Single Crystal Electron Spin Resonance Spectra of Magnetically Dilute Copper(II) Ion in Some Five-coordinate Adducts of Zinc(II) β-Diketonate Complexes

Seizo MISUMI, Toshiyuki ISOBE, and Kuniyoshi SUGIYAMA
Inorganic Chemistry Laboratory, Faculty of Science, Kyushu University, Fukuoka 812
(Received July 3, 1973)

The single crystal ESR spectra of some five-coordinate adducts of copper(II)-doped zinc(II) β-diketonate complexes [Cu/Zn(acac)$_2$H$_2$O], [Cu/Zn(acac)$_2$γ-pic], [Cu/Zn(bzac)$_2$MeOH], and [Cu/Zn(bzac)$_2$py] (acac= acetylacetone anion, bzac=benzoylacetone anion, py=pyridine, γ-pic=γ-picoline, MeOH=methanol) were measured at room temperature. The principal values of the g tensor and A tensor of ^{63}Cu were calculated. The single crystal g-values of all the adducts suggested a $d_{x^2-y^2}$ ground state for the approximately square-based pyramidal structure, and were found to be consistent with crystallographic data. In the single crystals of [Cu/Zn-(acac)$_2$H$_2$O] and [Cu/Zn(bzac)$_2$py], two magnetic centers were determined, this being the first time for them to have been found by ESR study.

A survey of well-known five-coordinate complexes shows the possibility of their being square pyramidal (SP) and trigonal bipyramidal (TBP). Most of them contain two bidentate ligands and one unidentate ligand. A central metal atom in the square pyramidal structure suggests two types of structure according to the coordination site of the unidentate ligand, one with a unidentate ligand in the apical position (SP-1) and the other in the basal plane (SP-2). The square-based pyramidal stereochemistry occurs much more frequently than the trigonal bipyramidal.

Bis-(*o*-hydroxyacetophenonato)γ-picoline copper(II)[1] and bis-(acetylacetonato)quinoline copper(II)[2] were reported to be of SP-1 structure, and bis-(acetylacetonato)4-aminopyridine copper(II)[3] of SP-2 structure by means of X-ray crystallography. The crystal structure of monoaquobis-(acetylacetonato) zinc(II) [Zn(acac)$_2$H$_2$O] has been determined by a three-dimensional X-ray crystal-structure analysis.[4,5] Lippert and Truter[4] reported that zinc atom is five-coordinated with the bonds arranged in a trigonal bipyramid. On the other hand, Montgomery and Lingafelter[5] confirmed that the structure is made up of discrete molecules, containing five-coordinate zinc-(II) with an intermediate coordination configuration between tetragonal pyramidal and trigonal bipyramidal.

The powder ESR spectra of the adduct complexes of SP-1 structure, such as [Cu(acac)$_2$quinoline], [Cu-(acac)$_2$γ-pic],[6] and [Cu(bzac)$_2$py],[7] show an axial pattern with $g_\parallel > g_\perp$ and the ground state is suggested to be $d_{x^2-y^2}$.[8] [Cu(acac)$_2$4-aminopyridine], which forms a typical SP-2 complex, gives typical rhombic pattern (neither rhombic nor axial) of the powder ESR spectrum and the ground state is also suggested to be $d_{x^2-y^2}$. In TBP complexes, the d_{z^2} ground state is usually observed, indicating that $g_\perp$ is greater than $g_\parallel$.

In this work, the single crystals of four five-coordinate adducts of copper(II)-doped zinc(II) β-diketonate complexes were prepared and their structures were estimated by comparing the single crystal ESR spectra with crystallographic data.

Experimental

Preparation. The single crystal of the five-coordinate adducts of copper(II)-doped (1 mol%) zinc(II) β-diketonate complexes was prepared by the method of Graddon and Weeden,[9,10] except that Zn(ClO$_4$)$_2$·6H$_2$O was used as the starting material.

Measurements. Single crystal ESR spectra were taken on a JEOL/JES-ME-3X spectrometer at room temperature. Calibration was made with a DPPH (g=2.0036). All the single crystal ESR spectra were recorded on a holder similar to that used by Hathaway and Billing,[11] except that it was made of silica rod. As the single crystal of all the adducts decomposed easily on exposure to air, it was coated with silicone grease throughout the measurements. The crystal was rotated about three orthogonal axes and the spectra were obtained in each rotation.[12-15]

Results and Discussion

For all the complexes, well-resolved ^{63}Cu hyperfine structures were observed in the magnetically dilute single crystal ESR spectra, in which the first and last lines are partly split due to the presence of the ^{65}Cu isotope.[16] The ESR spectra of [Cu/Zn(acac)$_2$γ-pic] and [Cu/Zn(bzac)$_2$MeOH] gave four hyperfine absorption lines. However, those of [Cu/Zn(acac)$_2$H$_2$O] and [Cu/Zn(bzac)$_2$py] gave eight lines, suggesting that there are two magnetic sites per unit cell. The single crystal ESR spectra at room temperature, shown in Figs. 1 and 2, exhibit strong Zeeman and hyperfine-

interaction anisotropies. Plots of the peak position as a function of the angle are shown in Figs. 3—5. The principal g- and A-values determined by the method of Schonland,[17] given in Table 1, are in agreement within experimental error with the approximate data obtained from powder ESR measurements.

a) *[Cu/Zn(acac)$_2\gamma$-pic] and [Cu/Zn(bzac)$_2$MeOH].* These two adduct complexes yield non-axial ESR spectra (neither axial nor rhombic) with $g_1 \sim g_2 < g_3$ and $A_1 < A_2 \ll A_3$, which suggests a characteristic square pyramidal symmetry indicating $d_{x^2-y^2}$ ground state. Thus the complexes are estimated to be of SP-1 structure *i.e.*, a γ-picoline or a MeOH molecule lies at the apical position of the square pyramidal structure. The ESR spectra of $[Cu/Zn(acac)_2\gamma\text{-pic}]$ at room temperature gave no superhyperfine interaction with a nitrogen atom of γ-picoline at the apical position of the square pyramidal structure.

Adduct		g_1	g_2	g_3	A_1 (G)	A_2 (G)	A_3 (G)
$[Cu/Zn(acac)_2H_2O]$[a]	I	2.060	2.071	2.316	21.2	38.1	153.4
	II	2.065	2.073	2.317	20.3	37.0	152.6
$[Cu/Zn(acac)_2\gamma\text{-pic}]$		2.058	2.076	2.312	12.0	52.0	150.6
$[Cu/Zn(bzac)_2MeOH]$		2.045	2.094	2.312	26.8	37.2	139.9
$[Cu/Zn(bzac)_2py]$[a]	I	2.055	2.094	2.330	29.4	38.9	123.8
	II	2.053	2.095	2.330	27.9	40.0	123.8

a) There are two units of this complex per unit cell.

TBP structure, whereas Montgomery and Lingafelter[5] reported it to be an intermediate configuration between SP-1 and TBP by X-ray measurements. A significant difference might be seen in the ESR spectra. Usually a $d_{x^2-y^2}$ ground state with $g_1 \sim g_2 < g_3$ is expected for SP-1 structure and a d_{z^2} ground state with $g_1 \sim g_2 > g_3$ for TBP structure. As shown in Table 1, the principal g-values for this adduct complex show $g_1 \sim g_2 < g_3$. Thus it does not seem to be of effective TBP symmetry. For $[Zn(acac)_2H_2O]$, the distorted square-based pyramidal structure or an intermediate configuration between SP-1 and TBP, rather than the distorted TBP, could be proposed. There are two magnetic sites per unit cell, two units being symmetric in 1·2-plane but not symmetric in 1·3- and 2·3-planes, as shown in Fig. 4. The crystal is monoclinic, and the 3-axis lies approximately parallel to the crystal needle axis, b. This is in line with the fact that the unit cell possesses the two-fold screw axis, as was expected from X-ray analysis.[4]

c) *[Cu/Zn(bzac)$_2$py]*. It was found that there are two magnetic sites of $[Zn(bzac)_2py]$ per unit cell from single crystal ESR spectra (Fig. 5). Measurement by the X-ray method has not yet been carried out, $[Cu/Zn(bzac)_2py]$ shows principal g-values with $g_1 \sim g_2 < g_3$. This indicates the ground state to be $d_{x^2-y^2}$ which would favor the square pyramidal coordination. Thus, it seems that a pyridine molecule lies in the apical position in the square pyramidal structure. The ^{14}N superhyperfine structure of a pyridine molecule was not resolved in these ESR spectra, nor in those of $[Cu/Zn(acac)_2\gamma\text{-pic}]$.

An ESR Study of Methylamino Radicals Photoproduced on the Porous Vycor Glass Surface

Keiichiro HATANO,* Norio SHIMAMOTO,** Takashi KATSU, and Yuzaburo FUJITA***

Faculty of Pharmaceutical Sciences, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received July 9, 1973)

The photochemical decomposition of methylamines adsorbed on the surface of the porous Vycor glass was studied at 77 K by the ESR method, and the ESR spectra of the methylamino radicals, CH_3NH, CH_3ND, CD_3NH, CD_3ND, CH_2DNH, and CH_2DND, were observed as primary radicals from variously-deuterated methylamines upon irradiation with the light of a low-pressure mercury lamp. This result shows that the primary process is preferentially a rupture of the N–H or N–D bond of methylamine. These spectra were characterized by an apparent quenching of the *N*-hyperfine splitting resulting from large hyperfine anisotropy, and by nearly isotropic proton hyperfine splittings in both methyl and amino groups. The hyperfine splitting constants of the N, H, and D nuclei of each radical were determined, and consequently a D-substitution effect on the β-proton hf splitting in the methyl group was found. The characteristics of the ESR spectra were discussed in relation to the adsorbed state of the methylamino radical on the porous Vycor glass surface.

It has generally been accepted that the CH_3, NH_2, CH_3NH, CH_2NH_2, and H radicals are produced in the primary processes of the photochemical decomposition of methylamine in the gas and liquid phases.[1] Among these radicals, the CH_3, NH_2, and H radicals have been studied extensively, and their ESR spectra have been unambiguously defined in various matrices and adsorbed states.[2] However, those of the CH_3NH[3] and CH_2NH_2[4] radicals have only been obtained as poorly-resolved spectra in randomly-oriented states; especially, the anisotropic hyperfine interaction of the ^{14}N-nucleus in the methylamino radical has not yet been studied extensively.[5]

As has been reported previously, simple molecules adsorbed on the surface of the porous Vycor glass (PVG) are photolyzed efficiently with the light of a low-pressure mercury lamp at room temperature and 77 K into simple radicals, which exhibit well-resolved hf splittings.[6] For example, the NH_2 radical, which is the simplest *N*-centered radical, has been photoproduced from NH_3 molecules adsorbed on the PVG surface and stabilized on the surface at 77 K.[7] Under appropriate conditions, well-resolved anisotropic hf splittings of ^{14}N have been clearly observed; from them one can deduce the adsorbed state of the radicals on the surface. A similar effect is expected to be observed in the case of the CH_3NH radical, which may be formed by the photolysis of the methylamine adsorbed on the PVG surface. The primary object of this work was to identify radical species generated by the primary photolysis of methylamine. For this purpose, variously deuterated methylamines were utilized as adsorbates. As a result, the dominant radical species produced by the photolysis of methylamines was identified conclusively as of the CH_3NH type, and at the same time valuable information on the interaction between the radical and the surface of the PVG was obtained.

In this report, the ESR findings on the photochemical decomposition of methylamines in the adsorbed state and on the analysis of the ESR spectra of the radical species will be presented.

Experimental

Materials. Two commercial reagents, CH_3NH_2 in an aqueous solution (Wako Junyaku, GR) and $CD_3NH_2 \cdot HCl$ (Merck, GR), were used without further purification. $CH_2DNH_2 \cdot HCl$, a special product of Merck, was kindly offered by Professor Masamichi Tsuboi and Dr. Keietsu Tamagake in this faculty.

Gaseous methylamine was prepared by adding an aqueous solution of methylamine or methylamine hydrochloride to a concentrated potassium hydroxide solution, and dried by passing it through a column packed with potassium hydroxide tablets.

The deuteration of the NH_2 group in methylamine was carried out in the usual manner, D_2O and KOD being used in place of H_2O and KOH.

Procedures. PVG rods (Corning code No. 7930; 4 mm in diameter; 2 cm in length; surface area 75 m^2/sample) were used in all the experiments. The PVG rod was dipped in conc. HNO_3 for a day and then in distilled water for several days. After several repetitions of this procedure, the PVG rod was dried in air at 100 °C and then preheated in air at 500 °C. After the retreatment of the PVG rod with oxygen and evacuation for several hours at 550—600 °C in a quartz sample tube attached to a conventional high-vacuum system, a specified amount of methylamine was introduced into the sample tube at room temperature. The sample tube was then gradually cooled from room temperature to that of liquid nitrogen in order to secure the homogeneous adsorption of methylamine on the PVG surface; it was subsequently submitted to the irradiation and the ESR measurement.

The sample tube was irradiated at 77 K with the light of a low-pressure mercury lamp (UL2-2HQ, 200 W, Ushio Electric Inc.) without any filter, after which the sample tube was immediately transferred into a Dewar vessel inserted in the cavity.

The ESR spectra were recorded at 77 K with a JEOL P-10 spectrometer (X-band, 100 kHz field modulation) equipped with a Dewar insert and a temperature-controlling apparatus.

Results and Discussion

Photoproduced Radical Species. The ESR spectra

*** To whom inquiries should be addressed.

of the photoproduced radicals did not practically alter with the change in the amount adsorbed in the range from the monolayer to less than 1/10 of the monolayer. Figures 1, 2, 3, 4, 5, and 6 show some typical ESR spectra of radicals trapped on the surface of PVG at 77 K by the photolysis of CH_3NH_2, CH_3ND_2, CD_3NH_2, CD_3ND_2, CH_2DNH_2, and CH_2DND_2 respectively. Since the free radicals produced from the variously-deuterated methylamines seem to have a common structure, it is appropriate to analyze the ESR spectrum of the simplest one.

In Fig. 2, the spectrum consists of a quartet, whose component splits into a triplet in the higher magnetic field, and of two humps which are on the outer sides of the quartet. Furthermore, besides these lines, there is observed a triplet which is denoted with arrows in the figure. Since this triplet becomes more distinct than the other lines upon prolonged irradiation, it can be attributed to a different radical species from that of the main quartet and humps. A similar distinctive effect of prolonged irradiation on the spectral pattern was also observed in the case of CH_3NH_2, as is shown in Fig. 1.

As to the spectrum of the quartet with a triplet, it can easily be interpreted that the quartet with the splitting of 34 G and the approximate intensity ratio of 1 : 3 : 3 : 1 arises from the hf interaction with three equivalent proton nuclei and its triplet component with one deuteron nucleus, taking account of its approximate intensity ratio of 1 : 1 : 1 and its splitting of 4 G. Moreover, considering that this radical is generated by the photolysis of CH_3ND_2, it can unambiguously be assigned to the CH_3ND radical. The absence of the hf splitting due to the ^{14}N nucleus can reasonably be explained by the fact that the ^{14}N-hf splitting in the NH_2 radical is obscured by a large anisotropy, as has been reported recently by many workers.[8] This interpretation is supported by the existence of outer humps in the spectrum. The present assignment of the radical species is confirmed by mutual and comparative analyses of the spectra in Figs. 1—6,

making use of the theoretical ratio of $a^H/a^D=6.5$. For example, the spectrum in Fig. 1 can be understood to consist of 5 main lines, which arise from the three protons in the methyl group and from one proton in the amino group of the CH_3NH radical; the latter is approximately equivalent with the former. The observed a^H/a^D ratio between the CH_3NH and CH_3ND radicals, 5.5, is close to the theoretical one.

Thus, all the spectra in Figs. 3, 4, 5, and 6 can be identified as those of CD_3NH, CD_3ND, CH_2DNH, and CH_2DND radicals respectively.

TABLE 1. HYPERFINE COUPLING PARAMETERS OF METHYLAMINO RADICALS (G)

Species	a^H_{CH}	a^D_{CD}	a^H_{NH}	a^D_{ND}	$a^N_\perp$	$a^N_\parallel$
CH_3NH	34		22		~0	~40
CH_3ND	34			4	~0	~40
CD_3NH		5	22		~0	~40
CD_3ND		5		5	~0	~40
CH_2DNH	37	4	22		~0	~40
CH_2DND	37	4		4	~0	~40

Observed $a^H/a^D=5\sim8$ (theor.; 6.5)
a^N; estimated from the position of the humps.

The ESR parameters of these radicals are listed in Table 1. The values of the anisotropic hf splitting constants of the ^{14}N nucleus are estimated approximately from the positions of the humps, assuming an axial symmetry in the ^{14}N hf tensors.

The extra triplet lines, growing on prolonged irradiation, may be assigned to the methyleneimino radical, $H_2C=N$,[9] judging from the extraordinary large hf splitting constant of ~87 G. Together with these two radicals, the spectrum of the H or D atom was observed to be small in intensity, in accordance with the poor trapping efficiency for hydrogen atoms on the PVG surface.[11] The ESR spectra of other radicals, such as CH_3 and NH_2, were hardly observed under irradiation for several minutes by means of the light of a low-pressure mercury lamp.

From the above results, the primary process of the photochemical decomposition of methylamine on the surface of PVG can be described as:

$$CH_3NH_2 \xrightarrow{h\nu} CH_3NH + H.$$

The methyleneimino radical may secondarily be produced from the methylamino radical by means of the light of a low-pressure mercury lamp;

$$CH_3NH \xrightarrow{h\nu'} H_2C=N + H_2.$$

However, this process does not seem to be a very efficient one, since the signal intensity of this radical is much smaller than that of the methylamino radical, regardless of the prolonged irradiation.

For comparison, the photolysis of the dimethylamine-d_1 ($(CH_3)_2ND$) adsorbed on the surface of the PVG was carried out under the same conditions. The result is shown in Fig. 7. Although the methyl radical is slightly perceptible in the spectrum, as is indicated by

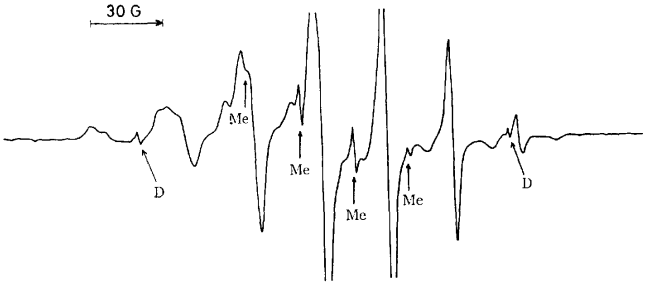

Fig. 7. ESR spectrum of $(CH_3)_2N$ radical on PVG.
Arrows: Me, CH_3 radical; D, D atom

the arrows in the figure, its signal intensity is very small compared with that of the $(CH_3)_2N$ radical. Therefore, the primary photochemical process is considered to be the rupture of the N–D bond, as in the case of monomethylamine, and the possibility of the C–N bond scission seems to be negligibly small. This was further supported by the finding that the $H_2C=N$ radical, which might secondarily be produced from the CH_3NH radical, was not observed, not even on prolonged irradiation.

It may be worthwhile to refer here to the important role of the PVG in the photodecomposition of methylamine. Since gaseous methylamine is essentially transparent above 240 nm, and since the PVG is opaque below 220 nm, it seems that the quantity of light quanta limited in a narrow range of wavelengths between 220 and 240 nm are not sufficient for the photodecomposition of methylamine as far as the direct absorption of photons by the methylamine molecule is concerned. Really, the efficiency of the photodecomposition of methylamine, as deduced from the signal intensities of the photoproduced radicals, is considerable. Therefore, the methylamino radicals are considered to be produced from methylamines not by the photochemical direct process, but by a photosensitized process resulting from some metal impurities in the PVG, analogously to our previous findings on the photosensitized decompositions of hydrocarbons and hydrogen molecules on the surface of the PVG coated with transition-metal oxides.[10,11]

Anisotropic ^{14}N-hf Splitting of the Methylamino Radical. As was described in the previous section, the hf interaction of ^{14}N is expected to have a large anisotropy. The angular-dependent hf values of $a_\perp^N\sim0$ and $a_\parallel^N\sim$ 40 G were estimated on due basis of the anisotropic spectral patterns of the radicals and the findings on the NH_2 radical.[8] Because of this anisotropy, the linewidth of the lines due to $m_I^N=\pm1$ is expected to be spread over about 40 G, so that the $m_I^N=\pm1$ lines are obscured. As a result, only the isotropic proton lines are observed as sharp lines, while the $m_I^N=\pm1$ lines are recognized as humps on both sides of the proton lines. This is the reason why the hf splitting due to ^{14}N is apparently quenched in all the spectra of the methylamino radicals observed in this study.

On the other hand, the linewidth of each line is too broad compared with the difference in the g tensors, $\Delta g=g_\perp-g_\parallel$, for the precise value of Δg to be decided.

However, a linewidth alternation with a change in the proton quantum numbers is clearly observable in most spectra. For example, in the case of the CD_3ND radical (Fig. 4), the hf splittings due to the D nucleus are much more distinct in the higher magnetic field. This phenomenon in the linewidth shows the simultaneous existence of small anisotropies in both g and hf tensors.[12] Therefore, the magnitude of the anisotropies in g and hf tensors is considered to be as small as the order of the linewidth of the spectra.

Isotope Effect of D-Substitution in the Methyl Group on the β-Proton Hf Splitting. As is shown in Table 1, the substitution of a D atom in the methyl group of the methylamino radical causes an abnormal increase in the β-proton hfs constant over than the value expected from that of the undeuterated radical; that is, it increases from the value of $a^{H}_{CH_3}=34$ G in the CH_3NH (or CH_3ND) to that of $a^{H}_{CH_2D}=37$ G in the CH_2DNH (or CH_2DND) radical. This rather large isotope effect can not be explained by that observed in deuterated methyl radicals, which has been extensively investigated by many workers from both experimental and theoretical aspects.[13] The latter isotope effect has now been established to be attributable to the change in the s-character of the carbon 2pπ-orbital occupied by an unpaired electron due to the change in the out-of-plane vibration, and the magnitude of this effect has been shown to be quite small; moreover, the effect due to the D-substitution is in the negative direction. Therefore, it seems that the isotope effect in the β-position is different from that in the α-position. This may be quite natural considering that the origin of the hf splitting of the β-proton can be explained by the hypercojugation mechanism, while that of the α-proton can be explained by the spin-polarization mechanism.

As is well known, the hf splitting of the β-proton is given by a relation such as:

$$a_{\beta}^{H} = B + A\cos^2\theta$$

where B and A are constants, and θ, the dihedral angle between the 2pπ-orbital and the C–H bond in the methyl group. For a rapidly-rotating methyl group in the methylamino radical, neglecting B compared with the second term, the $\cos^2\theta$ in the second term is averaged to 1/2, thus leading to this equation: $a_{\beta}^{H}=1/2A$. As long as the isotropic free rotation of the methyl group is assumed, the ratio between the hfs constants of H and D in the methyl group of the CH_2DNH (or CH_2DND) radical should also coincide with the theoretical one. However, this is not the case. This rather large deviation may be explained by the following postulation;[14] the internal rotation of the methyl group resulting from asymmetric substitution with a deuterium atom is no longer isotropic, and an anisotropic averaging may occur over internal rotation, with a preferential orientation of the 2pπ-orbital coplanar with the C–H bond in the methyl group of the β-substituted methylamino radical.

The same isotope effect has recently been observed more distinctively in a complete set of deuterated ethyl radicals, which have been produced by the trapping of hydrogen atoms with ethylene molecules preadsorbed on the surface of the PVG coated with vanadium oxide, which acts as a photosensitizer for the dissociation of hydrogen molecules with the light of a wavelength longer than 350 nm.[11]

According to the above explanation, it is necessary also that $a^{D}_{CH_2D}$ be smaller than $a^{D}_{CD_3}$. Unfortunately, however, the experimental accuracy is not sufficient to ascertain this point because of the rather large linewidth of the adsorbed radicals.

Rotational State of the Methylamino Radical on the PVG Surface. As has been described above, the methylamino radicals trapped on the surface of the PVG have the following characteristics:

(1) Little anisotropy is observed in the methyl-proton hf splitting.

(2) The anisotropy in the nitrogen-proton hf is relatively larger than that of the methyl-proton, judging from the linewidth difference between the CH_3ND and CH_2DNH radicals.

(3) The anisotropy in the ^{14}N hf splitting is quite large, and the values of $a_{\parallel}^{N}\sim40$ and $a_{\perp}^{N}\sim0$ G were estimated.

From (1), the rotation of the methyl group around the axis of the C–N bond is inferred to be rapid enough, and the methyl group is judged to be free from interaction with the surface of the PVG. The (2) and (3) show that the NH group interacts strongly with the surface, and that it rotates approximately around the axis of the 2pπ-orbital of nitrogen. The rotation around the 2pπ-axis may be explained by the fact that the value of $a_{\parallel}^{N}\sim40$ G for the methylamino radical is very close to that of $a_{\parallel}^{N}=\sim38$ G for the NH_2 radical, which is the principal value for the direction of the 2pπ-orbital of the nitrogen of the NH_2 radical.[7,8]

The authors are indebted to Professor Masamichi Tsuboi and Dr. Keietsu Tamagake for their kind offer of the precious reagent $CH_2DNH_2\cdot HCl$.

The Phenanthrene/Anthracene–Picric Acid System

Shigeo KOIZUMI* and Yoshio MATSUNAGA**

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received July 17, 1973)

The phase relations in the phenanthrene/anthracene–picric acid system have been determined by calorimetry and X-ray diffraction. Four series of solid solutions occur in this system: the terminal solid solutions P and A, which are based on the parent picrate lattices, and the I and II solutions, which are based on the incongruently-melting ternary compounds. A eutectic is observed at about 47 mol% anthracene and at 124 °C. Enantiotropic transitions appear at about 76, 103, and 120 °C in the I solid solution and at about 80, 103, and 120 °C in the II solid solution. The Gibbs energy of formation from the solid component compounds has been estimated as −2.04, −1.67, −1.21, and −0.68 kcal/mol for the stable forms at the room temperature of the phenanthrene picrate, the I solid solution (at 34.58 mol% anthracene), the II solid solution (at 58.96 mol%), and the anthracene picrate respectively. The two transitions in the phenanthrene picrate have been shown to be easily detectable by recording the electrical resistivity as a function of the temperature.

The mutual solid solubility in many pairs of molecular complexes has been examined by Rheinboldt and Senise and by Lower;[1,2] however, no determination of the phase boundaries in the solids has been reported except for phenanthrene/anthracene–*s*-trinitrobenzene. In connection with our finding of the marked effects of impurities on an enantiotropic transition at 77 °C in phenanthrene picrate,[3,4] we have determined the phase diagram of the phenanthrene/carbazole–picric acid system. As part of our general interest in the physical properties of solid molecular complexes, we decided to study further the phase diagram of a binary system with phenanthrene picrate as one component. The system chosen was phenanthrene/anthracene–picric acid because a comparison of it with the phenanthrene/anthracene–*s*-trinitrobenzene system studied by Lower seemed to be interesting.

Experimental

Materials. Phenanthrene, Eastman white label, was purified according to the method reported by Feldman *et al.*[5] and then zone-refined. Pure anthracene was obtained by the reduction of anthraquinone prepared starting from benzene and phthalic anhydride. Picric acid, Wako special reagent, was twice recrystallized from ethanol. The picrate of the former hydrocarbon was crystallized from methanol and that of the latter, from carbon tetrachloride, as has been described by Kofler.[6] They were mixed together in various ratios and then fused in a small test tube by heating in an oil-bath for a short time. The melt was well shaken and then rapidly cooled. Finally the samples were kept at room temperature for various periods of time. Over forty samples were prepared for the examinations.

Measurements. Calorimetric curves up to the thaw points were recorded on a Rigaku Denki differential scanning calorimeter, Model 8001 SL/C, at a heating rate of 3 °C/min. The heats of transitions were estimated by comparing the peak areas with that for the transition in hexamethylbenzene, which is known to take place at 110.6 °C with ΔH=0.422 kcal/mol.[7] The melting points were visually measured with a magnifying lens and a polarizer. X-Ray measurements on powdered samples were made with a Toshiba recording diffractometer, Model ADG-301, with filtered copper radiation. In order to examine the powder pattern at various temperatures, the sample was mounted on an aluminum plate with a 20 W heater attached to the other side. The temperature of the plate was controlled with the aid of an autotransformer and was monitored by means of a copper-constantan thermocouple.

The approximate values of the Gibbs energy of formation at 25 °C from the solid-component compounds (ΔG_f, kcal/mol) were determined from the $\Delta G_f = RT \cdot \ln(c_2/c_1)$ relation, where c_1 (mol/l) is the concentration of undissociated picric acid in the saturated aqueous solution of picric acid and where c_2 is its concentration in equilibrium with a solid complex and solid hydrocarbon.[8] The assumption is made that the solutions are sufficiently dilute for the activities to be proportional to the concentrations. The total concentrations of picric acid (C, mol/l) in these solutions were measured by the spectrophotometric method and also by the gravimetric method.

The electrical resistivity of the hydrocarbon picrates was measured on pressed pellets by the two-probe method. The pellet and its holder were accommodated in a brass cylinder and were slowly heated with an electric furnace. During this process, the temperature of the holder was recorded on the X-axis of a Yokogawa X–Y recorder, Type 3078, and the current was amplified by a Keithley 3010 operational amplifier on the Y-axis.

Results and Discussion

Phase Diagram. If only the thaw-point-melting-point method of Rheinboldt was employed,[9] one would conclude that this system is of the V type in the Roozeboom classification of two-component solid solutions,[10] as are the phenanthrene/anthracene–*s*-trinitrobenzene and phenanthrene/carbazole–picric acid systems.[2,4] The eutectic is located at about 47 mol% anthracene and at 124 °C. Actually, the phase relations in this "immiscibility region", extending from about 20 to 80 mol% anthracene, are not at all simple. The appearance of two solid solutions is shown by X-ray diffraction patterns distinctly different from those of the terminal solid solutions. Although peritectics cannot be located in Fig. 1, these two solid solutions based on new ternary molecular complexes appear to melt incongruently. Therefore, the whole diagram is a combination of two diagrams of the IV type and

one of the V type in the Roozeboom classification. The solid solutions, I and II, may be regarded as non-stoichiometric compounds.

As was described in our earlier notes,[3,4] two enantiotropic transitions are observed in the P solid solution. The three phases, denoted as P_α, P_β, and P_γ in Fig. 1, can be well distinguished from each other by the X-ray method (see Fig. 2). It must be noted that the pattern given by the P_γ phase is very simple. The change from P_β to P_α is slow, and it becomes slower upon the addition of anthracene picrate;[3] therefore, the P_α phase can be observed up to only 4 mol% with the samples annealed for one week instead of 9 mol%, as is indicated in Fig. 1. After the same period of storage, the samples in the composition range from 4 to 6.5 mol% were shown by X-ray examination to be mixtures of P_α and P_β and only the P_β phase was found between 6.5 and 12 mol%. These observations are in reasonable agreement with the results of calorimetry reported previously.[3] The anthracene-rich solid solution P is metastable. The samples in the composition range from 9 to 12 mol% became mixtures of the P_α and I_α phases upon standing for five months. The P_β phase is gradually transformed into P_γ upon heating when the anthracene picrate is added. The dotted curve indicates the upper limit of the temperature range given by the point of return to the base line of the calorimetric curve. The temperature-dependence of the X-ray diffraction pattern also shows the coexistence of the P_β and P_γ phases over a wide temperature range.

The I solid solution, examined within one week after melting, exhibits only an enantiotropic transition near 120 °C. After the samples have been left at room temperature for three months, the I_α phase, extending from about 25 to 45 mol% anthracene, appears. Upon heating, two more well-separated endothermic peaks are observed at about 76 and 103 °C (see Fig. 1). Although the enthalpy changes at these transitions are comparable, the I_γ phase cannot be distinguished from I_β by X-ray diffraction. In addition, one or two extra peak(s) partially overlapped with the one near 120 °C are detectable below 40 mol% anthracene. The dotted curve in this composition range was drawn on the basis of the point of departure from the base line of the calorimetric curve. The X-ray diffraction also shows that the solid solution above this boundary is heterogeneous. The phase(s) appearing in this region could not be clarified; therefore, the region is denoted as I_x in the diagram. The absence of the transitions from I_α to I_β and from I_β to I_γ, the temperatures of which are close to those of the transitions from P_α to P_β and from P_β to P_γ, in newly-prepared samples can be considered as additional evidence of the appearance of the I solid solution. The range of the solid solution embraces such simple compositions as 2:5, 1:2, 2:3, and 3:4. For the present, there is no *a priori* reason for preferring any one of the possible compositions.

The II solid solution extends from about 49 to 63 mol% anthracene after storage for several months. Upon heating, three transitions, the temperatures of which are essentially the same as those in the I solid solution, are observed by the calorimetric method. The enthalpy change at the transition from II_β to II_γ is small, and these two phases are not distinguishable from each other by X-ray diffraction. Nevertheless, the recovery of the II_β phase from the II_γ phase is so slow that II_γ and II_δ are the only phases observable if the sample is examined within a day after melting. Qualitatively speaking, the behavior of the II solid

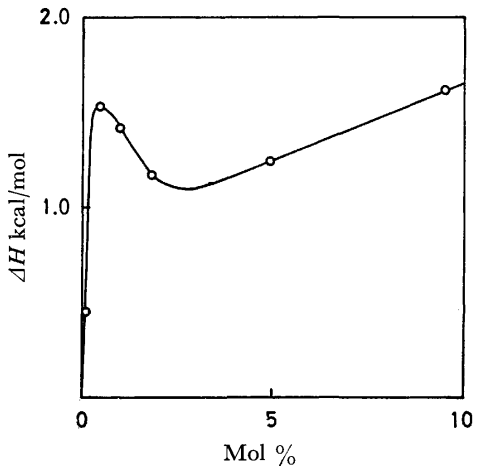

Fig. 3. Heat of the transition from A_β to A_γ plotted against the amount of added phenanthrene picrate.

solution is similar to that of the I solid solution. However, it must be noted that the diffraction patterns observed with the former solid solution are more complicated than those observed with the latter. Possible simple compositions included in the range of solid solution are 1:1, 5:4, 4:4, 3:2, and so forth.

The limit of the solubility of phenanthrene picrate into anthracene picrate is about 20 mol%. Although only one transition (at 85 °C) is seen in pure anthracene picrate, an additional transition detectable only by the calorimetric method appears in this terminal solid solution. Even the addition of as little as 0.1 mol% of phenanthrene picrate is enough to induce a sizable peak. The amount of the heat of this new transition is plotted against the composition in Fig. 3. The enthalpy and entropy of the transition both reach their maximum values at 0.5 mol% phenanthrene, and then reach their shallow minima around 3 mol%. The transition temperature and the amount of the enthalpy and entropy changes for representative samples of the four series of solid solutions are summarized in Table 1.

picric acid (C) in equilibrium with the solid hydrocarbon picrates and the Gibbs energies of formation (ΔG_f) from their parent solids are collected in Table 2. As naphthalene picrate is the only hydrocarbon picrate for which the Gibbs energy of formation is available in the literature, this picrate was included in our measurements for the sake of comparison. The concentrations given here were spectrophotometrically measured and were in reasonable agreement with those obtained by the evaporation of the solutions to dryness—*e.g.*, 0.0572 mol/l for picric acid and 0.0173 mol/l for the II solid solution. The dissociation constant of picric acid in an aqueous solution is required in order to calculate the concentration of undissociated acid. Four values ranging from 0.196 to 0.60, have been compiled by Kortüm *et al.*[11] Of these, the compilers have considered the value of 0.381 by Halban and Seiler to be most reliable.[12] However, the Gibbs energy of the formation of naphthalene picrate calculated with this constant, −2.44 kcal/mol, is appreciably larger than the value of −2.05 kcal/mol at 20 °C reported by Brönsted,[8] the value of −2.08 kcal/mol at 3 °C reported by Brown from cryoscopic measurements in nitrobenzene,[13] and also the value of −2.07 kcal/mol at 25 °C reported by Bell and Fendley from direct electrometric measurements.[14] On the other hand, the constant determined by Dippy *et al.* gives a value of 2.10 kcal/mol, which is in fair agreement with the above-mentioned literature values. Consequently, the energies in Table 2 were calculated using the latter value, that is, 0.196.[15]

Hammick and Hutchison have determined the Gibbs energies of formation for ten hydrocarbon-*s*-trinitrobenzene complexes and have noted that the value for the naphthalene complex is very close to that of the corresponding picrate.[16] On the basis of the data of this pair only, they have concluded that there is no very great difference in the stabilities of the solid picrates and the corresponding *s*-trinitrobenzene complexes. Our results are in accordance with their conclusion. However, it may be noted that the relative stabilities are not parallel in these two series. Such an inversion of the relative stabilities of naphthalene and phenanthrene has also been found in the *s*-tri-

nitrobenzene and the trinitrotoluene complexes studied by Hammick and Hutchison.

The values of the Gibbs energy of formation listed in Table 2 indicate that the I_α phase is more stable by 0.10 kcal/mol, while the II_α phase is less stable by 0.03 kcal/mol, than mixtures of the parent picrates. Although the latter difference is within the limits of our experimental error, strictly speaking, the comparison must be made with mixtures of the P_α phase containing about 9 mol% anthracene and the A_α phase containing about 20 mol% phenanthrene. As these solid solutions are, to some extent, more stable than the pure picrates, it is almost certain that the II_α phase is metastable. So far, though, we have not succeeded in the crystallization of the I and II solid solutions from solutions. The possibility that the I solid solution disappears if the samples are stored for a sufficiently long time cannot be completely eliminated.

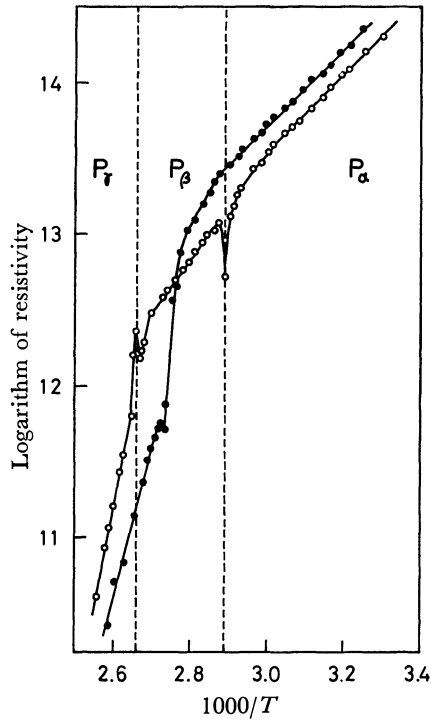

Fig. 4. Electrical resistivity of compressed phenanthrene picrate: ○ ascending temperature, ●: descending temperature.

Electrical Resistivity. The logarithm of the resistivity of the phenanthrene picrate, recorded at ascending and descending temperatures, is plotted against the reciprocal temperature in Fig. 4. In the former process, not only the changes in the slope but also the minima were observed at the transition temperatures. The minimum at the transition from P_α to P_β is deep and sharp, while that from P_β to P_γ is shallow and broad. The activation energy for semiconduction tends to be large in the high-temperature phase. The resistivity at 25 °C is in the order of 10^{14} ohm cm. This value is appreciably smaller than that reported for the corresponding *s*-trinitrobenzene complex. Kuroda *et al.* have measured the temperature-dependence of the resistivity of the *s*-trinitrobenzene complex in a range from room temperature to a little below the melting point; they obtained 7×10^{18} ohm cm for the resistivity at 15 °C and 1.24 eV for the activation energy.[17] The latter quantity in the picrate is smaller by a factor of approximately two in the P_α and P_β phases and larger almost by the same factor in the P_γ phase. The presence of an enantiotropic transition located 15 °C below the melting point has been reported in the phenanthrene–*s*-trinitrobenzene complex by Kofler.[6] Nevertheless, no anomaly in the resistivity due to this transition has been noted by Kuroda *et al.* The appearance of a sharp resistivity minimum at the transition point has been found in Würster's blue perchlorate by Pott and Kommandeur.[18] Contrary to our case, this phenomenon could be observed only on crystals, not in compressed polycrystalline samples. As is shown in Fig. 4, there is a large hysteresis in the high-temperature region. A delayed transition from P_γ to P_β could be detected by the resistivity measurements. Moreover, the activation energies observed in the cooling process are little smaller than those observed in the heating process.

Although a gradual change in slope in the resistivity curves was observed near the transition temperature(s) in the anthracene picrate and in that doped with phenanthrene picrate (1 mol%) upon an increase in the temperature, no resistivity minimum at the transition temperature(s) was detected with these samples. Again, the resistivity at 25 °C is in the order of 10^{14} ohm cm, which is about one-hundredth of the resistivity of the anthracene–*s*-trinitrobenzene reported by Kuroda *et al.* Such a large difference is in marked contrast to the observations made by Labes *et al.* that the resistivity of coronene–picric acid is of the order of 10^{12} ohm cm, while that of the corresponding *s*-trinitrobenzene complex is 10^{13} ohm cm at room temperature.[19]

The authors wish to express their thanks to Professor Toshio Yokokawa for letting them use the X-ray diffractometer.

The ESR of the Fast-rotating $-CH_2$ of the Radical Formed by the Photolysis of CH_2I_2 on Silica Gel

Kazuo SHIMOKOSHI

Department of Chemistry, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo 152

(Received July 26, 1973)

The electron spin resonance spectra have been measured for the radical formed by the photolysis of methylene iodide adsorbed on silica gel. The spectra were anisotropic and were attributed to the radical of the $\equiv Si-O-CH_2$ form by an analysis of the hyperfine splittings due to two protons, taking into consideration the photochemical processes on the silica gel surface. From a line-shape analysis of the observed spectrum, the following anisotropic hyperfine interaction parameters for the protons and g-value have been obtained:

$$\mathbf{A}_{//} = 28.5 \pm 0.5\text{G}, \quad \mathbf{A}_{\perp} = 18.8 \pm 0.5\text{G}, \quad g = 2.0030 \pm 0.0005.$$

It has been concluded from the analysis of the spectra that the hyperfine structure observed with axially-symmetric tensors is a result of the fast internal rotation of the methylene group of the radical.

The effects of the internal motion of radicals on the ESR spectrum have been reported by many authors. The reorientation of terminal methylene has been found in the CH_2COO^- radical, formed by the irradiation of glycine,[1] triglycinesulphate,[2] zinc acetate, and sodium acetate.[3] Of these, CH_2COO^- in zinc acetate has been studied extensively by Hayes *et al.*[4] and by Ohigashi and Kurita,[5] who have studied the temperature dependence of the hyperfine pattern in the light of the internal rotation of the methylene group. Lefebvre and Maruani[6] have theoretically shown the effect of the fast-rotating methylene group on the spectrum of randomly-oriented radicals in solids, in particular the case of CH_2COOH, by means of computer simulation. More recently, McDowell, Raghunathan and Shimokoshi[7] have reported this effect in the interpretation of the anisotropic spectrum of an ethyl radical trapped in an argon matrix at 4.2 K, taking into consideration the free rotation of the methylene group in the radical.

On the other hand, the surface properties of silica gel have been the subject of much research. ESR investigations of the radicals formed on the surface have also provided detailed information about the surface properties, together with the mechanism of the radical formation. Recently, Melamund *et al.*[8] have observed the radical ($\equiv Si-O-CH_2$) formed by the photolysis of methylated Vycor glass and have discussed the mechanism of the formation of the radical. However, they did not give the anisotropic hyperfine coupling of the protons based on the internal rotation of the methylene group. This paper will report the results of our ESR studies of the fast-rotating methylene group of the radical formed by the photolysis of CH_2I_2 on silica gel.

Experimental

Silica gel (SILICAR TLC-7GF) was introduced into a 3 mm *i.d.* quartz tube and pretreated at various temperatures (200—900 °C) for 2—12 hr in a vacuum. Methylene iodide obtained from the Eastman Co., Ltd., was purified by vacuum distillation before use. After the pretreatment, the silica gel was brought into contact with various amounts of methylene iodide at room temperature. In order to obtain a high concentration on the surface, methylene iodide was condensed by cooling the samples to 77 K.

In addition to this procedure, the pretreated silica gel was exposed to a small amount of water vapor (0.1—2.0 Torr) before the contact of methylene iodide. Remarkable effects were thus observed in the case of the samples pretreated at temperatures higher than 600 °C.

After sealing off the tube, the samples were cooled in a liquid nitrogen Dewar, placed in an X-band cavity of a JES 3 BSX spectrometer, and irradiated by means of a low-pressure mercury lamp which emitted the 2537 and 1849 Å wavelengths. For purposes of comparison, samples which had never been exposed to methylene iodide were irradiated under the same conditions as those used for the methylene iodide samples.

Results and Discussion

After irradiation for several minutes, the samples turned brown and the ESR spectra were observed. The spectrum shown in Fig. 1 is typical; it was obtained at 77 K by the irradiation of samples pretreated at 400 °C or lower for 2—6 hr. When the samples pretreated at 700 °C or higher for 2—12 hr, the spectra obtained by the irradiation were complicated and very different from that shown in Fig. 1. However, the

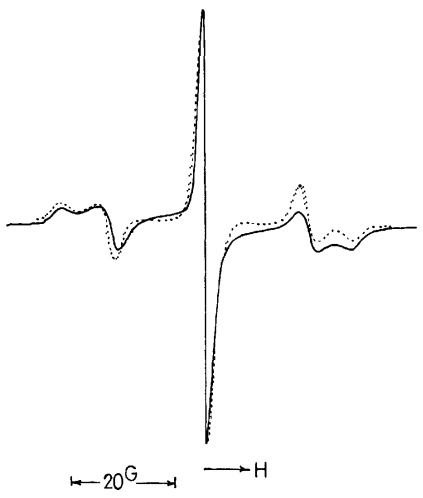

Fig. 1. The spectrum (full line) obtained by the photolysis of CH_2I_2 on silica gel at 77 K. The broken line shows calculated spectrum with the ESR parameters of $\mathbf{A}_{//}=28.5$ G, $\mathbf{A}_{\perp}=18.8$ G and $g=2.0030$.

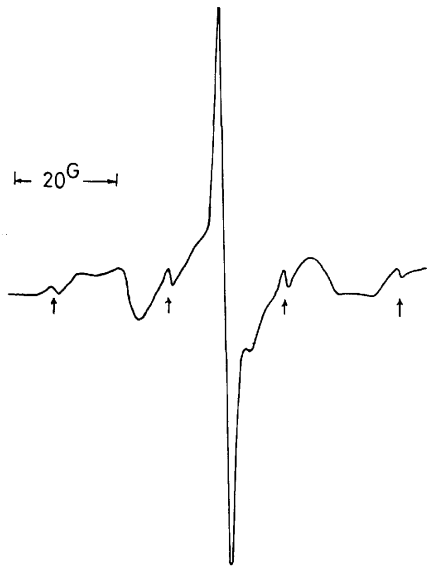

Fig. 2. The spectrum obtained by the photolysis of condensed CH_2I_2 on silica gel at 77 K. Arrows show the lines due to methyl radical.

same spectrum as that of Fig. 1 appeared again with much less intensity upon the irradiation of the samples treated at 700 °C when a small amount of water vapor was admitted onto the samples before they adsorbed the methylene iodide. The spectrum shown in Fig. 2 was obtained by the irradiation of concentrated methylene iodide on silica gel pretreated at 400 °C. Obviously, the spectrum is identical with that shown in Fig. 1 except that weak signals due to the methyl radical are present. This spectrum disappeared when the samples were warmed to 150 K. The irradiation of silica gel under the same conditions as in the case of methylene iodide samples showed very weak signals. The absorption lines due to the hydrogen atom and an asymmetric line near $g=2$, which is also seen in Figs. 1 and 2 with much less intensity than the other lines, were observed upon further irradiation.

Methylene iodide has absorption maxima at 2890, 2490, and 2120 Å.[9] Gregory and Style[10] have done the photolysis of this compound at 3100 Å mainly and have thus produced methylene, although they were not certain whether the primary process was

$$CH_2I_2 + h\nu \longrightarrow CH_2I + I \quad (1)$$

followed by

$$CH_2I \longrightarrow CH_2 + I \quad (2)$$

or a direct process;

$$CH_2I_2 + h\nu \longrightarrow CH_2 + I_2(2I) \quad (3)$$

The primary process in the vacuum ultraviolet photolysis has been studied by Style and Ward,[11] who suggested that the irradiation with 1250—2000 Å excites the fluorescence spectrum of iodine. They concluded that the process was as follows:

$$CH_2I_2 + h\nu \longrightarrow CH_2 + I_2^* \quad (4)$$

Therefore, it is likely that methylene is formed primarily in the present system by photolysis.

It is also of interest to observe the ESR spectrum of the free methylene radical formed in the present system. The methylene radical is triplet in its ground state; its ESR spectrum has been observed by Bernheim *et al.*[12] and by Wasserman *et al.*,[13] who have reported the values of spin-spin interaction as $D=0.7$—$0.9\ cm^{-1}$ and $E\cong 0.03\ cm^{-1}$. However, no spectrum could be detected up to 10000 G in the present experiments except for that shown in Figs. 1 and 2. If the motion of the radical is random and rapid enough to average out such a large spin-spin interaction, it may be possible to observe the spectrum of the radical in the near $g=2$ region. In this case, however, the spectrum is expected to be rather isotropic in its hyperfine structure, unlike the spectrum shown in Fig. 1, even though the hyperfine splittings due to the protons of free methylene are comparable to that measured from the observed spectrum.*1 Further, a preferential rotation of the radical around any axis may not cancel out the fine structure in the spectra of the randomly oriented powder specimens. Therefore, the spectrum shown in Fig. 1 could not be identified with that of the free methylene radical.

In the identification of the spectrum, a possibility of another radical, CH_2I, which may be formed by Process (1), may be excluded, because there seems to be no evidence for any further splitting or line-broadening due to a magnetic iodine nucleus ($\mathbf{I}=5/2, 7/2$).

The observed spectrum of Fig. 1 is very similar to that of $\equiv Si-O-CH_2$ reported by Melamud *et al.*,[8] who obtained the radical by the photolysis of methylated Vycor glass. Therefore, although the radicals on Vycor glass were more stable and although the line-shape of the outer components was slightly different from the present one, the radical species observed in the present experiments may also be $\equiv Si-O-CH_2$ formed by processes on the silica gel surface subsequent to the photolysis, as will be discussed later.

It may readily be seen in Fig. 1 that the spectrum consists of three lines, *i.e.*, the intense, symmetrical, and sharp line in the center and two other asymmetric lines, suggesting the presence of two equivalent protons with axially-symmetric hyperfine tensors. The spectrum was then simulated with the aid of a HITAC 8700 computer, using a Fortran IV program that solved the spin Hamiltonian:

$$H = \beta \mathbf{H}\tilde{g}\mathbf{S} + \mathbf{I}\tilde{A}\mathbf{S}$$

to the second order in hyperfine interaction with a good approximation for the present purposes.[6] The best-fitting spectrum (shown in Fig. 1) was thus obtained, assuming an isotropic g value ($g=2.0030$) and

*1 Acording to a recent calculation by T. A. Claxton (*Trans. Faraday Soc.*, **66**, 1537, 1540 (1970)), the isotropic hyperfine splitting due to a proton in the NH radical, which has two unpaired electrons, is about twice that in the single unpaired electron radical, NH_2. However, the values of the spin-spin interaction (D, E)[12,13] reported predict the bent structure for the free methylene radical. This may reduce the isotropic hyperfine coupling of the protons, because in the bent structure s-p hybridization is positive; it may therefore cancel out the negative contribution of the π-electron to the hyperfine couplings.[13]

TABLE 1. ESR PARAMETERS of Si–O–CH_2

	Observed	Calculated by Eq. (7)[a]
g	2.0030	
$\mathbf{A}_{//}$	28.5±0.5 G	−27.4 G
$\mathbf{A}_{\perp}$	18.8±0.5 G	−18.4 G
$\mathbf{A}_{iso}$	22.0±0.5 G	−21.1 G

a) In the case of CH_2COOH produced in a single crystal of $CH_2(COOH)_2$ two α protons were not equivalent because of its different crystalline environment. Therefore, the averaged values were used.

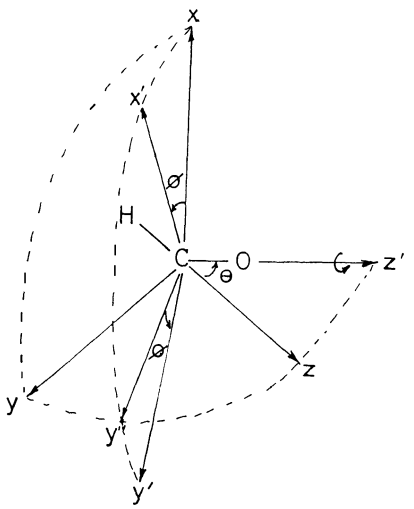

Fig. 3. Coordinate systems chosen for the transformation of hyperfine tensors from the principal system to the rotating system.

equal values of the hyperfine tensor ($\mathbf{A}_{\perp}$=18.8 G and $\mathbf{A}_{//}$=28.5 G) for both protons, with a gaussian linewidth of 3 G. The parameters obtained in this way are listed in Table 1, where $\mathbf{A}_{iso}$ was determined assuming that $\mathbf{A}_{\perp}$ and $\mathbf{A}_{//}$ have the same sign.

The sharpness and the symmetricity of the central line show that when the two proton spins are antiparallel, the hyperfine anisotropy is cancelled out. This means that the two protons are magnetically equivalent and that the $-CH_2$ group reorients sufficiently rapidly for the hyperfine interaction by the protons to be averaged out over all the orientations of the $-CH_2$.

The averaged hyperfine coupling tensors can be obtained by first transforming from the principal-axis system to a coordinate system in which the rotation axis lies along the C–O bond, and then by rotating about this axis, as is shown in Fig. 3. The transformation is performed according to the following unitary relation;

$$\mathbf{A}_r = \mathbf{U}\mathbf{A}^0\mathbf{U}^{-1} \tag{5}$$

where $\mathbf{A}_r$ is the tensor for the rotating coordinate system and where U is the transformation matrix, which can be expressed by the angles, θ and ϕ, associated with the transformation between the two reference frames;

$$\mathbf{U} = \begin{pmatrix} \cos\phi & -\sin\phi & 0 \\ \cos\theta\sin\phi & \cos\theta\cos\phi & -\sin\theta \\ \sin\theta\sin\phi & \sin\theta\cos\phi & \cos\theta \end{pmatrix} \tag{6}$$

One can obtain the following simple expressions for the tensor in the rotating system, as have been previously derived by the present author;[7]

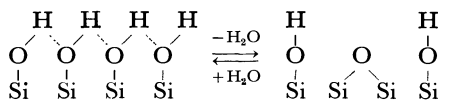
$$\langle \mathbf{A}^r_{x'x'} \rangle_{av} = \langle \mathbf{A}^r_{y'y'} \rangle_{av} = 1/2(\mathbf{A}^0_{xx} + \mathbf{A}^0_{yy}\cos^2\theta + \mathbf{A}^0_{zz}\sin^2\theta)$$
$$\langle \mathbf{A}^r_{z'z'} \rangle_{av} = \mathbf{A}^0_{yy}\sin^2\theta + \mathbf{A}^0_{zz}\cos^2\theta$$
$$\langle \mathbf{A}^r_{x'y'} \rangle_{av} = \langle \mathbf{A}^r_{y'z'} \rangle_{av} = \langle \mathbf{A}^r_{x'z'} \rangle_{av} = 0 \tag{7}$$

where z' is the rotation axis and where θ is the angle between the z axis in the principal system and the rotation axis. Apparently, these equations give the axially-symmetric tensor corresponding to the hyperfine coupling in the fast-rotating system, with

$$\langle \mathbf{A}^r_{z'z'} \rangle_{av} = \mathbf{A}_{//} \text{ and } \langle \mathbf{A}^r_{x'x'} \rangle_{av} = \mathbf{A}_{\perp}.$$

It was not possible to obtain the principal values from the observed parameters and from those given by Eq. (7), for, in the present experiment, the spectrum of non-rotating $-CH_2$ could not be obtained. However, this type of radical may have a relatively narrow range of principal values whose principal axes are parallel to the C–H bond, perpendicular to the CH_2 plane, and parallel to the direction perpendicular to them. Therefore, using the values obtained for CH_2COOH trapped in irradiated single crystals of $CH_2(COOH)_2$[14] and using Eq. (7), the rotationally-averaged values were obtained; they are listed in the second column of Table 1, where the HCH angle was assumed to be 120°.

According to the above discussion, the spectrum can be well explained in terms of the ≡Si–O–CH_2 radical formed on the silica gel. Therefore, it is of interest to consider the processes occurring on the surface. It has now been established by infrared studies[15] that silica gel surfaces may possess both a "free" hydroxyl group and an "interacting" hydroxyl group, depending on their mutual distances. By dehydration at temperatures lower than 400 °C, the adsorbed water and part of the terminal hydroxyl group are eliminated to form both monomeric (free) and dimeric (interacting) surface hydroxyl groups, but most of the surface silanols remain. This process occurs reversibly; it can be shown as follows:



(8)

It has been established that evacuation at temperatures higher than 400 °C gives rise to an irreversible loss of surface hydroxyl groups, especially of interacting hydroxyl groups.[15] This effect of the pretreatment upon the nature of the silica gel surface suggests the participation of the surface hydroxyl groups in the formation of the radical; this fact can be used in interpreting the observation of the spectrum shown in Fig. 1 upon the photolysis of the samples pretreated at lower temperatures and by admitting water vapor onto the silica gel pretreated at higher temperatures before the photolysis. Therefore, a possible mechanism for the formation of the radical is as follows:

A) methylene iodide photolized by 2537 or 1849 Å gives CH_2 and 2I and/or an excited iodine molecule, I_2*; these iodine species then abstract hydrogen

from the surface silanol to make it possible to form the $\equiv Si-O-CH_2$ radical through recombination, or

B) the recombination of CH_2 and the surface siloxy which was produced independently by the photolysis of the surface silanol.

Since the formation of atomic hydrogen from silica gel without methylene iodide was much less efficient than that of $-CH_2$ from methylene iodide, A) is more likely in this case.

The formation of CH_3 by the photolysis of condensed methylene iodide is possibly due to the abstraction of hydrogen from methylene iodide or to that of the surface silanol by the CH_2 formed primarily.

In conclusion, the photolysis of methylene iodide on the silica gel, which has surface hydroxyl groups, gives rise to the formation of the radical $-CH_2$ chemically bonded to the silica gel surface. The ESR spectrum of this radical observed at 77 K shows the anisotropic hyperfine structure to be expected from the axially-symmetric hyperfine interaction of two equivalent protons. The observed hyperfine splittings due to two protons can be reasonably explained by taking into consideration the free rotation of the methylene group.

The author wishes to thank Professor C. A. McDowell of The University of British Columbia for his interest in this work. Part of the present work has been done during the author's staying at The University of British Columbia.

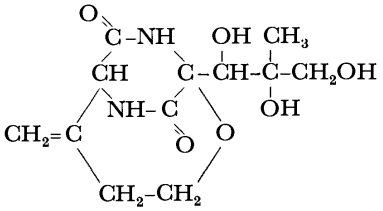
The Crystal and Molecular Structure of Bicyclomycin, a New Antibiotic

Yoji TOKUMA, Shigetaka KODA, Toshio MIYOSHI, and Yukiyoshi MORIMOTO
Research Laboratories, Fujisawa Pharmaceutical Co., Ltd., Higashiyodogawa-ku, Osaka 532
(Received August 27, 1973)

The molecular structure of a new antibiotic, Bicyclomycin ($C_{12}H_{18}O_7N_2$), has been elucidated by X-ray diffraction analysis. Bicyclomycin crystallizes from aqueous solution in two forms, an orthorhombic and a monoclinic systems. The crystal data for the former are $a=11.72$, $b=12.72$, $c=8.80$ Å and the space group $P2_12_12_1$, while those for the latter are $a=10.27$, $b=10.91$, $c=6.67$ Å, $\beta=101.4°$, and the space group $P2_1$. The crystal structure of the former was solved by the direct method and refined by least-squares method to a final R factor of 0.07 for 1623 reflections. The established structure is



The diketopiperazine ring is folded into a boat form. The conformations of the side chain are all *gauche* or nearly so. All the oxygen and nitrogen atoms participate in two intramolecular and four intermolecular hydrogen bonds.

A new antibiotic Bicyclomycin was obtained from the culture filtrate of *Streptomyces sapporonensis* which was isolated from a soil sample collected at Sapporo City. Bicyclomycin has an antibacterial activity against Gram-negative bacteria and exhibits no cross resistance to major antibiotics for human use.[1] Chemical and spectroscopic investigations[2] suggested several functional groups in the molecule, but the precise stereochemistry of the structure remained to be unknown. X-Ray diffraction study was thus undertaken to establish the whole structure of the molecule.

Experimental

Bicyclomycin crystallizes from aqueous solution in two forms, colorless prisms and plates. Oscillation and Weissenberg photographs uniquely identified the space groups as $P2_12_12_1$ for the former and $P2_1$ for the latter. The unit cell dimensions were determined by the least-squares calculation using the high angle spots of Cu$K\alpha_1$ and Cu$K\alpha_2$ on zero-layer Weissenberg photographs superimposed by the Al wire patterns for calibration. The densities were measured by a floatation method in a chloroform–carbon tetrachloride mixture for the orthorhombic crystal and a benzene–carbon tetrachloride mixture for the monoclinic one, respectively. Crystal data were summarized in Table 1. The intensity data for the orthorhombic modification were collected from the multiple-film equi-inclination Weissenberg photographs for the layer lines 0 to 8 on the a axis and 0 to 6 on the c axis, respectively using the Ni-filtered Cu$K\alpha$ radiation. The intensities were estimated visually by comparison with a calibrated film strip. Corrections were made for Lorentz and polarization factors and spot sizes. A total of 1623 intensities was recorded, but 74 of these were too weak to be measured. Structure factor magnitudes $|F|$ and normalized structure factor magnitudes $|E|$ were derived by the Wilson's method. The values of the statistical average, $\langle|E|\rangle$ and $\langle|E|^2-1\rangle$, were 0.867 and 0.778, respectively, as compared with 0.886 and 0.736, the theoretical values for noncentrosymmetric space groups.

Table 1. Crystal data

Crystal system	orthorhombic	monoclinic
Molecular formula	$C_{12}H_{18}O_7N_2$	$C_{12}H_{18}O_7N_2\cdot H_2O$
Unit cell constants	$a=11.72(1)$Å	$a=10.27(1)$Å
	$b=12.72(1)$	$b=10.91(1)$

Absent spectra	$h00$ when h is odd,	$0k0$ when k is odd.
	$0k0$ when k is odd,	
	$00l$ when l is odd.	
Space group	$P2_12_12_1$	$P2_1$

Structure Determination

The structure of Bicyclomycin was solved using the symbolic addition technique applied to noncentrosymmetric structures.[3] The Eq. (1) was used to define 30 phases ($|E|\geq1.5$) in terms of initial set of phases listed in Table 2. From multiple indications, it soon became obvious that $2b\simeq0$, $2c\simeq\pi$, and $2p\simeq\pi$. As for the value a, there were no confirmative indications.

$$\varphi_{\boldsymbol{h}} \simeq \langle\varphi_{\boldsymbol{k}}+\varphi_{\boldsymbol{h}-\boldsymbol{k}}\rangle_{\boldsymbol{k}r} \quad (1)$$

Thus, various combinations of symbolic phases for

Table 2. Initial set of phases

Reflection	Phase	$\|E\|$
0 3 7	$\pi/2$	2.56
0 9 4	$\pi/2$	2.73
5 0 8	0	3.29
4 2 10	a	2.67
5 10 4	b	2.69
10 4 1	c	2.78
4 5 8	p	2.57

the use of the tangent formula were assigned as follows:

$$a = \pi/6, 3\pi/6, 5\pi/6, -\pi/6, -3\pi/6, -5\pi/6$$
$$b = 0, \pi$$
$$c = \pi/2, -\pi/2$$
$$p = \pi/2, -\pi/2.$$

For each of the 48 sets with 185 phases ($|E| \geq 1.50$), six cycles of tangent refinement were carried out. Only four sets of them converged characteristically at lowest R' index,[3] defined by

$$R' = \frac{\sum_{kr} ||E_h|_{obs} - |E_h|_{calc}|}{\sum_{kr} |E_h|_{obs}} \quad . \quad (2)$$

Further eight cycles of tangent refinement for each of these four sets of 391 phases ($|E| \geq 1.20$) converged at the same R' index of 0.26.

Three dimensional E-maps with 391 terms were then calculated for these sets. The 21 largest peaks appeared on the respective four E-maps; each of them was found to give the same molecular structure. There was only one unique set, however, to which the other three were related by a mirror symmetry or by a translation. Assuming all the atoms to be nitrogen atom, structure factor calculation based on these 21 atoms gave an R factor of 0.25 for all reflections, and the corresponding Fourier synthesis showed no spurious peaks. All the 21 non-hydrogen atoms were assigned to 12 carbon, 7 oxygen and 2 nitrogen atoms, respectively on the basis of this Fourier map and the partial structure known from chemical and spectroscopic investigations.[2]

The atomic coordinates and isotropic thermal parameters for the 21 atoms were refined by block-diagonal least-squares method for four cycles. The function minimized was $\sum w(|F_o| - |F_c|)^2$. Then, anisotropic temperature factors for all non-hydrogen atoms were introduced, and two more cycles of refinement reduced the R factor to 0.09. A difference map calculated at this stage revealed all the 18 hydrogen atoms. Setting the isotropic temperature factor of each hydrogen atom

The mean standard deviation in atomic coordinates is 0.08 Å, and that of the distance X–H is 0.09 Å.

equal to 3.0 Å^2, four more cycles of least-squares refinement brought the R factor down to 0.07, the positions of all the hydrogen atoms being converged satisfactorily. The maximum shift of the non-hydrogen atom coordinates became less than the estimated standard deviations; their mean value for C, N, and O was 0.004 Å (0.003~0.007 Å). The weighting scheme adopted in the final least-squares calculation was:

$$w = 0.4 \quad \text{for } |F_0| < 2.0$$

$$w = 1.0 \quad \text{for } 2.0 \leq |F_0| < 10.0$$

$$w = 10.0/|F_0| \quad \text{for } |F_0| \geq 10.0.$$

The scattering factors for H, C, N, and O were taken from International Tables for X-ray Crystallography.[4] The final atomic coordinates and thermal parameters for non-hydrogen atoms are given in Tables 3 and 4, and those for hydrogen atoms in Table 5. The observed and calculated structure factors are given in Table 6.

Most of the computer programs used were in the UNICS.[5] Tangent refinement was performed with the program TANG, written by T. Ashida. All the programs were modified by the authors to allow calculations on middle size of computer, HITAC 8400 at Nippon Business Consultant and Fujisawa Pharmaceutical Co., Ltds.

Results and Discussion

The configuration of the Bicyclomycin molecule can be seen in Fig. 1. The bond distances and angles of the non-hydrogen atoms are shown in Fig. 2. The mean estimated standard deviations are 0.006 Å and 0.3° for bond distances and angles, respectively. The bond lengths involving the hydrogen atoms are listed in Table 5.

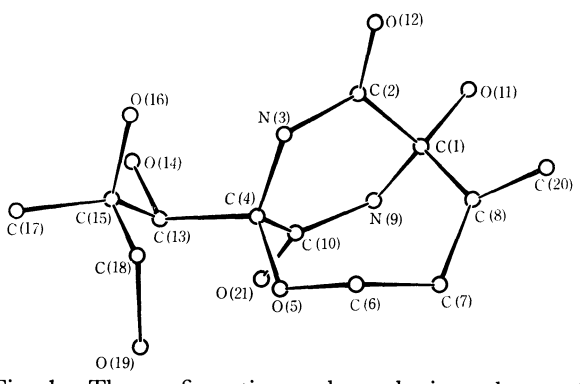

Fig. 1. The configuration and numbering scheme of Bicyclomycin molecule.

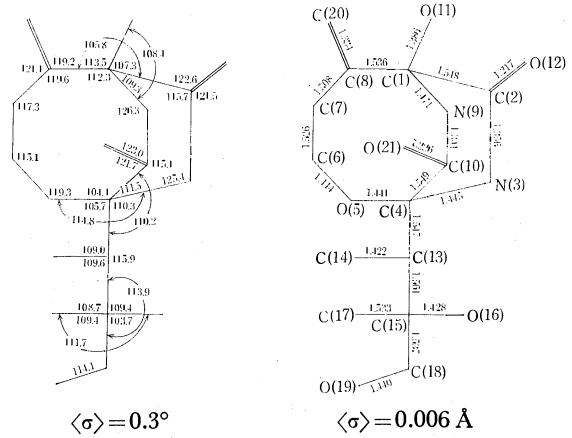

Fig. 2. Bond distances and angles.

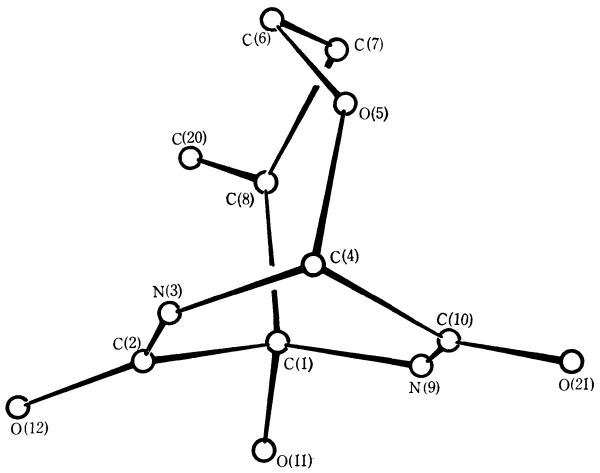

Fig. 3. A part of the molecule showing the cage type of ring system.

The diketopiperazine ring is folded into a boat conformation. Bridging the axial bonds of C(1) and C(4) in the ring, four atoms, O(5), C(6), C(7), and C(8), constitute the two eight-membered rings together with ⩾C–CO–NH–C⩽ moieties of the six-membered ring and thus establish the cage type of ring system. These features are shown in Fig. 3. There exists an approximate two fold axis going through the center of the diketopiperazine ring and the middle point of the C(6)–C(7) bond.

Atoms C(1), C(2), N(3), and O(12) are coplanar within 0.03 Å (amide plane I) and those C(1), C(4), N(9), C(10), and O(21) are also coplanar within 0.03 Å (amide plane II). The dihedral angle between amide plane I and II is 144°. The moiety, C(1), C(8), C(7), and C(20) involving the methylene group, displays the good planarity (methylene plane). The equations of the best planes and the deviations of respective atoms from the planes are listed in Table 7.

The distances, C(2)–N(3) (1.36 Å) and C(10)–N(9) (1.34 Å) significantly shorter than that of C–N single

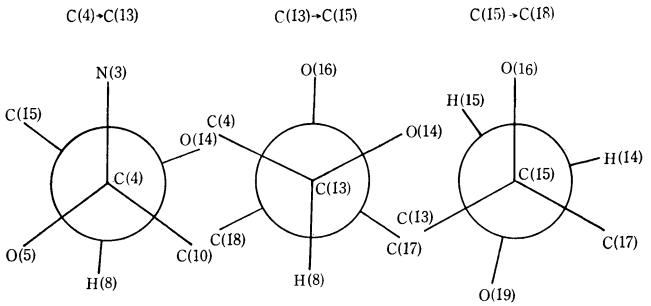

Fig. 4. Newman projections about C(4)–C(13), C(13)–C(15), and C(15)–C(18) bonds.

bond length (1.47 Å), indicate some double bond character; similar shortening of the bond length has been reported in diketopiperazine[6] and in many peptides.[7] The distance C(1)–O(11) (1.39 Å) seems to be shorter than that of the corresponding single bond length.

The conformation of the side chain is presented by the Newman projections down the C(4)–C(13), C(13)–C(15), and C(15)–C(18) bonds. As shown in Fig. 4,

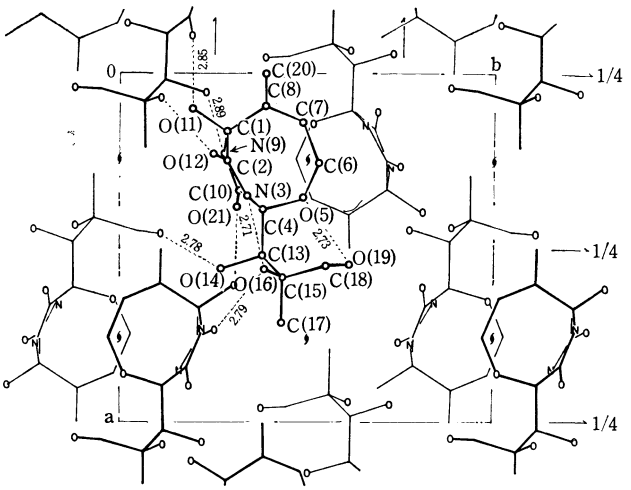

Fig. 5. The crystal structure viewed along the c axis. The hydrogen bonds are indicated by dashed lines.

Table 8. Inter- and intramolecular hydrogen bonds (D–H···A)

Donor	H	Acceptor	D···A (Å)	H···A (Å)	D–H···A (°)
I) Intermolecular					
N(9)	H(6)	$O(14)^{I}$	2.89	2.07	166
O(11)	H(7)	$O(21)^{I}$	2.85	1.89	156
O(14)	H(9)	$O(19)^{II}$	2.78	1.99	161
O(16)	H(10)	$O(12)^{III}$	2.79	1.93	178
II) Intramolecular					
N(3)	H(1)	O(16)	2.71	1.91	144
O(19)	H(16)	O(5)	2.73	1.80	146

Roman numerals as superscripts denote the following transformations relative to the reference molecule at x, y, z:

I	$-1/2+x$,	$1/2-y$,	$-z$,
II	$1-x$,	$-1/2+y$,	$1/2-z$,
III	$1/2+x$,	$1/2-y$,	$1-z$,

all the conformations are *gauche* or nearly so.

All the oxygen and nitrogen atoms in the molecule participate in two intramolecular and four intermolecular hydrogen bonds. Two oxygen atoms, O(16) and O(19), in the side chain participate in intramolecular hydrogen bonds, N(3)–H(1)···O(16) and O(19)–H(16)···O(5). These hydrogen bonds are of particular contribution to retain the molecular frameworks.

The crystal structure viewed along the *c* axis is shown in Fig. 5. The hydrogen bonds are indicated by dashed lines and detailed features of these hydrogen bonds are listed in Table 8.

The authors are indebted to Professor Masao Kakudo and Dr. Tamaichi Ashida, Institute for Protein Research, Osaka University, for discussions and suggestions in the progress of this work and for permitting us to use original program, TANG.

Fluorescence Depolarization Study of Hydrogen Bonded 1-Anthrol

Sanyo HAMAI and Hiroshi KOKUBUN

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received September 17, 1973)

Rotaional depolarization of 1-anthrol fluorescence was studied in liquid paraffin. The molecular volume of 1-anthrol becomes large when it forms a hydrogen bonded complex. The molecular volume of the complex depends on the concentration of acceptor as well as the kind of acceptor. The molecular volume obtained by extrapolation to nil acceptor concentration increases with increasing size of acceptor molecule and is appreciably larger for amines than for ethers. The emitting species in the case of amines is 1-anthrolate ion pair whose strong dipolar nature may cause further interaction with excess amine molecules. It is probable that more than one molecule of amine participate in the rotating unit, leading to a large molecular volume. The rotational relaxation time was evaluated and found to depend on acceptor concentration. Two competitive effects occur by the increase in acceptor concentration, one shortening the relaxation time because of reduction of viscosity, and the other lengthening it because of molecular volume enlargement.

Fluorescence from the viscous solution is more or less polarized. The degree of polarization P depends on viscosity η and temperature T. For linearly polarized excitation light, the degree of polarization is given by the following equation derived by Perrin[1] assuming a spherical molecular shape of fluorescent solute.

$$\frac{1}{P}-\frac{1}{3}=\left(\frac{1}{P_0}-\frac{1}{3}\right)\left(1+\frac{kT}{V\eta}\tau\right) \quad (1)$$

where P_0, V, and τ stand for the limiting polarization, the molecular volume, and the mean fluorescence lifetime respectively.

From the measurements of the degree of polarization as a function of T/η aided by the lifetime determination, it is possible to obtain the molecular volume as well as the rotational relaxation time ρ, which is defined as $\rho=3V\eta/kT$. Depolarization studies have been made so far mostly in alcoholic solutions such as glycerol and cyclohexanol.[2] However, a molecular volume obtained from these highly associative solutions involves the solvated shell and becomes extremely large in some cases.[2] In order to minimize the solvation effect, liquid paraffin was employed as a viscous solvent. Since liquid paraffin consists of mainly alkyl naphthenes, the interaction between solute and solvent is expected to be small enough to prevent the solvation shell formation.

As a fluorescent solute, 1-anthrol (1-A) was selected. The molecular volumes, the rotational relaxation times and the activation energies of rotational motion were determined for the liquid paraffin solutions of 1-A containing various kinds of proton acceptor.

Experimental

Apparatus and Procedure. Absorption spectra were measured with a Hitachi EPS-3T spectrophotometer. Fluorescence polarization measurements were made with an apparatus similar to that of Weber.[3] A Polacoat PL-40 polarizing plate and a Polaroid KN-36 were employed as polarizer and analyzer, respectively. A sheet of pergament paper as a depolarizer was placed in front of a photomultiplier. Excitation light was obtained by combining a Xe arc lamp and a Hitachi G-3 grating monochromator. 0–0 absorption band was excited in every case.

Fluorescence lifetime was measured with a phase fluorometer similar to that described elsewhere.[4] Fluorescence spectra were recorded on a modified Hitachi EPU spectrophotometer equipped with an EMI 9558QB photomultiplier. Excitation light source was the same type as in the polarization measurements. The spectral calibration factors of this photometer were obtained by the method of Lippert *et al.*[5]

Viscosity was measured with an Ostwald viscometer.

Material. Scintillator grade anthracene was employed. 1-A was synthesized and recrystallized 5 times from a water–ethanol mixture.[6] Triethylamine (Wako G.R.) was dried with calcium chloride or alumina, and fractionally distilled under reduced pressure. *N,N*-Dimethylbenzylamine (Tokyo Kasei G.R.) was passed through a column of activated alumina.

Ethyl ether, *n*-butyl ether, *n*-hexyl ether, and *p*-dioxane (Wako G.R.) were distilled over sodium wire. Benzyl ether (Wako G.R.) was distilled over sodium wire under reduced pressure.

Liquid paraffin (Merck) was treated with columns of silica gel until the optical density for the 1 cm path around 270—280 nm became less than 0.02. Glycerol was distilled under reduced pressure. *n*-Hexane was purified by the standard method.

Results and Discussion

Molecular Volume. Absorption and fluorescence spectra of 1-A in liquid paraffin are given in Fig. 1.

