus. Frequently, the desired derivative has a decisive value in elucidating the structure of the parent compound by comparing the obtained derivative with a known product. The chemist has encountered this handicap during his study of some natural products, which were available in only minute amounts, and yet required for their study the detection of certain functional groups and the preparation of certain derivatives. For this objective, we were interested in carrying out some chemical reactions on thin-layer chromatoplates and in making this technique broad enough to involve not only the application of some chemical reactions of triterpenes[1] and amino-acids,[2] but also most of those other fields of natural products, to show which reactions can or cannot proceed on chromatoplates.

Our aim in this work is to carry out some reactions of the monoterpenoids on the plates, in order to serve in widening the aspect of the technique and to overcome some difficulties encountered in our work on natural products.

Generally, the reaction is carried out by mixing the substance under examination, mostly in solution form, with the suitable reactants within the area of a small spot at the starting line of a chromatoplate on an inert adsorbent. The mixture of reactants is then subjected to the favorable conditions and suitable length of time to simulate, as far as possible, the normal reaction conditions in the flask. At the end of the reaction period a simplified "working up" may be necessary which is also performed within the confines of the spots. The adsorbed layer is then treated in the normal manner as a chromatographic medium for reaction of the components of the reaction mixture. Thus, development with a suitable solvent system enables the detection of the formed derivative and the comparison with the expected material, spotted at the starting line immediately prior to development. Differentiation of the derivative from the starting material, if any remains, is always possible if the appropriate conditions are used.

Results and Discussion

Reactions involving acetylation at 40 °C, proceeded smoothly and almost completely on both silica gel and alumina chromatoplates for monoterpene alcohols (compd. 1—2; *cf.* Table 1). We found that the acetylation reaction did not affect by changing the adsorbent.

Saponification of the monoterpene esters on silica gel chromatoplates was difficult and most of the esters remained unreacted, this is in contrast to saponification on alumina plates which proceeded successfully. This phenomena is in support to the saponification tried previously on triterpene esters.[1,4]

Benzoylation proceeded smoothly at 0 °C for the compounds investigated, and the benzoate derivatives were obtained in a good yield (Table 1).

Dehydration of monoterpene compounds containing tertiary hydroxyl groups with thionyl chloride and dry pyridine at 0 °C proceeded smoothly for compound 5 but gave poor yield for compound 6 (*cf.* Table 1), and no other products were detected on the plate.

Oxidation with chromium trioxide in acetic acid at 70 °C for 20 min was successful and the ketones were obtained in a reasonable yields. While oxidation with chromium trioxide in dry pyridine at room temperature overnight did not proceed.

Reaction of monoterpene aldehydes or ketones with 2,4-dinitrophenylhydrazine in acetic acid at room temperature for 2 hr on plates were proceeded smoothly and the 2,4-dinitrophenylhydrazone derivatives were obtained in a good yield.

The formation of monoterpene chlorides was achieved successfully by reacting the desired alcohols with thionyl chloride in dry benzene for 4 hr at room temperature. The chloride was obtained in a good yield.

Reduction with lithium aluminium hydride in dry ether was proceeded smoothly and the alcohols were

a) Solvent system: I=benzene–light petroleum (1:1), II=benzene–light petroleum (1:2), III=light petroleum, IV=benzene.

obtained in a good yield.

The reaction of the monoterpene alcohols with *p*-toluenesulphonyl chloride was difficult and most of the starting alcohols were obtained unchanged.

Since the monoterpenes are volatile and sensitive to high temperature, the reduction of the ketonic groups in the monoterpenes to methylene groups by the normal Clemmensen method was shown to be unsatisfactory. However, a modified procedure for Clemmensen reaction which was detected by Toda *et al.*[3] and carried out by us on monoterpene ketones was proceeded smoothly under very mild conditions and a reasonable yield for compounds 11 and 8 but not for compound 9 was obtained (see Experimental and Table 1). The reaction was achieved with active zinc dust in presence of either dry ether or acetic anhydride and hydrogen chloride gas at 0 °C for 2 hr. We found that when acetic anhydride was used it gave better results of the expected hydrocarbons than the dry ether, and no other products were detected on the plate.

Conclusion. As we have seen from the above discussion it appears that the application of chemical reactions of monoterpenoids on an inert chromatographic adsorbent, within the usual area of a spot can produce results comparable to those obtained in conventional reaction apparatus.

Experimental

Chromatoplates. Both the silica gel and the alumina plates were prepared by slurring Kiesel gel G. (Merck) or alumina grade II in water (1:2 by weight, and applied manually onto glass plates 5×12 cm), followed by drying at 120 °C for 2 hr. The development of the plates was achieved by placing them in a closed tank containing iodine.

Acetylation. (A) Acetylation at 40 °C on silica gel plates was performed by treating the monoterpene alcohol under examination at the starting line followed by treatment with an acetic anhydride–pyridine mixture (3:1), which was applied in the form of a spray over the chromatoplate. The latter was placed in a desiccator containing a saturated atmosphere of acetic anhydride, then heating the desiccator until the temperature reaches 40 °C for 2 hr. At the end of the reaction-period, the chromatoplate was freed from the reagents by standing at room temperature for 1 hr. The chromatoplate is then ready for chromatographic development.

(B) Acetylation at 40 °C on alumina plates was conducted exactly as mentioned in the previous procedure.

Saponification. (A) Saponification of the monoterpene esters on silica gel was conducted by treating the ester spot under examination with ethanolic potassium hydroxide (10%). The plate was then placed in a desiccator containing a saturated solution of potassium hydroxide and the desiccator was heated until the temperature reached 70 °C for 6 hr, after which the plate was cooled and ready for development.

(B) Saponification of the esters on alumina plates was performed in the same manner mentioned above.

Benzoylation. This reaction was done by treating monoterpene hydroxy compound spot, at the starting line of the chromatoplate, with a mixture of benzoyl chloride-pyridine (1:2) on the same spot. The chromatoplate was then placed in a desiccator saturated with the same mixture of benzoyl chloride-pyridine and the whole was cooled at 0 °C for 2 hr. At the end of the reaction period, the plate

was freed from the solvent and then was ready for development.

Dehydration. This reaction was performed by applying the substance under examination which contains a tertiary hydroxyl group (5 and 6 in Table 1), in the form of a solution at the starting line, followed by adding a mixture of thionyl chloride–pyridine (1:8) on the same spot. The plate was placed in a desiccator saturated with the same mixture,and the whole were cooled at 0 °C for 10 min. The plate was freed from the solvent by leaving it at room temperature for 1 hr prior to development.

Oxidation with Chromium Trioxide. *(A) In Acetic Acid*: This reaction was achieved by applying the alcohol under examination in the form of a solution at the starting line of the chromatoplate, followed by treating the alcohol spot with a solution of chromium trioxide–acetic acid (2%). After leaving the plate in a closed vessel containing saturated atmosphere of acetic acid, at room temperature for 50 min, the whole was heated at 70 °C for 20 min. The plate was then sprayed with methanol to destroy the excess of the oxidant and dried again in air prior to development.

(B) In Pyridine: A simple oxidation was performed by spotting the hydroxy compound at the starting line on the plate followed by treatment with a solution of chromium trioxide in dry pyridine. The plate was then placed in a desiccator saturated with dry pyridine and left standing at room temperature for overnight. The plate was then sprayed with methanol to destroy the excess of chromium trioxide and dried in air prior to development.

Chloride Formation.[4] This reaction was performed by treating the monoterpene alcohol spot under examination with a solution of thionyl chloride in dry benzene (50%). The plate was placed in a desiccator containing a saturated solution of thionyl chloride–benzene mixture and left standing at room temperature for 4 hr, after which it was dried in air prior to development.

Reduction with Lithium Aluminium Hydride. The carbonyl compound spot at the starting line of a chromatoplate, was treated with a suspension of lithium aluminium hydride in dry ether. The plate was then placed in a desiccator saturated with dry ether for 3 hr at 30 °C, after which the plate was freed from the solvent and the spot was acidified with sulphuric acid (1M) prior to chromatographic development.

Reaction with p-*Toluenesulphonyl Chloride.* This reaction was performed by treating the monoterpene alcohol spot at the starting line of a chromatoplate by a solution of *p*-toluenesulphonyl chloride in dry pyridine. The plate was then placed in a desiccator containing a saturated atmosphere of pyridine for 36 hr at room temperature. At the end of the reaction period, the chromatoplate was dried in air prior to development.

A Modified Clemmensen Reduction.[3] *(A) In Ether*: This reaction was achieved by treating the ketonic spot under examination at the starting line of a chromatoplate with a suspension of active zinc dust in ether. The plate was then placed in a vacuum desiccator containing a saturated atmosphere of dry ether and the whole was cooled at 0 °C. Hydrogen chloride gas was passed into the desiccator until the space inside it was saturated with the hydrogen chloride gas, then the whole system was left standing for 2 hr, at 0 °C. The spot was treated with a solution of sodium carbonate and the plate was dried in air prior to development.

(B) In Acetic Anhydride: The reaction was performed as mentioned under method (A) above, except dry ether was replaced by acetic anhydride.

Ionization Potentials of Radicals as Determined by the Unrestricted MINDO/2 Method[1]

Hiroshi ICHIKAWA and Michihiko OGATA

Hoshi College of Pharmacy, Ebara, Shinagawa-ku, Tokyo 142

(Received December 24, 1973)

Synopsis. The parametrization in the MINDO/2 theory has been applied to the unrestricted Hartree-Fock method to give the appropriate ionization potentials of various radicals.

A knowledge of the ionization potentials (IP's) of radicals is of importance when considering the various theories of molecular structures. This knowledge, for example, when combined with the electron-impact appearance potentials, yields useful information on the heats of formation of free radicals. In order to interpret the mass spectra of organic compounds it is necessary to know the IP's of various radicals, since, in the fragmentation of a molecular ion such as $[P\text{–}Q]\cdot^{+}\rightarrow P\cdot+Q^{+}$ or $[P\text{–}Q]\cdot^{+}\rightarrow P^{+}+\cdot Q$, the positive charge is indicated by Stevenson's rule[2] as remaining predominantly on the fragment with the lower IP.

From both the kinetic and mass spectroscopic methods it is difficult to get all the values of the IP's of the individual fragments.[3] Alternatively several molecular orbital (MO) theories can predict those values. As will be discussed, the CNDO/2[4] and INDO[5] theories provide unrealistic values. Therefore, the MINDO/2 theory,[6] which gives IP's for the closed-shell molecules close to those found experimentally, has been adopted in this study. However, the formal extension of the semi-empirical MO theory for closed-shell systems to open-shell systems involves a fundamental problem. The parameters in the original MO theory have been so adjusted as to give appropriate results for the closed-shell systems. This paper will discuss the adaptability of the unrestricted MINDO/2 method in the calculation of IP's, comparing those obtained by the CNDO/2, INDO, and experimental methods.

Method of Calculation

The calculations here are based on the unrestricted INDO methods of Pople *et al.*[5,7] The one-center integrals, the two-center repulsion integrals, the core-electron attractions, the one-electron resonance integrals, and the core-core repulsions were estimated as in the original MINDO/2 method,[6] where none of parameters were changed. Further details will not be repeated here. The bond-lengths (in Å) of the fragments are assumed to be as follows: C(sp^3)–C(sp^3), 1.54; C(sp^3)-C(sp^2, sp), 1.50; C–C, 1.35; C–O, C=N, 1.25; C=C(conj.), 1.40; C(sp)=O, 1.15; C–H,

TABLE 1. IONIZATION POTENTIALS[a] OF FRAGMENTS BY MEANS OF CNDO/2, INDO, AND MINDO/2 METHODS

1.09; O–H, 1.00; N–H, 1.02. The unpaired electron in each radical was assumed to occupy a 2p atomic orbital.

Results

Calculations were carried out for specific radicals (by the unrestricted methods) and ions (by the restricted methods). Table I shows the differences in total energies (DIP's) between the ion and the radical, the values of $-\varepsilon^{ho}$'s (KIP's) (where the ε^{ho}'s are the energies of the highest occupied MO's), and, in the last columns, the experimental values determined by the electron-impact method (with an error of *ca.* 0.1 eV). From Koopmans' theorem, the KIP value should be approximately equal to the IP value. It can be seen that the KIP values determined by the unrestricted CNDO/2 and INDO include an inconstant error of more than 3 eV in comparison with the experimentally-determined values. In the present method, the error is kept within 1.5 eV.

The CNDO/2 and INDO methods also yield DIP values with an inconstant error, though this error is considerably less than in the KIP values determined by the same methods. It is interesting that the difference between the DIP values and the corresponding experimental values becomes smaller as the number of substituents of the carbon atom of the radical center decreases.

Although the bond-lengths and the bond-angles have not been optimized, the DIP values obtained by the MINDO/2 method are far closer to the experimentally-determined values than those calculated by any other method. The difference between the DIP and the experimental values is relatively constant according as the type of radical, *i.e.*, *ca.* 0.25, 0.75, and −0.3 eV for alkyl radicals, unsaturated radicals, and radicals with an N or O atom respectively. This suggests that such a difference must be brought about by the inappropriate molecular geometries.

This research has been supported by a Grant-in-Aid from the Ministry of Education of Japan (877358). The computations[8] were all carried out on HITAC-8800/8700 computers at the Computer Centre of the University of Tokyo.

Blue-colored Matter Appearing in an Alkaline Solution of Benzoin and Benzil in Aqueous Dimethyl Sulfoxide

Takehiro ABE and Masamoto IWAIZUMI*

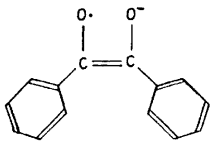
College of General Education, Tohoku University, Kawauchi, Sendai 980

* *Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira-2-chome, Sendai 980*

(Received January 16, 1974)

Synopsis. Blue-colored matter appearing in the alkaline solution of benzoin and benzil in aqueous dimethyl sulfoxide (DMSO) was confirmed to be a benzil anion-radical by visible and ESR spectroscopy.

The intensely purple-colored matter appearing during the course of the oxidation of benzoin to benzil in an alkaline alcoholic solution was confirmed by Ihrig and Caldwell[1] to be stable free radical with a Gouy-type magnetic balance. Although they assigned the colored matter to an aliphatic semiquinone such as benzil anion-radical (I), no evidence for the structure was given. The visible spectrum has not been given, since the matter is usually very labile.[2]



I

The colored matter can be more distinctly observed on addition of sodium hydroxide to a solution of benzoin and benzil in DMSO (blue) than in alcohol (purple). Benzil is an oxidizing agent appropriate for the formation of the colored matter.[1,3] We have investigated the colored species in DMSO by visible and ESR spectroscopy.

The blue species has bands at *ca.* 620 (shoulder), 650 and 720 nm (shoulder) in the visible region (Fig. 1). The disagreement in absorbance at 700 nm between the two measurements is due to the gradual disappearance of the blue matter. The solution resulting

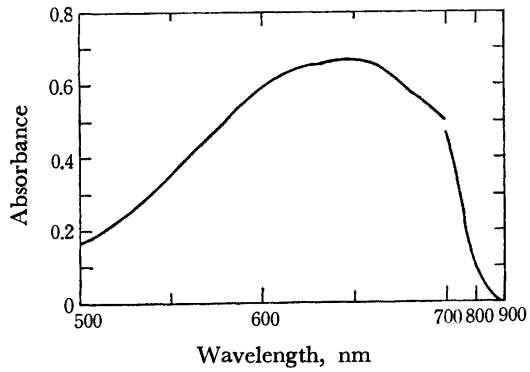


Fig. 1. The spectrum observed with the DMSO solution containing benzoin (5.5×10^{-4} M), benzil (6.3×10^{-4} M), sodium hydroxide (3.9×10^{-3} M) and 2%(v/v) water, at *ca.* 1 min after mixing.

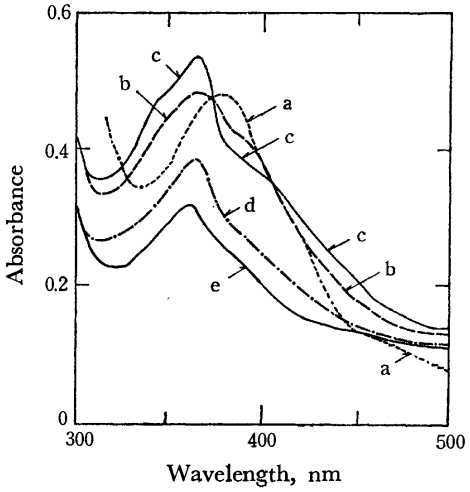

Fig. 2. The spectra observed with the DMSO solution containing benzoin (5×10^{-4} M), benzil (5×10^{-4} M), sodium hydroxide (3.9×10^{-3} M) and 2%(v/v) water. Time after mixing: a, 5 s; b, 30 s; c, 1 min; d, 8.3 min; e, 13.3 min.

from mixing shows an absorption peak at 380 nm at the initial stage and a peak at 359 nm later on (Fig. 2). The initial 380-nm band appeared before the appearance of the visible bands and disappeared with the increasing absorption intensities in the visible region, and it is therefore not due to the blue matter. On the other hand, the band at 359 nm seems to be ascribed to the blue matter, since the band decreased in intensity with the decreasing absorption intensities in the visible region.

The benzil anion-radical generated by electrolytic reduction in dimethylformamide solution[4] and by reduction with alkali metals in several solvents[5] is blue and purple, respectively. The benzil anion-radical produced in a γ-irradiated rigid solution in methyltetrahydrofuran at 77 K shows absorption bands at 650, 700 and 750 nm.[6] Thus the blue matter could be assigned to the benzil anion-radical.

The purple solution prepared by adding sodium hydroxide to a solution of benzoin and benzil in aqueous ethanol showed a very broad band with an absorption maximum at *ca.* 550 nm. The whole broad band shifted to the blue as compared with that of the blue DMSO solution. The difference in color between the blue DMSO solution and the purple ethanolic one seems to be due to a solvent effect.

The calculation made by Kawai[2] by the free-electron method predicts the peak position of 667 nm for radical I. The predicted position agrees closely with that observed in the present work.

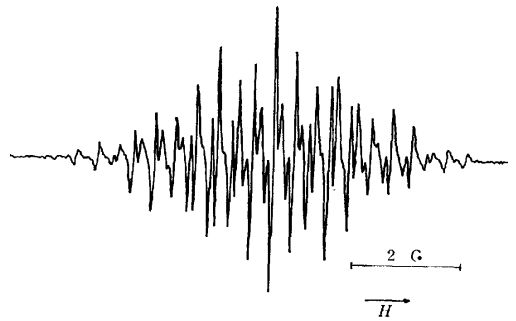

Fig. 3. The ESR Spectrum of the blue-colored species (the benzil anion-radical) produced by adding a drop of 4.9 M NaOH solution into the DMSO solution of benzoin (1×10^{-2} M) and benzil (1×10^{-2} M) in a thin sample tube open to the air at room temperature.

Table 1. Hyperfine splitting constants of the benzil anion-radical

Position	Splitting constants (G)		
	Present work	Ref. 4	Ref. 7
ortho	1.010	0.99	0.99
meta	0.368	0.36	0.37
para	1.123	1.12	0.99

The assignment of the benzil anion-radical for the blue matter can be confirmed by its ESR spectrum (Fig. 3), which is similar to that of the blue benzil anion-radical.[4] We see from Table 1 that the hyperfine splitting constants obtained from Fig. 3 agree closely with those reported for the benzil anion-radical.[4,7] Thus the blue matter can be confirmed to be the benzil anion-radical.

The DMSO solution of benzil in the presence of sodium hydroxide showed a band at 385 nm at the initial stage but no absorption bands in the visible region. In the DMSO solution of benzoin (1.5×10^{-3} M) and sodium hydroxide (3.9×10^{-3} M) in the absence of benzil, the blue-colored matter showing a visible spectrum similar to that shown in Fig. 1 appeared and disappeared later on. In this case the oxidation of benzoin proceeds owing to the presence of the oxygen dissolved in the solution.[3] It is thus evident that the blue matter is produced from benzoin. In the presence of benzil, however, it may also be produced by the reduction of benzil with benzoin.

Experimental

Commercial benzoin (G. R. Tokyo Kasei) was purified by recrystallization. Benzil (ultra-pure grade, Tokyo Kasei) was used. DMSO was dried with calcium hydride and fractionated under reduced pressure.

The electronic absorption spectra of the solutions were measured at room temperature with a Hitachi recording spectrophotometer EPS-3 having a path length of 1.00 cm, and with a Hitachi rapid scan spectrophotometer RSP-2 having a path length of 1.0 cm. Water was used as a reference. The ESR spectrum was measured with a Hitachi ESR spectrometer, Model 771, at 22 °C.

The authors are indebted to Professor Taro Isobe, Tohoku University, for his kind advice

Isomerization of 2-Pinene over Monohydrates of Metal Sulfates

Ryuichiro OHNISHI, Akira MATSUI, and Kozo TANABE*

Research Institute for Catalysis, Hokkaido University, Sapporo 060

* *Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060*

(Received February 13, 1974)

Synopsis. Catalytic activity of the monohydrates of various metal sulfates for the isomerization of 2-pinene was found to be related to the infrared wave numbers of the rocking mode of the water of crystallization and the transition temperatures from the monohydrates to the anhydrates, but not to the electronegativity of metal ions.

The catalytic activity of various metal sulfates for some acid-catalyzed reactions is related to the electronegativity of the metal ions.[1-3] The activity as well as acidity of metal sulfates is known to change a great deal with amount of water of crystallization of sulfates.[4] Since the electronegativity values of metal ions are those of bare ions independent of water molecules, they can not necessarily be correlated with the activity of metal sulfates which contain various amounts of water of crystallization. If the amount of water of crystallization is kept constant for all sulfates, a more definite relationship is expected between the electronegativity and catalytic activity. However, the effect of water of crystallization on activity has not been taken into careful consideration. We have studied the isomerization of 2-pinene over *the monohydrates* of various metal sulfates. It was found that, contrary to expectation, there is no correlation of activity with electronegativity, but good correlation between activity and the strength of the coordination of water of crystallization to metal ion.

Experimental

Monohydrates of metal sulfates were prepared by first calcining the polyhydrates (guaranteed reagents, Kanto Chemical Co., except for $Cr_2(SO_4)_3 \cdot 4H_2O$, extra pure) at 120—130 °C, by sieving below 150 mesh after grinding to powder and then calcining for further 3 hr in air at temperatures chosen to obtain the monohydrates (Table 1). 2-Pinene was purified from turpentine oil (Wako Pure Chemical Co.) by distillation over sodium under a stream of nitrogen after separation by a preparative gas chromatograph (Perkin-Elmer F-21). All the reagents and catalysts were stored in sealed ampoules. The acidic properties of the catalysts were determined by the amine titration method with various Hammett indicators.[5] Specific surface area was obtained by applying the BET method to the adsorption isotherm of nitrogen at −196 °C.

The isomerization reaction was carried out in the temperature range 133—134 °C, except for nickel sulfate (109 °C), by stirring the reaction mixture in a cell containing 2.5—3.0 ml of 2-pinene and 0.5—1.0 g of catalysts in nitrogen atmosphere. The reaction products were analyzed by a gas chromatograph (Hitachi-Perkin-Elmer F-6D), with a 45 m capillary column of Ucon LB-550-X, after the catalyst had been removed by centrifuging.

Results and Discussion

The isomerization reaction of 2-pinene (I) gave mainly tricyclic monoterpene of 1,7,7-trimethyl-tricyclo[2.2.1.$0^{2,6}$] heptane (TTH, II), bicylic mono-

Mn(II)	150	1.09	8.7×10^{-3}	1.8×10^{-2}	0.73	7.5

a) Reaction temperature 133—134 °C except for 109 °C for Ni(II). b) Selectivity for formation of bicyclic monoterpenes [mol% of (II+III+IV)/mol% of I]. c) Quoted from Ref. 1. d) Monohydrates unstable. e) Unreliable because of small amount of products.

terpenes of camphene (III) and 2(10)-pinene (IV), and monocyclic monoterpene of *p*-mentha-1,8-diene (V) as shown in Scheme 1.

In order to see the selectivity of this reaction, mol% of 2-pinene remaining at reaction time t was plotted against mol% of camphene+TTH+2(10)-pinene or *p*-mentha-1,8-diene formed at time t, respectively. The plots gave straight lines in the region 100—20 mol% of 2-pinene as in nickel sulfate.[6] From the slope of the straight line, the selectivity for the formation of camphene+TTH+2(10)-pinene from 2-pinene was obtained (Table 1). The selectivity values do not vary much with the kind of sulfate.

Catalytic activity of metal sulfates expressed by initial rates per unit weight or unit surface area of catalyst is also given in Table 1. The catalysts are arranged in the order of activity per unit weight of catalyst. Either the activity per unit weight or unit surface area was found to have no correlation with the electronegativity of metal ions. The relation between activity per unit weight of catalyst and the acidic property is given in Table 2. A tendency is seen for the sulfates to have weaker acid strength or less acid amount to show less activity.

We have found that the order of activity per unit weight of catalyst agrees better with the order of the infrared wave number of rocking mode of the water of crystallization: Ni(933) > Mg(883) > Co, Cd(875) > Zn(870) > Cu(865 cm^{-1})[7] Ni(928) > Mg(889) > Co(875) > Zn(872) > Cu(865) > Mn(828 cm^{-1}).[8] This agrees also with the order of the temeratures at which the monohydrates are converted into anhydrates.[7]

Ni(420) > Mg(354) > Co, Zn(320) > Cu(270) > Mn(260) > Cd(205 °C).

The order of the temperatures and the wave numbers is considered to show the order of the bond strengths between the water of crystallization and the metal ions of the monohydrates, since, in the case of metal amine complex, Nakamoto[10] points out that the higher the NH_3 rocking frequency, the stronger the metal-nitrogen bond. The catalytic activity seems to be related with the bond strengths. The fact that the distances between the water of crystallization and the metal ions of the monohydrates measured by X-ray diffraction[9] are related to the activity supports the view:

$Ni(2.0_6) > Zn(2.1_5) > Co(2.1_7) > Mn(2.2_5$ Å).

However, the reason for the intensive properties such as transition temperature and wave number being correlated with the activity per unit weight and not with the activity per unit surface area has not been clarified.

TABLE 2. ACID PROPERTY OF MONOHYDRATES OF METAL SULFATES

Catalyst	Acid amounts ($\times 10^2$ mmol/g) at various acid strengths (pK_a's)

The Basic Compound Produced in the γ-Radiolysis of Liquid Nitrogen Containing Hydrocarbons

Kaname Ishizaki and Shin Sato

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received April, 2, 1974)

Synopsis. The *G*-values of the basic compounds produced in the γ-radilysis of liquid nitrogen containing hydrocarbons have been measured by Conway's method. The concentration dependence of the *G*-values suggests that the basic compounds observed are the products of the reaction between nitrogen atoms and the hydrocarbon radicals eventually formed in the system.

In spite of the considerable number of studies, our understanding of the reactions of nitrogen atoms with hydrocarbons is limited.[1] One of the main reasons is that we have no proper method to produce nitrogen atoms.[2] A few years ago, our laboratory started to use the γ-radiolysis of liquid nitrogen to produce nitrogen atoms.[3] Since small hydrocarbons are soluble in liquid nitrogen, even though the solubilities are not very large, we could investigate a part of the complicated reactions of nitrogen atoms with hydrocarbons. Our concern at that time was mainly with the formation of hydrogen cyanide and nitrile compounds. During these studies, we recognized that there were some other products which were polymeric and basic in nature. We, therefore, tried to measure the *G*-values of these basic products, our results will be reported below. Unfortunately, however, we are still not successful in identifing these products.

Experimental

The dried high-purity nitrogen was purchased from the Japan Oxygen Co., Ltd., and was used after passing it through sulfuric acid. All the hydrocarbons and hydrochloric acid gas were supplied by the Takachiho Shoji Co. The Nessler reagent was the product of the Kishida Chemical Co.

The samples for γ-irradiation were prepared in almost the same way as has been described before; *i. e.*, the amount of the hydrocarbon is first measured by the *p-v* method, using an oil manometer, and the hydrocarbon is condensed in a glass sampling tube. Then, pure nitrogen is introduced into the tube at 77 K under the pressure a little higher than the atmosphere. The nitrogen is then easily liquified. The amount of the liquid is measured by the scale plotted on the sampling tube. At the top of the tube, a joint is connected by small springs which are easily dislocated if a sudden rise of pressure occurs inside the tube.

The γ-irradiation was carried out in a liquid nitrogen-Dewar flask with the dose rate of 0.65×10^6 R hr^{-1}, usually for one hour.

After irradiation, the sampling tube was again connected to a vacuum system and the inside was slowly pumped out at 77 K. Usually, two hours were taken for complete evacuation. After the evacuation, a small amount of hydrochloric acid gas was introduced into the tube and the tube was warmed up to room temperature. Then, the tube was opened to the atmosphere, and 1 ml of distilled water was poured into it. The aqueous solution thus prepared was subjected to the following analysis.

If nitrogen-containing products are present in the form of ammonia, amine, or imine, the amount may be measured by Conway's method.[4] A half ml of an aqueous solution is put into the outer section of a Conway vessel, and on the other edge of this section is put 1 ml of K_2CO_3 (30 g ml^{-1}). In the middle section of the Conway vessel, 1 ml of 1/400 M H_2SO_4 is placed. The vessel is then covered tightly with a greased lid and is gently moved in order to mix the product solution and the K_2CO_3 solution. The vessel is warmed in an oven at 38 °C for two hours. After having been cooled to room temperature, the solution in the middle part of the vessel is placed in a 10-ml measuring flask. 1 ml of Nessler reagent is poured into this solution, and then distilled water is added up to 10 ml. When nitrogen-containing products are present, the solution is slightly colored yellow. The absorption of this solution at 430 nm is measured with a Beckman spectrometer against a blank sample exactly 20 min after the Nessler reagent is poured into the solution. The calibration curve was obtained by using ammonia as the test substance. The lowest detectable concentration was 10^{-8} g ml^{-1}.

Results

All of the results are summarized in Fig. 1. From this figure, the following three conclusions may be drawn: 1) The *G*-values of basic compounds are saturated in the order of the solubilities of hydrocarbons in liquid nitrogen. In the case of ethane, the reported solubility is a 7.8×10^{-3} mole fraction,[5] although this value is not fully reliable.[6] 2) The concentration dependence of the *G*-values is very similar to that of the *G*-values of the hydrocarbons produced in the same system, while it is quite different from that of nitrile compounds. One example is shown in Fig. 2. 3)

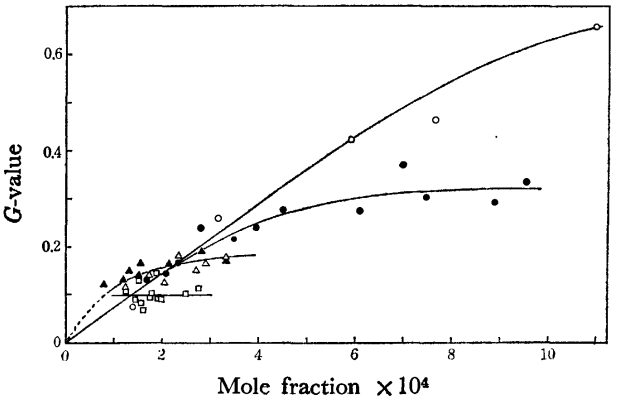

Fig. 1. *G*-Values of basic compounds as a function of the concentration of hydrocarbons.
○: ethane, ●: ethylene, △: propane, ▲: propylene, □: 1-butene.

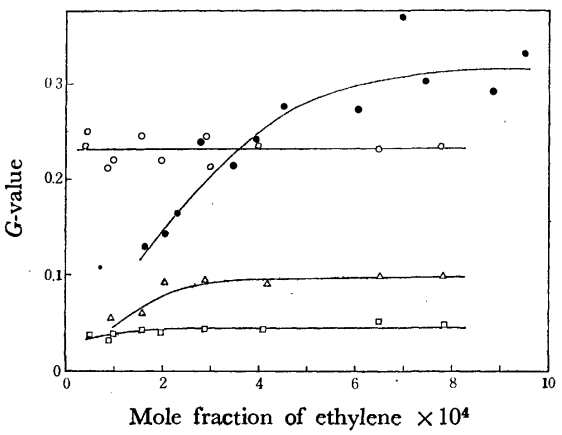

Fig. 2. *G*-Values of hydrogen cyanide (○), acetonitrile (□), acetylene ×10 (△), and basic compounds (●) from the liquid nitrogen solution of ethylene.

At the lowest concentration of hydrocarbons, the rate of formation of the basic compounds is faster for the larger hydrocarbons.