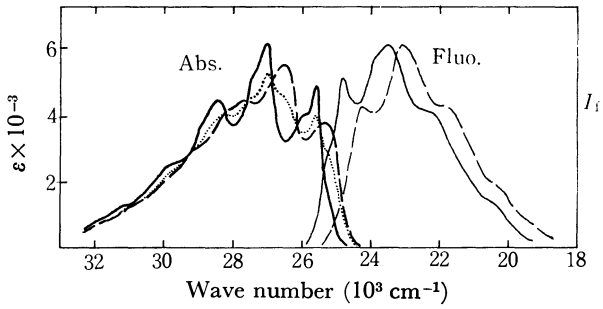

Fig. 1. Absorption and fluorescence spectra of 1-A in liquid paraffin.
Absorptoin; [1-A]$=1.41\times10^{-4}$M
——: [ethyl ether]$=0.0$ M, ----: [ethyl ether]$=9.62\times10^{-2}$M, — —: [ethyl ether]$=4.81\times10^{-1}$M
Fluorescence;
——: 1-A, — —: hydrogen bonded 1-A with ethyl ether.

The mirror image relationship between absorption and fluorescence spectra is rather poor. The excitation spectra at several points in the fluorescence band agree well with absorption spectrum. Thus, the observed fluorescence is intrinsic for 1-A and not an artifact such as impurity. $1/P$ *vs.* T/η plots for 1-A and for anthracene are shown in Fig. 2 for the sake of comparison. T/η varied with temperature. The solute concentrations were sufficiently low to prevent undesirable depolarizing effects such as reabsorption and concentration quenching.

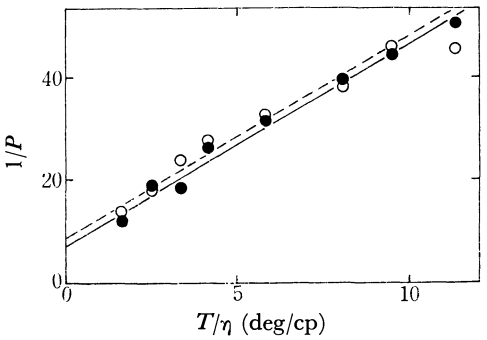

Fig. 2. Perrin plots for anthracene (--○--) and 1-A (—●—) in liquid paraffin.

Fluorescence lifetimes of anthracene and 1-A were determined respectively as 5.1 and 6.9 ns. They did not change within the experimental error in the temperature range studied. The molecular volume of anthracene was thus found to be 138 Å^3. This value corresponds to the radius of 3.21 Å assumed to be a sphere. Assuming one half of the length of the long axis, 4.6 Å, for the radius we obtain the volume 408 Å^3. The experimental value is much smaller and is close to the value of 120 Å^3 estimated for a prolate shape.

The molecular volume of 1-A was found to be 172 Å^3 which corresponds to the radius 3.43 Å. It may be due to volume expansion by the substituent that the molecular volume is larger for 1-A than for anthracene. Rather small molecular volumes obtained suggest that there is no participation of the solvation shell in the solute–liquid paraffin system.

1-A forms a hydrogen bonded complex with many acceptors. The absorption spectrum of 1-A in liquid paraffin containing various amount of ethyl ether is shown in Fig. 1. A similar result to that of Suzuki and Baba was obtained.[7] At ether concentration higher than ~0.5 M, the complexing seems to be almost complete in the ground state. The fluorescence spectrum of this solution is less structured than that of free 1-A as shown in Fig. 1. Beyond ether concentration of ~0.2 M, the fluorescence spectrum becomes a single component which is attributed to the hydrogen bonded 1-A. 1-A becomes a stronger hydrogen bond donor upon excitation to the first singlet excited state as expected from the spectral shifts by hydrogen bond formation. For other ethers absorption and fluorescence spectra are similar to the case of ethyl ether except for slight changes in shape and band positions.

Depolarization studies for hydrogen bonded 1-A were performed in liquid paraffin containing various amounts

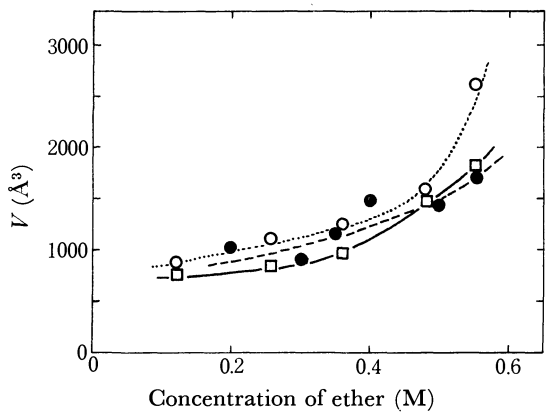

Fig. 3. Change of the molecular volume for various concentrations of ether.
—□—: *n*-butyl ether, ---○---: *n*-hexyl ether,
--●--: benzyl ether.

of ether. Linear $1/P$ *vs.* T/η plots were obtained for all the solutions studied. Fluorescence lifetimes of hydrogen bonded 1-A with ethers were found to be 14—15 ns and did not differ appreciably from each other. It was found that the molecular volume increased with the increase of acceptor concentration. As a typical example, Fig. 3 shows the molecular volume changes as a function of ether concentration. The increase of the molecular volume might be attributed to the formation of the solvation shell around the hydrogen bonded 1-A by excess ether molecules. This view is supported by the fact that the fluorescence spectrum changes in shape slightly at higher acceptor concentration in the case of benzyl ether. Solvent effect on the fluorescence spectrum of hydrogen bonded complex was found in the case of acridone–acetic acid in benzene.[8]

An empirical equation which fits the dependence of molecular volume on the concentration of ether added at a given temperature was found to be:

$$V = V_0 + A\frac{[C]^2}{\eta}$$

where V_0 is the molecular volume of the hydrogen bonded complex free from the solvation and [C] the ether concentration. V *vs.* $[C]^2/\eta$ plots for several

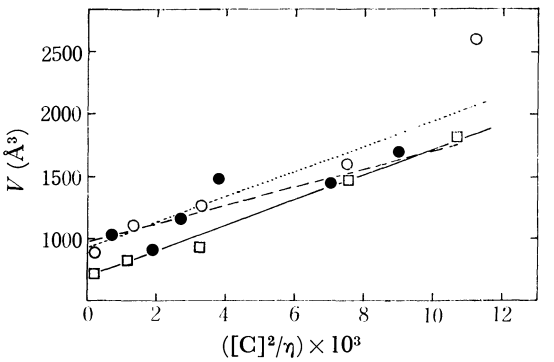

Fig. 4. Plots according to the empirical formula at 15 °C: $V = V_0 + A \cdot [C]^2/\eta$.
—□—: *n*-butyl ether, ---○---: *n*-hexyl ether,
--●--: benzyl ether.
[C] is the concentration of ether.

TABLE 1.

Proton acceptor	V_0 (A^3)
Ethyl ether	~200
p-Dioxane	~500
n-Butyl ether	700
n-Hexyl ether	920
Benzyl ether	960
Triethylamine	1720
N,N-Dimethylbenzylamine	2300

ethers are shown in Fig. 4. The V_0 values thus obtained are summarized in Table 1. There is a clear tendency for the molecular volume to increase with the increase in size of acceptor molecule.

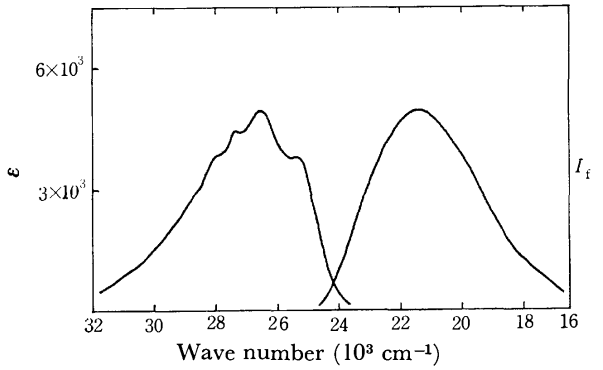

Fig. 5. Absorption and fluorescence spectra of 1-A in glycerol–water (9:1).

As a different kind of solvent, a glycerol–water mixture (9:1) was employed. Absorption and fluorescence spectra in this solution are shown in Fig. 5. Due to hydrogen bonding and strong solvent effects, structures in the spectra are considerably blurred, the spectrum showing no structure particularly for fluorescence.

The molecular volume of 1-A was obtained from the slope of Perrin's plot and the measured lifetime of 18.6 ns as 688 Å^3. This volume is considerably larger than the molecular volume of free 1-A in liquid paraffin, but smaller than that of hydrogen bonded 1-A with some larger ethers. This might suggest that the solvated shell of 1-A water–glycerol mixture is smaller than that expected from the highly associative nature of solvent. However, the evaluation of molecular volume is not based on the 'micro' viscosity, but on the measured 'macro' viscosity. Furthermore, the shape of rotating unit may differ for liquid paraffin and glycerol–water. A straightforward comparison of the results obtained for different solvents may lead to an erroneous conclusion.

Triethylamine and *N,N*-dimethylbenzylamine were employed as stronger proton acceptors than ethers. The absorption spectrum in liquid paraffin containing various amounts of triethylamine is shown in Fig. 6. At 0.4 M of amine concentration, the hydrogen bond formation seems almost complete. Absorption maxima of hydrogen bonded complex lie in a slightly smaller wavenumber compared to the case of ethers. In contrast to absorption, the fluorescence spectrum

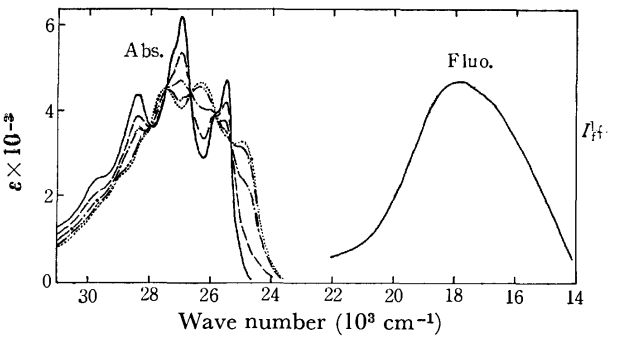

Fig. 6. Absorption and fluorescence spectra of hydrogen bonded 1-A with triethylamine.
Absorption spectra: [1-A]=1.33×10^{-4}M
——: [triethylamine]=0.0 M, — —: [triethylamine]=3.56×10^{-3}M, — · —: [triethylamine]=1.43×10^{-2}M, —·· —: [triethylamine]=3.56×10^{-2}M, ------: [triethylamine]=7.17×10^{-1}M.

changes drastically, being almost structureless and shifting to a smaller wavenumber to a great extent. Fluorescence maxima lie at 17900 and 17500 cm^{-1} for triethylamine and *N,N*-dimethylbenzylamine, respectively, which are smaller by 3600 and 4000 cm^{-1} than those in the glycerol–water mixture. The fluorescence spectrum resembles that of aqueous alkaline solution of 1-A in which maximum lies at 15000 cm^{-1}. We thus concluded that in the 1-A–amine–liquid paraffin system the usual hydrogen bond is formed between 1-A and amine in the ground state, while proton transfer occurs through the hydrogen bond in the excited state. On account of a low dielectric constant of liquid paraffin, 1-A–amine complex can exist as a hydrogen bonded ion pair. The difference in fluorescence maxima of liquid paraffin and aqueous alkaline solutions might be due to the solvent effects resulting from a very large difference in the dielectric nature.

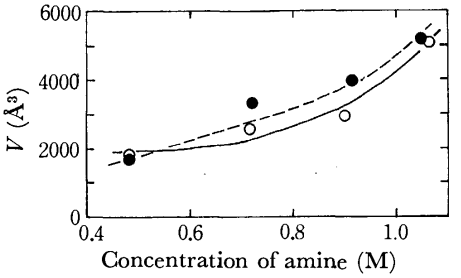

Fig. 7. Change of the molecular volume for various concentrations of amine.
—○—: triethylamine, --●--: *N,N*-dimethylbenzylamine.

Molecuar volumes obtained for the system containing amines depend also on the amine concentration (Fig. 7). The same empirical formula as that for ether fits the results. The V_0 values for triethylamine and benzylamine are given in Table 1. The molecular volume for benzylamine is considerably larger than that for triethylamine reflecting the larger size of benzylamine. However, the molecular volume for triethylamine is considerably large as compared with that for ethers such as butyl , hexyl-, and benzyl ether which

have larger molecular size than that of triethylamine. The most significant difference between amines and ethers is that the fluorescent molecule exists as a hydrogen bonded ion pair. The highly dipolar species may further interact with excess amine molecules which have a large dipole moment. Thus, there is a possibility that even at an amine concentration lower than 0.4 M more than one molecule of amine take part in the rotating fluorescent unit by forming an amine-shared ion pair or some other kind of aggregate. This may be the reason why V_0 for the amine system is appreciably large compared with that for the ether one.

Due to the short lifetime of the amine complex, the degree of polarization is relatively large. Consequently, viscosity can be varied in a wide range by adding less viscous *n*-hexane instead of varying the temperature. The molecular volume of the amine complex was proportional to the concentration of *n*-hexane added. At a given temperature, viscosity was inversely proportional to *n*-hexane concentration up to at least 4×10^{-2} M. The molecular volume, therefore, was proportional to the reciprocal of viscosity. The reason for such a relation is not clear. The difference between 'macro' and 'micro' viscosity is a possible explanation.

Rotational Relaxation Time. Rotational relaxation times in various solutions were evaluated. For anthracene in liquid paraffin, ρ is 5.2 ns at 22 °C. The rotational relaxation time of benzophenone in benzene at room temperature determined by the dielectric relaxation method is 18.7 ps. Viscosity of benzene at 20 °C is 0.65 cp, which is ~1/100 of liquid paraffin. Hence, the relaxation time in liquid paraffin should be several ns. The ρ value obtained by fluorescence depolarization method gave the same order of magnitude as that obtained by other methods.

Temperature dependence of ρ is given by

$$\rho = \rho_0 \exp(E_{rot}/kT)$$

where E_{rot} is the activation energy of rotational relaxation. The values of E_{rot} for various solutions were 11—14 kcal/mol. These values correspond to the activation energy of viscous flow of each solution as expected.

The rotational relaxation time of hydrogen bonded 1-A is given in Fig. 8 as a function of acceptor concentration. In the case of ethers, a minimum value of ρ appears at certain ether concentration. At low acceptor concentration, the molecular volume is small but viscosity is large enough to give a greater ρ value.

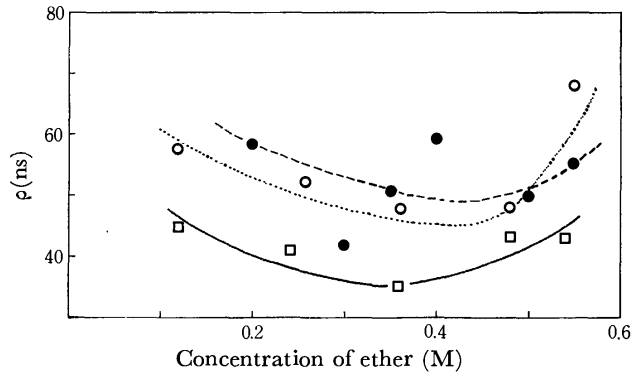

Fig. 8. Relationship of the rotational relaxation time to the concentration of ether at 12 °C.
—□—: *n*-butyl ether, ---○---: *n*-hexyl ether, --●--: benzyl ether.

With increasing acceptor concentration, viscosity decreases to give shorter ρ value. Further increase of acceptor concentration gives rise to a prominent increase in molecular volume reducing the viscosity. However, the trend for volume expansion to lengthen ρ overcomes that to shorten ρ by viscosity change, giving longer ρ as a whole. In the case of amines, the presence of minimum is not clear because of scattering of data.

(Received October 30, 1972)

Experiments were carried out in order to elucidate the formation mechanism of $C_2H_5\cdot$ radicals formed by the UV irradiation ($250<\lambda<350$ nm) of $CH_3\dot{C}HOH$ radicals. The kinetics of the formation of the $C_2H_5\cdot$ radical was examined by means of ESR in neutral, acidic, and alkaline ethanol glasses at 77 K. The initial rate of the formation of $C_2H_5\cdot$ was nearly independent of the concentration of added acid (H_2SO_4), but it decreased sharply with that of added NaOH. Moreover, the limiting yield of $C_2H_5\cdot$ decreased with the concentrations of both the acid and the base. Our experimental results suggest that the $C_2H_5\cdot$ radicals are formed by this reaction:

$$C_2H_5OH_2^+ + e^- \longrightarrow C_2H_5\cdot + H_2O$$

The $C_2H_5OH_2^+$ ion and the electron result from the photoionization of $CH_3\dot{C}HOH$ radicals according to these reactions:

$$CH_3\dot{C}HOH \xrightarrow{h\nu} (CH_3CHOH)^+ + e^-$$
$$(CH_3CHOH)^+ + C_2H_5OH \longrightarrow CH_3CHO + C_2H_5OH_2^+$$

The free radicals produced by the abstraction of α hydrogen atoms from aliphatic alcohols have an absorption band between 200 and 350 nm.[1,2] Under irradiation in this wavelength range, $R\dot{C}HOH$ radicals are photolyzed, giving rise to $R\cdot$ and/or $RCH_2\cdot$ alkyl radicals.[3-6] The mechanism of the formation of $RCH_2\cdot$ radicals has not yet been definitely established, however.

By the photolysis of the $CH_3\dot{C}HOH$ radical (generated by the γ-irradiation of ethanol and trapped in the glassy state), which has been the most extensively studied,[3-6] both $\dot{C}H_3$ and $\dot{C}_2H_5$[3,5] are produced. The former disappears quickly upon hydrogen abstraction, whereas $C_2H_5\cdot$ reaches a stationary concentration. Moreover, it has been calculated[7] and confirmed experimentally[8] that $CH_3\dot{C}HOH$ trapped in polar solids may be photoionized in the near UV region, since its ionization potential is lowered from 7 eV in the gas phase to 2.5 eV in the solid state (2.5 eV corresponds to 495 nm).

The present work has been designed to show, using the example of $CH_3\dot{C}HOH$, that the photolytic formation of $RCH_2\cdot$ from $R\dot{C}HOH$ radicals trapped in glassy alcohols is a consequence of the photoionization rather than of the reaction of excited hydroxyalkyl radicals on the substrate, as has been suggested.[9]

Experimental

The ethanol was purified by fractional distillation. Neutral, acidic, and alkaline samples of ethanol containing 5% of water were degassed in "spectrosil" silica tubes and then γ-irradiated at 77 K in the glassy state, using a ^{60}Co source and a dose of 8×10^{19} eV ml^{-1}.

After irradiation, the samples were bleached by visible light to remove the trapped electrons. The ESR spectra were then recorded with a "STRAND Labs" 601 BX Spectrometer operating at 9.3 GHz. The concentration of radicals was determined by double integration and by comparison with a reference sample of pure glassy ethanol, taking $G(CH_3\dot{C}HOH)=8$[6] after bleaching. The UV irradiation was carried out by focusing the output of a 500 W mercury arc (Phillips SP. 500) onto the sample placed in a liquid-nitrogen Dewar vessel located in the cavity. Two intensities of illumination were used: 10^{17} quanta cm^{-3} s^{-1} and 2×10^{16} quanta cm^{-3} s^{-1} ($250\text{ nm}<\lambda<400$ nm).

Results and Discussion

The rate of the formation and the limiting yield of $C_2H_5\cdot$ from UV-irradiated $CH_3\dot{C}HOH$ produced by γ irradiation have been studied in neutral ethanol, as well as in acidic and alkaline media, as a function of the concentrations of the added H_2SO_4 and NaOH.

During photolysis the overall concentration of radicals ($CH_3\dot{C}HOH$ and $C_2H_5\cdot$) was determined by integration, as has been indicated previously.

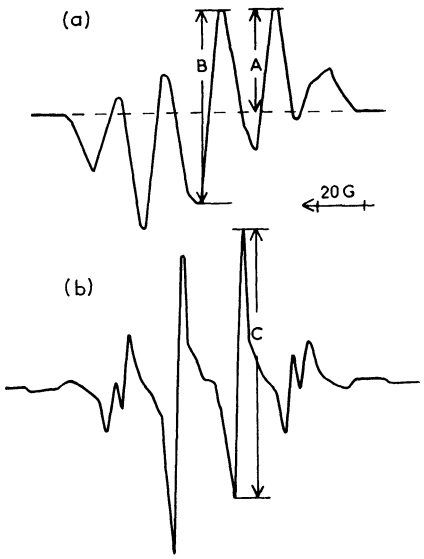

Fig. 1. a) ESR spectrum of $CH_3\dot{C}HOH$ radical observed at 77 K after γ irradiation of pure C_2H_5OH and subsequent bleaching to trapped electrones.
b) Spectrum of $C_2H_5\cdot$ observed at 77 K after UV photolysis of $CH_3\dot{C}HOH$.

The relative concentration of radicals was determined by measureing the amplitude of Bands A and B for $CH_3\dot{C}HOH$ (Fig. 1a) and of Band C for $C_2H_5\cdot$ (Fig. 1b). These amplitudes were correlated with the true concentration of radicals by calibration with the spectra of both radicals obtained separately, and then integrated.

The variations in the concentrations of the $CH_3\dot{C}HOH$ and $C_2H_5\cdot$ radicals with the time of UV irradiation are represented in Figs. 2 and 3.

In the case of neutral ethanol, the signal amplitude of $CH_3\dot{C}HOH$ falls to an undetectable level after 5 to 15 min of illumination, the rate of decrease depending on the UV-light intensity, while the concentration of $C_2H_5\cdot$ passes through a maximum and decays slowly by recombination after the complete consumption of $CH_3\dot{C}HOH$. The logarithmic plot of $CH_3\dot{C}HOH$ against the time of illumination is linear the slope being pro ortional to the intensity of UV irradiation, indicating a first-order decay of this radical (Fig. 4). This means that the optical density of the $CH_3\dot{C}HOH$ radical may be very small. Under the same conditions, the rate of the formation of $C_2H_5\cdot$ and its limiting

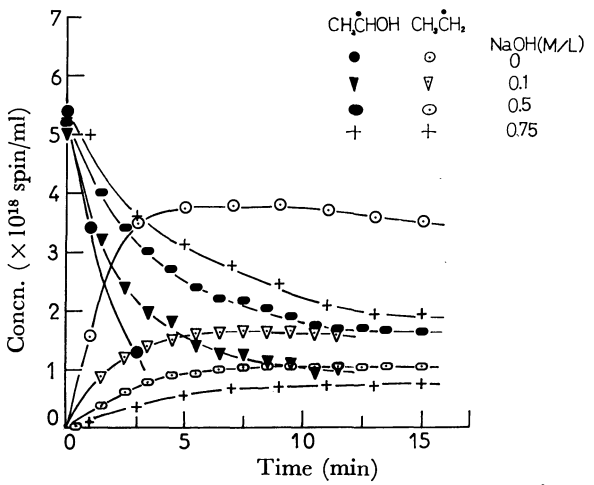

Fig. 2. Variation of the concentration of $CH_3\dot{C}HOH$ and $C_2H_5\cdot$ radicals in the course of UV photolysis ($I=2\times10^{16}$ quanta $cm^{-3}s^{-1}$): neutral and alkaline matrices.

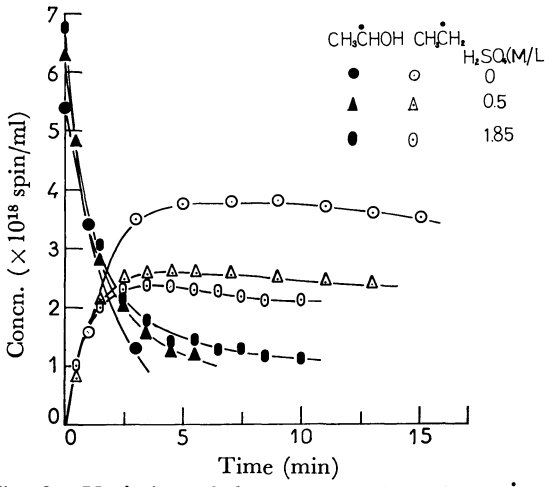

Fig. 3. Variation of the concentration of $CH_3\dot{C}HOH$ and $C_2H_5\cdot$ radicals in the course of UV photolysis ($I=2\times10^{16}$ quanta $cm^{-3}s^{-1}$): neutral and acidic matrices.

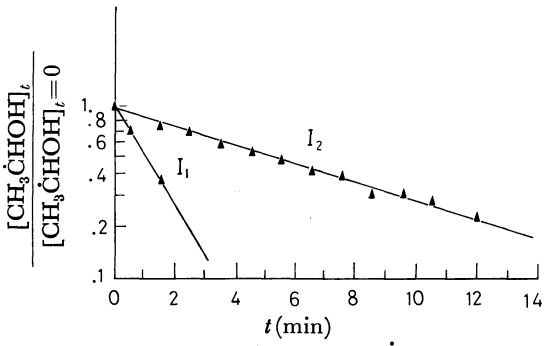

Fig. 4. Logarithmic plot of $[CH_3\dot{C}HOH]_t$ *versus* UV irradiation time, $[CH_3\dot{C}HOH]_t=0$ being the initial concentration. $I=10^{17}$ quanta cm^{-3} s^{-1}, $I_2=2\times10^{16}$ quanta cm^{-3} s^{-1}.

yield are drastically reduced as the concentration of NaOH is increased (Fig. 2). On the other hand, the initial rate of the formation of $C_2H_5\cdot$ is about the same in acidic and neutral media, while its limiting yield is lowered by the presence of H_2SO_4.

In order to interpret these results, which are summarized in Figs. 5 and 6, the reaction scheme proposed in a previous paper[8] by one of the present authors has been somewhat modified as follows.

The photoionization of $CH_3\dot{C}HOH$ and the consecutive ion-molecule reactions are:

$$CH_3\dot{C}HOH \xrightarrow{h\nu} (CH_3CHOH)^+ + e^- \quad (1)$$

$$(CH_3CHOH)^+ + C_2H_5OH \longrightarrow C_2H_5OH_2^+ + CH_3CHO \quad (2)$$

An increase in the concentration of $CH_3\dot{C}HO$ has actually been observed in the course of the photolysis of $CH_3\dot{C}HOH$.[9]

The released electron can participate in the competitive reactions:

$$e^- + 2C_2H_5OH \longrightarrow CH_3\dot{C}HOH + C_2H_5O^- + H_2$$

and/or

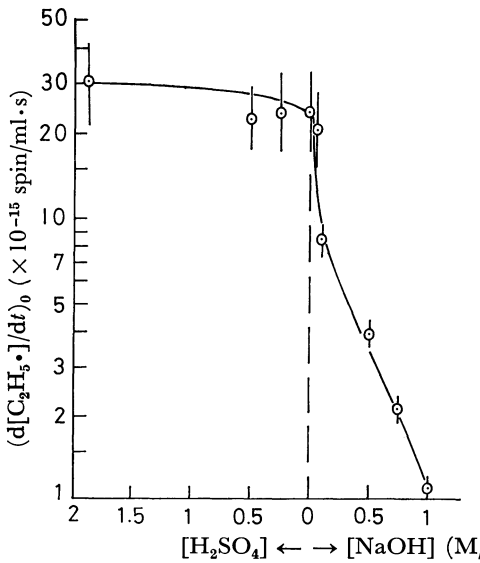

Fig. 5. Initial rate of formation of $C_2H_5\cdot$ as a function of H_2SO_4 and NaOH concentrations.

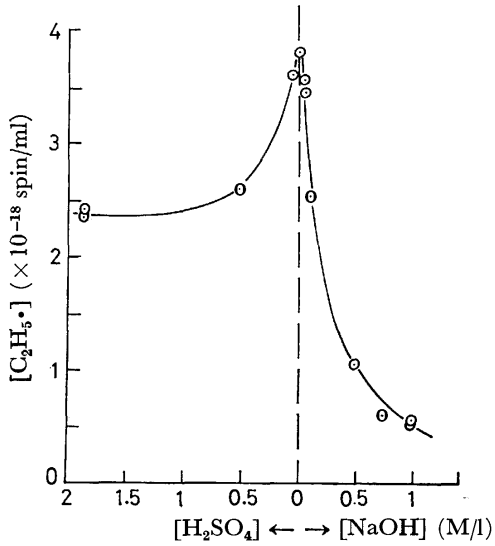

Fig. 6. Maximum yield of $C_2H_5\cdot$ as a function of H_2SO_4 and NaOH concentrations.

$$\left\{\begin{array}{l} e^- + C_2H_5OH \longrightarrow C_2H_5O^- + H\cdot \\ H\cdot + C_2H_5OH \longrightarrow CH_3\dot{C}HOH + H_2 \end{array}\right. \quad (3)$$

$$e^- + C_2H_5OH_2^+ \longrightarrow H_2O + C_2H_5\cdot \quad (4)$$

Reaction (3) is supported by the experimental finding that the $CH_3\dot{C}HOH$ radicals are formed by the decay of electrons formed when alkali metals are added to C_2H_5OH glass at 77 K,[10] while Reaction (4) has been suggested by Yoshida *et al.*[11] However, in the present case, the rate of Reaction (4) is most likely larger than that of Reaction (3).

A reaction similar to (4) has been proposed by Symons *et al.*[12] to account for the formation of methyl and isopropyl radicals in γ-irradiated solutions of methanol and isopropanol in glassy acidic ice. It may be pointed out that Reaction (4) is energetically favourable, the electron affinity of H_2O^+ being markedly larger than the C–O bond energy (12.6 eV against 4 eV[13]).

In the alkaline matrix, the $C_2H_5OH_2^+$ ions, precursors of $C_2H_5\cdot$, are scavenged by an excess of $C_2H_5O^-$ and/or OH^- ions:

$$C_2H_5O^- + C_2H_5OH_2^+ \longrightarrow 2C_2H_5OH$$

and/or (5)

$$OH^- + C_2H_5OH_2^+ \longrightarrow C_2H_5OH + H_2O$$

$CH_3\dot{C}HOH$ being regenerated by Reaction (3). The failure to observe the ESR spectrum of the solvated electron, even in the alkaline medium may be attributed to its high quantum yield of untrapping by UV light.[2]

It could be expected that, in the acidic matrix, the contribution of Reaction (4) would be enhanced by the increase in the concentration of $C_2H_5OH_2^+$. The decay in the yield of $C_2H_5\cdot$ as the concentration of H_2SO_4 is increased suggests that the electrons released by Reaction (1) are partially scavenged by HSO_4^-, producing $CH_3\dot{C}HOH$ radicals according to these reactions:

$$e^- + HSO_4^- \longrightarrow SO_4^{2-} + H\cdot \quad (6)$$

$$H\cdot + C_2H_5OH \longrightarrow CH_3\dot{C}HOH + H_2 \quad (7)$$

The hypothesis of an ionic contribution to the near-UV photolysis of hydroxyalkyl radials, trapped in glassy alcohols, seems, therefore, supported by the effect of added acids and bases presented here.

The Radiophoto-luminescence of γ-Irradiated Hydrocarbon Glasses at 77 K

Hideo YAMAZAKI, Koichi OKA, Masabumi SATO, and Shoji SHIDA
Laboratory Physical Chemistry, Tokyo Institute of Technology, Meguro-ku, Tokyo 152
(Received March 9, 1973)

The radiophoto-luminescence (RPL) from γ-irradiated hydrocarbon glasses, *i.e.*, 3-methylhexane, methylcyclohexane, and ethylcyclohexane, containing small amounts of various aromatics (1,3,5-trimethylbenzene, biphenyl, naphthalene, and 1,4-diazine) is investigated at 77 K by infrared-light irradiation. The spectra of the RPL consist of the fluorescence and phosphorescence of the guest aromatic molecule, and the ratio of the phosphorescence to the fluorescence intensity is larger than that in the photoexcitation, indicating the existence of another path to the triplet state. The RPL is quenched by the addition of N_2O, but it is not much affected by that of NH_3. A possible mechanism for the RPL is considered, and its analysis is given.

In the primary process of the radiation chemistry of hydrocarbons, the mechanism of neutralization is not quite understood because of the rapidity of the process. The rigid-solvent method has been used to slow down the reaction rate and to facilitate the measurements. The radiation energy stored in a rigid matrix can be liberated by means of several methods; elevation of temperature[1,2] (radiothermo-luminescence), irradiation by infrared light[3-6] (radiophoto-luminescence, RPL), and application of an electric field.[7-10] The control of the luminescence intensity is easiest in RPL, and the relaxation time of emission can be measured from the response time of the luminescence by intermittent irradiation of infrared light, so the RPL is used in this study. Hamill *et al.*[3,4] have measured the RPL from biphenyl in a 3-methylpentane solution and obtained a rather diffused spectrum of the phosphorescence of biphenyl by rapid scanning with an oscilloscope. Magat *et al.*[5,6] studied the RPL spectrum of biphenyl and its excitation spectrum in a methylcyclohexane solution. In their measurement of the excitation spectrum, a filter was used to pass through the whole wavelength of the phosphorescence. A more precise experiment is necessary, however, to obtain detailed information.

Experimental

Hydrocarbon samples purchased from Merck, Aldrich Chemical, and the Phillips Co. were passed through an activated silica gel column and then outgassed by the freeze-pump method and stored with a sodium mirror. The biphenyl and naphthalene were purified by the zone-melting method. The 1,4-diazine and 1,3,5-trimethylbenzene (Merck and Tokyo Kasei Co.) were used without further purification. The sample tubes used were made of high-purity quartz or of molybdenum glass; the dimension of diameters are 5 and 10 mm. After degassing *in vacuo*, the samples were irradiated by γ-rays from ^{60}Co with total doses of 10^4—10^5 r at 77 K in darkness. The spectra of RPL were measured with a Hitachi MPF-2A fluorometer, the intensity of emission was standardized by using the data of emission from β-naphthol in photoexcitation.[11] The sample was irradiated by diffracting infrared light of the zeroth order through a grating from a light source of a 150 W Xe-lamp equipped with Toshiba IR-D1A and VB-46 filters. The average intensity of emission was used to obtain a spectrum by repeating the forward and backward scanning, since the intensity of emission decreased slowly as the concentration of trapped electrons decreased.

Results and Discussion

The RPL spectra of 3-methylhexane, methylcyclohexane, and ethylcyclohexane (3-MHX, MCHX, and ECHX) showed a weak and broad spectrum with a maximum at about 420 nm; the response time of the emission by the infrared light was several seconds, so it is likely that the emission is due to the transition of a different spin multiplicity. Such a diffuse emission spectrum was also observed in the RTL and RPL of 3-methylpentane.[12,13] The low-lying electronic states of saturated hydrocarbons have been observed by Hamill in a solid matrix with the energy-loss spectrum[14] of electrons and with the emission spectrum upon electron impact.[15,16] When small amounts of aromatic hydrocarbons (10—100 ppm) were added to these solvents, distinct fluorescence and phosphorescence of aromatic hydrocarbons were observed. Figure 1 shows the relaxation of the phosphorescence at 465 nm from biphenyl in 3-MHX due to the intermittent irradiation of infrared light. The relaxation time is determined by the lifetime of the phosphorescence, and the intensity of the emission decreases slowly as the concentration of trapped electrons in the matrix decreases. Figures 2—4 show the emission (solid curves) of fluorescence and phosphorescence with reference to those (dotted curves) of the photoexcitation in the ultraviolet region. In these figures the maximum values of the intensities of the fluorescence for both cases were standardized as unity. No appreciable difference in the spectrum was observed with the change

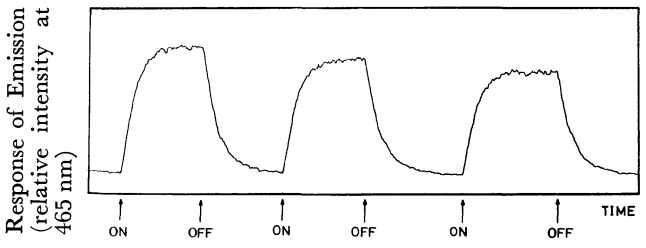

Fig. 1. Response of the emission at 465 nm from biphenyl in 3-MHX at 77 K by the intermittent irradiation of infrared light. The interval between "on" and "off" is 30 s in the time scale.

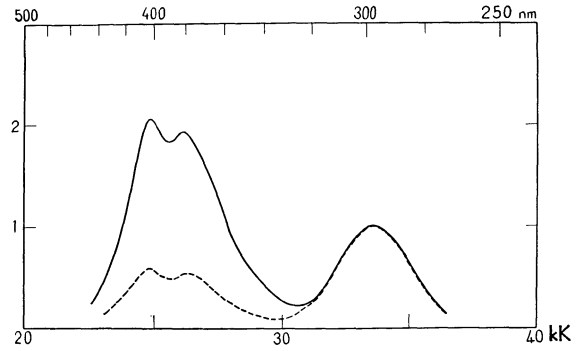

Fig. 2. RPL (full curve) and photoexcited emission (dotted curve) from 1,3,5-trimethylbenzene in 3-MHX at 77 K.

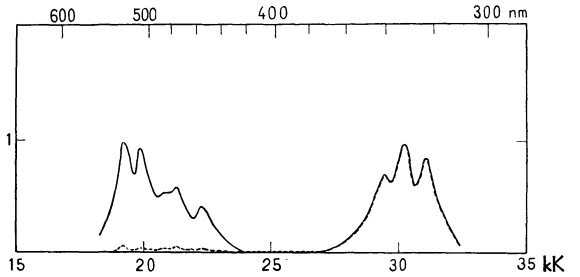

Fig. 3. RPL (full curve) and photoexcited emission (dotted curve) from naphthalene in 3-MHX at 77 K.

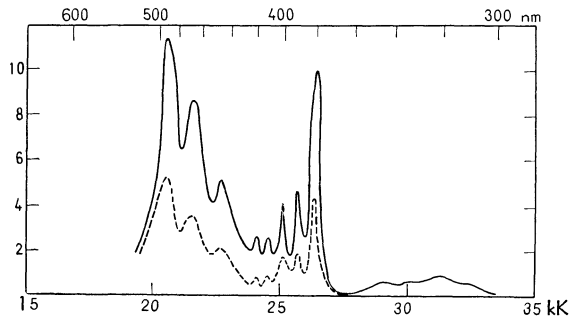

Fig. 4. RPL (full curve) and photoexcited emission (dotted curve) from the one-to-one mixture of 1,4-diazine and biphenyl in 3-MHX at 77 K.

in the solvents (3-MHX, MCHX, and ECHX). The ratio of the intensity of the phosphorescence to the fluorescence was larger in the case of RPL than in that of photoexcitation as observed by a number of authors.[12,17,18] The ratio of the phosphorescence and fluorescence depends on the sample. A very large relative intensity of phosphorescence was observed in a naphthalene solution, as is shown in Fig. 3. The proportion of phosphorescence in the total emission gradually changed upon prolonged irradiation by infrared light. The dilute solution of a one-to-one mixture of two aromatic compounds generally showed the phosphorescence of each component with a certain ratio of intensity; *e.g.*, the ratio of the intensity of the phosphorescence of a one-to-one mixture of 1,4-diazine and biphenyl in 3-MHX was about 1 : 4 (Fig. 4). The ratio of the intensities of the component fluorescences from such a solution depended on the concentration, since the ratio was much perturbed by the energy-transfer process. The RPL was quenched by the addition of an electron scavenger such as N_2O, as was observed in the emission due to a recombination process after photoionization,[19-21] but it was not much affected by the addition of NH_3, which was used as a positive-charge scavenger in the liquid phase.

The emission process must be followed by the excitation of aromatic compounds. The production of the excited states of aromatic compounds is expressed by the following scheme:

$$e_t^- \xrightarrow{h\nu} e_m^- \quad (1)$$

$$RH^+ + e_m^- \longrightarrow RH^* \quad (2)$$

$$RH^* + RH \longrightarrow RH + RH^* \quad (3)$$

$$RH^* \longrightarrow RH + h\nu \quad (4)$$

$$RH^* + A \longrightarrow RH + A^* \quad (5)$$

where e_t^- and e_m^- are the trapped and mobilized electrons and where RH and A refer to the hydrocarbon and aromatic molecules. By the absorption of infrared light, the trapped electrons are mobilized by means of Reaction (1).

$$RH^+ + A^- \longrightarrow RH + A^* \quad (6)$$

$$A^+ + A^- \longrightarrow A^* + A \quad (7)$$

$$A^+ + e_m^- \longrightarrow A^* \quad (8)$$

$$A^* \longrightarrow A + h\nu' \quad (9)$$

The geminate and random recombination can produce RH* by means of Reaction (2), and the energy migration may take place in solid hydrocarbon, as is expressed by Reaction (3). In the absence of an aromatic compound, a weak emission at 420 nm was detectable; this may be attributed to Reaction (4). In the presence of aromatic additives, the excited states of the aromatic molecule, A*, can be produced by the energy-transfer reaction (5), the ionic neutralizations (6) and (7), and the recombination of A^+ with an electron by means of Reaction (8).

Three types of direct excitations of aromatic molecule are considered, namely, the excitation by the reaction between A^+ and an electron (8), that by A^- and RH^+ (6), and that by A^+ and A^- (7). From the experimental results that the mobilities of A^-, A^+, and RH^+ are not large and that the excitation spectrum of the RPL is similar to the absorption spectrum of a trapped electron,[5] the process involving the transport of these species (A^-, A^+, and RH^+) can be ignored. The neutralization between A^+ and an electron is not important under the present condition of a low concentration (10—100 ppm) of A, because A^+ can be detected only at high concentrations of aromatic additives in hydrocarbon matrices. Therefore, the indirect excitation by the energy transfer from RH* produced by the neutralization between RH^+ and electron is most probable in forming A*. Such an energy transfer from the excited states of paraffins to additives was observed by the measurement of the emission[16] and by the method of product analysis[22,23] in the vacuum ultraviolet photolysis of liquid paraffins. This explanation is consistent with the experimental result that the RPL is quenched by the addition of an electron scavenger and not much affected by the addition of a positive-charge scavenger.

Apart from the detailed mechanism of the excitation, the aromatic molecule can be excited to the singlet- or triplet-excited state by the liberation of a trapped electron. The process can be symbolically written by Reactions (10) and (11). Therefore, the emission process from the transition of these excited states is described by the following reactions:

$$A \dashrightarrow A^*(\text{singlet}) \qquad k_s \qquad (10)$$

$$A \dashrightarrow A^*(\text{triplet}) \qquad k_t \qquad (11)$$

$$A^*(\text{singlet}) \longrightarrow A + h\nu_f \qquad k_f \qquad (9')$$

$$A^*(\text{triplet}) \longrightarrow A + h\nu_p \qquad k_p \qquad (9'')$$

$$A^*(\text{singlet}) \longrightarrow A^*(\text{triplet}) \qquad k_{isc} \qquad (12)$$

$$A^*(\text{singlet}) \longrightarrow A \text{ or products} \qquad \sum k_x \qquad (13)$$

$$A^*(\text{triplet}) \longrightarrow A \text{ or products} \qquad \sum k_y \qquad (14)$$

where k_s, k_t, k_f, k_p, k_{isc}, $\sum k_x$, and $\sum k_y$ are the rate constants for the production of the singlet state and for the triplet state, for the emission of fluorescence and of phosphorescence for the intersystem crossing, for reactions from the singlet state and for reactions from the triplet state respectively.

From Reactions (9'), (9''), (10)—(14), the intensity ratio between the fluorescence and the phosphorescence (F/P value) in the electron-recombination process can be evaluated by:

$$\sigma_e \equiv (F/P)_e = \frac{k_f k_s (k_p + \sum k_y)}{(k_s k_{isc} + k_t k_f + k_t k_{isc} + k_t \sum k_x) k_p} \qquad [1]$$

In the photoexcitation by the first singlet-excited state, the F/P value is given by:

$$\sigma_h \equiv (F/P)_h = \frac{k_f (k_p + \sum k_y)}{k_{isc} k_p} \qquad [2]$$

The ratio of the initial distribution of the singlet state to the triplet state of the aromatic molecule is given by:

$$\rho = (k_s/k_t) = \frac{\sigma_e \sigma_h k_p/(k_p + \sum k_y) + \sigma_e + \sigma_e \sum k_x/k_{isc}}{\sigma_h - \sigma_e} \qquad [3]$$

Under the conditions of $\sum k_x = 0$ and $\sum k_y = 0$, the F/P values, σ_e and σ_h, are reduced to:

$$\sigma_e = \frac{k_f (k_s/k_t)}{k_{isc}(k_s/k_t) + k_f + k_{isc}} \qquad [4]$$

and:

$$\sigma_h = k_f/k_{isc} \qquad [5]$$

Then, the singlet-triplet ratio is expressed by:

$$\rho = k_s/k_t = (\sigma_h \sigma_e + \sigma_e)/(\sigma_h - \sigma_e) \qquad [6]$$

In Eq. [3] the increase in $\sum k_x$ may cause the increase in ρ, but the increase in $\sum k_y$ may cause the decrease in ρ. If both the values $\sum k_x$ and $\sum k_y$ increase from zero in Eq. [3], the value of ρ will not change much from the value of ρ given by Eq. [6]. Thus, Eq. [6] is still a plausible approximation for the small values of $\sum k_x$ and $\sum k_y$. For example, the values of ρ calculated from the spectra (Figs. 2 and 3) and assuming Eq. [6] are 0.93 and 1.0 for 1,3,5-trimethylbenzene and naphthalene respectively in 3-MHX. These results indicate that the values of k_t and k_s are almost equal. However, the value of k_t would be expected to be three times larger than that of k_s if the triplet and singlet states are produced by random recombination with the spin conservation. The departure from the statistical value in the ρ value may be another evidence of indirect excitation. Recently Tsubomura *et al.*[24] found that the F/P value was 0.7—0.8 for the photothermoluminescence of *N,N,N',N'*-tetramethyl-*p*-phenylene diamine in various matrices and that the F/P value was approximately equal to the ratio of the production of singlet and triplet states, therefore, the simple spin conservation rule does not hold in their case, either.

The authors wish to thank Professor Hiroshi Tsubomura, Drs. Naoto Yamamoto and Yoshihiro Nakato of Osaka University for reading the preliminary manuscript of this paper and for their helpfull discussions.

A Molecular Orbital Study on the Effects of Excess Charges at the Donor and Acceptor Atoms on the Hydrogen Bond

Akira IGAWA and Hideo FUKUTOME
Department of Physics, Kyoto University, Kyoto 606
(Received April 6, 1973)

Effects of the excess charges at the donor and acceptor atoms on the properties of the hydrogen bond were studied in a simple three-center four-electron model for a hydrogen bond system using CNDO/2 type molecular orbital calculation. It was shown that three types of hydrogen bonds, normal, proton transferred and abnormal, are possible according to the value of the excess charges. The dependence of the hydrogen bond distance, proton equilibrium distance, frequency of proton stretching vibration and hydrogen bond energy on the excess charges were calculated for the normal type hydrogen bond. The correlations between these quantities obtained by changing the amounts of the excess charges are in good agreement with the experimental results, suggesting that the excess charges at the donor and acceptor atoms primarily determine the correlation. The potential of proton movement at the equilibrium hydrogen bond distance is shown not to have double minima for any value of the excess charges, indicating that the excess charges are not essential for producing a double well potential.

Many theoretical works have been carried out on the hydrogen bond (HB) which can be classified into two categories, those based on the simplified three-center four-electron model using the valence bond (VB)[1-3] or the molecular orbital (MO)[4,5] method and those on the calculations for total HB systems using the non-empirical[7-9] or the semi-empirical[6] MO method. The early works belong to the former category, but the main trend in recent works seems to be in the latter one. Morokuma and Pedersen[7] and Kollman and Allen,[8] from their non-empirical calculation for total HB systems, emphasized that electron reorganization within them is important, and the simple three-center model has nothing to do with the explanation of the properties of the HB. Their criticism is sound as far as the original simple three-center model is concerned. However, they seem to underestimate the usefulness of a suitably modified three-center model in explaining the properties of the HB. The three-center model can be modified to incorporate some effects of the residual part of the HB system into its parameters. Such modifications of the three-center model were studied for the HB in ice with positive and negative defect,[4] the HB coupled with π electron system[5] and the HB with donor and acceptor atoms of varying net charges.[3]

We have studied the effects of the excess charges at donor and acceptor atoms on the properties of the HB by means of the three-center model and semi-empirical MO calculation. Change in the net charges at the donor and acceptor atoms is considered to be one of the most important factors of the residual part of the HB system which would strongly affect the properties of the HB. The model was studied by Hasegawa *et al.*[3] with use of the VB method. However, their calculation was not extensive enough to confirm the importance of the change of the net charges at the donor and acceptor atoms. We have shown that this model can satisfactorily explain the empirical correlations between the HB distance, proton equilibrium position, frequency of proton stretching vibration and HB energy. A comparison of the calculations for this model and those for total HB systems provides a quantitative estimation of the dynamical effects of the residual part of HB system which cannot be renormalized into the effect of the net charges of the donor and acceptor atoms.

Model and Method of Calculation

We take the three-center four-electron model of the HB system (Fig. 1) and consider the case in which donor A, acceptor B and proton H are arranged linearly, both A and B being oxygen atoms. The HB MO is constructed from the three atomic orbitals (AO), the 1s AO of H and the two AO's, one from A and the other from B each extending toward H. The hybridization of the AO's of A and B is assumed and fixed to be sp^3. Four electrons, two from B and one from A and one from H, enter into the HB MO. The electrons in the other hybridized AO's of A and B are treated as the source of external charges, and they are not constrained to be the integers 5 and 4 respectively. The excess charges at A and B are denoted by $\delta_A e$ and $\delta_B e$ respectively. The 1s cores of A and B are treated as the points with charge of 6e. In the following, we use the term "the core of A or B" meaning that it represents the 1s core and the electrons in the hybridized AO's at A or B not involved in the HB MO.

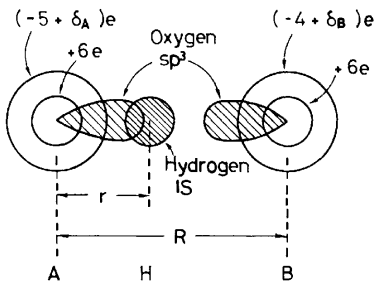

Fig. 1. Three-center four-electron model of hydrogen bond with excess charges.

The HB MO was calculated by CNDO/2 approximation.[10] To obtain consistency with CNDO/2 approximation, the core-core interaction between A and B should be estimated by

$$E_{cc} = \frac{(6e)^2}{R} + \gamma_{AB}\{(5-\delta_A)(4-\delta_B)-6(5-\delta_A)-6(4-\delta_B)\}, \quad (1)$$

and the electron-core interactions by

$$V_{iA} = (1+\delta_A)\gamma_{iA}$$
$$V_{iB} = (2+\delta_B)\gamma_{iB} \quad (2)$$

where i is either A, B, or H. The values of the ionization potential 24.39 eV and electron affinity 6.11 eV were used for the sp^3 AO's involved in HB MO after Hinze and Jaffé.[11]

Calculations were carried out for the mesh of R and r with a 0.1 Å interval and that of δ_A and δ_B in the range from -1.0 to 1.0 with a 0.2 interval. The equilibrium distance R_e of A–B and r_e of A–H, the potential energy E_{eq} and the stretching frequency ν_s of proton at the equilibrium position of proton were calculated by an interpolation of the four mesh points of R and r around the energy minimum. The HB energy ΔE_e at the equilibrium position of A, B, and H was calculated by

$$\Delta E_e = \left(E_{eq}+\frac{1}{2}h\nu_s\right)^{\delta_A,\,\delta_B}_{R=R_e} - \left(E_{eq}+\frac{1}{2}h\nu_s\right)^{\delta_A,\,\delta_B}_{R=\infty}, \quad (3)$$

taking into account the zero point energy of proton motion since the frequency shift due to it is not negligible when δ_A or δ_B is large.

Results

Three Types of Hydrogen Bonds in Relation to the Excess Charges at the Donor and Acceptor Atoms. The dependence of ΔE_e on δ_A and δ_B is shown in Table 1. We see that an attractive HB occurs in the region of δ_A and δ_B with opposite signs. The region may be divided into regions I, II, and III (Fig. 2). When δ_A and δ_B satisfy the relation

$$\delta_A = \delta_B + 1, \quad (4)$$

we see from Eqs. (1) and (2) that the cores of A and B are equivalent and the system becomes symmetric, *viz.*, the potential curve of proton is always symmetric for any value of R. For two points in regions I and II which are mirror images of each other with respect to the straight line (4), the potential curves of proton for the two systems are mirror images of each other for any value of R.

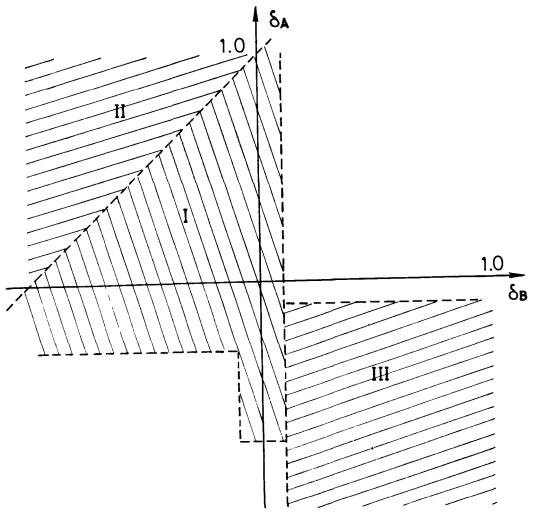

Fig. 2. Three regions of attractive HB.
I: normal HB, II: proton transferred HB, III: abnormal HB.

Region I corresponds to the normal HB in the form of $A^{\delta+}$–H---$B^{\delta'-}$ where the equilibrium position of H is on the side of A. Region II corresponds to the HB in

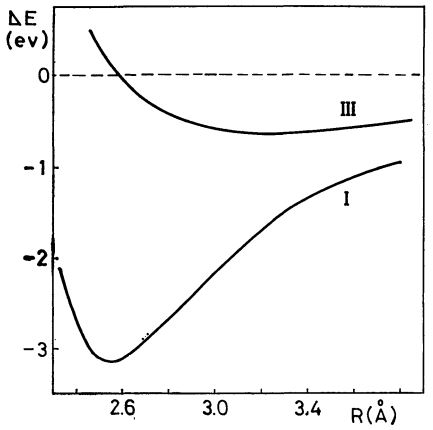

Fig. 3 (a).

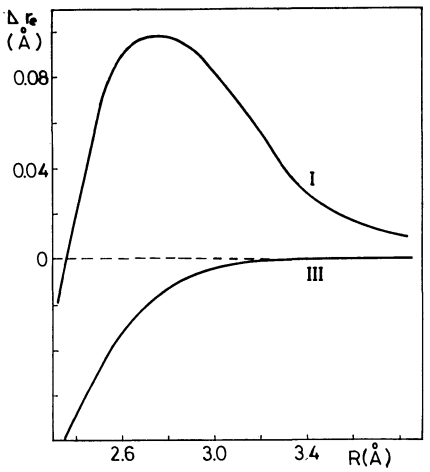

Fig. 3 (b).

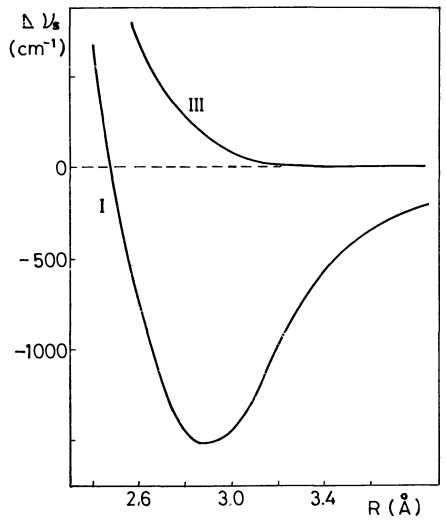

Fig. 3 (c).

Fig. 3. Dependences of the hydrogen bond energy ΔE(a), the shift of proton equilibrium distance Δr_e (b) and the shift of frequency of stretching vibration of proton $\Delta\nu_s$ (c) on the A–B distance R. Typical cases are represented;
I($\delta_A=0.4$, $\delta_B=-0.4$) and III ($\delta_A=-0.4$, $\delta_B=0.4$).

the form of $A^{\delta+}$---H–$B^{\delta'-}$ in which the effect of the excess charge is so strong that the equilibrium position of H is shifted toward the side of B, namely, the HB of proton transferred state. The HB in the region III is of the form $A^{\delta-}$–H---$B^{\delta'+}$ and abnormal. The R dependence of ΔE, Δr_e and $\Delta\nu_s$ for typical systems in regions I and III is shown in Fig. 3, where ΔE, Δr_e and $\Delta\nu_s$ are respectively the HB energy and the shifts of r_e, ν_s being due to HB at A–B distance R. For the HB system in region I, $\Delta r_e>0$ and $\Delta\nu_s<0$ at $R=R_e$ exhibit the normal character of HB (Fig. 3). Distance R giving the maximal Δr_e and $\Delta\nu_s$ coincides with R_e in a weak HB with a small ΔE_e, while Δr_e and $\Delta\nu_s$ at R_e tend to be somewhat smaller than their maximal values in a strong HB with large ΔE_e. This seems to be the effect of compression of R_e in the strong HB.

Fig. 4. Correlations between the hydrogen bond distance R_e, the proton equilibrium position r_e, the shift Δr_e of r_e due to formation of HB, the frequency of proton stretching vibration ν_s, the shift $\Delta\nu_s$ of ν_s and hydrogen bond energy ΔE_e. The correlations shown are those between $-\Delta E_e$ and $-\Delta\nu_s$ (a), R_e and $-\Delta\nu_s$ (b), r_e and $-\Delta\nu_s$ (c), Δr_e and $-\Delta\nu_s$ (d), ν_s and R_e (e) and between R_e and r_e (f).

The values of the excess charges δ_A and δ_B are discriminated by the following symbols;
$\delta_A=-0.2$(●), 0(○), 0.2(▲), 0.4(△).
$\delta_B=0$(1), -0.2(2), -0.4(3), -0.6(4), -0.8(5), $-1.$(6).

The solid line in (a) is the experimental curve given by Badger and Bauer[13] for water and alcohol.

The points x in (b) and (e) are the experimental points compiled by Nakamoto *et al.*[14] for O–H---O bonds and those in (f) are the data compiled by Hamilton and Ibers[15] for O–H···O bonds in solid.

The dashed line in (f) represents the case of symmetric HB with $r_e=R_e/2$.

On the other hand, for the HB system in region III, we have $\Delta r_e<0$ and $\Delta\nu_s>0$ at $R=R_e$ exhibiting an abnormal character in contrast to the normal HB.

Correlation between the Hydrogen Bond Distance, Proton Equilibrium Position, Frequency of Proton Stretching Vibration and Hydrogen Bond Energy. We may obtain the theoretical correlation between R_e, r_e, Δr_e, ν_s, $\Delta\nu_s$ and ΔE_e for the normal HB by adjusting δ_A and δ_B within region I. The results are shown in Fig. 4. The theoretical correlation plots including r_e or ν_s are shifted toward larger values of r_e and ν_s (Figs. 4e and f). However, when we subtract the constant amounts of 0.2 Å and 1300 cm^{-1} from r_e and ν_s respectively, the theoretical correlation plots overlap the observed ones. Apart from these constant deviations of r_e and ν_s, agreement of the theoretical correlation plots with the observed ones is good. The deviation of theoretical values of r_e and ν_s in a larger direction than the observed ones is already present in the isolated A–H system and seems to be due to a failure of the CNDO/2 method to give a correct potential for the covalent bond.

In some of the observed correlation plots, the experimental points exhibit a considerable scattering (Figs. 4b, e, and f). However, if the experimental points are selected in such a way that either one of the acid or base is fixed and the other changed, then the correlation plot, which exhibits considerable scattering when both acid and base are arbitrarily changed, becomes a smooth one. This behavior is also reproduced in the present calculation. When either one of δ_A or δ_B is fixed and the other changed, then the theoretical correlation plot becomes a smooth one, but

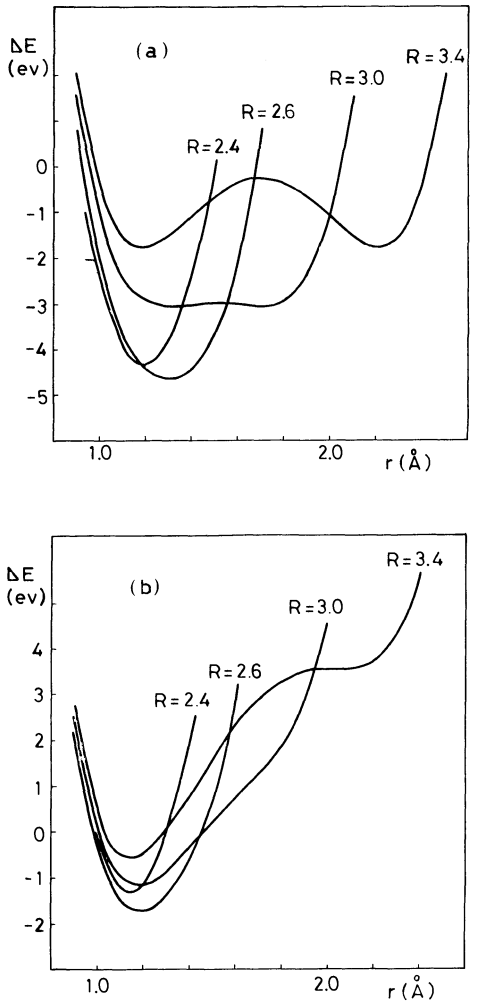

Fig. 5. The proton potential curves at various AB distances R.
(a) The symmetric system with $\delta_A=0.2$, $\delta_B=-0.8$
(b) The asymmetric system with $\delta_A=0.0$, $\delta_B=-0.6$

the correlation plots with different values of the fixed δ are not identical, and each of the theoretical correlation exhibits a spread (Fig. 4).

The good agreement between the theoretical correlation plots and the experimental ones strongly suggests that the correlation plots are primarily determined by the excess charges at the donor and acceptor atoms.

Potential Shape for Proton Movement. Many studies have been carried out concerning the potential shape for proton movement in the HB system, particularly the existence or non-existence of double minima. Hardly any MO calculations carried out so far on total systems with a single HB between oxygens led to a double well potential at theoretical R_e although it may be obtained at larger R. Clementi[9] emphasized in his non-empirical calculations that a coupling between more than two HB's would be a necessary requisite for the second minimum to occur. Nevertheless, the factors principally responsible for occurrence of double minima do not seem to have been determined.

The present model does not give a double well potential at R_e for all values of δ_A and δ_B. If δ_A and δ_B are close to the symmetric system satisfying Eq. (4), then a double well potential appears at slightly larger R than R_e (Fig. 5a). For the system in region I, the minimum of the potential well is on the side near A, but for that in region II it is on the side near B. If the asymmetry of the system becomes large, the R where the double well potential appears shifts toward much larger R than R_e (Fig. 5b). Thus, the excess charges at the donor and acceptor atoms are not the essential factor to produce a double well potential although the excess charges with the signs $\delta_A>0$ and $\delta_B<0$ stabilize the configuration A···H–B and facilitate occurrence of the second minimum.

Mechanism of the Effect of Excess Charges on the Hydrogen Bond and Proton Transfer. We now consider the mechanism of how the excess charges with the signs $\delta_A>0$ and $\delta_B<0$ enhance HB and proton transfer. As represented in the scheme $A\text{–}H+B\rightarrow A^{\delta-}\text{–}H\cdots B^{\delta+}$, formation of the HB leads to an increase in the electron density at A and a decrease at B. This change in the electron density is due to an increase of the lone pair electron density at A by transfer of the lone pair electrons at B to the antibonding orbital of A–H as seen from the HB MO (Fig. 6b). Let $E_l(z)$ and $E_s(z)$ respectively be the energies of the lone pair in A^- or

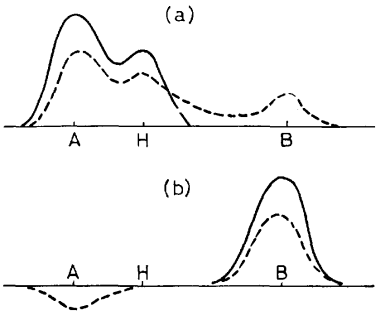

Fig. 6. A change in molecular orbitals induced by HB. Isolated state (——) and hydrogen bonding state (----). Bonding orbital (a) and lone pair orbital (b).

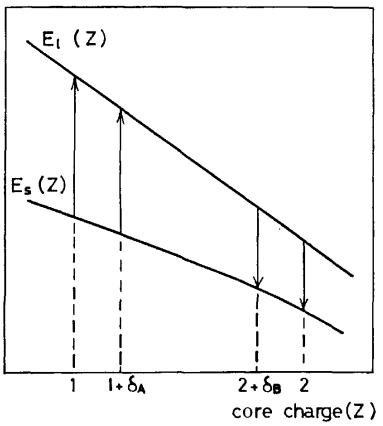

Fig. 7. Dependences of the lone pair energy E_l and the single bond energy E_s on the core charge.

B and the single bond A–H or $H\text{–}B^+$ regarded as the functions of the core charge z. We show their z dependence in Fig. 7. The energy loss by the process $A\text{–}H\rightarrow A^-$ may be related to $E_l(1+\delta_A)-E_s(1+\delta_A)$. Since the effect of the core charge is greater for the lone pair electrons than those in the single bond, a greater change is induced in $E_l(1+\delta_A)$ than in $E_s(1+\delta_A)$ by an increase in δ_A. Thus it follows that $E_l(1)-E_s(1)>E_l(1+\delta_A)-E_s(1+\delta_A)$ for $\delta_A>0$ (Fig. 7). This means that the energy loss accompanied by the process $A\text{–}H\rightarrow A^-$ is smaller for $\delta_A>0$ than for $\delta_A=0$, and the HB and proton transfer are made easier by the excess charge $\delta_A>0$.

As site B, HB formation leads to a decrease of the lone pair density and to an increase of electrons in the single bond $H\text{–}B^+$. The energy gain by the process $B\rightarrow H\text{–}B^+$ may be related to $E_l(2+\delta_B)-E_s(2+\delta_B)$. As seen in Fig. 7, $E_l(2+\delta_B)-E_s(2+\delta_B)>E_l(2)-E_s(2)$ for $\delta_B<0$. This means that the lenergy gain accompanied by the process $B\rightarrow H\text{–}B^+$ is greater for $\delta_B<0$ than $\delta_B=0$, and HB and proton transfer are enhanced by the excess charge $\delta_B<0$. As both processes occur in the HB, the quantity

$$\Delta(\delta_A,\delta_B)=\{E_l(1+\delta_A)-E_s(1+\delta_A)\}-\{E_l(2+\delta_B)-E_s(2+\delta_B)\}$$

may well be related to the power of the HB. Since there is an approximately linear correlation between ΔE_e and Δ (Fig. 8), a very simplified picture of the HB regarded as a combined process of $A\text{–}H\rightarrow A^-$ and $B\rightarrow H\text{–}B^+$ might explain the dependence of HB strength on the excess charges, though it might fail to explain more detailed properties of the HB. The functional dependence of $\Delta(\delta_A,\delta_B)$ on δ_A and δ_B is similar to ΔE_e when either one of δ_A or δ_B is changed, but it leads to a different ordering of HB energy from that of MO calculation when both δ_A and δ_B are changed. For instance, $\Delta(\delta_A=0,\ \delta_B=-0.2)>\Delta(\delta_A=0.2,\ \delta_B=0)$ although the MO calculation leads to $\Delta E_e(\delta_A=0,\ \delta_B=-0.2)<\Delta E_e(\delta_A=0.2,\ \delta_B=0)$. A similar correlation between ΔE_e and Δ is obtained for the calculation on the total HB systems.[12]

In the process of proton transfer, $A\text{–}H\rightarrow A^-$ and $B\rightarrow H\text{–}B^+$ occur to a greater extent than in the normal

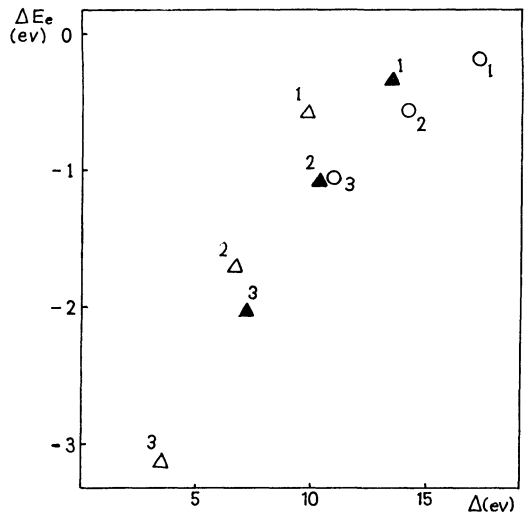

Fig. 8. Correlation between ΔE_e and Δ.
δ_A and δ_B for each point are discriminated by the same symbols as Fig. 4.

HB. Thus, the above interpretation for the effect of the excess charges is more applicable to the systems in region II.

Discussion

In contrast to our result, Hasegawa *et al.*[3] obtained a double well potential in their VB calculation with changing orbital exponents using a similar model to ours. They calculated the potential at an R near the experimental one without confirming whether it was close to the theoretical equilibrium distance or not. However, even if the R they chose was the one deviated from the theoretical R_e, the extent of the appearance of the double minima was more enhanced than that in the present result. Thus, either the electron correlation or the change of the orbital exponent, which are not taken into consideration in the present MO calculation, might be important for producing the double well potential.

In the present model the amounts of excess charges δ_A and δ_B are fixed parameters, but in a real hydrogen bond system they may be changed by the dynamic polarization of the molecules caused by HB formation. It seems possible that the dynamic polarization affects the HB dominantly through a change of the excess charges at the donor and acceptor atoms. The present model may be utilized as a reference system to evaluate validity of such mechanism. If the dynamic polarization affects the HB mainly through a change of the excess charges, the correlation plots between the quantities such as R_e, r_e *etc.* obtained for the system with the effect of dynamic polarization should be almost the same as those obtained for the present model. A good agreement of the theoretical correlation plots in the present model with the experimental ones offers indirect support for such a mechanism.

The shape of the proton potential, in contrast to the correlation curves, is affected by the change of the excess charges due to dynamic polarization. It is of interest to see how the proton potential is affected by dynamic polarization.

The INDO and CNDO/2 SCF LCAO MO Calculation of Intermolecular Forces and Their Pairwise Additivity

Masao HASHIMOTO and Taro ISOBE

The Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira, Sendai 980

(Received June 28, 1973)

The assumption of pairwise additivity of the intermolecular forces was examined within a CNDO/2-Clementi approximation. It was found that the deviation from the pairwise additivity, defined as the difference between the three-body interaction and the sum of the two-body interaction energies in the system of three neighboring molecules in a crystal, was small enough to be neglected as compared with the lattice energy. The CNDO/2-Clementi method, in which the overlap integrals are calculated by using the Clementi AO's, was found to be more useful than the usual CNDO/2 method, in which the overlap integrals are calculated by means of Slater AO's. The discrepancy in the calculated interaction energies from the experimental ones in the form of the heat of sublimation was found to be quite large for CO. This discrepancy becomes small, though, if the centers of the molecules are displaced away from the origin and along the nonintersecting threefold axes of the unit cell; the crystal structure belongs not to the Pa3 space group, but to the $P2_13$ space group. From a comparison of the CNDO/2-Clementi results and the results of the exp-6 potential superimposed on the quadrupole-quadrupole interaction potential, it was found that the former is superior to the latter in anticipating the conformation of the $(CO_2)_2$ dimer.

In a previous paper[1] (designated **I** henceforth), we calculated the intermolecular forces between closed-shell molecules in the ground-state, treating the dimer system as if it were one molecule and using the difference between the total energy of this system and that of the monomeric molecules. The total energies were calculated with the CNDO/2 SCF LCAO MO (completely neglecting the differential overlaps in self-consistent field molecular orbital approximated by a linear combination of atomic orbitals) method by using the Clementi AO's (we will designate this by "CNDO/2-Clementi method" henceforth).

In **I**, the calculated interaction energy was compared with the experimental one in the form of the lattice energy by assuming a pairwise additivity of the intermolecular forces. This assumption is justified if the deviation from the pairwise additivity is relatively small. However, no examination for the pairwise additivity was made in **I**.

In the present paper, we will calculate the interaction energy among three molecules treating them as if they were one molecule. The deviation from the pairwise additivity will, then, be obtained as the difference between the three-body interaction energy and the sum of the two-body interaction energies. We will compare the interaction energy obtained by using the Slater AO's and that obtained by using Clementi AO's. This comparison was made in **I** only for ethylene. Furthermore, the INDO (with an intermediate neglect of the differential overlaps) and CNDO/2 results will be compared.

The substances treated in this paper and their crystal data are summarized in Table 1.

Theoretical

In this section, we will supplement the theoretical part of **I**.

INDO Parametrization. The F matrix in INDO is as follows:

$$F_{rr} = U_{rr} + \frac{1}{2}P_{rr}\gamma_{AA} + \sum_{s(\neq r)}^{(A)} P_{ss}\left[(rr/ss) - \frac{1}{2}(rs/rs)\right] + \sum_{B(\neq A)} (P_{BB} - Z_B)\gamma_{AB} \quad (r, s \in A) \tag{1}$$

$$F_{rs} = P_{rs}\left[(3/2)(rs/rs) - \frac{1}{2}(rr/ss)\right] \quad (r \neq s,\ r, s \in A)$$

$$F_{rs} = \frac{1}{2}S_{rs}(\beta_A + \beta_B) - \frac{1}{2}P_{rs}\gamma_{AB} \quad (r \neq s,\ r \in A,\ s \in B)$$

The integrals appearing in (1) are expressed as follows:

$$\begin{aligned} (ss/ss) &= (ss/xx) = F^0 = \gamma_{AA} \\ (xx/xx) &= F^0 + (4/25)F^2 \\ (xx/yy) &= F^0 - (2/25)F^2 \\ (xs/xs) &= (1/3)G^1 \\ (xy/xy) &= (3/25)F^2, \text{ etc.,} \end{aligned} \tag{2}$$

where s, x, y, *etc.* are 2s, $2p_x$, $2p_y$, and so on; F^2 and G^1 are semiempirical parameters given by Pople *et al.*[9] F^0 is calculated theoretically by using the Slater AO's.[10] The bonding parameters β's, were parametrized as usual.[9]

The overlap integrals, S_{rs}, were calculated by using both Slater AO's and Clementi AO's (see **I**); they are compared in part in Tables 2 and 3.

In this series of papers, one- and two-center electron repulsion integrals, γ_{AA} and γ_{AB}, are always calculated by using the Slater AO's. There is no clear *rationale* for this. However, the final results using the γ_{AA} and γ_{AB}, which were calculated with the Clementi AO's, did not seem to be superior to those calculated with the Slater AO's.

Deviation from Pairwise Additivity. In the previous paper, we calculated the lattice energy taking the summation of the pair interaction energies over the 1st and the 2nd neighboring pairs in a crystal, and assuming the pairwise additivity of the intermolecular forces. This assumption is, however, not strictly justified. Several authors[11-15] have approached the problem of the non-additive part of molecular interactions in $(He)_3$ using an SCF LCAO MO approximation. Novaro and Beltran-Lopez[15] have indicated that the three-body effect, which is considered to be the main part of the deviation from the pairwise additivity in many particle systems, can be quite large at smaller distances, but wanes quickly when approaching the region of the $(He)_2$ van der Waals well.

The three-body effects, or the deviation from the pairwise additivity, is defined as follows:

$$D = U_{abc} - (U_{ab} + U_{bc} + U_{ca}) \quad (3)$$

where:

$$U_{abc} = E(M_a, M_b, M_c) - [E(M_a) + E(M_b) + E(M_c)] \quad (4)$$

and

$$U_{ab} = E(M_a, M_b) - [E(M_a) + E(M_b)], \text{ etc.} \quad (5)$$

In Eqs. (4) and (5), the E's are the sums of the total electronic and Coulombic repulsion energies between the cores (see **I**).

Results and Discussion

In Figs. 1 and 2, D, the deviation from the pairwise additivity, is plotted against the intermolecular distances, R, keeping the relative orientations of the molecules fixed to those in real crystals. These figures show that, D at R_0, which is the intermolecular distance in a real crystal, can be neglected in comparison with the lattice energy (see Table 4). The assumption of the pairwise additivity in **I** is thus satisfied approximately.

In Table 4, the calculated heats of sublimation (a half of the lattice energy) are compared with the experimental ones. These calculated values were obtained by taking the summation of (5) over the nearest and the 2nd-nearest neighbor molecules in the crystals. The contribution of the higher neighbors is small enough to be neglected (see **I**). The 3rd column of Table 4 shows the CNDO/2-Clementi results obtained by using the Clementi AO's to calculate the overlap integrals. The 5th column shows the corresponding INDO-Clementi resulst. The 2nd and 4th columns show those for usual CNDO/2 and INDO calculations. From this Table we can see that the best agreement between the calculated and the observed interaction energies is obtained when the calculation is done by using the Clementi AO's. We can also see that the INDO results are not so superior to the CNDO/2 results as is generally expected.

The deviation of the calculated heat of sublimation from the experimental one in CO becomes small if we assume that the molecules in the crystal are displaced from the approximate centers of inversion and, hence, if we assume that the resultant space group is not Pa3, but $P2_13$. Defining the displacement from the centrosymmetric positions by δ, as is shown in Fig. 3, we calculated the δ-dependency of the heat of the sublimation of α-CO crystals. $\delta=0.0$ Å corresponds to the Pa3 space group. The results are shown in Table 5. We can see that the Pa3 space group is not preferable in explaining the heat of the sublimation of

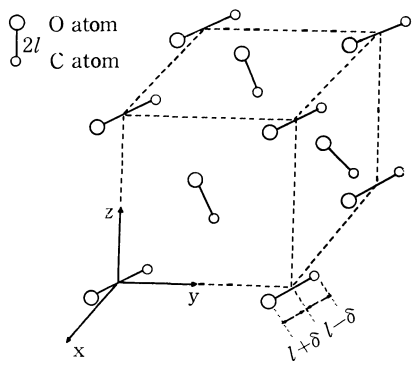

Fig. 3. Definition of displacement δ from centrosymmetric positions of the structure with space group Pa3.

+0.20	−0.34674	−0.09900

the α-CO crystal. Thus, the crystal structure of α-CO may belong to the $P2_13$ space group. This situation is somewhat analogous to that with the α-N_2 crystal, for which the space group might be $P2_13$, according to recent far-IR absorption spectral data.[16] In order to check this, we calculated the δ-dependency of the α-N_2 crystal (see Table 5). It may be seen that the agreement with the experimental heat of sublimation is best when $\delta=-0.1$ Å. X-Ray diffraction study of α-N_2 by Lipscomb *et al.*[17] has given this δ-value as from −0.1 to −0.2 Å. By the way, the deviation from the pairwise additivity of α-N_2 is small, even with the $P2_13$ space group, compared with the heat of sublimation, as may be seen from Curve (b) of Fig. 2 ($\delta=-0.1$ Å). Thus, evidence has been reported both for [16–18] and against [19] the $P2_13$ space group for α-N_2 in experiments; our calculations support $P2_13$.

Thus, the CNDO/2-Clementi method for the calculation of the intermolecular forces is quite useful, as may be seen from Table 4, if we use the Clementi AO's to calculate the overlap integrals. Moreover, this method is more rigorous from the theoretical point of view than is the usual method,[20] in which intermolecular forces are divided into three parts (exchange repulsion, dispersion, and electrostatic interaction forces) and calculated separately in terms of each different method. The CNDO/2-Clementi method unifies these forces and reduces the unknown errors due to the above

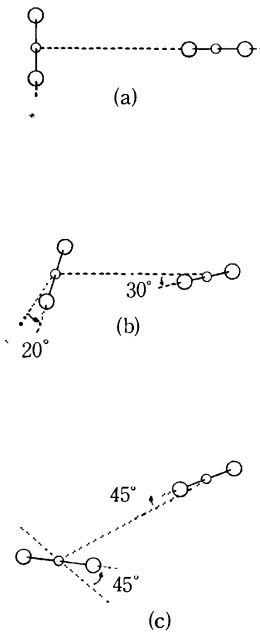

Fig. 4. Typical configurations of two CO_2 molecules separated by distance 4.1 Å.

division of intermolecular forces.

Now let us examine the reliability of the present method. This has been discussed partially in **I**; we would now like to add the following facts.

Figure 4 shows three typical configurations of two CO_2 molecules, separated by an R_0 distance of 4.1 Å. The interaction energies calculated by the present method are −0.17135, −0.08876, and −0.06419 eV for Configurations (a), (b), and (c) respectively. We can see that the (a) configuration, that is, the T-configuration, is the most stable one; this corresponds to the experimental results of Welsh *et al.*[21] They found that the two components of the (ν_1, $2\nu_2$) Fermi doublet of gaseous CO_2 show a complex structure in a long-absorption pathlength at a low temperature. They analyzed this absorption and interpreted it in terms of the rotation and vibration of $(CO_2)_2$ dimers held in a locked T-position at an intermolecular distance of 4.1 Å.

For comparison, we have done this configuration calculation by using the non-bonded-atom-atom pair interaction potential superimposed on the quadrupole-quadrupole interaction potential. This is shown by the following equation:

$$V(R,\theta,\theta',\phi,\phi') = V_{\exp-6} + V_{Q-Q} \tag{6}$$

$$V_{\exp-6} = \sum_j [a_j \exp(-b_j r_j)/r_j^{d_j} - c_j/r_j^6] \tag{7}$$

$$\begin{aligned} V_{Q-Q} = 3Q^2\{&1-5(\sin^2\phi\sin^2\theta+\sin^2\phi'\sin^2\theta') \\ &-15\sin^2\phi\sin^2\theta\sin^2\phi'\sin^2\theta' \\ &+2[4\sin\phi\sin\theta\sin\phi'\sin\theta' \\ &-(1-\sin^2\phi\sin^2\theta)^{1/2}(1-\sin^2\phi'\sin^2\theta')^{1/2} \\ &\times\cos(\theta-\theta')]^2\}/4R^5 \end{aligned} \tag{8}$$

Table 6. Parameters in Eq. (7), in kcal/mol and Å units

j	$a_j\times10^5$	b_j	c_j	d_j
C···C	3.012	0.0	327.0	12.0
C···O	1.785	2.304	202.2	6.0
O···O	1.057	4.608	125.10	0.0

In Eq. (7), the summation over j is taken over all the pairs of atoms between two molecules. The four parameters, a_j, b_j, c_j, and d_j, were derived from the Table of Liquori *et al.*[22] (Table 6). In Eq. (8), Q is a molecular quadrupole moment and is 4.3×10^{-26} cm^2 esu for CO_2 molecule;[23] the relative orientation $(\theta,\theta',\phi,\phi')$ of the two molecules is defined as is shown in Fig. 5.

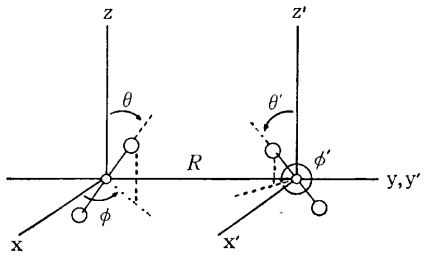

Fig. 5. Geometrical representation of two CO_2 molecules in interaction.

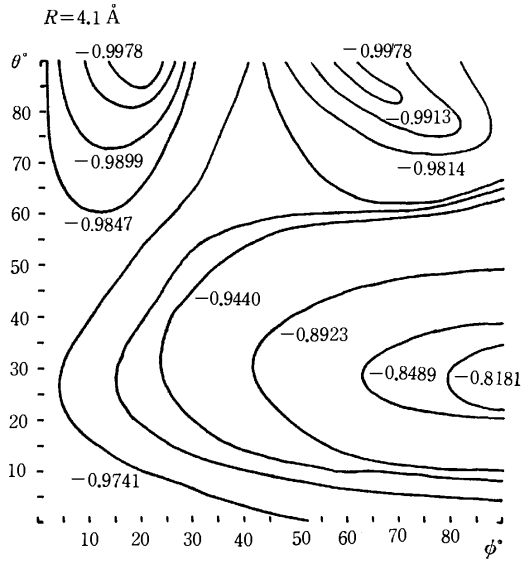

Fig. 6. θ-ϕ energy surface between two CO_2 molecules. The values in the figure are the minimum with regard to θ' and ϕ'. (in kcal/mol unit)

In Fig. 6, the θ–ϕ dependency of the interaction energy (6) is indicated, in which each point, $P(\theta,\phi)$, corresponds to the most stable configuration with regard to the θ' and ϕ' values. From Fig. 6, we found that the most stable configuration at R_0=4.1 Å is the one indicated in Fig. 4(b); this is somewhat different from the experimental findings.

Thus, the present CNDO/2 method is superior to a method using such a potential as (6).

In conclusion, the CNDO/2-Clementi method is useful in calculating the interaction energy between such molecules, as is indicated in Table 1.

We are now proceeding to calculate the interaction energy of more complex molecules by the same method. The results will be reported elsewhere.

All the computing in the present paper was done at the Computer Center of Tohoku University using the NEAC-2200 model 700 and its TSS.

An ENDOR Study of the Relaxation Behavior of the Nuclei in Several Semiquinone Anion Radicals[1]

Yashige KOTAKE and Keiji KUWATA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received July 20, 1973)

The ENDOR intensities of several semiquinone anion radicals were measured at various temperatures. The optimum temperature for the ENDOR intensity of protons in a radical was interpreted on the basis of their characteristic ways of relaxation. The electron nuclear dipolar (END) mechanism could be applied very well in most cases. However, in the case of protons whose END terms are very small this interaction might not explain the optimum temperature. Possible substitute mechanisms were discussed.

The ENDOR signal intensity depends on both the electron and nuclear relaxation times. As the temperature of a system changes, these relaxation times change in their characteristic ways, and this causes the temperature dependence of the intensity of the ENDOR signal. When the nuclei in a radical have their own relaxation paths of different temperature dependences, their ENDOR lines show a characteristic temperature dependence. Therefore, the ENDOR intensity is not an intrinsic parameter of the free radical. For this reason, ENDOR has a limitation as an analytical tool.

The investigation into the relaxation behavior which affects the ENDOR intensity is essential in providing fundamental knowledge for the assignment of the ENDOR spectra. Moreover, by the analysis of the temperature dependence, especially of the optimum temperature at which the strongest ENDOR line appears, we can find the relaxation mechanism of a nucleus relating to its position and its surroundings in a radical.

Freed[2,3] has developed a theory of the ENDOR enhancement on the basis of the equation of motion for the density matrix of a system and has obtained qualitative agreement with Hyde's experimental results.[4] He has explained the characteristic optimum temperature for each nucleus in terms of the electron nuclear dipolar (END) interaction being the dominant cause of the nuclear spin relaxation process in the liquid phase. In this process, a nucleus which has larger dipolar *hf* interaction with an electron spin must have a higher optimum temperature.

Allendoerfer and Maki[5] have made a unique study of the optimum conditions for the ENDOR enhancement in the tri-*t*-butyl phenoxyl radical in the liquid phase. However, no other detailed study of the optimum temperature for the ENDOR enhancement has yet been done; thus, it is not clear whether or not the END interaction is a common process in the nuclear relaxation in solution ENDOR. Especially in the case of protons which have a small END term, like the *t*-butyl protons, the END interaction seems to be inefficient in explaining the optimum temperature.

In the present study, using some semiquinone anions as probes in an ENDOR study, the END interaction was proved to be the dominant cause of proton relaxation when the anisotropic *hf* interaction between a proton and an electron spin is of a considerable magnitude. Also, the temperature dependence of the ENDOR intensity for the protons with small anisotropic *hf* coupling was proved not to be explainable in terms of the END interaction, and other nuclear relaxation mechanisms which may explain the ENDOR intensity were discussed.

Experimental

Though the measurement of the temperature dependence of the ENDOR intensity is useful for the investigation of the relaxation phenomena in a radical, its quantitative measurement involves some experimental difficulties. These difficulties arise for the following reasons.

1. Change in the radical concentration by a chemical equilibrium.

This causes not only a change in the intensity itself, but also many incidental effects. Upon the change in the concentration, the rate of Heisenberg spin exchange varies according as this equation:[6]

$$\omega_{HE} = 4\pi Da[R] \quad (1)$$

where D is the translational diffusion coefficient, a is the molecular radius, and [R] is the radical concentration. ω_{HE} lowers with the decrease in the temperature and affects the ENDOR enhancement factor.[2]

2. Change in the spin-lattice relaxation time of the electron.

The viscosity of the solvent accordingly varies with the temperature. There are many electron-relaxation processes which are viscosity-dependent, *e.g.*, the relaxation *via g*- and *hf*-tensor anisotropy and that *via* spin-rotational interaction. Therefore, the saturation factor of an ESR line changes with the temperature and the degree of saturation changes when the microwave power level is kept fixed during the measurements.

Freed's theory shows[2] that the Heisenberg exchange process diminishes the percentage of the enhancement of an ESR line by the ENDOR effect, but does not affect the optimum temperature, this has been confirmed by the experimental results of Hyde.[4] Thus, the exchange process does not move the optimum temperature for the ENDOR intensity. These facts show that, by suitable arrangements, *e.g.*, the dilution and the calibration of the ENDOR intensity by its ESR intensity, the first experimental difficulty can be removed.

The incident microwave power which gives the strongest ENDOR signal shifts as the temperature changes, but in the case of the semiquinone anion the shift is within the range of several db of microwave power. The measurement of the temperature dependency was done without changing the incident microwave power fed into the cavity. This may cause an error of the measurement of the optimum temperature.

The quinones used were of a guaranteed grade, and their anion radicals were produced by dissolving them into an alcohol which was in contact with the sodium metal. The solution was degassed thoroughly and then transferred into

a glass sample tube 4 mm in o.d.

All the radicals formed were assigned to the primary radicals of the semiquinone anions on the basis of their ESR spectra. In the case of 2,5-dimethyl benzoquinone, the concentration of sodium ethylate was kept low in order to avoid further reaction.[7,8]

The ENDOR spectra were observed at various temperatures by controlling the flow of the chilled nitrogen passing through the sample. The ENDOR spectrometer was based upon an ordinary ESR spectrometer with a 200 Hz field modulation. The RF power supply delivered a maximum output of peak 600 watts of sinusoidally amplitude-modulated power, and the modulation frequency was variable from 5 to 15 kHz. The field lock[4] obtained by observing the ESR signal of DPPH was partly used.

Results

The features of the ENDOR signals of the 2,5-di-*t*-butyl-*p*-benzosemiquinone (DBQ) anion at various temperatures are shown in Fig. 1. This radical has two ring protons with a 6.13 MHz isotropic *hf* coupling and eighteen *t*-butyl protons with a 0.19 MHz isotropic *hf* coupling. The temperature dependences of the intensities of these lines in methanol, ethanol, and 2-propanol solution are shown in Figs. 2a and 3a, while the plots *versus* η/T, where η is the viscosity of the solvent, are shown in Figs. 2b and 3b. The intensity plotted on the ordinate was an integrated intensity because there was considerable variation in the ENDOR linewidths. In the case of the lines for the *t*-butyl group especially, two lines were very close to each other; these overlapping two lines were integrated together.

The η/T dependences of the intensity of the ENDOR line in the 2,5-dimethyl-*p*-benzosemiquinone (DMQ) anion and the 9,10-anthrasemiquinone (ANQ) anion in ethanol were also measured by the same procedure; they are shown in Figs. 4 and 5.

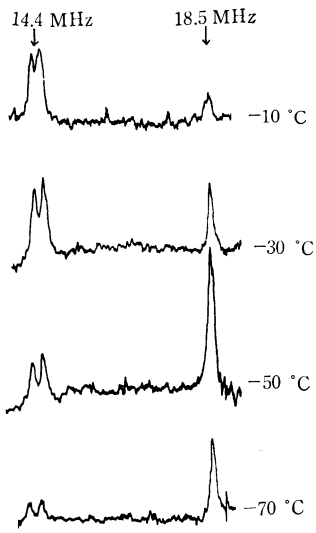

Fig. 1. The ENDOR spectra of 2,5-di-*t*-butyl-*p*-benzosemiquinone anion radical in ethanol at various temperatures.

Discussion

In an organic radical, *g*- and *hf*-anisotropy play dominant roles in the electron-spin relaxation. In this situation the assumption of a simple exponential correlation function with a correlation time of τ_R leads to the transition probability of the electron spin

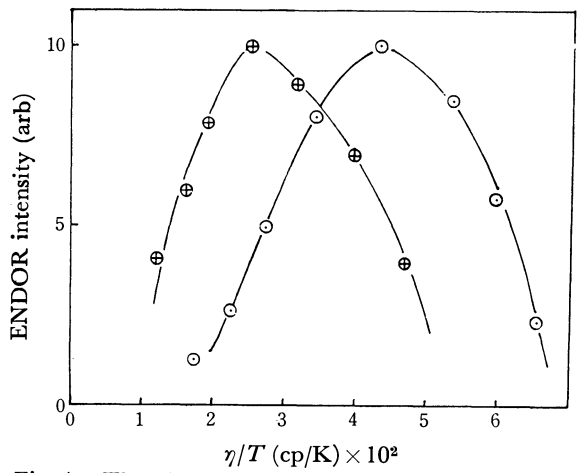

Fig. 4. The η/T dependence of ENDOR intensity of 2,5-dimethyl-*p*-benzosemiquinone anion radical in ethanol, ⊕ ring proton, ⊙ methyl proton.

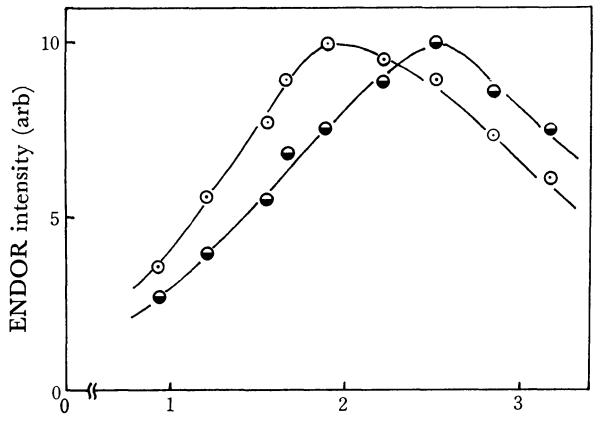

Fig. 5. The η/T dependence of ENDOR intensity of 9, 10-anthrasemiquinone anion radical in ethanol, ◒ 1-proton, ⊙ 2-proton.

W_e, which is identical with $1/T_{el}$ as:

$$W_e \propto \tau_R/(1+\omega_e^2\tau_R^2) \quad (2)$$

where ω_e is the Larmor frequency of the electron spin.

At high temperatures spin-rotational relaxation occurs by the fluctuating field caused by a molecular tumbling motion, but the deviation of the g values of semiquinone anions from the free electron g value is too small to cause spin-rotational relaxation.[9]

On the other hand, the nuclei in a radical are in the special situation because of the large magnetic dipole moment of an electron spin very close to them. Thus, the magnetic relaxation behavior of the nuclei may be very different from that in a diamagnetic molecule.

The nuclear transition probability for a radical is decided mainly by the electron-nuclear dipolar (END) interaction fluctuating by the Brownian motion of the molecule, because other nuclear relaxation processes, *e.g.*, nuclear dipole-dipole interaction, chemical shift anisotropy, and nuclear spin-rotational interaction, are comparatively small and may be neglected when the anisotropic *hf* interaction is of a considerable magnitude.

In a fluctuating END interaction, the nuclear transition probability can be written as:

$$W_n^{END} \propto \tau_R/(1+\omega_n^2\tau_R^2) \quad (3)$$

where ω_n is the Larmor frequency of the nucleus. When we adopt the Stokes-Einstein model, the isotropic rotational correlation time is given by:

$$\tau_R = 4\pi\eta a^3/3kT \quad (4)$$

where η is the viscosity of the solvent and a is the molecular radius. A schematic figure of the η/T dependence of W_e and W_n is shown in Fig. 6. Under ordinary experimental conditions in the liquid phase,

$$\omega_e^2\tau_R^2 \gg 1 \quad (5)$$

and

$$\omega_n^2\tau_R^2 \ll 1 \quad (6)$$

Under these conditions, W_e slows down when the sample is cooled, while, on the contrary, W_n becomes larger.

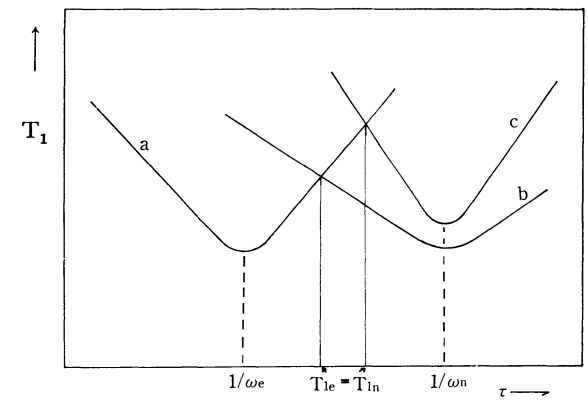

Fig. 6. The schematic figure of the τ dependence of T_{1e} and T_{1n}.
a: T_{1e}, b: T_{1n} with smaller END term, c: T_{1n} with larger END term.

In the temperature range where Eqs. (5) and (6) hold, W_e can be written as:[2]

$$W_e = A(1/\tau_R) \quad (7)$$

where A is the constant relating to the magnitude of the g and hf anisotropy. Moreover, W_n^{END} can be written as:[1]

$$W_n^{END} = B\tau_R \quad (8)$$

where B is the constant which is related to the magnitude of the anisotropic hf interaction.

Thus, the ratio of the two transition probabilities becomes:

$$b = \frac{W_n^{END}}{W_e} = (B/A)\tau_R^2 \quad (9)$$

The optimum conditions for the observation of the ENDOR signal are realized when the two transition probabilities become almost comparable,[2,3] that is, when:

$$b \sim 1 \quad (10)$$

The optimum η/T of an ENDOR line is decided by B/A and when a radical has two groups of protons, the ratio of the optimum η/T's becomes:

$$\frac{(\eta/T)_1}{(\eta/T)_2} = \left(\frac{B_2}{B_1}\right)^{1/2} \quad (11)$$

Thus, the ENDOR line of protons in a radical which have larger END terms has a smaller optimum η/T, *i.e.*, a higher temperature. This situation is shown schematically in Fig. 6.

ANQ Anion. In order to confirm the results described above, the ANQ anion radical in ethanol was studied. The ENDOR spectrum of this radical shows simple features because there are only two groups of equivalent protons; their isotropic *hf* coupling constants are $a_1=1.50$ MHz and $a_2=2.73$ MHz.

The magnitude of the B constant is proportional to the square of the END terms. The contribution of the END terms to the magnitude of B may be assumed to be proportional to $<1/r^3>_{av}^2$, where r is the distance between the proton and the unpaired electron and where $<\ >_{av}$ denotes the averaged value over the unpaired electron distribution. The END terms of the ring protons are approximately proportional to the spin density of adjacent carbon atoms if the cross contribution from the spin density on other carbon atoms is neglected. According to the McConnell relationship between the spin density on a carbon atom and the Fermi contact term of a proton,[10]

$$\rho_i = \frac{a_i}{Q} \tag{12}$$

where ρ_i is the spin density on the i-th carbon atom, a_i is the isotropic *hf* coupling constant of the proton bonded to the i-th carbon atom, and where Q is a constant peculiar to the radical.

The results of the above discussion lead to this equation:

$$B_i \propto <1/r^3>_{av}^2 \propto \rho_i^2 \propto a_i^2 \tag{13}$$

Thus,

$$\frac{(\eta/T)_1}{(\eta/T)_2} = \frac{a_2}{a_1} \tag{14}$$

In the ANQ radical, the ratio of the optimum η/T's between the protons of Positions 1 and 2 is estimated to be:

$$\left[\frac{(\eta/T)_1}{(\eta/T)_2}\right]_{ANQ} = 1.8 \tag{15}$$

The ratio of the η/T's which give the maxima in Fig. 5 is *ca.* 1.3. The coincidence between the theory and the experiment is fairly good and shows that the dominant mechanism of the relaxation of nuclear spins at Positions 1 and 2 in the ANQ anion is the END mechanism.

DMQ Anion. Figure 4 shows the η/T dependence of the ENDOR intensity for the ring ($a_1=5.24$ MHz) and the methyl protons ($a_2=6.47$ MHz) in the DMQ anion. Even though the isotropic *hf* coupling constant is larger than the ring protons, the optimum η/T of the methyl protons is larger than that of the ring protons.

According to Eq. (14), this result seems to conflict with the theoretical prediction of the optimum η/T. In the ANQ anion both protons are ring protons, and the electronic structures around them are very similar, whereas in the DMQ anion the comparison is made between the ring and methyl protons.

Generally, the *hf* anisotropy of the methyl proton is small compared to that of the ring proton, as has been shown by single crystal studies. The results for the DMQ anion can be interpreted in terms of the small END interaction of the methyl protons in spite of the large isotropic *hf* interaction.

The assumption of the END mechanism enables us to estimate the amount of the END term of the methyl protons. From Fig. 4, the ratio of the optimum η/T's for the methyl and ring protons is 1.8: 1. By a simple calculation, the $g_e\beta_e g_N\beta_N <1/r^3>_{av}$. of the methyl protons was estimated to be 2 MHz.

There is another plausible interpretation which has been proposed by Atherton and Day for the β-proton in the 2,6-di-*t*-butyl-4-cyclohexyl phenoxyl radical.[11] They proposed the fluctuation of the isotropic *hf* coupling of the β-proton as a cause of the nuclear relaxation. They made use of the difference in selection rules for the relaxation *via* the END interaction and isotropic *hf* modulation in explaining the dependence of the ENDOR intensity on the sitting ESR line of the magnetic field during the ENDOR measurement. However, there is still a quantitative uncertainty concerning the rotational correlation time of a substituent and the amount of the END interaction which has the same selection rule (S^+I^- and S^-I^+) as the isotropic *hf* modulation.

In the case of DMQ anion there was no apparent change in the relative signal intensity upon a change in the sitting point of the ESR spectra during the ENDOR measurements. No other experimental result which can be the evidence for the isotropic modulation mechanism was found in the present study.

DBQ Anion. The ring protons of the DBQ anion showed the most intense ENDOR signal at $\eta/T=3.5\times10^{-2}$ cp/K (Fig. 2). The optimum temperatures are very different for the three solvents, *i.e.*, methanol, ethanol, and 2-propanol, but the curves almost coincide with each other in the η/T plot. This shows all the relaxation processes relating to the ENDOR intensity are η/T-dependent in the present system.

The optimum η/T for the *t*-butyl protons is much smaller than that of the ring protons. This result could not be interpreted by the nuclear relaxation mechanism caused by END interaction, because the *t*-butyl protons which have the isotropic *hf* coupling of 0.19 MHz are not thought to have a larger END interaction than the ring protons, which have a 6.13 MHz isotropic *hf* coupling. In fact, in the liquid crystal phase the shift of the *t*-butyl *hf* coupling in the 2,4,6-tri-*t*-butylphenoxyl radical is negligibly small.[12]

On the basis of the difference in the magnitudes of the END interactions of two types of protons in the DBQ anion, we can predict a larger optimum η/T for the *t*-butyl protons than that of the ring protons by applying the END mechanism. The experimental results show, however, that the *t*-butyl protons have a much smaller optimum η/T than the ring protons. The same tendency was found in the experimental results of the ENDOR of the 2,4,6-tri-*t*-butylphenoxyl radical.[5]

The transition probability of electron spin[13] may

show the η/T dependence, which is characteristic of the relaxation by the g and hf anisotropy even at room temperature, because the difference in the components of the g-tensor from the free electron g-value is small enough for us to neglect the contribution of the electron spin-rotation to W_e. The normal situation of the electron-spin relaxation as discussed above suggests that the nuclear relaxation is effective in determining the optimum η/T for the t-butyl protons.

The fact that the optimum η/T for the t-butyl protons is much smaller than that of the ring protons shows the existence of a nuclear relaxation mechanism which is effective when η/T becomes small. Some of the mechanisms described below may become effective in determining the optimum conditions:

1. Nuclear Spin-rotational Relaxation: When the nuclear spin-rotational interaction is effective, W_n increases with an increase in the temperature (decreasing η/T).[14] As a result, the η/T where W_e and W_n become comparable shifts to a lower value. However, in order to get a W_n as high as W_e the spin-rotational constant should be as large as 1 MHz, which is exceptionally large.

2. Isotropic Modulation: When this mechanism is dominant for the ENDOR enhancement, the enhancement factor is expressed by W_{x2}/W_e,[2,3] where W_{x2} is the nonsecular $(+-\longleftrightarrow-+)$ transition probability. The effective correlation time for the t-butyl substituent is smaller than that of the electron spin and W_{x2} has a maximum at a slightly larger η/T value than the point where $\omega_e\tau_R\sim1$. The enhancement factor reaches its maximum at the η/T where W_{x2} is at its maximum; this η/T possibly has a smaller value than that of the optimum η/T for the ring proton. The modulation amplitude of *hfs* for the t-butyl protons may be small because the absolute value of its *hf* coupling constant is very small.

3. The Violation of the $\omega_e\tau_R\gg1$ Condition: At high temperatures $\omega_e\tau_R\gg1$ condition is not always valid. When $\omega_e\tau_R<1$, there is a temperature where $W_e\sim W_n$. The measurement of T_1 and T_2 showed, however, that even at 25 °C T_1 was longer than T_2. By the rough estimation of τ_R at the optimum η/T for the t-butyl protons, it becomes 2×10^{-9} s, much larger than $1/\omega_e$ (2×10^{-11} s).

In the present stage of this study, the lack of quantitative data prevents a detailed determination of the ENDOR mechanism of the t-butyl protons. The first and the second mechanism may, however, explain the optimum temperature to some extent. We also cannot discard such intermolecular mechanism as the intermolecular dipolar mechanism or the modulation of the intermolecular contact interaction by molecular motion.

X-Ray Photoelectron Spectroscopy of EDTA

Tooru YOSHIDA and Shigemasa SAWADA

Osaka Prefectural Industrial Research Institute, Enokojima, Nishi-ku, Osaka 550

(Received August 3, 1973)

The binding energies of N(1s) in ethylenediaminetetraacetic acid (EDTA) and its related compounds were measured by means of a photoelectron spectrometer, and the molecular structures of EDTA were discussed. Two kinds of peaks were observed in the N(1s) spectra of EDTA and its related compounds, with binding energies of about 401 and 399 eV. In EDTA-4H, the heights of the two peaks were almost equal, while in its sodium salts the peak height with the higher binding energy decreased as the number of carboxylate groups in the molecule increased. In EDTA-4Na, only a single peak with a low binding energy was observed. In EDTP-4H and GEDTA-4H, the spectra showed two peaks with different heights. The binding energy values of the main peaks of simple amino acids, such as glycine and alanine, were about 401 eV. From the above results, it can be deduced that there are two kinds of N atoms, $=N^{+}H-$ and $=N-$ types, in an EDTA molecule.

Ethylenediaminetetraacetic acid (EDTA) is widely used as a chemical reagent because of its ability to form stable and soluble chelate complexes with metal ions. Since the complex stability is partly related to the proton affinity of the acid, a clear idea of the structure of the acid could lead to a better understanding of the metal-complex formation.

EDTA is a compound belonging to the group of amino acids including glycine or alanine, and it may take a zwitterion structure even in the solid state. However, the results obtained from the IR spectra do not always give the obvious conclusion. Chapman[1] concluded that the tendency to form a zwitterion in both EDTA-4H and EDTA-2Na·$2H_2O$ is less than in simple mono-amino acid, while Nakamoto *et al.*[2] reported that EDTA-2Na·$2H_2O$ is almost zwitterionic.

The exact crystal structure of EDTA-4H was determined by Cotrait[3] by X-ray analysis. According to his conclusions, two of the four carboxyl groups are used to make intermolecular hydrogen bonds with neighboring molecules, while the remaining two are bonded to the nitrogen atoms intramolecularly.

Recently a new technique of X-ray photoelectron spectroscopy called ESCA has been developed; this method is a very useful tool for learning new aspects of the natures of chemical bonds. A detailed description of the ESCA method has been published by Siegbahn *et al.*[4]

Experimental

The X-ray photoelectron spectra were measured on an AEI ES100 spectrometer under the control of a DS100/32 computer data processing system. Al-Kα (1486.6 eV) and Mg-Kα (1253.6 eV) X-ray lines were used as the excitation sources. The abscissa of the chart is the binding energy (BE), while the ordinate is the relative intensity of each peak.

All the compounds measured are given in Table 1. They were all commercially available, were of an analytical grade, and were used without further purification. The samples were ground to powder, dusted onto a double-backed adhesive tape or pressed on a copper mesh, and set inside the measuring chamber. The measurements were then run at room temperature under a vacuum of about 10^{-6} Torr.

Results

1s Spectra of Carbon. Figure 1 shows the spectrum of the C(1s) of EDTA-4H. Two peaks with the different binding energies shown by the broken lines in the figure were obtained by a curve resolution. The

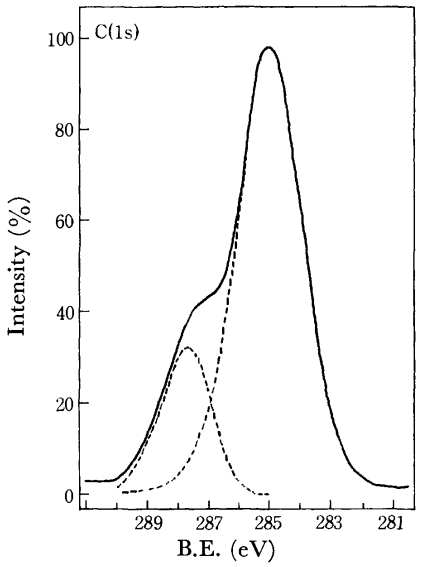

Fig. 1. C(1s) electron spectrum of EDTA-4H.

C(1s) spectra of the other compounds also give profiles similar to that of EDTA-4H. The taller peak (the right-hand one of the two) was used as the energy standard throughout the present experiments.

The differences in binding energy between the two peaks of EDTA-4H and EDTA-4Na were 2.7 and 3.1 eV respectively.

1s Spectra of Nitrogen. In Figs. 2, 3, 4, and 5, the N(1s) spectra of some EDTA derivatives and mono-amino acids are given. EDTA-4H and EDTA-2Na·2H_2O show two peaks very clearly, while EDTA-4Na shows a well-defined single peak. The other compounds show spectra with a shoulder or an asymmetric broad profile which suggests the existence of two peaks.

Table 1. N(1s) binding energy valufs

Compounds		N(1s) B.E. (eV)	
Ethylenediaminetetraacetic acid (EDTA-4H)	$HOOCH_2C\diagdown\ \ \diagup CH_2COOH$ $N(CH_2)_2N$ $HOOCH_2C\diagup\ \ \diagdown CH_2COOH$	401.3 (1)	399.1 (1)
Disodium ethylenediaminetetraacetate (EDTA-2Na)		401.4 (2)	399.3 (5)
Trisodium ethylenediaminetetraacetate (EDTA-3Na)		401.4 (1)	399.3 (3)
Tetrasodium ethylenediaminetetraacetate (EDTA-4Na)			399.2
Ethylenediaminetetrapropionic acid (EDTP-4H)	$HOOC(H_2C)_2\diagdown\ \ \diagup (CH_2)_2COOH$ $N(CH_2)_2N$ $HOOC(H_2C)_2\diagup\ \ \diagdown (CH_2)_2COOH$	401.4 (3)	399.3 (1)
Glycoletherdiaminetetraacetic acid (GEDTA-4H)	$HOOCH_2C\diagdown\ \ \diagup CH_2COOH$ $N(CH_2)_2O(CH_2)_2O(CH_2)_2N$ $HOOCH_2C\diagup\ \ \diagdown CH_2COOH$	401.3 (2)	399.1 (1)
Disodium ethylenediaminetetraacetate dihydrate (EDTA-2Na·2H_2O)		401.4 (2)	399.3 (3)
Tetrasodium ethylenediaminetetraacetate dihydrate (EDTA-4Na·2H_2O)			399.2
Zinc disodium ethylenediaminetetraacetate (EDTA-Zn)			399.5
Aminoacetic acid (AA)	H_2NCH_2COOH	400.8 (5)	398.9 (1)
Iminodiacetic acid (IDA)	$HN\langle^{CH_2COOH}_{CH_2COOH}$	400.9 (3)	399.1 (1)
Nitrilotriacetic acid (NTA)	$N-CH_2COOH$	400.9 (2)	398.9 (1)
β-Aminopropionic acid (β-AP)	$H_2N(CH_2)_2COOH$	400.9 (4)	399.1 (1)
γ-Aminobutyric acid (γ-AB)	$H_2N(CH_2)_3COOH$	401.0 (3)	399.0 (1)

The numbers in parentheses are the relative intensities roughly determined from the two peaks.

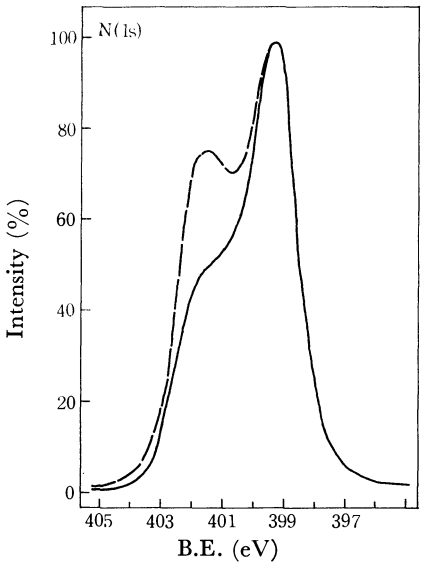

Fig. 5. N(1s) electron spectra.
——: EDTA-2Na, ——: EDTA-2Na·$2H_2O$

The measured values for the N(1s) binding energy are listed in Table 1. The numbers in parentheses indicate the relative intensities roughly determined from the two peaks.

Discussion

C(1s) Signal. There are two kinds of carbons, $-CH_2-$ and $-CO-$, in EDTA distinguishable by the ESCA method. As the O atom has a higher electronegativity than the H atom, the electron density on the C atom in $-CO-$ is lower than that in $-CH_2-$. Accordingly, the C(1s) signal of $-CO-$ must have a higher binding energy than that of the $-CH_2-$. The fact that the binding-energy difference between these two kinds of carbons in EDTA-4H is about 0.4 eV lower than that in EDTA-4Na may be explained as follows; the electron density on the C atom in $-CO-$ in the former is higher than that in the latter because of the presence of an intermolecular hydrogen bond in the former, so the binding energy of the C atom in $-CO-$ in the former is lower than that in the latter.

As many precise discussions[5] based on some theoretical calculations have been reported with regard to this difference in binding energy, which is called a chemical shift, no further discussion will be given here. The binding energy value of C(1s) of $-CH_2-$ is taken to be 285.0 eV.

N(1s) Signals. Figure 2 shows the existence of two different states of the nitrogen atom in EDTA. From the binding energy values of the major peaks of N(1s) observed in simple amino acids, such as AA, IDA, NTA, β-AP, and γ-AB, it may be concluded that the higher binding energy peak of the two in EDTA can be assigned to the N atom with the $-\overset{+}{N}H-$ structure. The value of this binding energy is about 401 eV. Hence, the remaining peak, with a lower binding energy, can be assigned to the ordinary N atom, which has the $=N-$ structure. The binding energy value of the remaining peak is about 399 eV, almost coincident with that of the single peak of EDTA-4Na, in which the zwitterion structure can not exist.

According to the analysis of the X-ray diffraction patterns, EDTA-4H belongs to the $C_{2/c}$ space group and has a symmetry center at the middle point of $=NCH_2CH_2N=$. Two of the four carboxylic H atoms have a shorter distance to the N atom than the other two, suggesting protonation or hydrogen bonding. On the contrary, the ESCA spectrum shows that, in a crystalline state, the two N atoms in an EDTA-4H molecule are not equivalent in electronic charge.

As for the series of the Na salts of EDTA, the spectra also show the existence of two kinds of nitrogen and a trend for the peak height of the protonated $=\overset{+}{N}H-$ group to decrease as the number of the carboxylate group in the molecule increases. The decrease in the number of carboxyl groups in a molecule will reduce the possibility of protonation to the N atom.

As is shown in Fig. 5, crystal water in EDTA-2Na seems to have a particular effect on the ESCA spectrum of N(1s), but it does not in EDTA-4Na. Assuming that the hydrated Na salt conforms the same spatial molecular arrangement as that[6] of the hydrated K or Rb salt, it may be considered that H atoms from crystal water are preferably used to make an intermolecular hydrogen bond, while the two H atoms of the carboxyl group serve to make an intramolecular hydrogen bond with their own nitrogen atom. Therefore, in EDTA-2Na·$2H_2O$ the opportunity to make a charged amino group will increase.

EDTP-4H and GEDTA-4H have chemical structures similar to that of EDTA-4H, but give different ESCA spectra; that is, the $=\overset{+}{N}H-$ peak is dominant over the $=N-$ peak. This may be explained as follows: in EDTP-4H, the distance between the two N atoms is the same as in EDTA-4H, but the side-chain is longer. Therefore, ring formation is easier than in EDTA-4H. In GEDTA-4H, the side-chain is the same as in EDTA-4H, but the N-to-N distance is longer, so the repulsion of the developed positive charge on each nitrogen atom is less than in EDTA-4H.

On the basis of the results obtained here, it may be considered that there are at least two factors affecting the appearance of two peaks on the ESCA spectrum of EDTA-4H. One is steric hindrance, which makes it hard to build up a five-membered ring, and the other is charge repulsion, which prevents too much density of the positive charge at the center of a molecule.

The N(1s) spectrum of the EDTA-Zn chelate showed a single peak with a binding energy falling between those of the protonated and the unprotonated N(1s) of EDTA-4H. Detailed discussions of this and other EDTA-metal chelates will be published elesewhere.

All of the N(1s) spectra in the simple amino acids examined are more or less doublets. Although no clear explanation of this can be given here, it may be conceived that the steric environment around the N atom in AA, IDA, and NTA will reduce the chance for the H atom to attach to the N atom.

The authors wish to thank Drs. Kyoozo Nakajima and Masao Wakae for their helpful comments and

discussions. In addition, they wish to thank Dr. Takanobu Hamaguchi for his aid in performing this experiment.

An Investigation of the Gas-Solid Interface Reaction on the Surface of Ag and Ag_2S

Masayuki KATSUMOTO, Kazuo FUEKI, and Takashi MUKAIBO

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received July 9, 1973)

In order to elucidate the mechanism of the redox reaction at the gas-solid interface, the isotopic exchange between H_2S and D_2 on Ag and Ag_2S has been studied in the temperature range from 410 to 521 °C. The transfer of isotopic species between "hydrogen sulfide" [1] and "hydrogen" [1] was found to proceed by means of the reaction:

$$\text{"}H_2S\text{"}^{1)} \underset{k_1'}{\overset{k_1}{\rightleftharpoons}} \text{"}H_2\text{"}^{1)} + S(ad)$$

on both surfaces. From the analysis of the kinetic data, the redox reaction rate constants, k_1 and k_1', were determined as a function of the sulfur activity. It was found that k_1 is inversely proportional to the sulfur activity, whereas k_1' is independent of it. The mechanism of the reaction on the surfaces of Ag and Ag_2S is discussed.

In previous works, the authors and their co-workers have kinetically studied the H_2S–D_2 exchange reaction on Cu_2S(p-type semiconductor),[2] β-$Fe_{1-x}S$(metallic conductor),[3] MoS_2(intrinsic semiconductor), and MnS-(p-type semiconductor)[4] in order to elucidate the mechanism of the redox reaction at the gas-solid interface. It was found that the activation energies and the dependence of the rate constants of the surface reaction on the sulfur activity are nearly the same for all these sulfides. Except in the case of Cu_2S, these results can not be explained by the theory proposed by Kobayashi and Wagner.[5] The mechanism proposed by the authors is that the rate-determining reaction is that between adsorbed sulfur atoms and gaseous molecules.[4]

The present work aims to study the redox reaction on Ag and Ag_2S(n-type semiconductor). Since the adsorption of sulfur atoms on Ag in "H_2S"–"H_2" gas mixtures, obeying a Langmuir-type adsorption isotherm, has already been reported,[6] one can confirm the validity of the theory proposed by the authors.

As the sulfur activity in the presence of both Ag and Ag_2S is 1/3.3~1/3.7 in the temperature range from 400 to 520 °C,[7] one can examine the H_2S–D_2 exchange reaction on Ag if the sulfur activity is smaller than 1/3.3~1/3.7. The sulfur activity, a_s, is defined as the pressure ratio of "hydrogen sulfide" to "hydrogen".

Experimental

Isotopic Exchange Study. The apparatus, the method of the purification of gases, and the experimental procedure were essentially the same as in previous works.[2-4] The samples were prepared as follows.

a) Ag sample: Silver powder of 99.9% purity was treated in "hydrogen" at 570 °C for 1 hour. The surface area of the powder was 2.86×10^3 cm^2 g^{-1}.

b) Ag_2S sample: Silver powder, treated as above, was sulfurized with a "H_2S"–"H_2" gas mixture at 570 °C until the sulfurization was completed. The surface area of the sulfide was 4.76×10^3 cm^2 g^{-1}.

Prior to the isotopic exchange run, the sample was equilibrated with the "H_2S"–"H_2" gas mixture, the sulfur activity of which was the same as that of the H_2S–D_2 gas mixture to be used. Therefore, the sulfur activity, a_s, was kept constant throughout the isotopic exchange run, irrespective of the change in the concentration of the isotopic species.

Results and Discussion

Isotopic Exchange Reaction. Figures 1 and 2 show the change in x_{H_2}, x_{HD}, and x_{D_2}, the mole fractions of

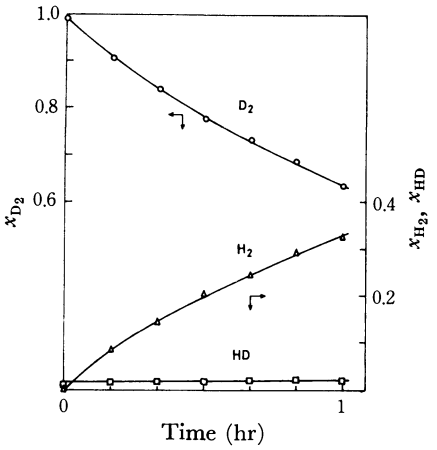

Fig. 1. Change in x_{H_2}, x_{HD}, and x_{D_2} with time. (Ag_2S, 446 °C, $P^\circ_{H_2S}$=278 mmHg, $P^\circ_{D_2}$=27.8 mmHg, a_s=10)

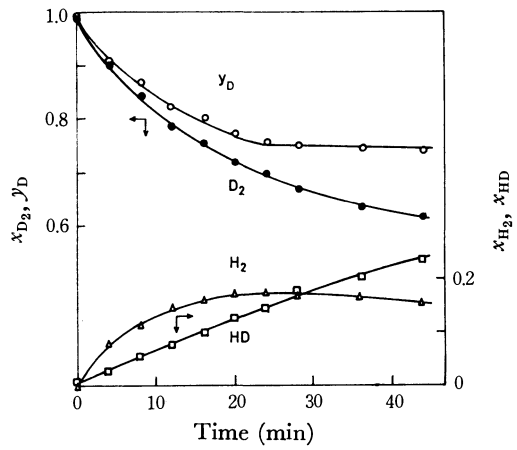

Fig. 2. Change in x_{H_2}, x_{HD}, and y_D with time. (Ag_2S, 480 °C, $P^\circ_{H_2S}$=27.3 mmHg, $P^\circ_{D_2}$=81.7 mmHg, a_s=1/3)

H_2, HD, and D_2 respectively, at different sulfur activities in the presence of Ag_2S. The higher range of a_S, x_{HD} remains unchanged, whereas x_{H_2} increases and x_{D_2} decreases. Thus, it may be concluded that the isotopic exchange occurs as follows:

$$H_2S + D_2 = D_2S + H_2 \quad (1)$$

This means that "H_2S" is directly converted to "H_2" by means of the reaction:

$$\text{"}H_2S\text{"} = \text{"}H_2\text{"} + S(ad) \quad (2)$$

where S(ad) represents the sulfur atom adsorbed on the surface. Reaction (2) is characterized as a redox reaction.

At $a_S=1/3$, the HD formation becomes remarkable. However, the fraction of D in "hydrogen", $y_D(=x_{D_2}+1/2x_{HD})$, reaches its isotopic equilibrium value, 0.75, at the time corresponding to the maximum of x_{H_2} (Fig. 2) and then remains constant. This fact suggests that the HD formation takes place mainly by virtue of these steps:

$$H_2S = H_2 + S(ad) \quad (2')$$

$$H_2 + D_2 = 2HD \quad (3)$$

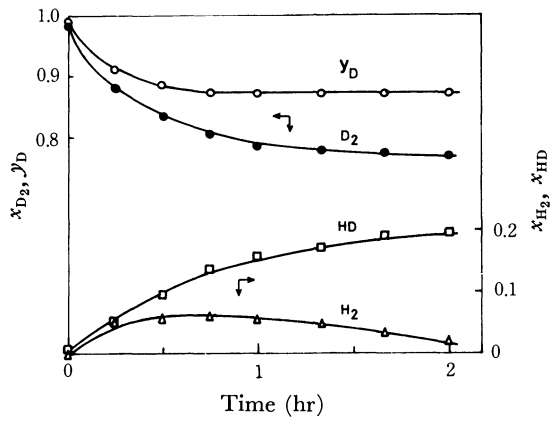

Fig. 3. Change in x_{H_2}, x_{HD}, x_{D_2}, and y_D with time. (Ag, 480 °C, $P^\circ_{H_2S}=14.8$ mmHg, $P^\circ_{D_2}=114.3$ mmHg, $a_S=1/7.7$)

Figure 3 shows the change in x_{H_2}, x_{HD}, x_{D_2}, and y_D at $a_S=1/7.7$ in the presence of Ag. The time variation of these quantities is essentially the same as in the case of Ag_2S. That is, y_D reaches its isotopic equilibrium value, 0.885, at the time corresponding to the maximum of x_{H_2}, and then it remains unchanged. Therefore, it may be concluded that the exchange reaction in the presence of Ag also proceeds *via* the (2')—(3) steps.

One can determine k_i and k_i', the rate constants of the sulfurization and reduction of Reaction (2) respectively, by the method proposed in the previous paper.[3] Figure 4 give the plots of $\log k_i$ and $\log k_i'$ against $\log a_S$. The plots are linear. The slopes are summarized in Table 1.

Therefore, the rate equation of Reaction (2) on the surfaces of Ag and Ag_2S is expressed in the form:

$$v = kP_{\text{"}H_2S\text{"}}a_S^{-1} - k'P_{\text{"}H_2\text{"}} \quad (4)$$

The Arrhenius plots of k_i at $a_S=1/5$ for Ag and that at $a_S=1$ for Ag_2S are given in Fig. 5. The activation

Appendix: High Temperature Entropy Calculation

John F. NAGLE
Department of Physics, Carnegie-Mellon University, Pittsburgh, Penn. 15213 USA

(Received September 27, 1973)

The heat capacity of $SnCl_2 \cdot 2H_2O$ and $SnCl_2 \cdot 2D_2O$ crystals, substances with layer structure, was measured from 13 to 300 K. Anomalies due to ordering of the hydrogen (deuterium) position were observed at $T_c(H_2O) = 217.94$ K and at $T_c(D_2O) = 234.47 \pm 0.05$ K. The total entropy change of the transition was estimated to be 4.6 J K^{-1} mol^{-1} for both compounds. An exact calculation of the high temperature entropy based on the two-dimensional lattice model gave 3.13 J K^{-1} mol^{-1}. The critical indices $\alpha_\pm$ of the divergent heat capacity anomalies are as follows: $\alpha_+(H_2O) = 0.53$, $\alpha_-(H_2O) = 0.48$, $\alpha_+(D_2O) = 0.57$, $\alpha_-(D_2O) = 0.54$. Another heat capacity anomaly was found at 140—160 K where the heat capacity values depended on the thermal history of the specimen. The enthalpy relaxation observed at the temperature region was analysed by use of the first-order rate equation, giving the activation enthalpies $\Delta H_a(H_2O) = 49.9$ kJ mol^{-1} and $\Delta H_a(D_2O) = 49.8$ kJ mol^{-1}. The concept of long-range-ordered glassy state was introduced for description of the non-equilibrium state of the present substances below 140 K. A general consideration of the relation between molecular relaxation and phase change in terms of the Deborah number is presented.

Stannous chloride dihydrate has a layer structure in which double layers of the stannous chloride molecules are sandwiched between the hydrogen-bonded networks of the water molecules.[1,2] A phase transition was found in this substance and its deuterate analogue by use of dielectric, nuclear magnetic resonance and electric conductivity measurements,[3] and was attributed to the order-disorder change of the hydrogen positions in the network. Since thermodynamic properties are of special interest in connection with the two-dimensional nature of the crystal structure, we measured the heat capacity of the hydrate and deuterate from 13 to 300 K. Both compounds exhibited sharp heat capacity peak at the transition point. In addition, an unexpected thermal relaxation phenomenon was observed at a lower temperature and could be interpreted quantitatively as caused by a slow ordering process of the hydrogen position. The phenomenon is interesting in connection with the recently proposed concept of the glassy crystalline state.[4]

Experimental

Sample Preparation. Commercially available stannous chloride dihydrate of the highest purity was molten in an air-tight flask (melting point: 40 °C), and cooled slowly in a temperature-controlled water bath. When about half of the material was crystallized, the remaining melt was discarded. The crystal was kept in a closed vessel before use. The water content of the crystal was determined from the weight loss accompanying the dehydration to the anhydrous salt. It was found to be 15.97% in an excellent agreement with the stoichiometric value, 15.96%. Spectrometric analysis of the specimen taken from the calorimeter cell after completion of the measurement showed that impurity ions in the crystal were copper, iron, nickel and calcium, each less than 10 ppm.

Before the above method of fractional melting was found to be successful, recrystallization from the saturated aqueous solution was attempted. The water content of the crystal obtained by this method was consistently higher than the ideal value by 0.2 to 0.3%. Heat capacity of the crystal containing the excess water was also measured from 13 to 300 K, though the main body of the experimental data refers to the crystal obtained by the improved method. Qualitative behaviors of the differently prepared crystals were similar to each other as will be described below.

The deuterate was prepared from the purified hydrate by the similar method as follows. The hydrate was first dehydrated to the stoichiometric anhydrous salt, to which an appropriate quantity of 99.75% heavy water and a small amount of deuterochloric acid were added. The mixture was heated to 45 °C, and when a clear solution was obtained, it was cooled slowly. The crystallization began at about 41 °C. The procedure taken thereafter was similar to that for the hydrate.

Calorimetric Apparatus. The calorimetric system used was the same one described elsewhere,[5] with minor modifications. The hand-set type of the potentiometer formerly used for the electric energy measurement was replaced with a digital voltmeter (Hewlett Packard model 3462 A) and the clock, with a digital time interval counter (Takeda Riken Model TR-5766 U/6). The cryostat, temperature measureing apparatus and the adiabatic control circuit remained unaltered. The overall accuracy of the measurement is believed to be about 1% at 20 K and better than 0.3% above 50 K.

Sample Handling. In order to avoid efflorescence and deliquescence of the specimen, the crystal was handled in a glove box in which the humidity was adjusted to the dissociation pressure of the crystal by placing in the box a quantity of the partially dehydrated crystal. Similar precaution was taken for the deuterate by using the crude deuterate material. The sample crystals were crushed to 2—3 mm in the linear dimension and loaded in the calorimeter cell. The loaded cell, with the gas-filling tube open, was cooled to liquid nitrogen temperature in a glass vessel. The glass vessel was evacuated,

* A brief account of the present paper was published in *Proc. Japan Acad.*, **48**, 237 (1972).

flushed twice, and filled with one atm of helium gas. After being allowed to warm up to the room temperature, the cell was taken out of the glass vessel and the filling tube was sealed promptly with low melting solder. The sample weight was 97.507 g and 92.949 g for the hydrate and the deuterate, respectively.

Calorimetric Procedure. As was stated above the heat capacity was measured first on a sample containing excess water. The calorimeter was first cooled to the liquid nitrogen temperature, at which the first series of measurement was commenced. At temperature around 150 K, a marked upward temperature drift was observed. At about 162 K, it changed to downward drift, indicating a slow equilibration in the calorimeter. An appreciable cooling was observed for more than 45 min after turning off the calorimeter heater, compared to the typical equilibration time of 6—7 min. The heat capacity curve exhibited a step-like anomaly at this temperature. The heat capacity value could not be defined precisely in this temperature region, because it depended on the annealing condition of the sample and on the time spent in the measurement. Another anomaly was found at around 218 K which corresponds to the phase transition temperature reported by Kiriyama.[3] The equilibration time did not change appreciably around the transition point. At still higher temperature a broad hump was found, which could be attributed to the eutectic melting due to the presence of the excess water. The cell was dismantled from the cryostat and the excess water was carefully removed. Subsequent measurement showed the broad hump was absent, though the first two anomalies remained unaffected. Since the relaxational anomaly mentioned above was quite unexpected, it was suspected that it might be caused by impurity in the sample crystal. The extremely pure crystal was prepared as was mentioned above. The measurement on the improved specimen yielded the same result in regard to the relaxational and the lambda anomalies. Therefore it was concluded that the first two anomalies are intrinsic properties of the crystal. Since different cooling history of the sample was found to cause change in the behavior of the crystal, a detailed measurement was attempted which enabled a quantitative analysis of the hysteretic phenomenon under controlled condition. The procedure was as follows. The calorimeter was cooled through the anomalous region as rapidly as possible to 133 K, at which temperature a series of measurement was started in the usual intermittent heating mode with the temperature step of 1—1.5 K. At 138.1 K a significant heat evolution began. The temperature rose linearly with time, indicating that the relaxational effect involved is a slow process. After following the temperature drift for 30 min, the temperature was raised by about 1 K by introducing the electric energy in the calorimeter and again the temperature rise was followed for 30 min. The same procedure was repeated to above 160 K. The rate of the spontaneous temperature rise reached its maximum at 149.5 K, above which it decreased rapidly, reaching null approximately at 154 K. Above 154 K, the temperature drift after turning-off of the heater current was endothermic and non-linear in time. The linear exothermic drift rate at the lower temperatures is plotted in Fig. 1 as a function of the temperature. A similar behavior was observed in the deuterate crystal. As is

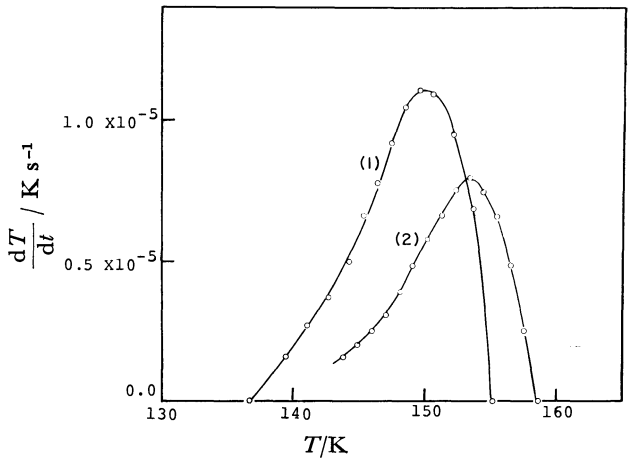

Fig. 1. Rate of spontaneous temperature rise of the calorimeter loaded with (1) $SnCl_2 \cdot 2H_2O$ and (2) $SnCl_2 \cdot 2D_2O$.

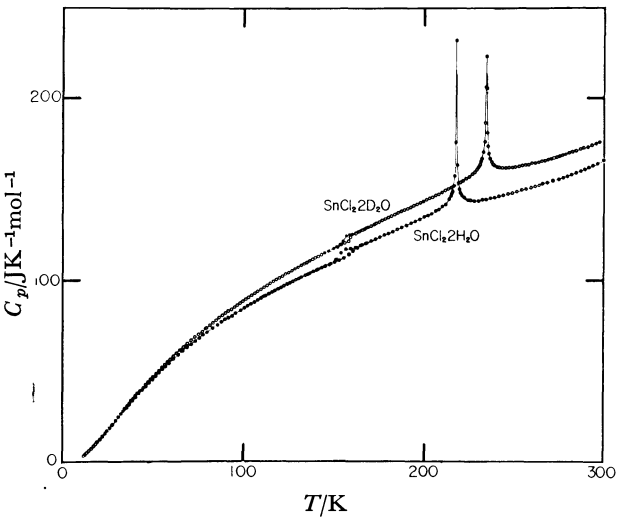

Fig. 2. Heat capacity of $SnCl_2 \cdot 2H_2O$ and $SnCl_2 \cdot 2D_2O$ crystals.

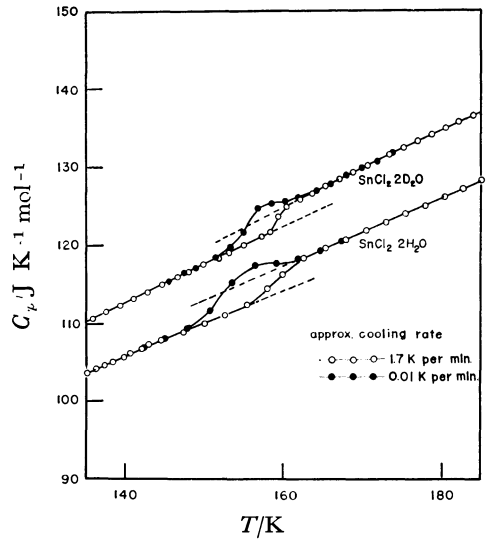

Fig. 3. Heat capacity of $SnCl_2 \cdot 2H_2O$ and $SnCl_2 \cdot 2D_2O$ around their "glass transition" temperatures. Because of spontaneous heat evolution and other non-equilibrium phenomenon, some arbitrariness is necessarily introduced to the observed values. The effect of different sample prehistory is indicated by the open and closed circles in the plot. Measurement after rapid cooling (1.7 K per min) gave the smaller values (open circles), and after slow cooling (0.01 K per min), the larger value (closed circles) in the temperature region 150—163 K.

shown in the figure the anomaly occurred in the deuterate at somewhat higher temperature. An analysis of the observed effect will be given in the later section.

After measuring the heat capacity for the entire temperature region, the transition region was investigated in more detail. The temperature increment for one step of measurement was 0.007—0.23 K, compared to 1—3 K for the normal region. The observed heat capacity was 10 times as large as the normal heat capacity at the peak, but no latent heat was observed.

Experimental Results. The heat capacity curves for the entire temperature region are shown in Fig. 2. The numerical values are given in Tables I and II. The lambda peaks at 218 K and 235 K are nearly symmetrical in shape with respect to the respective peak temperature. In Fig. 3, the anomalies around 150 K are represented in an expanded scale. The open circles correspond to the quenched sample and the filled circles to the annealed. Similar curves for the deuterate are also shown in the figure. As was stated earlier, the *endo-* and *exo-*thermic effects made it difficult to determine unambiguously the heat capacity around the temperature. The values plotted in the figure are those calculated by employing the temperatures extrapolated to the mid-point of the heat-on period in case of the linear exothermic drifts. In the endothermic case, the temperatures observed at 30 minutes after the heat input interval were taken as the final temperatures. This convention of the data reduction is arbitrarily adopted.

General feature of the heat capacity curve and the enthalpy relaxation observed around this temperature are quite similar to those reported in a number of glass forming substances including the glassy crystals.[4] However, the heat capacity jump (2—3 J K^{-1}mol^{-1}) is considerably smaller than is usual in a glassy crystal (30—50 J K^{-1}mol^{-1}). Absence of any effects attributable to crystallization is also in clear contrast to the typical behavior of the glassy state formed by low molecular-weight substances. As will be discussed later in more detail, the newly found non-equilibrium state may be regarded as a new type of glassy states in which incompletely long-range-ordered proton (or deuteron) configuration is frozen in the immobile state.

Discussion

The Relaxational Anomaly. In order to derive physically informative parameters from the heat evolution rate observed around 150 K, the heat evolution rate given in Fig. 1 was integrated numerically with time, to give the enthalpy-temperature relation shown in Fig. 4, where the configurational enthalpy was separated from the rest by taking the low temperature

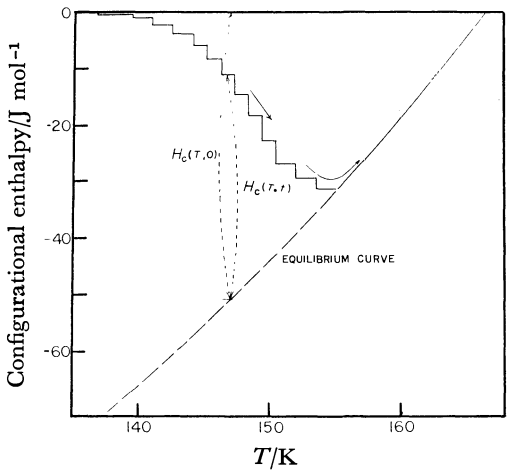

Fig. 4. Temperature-configurational enthalpy relation of $SnCl_2 \cdot 2H_2O$ crystal around its "glass transition" temperature. The arrows indicate the path followed by the crystal in this particular measurement. $H_c(T_0,)$ and $H_c(T,t)$ is the variables in the rate equation given in the text. The equilibrium curve below 155 K is calculated from the extrapolated configurational heat capacity.

heat capacity as the back-ground contribution. The reference temperature was chosen arbitrarily as T_0= 166.50 K for the hydrate. The equilibrium curve was calculated by integrating numerically the difference between the extrapolated high temperature heat capacity and the low temperature one. The zig-zag chain in Fig. 4 is the path whicn the configurational enthalpy followed as the crystal was warmed after rapid cooling. A similar zig-zag curve was obtained for the deuterate. Decrease of the enthalpy with increasing temperature indicates, of course, that the process is not a thermodynamically equilibrium one. Moreover, the enthalpy-temperature relation shown by the curve is not a unique representation of the property of the crystal, but depends on the thermal history of the crystal, particularily on the cooling rate and the time spent on the measurement. The nearly horizontal segments in the curve correspond to the heat-on period, while the nearly vertical segments to the drift period. From the observed drift rates, the relaxation time was evaluated as follows. If an exponential law is assumed for the approach to the equilibrium configuration, the rate law can be written as follows:

$$\frac{dH(T,t)}{dt} = -\frac{H(T,t)}{\tau} \quad (1)$$

where $H(T,t)$ is the configurational enthalpy referred to the equilibrium value at temperature T and time t and τ the relaxation time. The left-hand side of Eq. (1) is related to the temperature drift rate dT/dt by the equation:

$$\frac{dH(T,t)}{dt} = -C\frac{dT}{dt}, \quad (2)$$

where C is the heat capacity of the cell containing the sample crystal. Combining the Eqs. (1) and (2), one obtains:

$$\tau = \frac{H(T,t)}{C\frac{dT}{dt}} \quad (3)$$

By taking $H(T,t)$ from Fig. 4 and C and dT/dt from the experimental values, the relaxation time could be evaluated as a function of temperature. The heat capacity C is not defined around this temperature but the fraction of the ambiguous portion is small compared with the total heat capactiy. The calculated τ is affected little by the ambiguity in the estimation of the heat capacity value. The relaxation time thus evaluated is shown in Fig. 5 as an Arrhenius plot. It is remarkable that the drift rate *vs.* temperature curves in Fig. 1 could be reduced to the straight lines in Fig. 5. The lines were least-square-fitted to a linear equation from which the activation energies were estimated to be 49.88±0.33 and 49.78±0.23 kJ mol^{-1} for the hydrate and the deuterate, respectively. The frequency factors evaluated are $(1.92\pm0.6)\times10^{13}$ and $(0.5\pm0.2)\times10^{13}$ Hz. The derived activation energies are significantly smaller than that obtained by Kiriyama from the temperature dependence of the DC conductivity (17 kcal mol$^{-1}\cong$71 kJ mol^{-1}). This may simply mean that the mechanisms involved in the two dissipative processes are different from each other. The DC conduction is caused by transportation of the ionic species in the crystal. On the other hand, the enthalpy relaxation can proceed without involving ionic species, so that the two activation energies should not necessarily be equal to each other. The activation energy, 49.8 kJ mol^{-1}, is twice as large as the typical hydrogen bond energy of O–H···O system. Molecular interpretation of this value seems to be complicated as is explained in the following.

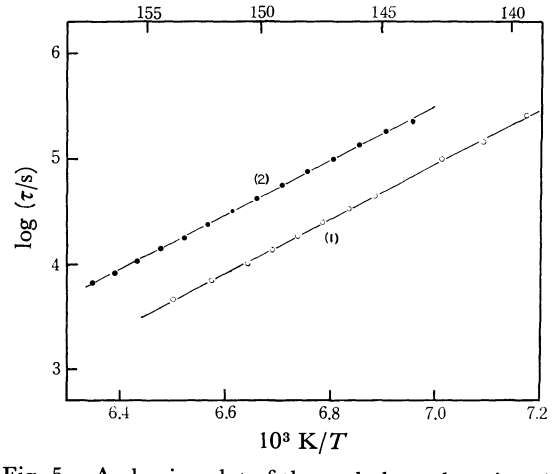

Fig. 5. Arrhenius plot of the enthalpy relaxation time τ of (1) $SnCl_2\cdot2H_2O$ and (2) $SnCl_2\cdot2D_2O$.

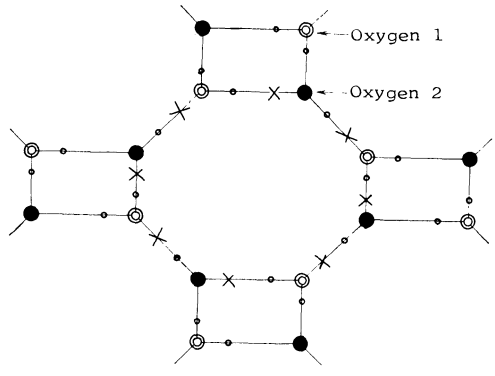

Fig. 6. Schematic diagram of the hydrogen bond network of $SnCl_2\cdot2H_2O$ and $SnCl_2\cdot2D_2O$. Oxygens 1 indicated by the double circles have two mobile hydrogen (or deuterium) atoms, while Oxygens 2 indicated by the closed circles have one mobile hydrogen and one immobile hydrogen. The latter not shown in the figure is hydrogen bonded to the chlorine atom. The small circles indicate the perfectly ordered hydrogen positions. The set of the eight crosses is the smallest unit by which the network deviates from the perfect order if the ice condition is imposed.

The hydrogen position determined by neutron diffraction[2] is described schematically in Fig. 6. This corresponds to the perfectly ordered situation, which could never be attained in the usual experimental time scale. But as is revealed in the configurational entropy diagram (Fig. 7) constructed by integrating the extrapolated anomalous heat capacity curve, the residual disorder retained in the real crystal is so small that the hydrogen position given by the diffrac-

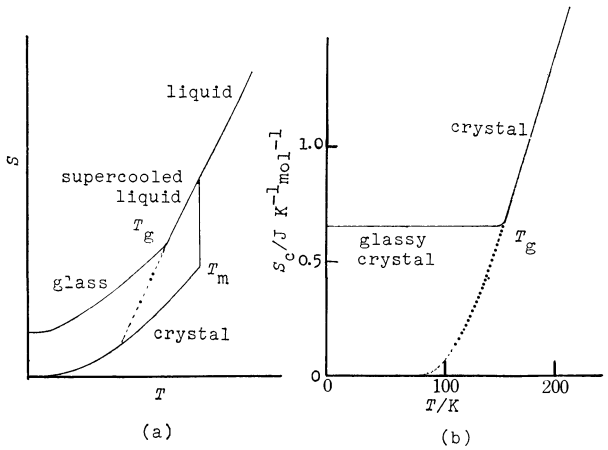

Fig. 7. Entropy of the glass-forming systems.
(a) Entropy of a typical substance forming a crystal, liquid and glass.
(b) Configurational entropy of $SnCl_2 \cdot 2H_2O$ crysatl retaining a small residual entropy (~ 0.65 J K^{-1} mol^{-1}). The broken portion of the curve is calculated from the extrapolated configurational heat capacity.

tion method and the weight assigned to each position are essentially those of the perfectly ordered crystal. Now, careful examination of this figure shows that if the ice condition is to be satisfied the smallest unit that can deviate from the perfect order is the eight-membered ring. The crosses in the figure indicate the position which the hydrogen atoms occupy in the locally disordered state. If this disordered state tries to approach the perfect order, the eight hydrogen atoms had to move in unison, so that the activation energy would be eight times as large as is needed to break one hydrogen bond, or 25 kJ mol$^{-1} \times 8 = 200$ kJ mol^{-1}. This is about four times as large as the experimental value. This seems to mean that some defect mechanism has to be invoked. Possibly, Bjerrum defects (D and L) take part in the reorientation process causing change of the order parameter.

It should be added here that the residual entropy indicated in Fig. 7 is an apparent one, since it is not based on equilibrium measurements but was simply calculated from the extrapolated heat capacity data. But it is believed to be close to the correct value because the structural data indicate that the crystal retains no other disorder than that of the hydrogen position.

In closing the discussion of the relaxational anomaly, relation of the present observation to the widely observed glass transitions is discussed. In addition to the widely-known polymeric glass-forming materials, a number of substances composed of relatively simple molecules were found to form glassy states.[4] The glassy states are classified into the glassy liquids, glassy crystals and glassy liquid crystals according to the type of disorder that is brought into the non-equilibrium state. In the first both the molecular position and molecular orientation are at random and do not possess long range periodicity. In the second the position is regular but the random orientation of the molecules is frozen in, and in the third, the positional disorder is retained, while the molecular orientation is in the ordered state. In stannous chloride dihydrate, the heavy atom positions are ordered and the hydrogen positions are nearly ordered, as is suggested by the entropy diagram (Fig. 7). It is, therefore, appropriate to classify it into a new type of glassy crystal in which the frozen-in degree of freedom has a long range order. Although there have not been examples of this kind reported so far, there seems to be nothing unnatural in the concept of the long-range-ordered glassy state. An important qualitative consequence is that a substance in this non-equilibrium state will not be induced to crystallize; only the long range order develops further without any discontinuous change of the crystal symmetry or other properties of the substance. This is one of the reasons why the relaxational effect could be investigated in detail to enable evaluation of the activation energy precisely.

Origin of the variety of the glassy states mentioned above can be traced back to the relation of the transition temperature and the temperature dependence of the molecular relaxation time. Here, the transition temperature means the temperature at which a long range order begins to develop in the (high-temperature) disordered degree of freedom of the substance. Temperature dependence of the order parameter is different from substance to substance. It may develop abruptly as in the first-order transitions (*e.g.* crystallization or transitions from plastic to non-plastic crystals). More gradual changes are typically observed in lambda anomalies in a number of order-disorder transitions. The molecular relaxation time, on the other hand, depends primarily on the barrier height which the molecules have to overcome if they are to reorient or to be redistributed in the substance. It increases generally rapidly with decreasing temperature, sometimes accompanied by a discontinuous change at transition temperatures. The ratio of the relaxation time to the experimental observation time is called the Deborah number[6] by Rheologists. By using the concept of Deborah number, the glassy state can conveniently be classified, together with other equilibrium and non-equilibrium states.

If the Deborah number of a substance is already large at high enough temperatures as compared to the hypothetical transition temperature, no relaxational effects will be observed thermally. This may be the case of CO, NO, or N_2O crystals. These crystals have residual entropies at 0 K[7] and are not known to exhibit thermal relaxation. In ice and heavy ice, for which the residual entropy has been discussed long, a small relaxational anomaly was recently discovered calorimetrically.[8,9] The temperatures at which the anomaly occurs are 95 and 105 K for the ordinary ice and heavy ice, respectively. It was proposed that the Deborah number happens to approach unity at the temperatures where the short range order of the proton configuration in the ice crystals begins to develop.

Next, if the Deborah number becomes unity at the temperature where the long range order is present but not complete, the relaxational effect will again be observed. This is what happens in the present case

of stannous chloride dihydrate. Finally if the ordering is already completed before the Deborah number approaches unity, no relaxational phenomena will be observed. This is the case for a number of substances for which the third law of thermodynamics is verified experimentally.

The variety of experimental observations could thus be classified according to the relative magnitude of the (in some cases, hypothetical) transition temperature and the temperature at which calorimetric Deborah number becomes unity.

The Phase Transition. The gradual anomaly at 218 K is due to the order-disorder transition of the hydrogen position. A similar anomaly occurs at 235 K in the deuterate. Structurally these are antiferroelectric to paraelectric transitions, as was shown by Kiriyama by use of magnetic resonance, X ray and neutron diffraction methods.[2] Although the heat capacity peak at 218 K is relatively narrow the outskirt region is extended over a wide temperature range. In fact, according to the interpretation of the relaxational anomaly discussed in the last section, the anomalous contribution is appreciable even at 150 K. The total entropy change is, therefore, difficult to estimate with certainty. In order to minimize arbitrariness, heat capacity of barium chloride dihydrate[10] was compared with the present heat capacity curve. This crystal has a similar layer structure and, moreover, its molecular weight is very close to that of stannous chloride dihydrate. Since barium chloride dihydrate does not show heat capacity anomaly below room temperature, it was expected to serve as a reference material. The heat capacity is a smooth function of temperature, and slightly smaller than that of stannous chloride dihydrate at 260 K. The normal heat capacity of stannous chloride dihydrate was assumed by joining the $BaCl_2 \cdot 2H_2O$ value at 260 K and the $SnCl_2 \cdot 2H_2O$ value at 150 K with a smooth curve. The anomalous part above 260 K was assumed to follow the T^{-2} law, as is expected for any interacting systems by a high temperature expansion. The low temperature contribution which could not be measured because of the long relaxation time was calculated from the extrapolated heat capacity curve. The total entropy change thus estimated is 4.6 J K^{-1} mol^{-1}, for the both crystals. Rigorous theoretical value given in the appendix is 3.13 J K^{-1} mol^{-1}. It is probable that the high temperature contribution to the estimated experimental value might be too large and also that other degrees of freedom than the hydrogen configuration would be contributing significantly to the observed transition entropy. Since the base line determination introduces a large uncertaintyin to the experimental value, detailed discussion of these values would be difficult at present.

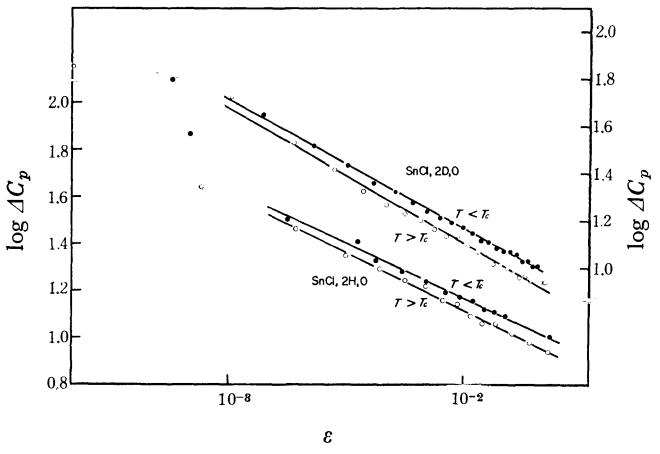

Fig. 8. Logarithmic plot of the anomalous part of the heat capacity of $SnCl_2 \cdot 2H_2O$ and $SnCl_2 \cdot 2D_2O$.

In the vicinity of the lambda transition the heat capacity diverges as is shown in Fig. 2. There has been discussion on the types of the singularity of the heat capacity curves at ferroelectric transitions. For the antiferroelectrics, there seems to be relatively fewer examples. It has been conjectured that the effect of domain formation and of finite crystal size would affect the critical behavior of the ferroelectric crystals. Such effects will be absent or at least relatively unimportant in antiferroelectrics. It is hoped that the present crystal would provide an ideal system to study the critical behaviors on. The anomalous heat capacity is plotted in Fig. 8 in a logarithmic scale, which, at least for $\varepsilon = |(T - T_c)/T_c| > 10^{-3}$, is linear, indicating that

$$\Delta C = A_{\pm} |(T - T_c)/T_c|^{-\alpha_{\pm}}$$

where $\alpha_{\pm}$ are given in Table 3. Attempts were made to fit the data to

$$\Delta C = A_{\pm} \ln |(T - T_c)/T_c|$$

But no good fits were obtained. Any possible change of the normal heat capacity does not alter the conclusion. It should be added that the calorimeter used was not entirely suitable for the high resolution measurement, so that the important region of $\varepsilon < 10^{-3}$ was missed. A high resolution calorimeter capable of the temperature resolution smaller than 10^{-5} K was constructed. Heat capacity measurement with the new apparatus was performed on a single crystal of $SnCl_2 \cdot 2H_2O$ in the close vicinity of the critical temperature. The result will be reported soon in a separate publication.

Table 3.

	$SnCl_2 \cdot 2H_2O$	$SnCl_2 \cdot 2D_2O$
T_c/K	217.94 ±0.05	234.47±0.05
α_+	0.534±0.021	0.574±0.010
α_-	0.478±0.010	0.544±0.010

The error bounds assigned to the α values refer to the scattering of the data about the linear plot. If the ambiguity in the estimation of the normal heat capacity is taken into account, they will be somewhat larger.

Finally, the thermal behavior of the present crystal is compared with that of other hydrate crystals. Copper formate tetrahydrate and its deuterate analogue have a similar layer structure, in which the water molecules form a hydrogen-bonded network.[11-14] The

Molecular Structure of Formamide as Studied by Gas Electron Diffraction

Mitsuo KITANO and Kozo KUCHITSU

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received September 10, 1973)

The structure of formamide $HCONH_2$ has been determined by gas electron diffraction. The rotational constants determined in previous microwave studies have also been used for determining the hydrogen parameters. From a joint least-squares analysis of the diffraction intensity and the rotational constants, where the out-of-plane vibrations are treated as finite-amplitude motions in the corrections for vibrational effects, the following r_g bond distances and r_z angles have been derived: C–N = 1.368±0.003 Å, C=O = 1.212±0.003 Å, ∠N–C=O = 125.0±0.4°, N–H(average) = 1.027±0.006 Å, C–H = 1.125±0.012 Å, ∠C–N–H(*cis* to C=O) = 118.7±1.0°, and ∠C–N–H (*trans* to C=O) = 119.7±1.0°, where the uncertainties represent estimated limits of experimental error. The C–N bond is about 0.07 Å longer, whereas the C=O bond is about 0.04 Å shorter, in the free molecule than in the crystal studied by X-ray diffraction. The C–N and C=O bonds are about 0.01 Å or more shorter, and the N–C=O angle is about 3° larger than the corresponding parameters in acetamide and *N*-methylacetamide.