Discussion

In active nitrogen, the lowest excited state of the nitrogen molecule (A $^3\Sigma_u^+$) is known to be long in life (0.9 s). The formation of hydrocarbon radicals in the present system, therefore, may be due to this reaction:

$$N_2^*(^3\Sigma_u^+) + RH \rightarrow N_2 + R\cdot + H\cdot$$

In the case of olefins, the hydrogen atoms thus produced may add to the olefins:

$$R'CH{=}CH_2 + H\cdot \rightarrow R'CH\text{-}CH_3$$

These radicals may react with nitrogen atoms to produce basic compounds.

In the case of ethylene, a possible reaction mechanism for the formation of basic compounds may be described as follows:

$$N_2^* + C_2H_4 \rightarrow N_2 + C_2H_2 + H_2 \quad (1)$$

$$\searrow\ N_2 + C_2H_3\cdot + H\cdot \quad (2)$$

$$H\cdot + C_2H_4 \rightarrow C_2H_5\cdot \quad (3)$$

$$C_2H_3\cdot + C_2H_4 \rightarrow C_4H_7\cdot \quad (4)$$

$$RCH_2\cdot + \cdot N: \rightarrow RCH_2N: \ (R{=}CH_3 \text{ or } C_3H_5) \quad (5)$$

$$RCH_2N: \rightarrow RCH{=}NH \quad (6)$$

It is well known that an aliphatic imine such as RCH=NH polymerizes at room temperature and is easily hydrolyzed with water to aldehyde and ammonia. In fact, the aqueous solution we obtained in the present experiment showed the silver mirror reaction.

For the formation of nitrile compounds, we previously suggested the following reaction:

$$\cdot N: + RCH{=}CH_2 \rightarrow R\text{-}\overset{\overset{\curvearrowright}{\cdot}}{CH}\text{-}CH_2\cdot \rightarrow RCN + CH_3\cdot \quad (7)$$

ESR Spectra of Radicals during Photolysis of Chloranil in Solutions

Hiroshi YOSHIDA, Yoshihiko KAMBARA, and Bengt RÅNBY*

Faculty of Engineering, Hokkaido University, Kita-ku, Sapporo 060

(Received April 30, 1974)

Synopsis. ESR spectra were recorded during photolysis of chloranil in 2-propanol, ethanol, methanol and benzene at room temperature. The spectra observed from solution in alcohols are identified as due to neutral seqmiuinone radical. It is also suggested that excited chloranil abstracts a hydrogen from benzene.

Principal aims of this investigation are in the identification of electron spin resonance (ESR) spectra of short-lived intermediates formed during photolysis of chloranil (tetrachloro-*p*-benzoquinone) in alcohols and also in the confirmation by ESR method of the possibility that excited chloranil abstracts a hydrogen atom from benzene. Hales and Bolton observed a single line spectrum of 0.80 G width in the photolysis of chloranil in ethanol and methanol and attributed it to chloranil radical anion on the basis of its *g*-value.[1] Later, Wong *et al.* observed a spectrum of 0.58 G width from the 2-propanol solution and attributed it to neutral semiquinone radical of chloranil mainly on the basis of decay kinetics.[2] Identification of the spectra seems to be still uncertain because of the lack of hyperfine structure in it.

By a recent study of flash photolysis, optical absorption spectra attributable to both neutral semiquinone radical and radical anion were observed from the solution of chloranil in methanol.[3] One of the present author (H.Y.) and others studied short-lived intermediates during photolysis of *p*-benzoquinone and its methyl derivatives by ESR and found that both neutral radicals and radical anions are formed in alcohols.[4] These results also suggest the necessity of re-examination of the single line spectra observed from chloranil in alcohols. In addition, the flash photolysis study showed an interesting result that the neutral semiquinone radical is formed in the solution of chloranil in benzene, which is not believed to be a hydrogen donor. It may be worthwhile to detect ESR spectrum of the neutral radical to confirm this flash photolysis observation.

Experimental

All chemicals were analytical grade and used as received without further purification except that chloranil was recrystallized from chloroform.

ESR measurements were carried out at room temperature with a conventional X-band spectrometer (JEOL, Model JEX-ME) with a specially designed rectangular TE_{102} cavity during photolysis with light from a super-high pressure mercury arc (Philips, SP 500). Sample solutions were purged with helium gas to remove dissolved oxygen for at least half an hour, flowed through quartz flat cell in the cavity at a 4 ml/min and photolyzed with the light through a grid wall of the cavity.

Results and Discussion

Alcohol Solutions. Figure 1a shows a typical ESR spectrum observed from solution of chloranil in 2-propanol during photolysis. It is a single line spectrum without resolved hyperfine structure, as reported previously,[1] and its width (peak-to-peak width in derivative curve) is 0.55 G. The lifetime of the spectrum is shorter than the response time of the spectrometer used (0.3 s). No change is observed in the spectral shape and intensity by adding acetic acid to the solution. This fact strongly suggests that the spectrum is due to the neutral semiquinone radical rather than the radical anion, because radical anions are readily transformed to neutral radicals by protonation reaction in acidic solutions in the case of *p*-benzoquinone and its methyl derivatives.[4]

When chloranil is reduced by sodium methoxide in isopropanol, a stable single line spectrum of 0.43 G width is observed without light. It is attributed to the radical anion of chloranil. The intensity of the

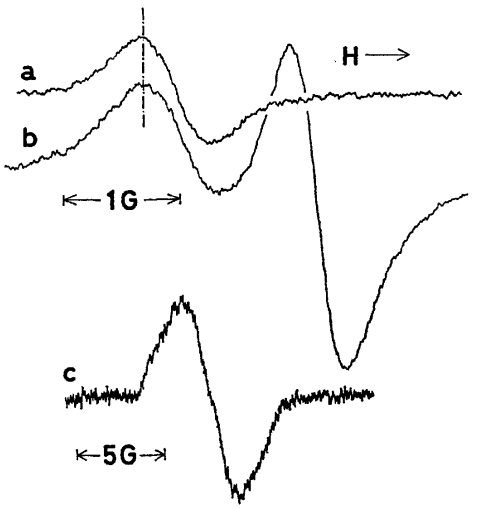

Fig. 1. ESR spectra observed at 20 °C during photolysis of solution of 1 mM chloranil (a) in isopropanol, (b) in 2-propanol with a small amount of sodium methoxide in it, and (c) in benzene. The vertical line gives a base for comparing the magnetic field position of the spectra (a) and (b) relative to each other. The signal curve (c) gives only the spectral shape and no information about the magnetic field position relative to that of (a) and (b).

* On leave from Royal Institute of Technology, Stockholm, as a visiting professor supported by Japanese Society for Promotion of Sciences during the period March—June, 1973.

spectrum is strong and depends on the concentration of methoxide. Figure 1b shows spectra recorded from the solution of chloranil in 2-propanol in the presence of low concentration of sodium methoxide during photolysis. The spectrum at lower field is the photo-induced unstable spectrum, which corresponds to that in Fig. 1a. The spectrum at higher field is the stable one just mentioned above. Coexistence of the two spectra during the photolysis indicates that the unstable spectrum is attributed to the neutral semiquinone radical formed by the hydrogen abstraction from solvent molecule by excited chloranil.

The *g*-value of the chloranil radical anion is smaller by 0.0008 than that of the corresponding neutral radical This contrasts to the absence of significant difference in *g*-value between radical anion and neutral radical formed from p-benzoquinone in ethanol (see the spectra in Fig. 1 of Ref. 4 and in 2-propanol.[2] Chlorine atoms having a large spin-orbit coupling constant may have caused a significant change in *g*-value, when the electronic state is modified by the attachment of a proton to the chloranil radical anion to form the neutral radical.

Observations are the same for the solution of chloranil in methanol or ethanol as solvent instead of 2-propanol. The unstable spectrum shows the width of 0.63 and 0.62 G in methanol and ethanol, respectively. The width of the stable spectrum is 0.49 G in methanol and 0.43 G in ethanol. The coexistence of the two spectra indicates that the photoinduced unstable spectrum is due to the neutral semiquinone radical in all alcohols examined.

As a conclusion, the ESR spectra observed during photolysis of chloranil in alcohols are due to the neutral radical regardless of which alcohol is used as solvent. This conclusion does not exclude the assignment of the optical absorption spectra observed by the flash photolysis study that they are due to both the neutral radical and the radical anion,[3] because the time scale of measurements is very much different between these two methods. It may be worth noting that the ESR spectrum of only the neutral radical is observed during photolysis of chloranil, while the spectra of both the neutral radical and the radical anion are simultaneously observed during the photolysis of benzoquinone and its methyl derivatives in the same solvents.

Benzene Solution. Figure 1c shows the spectrum observed from solution of chloranil in benzene during photolysis. The spectrum has a width of 3.4 G without resolved hyperfine structure, which is much wider than the spectrum of neutral semiquinone radical formed from chloranil in aprotic solvent of dioxane.[2] Although the reason why the present spectrum in benzene is so much wider is not known at this moment, it is suggested to be due to the neutral semiquinone radical, because the addition of acetic acid causes no change in the shape and intensity of the spectrum. The integrated intensity of the spectrum is comparable to or somewhat larger than that of the unstable spectrum observed from the alcohol solutions under the measuring conditions unchanged. The presence of dissolved oxygen reduces remarkably the efficiency of radical formation.

The above interpretation of the spectrum may raise a question what the excited chloranil abstracts a hydrogen atom from. Even if 5 vol% of isopropylbenzene is added as hydrogen donor into the solution, no increase is found in the intensity of the spectrum. The photolysis of chloranil in toluene gives the same spectrum as in the benzene solution, the intensity of which is also the same as in benzene. These results infer that the photochemical reactions involved are rather complex but the excited chloranil molecule abstracts a hydrogen atom from the benzene ring. The above interpretation is consistent with the previous flash photolysis study where transient optical absorption bands observed from the solution of chloranil in benzene were attributed to the neutral semiquinone radical.[3]

In addition to the main broad spectrum, spectra composed of several sharp hyperfine lines of 0.25 G width are traced from both the benzene and toluene solutions. However, the spectra are too weak to be recorded clearly. They are believed to be due to free radicals formed from solvent molecules, and their identification, if possible, may give an essential information of the reaction involved.

The Crystal Structure of *dl*-Bi-1,4-dioxanyl

Akio FURUSAKI, Shunjiro MISUMI, and Takeshi MATSUMOTO

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received May 24, 1974)

Synopsis. The two forms of bi-1,4-dioxanyl (mp 157.5—158.0 °C and 133.5—134.0 °C), obtained by the photochemical reaction of 1,4-dioxane with acetophenone, have been assigned unequivocally to the *meso* and *dl* forms respectively by the X-ray method.

In the absence of copper ions, the photochemical reaction of 1,4-dioxane with *t*-butyl peracetate yielded two isomeric products ($C_8H_{14}O_4$), mp 157 °C and 132 °C.[1] From the results of microanalyses and molecular-weight determinations, it was inferred that one product was the *meso* form of bi-1,4-dioxanyl and the other was the *dl* form. It has recently been found in this laboratory that the same products, mp 157.5—158.0 °C and 133.5—134.0 °C, are obtained also by the photochemical reaction of 1,4-dioxane with acetophenone.[2] In order to assign unambiguously the configurations of these two products, an X-ray crystallographic analysis has been made on the product with the lower melting point.

The crystals are monoclinic, with four molecules in a unit cell of the dimensions; $a=12.198\pm0.004$, $b=4.645\pm0.002$, $c=14.660\pm0.004$ Å, and $\beta=93.56\pm0.07°$. These dimensions were measured on a single-crystal diffractometer using Cu$K\alpha$ radiation ($\lambda=1.54178$ Å). The calculated density is 1.395 g/cm^3. The systematic absences, hkl for $h+k=2n+1$ and $h0l$ for $l=2n+1$, showed that the space group was either Cc or C2/c. At the beginning of the study, the latter was assumed; this choice was confirmed later by successful refinement. A crystal with dimensions of about $0.1\times0.2\times0.5$ mm was used, and the intensity data were collected on a Rigaku automatic four-circle diffractometer using Cu$K\alpha$ radiation monochromatized with a LiF crystal. The intensities were corrected for the usual Lorentz and polarization factors, but not for either the absorption or the extinction effect. In the range of 2θ values up to 140°, 693 structure factor magnitudes above $2\sigma(F)$ were selected for the structural study.

The structure was solved by the symbolic addition procedure using 148 $|E|$ values above 1.30. Approximate positions of all non-hydrogen atoms were obtained from an *E*-map based on 143 phases. These atomic coordinates were refined by the block-diagonal-matrix least-squares method, at first with isotropic and then with anisotropic thermal parameters. A difference Fourier map yielded the locations of all 7 hydrogen atoms. Further least-squares refinement including these hydrogen atoms with isotropic temperature factors was carried out. In this refinement, the following weighting scheme was introduced:

$$W = 1/\{\sigma(F)^2 \exp(AX^2 + BY^2 + CXY + DX + EY)\}$$

where $X=|F_o|$ and $Y=\sin\theta/\lambda$. The coefficients, *A*, *B*, *C*, *D*, and *E*, are constants which have been determined from $(\Delta F)^2$ values. The *R* value reached 4.9%. The atomic parameters are listed in Table 1. The tables of the observed and calculated structure factors are preserved by the Chemical Society of Japan (Document No. 7422). The atomic scattering factors were taken from International Tables for X-ray Crystallography, Vol. III. All calculations were performed on a FACOM 230—60 computer at the Computer Center of Hokkaido University.

TABLE 1. THE FINAL ATOMIC PARAMETERS AND ESTIMATED STANDARD DEVIATIONS

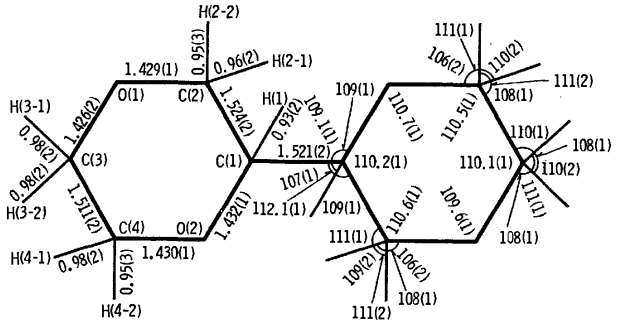

Fig. 1. The bond distances (Å) and angles (°).

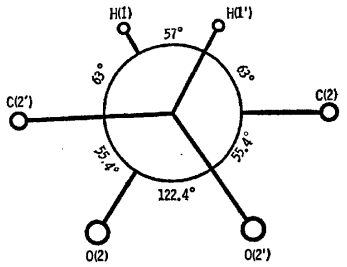

Fig. 2. The Newman projection along the C(1)-C(1′) bond.

As is shown in Fig. 3, the present molecule has the C_2 symmetry. Thus, out of the two crystalline forms of bi-1,4-dioxanyl, the one with the melting point of 133.5—134.0 °C is assigned to the *dl* form.

The bond distances and angles are given in Fig. 1. The dioxane rings in a molecule have normal chair-forms, with the C(1)–C(1′) bond oriented equatorially, and the molecule takes such a staggered conformation around the C(1)–C(1′) bond as is shown in Fig. 2.

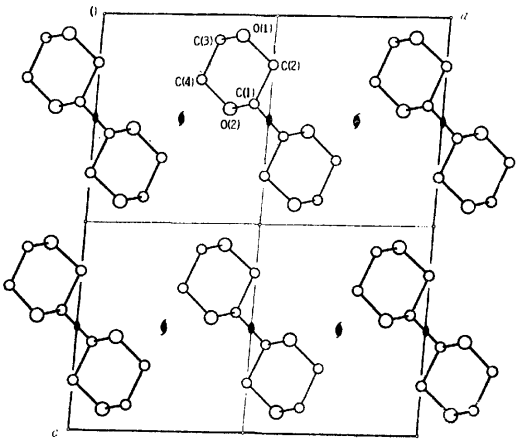

Fig. 3. The molecular arrangement viewed along the *b* axis.

This conformation, in which the largest groups, $C(2)H_2$ and $C(2')H_2$, are farthest from each other, is probably the most stable of the three possible staggered ones. The average of three independent C–C bond distances, 1.519 Å, is somewhat smaller than the normal distance for C–C, while the average of four C–O distances, 1.429 Å, is in good agreement with the standard value, 1.43 Å.

The crystal structure viewed along the *b* axis is shown in Fig. 3. The molecules are held together mainly by the van der Waals interactions.

A Study on the Hydrolysis of Cadmium Ion in Aqueous 3M (Li)ClO_4 Solution

Haruo MATSUI* and Hitoshi OHTAKI

Department of Electrochemistry, Tokyo Institute of Technology, O-okayama, Meguro, Tokyo 152

(Received April 25, 1974)

Synopsis. The equilibrium constants of hydrolytic reactions of cadmium ion have been determined in a 3M (Li)ClO_4 aqueous medium at 25 °C as follows: log $*\beta_{1,1}=-10.3\pm0.1$ and log $*\beta_{1,2}=-9.13\pm0.01$.

Concerning the hydrolytic reactions of cadmium ion many authors reported the formation of mononuclear complexes.[1–6] The work by Biedermann and Ciavatta[7] was the only case in which polynuclear complexes were found. They prepared the solution by the addition of CdO powder to a slightly acidic 3M (Li)ClO_4 solution containing a suitable amount of $Cd(ClO_4)_2$, stirring the resulting mixture for about half a day. The supernatant was then subjected to titration. Schindler,[5] however, stated that a much longer time is required in order to establish an equilibrium between solid CdO (or $Cd(OH)_2$) and the aqueous phase which is saturated with hydroxo complexes of cadmium ions. Experiments we carried out for the preparation of test solutions containing hydrolyzed cadmium ions showed that a white precipitate is gradually formed after the CdO powder, turned white due to the formation of $Cd(OH)_2$ on the surface, has been removed from the solution which should be left to stand for at least ten days under agitation.

From these observations the question arose as to whether some polynuclear complexes really can be present as equilibrium species of hydrolyzed cadmium ions in solution. We have reexamined the procedure of Biedermann and Ciavatta[7] in order to confirm the formation of polynuclear complexes of hydrolyzed species of cadmium ions.

Experimental

Reagents and Apparatus. Cadmium perchlorate was prepared by dissolving CdO (99.99%, Mitsuwa Pure Chemicals Co., Osaka) in 1 : 1 $HClO_4$ (reagent grade). The purity of the cadmium oxide was checked by emission spectroscopy. The cadmium perchlorate was recrystallized twice from water.

Lithium perchlorate was prepared according to the method of Biedermann and Ciavatta.[7]

An Orion Digital pH Meter Model 801 was used in combination with a Beckman Glass Electrode No. 40498 and a Silver-Silver Chloride electrode.

A Metrohm E 211 A Type coulometer was employed as a current source for generation of hydrogen ions in a solution during the course of titration.

Preparation of Test Solutions. A small amount of CdO powder was added to 50 ml of a lithium perchlorate solution containing a suitable amount of $Cd(ClO_4)_2$, the total concentration of perchlorate ion being kept at 3M, and that of cadmium ion in the range 0.2261—1.401 M. The mixture was allowed to stand 3—7 days under agitation in nitrogen atmosphere and white precipitates formed were removed with a set of G-3 and G-4 glass filters. The filtrate was left to stand 7—20 days. When a precipitate was recognized in the solution, the solution was filtered again with the G-3 and G-4 glass filters. A twenty-five milliliter portion of the clear solution was used for emf measurements.

The method of measurement was essentially the same as those described previously.[8–10] All the measurements were carried out at 25.00 °C±0.01 °C. 3M (Li)ClO_4 was used as an ionic medium.

Results and Discussion

The results are given in Fig. 1 as the plot, Z *vs.* $-\log h$, where Z denotes the average number of hydrogen ions set free per cadmium atom and h the concentration of hydrogen ion at equilibrium. Since the Z values are low, the concentration of free cadmium ion (b) can approximately be made equal to the concentration of total cadmium (B) in preliminary calculations. Thus,

$$BZ = \sum_p \sum_q p[Cd_q(OH)_p{}^{(2q-p)+}] = \sum_p \sum_q p*\beta_{p,q}B^q h^{-p}$$

where

$$*\beta_{p,q} = [Cd_q(OH)_p{}^{(2q-p)+}][H^+]^p/[Cd^{2+}]^q.$$

Plots of Zh *vs.* h^{-1} gave a set of horizontal lines with intercepts dependent on B. A family of curves drawn according to a normalized function $y=x=f(\log x)$ fitted the Z *vs.* $-\log h$ plots. We thus conclude that the species formed are only the $CdOH^+$ and Cd_2OH^{3+}

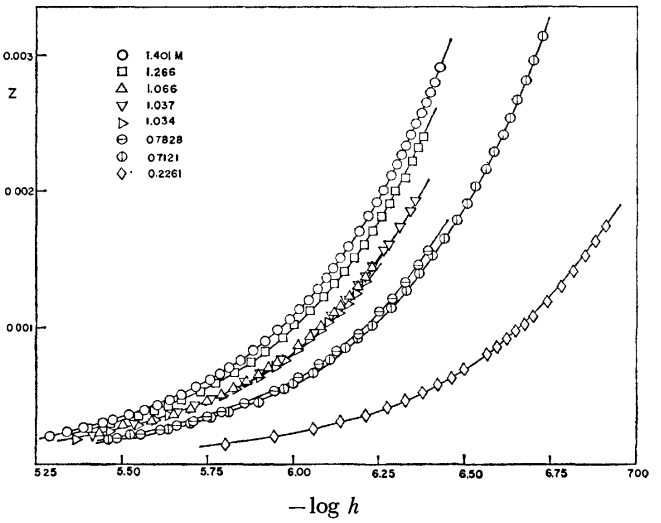

Fig. 1. The average number of hydrogen ion set free per cadmium atom Z plotted against $-\log h$. The solid lines show calculated curves using values finally obtained. The experimental data are available by request.

* Research fellow from the Government Industrial Research Institute of Nagoya, Kita-ku, Nagoya 462

complexes and the $Cd_4(OH)_4^{4+}$ complex proposed by Biedermann and Ciavatta was not formed.

The formation constants of the $CdOH^+$ and Cd_2OH^{3+} complexes were finally determined by means of a generalized least-squares method with the help of an electronic computer HITAC 8700. The values obtained were as follows:

$$\log {}^*\beta_{1,1} = -10.3 \pm 0.1$$
$$\log {}^*\beta_{1,2} = -9.13 \pm 0.01$$

These values agree with those reported by Biederamnn and Ciavatta ($\log {}^*\beta_{1,1} = -10.2 \pm 0.1$ and $\log {}^*\beta_{1,2} = -9.10 \pm 0.05$).

The maximum values of Z we obtained ($Z_{max} \approx 0.003$) were much lower than theirs ($Z_{max} = 0.01 \sim 0.02$). This suggests that the $Cd_4(OH)_4^{4+}$ complex and any other highly polymerized complexes, if formed at all, were unstable and precipitated and could not be present as equilibrium species of hydrolyzed cadmium ions in the solution.

Phase Diagrams of the Binary Systems of Some Metal β-Diketonates[1]

Isao YOSHIDA, Hiroshi KOBAYASHI, and Keihei UENO

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received April, 30, 1974)

Synopsis. Phase diagrams of the binary systems consisting of some unchanged β-diketone chelates were determined. A combination of the chelate compounds which had the same coordination structures gave a mixed crystal system, and that of different coordination structures gave a eutectic system.

Separation of an impurity from a matrix compound by zone refining is governed by their solid-liquid phase diagram. A great number of phase diagrams have been determined on metals and inorganic and organic substances. However, those of metal chelate compounds are little known, and this is, in part, due to their thermal instabilities such as decomposition prior to melting.

We have prepared a certain range of metal 1,5-dialkylpentane-2,4-dionates which are stable enough in molten state without any decomposition, in connection with their application to zone refining.

This note is to report on the solid-liquid phase diagrams of binary mixtures consisting of such chelate compounds with common ligands.

Experimental

Materials. All the chelates were reported previously,[2,3] except $Zr(DNPM)_4$ and $Hf(DNPM)_4$, where DNPM stands for a dipropionylmethanate anion. The last two chelates were prepared by an addition of aqueous sodium carbonate into a water-methanol mixture containing the β-diketone ligand and a metal oxychloride (4 : 1 mole ratio of a ligand to a metal ion) until pH 6. Yellow tinged white precipitate was collected by filtration, then recrystallized from aqueous methanol to yield white needles. mp 59.0—60.0 °C, Found: C, 55.59; H, 7.24%. Calcd for $C_{28}H_{44}O_8Zr$: C, 56.09; H, 7.34%, λ_{max} in cyclohexane 272 nm, log ε_{max} 4.53. mp 54.0—55.0 °C, Found: C, 48.61; H, 6.61%. Calcd for $C_{28}H_{44}O_8Hf$: C, 48.96; H, 6.41%, λ_{max} in cyclohexane 272 nm, log ε_{max} 4.57.

Measurements. Temperatures of phase transitions were determined by differential thermal analysis method[4,5] with 3—6 mg of chelate samples of various compositions on a Rigakudenki Thermoflex 8001, α-alumina powder being used as a reference meterial. The heating rates were kept constant in the region of 10—15 °C/min. Electronic spectra were measured at room temperature with a Hitachi 124 double beam spectrophotometer in appropriate solvents.

Results and Discussion

A $Pd(DNBM)_2$-$Cu(DNBM)_2$ system forms mixed crystal over the entire range of compositions, as shown in Fig. 1. Binary systems which form mixed crystals are summarized in Table 1.

Figure 2 shows the eutectic phase diagram of a $Zr(DNPM)_4$-$Be(DNPM)_2$ system. Some other eutectic system are listed in Table 2.

few of them showing a slight increase in the ligand field due to the electronic effect of alkylsubstituents.[6] It is obvious, therefore, that the 1,5-dialkylpentane-2,4-dionates have the same coordination structures with those of the corresponding acetylacetonates. Coordination structures of the acetylacetonates are well known as listed in Table 3, as well as their crystal structures. The crystal structures therein seem to correlate with the coordination structures of the central metal ions, if the ligand is acetylacetonate anion in common.

Coordination structures of the present chelate compounds listed in Tables 1 and 2 are those presumed on the basis of the above presumption, except those of the acetylacetonates. One can readily notice that the combinations of chelates which form mixed crystals have the same coordination structures, and those forming eutectic have different ones.

In general, component substances of similar molecular structures afford a mixed crystal system of a substitution form. In the metal chelate compounds with a common ligand anion, the structural similarity requires not only the same coordination structure but also similar sizes of the central metal ions. Difference in ionic radii, 0.6 Å, between palladium(II) and copper (II) would be the largest among those of the combinations of metal ions which form metal chelates of the same coordination structures, and the chelates of these metal ions are still capable of forming a binary mixed crystal.

** *Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira-2-chome, Sendai 980*

(Received November 29, 1973)

Synopsis. The conformation of eight benzyl alcohol derivatives has been examined by the measurements of OH stretching absorptions. Preference of the OH quasi-axial structure was shown.

The measurements of the OH stretching absorption bands of epimeric 1-tetralol, 4-chromanol, 4-thiochromanol, and 4-thiochromanol 1,1-dioxide were found to be useful for elucidation of their conformations and for estimation of their conformational free energies ($\Delta G°$).[1,2] A further study concerning OH conformation has been carried out for the epimers of the β-methyl derivatives of these compounds in carbon tetrachloride. The results are reported in this paper.

Results and Discussion

Table 1 shows the OH stretching absorption maxima of the β-methyl derivatives of 1-tetralol (**1**), 4-chromanol (**2**), 4-thiochromanol (**3**), and 4-thiochromanol 1,1-dioxide (**4**) together with their half-widths and intensities. We see that the OH absorption of the *cis*-epimers **1a, 2a, 3a,** and **4a** each shows a singlet band and the *trans*-epimers **1b, 2b, 3b,** and **4b** a doublet band. The lower frequency bands are stronger than the higher ones for the *trans*-epimers **1b** and **4b**, but weaker for **2b** and **3b**.

4a : X=SO_2, R_1=CH_3, R_2=H
4b : X=SO_2, R_1=H, R_2=CH_3

Referring to the preferred conformations of OH groups in 1-tetralol and 4-chromanols and their ν_{OH} bands,[2] the following consideration is given on the conformational equilibrium shown in Fig. 1. Since only a singlet band due to the axial OH group was observed for compounds **1a**, **2a**, **3a** and **4a**, it can be assumed that conformation A with the axial OH and equatorial CH_3 groups is decisively predominant over B.

Measurements for compounds **1b**~**4b** with *trans*-relation between the OH and CH_3 groups might be explained as follows. The axial OH conformation is usually predominant in such compounds if there is no other factor governing the conformation. The axial OH conformation, however, leads to the axial conformation of the CH_3 group as D, which will be unstable when X is a bulky group because of the steric repulsion with the CH_3 group. Thus, the 1,3-diaxial interaction between CH_3 and X would cause the preferential existence of the stable conformation C for **1b** and **4b** with bulky X. This is in line with the fact that a CH_3 group is more bulky than an OH group and has a larger conformational free energy than that of OH group in such a compound.[3] The "volume requirement" of the lone-paired electrons either on the oxygen atom in **2b** or the sulfur in **3b** will not cause sufficient 1,3-diaxial interaction for conversion of conformation. Such a small 1,3-diaxial interaction has been pointed out by Eliel and Knoeber[5] in their stereochemical study on *cis*-2-alkyl-4-butyl-1,3-dioxane, in which the axial conformation of the *t*-butyl group with a chair form was

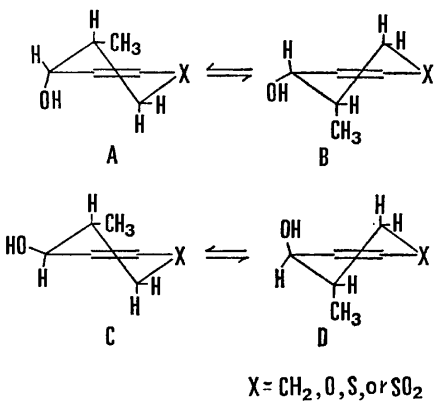

Fig. 1. Conformational equilibria for the β-methyl derivatives of 1-tetralol, 4-chromanol, 4-thiochromanol, and 4-thiochromanol 1,1-dioxide.

* A part of the study was presented at the 24th Annual Meeting of the Chemical Society of Japan, April, 2, 1971, Osaka.

Table 2. Temperature dependence of the OH stretching absorption band for *trans*-3-methyl-4-chromanol

Temperature °C	ν_{OH} cm^{-1}	ε_h	ν_{OH} cm^{-1}	ε_l	$\varepsilon_l/\varepsilon_h$
−20	3616	98	3588	35	0.35
0	3611	93	3588	35	0.37
23	3613	84	3592	31	0.37
55	3613	76	3591	32	0.42

Table 3. Temperature dependence of the OH stretching absorption band for *trans*-3-methyl-4-thiochromanol

Temperature °C	ν_{OH} cm^{-1}	ε_h	ν_{OH} cm^{-1}	ε_l	$\varepsilon_l/\varepsilon_h$
−23	3609	118	3588	18	0.15
0	3610	119	3588	22	0.19
23	3611	98	3590	17	0.17
55	3612	83	3591	17	0.21

predominant. They also suggested a small interaction between the *t*-butyl group and the sulfur atom in 5-*t*-butyl-4,6-dimethyl-1,3-dithiane on the basis of small conformational free energy.[6]

In order to confirm the conformational equilibrium (Fig. 1), the temperature dependence of the OH absorption was examined for **2b** and **3b** in the temperature range −23—55 °C. The results (Tables 2 and 3) indicate that the intensity of the lower frequency band increased with a rise in temperature for both **2b** and **3b**. This indicates that the stable form holds an axial OH conformation, supporting the above view. The $\Delta H°$ values were estimated to be 1.0 and 3.5 kcal·mol^{-1} for **2b** and **3b**, respectively.

Experimental

Materials. *cis*- and *trans*-2-Methyl-1-tetralols,[7] *cis*- and *trans*-3-methyl-4-chromanols[8] were prepared as reported. *cis*-3-Methyl-4-thiochromanol, *cis*- and *trans*-3-methyl-4-thiochroman ol1,1-dioxides were prepared by reduction with sodium borohydride or the Meerwein-Ponndorf reduction of the corresponding ketones. *trans*-3-Methyl-4-thiochromanol was prepared by the hydroboration-oxidation of 3-methyl-3-thiochromene.[9] *cis*-3-Methyl-4-thiochromanol (**3a**): mp 78—80 °C (lit.[9] 78—80 °C). *trans*-3-Methyl-4-thiochromanol (**3b**): mp 73—75 °C. Found: C, 66.40; H, 6.85%. Calcd for $C_{10}H_{12}OS$: C, 66.65; H, 6.71%. *cis*-3-Methyl-4-thiochromanol 1,1-dioxide (**4a**): mp 173—174.5 °C. Found: C, 56.75; H, 5.61%. Calcd for $C_{10}H_{12}O_3S$: C, 56.60; H, 6.70%. *trans*-3-Methyl-4-thiochromanol 1,1-dioxide (**4b**): mp 117—118 °C (lit.[10] 117—118 °C).