The primary purpose of the present study is to determine the skeletal structure of formamide as accurately as possible, since neither spectroscopic nor diffraction studies have yet afforded a structure accurate enough to enable a critical comparison with analogous amide structures determined in the vapor and crystal phases. Particularly, a comparison of the skeletal structure of formamide with those of acetamide[1] and *N*-methylacetamide[2] determined in our preceding studies is intended in order to appraise the effect of methyl substitutions on simple amide structures. The r_g distances and r_z angles[3,4] should provide more consistent and suitable measures for this comparison than the r_s parameters, since the skeletal r_s parameters in formamide determined by microwave studies[5–7] suffer from appreciable uncertainties in the carbon coordinates, and no r_s structures are yet available for other amides.

On the other hand, the rotational constants of formamide determined by microwave spectroscopy[5–8] for the normal and deuterated species supply valuable information on the positions of the hydrogen atoms, particularly on the planarity of the molecule and the potential function in regard to the NH_2 wagging motion,[7] which is hard to determine precisely by the diffraction experiment.[4] Therefore, the diffraction intensity measured in the present study has been merged with the rotational constants in a least-squares analysis. Because of the relatively low frequencies of the out-of-plane vibrations, a finite-amplitude treatment[9] instead of the conventional treatment based on infinitesimal vibrational amplitudes[3] has been made for the vibrational corrections in the comparison of the diffraction and spectroscopic observables.

Experimental

A commercial guaranteed reagent was heated to about 160 °C by a high-temperature nozzle,[10] and diffraction photographs were taken with 40 kV electrons at camera distances of 112.30 mm (short) and 246.86 mm (long).[11] The scale factors of the diffraction patterns were calibrated to within 0.1% with reference to the r_a (C=O) distance of carbon dioxide (1.1646 Å).[11] The densities of four plates taken at each

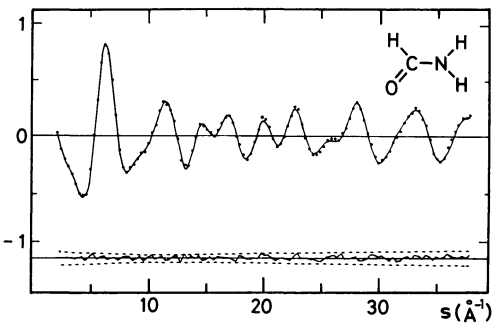

Fig. 1. Experimental and theoretical molecular intensities for formamide. Typical observed $sM(s)$ values are shown in dots, and the best-fit theoretical is shown in the solid curve. The indices of resolution for long and short camera-distances are 0.752 and 0.912, respectively. The lower solid and broken curves represent the residuals and the error limits in the $sM(s)$ to a fractional error of 1×10^{-3} of the original photocurrent,[12] respectively.

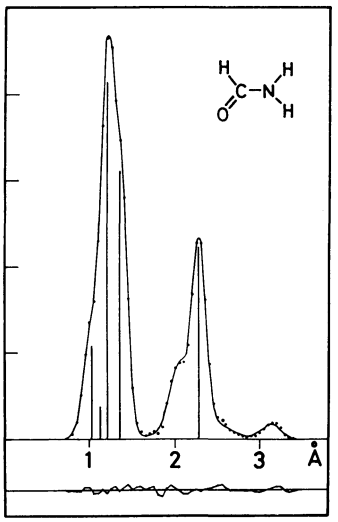

Fig. 2. Experimental (dots) and theoretical radial distribution curves for formamide. The lower curve represents residuals. Vertical bars correspond to principal internuclear distances. A damping factor, $\exp(-0.0016\ s^2)$, is used.

camera distance were measured by a digital microphotometer.[12] Other experimental procedures have been described elsewhere.[11,13]

Molecular intensities were obtained in the ranges of s= 2.2—15.7 Å^{-1} and 9.4—37.7 Å^{-1} from the long and short camera-distance data, respectively.[14] They agreed with each other in the overlapping region within experimental error of about 0.03 in the absolute $sM(s)$ scale, and hence were joined at s=12.7 Å^{-1} (Fig. 1). A hand-drawn background was adjusted to get the radial distribution curve shown in Fig. 2. Most calculations were carried out on a HITAC 5020E and 8700/8800 in the Computer Center of the University of Tokyo.

Analysis of Electron Diffraction Data

The skeletal parameters, r_g(C–N), r_g(C=O), and ϕ_α(N–C=O), and the average r_g(N–H) distance were determined by a least-squares analysis of the molecular intensity with a uniform empirical weight function.[15] The molecule was assumed to be planar in equilibrium,[7] and the r_α(C–H) distance and all the ϕ_α angles involving the hydrogen atoms were fixed to the corresponding r_s-values.[7] The mean amplitudes and the vibrational corrections (r_a-r_α)[3,16] were calculated by the use of an approximate set of the modified Urey-Bradley force constants for the in-plane vibrations shown in Table 1; they were taken from those reported by Suzuki[17]

Table 1. Approximate in-plane force constants for formamide[a] (in md/Å)

	I	II		I	II
K(N–H)	6.58	5.80	H(H–C=O)	0.20	0.20
K(C–H)	3.50	3.74	H(N–C=O)	0.14	0.34

a) See Ref. 17 for definitions of the modified Urey-Bradley force constants, K, H, and F.
I: Present estimates, II: Estimated by Suzuki, Ref. 17.

and adjusted slightly to reproduce the vibrational frequencies observed recently by King[18] in the gas phase. For the NH_2 rocking frequency, however, that assigned tentatively by King (602 cm^{-1}) seems to be unlikely, since the calculated value (about 958 cm^{-1}) deviated significantly from it and it was impossible to reporduce the former value by a reasonable adjustment of the force constants. A further spectroscopic work, particularly on the deuteride vapors, is necessary to make a decisive assignment.

In calculations of the vibrational corrections, the contributions from the out-of-plane vibrations were excluded, since their amplitudes cannot be treated as infinitesimal[9] (see next section). All but the skeletal mean amplitudes were fixed to the calculated values listed in Table 2. The asymmetry parameters κ for the bonded C–H and N–H distances were assumed to be 1.8×10^{-5} Å^3, and the rest of the κ parameters were ignored.[19]

The structural parameters and the mean amplitudes

Table 2. Mean amplitudes and vibrational corrections for formamide[a] (in 10^{-4} Å)

a) Distances in Å and angles in degrees. The numbers in parentheses represent uncertainties attached to the last significant figures. For definitions of r_g, r_α, r_z, and r_s, see Ref. 3.
b) Structures based on the analysis of electron-diffraction intensity with estimated limits of error.
c) Structures based on the analysis of electron-diffraction intensity and rotational constants, with estimated limits of error. The r_z structure derived in this procedure is sometimes denoted as r_{av}.[22]
d) The r_s structure determined by Hirota *et al.* by microwave spectroscopy. Ref. 7.
e) Mean amplitudes with estimated limits of error.
f) Indices of resolution for diffraction intensities taken with the long (l) and short (s) camera-distances.

derived from the least-squares analysis are listed in Table 3. The quoted limits of error were estimated as 2.5 times the random errors plus systematic errors.[20,21]

Joint Analysis of Diffraction Intensity and Rotational Constants

A further analysis was made by the use of the observed rotational constants for the normal and four deuterated species for the ground vibrational state[6] for testing the accuracy of the diffraction parameters and for refinement of the hydrogen parameters.[22] The analysis was

based on the rotational constants A_z, B_z, and C_z (hereafter represented, as a set, by B_z) corresponding to a hypothetical set of the planar nuclear positions averaged over the in-plane vibrations.

The B_z constants were estimated in the following steps of eliminating the effect of in-plane and out-of-plane vibrations.

From the spectroscopic side, the B_z constants were obtained from the corresponding B_0 constants by making the following corrections:[23]

$$B_z = B_0 + \Delta B_{\text{electronic}} + \Delta B_{\text{centrifugal}} + \Delta B_{\text{Coriolis}} + \sum_s \Delta B_s + \sum_t \Delta B_t \quad (1)$$

where the electronic corrections were estimated by Oka's formulation[24] from the molecular g-values observed by Flygare and Benson,[25] and the centrifugal corrections[24] were ignored. The Coriolis corrections and the vibrational corrections for the in-plane modes were calculated in a conventional way by the use of the force constants given in Table 1 as[3,23]

$$\Delta B_{\text{Coriolis}} = -4B_e^2 \sum_s \omega_s \sum_{s'} (\zeta_{ss'}^{(\alpha)})^2/(\omega_s^2 - \omega_{s'}^2) \quad (2)$$

and

$$\Delta B_s = -(B_e^2/\omega_s)[3A_{ss}^{(\alpha\alpha)} - 4\sum_{s'}(\zeta_{ss'}^{(\alpha)})^2] \quad (3)$$

where Nielsen's notations[26] are followed. Individual in-plane and out-of-plane modes are represented by s and t, respectively, and s' includes all s and t. The vibrational corrections for the out-of-plane motions were approximated on the assumption that the NH_2 wagging, torsion and C–H out-of-plane bending motions were independent of one another,

$$\sum_t \Delta B_t \cong \Delta B_{\text{wag}} + \Delta B_{\text{torsion}} + \Delta B_{\text{bend}} \quad (4)$$

The correction for the wagging motion followed the calculation by Hirota *et al.*,[7]

$$\Delta B_{\text{wag}} = -B_1\langle\tau^2\rangle_0 - B_2\langle\tau^4\rangle_0 \quad (5)$$

where the coefficients B_1, B_2 and the average values of the NH_2 wagging displacement τ for the ground state are given in their paper. The corrections for the torsion and the C–H bending motion were estimated in a similar way. A two-fold harmonic potential for the torsion with V_2=20 kcal/mol[27] and the C–H bending frequency[18] of 1050 cm^{-1} were assumed, and only quadratic averages of the displacements were taken into account. The correction terms are listed in Table 4. The inertia defects calculated from the present B_z do not vanish exactly, as mentioned by Hirota *et al.*,[7] but they fall within the limits of uncertainty in the correction terms estimated above (-0.04 ± 0.10 amu. Å^2 for all the isotopic species).

From the diffraction side, the r_g parameters were related to the r_a parameters by making conventional shrinkage corrections[3] for the in-plane contributions, and for the nonbonded distances which vary with the out-of-plane vibrations, classical averages over the motions based on a rigid frame, analogous to Karle's shrinkage correction for internal rotation,[28] were made[9] by the use of the mean displacements used in the spectroscopic corrections. Then the r_a parameters were assumed to be equal to the corresponding r_z parameters, since the frequencies of the in-plane vibrations are so high that thermal effects are unimportant.[3,29]

b) The deuterium atom is *cis* to the C=O bond.
c) The deuterium atom is *trans* to the C=O bond.

The relative statistical weights assigned to the rotational constants were such that their standard errors were approximately equal to their estimated uncertainties.[20] They were taken by a trial and error procedure as 1×10^2, 2×10^5, and 1×10^6 for A_z, B_z, and C_z, respectively, for all the isotopic species, whereas a unit weight was assigned to each molecular intensity of electron diffraction from s=6.3 to 26.7 Å^{-1} taken at unit q ($10\ s/\pi$) intervals.

All the independent structural parameters were varied except that the r_z(N–H) distances were set equal to each other and that the ϕ_z(H–C–N) angle was fixed to 112.7°, the r_s angle reported by Hirota *et al.*[7] As for the mean amplitudes, all but the bonded C–N and C=O amplitudes were fixed to the calculated values given in Table 2. The isotopic differences for the r_z(N–H)$-r_z$(N–D) and r_z(C–H)$-r_z$(C–D) distances were initially estimated by use of an approximate formula,[22,29]

$$r_z(\text{H}) - r_z(\text{D}) \cong \frac{3}{2}a_3[\langle\Delta z^2\rangle_0(\text{H}) - \langle\Delta z^2\rangle_0(\text{D})] - [\langle\Delta x^2\rangle_0(\text{H}) - \langle\Delta x^2\rangle_0(\text{D})]/2r_z \quad (6)$$

where the anharmonicity parameters a_3 for N–H and C–H were assumed to be[30] 2.19 Å^{-1} and 1.98 Å^{-1}, respectively, and the in-plane relative displacements of the nuclei parallel and perpendicular to the equilibrium bond axes, Δz and Δx, respectively, were taken into account. In line with the finite-amplitude treatment mentioned above, contributions from the out-of-plane displacements, Δy, were not included in the calculation. The isotopic differences were estimated to be 0.003_2 and 0.002_0 Å, respectively, for N–H and C–H. (A conventional treatment including the out-of-plane contributions resulted in -0.004_8 and 0.000_6 Å, respec-

in Table 7 and also in Table 8, where observed carbon valence angles formed by a single bond and a double bond are listed. The methyl substitutions in formamide forming acetamide and *N*-methylacetamide increase the C–N and C=O bond lengths simultaneously by about 0.01 Å or more and decrease the N–C=O angle by about 3°. Analogous trends are observed in the acetaldehyde[38,39]–acetone[40]–methyl ethyl ketone[41] system and in the propene[9]–isobutene[42] system. These systematic trends conform to those observed in many more methyl-substituted compounds collected by Jacob *et al.*,[43] who accounted for the trends consistently in terms of the influence of interactions among nonbonded atoms.

The $r_g(N–H_{av})$ and $r_g(C–H_a)$ distances listed in Table 3 (ED+MW) are essentially equal to, respectively, the r_g(N–H) distance in NH_3 (1.030±0.002 Å)[44] and the r_g(C–H) distances in a number of aldehydes (1.13 Å).[4]

The authors are indebted to Professor Eizi Hirota of Kyushu University for his supply of numerical data prior to publication and for his helpful discussions.

Rotational Isomerism in Methyl-*d*-amine

Keietsu TAMAGAKE and Masamichi TSUBOI

Faculty of Pharmaceutical Sciences, University of Tokyo, Bunkyo-ku, Tokyo 113

(Received August 1, 1973)

Infrared absorption spectra of methyl-*d*-amine and methyl-*d*-amine-d_2 have been observed in their gaseous states. For each of seven vibrations of the former and seven vibrations of the latter, two Q-branch peaks are observed assignable to *trans* and *gauche* forms of the molecule. In the microwave absorption spectrum of methyl-*d*-amine 60 lines assignable to the *trans* form (whose rotational constants are $A=86085$, $B=20546$, and $C=20475$ MHz) and 140 lines assignable to the *gauche* form ($A=86512$, $B=21243$, and $C=19911$ MHz) are found. Every *trans* line shows an inversion doubling which is considered to reach an observable amount only through a *trans-gauche* mixing of the vibration-rotation wavefunctions. This *trans-gauche* mixing should in turn depend upon the energy difference ΔE_{TG} between the ground vibration-rotation levels of the *trans* and *gauche* forms. On the basis of the observed amount of the inversion splitting, ΔE_{TG} has been determined to be 6.7 ± 0.4 cm^{-1}. The ΔE_{TG} value has then been refined by observing an accidental degeneracy of the *trans* and *gauche* energy levels, so that $\Delta E_{TG}=7.06\pm0.03$ cm^{-1}.

For the normal methylamine (CH_3NH_2) molecule, there are three equivalent equilibrium positions of the methyl group in the internal rotation with respect to the amino group. On substituting one of the methyl hydrogens by deuterium (*i.e.*, on going from CH_3NH_2 to CH_2DNH_2), the threefold symmetry of the torsion Hamiltonian is removed. The three potential minima are not equivalent any more; one of them corresponds to the *trans* and the other two *gauche* conformations (see Fig. 1). It should be remembered, however, that the intramolecular potential itself is not affected by an isotopic substitution. Thus, the shape of the potential function is exactly equal in the vicinity of the *trans* conformation to that in the vicinity of the *gauche* conformation even in the methyl-*d*-amine molecule. In addition, the reduced moment of inertia of the torsional oscillation would not greatly different in the *trans* form from that in the *gauche* form. Therefore, at first thought, one might guess that the energy difference between the torsional levels of *trans* and *gauche* forms would be very small and a pronounced mixing between the wavefunctions of these forms may take place so that no appreciable rotational isomerism can be observed.

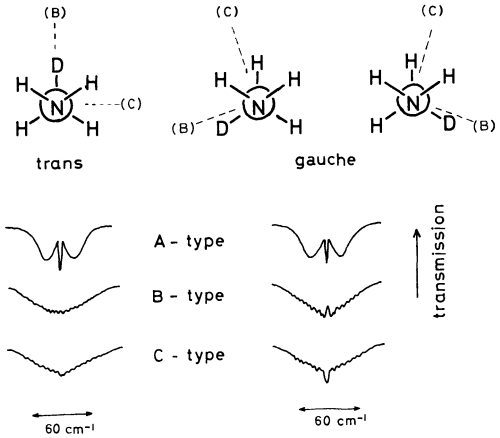

Fig. 1. Three equilibrium positions of the CH_2D group in the internal rotation with respect to the NH_2 group of the CH_2DNH_2 molecule. Of the three principal axes of inertia, A-axis is nearly along the C–N bond, while B- and C-axes are directed as shown in this figure. The band envelope of each of the A-, B-, and C-type bands expected with the resolving power 3 cm^{-1} of CH_2DNH_2 is also given on the basis of a calculation made by Ueda and Shimanouchi (*J. Mol. Spectroscopy*, **28**, 350 (1968)).

Actually, however, our analysis[1] of the far-infrared absorption spectrum of CH_2DNH_2 indicated that, in the ground torsional state ($n=0$) and in the first excited state ($n=1$), there are well-defined *trans* and *gauche* rotational isomers. Such a lack of mixing was attributed mostly to the situation that the mode of coupling of the torsional oscillation with other vibrations is different in the *trans* and *gauche* forms. Only in the higher excited states ($n\geqq2$), a pronounced mixing was found to take place between the *trans* and *gauche* torsional wavefunctions. In the present paper, we report our examination on how this isomerism appears in the infrared and microwave absorption spectra. From an analysis of the microwave spectrum, the energy difference of the rotational isomers in the vibrational ground state has been determined. This will also be reported below.

Infrared Absorption Spectra

Infrared absorption spectra of methyl-*d*-amine (CH_2DNH_2) and methyl-*d*-amine-d_2 (CH_2DND_2) have been observed in their gaseous states.

The sample of CH_2DNH_2 gas used is the same as what was used in our previous work.[1] The sample was placed in a gas cell, with two KBr windows, a pathlength of 10 cm, and potassium hydroxide as a desiccant. CH_2DND_2 gas was obtained by adding D_2O solution of methyl-*d*-ammonium-d_3-chloride (CH_2DND_3Cl) on solid sodium deuteroxide (NaOD). Here, CH_2DND_3Cl was prepared by dissolving methyl-*d*-ammonium chloride into D_2O, by removing the solvent in vacuum, and by repeating this procedure several times. Before introducing the CH_2DND_2 sample in a gas cell (10 cm^{-1}), D_2O gas was filled in the cell several times so that the absorbed gas on the cell wall was completely deuterated. As a desiccant, metallic sodium was placed in the cell.

Infrared absorption measurements were made in the

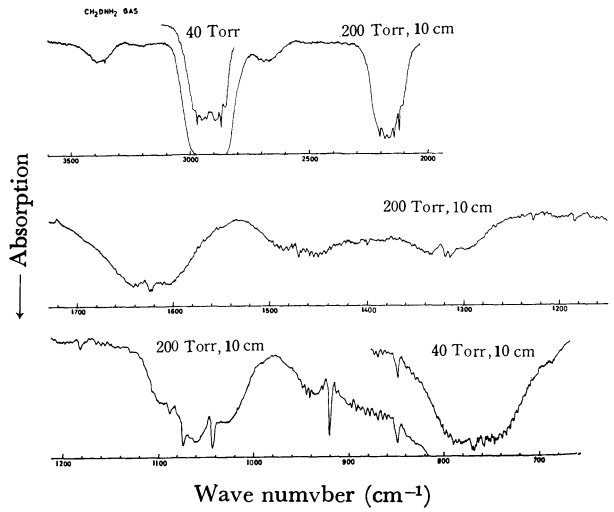

Fig. 2. Infrared absorption spectrum of CH_2DNH_2 (gas).

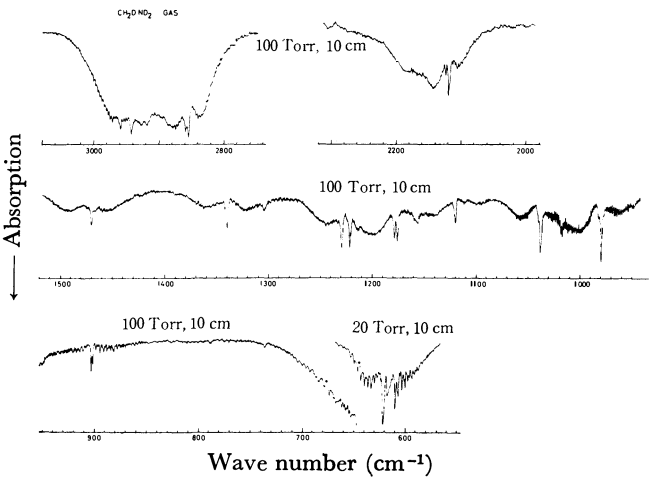

Fig. 3. Infrared absorption spectrum of CH_2DND_2 (gas).

4000—400 cm^{-1} region by the use of a Perkin-Elmer 621 spectrophotometer. The results are shown in Figs. 2 and 3.

A Normal Coordinate Treatment

In an attempt to obtain a guide in our interpretation of the infrared spectra, we have made a calculation of the vibrational frequencies and normal modes of vibration of *trans* and *gauche* forms of CH_2DNH_2 and CH_2DND_2 molecules. The relation between the force constants and the vibrational frequencies is given by the secular equation

$$|\mathbf{GF}-\mathbf{E}\lambda| = 0 \qquad (1)$$

where **G** is the inverse kinetic energy matrix, **F** the potential energy matrix, **E** the unit matrix, and λ is equal to $4\pi^2c^2\nu^2$, c being the light velocity, N the Avogadro number, and ν the vibrational wave number. As the basis of the **G** and **F** matrices, we choose a set of symmetry coordinates S defined in our previous paper on the five isotopic species of methylamine.[2] The set of normal coordinates **Q** is given as

$$\mathbf{S} = \mathbf{L}_S\mathbf{Q} \qquad (2)$$

In our treatment we chose the local symmetry force field.[3] The values of force constants, *i.e.* the **F** matrix elements are assumed as shown in Table 1, for all of the four molecules, CH_2DNH_2 (*trans*), CH_2DNH_2 (*gauche*), CH_2DND_2 (*trans*), and CH_2DND_2 (*gauche*). This set of force constants explains reasonably well the vibrational spectra of CH_3NH_2, CH_3ND_2, CD_3NH_2, CD_3ND_2, and $CH_3{}^{15}NH_2$,[2] and we did not attempt any further adjustment of the force constant values this time. The calculation was made by a HITAC 5020E at the Computer Centre of the University of Tokyo, by the use of programs written by Professor T. Shimanouchi and his collaborators.[4] The calculated fre-

a) Unit: mdyn/Å for stretch-stretch elements, mdyn/rad for stretch-deform elements, and mdyn·Å/rad² for deform-deform elements.

b) A′ and A″ mean the vibrational modes which would be symmetric and antisymmetric, respectively, with respect to the symmetry plane of the molecule if CH_2D group were ordinary CH_3 group.

quencies are given in Table 2 with approximate statements of the vibrational modes which were derived from the calculated $\mathbf{L}_S$ matrix elements and potential energy distribution.

Ferquency Differences of the *trans* and *gauche* Forms

Some of the observed frequencies assignable to the calculated frequencies are listed also in Table 2.

a) "In-pl." means symmetric with respect to the symmetry plane of the CH_2D group, and "out-of-pl." means antisymmetric with respect to this plane.

For each of the CH_2 wagging, CN stretching, NCD bending (along the direction parallel to the symmetry plane of the CH_2D group), and NH_2 wagging vibrations a sharp Q-branch peak is expected both for *trans* and *gauche* forms (see Fig. 1). The calculation indicates that the frequencies of *trans* and *gauche* forms should be appreciably different for each of these vibrations. In fact for each of these vibrations two sharp Q-branch peaks are observed, one of which may be assigned to the *trans* form and the other to the *gauche* form. Likewise, for each of the ND_2 scissoring, C–N stretching, NCD bending, and ND_2 wagging vibrations of CH_2D-ND_2, two bands are observed as are expected from the normal coordinate treatment.

Two bands are also observed for each of the CH_2 antisymmetric stretching, CH_2 symmetric stretching and CD stretching vibrations of both of the CH_2DNH_2 and CH_2DND_2. In our present calculation, the frequency of each of these vibrations does not come out to be different in the *trans* form from that in the *gauche* form. Obviously this is because the assumed values of **F**-matrix elements are not proper. Thus, an equal value was assigned to the diagonal elements $F(S_3, S_3)$ and $F(S_{11}, S_{11})$, and the off-diagonal element $F(S_2, S_3)$ was arbitrarily set at zero. The CH stretching frequencies depend almost only upon the **F**-matrix elements $F(S_2, S_2)$, $F(S_3, S_3)$, $F(S_{11}, S_{11})$ and $F(S_2, S_3)$. The normal methylamine CH_3NH_2 molecule gives only three observed CH frequencies (CH_3 symmetric stretching, and two CH_3 "degenerate" stretching frequencies), and therefore it has not been possible so far to fix the values of the four **F**-matrix elements.[2] While, CH_2D-NH_2 molecule gives four CH frequencies (*i.e.*, CH_2 symmetric stretching frequencies of *trans* and *gauche* forms and CH_2 antisymmetric stretching frequencies of *trans* and *gauche* forms). Therefore, if the assignments of these observed frequencies to the *trans* and *gauche* forms are fixed (by an analysis of the rotational-structures, for example), then the four **F**-matrix elements should be almost uniquely determined. This should lead us to an interesting piece of information on how one of the CH bonds in methylamine molecule is chemically different from the other two.

Microwave Spectrum

Microwave absorption spectrum of CH_2DNH_2 in its gaseous state was observed by the use of an instrument constructed by Professor Y. Morino, Professor E. Hirota, and their collaborators in the Department of Chemistry, Faculty of Science, here in the University, through their kindness. Assingments of rotational transitions to the observed lines were made by examining the Stark effect and also by some double-resonance experiments. On the basis of the molecular parameters of the so-called r_0-structures (effective structures at vibrational ground state and at $J=0$ and $K=0$) of CH_3NH_2

Table 3. Rotational constants of CH_2DNH_2 (in cm^{-1})

b) See text.

and CH_3ND_2 molecules determined by Takagi and Kojima,[5] the rotational constants A, B, and C are calculated for *trans* and *gauche* forms as shown in Table 3. Absorption lines of the *trans* and *gauche* forms are actually found nearly at the frequencies predicted from these values of the rotational constants. They are 34 Q-branch lines ($\Delta J=0$) and 26 P- and R-branch lines ($\Delta J=\pm 1$) of the *trans* form, and 72 Q-branch lines and 68 P- and R-branch lines of the *gauche* forms. All of the *trans*-form lines are explained by considering that every transition expected for a rigid-rotor splits into two components because of the inversion. On the other hand, all of the *gauche*-form lines are explained by considering that every transition expected for a rigid-rotor splits into four components because of the inversion and internal-rotation. After taking an average of the frequencies of these split lines the rotational constants of the *trans*- and *gauche*-form molecules are derived as given in the last column of Table 3.

The results of our microwave study on this molecule will be detailed elsewhere. Only an outline of our work on the energy difference ΔE_{TG} between the *trans*- and *gauche*-forms will be reported below.

ΔE_{TG} from Inversion Splitting

By means of the microwave spectroscopy, we can determine the positions of the energy levels of the *trans* form with respect to one another and those of the *gauche* form with respect to one another. It is not usually easy, on the other hand, to determine the positions of the *trans* levels with respect to the *gauche* levels, because there are no transitions allowed between the *trans* and *gauche* levels (unless there is a strong *trans-gauche* mixing). In the present particular case, however, the *trans-gauche* energy difference ΔE_{TG} at $J=0$, $K=0$ can be estimated from the amounts of the inversion splitting of the *trans* levels.

In addition to the internal-rotation, the methylamine molecule experiences another large-scale internal motion, *i.e.*, the inversion of the amino group. Thus, the molecule in question has a two-dimensional six-minimum potential, which is schematically shown in Fig. 4. The inversion splitting of the *trans* form is considered to be caused by a resonance of the energy levels in the two equivalent *trans* valleys in this potential map. If the wavefunction of a vibration-rotation level were completely localized in each of these valleys, however, the amount of the inversion splitting should be negligibly small, because the two *trans* valleys are situated far away from each other (Fig. 4). While, if an appreciable amount of mixing of the *trans* and *gauche* states takes place, an appreciable amount of the inversion splitting of the so-called "*trans*" level (which now involves a small contribution from the *gauche* state) may occur. As has been shown by Itoh,[6] by Kivelson and Lide,[7] and by Tsuboi *et al.*,[8] the inversion splitting of the amino group in the molecule with the rotational quantum number K should be given as

$$E^a - E^s = (-1)^K(E^- - E^+)\int_0^{2\pi} \phi_{\tau K}(x)^* \phi_{\tau K}(x+\pi)\mathrm{d}x, \quad (3)$$

where $E^- - E^+$ is the hypothetical inversion splitting when the coupling were absent between the inversion and internal-rotation, and $\phi_{\tau K}(x)$ is the internal-rotation eigenfunction for the vibration-rotation state now in question. This $\phi_{\tau K}(x)$ is not a completely localized function but an eigenfunction of a proper internal-rotation Hamiltonian. The subscript τ is for distinguishing three internal-rotation sublevels of the $n=0$ state. The value of the overlap integral in the right side of Eq. (3) for the "*trans*" form should be sensitive to how much mixing takes place of the *trans* and *gauche* states, and hence to the amount of ΔE_{TG}. The integral can be estimated on the basis of a theory of asymmetric internal rotor developed in our previous paper.[1] It comes out as a periodic function of K (rotational quantum number). Therefore, the inversion splitting of the $K+1 \leftarrow K$ transition frequency should also be a periodic function of K. In Fig. 5, the amounts of inversion splitting actually observed in the microwave absorption lines of $K+1 \leftarrow K$ transitions are plotted against K. The observed values are reproduced by an empirical formula

$$E^a - E^s = 81.85 \sin\left[51°41' \times \left(K+\frac{1}{2}\right)\right] \text{ MHz} \quad (4)$$

The observed set of values is found to be in a good

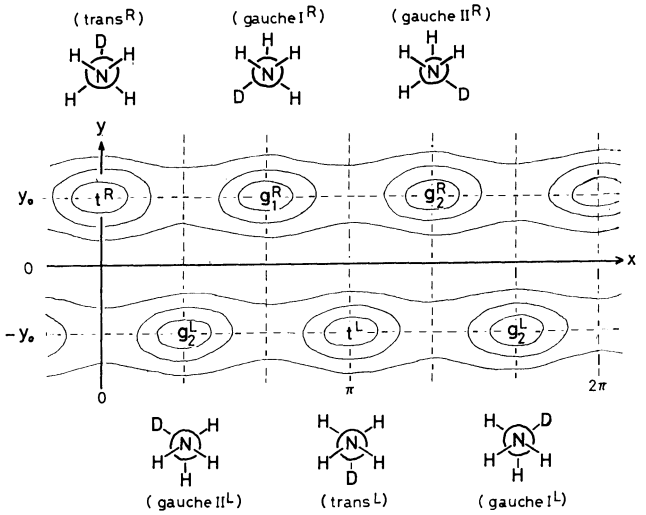

Fig. 4. A schematic drawing of the two-dimensional six-minimum potential function of the CH_2DNH_2 molecule. x: internal rotation. y: inversion.

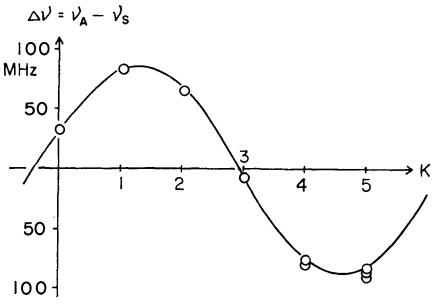

Fig. 5. The amount of inversion splitting, ν_a—ν_s, of the absorption lines of the $K+1 \leftarrow K$ transitions plotted against K. o: observed. ——: calculated by equation (4).

agreement with the calculated set (on Eq. (3)) if ΔE_{TG} is assumed to be 6.7 cm^{-1}. The ambiguity of this value is ± 0.4 cm^{-1} here.

ΔE_{TG} from a *trans-gauche* Accidental Degeneracy

The ΔE_{TG} value (6.7 cm^{-1}) just estimated happens to be close to the value (6.6 cm^{-1}) of $3[A-(B+C)/2]$ of this molecule. Therefore, the $K=1$ levels of the *trans* form should be situated close to the $K=2$ levels of the *gauche* form (see Fig. 6), and an interaction may be

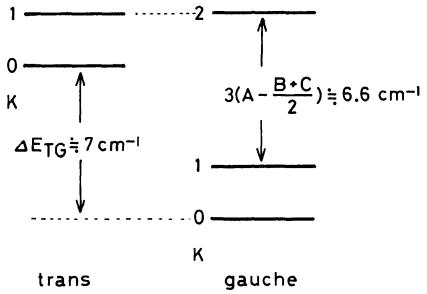

Fig. 6. Accidental degeneracy of the *trans* ($K=1$) and *gauche* ($K=2$) levels.

expected between one of such *trans* levels and a *gauche* level with the same J-value. In fact, an anomaly in the observed frequency of the *trans* form has been found for $K=1\leftarrow 0$ and $J=10\leftarrow 10$ transition (see Fig. 7). This fact is interpreted by considering that the ($K=1$, $J=10$) level of the *trans* form is accidentally coincident with the ($K=2$, $J=10$) level of the *gauche* form. On the basis of this interpretation the difference (ΔE_{TG}) between the ($K=0$, $J=0$) levels of the *trans* and *gauche* forms is determined to be 7.06 ± 0.03 cm^{-1}. This is probably the first example of the energy difference precisely determined of rotational isomers caused by an isotopic substitution.

We wish to express our deep appreciation to Professor Yonezo Morino, Professor Eiji Hirota, and Professor Takehiko Tanaka for their kindness in allowing us to use their microwave instrument, for their kind instruction and valuable discussions.

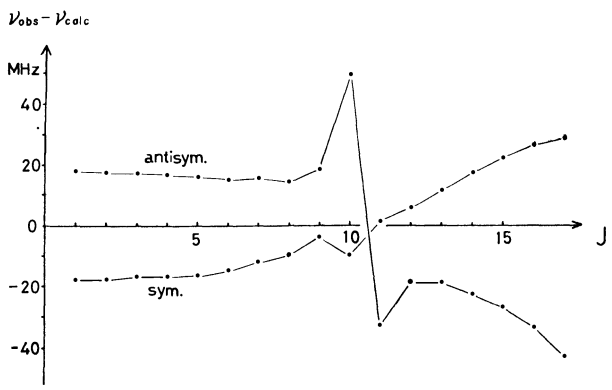

Fig. 7. $\nu_{obs}-\nu_{calc}$ plotted against J. Here ν_{obs} are the observed frequencies (MHz) of the Q-branch lines ($J_{1,J-1}\leftarrow J_{0,J}$) of the trans form. ν_{calc} are the frequencies calculated on the assumption that the molecule is a rigid rotor with the ratotional constants given in Table 3. For every ($K=1\leftarrow 0$, $J=J\leftarrow J$) transition two absorption lines are observed, and they are considered to be caused by the inversion of the amino group.

Resonance Raman Spectra of Acid-Base Indicators. I. *p*-Aminoazobenzene Derivatives

Katsunosuke MACHIDA, Bak-Kwang KIM, Yutaka SAITO, Kyoko IGARASHI, and Toyozo UNO

Faculty of Pharmaceutical Sciences, Kyoto University, Sakyo-ku, Kyoto 606

(Received July 17, 1973)

Resonance Raman spectra between 1800 and 1000 cm^{-1} of methyl orange and a few other *p*-aminoazobenzene-type acid-base indicators have been investigated at various pH, and a marked spectral change has been observed on the transformation between the acid and the base forms of these indicators. The characteristic Raman frequencies have been assigned by referring to the spectra of related compounds and the deuteration effects. The spectra of the acid form are well elucidated on the basis of the quinoid-type structure.

The color change of acid-base indicators is generally understood as a consequence of the change in molecular structures accompanying various redistributions of electrons on the transformation between the indicator acids and their conjugate bases. Spectroscopic evidence, however, has rarely been obtained for details of such a structure change of indicators. The visible and ultraviolet spectra should reflect the electron redistributions directly, but they are too simple in most cases to afford sufficient information on the complicated structure of indicator molecules. The infrared and ordinary Raman spectra may be informative, but their application is severely restricted by the solvents and the concentrations with which indicators are practically used. These difficulties are expected to be overcome by the recently developed technique of the laser-excited resonance Raman spectra, which seem to be very promising to inquire into the molecular structure of indicators in dilute aqueous solutions. Most of the acid-base indicators show absorption maxima in the spectral region around 500 nm, where two intense excitation lines, 488.0 and 514.5 nm, are available from the Ar^+ laser, and rigorous resonances with high sensitivities are expected even at very low concentrations.

The resonance Raman spectrum of methyl orange in the neutral aqueous solution has been reported by Hacker[1] and Carey *et al.*[2] and several bands attributable to the azobenzene structure postulated for the base form have been identified. For any acid-base indicator, however, the pH dependence of the Raman spectrum does not seem to have been investigated. In this paper we report the resonance Raman spectra of methyl orange and a few other *p*-aminoazobenzene type indicators at various pH. The structures of the acid and the base forms of these indicators are discussed by referring to the spectra of related compounds and deuteration effects.

Experimental

Materials. The azobenzene derivatives listed with the abbreviations in Table 1 and two other reference compounds, quinone dioxime and diazoaminobenzene, were obtained from commercial sources, and were recrystallized several times from water or ethanol. *O*-Deuterated quinone dioxime and *N*-deuterated diazoaminobenzene were prepared by the usual exchange reaction with ethanol-*d*.

Measurements. The Raman spectra between 1800 and 1000 cm^{-1} were recorded on a JEOL S-1 laser Raman spectrophotometer with the excitation lines 488.0 nm and 514.5 nm of a Coherent 52G Ar^+ laser (2 W). The spectral slitwidth was 12 cm^{-1} and 14 cm^{-1} for the 514.5 nm and the 488.0 nm excitations, respectively. The measurements were made for solid samples of quinone dioxime and its *O*-deuterated compound and for the solutions of the other compounds in various solvents. Each sample was sealed in a 1 mm capillary tube. The pH of the aqueous solutions was adjusted by using 0.1M HCl, 0.1M NaOH and the phthalate buffers.[5] When the desired solubility was not attained with water alone, suitable amounts of ethanol or acetone-d_6 were added to the solvents. At the concentrations adopted presently, acetone-d_6 shows no interfering Raman band in the region between 1650 and 1100 cm^{-1}, but shows a weak band at 1690 cm^{-1} which may be used as an internal standard. For the measurements of the deuterated compounds, the stock solution of 1M DCl was prepared by mixing the calculated amounts of 20% DCl (Merck) and heavy water in a 1 ml syringe, and was reserved in a sealed ampule. Similarly, 1M NaOD in heavy water was prepared from 40% NaOD (Merck). These solutions were diluted with heavy water to the desired concentration before use.

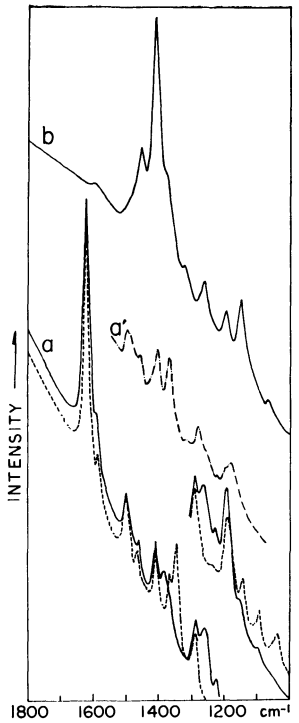

Fig. 2. Resonance Raman spectra of MR: (a) 1×10^{-4} M in 0.1M HCl (solid line) and in 0.1M DCl (broken line), 514.5 nm; (a') 1×10^{-4} M in a 1:3 mixture of ethanol and the phthalate buffer (pH 4), 514.5 nm; (b) 2×10^{-4} M in 0.1M NaOH, 488.0 nm.

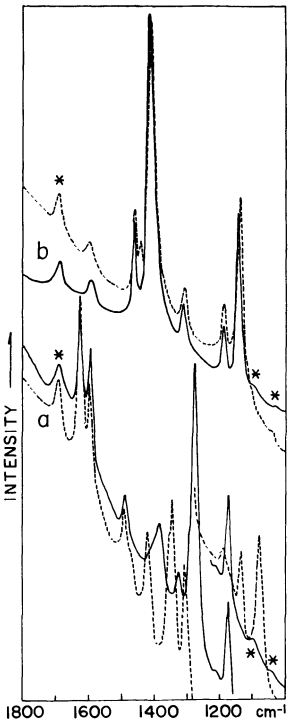

Fig. 4. Resonance Raman spectra of AAB: (a) 5×10^{-4} M in a 1:4 mixture of acetone-d_6 and 0.1M HCl (solid line) and in a 1:4 mixture of acetone-d_6 and 0.1M DCl (broken line), 488.0 nm; (b) 5×10^{-3} M in a 1:4 mixture of acetone-d_6 and water (solid line) and in a 1:4 mixture of acetone-d_6 and heavy water (broken line), 488.0 nm.

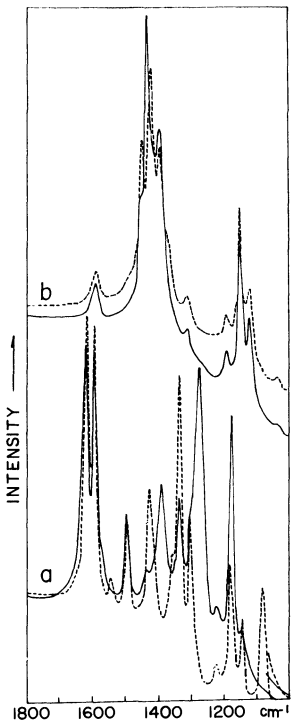

Fig. 5. Resonance Raman spectra of TOO: (a) 1×10^{-4} M in 0.1M HCl (solid line) and in 0.1M DCl (broken line), 514.5 nm; (b) 5×10^{-4} M in water (solid line) and in heavy water (broken line), 488.0 nm.

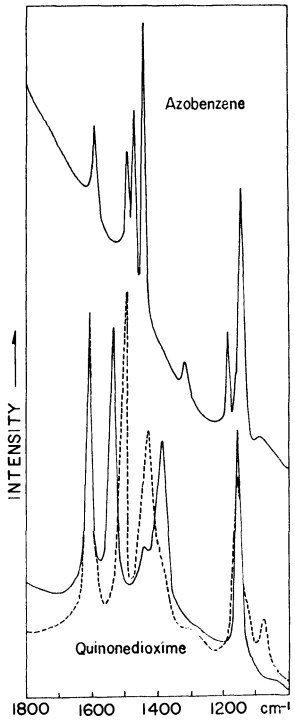

Fig. 6. Resonance Raman spectrum (488.0 nm) of azobenzene in methanol-d_6 (1×10^{-2} M) and Raman spectra (514.5 nm) of solid sample of quinone dioxime (solid line) and its *O*-deuterated compound (broken line).

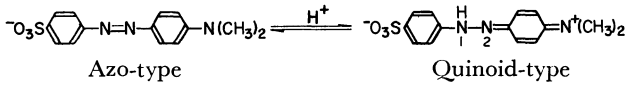
The concentration dependence of the Raman intensities was briefly surveyed for MO between 1×10^{-7} M and 1×10^{-3} M, and the optimum concentration was found to be about 1×10^{-4} M for the acid form excited by the 514.5 nm and the 488.0 nm lines and about 3×10^{-4} M for the base form excited by the 488.0 nm line. For the base form, a little higher concentration (about 1×10^{-3} M) was found suitable when the 514.5 nm line was used. The change in the relative intensities of Raman bands on changing the excitation wavelength from 488.0 nm to 514.5 nm was not appreciable and was left out of detailed examination. At the concentrations investigated, no detectable spectral change due to the thermal effect or the decomposition was observed on the prolonged exposure of the samples to the excitation beam. The representative Raman spectra are shown in Figs. 1—6.

The electronic spectra between 380 and 600 nm were recorded on a Shimadzu W-40 spectrophotometer for the same solutions of the indicators as those used for the Raman measurement by using a cell of 1 mm path length. The absorption maxima obtained are given in Table 1. They are essentially the same as those in literatures. The electronic spectra of the indicators in the deuterated solutions, either acidic or basic, were identical with those for the corresponding undeuterated solvents. The infrared spectra of solid samples of diazoaminobenzene and its *N*-deuterated compound were recorded on a JASCO DS-301 infrared spectrophotometer for Nujol or hexachlorobutadiene mulls (Fig. 7).

Results and Discussion

The yellowish color of any *p*-aminoazobenzene type indicator in a neutral or a basic solution changes to a reddish color when the solution is acidified to a pH below the color-change interval of the indicator. This color change has been attributed to a change of the molecular structure from an azo-type to a quinoid-type with the protonation to the azo group as shown in



Azo-type Quinoid-type

Chart 1

Chart 1.[3,6] Such a structure change is expected to give rise to a marked change in the resonance Raman spectra, in which the band intensity is often enhanced for the group vibrations participating in the resonant electronic transition. Previously, Hacker investigated the resonance Raman spectra of a number of azo compounds among which MO in water and MR, AAB, and AB in methanol and CCl_4 were included.[1] The presently recorded spectra for the neutral to alkaline solutions of these compounds are essentially the same as Hacker's result, except the N=N stretching frequency ($\nu_{N=N}$) of MR, for which the present value is about 40 cm^{-1} lower than Hacker's value. Table 2 summarizes the characteristic Raman frequencies of the base form identified by referring to the previous works on the vibrational spectra of azobenzene derivatives.[1,7] By the revision of $\nu_{N=N}$ of MR, a correlation between $\nu_{N=N}$ and the nature of the *p*-substituent was revealed. If we take the $\nu_{N=N}$ of MO to be the mean value of the doublet frequencies 1395 and 1420 cm^{-1}, the substituents arranged in the decreasing order of $\nu_{N=N}$,

$$H- > C_6H_5NH- > NH_2- > (CH_3)_2N-$$

follow well the order that both the electron donating effect and the pH of the color-change interval (Table 1) increase.

Table 2. Observed frequencies (cm^{-1}) and assignments for the base form

$\Delta\nu = \nu$ (in the ordinary solvent) $-\nu$(in the deuterated solvent)

The deuteration of the solvent gives no change in the resonance Raman spectra of the base form of MO, MR, and MY as expected from the azo structure of these indicators containing no active hydrogen. The base form of TOO and AAB in the deuterated solvent gives essentially the same spectra as those in the undeuterated solvent, but the $\nu_{N=N}$ of these compounds are affected a little on the deuteration of the NH or NH_2 group, suggesting a slight coupling of this vibration with the ND or ND_2 deformation vibrations (Figs. 4 and 5).

The resonance Raman spectrum of MO in the 0.1M HCl solution is completely different from that in the neutral solution as shown in Fig. 1. When the pH is adjusted close to the pK_a of MO (3.4 at 25 °C),[8] an intermediate spectral feature between the acid and the base forms is observed in accord with the color change in the visible region (Fig. 1c). The acid form shows no strong Raman band assignable to the N=N stretching vibration near 1420 cm^{-1}, but shows a very strong Raman band at 1624 cm^{-1}, which may be assigned to a stretching vibration of the ring C=C bonds of the quinoid structure. This frequency, however, is appreciably lower than the C=C symmetric stretching frequency of *p*-quinone (1667 cm^{-1} [9,10]), and it is desirable to clarify how far the latter may diminish on replacing both the C=O groups by the C=N– groups. Since the Raman spectra of quinonediimine-like compounds were not found in literatures, we examined the Raman spectra of quinone dioxime and its *O*-deuterated compound, regarding them as the simplest reference compounds. As shown in Fig. 6, quinone dioxime exhibits two strong Raman bands at 1617 and 1544 cm^{-1} assignable to the symmetric C=C and C=N stretching vibrations, respectively. The low-frequency shift of the latter on the *O*-deuteration is quite analogous to the case of the C=N stretching band in the infrared spectrum of quinone monoxime reported by Hadži.[11] Based on this result, the characteristic 1624 cm^{-1} band of MO can be assigned to the C=C stretching vibration. The absence of any strong band assignable to the C=N stretching vibration in the resonance Raman spectrum of MO may be due to the difference either in the substituents on the nitrogen atoms between MO and quinone dioxime or in the sensitivity to the resonance enhancement between the C=C and the C=N stretching vibrations.

The quinoid structure shown in Chart 1 has an active hydrogen atom attached on N_1. If the acid form of MO takes such a structure, the deuteration of this hydrogen by a simple exchange reaction may give rise to a change in the resonance Raman spectrum. In agreement with this expectation, MO in 0.1M DCl shows a much different spectrum from that in 0.1M HCl in the region between 1400 and 1000 cm^{-1} (Fig. 2). In order to clarify the difference in the vibrational frequencies between the Ph–NH–N= and the Ph–ND–N= groups, we examined the effect of the *N*-deuteration on the infrared spectrum of diazoaminobenzene, C_6H_5–NH–N=N–C_6H_5. For this compound, reliable assignments of the Ph–NH–N= group frequencies have been made on the basis of a detailed analysis of various N^{15} isotope shifts in the infrared spectra,[7] but the vibrational spectra of the *N*-deuterated diazoaminobenzene have not yet been reported. Unfortunately, the Raman spectra of diazoaminobenzene could not be recorded because of a very strong fluorescence. According to Kübler *et al.*,[7] the infrared bands at 1520 and 1248 cm^{-1} of diazoaminobenzene arise from the N–H deformation and the Ph–N stretching vibrations, respectively. As shown in Fig. 7, both these bands disappear on the *N*-deuteration, and new bands arising possibly from a coupling which may involve the Ph–N stretching and the N–D deformation vibrations are observed at 1364, 1105, and 1068 cm^{-1} for diazoaminobenzene-*d*. Correspondingly, the resonance Raman band at 1272 cm^{-1} of the acid form of MO is replaced by three bands at 1338, 1145, and 1076 cm^{-1} on changing the solvent from 0.1M HCl to 0.1M DCl. This result is a strong support to the presence of a Ph–NH–N= group in the acid form of MO.

The resonance Raman spectra of MR and MY show marked changes analogous to the case of MO

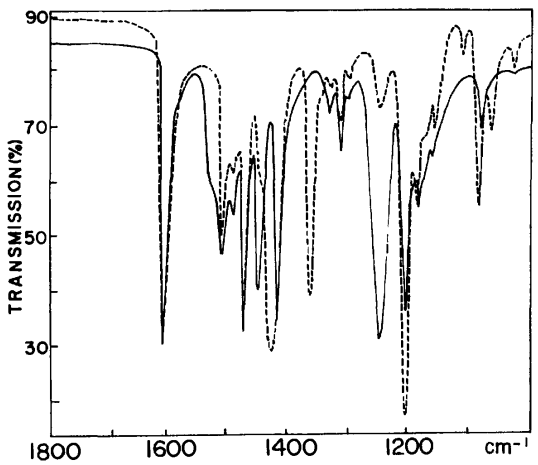

Fig. 7. Infrared spectra of diazoaminobenzene (solid line) and its *N*-deuterated compound (broken line).

not only on the color change from the base form to the acid form but also on the deuteration of the latter. Besides the strongest C=C stretching band around 1620 cm^{-1} and the deuteration sensitive Ph–N stretching band around 1270 cm^{-1}, four bands around 1600, 1500, 1380, and 1180 cm^{-1} are commonly observed for the undeuterated acid forms of MO, MR, and MY. The 1600 and 1500 cm^{-1} bands, which persist in the 0.1M DCl solution, may be assigned to the benzene ring vibrations. The origin of the 1380 cm^{-1} band, which is very weak but is clearly recognized from its disappearance on the *N*-deuteration, is not obvious at this stage. A possible interpretation of this band will be given later. The 1180 cm^{-1} band seems to be the counterpart of the infrared band at 1202 cm^{-1} of diazoaminobenzene due to the N–N stretching vibration,[7] since no effect of the *N*-deuteration is observed in either case. For the quinoid structure of MR, an acid-base equilibrium was suggested from the pH gradient thin layer chromatography.[12] We accordingly measured the resonance Raman spectrum of the acid form of MR at various pH's below the color change interval, and observed a little spectral change around 1400 and 1200 cm^{-1} accompanying the pH change (Fig. 2). This result supports the existence of the equilibrium shown in Chart 2, since the coupled vibrations of the C–O stretching and the OH deformation vibrations of the COOH group[13] and the symmetric stretching vibration of the CO_2^- group[14] are expected to give Raman bands around these frequencies.

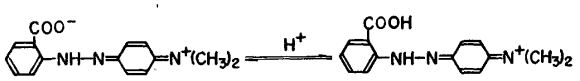

Chart 2

The acid forms of TOO and AAB show similar resonance Raman spectra to that of MO. On changing the solvent from 0.1M HCl to 0.1M DCl, the spectra of these compounds change complicatedly as shown in Figs. 4 and 5, but the characteristic features of the spectral change observed for MO, MR, and MY are recognized also for these compounds. Both TOO and AAB show a band around 1390 cm^{-1} which is replaced by a band around 1430 cm^{-1} on going to the 0.1M DCl solution. The disappearance of the 1390 cm^{-1} band on the *N*-deuteration suggests a common nature between this band and the weak 1380 cm^{-1} band of MO, MR, and MY mentioned above. The high-frequency shift of the latter seems to be obscured by the overlap of a band near 1410 cm^{-1} attributable to the N–CH_3 group. For quinone dioxime, an analogous shift of a Ramanb and from 1391 cm^{-1} to 1439 cm^{-1} is observed on the *O*-deuteration. Probably, this band of quinone dioxime corresponds to the b_{1g} C–C stretching band of *p*-quinone[9] and the 1390 cm^{-1} band of TOO and AAB as well as the 1380 cm^{-1} band of MO, MR, and MY may be interpreted on the same basis. The proposed assignments of the resonance Raman bands of the acid form are summarized in Table 3.

According to the present assignment, the quinoid ring C–C stretching frequency for each of the undeuterated and the deuterated acid form increases in almost the same order as the $\nu_{N=N}$ of the base form. This trend is reasonable since both the azo N=N and the quinoid ring C–C bond orders increase on the increase of the azo-type character of the conjugate system, and the electron donation from the amino-nitrogen to the ring opposes this change. For the suructure of the acid form, a resonance hybrid between the quinoid-type and the protonated azo-type has been postulated, the latter being pictured as the azo-type with a hydrogenated and positively charged nitrogen,[15,16] *p*-$(CH_3)_2N$–C_6H_4–N=N$^+$H–C_6H_4–SO_3^-. The resonance Raman spectra of the acid form as revealed in this work indicate that the quinoid-type is much predominant over the azo-type in this resonance, if any. As suggested by the behavior of the C–C stretching frequency, however, the contribution of the azo-type is not entirely excluded at present. More knowledge on the vibrations of both the quinoid- and azo-type structures seems to be necessary to deal with this hybridization quantitatively.

We wish to thank Professor H. Tanaka for helpful discussions and for the use of the W-40 spectrophotometer.

Dielectric Relaxation and Molecular Structure. VIII. Dielectric Relaxation of Alkyl Acetates in Benzene Solution

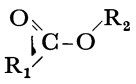
Yoshinori KOGA, Hiroaki TAKAHASHI, and Keniti HIGASI

School of Science and Engineering, Waseda University, Shinjuku, Tokyo 160

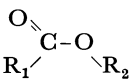
(Received October 1, 1973)

Dielectric constants and losses at the microwave frequency of 96.52 GHz have been measured at 25 °C for methyl, ethyl, *n*-butyl, isobutyl, *s*-butyl, *t*-butyl, *n*-amyl, isoamyl, *n*-hexyl, and *n*-octyl acetates in benzene solutions. Static dielectric constants, refractive indices and densities have also been measured. The effective mean relaxation times of normal alkyl acetates increase with increasing chain length of the alkyl radical, eventually approaching a steady value. The distribution parameters α of all these molecules seem to have appreciable values which may be due to various segment orientations by internal rotation.

According to Wheland[1] the esters of carboxylic acids provide an example with which there appears to be little, if any, freedom of rotation about the bond that links the carbon atom of the carbonyl group to the oxygen atom of the alkoxyl group. If this C–O bond has no freedom of rotation at all, the molecule will have only two planar configurations I (*trans*) and II (*cis*).



I (*trans*)



II (*cis*)

From this viewpoint Marsden and Sutton[2] reached a conclusion from dipole moment measurements that the *trans* form (I) would be more stable than the *cis* form (II).

Williams, Owen, and Sheridan[3] studied the molecular configuration of methyl acetate, *i.e.* $R_1=R_2=CH_3$ by means of microwave spectroscopy and showed that it has the *trans* planar configuration. And methyl and ethyl formates were also shown by microwave spectroscopy[4,5] to exist only in the *trans* planar form. On the other hand Karpovitch[6] suggested the existence of two isomers I and II based on his results of ultrasonic absorption measurements. By use of various spectroscopic methods Ōki and Nakanishi[7] examined the possibility of having two isomers and found that the *cis* conformation, which is very much stabilized in some special cases, does not exist in a great majority of alkyl acetates.

The results of electron diffraction are puzzling because O'Gorman, Shand, and Shomaker[8] showed that the structures of methyl acetate and methyl formate are not perfectly *trans* planar but slightly twisted, that is, the R_2–O bond makes an average dihedral angle 25° with the O=C–R_1 plane of the molecule. They suggested as one of the possibilities that a rather wide oscillation occurs about the completely planar *trans* configuration for these molecules.

The present work was undertaken in order to make a systematic study of dielectric behavior of alkyl acetates in solution and also to examine the aspect of internal motion in these molecules. The molecules examined are ten alkyl acetates, *i.e.* $R_1=CH_3$ and $R_2=C_nH_{2n+1}$, $n=1, 2\cdots8$.

Experimental

All compounds used in this study were obtained from commercial sources. Further, they were purified by distillation after drying over Molecular Sieve 4A for 24 hours. The apparatus and the experimental technique for dielectric measurements of the free-space method at 100 GHz employed in this work were described in a previous paper.[9] Static dielectric constants at 1 MHz were measured by the heterodyne beat method and refractive indices for sodium D-line were measured with use of a Pulfrich refractometer.

Results

The values of the so-called "slopes" a_0, a', a'', a_D, and b obtained in this experiment for alkyl acetates in benzene solutions are shown in Table 1. The definition of these slopes is given by Eqs. (1) and (2). The dielectric constants ε' and losses ε'' of the dilute solutions are linear functions of the concentration (weight fraction w_2) of the solute.

Table 1. Slopes a', a'' obtained at 96.52 GHz in benzene (25 °C) and a_0, a_D and b

Substance	a_0	a'	a''	a_D	b
Methyl acetate	3.989	1.227	1.321	−0.412	−0.055
Ethyl acetate	3.722	0.757	0.972	−0.410	−0.018
n-Butyl acetate	2.963	0.449	0.563	−0.352	−0.002
Isobutyl acetate	2.951	0.466	0.589	−0.336	0.017
s-Butyl acetate	2.942	0.287	0.460	−0.370	0.021
t-Butyl acetate	3.122	0.264	0.632	−0.363	0.022
n-Amyl acetate	2.648	0.348	0.493	−0.312	0.009
Isoamyl acetate	2.606	0.351	0.470	−0.337	0.019
n-Hexyl acetate	2.347	0.331	0.416	−0.301	0.017
n-Octyl acetate	1.909	0.202	0.311	−0.270	0.024

$$\varepsilon' = \varepsilon_1' + a'w_2$$
$$\varepsilon'' = a''w_2 \qquad (1)$$

in which subscripts 1 and 2 refer to the pure solvent and to the solute, respectively. Similarly, the static dielectric constants, ε_0, the infinite dielectric constants (the dielectric constants at high-frequency limit), ε_∞, the square of refractive indices, n_D, (for the sodium D-line), and the specific volumes, v, are also assumed to be linear with the concentration.

$$\varepsilon_0 = \varepsilon_{10} + a_0 w_2, \quad \varepsilon_\infty = \varepsilon_{1\infty} + a_\infty w_2$$
$$n_D^2 = n_{1D}^2 + a_D w_2, \quad v = v_1 + b w_2 \tag{2}$$

The total molar polarization ${}_\infty P_2$, the distortion polarization P_A+P_E, the molecular refraction R_D and the dipole moment μ together with the literature values are recorded in Table 2. The total molar polarization of the solute at infinite dilution ($w_2 \to 0$) was obtained from the Halverstadt-Kumler equation.[10]

Table 2. Total molar polarizations ${}_\infty P_2$, molecular refraction R_D, and dipole moments μ of alkyl acetates in benzene at 25 °C with the literature values

Substance	${}_\infty P_2$ [cm³]	R_D [cm³]	μ [a)] [D]	μ (lit[b)]) [D]
Methyl acetate	79.6	17.8	1.72	1.77
Ethyl acetate	91.2	22.2	1.82	1.83
n-Butyl acetate	104.3	31.1	1.87	1.87
Isobutyl acetate	104.7	32.1	1.86	1.89
s-Butyl acetate	104.6	31.5	1.87	—
t-Butyl acetate	108.6	31.7	1.92	1.93 (22 °C)
n-Amyl acetate	109.6	36.3	1.87	1.93
Isoamyl acetate	108.9	36.0	1.86	1.8
n-Hexyl acetate	113.5	40.8	1.86	—
n-Octyl acetate	121.8	50.0	1.84	—

a) $\mu = 0.0128\sqrt{({}_\infty P_2 - 1.05R_D)T}$

b) A. L. McClellan, "Tables of Experimental Dipole Moments," W. H. Freeman and Co., San Francisco and London (1963).

$${}_\infty P_2 \simeq M_2\left\{\frac{3a_0v_1}{(\varepsilon_{10}+2)^2} + (v_1+b)\frac{\varepsilon_{10}-1}{\varepsilon_{10}+2}\right\} \tag{3}$$

in which M_2 is the molecular weight of the solute. The distortion polarization P_A+P_E is obtained by using a_∞ and $\varepsilon_{1\infty}$ instead of a_0 and ε_{10} in Eq. (3), respectively.[11]

$$P_A + P_E \simeq M_2\left\{\frac{3a_\infty v_1}{(\varepsilon_{1\infty}+2)^2} + (v_1+b)\frac{\varepsilon_{1\infty}-1}{\varepsilon_{1\infty}+2}\right\} \tag{4}$$

Similarly, the molecular refraction for the D-line is given by

$$R_D \simeq M_2\left\{\frac{3a_D v_1}{(n_{1D}^2+2)^2} + (v_1+b)\frac{n_{1D}^2-1}{n_{1D}^2+2}\right\} \tag{5}$$

The dielectric relaxation times $\tau(1)$, $\tau(2)$, and τ_0 and the distribution parameter α are shown in Table 3. The relaxation times $\tau(1)$ and $\tau(2)$ were calculated from the following equations[12]

$$\tau = \frac{1}{\omega}\frac{a''}{a'-a_\infty} \equiv \tau(1) \tag{6}$$

$$\tau = \frac{1}{\omega}\frac{a_0-a'}{a''} \equiv \tau(2) \tag{7}$$

on the assumption of a single Debye relaxation. On the other hand, if the system is not of the single relaxation but of the multi-relaxation times which follow Cole-Cole's[13] rule, Eq. (8) will become valid instead.

$$a^* = a' - ja'' = a_\infty + \frac{a_0-a_\infty}{1+(j\omega\tau_0)^{1-\alpha}} \tag{8}$$

The probable relaxation time τ_0 and the distribution parameter α are estimated by measurements of a' and a'' at a single frequency.[14]

$$\tau_0 = \frac{1}{\omega}\left\{\frac{A^2+B^2}{C^2}\right\}^{(1-\alpha)/2} \tag{9}$$

$$1-\alpha = \frac{2}{\pi}\tan^{-1}\left(\frac{A}{B}\right) \tag{10}$$

where

$$A = a''(a_0-a_\infty)$$
$$B = (a_0-a')(a'-a_\infty) - a''^2 \tag{11}$$
$$C = (a'-a_\infty) + a''^2$$

The term a_∞ which we find in Eqs. (6) and (11) may be estimated in the following way. Assuming the familiar assumption of $P_A+P_E \simeq 1.05R_D$ for the dipole moment work to be valid, we shall obtain probable but tentative values of a_∞ from Eqs. (4) and (5). That is,

$$a_\infty = \frac{(\varepsilon_1'+2)^2}{3v_1}\left\{\frac{1.05R_D}{M_2} - (v_1+b)\frac{\varepsilon_1'-1}{\varepsilon_1'+2}\right\} \tag{12}$$

where $\varepsilon_{1\infty} \simeq \varepsilon_1'$ for non-polar solvent is assumed. The probable relaxation time τ_0 is found to be nearly equal to the geometrical mean, $\sqrt{\tau(1)\tau(2)}$, of $\tau(1)$ and $\tau(2)$. (See Table 3.)

Table 3. Dielectric relaxation times $\tau(1)$, $\tau(2)$ and τ_0 and distribution parameters α and a_∞ obtained from Eq. (12) on the assumption of $P_A+P_E \simeq 1.05\ R_D$

Substance	a_∞	$\tau(1)$ [ps]	$\tau(2)$ [ps]	$\sqrt{\tau(1)\tau(2)}$ [ps]	τ_0 [ps]	α

n-Octyl acetate	−0.228	1.2	9.1	3.3	3.0	0.49

Discussion

Among the observed dipole moments of ten alkyl acetates in benzene solutions recorded in Table 2, those for *s*-butyl acetate (1.87 D), *n*-hexyl acetate (1.86 D) and *n*-octyl acetate (1.84 D) are new values; and all the moments (1.72—1.92 D) are in good agreement with literature values.

The dielectric relaxation time of methyl acetate in benzene has been given by Krishna[15] to be 2.2 ps at 28 °C, by Cripwell and Sutherland[16] 3.73 ps at 18.5 °C and Whiffen and Thompson[17] 3.1 ps at 19 °C. The average relaxation time of methyl acetate τ_0 obtained in this study is 2.1 ps, which is near to Krishna's value. The observed relaxation time for ethyl acetate $\tau_0 = 2.7$ ps in benzene solution is smaller than 4.4 ps in liquid at 20 °C by Smyth *et al.*[18]

Three relaxation times, $\tau(1)$, $\tau(2)$, and τ_0 of normal alkyl acetates are plotted against the carbon number

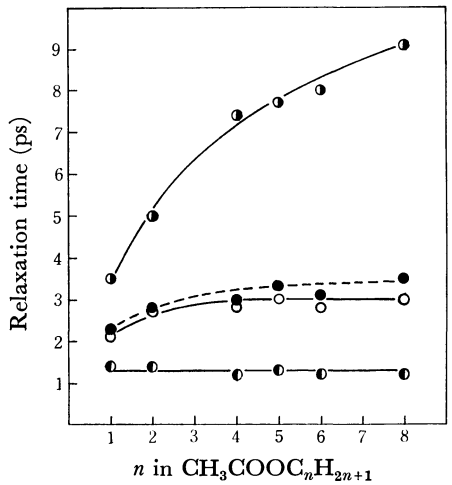

Fig. 1. The dependence of the relaxation times $\tau(1)$, $\tau(2)$, τ_0 and τ_0' upon the carbon number (n) of the alkyl radical (R_2) in normal alkyl acetates.
◐: $\tau(1)$, ◑: $\tau(2)$, ○: τ_0, ●: τ_0'.

(n) of the alkyl radical, R_2. (See Fig. 1.) The increase in the carbon number (n) of the alkyl radical is accompanied with a large increase in $\tau(2)$ while it gives little effect upon $\tau(1)$. The most probable relaxation time τ_0 from the Cole-Cole equation based on the assumption $P_A+P_E\simeq 1.05\,R_D$ are also plotted in Fig. 1. For the sake of comparison the values τ_0' calculated on $P_A+P_E\simeq 1.10\,R_D$ are shown in the same figure by a broken line—the latter relaxation times are denoted by τ_0' in order to distinguish from τ_0 based on $P_A+P_E\simeq 1.05\,R_D$. Both τ_0 and τ_0' values increase with increasing chain length of the alkyl radical and eventually approach steady values of 3.0 and 3.5 ps, respectively. The above tendency, if it is true, could be explained by supposing that with long alkyl chains the dipole can rotate more or less freely without much affecting the other end of the chain to which it is attached.

According to the analysis[19] of the systems with two Debye dispersions, $\tau(1)$ obtained at a very high frequency *e.g.* 100 GHz is slightly larger than the shorter relaxation time, while $\tau(2)$ is a weighted mean of the two relaxation times and then the longer relaxation time becomes important. Although the present system seems to have more than two dispersions, the above results can be used in a qualitative manner. It is striking to notice that $\tau(1)$ for all the alkyl acetates have values between 1.2—1.4 ps which correspond to the relaxation time for a very small rotating unit. Contrary to $\tau(1)$, the other average relaxation time $\tau(2)$ regularly increases with increasing chain length, which may suggest that molecular rotation as a whole could occur to a certain extent. As shown before the probable relaxation time τ_0 approximates a geometrical average of $\tau(1)$ and $\tau(2)$ and its distribution parameter α increases with increasing chain length (see Table 3).

The free energy of activation ΔF^* can be calculated from the relaxation time τ by the following equation

$$\Delta F^* = 2.303RT\log\frac{kT\tau}{h} \qquad (13)$$

Table 4. Free energy of activation ΔF^* and heat of activation ΔH^* on the assumption of $\tau=\tau_0$ and $\Delta S^*=-1$ e.u.

Substance	ΔF^* (kcal/mol)	ΔH^* (kcal/mol)
Methyl acetate	1.52	1.22
Ethyl acetate	1.66	1.36
n-Butyl acetate	1.69	1.39
Isobutyl acetate	1.70	1.40
s-Butyl acetate	1.76	1.46
t-Butyl acetate	1.85	1.55
n-Amyl acetate	1.74	1.44
Isoamyl acetate	1.71	1.41
n-Hexyl acetate	1.70	1.40
n-Octyl acetate	1.73	1.43

where R is the gas constant and T is the absolute temperature and k, h are Boltzmann and Planck constants. Assuming τ is equal to τ_0, ΔF^* are estimated to have 1.5—1.9 kcal/mol for all the alkyl acetates. (See Table 4.)

The heat of activation is given by

$$\Delta H^* = \Delta F^* + T\Delta S^* \qquad (14)$$

The values ΔH^* recorded in Table 4 are obtained from ΔF^* on a very tentative assumption[20] $\Delta S^*=-1$ e.u. for all the acetates—it will be expected that ΔS^* will increase with increasing chain length, thus ΔH^* will become much larger. If $\tau(1)$ is used instead of τ_0, ΔF^* would become 1.2—1.3 kcal/mol and $\Delta H^*=0.9$—1.0 kcal/mol.

The observed dipole moments of alkyl acetates are 1.72—1.92 D, which are between those calculated for the *trans* 1.64 D and the *cis* 3.51 D. Consequently we may infer that the *cis* configuration is not completely ruled out but there are a small amount (3—10%) of the *cis* isomers present. Smyth[21] favored a view that a wide oscillation occurs about the *trans* position. From this viewpoint it is found that the average twisted configuration out of the *trans* position would have a dihedral angle 20—38°. Lastly there is the remaining possibility that the *trans* planar configuration alone exists with the observed polarity.[2]

From the probable dielectric relaxation times τ_0 and the distribution parameters α obtained in this work, we shall be able to say that all the alkyl acetates have multiple relaxation times and they have flexible and nonrigid configurations. The small value $\tau(1)=1.2$—1.4 ps suggests a small unit of rotation or a very small barrier for the rotating polar group. Estimated values of both ΔF^* and ΔH^* (using τ_0) are also small in magnitude compared with the size of the molecule.

In the present work a_∞ is very tentatively estimated on the assumption of $P_A+P_E\simeq 1.05\ R_D$. Alternatively, if the assumption of single Debye dispersion is valid, we can calculate a_∞ from[9]

$$a_\infty = a_G = a' - \frac{(a'')^2}{a_0-a'} \qquad (15)$$

and if Eq. (15) is used in acetates, we shall find both $\tau(1)$ and τ_0 to be equal to $\tau(2)$ and hence $\alpha=0$. However, the use of $a_\infty=a_G$ would result in a considerably

large atomic polarization which is inconsistent with experimental data. It seems that Eq. (15) is invalid and the dielectric system of acetates in benzene has multi-relaxation times.

We thank Professor Mansel Davies, the University College of Wales, for his interest in this work and also for correcting errors of English in this manuscript. We are also grateful to Toray Science Foundation for financial aids.

Theoretical Considerations of Lower Excited States of *trans*-Polyene Carbaldehydes. I. Electronic Structure and Oscillator Strength of π-π^* Transition

Kozo INUZUKA and Ralph S. BECKER*

Tokyo Electrical Engineering College, Kanda, Chiyoda-ku, Tokyo 101

**Department of Chemistry, University of Houston, Houston, Texas 77004, U.S.A.*

(Received July 9, 1973)

The lower n,π^* and π,π^* excited state energies of four *trans*-polyenecarbaldehydes, acrolein, 2,4-pentadienal, 2,4,6-heptatrienal, and 2,4,6,8-nonatetraenal, were calculated within the framework of the conventional P-P-P SCF-MO-CI method and then discussed. Also, the oscillator strength for the π-π^* transition was obtained in terms of the dipole length and the dipole velocity.

So far systematic studies of the electronic properties of polyenecarbaldehydes have been relatively rare. Among them, only two compounds, acrolein,[1-4] which is a fundamental molecule of this series, and retinal[5-10] which corresponds to 2,4,6,8,10-dodecapentaenal in the skeletal structure of the π-electron system, have been well studied both experimentally and theoretically in terms of their electronic properties. The purpose of this investigation was to study theoretically the properties of the lower electronic states of certain *trans*-polyenecarbaldehydes, that is, acrolein, 2,4-pentadienal, 2,4,6-heptatrienal, and 2,4,6,8-nonatetraenal. In this series we want to discuss the following three subjects from a theoretical point of view; (i) the electronic structure of the lower n,π^* and π,π^* states of *trans*-polyenecarbaldehydes and their oscillator strengths for π-π^* transition, (ii) their emission spectra, and (iii) their triplet-triplet transition and oscillator strength.

In this investigation the lower n,π^* and π,π^* excited-state energies of four *trans*-polyenecarbaldehydes were calculated within the framework of the conventional P–P–P SCF–MO–CI method[11,12] and then discussed. Also, their oscillator strengths for the π-π^* transition were obtained in terms of the dipole length and the dipole velocity.[13-15] These results were then compared with the experimental values.

Method of Calculation

Electronic Structure. The following numerical values[16] were assumed for the skeletal structure of the four polyenecarbaldehydes in the present paper: 1.36 Å for the carbon double bond, 1.46 Å for the single bond, and 1.22 Å for the carbonyl group. Moreover, the value of 120° was assigned to the ∠CCC and ∠CCO bond angles. *Only the trans and planar skeletal structures were taken into account.*

All the calculations were carried out within the framework of the general semi-empirical SCF-MO-CI method,[11,12] and the Pariser-Parr approximation[11] was used for the π-electron repulsion integrals, with Z_c= 3.25 and Z_o=4.55. All the penetration terms were neglected. The resonance integral for the nearest neighbor carbon atom was treated as a parameter, and the values of −2.50 and −2.30 eV were used for the carbon double and single bonds respectively. The resonance integral value for the carbonyl group was obtained by means of Kon's equation,[17] and the value of −2.67 eV was used for all the polyenecarbaldehydes. The n,π^* and π,π^* state energies were calculated including all singly-excited configurations.

On the other hand, Sidman[18] carried out n,π^* state energy calculations for the several carbonyl molecules within the framework of the P-P-P SCF-MO-CI method. He assumed that the energy of the *n*-orbital of the carbonyl molecule is constant, and −10.50 eV was assigned to the *n*-orbital energy of carbonyl molecule. In this paper, the *n*-orbital on the oxygen atom is assumed to be a 2pπ atomic orbital,[19] and its energy, ε_n, was calculated by means of the following equation:[19,20]

$$\varepsilon_n = U_n + \sum_{\mu \neq o}(P_{\mu\mu}-1)\gamma_{\mu n} + (P_{oo}-1)(\gamma_{no}-\delta_{no}/2) \quad (1)$$

The two one-center integrals concerning the oxygen atom, γ_{no} and δ_{no}, represent $\langle n_o\pi_o|r_{12}^{-1}|n_o\pi_o\rangle$ and $\langle n_o\pi_o|r_{12}^{-1}|\pi_o n_o\rangle$ respectively. The value of 12.865 eV[18] was used for the former integral, while the value of 0.903 eV[21] was assigned to the latter one. The $\gamma_{\mu n}$ is a two-center atomic repulsion integral between the π-electron of the carbon atom, μ, and the *n*-electron of the oxygen atom. The $\gamma_{\mu n}$ was calculated by means of the usual Pariser-Parr approximation.[11] U_n is treated as a parameter for the *n*-electron orbital energy. The calculated n,π^* singlet state energy of acrolein was adjusted to the corresponding observed value for acrolein by means of parameter, U_n, and the value of −15.25 eV was assigned to it. In a previous paper,[19] the value of −14.75 eV[22] was used for U_n, but this value brought about a lower value in the n,π^* singlet-state energy than the value observed in the case of the P–P approximation.

Oscillator Strength of the π-π^* Electronic Transition. A. Transition Density: In MO theory, the transition probability is related to the transition density, ρ. In the absence of degeneracy, the transition density for an allowed singlet absorption from a closed-shell ground state to an upper state is given by:

$$\rho = \sqrt{2}\,\phi_i\phi_j \quad (2)$$

where ϕ_i and ϕ_j are the molecular orbitals concerning an electron excitation. Expressing the molecular orbitals as linear combinations of atomic orbitals:

$$\phi_j = \sum_t c_{tj}\chi_t \quad (3)$$

one gets the transition density matrix, ρ, in the atomic

orbital basis with elements:

$$\rho_{st} = \sqrt{2}\, c_{st} c_{tj} \tag{4}$$

The transition moment becomes:

$$M = \sum_s \sum_t \rho_{st} m_{st} \quad \text{where } m_{st} = \langle \chi_s | r | \chi_t \rangle. \tag{5}$$

In an analogous manner, the transition gradient is:

$$D = \sum_s \sum_t \rho_{st} d_{st} \quad \text{where } d_{st} = \langle \chi_s | \text{grad} | \chi_t \rangle. \tag{6}$$

The oscillator strengths, f_1 and f_2, are given by Eqs. (7) and (8):

$$f_1 = 1.085 \times 10^{11} \nu M^2 \tag{7}$$

$$f_2 = 1.465 \times 10^5 D^2/\nu \tag{8}$$

where ν is in wave number and where the integral is expressed in atomic units. In the present calculation, the f_1 oscillator strength is represented in terms of the conventional dipole length assuming a zero-differential overlap.