Instrumentation. The infrared spectra were measured with a Perkin-Elmer 125 or a JASCO DS-403G double beam grating high resolution infrared spectrophotometer. A KCl cell of 30 mm in optical length was used. The concentration of the solutions was *ca.* 0.005 mol/l in carbon tetrachloride, purified by distillation over phosphorus pentoxide. The band due to intermolecular hydrogen bonding was not observed at this concentration.

The authors wish to express their gratitude to Associate Professer Hiizu Iwamura, the University of Tokyo, for his valuable discussion and suggestions.

The Photoinduced Substitution Reaction of 4-Quinolinecarbonitrile

Norisuke HATA, Isao ONO, and Hiroshi SUZUKI

Department of Chemistry, College of Science and Engineering, Aoyama Gakuin University, Chitosedai, Setagaya-ku, Tokyo 157

(Received January 25, 1974)

Synopsis. The photochemical reactions of 4-quinolinecarbonitrile with alcohol (ethanol, 1-propanol, 2-propanol, or *t*-butyl alcohol) resulted in the substitution of the 1- and/or 2-hydroxyalkyl group at the 2-position of a quinoline nucleus.

As has been reported previously,[1-3] 2-quinolinecarbonitrile in alcoholic solvents undergoes a photochemical replacement of the cyano group at the 2-position of a quinoline nucleus by a hydroxyalkyl group in an atmosphere of oxygen, while, under a nitrogen atmosphere, a certain triazapentaphene is also produced in addition to the photosubstitution product. On the other hand, 3-quinolinecarbonitrile in methanol has been reported by Natsume and Wada to undergo the addition of methanol to afford 1,2-dihydro-2-hydroxymethylquinoline.[4] From the synthetic and mechanistic points of view, therefore, it is of interest to investigate whether 4-quinolinecarbonitrile is photochemically susceptible to the replacement of the cyano group by the hydroxyalkyl one or to the addition of alcohol to give 1,2-dihydro-2-hydroxyalkylquinoline.

4-Quinolinecarbonitrile[5] (0.5 g) dissolved in 350 ml of alcohol (ethanol, 1-propanol, 2-porpanol, or *t*-butyl alcohol) in a Pyrex vessel was irradiated with a 100W high-pressure immersion mercury lamp (Riko Kagaku Sangyo Co.) for 3 to 4 hr while oxygen was being bubbled in. After the removal of the solvent under reduced pressure, the residue was chromatographed on a slica-gel column by elution with dichloromethane to separate the products. As a result, as is shown in Table 1, white crystalline solids (Ia, Ic, Id, IIb, and IIc) and a colorless liquid (Ib) were isolated as the main products. The UV absorption spectra of these products were quite similar to that of 4-quinolinecarbonitrile; also, the IR spectra in KBr showed absorptions at 3200 cm^{-1} (O–H stretching), ~2900 cm^{-1} (aliphatic C–H stretching), and 2230 cm^{-1} (C≡N stretching).[6] The NMR spectra in $CDCl_3$ indicated the presence of a 1-hydroxyalkyl (Products Ia—Id) or 2-hydroxyalkyl group (Products IIb and IIc), which corresponds to the alcohol used as a reaction medium, at the 2-position of a quinoline nucleus.[7] In addition, the products were identified on the basis of the mass spectra[8] as well as by means of elemental analyses;

a) Measured in $CDCl_3$ solution using TMS as an internal standard. b) The picrate. c) Deuterium exchangeable. d) Estimated from the result of the mass analysis performed with a JEOL JMS-O1SG-2 mass spectrometer.

the analytical data are summarized in Table 1. The results definitely indicate that the 4-quinolinecarbonitrile in alcoholic solvents undergoes photochemically 1-hydroxyalkyl and/or 2-hydroxyalkyl substitution at the 2-position of a quinoline nucleus. Quite a similar photoreaction also occurred in an atmosphere of nitrogen.

The photoinduced-substitution reaction of 4-quinolinecarbonitrile is probably initiated by a hydrogen-atom abstraction from the alcoholic solvent by the ring nitrogen, just as in the case of 2-quinolinecarbonitrile.[3] It should be noticed that, in a 1- or 2-propanol solution, the product (IIb or IIc) arising from the β-hydrogen abstraction was obtained in addition to that from the α-hydrogen abstraction, quite unlike the case of 2-quinolinecarbonitrile. This could be interpreted as follows. In the case of 2-quinolinecarbonitrile, as has been discussed in a pervious paper,[3] the β-hydrogen abstraction from the alcohol hydrogen-bonded with the nitrogen of the quinoline nucleus is quite difficult because of the steric effect of a cyano group. On the other hand, such a steric hindrance does not exist in the case of 4-quinolinecarbonitrile, so the α- and β-hydrogen abstraction from 1- or 2-propanol by the ring nitrogen are considered to be possible, thus resulting in the IIb or IIc in addition to the Ib or Ic product.[9] In this respect, the present experimental results seem to support the idea that the photochemical hydroxyalkyl substitution reaction of 2- or 4-quinolinecarbonitrile in alcohol is initiated by a hydrogen-atom abstraction from the alcohol hydrogen-bonded with the nitrogen atom of the quinoline nucleus.[3]

The Determination of Ruthenium in a Sulfuric Acid Solution by Atomic Absorption Spectrophotometry

Reiko IWATA and Ikuei OGATA

National Chemical Laboratory for Industry, Honmachi, Shibuya-ku, Tokyo 151

(Received February 4, 1974)

Synopsis. The addition of sodium salts was found to make possible the determination of ruthenium in a sulfuric acid solution by atomic-absorption spectroscopy, something which is usually impossible because of the serious depressive interference of sulfuric acid.

We have recently synthesized a ruthenium complex which bears a polycyclic aromatic compound as a π-ligand and which is completely decomposable into a solution only with concentrated sulfuric acid. During the process of analyzing the ruthenium content by atomic absorption spectroscopy, we observed that sulfuric acid remarkably reduces the optical absorption of Ru. It has been reported that the atomic absorption of Ru is subject to various interferences; *e.g.*, Rowston and Ottaway[1] and Montford and Cribbs[2] have investigated the effects of various anions and cations, and Mallett *et al.*,[3] the mutual interference of noble metals. They eliminated the interferences through the addition of copper and cadmium sulphates[1] or uranium[2] as releasing agents. However, they studied only with aqueous and HCl solutions, and no reports have been made on the degree of interference encountered in a practical quantitative analysis of Ru in a sulfuric acid solution. Interference by H_2SO_4 has already been noted on other metals; it is generally eliminated by removing the sulfuric acid by vigorous fuming or by extraction with solvents. In the case of Ru, however, this technique could well cause a loss of Ru if the analysis were done by the inexperienced. The distillation of Ru as a volatile tetroxide is also recommended for the separation of Ru from complex mixtures, but it is troublesome and time-consuming, and a more direct approach would be advantageous.

After various studies, we would like to report here a very simple method in which sodium compounds are added to sample solutions.

The spectrophotometer used was a Techtron AA-100. Measurements were done with a fuel-rich air–acetylene flame[4] at a wavelength of 349.9 nm and a lamp current of 10 mA. The sample solutions used were prepared as follows: ruthenium acetylacetonate ($Ru(acac)_3$) was decomposed with concentrated acids, followed by the dilution of the resulting solutions to a Ru concentration of 50 ppm and also to stipulated values of the acid concentration. Acids of the Super-Special-Grade for precision analysis were used. The various foreign additives and acetylacetone used here were all of a reagent grade.

As may be seen in Fig. 1, which shows the interferences of H_2SO_4, HNO_3 and HCl, sulfuric acid remarkably suppressed the absorption of Ru; the absorbance was of the order of 0.01 even at a Ru concentration of 50 ppm. Therefore, the quantitative analysis of Ru in a sulfuric acid solution was practically impossible. Though not so large as H_2SO_4, nitric acid showed a fairly large suppressive effect. Further, during the process of decomposition by the boiling of $Ru(acac)_3$, $RuCl_3$, and other ruthenium-containing samples in concentrated HNO_3, a loss of Ru, presumably as a volatile oxide, was observed. Therefore, the use of HNO_3, which is generally used for atomic-absorption analysis as a less interferant acid, is undesirable in the case of Ru. Hydrochloric acid showed the least interference of the three.

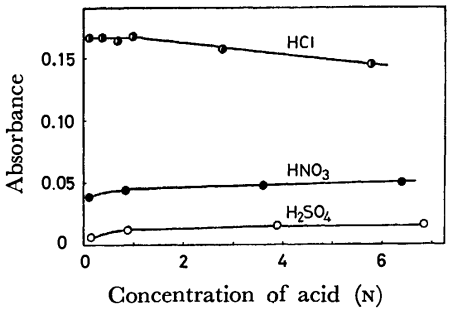

Fig. 1. Relations between interference and concentration of acids. Concentration of Ru: 50 ppm (in the cases of H_2SO_4 and HNO_3), 49 ppm (in the case of HCl).

When a large excess of acetylacetone to Ru was added to a sulfuric acid solution of Ru and the solution was allowed to stand at 50 °C, it gradually developed a pink color, indicating the formation of an acetylacetone chelate, while the absorbance increased. With the addition of 8 vol% of acetylacetone, about 5.6 times enhancement was observed in the 0.85 N H_2SO_4 solution of 48 ppm of Ru. Although the interference of H_2SO_4 can be removed in this way to a certain degree, the demerit is that this method requires a long time for the absorbance to become constant (about 10 hr).

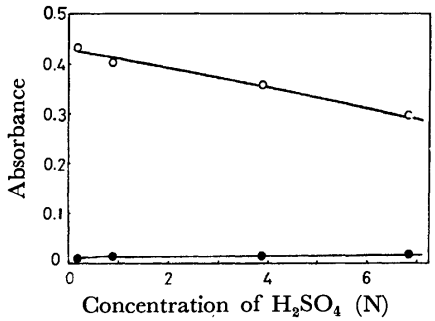

Fig. 2. Enhancement of atomic absorption of ruthenium by addition of sodium bicarbonate.
Concentration of Ru: 50 ppm. ●: without $NaHCO_3$, ○: with $NaHCO_3$ (25.2 mg/ml).

The further addition of $NaHCO_3$ to this solution containing acetylacetone in order to make the transformation of a sulfate into an acetylacetonate more efficient caused a further prominent increase of the absorbance. From the following experiments, however, it was found that this enhancement effect was not due to the formation of an acetylacetone chelate.

The addition of $NaHCO_3$ to the sample solution, even without acetylacetone, made the atomic absorption of Ru increase greatly as shown in Fig. 2. The same, but only a slight, effect of sodium salt has been reported in the case of the HCl solution of $H_2[RuCl_6]$ by Makarov and Kukushkin.[5] If the acid concentration was high, the degree of the enhancement decreased. The enhancement effect was smaller in a less interferant acid; *i.e.*, the magnitudes of the enhancement effect were in the order of $H_2SO_4 \gg HNO_3 > HCl$.

The study of the relation between the added amounts of $NaHCO_3$ and the enhancement effect revealed that the most appropriate amount of addition should be determined not on the basis of the concentration of the acid but on the basis of that of the $NaHCO_3$ in the solution. In a Ru solution of 50 ppm, it is over 4 mg/ml; especially, the range of 10–30 mg/ml is the most appropriate. When the amount of $NaHCO_3$ added was too large, the absorption tended to decrease. Further, as the amount added increases, a defective outcome develops since a separated salt attaches to the slit of the burner.

The relation between the kind of foreign additives and the enhancement effect was also studied. Table 1 shows a comparison on the basis of the relative ratio of absorbance, where the absorbance in the case of no foreign additive is defined as 1.0. Sodium compounds caused almost the same degree of enhancement, no matter what the counter anion was; this was also true in the cases of alkali and salt. Therefore, it can be seen that the enhancement is caused by Na. The effects of various sodium salts in aqueous and HCl solutions have been reported;[2] they are very complex and are not similar to those in our case of a sulfuric acid solution; some sodium compounds increased the absorbance, while some reduced it. A comparison of NaCl, $CoCl_2$, and $ZnCl_2$ showed that the higher the ionization potential of the metal, the lower the degree of relative enhancement. It is said that NH_4Cl is effective in suppressing the interference of H_2SO_4 in the determination of Mo,[6] but it caused only a very low enhancement in the case of Ru.

Table 1. Comparison of enhancement effect of foreign additives by relative ratio of absorbance[a]

Additive,[b] MX (0.3 m atom of M/ml)	Relative ratio of absorbance	Ionization potential M+ (eV)
none	1.0	
$NaHCO_3$	16.1	5.138
Na_2CO_3	16.3	
Na_2SO_4	16.2	
NaOH	16.0	
NaCl	15.9	
$CoCl_2$	6.5	7.86
$ZnCl_2$	4.9	9.391
NH_4Cl	2.2	

a) Ru 50 ppm in 0.9 N H_2SO_4. b) Additives were added in a solid state.

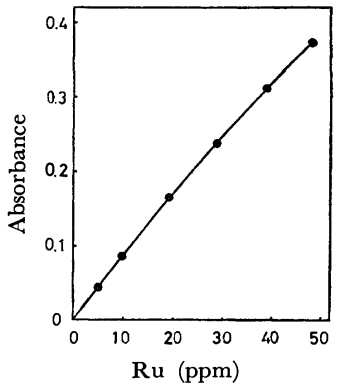

Fig. 3. Calibration curve of ruthenium in 1.48 N H_2SO_4 solution with 40 mg/ml of $NaHCO_3$ (Ru 349.9 nm, an air-acetylene flame).

Table 2. Analyses of ruthenium by atomic-absorption spectroscopy

Compound	Ru content (%) Found	Calcd
$[RuCl_2(C_6H_6)Me_2SO]_2$	30.3 29.5	30.79
$[RuCl_2(C_6H_6)PBu_3]_2$	22.1 21.7	22.34

Conditions for analysis are the same as in Fig. 3.

In order to confirm the practical applicability, a calibration curve was drawn by using the method in which a certain amount of $NaHCO_3$ is added to a sample solution containing H_2SO_4. It was a straight line until the Ru concentration was approximately 20 ppm, and a slight curve in the range over 20 ppm, as is shown in Fig. 3. Using this Ru calibration curve, satisfactory results were obtained in the analyses of some known ruthenium compounds, as is shown in Table 2.

We can conclude that, this is a simple and effective enough method to remove interference in the determination of Ru in a sulfuric acid solution with a large depressive interference.

Synthesis of 2,3,6-Trimethylbenzyl Alcohol

Tadashi KAWAI, Yasuo YAMAZAKI, and Shuei YUHASHI

Department of Industrial Chemistry, Faculty of Technology, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158

(Received February 26, 1974)

Synopsis. 2,3,6-Trimethylbenzyl alcohol was prepared by the Cannizzaro reaction of 2,3,6-trimethylbenzaldehyde; mp 83—85 °C. It was found that the substance regarded by Golivets *et al.* as 2,3,6-trimethylbenzyl alcohol is an eutectic mixture of 2,3,6- and 2,4,5-trimethylbenzyl alcohol.

In the condensation of 1,2,4-trimethylbenzene(1,2,4-TMB) with formaldehyde, bis(2,4,5-trimethylphenyl)-methane was formed as the main product, and a few asymmetric hexamethyldiphenylmethanes(HeMDPM) such as 2,3,6,2′,4′,5′-HeMDPM were formed as by-products.[1] As the routes for the formation of 2,3,6,-2′,4′,5′-HeMDPM, the reaction of 1,2,4-TMB with 2,3,6-trimethylbenzyl alcohol(2,3,6-TMBA) and/or the reaction of 1,2,4-TMB with 2,4,5-TMBA are considered. These TMBA's are formed a sprimary products in the condensation of 1,2,4-TMB with formaldehyde.

In order to obtain the starting materials for an investigation of this reaction scheme we attempted the synthesis of alcohols.

In the preparation of 2,4,5-TMBA(mp 83—84 °C) by the hydrolysis of monoacetoxymethyl-1,2,4-trimethylbenzenes obtained by the chloromethylation of 1,2,4-TMB and subsequent acetoxylation, Golivets *et al.*[2] isolated a substance (A) melting at 55—56 °C, which they regarded as 2,3,6-TMBA.

We also obtained a small amount of the substance (mp 54—55 °C) by the above reactions. However, from its IR and NMR spectra measurements, and mixed melting point test, it was suggested that the substance is not pure and that it might be an eutectic mixture of 2,3,6- and 2,4,5-TMBA.

We have applied the Cannizzaro reaction of 2,3,6-trimethylbenzaldehyde to the synthesis of 2,3,6-TMBA.

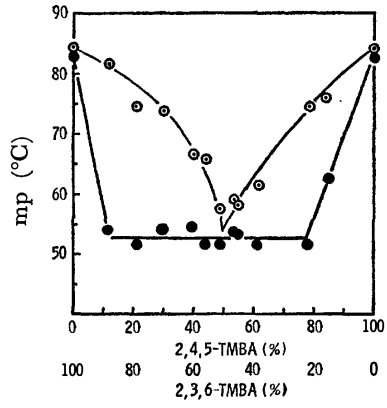

Fig. 1. Melting-point curve of 2,3,6-TMBA and 2,4,5-TMBA.

This was prepared by Lowe *et al.*[4] We obtained 2,3,6-TMBA as colorless needles, melting at 83—85 °C. For an estimation of its purity we attempted its hydrogenolysis[3] with a CoO-MoO_3-Al_2O_3 catalyst. The products obtained were tetramethylbenzenes(TeMB) and 1,2,4-TMB. The former consists of 1,2,3,4-: 98%, 1,2,4,5-: 1.1%, and 1,2,3,6-TeMB: 0.9%. The latter was formed by the dehydroxymethylation of the TMBA. Thus it was found that the purity of 2,3,6-TMBA obtained was 98%.

The IR spectrum of 2,3,6-TMBA showed a characteristic band assigned to two adjacent hydrogen systems at 805 cm^{-1}, and that of 2,4,5-TMBA three bands due to one adjacent hydrogen system in the 900—875 cm^{-1} regions. The IR spectrum of (A) showed two absorption bands in both regions. The NMR spectrum of (A) showed two absorptions at δ 4.52 and 4.39, assigned to the methylene hydrogens of 2,3,6- and 2,4,5-TMBA, respectively. The results suggest that (A) is a mixture of these alcohols.

We have made the melting-point curve of binary system of these alcohols. The eutectic mixture of the system consists of 2,3,6- (50%) and 2,4,5-TMBA (50%), melting at 53—54.5 °C. The melting point of the eutectic mixture agrees with that of (A).

Experimental

Hydrolysis of Monoacetoxymethyl-1,2,4-trimethylbenzenes: Monoacetoxymethyl-1,2,4-trimethylbenzenes (145 g, bp 105—108 °C/1 mmHg), prepared by acetoxylation of chloromethylated 1,2,4-TMB, KOH (46.9 g) and absolute methanol (295 ml) were refluxed with stirring for 2 hr. After cooling the separated crystal was collectd. White precipitate was formed by the dilution of the filtrate with twice its volume of water. By recrystallization of these solids from 30% methanol aqueous solution, white needles, 2,4,5-TMBA (mp 83—84 °C, 85 g, 63% yields) were obtained. White needles (substance (A)) (mp 54—55 °C, 1 g) were separated from the mother liquid.

A mixture of (A) and 2,4,5-TMBA showed no depression in melting point.

2,3,6-Trimethylbenzaldehyde: This was prepared by the method of Lowe *et al.* bp; 87—88 °C/1 mmHg (lit,[4] bp 111—114 °C/5 mmHg).

2,3,6-Trimethylbenzyl Alcohol: To a methanolic solution (75 ml) of KOH (50 g) was added a mixture of 2,3,6-trimethylbenzaldehyde (44 g) and formalin (37% concn., 29 ml) in methanol (30 ml) with stirring at 60 °C. After being kept at 60—70 °C for 3 hr, 90 ml of ice water was added. The yellowish solid was separated and recrystallized from 25% methanol aqueous solution. Colorless needles, 2,3,6-TMBA (mp 83—85 °C, 12 g), were obtained.

Found: C, 79.71; H, 9.41; O, 10.88%. Calcd for $C_{10}H_{14}O$: C, 79.95; H, 9.39; O, 10.65%.

The Photochemistry of 3,3-Dialkoxy-1-phenylpropan-1-ones

Takehiko NISHIO and Hiromu AOYAMA

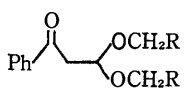
Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo 112

(Received March 6, 1974)

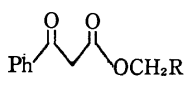
Synopsis. The irradiation of 3,3-dialkoxy-1-phenylpropan-1-ones (Ia-b) in a benzene solution afforded β-keto-esters (IIa-b), phenyl β-alkoxyvinyl ketones (IIIa-b), and tetrahydrofuranols (IVa-b).

The photoreaction of aliphatic ketones to give smaller ketones, olefins, and cyclobutanols has been widely studied.[1] It is well established that the reaction proceeds *via* γ-hydrogen abstraction to give 1,4-diradicals which can either cleave to olefins, ring closure to cyclobutanols, or return to starting materials. Recently, the ultraviolet irradiation of β-alkoxy ketones has been reported to give the tetrahydrofuranols as the major product.[2-4] They have been considered to arise *via* δ-hydrogen abstraction by excited carbonyl oxygen. We will report here on the photochemistry of 3,3-dialkoxy-1-phenylpropan-1-ones (Ia-b), which includes a new photooxidation (IIa-b) as well as photoelimination (IIIa-b) and δ-hydrogen abstraction (IVa-b).

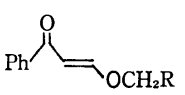
The irradiation of 3,3-dimethoxy-1-phenylpropan-1-one (Ia) in a benzene solution with a high-pressure mercury lamp through a Pyrex filter under nitrogen for 20 hr gave methyl benzoylacetate (IIa) (35%), phenyl β-methoxyvinyl ketone (IIIa) (6.5%), and 3-phenyl-3-hydroxy-5-methoxy-tetrahydrofuran (IVa) (5%). Compounds IIa and IIIa did not show any H-abstraction under further irradiation and were recovered almost quantitatively. The structures of IIa[5] and IIIa[6] were confirmed by a direct comparison with their authentic samples. The structure of IVa was elucidated using its physical data and by elemental analysis. The NMR spectrum showed two doublets of a doublet at δ 2.23 (J=13.5, J=1.8 Hz, 1H at C-4) and δ 2.49 (J=13.5, J=3.5 Hz, 1H at C-4), two doublets at δ 4.06 and 4.26 (J=10 Hz, 2H at C-2), a doublet of a doublet at δ 5.19 (J=1.8, J=3.5 Hz, 1H at C-5), a singlet at δ 3.40 (3H, $-OCH_3$), a broad singlet at δ 3.90 (1H, –OH, exchangable with D_2O), and the multiplet at δ 7.15—7.65 (5H) due to the aromatic protons. The IR spectrum exhibited bands at 3500 cm^{-1} due to the hydroxy group and at 1100 cm^{-1} attributable to the ether group. The mass spectrum displayed prominent peaks at m/e 176 (M^+-H_2O), 164 ($M^+-CH_2{=}O$), 144 ($M^+-(H_2O+MeOH)$), and 115 ($M^+-(H_2O+MeOH+CHO)$).



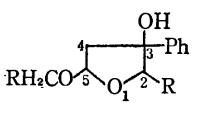
Ia R=H
Ib R=CH_3



IIa R=H
IIb R=CH_3



IIIa R=H
IIIb R=CH_3



IVa R=H
IVb R=CH_3

Similarly, ethyl benzoyl acetate (IIb), phenyl β-ethoxyvinyl ketone (IIIb), and 2-methyl-3-phenyl-3-hydroxy-5-ethoxy-tetrahydrofuran (IVb) were obtained in 15, 15, and 6% yield respectively by the irradiation of 3,3-diethoxy-1-phenylpropan-1-one (Ib). The structures of IIb[5] and IIIb[7] were confirmed by a direct comparison with their authentic samples, while that of IVb was elucidated by means of its spectral data and by elemental analysis.

The formation of IIa-b is presumed to proceed through the oxidation of Ia-b by light. The formation of IIIa-b can be explained by the elimination of the alcohol.[8] On the other hand, the formation of IVa-b is considered to arise *via* δ-hydrogen abstraction by an excited carbonyl through a seven-membered ring transition state.

Experimental

All the boiling points are uncorrected.

The 3,3-dimethoxy-1-phenylpropan-1-one (Ia, bp 175—178 °C/20 mmHg (lit,[9] 111—111.5 °C/2 mmHg)) and 3,3-diethoxy-1-phenylpropan-1-one (Ib, bp 165—170 °C/20 mmHg (lit,[10] 111—112 °C/1 mmHg)) were prepared according to the methods of previous reports.

Irradiation of Ia. A solution of 1g of Ia in 150 ml of benzene was irradiated with a high-pressure merucry lamp through a Pyrex filter under nitrogen for 20 hr at room temperature. After irradiation, the benzene was evaporated *in vacuo*, and the residue was chromatographed on a silica gel column with benzene–ethyl acetate(50 : 1) to give 350 mg of methyl benzoyl acetate (IIa; bp 155—158 °C/20 mmHg (lit,[5] 152 °C/15 mmHg)), 65 mg of phenyl β-methoxyvinyl ketone (IIIa; bp 114—117 °C/2 mmHg (lit.[6] 135 °C/5—6 mmHg)), 50 mg of 3-phenyl-3-hydroxy-5-methoxy-tetrahydrofuran (IVa), and 50 mg of the recovered ketone.

3-Phenyl-3-hydroxy-5-methoxy-tetrahygrofuran (IVa): Bp 80 °C/2 mmHg. IR: ν_{max}^{film} cm^{-1}, 3500, 3050, 2830, 1600, 1492, 1100, 750, 690. Found: C, 67.77; H, 7.18%. Calcd for $C_{11}H_{14}O_3$: C, 68.02; H, 7.27%.

Irradiation of Ib. A solution of 1 g of Ib in 150 ml of benzene was irradiated under the same conditions as have been described above for 20 hr. After the removal of the solvent, the residue was chromatographed on a silica gel column with benzene–ethyl acetate (30 : 1) to give 150 mg of ethyl benzoylacetate (IIb; bp 152—158 °C/18 mmHg (lit.[5] 147 °C/11 mmHg)), 150 mg of phenyl β-ethoxyvinyl ketone (IIIb; bp 150—152 °C/20 mmHg (lit.[7] 156—158 °C/28 mmHg)), 60 mg of 2-methyl-3-phenyl-3-hydroxy-5-ethoxy-tetrahydrofuran (IVb), and 100 mg of the recovered ketone.

2-Methyl-3-phenyl-3-hydroxy-5-ethoxy-tetrahydrofuran (IVb): bp 93 °C/2 mmHg. IR: ν_{max}^{film} cm^{-1}, 3500, 3050, 1603, 1492,

1100, 750, 690. NMR: (δ in $CDCl_3$) 1.25 (t, 3H, J=9 Hz, methyl), 1.20 (d, 3H, J=6.5 Hz, methyl), 2.25 (d, 1H, J=13.5 Hz, methylene at C-4) and 2.63 (dd, 1H, J=13.5, J=5 Hz, methylene at C-4), 3.2—4.1 (m, 2H, methylene), 4.23 (q, 1H, J=6.5 Hz, methine at C-2), 5.23 (d, 1H, J= 5 Hz, methine at C-5), 7.2—7.65 (m, 5H, aromatic protons). When the signal of the methyl protons at δ 1.25 was irradiated, the signal of the methylene protons of the ethoxy group appeared as two doublets at δ 3.49 and 3.91 with the same coupling constant of 9 Hz. This phenomenon is considered to arise from the restriction of free rotation by the weak interaction of hydroxy and ethoxy groups. Mass spectrum: *m/e* 204 (M^+-H_2O), 178 ($M^+-CH_3CH{=}O$), 158 (M^+-H_2O+EtOH)), 115 ($M^+-(H_2O+EtOH+CH_3C{=}O)$). Found: C, 70.16; H, 8.09%. Calcd for $C_{13}H_{18}O_3$: C, 70.24; H, 8.16%.

The Stereoselective Reduction of Tropinone to Tropine

Yoshihiro HAYAKAWA and Ryoji NOYORI

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464

(Received March 11, 1974)

Synopsis. The reduction of tropinone with diisobutylaluminum hydride in tetrahydrofuran at −78 °C leads to tropine selectively.

The sterochemistry of the reduction of tropinone (**1**) has been extensively studied.[1] The kinetically-controlled reduction with lithium aluminum hydride, sodium borohydride, or potassium borohydride afforded a mixture of tropine (**2**) and ψ-tropine (**3**), with a ratio between 28 : 72 and 55 : 44.[2,3] Although an increased proportion of **2** was obtained by the use of Meerwein-Pondorf-Verley reduction (the highest **2** : **3** ratio was 71 : 29), a prolonged reaction gave a mixture in which the unnatural isomer, **3**, was favored.[2] The **2** : **3** stereoisomeric composition after equilibrium had been reached was 11 : 88. The treatment of the ketone, **1**, or the α alcohol, **2**, with sodium metal in alcoholic solvents also led thermodynamically to the more stable β epimer, **3**. The treatment of **1** with zinc–hydriodic acid gave a mixture of **2**, **3**, and an over-reduction product, tropane, the ratio of **2** and **3** being 5 : 2.[4] The conversion of **1** to **2** with high stereoselectivity has thus been achieved only by catalytic reduction.[5] During the course of the development of a new tropane alkaloid synthesis[6,7] which requires a method for the *chemical* reduction of tropinone derivatives to the corresponding α alcohols, we have found that the use of diisobutylaluminum hydride in tetrahydrofuran solvent is suitable for this purpose. The present procedure was both highly efficient and selective; the tropine (**2**) thus obtained from **1** in a 95% yield was contaminated with only 3% of the epimer, **3**.

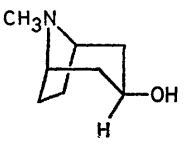
2



3

Experimental

*Reduction of Tropinone (**1**).* A solution of 1.0 g (7.0 mmol) of tropinone (**1**) (97% pure, Aldrich) in 45 ml of dry tetrahydrofuran was flushed with argon and cooled at −78 °C. Into the magnetically-stirred solution was then added 3.6 g (25 mmol) of diisobutylaluminum hydride (Alpha Inorganics) over a period of 20 min. The mixture was stirred at the same temperature for 17 hr and then quenched by adding 3 ml of water carefully ovre a 20-min period. The resulting voluminous gel was treated with 50 ml of ethyl acetate and filtered. The filter cake was washed with 100 ml of ethyl acetate. The combined organic solutions were concentrated *in vacuo* to give 1.2 g of a crude viscous oil, which consisted mainly of tropine (**2**) and ψ-tropine (**3**) (97 : 3 ratio, 95% combined yield). The isomeric ratio was determined by a comparison of the characteristic NMR signals due to the NCH_3 groups. The bulb-to-bulb distillation of the oil at 100—110 °C/0.1 mmHg (bath temperature) gave 0.869 g (89%) of a 97 : 3 mixture of **2** and **3** as a crystalline solid; mp 61—63 °C. A pure sample of **2** was obtained readily by recrystallization from benzene; mp and mmp 62—63 °C (lit,[8] 63—64 °C). IR ($CHCl_3$) 3600 and 3400 cm^{-1} (OH); NMR ($CDCl_3$, 100 MHz) δ 1.66 (br d, J= 13.5 Hz, 2H, equatorial protons at C(2) and C(4)), 1.9—2.3 (m, 7H, C(6)H_2, C(7)H_2, axial protons at C(2) and C(4), and OH), 2.28 (s, 3H, NCH_3), 3.25 (m, 2H, NCH), and 4.05 (br t, J=5.1 Hz, 1H, C<u>H</u>OH). The chromatography of the mother liquor of recrystallization on a column packed with neutral alumina (Merck, activity II—III) gave pure samples of **2** (1 : 20 methanol–ethyl acetate as the eluent) and **3** (1 : 10 methanol–ethyl acetate). The identity of the latter was established by a comparison of its physical properties with those of an authentic sample. Mp and mmp 106—108 °C (from *n*-hexane–benzene) (lit,[9] 108 °C); IR (CCl_4) 3600 and 3400 cm^{-1} (OH); NMR ($CDCl_3$, 100 MHz δ 1.5—1.9 (m, 6H, C(6)H_2, C(7)H_2, and equatorial protons at C(2) and C(4)), 1.9—2.2 (m, 2H, axial protons at C(2) and C(4)), 2.34 (s, 3H, NCH_3), 3.10 (br s, 1H, OH), 3.20 (m, 2H, NCH), and 3.88 (m, 1H, C<u>H</u>OH).