B. Transition Gradient Integral: In Cartesian coordinates in terms of the unit vectors, **i**, **j**, and **k**, the transition gradient integral between 2pπ atomic orbitals, a and b, is expressed by Eq. (9):

$$\langle a | \sum_j \nabla_j | b \rangle = (\mathbf{i} \cos x_{ab} + \mathbf{j} \cos y_{ab} + \mathbf{k} \cos z_{ab}) V_{ab} \tag{9}$$

where $\cos x_{ab}$ is the direction cosine of the directed line connecting the atom a to the atom b with respect to the x axis. Similarly for y and z, V_{ab} is the absolute value of the $\langle x_a | \nabla | x_b \rangle$. The only component which contributes to the integral, V_{ab}, is the one directly along the bond from the atom a to the atom b, because of the symmetry of the 2pπ atomic orbital, the value of the intergral remains unchanged by reflection in the plane perpendicular to the orbital axis.

Let the molecule lie on the y z plane and let the 2pπ atomic orbital be along the x-axis. Then, the 2pπ atomic orbital of the q atom is:

$$\chi_q = (\mu_q^5/\pi)^{1/2} r \exp(-\mu_q r) \sin\theta \cos\phi \tag{10}$$

The μ_q corresponds to the Slater-μ-value of the orbital exponent of the q atom. In the present calculation, the values of 1.625 and 2.275 were used as the Slater-μ-values for the carbon and oxygen atoms respectively. The z axis is taken directly along the bond from the a atom to the b atom. The z component of the gradient primitive integral is:

$$V_{ab} = \langle \chi_a | \partial/\partial Z | \chi_b \rangle \tag{11}$$

Then,

$$V_{ab} = -\mu_b \langle \chi_a | z/r | \chi_b \rangle \tag{12}$$

The integral (12) was transformed into elliptical coordinates[23] after the substitution of the atomic orbital (10); it was evaluated as follows:

$$V_{ab} = -\mu_b (R/2)^5 (\mu_a \mu_b)^{5/2} \{(B_1 - B_3)(A_4 - 2A_2 + A_0) + (B_4 - 2B_2 + B_0)(A_1 - A_3)\} \tag{13}$$

In the case of $t=0$, Eq. (12) may be simplified as follows:

$$V_{ab} = -\mu_b (p/5)(1 + p + p^2/3) \exp(-p) \tag{14}$$

where

$$p = (1/2)(\mu_a + \mu_b) R/a_0, \quad t = (\mu_a - \mu_b)/(\mu_a + \mu_b) \tag{15}$$

R is the bond distance between the a and b atoms, and a_0 is the Bohr radius (0.529 Å).

Results and Discussion

The calculated results of the π,π^* state energy and the oscillator strength of the present polyenecarbaldehydes are shown in Table 1, along with their calculated n,π^* state energies. The calculated values for the lowest singlet and triplet states are plotted in Fig. 1. The calculated n-π^* transition energies for the

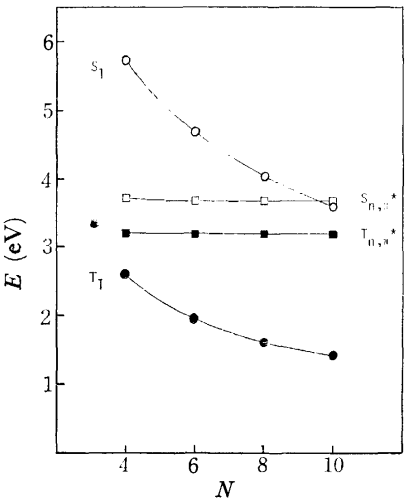

Fig. 1. Calculated lowest n,π^* and π,π^* state energies of *trans*-polyene aldehydes. N corresponds to the number of atom in the conjugated system of polyene aldehyde.

four *trans*-polyenecarbaldehydes from acrolein to 2,4,6,8-nonatetraenal are almost all the same. The present theoretical calculation suggests that the n,π^* singlet state is lower than the π,π^* singlet state from *trans*-acrolein to *trans*-2,4,6-heptatrienal, while the former state of *trans*-2,4,6,8-nonatetraenal is higher than its latter state. However, from the experimental fact about retinals,[7] the n,π^* singlet state of *trans*-2,4,6,8-nonatetraenal may be still lower than its π,π^* state. Judging from the experimental results[7] and the fact that the π-electronic structure of retinal is not exactly the same as that of the corresponding polyenecarbaldehyde because of the difference in the molecular structure between retinal and dodecapentaenal, the relative order of the n,π^* and π,π^* singlet states of dodecapentaenal may be critical. The n,π^* singlet state of a polyenecarbaldehyde larger than dodecapentaenal should be higher than its π,π^* singlet state.

On the other hand, all the calculated n,π^* triplet states of the present molecules are higher than their π,π^* triplet states, though the experimental result for acrolein shows that the n,π^* triplet state, 3.01 eV,[4,24] is lower than the π,π^* triplet state, 3.05 eV.[3] The energy difference in acrolein between the n,π^* singlet and triplet states is about 0.7 and 0.5 eV in the experimental and theoretical values respectively. The energy difference between the two states depends on the one-center integral, $\langle n_O \pi_O | r_{12}^{-1} | \pi_O n_O \rangle$; the value of 0.903 eV[21] was assigned to that. To improve the present difference, a larger one-center integral value may be better. Plotnikov[25] used the value of 1.26 eV for this

integral in his calculation. The calculated n,π^* triplet states of the other molecules are higher than their π,π^* triplet states. This result seems reasonable in view of experimental results on acrolein and the n,π^* and π,π^* singlet-triplet energy separation.

Judging from the present results, the lowest triplet state of polyenecarbaldehyde may be said to be of the π,π^* character, but not of the n,π^* character except for the case of acrolein. The slope of the n,π^* state energy curves in Fig. 1 is nearly flat compared with that of the π,π^* state energy curves. This result suggests that the lowest n,π^* triplet state may also be higher than the lowest π,π^* singlet state from the polyenecarbaldehyde larger than nonatetraenal. The calculated π,π^* triplet state energies of the present molecules are not in good agreement with the observed values.[26] The energy difference between the calculated and observed values is within the range of about 0.5 eV. The theoretical values are lower than the experimental values.[26] A similar result was reported by Forster[27] in the triplet-state calculation of polyene by the SCF-MO method using the Mataga-Nishimoto approximation.[28] In his case, the calculated values range from 1.43 to 0.98 eV as the carbon chain varies from C_4 to C_{22}. We also have obtained the similar result that SCF-MO calculation using the Mataga-Nishimoto approximation gives lower values than the values calculated by means of the Pariser-Parr integral with respect to the triplet state of polyenecarbaldehyde. Figure 1 shows that the singlet-triplet splitting of polyenecarbaldehyde decreases in the n,π^* and π,π^* states as the number of the atom in the conjugated system increases.

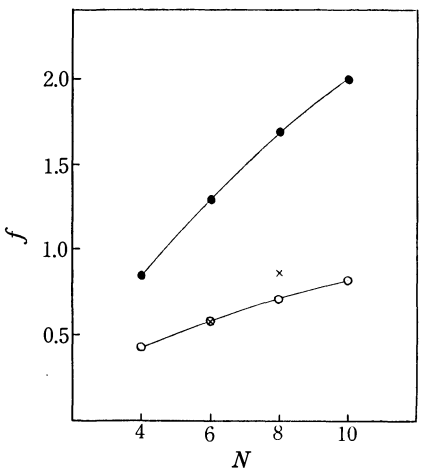

Fig. 2. Oscillator strength of the lowest π-π^* transition of *trans*-polyene aldehydes.
● corresponds to f_1, ○ to f_2, and × to f_{obsd}

The oscillator strengths, f_1, f_2, and f_{obsd}, are plotted in Fig. 2. The oscillator strengths calculated by means of Eq. (7) are larger than the observed values, and they increase rapidly as the number of the atom, N, increases. The ratio of f_1 to f_{obsd} is about 2.

On the other hand, the oscillator strengths calculated by means of Eq. (8) are smaller than the observed values, but the agreement between them is much better. The ratio of f_2 to f_{obsd} ranges from 0.8 to 1. The trend of the f_2 curve is closer to that of f_{obsd} than the trend of the f_1 curve in Fig. 2. Comparison with the

both theoretical results suggests that the dipole-velocity treatment is better than the dipole-length method in the molecular orbital calculation of conjugated molecules as long as the point charge approximation is adopted to the calculation of the oscillator strength.

Interaction between Carbon Dioxide and the Zinc Oxide Surface

Tetsuo MORIMOTO and Kunimitsu MORISHIGE

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama 700

(Received May 1, 1973)

The adsorption of carbon dioxide has been measured at 25 °C on zinc oxide surfaces with different amounts of preadsorbed carbon dioxide. As a result, it has been found that carbon dioxide molecules are chemisorbed more weakly to zinc oxide surfaces than water; the desorbability of carbon dioxide is almost complete upon evacuation at temperatures higher than 300 °C, whereas upon evacuation at 25 °C 80% of the carbon dioxide remains on the surface. Also, the adsorption isotherms of carbon dioxide have been obtained at 25 °C on differently-hydroxylated surfaces of zinc oxide. On such surfaces, the adsorption amount of carbon dioxide decreases linearly with an increase in the amount of surface hydroxyl groups. This suggests that most of the carbon dioxide is adsorbed strongly on the vacant sites formed by dehydroxylation, and not on the surface hydroxyl groups.

Recently, it has been reported that surface hydroxyl groups react with carbon dioxide to form bicarbonate species on a variety of metal oxides.[1-5] Especially, Boehm has applied the adsorption measurement of carbon dioxide to the titration of basic hydroxyl groups on η-Al_2O_3.[2] On the other hand, Taylor and Amberg[6] and Hockey *et al.*[7] have discovered, from IR studies, that absorption bands due to surface hydroxyl groups on zinc oxide are not disturbed by the chemisorption of carbon dioxide. It would probably be difficult to ascertain the formation of bicarbonate species on zinc oxide surfaces from such IR spectra, since the perturbation in the surface hydroxyl region due to bicarbonate formation is very small.

Consequently, it seems that it would be interesting to examine the adsorption of carbon dioxide on zinc oxide in connection with the population of surface hydroxyl groups. Hitherto, though many authors have measured the adsorption isotherms of carbon dioxide on zinc oxide, most of them have been concerned with the measurements to obtain isosteric heats of adsorption at elevated temperatures.[8-11] Very recently, it has been found[12,13] that surface hydroxyl groups on zinc oxide can be removed by degassing at rather higher temperatures, and that a two-dimensional condensation of water occurs on such hydroxylated surfaces. In relation to these problems, the measurements of the adsorption of various gases on well-defined zinc oxide surfaces are desirable.

This work will deal with the interaction between carbon dioxide and zinc oxide surfaces covered with controlled amounts of preadsorbed carbon dioxide or surface hydroxyl groups, on the basis of the adsorption measurements of carbon dioxide at room temperature.

Experimental

Materials. Zinc oxide was prepared by burning zinc metal in air in our laboratory. The purity of the zinc metal used was, according to the maker's assay, 0.01% Pb, 0.002% Cu, 0.005% Cd and Fe, 0.00005% As, and traces of S and P. X-ray analysis showed that the zinc oxide thus prepared was highly crystalline. Carbon dioxide gas from dry ice was purified by trapping and degassing at the temperature of liquid nitrogen and by following to sublimation at the temperature of the dry ice-ethanol mixture.

Adsorption of Carbon Dioxide. The adsorption of carbon dioxide was measured volumetrically by means of a conventional adsorption apparatus equipped with an oil manometer. Prior to the adsorption measurements, a zinc oxide sample of *ca.* 6 g was degassed at 600 °C under a reduced pressure of 10^{-5} Torr for 30hr in order to remove the chemisorbed water and carbon dioxide.

The adsorption isotherm of carbon dioxide was first measured at 25 °C on a fresh surface of a sample degassed at 600 °C. After this, the sample was degassed for 4 hr at 25 °C and was then applied to the second adsorption isotherm at 25 °C. By increasing the degassing temperatures, the adsorption isotherms on the surfaces with partially-preadsorbed carbon dioxide were obtained at 25 °C by using the same sample.

In order to examine the influence of surface hydroxyl groups upon the adsorption of carbon dioxide, the sample was degassed for 30 hr at 600 °C and was then exposed to the saturated water vapor over night at room temperature. This sample was again degassed for 4hr at different temperatures (100, 300, 350, and 400 °C) to prepare differently-hydroxylated surfaces. On these surfaces, the adsorption of carbon dioxide was measured at 25 °C.

Measurement of the Water Content. The surface water content was measured by the successive-ignition-loss method on a sample which had been pretreated at 600 °C, exposed to the saturated water vapor overnight at room temperature, and degassed for 4 hr at 30 °C in a vacuum of 10^{-5} Torr in order to remove the physisorbed water. A small amount of carbon dioxide expelled from the sample together with the water vapor was removed from the mixture by evacuating the mixture in a condensed state at −78 °C.[14]

Measurement of the Surface Area. The surface area of zinc oxide was measured by the BET method with nitrogen as an adsorbate. The specific surface area of the sample evacuated at 600 °C for 30 hr was 3.5 m^2/g.

Results and Discussion

The adsorption amount of carbon dioxide at 300 °C on the zinc oxide evacuated at 600 °C for 30 hr changes with the time, as is shown in Fig. 1. It can be seen from Fig. 1 that the initial fast adsorption is followed by a slow process for every dose of carbon dioxide, and that the slow adsorption increases linearly with the time and that its rate is proportional to the pressure. The adsorption at the initial stage is too rapid to pursue accurately by means of an oil manometer, and it largely finishes within a few minutes. The same trend also appears in adsorption experiments at different temperatures, but the lower the adsorption temperature, the shorter the time required for the attainment of

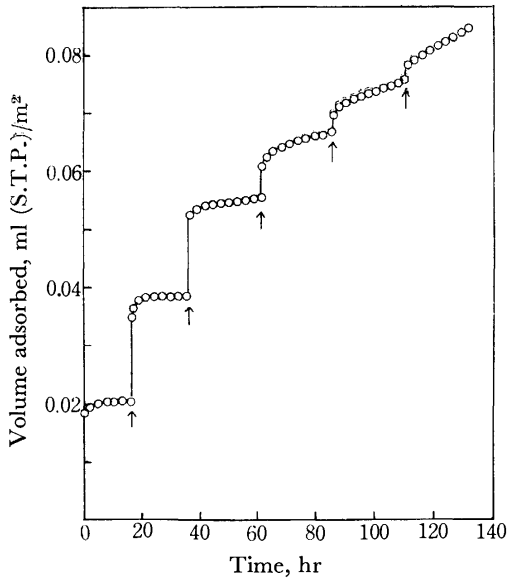

Fig. 1. Change in the amount of adsorbed CO_2 with time; arrows indicate admissions of small amount of CO_2.

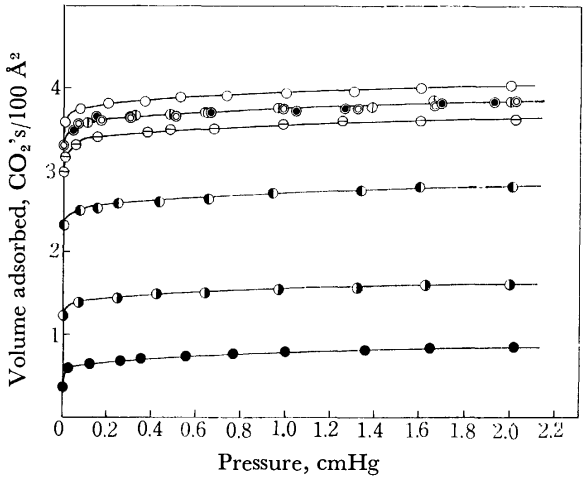

Fig. 2. Adsorption isotherms (25 °C) of CO_2 on ZnO pretreated at various temperatures. ○: after initial degassing at 600, ●: after degassing at 25, ◑: 100, ◐: 200, ⊖: 300, ◎: 400, ⊙: 500, ⓘ: 600 °C.

the adsorption equilibrium. Thus, it follows that the adsorption measurements based on the pressure reading within one or two hours after every dose of carbon dioxide should refer only to the fast adsorption.

Figure 2 is an example of the adsorption isotherms of carbon dioxide obtained at 25 °C over various surfaces with preadsorbed carbon dioxide; the ordinate is expressed in the number of carbon dioxide molecules adsorbed per 100 Å² of the surface. The isotherm obtained on a fresh surface degassed at 600 °C is much higher than that obtained on a sample degassed at 25 °C after the first adsorption experiment. The amount of carbon dioxide adsorbed on the surfaces with preadsorbed carbon dioxide increases with the evacuating temperature, and approaches that on the fresh surface when the surfaces are evacuated above 300 °C. All the adsorption data thus obtained can be

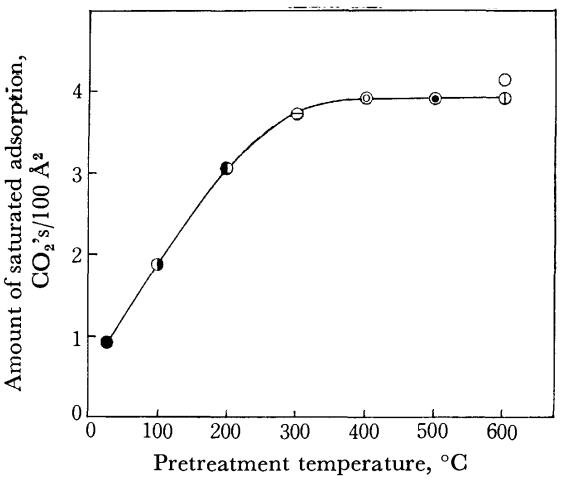

Fig. 3. Dependence of the amount of adsorbed CO_2 at 25 °C upon degassing temperature, ○: after initial degassing at 600, ●: after degassing at 25, ◑: 100, ◐: 200, ⊖: 300, ◎: 400, ⊙: 500, ⓘ: 600 °C.

expressed approximately by the Langmuir equation, which makes it possible to calculate the saturated values of adsorbed carbon dioxide, as is shown in Fig. 3. It may be seen clearly from Fig. 3 that the higher the degassing temperature before the second adsorption, the larger the second adsorption amount of carbon dioxide; the amount of adsorption on the zinc oxide degassed at 300 °C is approximately equal to that on the zinc oxide degassed at 600 °C. In other words, the carbon dioxide adsorbed on zinc oxide is almost completely desorbed at temperatures higher than 300 °C, while about 20% of the adsorbed carbon dioxide can be removed by evacuation at 25 °C.

Infrared studies performed by Taylor and Amberg[6] point out that the adsorption of carbon dioxide on zinc oxide at room temperature can be classified into three types of adsorption: physisorption, and weak and strong chemisorption, and that the former two are desorbable by degassing at room temperature. Therefore, the 80% of the carbon dioxide remaining on zinc oxide surfaces may be the strong chemisorption of Taylor's classification.

Table 1. Water content of zinc oxide (OH's/100 Å²)

Treatment	Initial 600 °C[a]	After hydration[b]	Temperature (°C) 100	200	300	350	400	500
Water content	0.34	9.13	8.82	7.17	7.00	4.86	2.63	1.53

a) Degassed at 600 °C for 30 hr.
b) Exposed to the saturated water vapor overnight at room temperature, and then degassed at 30 °C for 4 hr.

The water content of zinc oxide is given in Table 1, which is the number of surface hydroxyl groups remaining on 100 Å² of the surfaces pretreated at the temperatures indicated. It is known that only a small amount of the surface hydroxyl groups on zinc oxide can be desorbed by evacuation up to 300 °C, while most of them can be removed at temperatures ranging

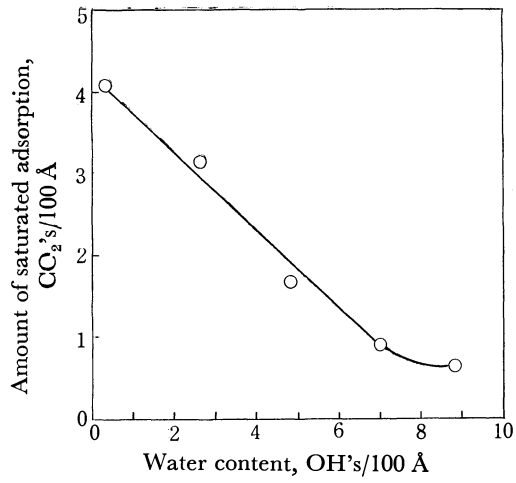

Fig. 4. Relation between amount of adsorbed CO_2 and water content on ZnO.

from 300 to 400 °C.[13] On the other hand, a large part of the strongly-adsorbed carbon dioxide can be removed by evacuating up to 300 °C, as may be seen from Fig. 3. This indicates that water is chemisorbed more strongly than carbon dioxide on the surface of zinc oxide. The adsorption isotherms of carbon dioxide, which were of the same type as those shown in Fig. 2, were also obtained at 25 °C on such differently-hydroxylated zinc oxides as are listed in Table 1. The amounts of the saturated adsorption of carbon dioxide computed from the isotherms are plotted against the water content in Fig. 4. It can be seen from Fig. 4 that the amounts of adsorbed carbon dioxide decrease linearly with an increase in the amount of the remaining surface hydroxyl groups. This suggests that carbon dioxide can be chemisorbed on the vacant sites free from hydroxyl groups; accordingly, under the conditions studied at least most of the chemisorbed carbon dioxide is not combined with the surface hydroxyl groups to form bicarbonate species, contrary to the results reported for the other systems of metal oxide-carbon dioxide.[1-5]

The authors wish to express their thanks to Dr. Mahiko Nagao for his kind advice during this study.

Emission Spectra of Carbon Disulfide, Hydrogen Sulfide, and Thiols by Controlled Electron Impact

Minoru TOYODA, Teiichiro OGAWA, and Nobuhiko ISHIBASHI
Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka 812
(Received May 22, 1973)

The emission spectra in the 200—600 nm region produced by the controlled electron impact method were investigated in the vapor phase on hydrogen sulfide, carbon disulfide, methanethiol, and ethanethiol at low pressures. The photoemissions were observed and assigned for an excited parent molecule, molecular ions, and fragments, such as CS_2, CS_2^+, H_2S^+, H, CH, CS, and HS^+. The intensities of the photoemission of most of the species were found to increase linearly with both the electron beam current and the gas pressure, and these species were concluded to be produced in some one-electron unimolecular processes.

The formation of excited molecules and excited molecular ions and their emission spectra have been investigated by a number of methods for excitation, such as by photons, flames, or electric discharges.[1] Although these methods are useful for chemical analyses, secondary reactions induce difficulties in a detailed analysis of the mechanism of fragmentation and excitation processes of the species concerned. A crossed-beam technique, in which the molecular vapor is excited by a controlled electron source, has been employed in recent years to overcome the above difficulties.[2] Since the gas pressure can be kept very low in the controlled electron impact method, the effect of molecular collisions is greatly reduced and, consequently, the bands of the primarily excited species appear with relatively high intensity. It is, therefore, possible to observe primary reactions more accurately; this may lead not only to the elucidation of the fragmentation processes of the parent molecule, but also to the information about the collision phenomena.

The emission spectra of aromatic molecules by controlled electron impact have been reported by the present authors.[3] Those of CS_2 and H_2S have been measured by Smith[4] and by Horani *et al.*[5,6] respectively, and the bands of CS ($A^1\Pi$—$X^1\Sigma^+$), CS_2^+ ($\tilde{B}^2\Sigma_u^+$—$\tilde{X}^2\Pi_g$), HS^+ ($A^3\Pi$—$X^3\Sigma^-$), and H_2S^+ (A^2A_1—$\tilde{X}^2B_1$) have been observed and assigned. In the present paper, the emission spectra of carbon disulfide, hydrogen sulfide, methanethiol, and ethanethiol under excitation by a controlled electron beam will be presented, and the mechanism of the excitation will be discussed in relation to the intensity measurements.

Experimental

The experimental method used in the present work has been described in detail in the previous papers.[3,7] The electrons from a heated tungsten filament were accelerated and introduced into the collision chamber through a slit (2×15 mm). The energies of the electrons were externally controlled from 15 to 300 eV. The sample gas was jetted through a nozzle (0.1 mm in diameter) and collided with the electron beam. The pressure during the operation, as measured with a Penning gauge, was of the order of 10^{-4} mmHg, though the density of the gas in the middle of the molecular jet was higher. The photoemission produced by collisions between electrons and molecules was measured photoelectrically with either a Jarrell Ash JE-25 or a JASCO CT-50 monochromator.

The H_2S was obtained from the Takachiho Chemical Ind., while the D_2S was prepared from FeS and D_2SO_4. The HDS[8] was prepared from FeS and a 1:1 mixture of H_2SO_4 and D_2O. The methanethiol was purchased from the Matheson Co., and the CS_2 and the ethanethiol, from the Wako Pure Chemical Ind. The samples were frozen and degassed repeatedly before use.

Results and Discussion

Carbon Disulfide. A typical emission spectrum of carbon disulfide in the 220—320 nm region is shown in Fig. 1. The impact energy was 100 eV with the electron beam current of 100 μA. The spectrum is in good agreement with the published one; the bands around 260 nm are assigned to CS ($A^1\Pi$—$X^1\Sigma^+$) and the most intense bands at 282 and 285 nm to CS_2^+ ($\tilde{B}^2\Sigma_u^+$—$\tilde{X}^2\Pi_g$).[4]

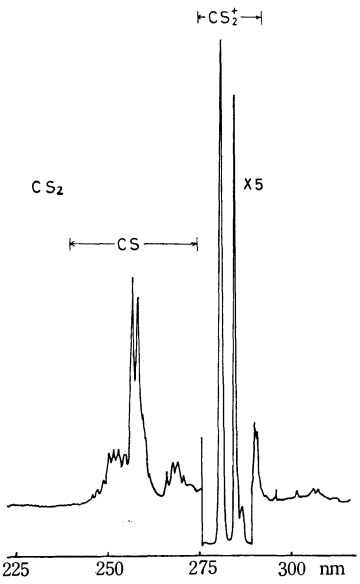

Fig. 1. Emission spectrum obtained from CS_2 excited by 100 eV electrons in the region of 220—320 nm. Beam current, 100 μA.

A typical spectrum of carbon disulfide in the 300—650 nm region is shown in Fig. 2. There seem to be two emission systems in this region, judging from the different intensity ratios for various impact energies. The first one is a continuous band extending from 340 to 640 nm. The second one, which is superimposed

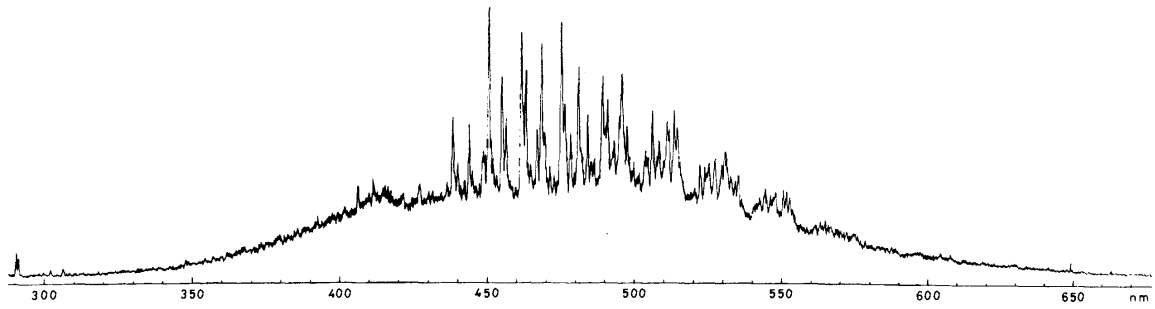

Fig. 2. Emission spectrum obtained from CS_2 excited by 200 eV electrons in the region of 300—650 nm. Beam current, 250 μA.

on the first one, is much sharper, shows a vibrational structure, and disappears much more rapidly than the other at lower impact energies. The intensities of the photoemission of these bands were determined for various currents of the incident electrons and were found to be proportional to the electron beam current, as is shown in Fig. 3.

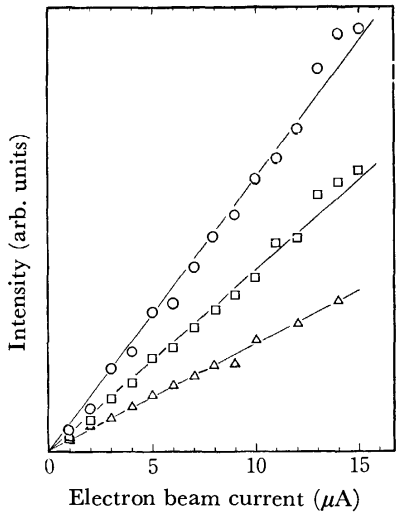

Fig. 3. Dependence of photoemission intensities of CS_2 (△), CS_2^+ (A–X transition) (○) and CS_2^+ (B–X transition measured in the second order) (□) from CS_2 on electron beam current. Electron energy was 200 eV.

The first band system in the 300—650 nm region is similar to the one observed in the discharge[9] and has been assigned to the CS_2 fluorescence. Arnold and Kimbel proposed a three-body recombination mechanism for this emission. In the present study, however, the pressure in the collision chamber is so low ($<10^{-2}$ mmHg) that the intermolecular collision seems to be negligible. An alternative suggestion as to the mechanism for the emission of CS_2* in the present research would be a direct excitation of CS_2;

$$CS_2 \xrightarrow{e} CS_2^* \longrightarrow CS_2 + h\nu$$

The linearity of the emission intensity to the electron beam current supports this mechanism. Furthermore, the finding that the intensity of this band relative to that of CS_2^+ at 282 nm did not vary with the pressure supports the above conclusion.

The second band system has complicated vibrational structures; the apparent intensity of the 449 nm band

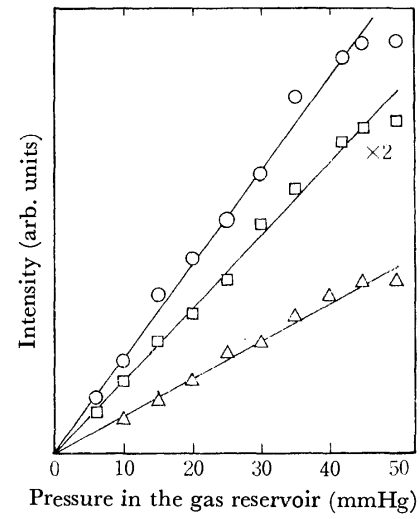

Fig. 4. Dependence of photoemission intensities of CS (△), CS_2^+ (A–X transition) (○) and CS_2^+ (B–X transition) (□) on gas pressure in the gas reservoir. Electron energy was 300 eV and beam current, 20 μA.

(the strongest one in this region) is about 1/10 of that of the 282 nm band of CS_2^+ (the quantum efficiency was not calibrated). The emission intensities of these bands are also proportional to the electron beam current and to the gas pressure, as are shown in Figs. 3 and 4 respectively. These facts suggest that the emitting species are produced directly from the parent molecules, as are those of the first band. The emission spectra of a mixture of CS_2 and H_2 was measured by this method as well as that of CS_2 and H_2S. The spectra were superpositions of the bands of the two parent molecules. These bands also appeared in the spectrum of methanethiol; in this case the intensity ratio between the band at 449 nm and that at 282 nm (CS_2^+) is about 1/10 as it is in the case of carbon disulfide, though the intensity of CS_2^+ from methanethiol is much smaller than that of CS. Among the possible photoemitting species of these bands, such as CS_2, CS, C, S or their ions, the complicated appearance of the band and related data in the literature[1,10] make it possbile to exclude the atomic species. If they were CS or CS^+, they should appear in the cases of thiols and methyl phenyl sulfide with much higher intensities. Furthermore, the A–X transition of the CS radical is in the region of 240—290 nm,[1] which is not coincident with that of the second bands. The adiabatic and the vertical transition energies of CS_2^+ to the first excited

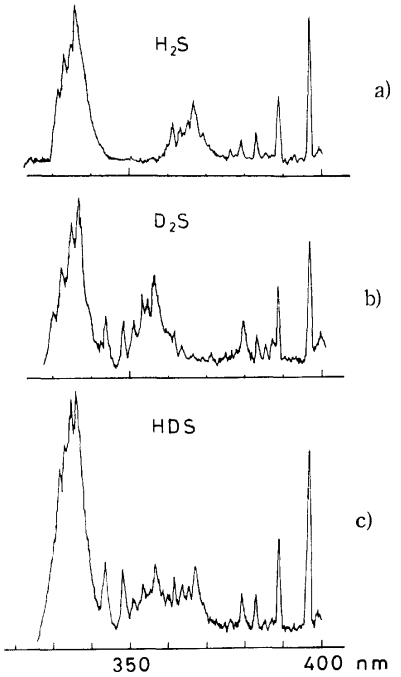

Fig. 5. Emission spectra obtained from H_2S (a), D_2S (b) and HDS[8] (c) excited by 200 eV electrons. Beam current, 500 μA.

state were determined to be 2.63 eV (472 nm) and 2.77 eV (448 nm).[11] The latter coincides with the position of the strongest band in the present spectrum. These results suggest that this second band can be assigned to CS_2^+ ($A^2\Pi_u$—$\tilde{X}^2\Pi_g$).

Hydrogen Sulfide. Some typical emission spectra of H_2S, D_2S, and HDS[8] in the region of 330—400 nm are shown in Fig. 5. The impact voltage was 200 V and the electron beam current was 500 μA in these measurements. The sharp lines at 486, 434, 410, 397, and 389 nm, which have been observed for all the molecules containing the hydrogen atom, are assigned to the hydrogen Balmer series. There are two intense bands at about 336 nm and at about 366 nm in the spectrum of H_2S; the latter seems to shift toward the shorter wavelength side, at about 357 nm, in the spectrum of D_2S. The spectrum of HDS may be regarded as a superposition of those of H_2S and D_2S. This finding suggests that these bands are related to a diatomic molecule containing both a hydrogen and a sulfur atom. This is confirmed by the facts that these bands also appeared in the spectra of methanethiol, ethanethiol, and benzenethiol, whereas they did not appear in CS_2, H_2, methyl phenyl sulfide or thiophene, which have no H–S bond; they may not form such species as HS since two-body collisions are infrequent at the pressure of $10^{-2\sim-3}$ mmHg. The A–X transition of the HS radical was observed below 324 nm[1] and seems to be undetectable in the emission because of predissociation.[12] Thus these bands can be assigned to the A–X transition of HS^+ and DS^+ radicals, as Horani *et al.* indicated.[5] The separations between successive bands of HS^+ and DS^+ are estimated to be 2470 ± 100 cm^{-1} and 1790 ± 100 cm^{-1} respectively. The former value is slightly smaller than that between

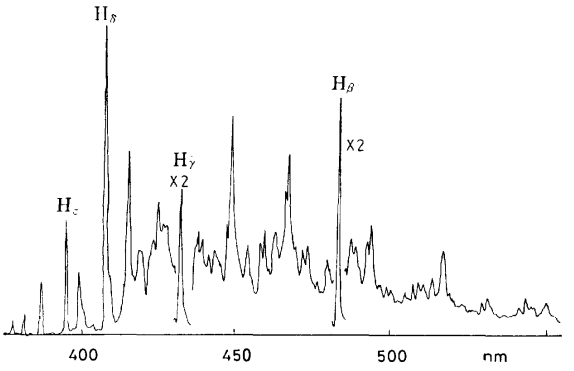

Fig. 6. Emission spectrum obtained from H_2S excited by 200 eV electrons in the region of 400—550 nm. Beam current, 500 μA.

successive bands of the HS radical in the ground state, 2582 cm^{-1}.[13] The difference in the separation between HS^+ and DS^+ may be interpreted as an isotopic shift; this finding also confirms the above assignment.

There are a number of prominent bands in the 400—550 nm region, as is shown in Fig. 6. These bands, except for the hydrogen Balmer series, were not observed in other molecules, such as methanethiol, ethanethiol, hydrocarbons, carbon disulfide, and thiophene. The observed spectrum of a mixture of CS_2 and H_2S was simply a superposition of the spectra of the parent molecules. This finding also suggests that the excited species come directly from the parent molecule, and the band can be assigned to H_2S^+, as did the previous authors.[6]

A number of MO calculations[14] on this molecule have been reported. If Koopmans' theorem holds in this molecule, the energy difference between the ground and the first excited states of H_2S^+ is estimated to be about 2.7 eV (459 nm). The adiabatic and the vertical transition energies between $^2A_1$—$^2B_1$ were determined to be 2.28 eV (544 nm) and 2.77 eV (448 nm) respectively in photoelectron spectroscopy.[11] The latter value

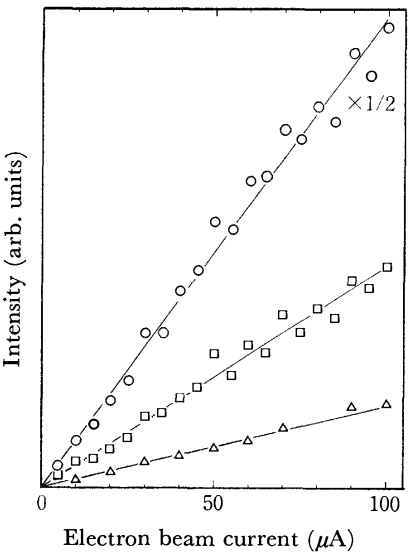

Fig. 7. Dependence of photoemission intensities of HS^+ (○), H (□) and H_2S^+ (△) on electron beam current. Electron energy was 200 eV.

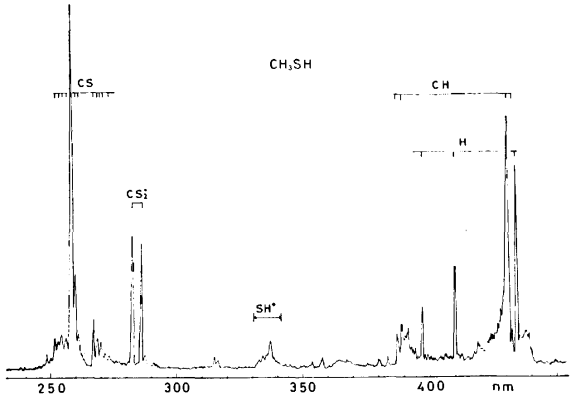

Fig. 8. Emission spectrum obtained from methanethiol excited by 200 eV electrons. Beam current, 400 μA.

is in good agreement with the strongest band of the H_2S^+ in the present work.

The intensities of the photoemission of H, HS^+, and H_2S^+ from H_2S for various electron beam currents are shown in Fig. 7. The linearity also holds for ethanethiol and proves that these species are excited in single-electron processes.

Thiols. A typical emission spectrum of methanethiol was observed by electron impact at 200 eV and a beam current of 1 mA, as is shown in Fig. 8. The spectrum of ethanethiol was similar to that of methanethiol except for the relative intensites of the fragments. The Balmer series of hydrogen is also the most prominent. The emission bands at 431 and 387 nm were assigned to the (0,0) bands of the CH radical in the $A^2\Delta$—$X^2\Pi$ and $B^2\Sigma^-$—$X^2\Pi$ transitions respectively. The bands at 282 and 285 nm were assigned to the CS_2^+ ion and the bands around 260 nm to the CS radical, as in the case of CS_2. In this case, however, the bands of CS are much more intense than those of CS_2^+ which would not be formed by a simple collision between an electron and a CH_3SH molecule.

The authors wish to thank Professor Tomoo Oyama for the use of his CT-50 monochromator and Mr. Masaharu Tsuji for his discussion.

The Electronic States of 2,5-Dibromo-3,6-dichloro-1,4-benzoquinone and Its Anion Radical as Studied by Means of Their Infrared Spectra

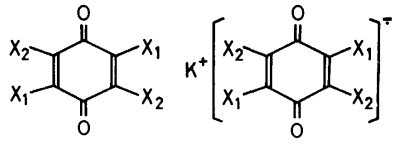
Yôichi IIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received June 30, 1973)

The infrared spectra (400—4000 cm^{-1}) of neutral 2,5-dibromo-3,6-dichloro-1,4-benzoquinone and its anion radical were measured in order to observe the appreciable frequency differences between their corresponding bands. The vibrational assignments were made and the simple Urey-Bradley force fields were determined for both the neutral 2,5-dibromo-3,6-dichloro-1,4-benzoquinone and its anion radical. The differences in the molecular and electronic structures between these two molecules were investigated on the basis of these experimental and theoretical results. The half-occupied molecular orbital of the anion radical was found to belong to the b_g irreducible representation.

The infrared spectrum of an ion radical is known to be appreciably different from that of its neutral molecule.[1-13] The spectrum difference seems to be attributable to the difference in their intramolecular force fields. Thus far, however, few attempts have been made to study such differences quantitatively.[8,12,13] In previous papers,[8,13] we examined the infrared spectra of *p*-chloranil (*p*-QCl_4), *p*-bromanil (*p*-QBr_4), and their anion radicals (see Fig. 1). For the neutral molecule and its anion radical, the fundamental frequencies were assigned and the simple Urey-Bradley force fields (UBFF's) were determined in order to explain the appreciable frequency differences between their corresponding bands.



(a); $X_1 = X_2 = Cl$

(c); $X_1 = Br$, $X_2 = Cl$

Fig. 1. The halogen-substituted *p*-benzoquinones and their anion radical salts with potassium cations; (a) *p*-chloranil, (b) *p*-bromanil and (c) 2,5-dibromo-3,6-dichloro-1,4-benzoquinone.

The present paper will describe the infrared spectra (400—4000 cm^{-1}) of neutral 2,5-dibromo-3,6-dichloro-1,4-benzoquinone (*p*-QBr_2Cl_2) and its anion radical (see Fig. 1). For these molecules, we also observed the appreciable frequency shifts between their corresponding bands. The normal coordinate treatments were carried out for the in-plane vibrations by using the simple UBFF's in order to make the vibrational assignments and in order to clarify the difference in the force constants between these molecules. It was shown that the force constants of *p*-QBr_2Cl_2 and its anion radical could be transferred from those of *p*-QX_4 (X=Cl or Br) and its anion radical respectively, as estimated in previous papers.[8,13] In this respect, it will be interesting to compare the effect of the symmetry degradation of *p*-QBr_2Cl_2 and its anion radical with that of the D_{2h} point group of *p*-QX_4 (X=Cl or Br) and its anion radical. The electronic states of the neutral *p*-QBr_2Cl_2 and its anion radical will also be discussed on the basis of these experimental and theoretical investigations. We shall examine how the extra electron on the anion radical causes the differences in the molecular and electronic structures between the neutral *p*-QBr_2Cl_2 and its anion radical.

Experimental

Materials. The neutral *p*-QBr_2Cl_2 was synthesized by the bromination of 2,5-dichloro-1,4-benzoquinone. It was purified by recrystallization from benzene or glacial acetic acid. Its anion radical salt with the potassium cation (K^+ *p*-$QBr_2Cl_2^-$) was prepared according to the method of Torrey and Hunter.[14]

Measurements. The infrared spectra of these solid compounds were measured as Nujol mulls in the range from 400 to 4000 cm^{-1} using a JASCO IR-G infrared spectrophotometer. Alternative measurements in the regions where the absorption due to Nujol appears were made using hexachlorobutadiene mulls. The spectra obtained for these compounds are reproduced in Fig. 2. Since the counter cation of the salt is a simple alkali metal cation, the observed spectrum of K^+ *p*-$QBr_2Cl_2^-$ in the 400—4000 cm^{-1} region is probably due to that of the *p*-QBr_2Cl_2 anion radical itself. The values of the absorption peaks observed for the neutral *p*-QBr_2Cl_2 and its anion radical are listed in Table 1.

Normal Coordinate Treatment for In-Plane Vibrations

In the infrared spectra of neutral p-QBr_2Cl_2 and its anion radical, we have observed appreciable frequency differences between their corresponding bands. For example, the C=O stretching mode of 1675 cm^{-1} in the neutral p-QBr_2Cl_2 is found to be considerably red-shifted to 1514 cm^{-1} in the anion radical. Since only the intramolecular vibrations are expected to appear in the region from 400 to 4000 cm^{-1}, we attributed the observed spectrum difference between the neutral p-QBr_2Cl_2 and its anion radical to the difference in their intramolecular force fields. The effect of crystal fields upon the vibrational frequencies is small in comparison with that of the intramolecular force fields. Therefore, to a first approximation, the contribution of the crystal fields to the spectra of p-QBr_2Cl_2 and its anion radical was ignored in the present investigation.

The vibrational spectra of p-QBr_2Cl_2 and its anion radical were then treated under the molecular point group, C_{2h}, and were analyzed by using the normal coordinate treatment. The molecular and crystal structures of the neutral p-QBr_2Cl_2 have not yet been ascertained, although those of p-QCl_4 were determined by Chu, Jeffrey, and Sakurai.[15] It was assumed that the p-QBr_2Cl_2 molecule was planar. By referring to the molecular structure of p-QCl_4, the equilibrium bond lengths of p-QBr_2Cl_2 were taken as $l(C{=}O)=1.195$ Å, $l(C{=}C)=1.342$, $l(C_1{-}C_2)=l(C_3{-}C_4)=1.477$, $l(C{-}Br)=1.89$, and $l(C{-}Cl)=1.714$, while the bond angles were taken as $\angle(O{=}C_1{-}C_2)=\angle(O{=}C_4{-}C_3)=121°22'$, $\angle(C{-}C{-}Br)=\angle(C{-}C{-}Cl)=116°15'$, and $\angle(C{=}C{-}Br)=\angle(C{=}C{-}Cl)=122°23'$ (see Fig. 1). Since the structure of K^+ p-$QBr_2Cl_2^-$ has not yet been determined, it was assumed that the molecular structure of the anion radical was almost identical with that of the neutral p-QBr_2Cl_2. This assumption meant that the $\boldsymbol{G}$ matrix calculated for p-QBr_2Cl_2 was also used for its anion radical (see below).

By taking the molecular C_{2h} point group into consideration, thirty normal modes of fundamental vibrations for p-QBr_2Cl_2 or its anion radical are reduced to the symmetry species:

$$\Gamma = 11A_g(R) + 10B_u(IR) + 4B_g(R) + 5A_u(IR), \quad (1)$$

where the first two are the in-plane vibrations, and the rest, the out-of-plane vibrations. The signs of (R) and (IR) indicate the Raman and infrared active modes respectively. In connection with the number and species of the fundamentals for p-QX_4 (X=Cl or Br) and its anion radical, the correlation diagram between the C_{2h} and D_{2h} point groups is given in Table 2.

TABLE 2. THE CORRELATION DIAGRAM BETWEEN THE C_{2h} POINT GROUP OF p-QBr_2Cl_2 OR ITS ANION RADICAL AND THE D_{2h} POINT GROUP OF p-QX_4, (X=Cl OR Br), OR ITS ANION RADICAL[a)]

	B_{3u} (5)

a) The number in parentheses indicates that of the fundamental vibrations.

Wilson's $\boldsymbol{GF}$ matrix method was applied to p-QBr_2Cl_2 and its anion radical.[16] We calculated only the in-plane vibrations, because no out-of-plane vibration is expected to appear in the region now under consideration. A simple UBFF was employed as the potential function. Note that the numbering of the carbon atoms in p-QBr_2Cl_2 or its anion radical is taken as 2,5-dibromo-3,6-dichloro-1,4-benzoquinone. Therefore, six bond-stretching ($K(C{=}O)$, $K(C{=}C)$, $K(C_1{-}C_2)$, $K(C_3{-}C_4)$, $K(C{-}Br)$, and $K(C{-}Cl)$), nine angle-bending ($H(O{=}C_1{-}C_2)$, $H(O{=}C_4{-}C_3)$, $H(C{-}C{-}Br)$, $H(C{-}C{-}Cl)$, $H(C{=}C{-}Br)$, $H(C{=}C{-}Cl)$, $H(C{-}C{-}C)$, $H(C_1{-}C_2{=}C_3)$, and $H(C_2{=}C_3{-}C_4)$) and nine non-bonded repulsion force constants ($F(O{=}C_1{-}C_2)$, $F(O{=}C_4{-}C_3)$, $F(C{-}C{-}Br)$, $F(C{-}C{-}Cl)$, $F(C{=}C{-}Br)$, $F(C{=}C{-}Cl)$, $F(C{-}C{-}C)$, $F(C_1{-}$

C_2=C_3), and $F(C_2=C_3-C_4)$) were necessary.

The trial force constants for the neutral *p*-QBr_2Cl_2 were transferred from the values for the neutral *p*-QX_4 (X=Cl or Br), while those for the *p*-QBr_2Cl_2 anion radical were transferred from the values for the *p*-QX_4 anion radical (X=Cl or Br).[8,13] For either the neutral *p*-QBr_2Cl_2 or its anion radical, it seems that $K(C_1-C_2)\approx K(C_3-C_4)$, $H(O=C_1-C_2)\approx H(O=C_4-C_3)$, $H(C_1-C_2=C_3)\approx H(C_2=C_3-C_4)$, $F(O=C_1-C_2)\approx F(O=C_4-C_3)$, and $F(C_1-C_2=C_3)\approx F(C_2=C_3-C_4)$. Refinements of the force constants were then carried out by the trial-and-error method, making use of the Jacobian matrix. In order to adjust the calculated frequencies to the observed fundamental frequencies, we paid much attention to the bond-stretching force constants, because the observed fundamental frequencies of the infrared spectra are almost all due to the bond-stretching modes. The final sets of force constants thus obtained for the neutral *p*-QBr_2Cl_2 and its anion radical are given in Table 3, while the frequencies calculated with these constants are in Table 1 compared with the observed values. In both of these molecules, the calculated vaues of the fundamental vibrations were found to agree well with the observed values, except for the following two points, which remain to be elucidated:

(1) In addition to the fundamental vibrations, shoulders or extra absorptions appear in both the neutral *p*-QBr_2Cl_2 and its anion radical. Some of them may arise from the splitting of the fundamental vibrations through the factor-group splitting.

(2) The calculated 1263 cm^{-1} band in the anion radical cannot be assigned to any of the observed bands, presumably because of its weak intensity.

Table 3. Some of the force constants estimated for the neutral *p*-QBr_2Cl_2, *p*-QCl_4 and *p*-QBr_4 molecules and their anion radicals (md/Å)[a]

Force constant	Neutral molecule			Anion radical		
	p-QBr_2Cl_2	*p*-QCl_4[b]	*p*-QBr_4[c]	*p*-QBr_2Cl_2	*p*-QCl_4[b]	*p*-QBr_4[c]
K(C=O)	9.62	9.7	9.62	7.10	7.3	7.10
K(C=C)	6.67	6.6	6.67	6.26	6.1	6.26
$K(C_2-C_1)$	2.96	3.0	2.96	3.33	3.5	3.33
$K(C_3-C_4)$	2.96	3.0	2.96	3.33	3.5	3.33
K(C-Br)	2.63	—	2.63	2.17	—	2.17
K(C-Cl)	2.67	2.67	—	2.45	2.67	—

a) The values of the bending and non-bonded repulsion force constants for the neutral *p*-QBr_2Cl_2 were transferred from those for the neutral *p*-QCl_4 and *p*-QBr_4, while the values for the *p*-QBr_2Cl_2 anion radical, from those for the *p*-QCl_4 and *p*-QBr_4 anion radicals. See Refs. 8 and 13.

Discussion

Comparison with the Results of p-QX_4 *(X=Cl or Br) and Its Anion Radical.* Since the observations of the fundamental frequencies are limited to the infrared spectra, we suspect that the sets of the force constants presented in Table 3 are not the best ones for either the neutral *p*-QBr_2Cl_2 or its anion radical. However, the stretching force constants are still meaningful, for the observed fundamental frequencies are almost all due to the bond-stretching modes. Therefore, below, we will discuss only the difference in the stretching force constants between the neutral *p*-QBr_2Cl_2 and its anion radical. From Table 3, we can easily see that an extra electron on the *p*-QBr_2Cl_2 anion radical markedly causes a decrease in the K(C=O), K(C=C), K(C-Br), and K(C-Cl) values and an increase in the $K(C_1-C_2)$ and $K(C_3-C_4)$ values. Regardless of the symmetry degradation, this situation is very similar to that of the bond-stretching force constant difference between *p*-QX_4 (X=Cl or Br) and its anion radical reported in previous papers.[8,13] Table 3 clearly shows that the force constants of the neutral *p*-QBr_2Cl_2 are transferable from those of the neutral *p*-QCl_4 and *p*-QBr_4, and that the force constants of the anion radical of *p*-QBr_2Cl_2 are transferable from those of the *p*-QCl_4 and *p*-QBr_4 anion radicals. We can further see that, in spite of the symmetry degradation, the force constants of the benzoquinone system of the neutral *p*-QBr_2Cl_2 or its anion radical are scarcely affected by exchanging the chlorine substituents for the bromine substituents. This fact means that the carbon atoms bonded to the chlorine and bromine substituents are practically identical, and that the molecular structure and the force field for the benzoquinone system of the neutral *p*-QBr_2Cl_2 or its anion radical are very similar to those of the neutral *p*-QX_4 (X=Cl or Br) or its anion radical respectively.[8,13]

Although the previous paper stated that the extra electron on the *p*-QCl_4 anion radical did not decrease the K(C-Cl) value,[8] this description is no longer adequate. More accurate assignments of the fundamental frequencies of *p*-QCl_4 and its anion radical show a decrease in the K(C-Cl) value in the anion radical[17]; this situation seems to be analogous to that of *p*-QBr_2Cl_2 and its anion radical.

The Electronic States of p-QBr_2Cl_2 *and Its Anion Radical.* The electronic state of the neutral *p*-QBr_2Cl_2 differs from that of its anion radical, since the extra electron on the anion radical causes a marked decrease in the K(C=O), K(C=C), K(C-Br), and K(C-Cl) values and an increase in the $K(C_1-C_2)$ and $K(C_3-C_4)$ values. In this section, we shall investigate the electronic states of the neutral *p*-QBr_2Cl_2 and its anion radical by using the difference in their force constants.

It is well known that the stretching force constant, $K(12)$, of a bond (12) in a conjugated system is greatly affected by its bond order, $p(12)$. According to Coulson and Longuet-Higgins,[18] $K(12)$ can be expressed by:

$$K(12) = \{(1-p(12))K_s+p(12)K_d\} + \left\{\frac{K_sK_d(s-d)}{K_s(1-p(12))+K_dp(12)}\right\}^2 \frac{\pi(1212)}{2}, \quad (2)$$

where K_s and K_d are the force constants associated with pure single and double bonds respectively; $\pi(1212)$ is the self-polarizability of the bond (12), and s and d

are the bond lengths of pure single and double bonds respectively.

In a homopolar carbon-carbon bond, the second term involving the self-polarizability may be small.[19] In this case, the stretching force constant, $K(12)$, is predominantly determined by the bond order, $p(12)$. An empirical relationship between $K(12)$ and $p(12)$ has been given in a previous paper,[8] where several standard points of $K(12)$ and $p(12)$ were connected smoothly. This relationship enables us to evaluate the bond orders of the C=C, C_1–C_2, and C_3–C_4 bonds for p-QBr_2Cl_2 and its anion radical. From the values of $K(C=C)$, $K(C_1–C_2)$, and $K(C_3–C_4)$ in the infrared spectra, the $p(C=C)$, $p(C_1–C_2)$, and $p(C_3–C_4)$ values for the neutral p-QBr_2Cl_2 were thus estimated to be 0.88, 0.27, and 0.27 respectively, while those for its anion radical were estimated to be 0.82, 0.36, and 0.36 respectively. Therefore, the extra electron on the p-QBr_2Cl_2 anion radical was found to cause a decrease in $p(C=C)$ by 0.06 and an increase in $p(C_1–C_2)$ and $p(C_3–C_4)$ by 0.09.

On the other hand, let us examine the heteropolar C=O bond. If we take, in Eq. (2), the $K_s=5.0$ md/Å and $K_d=10.7$ md/Å values proposed by Bratoz and Besnainou,[20] and if we neglect the contribution of the self-polarizability to $K(C=O)$, those C=O stretching force constants for p-QBr_2Cl_2 and its anion radical give the values of $p(C=O)$ as 0.81 and 0.37 respectively. Therefore, the extra electron on the p-QBr_2Cl_2 anion radical definitely decreases the $p(C=O)$ values.

The values for the bond orders of the benzoquinone system of the neutral p-QBr_2Cl_2 and its anion radical were found to coincide well with those of the neutral p-QX_4 (X=Cl or Br) and its anion radical respectively.[21] We can further see that, for either of the neutral p-QBr_2Cl_2 or its anion radical, the $p(C_1–C_2)$ value is practically equal to the $p(C_3–C_4)$ value. For the molecular D_{2h} point group, the half-occupied molecular orbital in the p-QX_4 anion radical (X=Cl or Br) has been reported to belong to the b_{3g} irreducible representation.[8,13] The half-occupied molecular orbital of the p-QBr_2Cl_2 anion radical should belong to the b_g irreducible representation, since the point group of the anion radical is degraded into C_{2h}. This symmetry consideration of the half-occupied molecular orbital of the p-QBr_2Cl_2 anion radical is strongly supported by the fact that the extra electron on the anion radical causes a decrease in the $p(C=C)$ and $p(C=O)$ values and an increase in the $p(C_1–C_2)$ and $p(C_3–C_4)$ values compared to the values of the neutral p-QBr_2Cl_2. The electronic states of the benzoquinone system of the neutral p-QBr_2Cl_2 and its anion radical, although their point groups are degraded into C_{2h}, seem to be very similar to those of the neutral p-QX_4 (X=Cl or Br) and its anion radical respectively, which were reported in previous papers.[8,13]

As for the C–Cl and C–Br bonds, although the description of $K(C–X)$ *versus* $p(C–X)$ (X=Cl or Br) for the neutral p-QBr_2Cl_2 and its anion radical is not so simple, the extra electron on the p-QBr_2Cl_2 anion radical causes a decrease in $K(C–Cl)$ and $K(C–Br)$, which will definitely lead to a decrease in $p(C–Cl)$ and $p(C–Br)$. However, the estimation of $p(C–Cl)$ and $p(C–Br)$ by the molecular orbital method is rather complicated, for there are some difficulties in taking appropriate parameters for the Cl and Br atomic orbitals.

Some Information on the Molecular Structures of p-QBr_2Cl_2 *and Its Anion Radical.* There is a well-known relation between the bond order, $p(12)$, and the bond length, $l(12)$, of a carbon–carbon bond (12); it was first derived by Coulson.[19,22] By using this relationship, the $p(C=C)$, $p(C_1–C_2)$, and $p(C_3–C_4)$ values estimated from the infrared spectra give $l(C=C)$, $l(C_1–C_2)$, and $l(C_3–C_4)$ respectively. The $l(C=C)$, $l(C_1–C_2)$, and $l(C_3–C_4)$ values for the neutral p-QBr_2Cl_2 were thus estimated to be 1.35_6, 1.47_5, and 1.47_5 Å, respectively, while those for its anion radical were estimated to be 1.36_8, 1.45_6, and 1.45_6 Å, respectively. The values of the neutral p-QBr_2Cl_2 are in good agreement with those of $l(C=C)=1.342$ Å, $l(C_1–C_2)=l(C_3–C_4)=1.477$ respectively, which were employed in the previous calculation. We can further see that the extra electron on the anion radical may cause an increase of 0.01 Å in $l(C=C)$ and a decrease of 0.02 Å in $l(C_1–C_2)$ and $l(C_3–C_4)$ compared to the values of p-QBr_2Cl_2. However, no observation of the molecular structure has yet been made for the anion radical.

As for the relation between the stretching force constant and the bond length of a C=O bond, Badger proposed the following equation:[23]

$$K(C=O) = 1.86/\{l(C=O)-0.68\}^3, \qquad (3)$$

where K and l are in md/Å and Å units respectively. For p-QBr_2Cl_2 and its anion radical, the values of $l(C=O)$ derived from their force constants by Eq. (3) are 1.26 Å and 1.32 respectively. The former value is rather larger than the observed value of 1.195 Å. We may expect that the C=O bond length of the p-QBr_2Cl_2 anion radical is longer than that of its neutral molecule by 0.06 Å; however, no experimental result is available at present.

Although we have no information on the relation between the stretching force constant and the bond lenght for the C–Cl and C–Br bonds, the extra electron on the p-QBr_2Cl_2 anion radical probably causes the difference in $l(C–Cl)$ and $l(C–Br)$ between p-QBr_2Cl_2 and its anion radical.

Concluding Remarks

In the present work, the difference in the vibrational spectra between the neutral p-QBr_2Cl_2 and its anion radical was interpreted in terms of the difference in their intramolecular force fields. On the other hand, the crystal-field effect may make some contribution to the frequency shifts in these vibrational spectra. Indeed, certain vibrational frequencies of the p-QBr_2Cl_2 anion radical salts will be influenced by the species of the counter cation. However, in a first approximation, this contribution can be neglected in comparison with that of the intramolecular force fields.

Rigorously speaking, the $\boldsymbol{G}$ matrix for the anion radical is not identical with that for the neutral p-QBr_2Cl_2, since the molecular structure of the anion radical

will be slightly different from that of the neutral p-QBr_2Cl_2. The difference in their $\boldsymbol{G}$ matrices may make some contribution to the frequency difference. However, this contribution is negligibly small for the bands due to the bond-stretching modes.

The set of force constants presented in Table 3 cannot be regarded as a unique solution, since the observations for the fundamental frequencies are limited to the infrared spectra. In this sense, it is quite desirable to measure the Raman spectra of p-QBr_2Cl_2 and its anion radical. We consider, however, that the set of force constants presented here is reliable enough for studying the difference in the stretching force constants between the neutral p-QBr_2Cl_2 and its anion radical.

The Chemistry of Protactinium. X. A Study of the Effect of Chromium(II) on the Solvent Extraction of Protactinium(IV), Using *N*-Benzoyl-*N*-phenylhydroxylamine, Tri-*n*-octylamine and Thenoyltrifluoroacetone as the Extractants

Isamu KAWASUJI and Shin SUZUKI

The Research Institute for Iron, Steel and Other Metals, Tohoku University, Katahira 2-Chome, Sendai 980

(Received May 25, 1973)

Cr(II) has been used for reducing protactinium in microquantities to the tetravalent state and for protecting it from re-oxidation. However, the effect of Cr(II) on the extraction behavior of Pa(IV) has not been taken into account by all of the previous investigators. On the basis of the above facts, the influence of Cr(II) on the extraction of Pa(IV) was studied by using such extractants as BPHA, TTA, and TOA. In every case, the distribution ratio of Pa(IV) decreased with an increase in the concentration of Cr(II) in the aqueous phase. One of the most reliable explanations for the phenomena is the possibility that a multi-nuclear complex between Pa(IV) and Cr(II) or Cr(III) is formed. However, the effect of Cr(II) on the absorption spectra of Pa(IV) could not be found, and many more experiments will be necessary to explain the effect of Cr(II) on the extraction behavior of Pa(IV).

Guillaumont[1] investigated the behavior of Pa(IV) in a perchlorate solution by means of the TTA-benzene extraction method and showed that Pa^{4+} was gradually hydrolyzed to $Pa(OH)_3^+$ in the pH range from −0.3 to 3.0 at the ionic strength of 3. The same author[2] also studied the chloro-, sulfato-, and fluoro-complexes in aqueous solutions and calculated their stability constants. Muxart and Arapaki[3] pointed out in their TOA-xylene extraction study that Pa(IV) formed an anionic ion in a sulfuric acid solution. Mitsuji[4] investigated the behavior of Pa(IV) in perchloric, hydrochloric, and sulfuric acid solutions by means of TTA-benzene extraction in the pH range from 0.5 to 1.1, and suggested that $Pa(OH)_2^{2+}$ and $Pa(SO_4)(OH)^+$ were the most probable ionic species in perchlorate and chloride solutions and in the sulfate solution respectively.

In these experiments, Pa(V) was reduced to Pa(IV) by means of a liquid zinc amalgam in the presence of about 10^{-2} M Cr(III). Protactinium in microquantitites can not be reduced only by the liquid zinc amalgam method, even in an argon atmosphere, because the contact between protactinium and amalgam is not sufficient and because the Pa(IV) reduced is affected by any traces of oxygen which might remain in the solution. The role of Cr(III) is considered to be that the Cr(II) formed by the liquid zinc amalgam reduction mediates the reduction of Pa(V) and protects Pa(IV) from re-oxidation. In view of the above facts, Cr(III) has generally been used as a carrier for reduction in studies of the aqueous chemistry of Pa(IV).

Mitsuji[5] reported that Pa(V) in the concentration range down to tracer level was readily reduced with a liquid zinc amalgam in the presence of more than 10^{-4} M of Cr(III), and that the co-precipitation with thorium fluoride was an excellent method for identifying the oxidation state of protactinium in a tracer concentration. It is very useful that the performance of the reduction of Pa(V) can be checked by the color change of the solution from green (Cr(III)) to light blue (Cr(II)). However, since the molar extinction coefficient of Cr(II) is only about 5 at its characteristic peak of 720 nm, about 10^{-2} M Cr(III) has been generally used in previous reports.[1-4] Therefore, a fairly large amount of Cr(II) is always present in a solution of Pa(IV). Nevertheless, the influence of Cr(II) on the extraction behavior of Pa(IV) has not been taken into account in all of the experiments described above.

Guillaumont[6] investigated the behavior of Pa(IV) in the perchlorate solution in detail by means of the TTA-benzene extraction method, and pointed out that TTA extracted not only Pa(IV), but also Cr(II). Therefore, the correction for the concentration of TTA, which chelates with Cr(II), was carried out, and it was found that the change in the distribution ratio of Pa(IV) was within the limits of experimental error for chromium concentration from 10^{-3} M to 10^{-1} M.

The purpose of the present study is to investigate the effect of the co-existence of Cr(II) on the extraction behavior of Pa(IV), using-*N*-benzoyl-*N*-phenylhydroxylamine (BPHA), tri-*n*-octylamine (TOA), or thenoyltrifluoroacetone (TTA) as an extractant.

BPHA is a weak acid ($pK_a=8.15$[7]) and has been widely used as a gravimetric or spectrophotometric reagent. Recently, it has also been used as an extracting agent for separation or purification; it is inclined to form chelate compounds with various metal ions, such as Ti(IV), Zr(IV), Hf(IV), Ta(V), Pa(V), and Pu(IV), but the extraction behavior of Pa(IV) or Cr(II) with BPHA has not yet been investigated. In this investigation we studied the BPHA extraction of Pa(IV) and Cr(II) in detail.

TTA[1,2,4] and TOA[3] have been widely used as extractants and also to investigate the behavior of Pa(IV). Taking account of the previously-reported information, we could define the experimental conditions without further study.

Experimental

Reagents. The ^{231}Pa was purified by the method reported previously[8], and its radiochemical purity was certified by α-ray and γ-ray spectroscopy. The concentration of protactinium in the ^{231}Pa solution was determined by gravimetry as Pa_2O_5 and by means of the absolute α-counting method. These two results agreed well within the limits of

experimental error, so we can confirm that there was no contamination by non-radioactive impurities. The ^{233}Pa was prepared by the method reported by Suzuki and Inoue[8].

The extraction behavior of Cr(II) and Cr(III) was examined using ^{51}Cr as a tracer. ^{51}Cr was obtained as a chemical form of Na_2CrO_4 and was reduced to the divalent state with a liquid zinc amalgam after adding some carriers of Cr(III). Cr(II) was readily oxidized to Cr(III) by exposure to air. After two cycles of reduction and oxidation, the Cr(III) thus prepared was used in this experiment. The radiochemical purity of ^{51}Cr was certified by γ-ray spectroscopy. The water used was purified by distillation, followed by ion-exchange treatment. The TTA, BPHA, TOA, and other reagents used in this experiment were of the highest purity.

Apparatus. Both the reduction and the extraction of protactinium were carried out in the reduction apparatus described in the previous report.[9] For the solvent-extraction procedure, an Iwaki universal mechanical shaker, Model V-S, was used. The α- and γ-ray spectra were measured with an Osaka-Denpa gridded ionization chamber and with a 1 3/4 in$\times$1 in NaI(Tl) detector respectively, coupled with a Toshiba 800-channel pulse-height analyzer. A Hitachi Model SP-3 well-type NaI(Tl) scintillation probe coupled with a Kobe Kogyo Model SA-250 scaler was used for the γ-activity measurements. For measuring the absorption spectrum, a Hitachi Model EPS-3 recording spectrophotometer and a 1 cm quartz cell were used.

Procedure. Ten milliliters of a perchlorate or a sulfate solution which included 10^{-7}M Pa(V) and a definite amount of Cr(III) were introduced into a reduction apparatus and thoroughly deoxygenated by bubbling with argon gas which had passed through a dilute sulfuric acid solution of ammonium metavanadate. By shaking the reduction apparatus for about 15 min, protactinium and chromium were reduced with a freshly-prepared liquid zinc amalgam. After the amalgam had been excluded from the apparatus, 10 ml of a TTA-benzene, BPHA-benzene, or TOA-xylene mixture was introduced. Then the solvent extraction was carried out with a mechanical shaker until the equilibrium was established. After the two phases had been completely separated, an aliquot of each phase was placed in a polyethylene test tube and its γ-radioactivity was counted. The distribution ratio (D) was calculated by the usual equation:

$$D = \frac{\gamma\text{-activity per ml of the organic phase}}{\gamma\text{-activity per ml of the aqueous phase}} \quad (1)$$

The ionic strength was kept constant by the use of $LiClO_4$, if needed. All the experiments were carried out in an argon atmosphere at room temperature, 17—20 °C.

Results

The Stability of Pa(IV). After protactinium is once reduced to the tetravalent state, it is fairly stable in an oxygen-free atmosphere. For example, the re-oxidation rate of Pa(IV) in a hydrochloric acid solution is 8% per 15 hr,[9] and Pa(IV) is more stable in a sulfuric acid solution.

The oxidation-reduction potential of the Pa(IV)–Pa(V) has been reported to be -0.29 ± 0.03 V,[10] and that of Cr(II)–Cr(III), -0.40 V.[11] It was known from two reasons to be described below that Cr(II), which had been expected to be less stable than Pa(IV), was stable in both the aqueous and organic phases for 6 hr after the BPHA-benzene extraction was carried out. One of the reasons for this is that, if Cr(II),

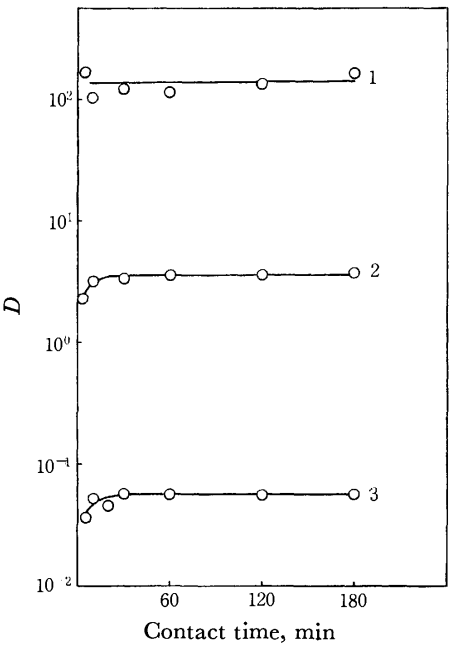

Fig. 1. Effect of contact time on distribution ratio of Pa.
Aq. phase: 0.125 M H_2SO_4, 6.22×10^{-3} M [Cr], 1: Pa(V), 2,3: Pa(IV)
Org. phase: 1,2: 0.05 M BPHA-benzene, 3: 0.03 M BPHA-benzene

which is extracted with BPHA from a weak acid solution as will be described below, is re-oxidized to Cr (III), it should not be extracted with BPHA from an acid solution; another is that the aqueous phase still shows the light-blue color of Cr(II) after the two phases are separated. For the same reason, it was found that Cr(II) was also stable in both the phases during the TTA-benzene extraction and in the aqueous phase during the TOA-xylene extraction, by which Cr(II) was not extracted. Moreover, the distribution ratio of Pa(IV) with BPHA reaches a nearly constant value within 30 min, as is clearly shown in Fig. 1. It should be noted that there is a wide difference in the distribution ratio between Pa(IV) and Pa(V); for instance, the distribution ratio of Pa(V) under the same conditions as those of Pa(IV) is about two orders greater than that of Pa(IV),[12] as is shown in Fig. 1. For these reasons, it may be concluded that Pa(IV) is very stable during the solvent extraction in both the aqueous and organic phases.

BPHA Extraction. The Effect of the Contact Time: From the results shown in Fig. 1, a 1-hr shaking was done in the case of the BPHA extraction of Pa(IV).

The Relation between the Distribution Ratio and the BPHA Concentration: The log-log plot of the distribution ratio of Pa(IV) in a sulfate solution and the concentration of BPHA shows a good linearity, with a slope of about 4; this value is independent of the concentration of Cr(II), as is shown in Fig. 2.

The BPHA Extraction of Cr(II): Cr(II) is also extracted with BPHA from an acid solution when the acid concentration is lower than 0.1 M, as is shown in Fig. 3. As is shown in Fig. 4, the log-log plot of the distribution ratio of Cr(II) and the concentration

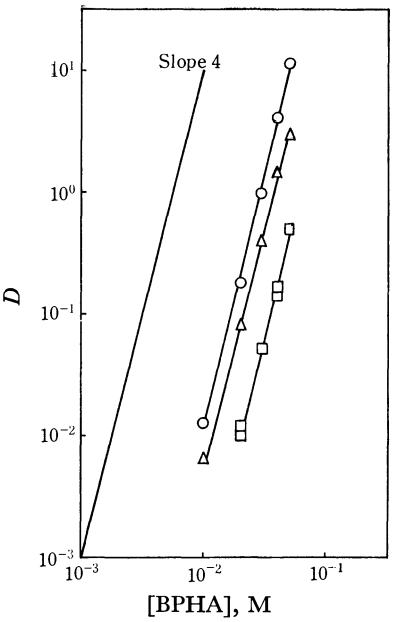

Fig. 2. Dependence of distribution ratio of Pa(IV) on BPHA concentration in benzene.
○: I=2 (adding $LiClO_4$), 1.7×10^{-2} M [Cr(II)], 0.159 M H_2SO_4, △: I=2 (adding Na_2SO_4), 1.7×10^{-3} M [Cr(II)], 0.159 M H_2SO_4, □: I=2 (adding Na_2SO_4), 8.5×10^{-3} M [Cr(II)], 0.159 M H_2SO_4.

of BPHA shows a linear relationship, with a slope of about 2. This means that one atom of Cr(II) chelates with two molecules of BPHA, and that its chelating compound is extracted into the benzene phase, the color of which is green. The concentration of BPHA can be corrected by Eq. (2), but it is not necessary when the acid concentration is higher than 0.1 M. Cr(III) was not extracted with BPHA-benzene under the same conditions as Cr(II).

The Influence of the Cr(II) Concentration on the BPHA Extraction of Pa(IV): As is shown in Fig. 5, the log-log plot of the distribution ratio of Pa(IV) and the concentration of Cr(II) shows a good linearity, and the distribution ratio of Pa(IV) decreases with an increase in the concentration of Cr(II).

TTA Extraction. *TTA Extraction of Cr(II)*: Cr(II) is extracted from a perchlorate or a sulfate solution with TTA-benzene. The log-log plot of the

Aq. phase: I=2, ○: 0.5 M $HClO_4$, 4.4×10^{-3} M [Cr (II)], ●: 0.5 M H_2SO_4, 6.8×10^{-3} M [Cr(II)], ▲: 0.033 M $HClO_4$, 2.2×10^{-3} M [Cr(II)], □: 0.01 M H_2SO_4, 4.6×10^{-3} M [Cr(II)].

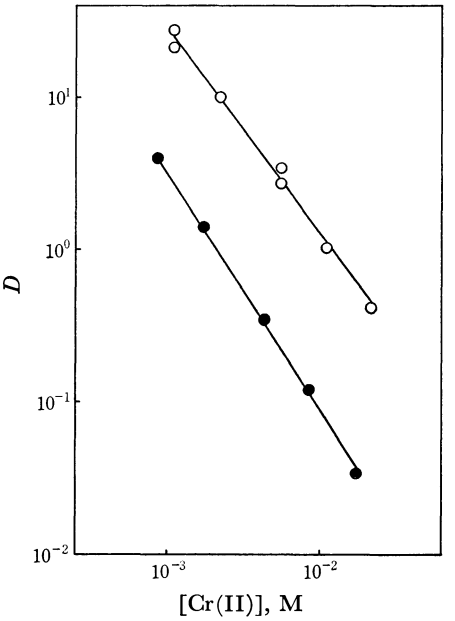

Fig. 5. Influence of Cr(II) concentration on extraction of Pa(IV) with BPHA.
Org. phase: ○: 0.01 M BPHA-benzene, ●: 0.03 M BPHA-benzene
Aq. phase: ●: I=2, 0.5 M H_2SO_4, ○: I=2, 0.5 M $HClO_4$.

distribution ratio of Cr(II) and the concentration of TTA shows a linear relation, with a slope of about 2, as is shown in Fig. 4. This means that one atom of Cr(II) chelates with two molecules of TTA, and that its chelating compound is extracted into the benzene phase, the color of which is yellow. On the other

hand, Cr(III) is not extracted under the same conditions.

The correction to the concentration of the TTA-benzene solution resulting from the co-existence of Cr(II) can be made by means of Eq. (2):

$$[HA]_e = [HA]_i - \frac{2D}{1+D}[Cr(II)]_i \quad (2)$$

where

$[HA]_e$=effective TTA or BPHA concentration in equilibrium

$[HA]_i$=initial TTA or BPHA concentration

$[Cr(II)]_i$=initial Cr(II) concentration

D=distribution ratio of Cr(II)

It is well known that one atom of Pa(IV) chelates with four molecules of TTA.[1,4,6] Consequently, we can correct the distribution ratio of Pa(IV) on the basis of these values.

The Influence of the Concentration of Cr(II) on the Extraction of Pa(IV) with TTA: Taking account of previous information,[4,6] the contact time of 30 min was chosen. The log-log plot of the distribution ratio of Pa(IV) and the concentration of Cr(II) is shown in Fig. 6. The distribution ratio of Pa(IV) decreases with an increase in the concentration of Cr(II).