The support of this research by the Takeda Science Foundation is gratefully acknowledged.

Electron Pairing Interaction and Electronic Spectra of Linear Polyene

Sadhan BASU

Department of Chemistry, University College of Science, Calcutta-9, India

(Received November 16, 1973)

Synopsis. Assuming the pairing interaction which arises in Hartree-Fock-Bogolyubov formulation in many-electron system, to be due to attraction between two electrons of opposite spin it has been shown that the longest wavelength singlet transition in linear polyenes will show convergence limit while the corresponding triplet transition will not.

In a previous communication[1] it has been shown that the convergence limit in the electronic spectra of linear polyene may be understood in terms of Δ_{i-i} (the pairing interaction) value in the Hartree-Fock-Bogolyubov (HFB) equation for many electron system. Since the Δ_{i-i} term is positive, it was assumed that it may be looked upon as attraction between a particle and a hole. If we are prepared to accept a non-classical conclusion, that is, there is residual attraction between electrons in a many electron system, then we may consider Δ_{i-i} to arise from attraction between electrons in states i and $-$i. The states i and $-$i have the same principal quantum number but one has the projection quantum number reversed in sign from the other. In spherical systems which are characterised by quantum numbers n, l, and m, the states i and $-$i differ from each other in the sign of m values. In linear polyene the good quantum number is n only (which appears in the electron-in-a-box calculation). Only way the states i and $-$i can differ from each other in these systems is by having spin $+1/2$ and $-1/2$. It is to be remembered, however, that HFB calculation do not take spin into account at any stage. We can only say that there is electron pairing in the same level of polyene, but to satisfy some basic requirements of the HFB theory, the two electrons must have opposite projection quantum number, which we consider to be spin. But this term does not arise from spin-spin interaction in any way. With this basic prescription we may analyse the electronic properties of linear polyenes in greater detail.

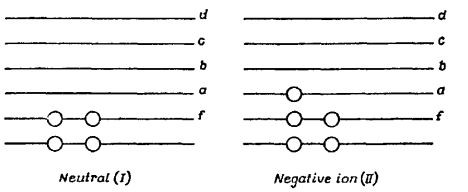

Fig. 1. Level scheme for neutral and mono-negative polyene.

Let us consider the level schemes for a neutral and a negatively charged polyene.

In the case (I) of Fig. 1 an electron from f (Fermi level) can go to a level c, such that $\varepsilon_c - \varepsilon_f \geq \Delta_{i-i}$ *i.e.* the low-lying excited levels cannot be populated as they are unable to break the pairing interaction. Therefore the minimum amount of energy which the system can take up is Δ_{i-i}, *i.e.* the spectrum should show convergence limit. In the case II on the other hand, the unpaired electron in level a, may be excited to any of the vacant levels as there is no pairing interaction to break. So these systems will not show any convergence limit. The same argument should hold for positive ions. We reached the same conclusion considering Δ_{i-i} as hole-particle interaction energy in the previous paper.

Let us consider the neutral molecule again. The two electrons in the level f have the spin $+1/2$ and $-1/2$. When one is excited to a level c, without changing the spin, we get a singlet state. For a triplet state excitation we have the electrons in f and c having the same spin, say $+1/2$. We may suppose that we have arrived at this state by electron transition from a virtual Fermi level having both the spins $+1/2$. In the HFB formulation there cannot be any pairing interaction between two electrons of the same spin in the virtual orbital. So the triplet transitions in linear polyenes will show no convergence limit. We may go over from the ground state to the virtual orbital by some type of spin-orbital interaction. Further when the energy difference $\varepsilon_f - \varepsilon_a$ becomes small, ε_a may be thermally populated by a triplet mechanism. So very large linear molecule may become paramagnetic and the magnetic moment increases with increasing temperature.[2]

This pairing interaction, however, fails to explain the convergence behaviour of cyanines for which hole-particle attraction model appears to be a better one.

Photochemistry of Acetophenone and Acetaldehyde in Ether Solvent —Formation of Diastereoisomeric Alcohols

Masao TOKUDA,* Miki HASEGAWA, Akira SUZUKI, and Mitsuomi ITOH

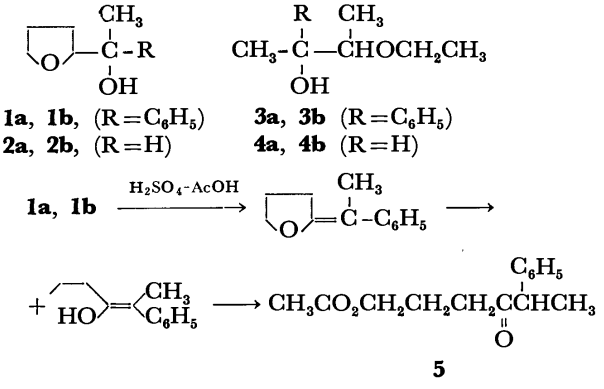
Department of Chemical Process Engineering, Faculty of Engineering, Hokkaido University, Sapporo 060

(Received March 26, 1974)

Synopsis. Irradiation of acetophenone and acetaldehyde in tetrahydrofuran or diethyl ether gave the following diastereoisomeric alcohols, 1-phenyl-1-(2-tetrahydrofuryl)-ethanol, 1-(2-tetrahydrofuryl)ethanol, 2-phenyl-3-ethoxy-2-butanol and 3-ethoxy-2-butanol.

Reports have been given on the steric effect in the addition reaction of the radical to the carbon-carbon double bond.[1,2] In order to investigate similar steric effects on the coupling reaction of unlike radicals, we isolated the diastereoisomeric alcohols obtained by the photochemical reaction of unsymmetric carbonyl compounds in ether solvent. Unsymmetric carbonyl compounds should provide a pair of radicals having asymmetrical radical centers when α hydrogen atom of diethyl ether or tetrahydrofuran (THF) is abstracted. A cross-coupling of these radicals should produce diastereoisomeric alcohols.

Irradiation of acetophenone in an excess of THF with 500 W high pressure mercury vapor lamp at room temperature for 8 hr gave diastereoisomeric alcohols **1a** (26%)[3] and **1b** (19%), *p*-(2-tetrahydrofuryl)acetophenone (4%), 2,2′-bitetrahydrofuryl and acetophenone pinacol in a 65% conversion. Diastereoisomeric alcohols could be separated by a preparative glpc and their structures were confirmed by spectral data and by means of dehydration. When each of these diastereoisomers was dehydrated with sulfuric acid–acetic acid solution,[4] both isomers (**1a, 1b**) were found to give an identical product (**5**) as in the following.



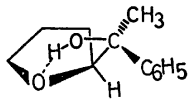
1a, 1b, (R=C_6H_5) **3a, 3b** (R=C_6H_5)
2a, 2b, (R=H) **4a, 4b** (R=H)

1a, 1b $\xrightarrow{H_2SO_4\text{-AcOH}}$ $\longrightarrow$

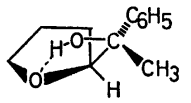
5

(1)

Methyl protons of **1a** and **1b** resonate at τ 8.61 and 8.42, respectively. An absorption of β-ring methylene of **1a** at τ 8.21 is shifted to a broad band at τ 8.0—9.0 in **1b**, indicating that some of the β-ring protons in **1b** lie over the plane of the aromatic ring. Accordingly, **1b** should correspond to conformation B and **1a** to A. Hydrogen bonded structures are suggested from the IR spectra of **1a** and **1b** and the NMR spectrum of 2-(2-tetrahydrofuryl)-2-propanol, which exhibits two methyl protons at different chemical shifts, *i.e.* τ 8.85 and 8.97.[5]



A



B

Irradiation of acetaldehyde in THF gave diastereoisomeric alcohols **2a** (23%) and **2b** (18%), and 2,2′-bitetrahydrofuryl. Diastereoisomers were separated by a preparative glpc, both isomers showing similar spectra in NMR.

Irradiation of acetophenone in diethyl ether gave diastereoisomeric alcohols **3a** (22%) and **3b** (22%), 1-phenylethanol (4%), 2,3-diethoxybutane (40%) in a 60% conversion. In this case, diastereoisomers could not be separated by glpc under various conditions. However, the NMR spectrum of a mixture of **3a** and **3b** indicates the presence of two isomers, exhibiting two singlets at τ 8.50 and 8.61, two doublets at τ 9.24 and 8.98 and two triplets at τ 8.81 and 8.92 attributable to the corresponding methyl protons. A mixture of **3a** and **3b** was treated with sulfuric acid-acetic acid to give a dehydration product (**6**) and a rearranged ketone (**7**).

3a, 3b $\xrightarrow{H_2SO_4\text{-AcOH}}$ $C_6H_5C(=CH_2)CH(CH_3)OC_2H_5$ + $C_6H_5CH(CH_3)C(=O)CH_3$ (2)

6 **7**

Irradiation of acetaldehyde in diethyl ether gave diastereoisomeric alcohols **4a** (20%) and **4b** (20%), 3-hydroxy-2-butanone (3%) and 2,3-diethoxybutane in a 70% conversion. The conformations of **4a** and **4b** could not be determined because of the spectral similarities of the isomers.

Most of the products obtained can be elucidated as combination products of the radicals resulting from a hydrogen abstraction by n-π^* excited carbonyls. A cross-coupling of the two radicals provides the diastereoisomeric alcohols. The isomeric ratio of these diastereoisomers is 1.0 when diethyl ether is employed as a hydrogen donor, and 1.4 and 1.3 when THF is used. Similar diastereoisomers were obtained in a nearly equal amount when β-keto esters were photolyzed in ether solvent.[6] In the case of acetophenone in THF, **1a** having conformation A predominates over **1b**. This might be explained from the point of view that an approach of nearly planar radicals *via* a sterically less hindered pathway should yield **1a** predominantly.

p-(2-Tetrahydrofuryl)acetophenone can be produced by a substitution reaction of tetrahydrofuryl radical to acetophenone.[7] A combination of acetyl and α-hydroxyethyl radical[8] should provide 3-hydroxy-2-butanone.

Experimental

Quantitative glpc analyses were carried out with an internal standard. All mps and bps are uncorrected.

Photochemistry of Acetophenone in THF. A mixture of acetophenone (0.01 mol) and THF (0.4 mol) in a quartz tube was cooled in water and externally irradiated with a 500 W high pressure mercury vapor lamp for 8 hr. Distillation and a preparative glpc (FFAP column; col. temp., 250°) of the irradiation mixture gave **1a**, **1b**, *p*-(2-tetrahydrofuryl)acetophenon and 2,2′-bitetrahydrofuryl.

1-Phenyl-1-(2-tetrahydrofuryl)ethanol (**1a**) has n_D^{23} 1.5344; IR(CCl_4) 3540, 3450 cm^{-1}; NMR(CCl_4) τ 8.61 (s, 3H), 8.21 (m, 4H), 7.54 (s, 1H), 5.9—6.9 (m, 3H), 2.8 (m, 5H); *m/e* 192(M^+), 121, 71. Found: C, 74.75; H, 8.33%. Calcd for $C_{12}H_{16}O_2$: C, 74.97; H, 8.39%.

The IR and mass spectra of **1b** are similar to those of **1a**. Diastereoisomer **1b** has n_D^{23} 1.5309; NMR(CCl_4) τ 8.42 (s, 3H) 8.0—9.0 (m, 4H), 7.58 (s, 1H), 5.9—6.5 (m, 3H), 2.7 (m, 5H). Found: C, 74.64; H, 8.38%.

p-*(2-Tetrahydrofuryl)acetophenone* was identified from spectral data: IR (CCl_4) 1760—2000 (characteristic absorption of *p*-substituted acetophenone), 1680 cm^{-1}; NMR(CCl_4) τ7.55 (s, 3H), 8.05 (m, 4H), 6.10 (m, 2H), 5.23 (t, 1H), 2.70 (d, 2H), 2.16 (d, 2H); *m/e* 190(M^+), 175, 147, 71, 43. Found: C, 75.48; H, 7.38%. Calcd for $C_{12}H_{14}O_2$: C, 75.76; H, 7.42%. 2,4-Dinitrophenylhydrazone, mp 169.0—170.5 °C.

Photochemistry of Acetaldehyde in THF. A preparative glpc of the irradiation mixture gave diastereoisomeric alcohols **2a**, **2b** and 2,2′-bitetrahydrofuryl.

1-(2-Tetrahydrofuryl)ethanol (**2a**) has n_D^{20} 1.4421; IR(CCl_4) 3560, 3440 cm^{-1}; NMR(CCl_4) τ 8.86 (d, 3H), 6.97 (s, 1H), 7.9—8.4 (m, 4H), 6.0—6.7 (m, 4H); *m/e* 101, 71, 45. Found: C, 61.85; H, 10.92%. Calcd for $C_6H_{12}O_2$: C, 62.04%; H, 11.03%.

The isomer **2b** has n_D^{20} 1.4060; NMR(CCl_4) τ 8.85 (d, 3H), 7.01 (s, 1H), 7.8—8.4 (m, 4H), 6.0—6.8 (m, 4H). Found: C, 61.88; H, 10.95.

Photochemistry of Acetophenone in Diethyl Ether. A preparative glpc (PEG 20M, 220 °C) of the irradiation mixture gave a mixture of diastereoisomers (**3a** and **3b**): IR(neat) 3470, 1110 cm^{-1}; NMR(CCl_4) τ 8.50 and 8.61 (s, 3H), 9.24 and 8.98 (d, 3H), 8.81 and 8.92 (t, 3H), 7.39 (s, 1H), 6.5 (m, 3H), 2.7 (m, 5H); *m/e* 194, 121, 73. Found: C, 74.02; H, 9.28%. Calcd for $C_{12}H_{18}O_2$: C, 74.30; H, 9.28%.

Photochemistry of Acetaldehyde in Diethyl Ether. A preparative glpc (PEG 20M, 120 °C) of the irradiation mixture gave the diastereoisomeric alcohols (**4a** and **4b**) and 3-hydroxy 2-butanone.

2-Hydroxy-3-ethoxybutane (**4a**) has bp 132 °C; n_D^{20} 1.4082; IR (CCl_4) 3560, 3470, 1115 cm^{-1}; NMR(CCl_4) τ 8.95 (d, 6H), 8.81 (t, 3H), 7.10 (s, 1H), 6—7 (m, 4H); *m/e* 73, 45. Found: C, 61.15; H, 11.75%. Calcd for $C_6H_{14}O_2$: C, 60.98; H, 11.94%.

The isomer **4b** has bp 125 °C; n_D^{20} 1.4112; IR(CCl_4) 3565, 3470, 1115 cm^{-1}; NMR(CCl_4) τ 8.90 (d, 6H), 8.78 (t, 3H), 7.07 (s, 1H), 6—7(m, 4H); *m/e* 73, 45. Found: C, 60.76; H, 11.72%.

*Dehydration of **1a** and **1b**.* Treatment of **1a** or **1b** (120 mg) with 0.15 ml of warm sulfuric acid-acetic acid solution[4] gave only 6-acetoxy-2-phenyl-3-hexanone (**5**): IR (CCl_4) 1735, 1715 cm^{-1}; NMR(CCl_4) τ 8.65 (d, 3H), 8.12 (s, 3H), 8.26 (q, 2H), 7.65 (t, 2H), 6.34 (q, 1H), 6.14 (t, 2H), 2.80 (5H); *m/e* 234, 129, 105, 87, 77. Found: C, 71.66; H, 7.53%. Calcd for $C_{14}H_{18}O_3$: C, 71.77; H, 7.74%.

*Dehydration of **3a** and **3b**.* Treatment of a mixture of **3a** and **3b** as mentioned above yielded 2-phenyl-3-ethoxy-1-butene (**6**) and 3-phenyl-2-butanone (**7**).

Product **6** has n_D^{20} 1.5092; IR(CCl_4) 1620, 910 cm^{-1}; NMR(CCl_4) τ 8.80 (t, 3H), 8.82 (d, 3H), 6.51 (q, 2H), 5.86 (q, 1H), 4.82 (s, 2H), 2.6—2.9 (m, 5H); *m/e* 161, 132, 117, 77, 73. Found: C, 81.60, H, 9.11%. Calcd for $C_{12}H_{16}O$: C, 81.77; H, 9.15%.

The other product **7** has n_D^{20} 1.5064; IR(CCl_4) 1715 cm^{-1}; NMR (CCl_4) τ 8.70 (d, 3H), 8.07 (s, 3H), 6.42 (q, 1H), 2.85 (m, 5H); *m/e* 148, 105. Found: C, 80.69; H, 8.32%. Calcd for $C_{10}H_{12}O$: C, 81.04; H, 8.16%.

The Preparation of 3,5-Dichloro-2,4,6-trifluorophenyl(cyclopentadienyl)-dicarbonyliron and Its Derivatives

Nobuo ISHIKAWA and Shuji IBUKI

Department of Chemical Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received March 18, 1974)

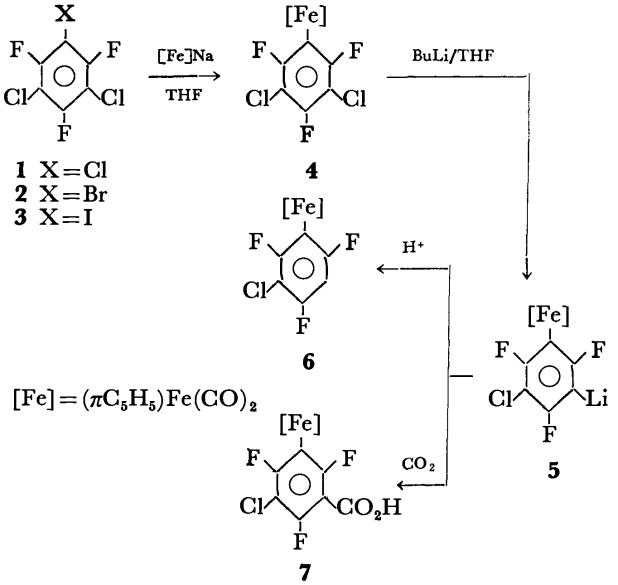
Synopsis. 3,5-Dichloro-2,4,6-trifluorophenyl(cyclopentadienyl)dicarbonyliron (**4**) was prepared by the nucleophilic substitution of *sym*-trichlorotrifluorobenzene with the (cyclopentadienyl)dicarbonyliron anion. One of the chlorine atoms of **4** was lithiated and the resulting lithio compound was hydrolyzed or carboxylated to give 3-chloro-2,4,6-trifluorophenyl(cyclopentadienyl)iron (**6**) or its 5-carboxylic acid (**7**) respectively.

A number of polyfluoroaryl(cyclopentadienyl)dicarbonylirons have recently been prepared by the nucleophilic substitution of a fluorine or other halogen atom of polyfluoro or monohalogenopolyfluoro aromatic compounds with the (cyclopentadienyl)dicarbonyliron anion.[1] For the preparation of further derivatives, however, polyfluoroaryliron compounds which carry other halogen atoms in addition to the fluorines on the aryl nucleus would seem to be more useful, because the halogen atom may be replaced by a functional group by means of the Grignard and similar reactions. As an example of such a kind of polyfluorohalogenoaryliron, bromotetrafluorophenyl(cyclopentadienyl)dicarbonyliron has been prepared by Cohen very recently.[2] We will here describe another compound of this type derived from *sym*-trichlorotrifluorobenzene (**1**).

The reaction between **1** and the iron complex anion, generated from the dimer of (cyclopentadienyl)dicarbonyliron and sodium amalgam, was carried out in tetrahydrofuran under a nitrogen atmosphere at −70 °C. At a higher temperature, only a tarry material resulted and no expected product was isolated, probably because of the formation of the (cyclopentadienyl)-dicarbonyliron dimer.[2]

In the usual nucleophilic reactions on *sym*-trichlorotrifluorobenzene, one or two fluorine atoms are replaced by the alkoxide ion or amines.[3,4] However, in the reactions between polyfluorohalogenobenzenes and the (cyclopentadienyl)dicarbonyliron anion, it is generally known that a chlorine or bromine atom is replaced in preference to a fluorine atom.[5] This can be explained by assuming that the elimination step of the halogen atom, and not the preceeding addition step of the anion, is the rate-determing step.[5] As expected, one chlorine atom of **1** was exclusively replaced by the (cyclopentadienyl)dicarbonyliron group to give 3,5-dichloro-2,4,6-trifluorophenyl(cyclopentadienyl)dicarbonyliron (**4**) in a yield of 14%.

The structure of **4** was evident from its ^{19}F NMR and mass spectra. In the ^{19}F NMR spectrum, two signals appeared, at +2.7 and +43.5 ppm,* in a 2 : 1 ratio of strength; those signals should be assigned to 2,6-F and 4-F respectively. These experimental values agree approximately with those calculated from the substituted shielding parameters of Bruce,[6] *i. e.*, +0.4 and +40.0 ppm. In the mass spectrum, *P* and *P*+2 peaks appeared at *m/e* 376 and 378 in a 100 : 65 ratio, as had been expected.



Bruce *et al.*[5] reported that the nucleophilic reactivity of the halogen atoms of polyfluorohalogenobenzenes towards the (cyclopentadienyl)dicarbonyliron anion increases in the order of Cl<Br<I. In order to have better yields, similar reactions with 3,5-dichloro-2,4,6-trifluorobromo- (**2**) and -iodobenzene (**3**) were examined. While a better yield (25%) was obtained from the bromo compound, **2**, the yield from the iodo compound, **3**, was poorer even than that from the chloro compound, **1**. We assumed that, while, in the cases of **1** and **2**, the elimination of the halogen atom is the rate-determining step, in the case of **3** it is the addition of the iron anion to the iodinated carbon atom.

The aryliron, **4**, is a very stable compound forming orange crystals; mp>200 °C (dec.); recrystallizable from various organic solvents including dimethylformamide. No chemical change occurred upon boiling in a methanolic solution either with sodium hydroxide or with concentrated hydrochloric acid for a long period. Concentrated sulfuric acid, however, hydrolyzed the C–Fe bond even at room temperature, giving 1,3-dichloro-2,4,6-trifluorobenzene.

One of the chlorine atoms of **4** could be lithiated with *n*-butyllithium in hexane–tetrahydrofuran, and from the resulting monolithio compound, **5**, 3-chloro-2,4,6-

* All ^{19}F NMR chemical shifts in this article are given in δ ppm from ext. CF_3CO_2H in tetrahydrofuran.

trifluorophenyl-(**6**) and 3-chloro-2,4,6-trifluoro-5-carboxyphenyl(cyclopentadienyl)dicarbonyliron (**7**) were derived by treatment with water and carbon dioxide respectively. The further lithiation of **6**, or dilithiation of **4**, to obtain a bifunctional aryliron compound was unsuccessful.

Experimental

*3,5-Dichloro-2,4,6-trifluorophenyl(cyclopentadienyl)dicarbonyliron (**4**).* A mixture of the dimer of (cyclopentadienyl)-dicarbonyliron (7.08 g, 20.0 mmol), 0.9% sodium amalgam (155 g, 60 mmol), and tetrahydrofuran (200 ml) was stirred for 1.5 hr at room temperature under a nitrogen atmosphere. The resulting solution of the (cyclopentadienyl)dicarbonyliron anion was cooled to −70 °C in a dry ice-acetone bath, into which a solution of *sym*-trichlorotrifluorobenzene (6.27 g, 26.7 mmol) in tetrahydrofuran (80 ml) was then added, drop by drop; the mixture was then gradually brought to room temperature, after which stirring was continued overnight. The tetrahydrofuran was evaporated at 0 °C under reduced pressure, and from the residue the product was extracted with benzene. The extract was passed through a column of activated alumina, and the first yellow band was eluted with benzene The eluate was concentrated to dryness to give a crude product of **4** (1.43 g, 14%). Recrystallization from tetrahydrofuran gave pale orange crystals, which gradually darkened and decomposed above 200 °C, without any definite melting or decomposing point. Found: C, 42.14; H, 1.30; Cl, 18.9; F, 15.3%. Calcd for $C_{13}H_5Cl_2F_3O_2Fe$: C, 41.42; H, 1.33; Cl, 18.8; F, 15.1%.

From the eluate of the second band, the dimer of (cyclopentadienyl)dicarbonyliron (3.60 g, 51%) was recovered.

1-Bromo-3,5-dichloro-2,4,6-trifluorobenzene and 1-iodo-3,5-dichloro-2,4,6-trifluorobenzene reacted in a similar manner to give **4** in yields of 25 and 12% respectively. In these cases, the dimer of (cyclopentadienyl)dicarbonyliron was also recovered in 56 and 79% yields.

*3-Chloro-2,4,6-trifluorophenyl(cyclopentadienyl)dicarbonyliron (**6**).* Into a solution of **4** (1.00 g, 2.66 mmol) in tetrahydrofuran (25 ml), a solution of *n*-butyllithium in hexane (2.39 M, 1.50 ml, 3.59 mmol) was added at −66 °C and stirred for 1 hr. The reaction mixture was thrown onto ice, and the resulting yellow precipitate (0.84 g, 92%) was collected by filtration. Recrystallization from *n*-hexane gave pale orange crystals; mp 151—153 °C. Found: C, 45.85; H, 1.76; F, 16.2%. Calcd for $C_{13}H_6ClF_3O_2Fe$: C, 45.59; H, 1.77; F, 16.6%. ^{19}F NMR*: 2-F, −1.1; 4-F, +41.5; 6-F, −0.5. Calcd:[6] 2-F, −1.8; 4-F, +37.9; 6-F, −1.7.

*3-Chloro-2,4,6-trifluoro-5-carboxyphenyl(cyclopentadienyl)dicarbonyliron(**7**).* Through a lithiated solution prepared as has been described above, carbon dioxide was bubbled in a course of 2 hr, with mechanical stirring. The reaction mixture was thrown onto ice water and made acidic with concd hydrochloric acid. Resulting yellow precipitate was collected by filtration and dissolved in a dilute aqueous solution of sodium hydroxide. After filtering to remove a small amount of an insoluble material, the carboxylic acid was reprecipitated with conc. hydrochloric acid to give **7** (0.87 g, 84%) as yellowish brown crystals; mp 181 °C (dec.). Found: C, 44.17; H, 1.61; F, 15.0%. Calcd for $C_{14}H_6ClF_3O_4Fe$: C, 43.50; H, 1.57; F, 14.8%. ^{19}F NMR*: 2-F, −4.2; 4-F, +40.8; 6-F −1.8. Calcd:[6] 2-F, −4.7; 4-F, +38.0; 6-F; −1.6.

Determination of Conformations of Esters with the Use of Lanthanide Shift Reagents

Kazuhiko SAKAMOTO and Michinori ŌKI*

Department of Chemistry, Faculty of Science, The University of Tokyo, Tokyo 113

(Received March 30, 1974)

Synopsis. Lanthanide shift reagents have been used for diagnosis of *s-trans* and *s-cis* conformations of esters. By taking a ratio of lanthanide-induced shift of (H)CH_2C=O protons *vs.* [shift reagent]/[substrate] as a reference, relative ratio of (H)CH_2O- of the *s-trans* form has been found to be almost unity, whereas that of the *s-cis* *ca.* 0.5.

Following the discovery of Hinckley[1] a large number of papers[2] on the utility of the lanthanide shift reagents have been reported. Structures of organic oxygen compounds were investigated with the aid of shift reagents.[3] Interestingly, however, the use of shift reagents in determination of conformations of esters has not so far been reported to our knowledge.

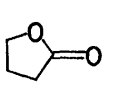
Ester can take either *s-trans* or *s-cis* conformation in principle. Ordinary esters take *s-trans* conformation probably because of the steric and dipolar effects.[4] On the contrary, lactones of small ring size exist as *s-cis* conformation because of the steric requirements.[5] Thus a problem arises whether it is possible to take *s-trans* conformation for a mediumsized lactone or an analogous ring. Hetera-*p*-cyclophanes containing oxygen(s) in an ansa chain, which we have been interested in for some years,[6] is an example of this sort.

It has long been hoped that an infrared carbonyl stretching absorption could be used for diagonsis of the ester conformation. In reality, however, absorptions due to *s-cis* and *s-trans* conformations are so close with each other that they are almost useless for the purpose. Only careful examinations in the presence of both conformations proved to be usefull.[7]

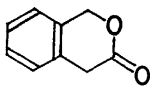
Lanthanide shift reagents are one of the possibilities to solve this problem. If the lanthanide ion is located closely to the carbonyl oxygen, its effect on the ether methylene of the ester group should be different according to its conformation. We now wish to report a successful use of lanthanide shift reagents for determination of conformations of lactones and esters.

Simple esters are known to exist as *s-trans* conformation only[4] and γ-butyrolactone (**1**) must take *s-cis* conformation because of the steric requirement. Thus they were taken as typical examples of *s-trans* and *s-cis* conformations in the lanthanide-induced shift (LIS) measurements. 3-Isochromanone (**2**) was also included as an example of *s-cis* form of 6-membered rings.

PMR spectra of these compounds in deuteriochloroform were determined by adding various amounts of a shift reagent, molar ratio of the shift reagent to the substrate being 0—0.3. LIS was plotted against [L]/[S], where [L] and [S] are the molar concentrations



(**1**)



(**2**)

of the shift reagent and the substrate, respectively, to show good linearity. Relative slopes of the straight lines were obtained by taking that of protons at α-position to the carbonyl as a reference and are summarized in Table 1. Changing the shift reagent from Eu(fod)$_3$-d_{27} to Eu(dpm)$_3$ did not seem to give a significant change in the relative slopes. The LIS of the alcoholic methyl signals of methyl acetate was reported by Hart and Love, using Eu(dpm)$_3$.[8] The relative slope was calculated to be 0.96, which is in good agreement with the present datum.

Generally the ether oxygen in an ester group is inactive toward lanthanide shift reagent and preferred site of complexation is the carbonyl oxygen.[3,8,9] If small-sized lactones preferred to form complexes at the ether oxygen, differing from the general tendency of the esters, the relative slopes of the straight lines for the CH_2O would have been larger than unity. Data in Table 1 suggest that the site of complexation is the same for *s-cis* and *s-trans* conformations.

However, the differences in relative slopes concerned with the methylene groups alpha to the ether oxygen do exist; the relative slope of the straight line involving CH_2O group of *s-trans* conformation is almost 1, whereas that of *s-cis* conformation is *ca.* 0.5. In order to discuss the difference of the slopes quantitatively, many factors like pseudo-contact *vs.* contact interactions, symmetry of the anisotropy and the conformational uniformity may have to be considered[10] in the use of McConnell-Robertson equation.[11] Yet this change in relative slopes is distinct and must be useful in diagnosing the conformations of carboxylic esters, provided that they

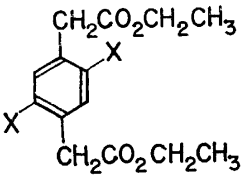
5_{12}	1	1.0	0.52	0.43
5_{13}	1	0.99	0.55	0.43
5_{14}	1	0.95	0.56	0.41
5_{15}	1	0.99	0.53	0.37
5_{16}	1	1.0(0.99)	0.57(0.55)	0.38(0.38)

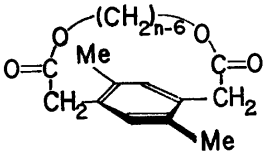
a) Values in parentheses are those obtained by using Eu(dpm)$_3$.

exist as a single conformation. If an ester should exist as a mixture of *s-cis* and *s-trans* conformations and signals due to those conformations should not be resolved it would be natural to expect that an intermediary value between 0.5 and 1 is obtained.

Application of the above findings to complicated systems will be worthwhile to try. We had diester precursors (**3** and **4**) for preparations of hetera-*p*-carbophanes. Testing with these compounds will be worthy because several rotational isomers are possible due to the presence of a RCH_2CO_2R' group[12] and two ester groups are present. The results are shown in Table 2.



(**3**): X=H, (**4**): X=Me



(5_n)

Relative slopes for the CH_2O group of these compounds are *ca.* 1.0. Doubtlessly, these esters exist as *s-trans* conformations. These observations are in conformity with the idea that the open chain esters take *s-trans* conformation usually and *s-cis* conformation is present in special cases only.[13] The results also suggest that the relative slope can be used in such complex esters also for diagnosis of the conformation.

It will be interesting to see the results applied to complex lactones. Dioxa[n]paracyclophanes (5_n)* show only a sharp C=O stretching band at *ca.* 1730 cm^{-1} which is not useful for determination of conformation. Since internal rotations of aromatic rings in the lower members of 5_n are known to be slow on the NMR time scale and rings are strained from the molecular model, a possibility exists that one or both of the ester groups assume *s-cis* conformation. The results of LIS measurements are also shown in Table 2. The relative slopes clearly suggest that these members take *s-trans* conformations irrespective to the ring size.

Usage of lanthanide shift reagents and relative slope of the straight lines obtained by plotting LIS against [L]/[S] of CH_2O signals are powerful tools in determination of conformations of esters. Eu(dpm)$_3$ and Eu(fod)$_3$-d_{27} gave almost the same numerical values. The slope values of methyl groups may be used as well as methylenes.

* *n* is the number of the members of the ansa chain.

Experimental

Syntheses. Syntheses of dioxa[n]paracyclophanes (5_n) will be reported elesewhere. γ-Butyrolactone (**1**) was of commercial origin and 3-isochromanone (**2**) was synthesized according to the method of literature.[14]

Diethyl 2,5-Dimethyl-1,4-phenylenediacetate (4). A mixture of 10 g (44 mmol) of 2,5-dimethyl-1,4-phenylenediacetic acid, 50 ml of ethanol, 100 ml of benzene, and a few drops of concentrated sulfuric acid was refluxed for several hours and worked up in a usual manner to give 9 g (71.8 %) of pale yellow crystals which were recrystallized from hexane-ether. Mp 55.5—56.5 °C. IR(KBr disk): 1725 cm^{-1} (ν_{CO}). NMR (CCl_4, δ,): 1.22 (6H, t); 2.23 (6H, s); 3.43 (4H, s); 4.04 (4H, q); 6.89 (2H, s). Mass spectrum: 278 (M^+). Found: C, 68.71; H, 7.91%. Calcd for $C_{16}H_{22}O_4$: C, 69.04; H, 7.97%.

Diethyl 1,4-Phenylenediacetate (3), mp 58.0—59.0 °C(lit,[15] mp 59 °C), was obtained similarly.

Measurement of Spectra. NMR spectra were recorded on a Hitachi R-20B spectrometer operating at 60 MHz. Shift reagents stocked over P_2O_5 were used.

Reaction of Polymethylbenzyl Cyanides with Fuming Nitric Acid. A New Route to Polysubstituted 3-Isochromanone Synthesis[1]

Hitomi SUZUKI and Terukiyo HANAFUSA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-sendamachi, Hiroshima 730

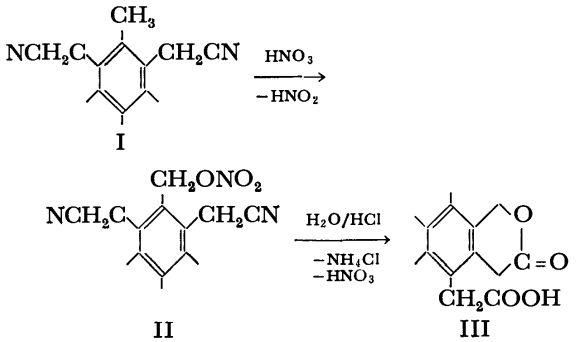
(Received April 23, 1974)

Synopsis. Treatment of pentamethylbenzyl cyanide and bis(cyanomethyl)tetramethylbenzenes with fuming nitric acid in dichloromethane led to the regiospecific nitrooxylation of the methyl group adjacent to the cyanomethyl group, giving the corresponding benzyl nitrates in good yields. On acid hydrolysis, these nitrates were readily converted into 3-isochromanone derivatives.

Action of cold fuming nitric acid upon polymethylbenzenes leads to the formation of benzyl nitrates.[2] High regiospecificity for the side-chain attack offers a potential as a new entry into various types of benzylic compound. As part of our study concerned with this type of reaction, we report here a convenient preparation of certain polysubstituted 3-isochromanones (3,4-dihydro-1*H*-2-benzopyran-3-ones), useful intermediates for 3(2*H*)-isoquinolinone synthesis. Previously reported routes to 3-isochromanones involve the haloalkylation of phenylacetic acids,[3] the Baeyer-Villiger reaction of 2-indanones,[4] or the lactonization of *o*-acylphenylacetic acid derivatives.[5]

4,6-Bis(cyanomethyl)-1,2,3,5-tetramethylbenzene (I), readily obtained by chloromethylation of isodurene and subsequent treatment of the bis-chloride with sodium cyanide, underwent reaction with fuming nitric acid in dichloromethane at 0—5 °C, giving a high yield of a crystalline product, mp 172—173 °C with decomposition, which had a formula $C_{14}H_{15}N_3O_3$ and showed strong infrared bands due to CH_2ONO_2 group at 1645, 1624, 1286, and 870 cm^{-1}. The unaltered presence of cyano group was shown by the peak at 2245 cm^{-1}. The proton NMR spectrum of the product exhibited absorptions at δ 2.33 (s, 3H), 2.40 (s, 6H), 3.82 (s, 4H), and 5.65 (s, 2H). Loss of the lower-field methyl peak of I indicated that the methyl group flanked with cyanomethyl groups on both sides had been converted into a nitrooxymethyl group. These data are only compatible with the formulation of the product as 5-nitrooxymethyl-4,6-bis(cyanomethyl)-1,2,3-trimethylbenzene (II).

When an ethanolic solution of II was heated with dilute hydrochloric acid under gentle reflux, there were obtained white prisms with the composition $C_{14}H_{16}O_2$, mp 187—189 °C. This compound showed the infrared bands at 3200—2600 (OH), 1738, 1706 (C=O), 1220 (O–CO), 1010 (C–O), and 927 cm^{-1} (OH), and proton NMR peaks at δ 2.23 (s, 6H), 2.27 (s, 3H), 3.70 (s, 2H), 3.75 (s, 2H), and 5.34 (s, 2H). With aqueous alkali it went into solution and was again precipitated on acidification. From its mode of reaction and spectral data, therefore, the product was formulated as 6,7,8-trimethyl-3-isochromanone-5-acetic acid (III).



A similar treatment of 3,6-bis(cyanomethyl)-1,2,4,5-tetramethylbenzene gave 5-nitrooxymethyl-3,6-bis(cyanomethyl)-1,2,4-trimethylbenzene, which was then converted into 5,7,8-trimethyl-3-isochromanone-6-acetic acid. Pentamethylbenzyl cyanide offered an easy access to 5,6,7,8-tetramethyl-3-isochromanone over 2-cyanomethyl-3,4,5,6-tetramethylbenzyl nitrate. In every case side-chain nitrooxylation took place on the methyl group adjacent to the cyanomethyl group. 4,6-Bis-(cyanomethyl)-5-ethyl-1,2,3-trimethylbenzene could, potentially, afford a substance analogous to III. However, treatment of this cyanide with nitric acid followed by acid hydrolysis resulted in the formation of intractable gummy substance.

Like existing methods of preparation, our route to 3-isochromanone synthesis is also subject to limited application. It appears to be applicable only to some fully substituted benzyl cyanides carrying two methyl groups in *para* relationship. However, easy access to starting materials, satisfactory yield, and ease of manipulation would make this procedure still useful for some 3-isochromanone synthesis.

Experimental

Melting points are uncorrected. Proton NMR spectra were recorded at 60 MHz using deuteriochloroform as a solvent and TMS as an internal standard. IR spectra were obtained in Nujol with a Jasco 402G spectrophotometer. Satisfactory analyses were obtained for all new compounds.

Polymethylbenzyl cyanides were prepared from the corresponding chlorides by treatment with sodium cyanide in aqueous acetonitrile. Physical properties of benzyl cyanides, benzyl nitrates, and 3-isochromanones obtained in context with the present work are listed in Table 1. No attempt has been made to optimize the conditions.

Procedure for the Nitration of Benzyl Cyanides. A solution of nitric acid (d=1.5; 6.3 g) in dichloromethane (5 ml) was added with stirring to a suspension of benzyl cyanide (0.01 mol) in the same solvent (15 ml) cooled to −5—0 °C in a salt-ice bath. After addition, the mixture was allowed to warm and maintained at room temperature for several hours. It was then worked up by pouring into water, sep-

arating the organic layer, and evaporating the solvent to give a nitrate as crystalline solid or somewhat pasty cake. It was recrystallized from ethanol. Yields ranged from 67 to 85%.

Procedure for the Hydrolysis of 2-Cyanomethylbenzyl Nitrates to 3-Isochromanones. Dilute hydrochloric acid (10%; 10 ml) was added to a solution of benzyl nitrate (2.5 g) in ethanol (20 ml) and the mixture was heated under gentle reflux for several hours. The yellow solution was then evaporated under reduced pressure to give a residue, which was extracted and crystallized from aqueous ethanol to give 3-isochromanone as fine needles or plates. Yields ranged from 47 to 75%.

The use of concentrated acid led to the extensive formation of an alkali-soluble resin. 3-Isochromanones are readily soluble in ethanol, sparingly soluble in hot water, and almost insoluble in light petroleum.

The Preparation of 1,5-Diaryl-3-Phenylsulfonylformazans from Phenylsulfonylacetarylamides and Their Arylazo Derivatives

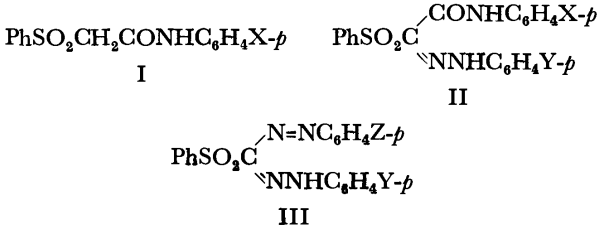
A. Sami Shawali and A. L. Elansari*

Department of Chemistry, Faculty of Science, University of Kuwait, Kuwait

(Received February 22, 1974)

Synopsis Azo coupling of phenylsulfonylacetarylamides(I) in presence of NaOAc gives the hydrazones (II). In presence of NaOH (and not NaOAc) both I and II couple with diazonium salts to give the formazans (III). mechanism is suggested for the formation of III.

In a previous paper[1] we reported that phenylsulfonylacetanilide (Ia, X=H) afforded 2-phenylsulfonylglyoxalanilide arylhydrazones (II, X=H; Y≠H) upon treatment with diazonium salts in NaOAc buffered solution of EtOH. In this communication we present the results of a study of this reaction in presence of excess of NaOH and an extension of it to the arylhydrazones of type II.



I II III

The treatment of Ia (X=H) with two equivalents of benzenediazonium ion in presence of sodium hydroxide gave a red crystalline product that was analyzed correctly for $C_{19}H_{16}N_4O_2S$. It was distinguished from Ia and IIa (X=Y=H) by the lack of the CONH bands in its IR spectrum. In addition, its electronic absorption spectrum in ethanol was quite different from that reported[1] for IIa (X=Y=H). It exhibits three maxima at 450 (log 3.85), 362 (log 4.25), and 285 (log 3.94) nm. These results suggest that the azo coupling of Ia with PhN_2^+ in presence of NaOH involves the concurrent hydrolytic cleavage of the phenylcarbamoyl group. This presumption was confirmed by the finding that similar treatments of the anilides Ib (X=Cl) and Ic (X=MeO) afforded products which were identical in every respect with that obtained from Ia (X=H). On the basis of these results, the product thus obtained was assigned the structure of 1,5-diphenyl-3-phenylsulfonylformazan (IIIa, Z=Y=H). Similar coupling of I with various diazonium ions yielded the corresponding symmetrically substituted formazans (IIIb—d) (Table 1).

When benzenediazonium chloride was added to IIa (X=Y=H) in NaOAc buffered solution of EtOH, the starting material IIa was recovered unchanged. However, when this coupling was repeated using excess of NaOH in place of NaOAc, IIIa (Y=Z=H) was obtained. The compound IIIa thus produced was identical with the sample obtained in the previous paragraph. Similar treatments of IIb (X=Cl, Y=H) and IId (X=MeO; Y=H) yielded IIIa. The mixture melting point of the three samples of IIIa prepared showed no depression.

The coupling of other hydrazones (IId—m) when similarly carried out with various diazotized arylamines gave the corresponding 3-phenylsulfonyl-1,5-diarylformazans (IIIe—i) in 26—50%. All formazans (IIIa—i) are new. They are intensely colored; exhibiting absorption bands above 400 nm (Table 2). Their electronic absorption spectral data are recorded in Table 2.

On the basis of the above considerations, we propose

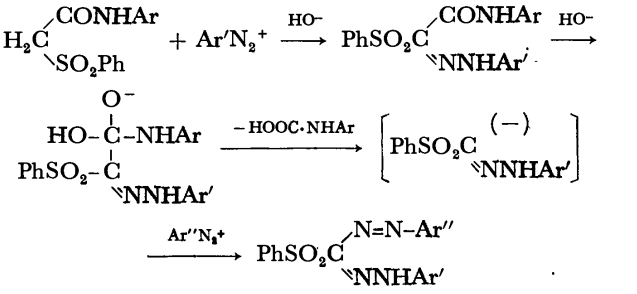
the tentative mechanism represented in Scheme 1 for the formation of formazans from I and II. The fact that both I and II gave the same formazan when similarly treated with diazonium ion support the involvement of II as intermediate in the conversion of I into III. The base catalysed hydrolytic cleavage of the arylcarbamoyl group during azo coupling is very similar to the Japp-Klingemann reaction[2] of the hydrazones of ketones. Thus, the arylhydrazones of α-keto acids and the α-arylhydrazones of α,β-diketobutyric esters have been converted into formazans by coupling with diazonium ion in presence of NaOH. With the first type coupling causes decarboxylation, and with the second type an acetyl group is replaced.[3]



Scheme 1

Experimental

Melting points are uncorrected. Elemental analyses were performed at the Microanalytical Laboratories at the University of Cairo, Egypt. IR spectra were recorded on a Perkin Elmer 337 spectrophotometer. UV spectra were measured on a Beckman DK spectrophotometer.

Phenylsulfonylacetarylamides (Ia—d). To a solution of sodium benzenesulfinate (prepared by neutralising benzenesulfinic acid[4] (0.06 mol) in EtOH (50 ml) with 10% NaOH solution (25 ml)) was added a solution of the appropriate chloroacetarylamide (0.059 mol) in EtOH (50 ml). The mixture was refluxed for 4 hr and left overnight at room temperature. The precipitated product was collected, washed with water and finally recrystallized from dil. EtOH. The anilides, ($PhSO_2CH_2CONHC_6H_4X$-*p*) prepared are: (No., X, mp °C, yield %, Anal.): Ia, H, 138—139 °C, 60 (lit,[1] mp 139 °C); Ib, Cl, 152 °C, 50, Calcd for $C_{14}H_{12}ClNO_3S$: C, 54.28; H, 4.23; Cl, 11.40; S, 10.32%. Found: C, 54.30; H, 4.03; Cl, 11.35; S, 10.18%; Ic, MeO, 149 °C, 55, Calcd for $C_{15}H_{15}NO_4S$: C, 59.00; H, 4.94; S, 10.50%. Found: C, 58.90; H, 4.80; S, 10.60%; Id, NO_2; 210 °C, 70, Calcd for $C_{14}H_{12}N_2O_5S$: C, 52.49; H, 4.09; S, 10.01%. Found: C, 52.50; H, 4.00; S, 10.04%.

2-Phenylsulfonylglyoxalarylamides Arylhydrazones (IIa—m). These were prepared by coupling Ia—d with diazotized arylamines in sodium acetate buffered solution of ethanol following the procedure described earlier.[1] All compounds were recrystallized from acetic acid. The physical properties of the compounds prepared are listed in Table 1.

1,5-Diaryl-3-phenylsulfonylformazans (IIIa—i). *Method A*: To an ice-cold solution of I (0.005 mol) in EtOH (50 ml) was added a cold solution of sodium hydroxide (0.8 g) in water (5 ml) and the mixture was cooled to 0 °C. The resulting solution was treated with 0.01 mol of diazonium salt (prepared in the usual way)[1] with stirring, the temperature being kept below 5 °C. After all the diazonium salt solution had been added, the reaction mixture was stirred for additional 10 min and left overnight in refrigerator. The product precipitated was collected, washed with water and recrystallized from acetic acid. The symmetrically substituted formazans (IIIa—d) prepared by this way are listed in Table 2. The azo coupling of either Ia, Ib or Id with benzenediazonium chloride, when carried out in the same manner, gave IIIa in 40—50% yield as the only isolable product in each case. Mixed melting point of the three samples obtained showed no depression.

Method B: In this method the hydrazone II was coupled with an equivalent amount of the appropriate diazonium salt following the procedure described in method-A. The product obtained from coupling of either IIa, IIb or IId with benzendiazonium chloride proved to be identical in all respects with that obtained from coupling of Ia with two equivalent of the same diazonium salt according to method A. The mixed mp of the four samples of IIIa thus obtained was 148 °C. The unsymmetrically substituted formazans (IIIe—i) prepared by this way are listed in Table 2.

ESR Study of γ-Irradiated Silk : Effect of Oxygen

Hisashi YOSHIOKA, Naoto KOIDE*, and Fukuji HIGASHIDE

Shizuoka College of Pharmacy, Oshika, Shizuoka, 422

* *Faculty of Education, Shizuoka University, Ohya, Shizuoka 422*

(Received May 14, 1974)

Synopsis. The ESR spectra of silk γ-irradiated in a vacuum showed a doublet at room temperature and at -196 °C. The doublet turns to a singlet at $g=2.006$ by admission of O_2. This is explained in terms of the formation of peroxide radicals.

ESR spectra of γ-irradiated proteins and polypeptides have been reported, the effect of O_2 being examined.[1,2] It is well-known that γ-irradiated polytetrafluoroethylene and polypropylene react with O_2 and form peroxide radicals.[3,4]

We report herewith on the ESR spectra of γ-irradiated silk and the effect of O_2.

Experimental

Raw silk, Japanese race Dōei×Kōhaku (spring 1974), was used. Silk fibroin was prepared by degumming with a 0.5% solution of Marseilles soap and rinsed thoroughly with Na_2CO_3 solution and deionized water. Oily matters were then extracted with ethyl ether with a Soxlet extractor.

Gamma-irradiation was carried out at a dose rate *ca.* 5×10^4 R/hr for 17—30 hr. ESR spectra were recorded at the X-band on a Japan Electron Optics Model JES-3BS.X spectrometer with 100 KHz field modulation.

Results and Discussion

The ESR spectrum of the silk fibroin, γ-irradiated in a vacuum at room temperature for 2 days and measured at room temperature, is shown in Fig. 1. It consists of a strong doublet and a weak background absorption. From the fact that about 50% amino-acid-residues are glycine, the doublet is thought to be attributed to

$$-NH-CO-\dot{C}H-NH-CO-$$

radicals formed at α-carbons of polymer main chains.[1,5]

The doublet turned to a singlet (Fig. 2-A) when the spectrum was measured one day after the admission of O_2 into the sample tube. The intensity of the singlet became only a few percent of that of the doublet. Thus most of the radicals were destroyed by O_2.

The spectrum became asymmetric at -196 °C due to an axially symmetric g-tensor. The values $g_\parallel=2.034$ and $g_\perp=2.002$ were calculated from the position of the peaks (Fig. 2-B). However, some uncertainty remains in the determination of the $g_\parallel$ value because of the weakness and broadness of the $g_\parallel$ peak. The values are almost equal to those of the peroxide radicals formed by the reaction of γ-irradiated polytetrafluoroethylene and polypropylene with O_2.[3,4] The results suggest that the peroxide radicals

$$-NH-CO-\underset{\displaystyle O-O\cdot}{\overset{\displaystyle |}{C}}H-NH-CO-$$

Fig. 1. ESR spectrum of γ-irradiated silk, measured at room temperature.

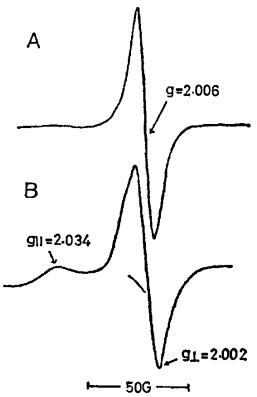

Fig. 2. ESR spectra of the peroxide radicals formed in γ-irradiated silk, measured at room temperature (A) and at -196 °C (B).

are formed in silk. Their molecular motion is considerably free at room temperature since it shows a singlet spectrum.

The doublet spectrum of γ-irradiated polyglycine does not turn to a singlet[1] in contrast to the above result. The difference is explained by assuming that the rate of the diffusion of O_2 into the solid is smaller than that of the decomposition of the peroxide radicals.[1] The glycine residues in silk are thought to exist in a coarse structure.

The ESR spectrum of silk γ-irradiated at -196 °C in the presence of O_2 showed no absorption due to the peroxide radicals when it was measured at -196 °C. However, when the temperature of the sample was elevated to -86 °C for a day, the formation of the radicals was observed. Thus the peroxide radicals are not formed at -196 °C.

The spectra of the raw silk did not differ from those of the silk fibroin.

The authors wish to express their thanks to Dr. Kunihiko Hasegawa for the experiments of γ-irradiation.

The Photoionization of Molecular and Crystalline Anthracene

Jun-ichi AIHARA* and Hiroo INOKUCHI
The Institute for Solid State Physics, The University of Tokyo, Roppongi, Tokyo 106
(Received January 12, 1974)

The photoionization efficiency curve of gaseous anthracene was examined by comparing it with the photoemission yield curve of solid anthracene. The direct ionization processes were found to dominate the two curves primarily. Some σ-valence orbitals of this compound were associated with considerably low ionization potentials. The cube law for the photoemission yield near the threshold was also established.

A considerable amount of effort has been devoted during the last decade to elucidate the ionization mechanism and the related valence-band structure of the organic crystal. The photoionization in the gas phase is an important phenomenon which provides a key to the electronic structure of the molecule; the solid-state ionization potential is, correspondingly, an important parameter governing the behavior of molecules in the solid state. Because of our great interest in the electronic behavior of polycyclic aromatics, anthracene and related molecules have recently been chosen for photoionization studies in the gas and solid phases.[1-11] In order to advance further the understanding of the molecular and solid-state photoionization, we attempted to measure the photoionization efficiency curve of molecular anthracene. In this article, we would like to examine the spectral response of the photoionization efficiency for this compound, and correlate the structure of the curve with that of the photoemission yield curve previously published.

Experimental

The photoionization efficiency (PIE) for the anthracene molecule was obtained as follows. The continuous flow of the anthracene vapor between the two electrodes was irradiated with a vacuum ultraviolet light. A 0.5 m vacuum monochromator was used under the same conditions as in Refs. 9 and 10. The light source was a hydrogen discharge tube. The photocurrent collected with the plate electrodes was arithmetically divided by the incident-light intensity. The spectral distribution thus defined is supposedly similar to that of the photoionization cross section,[12] since the vapor pressure employed was considerably lower than the saturated vapor pressure at room temperature. The synthetic anthracene was further purified and then used.

Results and Discussion

The PIE curve of the gaseous anthracene is shown in Fig. 1. The ionization efficiency increases gradually with an increase in the exciting photon energy, exhibiting several distinct breaks, *i.e.*, inflection points, in the observed energy region. The curve is composed of a series of smoothed-step functions of a photon energy. The various sharp bands characteristic of the PIE curve are not present. The possible autoionization peaks seem to be effectively suppressed for this compound. The smoothness of the curve can be phenomenally ascribed to the large molecular dimension of anthracene, since the PIE curves of simpler molecules generally display a more complex dependence on the photon energy.[13-18]

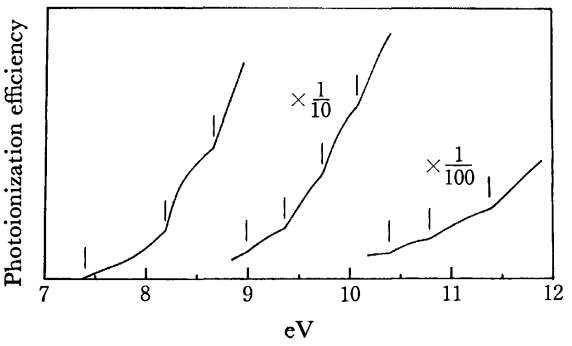

Fig. 1. Photoionization efficiency curve of the molecular anthracene. (Breaks are indicated by lines.)

This effect strongly suggests that, as for anthracene, most photoelectrons are emitted through the direct ionization processes. As long as the possibility of the autoionization processes can be ruled out, the breaks in the curve should correspond to the minimum energies needed to excite the ground-state molecule to the excited-state molecular cations. Every spacing between the adjacent two breaks is obviously too large to be explained in terms of vibrational levels. In other words, these breaks express the adiabatic ionization potentials associated with the lower-lying valence bands in the anthracene molecule.

The structure of the PIE curve is straightforwardly identified by comparing it with the external photoemission data on the crystalline anthracene. In 1963, Vilesov *et al.* carried out a photoemission study of the anthracene crystal and determined the valence-band structure from the kinetic energy distribution curves (EDC) of photoelectrons.[7] Furthermore, Kochi *et al.* observed the existence of several distinct breaks in the photoemission yield (PEY) curve.[10] The PEY curve itself is also a monotonously-varying function of the photon energy. The locations of the breaks in both phases are all listed in Table 1. The values in parentheses are given relative to the first ionization potential or to the threshold energy.

First of all, it is noteworthy that the breaks in the PIE curve are well reproduced in the PEY curve. The breaks in the PIE curve almost coincide with those in the PEY curve, if the threshold of the former curve is appropriately shifted to that of the latter one. The energy differences between the corresponding breaks

are also listed in Table 1.

According to Lyons,[19] the ionization potential of the molecular crystal, I_c, is related to the gaseous ionization potential of the component molecule, I_g, by:

$$I_c = I_g - P, \qquad (1)$$

where P is the positive polarization energy of the crystal. This equation implies that the energy of the crystalline state can be described in terms of the molecular properties and the electrostatic polarization energy. This equation has often been applied to the explanation of the photoemission threshold energy of the molecular crystal.

However, the present results show that the energy difference between the corresponding breaks, which is considered the pertinent polarization energy, is almost preserved among the higher ionization potentials of the crystal. The polarization energy related to the first ionization potential is 1.75 eV. The energies for the first five ionization potentials are substantially the same. This means that the polarization energy is almost independent of the orbital symmetry of the molecular ion formed in the crystal. Several authors have calculated the polarization energy for the anthracene crystal.[20,21] The experimental polarization energy is, however, situated at the upper limit of the theoretical values (1.63 and 1.38 eV,[20] and 1.52 eV[21]). The accordance of the structures in the two curves gives further support to the first-mentioned aspect that both the PIE and PEY curves are primarily determined by the direct ionization processes, though different autoionization processes are possible for the different phases.[22-25]

Next, let us classify the breaks in the two curves. The assignment of the π-ionization potentials of anthracene has been completely established on the basis of recent molecular orbital calculations,[2-4] since these calculations are quite consistent with each other. These π-ionization potentials have all been identified by photoelectron (PE) spectroscopy.[2-4] Accordingly, breaks which correspond to such π-ionization potentials can readily be ascribed to the π-valence orbitals. However, additional breaks are also present in the PIE curve. They have no counterparts in the PE spectrum, the lower part of which comprises only photoelectrons ejected from π-valence orbitals. These breaks were necessarily attributed to the σ-valence orbitals, now that the locations of all the π-valence orbitals have been established with little doubt.

Here, it should be noted that the lowest σ-ionization potential of anthracene is as low as 8.19 eV. If one remembers the fact that the ionization potentials of n-alkanes converge to about 10 eV,[26] this value seems to be too small. The counterpart of the 8.19 eV break in the PIE curve is nevertheless found at 6.40 eV in the PEY curve. This break is found noticeably in the PEY curve obtained by Lyons and Morris.[27] Marchetti and Kearns also observed a PEY curve with a similar structure.[28] Such a common feature of the PEY curve appears to favor our interpretation of the 8.19 eV break in the PIE curve.

Why are these breaks undetected in the PE spectrum? The reason is presumably that such transitions induce appreciable ionization cross sections only when the photon energy does not much exceed the corresponding minimum ionization energies. This explanation is just the same one as Momigny and Lorquet presented for the photoionization of benzene.[29] Dewar *et al.* also suggested that there might be some missing bands, especially some bands related to the σ-valence orbitals, in the PE spectra of aromatic hydrocarbons.

The EDC curves of the solid species generally resemble the PE spectrum of the molecule.[7,10] Exceptionally, some trace of the 8.19 eV break is found, though it is not pronounced, in the EDC curves observed by Vilesov *et al.*[7] A shoulder is present between the first two peaks ascribed to the π-valence orbitals in some EDC curves. This is the most direct evidence for the presence of the valence orbital associated with it. The other σ-electron bands are substantially dissipated except for the higher-energy ones. Such an aspect of the σ-ionization potentials can be traced in Fig. 1, where the second step, beginning at 8.19 eV, is somewhat rounder, suggesting an abrupt decrease in the partial ionization cross section of the second transition with an increase in photon energies.

With the EDC data, we can estimate further the polarization energy of the crystal. The first σ-ionization potential which was clearly detected in the EDC curve of anthracene is located 3.4 eV above the first π-ionization potential.[7] On the other hand, the corresponding break in the PIE curve is found at 10.78 eV. Accordingly, the polarization energy concerned amounts to about 1.7—1.8 eV. This is almost the same value as that determined for lower ionization potentials. For the present, there is little evidence for the rearrangement of the molecule in the crystal, the occurrence of which was suggested in the carbon suboxide crystal.[31]

The above-mentioned results can be used to examine the threshold law for the photoemission from the organic solid. In general, the quantum efficiency of the photoemission near the threshold is very low and does not show any abrupt change.[8-10] Therefore, it is quite

difficult to determine the accurate photoemission threshold energy. This is in marked contrast to the distinct threshold behavior of the gaseous photoionization.[12]

However, the onsets of the transitions related to the higher ionization potentials are often easily distinguished as breaks in the PEY curve.[8,10] Supposing that the polarization energy is preserved among the first and higher ionization potentials, these breaks can be employed as a secondary standard in determining the actual threshold energy for the photoemission from the crystal. If the higher ionization potentials of the crystal could be identified by comparing the breaks in the PEY curve with those in the PIE curve, the threshold energy of the PEY curve would be the first ionization potential of the gaseous species minus the polarization energy associated with the higher ionization potentials. As has been mentioned above, the experimental threshold energy for the anthracene crystal satisfies these requirements, and so it can be regarded as the actual ionization potential of the crystal.

This fact verifies that the cube law for the photoemission threshold is valid for an organic crystal such as anthracene.[9,10] According to this law, the experimental threshold energy of anthracene (5.65 eV) can almost be reproduced by the extrapolated value of 5.68 eV.[10] This implies that the quantum efficiency of the photoemission near the threshold, $Y(h\nu)$, is adequately expressed as:

$$Y(h\nu) \propto (h\nu - E_{th})^3, \quad (2)$$

where E_{th} signifies the extrapolated threshold energy.

On the other hand, the threshold energy derived by Marchetti and Kearns (5.85—5.95 eV) seems to be somewhat larger,[28] probably because they did not take into account the discrete valence band structure and the related vibrational structure of the crystal in constructing their threshold law. Another power law was presented by Sworakowski.[32] According to his square-root law, the threshold energy must be 6.25 eV for the anthracene crystal. However, this law apparently retains the spectral behavior of the gaseous photoionization, since the photoionization efficiency of the gaseous molecule is approximately proportional to the square root of the energy difference between the threshold and the applied photon.[17,18] This aspect of the law is in contradiction to his theory, in which the escape probability and so on are also taken into consideration.[32] This is probably due to his density-of-state function which is not fit for the polycyclic aromatics.

In conclusion, the agreement between the structures of the PIE and PEY curves confirms the predominant direct ionization processes and the parallel valence-band structures in both phases. The parallel valence-band structures appear to characterize the organic molecular crystal and indicate that the whole valence-band structure of the solid is expressed in terms of molecular ionization potentials and a single polarization energy, as is suggested by Eq. (1). In this connection, the cube law for the photoemission threshold was established. It is noteworthy that the measurement of the PIE curve complements the PE spectroscopy well. A comparative study of these phenomena would be very helpful to a deeper understanding of the ionization mechanism in both gas and solid phases.

Effect of Alcohols on the Micelle Formation of Nonionic Surfactants in Aqueous Solutions

Nagamune NISHIKIDO, Yoshikiyo MOROI, Hiromoto UEHARA,* and Ryohei MATUURA

Department of Chemistry, Faculty of Science, Kyushu University, Fukuoka 812

(Received February 8, 1974)

The variation of critical micelle concentrations (CMC) of polyoxyethylene lauryl ethers having various ethylene oxide chain lengths $\bar{n}$($\bar{n}$=6, 11, 20, and 31) on addition of short chain alcohols to the surfactant aqueous solutions was determined at 20 °C. Thermodynamic quantities of micelle formation in methanol- and ethanol-water mixtures and in pure water were obtained in connection with the heat of micelle formation determined by direct calorimetry. Methanol and ethanol showed a CMC-increasing effect only, whereas the addition of *n*-propanol, *n*-butanol, and *n*-pentanol showed a CMC-decreasing effect. The overall CMC-increasing effect is interpreted as being mainly due to the fact that methanol and ethanol weaken the hydrophobic bond. However, the effect also has a secondary effect of lowering the CMC slightly on the polyoxyethylene portion of a surfactant. Several factors are suggested for explaining this secondary effect. The CMC-decreasing effect is explained by a decrease in the free energy of mixing resulting from the solubilization of alcohol molecules into the micelle.