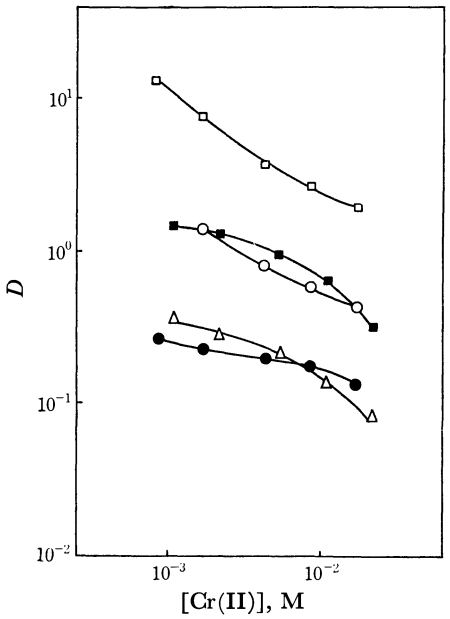

Fig. 6. Influence of Cr(II) concentration on extraction of Pa(IV) with TTA and TOA.
Org. phase: ●: 0.3 M TTA-benzene, ■,△: 0.1 M TTA-benzene, □,○: 5 v/v% TOA-xylene
Aq. phase: ●: I=2, 0.5 M H_2SO_4, ■: I=2, 0.5 M $HClO_4$, △: I=2, 1.0 M $HClO_4$, □: 0.236 M H_2SO_4, ○: 0.516 M H_2SO_4.

TOA Extraction. From the results of the previous paper,[3] the contact time of 30 min was chosen. As an anionic species of Pa(IV) is extracted with TOA, we investigated it only in a sulfuric acid solution, in which Pa(IV) was expected to form an anionic complex. The extraction of Pa(IV) from 0.263 and 0.516 M sulfuric acid solutions with 5 v/v % TOA-xylene was carried out; the log-log plot of the distribution ratio of Pa(IV) and the concentration of Cr(II) is shown in Fig. 6. The distribution ratio of Pa(IV) decreases as the concentration of Cr(II) increases, much as in the above results for the BPHA and TTA extractions. Under the same conditions, Cr(II) and Cr(III) were not extracted at all.

Discussion

Chromium(II) has been used in the investigation of the aqueous chemistry of Pa(IV) in microquantities, and protactinium exists quantitatively in the tetravalent state in the presence of more than 10^{-4} M of Cr(II). However, there is no particular information about the influence of Cr(II) on the study of Pa(IV). The present authors, therefore, investigated the effect of Cr(II) on the extraction behavior of Pa(IV). The relations between the concentration of Cr(II) and the distribution ratio of Pa(IV) were examined by the use of such extractants as BPHA, TTA, and TOA, and it was found that the distribution ratio of Pa(IV) decreases with an increase in the concentration of Cr(II) in every case. It is considered that one of the causes leading to these results may be the re-oxidation of Pa(IV). However, Pa(IV) is fairly stable in an oxygen-free atmosphere. From the above experiments, it was found that Cr(II), which is less stable than Pa(IV), is sufficiently stable in both aqueous and organic phases after extraction. Moreover, in the BPHA extraction, if Pa(IV) is re-oxidized the apparent distribution ratio of Pa(IV) should be increased with an increase in the contact time, because Pa(V) has a larger distribution ratio than Pa(IV). The distribution ratio, however, becomes constant after about 30 min, as is shown in Fig. 1. In the TTA extraction, the distribution ratio must be increased because Pa(IV) has a larger distribution ratio than Pa(V),[13] but Fig. 6 shows the reverse of this, contrary to expectation. For these reasons, it is clear that protactinium is quantitatively in the tetravalent state during the extraction.

It is considered that one of the most reliable explanations of the results shown in Figs. 5 and 6 is the possibility that a multi-nuclear complex between Pa(IV) and Cr(II) or Cr(III) is formed. There is some previously-reported information on the Cr(III)–Np(V) complex[14] and Cr(III)–U(IV) complex[15] which is confirmed by the spectrophotometric measurement of the solution. The present authors also tried to measure the absorption spectra of Pa(IV), but could not find any influence of Cr(II) on it. However, it does not necessarily follow that the possibility of the Cr(II)–Pa(IV) complex cannot be denied, because the formation of a multinuclear complex does not always cause a change in the absorption spectrum. The influence of Pa(IV) on the absorption spectrum of Cr(II) could not be found because of its small molar extinction coefficient.

Much more investigations will be necessary to explain the direct interaction between Pa(IV) and Cr(II) completely.

The Preparation and Characterization of Bis[2-(2-pyridyl)-imidazole]iron(II) Complexes

Yoshihiro SASAKI and Tsunenobu SHIGEMATSU
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611
(Received June 21, 1973)

Bis[2-(2-pyridyl)imidazole]iron(II) complexes, $Fe(PI)_2X_2$ ($X=Cl^-$, Br^-, NCS^-, N_3^-, and CN^-), were prepared and characterized on the basis of their infrared and Mössbauer spectra and their magnetic data. In $Fe(PI)_2(NCS)_2$, the NCS^- groups are N-bonded and are in a *cis* position. $Fe(PI)_2(CN)_2H_2O$ also has a *cis* configuration about the CN^- ligands. Except for $Fe(PI)_2(CN)_2H_2O$, the magnetic moments of the complexes lie in the 4.94—5.27 B.M. range. $Fe(PI)_2(CN)_2H_2O$ is a diamagnetic compound.

In the series of bis(1,10-phenanthroline)iron(II) complexes, $Fe(phen)_2X_2$, four types of compounds may be classified on the basis of their magnetic properties: (i) if the X ligand gives rise to a weak ligand field, the ground state is $^5T_2$[1]; (ii) if X affords a strong field, the complex is diamagnetic[1]; (iii) if X is F^-, 1/2 mal^{2-}, and 1/2 ox^{2-}, a spin triplet ground state is produced[2,3]; (iv) if $X=NCS^-$ or $NCSe^-$, a transition between the $^5T_2$ and $^1A_1$ ground states is observed at $T_c=174$ and 232 K.[4] In $Fe(bipy)_2(NCS)_2$, such a second-order transition at 216 K has also been reported.[5]

2-(2-Pyridyl)imidazole, possessing the characteristic of α-diimine, gives rise to a slightly weaker ligand field than does 2,2'-bipyridyl in nickel(II) complexes.[6,7] Certain tris[2-(2-pyridyl)imidazole]iron(II) complexes exhibit anomalous magnetic behavior indicative of the $^5T_2$–$^1A_1$ crossover.[8,9]

We have prepared bis[2-(2-pyridyl)imidazole]iron(II) complexes $Fe(PI)_2X_2$ ($X=Cl^-$, Br^-, NCS^-, N_3^-, and CN^-) and investigated their physical properties by means of infrared spectroscopy, Mössbauer-effect, and magnetic-susceptibility measurements; we will report our results here.

Experimental

2-(2-Pyridyl)imidazole was prepared by using a procedure similar to that described by Chiswell, *et al.*[10]

Preparation of Complexes. All the preparations were carried out in a nitrogen atmosphere using air-free water, acetone, and 3-methyl-1-butanol. All the complexes were dried *in vacuo* over silica gel at room temperature.

(a) Dichlorobis[2-(2-pyridyl)imidazole]iron(II), $Fe(PI)_2Cl_2$. The complex was prepared by suspending $Fe(II)(PI)_3Cl_2$-H_2O in 3-methyl-1-butanol and by then refluxing the mixture for 6 hrs. The orange crystals were washed by 3-methyl-1-butanol and were not recrystallized.

(b) Dibromobis[2-(2-pyridyl)imidazole]iron(II), $Fe(PI)_2Br_2$. 2-(2-Pyridyl)imidazole dissolved in acetone was added to a ferrous bromide solution prepared by mixing ferrous sulfate heptahydrate and barium bromide dihydrate solutions. When acetone was added to the filtered solution, orange crystals were precipitated.

(c) Dithiocyanatobis[2-(2-pyridyl)imidazole]iron(II), $Fe(PI)_2$-$(NCS)_2$. A concentrated aqueous solution of NaSCN was added to a mixed solution of $FeCl_24H_2O$ and 2-(2-pyridyl)-imidazole. The orange precipitate was washed with an ice-cold acetone-water mixture.

(d) Dicyanobis[2-(2-pyridyl)imidazole]iron(II) Monohydrate, $Fe(PI)_2(CN)_2H_2O$. A concentrated aqueous solution of KCN was added to a filtered solution of $FeCl_24H_2O$ and 2-(2-pyridyl)imidazole. After the acetone has been removed by using an evaporator, reddish-brown crystals were precipitated. One mole of H_2O per mole of the resulting compound was determined by the weight loss at 95 °C over P_2O_5.

(e) Diazidobis[2-(2-pyridyl)imidazole]iron(II), $Fe(PI)_2$-$(N_3)_2$. A concentrated aqueous solution of NaN_3 was added to the filtered starting solution, and the wine-red crystals thus precipitated were washed by water.

The analytical results of these complexes are given in Table 1. The quantitative determination of N in $Fe(PI)_2(N_3)_2$ met with difficulties.

Infrared Spectra. The infrared spectra were measured in Nujol mull with a Perkin-Elmer 521 spectrophotometer.

Magnetic Measurements. The magnetic susceptibilities were measured with a torsion-balance magnetometer. All the measurements were made at two different field strengths; no field dependence of the magnetic susceptibility was observed. The molar susceptibilities were corrected for diamagnetism, the following corrections: Fe^{2+}, −13; H_2O, −13; Cl^-, −23.4; Br^-, −34.6; NCS^-, −31.0; CN^-, −13; N_3^-, −13.7; 2-(2-pyridyl)imidazole, −82 (in units of 10^{-6} cgs/mol). The effective magnetic moment, μ_{eff}, was obtained from the $\mu_{eff}=2.828\sqrt{\chi_{M'}T}$ relation, $\chi_{M'}$ being the fully corrected molar susceptibility, and T, the temperature in K.

Mössbauer Effect Measurements. The Mössbauer spectra were obtained with a scanning velocity spectrometer in the time mode. The radiation source was ^{57}Co diffused in a copper foil and kept at room temperature during all the

measurements. The velocity scale was calibrated with metallic iron, and the velocity was determined to an accuracy of ± 0.04 mm/s.

Results and Discussion

Infrared Spectra. The frequencies of the band maxima of the X ligands in the $Fe(PI)_2X_2$ complexes (X=NCS^-, CN^-, and N_3^-) are listed in Table 2. Since the absorption bands due to the 2-(2-pyridyl)-imidazole of these complexes change little from those of $Fe(PI)_2Cl_2$ and $Fe(PI)_2Br_2$, it is easy to assign the bands due to the X ligands.

Table 2. Infra-red frequencies of ligands X in $Fe(PI)_2X_2$ complexes (in cm^{-1})

Complex	Frequencies of band maxima	Assignment
$Fe(PI)_2(NCS)_2$	2071 vs, 2083 vs	C–N stretching
	975 s	C–S stretching
	460 m	N–C–S bending
$Fe(PI)_2(CN)_2H_2O$	2043 vs, 2051 vs	C–N stretching
$Fe(PI)_2(N_3)_2$	2037 vs, 2056 vs	N–N stretching

The thiocyanate group has three fundamental frequencies, *i.e.*, ν_1 (C–N stretching), ν_2 (N–C–S bending), and ν_3 (C–S stretching). Since thiocyanate is a bifunctional ligand, the positions of ν_1, ν_2, and ν_3 depend on whether this group is attached to the metal ion through N or through S. In $Fe(PI)_2(NCS)_2$, ν_1, ν_2, and ν_3 are in the range characteristic of N-bonded thiocyanate.[11-13] A splitting of the C–N stretching mode is observed. A *cis* configuration has been reported for both $Fe(phen)_2(NCS)_2$ and $Fe(bipy)_2(NCS)_2$, which exhibit splittings of the C–N stretching band of 12 and 10 cm^{-1} respectively[4,5] as well as for $Fe(phen)_2(CN)_2$, where the C–N stretching shows two peaks at 2075 and 2062 cm^{-1}.[14] In $Fe(PI)_2(NCS)_2$, the splitting of the C–N stretching mode is, therefore, taken as an indication of a *cis* configuration about the thiocyanate ligands. In $Fe(PI)_2(CN)_2H_2O$, the splitting of the C–N stretching mode is also observed. Therefore, this complex may have a *cis* configuration about the cyano ligands. Though $Fe(PI)_2(CN)_2H_2O$ is a low-spin compound, as will be described later, the absorption bands due to 2-(2-pyridyl)imidazole are similar to those of other complexes.

Magnetic Data. The results of magnetic-susceptibility measurements of polycrystalline samples between 77.2 and 283.0 K are compiled in Table 3. Except for $Fe(PI)_2(CN)_2H_2O$, the magnetic moments of the present complexes are characteristic of an iron(II) ion in a $^5T_2$ ground state. Within the temperature range of 77.2—283.0 K, the susceptibilities follow the Curie-Weiss law, $\chi_M'=C/(T-\Theta)$. The resulting values of the Weiss constant are included in Table 3. The magnetic moment observed in $Fe(PI)_2(CN)_2H_2O$ is indicative of a $^1A_1$ ground state of iron(II).

Mössbauer Spectra. The Mössbauer parameters are listed in Table 4. Some typical spectra of $Fe(PI)_2(N_3)_2$ are shown in Fig. 1. It was impossible to

a: 298 K b: 77.2 K

observe the Mössbauer effect of $Fe(PI)_2Br_2$ at 298 K. The parameters of $Fe(PI)_2X_2$ ($X=Cl^-$, Br^-, NCS^-, and N_3^-) are in the range characteristic of a Fe^{2+} ion in a high-spin form.[15] The spectra of $Fe(PI)_2(N_3)_2$ show marked features in the magnitude and the temperature dependency of the quadrupole splitting. In addition, the spectrum at 298 K exhibits a difference in the peak intensity of the doublet lines. The variation with the temperature predicts that there is an anisotropic recoilless fraction in this complex. On the other hand, the parameters of $Fe(PI)_2(CN)_2H_2O$ are characteristic of an iron(II) ion in a low-spin form.

The bis[2-(2-pyridyl)imidazole]iron(II) complexes, $Fe(PI)_2X_2$, may be classified into three groups on the basis of their magnetic properties: (i) if $X=Cl^-$, Br^-, NCS^-, and N_3^-, $Fe(PI)_2X_2$ is a high-spin compound; (ii) $Fe(PI)_2(CN)_2H_2O$ is a diamagnetic complex; (iii) $[Fe(PI)_3]^{2+}$ complexes in which X=1/2[2-(2-pyridyl)-imidazole] exhibit a spin equilibrium between $^1A_1$ and $^5T_2$ states.[8,9] The tris(1,10-phenanthroline)iron(II) and tris(2,2'-bipyridyl)iron(II) complexes are diamagnetic compounds, and $Fe(phen)_2(NCS)_2$ and $Fe(bipy)_2(NCS)_2$ have an anomalous magnetic property due to a $^1A_1$ and $^5T_2$ crossover.[4,5] Such a change in the spin state from ligand to ligand indicates that 2-(2-pyridyl)-imidazole gives rise to a weaker ligand field than do 1,10-phenanthroline and 2,2'-bipyridyl in iron(II) complexes.

The authors wish to thank Dr. T. Shinjo and Mr. T. Matsuzawa for permitting to use the equipment for the Mössbauer and magnetic measurements respectively.

Acid Dissociation Constants of Some Histidine-containing Peptides and Formation Constants of Their Metal Complexes

Akira YOKOYAMA, Hiroji AIBA, and Hisashi TANAKA
Faculty of Pharmaceutical Sciences, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606
(Received June 18, 1973)

Glycyl-L-histidine, L-histidylglycine, glycylglycyl-L-histidine, glycyl-L-histidylglycine, and L-histidylglycylglycine were synthesized by the carbobenzoxy azide procedure. The acid dissociation constants of these peptides and their related compounds were determined from the potentiometric titration curves of 0.01 M solutions at 21 °C. The dissociation of one ionization group is greatly influenced by the charge on the other groups. The formation constants of metal complexes of L-histidylglycine, L-histidylglycylglycine, and L-3-benzylhistidine were calculated by the least-squares method from the titration curves of the solution containing the ligand (0.01 M) and metal in the molar ratio 2: 1, assuming the formation of 1: 1 and 2: 1 normal complexes (ML^+ and ML_2), and the results were compared with those of L-histidine-metal complexes. For any metal ion, the order of formation constants was found to be histidine≈3-benzylhistidine>histidylglycine>histidylglycylglycine, in agreement with that of the basicity of amino and imidazole groups. In these metal complexes, metal ion is considered to bind through amino, imidazole, and carboxyl or carbonyl groups of histidine residue.

Histidine residue of the protein molecule plays a particularly important role in the interaction with metal ion, due to the presence of three coordinating groups, but detailed studies on the complex formation of the peptides with metal ions as a model system of the protein-metal interaction have been mostly confined to a limited number of simple peptides not containing histidine residue. Recently, however, some valuable information has been given on the complex formation of histidine-containing peptides.[1-5] Because of its significance in the study of protein-metal interaction, we have undertaken an extensive study on the complex formation of various histidine-containing peptides in order to obtain more information. This paper deals with the syntheses and the acid dissociation constants of glycyl-L-histidine, L-histidylglycine, glycylglycyl-L-histidine, glycyl-L-histidylglycine, and L-histidylglycylglycine (abbreviated as H–Gly–His–OH, H–His–Gly–OH, H–Gly–Gly–His–OH, H–Gly–His–Gly–OH, and H–His–Gly–Gly–OH, respectively) and the formation constants of some metal complexes of these peptides.

Experimental

Syntheses. *L-Histidylglycine*: H–His–Gly–OH was synthesized according to the method given by Photaki *et al.*,[6] with some modifications.

Carbobenzoxyglycyl-L-histidine Methyl Ester (Z–Gly–His–OCH_3): To a solution of 0.02 mol of carbobenzoxyglycine hydrazide[7] in 20 ml of 2 M hydrochloric acid and 100 ml of *N,N*-dimethylformamide (DMF) was added a cold concentrated aqueous solution of 0.02 mol of sodium nitrite under cooling with an ice-bath. After 30 min, 0.02 mol of L-histidine methyl ester dihydrochloride was added and the solution was neutralized with triethylamine. The solution was then allowed to stand under cooling for 24 hr. The solvent was evaporated and the residue was dissolved in water. The pH of the solution was adjusted to 8—9 with the addition of 1 M sodium hydroxide, and the resulting precipitate was collected and washed with water; yield 80%.

Carbobenzoxyglycyl-L-histidine (Z–Gly–His–OH): To a solution of 0.01 mol of Z–Gly–His–OCH_3 in 20 ml of methanol was added 10 ml of 1 M sodium hydroxide. After 30 min the solution was neutralized by the addition of 1 M hydrochloric acid and evaporated to dryness. The residue was dissolved in methanol. After removing the insoluble material, the solution was allowed to stand. The crystals of Z–Gly–His–OH precipitated within about 30 min. After 1 hr, the product was collected and used in the subsequent procedure without further purification; yield 95%.

Glycyl-L-histidine: To a solution of 0.005 mol of Z–Gly–His–OH in 20 ml of methanol, 10 ml of water and 1 ml of glacial acetic acid was added 100 mg of 10% Pd/C, and hydrogen was bubbled for 3 hr. The catalyst was removed by filtration. The filtrate was concentrated and applied to a column of Dowex 50-X2, H-form. Water was passed until no chlorine ion was detected in the effluent. H–Gly–His–OH was eluted with 1 M ammonium hydroxide and the effluent was concentrated to dryness. Dehydrated ethanol was added and evaporated. The procedure was repeated to obtain H–Gly–His–OH as amorphous powder; yield 95%.

Carbobenzoxyglycylglycyl-L-histidine Methyl Ester (Z–Gly–Gly–His–OCH_3), Carbobenzoxyglycyl-L-histidylglycine Ethyl Ester (Z–Gly–His–Gly–OC_2H_5), and Carbobenzoxy-L-histidylglycylglycine Ethyl Ester (Z–His–Gly–Gly–OC_2H_5): These peptides were prepared in the same way as in the syntheses of Z–Gly–His–OCH_3, from carbobenzoxydipeptide hydrazides[7] with amino acid ester hydrochlorides; yield 80%.

Carbobenzoxyglycylglycyl-L-histidine (Z–Gly–Gly–His–OH) and Carbobenzoxyglycyl-L-histidylglycine (Z–Gly–His–Gly–OH): To a solution of 0.01 mol of carbobenzoxytripeptide ester in 20 ml of DMF was added 10 ml of 1 M sodium hydroxide. After 30 min the solution containing carbobenzoxytripeptide was neutralized with 1 M hydrochloric acid and used in the subsequent procedure.

Glycylglycyl-L-histidine and Glycyl-L-histidylglycine: These peptides were prepared from the solutions of carbobenzoxytripeptides in the same way as in the synthesis of H–Gly–His–OH; yield 90%.

L-Histidylglycylglycine Ethyl Ester (H–His–Gly–Gly–OC_2H_5): To a solution of 0.005 mol of Z–His–Gly–Gly–OC_2H_5 in 50 ml of DMF was added 100 mg of 10% Pd/C, and hydrogen was bubbled for 3 hr. The catalyst was removed and the solution containing H–His–Gly–Gly–OC_2H_5 was used in the subsequent reaction.

L-Histidylglycylglycine: To a solution of H–His–Gly–Gly–OC_2H_5 was added 5 ml of 1 M sodium hydroxide. After 1 hr, the solution was neutralized with 1 M hydrochloric acid and concentrated. NaCl was removed in the same way

as in the case of H-Gly-His-OH; yield 90%.

Other Materials. L-3-Benzylhistidine (3-Bzl-His-OH) (from Peptide Institute, Protein Research Foundation) and commercial ligands and metal salts were used. Metal ion solutions prepared from metal chlorides or metal sulfate were standardized with EDTA.

Potentiometric Titration. Potentiometric titration was carried out with a Radiometer Titrator TTT 1 and a Titrigraph according to the prescription given by Albert and Serjeant.[8] A solution (10 ml) containing a ligand (10^{-2}M) and hydrochloric acid (0—2.0×10^{-2} M), or a ligand (10^{-3} M), hydrochloric acid (1.0—2.0×10^{-3} M) and a metal ion (0.5×10^{-3} M) was titrated with 0.1 M potassium hydroxide. During the course of titration, the temperature was maintained at 21 °C and a stream of CO_2 free nitrogen was passed through the titration vessel.

Results and Discussion

Syntheses. Histidine-containing peptides were synthesized by the carbobenzoxy azide method.[6,7] A slight modification was necessary in some cases. In the synthesis of H-His-Gly-Gly-OH, catalytic reduction was carried out prior to the hydrolysis of Z-His-Gly-Gly-OC_2H_5, because a side reaction took place in the hydrolysis. The analytical data of the peptides synthesized are shown in Table 1, together with their melting points. The results of the electrophoresis and thin layer chromatography confirmed the purity of these peptides.

Acid Dissociation Constants. The potentiometric titration curves for histidine-containing peptides and their related compounds are shown in Figs. 1 and 2. Acid dissociation corresponding to three coordinating groups, namely amino, imidazole, and carboxyl groups, are observed in all these ligands. The equilibria in the dissociation are expressed as follows.

$$LH_3^{2+} \rightleftharpoons LH_2^+ + H^+$$
$$K_{COOH} = [LH_2^+][H^+]/[LH_3^{2+}] \quad (1)$$

$$LH_2^+ \rightleftharpoons LH + H^+$$
$$K_{Im} = [LH][H^+]/[LH_2^+] \quad (2)$$

$$LH \rightleftharpoons L^- + H^+$$
$$K_{NH_2} = [L^-][H^+]/[LH] \quad (3)$$

The values of K_{Im} and K_{NH_2} were calculated simultaneously as shown below, since the acid dissociations of amino and imidazole groups overlap in most of the ligands. In the range where a value, which represents moles of KOH added per mole of completely protonated ligand, is between 1 and 3, total concentration of the ligand and the electroneutrality are expressed by

$$[L]_T = [LH_2^+] + [LH] + [L^-] \quad (4)$$

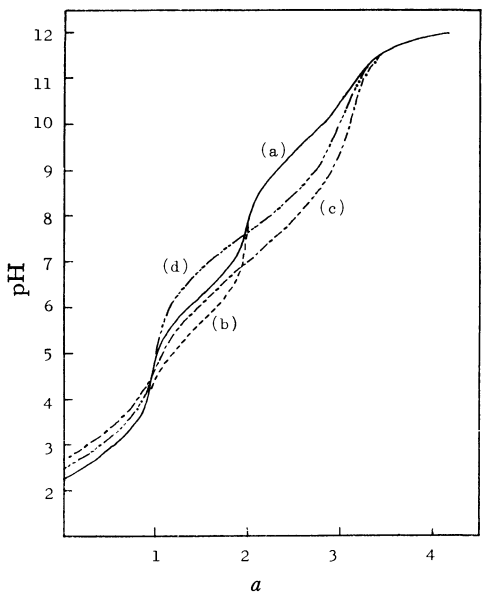

Fig. 1. Titration curves of histidine-containing dipeptides and related compounds;
(a) histidine·HCl+HCl, (b) 3-Bzl-His-OH+2HCl, (c) H-His-Gly-OH+2HCl, (d) H-Gly-His-OH+2HCl; ligand concentration: 10^{-2} M.

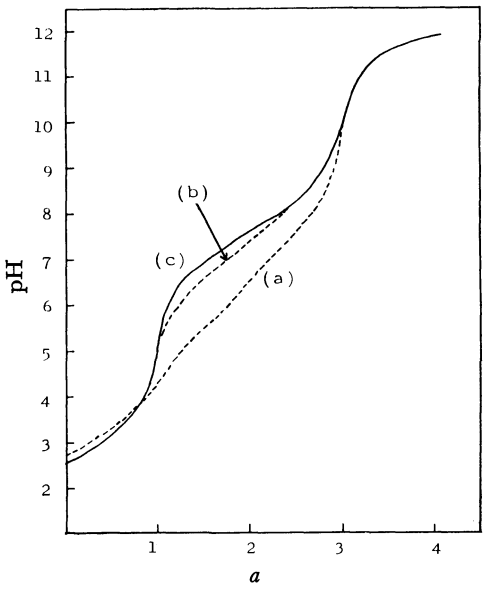

Fig. 2. Titration curves of histidine-containing tripeptides;
(a) H–His–Gly–Gly–OH+2HCl, (b) H–His–Gly–OH +2HCl, (c) H–Gly–Gly–His–OH+2HCl; ligand concentration: 10^{-2} M.

$$[LH_2^+] + [H^+] + [K^+] = [OH^-] + [Cl^-] + [L^-]. \quad (5)$$

From Eqs. (2)~(5), we obtain

$$[H^+]([L]_T - P)/P = K_{Im} + ([L]_T + P)K_{Im}K_{NH_3}/P[H^+] \quad (6)$$

where $[L]_T$=total concentration of ligand
$[L^-]$=concentration of completely deprotonated ligand
$[LH]$=concentration of monoprotonated ligand
$[LH_2^+]$=concentration of diprotonated ligand
$[LH_3^{2+}]$=concentration of triprotonated ligand
$P=[L^-]([H^+]^2/K_{Im}K_{NH_3}-1)$.

The values of K_{Im} and K_{NH_3} were calculated by the least-squares treatment of Eq. (6). The constants of L-histidine methyl ester (H–His–OCH_3) were similarly calculated. The values of K_{COOH} were calculated by the usual method. The results are shown in Table 2.

The value of pK_{COOH} increases in the order histidine ≈3-Bzl–His–OH < H–Gly–His–OH < H–Gly–Gly–His–OH < H–His–Gly–OH < H–His–Gly–Gly–OH ≈ H–Gly–His–Gly–OH. This indicates that the dissociation of the carboxyl group is greatly influenced by the electrostatic effect[9] of the positive charges on amino and imidazole groups. The basicity of the imidazole group decreases in the order H–Gly–Gly–His–OH > H–Gly–His–OH > H–Gly–His–Gly–OH > histidine > H–His–Gly–OH > 3-Bzl–His–OH > H–His–Gly–Gly–OH. This order agrees with that expected from the electrostatic effect of the amino and the carboxyl groups, except for the case of 3-Bzl–His–OH, *viz.*, the basicity of the imidazole group is strengthened by the negative charge but weakened by the positive charge. A weaker basicity of the imidazole group of 3-Bzl–His–OH than expected is explicable in terms of the decrease of the electron-delocalization in the imidazole ring. Similarly, it seems that the values of pK_{NH_3} are mainly governed by the electrostatic effect based on the carboxyl and

imidazole groups. The higher values of pK_{Im} and pK_{COOH_3} of carbobenzoxy dipeptides, in which amino groups are blocked, than those of corresponding free dipeptides can be accepted in view of the influence of electrostatic effect. The lower values of pK_{Im} and pK_{NH_3} of H–His–OCH_3 than those of histidine are explicable in terms of the absence of the electrostatic effect of the carboxyl group.

Complex Formation of H–His–Gly–OH and H–His–Gly–Gly–OH with Some Transition Metal Ions. The titration curves of the solutions containing H–His–Gly–OH, H–His–Gly–Gly–OH, and 3-Bzl–His–OH and metal ions with the ratio of 2 to 1 are shown in Figs. 3, 4, and 5. They are very similar to those of histidine and metal ions. The inflection of pH was observed at $a=3$, indicating the formation of 2: 1 (ligand to metal) complexes in all cases. The following equilibria are postulated in the complex formation which occurred in the range where a value is between 1 and 3. The formation constants are denoted by K_1 and K_2.

$$M^{2+} + L^- \rightleftarrows ML^+ \quad K_1 = [ML^+]/[M^{2+}][L^-] \quad (7)$$

$$ML^+ + L^- \rightleftarrows ML_2 \quad K_2 = ML_2/[ML^+][L^-] \quad (8)$$

The formation constants were calculated by the least-squares treatment of the equation of Irving and Rossotti.[10,11]

$$\bar{n}/(\bar{n}-1)[L^-] = (2-\bar{n})[L^-]K_1K_2/(\bar{n}-1) - K_1 \quad (9)$$

The calculated values do not vary significantly with pH values in most cases. In the systems H–His–Gly–OH–Fe(II) and H–His–Gly–Gly–OH–Fe(II), only log K_1 was approximately obtained from the formation curves, assuming $\log K_1 = -\log[L^-]$ at $\bar{n}=0.5$, since the precipitation occurred in the course of the titrations and the accurate values were not obtained by least-squares treatment. In the systems 3-Bzl–His–OH–Cu(II) and histidine-Cu(II), the occurrence of complicated complex formation is suggested, since consistent values were not obtained. The results are shown in Table 3. The validity of these constants was approved in most cases, by the coincidence of the experimental and calculated formation curves, obtained from the formation constants determined (Figs. 6, 7, and 8). The results might indicate that the formation of species other than normal complexes can be neglected. In the case of 3-Bzl–His–OH–Cu(II) and histidine-Cu(II) sys-

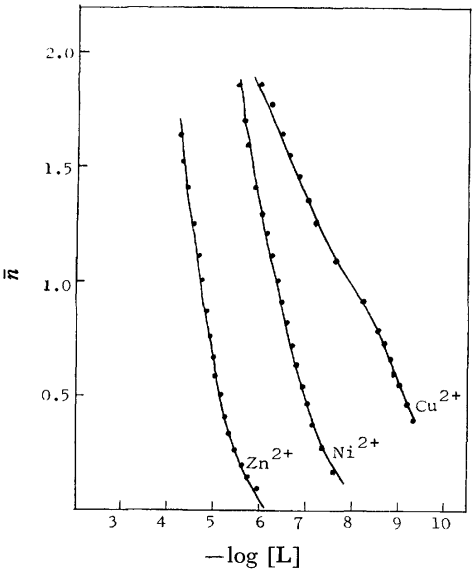

Fig. 7. Formation curves of metal complexes of H-His-Gly-OH.

tems, experimental and calculated formation curves did not coincide. In histidine-Cu(II) system the discrepancy has been explained on the basis of the formation of the protonated complex, in which Cu(II) is assumed to bind to imidazole and carboxyl groups, in addition to the normal complex.[11-14] Accordingly, the formation of a similar protonated complex can possibly be presumed also in 3-Bzl-His-OH-Cu(II) system. In this connection, the coincidence between experimental and calculated formation curves in the systems H-His-Gly-OH-Cu(II) and H-His-Gly-Gly-OH-Cu(II) suggests that the formation of the protonated complex might be neglected in these systems. The low stability of the protonated complex is explained in the light of the structure of these ligands, *viz.*, the existence of imidazole and carboxyl groups with long distance. It is clear from Table 3 that the Irving-

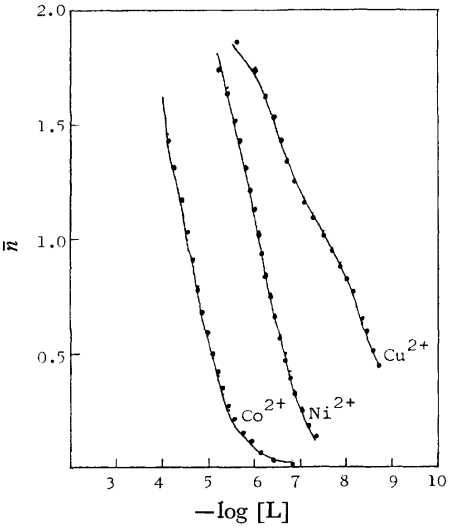

Fig. 8. Formation curves of metal complexes of H-His-Gly-Gly-OH.

Williams' order,[19] Fe(II)<Co(II)<Ni(II)<Cu(II)>Zn(II), is satisfied for all ligands. Further, with any given metal ion, the order of the stability constants with respect to the four ligands is 3-Bzl-His-OH≈histidine>H-His-Gly-OH>H-His-Gly-Gly-OH, agreeing with that of the basicity of amino and imidazole groups. This indicates that metal ions strongly bind to amino and imidazole groups in 3-Bzl-His-OH, H-His-Gly-OH, and H-His-Gly-Gly-OH, as in the case of histidine. The third coordination site may be oxygen atom of carboxyl or carbonyl groups. The probable structures of the 2: 1 complexes, ML_2, may be expressed as **I** and **II**. In the region where *a* value is larger

The Extraction of Tris(1,10-phenanthroline)ruthenium(II). I. Distribution Studies

Takejiro TAKAMATSU

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606

(Received June 26, 1973)

Tris(1,10-phenanthroline)Ru(II) was extracted into various organic solvents with several anions, such as the perchlorate ion, the iodide ion, or the thiocyanate ion. The association constants of ion-pairs were successfully determined by analysis of the extraction curves in the solvents with low polarities. It was found that the ion-pairs were extracted mainly as the associated form and that only the first-step dissociation could slightly occur ($<10^{-7}$) in such solvents; furthermore, the degree of association was considerable even in water. Therefore, the distribution ratio of the complex cation must be governed by both the hydration energy of the counter anion and the solubility parameter of the extraction solvent rather than its dielectric property. An abnormal decrease in the distribution ratio was observed when the tetraphenylborate ion was used as the counter anion. This phenomenon can be explained clearly in terms of the hydrotropism which was often encountered in the solution of an electrolyte with a large ion.

In recent years, the ion-pair extraction systems have been widely investigated, mainly out of analytical interest.[1] However, very few theories which can satisfactorily explain its mechanism have yet been developed. Some authors have successfully tried to discuss the extraction mechanism in connection with the dielectric properties of the solvents.[1,2] On the other hand, Freiser[3] suggested the possibility that the regular solution theory could also be applied to the ion-pair distribution with the organic solvent of a low polarity (≤ 10), much as in the case of chelate distribution.[4] Gibson and Weatherburn[5] have tried to discuss the extraction behavior in connection with the hydration energies of the ions.

In this paper, in order to describe one approach to the systematic investigation of the ion-pair extraction system, tris(1,10-phenanthroline)Ru(II), $Ru(II)(phen)_3$ has been chosen as the extractant to be transferred into various organic solvents in the presence of such anions as the perchlorate ion, the iodide ion, the thiocyanate ion, the tetrafluoroborate ion, and the tetraphenylborate ion. The extraction mechanism can be analysed clearly in the $Ru(II)(phen)_3$ system, because $Ru(II)(phen)_3$ is very substitution-inert so that the interference of the free ligand can be neglected. The distribution ratios were discussed as a function of the bulk character of the solvents and of the hydration energies of the anions. The distribution ratios of sodium perchlorate into chloroform, *o*-dichlorobenzene, *etc.*, which could hardly be determined by direct-extraction measurements, can also be determined indirectly by analyses of the extraction curves of $Ru(II)(phen)_3$. In the extraction of $Ru(II)(phen)_3$ with the tetraphenylborate ion, the decrease in the distribution ratio appeared in the region where the concentration of the tetraphenylborate ion was high. This abnormal phenomenon was explained in terms of the hydrotropism advanced by Neuberg[6] in 1916.

In the next paper,[7] the distribution ratio will be discussed in connection with the solubilities by applying the regular solution theory and the electrostatic theory.

Experimental

Reagents. All the reagents were of a reagent-grade purity. The organic solvents were purified mainly by distillation before use. Sodium perchlorate was used as an anhydrous salt after recrystallization. ^{106}Ru (Lot. No. 1210) was supplied by the Japan Radioisotope Association. The radiochemical purity was checked by means of the γ-ray spectrum. The water was distilled twice with an all-quartz distillation apparatus.

Molar absorptivity of $Ru(II)(phen)_3$. The determination of the molar absorptivity of Ru(II) $(phen)_3$ was carried out by using a ruthenium chloride solution (ruthenium content: 0.07392 mg/ml) in a manner almost identical with that of Banks and ÓLaughlin[8] except that 0.5 M KH_2PO_4–Na_2HPO_4 was used to maintain the pH at 6 during the reaction. The calculated molar absorptivity at 448 nm was 18500 liters per mole-cm. In this series of extraction studies, the concentration of Ru(II) $(phen)_3$ was determined from this value.

Preparation of the $^{106}Ru(II)(phen)_3$ Solution. A crude aqueous solution of $^{106}Ru(II)(phen)_3$ was prepared from $^{106}RuCl_3$ (containing as adequate amount of the carrier) as has been described above except that the NaOH–HCl system was used to adjust the pH to 6. After the reacted mixture has been washed several times with chloroform and then with *n*-hexane, the $Ru(II)(phen)_3$ was extracted with the perchlorate ion into 1,2-dichloroethane. This organic phase was evaporated to dryness and then dissolved with a minimum volume of acetonitrile. If any residue was detected, it was filtered out. This filtrate was dried again and then dissolved in a small amount of water. This resulting solution was passed through the anion-exchanger column in order to convert the counter anions to chloride or sulfate. It is recommended that a labelled complex of a high specific activity should be used immediately after preparation, since serious radiation decomposition was noticed; in a sample of 1 μCi/ml, several percent were found to be decomposed within one week.

Extraction Procedure of $Ru(II)(phen)_3$. An appropriate amount of the $^{106}Ru(II)(phen)_3$ solution and various amounts of sodium-salt solutions of different anions, such as the perchlorate ion, the iodide ion, and the thiocyanate ion, were placed in a 50 ml glass centrifuge tube equipped with a ground stopper. After sodium chloride or sodium sulfate has been added to keep the ionic strength constant and after the aqueous phase has been diluted up to 10 ml with water, a 10 ml portion of the organic solvent was added. The two phases were shaken vigorously for 30 min in the thermostat at 25 ° and

then separated by centrifugation. The net distribution ratio was calculated by measureing the γ-radioactivities of both the phases with a single-channel pulse-height analyser (Osaka Denpa Model LA-3T, or Nuclear-Chicago 1185 series).

Theoretical

The ion-pair extraction equilibrium is independent of the salt which is added in the aqueous phase to keep the ionic strength constant except in the very low concentration region of the counter anion, A^-. Therefore, in the extraction of $Ru(II)(phen)_3$ with various anions, the following concentration constants have been defined in the two phases:

$$k_1 = \frac{[MA^+]_a}{[M^{2+}]_a[A^-]_a} \quad (1)$$

$$k_2 = \frac{[MA_2]_a}{[MA^+]_a[A^-]_a} \quad (2)$$

$$K_D = \frac{[MA_2]_o}{[MA_2]_a} \quad (3)$$

$$K_1 = \frac{[MA^+]_o[A^-]_o}{[MA_2]_o} \quad (4)$$

$$K_2 = \frac{[M^{2+}]_o[A^-]_o}{[MA^+]_o} \quad (5)$$

In these expressions, the subscripts a and o refer to the aqueous and organic phases respectively, M^{2+}, to the complex cation $Ru(II)(phen)_3$, and A^-, to the counter anion.

At the distribution equilibrium, the distribution ratio, D, of MA_2 is written as:

$$D = \frac{[M^{2+}]_o+[MA^+]_o+[MA_2]_o}{[M^{2+}]_a+[MA^+]_a+[MA_2]_a} \quad (6)$$

By combining Eqs. (1)—(6), D can be expressed as:

$$D = K_D \times \frac{k_1k_2[A^-]_a^2}{1+k_1[A^-]_a+k_1k_2[A^-]_a^2} \times \frac{K_1K_2+K_1[A^-]_o+[A^-]_o^2}{[A^-]_o^2} \quad (7)$$

In the application of Eq. (7), the following four cases can be assumed:

(i) When the dissociation does not occur at all in the organic phase, Eq. (7) can be simplified to Eq. (8):

$$D = K_D \times \frac{k_1k_2[A^-]_a^2}{1+k_1[A^-]_a+k_1k_2[A^-]_a^2} \quad (8)$$

This equation shows that the D values depend only upon $[A^-]_a$. Therefore, the D values are kept constant, even though the concentration of the complex cations changes.

(ii) When the first-step dissociation occurs alone in the organic phase ($K_2=0$), Eq. (7) can be represented as Eq. (9):

$$D = K_D \times \frac{k_1k_2[A^-]_a^2}{1+k_1[A^-]_a+k_1k_2[A^-]_a^2} \times \frac{K_1+[A^-]_o}{[A^-]_o} \quad (9)$$

The electrical neutrality in the organic phase requires the following equation:

$$[MA^+]_o = [A^-]_o \quad (10)$$

In addition, the total concentration of the extracted species, $(C_M)_o$, is represented by Eq. (11):

$$(C_M)_o = [MA^+]_o + [MA_2]_o \quad (11)$$

By combining Eqs. (4), (10), and (11), the next relation is obtained:

$$[A^-]_o = (\sqrt{K_1^2+4K_1(C_M)_o}-K_1)/2 \quad (12)$$

From Eqs. (9), and (12), we obtain Eq. (13):

$$D = K_D \times \frac{k_1k_2[A^-]_a^2}{1+k_1[A^-]_a+k_1k_2[A^-]_a^2} \times \frac{K_1+\sqrt{K_1^2+4K_1(C_M)_o}+2(C_M)_o}{2(C_M)_o} \quad (13)$$

According to Eq. (13), if $[A^-]_a$ is kept constant, the slope of the plot of log D *vs.* $\log(C_M)_o$ must be -1 in the low $(C_M)_o$ region, must increase with the increase in $(C_M)_o$, and must finally reach 0 in the high $(C_M)_o$ region. In the region where D is independent of the change of $(C_M)_o$, the third term of Eq. (13) becomes 1 and Eq. (13) is simplified to Eq. (8). Equation (8) can be converted into Eq. (14) by using the method of Sillén:[9]

$$(K_D-D)D^{-1}[A^-]_a^2 = k_2^{-1}[A^-]_a + k_1^{-1}k_2^{-1} \quad (14)$$

If K_D is known, k_1 and k_2 can be calculated from the plot of $(K_D-D)D^{-1}[A^-]_a^2$ *vs.* $[A^-]_a$. K_D, here, is experimentally obtained by taking the D value to be equal to K_D in the high $[A^-]_a$ region on the plot of log D *vs.* log $[A^-]_a$, where D becomes constant. If k_1, k_2, and K_D are obtained in this way, K_1 can be estimated from the slope of the plot of D *vs.* $1/(C_M)_o$ in the region where the slope of the plot of log D *vs.* log $(C_M)_o$ becomes -1, because its slope is represented by

$$K_DK_1k_1k_2[A^-]_a^2/(1+k_1[A^-]_a+k_1k_2[A^-]_a^2).$$

(iii) When the first-step dissociation occurs almost completely in the organic phase, that is, when K_1 is very large, Eq. (7) can be written as follows:

$$D = K_D \times \frac{k_1k_2[A^-]_a^2}{1+k_1[A^-]_a+k_1k_2[A^-]_a^2} \times \frac{K_1K_2+K_1[A^-]_o}{[A^-]_o^2} \quad (15)$$

From the electrical neutrality in the organic phase, the following relation can be said to hold:

$$[MA^+]_o + 2[M^{2+}]_o = [A^-]_o \quad (16)$$

Further, $(C_M)_o$ is represented as:

$$(C_M)_o = [MA^+]_o + [M^{2+}]_o \quad (17)$$

By combining Eqs. (5), (16), and (17), the next relation is obtained:

$$[A^-]_o = \{(C_M)_o-K_2+\sqrt{K_2^2+(C_M)_o^2+6K_2(C_M)_o}\}/2 \quad (18)$$

From Eqs. (15), and (18), we obtain:

$$D = K_D \times \frac{k_1k_2[A^-]_a^2}{1+k_1[A^-]_a+k_1k_2[A^-]_a^2} \times \frac{K_1[K_2^2+4K_2(C_M)_o-(C_M)_o^2+\{K_2+(C_M)_o\}\sqrt{K_2^2+(C_M)_o^2+6K_2(C_M)_o}]}{8K_2(C_M)_o^2} \quad (19)$$

According to Eq. (19), if $[A^-]_a$ is kept constant, the slope of the plot of log D *vs.* log $(C_M)_0$ must change from -2 in the low-$(C_M)_0$ region to -1 in the high-$(C_M)_0$ region.

(iv) When the first- and second-step dissociations occur to a considerable extent in the organic phase, from Eq. (7) the slope of the plot of log D *vs.* log $(C_M)_0$ can be assumed to change from -2 in the low-$(C_M)_0$ region to -1 in the intermediate-$(C_M)_0$ region, finally reaching 0 in the high-$(C_M)_0$ region.

In the last two cases, (iii) and (iv), the estimation of the constants by analysis of the extraction curves becomes complicated. Fortunately, however, no such case has been encountered so far, except when a solvent with a relatively high dielectric constant, such as nitrobenzene, has been used.

Results and Discussion

The Extraction of Ru(II)(phen)$_3$ with the Perchlorate Ion into Various Solvents. In Figs. 1 and 2 the relations between log D and log $[ClO_4^-]_a$, with several organic solvents, are shown. In these studies the initial concentration, C_M, of the complex cation in the aqueous phase was fixed at 3.15×10^{-6} M, while the ionic strength in the aqueous phase was controlled either at 0.75 with sodium sulfate or at 0.1 with sodium chloride. The extraction curves represented in Fig. 1 are sigmoidal ones which are encountered in oridnary chelate extraction systems with low formation constants. On the other hand, those in Fig. 2 possess inflection points. This phenomenon will be explained by the distribution of sodium perchlorate. From the extraction curves in Fig. 1, the K_D values can be obtained graphically by taking the D values at the high-$[ClO_4^-]_a$ regions, where the slopes of the plots of log D *vs.* log $[ClO_4^-]_a$ are 0. These values are shown in Table 1. In Figs. 3—8, log D is plotted against log $(C_M)_0$ at the fixed $[ClO_4^-]_i$, where $[ClO_4^-]_i$ shows the initial concentration of the perchlorate ion added to the aqueous phase. As is shown in most of the figures, the slope of the plot of

log D *vs.* log $(C_M)_0$ changes from -1 in the low-$(C_M)_0$ region to 0 in the high-$(C_M)_0$ region. This result suggests that, in the solvents with low dielectric constants, the extracted Ru(phen)$_3$(ClO_4)$_2$ dissociates only at the first step. When $[ClO_4^-]_i$ is kept high, D becomes constant independently of the change in $(C_M)_0$. This tendency is observed in all the solvents examined. This phenomenon can be explained by the fact that,

TABLE 1. VARIOUS CONSTANTS OF Ru(phen)$_3$(ClO_4)$_2$

Solvent	K_D	k_1	k_2	K_1	K_2
		(from extraction)

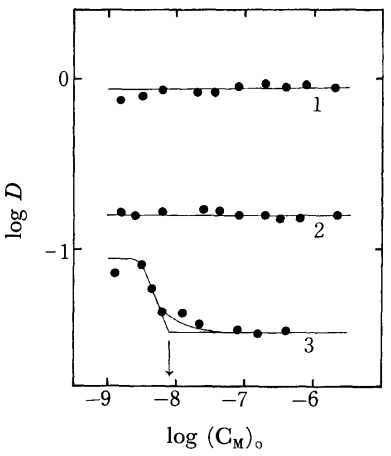

Fig. 6. The relation between log D and log $(C_M)_o$ in MIBK. $[ClO_4^-]_i$: (1) 5×10^{-3}M, (2) 1×10^{-3}M, (3) 1×10^{-4}M. I=0.75 (Na_2SO_4).

in the high-$[ClO_4^-]_i$ region, the $[A^-]_0$ in the third term of Eq. (9) is no longer determined by the dissociation of $Ru(phen)_3(ClO_4)_2$, but by the dissociation of the sodium perchlorate present in the organic phase; the sodium perchlorate in the organic phase begins to act as an anion buffer. This phenomenon can be used in the estimation of the distribution coefficient of sodium perchlorate.

The Determination of the Association and Dissociation Constants. If chloroform is used as the extraction solvent, the third term of Eq. (9) can be taken as 1 in the region where $(C_M)_o$ is more than 10^{-7} M. (See Fig. 3) Therefore, the extraction curve can be analysed according to Eq. (8) in the range where D is

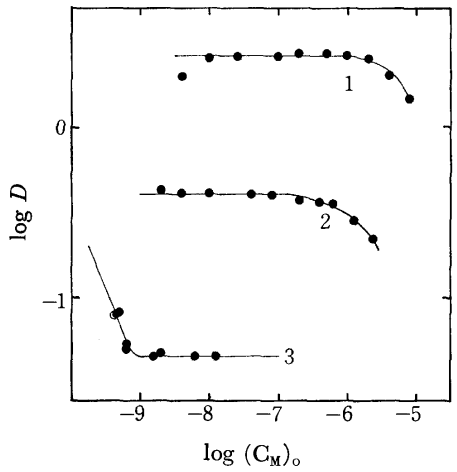

Fig. 7. The relation between log D and log $(C_M)_o$ in acetophenone. $[ClO_4^-]_i$: (1) 5×10^{-5}M, (2) 1×10^{-5} M, (3) 1×10^{-6}M. I=0.75 (Na_2SO_4).

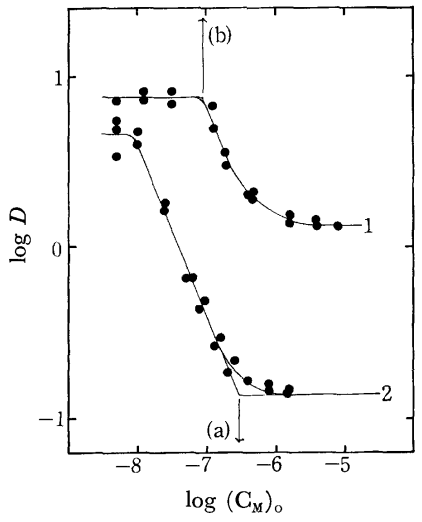

Fig. 8. The relation between log D and log $(C_M)_o$ in o-dichlorobenzene. $[ClO_4^-]_i$: (1) 1×10^{-2}M, (2) 1×10^{-3}M. I=0.75 (Na_2SO_4).

above 3.3×10^{-2}. Figure 9 demonstrates the plot of $(K_D-D)D^{-1}[ClO_4^-]_a^2$ *vs.* $[ClO_4^-]_a$ in that region; it shows a good linearity. k_1 and k_2, as calculated from the slope and the intercept on the $(K_D-D)D^{-1}[ClO_4^-]_a^2$ axis in Fig. 9, are 2.4×10^2 and 54 respectively.

In order to calculate K_1, D was plotted as a function of $1/(C_M)_o$ in the region where the slope of the plot of log D *vs.* log $(C_M)_o$ is -1 in Fig. 3. (See Fig. 10) From the slope of the plot in this figure, the estimation of K_1 can be made by using the k_1 and k_2 values calculated previously. For determining K_1, the slope (1) at 1×10^{-3} M $[ClO_4^-]_i$ was used, since the effect of sodium sulfate, added in the aqueous phase to maintain the ionic strength constant, and other experimental errors are minimized in that region.

Another example is shown in the case of acetophenone. As is shown in Fig. 7, the third term of Eq. (9) could be taken as 1 in the region where $(C_M)_o$ is more than 10^{-7} M, much as in the case of chloroform. Therefore, from the plot of Eq. (14), we can calculate

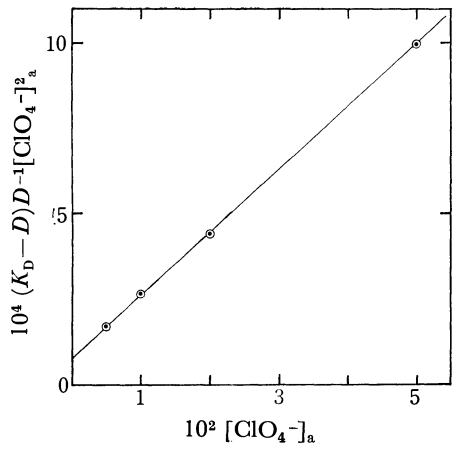

Fig. 9. Linear plot between $(K_D-D)D^{-1}\,[ClO_4^-]^2_a$ and $[ClO_4^-]_a$ in chloroform.
Slope$=k_2^{-1}=1.84\times10^{-2}$, Intercept$=k_1^{-1}k_2^{-1}=7.7\times10^{-5}$.

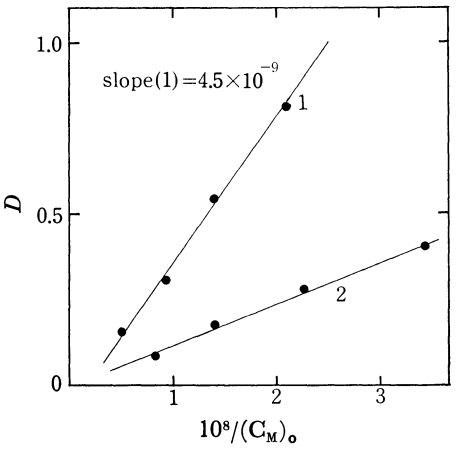

Fig. 10. The relation between D and $1/(C_M)_o$.
$[ClO_4^-]_i$: (1) 1×10^{-3}M, (2) 1×10^{-4}M.

k_1 and k_2. The k_1 and k_2 values thus obtained are 2.7×10^5 and 3.1×10^2 respectively, which are considerably larger than those obtained in the chloroform system. Perhaps this difference is caused by the apparent decrease in the dielectric constant of the aqueous phase, since acetophenone is more soluble in chloroform than water. The ionic equilibrium in the acetophenone phase is governed by sodium perchlorate, which is extracted in a small amount. Therefore, the slope of -1 in the plot of log D *vs.* log $(C_M)_o$ does not appear until $[ClO_4^-]_i$ gets down as low as 1×10^{-6} M under the experimental conditions employed, as is shown in Fig. 7. As can be seen from Curve (3) in Fig. 7, the concentration of the perchlorate ion in the aqueous phase should be constant, because the concentration of the perchlorate ion which is extracted with Ru(II)(phen)$_3$ into the organic phase is negligible. Therefore, the plot of D *vs.* $1/(C_M)_o$ in the region where the slope of the plot of log D *vs.* log $(C_M)_o$ shows -1 can be utilized for the calculation of K_1. The K_1 thus calculated was 8.2×10^{-10}.

In the other solvents the plot of Eq. (14) did not show a good linearity. Therefore, the precise values of k_1 and k_2 in these systems could not be estimated on the basis of the theoretical analysis. Therefore, in such systems K_1 was assumed to be equal to $(C_M)_o$ at the inflection point (for example, point (a) in Fig. 8), which appears between the slope of -1 and 0 in the plot of log D *vs.* log $(C_M)_o$.

As has been shown, in the system where the solvent has a low dielectric constant (<20), the calculation of those constants can be done either by fitting numerical values to the equations or by graphical analysis. On the other hand, in the system where a solvent with a high dielectric constant is used, such analysis becomes impossible, because sodium perchlorate is considerably extracted into the organic phase and, furthermore, K_D can not be estimated from the extraction curves. In addition, to make the k_1 and k_2 values obtained from the extraction studies more reliable, those values were reexamined from the point of view of solubility. The solubility product, K_{sp} in water, which was defined as $K_{sp}=[M^{2+}][ClO_4^-]^2$, was calculated at 1.52×10^{-10} at 25°.

All the constants are summarized in Table 1. From these results, Ru(phen)$_3$(ClO$_4$)$_2$ can be said almost to be associated with the solvents with low dielectric constants. When ketones are the extraction solvents, the K_D values are fairly much larger than those in the other solvents. This can be explained by the tendency of Ru(II)(phen)$_3$ to solvate with ketones, since Ru(II)-(phen)$_3$ has considerable electron affinity because of its double positive charge, although it is a very large cation. The distribution to the solvent with a high dielectric constant (>20) is also promoted by the dissociation in the organic phase. Our data on both the extraction and the solubility show that Ru(phen)$_3$-(ClO$_4$)$_2$ is considerably associated in water. This is contradictory to the conclusion of Yamamoto[1] in a similar study with Fe(phen)$_3$(ClO$_4$)$_2$; they concluded that this ion-pair is completely dissociated in water and in nitrobenzene. In Fig. 1, the distribution ratio into isoamyl alcohol is relatively higher than that into other solvents in the low-$[ClO_4^-]_a$ region. This can be explained by the high solubility of chloride in alcohol; this phenomenon was confirmed by the solubility measurements, which will be reported in the next paper.[7]

IO_4^-	3.7	2.9×10^3	43.0

Extraction of Ru(II)(phen)$_3$ into Chloroform with Various Anions. Ru(II)(phen)$_3$ was extracted into chloroform with several anions; the relations between log D *vs.* log $[A^-]_a$ are shown in Fig. 11. In Fig. 12, the extraction behavior on changing counter anions is shown by plotting log D as a function of log $(C_M)_o$. The constants, K_D, k_1, and k_2, which were obtained by means of the theoretical analysis described in the previous sections, are summarized in Table 2.

By examining the extraction curves shown in Fig. 12, it becomes obvious that the ion-pairs extracted into chloroform dissociate only at the first step, and that the calculated values of K_1 were present in the $10^{-8}\leq K_1\leq10^{-7}$ region in all the systems. Therefore, these ion-pairs exist mostly as associated molecules in chloroform. The order of extractability as a measure of half-extraction $[A^-]_a$ is as follows: $B(C_6H_5)_4^-\gg IO_4^-\sim ClO_4^->I^->SCN^->BF_4^-\gg NO_3^->Cl^-\sim OH^-\gg SO_4^{2-}$. This sequence suggests that the enthalpy of the hydration of the anion is the major factor determining the distribution ratio, because, in this system, the enthalpy of the hydration of the cation is negligible compared with that of the anion. Strongly hydrated ions, such as SO_4^{2-} and F^-, are scarcely extracted at all. This result is in good agreement with those obtained by Gibson and Weatherburn[5] with the quatenary phosphonium and arsonium, by Biswas and Mandal[10] with surfactant cations, and by Diamond *et al.*[11,12] with ammonium. As is shown in Fig. 11, the great change in the distribution ratio appears between NO_3^- and BF_4^-. This observation also agrees with that obtained by Gibson and Weatherburn;[5] the distribution ratio increases remarkably when the enthalpy of hydration of the anions is below 70—80 kcal/mol. This phenomenon can be explained successfully by the equation derived by Ionin and Kurina,[13] assuming that the distribution ratio is determined solely by changes in the enthalpies of the hydration of the anion. Moreover, as is shown in Table 2, the association constants, k_1 and k_2 increase with the decrease in the enthalpy of the hydration of the anion and with the increase in the size of the anion. It is also noticeable that the ratio of k_1 to k_2 becomes larger with the increase in the size of the anion. This tendency can be understood in terms of the repulsion between the anions which combine with Ru(II)(phen)$_3$. When quite large anions such as ClO_4^- are used, k_1 and k_2 become larger than would be expected from the electrostatic theory. Therefore, the concept of water structure-enforced ion-pairing should be applied.[14]

On the basis of the above discussion, the distribution ratio is mainly determined by both the degree of association of the ion-pair in the aqueous phase and the distribution of the associated ion-pair when the solvent, whose dielectric constant is low and whose solvation power is weak, is used for ion-pair extraction. The former depends on the enthalpy of the hydration of ion, and the latter, on the solubility of the associated ion-pair in the extraction solvent, which might be correlated with the solubility parameter.

It should be mentioned that the above discussion is not applicable to a system with a strong basic or acidic solvent; in such a system the distribution of ion-pairs is influenced not only by the solubility of the associated form, but also by the dissociation due to the ion-solvent interaction in the organic phase.

The Extraction of Ru(II)(phen)$_3$ with the Tetraphenylborate Ion. Ru(II)(phen)$_3$ was extracted into chloroform, ethyl acetate, MIBK, or nitrobenzene with the tetraphenylborate ion. The relations between log D *vs.* log $[B(C_6H_5)_4^-]_i$ in chloroform and MIBK respectively are shown in Figs. 13 and 14. An abnormal

decrease of D at the higher concentrations of sodium tetraphenylborate was more or less observed in every solvent so far examined. Moreover, the extraction behavior is largely dependent upon the concentration of sodium chloride in the aqueous phase. In the extraction, the adsorption of Ru(II)(phen)$_3$ on the wall of the glass tube and on the interface was observed at low concentrations of sodium chloride. Therefore, it seems that the ion-pair is difficult to dissolve in both the phases. Such results have not been observed in the systems with anions other than the tetraphenylborate ion.

In order to compare this abnormal tetraphenylborate system with another anion system, the behavior of sodium tetraphenylborate itself should be considered. For this purpose, its distribution into chloroform or MIBK was examined by using the tracer technique (see Fig. 15); furthermore, its association in both the phases was also measured on the basis of the conductivity by applying the Shedlovsky method[15] (see Table 3).

By correcting for the behavior of sodium tetraphenylborate, it becomes clear that the tetraphenylborate ion possesses a very high extractability compared with the other anions such as ClO_4^- and I^-. This observation can be explained by the facts that the tetraphenylborate ion has a very low enthalpy of hydration and a very hydrophobic structure, and that the ion-pairing with such anions is promoted by the structure-making force of water. Moreover, in the MIBK system, the extraction behavior is influenced greatly in the low $[B(C_6H_5)_4^-]_i$ region by the presence of sodium chloride in the aqueous phase; the decrease is caused by the high distribution of sodium tetraphenylborate into the organic phase because of the addition of sodium chloride. On the other hand, the partition of sodium tetraphenylborate into chloroform is so rare that the extraction curves have not been influenced by the addition of sodium chloride to the aqueous phase, as would be expected. Therefore, its influence on the distribution ratio of Ru(II)(phen)$_3$ must be due to the salting-out effect, which will be described later.

TABLE 3. ASSOCIATION CONSTANTS OF SODIUM TETRAPHENYLBORATE AT 25°

Solvent	ε	K(association)
H_2O	78.304	8.46
H_2O saturated with MIBK	76.922	10.92
MIBK	13.11	4.03×10^2 (3.21×10^2)[a]
MIBK saturated with H_2O	14.65	2.55×10^2

a) The value calculated from the Fuoss equation, $K(\text{diss.})=(3000/4\pi a^3N)\exp(-e/a\varepsilon kT)$, $a=7.5$(Å).

It has been described how the distribution of sodium tetraphenylborate into the organic phase influences the extraction curve of Ru(II)(phen)$_3$. However, as far as the abnormal phenomenon is concerned, it can not be explained by this correction. Accordingly, in order to elucidate this phenomenon, the following three possibilities were examined; (1) an anion such as Cl^- or OH^- might be involved in the associated species; this seems probable judging from the fact that the associated ion-pair has a low solubility in the organic phase in spite of its hydrophobicity; (2) this phenomenon might be explained by selecting appropriate values of the constants, k_1, k_2, K_1, and K_2, or (3) the distribution constant of the associated ion-pair might decrease greatly as a result of the change in the bulk properties of both the phases in the high $[B(C_6H_5)_4^-]_i$ region, or as a result of the increased solubility of molecules due to solubilization in a surfactant solution.

The first possibility was examined by the extraction study of $^{36}Cl^-$, which was added in an equivalent amount to Ru(II)(phen)$_3$ in the presence of various concentrations of sodium tetraphenylborate. As a result, no uptake of chloride into the organic phase was observed at all. In addition, the extraction behavior of Ru(II)(phen)$_3$ in the presence of sodium fluoride or sodium sulfate exhibits a pattern similar to that in the presence of sodium chloride in spite of the fact that the hydration energies of the fluoride ion and the sulfate ion are much larger than that of the chloride ion.

Therefore, it is not feasible to consider that the associated ion-pair contains an anion other than the tetraphenylborate ion.

Next, if k_1 and k_2 are very large and if K_1 is much larger than K_2, then the extraction curve will exhibit the pattern shown in Figs. 13 and 14, according to Eq. (9). Although those theoretical conditions could be fulfilled provided the theory of Diamond[14] is applied, $\log K_D$ in this system would then have to become a negative value. This is very improbable, because the $Ru(phen)_3(B(C_6H_5)_4)_2$ has a very hydrophobic property and the K_D values in the systems of the other anions have large positive values.

The last possibility was examined as follows: the solubilities of $Ru(phen)_3(B(C_6H_5)_4)_2$ were measured in two systems; in one system the precipitates of $Ru(phen)_3(B(C_6H_5)_4)_2$ were added to an aqueous sodium tetraphenylborate solution (1% sodium bicarbonate has been added), while in the other system an aqueous sodium tetraphenylborate solution (1% sodium bicarbonate has been added) was added to a $\sim 10^{-6}$ M $Ru(phen)_3Cl_2$ solution. This means that both the crystallization and dissolution processes were cross-checked. As a result, it was found that the presence of sodium chloride (0.01—0.1 M) accelerates the rate of attaining the equilibrium between the precipitate and the solution; therefore, the solubilities have been measured both in the presence and in the absence of sodium chloride. The absorbance or the radioactivity was measured after equilibriating for 2 days' shaking in a thermostat at 25°; sodium tetraphenylborate decomposes after longer standing. The results obtained with the two systems are in good agreement with each other except when sodium chloride was not added; in the absence of sodium chloride, in the latter system equilibrium was not attained completely.

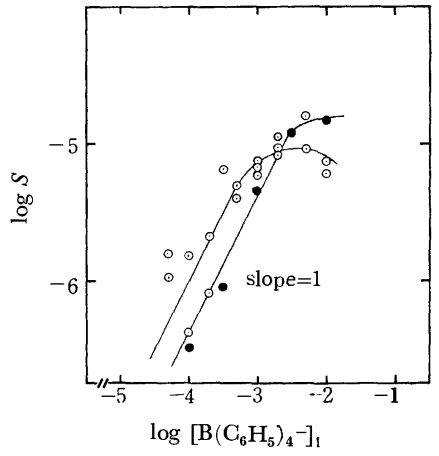

Fig. 16. The solubility of $Ru(phen)_3(B(C_6H_5)_4)_2$ in the sodium tetraphenylborate solution at 25 °C. (○) in the absence of NaCl, (●) 0.1 M NaCl is added.

In Fig. 16, $\log S$ is plotted against $\log [B(C_6H_5)_4^-]_i$. The solubility of $Ru(phen)_3(B(C_6H_5)_4)_2$ increases remarkably with the increase in the concentration of sodium tetraphenylborate, and the slope of the plot of $\log S$ *vs.* $\log [B(C_6H_5)_4^-]_i$ becomes about 1. This phenomenon can be explained on the assumption that the increase in the solubility is due to the formation of a large anion, $[Ru(phen)_3(B(C_6H_5)_4)_3]^-$, which is produced as a result of the addition of one more $B(C_6H_5)_4^-$ to the neutral ion-pair. This assumption seems probable if the concept of water structure-enforced ion-pairing can be extended to this system. $Ru(phen)_3(B(C_6H_5)_4)_2$ and $B(C_6H_5)_4^-$ are alike with respect to their hydrophobic and poorly hydrated character. Therefore, it is much more probable for $Ru(phen)_3(B(C_6H_5)_4)_2$ and $B(C_6H_5)_4^-$ to form one large anion, which causes only one disturbance of the water structure, instead of surviving as two species which produce two disturbances.

Another possible assumption is that the increase in the solubility is to be explained not by the formation of a rigid anion such as $[Ru(phen)_3(B(C_6H_5)_4)_3]^-$, but by a solubilization similar to that with surfactant solutions. However, the micelle formation can not be considered, because the tetraphenylborate ion has no long alkyl chain in its structure and is a spherical ion. Therefore, this solubilization must be a kind of hydrotropism, an idea which was advanced by Neuberg[6] in 1916. Hydrotropism[16] is the general term for the phenomenon in which many nonelectrolytes, mostly polar but including nonpolar ones, are salted in by salts with large ions, such as tetraalkylammonium chloride and sodium *p*-toluenesulfonate.

In order to examine which assumption is more suitable to explain the present system, two additional investigations were performed—paper-electrophoresis and dialysis. The electrophoresis on paper strips (17—46 V/cm, 1—5 hr, 5 mA) revealed that $Ru(II)(phen)_3$ did not migrate at all in the 10^{-2}—10^{-1} M sodium tetraphenylborate solution. The dialysis was carried out by using a cellulose tube which had holes of 15—20(Å) and which was permeable for molecules with molecular weights below 10000—20000. $Ru(II)(phen)_3$ was dialyzed for two days against a 1×10^{-2} M sodium tetraphenylborate solution or against a 1×10^{-2} M sodium chloride solution. However, no $Ru(II)(phen)_3$ was dialyzed into the sodium tetraphenylborate solution, although the dialysis equilibrium was achieved within several hours in the sodium chloride solution.

In addition to the results presented above, the solubilized $Ru(phen)_3(B(C_6H_5)_4)_2$ solution often became colloidal. The addition of excess salts to this solution induced a salting-out effect. Therefore, the latter assumption seems to explain more satisfactorily the phenomenon of the present system, and we believe that $Ru(phen)_3(B(C_6H_5)_4)_2$ is solubilized by forming such an anionic colloid as $[Ru(phen)_3(B(C_6H_5)_4)_2]_n$-$[B(C_6H_5)_4^-]_m$. The actual structure is assumed to be that of aggregated molecules, *i.e.*, $[Ru(phen)_3(B(C_6H_5)_4)_2]_n$ surrounded with $B(C_6H_5)_4^-$. The aggregation numbers, n and m, are expected to be almost equal, because, as is shown in Fig. 16, the slope of the plot of $\log S$ *vs.* $\log [B(C_6H_5)_4^-]_i$ is almost 1.

Polarographic Studies of Some Metal(II)-Thiocyanate Complexes in Acetonitrile

Seizo MISUMI, Makoto AIHARA, and Setsuko KINOSHITA

Inorganic Chemistry Laboratory, Faculty of Science, Kyushu University, Fukuoka 812

(Received April 14, 1973)

The formation of thiocyanate complexes of cadmium(II), copper(II), cobalt(II), and iron(II) has been studied in acetonitrile by polarographic, conductometric, and spectrophotometric methods. The values of overall stability constants were found to be; $\log \beta_4 = 19.7$ for $[Cd(SCN)_4]^{2-}$, $\log \beta_2 = 7.6$ for $[Cu(SCN)_2]^-$ and $\log \beta_4 = 15.5$ for $[Co(NCS)_4]^{2-}$. The reaction between copper(II) species and mercury metal was investigated and the electrode reaction was estimated. Kinetic current for cobalt(II)-thiocyanate complex was observed and the rate constant for the dissociation of the complex was obtained. The rate constant of reduction in the iron(II)-thiocyanate system was determined to be 1.9×10^{-3} cm/s by cyclic voltammetry.

In the previous work,[1] cadmium(II), zinc(II), and manganese(II) iodide complexes were studied polarographically in acetonitrile and the overall formation constants of the complexes were evaluated. These values for other halide complexes of cadmium(II) and zinc(II) were determined by potentiometric titration using a saturated metal amalgam indicator electrode.[2]

In this work, the association constant of tetraethylammonium thiocyanate was determined by conductance measurements, and cadmium(II), copper(II), cobalt(II), and iron(II) thiocyanate complexes have been investigated in acetonitrile by polarography, conductometry and spectrophotometry.

Experimental

Materials. Tetraethylammonium thiocyanate (Et_4NSCN) was synthesized by the reaction of tetraethylammonium perchlorate and potassium thiocyanate in ethanol and fractionated by using acetone-ethyl ether mixture.

Found: C, 57.16; H, 10.65; N, 14.76%. Calcd for Et_4NSCN: C, 57.40; H, 10.71; N, 14.87%.

Et_4NClO_4 (TEAP) was used to keep the concentration of Et_4N^+ to be 0.1 M, and Triton X-100 as maximum suppressor. Other reagents were the same as described previously.[1]

Apparatus. Polarographic measurements have been described previously.[1] Conductance measurements were done by a Yokogawa universal bridge using a cathode ray tube as a detector. The cell, which was of the Pyrex cylinder type, had bright platinum electrodes. A Hitachi EPS-2 spectrophotometer was utilized in the spectral studies.

Procedure. A sample solution was prepared by dissolving 0.5 mM metal(II) perchlorate and an appropriate amount of Et_4NSCN in TEAP-acetonitrile and it was introduced into a polarographic or spectrophotometric cell. Conductance was measured at 1 kHz to 20 kHz at 25 ± 0.01 °C and extrapolated to the infinite frequency (R *vs.* f^{-1}).[3] The cell constant was determined by using the Fuoss' equation[4] for the conductance of potassium chloride solution in water. The cell constant was found to be 0.09975 cm^{-1}.

Other procedures were the same as described previously.[1]

Results and Discussion

Determination of the Association Constant of Tetraethylammonium Thiocyanate. The data for Et_4NSCN were analyzed by the Fuoss-Onsager conductance theory.[5] The parameters obtained are as follows; $\Lambda_0 = 198.35$, $\hat{a} = 2.85$ and $K_A = 0$. (refer to the values of $\lambda_0^+ = 85.05$[6] for Et_4N^+ and $\lambda_0^- = 113.4$[7] for SCN^- in acetonitrile) Conductance data for Et_4NSCN in acetonitrile are shown in Table 1. The values of Λ_{calcd} in Table 1 were calculated by the Fuoss-Onsager conductance equation[5] for non-associated electrolyte. Therefore, tetraethylammonium thiocyanate used was assumed to be completely dissociated in the range from 0.5 to 50 mM in acetonitrile.

TABLE 1. CONDUCTANCE DATA FOR TETRAETHYLAMMONIUM THIOCYANATE IN ACETONITRILE

10^4C M	Λ_{obsd} $cm^2/(\Omega \cdot equiv)$	Λ_{calcd} $cm^2/(\Omega \cdot equiv)$	$\Delta\Lambda$ $cm^2/(\Omega \cdot equiv)$
8.181	186.87	186.87	0.00
17.902	181.36	181.37	0.01
28.817	177.03	176.95	−0.08
28.232	173.99	173.88	−0.11
50.983	170.30	170.41	0.11
64.781	167.12	167.27	0.15

Cd(II)–SCN^- System. The electrode reaction of solvated cadmium(II) is reversible and of two-electron reduction and diffusion-controlled. The half-wave potential of the polarographic wave was −0.275 V *vs.* SCE. The wave due to the complexed species appeared by addition of thiocyanate ion. The electrode reaction was the same as that of solvated cadmium(II) and the plot of the difference of the half-wave potential, $\Delta E_{1/2}$ *vs.* $\log [SCN^-]_0$ was found to be linear. The value of number p of ligands attached to Cd(II) was calculated to be 4.2. The value of $\log \beta_4$ was 19.7.

Cu(II)–SCN^- System. The Cu(II)–SCN^- system was investigated in acetonitrile by conductometric titration. When the conductance was plotted against mole ratio $[SCN^-]_t/[Cu(II)]_t$, the distinct inflection points were observed at 1.1 and 4.0, indicating the formation of $[CuSCN]^+$ and $[Cu(SCN)_4]^{2-}$ and other inflection points were ill-defined.

Polarograms of 0.5 mM Cu(II) in the presence of thiocyanate ions are shown in Fig. 1. Cu(II) perchlorate shows double wave. The half-wave potentials of the first and second waves are *ca.* +0.56 and −0.335 V *vs.* SCE. The first wave decreased and new waves (II and III) developed by addition of thiocyanate

i n. The second wave was shifted to more negative potentials (Wave IV) with increasing concentration of thiocyanate ion. The electrode reactions of the first and third waves were found to be two-electron reduction and diffusion-controlled. The electrode reaction of the fourth wave was one electron and of reversible and diffusion-controlled.

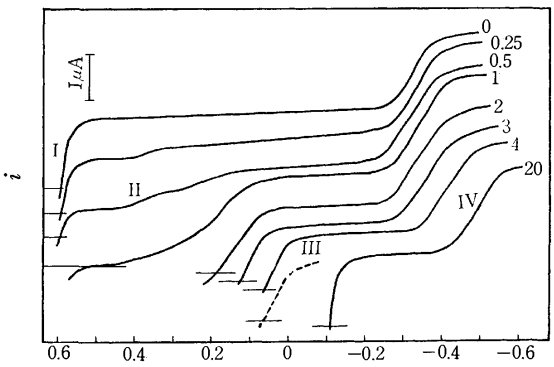

Fig. 1. DC polarograms of acetonitrile solutions containing copper(II)-thiocyanate complexes. Numbers on curves indicate mole ratio, $[SCN^-]_t/[Cu(II)]_t$.

Solvated Cu(II) reacts completely with mercury metal in acetonitrile as follows[8]

$$Cu^{2+}_{solv} + \frac{1}{2}Hg \longrightarrow Cu^{+}_{solv} + \frac{1}{2}Hg^{2+}_{solv} \quad (3)$$

A solution containing Cu(II) and thiocyanate ions was reddish brown in color in acetonitrile. It's color disappeared after a polarograms was recorded at $[SCN^-]_t/[Cu(II)]_t<10$. Even at $[SCN^-]_t/[Cu(II)]_t=50$, decolorization was complete when the solution containing metallic mercury was shaken. The polarograms did not give any changes for the solutions before and after decolorization. Therefore, the following chemical reaction must proceed at the electrode surface before the electrode reaction took place.

$$[Cu(SCN)_4]^{2-} + \frac{1}{2}Hg \longrightarrow [Cu(SCN)_2]^- + \frac{1}{2}[Hg(SCN)_4]^{2-} \quad (4)$$

The electrode reaction for each wave was presumed. The first wave corresponds to the reduction of Hg^{2+}_{solv} formed in solution according to Eq. (3).

$$Hg^{2+}_{solv} + 2e \rightleftarrows Hg(0) \quad (5)$$

This wave decreased with increasing concentration of thiocyanate ion and disappeared at mole ratio $[SCN^-]_t/[Cu(II)]_t=1$. This is caused by complex formation of mercury ion with thiocyanate ion.

The second wave may correspond to the reduction of Hg(II)–SCN^- species, *e.g.* $[Hg(SCN)_3]^-$ *etc.*

The dashed line in Fig. 1 shows the reduction wave of tetrathiocyanato-mercurate(II) in acetonitrile. Therefore, the electrode reaction for the third wave is

$$[Hg(SCN)_4]^{2-} + 2e \rightleftarrows Hg(0) + 4SCN^- \quad (6)$$

The fourth wave was always observed in the presence or the absence of thiocyanate ion. The half-wave potential was shifted to more negative potentials with increasing concentration of thiocyanate ion (Table 2). The electrode reactions of Cu(I) and Cu(I) complex are reversible, of one electron reduction and diffusion-controlled. The plot of $\Delta E_{1/2}$ *vs.* $\log [SCN^-]_0$ was found to be linear and p was calculated to be $2._3$. The value of $\log \beta_2$ was 7.6 for $[Cu(SCN)_2]^-$.