The mechanism of micellization of nonionic surfactant in aqueous solution is analogous to that of ionic surfactant from the viewpoint that micellization is controlled by two opposing factors, the driving force for association and the factor preventing association.[1,2] However, detailed studies on the micelle formation of nonionic surfactants are few in number as compared with those of ionic surfactants.

We can gain useful information for clarifying the various factors governing micelle formation from a study of the effect of additives on the critical micelle concentration (CMC) of surfactant. In order to evaluate relative efficacies of protein denaturants weakening hydrophobic interaction, a convenient approach to assess their effects on the CMC of surfactants has been used.[3,4] Short chain alcohols, urea and guanidine salts are known to be denaturating agents, *viz.*, hydrophobic bond breakers. Their effect on the CMC of nonionic surfactants is of interest in view of protein denaturation.

The effect of alcohols on the CMC of ionic surfactants has been investigated extensively,[5] but not that of nonionic surfactants.[6-10] We have studied the effect of methanol, ethanol, *n*-propanol, *n*-butanol, and *n*-pentanol on the micelle formation of polyoxyethylene lauryl ethers having various mean ethylene oxide chain lengths. The CMC of polyoxyethylated surfactants in alcohol-water mixtures was determined by the surface tension method. Heats of micelle formation were obtained by direct calorimetric measurements.

Experimental

Materials. The surfactants used (Kao Soap Co., Ltd.) were polyoxyethylene lauryl ethers ($C_{12}H_{25}O(CH_2CH_2O)_{\bar{n}}H$, $\bar{n}$=6, 11, 20, 31, $\bar{n}$: the average number of ethylene oxide groups). The average chain lengths of the ethylene oxide adducts were determined from their hydroxyl values. The impurities, potassium acetate and polyethylene glycol, were checked by means of atomic absorption spectrophotometry and paper chromatography and found to be minute. Elementary analysis also showed that the samples were sufficiently pure. All the alcohols were thoroughly purified. Water was redistilled from alkaline permanganate solution and had 1.5×10^{-6} mho/cm specific conductance.

Method. The surface tension measurements were performed at 20 °C by the Wilhelmy method with a 22×22 mm glass plate and a Kyowa Electro Surface Balance. Before the measurement the plate was cleaned by heating in a chromic acid mixture for two hours and was washed thoroughly with water. Surfactant solutions were left to stand at the temperature of measurement for a day, preventing evaporation. It took about an hour to obtain equilibrium surface tension after the surfactant solution surface had been cleaned by suction with a fine glass capillary. The CMC was determined from sharp breaks in the surface tension *vs.* logarithm of concentration plots.[10] Precision of the CMC determinations was within ±7%. The CMC was also checked by the spectral method,[11] good agreement being found between the two methods.

The heats of micelle formation were obtained at 20 °C by the heat of dilution method according to Corkill *et al.*[12] with a modified Applied Electric Laboratory Microcalorimeter, Model CM-204S1.

Results and Discussion

Since alcohols are surface active, sharp breaks in the surface tension *vs.* logarithm of the surfactant concentration plots become uncertain with an increase in the concentration of the alcohol. Thus, the surface tension method was used up to *ca.* 8 mol/l alcohol concentration. Within this range well-defined CMC values could be obtained. A small minimum appeared near the CMC in the surface tension *vs.* concentration curve of $\bar{n}$=11, 20 and 31 in water. This may be due to the distribution of the ethylene oxide chain length of a surfactant molecule.[13] Surfactants used in this study might fall in the category of polydisperse materials defined by Gibbons,[14] but we believe that they have sufficient purity[15] for attaining the aim of the present work, since the appearance of the minimum in the surface tension-concentration curve is not remarkable and analytical result shows sufficient purity.

CMC in alcohol–water mixtures are shown in Figs. 1, 4, and 5 as a function of alcohol concentrations. Methanol and ethanol show only a CMC-incresing

○: methanol, $\bar{n}$=20 ●: ethanol, $\bar{n}$=20
◐: methanol, $\bar{n}$=31 ◓: ethanol, $\bar{n}$=31

effect (Fig. 1). *n*-Propanol shows a CMC-decreasing effect in the low concentration range for all $\bar{n}$'s and a CMC-increasing effect at higher concentration for $\bar{n}$=6 and 11 (Figs. 4 and 5), while *n*-butanol and *n*-pentanol show a CMC-decreasing effect (Figs. 4 and 5). However, the CMC-increasing tendency may be expected to appear in excess of the decreasing effects by more addition of these alcohols to the surfactant solutions in analogy with *n*-propanol. These results are in line with those for ionic surfactants.[16]

The CMC-increasing effect of methanol and ethanol is attributable to the increasing solvent power of these alcohol-water mixtures, if we neglect the solubilization of alcohols into the palisade layer of the micelle. At low concentrations of alcohols, ethanol behaves almost the same as methanol with respect to the efficiency of the CMC-increasing effect. With increasing concentrations, however, ethanol becomes much more effective than methanol.

In order to clarify the above behavior, the heats of micellization in methanol- and ethanol-water mixtures

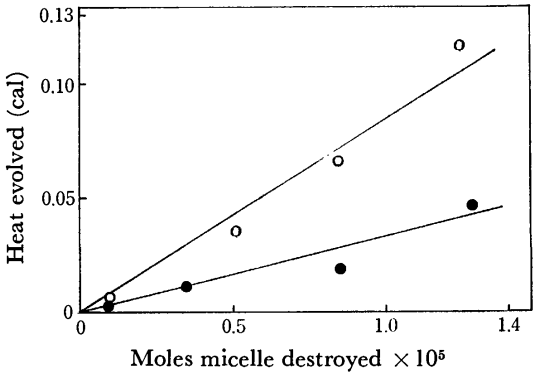

Fig. 2. The plots of heat evolved against moles of $\bar{n}$=31 surfactant demicellized at 20 °C in water (○) and 0.87 M ethanol (●).

are compared. The examples of measured heat of micellizatlon are shown in Fig. 2 with $\bar{n}$=31, in water and in 0.86 M ethanol. The abscissa represents the amount of micelle destroyed on dilution and the ordinate the observed heat change. The plot is almost linear and crosses close to the origin. Hence, within experimental error the assumption of Corkill *et al.*[12] is satisfied, *viz.* the heats of dilution of monomers and micelles are negligibly small as compared to the heat of micellization which is independent of concentration. The slope (Fig. 2) is the heat of micelle formation and equal to the standard enthalpy ΔH_m^0 with an opposite sign to that of the observed heat change.[12] The standard enthalpy ΔH_m^0 in conjunction with the standard free energy of micellization ΔG_m^0 gives the standard entropy ΔS_m^0. We take the pseudo-phase separation approach and get the following equations:[17,18]

$$\Delta G_m^0 = RT \ln X_c \quad (1)$$

$$\Delta S_m^0 = \frac{\Delta H_m^0 - \Delta G_m^0}{T} \quad (2)$$

where X_c is CMC expressed in mole fraction, since the CMC is small enough to replace activity by mole fraction. The solubilization of methanol and ethanol is considered to be negligible. Thus, the micelles in these short chain alcohol-water systems are single-component ones. The standard enthalpy ΔH_m^0 can be obtained in the above way (Fig. 2), and Eqs. (1)

Table 1. Thermodynamic quantities of micelle formation for surfactants of $\bar{n}$=6 and 31 in pure water, methanol- and ethanol-water mixtures at 20 °C

Additive	$\bar{n}$=6			$\bar{n}$=31

and (2) are valid for these systems, regarding the alcohol–water mixtures as solvents.

The values of ΔH_m^0 and ΔS_m^0 for representative methanol– and ethanol–water mixtures of $\bar{n}=6$ and 31 together with those in water are given in Table 1.

For the results in water, the large positive entropy ΔS_m^0 is responsible for the negative free energy ΔG_m^0 for micelle formation, since the enthalpy ΔH_m^0 is positive. Several causes for the positive entropy can be considered. Current views[18-28] are as follows. The ordered water around the hydrocarbon chains is released on micellization, contributing to the positive entropy. The gain in the conformational entropy of hydrocarbon chains may also give a positive value. Contribution of the change in solvation of hydrophilic chains is complicated. Desolvation of polyethylene oxide chains, which gives rise to a positive entropy change, has been proposed.[21-24] Elworthy and Florence[25,26] suggested that the mesh of polyethylene oxide chains in the micellar state can trap more solvent than the single chains in monomer, leading to a negative change. The negative contribution of the decrease of the configurational entropy of the flexible hydrophilic chains on micellization is also involved.

Studies on the dependence of ΔS_m^0 on the ethylene oxide content with the same hydrocarbon chains might elucidate the contribution of polyoxyethylene chains to ΔS_m^0. We have obtained the following data of ΔS_m^0 for various values of $\bar{n}$ in aqueous solution at 20 °C.

$\bar{n}$	6	11	20	31
ΔS_m^0 (e.u./mol)	54	54	50	51

It is seen that no essential difference of ΔS_m^0 in water exists among the surfactants having various oxyethylene chain lengths, so that we can consider that the contribution of polyoxyethylene chains is secondary. Thus, the large positive entropy ΔS_m^0 in water is considered to be primarily due to the loss of iceberg structure during the course of micellization. We see that the addition of methanol and ethanol to the surfactant aqueous solutions reduces the entropy ΔS_m^0, and the effectiveness of reducing ΔS_m^0 of ethanol becomes greater than that of methanol. At least qualitatively these alcohols primarily weaken the hydrophobic interactions, the important driving force for micellization, although other effects may also be involved.[29]

The difference in the effect of alcohol on ΔS_m^0 among various ethylene oxide chain lengths is ambiguous, but the effect on ΔG_m^0 displays the difference. In water and at constant concentrations of methanol and ethanol, ΔG_m^0 *vs.* $\bar{n}$ plots are almost linear. Thus, the gradient of the ΔG_m^0 *vs.* $\bar{n}$ plots is the free energy increment of the hydrophilic part of a surfactant in the process of micellization. The gradient $\Delta(\Delta G_m^0)/\Delta\bar{n}$ is plotted against the alcohol concentration in the solvent (Fig. 3). With increasing concentration of alcohols, the parameter $\Delta(\Delta G_m^0)/\Delta\bar{n}$ decreases rapidly, the rate being greater for ethanol than methanol. Alcohols might reduce the hydration of polyoxyethylene chains through the hydrogen bonding with water, but the interaction of alcohols with water is complicated.[30,31] According

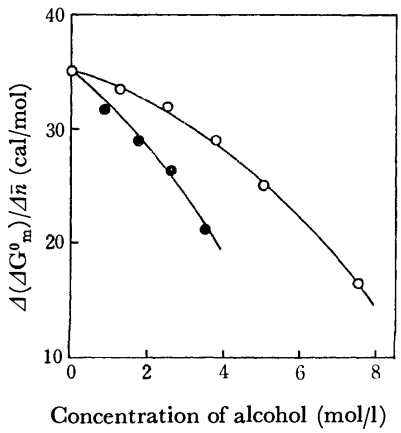

Fig. 3. $\Delta(\Delta G_m^0)/\Delta\bar{n}$ *vs.* methanol (●) and ethanol (○) concentration plots.

to Ray and Nemethy,[8] it is probable that alcohols have a solvent effect on the ethylene groups in the oxyethylene chains as well as the hydrocarbon chains of surfactants, since the ethylene groups may also be expected to increase the structual order in the surrounding water.

The CMC-increasing effect of methanol and ethanol is considered to contain two opposing factors: the primary effect on the hydrocarbon part, in which the alcohols weaken the hydrophobic bond, and lead to increasing the CMC; a secondary effect on the polyoxyethylene chains, which is a small effect of CMC-decreasing. The overall effect of methanol and ethanol is inclined towards raising the CMC.

Alcohols which have longer hydrocarbon chains than ethanol show a CMC-decreasing effect. The results are shown in Figs. 4 and 5 with $\bar{n}=6$ and 31, respectively. A similar behavior was obtained for $\bar{n}=11$ and 20. At low concentrations of alcohols, the CMC-decreasing effects are attributable to the penetration of alcohols into the palisade layer of the micelle, forming

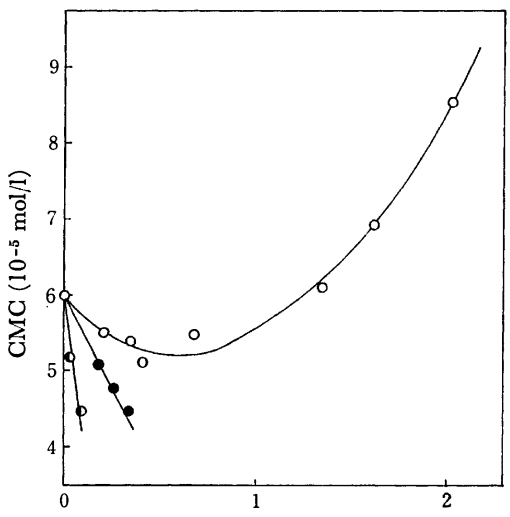

Fig. 4. The CMC's of $\bar{n}=6$ surfactant as a function of the concentrations of *n*-propanol (○), *n*-butanol (●) and *n*-pentanol (◐) at 20 °C.

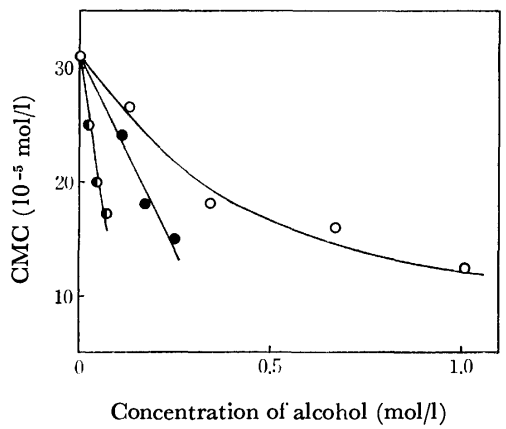

Fig. 5. The CMC's of $\bar{n}=31$ surfactant as a function of the concentrations of *n*-propanol (○), *n*-butanol (●) and *n*-pentanol (◐) at 20 °C.

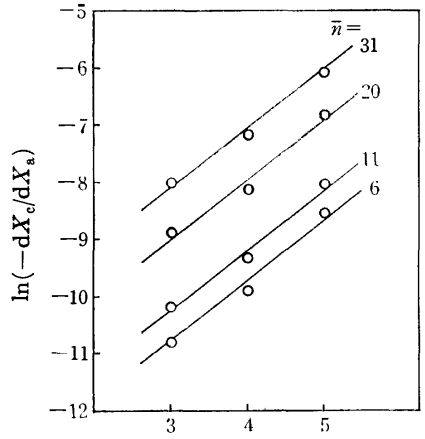

Fig. 6. The logarithm of the rate of change of the CMC with alcohol concentration, $\ln(-dX_c/dX_a)$ *vs.* the number of carbon atoms in alcohol, *m'*.

a mixed micelle.[16] At higher concentrations of *n*-propanol, the CMC-increasing effect overcomes the decreasing effect. This is due to the solvent effect as in the case of methanol and ethanol, although it is not seen in the case of *n*-butanol and *n*-pentanol. The CMC initially decreases linearly with alcohol concentration, which resembles closely the case of ionic surfactants (Figs. 4 and 5). The CMC-decreasing effects of alcohols have been explained by Shinoda in the case of ionic surfactants.[16] His view is herewith applied to the case of nonionic surfactants.

We take the phase separation model, equating the chemical potential of the surfactant molecule in the micelle phase to that in the bulk phase, assuming that the standard chemical potentials in water and alcohol–water system are approximately the same if the concentration of alcohols added is sufficiently low. We then have

$$\frac{X_c'}{X_c} = 1 - x; \quad x \ll 1 \tag{3}$$

where x is the mole fraction of alcohol in the mixed micelle, and X_c and X_c' are the CMC in the mole fraction unit in water and in the mixed solvent, respectively. Alcohols are considered to undergo partition between the micellar and bulk phase. The partition law is as follows.

$$\frac{X_a}{x} = K\exp\left(-\frac{m'\omega}{kT}\right); \quad X_a \ll 1 \tag{4}$$

where K is a constant, m' the number of carbon atoms in an alcohol, and ω the free energy change per methylene group transferred from water into the micelle phase. Near the CMC, the amount of solubilized alcohol is negligible. Thus, X_a can be put equal to the mole fraction of alcohol in the aqueous surfactant solution.

From Eqs. (3) and (4) we get

$$\ln\frac{X_c - X_c'}{X_a} = \ln X_c + \frac{m'\omega}{kT} - \ln K$$
$$= \ln X_c + 1.1m' - \ln K \tag{5}$$

where the value of ω is adopted to be $1.1\,kT$.[32,33]

This gives the relation between the logarithm of the rate of change of CMC with alcohol concentration, $\ln(-dX_c/dX_a)$, and the number of carbon atoms in alcohol, m'. The former, obtained from experimental data is plotted against the latter in Fig. 6. The values of the gradients of these plots are close to 1.1, the experimental data fitting Eq. (5) fairly well. The value of K obtained for each $\bar{n}$ is:

$\bar{n}$	6	11	20	41
K	1.57	1.51	0.64	0.55

It can be seen from Eq. (4) that x is inversely proportional to K when m' and X_a are fixed. We see that the surfactant with a larger oxyethylene chain length has a greater mole fraction of alcohol in mixed micelle. It seems that the surfactant solution with larger $\bar{n}$ solubilizes the alcohols to a greater extent. The result for *n*-propanol reflects the situation. At higher concentrations of alcohol, the CMC-increasing effect overcomes the CMC-decreasing effect on account of the increase of non-solubilized alcohol. It is seen that the CMC-increasing effect of *n*-propanol is more enhanced for the smaller $\bar{n}$, the CMC-decreasing effect prevailing for the larger $\bar{n}$ (Figs. 4 and 5). The results indicate that the CMC-decreasing effect (solubilization effect) increases with the increase of oxyethylene chain length. This conclusion agrees with Cohen's result in the case of *n*-heptanol.[34]

We express our hearty thanks to Kao Soap Co., Ltd. for the supply of nonionic surfactants.

An Ultrasonic Method for Determination of the Volume Change Due to Internal Rotation in 1,2-Dichloroethane

Masakatsu Aoi and Kiyoshi Arakawa

Research Institute of Applied Electricity, Hokkaido University, Sapporo 060

(Received March 6, 1974)

A simple method for determining the volume change, ΔV, in conformational isomerism from sound velocity has been worked out from the theory of binary mixtures. The method was applied for obtaining the volume change due to internal rotation in 1,2-dichloroethane. The sound velocity was measured with an ultrasonic interferometer. The method was found useful.

The conformational equilibrium of halogenated ethanes has long been the subject of study from the viewpoint of molecular structure theory, the equilibrium between *trans* and *gauche* forms of 1,2-dichloroethane (DCE) having been clarified.[1-4] The energy difference between them is nearly zero in a liquid state,[1] while the ratio N_g/N_t in this state is 1.93 at room temperature, where N_g is the number of *gauche* molecules and N_t that of *trans* molecules.[3]

The molecular interaction in binary mixtures including DCE has been investigated by various methods such as the Raman effect, infra-red[2-5] and NMR[6] spectroscopy, and dielectric,[7-13] thermodynamic[14-20] and ultrasonic[21-25] methods.[26] However, the essential feature of the interactions between DCE and other compounds such as benzene has been a topic of controversy. Findenegg and Kohler[18,19] and Kiyohara and Arakawa[25] studied the DCE–benzene system by means of an ultrasonic method using theory of solutions, and Higasi *et al.*[12,13] by means of a dielectric method. Their conclusions did not agree.

In the above studies the volume change in conformational isomerism between *trans* and *gauche* forms of DCE[2,8,18,25] has not been taken into consideration, which seriously influences the determination of the magnitude of enthalpy difference ΔH and other thermodynamic quantities. This has been pointed out recently.[27-29]

Recent advancement in ultrasonic absorption technique made it possible to determine ΔV.[21] However, the determination is impossible when the frequency range does not cover the relaxation range of the system to be studied, the error being fairly large. ΔV has been usually neglected in studies of conformational equilibrium in which the assumption $(\Delta V/V)(C_p/\alpha) \ll \Delta H$ is valid.[21]

It has been reported[30] that the magnitude of $\Delta V/V$ in conformational isomerism for 1,1,2-trichloroethane (TCE) and other compounds in various solvents is 1—3%, but DCE was not included in the studies. We have undertaken to apply a simple method for obtaining ΔV from sound velocity on the basis of theory of solutions to DCE.

Method of Analysis

The solution of Percus-Yevick equation for binary liquid mixtures was given as follows.[31,32]

$$\frac{p}{kT} = \frac{1}{(1-\xi)^3}\left[(\rho_1+\rho_2)(1+\xi+\xi^2) - \frac{18}{\pi}\eta_1\eta_2(R_1-R_2)^2 \times \{R_1+R_2+R_1R_2(\eta_1R_1^2+\eta_2R_2^2)\}\right] \quad (1)$$

where R_i is the hard core diameter of i-th component, p pressure, T temperature, $\rho_i = N_i/V$ number density, $\eta_i = \pi\rho_i/6$, and ξ the volume fraction defined by

$$\xi = (\pi/6)(\rho_1R_1^3+\rho_2R_2^3). \quad (2)$$

We express here R_i as follows

$$R_1 = R,\ R_2 = R(1+\delta). \quad (3)$$

In actual cases of conformational equilibrium, δ is taken to be smaller than 0.1, thus Eq. (1) becomes

$$\frac{p}{kT} = \frac{1}{(1-\xi)^3}\left[\rho(1+\xi+\xi^2) - \frac{\pi}{2}x_1x_2R^3\rho^2\delta^2\left\{2+\frac{\pi}{6}R^3\rho + \delta\left(1+\frac{\pi}{6}R^3\rho(x_1+3x_2)\right) + \delta^2\left(\frac{\pi}{2}R^3\rho x_2\right) + \delta^3\left(\frac{\pi}{6}R^3\rho x_2\right)\right\}\right] \quad (4)$$

where $x_i = N_i/(N_1+N_2) = N_i/N$.

In order to obtain the isothermal compressibility κ_T defined by

$$\kappa_T = -\frac{1}{V}\left(\frac{\partial V}{\partial p}\right)_T = -\left(\frac{\rho}{N}\right)\left(-\frac{N}{\rho^2}\right)\left(\frac{\partial \rho}{\partial p}\right)_T = \frac{1}{\rho}\left(\frac{\partial \rho}{\partial p}\right)_T \quad (5)$$

Equation (4) is differentiated with respect to pressure, and we obtain

$$\frac{1}{kT} = \left(\frac{\partial \rho}{\partial p}\right)_T \frac{(1+2\xi)^2}{(1-\xi)^4}\left[1 - \frac{(\pi/2)x_1x_2R^3\rho\delta^2}{(1+2\xi)^2}\left\{4+2\xi+\frac{\pi}{2}R^3\rho + \delta\left(2+\xi+\frac{\pi}{2}R^3\rho(x_1+3x_2)\right) + \delta^2\left(\frac{3\pi}{2}R^3\rho x_2\right) + \delta^3\left(\frac{\pi}{2}R^3\rho x_2\right)\right\}\right]. \quad (6)$$

The magnitude of ξ is the order of 0.5, and

$$(\pi/6)R^3\rho < 1,\quad x_1x_2 \leqq 0.25.$$

Thus

$$(\pi/2)x_1x_2R^3\rho/(1+2\xi)^2 < 0.2,$$

$$4 + 2\xi + (\pi/2)R^3\rho < 8.$$

The second term in the bracket [ ] in Eq. (6) is much smaller than 0.02, and can be neglected in comparison with the first term, 1.

Thus we get

$$\frac{1}{kT} = \left(\frac{\partial \rho}{\partial p}\right)_T \frac{(1+2\xi)^2}{(1-\xi)^4}. \quad (7)$$

$\kappa_{T,0}$ which is attributed to repulsive forces only is

derived from Eqs. (5) and (7).

$$\kappa_{T,0} = \frac{1}{\rho kT}\frac{(1-\xi)^4}{(1+2\xi)^2} = \frac{\pi a^3}{6kT}\frac{(1-\xi)^4}{\xi(1+2\xi)^2}, \quad \delta<0.1 \tag{8}$$

Here, ξ is treated as follows

$$\xi = \frac{\pi}{6}(\rho_1 R_1^3+\rho_2 R_2^3) = \frac{\pi}{6}\frac{N_1R_1^3+N_2R_2^3}{V}$$
$$= \frac{\pi N(N_1R_1^3+N_2R_2^3)}{6V(N_1+N_2)} = \frac{\pi}{6}\rho\langle R_i^3\rangle = \frac{\pi}{6}\rho a^3,$$
$$\langle R_i^3\rangle \equiv a^3 \tag{9}$$

ξ is denoted by the "average hard core diameter" a, and indicates the "fraction of the hard core volumes of all molecules to whole volume of the mixture". Equation (8) is formally identical with the formula for a pure liquid derived by Reiss.[33]

Equation (1) is approximated as follows according to the above procedure.

$$\frac{p}{kT} = \left[\frac{1+\xi+\xi^2}{(1-\xi)^3}\right]\rho, \quad \delta<0.1 \tag{10}$$

This formula also agrees formally with that for a pure liquid,[33-36] ξ having the same expression and physical meaning as defined in Eq. (9).

It is necessary to consider the attractive forces, since the repulsive force only is considered in the above treatment. The average attractive potential is given by

$$-\langle U_N\rangle_{av.} = N\chi_0 = \Delta H_{vap.} - pV_{gas} = \frac{\text{const.}}{V^n} \tag{11}$$

where $\Delta H_{vap.}$ is enthalpy of vaporization and $n=1$ for van der Waals liquids.

The partition function for liquids is given by

$$Z = \left(\frac{2\pi mkT}{h^2}\right)^{3N/2} Q \exp(N\chi_0/kT) \tag{12}$$

where Q denotes the configurational integral.[17] It is well-known that

$$\left(\frac{\partial p}{\partial V}\right)_T = kT\left(\frac{\partial^2 \ln Z}{\partial V^2}\right)_T. \tag{13}$$

κ_T is obtained from Eqs. (5), (12), and (13) as follows.

$$\kappa_T = \left[-VkT\left(\frac{\partial^2 \ln Q}{\partial V^2}\right) - NV\left(\frac{\partial^2\chi_0}{\partial V^2}\right)\right]^{-1}$$
$$= \left[\frac{1}{\kappa_{T,0}} - \frac{2}{V}(\Delta H_{vap.}-RT)\right]^{-1}$$
$$= \left[\frac{RT}{V}\frac{(1+2\xi)^2}{(1-\xi)^4} - \frac{2}{V}(\Delta H_{vap.}-RT)\right]^{-1} \tag{14}$$

Adiabatic compressibility κ_S can be obtained from sound velocity, and isothermal compressibility κ_T from κ_S by means of the relation

$$\kappa_S = \frac{1}{\rho v^2}, \quad \kappa_T = \kappa_S + \frac{TV\alpha^2}{C_p} \tag{15}$$

where ρ is density in g/cm^3, v sound velocity, V molar volume of liquid, α thermal expansion coefficient, and C_p molar heat capacity.

When the values of κ_T and $\Delta H_{vap.}$ are substituted into Eq. (14), ξ can be evaluated, and we obtain the "average hard core diameter".

Thus, when the hard core diameter of one component in binary mixtures is known, that of another component is determined by Eq. (9).

Experimental

DCE (guaranteed reagent, Nakarai Chemicals Ltd.) was used with further purification.[37] Sound velocity was measured with an interferometer working at 3MHz.[25] Density was measured with a pycnometer. Measurements were carried out at 15—45 °C at 5 °C intervals. The temperature was controlled within ±0.05 °C. The results obtained were compared with the data in the literature (Table 1). The observed sound velocity agrees with the literature data, the accuracy being within 0.5 m/s.

Table 1. Comparison of observed values of sound velocity v (m/s) and adiabatic compressibility κ_S(10^{-12}cm^2/dyn) at 20 °C with literature values

	v	κ_S	Lit.

	1213.2	54.2_3	19
	1213.5	54.2_0	25
		56.0	15

Results

The following values have been used in the calculation: α, 1.162×10^{-3} deg^{-1}; C_p, 129 J/mol deg; and $\Delta H_{vap.}$, 34.31 kJ/mol (Table 2). The value of N_g/N_t is taken to be 1.93 for DCE.[3]

The experimental values of κ_S and κ_T have been obtained from observed values of v. Values of hard core volume $\pi a^3/6$ have been determined from those of κ_T by Eq. (14) and are given in Table 3, the last row giving the average value of *trans* and *gauche* molecules.

The hard core volume of *trans* molecule V_t has been determined from X-ray analysis of solid DCE,[38] in which all molecules are known to be in the *trans* state,[1] and also from other molecular structure data.[39,40] The value of V_t obtained from various sources is found to be 78.5×10^{-24} cm^3 per molecule.

V_g is estimated to be 59.8×10^{-24} cm^3 from Eq. (9), and $\Delta V/V_t$ 23.8% from the values of $\pi a^3/6$ and V_t.

Discussion

ΔV was not considered in previous studies owing to the lack of data.[2,8,18,25] Verma and others pointed out that the value of ΔV plays an important role in the determination of ΔH.[27] According to their estimation, if $\Delta V/V$ in methylcyclohexane increases from 0 to 10%, ΔH varies from 2.9 to 6.0 kcal/mol and other thermodynamic quantities also vary drastically.

In studies on dipolar and multipolar interactions in liquid state having various forms of isomers,[6] the influence of ΔV has often been neglected. The estimation of molecular interaction energy attributed to dipolar and quadrupolar fields is greatly affected by the estimation of ΔV. The difference of molecular volumes between various isomers affects the determination of molecular interaction energy a great deal. Thus the knowledge of ΔV in conformational isomerism is necessary to estimate ΔH and other thermodynamic variables exactly, and to explain the nature of the molecular interaction.

ΔV is determined by ultrasonic absorption technique.[21] However, determination is impossible when the frequency range of the apparatus does not cover the relaxation range of the system under investigation. In many cases conformational equilibrium was studied on the assumption,[21] $(\Delta V/V)(C_p/\alpha)\ll\Delta H$. In the case of DCE in liquid state, this does not hold since ΔH is nearly zero.[1]

The $\Delta V/V$ in conformational isomerism for TCE and other compounds in various solvents has been reported to be 1—3%,[30] but DCE was not included. The error is 50%.

In order to determine ΔV for liquid DCE, we should know the value of V_t. We can obtain V_t from the results of studies on solid DCE, in which all the molecules are known to be in the *trans* state.[1] The value of V_t can be obtained from X-ray analysis of solid DCE and other data.[38-40]

In solid DCE, the volume assigned to one molecule is found to be 106×10^{-24} cm^3 from its density.[38] Taking the magnitude of packing parameter to be 0.7405[41] (face-centered cubic), we estimate the value of V_t to be 78.5×10^{-24} cm^3. This value is regarded as an "equivalent" hard core volume of the molecule in a close-packed state.

On the other hand, DCE is assumed to be a rotational ellipsoid having a major axis of 6.90 Å and a minor axis of 4.68 Å from diffraction data.[38-40] The Cl–Cl distance estimated from X-ray data is 4.24 Å and the diameter of Cl atom 2.66 Å,[42] and we can thus estimate the major axis of the ellipsoid to be 6.90 Å. The minor axis is estimated from (1, 0, 0) projected surface, the most dense one.[38] V_t is thus calculated to be 79.1×10^{-24} cm^3 per molecule. This agrees with the value calculated from density. Thus the value 78.5×10^{-24} cm^3 is chosen for V_t.

The ratio N_g/N_t is also necessary for determining ΔV. The value is found from studies of molecular structure theory to be in the range 1.90—1.93 at room temperature.[1,3] We have used the value 1.93.[3] The fluctuation of ΔV for variation of N_g/N_t is very small, being of the order 0.1%.

The calculated hard core volume of DCE in the liquid state is held constant in the range 15—45 °C (Table 3), which shows the validity of the present method. It would be noted that the fraction N_g/N_t remains constant within the range of temperature in this study.