Table 2. Polarographic data for copper(II)-thiocyanate system (The fourth wave)
$[Cu(II)]=0.5$ mM

$[SCN^-]_t$ mM	i_d μA	$E_{1/2}$ V *vs.* SCE
0	1.58	−0.335
5	1.56	−0.465
10	1.56	−0.508
15	1.64	−0.531
20	1.57	−0.556
25	1.60	−0.559

The electrode reactions are expressed as Eqs. (7) and (8) in the absence or the presence of thiocyanate ion, respectively.

$$Cu^{+}_{solv} + e + Hg \rightleftarrows Cu^{\circ}(Hg) \quad (7)$$

$$[Cu(SCN)_2]^- + e + Hg \rightleftarrows Cu^{\circ}(Hg) + 2SCN^- \quad (8)$$

The stability ($\log \beta_2$) of CuX_2^- (X^-: halide and thiocyanate ion) is in the order $Br^-(7.1)<SCN^-(7.6)<Cl^-(10.5)$[9] in acetonitrile.

Co(II)–SCN^- System. Cobalt(II) and thiocyanate ion are known to form $[Co(NCS)]^+$, $[Co(NCS)_3]^-$, and $[Co(NCS)_4]^{2-}$ [10] but the formation constants for these complexes were not yet determined. The cobalt-(II)-thiocyanate complex has an absorption spectrum characterized by maxima at 16000 and 31447 cm^{-1}. The intensity of these bands increases with increasing concentration of thiocyanate ion until $[SCN^-]_t/[Co(II)]_t$ attained to 4. The relation between absorbance for unit concentration of Co(II) at 16000 cm^{-1} *vs.* mole ratio, $[SCN^-]_t/[Co(II)]_t$ is shown in Fig. 2. This indicates the formation of $[Co(NCS)_4]^{2-}$ in acetonitrile. The value of β_4 was calculated by the molar ratio method.[11] From absorbance at 16000 and 31447 cm^{-1}, the values of $\log \beta_4$ (15.6_4 and 15.5_3) were obtained, respectively. (The following spectral data were

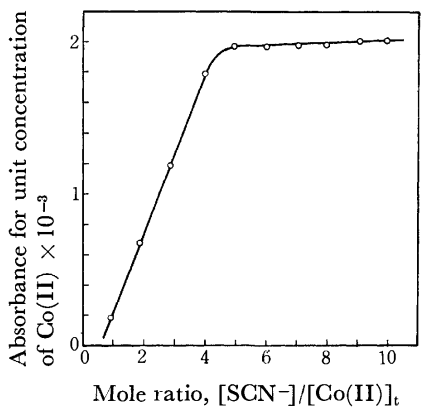

Fig. 2. Absorbance for unit concentration of Co(II) at 16000 cm^{-1} *versus* mole ratio, $[SCN^-]_t/[Co(II)]_t$.

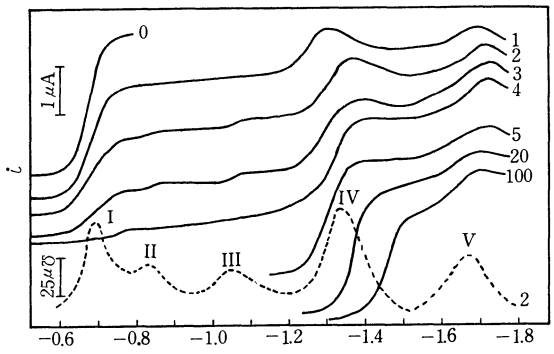

Fig. 3. DC and AC polarograms of cobalt(II)-thiocyanate complexes. Numbers on curves indicate mole ratio, $[SCN^-]_t/[Co(II)]_t$.

used for calculation. E_m=0.994 and E_s=0.890 at 16000 cm^{-1}. E_m=0.762 and E_s=0.678 at 31447 cm^{-1}.) The value of log K_4, 5.2 for $[Co(NCS)_4]^{2-}$ was obtained by assuming that the concentration of $[Co(NCS)]^+$ and $[Co(NCS)_2]$ to be negligible at excess thiocyanate ion.

DC and AC polarograms of 0.5 mM cobalt(II) in the presence of thiocyanate ion are shown in Fig. 3. The electrode reaction of solvated cobalt(II) in acetonitrile is reversible, of two-electron reduction and diffusion-controlled. The original first wave decreased with increasing concentration of thiocyanate ion and the new waves appeared at more negative potentials. The waves in AC polarogram were termed as I, II, III, IV, and V. The waves II and III were ill-defined in DC polarogram. The wave IV had a maximum till $[SCN^-]_t/[Co(II)]_t$=4 but no maximum wave was observed at higher thiocyanate concentrations. The wave V appeared at low concentration of thiocyanate ion. The plots of limiting current and peak admittance *vs.* mole ratio, $[SCN^-]_t/[Co(II)]_t$ are shown in Fig. 4. The wave I which corresponds to the reduction of solvated cobalt(II) disappeared at $[SCN^-]_t/[Co(II)]_t$= 4. The waves II and III may correspond to the reduction of Co(II)–SCN^- species, *e.g.*, $[Co(NCS)]^+$ *etc.*, but the heights of these waves are small because of large stability of $[Co(NCS)_4]^{2-}$. The wave IV increased till $[SCN^-]_t/[Co(II)]_t$=6 and decreased slightly at the above ratio. The wave V was almost constant. The wave IV did not diminish at high excess of thiocyanate ion ($[SCN^-]_t/[Co(II)]_t$=100) as shown in Fig. 3. Therefore, this wave must be due to the species of $[Co(NCS)_4]^{2-}$ and the current was found to be kinetic current. This kinetic current was treated by assumption of the following reaction layer.[12] Consider the reduction of $[Co(NCS)_3]^-$ according to the following reaction

$$Co^{2+}_{solv} + 4SCN^- \rightleftharpoons [Co(NCS)_4]^{2-} \quad (9)$$

$$[Co(NCS)_4]^{2-} \underset{\overleftarrow{k}}{\overset{\vec{k}}{\rightleftharpoons}} [Co(NCS)_3]^- + SCN^- \quad (10)$$

$$[Co(NCS)_3]^- + 2e \rightleftharpoons Co(0) + 3SCN^- \quad (11)$$

The kinetic current, i_k is expressed as follows

$$\frac{i_k}{i_d - i_k} = 0.81 \frac{\vec{k}^{1/2} t^{1/2}}{K_4^{1/2}[SCN^-]_0^{1/2}} \quad (12)$$

where $[SCN^-]_0$ is the concentration of the thiocyanate ion at the electrode surface. $[SCN^-]_0$ was calculated by using $[SCN^-]_0 = [SCN^-]_t - 4\{(i_d - i_k)/i_d\}[Co(NCS)_4^{2-}]_{eq}$. Equation 12 predicts a slope −0.5 for a plot of log $i_k/(i_d - i_k)$ *vs.* log $[SCN^-]_0$. The value of slope was found experimentally to be −0.44 as given in Fig. 5. $\vec{k}$ was calculated to be 1.2×10^4 s^{-1} using log K_4= 5.2 and t=5.88 sec. This indicates that kinetic current due to the fast dissociation of $[Co(NCS)_4]^{2-}$ occurs.

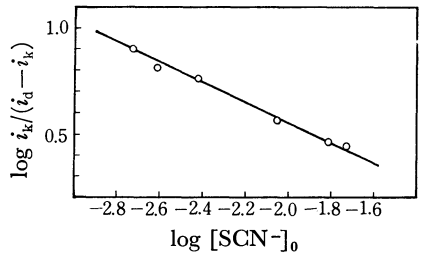

Fig. 5. Log $i_k/(i_d - i_k)$ *versus* log $[SCN^-]_0$ for cobalt(II)-thiocyanate system.

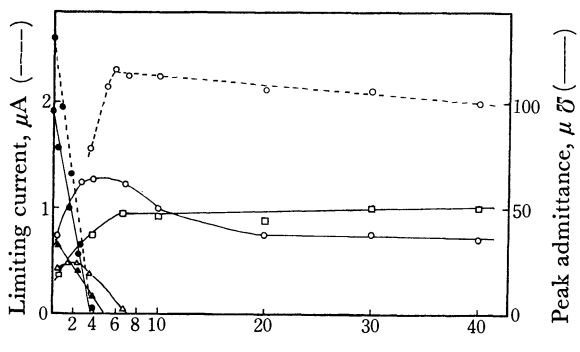

Fig. 4. Limiting current and peak admittance *versus* mole ratio, $[SCN^-]_t/[Co(II)]_t$ for cobalt(II)-thiocyanate system. ●, wave I; ▲, wave II; △, wave III; ○, wave IV; □, wave V.

Fe(II)-SCN^- System. The formation of iron(II)-thiocyanate complexes was investigated by conductometric and spectrophotometric methods.

In conductometric titration curve for Fe(II)–SCN^- system, the inflection point was at $[SCN^-]_t/[Fe(II)]_t$= 1.0 and other points were ill-defined. The thiocyanate complex of iron(II) has an absorption band at 20284 cm^{-1}. The intensity of this band increased until $[SCN^-]_t/[Fe(II)]_t$=3. Above this ratio, this band was shifted to 20619 cm^{-1}. The curves of absorbance for unit concentration of Fe(II) at 20284 and 20619 cm^{-1} *vs.* mole ratio, $[SCN^-]_t/[Fe(II)]_t$ showed the inflection points at $[SCN^-]_t/[Fe(II)]_t$=3 and 4. These indicate the formation of $[Fe(NCS)]^+$, $[Fe(NCS)_3]^-$ and $[Fe(NCS)_4]^{2-}$.

The polarograms of Fe(II)–SCN^- system are shown in Fig. 6. Solvated Fe(II) perchlorate has a single reduction wave with the half-wave potential of −0.995 V *vs.* SCE. The electrode reaction was found to be two-electron reduction and diffusion-controlled. This

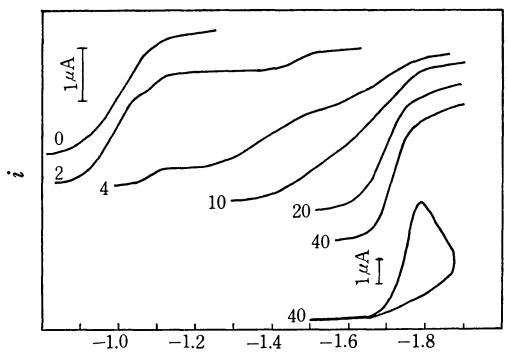

Fig. 6. DC polarograms and cyclic voltammogram of iron(II)-thiocyanate complexes. Number on curves indicate mole ratio, $[SCN^-]_t/[Fe(II)]_t$.

wave decreased with increasing concentration of thiocyanate ion and the new waves appeared at more negative potentials. The wave of complex ion appeared due to the reduction of $[Fe(NCS)_4]^{2-}$ at $[SCN^-]_t/[Fe(II)]_t \geq 20$. The electrode reaction was two-electron reduction and diffusion-controlled.

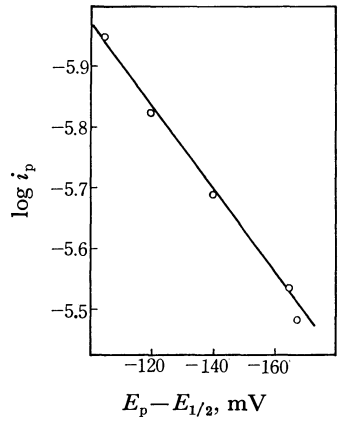

Fig. 7. Determination of the rate constant for solvated iron(II).

The rate constants of the electrode reaction were determined by cyclic voltammetry. Typical cyclic voltammogram (scan rate 0.2 V/s) is shown in Fig. 6. The determination of the rate constants was made by using the method proposed by Matsuda and Ayabe.[13]

The plot of log i_p *vs.* $(E_p-E_{1/2})$ for solvated Fe(II) system is shown in Fig. 7 for example. The value of standard rate constant, k_s was calculated from the point of intersection on ordinate. Polarographic data for Fe(II)–SCN^- system are shown in Table 3. These data indicate that the electrode reactions for solvated Fe(II) and Fe(II)-thiocyanate complex are quasi-reversible.

Table 3. Polarographic data for iron(II)-thiocyanate system

[Fe(II)]=0.5 mM

Optical Resolution and Racemization of Tris(acetylacetonato)-germanium(IV) in Organic Solvents

Akira NAGASAWA and Kazuo SAITO

Chemistry Department, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received September 28, 1973)

The tris(acetylacetonato)germanium(IV) has been resolved by the crystallization of its hydrogen-*R,R*-dibenzoyltartrate in a mixture of acetonitrile, ethanol, and water. The racemization kinetics of perchlorate of the *Δ*-enantiomer has been studied in 1,1,2,2-tetrachloroethane (TCE), nitromethane, acetonitrile (AN), and *N,N*-dimethylformamide, the activation enthalpies ($\Delta H^{\ddagger}$/kcal·mol^{-1}) and the activation entropies ($\Delta S^{\ddagger}$/cal·K^{-1} mol^{-1}) being 27.9, 26.6, 24.3, and 23.3, and +3.7, −1.1, −4.4, and −5.0, respectively. The ligand isotopic exchange is much slower than the racemization under similar conditions. Consideration of acid (in TCE) and base (in AN) catalysis, influence of ionic strength and solvent effect suggests an intra-molecular mechanism *via* an intermediate in which one of the ligands is in unidentate state.

The number of work concerning germanium compounds has been increasing in these decades. However, most of them are related to tetrahedral organometallic compounds, and much less to octahedral and co-ordination compounds. Especially, the dynamic properties of six co-ordinated germanium complexes are almost unknown.[1-3]

Geometrical isomerization and racemization of octahedral complexes with tris-bidentate ligands have been studied by many workers with *β*-diketonato complexes of various metal ions. Most of these reactions in organic solvents are claimed to proceed *via* intra-molecular mechanism.[4] These works centered around chargeless complexes, and those related to univalent cationic complexes are limited to tris(acetylacetonato)-silicon(IV).[5]

We intended to extend the work to those with germanium(IV) analogues. Morgan and Drew[6] first prepared the tris(acetylacetonato)germanium(IV) ion, $[Ge(acac)_3]^+$, and its physical properties are better known than others. We have resolved this complex and studied the racemization kinetics in various organic solvents. The mechanism has been discussed and the lability of this complex compared with those of related compounds.

Experimental

Materials. Preparation of Tris(acetylacetonato)germanium-(IV) Perchlorate: The complex ion $[Ge(acac)_3]^+$ was synthesized as hexachloroantimonate by Cox and co-workers' method.[7] This salt (3.5 g, 5×10^{-3}mol) was dissolved in 30 ml of chloroform–ethanol (3: 1), and mixed with silver perchlorate (1.25 g, 6×10^{-3}mol) in 20 ml chloroform–ethanol (1: 1). Silver chloride was filtered off, and the filtrate was treated with magnesium perchlorate (1.3 g) in 20 ml of chloroform–ethanol (1: 3). Crystals of $[Ge(acac)_3]ClO_4$ obtained on addition of diethyl ether (450 ml) were filtered off, washed with ether, recrystallized from chloroform solution by adding diethyl ether, washed with diethyl ether, and dried *in vacuo*. Yield, 80—87%. Found: C, 38.45; H, 4.64%. Calcd for $C_{15}H_{21}O_{10}ClGe$: C, 38.38; H, 4.51%. Colorless needles melt at 245—251 °C with decomposition. IR spectra in KBr disk and Nujol mull gave the absorption peaks of carbonyl group co-ordinated to metal ions, perchlorate anion, but not of hydroxyl groups. Proton NMR in deuterochloroform has singlet signals at 2.33 and 6.18 ppm (*δ*, TMS), corresponding to six methyls and one methyne, respectively. Figure 1 shows the UV absorption spectrum in acetonitrile. The pattern and the peaks agree with those of $[Ge(acac)_3]^+$ in $[Ge(acac)_3][FeCl_4]$.

Optical Resolution: The complex ion was resolved into optical isomers by the crystallization of its hydrogen-*R,R*-dibenzoyltartrate. Racemic perchlorate (1.6 g, 3.4×10^{-3} mol) was dissolved in 75 ml of acetonitrile–ethanol–water (1: 1: 1), treated with 20 ml of sodium hydrogen dibenzoyltartrate (5.3×10^{-3}mol) in water, the mixture was poured into 130 ml of cold water, and set aside in an ice bath. The colorless needles were filtered off within 30 minutes and dried. The product was recrystallized from acetonitrile–ethanol (1: 1) solution by adding twice volume of water, filtered off and dried *in vacuo*. Found: C, 54.31; H, 4.53%. Calcd for $C_{33}H_{34}O_{14}Ge$: C, 54.40; H, 4.71%. mp 141—143 °C (decompn.). $[\alpha]_{589}$ −656 ° (4.4×10^{-4}M in AN, 20 °C).

This diastereoisomer (1.0 g, 1.4×10^{-3}mol) and magnesium perchlorate (1.0 g, 4.5×10^{-3}mol) were dissolved in 60 ml of

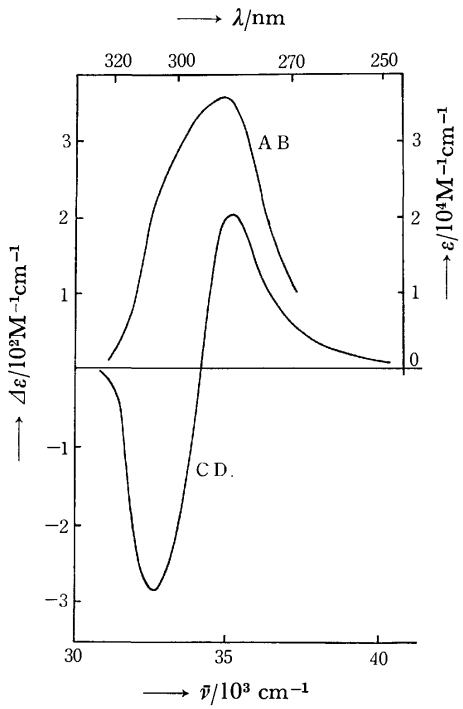

Fig. 1. Ultraviolet absorption (AB) and circular dichroism (CD) spectrum of $(-)_{589}$-$[Ge(acac)_3]^+$ in acetonitrile.

glacial acetic acid, and poured into diethyl ether. The crystals were washed with diethyl ether, recrystallized from chloroform solution with diethyl ether, and dried. The yield was 20% on the basis of racemic perchlorate. Found: C, 38.50; H, 4.63%. Calcd for $C_{15}H_{21}O_{10}ClGe$: C, 38.38; H, 4.51%. $[\alpha]_{589}$ −930° (3.2×10^{-4}M in AN, 20 °C). Circular dichroism (CD) spectrum of the complex is shown in Fig. 1.

Solvents for Kinetic Runs: Acetonitrile (AN) was dried with calcium chloride, refluxed with diphosphorus pentoxide and distilled. This procedure was repeated and the middle fraction was finally distilled. Nitromethane was washed successively with aqueous sodium bicarbonate, sodium bisulfite, 5% sulfuric acid and water. One fourth volume of water was added and refluxed. The mixture was distilled slowly, a large amount of the first fraction was discarded and the oily layer of the middle fraction was again distilled. 1,1,2,2-Tetrachloroethane (TCE) was shaken with several portions of concentrated sulfuric acid until the acid remained colorless, and distilled under reduced pressure. Chloroform was washed with aqueous sodium hydroxide, sulfuric acid and water, and distilled. *N*,*N*-Dimethylformamide (DMF) was dried with anhydrous copper sulfate and distilled under reduced pressure. Dimethyl sulfoxide (DMSO) was dried with activated alumina and distilled under reduced pressure.

The purities of these solvents were checked by gas chromatography, and the water contents titrated by Karl Fischer method.

Other Reagents: Pyridine was recrystallized as perchlorate and dissolved in a small amount of water, treated with solid sodium hydroxide, the pyridine layer decanted and distilled under reduced pressure. Glacial acetic acid was frozen at 5 °C and distilled. Commercially available extra pure sodium perchlorate and magnesium perchlorate were used without purification. Acetylacetone (Hacac) was distilled by the usual method. The labelled acetylacetone (Hacac-^{14}C) was prepared as reported in the literature.[8]

Kinetic Procedure. Racemization: The optically active perchlorate (0.01 g) was dissolved in a given solvent (25 ml) and, whenever necessary, other reagents were mixed. Aliquots of the solution were sealed in small glass test tubes with silicone rubber stoppers. All these procedures were operated in a dry grove box. Several ampoules were prepared, placed in a thermostat (30 to 70 °C±0.1 °C) and picked up one by one at proper intervals. They were cooled in ice water for 30 s, and their optical rotation and UV absorption were measured at room temperature (15—25 °C) at a proper wavelength in the range 310 to 365 nm. (AN, 310—325 nm; chloroform, 316 nm; TCE, DMF, and DMSO, 318 nm; nitromethane, 360—365 nm). The rate constant was calculated by the following equation,

$$k_{obsd} = (1/2t)\ln(\alpha_0/\alpha_t) \quad (1)$$

where α_0 and α_t are the optical rotation at time zero and t, respectively, and t is the lapse of time in second.

Isotopic Exchange: The complex and acetylacetone-^{14}C (10^{-3} M) were dissolved in acetonitrile. Aliquots were sealed in glass tubes, and kept in a thermostat (60 to 80 °C). They were chilled one by one at proper time intervals, the ampoules cut and poured into cold diethyl ether. The precipitated complex was filtered off with a piece of filter paper, washed with diethyl ether, and dried *in vacuo*. The activity of a weighed amount of crystals was counted with a 2π gas flow counter in a current of Q-gas.

Apparatuses. JASCO model ORD/UV-5 was used for the measurement of optical rotation and the recording of CD spectra. JASCO DIP-SL Polarimeter was used for optical rotation measurement at Na-D line. Hitachi 323 Spectrophotometer was used for the recording of absorption spectra, and K53 Gas Chromatograph with TCD for detecting the impurity of the solvents. Aloka FC-1E Counter was used for the β-activity counting of ^{14}C. The water content was measured by the Karl Fischer method. Metrohm E 365 B Konduktoskop and EA 608 bright platinum electrodes were used for the conductance measurement.

Results

The Kinetics of Racemization in Acetonitrile. The changes in optical rotation at 312 nm are illustrated in Fig. 2. The absorbances at 305 and 288 nm showed no change during several half-lives, and the decrease in optical rotation should be due to net racemization of the complex. The rate constant was found to be independent of the complex concentration. Hence the rate formula is expressed as follows:

$$\text{Rate} = k_{obsd}[\text{complex}] \quad (2)$$

The water content of the solution gave no significant effect on the racemization rate in the range from 10^{-2} to 2×10^{-1} M. (Fig. 3). Free acetylacetone (Hacac) and acetic acid gave no catalytic effect on the racemiza-

tion rate (Fig. 3) in the ranges from 10^{-5} to 10^{-2} M and from 5×10^{-4} to 10^{-2} M, respectively.

The relationship between pyridine concentration and racemization rate is illustrated in Fig. 4. The diagrams are linear at least up to 4×10^{-2} M of pyridine. The intercepts coincide with the k_{obsd} values in the absence of pyridine. Hence the k_{obsd} is expressed by

$$k_{obsd} = k_1 + k_2[py] \quad (3)$$

The values of k_1 and k_2 at several temperatures and the activation parameters are shown in Table 1.

The values of k_1 and k_2 depend on the concentration of sodium perchlorate. Conductance measurements suggested that sodium perchlorate is a strong, while the complex is a weak electrolyte in AN. Hence the increase in k_{obsd} with the electrolyte concentration seems to be due to ionic strength effect (see Fig. 5).

When the water content was increased to 1 M, UV absorption changes, but no isosbestic point was observed. The decrease in absorbance at 316 nm was in accord with the first-order kinetic formula at 70 °C and the apparent rate constant linearly increases with increase in water concentration up to 8 M. It seems that such a change is due to hydrolysis of the complex, presumably taking place step by step. The rate is so small, ($1\times10^{-4}/M^{-1}s^{-1}$ at 70 °C), however, that it can be ignored when the racemization mechanism is discussed.

Racemization in Other Solvents. No change in absorption of the complex was observed for several half-lives in nitromethane, and for a few half-lives in TCE. The racemization was catalyzed by acetic acid in TCE. The decrease in optical rotation in DMF was accompanied by the change in absorption. The absorption spectrum has an isosbestic point at 279 nm, and this change seems to be due to a reaction giving free acetylacetone. The net racemization was followed by use of the quotient (optical rotation at 316 nm)/(absorbance at 305 nm), and the calculated k_{obsd} values are shown in Table 2. The decrease in optical activity in DMSO and chloroform is mostly due to decomposition of the complex. Intrinsic racemization may be taking place, but it is distinguished with difficulty. The k_{obsd} values and the activation parameters in various solvents are summarized in Table 2.

Ligand Isotopic Exchange in Acetonitrile. No exchange took place within 2000 minutes at 60 °C both in the presence and the absence of pyridine. No exchange was either observed at 80 °C suggesting a negligibly smaller rate of ligand isotopic exchange than the racemization.

Discussion

Mechanism of Racemization of Tris(acetylacetonato)germanium(IV). Absence of ligand isotopic exchange and of decomposition clearly indicates that the racemization proceeds *via* an intra-molecular mechanism. Independence of the rate constant on the complex and the ligand concentration also supports such a mechanism.

An intra-molecular mechanism can proceed with or without break of one of the metal-ligand bonds. The former involves an intermediate with a unidentate ligand and the latter that with tris-bidentate ligands. It is difficult, however, to give a direct evidence for distinguishing them, and the discussion should be based on indirect evidences as follows.

The racemization was catalysed by acetic acid in TCE and by pyridine in AN. It is not likely that an acid or a base gives catalytic effect on the twisting of the complex without bond-break. Further, the racemization rate was found to increase with increase in ionic strength. It is likely that increase in ionic strength facilitates the bond break resulting in charge separation.

The values of ΔH^* and ΔS^* are not very different from one another in various solvents (Table 2), and the overall mechanism should not be very different in all of them, although the above observations were mainly made in AN. As Table 2 shows, the dielectric constant and the dipole moment do not seem to play an important role in determining the racemization rate. It seems that the rate increases and ΔH^* decreases with increase in donor number[9] of the solvents. The donor number reflects the ease with which the solvent molecules have interaction with the central metal ion, and its increase would facilitate the break of Ge–O bond of the complex. In those solvents with bigger donor numbers, even decomposition of the complex was observed to produce free acetylacetone.

On the basis of these facts, we propose a racemization mechanism involving an intermediate with a unidentate ligand, as shown in Fig. 6. Such a mechanism can have either the bond break or the succeeding intra-molecular rearrangement as rate-determining step. Although a direct evidence is given with difficulty, we tend to think that the rate-determining step would be the solvent-assisted break of the first metal-ligand bond. If the solvent molecules did not assist the bond break but just occupied the vacant coordination site of the intermediate, or if they gave an indirect effect to ease the break of ionic Ge–O bond, not the donor number but rather the dipole moment or the dielectric constant would be related to the rate and the activation enthalpy of the complex. Further, if the internal rearrangement were the rate determining step, the effect of the solvents would be reversed.

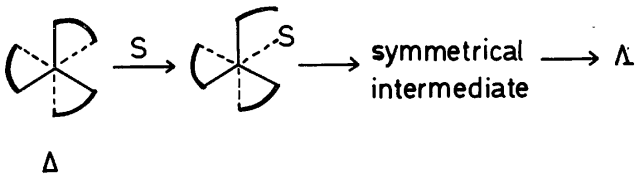

Fig. 6. Plausible reaction mechanism.
(The "symmetrical intermediate" can be either trigonal bipyramid or square pyramid, but its structure is not known from the present experiments.)

Holm and co-workers measured the coalescence of the proton signals of tris-type germanium(IV) complexes of substituted tropolonate in various chlorohydrocarbons by NMR, and discussed the mechanism of intra-molecular geometrical isomerization and racemization.[3] It was suggested that the intramolecular rearrangement proceeds without involving bond-break. They obtained ΔH^* values 12 to 17 kcal/mol and log A 12, which are common with those of other tris-α-diketonato complexes. Our ΔH^* values are significantly larger than theirs and our present racemization is more adequately presumed to have a different rate-determining step from theirs.

Comparison with Related Compounds. Tris(acetylacetonato)germanium(IV) gives very similar absorption and circular dichroism spectra to those of tris(acetylacetonato)silicon(IV). The $(-)_{589}$-isomer of $[Ge(acac)_3]^+$ can be assigned to absolute configuration Δ from comparison of the CD spectrum in the UV π-π^* transition region with that of tris(acetylacetonato)-silicon(IV),[10] whose absolute configuration was supported by the CD spectrum[11] and X-ray crystallography of tris(catecholato)arsenic(V).[12]

The solubility of various salts of $[Ge(acac)_3]^+$ in various organic solvents is also very similar to that of $[Si(acac)_3]^+$ salts.

Table 1 shows the values of rate constants and activation parameters of racemization of $[Si(acac)_3]^+$, too. The ligand isotopic exchange of the silicon complex is also very slow. Its racemization is catalysed by acids in TCE and by bases in AN, and an intramolecular mechanism involving bond-break was proposed. The activation parameters for the germanium and silicon complexes are very near to each other. All these facts are reckoned as to reflect the overall similarity of these two elements.

A number of studies have been published concerning the kinetics of geometrical isomerization and racemization ("site-exchange") of α-[3,13] and β-diketonato[4] complexes of various metal ions. The site exchange is generally understood to proceed intra-molecularly in organic solvents, but various mechanisms have been proposed for their detailed progress. Examination of the references suggests that tris-β-diketonato complexes mostly undergo site exchange with one bond-break, whereas tris-α-diketonato complexes without bond-break. However, the experimental evidence for such a statement is rather indirect, and our present discussion provides more concrete support to the mechanism. Semi-empirical calculation on the basis of structural parameters also supports such a mechanism.[14] Most of these studies were made with chargeless complexes, but the discussion seems to be applicable to cationic complexes with +1 charge, *i.e.* our study with β- and Holm's with α-diketonatogermanium(IV).

The approximate order of overall site-exchange rate for tris-β-diketonato complexes of various metal ions is given below:[4]

$$\text{Fe(III), In(III)}>\text{Mn(III)}>\text{Ga(III)}>\text{Al(III)}>\text{Si(IV)}\gtrsim \text{Ge(IV)}>\text{Co(III)}>\text{Cr(III)}>\text{Ru(III)}\gtrsim\text{Rh(III)} \quad (4)$$

The labilities of silicon(IV) and germanium(IV) complexes are larger than that of cobalt(III) complexes and smaller than those of Family IIIB elements. The activation enthalpies (ΔH^*/kcal·mol^{-1}) involving bond-rupture process for site exchange of cobalt(III)[15] and aluminium(III)[16] are 20 to 30 and 15 to 20, and the log A's 14 to 16 and 13 to 17 respectively. The ΔS^* values are all positive. Although the present silicon and germanium complexes have +1 charge, the activation parameters for racemization are between those of Co(III) and Al(III) complexes. The sequence 4 seems to reflect the order of ease of break of the first metal-ligand bond.

On the other hand, ligand isotopic exchange studies suggested the break of the remaining bond of the unidentate ligand in the intermediate as rate-determining step. The rate of such inter-molecular reactions of octahedral β-diketonato complexes decrease approximately in the order,[5,8,17–19]

$$\text{In(III)}>\text{Ga(III)}>\text{Al(III)}>\text{Co(III)}>\text{Si(IV)},\ \text{Ge(IV)}>\text{Cr(III)} \quad (5)$$

While the major part of this sequence is similar to sequence 4, silicon(IV) and germanium(IV) come next to cobalt(III). Such a difference may be related to the stability of the intermediate with five metal-ligand bonds. These ions with higher positive charge may interact with solvent molecules at the vacant coordination site more significantly to stabilize the intermediate.

Copper(II) Complexes of L-Histidylglycine and L-Histidylglycylglycine in Aqueous Solution

Hiroji AIBA, Akira YOKOYAMA, and Hisashi TANAKA
Faculty of Pharmaceutical Sciences, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606
(Received July 30, 1973)

Equilibrium constants were determined in the complex formations of L-histidylgylcine (HG) and L-histidylglycylglycine (HGG) with copper(II) ion in aqueous solution by potentiometric titration, and the structures of the complexes were discussed based on the observations in the titration and infrared and electronic absorption spectra. In the acid region, a cationic chelate, in which copper(II) binds to nitrogen atoms of amino and imidazole groups, is formed. In the neutral region, deprotonation of the peptide amide group occurs to form a dimer, in which four coordination positions of copper(II) are occupied by nitrogen atoms of deprotonated amide and amino groups and an oxygen atom of carboxyl or carbonyl group in one molecule and a nitrogen atom of imidazole group of another molecule. In HGG–Cu(II) system, the dimer is decomposed in the alkaline region with further deprotonation of the second peptide amide group to form an anionic chelate as in the case of the glycylglycylglycine-Cu(II) complex.

The complex formation of some histidine-containing peptides has been studied by various physico-chemical methods,[1-12] based on the importance of the histidyl residue as a binding site with metal ions in protein. However, the experimental results, such as the data on the potentiometric titration, the spectral measurement and X-ray analysis, are not always sufficiently detailed to discuss the behavior of these peptides in the interaction with the metal ions in aqueous solution. The copper(II) complex of L-histidylglycine has been studied by the potentiometric titration[12] and the visible and CD spectra,[5] but the behavior and the structure of the complex in aqueous solution were not interpreted in detail with the experimental results. The complex formation of L-histidylglycylglycine has not been investigated so far.

In the preceding paper,[13] we reported the syntheses and the acid dissociation constants of some histidine-containing peptides, and also the formation constants of some 2:1 (ligand:metal) metal complexes of L-histidylglycine and L-histidylglycylglycine (abbreviated as HG and HGG hereafter). Further, the dimer formation in the reaction of HG and HGG with copper(II) ion was briefly reported.[14] This paper deals with the detailed description of the study and the discussions on the complex formation of these peptides with copper(II) ion in aqueous solution.

Experimental

Materials. The preparations of HG and HGG were described in the preceding paper.[13] All other reagents were commercially obtained.

Potentiometric Titrations. The details of the method and the experimental conditions have been described previously.[13] Titrations were carried out in the solutions (10 ml) containing a ligand (10^{-3}M), HCl (2×10^{-3}M) and $CuCl_2$ (10^{-3}M) with 0.1 M KOH.

Infrared Absorption Spectra. The infrared absorption spectra were recorded on a Koken DS-301 infrared spectrophotometer equipped with sodium chloride prisms. Measurements were made on the D_2O solutions of a ligand with or without copper(II) ion, in a KRS-5 cell. The concentration of the ligand was approximately 0.3 M.

Visible Absorption Spectra. The visible absorption spectra were recorded on a Shimadzu Double 40-R spectrophotometer. Spectral measurements were made on the solutions of a ligand containing copper(II) ion with the concentration ranging from 4×10^{-3}M to 1×10^{-2}M.

Results and Discussion

Potentiometric Titrations. Titration curves for the solutions containing 1:1 molar ratio of copper(II) ion to ligand in the presence of two equivalents of HCl are given in Figs. 1 and 2. Both curves show sharp pH inflections at $a=3$ and $a=4$, where a represents moles of KOH added per mole of the ligand. Another pH inflection is observed at $a=5$ in the HGG–Cu(II) system. The pH inflection at $a=3$ suggests the formation of the 1:1 ligand-copper(II) complex in both systems. Therefore, the following reactions were assumed in the region where a value is between 1 and 3.

$$LH_3^{2+} \rightleftharpoons LH_2^{+} + H^{+}$$

$$K_{COOH} = [LH_2^{+}][H^{+}]/[LH_3^{2+}] \quad (1)$$

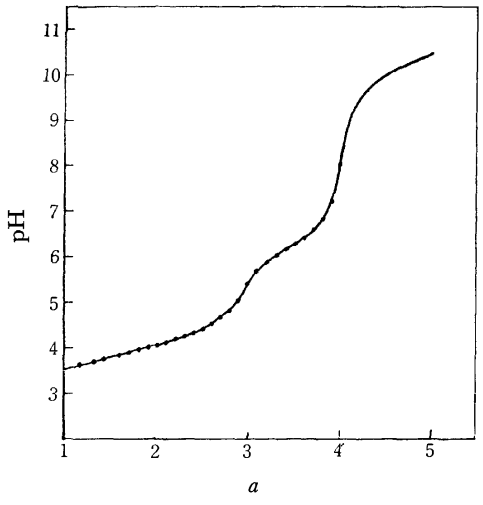

Fig. 1. Titration curve of HG in the presence of equimolar $CuCl_2$ and two equivalents of HCl.
At $a=0$, $[HG]_T=[Cu]_T=10^{-3}$M. The line is experimental curve. The points are the values calculated from equilibrium constants.

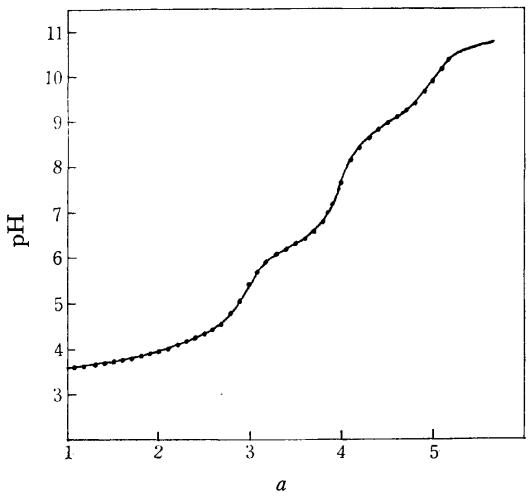

Fig. 2. Titration curve of HGG in the presence of equimolar $CuCl_2$ and two equivalents of HCl.
At $a=0$, $[HGG]_T=[Cu]_T=10^{-3}$M. The line is experimental curve. The points are the values calculated from equlibrium constants.

$$LH_2^+ \rightleftarrows LH + H^+$$
$$K_{Im} = [LH][H^+]/[LH_2^+] \quad (2)$$
$$LH \rightleftarrows L^- + H^+$$
$$K_{NH_2} = [L^-][H^+]/[LH] \quad (3)$$
$$Cu^{2+} + L^- \rightleftarrows CuL^+$$
$$K_1 = [CuL^+]/[Cu^{2+}][L^-] \quad (4)$$

Electroneutrality requires Eq. (5).

$$2[Cu^{2+}] + [CuL^+] + 2[LH_3^{2+}] + [LH_2^+] + [K^+] + [H^+] = [L^-] + [Cl^-] + [OH^-] \quad (5)$$

The total concentrations of copper(II) and the ligand are expressed as Eqs. (6) and (7).

$$[Cu]_T = [Cu^{2+}] + [CuL^+] \quad (6)$$
$$[L]_T = [CuL^+] + [LH_3^{2+}] + [LH_2^+] + [LH] + [L^-] \quad (7)$$

Since copper(II) ion was added as chloride and two equivalents of HCl per ligand were added, the concentration of Cl^- is expressed as Eq. (8).

$$[Cl^-] = 2[Cu]_T + 2[L]_T \quad (8)$$

Equation (9) is derived from these equations.

$$K_1 = \beta(\beta[Cu]_T - \alpha\gamma)/\alpha\gamma^2, \quad (9)$$

where

$$\alpha = 1 + [H^+]/K_{NH_2} + [H^+]^2/K_{Im}K_{NH_2} + [H^+]^3/K_{COOH}K_{Im}K_{NH_2},$$
$$\beta = [H^+]/K_{NH_2} + 2[H^+]^2/K_{Im}K_{NH_2} + 3[H^+]^3/K_{COOH}K_{Im}K_{NH_2},$$
$$\gamma = [Cu]_T + 2[L]_T + [OH^-] - [H^+] - [K^+].$$

The formation constant, K_1, was calculated at each point of the experiments from Eq. (6), based on the data of the titration in the region where a value is between 1 and 3. The results are given in Table 1. Fairly good constant values of $\log K_1$ were obtained with varying a values in each system. These values are in good agreement with those we obtained in the 2:1 systems.[13] In CuL^+, the nitrogen atoms of α-amino and imidazole groups may be bound to the copper atom, as we mentioned previously.[13]

The deprotonation in the region where the a value is between 3 and 4 can not be interpreted by a simple ionization (Table 2). On the other hand, the spectral features of the complexes in the visible region suggested the formation of a polymer (Cu_nX_n) accompanying the

Average value of pK_c^2 between $a=3.2$ and $a=3.8$; His-Gly-Cu(II): 9.46±0.02, His-Gly-Gly-Cu(II): 9.67±0.04.

deprotonation, as shown later. Therefore, the equilibrium constants for the polymer formations were calculated based on Eq. (10), where $L^-=XH^-$.

$$n\mathrm{CuL}^+ \rightleftarrows \mathrm{Cu}_n\mathrm{X}_n + n\mathrm{H}^+$$

$$K_c^n = [\mathrm{Cu}_n\mathrm{X}_n][\mathrm{H}^+]^n/[\mathrm{CuL}^+]^n \qquad (10)$$

Table 2 represents the results of the calculations for pK_c^n, where n is from 1 to 5. The values of pK_c^1 which corresponds to the simple ionization decrease with the increase of the a value, while the values of pK_c^n for the trimer, tetramer, and pentamer increase with the increase of the a value. On the other hand, values of pK_c^2 which are applied to the formation of a dimer remain constant over the wide range. These facts support the presence of a dimer produced by the release of a proton from each CuL^+ complex.

As shown later by visible absorption spectra, further deprotonation in the region where the a value is between 4 and 5 in the HGG–Cu(II) system seems to be accompanied by the formation of an anionic chelate, CuY^-, as well as in the case of glycylglycylglycine.[16] For this deprotonation, the following reaction is assumed, where $YH_2^-=XH^-=L^-$.

$$\mathrm{Cu}_2\mathrm{X}_2 \rightleftarrows 2\mathrm{CuY}^- + 2\mathrm{H}^+$$

$$K_c'^2 = [\mathrm{CuY}^-]^2[\mathrm{H}^+]^2/[\mathrm{Cu}_2\mathrm{X}_2] \qquad (11)$$

The values of $pK_c'^2$ calculated according to Eq. (11) are roughly constant as seen in Table 3. Slight scatter among the values in Table 3 suggests that the deprotonation overlaps to some extent with the preceding deprotonation.

TABLE 3. $pK_c'^2$ CALCULATED ACCORDING TO Eq. (11)

a	pH	$pK_c'^2$
4.1	7.85	20.37

4.8	9.31	20.90
4.9	9.47	20.89

Average value of $pK_c'^2$ between $a=4.4$ and $a=4.9$: 20.87 ± 0.07.

In the reactions mentioned above, the proton is presumed to be liberated from the amide group of the peptide. However, the pH values of the region where the deprotonations occur are rather higher than those in the glycylglycine–Cu(II)[15] and glycylglycylglycine–Cu(II)[16] systems. The difficulty of the deprotonation in HG–Cu(II) and HGG–Cu(II) complexes may be due to the higher stability of the complexes, CuL^+ and Cu_2X_2, because the cleavage and recombination of the coordination bonds are necessary to cause these deprotonations. This structural conversion will be described later. The second deprotonation in the region where the a value is between 4 and 5 is also observed in the HG–Cu(II) system. Since this deprotonation occurs in the high pH region, equilibrium constants could not be determined accurately. The apparent ionization constant, which is the pH value at the half-neutralization point, is 10.00. The proton may be liberated from the imino group of the imidazole ring to give an anionic chelate, $Cu_2Y_2^{2-}$. It has been reported that the deprotonation of imino group occurs at the extremely high pH region in free imidazole and histidine[17] ($pK_a\approx14$). In the HG–Cu(II) complex, it is presumed that the electron-withdrawing effect of Cu(II) which binds to pyridine-type nitrogen of imidazole ring weakens the basicity of imino group.

From the equilibrium constants obtained, the titration curves were re-calculated and they were compared with the experimental curves. Coincidence of both titration curves as seen in Figs. 1 and 2, supports the validity of these constants. Based on the constants, the distribution ratios of various complexes were calculated at various pH. The results shown in Figs. 3 and 4, indicate that main species in the region of pH 5 is a cationic chelate, CuL^+. The distribution ratio for the dimer, Cu_2X_2, increases with the increase of pH and reaches its maximum at the neutral region. In the alkaline region, anionic chelates, $Cu_2Y_2^{2-}$ or CuY^-, are predominant species.

Infrared Absorption Spectra. Infrared absorption spectra of D_2O solutions of HG in the absence and the presence of copper(II) ion were measured in the carbonyl absorption region to provide the information for the copper(II) binding sites. Figure 5 shows the infrared absorption spectra of HG. Figures 6 and 7 show the spectra of the 1 : 1 and 2 : 1 HG–Cu(II) complexes. The carbonyl and carboxylate absorption bands are observed in both spectra. The assignments of these bands were made by reference to those in the infrared absorption spectra of glycine peptides[18] and their Cu(II) complexes.[15,16] The results are given in

Table 4. Carbonyl and carboxylate bands in infrared absorption spectra of HG and its Cu(II) complexes in D_2O solution

HG+½Cu(II)	0	1725	1680		1595 (w)
	1	1725	1680	1647 (w)	1595
	2		1675	1645 (sh)	1595
	3			1645	1595

Table 4. For the convenience of the interpretation of the spectra, a values which are equivalent to those in the titrations are used.

In Fig. 5 two bands assigned to be due to undissociated carboxyl and peptide carbonyl groups respectively are observed at 1720 and 1680 cm^{-1}, in the spectrum before the addition of alkali. In the region where the a is larger than 1, the band of carboxylate appears at 1595 cm^{-1}. The bands at 1675 and 1632 cm^{-1} observed at $a=2$ and $a=3$ respectively, are assigned to the peptide carbonyl group. These shifts of carbonyl band to the lower frequency will be attributed to the deprotonation of imidazole and α-amino groups. The inductive effect of the α-amino group is much stronger than that of imidazole group. The spectral features of HG described above are similar to those of glycylglycine.[18]

In the 1 : 1 HG–Cu(II) system, a new band appears at 1647 cm^{-1} in the region where CuL^+ is predominantly present. This band will be assigned to the peptide carbonyl group in CuL^+. The appearance of the band of carbonyl group at the higher frequency in the complex CuL^+ than in the ligand is worth noticing. In the glycylglycine–Cu(II) system,[15] the band of carbonyl group moves to the lower frequency (1632 $cm^{-1}\rightarrow$ 1625 cm^{-1}). The shift of the carbonyl band may be controlled by two contrastive effects, namely the inductive effect of Cu(II) and the reduction of the bond order of the carbonyl group based on bonding between Cu(II) and carbonyl oxygen. The shift to the higher frequency observed in the HG–Cu(II) system suggests that the latter effect is very weak. This finding is in accord with the conclusion that the peptide carbonyl group does not bind to Cu(II) in the plane. In the 2: 1 HG–Cu(II) system, the same band appears at

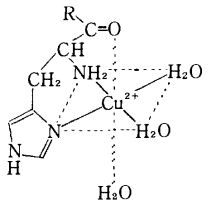
(a) HGG+Cu(II)+KOH, (b) HGG+Cu(II)+2KOH, (c) HGG+Cu(II)+3KOH, (d) GGG+Cu(II)+3KOH. GGG=glycylglycylglycine.

1645 cm^{-1} in the region where the a value is between 1 and 3 and this band may be attributed to the complexes CuL^+ and CuL_2.

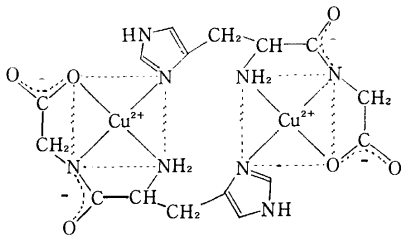
At $a=4$ in the 1 : 1 system, where the dimer, Cu_2X_2, is the predominant species, a new band appears at 1608 cm^{-1} with a shoulder at ~1570 cm^{-1}. The band at 1608 cm^{-1} is assigned to the carbonyl group of the peptide which involves deprotonated peptide nitrogen bound to Cu(II).[15] Accordingly, it is proved that the neutral dimer Cu_2X_2 has metal-peptide nitrogen bonds.

Visible Absorption Spectra. The visible absorption spectra of Cu(II) complexes in solution were studied to provide further evidence for the structures of the species formed in solution. Figures 8 and 9 show the spectra obtained on the solutions of 1 : 1 ligand–Cu(II) systems. For the convenience of the interpretation of the spectra a values which are equivalent to those in the titrations are used. The absorption spectra of the HG–Cu(II) and HGG–Cu(II) systems at $a=3$ are similar to the absorption spectrum of histidine–Cu(II) system. This observation suggests that the coordination structures of these complexes are similar each other. Consequently in this region, HG and HGG seem to bind to copper(II) through the nitrogen atoms of amino and imidazole group, as also presumed from the results of the titrations and infrared spectra. The structure of CuL^+ is given by **I**.

In the HG–Cu(II) system a shift of the absorption maximum to the shorter wavelength with a remarkable



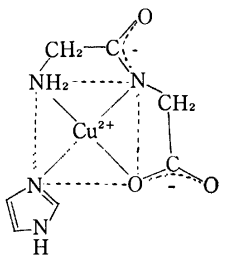
(I)



(II)

(I), CuL^+, $R=NHCH_2COO^-$: HG-Cu(II)
$R=NHCH_2CONHCH_2COO^-$: HGG-Cu(II)
(II), Cu_2X_2, HG-Cu(II)

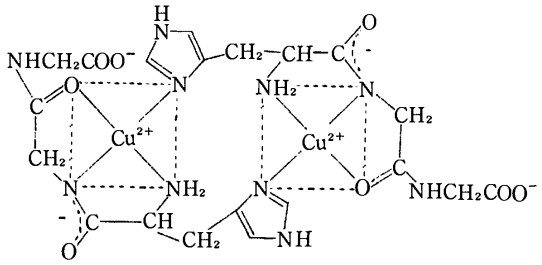
increase of the absorbance was observed when the a value increases from 3 to 4. An absorption maximum appears at 613 nm ($\varepsilon=99$). This spectral change suggests the coordination of the copper(II) to the peptide nitrogen with a displacement of the proton and the formation of a neutral chelate, similar to glycylglycine–Cu(II) complex. However, it is noteworthy that the absorption maximum is observed at the shorter wavelength and the absorbance is larger than that in the case of glycylglycine–Cu(II) system (Fig. 8). These spectral features of HG–Cu(II) complex can be explained in terms of the following assumption. One imidazole group dissociates from the copper(II) with the deprotonation of the peptide amide group and then occupies the fourth coordination position of another copper atom to form a polymer. This structural change is reasonable from the molecular model, because the simultaneous coordination of one copper(II) ion to the nitrogen atoms of amino, imidazole, and deprotonated amide groups in one molecule of peptide are sterically unfavorable. The coordination of the imidazole group of the other molecule to the fourth position will form a somewhat stronger ligand field around copper(II) ion than in the case of the glycylglycine–Cu(II) complex. Consequently, the absorption maximum appears at the shorter wavelength than in glycylglycine–Cu(II) complex. The larger absorbance may be attributed to the steric strain caused by the coordination of the imidazole group. The structural change mentioned above leads to the formation of a polymer through imidazole group. The formation of a dimer is already indicated by the quantitative analysis on the results of the potentiometric titrations. The absorption spectrum of the 1 : 1 : 1 solution of glycylglycine, copper(II) ion and imidazole agrees with that of the HG–Cu(II) system. This agreement suggests the similarity of the coordination structures of both systems and supports the assumption mentioned above strongly.



(III), GG-Cu(II)-Im

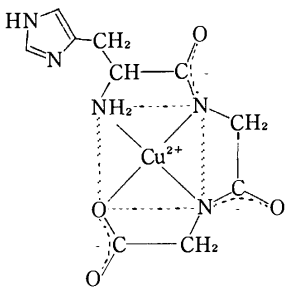
The structures for the HG–Cu(II) and glycylglycine–Cu(II)–imidazole complexes are given by **II** and **III**. It is interesting that the dimer structure is also proposed in β-alanyl-L-histidine–Cu(II) complex.[1]

In the HGG–Cu(II) system, similar spectral features are observed at $a=4$ (Fig. 9). Therefore, similar dimer complex seems to form in this region, as shown by **IV**.



(IV), Cu_2X_2, HGG-Cu(II)

In this system, further shift of the absorption maximum to the shorter wavelength with a remarkable increase of the absorbance is observed where the a value is larger than 4. The spectrum at $a=5$ shows the absorption maximum at 555 nm ($\varepsilon=150$) and is similar to that of the 1 : 1 glycylglycylglycine–Cu(II) system under the same condition. This fact suggests that in this region the dimer is decomposed with the dissociation of the hydrogen of the second peptide amide group to form an anionic chelate, CuY^-, similar to the 1 : 1 glycylglycylglycine–Cu(II) complex.[16] The structure of CuY^- can be represented by **V**.



(V), CuY^-, HGG-Cu(II)

The authors wish to express their thanks to Dr. K. Machida, Kyoto University, for his helpful advices in IR measurements, to the staff of the Kyoto University Computer Center for the use of FACOM 203-60 Computer, and to the members of the Micro Analytical Center of Kyoto University for elemental analysis.

The Chlorobromination of Olefins with Antimony (III and V) Chlorides

Sakae UEMURA,* Akira ONOE, and Masaya OKANO
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611
(Received June 5, 1973)

By the reaction of olefins with equimolar mixtures of $SbCl_5$ and Br_2 or LiBr, and of $SbCl_3$ and Br_2, in carbon tetrachloride, various bromochloroalkanes were obtained in good yields. The mixtures of certain metal chlorides of the Lewis acid type (*e.g.*, $FeCl_3$, $SnCl_4$, and $TiCl_4$) and Br_2 could also be used as chlorobrominating agents, but these mixtures were found to be inferior to the $SbCl_5$–Br_2 mixture in product selectivities.

The *in situ* formation of ICl and its addition to olefins, by the use of mixtures consisting of certain metal chlorides (*e.g.*, AgCl, $HgCl_2$, CuCl, *etc.*) and I_2

$$MCl_n + I_2 \longrightarrow MCl_{n-1}I + ICl \quad (1)$$

[Eq. (1)], have been known for a long time.[1] Baird *et al.* have recently found a more efficient system containing $CuCl_2$, in which the oxidation of the iodide anion with the copper(II) salt is involved and a com-

$$2CuCl_2 + I_2 \longrightarrow 2CuCl + 2ICl \quad (2)$$

plete utilization of I_2 is achieved [Eq. (2)].[2] A similar chlorobromination using the $CuCl_2$–Br_2 mixture, however, appears to be less satisfactory in yield and product selectivity.[2b] Though a mixture of bromine and chlorine has also been used as a source of BrCl, the reported yields of bromochloroalkanes are not very high.[3] During the studies of halogenation reactions with $SbCl_5$, we have found convenient new chlorobrominating agents consisting of $SbCl_5$ or $SbCl_3$ and Br_2. When various olefins were treated with these equimolar mixtures in carbon tetrachloride, bromochloroalkanes were obtained in good yields, just as when the mixture of *N*-bromoacetamide and hydrogen chloride was used.[4] This paper will describe some results of mixed halogenations with these metal chloride–halogen mixtures.

Results and Discussion

The reaction of cyclohexene with an equimolar mixture of $SbCl_5$ and Br_2 in carbon tetrachloride was completed at room temperature within a few minutes. Some other metal chlorides which were soluble in carbon tetrachloride were also examined as chloride components under somewhat different reaction conditions. In these reactions, *trans*-1-bromo-2-chlorocyclohexane was generally obtained in good yields, together with smaller amounts of *trans*-1,2-dibromocyclohexane. All the results are given in Table 1a. As can be seen from the table, the $SbCl_5$–Br_2 mixture in carbon tetrachloride was found to be superior to the other ones in yield and in product selectivity. Dichloroethane could be used as an effective solvent, but the use of carbon disulfide resulted in less satisfactory results (compare Runs 1—3 in Table 1a).

When $SbCl_5$ was used as a chloride component, nearly two moles of the bromochloride were formed from one mole of Br_2; hence, the stoichiometry of the reaction is given by Eq. (3).

$$2C_6H_{10} + SbCl_5 + Br_2 \longrightarrow 2C_6H_{10}BrCl + SbCl_3 \quad (3)$$

Here, the generation of two moles of BrCl can be rationalized by assuming the following successive re-

$$SbCl_5 + Br_2 \rightleftharpoons BrCl + SbCl_4Br \quad (4)$$

$$SbCl_4Br \rightleftharpoons BrCl + SbCl_3 \quad (5)$$

actions [Eqs. (4) and (5)]. Since the BrCl formation of the former type is similarly observed for certain metal chlorides (see below), the presumed participation of Eq. (4) may not be unreasonable. The latter reductive dissociation may be anticipated from the favorable reduction potential of Sb(V)[5] and facilitated by the presence of the more electropositive bromine atom in the ligands,[6] but the reverse reaction does not seem to be easy. Thus, the overall reaction [(4)+(5)] would be highly in favor of the BrCl formation. In connection with this a similar observation has been reported in the literature[7] that $SbCl_5$ reacted with I_2 to afford ICl and $SbCl_3$ and that no isolation of $SbCl_4I$ was achieved. Another possibility, that of BrCl formation from Br_2 and Cl_2 (liberated from $SbCl_5$), can be excluded, because Cl_2 generation has not been observed in the chlorination of olefins with $SbCl_5$ under similar reaction conditions.[8]

Though the *in situ* formation of BrCl in this reaction is highly probable, as has been described above, its attacking form is not decisive. The following observation, however, appears to suggest that the attacking entity is the BrCl molecule itself (probably somewhat activated by $SbCl_5$ or $SbCl_3$). In the competitive bromination of benzene and toluene with the $SbCl_5$–Br_2 mixture under the same conditions (in CCl_4 at 25 °C), a considerably high selectivity (k_T/k_B value) was observed;[9] this selectivity was slightly less than that for the attack of the Br_2 molecule itself.

On the other hand, when other metal chlorides of the Lewis acid type, such as $FeCl_3$, $SnCl_4$, and $TiCl_4$, were used as chloride components, nearly one (but not more than one) mole of the mixtures of the bromochloride and dibromide, with the amount of the former being dominant, were obtained from one mole of Br_2 (Runs 4—6 in Table 1a). Further, in the halogenation with the $FeCl_3$–Br_2 mixture, it was confirmed that the reaction was accompanied by almost no reduction of the Fe(III) cation (<10% by iodometry). The oxidations of Br^- with the above metal chlorides (except for $SbCl_5$) were also not observed appreciably (see below). These results seem natural because of the very low reduction potentials of the metal cations. The *in situ* BrCl formation was similarly observed even in the case

Table 1. Chlorobromination and chloroiodination of cyclohexene in carbon tetrachloride

c) Solvent, dichloroethane.
d) Solvent, carbon disulfide.
e) Isolated yield.

of a low-valence compound, $SbCl_3$ (see Runs 7 and 8). Thus, it seems very likely that BrCl is formed by the

$$MCl_n + Br_2 \rightleftharpoons BrCl + MCl_{n-1}Br \quad (6)$$

halogen exchange reaction [Eq. (6)], though no direct evidence for the formation of the mixed metal halide is available at present. Since it is known that all these metal chlorides have a considerable affinity for Cl^-,[10] this transformation may proceed *via* an ionic adduct intermediate, *e.g.*, $Br^+[FeCl_3Br]^-$. The stoichiometry of the halogenation using the mixtures of these metal chlorides and Br_2 may be expressed by Eq. (7).

$$C_6H_{10} + MCl_n + Br_2 \longrightarrow C_6H_{10}BrCl + MCl_{n-1}Br \quad (7)$$

The formation of the by-product, *trans*-1,2-dibromocyclohexane, can be explained in terms of the attack of Br_2, which is equilibrated [*cf.* Eq. (6)].

Furthermore, when various metal chlorides were mixed with LiBr in carbon tetrachloride and the mixtures (slightly heterogeneous, probably because of the lower solubility of the LiCl formed) were treated with cyclohexene, no significant red-coloration (due to the generation of BrCl) and no, or only a slight, formation of 1-bromo-2-chlorocyclohexane was observed, except only for the case of $SbCl_5$ (see Runs 9—12 in Table 1a). In the $SbCl_5$–LiBr system, the use of an equimolar mixture of both salts was required for the chlorobromination. Perhaps the BrCl[11] may arise from the mixed pentahalide formed by means of Eq. (8) and

$$SbCl_5 + LiBr \rightleftharpoons Li^+[SbCl_5Br^-] \rightleftharpoons LiCl + SbCl_4Br \quad (8)$$

$$SbCl_4Br \rightleftharpoons BrCl + SbCl_3 \quad (5)$$

$$C_6H_{10} + SbCl_5 + LiBr \longrightarrow C_6H_{10}BrCl + SbCl_3 + LiCl \quad (9)$$

the stoichiometry of the reaction may be represented by Eq. (9). Excess $SbCl_5$ caused a considerable formation of *cis*- and *trans*-1,2-dichlorocyclohexanes as by-products,[8] and excess LiBr resulted in contamination with the dibromide [see Eq. (10)]. In addition, the use of KBr instead of LiBr was not successful because of its lower solubility in the solvent.

$$BrCl + LiBr \rightleftharpoons Br_2 + LiCl \quad (10)$$

The method using $SbCl_5$ or $SbCl_3$ as a chloride source was found to be applicable to the chloroiodination of olefins. The data for cyclohexene are given in Table 1b. Though somewhat severe reaction conditions were required as compared to those in the chlorobromination, the yield was satisfactory. Both our results and Baird's data show that, in the chlorobromination, some competitive bromination always occurred, the quantity depending on the combination of metal chlorides and bromine, whereas in the chloroiodination no competitive iodination was observed. Such trends may be reasonably explained by differences in the reactivities between halogens and interhalogens (reported relative rates for the addition to olefins in acetic acid:[12] BrCl: Br_2=400: 1, ICl: I_2=10^5: 1). The use of $SnCl_4$ instead of $SbCl_5$ or $SbCl_3$ was also successful, but the system containing $FeCl_3$ was ineffective.

The chlorobromination of various olefins other than

cyclohexene was easily achieved by the use of mixtures of $SbCl_5$ or $SbCl_3$ and Br_2. Unsymmetrical olefins, such as 1-octene and allyl chloride or bromide, yielded mixtures of the Markownikov and *anti*-Markownikov adducts. 1-Octene afforded the former adduct predominantly, while the reverse was found for allyl halides. Such an abnormal orientation has also been found in the reaction of allyl halides with HOCl; it can be explained by neighbouring group participation.[13] Styrene, vinyl acetate, and ethyl cinnamate gave only products in accordance with Markownikov's rule, as anticipated on the basis of electronic and steric effects. For certain olefins, the $SbCl_3$–Br_2 mixture would be useful—*e.g.*, the use of $SbCl_5$ resulted in a decrease in the product selectivity in the reaction with 1-octene and a considerable formation of a tarry product in the reaction with styrene.

Experimental

Materials. All the organic starting materials, including the solvents, were distilled before use. Commercial metal halides, Br_2, and I_2 (best grade) were used without further purification.

Reaction of Cyclohexene with Metal Chlorides and Bromine Donors. To a nearly homogeneous solution of a metal chloride (25 or 50 mmol) and Br_2 or LiBr (25 or 50 mmol) in CCl_4 (100 or 150 ml), cyclohexene (100 mmol) was gradually added at the prescribed temperature. After stirring was continued for a definite period, the reaction mixture was treated with water, and the inorganic precipitate thus formed was removed by filtration. The CCl_4 layer was separated from the aqueous one, and the solvent was evaporated. A liquid fraction boiling at 91—95 °C/17 mmHg was collected; it consisted of *trans*-1-bromo-2-chlorocyclohexane and *trans*-1,2-dibromocyclohexane, and occasionally also *cis*- and *trans*-1,2-dichlorocyclohexanes. The structural confirmation of these products was made by a comparison of the NMR spectra with those reported in the literature.[14] The composition of the above fraction was determined by means of the glc analysis [apparatus, Shimadzu 5APTF; columns, PEG 6000 (25%)-Chromosorb W(3m), Silicon D.C. 550 (25%)-Shimalite (3m), and Apiezon L(30%)-Celite (1m); carrier gas, N_2].

Syntheses of Bromochloroalkanes and Chloroiodoalkane. Several examples are given below.

1-Acetoxy-1-chloro-2-bromoethane. Vinyl acetate (8.6 g, 100 mmol) was added drop by drop to a mixture of $SbCl_5$ (7.5 g, 25 mmol) and Br_2 (4.0 g, 25 mmol) in CCl_4 (100 ml) near 5 °C. Stirring was continued for 10 min at that temperature, after which the reaction mixture was worked-up as has been described above. Distillation gave the chlorobromide (8.0 g, 39.4 mmol) in a 79% yield; bp 64—65 °C/10 mmHg. NMR: τ 3.45 (t, 1H), 6.25 (d, 2H), 7.84 (s, 3H).

Found: C, 23.90; H, 3.01; Br, 39.30; Cl, 17.43%. Calcd for $C_4H_6BrClO_2$: C, 23.85; H, 3.00; Br, 39.66; Cl, 17.59%.

Diethyl erythro- *and* threo-*α-Bromo-β-chlorosuccinate.* The procedure was the same as that described for vinyl acetate except that the reaction temperature and time were 76 °C and 60 min respectively. From diethyl fumarate (8.6 g, 50 mmol), the *erythro* isomer of diethyl α-bromo-β-chlorosuccinate was obtained in a 66% yield (based on $SbCl_5$ used); bp 121—122 °C/6 mmHg. NMR: τ 5.30—5.40 (m, 2H), 5.72 (q, J=7.5 Hz, 4H), 8.69 (t, J=7.5 Hz, 6H).

Found: C, 33.09; H, 4.08; Br, 28.12; Cl, 12.47%. Calcd for $C_8H_{12}BrClO_4$: C, 33.42; H, 4.21; Br, 27.79; Cl, 12.33%.

In addition, when this ester (5.0 g, 17.4 mmol) was treated with Zn (10.0 g, 154 mmol) (a reagent for specific *trans*-dehalogenation) in boiling ethanol for 5 hr, only the original fumarate was formed as a product (70%).

In a similar way, the *threo* ester was obtained from diethyl maleate in a 52% yield; bp 123—124 °C/9 mmHg. NMR: τ 5.30 (s, 2H), 5.75 (q, J=7.5 Hz, 4H), 8.70 (t, J=7.5 Hz, 6H).

Found: C, 33.73; H, 4.28; Br, 27.54; Cl, 12.20%. Calcd for $C_8H_{12}BrClO_4$: C, 33.42; H, 4.21; Br, 27.79; Cl, 12.33%.

1-Chloro-1-phenyl-2-bromoethane. To a stirred solution

of $SbCl_3$ (11.4 g, 50 mmol) and Br_2 (8.0 g, 50 mmol) in CCl_4 (200 ml), styrene (10.4 g, 100 mmol) was added, drop by drop so that the temperature remained near 0 °C. After stirring had been continued for an additional 10 min, the reaction mixture was worked-up as before. Distillation afforded the chlorobromide (9.6 g, 43.7 mmol) in an 87% yield; bp 85—86 °C/2 mmHg (lit,[4] 95—99 °C/3.5 mmHg). The structure was confirmed by a comparison of its IR spectrum with that of an authentic sample prepared from styrene, *N*-bromoacetamide, and HCl.[4]

1,2-Dibromo-3-chloropropane (1) and 1,3-Dibromo-2-chloropropane (2). When allyl bromide (12.1 g, 100 mmol) was treated similarly with a CCl_4 solution (100 ml) containing $SbCl_3$ and Br_2 at the refluxing temperature, a mixture of two isomeric dibromomonochloropropanes (**1** and **2**) was obtained in an 83% yield; bp 94—97 °C/26 mmHg. IR: 725 (s), 650 (m), 627 (m), 610 (m), 568 cm^{-1} (s). The ratio of **1** and **2** was determined by comparisons of the IR spectrum with those of mixtures of a known composition; it was found to be *ca.* 7: 3. Here, an authentic sample of **1** was prepared from allyl chloride and bromine (bp 84.5—85 °C/18 mmHg [IR: 725 (s), 650 (m), 568 cm^{-1} (s)]), while the authentic sample of **2** was prepared by the chlorination of 1,3-dibromopropan-2-ol with PCl_5 (bp 84—85 °C/18 mmHg [IR: 722 (m), 623 (s), 609 (s), 568 cm^{-1} (m)]).

Some physical data on the other chlorobromide, which was a new compound are given below.

erythro-*1-Carboethoxy-1-bromo-2-chloro-2-phenylethane.* Bp 116—117 °C/11 mmHg. NMR: τ 2.63 (s, 5H), 4.22 (d, 1H), 5.38 (d, 1H), 5.67 (q, 2H), 8.66 (t, 3H).

Found: C, 45.61; H, 4.12; Br, 27.19; Cl, 12.06%. Calcd for $C_{11}H_{12}BrClO_2$: C, 45.31; H, 4.15; Br, 27.40; Cl, 12.16%.

trans-*1-Chloro-2-iodocyclohexane.* To a boiling CCl_4 solution (200 ml) containing $SbCl_5$ (7.5 g, 25 mmol) and I_2 (6.3 g, 25 mmol), cyclohexene (8.2 g, 100 mmol) was added gradually. After stirring had been continued for an additional 10 min, the reaction mixture was worked-up as before with water. The yield of the chloroiodide (11.5 g, 47.0 mmol) was 94%; bp 49—50 °C/1 mmHg (lit,[2a] 37 °C/0.2 mmHg).

Aromatic Bromination and Iodination with Mixtures of Antimony(V) Chloride and Halogens

Sakae UEMURA,* Akira ONOE, and Masaya OKANO
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611
(Received June 5, 1973)

Equimolar mixtures of $SbCl_5$ and Br_2 or I_2 were found to be elegant reagents for the halogenation of certain aromatic substrates. In carbon tetrachloride, halogenobenzenes afforded the corresponding bromo- and iodo-derivatives with high *para*-selectivities (more than 95%) in good yields. The bromination of aromatic compounds with deactivating groups, such as ethyl benzoate and nitrobenzene, was simply achieved in 1,2-dichloroethane. Based on competitive halogenation data, the attack of BrCl or ICl (both formed *in situ*) on aromatics has been suggested.

Though aromatic halogenation with elementary halogens has been thoroughly investigated from the synthetic and mechanistic points of view, little is known about the halogenation by means of mixed halogens. The synthetic usage of ICl[1] for aromatic iodination and that of IBr[2] or BrCl (*in situ*)[3] for bromination are discussed in the literature, but the given examples are limited to reactive substrates, such as phenols and aromatic amines. Recently, a new aromatic iodination using copper(II) chloride–iodide donor (*e.g.*, I_2, AlI_3, or $FeI_2 \cdot 4H_2O$) mixtures has been reported by Baird and Surridge,[4] though the formation of ICl as a potent iodinating agent as not definitely stated. In a previous paper,[5] we reported the mixed halogenation of olefins with ICl or BrCl formed *in situ* by the interaction of antimony(V) chloride and halogens. When this system was applied to aromatic substrates in carbon tetrachloride or 1,2-dichloroethane, aryl bromides and iodides were obtained in good yields even from less-reactive aromatics. The present paper will describe some characteristics of this reaction.

Results and Discussion

The treatment of aromatic compounds with equimolar mixtures of $SbCl_5$ and halogens (Br_2 or I_2) in chlorinated solvents afforded the corresponding aryl bromides and iodides with ease. Aromatic compounds bearing an activating group were readily brominated at 25 °C and iodinated at the refluxing temperature, both in carbon tetrachloride, with high yields. In the cases of less-reactive aromatic compounds (*e.g.*, ethyl benzoate and nitrobenzene), the use of a more polar solvent such as 1,2-dichloroethane was revealed to be preferable. In the bromination of acetophenone, three equivalents of $SbCl_5$ (to Br_2) were used, since the formation of a complex with ketone was expected, as in the case of $AlCl_3$ catalyst.[6] All the results are summarized in Table 1.

In these halogenations, more than one (nearly two) moles of aryl halides were generally formed from one mole of the halogenating agent; thus, the reaction appeared to occur in accord with the stoichiometry

$$2ArH + SbCl_5 + X_2 \longrightarrow 2ArX + SbCl_3 + 2HCl \quad (1)$$
$$(X = Br \text{ or } I)$$

shown by Eq. (1). Here, the net oxidation of X^- with $SbCl_5$ is involved, and the complete utilization of halogens is achieved. The $SbCl_5$–LiX mixture was also revealed to be effective as a halogenating agent, but the yields of halogenated compounds were somewhat unsatisfactory [see Runs 16, 17, and 26 in Table 1 and Eq. (2)].

$$ArH + SbCl_5 + LiX \longrightarrow ArX + SbCl_3 + LiCl + HCl \quad (2)$$

As can be seen in Table 1, two marked characteristics noteworthy from the synthetic point of view are found in our halogenation. First, this method may serve as a simple procedure for the bromination of aromatic compounds bearing an electron-withdrawing group. For example, nitrobenzene afforded *m*-bromonitrobenzene in a 63% yield by treating with an equimolar mixture of $SbCl_5$ and Br_2 in 1,2-dichloroethane at 84 °C for 3 hr; ethyl benzoate was similarly brominated (yield, 74%) or iodinated (48%) on refluxing for 3—5 hr in the same solvent. The halogenations of these compounds are usually carried out under drastic conditions; that is, high temperatures and/or stronger electrophilic catalysts are necessary [*e.g.*, for benzoic acid, its ester, and nitrobenzene, the Fe-catalysed bromination (above 140 °C)[7] and the Ag(I) salt-catalysed bromination[8] or iodination[9] (in concentrated HNO_3 or H_2SO_4)]. Further, in the bromination of acetophenone, our method made the preformation of the ketone-Lewis acid complex before bromine addition unnecessary (see Experimental section and compare with the procedure in Reference 6; in CCl_4, yield 86%). Though our iodinating system was found to be more efficient than the $CuCl_2$–iodide system[4] (*e.g.*, for benzene, 76 °C, 0.5 hr, in CCl_4 *vs.* 80 °C, 5 hr, neat), its reactivity did not appear to be high enough. For example, attempts to prepare *m*-iodonitrobenzene and *o*-, *p*-diiodobenzenes were unsuccessful (86 °C, in dichloroethane), and the unreacted aromatics were recovered.

Secondly, this halogenation may provide a convenient method for preparing *p*-dihalogenobenzenes with similar or dissimilar halogen atoms, since the *para*-selectivity of the reaction is quite high. In the bromination of chloro-, bromo-, and fluorobenzenes by a bromine molecule with a Fe- or $AlBr_3$-catalyst, the degree of *para*-substitution has been known to be in the 84—89% range,[10] except only for the Fe-catalysed reaction of fluorobenzene, in which a *para*-selectivity of 98% has been observed.[11] The iodination of

a) Isolated yield (based on halogen donor, *cf.* Eqs. 1 and 2).
b) Determined by glc before isolation.
c) Determined also by NMR.
d) No *m*-isomer was formed (confirmed by NMR).
e) No *o*- and *p*-isomers were formed (confirmed by glc).

chloro- and bromo-benzenes with CuI_2–AlI_3 showed *o*/*p* ratios of 18/82 and 0/100 respectively, and the yields were rather low (*ca.* 30%).[4] In contrast to this, the halogenation of halogenobenzenes with $SbCl_5$–X_2 in carbon tetrachloride, where the molar ratio of a halogenobenzene and the halogenating agent was 2:1, showed high selectivities in the *para*-attack (over 95% in bromination and over 98% in iodination). Moreover, the yields were generally good—nearly 85—90% in bromination and 70—75% in iodination. When excess amounts (more than 2 equivalents) of halobenzenes or anisole were used, a decrease in the *para*-selectivity was observed, while in the case of toluene no variation in selectivity was found. Thus, the preferred *para*-substitution might be the result of the coordination between the antimony salt and the hetero atom with lone pairs of electrons in aromatic substrates, which may depress an *ortho*-attack of the halogenating agent for steric reasons.

In order to obtain some information on the attacking species, the competitive halogenations of benzene and toluene were carried out under various conditions. Some data on the relative rate ratio (k_T/k_B) and on the isomer ratio (*o*/*p*) in the halotoluenes formed are shown in Table 2. The k_T/k_B and *o*/*p* ratios for iodination with $SbCl_5$–I_2 in CCl_4 were almost identical with

those for the $SbCl_5$-catalyzed iodination with ICl, while somewhat higher k_T/k_B values were obtained in the $SbCl_3$-catalyzed one. All these k_T/k_B values, however, are of the same order as the reported one (>140, in HOAc) for the $ZnCl_2$-catalyzed iodination with ICl,[12] and they differ greatly from that (2.0, in CH_3CN) for an electrochemical iodination involving the attack of I^+ species.[13] Besides, the obtained k_T/k_B value for the ICl iodination (without catalyst) was considerably higher than those for the catalyzed reactions. Thus, it may be suggested that the formation of ICl *in situ* and the attack of polarized ICl (activated by $SbCl_5$) rather than I^+ are involved in our iodination in CCl_4. As to BrCl, though its formation *in situ* is highly probable, as has been shown previously in the bromochloriantion of olefins using the same halogenating system, a direct confirmation as in the case of ICl was difficult because of the inaccessibility of BrCl in the pure state. In the bromination with $SbCl_5$–Br_2 in CCl_4, however, the observed k_T/k_B and *o*/*p* ratios were similar in magnitude to those (340 and 0.45, respectively) for the uncatalyzed bromination with Br_2 in aqueous HOAc, where the attack of molecular bromine is supposed.[14] On the other hand, when 1,2-dichloroethane was used as a solvent, quite a low k_T/k_B value and a high *o*/*p* ratio were obtained. These values are comparable to those (3.6 and 2.33, respectively) for the $FeCl_3$-catalyzed bromination in CH_3NO_2, where Br^+ is considered to be the attacking species.[15] Thus, the existence of two different attacking species derived from BrCl is feasible, in view of the solvent used; *i.e.*, the attack of polarized BrCl (activated by $SbCl_5$) and Br^+ (probably as an ion-pair). The following facts should be noted here. In the bromination of anisole, the exclusive *para*-substitution has been previously reported in a synthetic procedure (Br_2 bromination in AcOH without catalyst);[16] we confirmed this by glc analysis. On the other hand, our bromination products were contaminated by the *o*-isomer. This can be explained by a higher reactivity of BrCl compared to that of the Br_2 species. In contrast to this, the iodination product was free from the *o*-isomer, as is anticipated from the mild reactivity of ICl.

Experimental

The NMR spectra were determined by means of a Varian A-60 spectrometer in $CDCl_3$, using TMS as the internal standard. Glc analysis was carried out on a Shimadzu 5APTF apparatus, using PEG 6000 (25%)-Chromosorb W (3m) and Apiezon L(30%)-Celite (1m) columns.