The value of $\Delta V/V_t$ is *ca.* 20%. The error is mainly due to the uncertainty in the determination of V_t. It is certain that the value for DCE is larger by one order than that for TCE, found to be 1—3% by Wyn-Jones *et al.*[30]

The authors thank Mr. Nobuo Takenaka for his help in carrying out this study.

41) The value of V_t needed is that of the "equivalent" hard core volume in thermal motions which is statistically defined. Thus we chose the value of packing parameter to be 0.7405 for the closest packing in spite of the fact that the crystal form of solid DCE is known to be monoclinic.
42) The radius of Cl atom is assumed to be equal to that of K^+, 1.33 Å.[40]

The Circular Dichroism and Magnetic Circular Dichroism Spectra of Bis(stilbenediamine) nickel(II) Complexes

Sumio ARAKAWA, Tsunenori NOZAWA, and Masahiro HATANO
Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Sendai 980
(Received September 19, 1973)

The temperature dependence of the absorption and circular dichroism spectra for $[Ni((+)\text{-stien})_2](ClO_4)_2$ is indicative of the equilibrium between the square planar (yellow) and tetragonal (violet) species in acetone solutions. On the other hand, the square planar species is predominant in a methanol solution, even at room temperature, in the case of $[Ni(meso\text{-stien})_2](ClO_4)_2$. The Cl^- as a counter anion favored an equilibrium slightly displaced to the tetragonal species. The analysis of the CD and MCD bands suggests an ordering of the d-orbital energy levels of $d_{x^2-y^2} \gg d_{z^2} > d_{xz}, d_{yz} > d_{xy}$.

Despite considerable efforts, the spectra exhibited by d^8 square planar complexes are still imperfectly understood. It was only recently that some workers[1-4] have demonstrated the usefulness of magnetic circular dichroism (MCD) studies in obtaining spectroscopic information about the d^8 square planar complexes. The main features of the theory of the dispersion of MCD through absorption (AB) bands have previously been reviewed.[5-7] For AB bands which are too broad to assign, MCD is definitely superior, so the MCD spectra of $[Ni(meso\text{- and } (+)\text{-stien})_2]X_2$, where X=Cl and ClO_4, were measured in this study.

On the other hand, the optical rotatory dispersion and circular dichroism (CD) spectra for the violet and yellow forms of $[Ni((-)\text{-stien})_2]^{2+}$ have been measured by Lifschitz *et al.*[8] and Bosnich *et al.*[9] respectively. Bosnich and his colleagues analyzed the electronic structure of the yellow complexes and suggested an energy scheme.

It is well known[10] that Lifschitz's complexes with the general fomula of $[Ni(meso\text{-stien})_2]X_2$, where X is the anion of an organic acid, are present as equilibrium mixtures of the blue or violet and yellow forms under a variety of conditions.

In this study, we found that the equilibrium between the violet and yellow forms occurs more easily in an acetone solution of optically-active $[Ni((+)\text{-stien})_2](ClO_4)_2$, than in a methanol solution of optically-inactive $[Ni(meso\text{-stien})_2](ClO_4)_2$.

Experimental

Materials. The *meso*-stilbenediamine(*meso*-stien) (Calcd for $C_{14}H_{16}N_2$: C, 79.32; H, 7.61; N, 13.21%. Found: C, 79.16; H, 7.67; N, 12.58%) and (+)-stien ($[\alpha]_D = 185°$ (in ether)) were prepared by the methods of Irving and Parkins[11] and of Lifschitz and Bos[12] respectively. The $[Ni(meso\text{-stien})_2]Cl_2$ (Calcd for $NiC_{28}H_{32}N_4Cl_2$: C, 60.75; H, 5.83; N, 10.12%. Found: C, 60.81; H, 5.82; N, 9.98%), $[Ni(meso\text{-stien})_2](ClO_4)_2$ (Calcd for $NiC_{28}H_{32}N_4Cl_2O_8$: C, 49.34; H, 4.73; N, 8.22; Cl, 10.40%. Found: C, 49.19; H, 4.67; N, 8.15; Cl, 10.02%), and $[Ni((+)\text{-stien})_2](ClO_4)_2$ (Calcd for $NiC_{28}H_{32}N_4Cl_2O_8$: C, 49.34; H, 4.73; N, 8.22; Cl, 10.40%. Found: C, 49.21; H, 4.72; N, 8.25; Cl, 9.97%) were prepared by the method of Lifschitz, Bos, and Dijkema.[8]

Measurements. The CD and MCD measurements were made with a JASCO model 20A dichrograph equipped with an electromagnet. The magnetic field was set at 12500 G in the case of the MCD measurements. The electronic absorption spectra were measured by using a Hitachi EPS-3T recording spectrophotometer. The spectra at 0.8 °C were measured by using jacketed cells regulated with circulating water held at a constant temperature. The spectra at −75 °C were measured by the use of a quartz-Dewar designed in our laboratory. The temperatures were measured directly using a thermometer.

Results and Discussion

The Temperature Dependence of the AB and CD Spectra of Bis((+)-stien)nickel (II) Diperchlorate in an Acetone Solution. The temperature dependence of the AB spectrum for $[Ni((+)\text{-stien})_2](ClO_4)_2$ in an acetone solution is shown in Fig. 1. The AB bands at 22500, 11300, 18000, and 28000 cm^{-1} are denoted as AB bands—Y, V_1, V_2, and V_3 respectively. As the temperature of the $[Ni((+)\text{-stien})_2](ClO_4)_2$ acetone solution is raised, the intensity of the Y AB band increases, while that of the V_1 AB band decreases. The lack of isosbesticity and the variation in the intensity of the V_2 and V_3 bands may be due to experimental errors. It is well known that the V_1, V_2, and V_3 AB bands are attributable to the violet paramagnetic species, while the Y AB band is due to the yellow diamagnetic species. The temperature dependence and reversibility of the variation in intensity for each AB band lead us to expect the occurrence of the following equilibrium for $[Ni((+)\text{-stien})_2](ClO_4)_2$ in an acetone solution:

$$[Ni((+)\text{-stien})_2]^{2+} + 2S \rightleftarrows [Ni((+)\text{-stien})_2 \cdot 2S]^{2+} \quad (1)$$

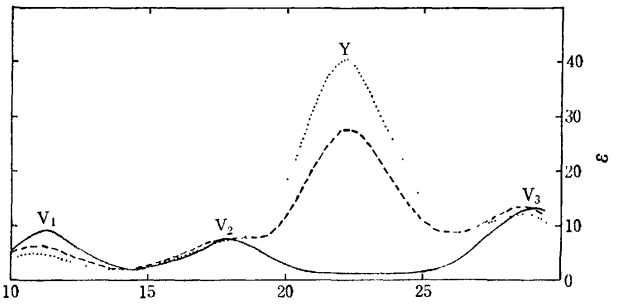

Fig. 1. AB spectra for $[Ni((+)\text{-stien})_2](ClO_4)_2$ in an acetone solution at +21 (·····), +0.8 (- - -), and −75 °C (——). Y and V denote the AB bands ascribed to the yellow and violet complexes, respectively.

where S is an acetone molecule. As the temperature increases, the equilibrium in Eq. (1) is shifted to the left side. Thus, the relative quantity of the violet species of the nickel(II) complex decreases with a rise in the temperature. It should be added that [Ni((+)-stien)$_2$]$^{2+}$ gives the violet species in a methanol solution, even at room temperature,[13] which means that methanol will coordinate to the [Ni((+)-stien)$_2$]$^{2+}$ much more strongly than will acetone.

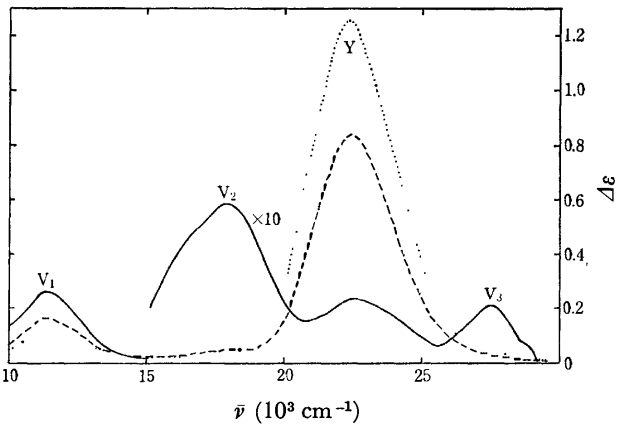

Fig. 2. CD spectra for [Ni((+)-stien)$_2$](ClO$_4$)$_2$ in an acetone solution at +21 (·····), +0.8 (-----), and −75 °C (——). Y and V denote the CD bands ascribed to the yellow and violet complexes, respectively.

The occurrence of the equilibrium discussed above was also confirmed by means of the CD spectra. In Fig. 2 the CD bands at 22500, 11400, 18000, and 27500 cm^{-1} are denoted as the Y, V_1, V_2, and V_3 CD bands respectively, corresponding to the AB bands.

First, it should be noted that the shape of the V_1, V_2, and V_3 CD bands are not symmetric, which suggests that they contain more than one transition. On the assumption of the octahedral (O_h) local symmetry of the complex, the V_1, V_2, and V_3 CD bands can be assigned to three spin-allowed d-d transitions $^3A_{2g}\rightarrow{}^3T_{2g}$, $^3A_{2g}\rightarrow{}^3T_{1g}$ (F), and $^3A_{2g}\rightarrow{}^3T_{1g}$ (P) respectively. However, in view of the facts that the violet complex [Ni((+)-stien)$_2$·2S]$^{2+}$ is presumably six-coordinated with the environment of *trans*-NiN$_4$O$_2$ with the two oxygen atoms furnished by acetone, and that these CD bands seem to contain more than one transition, the symmetry of the ligand field may be anticipated to be an octahedron elongated along the *z*-axis—namely, tetragonal (D_{4h}). The assignment of the CD bands can thus be examined as follows, assuming the D_{4h} symmetry. In this symmetry, the $^3T_{2g}$ and $^3T_{1g}$ levels of an octahedral complex split into $^3B_{2g}+{}^3E_g$ and $^3A_{2g}+{}^3E_g$ levels, respectively (see Fig. 3). According to Fig. 3, three CD bands, V_1, V_2, and V_3, can thus be assigned to spin-allowed transitions—$^3B_{1g}\rightarrow(^3E_g, {}^3B_{2g})$, $^3B_{1g}\rightarrow(^3A_{2g}, {}^3E_g)$, and $^3B_{1g}\rightarrow(^3E_g, {}^3A_{2g})$ respectively. The magnetic dipole forbidden transition, $^3B_{1g}\rightarrow{}^3A_{2g}$, in D_{4h} seems to appear as a shoulder in the V_2 and V_3 CD bands. This possibly implies that [Ni((+)-stien)$_2$·2S]$^{2+}$ contains lower symmetry components than does D_{4h}.

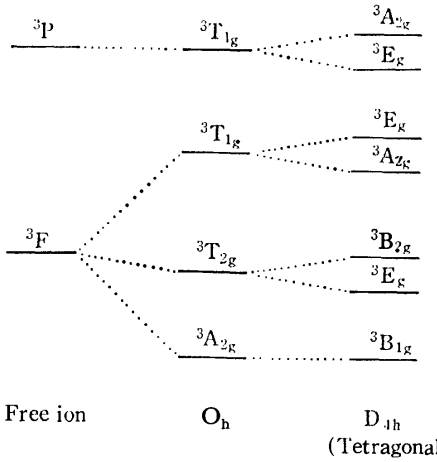

Fig. 3. Correlation diagram (Spin triplet only) for a d^8 ion in an octahedral (O_h) and tetragonal (D_{4h}) field.

Secondly, it should be noted that the shape of the Y CD band, which is characteristic of the yellow diamagnetic square planar complexes, is not symmetric. Although the Y CD band has already been assigned by Bosnich *et al.* for complexes of Ni(II) with (+)-propylenediamine,[9] we reassigned this CD band using the same line of reasoning as was employed. For the spin-paired Ni(II) complexes in a ligand field of approximately D_{4h} symmetry, three bands resulting from the $d_{xy}\rightarrow d_{x^2-y^2}$ ($^1A_{1g}\rightarrow{}^1A_{2g}$), $d_{xz}, d_{yz}\rightarrow d_{x^2-y^2}$ ($^1A_{1g}\rightarrow{}^1E_g$), and $d_{z^2}\rightarrow d_{x^2-y^2}$ ($^1A_{1g}\rightarrow{}^1B_{1g}$) transitions, may be expected in almost the same wave number region (Fig. 6). Only the first two transitions are magnetic-dipole allowed transitions. The Y CD band, centered around 22500 cm^{-1}, is situated on the higher-frequency side of the AB band (ν_{max}=22200 cm^{-1}). On the higher-frequency side of the Y CD band, its anisotropy factor ($\Delta\varepsilon/\varepsilon$) is about 0.03, while on the lower-frequency side, below 22200 cm^{-1}, it decreases below 0.03. This trend was also observed in other solvents such as nitromethane and ethylacetate.[15] This suggests that the apparently single Y CD band contains two transitions. The magnetic dipole-allowed transitions, $^1A_{1g}\rightarrow{}^1A_{2g}$ and $^1A_{1g}\rightarrow{}^1E_g$, are well-separated and give strongly negative and moderately negative CD bands respectively in the case of *trans*-[Co((−)-stien)$_2$Cl$_2$]ClO$_4$.[16] If we can assume that the similarity concerning the relative CD magnitudes with opposite signs will also be observed in the corresponding transitions for the square planar [Ni((+)-stien)$_2$](ClO$_4$)$_2$, it can be expected that the strongly positive and moderately positive CD bands are to be assigned to the $^1A_{1g}\rightarrow{}^1A_{2g}$ and $^1A_{1g}\rightarrow{}^1E_g$ respectively in the [Ni((+)-stien)$_2$]$^{2+}$ complex. The large amount of overlap between these transitions is believed to account for the apparently single band with a dissymmetric shape. This assignment suggests that the d_{xy} orbital lies below the degenerate d_{xz}, d_{yz} orbitals in the yellow diamagnetic species of [Ni((+)-stien)$_2$](ClO$_4$)$_2$.

MCD Spectra of Bis(stien)nickel(II) Complexes. Figure 4 shows the MCD spectra for the [Ni((+)-stien)$_2$](ClO$_4$)$_2$, along with its AB spectra. As was discussed in the previous section, both the yellow dia-

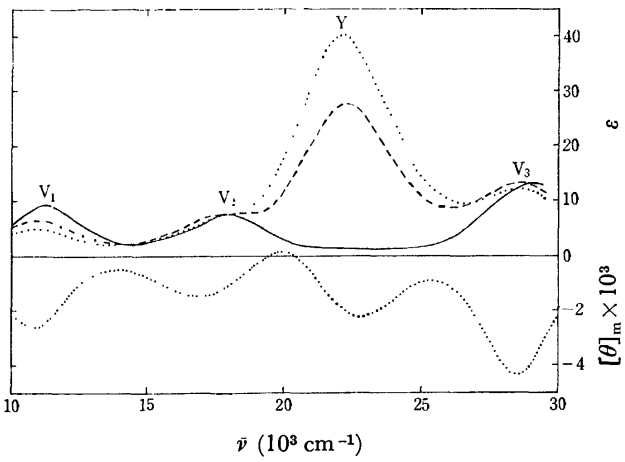

Fig. 4. AB and MCD spectra for [Ni((+)-stien)$_2$]-(ClO_4)$_2$ in an acetone solution at +21 (·····), +0.8 (------), and −75 °C (——). Y and V denote the AB bands ascribed to the yellow and violet complexes, respectively.

magnetic and violet paramagnetic species are present in an acetone solution at 21 °C. The temperature-variation studies of the AB and CD spectra in Figs. 1 and 2 indicate that the violet paramagnetic species is predominant in an acetone solution at −75 °C. The CD magnitude ($\Delta\varepsilon$) for the V_1 band, then, gives the approximate percentage of the violet paramagnetic species present. The calculation shows that the molar ratio of the violet paramagnetic species to that of the yellow diamagnetic species is 1 : 2 at 21 °C in an acetone solution. Hence, the MCD spectra in an acetone solution at 21 °C (Fig. 4) reveal that the MCD intensity of the V_3 band is about four times stronger than that of the negative band, Y.

Figure 5 shows the MCD spectrum for the [Ni-(*meso*-stien)$_2$](ClO_4)$_2$ in a methanol solution. Though methanol is a solvent which gives the violet species more preferably than acetone, the [Ni(*meso*-stien)$_2$](ClO_4)$_2$ in a methanol solution does not show any MCD due to the main violet species band (V_3) at around 27000 cm^{-1}. The most plausible reason why [Ni(*meso*-stien)$_2$](ClO_4)$_2$ tends to give the yellow species more easily than [Ni((+)-stien)$_2$](ClO_4)$_2$ seems to be a steric effect; that is, the axial phenyl group in the complexes will exert more steric hindrance toward the axial ligands than will the equatorial one. The molecular model and the X-ray analysis indicate that one of the phenyl groups in a *meso*-stien of the Ni(II) complex will be in an axial position, and the other in an equatorial position, relative to the NiN_4 plane in the [Ni(*meso*-stien)$_2$](ClO_4)$_2$, while both phenyl groups of (+)-stien in the [Ni((+)-stien)$_2$](ClO_4)$_2$ will be in equatorial positions in an energetically-favored form.[17]

It has been reported by Kobayashi[4] that the A term MCD in the diamagnetic yellow Ni(II) complex shows a normal A-term dispersion. If this is also the case for the yellow diamagnetic [Ni(*meso*-stien)$_2$](ClO_4)$_2$, the positive part for a normal A term will be nearly the positive peak at around 21500 cm^{-1}. Hence, three possibly B terms above, at and below the transition for the A term, are necessary to explain the experimental MCD curve for the [Ni(*meso*-stien)$_2$](ClO_4)$_2$ in Fig. 5. Thus, the MCD for [Ni(*meso*-stien)$_2$](ClO_4)$_2$ may be considered to consist of a normal A term with three possibly B terms with lower, the same, and higher transition energies. These MCD results suggest that the degenerate transition may be in the middle of the two nondegenerate transitions. This MCD assignment with the CD assignment for the yellow diamagnetic [Ni((+)-stien)$_2$](ClO_4)$_2$, as described in the previous

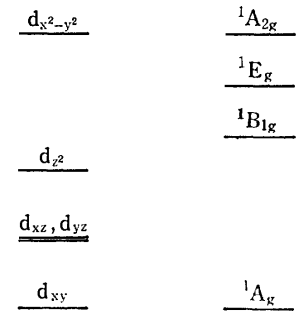

Fig. 6. Ordering of the d-orbital energy levels and the energy level diagram for a d^8 ion in a square-planar (D_{4h}) field.

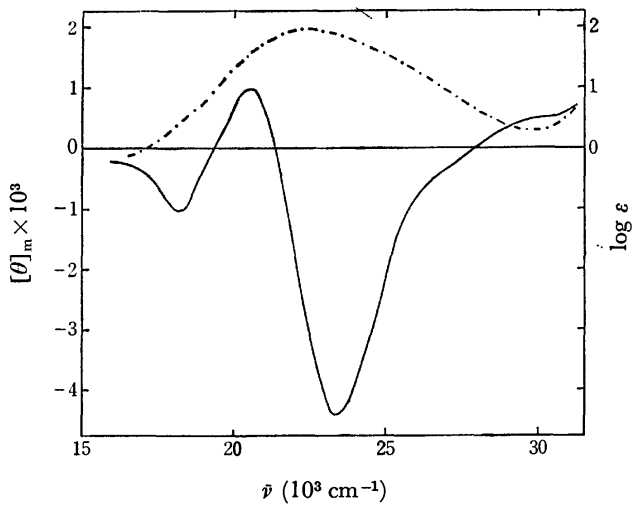

Fig. 5. AB (·····) and MCD (——) spectra for [Ni-(*meso*-stien)$_2$] (ClO_4)$_2$ in a methanol solution at room temperature.

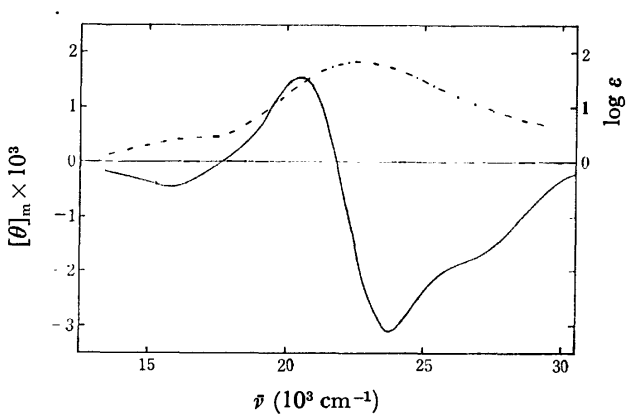

Fig. 7. AB (·····) and MCD (——) spectra for [Ni-(*meso*-stien)$_2$]Cl_2 in a methanol-water (4: 1) solution at room temperature.

section, implies an energy order of the d-orbital of $d_{z^2}>d_{xz}$, $d_{yz}>d_{xy}$. (Fig. 6)

The effect of counter anions on the equilibrium between the yellow diamagnetic and violet paramagnetic species was examined using [Ni(*meso*-stien)$_2$]-Cl_2, the MCD and AB spectra of which are shown in Fig. 7. Figure 7 indicates that the [Ni(*meso*-stien)$_2$]Cl_2 in a methanol-water solution has the violet paramagnetic species besides the yellow diamagnetic species, and that the ratio of the former to the latter is about 1 : 8. The existence of the violet paramagnetic species in the case of [Ni(*meso*-stien)$_2$]Cl_2 in a methanol-water solution at room temperature should be compared with the finding that [Ni(*meso*-stien)$_2$]$(ClO_4)_2$ has no violet paramagnetic species under the same conditions. This might be attributed to the greater bulkiness of ClO_4^- in comparison with that of Cl^-.

The authors wish to thank Professors Taro Isobe, Nobuyuki Tanaka, Kazuo Saito, and Junnosuke Fujita of Tohoku University for their useful discussions. A part of the expense for this work was defrayed by a grant from the Ministry of Education, to which the authors' thanks are due.

The Solubility Study of Ion-pairs in Organic Solvents

Takejiro TAKAMATSU

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606

(Received January 5, 1974)

The solubilities of alkali picrates were measured in alcohols (13 species) and esters (19 species) at 25±0.2°C. It was found that the solubility data are well correlated with the solubility parameters of the solvents. It is also pointed out that the distribution ratios of the cesium picrate between the aqueous phase and the organic phase are apparently correlated with the solubility parameters of the extraction solvents.

In a previous paper,[1] it was reported that the solubilities of such ion-pairs as chloride, perchlorate, and tetraphenylborate salts of alkali metals and Ru(II)-(phen)$_3$ could be well correlated with the solubility parameters of solvents (δ_2). In the potassium halide systems,[2] the best linearity was found between the logarithmic solubilities (log S) and $(\delta_1-\delta_2)^2$, where δ_1, corresponding to the hypothetical solubility parameters of the ion-pairs, was calculated to be $(U/V)^{1/2}$, (U: lattice energy of the ionic crystal; V: molar volume).

In the present paper, the solubilities of alkali picrates in 13 alcohols and 19 esters and the distribution ratios of cesium picrate in liquid-liquid partition systems were measured at 25±0.2°. Both sets of data are discussed in relation to the solubility parameters of solvents from the empirical point of view.

Experimental

Reagents. All the reagents used here were of a reagent-grade purity. The organic solvents were purified mainly by distillation, as has been described before.[1] The alkali picrates (K-Pic, Rb-Pic, Cs-Pic) were synthesized as follows. Picric acid was neutralized by the corresponding alkali carbonates in an acetone–water (1:1) mixture. The resulting precipitates were filtered and washed with water several times. After being recrystallized in water, the precipitates were dried *in vacuo* for 5 day.

Solubilities. The solubility measurements of alkali picrates were performed as follows: 10 ml portions of the organic solvents were placed in test tubes equipped with ground stoppers which contained appropriate amounts of the precipitates of alkali picrates. After the test tubes had been tightly sealed with parafilm, the solubility equilibria were established by shaking them in a thermostat at 25±0.2°C for 10 day. The solubilities were then measured spectrophotometrically (λ_{max}=355 nm, ε_{max}=16110).

Extraction. The distribution of the cesium picrate was investigated as follows: 1 ml of a 2.0×10^{-5} M aqueous Cs_2SO_4 solution (containing ^{137}Cs as a tracer) and 4 ml of the 3.62×10^{-4} M aqueous sodium picrate (in alcohols) or 4 ml of the 2.42×10^{-2} M aqueous sodium picrate (in esters) were placed in polypropylene test tubes equipped with silicone rubber stoppers. After 5 ml of the organic solvent had then been added, the test tube was shaken vigorously for 10 min at 25±0.2°C. After the two phases had been separated by centrifugation, the distribution ratio was calculated as the ratio of the γ-radioactivities of the two phases. The γ-radioactivities were counted by using a well-type single-channel pulse-height analyzer (Osaka Dempa, Model LA-3T). Measurements in both the solubility study and the extraction study were repeated three times; the averages of the results are given in the table and figures.

Results and Discussion

Relation between log S and δ_2. The observed solubilities of alkali picrates in organic solvents are listed in Table 1, together with the solubility parameters of the solvents (δ_2). The logarithmic solubilities (log S) are shown in Figs. 1 and 2 as a function of δ_2

a) Calculated by using ΔH_{25} values cited from the literature.[4] b) Calculated by using ΔH_{25} values estimated according to the Hildebrand rule.

*) $\delta_2=\left(\frac{\Delta H_{25}-RT}{V}\right)^{1/2}$

of the solvents. Although smooth correlations are obtained between log S and δ_2, a slight bending is observed for all the systems. Exceptional deviations from the curves are noticed in the two phenyl-substituted esters, *i.e.*, benzyl acetate and ethyl benzoate. The difference in slope was noticeable between the alcohol system and the ester system. Although no clear explanation can be given here, the difference may be due to the high δ_2 values of alcohols, which seem to be derived from the structural characteristics of alcohols, such as H-bonding.

Table 2. The calculated δ_1 values of ion-pairs

	r_c+r_a (Å)	U (kcal/mol)	V(ml)	δ_1
K-Pic	4.33	122.09	97.8	35.33
Rb-Pic	4.48	118.33	108.3	33.06
Cs-Pic	4.69	113.45	124.3	30.21

(●): K-Pic, (○): Rb-Pic, (◑): Cs-Pic

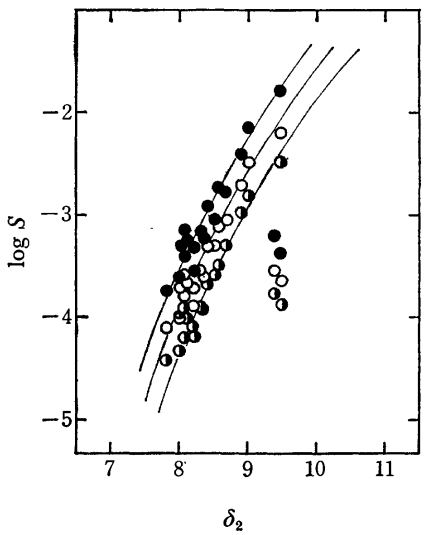

Fig. 2. The relation between log S and δ_2 in ester system.
(●): K-Pic, (○): Rb-Pic, (◑): Cs-Pic

Relation between log S and $(\delta_1-\delta_2)^2$. In order to find out a clearer correlation, the logarithmic solubilities (log S) were plotted against the difference in the solubility parameters of the solute and solvents as is shown in Figs. 3 and 4. The solubility parameters of the ion-pairs (δ_1) were approximated from the square root of the lattice-energy densities, $(U/V)^{1/2}$, as has been described in a previous paper.[2] In this calculation, 3.0 Å was used as the r_a value of the picrate anion.[3] The calculated values are shown in Table 2. As is shown in these figures, the plots, other than the two deviated plots in phenyl-substituted esters, give excellent straight lines.

(●): K-Pic, (○): Rb-Pic, (◑): Cs-Pic

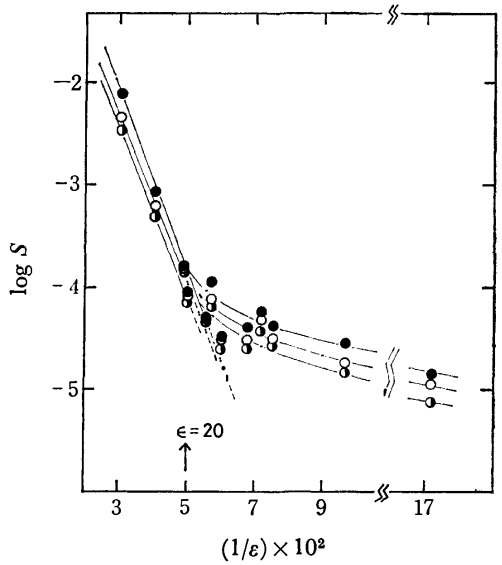

Fig. 5. The relation between log S and $1/\varepsilon$ in alcohol system.
(●): K-Pic, (○): Rb-Pic, (◑): Cs-Pic

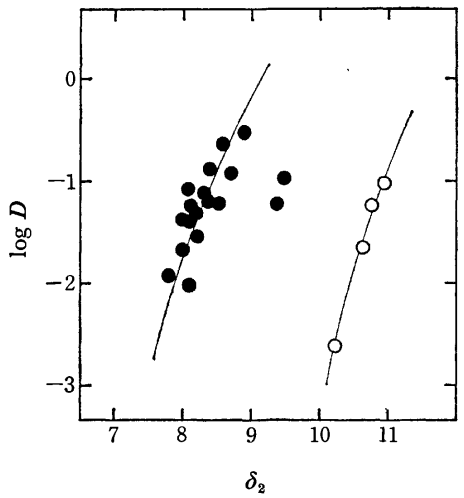

Fig. 6. The relation between log D and δ_2.
(○): alcohols, (●): esters

Relation between log S and 1/ε. In Fig. 5, for the sake of comparison one example of the plots between log S and the reciprocal of the dielectric constants ($1/\varepsilon$) of the solvents is shown in the alcohol system. Although a fairly good correlation is observed in the range of high dielectric constants ($\varepsilon \geq 20$), no lenear relationship holds in the range of low dielectric constants. The same pattern was also obtained in the ester system.

Relation between log D and δ_2. In Fig. 6, the logarithmic distribution ratios (log D) are plotted against the δ_2 values of the extraction solvents. The deviations of the solubility parameters, which are caused by the mutual solubilities of the two phases, are not taken into account here. However, it can be concluded that fairly good correlations hold between log D and δ_2.

Conclusion

In the ion-pair system whose cation and anion are bulky and possess quite a low charge density, the solubilities and the distribution ratios may both be predicted from the δ_2 values of the solvents, so long as one sort of solvent is used. However, no clear discussion with respect to the slopes of the plots is developed here because of the lack of data.

The author would like to express his thanks to Professor Taitiro Fujinaga and Dr. Mutsuo Koyama of Kyoto University for their helpful discussions and directions throughout the course of this study.

The Electrochemical Reduction of Purine in Nonaqueous Solvents

Toshio YAO and Sōichirō MUSHA

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Mozuumemachi, Sakai 591

(Received February 18, 1974)

The electrochemical reduction of purine, which is the model compound for the reduction of the biologically-important purine bases, has been investigated in nonaqueous solvents (acetonitrile and DMF) by polarography, cyclic voltammetry, controlled potential electrolysis, and the ESR technique. In neutral solutions, purine is initially reduced in a one-electron, diffusion-controlled process at a fairly negative potential to produce an unstable radical anion, which then abstracts a proton from the parent purine to produce a free radical and an electroinactive purine anion. The free radical is quickly deactivated by fast dimerization to form a purine dimer and by a further one-electron reduction to produce, ultimately, 1,6-dihydropurine. The addition of various acids to purine solutions results in the appearance of a new, drawn-out wave at a more positive potential than the original purine reduction wave, which is attributed to the two-electron reduction of *N*-protonated purine species to produce 1,6-dihydropurine.

In recent years, the electrochemical reduction and oxidation of biologically-important compounds have been investigated with much interest. It is important to fully understand the redox behavior of these in considering the metabolism and analytical determination of biologically-important compounds. Recent works[1-3] have suggested a possible parallelism between the modes of electrochemical behavior and the biological transformation, *e.g.*, the enzymatic oxidation. It is also important, however, to fully investigate the electrochemical reduction behavior of biologically-important molecules, especially regarding those factors that influence the electron transfer processes, such as, *e.g.*, the pH.

A few works[4-6] have been done on purine itself and various purine derivatives in aqueous solutions. However, these works are due to the reduction of prototype purines. Consequently, the electrochemical reduction of purine, which is the model compound for the reduction of the biologically-important purine series, has been investigated in aprotic solvents on the basis of the idea that the information obtained in an inert solvent would reflect, more directly, the properties of purine itself and not its solvent-solute interaction. Another reason for investigating the purine reduction mechanism in nonaqueous solvents is to understand the properties and behavior of the anion free radical expected in a proton-poor medium.

Experimental

Chemicals. The purine (Sigma chemical company) was recrystallized four times from toluene. The acetonitrile was purified essentially by the method of Coetzee *et al.*[7] The dimethylformamide (DMF) was purified by the method of Hatano.[8] The moisture in the purified acetonitrile and DMF was determined by Karl-Fischer titration to be 0.01—0.02%. Tetraethylammonium perchlorate (TEAP) was used as the supporting electrolyte. TEAP was prepared following Fujinaga *et al.*,[9] and was recrystallized five times from distilled water before drying at 60 °C *in vacuo*. All the other reagents were of an extra-pure grade.

Apparatus. The polarographic curves were recorded using a Yanagimoto P-8 type Polarograph. Cyclic voltammograms were obtained with a versatile solid-state instrument constructed in this laboratory following the design of Goolsby and Sawyer.[10] The electrolysis cell consists of three electrodes. The reference electrode was constructed by dipping a coil of silver wire into a solution of 0.1 M $AgClO_4$ in solvents (acetonitrile or DMF)–0.1 M TEAP contained in a glass tube with a medium-porosity glass frit and salt bridge at one end. DME was used for the polarography ($m^{2/3}t^{1/6}=3.14$ $mg^{2/3}s^{1/6}$ in a 0.1 M TEAP–acetonitrile medium at −2.2 V *vs.* $Ag/AgClO_4$), and a hanging-drop mercury electrode (HDME) was used for cyclic voltammetry as the working electrode. A platinum wire served as the counter electrode. The ESR spectra were recorded on a Hitachi MES-4001 ESR spectrometer, and the sample was electrolyzed in the cavity of the ESR spectrometer. The temperature control of the samples was done by means of a Hitachi M-4602 variable-temperature accessory.

Procedure. A freshly-prepared sample solution which contained 0.1 M TEAP as the supporting electrolyte was placed in a cell. The dissolved oxygen was removed by bubbling with highly-purified nitrogen gas saturated with solvent vapor for about 15 min, and polarograms were recorded with nitrogen passing over the solution. All the experiments were carried out at 25.0±0.1 °C.

Results and Discussion

Polarography. The polarographic data for purine in various solvents are shown in Table 1. Purine is reduced at a very negative potential in aprotic solvents. The initial purine reduction wave is quite similar in both acetonitrile and DMF, but in the case of DMF the second wave appears at a more negative potential. In an aqueous solution, it is known[6] that purine exhibits two pH-dependent waves when in an acidic solution but none when in a neutral or alkaline solution, and that the first wave of these is attributable to a two-electron, diffusion-controlled process. The diffusion-current constant corrected for the change in viscosity obtained in nonaqueous solvents is about 1/4 that of the first wave obtained in an aqueous solvent; therefore, purine is initially reduced in a 1/2-electron process in aprotic solvents.

The limiting current of purine increases linearly with the concentration below 2 mM, as is shown in Fig. 1. The effect of the height of the mercury reservoir is shown in Fig. 2. The limiting current of purine is approximately proportional to $h^{1/2}$. The temperature

Table 1. Polarographic data for purine reduction in various solvents

Solvent	$E_{1/2}$, V	$E_{3/4}-E_{1/4}$ mV	I_d[d]	$\eta_{25°C}$	$I_d\eta^{1/2}$
CH_3CN	−2.16[a]	80	1.60	0.345	0.91
DMF	−2.38[b]	110	1.03	0.802	0.92
	−2.66[b]		0.22		0.20

	−0.910−0.080pH[c]	89	5.67		5.36

a) V *vs.* Ag-$AgClO_4$ (0.1 M) electrode in CH_3CN. b) V *vs.* Ag-$AgClO_4$ (0.1 M) electrode in DMF. c) V *vs.* SCE (aqueous). d) Diffusion current constant.

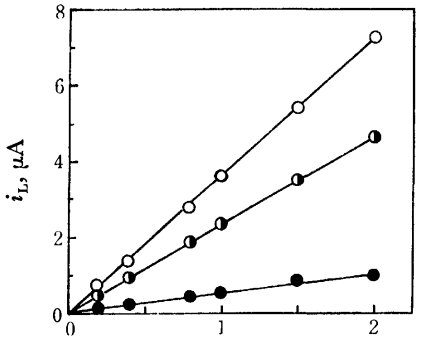

Fig. 1. Calibration curves of initial reduction waves of purine in acetonitrile (○) and DMF (◑: 1st wave, ●: 2nd wave).

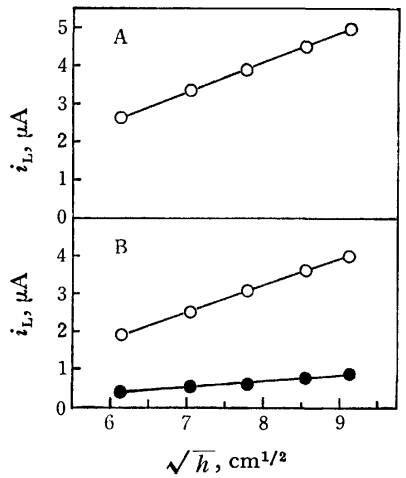

Fig. 2. Effect of the height of the mercury reservoir.
A: 1.0 mM purine in acetonitrile
B: 1.0 mM purine in DMF
(○: 1st wave, ●: 2nd wave)

coefficient of the limiting current of purine in acetonitrile is 1.2% per degree in the temperature range from 15 to 40 °C. These results show that the initial reduction wave of purine is diffusion-controlled in both acetonitrile and DMF.

Cyclic Voltammetry. The cyclic voltammograms are shown in Fig. 3. In the case of acetonitrile, purine first gives a cathodic peak corresponding to the polarographic wave, whose height is proportional to the concentration and the square root of the scan rate. However, on the return sweep, no anodic peak is seen until about −0.56 V (peak 3a), and a redox couple (peak 4a and 4c) on the positive-potential side of Peak 3a appears. In the case of DMF, a typical curve indicates a cathodic peak, followed by a reversible reduction step. However, the other voltammetric behavior for purine in DMF is similar to that in acetonitrile.

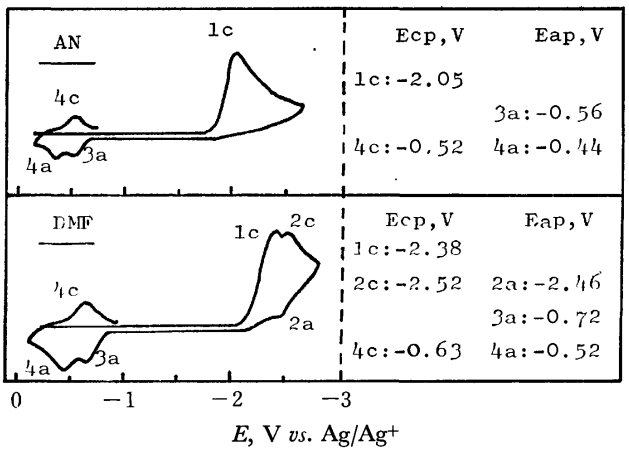

Fig. 3. Cyclic voltammogram of purine in aprotic solvents.
scan speed: 0.20 V/s

ESR Spectroscopy. The electrogenerated radical species of purine and the various biologically-important purine bases have not been detected[11] at room temperature. This is presumably because of the rapid dimerization of the radical anion of purines. There-

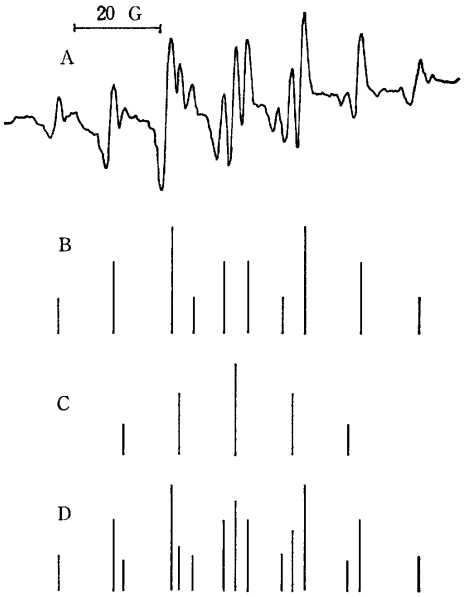

Fig. 4. A; Observed ESR spectrum obtained by controlled potential electrolysis at the potential of the first polarographic wave in DMF at −60 °C. B; calculated ESR spectrum of radical (1) with coupling constant A_H(6-Position) = 30.4 gauss and A_N(1 and 3-Position) = 12.7 gauss. C; calculated ESR spectrum of radical (2) with coupling constant A_N(1 and 3-Position) = 12.6 gauss. D; combined spectrum of B and C.

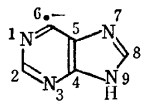
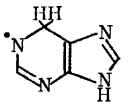
fore, the ESR technique at a low temperature was used to detect the electrogenerated radicals of purine. A typical ESR spectrum obtained by controlled potential electrolysis at the potential of the first polarographic wave in DMF at −60 °C is shown in Fig. 4A. The half-peak width of the hyperfine components is about 1.6 gauss, and the total width between the centers of the outermost observed lines is 41.0 gauss.

The results of the interpretation indicate that this spectrum consists of a combination of the hyperfine splitting of the two radical species shown below.



(1)



(2)

The spectrum (Fig. 4B) obtained by the use of Radical (1) is interpreted as deriving from the interaction of the unpaired electron with a proton (A_H=30.4 G) and an equivalent pair of the nitrogen nucleus (A_N=12.7 G). It may also be interpreted that the spectrum (Fig. 4C) obtained by the use of Radical (2) is attributable to the interaction of the unpaired electron with an equivalent pair of the nitrogen nucleus (A_N=12.6 G). The combined spectrum of B and C is shown in Fig. 4D; it is in good agreement with the observed ESR spectrum. The results of this ESR spectrum and the diffusion-current constant which corresponds to the 1/2-electron reduction wave indicate that purine is initially reduced in a one-electron process to produce an unstable radical anion, which then abstracts a proton from the parent purine to produce a free radical and an electro-inactive species.

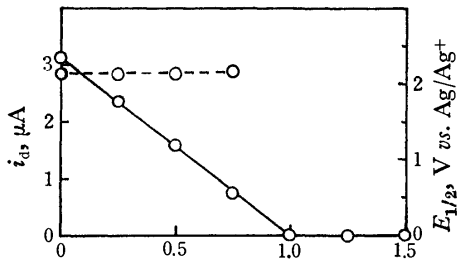


Fig. 5. Effect of strong base addition on polarograms of 1 mM purine in acetonitrile.
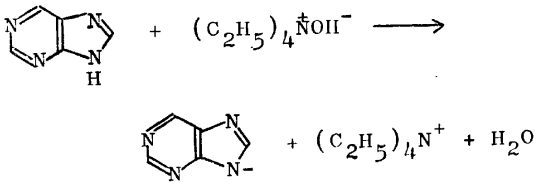
(——): i_d, (------): $E_{1/2}$

Effect of Base Addition. An acetonitrile solution of tetraethylammonium hydroxide (TEAH), which is a strong base in acetonitrile, was added to an acetonitrile solution of purine. The polarographic behavior of purine in the presence of TEAH is shown in Fig. 5. The presence of TEAH in the solution causes the wave-height of the original purine wave to decrease, approximately in proportion to the base concentration, and at a molar ratio of TEAH/purine ratio of about 1.0 the wave dissappears entirely. However, $E_{1/2}$ is constant in spite of the addition of TEAH. This behavior can be explained in terms of the production of an electro-inactive anion by a kind of acid-base reaction like that shown below:



Effect of the Acid Addition. The various acids were added to both acetonitrile and a DMF solution of purine, and their effects on the polarograms were studied. In general, the addition of strong acid produces a new, drawn-out wave at a more positive potential than the original purine reduction wave.

On the addition of monochloroacetic acid to an acetonitrile solution of purine, a new wave appears at −1.89 V. With an increase in the acid/purine ratio, the wave-height of the new wave, that is approximately constant, in $E_{1/2}$ increases, and that of the original wave decreases, as is shown in Fig. 6. At a molar ratio of acid/purine higher than about 2.2, the new

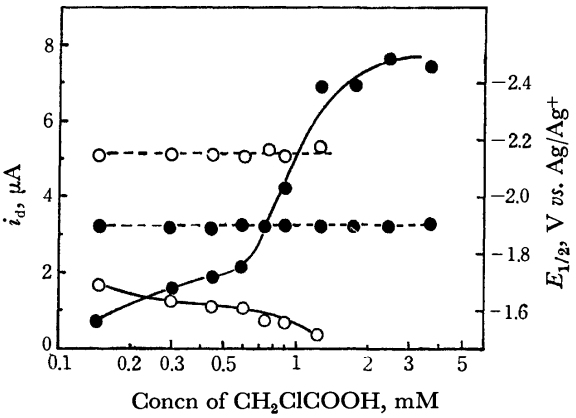


Fig. 6. Effect of monochloroacetic acid on the polarographic reduction of 0.6 mM purine in acetonitrile.

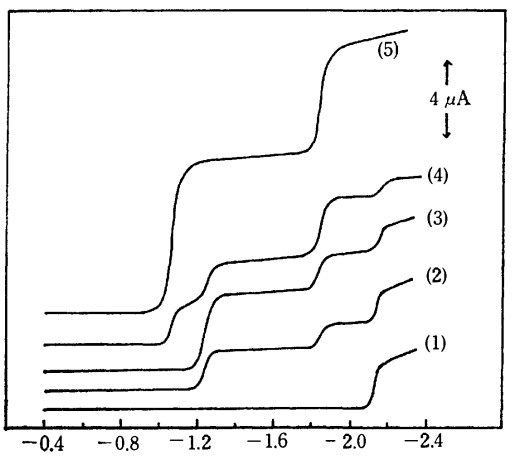

Fig. 7. Effect of $HClO_4$ concentration on polarograms of 0.6 mM purine in acetonitrile.
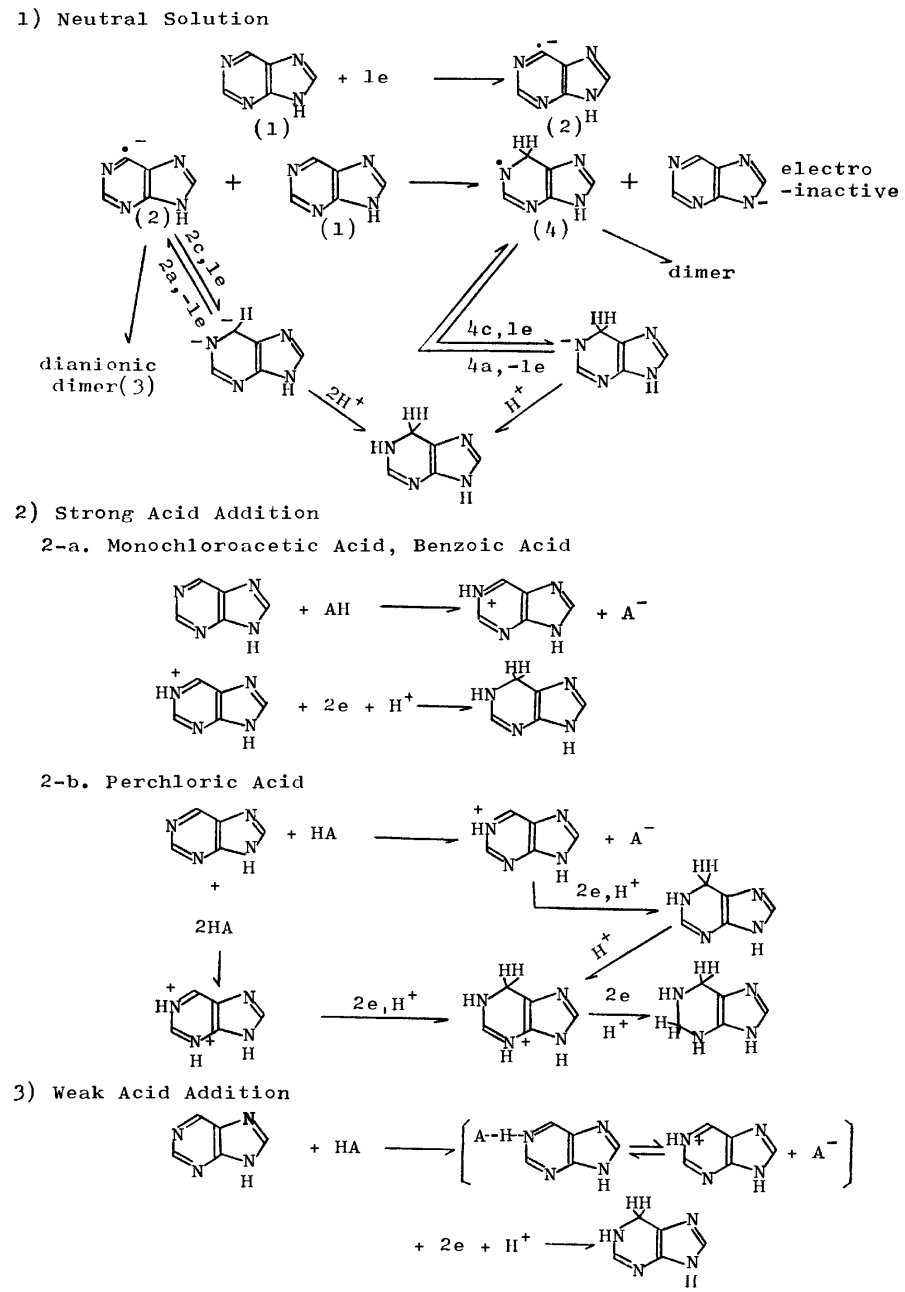
[$HClO_4$]/[purine] ratio: curve (1), 0; (2), 0.5; (3), 1.0; (4), 1.5; (5), 2.5

wave becomes constant, with a height that corresponds to that of the 2-electron reduction wave, and the original wave disappears. In the case of the addition of benzoic acid, the same behavior was observed.

The addition of a very strong acid, perchloric, results in the appearance of several waves at more positive potentials than the original purine wave, as is shown in Fig. 7. At a molar ratio of acid/purine lower than 1.0, two new waves appear at −1.24 and −1.84 V; their heights increase in proportion to the acid concentration. Perchloric acid present in a molar ratio of 1:1 decreases the height of the original wave to about 1/2 of the original value, and the wave at −1.24 V increases in height to nearly double the value of the original wave. A further increase in the perchloric acid concentration causes a new wave to appear at −1.07 V; its height increases until it is about 4 times the value of the original purine wave. However, the wave at −1.24 V and the original purine wave completely disappear at an acid/purine ratio of about 2.1, and the polarographic behavior is close to that observed for purine in unbuffered aqueous solutions. These results are consistent with a prior protonation of the purine molecule at one of the nitrogen atoms to give a species more easily reducible than the original purine wave. Consequently, the waves at −1.24 V and −1.07 V presumably contribute to the reduction of monoprotonated and diprotonated purine respectively. The presence of a weak acid, such as acetic acid and water, causes the half-wave potential of the original wave to shift to more positive values, also increasing its height until it is about 4 times that in dry acetonitrile. The polarographic behavior of purine in DMF in the presence of various acids is similar to that in



Scheme 1.

TABLE 2. CORRELATION OF POTENTIAL FOR THE PURINE REDUCTION WAVE WITH THE STRENGTH OF THE ADDED ACID

Acid added	pK_a^{aq}	$E_{1/2}$, V *vs.* Ag/Ag^+	
		Acetonitrile	DMF
Perchloric acid	a)	−1.07, −1.24, −1.84	−1.86+0.15 log[Acid]
Monochloroacetic acid	2.8	−1.89	−1.92+0.10 log[Acid]
Benzoic acid	4.2	−2.01	−2.02+0.10 log[Acid]
Acetic acid	4.8	−1.64+0.16 log[Acid]	−2.29+0.03 log[Acid]
Water		−2.11+0.09 log[Acid]	

a) Perchloric acid is completely dissociated in both acetonitrile and water.

acetonitrile in the presence of acetic acid and water.

The half-wave potentials of the purine reduction waves produced by adding the various acids are indicated in Table 2 in relation to the strengths of the added acids. The potential of the acid-produced purine reduction is more positive the stronger the acid added. The nature of the purine-acid species formed on acid addition is most probably a hydrogen-bonded or an ion-pair complex.

Mechanism of Purine Reduction. The mechanism presumed for purine reduction in acetonitrile and DMF at the mercury electrode is summarized in Scheme 1. In a neutral nonaqueous solution, purine undergoes a one-electron reduction to produce an unstable anion radical (2), which then abstracts a proton from the parent purine to produce a free radical (4) and an electro-inactive purine anion. The redox couple (peak 2c and 2a) which appears when DMF is used as the solvent, presumably corresponds to the further reduction of a solvated anion radical stabilized by the solvation with DMF, because this solvation effect prevents the fast dimerization reaction from producing the purine dianionic dimer (peak 3a). This is apparent from the fact that the line intensity of the ESR spectrum in the case of acetonitrile is smaller than that in the case of DMF. The three peaks (3a, 4a, and 4c) which appear at the positive potential above −0.7 V presumably correspond to the anions disappearing on addition of the acids. The unstable purine free radical (4) undergoes a fast dimerization to produce a purine dimer, but a part of that is further reduced almost instantaneously to produce the 6-hydropurine anion (peak 4c). When monochloroacetic acid and benzoic acid are present, a preprotonation reaction can occur, which is reduced in a two-electron process to produce 1,6-dihydropurine.[6] When perchloric acid is present, monoprotonated and diprotonated purine species are initially reduced in a two-electron process; this is followed by a further two-electron reduction to produce 1,2,3,6-tetrahydropurine.[6] The addition of weak acids produces an acid-base equilibrium between purine and acids, which equilibrium is reduced in a two-electron process.

The Equilibria of Protonation Reaction of *N,N'*-Ethylenebis(salicylideneiminato)cobalt(II) and of Its Oxygenated Binuclear Complex by Perchloric Acid in Dimethyl Sulfoxide

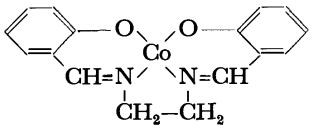
Yuriko ABE* and Goro WADA

Department of Chemistry, Faculty of Science, Nara Women's University, Nara 630

(Received July 22, 1974)

Acid dependence of oxygen uptake by Co(II)salen in DMSO was studied. As the concentration of perchloric acid increases in the absence of O_2, Co(II)salen forms 1:1 and 1:2 protonated complexes, with the formation constants $K_1=8.3\times10^3$ M^{-1} and $K_2=1.6\times10^3$ M^{-1} measured spectrophotometrically by the linearity method. The oxygen uptake ratio n of Co(II)salen in the absence of acid is 0.5, indicating formation of a 2:1 O_2-bridged binuclear complex, with an immeasurably large formation constant K_3. The oxygenated complex is protonated by addition of acid with a formation constant $K_4=3.3\times10^5$ M^{-1} as observed again spectrophotometrically. When Co(II)salen is oxygenated in the presence of acid, n decreases considerably from 0.5 with increasing acid concentration. This is because the protonated Co(II)salen complexes are inert to oxygenation and both the rate of oxygenation of Co(II)salen and that of deoxygenation of oxygenated binuclear species are slow, as compared to the rapid processes of protonation.

In the last decade, much attention has been paid on the reversible oxygenation of some cobalt complexes by many investigators, especially on the reaction mechanisms and the electronic and the molecular structures of the oxygenated complexes,[1-3] because they have been taken as nice models for oxygen carriers in living systems. *N,N'*-Ethylenebis(salicylideneiminato)cobalt(II) (abbreviated as Co(II)salen below) was the first



Co(II)salen

synthetic complex with a nature of reversible oxygenation,[4] which was mostly investigated in its solid state.[5] Recently, Floriani *et al.* found that Co(II)salen absorbs oxygen to form a binuclear complex Co(III)salen·O_2·-Co(III)salen in aprotic solvents such as dimethyl sulfoxide (DMSO) and *N,N*-dimethylformamide (DMF) at room temperature,[6] while Ochiai showed that Co(II)salen forms a 1:1 complex with an oxygen molecule at 77 K and that the stability of oxygenated species depends upon the ligand which is situated at the *trans* position with respect to the oxygen.[7,8] However, since the function of acid existing in the organic solvents towards the oxygenation reaction is not known yet to date, we investigated the thermodynamic equilibria among Co(II)salen, O_2, and hydrogen ion in DMSO in the present paper.

Experimental

Materials. The purification of commercial DMSO and the preparation of DMSO solution of perchloric acid was carried out according to our previous procedure.[9] Co(II)salen was prepared by a method in the literature.[10] Sodium perchlorate was recrystallized twice from aqueous solution and was used for the purpose of adjusting the ionic strength of DMSO solutions.

Oxygen Uptake Measurements. The volume of oxygen absorbed by Co(II)salen was measured by the use of a Warburg apparatus at 25 °C and an ionic strength 0.25 M, by dissolving a weighed amount of crystalline Co(II)salen into DMSO of a given ionic strength, under various partial pressures of oxygen.

Spectrophotometry. The optical absorbances of complexes were measured by a Hitachi spectrophotometer Model 101 and a Hitachi recording spectrophotometer Model EPS-3T with a quartz cell of 10 or 1 mm light path. In the case of complexes containing no oxygen, the measurements were performed under nitrogen atmosphere.

Results

Absorption Spectra and Formation Constants of Mono- and Di-Protonated Complexes. Figure 1 shows absorption spectra of Co(II)salen (Curve a) and of partly proto-

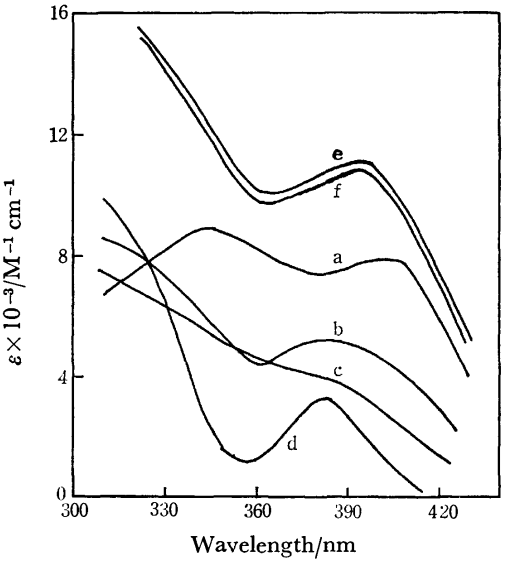


Fig. 1. Absorption spectra of Co(II)salen and its protonated and oxygenated species at $\mu=0.25$ M. (a) Co(II)salen, (b) $[Co(II)salen]_0=5.70\times10^{-4}$ M, $[HClO_4]_0=3.00\times10^{-4}$ M, (c) $[Co(II)salen]_0=5.70\times10^{-4}$ M, $[HClO_4]_0=2.00\times10^{-3}$ M, (d) Co(II)-salenH$^+$, (e) $(Co(III)salen)_2O_2$, (f) $[(Co(III)salen)_2O_2]_0=3.12\times10^{-4}$ M, $[HClO_4]_0=1.00\times10^{-4}$ M

* *Nee*: Yuriko Unno.

nated ones (Curve b for $[Co(II)salen]_0=5.70\times10^{-4}$ M and $[HClO_4]_0=3.00\times10^{-4}$ M and Curve c for $[Co(II)salen]_0=5.70\times10^{-4}$ M and $[HClO_4]_0=2.00\times10^{-3}$ M, where $[\ ]_0$ represents the total concentration). When acid concentration is lower than 3×10^{-4} M, an isosbestic point appears at 325 nm, indicating that there occurs a single species of protonated complex, although many curves between a and b passing the same isosbestic point are omitted in the figure. At higher acid concentrations, absorption spectrum gradually deviates from the isosbestic point because of probable occurrence of another protonated species.

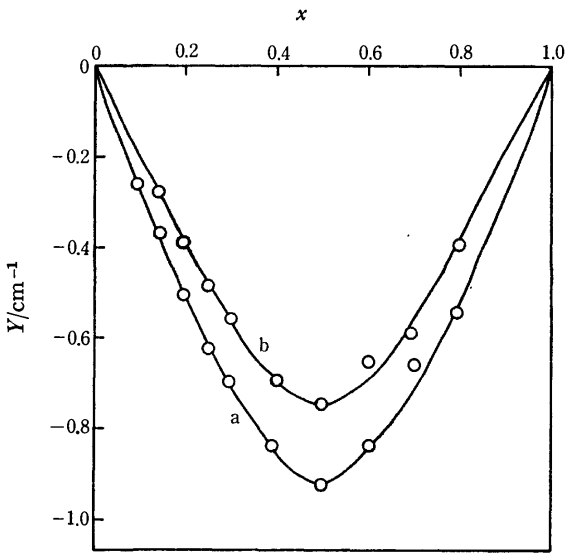

Fig. 2. Job's curves for Co(II)salen-$HClO_4$ system at 410 nm and $\mu=0.25$ M.
(a) $[Co(II)salen]_0+[HClO_4]_0=5.00\times10^{-4}$ M
(b) $[Co(II)salen]_0+[HClO_4]_0=4.00\times10^{-4}$ M

According to Job's curves of continuous variation for solutions of Co(II)salen and perchloric acid observed at 410 nm as shown in Fig. 2, minimum points are recognized at concentrations of $[Co(II)salen]_0=[HClO_4]_0$, proving formation of a 1 : 1 complex, namely monoprotonated complex Co(II)salenH$^+$, holding an equilibrium,

$$Co(II)\ salen + H^+ \rightleftarrows Co(II)\ salenH^+ \quad (1)$$

$$K_1 = \frac{[Co(II)\ salenH^+]}{[Co(II)\ salen][H^+]} \quad (2)$$

In Fig. 2, the values of Y as defined below are plotted against the mole fraction of Co(II)salen, $x=[Co(II)salen]_0/([Co(II)salen]_0+[HClO_4]_0)$ at two different total concentrations of Co(II)salen and acid.

$$\begin{aligned} Y &= \text{Absorbance} - \varepsilon_0[Co(II)\ salen]_0 \\ &= \varepsilon_0[Co(II)\ salen] + \varepsilon_1[Co(II)\ salenH^+] \\ &\quad - \varepsilon_0[Co(II)\ salen]_0 \\ &= (\varepsilon_1-\varepsilon_0)[Co(II)\ salenH^+] \end{aligned} \quad (3)$$

Here, ε_0 and ε_1 stand for the molar absorptivity of Co(II)salen and Co(II)salenH$^+$, respectively. By adopting our method[11] to Curves a and b in Fig. 2, the values of K_1 and ε_1 are calculated which are listed in Table 1, along with other related data. By using the value of K_1, the absorption spectrum of Co(II)salenH$^+$ can be obtained which is shown as Curve d in Fig. 1. The absorption spectrum of Co(II)salen (Curve a) exhibits two peaks at 345 and 405 nm, while the absorption spectrum of Co(II)salenH$^+$ (Curve d) appears generally below that of Co(II)salen at the wavelength range longer than the isosbestic point 325 nm, having a single peak at 383 nm.

Table 1. Formation constants and molar absorptivities of protonated Co(II)salen at $\mu=0.25$ M and 25 °C

Wavelength nm	K_1 M^{-1}	ε_1 $M^{-1}cm^{-1}$	K_2 M^{-1}	ε_2 $M^{-1}cm^{-1}$	Method
410	1.17×10^4	8.13×10^2	—	—	Job's
400	1.27×10^4	1.66×10^3	—	—	Job's
360	0.83×10^4	1.0×10^3	1.6×10^3	5.9×10^3	Linearity

At higher acid concentration, however, Curve c represents an absorption spectrum of a probable mixture of mono- and di-protonated Co(II)salen. When the apparent molar absorptivity of the mixture and the molar absorptivity of Co(II)salenH$_2^{2+}$ are expressed by ε and ε_2 respectively, the following relationship may be established.[11]

$$\varepsilon = \varepsilon_1 + \frac{1}{K_1}\frac{\varepsilon_0-\varepsilon}{[H^+]} + (\varepsilon_2-\varepsilon)K_2[H^+] \quad (4)$$

$$Co(II)\ salenH^+ + H^+ \rightleftarrows Co(II)\ salenH_2^{2+} \quad (5)$$

$$K_2 = \frac{[Co(II)\ salenH_2^{2+}]}{[Co(II)\ salenH^+][H^+]} \quad (6)$$