Materials. All the organic substrates, including the solvents, were used after distillation, while commercial $SbCl_5$, LiBr, LiI, Br_2, I_2, and ICl of the best grade were used without further purification.

Aromatic Halogenation with $SbCl_5$–Halogen Mixtures. Several examples are given below; they should be synthetically useful.

(a) p-*Dibromobenzene.* To a homogeneous solution of $SbCl_5$ (7.5 g, 25 mmol) and Br_2 (4.0 g, 25 mmol) in CCl_4 (100 ml), bromobenzene (7.9 g, 50 mmol) was added, drop by drop, at 78 °C. Stirring was continued for 30 min. The reaction was accompanied by a considerable evolution of HCl gas, and the dark-red color of the solution disappeared. The reaction mixture was then cooled and treated with water. The inorganic precipitate thus formed was removed by filtration. The organic layer was separated from the aqueous one, and the solvent and unreacted bromobenzene were evaporated. A liquid fraction corresponding to isomeric dibromobenzenes (bp 102—103 °C/22 mmHg) was collected by distillation. The yield was 86% (10.2 g, 43.2 mmol). By a comparison of the retention times on glc with those of authentic samples, the *o*/*p* ratio was found to be 5/95. A single recrystallization from ethanol afforded the pure *p*-isomer; mp 88 °C (lit,[17] 87.3 °C).

(b) m-*Bromoacetophenone.* Acetophenone (6.0 g, 50 mmol) was added to a stirred mixture of $SbCl_5$ (22.5 g, 75 mmol) and Br_2 (4.0 g, 25 mmol) in CCl_4 (100 ml) at 35 °C. After 30 min, the reaction mixture was worked up as has been described above. Subsequent distillation afforded the product (8.6 g, 43.2 mmol) in an 86% yield; bp 92.5—93 °C/4 mmHg (lit,[6] 75—76 °C/0.5 mmHg). NMR: τ 1.98 (m, 4H), 7.49 (s, 3H).

(c) m-*Bromonitrobenzene.* A stirred mixture of $SbCl_5$ (7.5 g, 25 mmol), Br_2 (4.0 g, 25 mmol), and nitrobenzene (12.3 g, 100 mmol) in 1,2-dichloroethane (100 ml) was heated at 84 °C for 3 hr. After the usual work-up procedure, the product was obtained in a 63% yield (6.5 g, 31.6 mmol); bp 136—136.5 °C/22 mmHg (lit,[7b] 117—118 °C/9 mmHg). The absence of the *o*- and *p*-isomers was confirmed by glc analysis.

(d) *Iodobenzene.* To a mixture of $SbCl_5$ (7.5 g, 25 mmol) and I_2 (6.3 g, 25 mmol) in CCl_4 (100 ml), benzene (3.9 g, 50 mmol) was added in small portions at 76 °C. Stirring was then continued for 30 min, after which the reaction mixture was worked-up as before. Distillation afforded iodobenzene in an 84% yield (8.6 g, 42.1 mmol); bp 80—80.5 °C/22 mmHg (lit,[18] 69 °C/15 mmHg).

(e) p-*Bromoiodobenzene.* The procedure was the same as that described for benzene except that the aromatic substrate was used in excess. From bromobenzene (15.7 g, 100 mmol), the corresponding *p*-iodo derivative was obtained in a 73% yield (10.4 g, 36.8 mmol); bp 118.5—119 °C/14 mmHg; mp 92 °C (lit,[19] 92 °C). In addition, glc analysis revealed that no other isomers were formed in this reaction.

(f) *Ethyl* p-*Iodobenzoate.* When ethyl benzoate (15.0 g, 100 mmol) was treated similarly with a 1,2-dichloroethane solution (100 ml) containing $SbCl_5$ and I_2 at the refluxing temperature for 3 hr, the product (5.9 g, 24.1 mmol) was isolated in a 48% yield; bp 93—94 °C/1.5 mmHg (lit,[20] 153.5 °C/14 mmHg).

Competitive Halogenations of Benzene and Toluene. The competitive iodination was carried out as follows; a mixture of benzene (250 mmol) and toluene (50 mmol) was added, drop by drop, to a stirred CCl_4 solution (100 ml) containing $SbCl_5$ (12.5 mmol) and I_2 (12.5 mmol) at 76 °C; the resulting mixture was kept for 30 min at that temperature under stirring. On the other hand, an inverse addition was adopted in the competitive bromination because of its rapid reaction; *i.e.*, a CCl_4 solution (30 ml) of $SbCl_5$ and Br_2 was slowly stirred into a mixture of benzene (250 mmol) and toluene (50 mmol) in CCl_4 (70 ml) at 25 °C, after which the solution was allowed to stand for another 5 min. Both reaction mixtures were then worked up as usual. In both cases, the amounts of halobenzene and isomeric halotoluenes were determined by glc and the *o*/*p* ratio was determined by NMR spectra (the methyl protons of *o*- and *p*-iodotoluene were observed at τ 7.60 and 7.70 respectively, and those of *o*- and *p*-bromotoluene at τ 7.62 and 7.73 respectively).

Studies of Unusual Amino Acids and Their Peptides.[1] V. The Synthesis and the Absolute Configuration of β-(2-Thiazolyl)-β-alanine Present in Bottromycin

Yasuhiko SETO, Kazuhira TORII, Kōichi BORI,* Kenichiro INABATA,**
Shigeru KUWATA, and Hiroshi WATANABE

Laboratory of Chemistry, Faculty of Science, Kōnan University, Okamoto, Higashinada, Kobe 658

(Received June 11, 1973)

In order to obtain an optically-active β-(2-thiazolyl)-β-alanine, *N*-acyl-L-aspartic α-thionamide-β-methyl ester was condensed with diethyl bromoacetal, but the amino acid thus obtained showed no perceptible optical activity. The racemic amino acid, however, could be resolved into its antipodes by treating its phthalyl derivative with brucine. Thus, the (+)-amino acid, a constituent of bottromycin, was isolated in a pure state; it was determined to belong to the L-series by examining its optical behavior. This amino acid was proved to racemize easily under the conditions of the acid hydrolysis of bottromycin.

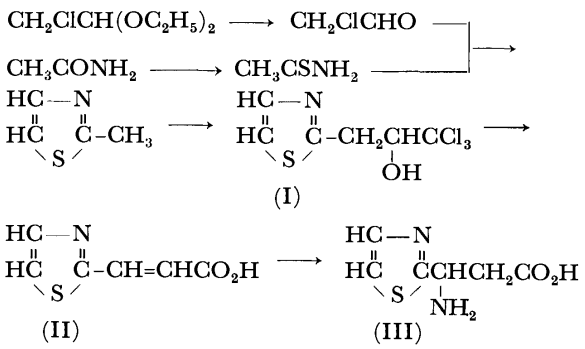
Bottromycin is a peptidic antibiotic first obtained by Waisvisz and his co-workers[2] from the fermentation broths of *Streptomyces bottropensis*. The chemical structure of this antibiotic was partly determined by the same authors,[3] and later the formula shown in Fig. 1 was proposed by Umezawa and his school.[4]

It differs from other peptidic antibiotics in several respects. In the first place, it is a linear oligopeptide ester, unlike usual peptidic antibiotics such as gramicidin S, tyrocidine or polymixin, which are cyclic oligopeptides containing D-amino acids. Secondly, it contains too many unusual amino acids. Bottromycin A, for instance, contains a total of 6 amino acids, 4 of which are unusual. Thirdly, it contains an iminopeptide bond in the middle of the molecule.

Interest in these differences, especially the relationship between these characteristics and its biological activities,[5] led us to make a synthetic study of this antibiotic.

In the proposed formula, the absolute configurations of the carboxyl-terminal two amino acids had been left undetermined. One of them, β-methylphenylalanine, was recently determined by Arold[6] to belong to the *erythro*-L-series. The other and last amino acid, β-(2-thiazolyl)-β-alanine, has had ambiguities from the beginning: by hydrolyzing the antibiotic with concentrated hydrochloric acid, Waisvisz[3] obtained a sample of this amino acid showing no optical activity. On the other hand, Umezawa and others[7] obtained an optically-active amino acid $[\alpha]_D^{18}$ +9° (*c* 1, water), by hydrolyzing the product produced by treating the antibiotic with acetic anhydride.

As the first step in our work concerning the study of bottromycin, we prepared β-(2-thiazolyl)-β-alanine and resolved it into two antipodes. The racemic form of this amino acid has already been synthesized by Waisvisz; here the same scheme was used. Though an effort was made to improve the yield, and though in effect the step giving (II) from (I) was improved



Scheme 1. The scheme of the synthesis of β-(2-thiazolyl)-β-alanine by the method of Waisvisz.

pretty well, on the whole there were too many steps and the overall yield was far from satisfactory. It should be mentioned that, in this series of experiments, we found a noticeable fact. Though the amination of β-(2-thiazolyl)-acrylic acid with hydroxylamine proceeded, the yield (30%) was so poor that in an experiment the hydroxylamine was replaced with ammonia. The yield of the addition product was remarkably enhanced, but it consisted cheifly of α-amino acid (yield, 70%); the desired β-amino acid was obtained only in a trace.

In order to resolve the racemate obtained here,

Z=benzyloxycarbonyl, Bz=benzoyl, Pht=phthalyl, and Tos=tosyl. +, crystalline salt; ±, amorphous solid; −, no precipitate

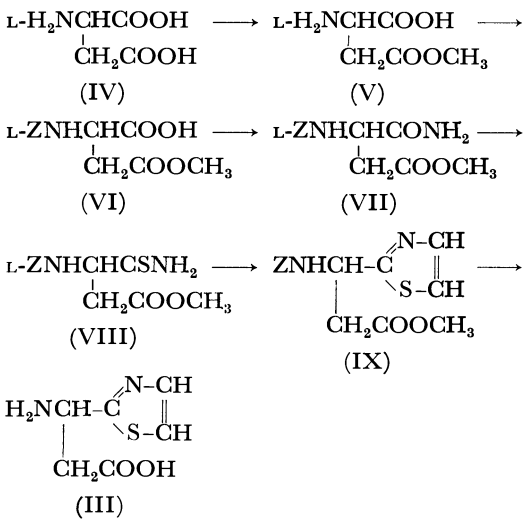
benzoyl, tosyl, benzyloxycarbonyl, and phthalyl derivatives were prepared and treated with quinine, brucine, and ephedrine in various solvents; the results are shown in Table 1. As may be seen there, the brucine salt of the phthalyl derivative was proved to be useful for the resolution when fractionally crystallized from a mixture of chloroform and acetone. By this treatment, a less soluble salt, $[\alpha]_D^{25}$ +10.6° (*c* 1, chloroform), and an easily soluble one, $[\alpha]_D^{25}$ −39° (*c* 1, chloroform), were obtained; from the former, the free acid of $[\alpha]_D^{25}$ +33.4° (*c* 1, methanol) was liberated and from the latter, that of $[\alpha]_D^{25}$ −35.4° (*c* 1, methanol). The hydrazinolysis of the (+)-phthalyl amino acid gave β-(2-thiazolyl)-β-alanine with $[\alpha]_D^{17}$ +22.4° (*c* 1, water).

The value of $[\alpha]_D$ of the amino acid isolated here is markedly larger than the one reported by Umezawa and his co-workers,[7] though the signs themselves are equal. This amino acid showed no detectable change in its optical activity when it was left to stand in 6 M hydrochloric acid at room temperature, but after the solution had been heated to reflux for 8 hr no activity was detected. This fact suggests that the optically-inactive β-(2-thiazolyl)-β-alanine obtained by Waisvisz[3] by a prolonged hydrolysis of bottromycin and the amino acid of $[\alpha]_D^{18}$ +9° obtained by Umezawa by a milder treatment from the same source were entirely or partly racemized products.

The susceptibility of this amino acid to racemization is also retained in its derivatives, *i.e.*, the *N*-phthalyl amino acid and its methyl ester, both of which lost their optical activity upon being heated with 6 M hydrochloric acid more easily than the amino acid itself, though no change was observed when they were treated with a sodium bicarbonate solution, when they were passed through a silica gel column, when the amino acid was allowed to stand in 0.1 M sodium hydroxide for 12 days, or when it was refluxed with a large excess of hydrazine hydrate in methanol. That other amino acids containing a thiazole nucleus, found in some antibiotics, also show the same tendency to racemize upon acid treatment has been described in some reports.[8]

Trying to determine the absolute configuration of the optically-active amino acids separated here, we attempted to prepare one of them starting from L-aspartic acid according to Scheme 2.

β-Methyl aspartate was prepared from L-aspartic acid by the thionyl chloride method and was then



Scheme 2. The scheme of a synthesis of β-(2-thiazolyl)-β-alanine from aspartic acid (a-series). In b-series phthalyl group was used as an amino protecting group in place of benzyloxycarbonyl group (Z).

derived to the benzyloxycarbonyl or phthalyl derivative in the usual way. The amides of these *N*-protected L-aspartic acid β-methyl esters were prepared by the mixed acid anhydride method. The thionamide (VIII) was obtained from the amide (VII) in a good yield of 70—80% by only stirring the amide with phosphorus pentasulfide in dioxane at room temperature. This simple method was also applicable to other *N*-protected amino acid amides, *e.g.*, the amides of benzyloxycarbonylated glycine and L-phenylalanine.

The thionamides thus obtained from the aspartic acid derivatives were proved unstable when they were in contact with silica gel. When these compounds were chromatographed on a thin-layer of Merck silica gel G (ethyl acetate–cyclohexane (1:1)), the sample gave two spots; a major one with a low R_f value, which was identical with that of the desired compound, and a minor one with a high R_f value, which was the same as that of the compound obtained as a by-product in the course of the preparation of the thionamide. The amount of the latter compound increased with the lapse of time after the spotting of the sample. With the benzyloxycarbonyl derivative, after 2 hr, while with the phthalyl derivative, after 15 min, the two spots of the low and high R_f values occupied about the same area; the spot of the low R_f value of the phthalyl derivative disappeared after 2 hr. It is apparent that the compound responsible for the spot of the high R_f value is identical with the by-product of thionamide-synthesis mentioned above, because both the isolated compounds showed no depression of the melting point when mixed. We may conclude that this compound is phthalylamino thionsuccinimide produced by the intramolecular condensation of the thionamide (VIII-b).

Thiazole-ring formation was performed by condensing the thionamide (VIII) with bromoacetaldehyde or, more conveniently, though in a somewhat lower yield, with bromoacetal.

The *N*-phthalyl derivative of β-(2-thiazolyl)-β-alanine methyl ester (IX-b) thus obtained unexpectedly showed

a melting point of 113—115 °C, identical with that of the racemic methyl ester, but quite different from that of the optically-active one (mp 100 °C). The corresponding *N*-benzyloxycarbonyl acid was also identical with the racemic one in melting point, IR spectrum, and thin-layer chromatogram. The optical activities of both the *N*-phthalyl (IX-b) and *N*-benzyloxycarbonyl esters (IX-a) were so obscure that it was difficult to deduce any conclusion concerning their configurations. On the other hand, the methyl ester obtained from the optically-active *N*-phthalyl amino acid by treating it with diazomethane was apparently optically active. From these facts, we could not but conclude that, during the step of cyclization ((VIII)→(IX)), a substantial racemization did occur.

We could not attain the initial aim of determining the absolute configuration of β-(2-thiazolyl)-β-alanine by synthesis, but the synthetic route itself is valuable for a larger scale preparation of this amino acid because the steps are fewer and the total yield is better than those in Waisvisz's method.

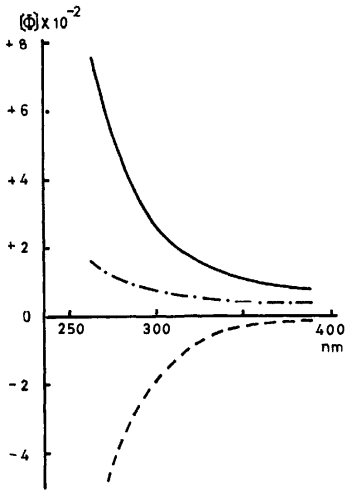


Fig. 2. Optical rotatory dispersion curves of (+)-β-(2-thiazolyl)-β-alanine; *c* 0.377, water, 26 °C.
——: neutral, —•—: acidic, ----: alkaline.

In order to determine the absolute configuration of this β-amino acid, we studied the optical properties of some optically-active β-amino acids, which have been reported previously.[9] When the optical rotatory dispersion (ORD) of (+)-β-(2-thiazolyl)-β-alanine was measured in acidic, neutral, and alkaline media, the value of the optical rotatory power decreased in the order of; neutral>acidic>alkaline (Fig. 2). This suggests that the amino acid belongs to the L-series.[9] The fact that the *N*-dithiocarbamate of this amino acid shows a negative Cotton effect in methanol, especially markedly in the presence of triethylamine, may also support this deduction.[9] Further evidence may be supplied by a comparison of the optical behavior of this amino acid derivative with that of the corresponding one of β-phenyl-β-alanine. (+)-β-(2-Thiazolyl)-β-alanine and L-β-phenyl-β-alanine gave positive ORD curves in water; the *N*-phthalyl derivatives of both the amino acids also gave positive Cotton effects in methanol. According to Freudenberg,[10] this means that both the amino acids have the same configuration. For these reasons, we conclude that the β-(2-thiazolyl)-β-alanine present in bottromycin belongs to the L-series.

Experimental[11]

2-(3',3',3'-Trichloro-2'-hydroxypropyl)-thiazole (I). (I) was synthesized from 2-methylthiazole and chloral; yield, 30%; mp 124—127 °C, lit,[12] mp 126—128 °C.

β-(2-Thiazolyl)-acrylic Acid (II). (II) was obtained by hydrolyzing 43 g of (I) with 87.5 g of potassium hydroxide in 500 ml of methanol at 40 °C for 1 hr and then at 70 °C for 30 min; yield, 26 g (64%); mp 184.5—185.5 °C, lit,[12] mp 187—190 °C.

DL-β-(2-Thiazolyl)-β-alanine (DL-III). This compound was obtained from (II) and hydroxylamine according to the method of Waisvisz; mp 198—199 °C, lit,[3] mp 199—202 °C. Circular paper chromatographies; R_f 0.30 (Solvent A) and 0.29 (Solvent B).

Acyl Derivatives of (DL-III). The following acyl derivatives were prepared by the usual method.

Phthalyl Derivative: Obtained by melting (DL-III) with phthalic anhydride at 150 °C for 40 min; yield, 75%; mp 161—162 °C.

Found: C, 55.58; H, 3.33; N, 9.21%. Calcd for $C_{14}H_{10}N_2O_4S$: C, 55.62; H, 3.33; N, 9.27%.

Benzyloxycarbonyl Derivative: Yield, 63%; mp 122.5—123.5 °C.

Found: C, 55.02; H, 4.56; N, 9.07%. Calcd for $C_{14}H_{14}N_2O_4S$: C, 54.89; H, 4.61; N, 9.14%.

Benzoyl Derivative: Yield, 50%; mp 169—170.5 °C.

Found: C, 56.32; H, 4.42; N, 10.10%. Calcd for $C_{13}H_{12}N_2O_3S$: C, 56.51; H, 4.38; N, 10.14%.

Tosyl Derivative: Yield, 36%; mp 164—165 °C.

Found: C, 47.84; H, 4.16; N, 8.62%. Calcd for $C_{13}H_{14}N_2O_4S_2$: C, 47.84; H, 4.32; N, 8.58%.

An Optical Resolution of DL-Phthalyl-β-(2-thiazolyl)-β-alanine. To a solution of 10.7 g of DL-phthalyl-β-(2-thiazolyl)-β-alanine and 14.0 g of brucine in 100 ml of chloroform, we added 100 ml of acetone; after the mixture had been allowed to stand at room temperature overnight, the separated crystals were collected; yield, 5.4 g; $[\alpha]_D^{22}$ −3.2° (*c* 1, chloroform). After repeated recrystallizations from chloroform–acetone, the optical rotation settled upon $[\alpha]_D^{22}$ +10.6° (*c* 1, chloroform); yield, 4 g. From the mother liquor, the more soluble salt of $[\alpha]_D^{22}$ −39° (*c* 1, chloroform) was obtained; yield, 7 g.

To remove the brucine, the salt was dissolved in hot water; the solution was ice-cooled quickly and then after a small excess of aqueous sodium hydroxide had been added, the freed base was extracted with chloroform. The aqueous layer was acidified to pH 2 with 6 M hydrochloric acid and then concentrated. After ice-cooling, the separated phthalyl derivative was collected. No change in the optical rotation was observed after recrystallization from methanol–water. The properties of the phthalyl-β-(2-thiazolyl)-β-alanine thus obtained were as follows:

From the less soluble brucine salt; $[\alpha]_D^{22}$ +33.4° (*c* 1, methanol), mp 138—140 °C (solidified immediately and melted again at 162—163 °C).

From the easily soluble brucine salt; $[\alpha]_D^{22}$ −35.4° (*c* 1, methanol); the melting point is completely identical with that of the above sample.

Phthalyl-(+)-β-(2-thiazolyl)-β-alanine Methyl Ester. This compound was obtained from the phthalyl-(+)-acid by treating it with diazomethane. Recrystallization from methanol–water gave a sample with a mp of 99—100 °C, $[\alpha]_D^{15}$

+23.5° (*c* 1.065, methanol).

(+)-β-(2-Thiazolyl)-β-alanine. ((+)-III). To a solution of the phthalyl derivative with $[\alpha]_D^{22}$ +33.4° in a small amount of methanol, we added 3 equivalents of hydrazine hydrate and then heated the mixture to reflux for 30 min. After the solvent had been distilled off, the residue was dissolved in water, acidified with acetic acid, and refluxed for 1 hr. The ice-cooled mixture was filtered, the filtrate was evaporated to dryness, and the remaining hydrazine hydrate was thoroughly removed under a high vacuum. By recrystallizing the residue from alcohol, (+)-β-(2-thiazolyl)-β-alanine was obtained as crystals; yield, 55%, mp 203.5—204.5 °C, $[\alpha]_D^{17}$ +22.4° (*c* 1, water). Further recrystallization from water–ethanol had no influence on the value of the specific rotatory power. Circular paper chromatographies; R_f 0.30 (Solvent A) and 0.29 (Solvent B).

Found: C, 41.62; H, 4.69; N, 16.26%. Calcd for $C_6H_8N_2O_2S$: C, 41.85; H, 4.68; N, 16.27%.

Lit,[7] mp 200—201 °C, $[\alpha]_D^{18}$ +9° (*c* 1, water).

((+)-III) in 6 M hydrochloric acid showed no perceptible change in optical rotation in the range of 270—700 nm after 24 hr at room temperature, but after 50 hr a little change was observed. When the solution was refluxed, however, for 1, 2.5, and 8 hr, the optical activity decreased to about 50%, less than 10%, and 0% respectively.

Addition of Ammonia to β-(2-Thiazolyl)-acrylic Acid (II). A solution of 1 g of (II) in 7 ml of 25% aqueous ammonia was heated in a sealed tube at 90 °C for 1 hr and then at 120 °C for a further 40 hr. After the reaction mixture had been treated with charcoal, it was evaporated to dryness and the residue was washed with ethanol. The yield of the crude product (mp 180—184 °C) was 0.79 g (70%). This product consisted of two components, because it gave two ninhydrin positive spots on circular paper chromatography. The major one was brown (R_f 0.26 (Solvent A) and 0.33 (Solvent B)), and the minor one, faint purple (R_f 0.30 (Solvent A) and 0.29 (Solvent B)). The latter was confirmed to be β-(2-thiazolyl)-β-alanine by comparing it with the authentic sample. By recrystallizing the crude product from methanol–water, the major component was obtained in a chromatographically pure state in a good yield, and it coincided with β-(2-thiazolyl)-α-alanine in all respects: mp 202—202.5 °C. Reported value for β-(2-thiazolyl)-α-alanine,[12] mp 197—198 °C. 2,4-Dinitrophenyl derivative, mp 209—210 °C. Lit,[3] mp 203—210 °C. Phthalyl derivative, mp 188.5—189 °C.

Found: C, 55.87; H, 3.42; N, 9.25%. Calcd for $C_{14}H_{10}N_2O_4S$: C, 55.62; H, 3.33; N, 9.27%.

L-Aspartic Acid β-Methyl Ester Hydrochloride (V). This compound was prepared by the method of Brenner;[13] yield, 97%, mp 186—187 °C, $[\alpha]_D^{19}$ +14.4° (*c* 1, ethanol–water (1:3)). Lit,[14] mp 199—200 °C, $[\alpha]_D^{25}$ +14.4° (*c* 1, ethanol–water (1:3)).

Benzyloxycarbonyl-L-aspartic Acid β-Methyl Ester (VI-a). This compound was prepared from (V) and benzyloxycarbonylchloride by the usual method; yield, 82%, mp 91—92 °C, $[\alpha]_D^{26}$ −18.2° (*c* 2.5, pyridine). Lit,[15] mp 97—98 °C, $[\alpha]_D^{25}$ −18.5° (*c* 2.5, pyridine). This product was used for the next reaction without further purification.

Benzyloxycarbonyl-L-aspartic Acid β-Methyl Ester α-Amide (VII-a). To a cold solution of 7.88 g of (VI-a) and 2.83 g of triethylamine in 60 ml of tetrahydrofuran, we added 3.05 g of ethyl chloroformate with ice-cooling over a 7 min period. After stirring for 20 min at −8 °C, 4.20 g (2.5 equivalents) of 28% aqueous ammonia were added; the stirring was continued at −4 °C for a further 40 min and then at room temperature overnight. The mixture was subsequently evaporated under reduced pressure, and the residue was dissolved in ethyl acetate. The extract was washed with water, dried with anhydrous sodium sulfate, and evaporated to yield needle crystals; yield, 5.16 g (66%); mp 118.5—120 °C. After recrystallization from benzene, mp 120—121 °C, $[\alpha]_D^{28}$ +5.3° (*c* 1, acetic acid). ORD; $[\phi]_{270}$ −560°, $[\phi]_{299}$ −280°, $[\phi]_{552}$ 0°, $[\phi]_{650}$ +15° (*c* 2, methanol). Lit,[16] mp 121 °C, $[\alpha]_D^{20}$ +9.0° (acetic acid).

Benzyloxycarbonyl-L-aspartic Acid β-Methyl Ester α-Thionamide (VIII-a). To a solution of 2 g of the amide (VII-a) in 10 ml of dry dioxane, we added 1.74 g of finely powdered phosphorus pentasulfide; stirring was continued for 8 hr at room temperature until the mixture became almost homogeneous. A little residual phosphorus pentasulfide was filtered off, and the filtrate was vigorously stirred into 100 ml of ice-water. The separated pale yellow oil was extracted with ether, and the ether extract was washed with water, dried with anhydrous sodium sulfate, and evaporated to the crude thionamide; yield, 1.81 g (86%); mp 67—87 °C. Recrystallization from tetrahydrofuran–petroleum ether gave crystals, mp 78.5—79.5 °C, $[\alpha]_D^{28}$ −22° (*c* 1, methanol). ORD; $[\phi]_{364}$ −680°, $[\phi]_{378}$ −950°, $[\phi]_{410}$ −470°, $[\phi]_{650}$ −44° (*c* 1, ethanol).

Found: C, 52.97; H, 5.45; N, 9.45%. Calcd for $C_{13}H_{16}N_2O_4S$: C, 52.69; H, 5.44; N, 9.45%.

From the mother liquor of the recrystallization we obtained fine long needles (mp 87—88 °C) which gave a spot with the same R_f value as the thionamide in thin-layer chromatography, but no details were investigated.

Thionamides of Benzyloxycarbonyl-glycine and -L-Phenylalanine. By the same method, both the thionamides were also prepared in good yields.

Benzyloxycarbonyl-glycine Thionamide: mp 146.5—148 °C.

Found: C, 54.18; H, 5.43; N, 12.49%. Calcd for $C_{10}H_{12}N_2O_2S$: C, 53.55; H, 5.39; N, 12.49%.

Benzyloxycarbonyl-L-phenylalanine Thionamide: mp 145—145.5 °C, $[\alpha]_D^{17}$ +13.0° (*c* 0.766, methanol).

Found: C, 64.95; H, 5.97; N, 8.87%. Calcd for $C_{17}H_{18}N_2O_2S$: C, 64.94; H, 5.77; N, 8.91%.

Benzyloxycarbonyl-β-(2-thiazolyl)-β-alanine Methyl Ester (IX-a). A mixture of 20.8 g of (VIII-a) and 80.5 g of diethyl bromoacetal in a vessel equipped with a condenser was kept at 60—65 °C in a water bath under reduced pressure (35 mmHg) for 1.5 hr with occasional shaking. After 20 min, the pale yellow solution began to separate into two layers. The upper layer, consisting of an excess of acetal, was decanted off, after which the orange-coloured lower oil was washed several times with ethyl acetate. After being made alkaline with aqueous sodium bicarbonate, the oil was extracted with ethyl acetate, and the extract was washed with water, dried with anhydrous sodium sulfate, and evaporated to dryness. The yield of the crude ester (mp 62—67 °C (sinter from 59 °C)) was 17.4 g (77%). After recrystallization from ethyl acetate–petroleum ether, the ester melted at 70.5—71.5 °C.

Found: C, 56.20; H, 5.10; N, 8.60%. Calcd for $C_{15}H_{16}N_2O_4S$: C, 56.24; H, 5.03; N, 8.74%.

Benzyloxycarbonyl-β-(2-thiazolyl)-β-alanine (X). This compound was obtained by hydrolyzing the ester (IX-a) with 6 M hydrochloric acid at 70 °C for 1 hr; mp 122—123.5 °C, $[\phi]_{280-700}$ 0° (*c* 2, ethanol). The thin-layer chromatograms, melting points (including mixed melting point), and IR spectrum of this compound were identical with those of the authentic sample prepared according to the Waisvisz method.

Phthalyl-L-aspartic Acid β-Methyl Ester (VI-b). This compound was prepared from (V) using the Nefkens reagent;[17] yield, 80%; mp 130—134 °C. After recrystalliza-

tion from benzene, mp 133.5—134.5 °C, $[\alpha]_D^{16}$ −75.8° (*c* 1, methanol).

Found: C, 56.32; H, 4.04; N, 5.00%. Calcd for $C_{13}H_{11}NO_6$: C, 56.32; H, 4.00; N, 5.05%.

Phthalyl-L-aspartic Acid β-Methyl Ester α-Amide (VII-b). Into a cold solution of 15 g of (VI-b) and 5.4 g of triethylamine in 75 ml of tetrahydrofuran, we vigorously stirred 5.90 g of ethyl chloroformate at −10 °C for 7 min. After additional stirring for 10 min at −10 °C, 5 g (1.5 equivalents) of 28% aqueous ammonia were added; the stirring was then continued at 0 °C for 2 hr and at room temperature for 3 hr. The reaction mixture was evaporated, and the residue was washed with water to give the crude amide; mp 163—166 °C. Recrystallization from ethanol gave 11.5 g (77%) of the amide; mp 167—168 °C. $[\alpha]_D^{19}$ −81° (*c* 1, dimethylformamide). ORD; $[\phi]_{326}$ −2150°, $[\phi]_{330}$ −2430°, $[\phi]_{350}$ −1200°, $[\phi]_{650}$ −80° (*c* 1, dimethylformamide).

Found: C, 56.56; H, 4.50; N, 10.05%. Calcd for $C_{13}H_{12}N_2O_5$: C, 56.52; H, 4.38; N, 10.14%.

In this reaction a small amount of a crystalline by-product was obtained from the mother liquor. After recrystallization from methanol, it melted at 227—228 °C and yielded aspartic acid upon hydrolysis. From this fact and the elemental analysis of this product, the by-product may be concluded to be the phthalylamino succinimide derived from (VII-b) by the removal of the methanol.

Found: C, 58.79; H, 3.34; N, 11.48%. Calcd for $C_{12}H_8N_2O_4$: C, 59.02; H, 3.30; N, 11.47%.

Phthalyl-L-aspartic Acid β-Methyl Ester α-Thionamide (VIII-b). To a solution of 162 g of the amide (VII-b) in 800 ml of dry dioxane, we added 162 g of finely powdered phosphorus pentasulfide. The mixture was stirred at room temperature for 9 hr. Any insoluble material was filtered off, and the residue was washed with dioxane. The combined filtrate and washings were concentrated to about 1/3 in volume and vigorously stirred into ice water. The oil thus separated, which soon solidified, was isolated by filtration, washed with water, dried over calcium chloride under a vacuum, and recrystallized from methanol; yield, 120 g (70%); mp 158—159.5 °C. Prisms (colourless, but once coloured it is difficult to remove the colour). Analytical sample; mp 163.5—164.5 °C, $[\alpha]_D^{17}$ −6.5° (*c* 1, tetrahydrofuran). ORD; $[\phi]_{358}$ −230°, $[\phi]_{383}$ −550°, $[\phi]_{409}$ −260°, $[\phi]_{650}$ −9° (*c* 1, tetrahydrofuran).

Found: C, 53.79; H, 4.19; N, 9.37%. Calcd for $C_{13}H_{12}N_2O_4S$: C, 53.42; H, 4.14; N, 9.58%.

From the mother liquor, a small amount of crystals was isolated as a by-product. It melted at 220—223 °C after recrystallization from methanol. This compound was found to be produced by treating the thionamide (VIII-b) with Merck silica gel G, *e.g.*, by passing the thionamide through the silica gel column. The identity of the two compounds obtained by the two different methods was proved by a comparison of their melting points, IR spectra, and analytical data; from this identity we conclude that the compound is 2-phthalylamino-L-thionsuccinimide. This compound showed a characteristic Cotton effect with a peak at 426 nm and a trough at 382 nm. ORD; $[\phi]_{360}$ −2500°, $[\phi]_{382}$ −2900°, $[\phi]_{406}$ −1500°, $[\phi]_{426}$ −150°, $[\phi]_{470}$ −360°, $[\phi]_{650}$ −100° (*c* 0.5, tetrahydrofuran).

Found: C, 55.06; H, 3.01; N, 10.79%. Calcd for $C_{12}H_8N_2O_3S$: C, 55.38; H, 3.10; N, 10.76%.

Phthalyl-β-(2-thiazolyl)-β-alanine. A solution of 8.9 g of thionamide (VIII-b) and 8.9 g of diethyl bromoacetal in 8 ml of tetrahydrofuran was heated to reflux over a 7 hr period. After the reaction mixture had then been evaporated, the residual oil was washed with petroleum ether to remove the excess of acetal, made alkaline with aqueous sodium bicarbonate, and extracted with ethyl acetate. The extract was washed with water, dried with anhydrous sodium sulfate, and evaporated to the crude ester (IX-b); yield, 7.4 g (77%); mp 106—110 °C. After recrystallization from methanol, the ester melted at 115 °C.

By the hydrolysis of this ester with 6 M hydrochloric acid at 60 °C for 2.5 hr, phthalyl-β-(2-thiazolyl)-β-alanine was obtained; mp 160—161.5 °C. No optical activity was detected in the range of 380—700 nm. A mixed melting point determination with the phthalyl derivative obtained from (DL-III) showed no depression, and the IR spectra of the two compounds were completely identical.

Kinetics of the Oxidation of Acrolein Initiated by Di-*t*-butyl Diperoxyoxalate

Takao HARA, Yasukazu OHKATSU,* and Tetsuo OSA*

Department of Chemistry, Faculty of Engineering, Yokohama National University, Ohoka, Minami-ku, Yokohama 233

**Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113*

(Received June 14, 1973)

The kinetics of the liquid-phase autoxidation of acrolein were studied using di-*t*-butyl diperoxyoxalate as an initiator. The ratios of the rate constants for the propagation *vs* the termination steps ($k_3k_6^{-1/2}$ and $k_2k_4^{-1/2}$) in the autoxidation mechanism were determined from the empirical rate equation thus obtained. The lower reactivity of acrolein was explained by comparing the ratios with those of saturated aldehydes.

There are only a few articles relating to the liquid-phase oxidation of α,β-unsaturated aldehydes to the corresponding carboxylic acids.[1-5] They refer mainly to the selective formation of the carboxylic acids and do not emphasize the kinetics and mechanisms. The absolute rate constants in the elementary steps of the oxidation or the ratio of the rate constants for the propagation *vs.* the termination steps have not yet been determined. In a series of studies of the liquid-phase oxidation of acrolein, we have mainly clarified the action of the metal-salt catalysts.[6-11]

In this paper, the kinetics of the autoxidation of acrolein initiated by a peroxy ester were studied. It is well known that di-*t*-butyl diperoxyoxalate (DBPO) is decomposed at room temperature in benzene or cumene to yield carbon dioxide and *t*-butoxy radicals.[12] It can be used as a radical initiator to be decomposed quantitatively in the liquid-phase oxidation. The ratios of the rate constants were first determined in the case of acrolein, and the lower reactivity of acrolein discussed in comparison with saturated aldehydes.

Experimental

The DBPO used as an initiator was prepared according to the method in the literature.[12] DBPO was usually stored in *n*-pentane below −25 °C. The crystals were filtered off just before an experiment and were dried *in vacuo* below 0 °C. An accurately-weighed amount of DBPO was used for the oxidation reaction.

The reaction apparatus used was the same as one described previously.[7] Carbon dioxide, evolved in the course of the reaction by the decomposition of DBPO and the reaction intermediates, was eliminated by placing the absorption tube packed with soda lime in a gas recycling system. It was also confirmed that other gaseous compounds did not affect the measurement of the absorbed oxygen. The total volume of the reaction solution was maintained at 75 ml, and the reaction was carried out under an atmospheric pressure by the dilution of the oxygen with nitrogen, if necessary. The partial pressure of oxygen was calculated after revision using the vapor pressure of acrolein.[13] The concentration of oxygen dissolved in a benzene solution under an atmospheric pressure of oxygen is given as 7.73×10^{-3} mol/l.[14] Besides, the stirring speed and the amount of oxygen flow were maintained so as not to have an effect on the reaction rate.[9]

All the peroxide products were estimated by iodometry; we thus obtained each concentration of hydrogen peroxide, hydroperoxides, and the other peroxides.[8,15] The concentration of hydrogen peroxide was below 3×10^{-3} wt% in any feedstock of the reaction solution, measured at the first step of the titration. Peracrylic acid and the peroxide complex (1:1 adduct from peracrylic acid and acrolein) could be completely analyzed at the second and the last steps, as has been reported previously.[8]

The formation rate of radicals by the decomposition of DBPO was measured by the method that Bawn and Mellish,[16] and Hammond *et al.*[17] used for benzoyl peroxide and azobisisobutyronitrile. DBPO was decomposed in benzene in the presence of diphenylpicryl hydrazyl (DPPH). The solution showed an absorption maximum at 520 nm which obeyed Beer's law throughout the range of concentrations used in the present work. The optical densities of the solution were measured at adequate intervals during the reaction by means of a spectrophotometer (Hitachi, ESP-2).

Results and Discussion

The oxidation of acrolein was carried out in benzene at 40 °C. In the absence of an initiator, the absorption of oxygen was not observed for 3 hr; this behavior was different from that of the oxidation of the corre-

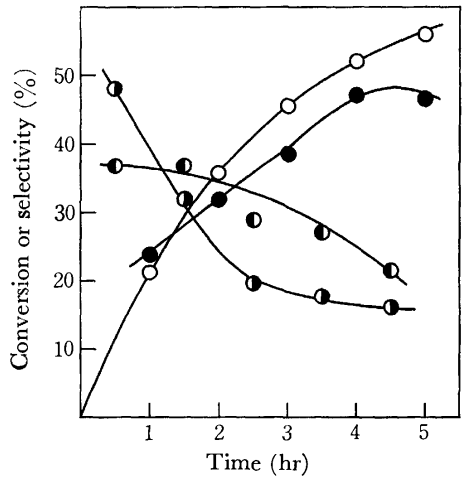

Fig. 1. Products in the oxidation of acrolein initiated by DBPO. Reaction conditions; [acrolein] 3.0 mol/l, [DBPO] 2.2×10^{-2} mol/l, 40 °C, in benzene. ○: conversion of acrolein, ●: selectivity of acrylic acid, ◑: selectivity of peracrylic acid, ◐: selectivity of the peroxide complex. Selectivities are based on consumed acrolein.

sponding saturated aldehydes. Oxygen was absorbed steadily without any induction period after the addition of DBPO. An aspect of the oxidation is illustrated in Fig. 1, with the selectivities of the products based on the acrolein consumed. The reaction intermediates, namely, peracrylic acid and the peroxide complex, remained rather stable at 40 °C, and 42% of the acrolein consumed was converted into these two kinds of peroxides at 4 hr. The formation of insoluble polymers was not observed throughout the oxidation.

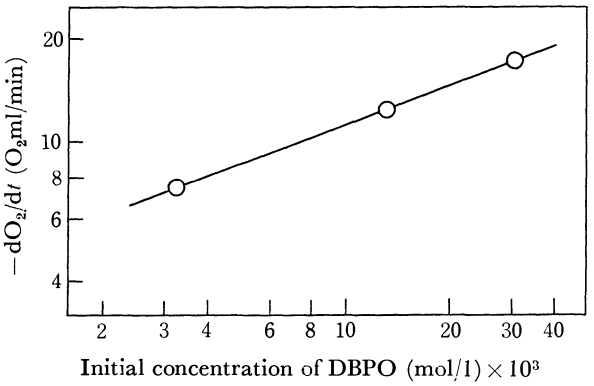

Fig. 2. Effect of DBPO on absorption rate of oxygen. Reaction conditions; [acrolein] 3.0 mol/l, $[O_2]$ 5.1×10^{-3} mol/l, 40 °C, in benzene.

The initial concentration of DBPO showed a half-order dependence on the absorption rate of oxygen (Fig. 2). The orders of the dependence of the initial concentration of acrolein and of the partial pressure of oxygen were also found to be near 0.6 and 0.5 respectively. These results give the following rate equation, as will be discussed in detail below (Table 1):

$$-dO_2/dt = \frac{A[O_2][\text{acrolein}]}{[\text{acrolein}]+B[O_2]} \qquad \text{(I)}$$

where A and B are constants which depend neither on the concentration of acrolein nor on the oxygen pressure. Moreover, the A constant contains a term of the initiation rate, as will be explained below.

Equation (I) can be transformed into Eq. (II):

$$1/-dO_2/dt = 1/A[O_2] + B/A[\text{acrolein}] \qquad \text{(II)}$$

A linear relationship was obtained between $1/-dO_2/dt$ and both $1/[O_2]$ and 1/[acrolein], as is illustrated in Figs. 3 and 4 respectively. The values of A and B could be calculated from the lines of both figures; they accorded well as is shown below:

	A (s^{-1})	B
From Fig. 3	2.8×10^{-2}	6.8×10^{2}
From Fig. 4	2.8×10^{-2}	6.6×10^{2}
Average	2.8×10^{-2}	6.7×10^{2}

The observed absorption rate of oxygen accorded quite well with those calculated by means of the assumed rate Eq. (I) when the values of A and B were taken as $2.8\times 10^{-2}\,s^{-1}$ and 6.7×10^{2} (Table 1).

Assuming that the oxidation proceeds through the autoxidation mechanism shown below, the theoretical rate Eq. (III) may be derived by appling the stationary-state treatment:

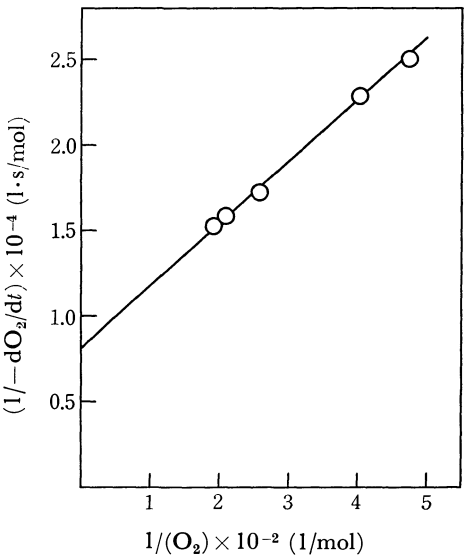

Fig. 3. Effect of oxygen pressure on absorption rate of oxygen. Reaction conditions; [acrolein] 3.0 mol/l, [DBPO] 3.4×10^{-3} mol/l, 40 °C, in benzene. Slope= $1/A=0.35\times 10^{2}$ s, B/A[acrolein]$=0.80\times 10^{4}$ l·s/mol.

Reaction conditions; [DBPO] 3.4×10^{-3} mol/l, 40 °C, in benzene.

a) Calculated by the Eq. (I), where the values of A and B are 2.8×10^{-2} s^{-1} and 6.7×10^2, respectively.

the rate of initiation respectively.

$$-dO_2/dt = \frac{R_i^{1/2}k_2k_3[RH][O_2]}{k_3k_4^{1/2}[RH]+k_2k_6^{1/2}[O_2]} \qquad (III)$$

The initiation reaction is considered to proceed in the following manner because the absorption rate in the absence of DBPO is negligible:[18]

$$DBPO \xrightarrow{k_{11}} 2t\text{-BuO}\cdot + 2CO_2$$

$$t\text{-BuO}\cdot + RH \xrightarrow{k_{12}} t\text{-BuOH} + R\cdot$$

Accordingly, R_i is given as the following expression and is dependent on neither the concentration of acrolein nor on the oxygen pressure:[18]

$$R_i = 2ek_{11}[DBPO]$$

The coefficient e is the efficiency of the radical initiator. In order to determine the value of ek_{11}, DBPO was decomposed in benzene at 40 °C in the presence of DPPH and the rate of decrease of DPPH was measured. According to Shine *et al.*,[19] if the concentration of peroxide is higher than that of the hydrazyl, the yield of carbon dioxide is not affected by the presence of the hydrazyl. Therefore, the formation rate of *t*-butoxy radicals can be derived from the rate of decrease of DPPH under the present reaction conditions. From Fig. 5 the value of ek_{11} was determined to be 8.5×10^{-5} s^{-1} at 40 °C. Bartlett *et al.* measured the decomposition rate of DBPO in benzene by observing the decline of the absorption of the carbonyl frequency and found that the decomposition occurred through a uni-molecular mechanism.[12] The rate constant of the decomposition at 40 °C can be calculated to be 10.5×10^{-5} s^{-1} from the reported values. The ratio of the two constants may correspond to an e value of 0.81 at 40 °C. Burnett *et al.* also determined the efficiency of azobisisobutyronitrile by DPPH-inhibitor techniques.[21]

Therefore, A and B in Eq. (I) can be expressed by the rate constants of the elementary steps in the following manner, and the ratios of the constants, $k_3k_6^{-1/2}$ and $k_2k_4^{-1/2}$, at 40 °C can be determined in the oxidation of acrolein:

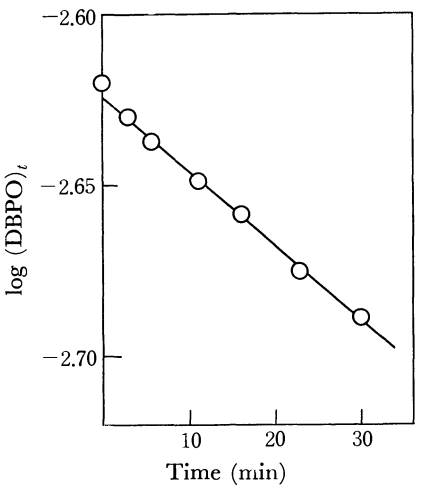

Fig. 5. Formation of *t*-butoxy radicals from the decomposition of DBPO. Reaction conditions; initial concentration of DBPO 2.40×10^{-3} mol/l, initial concentration of DPPH 1.82×10^{-3} mol/l, 40 °C, in benzene. $[DBPO]_t=[DBPO]_0-1/2\ \{[DPPH]_0-[DPPH]_t\}$. $[X]_t$ and $[X]_0$ denote the concentrations of X at $t=t$ and 0, respectively.

$$A = \{2ek_{11}[DBPO]\}^{1/2}k_2k_4^{-1/2},\quad B = k_2k_4^{-1/2}/k_3k_6^{-1/2}$$

$$k_3k_6^{-1/2} = 5.5\times 10^{-2}\ (l^{1/2}\cdot mol^{-1/2}\cdot s^{-1/2})$$

$$k_2k_4^{-1/2} = 3.7\times 10\quad (l^{1/2}\cdot mol^{-1/2}\cdot s^{-1/2})$$

The ratios of the rate constants, $k_3k_6^{-1/2}$, have been reported in many kinds of hydrocarbons; they seem to be dependent both on the property of the hydrogen being abstracted and on the structure and reactivity of the peroxy radicals.[20] In the oxidation of acetaldehyde, $k_3k_6^{-1/2}$ has been reported to be 2.7×10^{-1} $(l^{1/2}\cdot mol^{-1/2}\cdot s^{-1/2})$ at 0 °C.[22] Considering that the activation energies of k_3 and k_6 are 2—4 and 0—2 kcal respectively,[23] the ratio in acetaldehyde may be said to be 10 times larger than that in acrolein.

On the other hand, Zaikov *et al.* found that, in the oxidation of various aldehydes, the values of $k_3k_6^{-1/2}$ differed only slightly from one another because there were compensating changes for the rate constants of propagation and termination,[24] the values of $k_3k_6^{-1/2}$ being substantially constant, independently of the kind of aldehyde. The termination rate constants, k_6, for acrolein and acetaldehyde may depend on the stability of these two kinds of acyloxy radicals formed in the tetroxide homolysis. Considering the more rapid decarboxylation of acetoxy radicals, the constant, k_6, of acrolein may be larger than that of acetaldehyde because of the existence of the conjugated double bond, as has been reported in the case between benzaldehyde and alkanals.[24] The propagation rate constant, k_3, may be discussed in two ways; (1) the reactivity of aldehyde hydrogen, that is, the C–H bond strength and the steric effect, and (2) the reactivity of the attacking acylperoxy radicals. The bond strength is estimated to be 74 kcal for benzaldehyde and 88 kcal for acetaldehyde.[25] The reason why compensating changes are

found between benzaldehyde and alkanals may be mainly attributed to the difference in the bond strength. On the contrary, though the bond strength may be smaller for acrolein than for acetaldehyde because of the resonance stabilization of acryloyl radicals, the value of $k_3k_6^{-1/2}$ in the oxidation of acrolein is smaller than that of acetaldehyde or benzaldehyde. Russell claimed that the polar effect of acylperoxy radicals played an important role in the propagation step:[26]

$$RO_2\cdot + RH \xrightarrow{k_3} [RO_2^-:H\ R^+] \longrightarrow RO_2H + R\cdot$$

Such an intermediate complex will be elucidated in this oxidation. However, there may be two forms of complexes ((1) and (2)) which are stabilized by the existence of the conjugated C=C double bond:

$$CH_2{=}CHCHO + RO_2\cdot \longrightarrow$$

$$\left[O{=}\overset{+}{C}\diagup CH{=}CH_2 \;\cdot\; H{:}\,O_2^-{-}R\right] \longleftrightarrow \left[O{=}C\diagup\!\!\diagup CH{-}C^+H_2 \;\cdot\; H{:}\,O_2^-{-}R\right]$$

(1) (2)

$$\longrightarrow CH_2{=}CH\dot{C}O + RO_2H$$

The (2) complex is considered to be more stabilized than the (1) complex because of its electronic structure, and the (1) complex may produce an acryloyl radical and peracrylic acid faster than the (2) complex. This results in the lower reactivity for the abstraction of the hydrogen of acrolein as compared with that of the other aldehydes, such as acetaldehyde, with only one form of an intermediate complex. Besides, the steric hindrance may arise for acrolein in the abstraction reaction, because the rotation about the C–C single bond is restricted. The proportion of s-*trans* to s-*cis* isomers was reported to be 95:5 at room temperature.[27] As the sum of these effects, it may be possible to consider that k_3 does not compensate for the change of k_6 for acrolein, resulting in the following order with regard to the values of $k_3k_6^{-1/2}$:

$$\text{benzaldehyde} \fallingdotseq \text{acetaldehyde} > \text{acrolein}$$

There are no reports concerning the values of $k_2k_4^{-1/2}$. In the oxidation of saturated aldehydes, the rate-determining step is Step (3) and oxygen reacts with an acyl radical so fast that the absorption rate has no dependence on the oxygen pressure. However, the k_2 constant is considered to be smaller for acrolein because of the resonance stabilization, as has been reported in the case of allyl or benzyl radicals.[28] The ratio of $k_2k_4^{-1/2}$ to $k_3k_6^{-1/2}$ reaches only 670 for acrolein. As the ratios of the concentrations of acrolein to dissolved oxygen are near 10^3 in the present work, the absorption rate has a certain dependence on the oxygen pressure. It has already been reported that a near-first-order dependence on the oxygen pressure can be observed in oxidations catalyzed by various metal salts.[29] Brill and Lister also reported a first-order dependence in the catalyzed oxidation of methacrolein.[2] As the catalyzed oxidation proceeds through the same reaction mechanism except for the initiation step (1), part of the higher dependence on the oxygen pressure may be ascribed to the initiation step; that is, the abstraction of aldehyde hydrogen by a metal ion may be accelerated by the presence of oxygen.

Asymmetric Synthesis with Sugar Derivatives. V.[1,2] The Synthesis of α-Hydroxy Acids on Insoluble Polymer Supports

Masajiro KAWANA and Sakae EMOTO

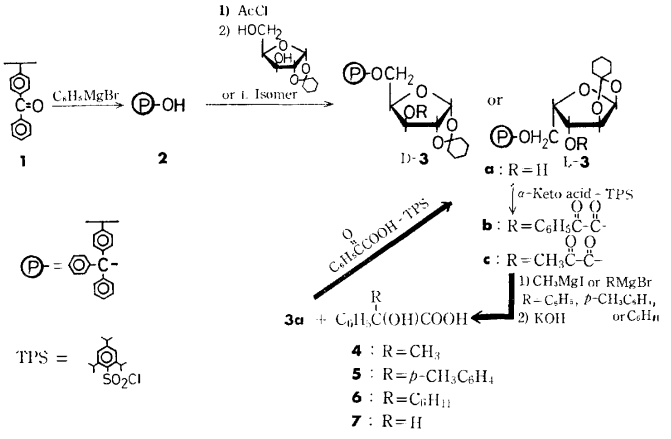
The Institute of Physical and Chemical Research, Wako-shi, Saitama 351

(Received July 2, 1973)

The styrene-2% divinylbenzene copolymer containing 1,2-*O*-cyclohexylidene-5-*O*-trityl-α-D- or -L-xylofuranose (D- or L-**3a**) was prepared. Asymmetric Grignard additions to benzoylformate (**3b**) and pyruvate (**3c**) were carried out using these polymers as chiral ester-components. Enantiomers of α-hydroxy acids, such as atrolactic acid (**4**) and 2-hydroxy-2-phenyl-2-(*p*-tolyl)acetic acid (**5**), were obtained in relatively good synthetic and optical yields, depending on the use of either D- or L-**3a**. The optical yields of **4** for the polymer were higher than those for a low-molecular-weight compound, 1,2-*O*-cyclohexylidene-5-*O*-trityl-α-D-xylofuranose (**8a**). It was shown that the polymer could be used repeatedly.

The application of the method[3] for the synthesis of polypeptides on polymer supports to asymmetric synthesis[4] seems to be very advantageous for the following reasons: (1) the isolation of a desired product from the reaction mixtures is very much simplified; (2) the polymer containing chiral groups which serve as a chiral environment for the asymmetric synthesis can be used repeatedly; and (3) the polymer chain may effect an increase in the stereoselectivities of the reagents.

Recently we have demonstrated[5] that sugar derivatives such as 1,2: 5,6-di-*O*-cyclohexylidene-α-D-glucofuranose can be used effectively as chiral alcohols for the asymmetric synthesis of atrolactic acid (2-hydroxy-2-phenylpropionic acid) (**4**)[6] by Grignard additions to the sugar-esters of benzoylformic acid, and that the increase in the steric bulkiness of a substituent on the C-4 of the furanose ring of gluco- or xylo-furanoside containing a 1,2-*O*-cyclohexylidene or -isopropylidene group causes the optical yield of the acid to increase. Therefore, the use of a cross-linked polystyrene-bound 1,2-*O*-cyclohexylidene-5-*O*-trityl-α-D- or -L-xylofuranose (D- or L-**3a**), which has a bigger substituent on the C-4 of the furanose ring, may be effected to increase the optical yield and provide a convenient method for the asymmetric synthesis.[7] In this paper we would like to report on the asymmetric synthesis of some α-hydroxy acids with insoluble-polymer supports, D- and L-**3a**, and on that with a low-molecular-weight compound, 1,2-*O*-cyclohexylidene-5-*O*-trityl-α-D-xylofuranose (**8a**).[8]



Scheme 1.

Results and Discussion

The polymer (**3a**) was prepared by a procedure similar to that reported earlier.[9] A commercially-available styrene-2% divinylbenzene copolymer (100—200 mesh) was converted into a 21 or 9 mol% benzoylated polymer (**1**) by the use of a limited amount of benzoyl chloride in the presence of aluminum chloride; hereafter, the polymers derived therefrom will be designated as P-21 or -9 respectively. The reaction of **1** with an excess of phenylmagnesium bromide gave a tritylated polymer (**2**) in an almost quantitative yield. On the treatment of **2** with an excess of acetyl chloride, followed by a reaction with 1,2-*O*-cyclohexylidene-α-D-[10] or -L-xylofuranose,[11] D- or L-**3a** was obtained in a 73—87% yield based on the amount of the trityl group in **2**; the remaining chloride was treated with absolute methanol. The hydrolysis of D-**3a** (P-21: 1.0 g) with an acid released ~0.9 mmol of 1,2-*O*-cyclohexylidene-α-D-xylofuranose, this value being very consistent with that calculated from the gain in weight.

The polymer (**3a**) was easily esterified with an excess of benzoylformic acid[12] or pyruvic acid and 2,4,6-triisopropylbenzenesulfonyl chloride (TPS)[13] to give the polymer-bound benzoylformate (**3b**) or the corresponding pyruvate (**3c**) respectively in an almost quantitative yield. In these reactions every 100 styrene units, ~15 and ~7 in P-21 and -9 respectively, were derivatized to the ester functions. The polymers of the P-9 series were much more swelled than those of P-21 in a solvent such as tetrahydrofuran or benzene.

The polymer (**3b** or **c**) thus obtained was subjected to an asymmetric Grignard reaction, which was completed at room temperature. The complete detachment of the acid moiety was effected with a solution of potassium hydroxide at room temperature. The isolated free acids were almost pure, judging from their IR and NMR spectra and from tlc analyses. The results are summarized in Table 1.

From the reaction of D- or L-**3b** (P-21) with methylmagnesium iodide, *R*-(−)- or *S*-(+)-**4**[14] was obtained respectively in a 65% (maximum) optical yield; the synthetic yields, based on the amount of the esters charged on the polymers, were also fairly high (Runs 1 and 5). Similar results were obtained in the case of

Table 2. Repetition of the asymmetric synthesis of *R*-(−)-atrolactic acid (**4**) with the polymer (D-**3b**)[a]

Repet.	Synthetic yield,[b] %	Optical yield,[c] %

2nd	80	61
3rd	69	55
4th	78	54
5th	78	56
6th	81	58
7th	72	60

a) P-21: see footnote a in Table 1.
b) and c) See the corresponding footnotes in Table 1.

be used for the asymmetric synthesis without any loss of capability.

Although at present a detailed explanation of the steric course of the reaction cannot be offered,[20] some general tendencies of the direction of the attack of the Grignard reagent on the α-keto carbonyl group of the sugar-ester are apparent, as can be seen in Table 1.

Experimental

The melting points are uncorrected. The IR spectra were recorded on a Shimadzu IR-27 instrument in KBr unless otherwise stated. The NMR spectra were obtained using a Model JNM-C-60 HL spectrometer (Japan Electronic Optics Laboratory Co.) with DSS as an internal standard. The chemical shifts are expressed in the δ values. The optical rotations were measured with a Perkin-Elmer Model 141 polarimeter and a 1 dm tube. The elemental analyses were performed by this Institute.

Thin-layer chromatography was accomplished on 2.5×10 cm plates coated with 0.25 mm layers of E. Merck GF-254 silica gel. The following products were detected on these plates: the sugar derivatives, by the use of a methanol–sulfuric acid–*p*-methoxybenzaldehyde (85: 10: 5, v/v) spray, followed by heating; the α-keto and hydroxy acids, under an UV light or by the use of a 0.1% methanolic methyl red spray, followed by heating. The following solvents were used as developers: chloroform or chloroform–methanol (9: 1) for the sugar derivatives; benzene–methanol–acetic acid (45: 8: 4) for the acids.

The polymers were dried over KOH–P_2O_5 at room temperature *in vacuo* overnight unless otherwise stated. The Grignard reagents were prepared by the reactions of magnesium and halides in ether. The crude acids obtained from the asymmetric reactions were identified by comparisons of their IR (in chloroform) and NMR spectra and thin-layer chromatograms with those of analytically-pure racemic samples which had been prepared from the reactions of methyl benzoylformate and Grignard reagents by the standard methods.

A styrene-2% divinylbenzene copolymer was purchased from the Protein Research Foundation (Minoo, Osaka).

The Benzoylated Polymer (1). To a stirred suspension of a styrene-2% divinylbenzene copolymer (100—200 mesh, 20.0 g, 0.19 mol of the phenyl group) in carbon disulfide (200 ml), we added benzoyl chloride (5.6 g, 39.8 mmol) at room temperature, and then added aluminum chloride (5.6 g) at 0—5 °C (bath). The mixture was stirred at 0—5 °C for 1 hr and at room temperature for 16 hr, and then stirred into a mixture of iced water (250 ml) and dioxane (250 ml). After the inorganic materials had been dissolved, the polymer was collected on a glass filter, washed successively with dioxane–water (500 ml, 1: 1), water (1 l), dioxane–water (500 ml, 1: 1), dioxane (400 ml), methanol (250 ml), and ether (500 ml), and then dried to give **1** (P-21). The yield was 24.1 g, which corresponded to 29.4 mmol of the benzoyl group, as judged by the increase in weight. Therefore, 21% of the starting phenyl groups were derivatized to the benzoyl groups. $\nu_{C=O}$, 1655 cm^{-1}.

Under similar conditions, **1** (P-9) was prepared using benzoyl chloride (3.0 g, 21.4 mmol) and aluminum chloride (3.0 g); the yield was 21.8 g (17.3 mmol of the benzoyl group).

The Tritylated Polymer (2). To a stirred suspension of **1** (P-21) (24.0 g, 38.4 mmol of the benzoyl group) in dry tetrahydrofuran (120 ml), we added a solution of phenylmagnesium bromide (78 mmol) in dry tetrahydrofuran (100 ml) at room temperature under a dry nitrogen atmosphere over a period of 30 min. After the completion of the addition, the mixture was stirred at room temperature for 18 hr and then refluxed gently for 6 hr. After the mixture had been cooled, it was stirred into iced 3 M HCl–acetic acid (500 ml, 1: 1). The polymer was collected on a glass filter, washed successively with 3 M HCl–acetic acid (500 ml, 1: 1), water (1 l), tetrahydrofuran–water (500 ml, 1: 1), dioxane–water (500 ml, 1: 1), dioxane (400 ml), methanol (400 ml), and ether (400 ml), and then dried to give **2** (P-21); the yield was 27.0 g (38.5 mmol of the trityl group). There was no carbonyl band detectable at 1655 cm^{-1}, indicating that the reaction had essentially been completed.

Under similar conditions, **2** (P-9) was prepared using **1** (P-9) (43.0 g, 35.3 mmol of the benzoyl group); the yield was 46.0 g, (38.5 mmol of the trityl group).

*The Polymer-bound 1,2-O-Cyclohexylidene-α-*D*- or -*L*-Xylofuranose (*D*- or *L*-3a).* To a suspension of **2** (P-21) (13.0 g, 18.4 mmol of the trityl group) in dry benzene (80 ml), we added acetyl chloride (10 ml), after which the mixture was gently refluxed for 16 hr with stirring. After the mixture had been cooled, the polymer was collected on a glass filter in a dry-box, washed successively with dry benzene (200 ml) and dry ether (200 ml), and then dried. To a suspension of this polymer in a mixture of dry pyridine (15 ml) and dry benzene (80 ml), we then added 1,2-*O*-cyclohexylidene-α-D-[10] or -L-xylofuranose[11] (6.0 g, 26 mmol), after which the mixture was stirred at room temperature under a dry nitrogen atmosphere for 48 hr. In order to decompose the unreacted trityl chloride groups, absolute methanol (5 ml) was added and the mixture was stirred for another 24 hr. The polymer was collected on a glass filter, washed successively with benzene (100 ml), benzene–chloroform (200 ml, 1: 1), chloroform (200 ml), chloroform–tetrahydrofuran (100 ml, 1: 1), tetrahydrofuran (100 ml), tetrahydrofuran–water (100 ml, 1: 1), water (400 ml), water–dioxane (100 ml, 1: 1), dioxane (100 ml), dioxane-methanol (100 ml, 1: 1), methanol (200 ml), methanol–ether (100 ml, 1: 1), and ether (200 ml), and then dried to give **3a**. The yields of D- and L-**3a** (P-21) were 16.1 and 16.4 g, which corresponded to 14.6 and 16.0 mmol of the sugar respectively. Therefore, 80—87% of the trityl groups were converted into the sugar functions.

Under similar conditions, D-**3a** (P-9) was prepared using **2** (P-9) (45.0 g, 37.8 mmol of the trityl group), acetyl chloride (35 ml), and 1,2-*O*-cyclohexylidene-α-D-xylofuranose (31.1 g, 57 mmol); the yield was 50.8 g (27.4 mmol of the sugar).

The Acid Hydrolysis of the Polymer-bound Sugar (D-3a; P-21). Freshly-distilled dioxane was used in this experiment.

To a strirred suspension of D-**3a** (P-20) (1.0 g, 0.91 mmol of the sugar) in dioxane (5 ml), we added dioxane–8 M HCl

(5 ml, 100: 1, v/v) at room temperature under a nitrogen atmosphere over a period of 15 min, after which the mixture was stirred for 24 hr. The polymer was collected on a glass filter, washed successively with dioxane (20 ml), dioxane–water (20 ml, 1: 1), water (5 ml), dioxane–water (10 ml, 1: 1), dioxane (10 ml), methanol (20 ml), and ether (20 ml), and then dried. The weight of the recovered polymer was 807 mg.

The combined filtrate and washings were treated with Dowex-1, X-2 (OH^- form, 5 ml) for 5 min. The ion-exchange resin was removed by filtration and washed with successively with dioxane–water (20 ml, 1: 1) and water (30 ml). The combined filtrate and washings were then concentrated to dryness to give 1,2-*O*-cyclohexylidene-α-D-xylofuranose as a crystal (208 mg, 0.9 mmol), the spectral data of which were almost identical with those of an authentic sample.[10] No free D-xylose was detected by the tlc analysis.

The recovered polymer (747 mg) was further treated with dioxane–12 M HCl (5 ml, 100: 1, v/v) for 48 hr under conditions similar to those described above, thus giving 1.5 mg of 1,2-*O*-cyclohexylidene-α-D-xylofuranose. The IR spectrum of the resulting polymer showed that only a trace of the sugar function remained.

The Polymer-bound Benzoylformate (3b). To a stirred suspension of D-**3a** (P-21) (15.0 g, 14.7 mmol of the sugar) in a mixture of dry benzene (75 ml) and dry pyridine (25 ml), we added benzoylformic acid (3.76 g, 25 mmol), and then we added TPS (7.6 g, 25 mmol) at room temperature under a dry nitrogen atmosphere. After the mixture had been stirred for 5 hr, absolute methanol (2.5 ml) was added; the stirring was then continued for another hour. The polymer was collected on a glass filter, washed successively with pyridine (80 ml), pyridine–iced water (200 ml, 1: 1), water (1 l), dioxane–water (300 ml, 1:1), dioxane (300 ml), dioxane–methanol (300 ml, 1: 1), methanol (200 ml), methanol–ether (200 ml, 1: 1), and ether (200 ml), and dried to give D-**3b** (P-21). The yield was 17.16 g, which corresponded to 16.4 mmol of the ester, as judged by the increase in weight. Therefore, the esterification had been essentially completed. $\nu_{C=O}$, 1740, 1691 cm^{-1}.

Under similar conditions, L-**3b** (P-21) (6.69 g, 5.23 mmol of the ester) and D-**3b** (P-9) (9.67 g, 5.1 mmol of the ester) were prepared starting from L-**3a** (P-21) (6.0 g, 5.88 mmol of the sugar) and D-**3a** (P-9) (9.0 g, 4.9 mmol of the sugar) respectively.

The Polymer-bound Pyruvate (3c). To a stirred suspension of D-**3a** (P-9) (9.0 g, 4.9 mmol of the sugar) in a mixture of dry benzene (60 ml) and dry pyridine (10 ml), we added freshly-distilled pyruvic acid (1.27 g, 14.7 mmol); we then added TPS (4.45 g, 14.7 mmol) at room temperature under a dry nitrogen atmosphere. The mixture was treated in a similar manner to that described for the synthesis of **3b**, giving D-**3c** (P-9). The yield was 9.38 g (5.4 mmol of the ester). $\nu_{C=O}$, 1760 (shoulder), 1734 cm^{-1}.

Analogously, D-**3c** (P-21) (14.98 g, 14.0 mmol of the ester) was prepared starting from D-**3a** (P-21) (14.0 g, 12.6 mmol of the sugar).

1,2-O-Cyclohexylidene-5-O-trityl-α-D-xylofuranose (8a). To a solution of 1,2-*O*-cyclohexylidene-α-D-xylofuranose[10] (23.0 g, 0.1 mol) in dry pyridine (100 ml), we added trityl chloride (32.3 g, 0.12 mol) at room temperature; the mixture was stirred for 1 hr and then allowed to stand at room temperature for 2 days. The mixture was poured into iced water (500 ml), and the undissolved materials were collected by decantation and dissolved in ether (600 ml). The ethereal solution was washed with water (2×100 ml) and dried over magnesium sulfate. The ether was then removed, and the pyridine was distilled by repeated co-evaporation with xylene. The residue was crystallized from benzene–*n*-hexane to afford **8a** (38.7 g, 82%). Further recrystallization gave an analytically pure sample: mp 145—147 °C; $[\alpha]_D^{25}$ −28.3° (*c* 1, EtOH); NMR (DMSO-d_6) 5.11 (d, 1H of the hydroxyl group on C-3).

Found: C, 76.45; H, 6.62%. Calcd for $C_{30}H_{32}O_5$: C, 76.24; H, 6.83%.

3-O-Benzoylformyl-1,2-O-cyclohexylidene-5-O-trityl-α-D-xylofuranose (8b). To a stirred solution of **8a** (4.7 g, 0.01 mol) in a mixture of dry pyridine (10 ml) and dry benzene (20 ml), we added benzoylformic acid (1.65 g, 0.011 mol); then we added TPS (3.34 g, 0.011 mol) at room temperature. After having been stirred for 3 hr, the mixture was stirred into iced water (100 ml) and then extracted with ether (300 ml). The extract was washed with water (2×50 ml) and dried over magnesium sulfate. The ether was then evaporated, and the pyridine was removed by repeated co-evaporation with toluene *in vacuo* to give a syrup, which was subsequently chromatographed on a silica gel column (100 g, 3.5×22 cm) packed with chloroform. Rapid elution (13 ml/min) was effected in order to avoid the decomposition of the product; 25 ml fractions were collected. Fractions 9—12 contained **8b** (3.5 g, 58%) slightly contaminated with impurities. Fractions 13—16 were combined, and the solvent was removed to give analytically pure **8b** (1.3 g, 22%) as a glass after drying over P_2O_5 at 100 °C *in vacuo* for 2 hr: $[\alpha]_D^{25}$ −23.1° (*c* 1, $CHCl_3$); $\nu_{C=O}$, 1740, 1695 cm^{-1}.

Found: C, 75.68; H, 5.92%. Calcd for $C_{38}H_{36}O_7$: C, 75.48; H, 6.00%.

1,2-O-Cyclohexylidene-3-O-pyruvinyl-5-O-trityl-α-D-xylofuranose (8c). To a stirred solution of **8a** (7.1 g, 15 mmol) in a mixture of dry pyridine (20 ml) and dry benzene (30 ml), we added freshly-distilled pyruvic acid (1.94 g, 22 mmol); following the subsequent addition of TPS (6.1 g, 20 mmol) at room temperature, the mixture was treated in a similar manner to that described for the synthesis of **8b**. The resulting syrup was crystallized from *n*-hexane–benzene to afford **8c** (4.5 g, 55%). Recrystallization from the same solvents gave an analytically pure sample: mp 149—152 °C; $[\alpha]_D^{25}$ −46.3° (*c* 1, $CHCl_3$); $\nu_{C=O}$, 1756, 1737 cm^{-1}.

Found: C, 73.20; H, 6.30%. Calcd for $C_{33}H_{34}O_7$: C, 73.04; H, 6.32%.

The Reaction Vessel for the Asymmetric Synthesis on the Polymer. The reaction vessel consisted of a three-necked flask (100 ml) fitted with a 2.5 cm medium-porosity fritted disk filter in the central part of the side of the flask. The tubing was led beyond the disk and sealed to a bore stopcock through which the solvents were removed under suction. A Grignard reagent which had been prepared in another three-necked flask (50 ml) was transferred directly into the above-mentioned flask through a tube fitted with a 1.3 cm rough-porosity fritted disk filter and a stopcock.

Asymmetric Synthesis of Atrolactic Acid (4). Some of the reaction conditions and results are presented in Tables 1 and 2.

(A) Synthesis on the polymer. To a stirred suspension of D- or L-**3b** (3—4 g, 2.1—2.5 mmol of the esters) in dry benzene (20—25 ml) in the reaction vessel, we added a solution of the Grignard reagent (6 mmol) in dry ether (18 ml) under a dry nitrogen atmosphere. After the reaction had been completed, the solvents were removed through the filter. The polymer was washed successively with a solution of ammonium chloride (10 g) in iced water–dioxane (200 ml, 1: 1), water (200 ml), dioxane–water (200 ml, 1: 1), dioxane (100 ml), dioxane–methanol (100 ml, 1: 1), and methanol (100 ml), and then dried over KOH–P_2O_5 at room tem-

perature *in vacuo* for 2—3 hr. The IR spectrum of the polymer showed the absence of the α-keto carbonyl group.

Freshly-distilled tetrahydrofuran was used in the next experiment. The polymer was swelled in tetrahydrofuran (15—25 ml), and then a solution of potassium hydroxide (600 mg, 11 mmol) in a tetrahydrofuran–methanol–water mixture (12 ml, 5: 5: 2) was added at room temperature under a nitrogen atmosphere over a period of 20 min. After the mixture had been stirred for 5 hr, the solvents were filtered; the polymer was then washed successively with tetrahydrofuran–methanol–water (100 ml, 20: 5: 2), water (50 ml), and tetrahydrofuran–water (100 ml). The resulting polymer could be used repeatedly; see (*B*). The combined filtrate and washings were concentrated to *ca.* 7 ml below 50 °C (bath) *in vacuo*. The residue was diluted with water (15 ml), and the undissolved material was removed by filtration through a Celite pad and washed with a small amount of water. The combined filtrate and washings were cooled, acidified with 12 M HCl (2 ml), and extracted with ether (3×100 ml). The ethereal extract was washed with water (10 ml) and dried over magnesium sulfate. The removal of the ether gave a slightly colored crystal, which was decolorized with active charcoal in water (20 ml). The water was removed *in vacuo*, and the crystalline residue was again dissolved in ethanol (15 ml). The solution was filtered through a Celite pad. The removal of the ethanol gave **4** as a colorless crystal, which was then dried over KOH–P_2O_5 at room temperature *in vacuo* for 20 min; yields, 52—308 mg.

(B) Repetition of the reactions. Under the same conditions as are described in (*A*), D-**3b** (P-20) (3.0 g, 2.5 mmol of the ester) was treated in the reaction vessel. The resulting polymer was washed with tetrahydrofuran (100 ml) and then stirred in a mixture of acetic acid–tetrahydrofuran–water (100 ml, 1: 95: 4) at room temperature for 30 min in order to remove the potassium hydroxide remaining in the polymer. After the solvents had been removed, the polymer was washed successively with tetrahydrofuran-water (100 ml, 19: 1), tetrahydrofuran–water (100 ml, 1: 1), tetrahydrofuran–pyridine (50 ml, 49: 1), tetrahydrofuran (100 ml), dioxane–methanol (50 ml, 1: 1), and methanol (100 ml), and then dried.

The polymer was then swelled in benzene (15 ml). To this suspension we added, successively, pyridine (3 ml), benzoylformic acid (750 mg, 5.0 mmol), and TPS (1.5 g, 5.0 mmol), after which the mixture was treated under the conditions described for the synthesis of **3b**. The resulting polymer was again subjected to the Grignard addition, and the subsequent reactions were repeated.

The yields were 288—336 mg. The IR and NMR spectra of **4** from the 1st and 7th runs were identical with those of an analytically pure racemic sample.

(C) Synthesis with low-molecular-weight compounds. **8b** (1.21 g, 2.0 mmol) or **8c** (1.25 g, 2.3 mmol) was treated under the conditions described in (*A*), except for the following conditions: (1) The Grignard adduct was hydrolyzed with a solution of ammonium chloride (10 g) in cold water (100 ml), and the resulting ester was extracted with ether (3×100 ml). The extract was then dried over magnesium sulfate, and the ether was removed. (2) The ester of **4** was completely hydrolyzed in methanol (15 ml) with a solution of potassium hydroxide in a mixture of methanol (6 ml) and water (3 ml). The concentrated reaction mixture was then diluted with water (20 ml) and extracted with chloroform (4×100 ml). The water layer was concentrated to *ca.* 10 ml and acidified. (3) In the case of **8c**, the crude product (**4**) was placed in a solution of sodium bicarbonate (300 mg) in water (15 ml), after which the mixture was extracted with ether (100 ml). The extract was washed with water (5 ml). The combined water layer was then acidified to give **4**.

The yields were 221—226 and 82 mg from **8b** and **c** respectively.

*Asymmetric Synthesis of 2-Hydroxy-2-phenyl-2-(*p*-tolyl)acetic Acid (5).* Some of the reaction conditions and results are listed in Table 1. To a stirred suspension of D-**3b** (P-21) (3.0 g, 2.64 mmol of the ester), L-**3b** (P-21) (3.0 g, 2.34 mmol of the ester), or D-**3b** (P-9) (4.0 g, 2.4 mmol of the ester) in dry benzene (20—25 ml) in the reaction vessel, we added a solution of *p*-tolylmagnesium bromide (6 mmol) in dry ether (18 ml) over a period of 35 min under a dry nitrogen atmosphere. The polymer was treated in a manner similar to that described for the synthesis of **4**, except that after the hydrolysis with potassium hydroxide, the diluted solution with water (15 ml) was decolorized at this stage. The crude **5** was crystallized on standing at room temperature over KOH–P_2O_5 for 1—2 days; the yields were 310—394 mg.

Asymmetric Synthesis of 2-Cyclohexyl-2-hydroxy-2-phenylacetic Acid (6). Some of the reaction conditions and results are listed in the Table 1. To a stirred suspension of D-**3b** (P-21) (4.0 g, 3.8 mmol of the ester) in dry benzene (30 ml) in the reaction vessel, we added a solution of cyclohexylmagnesium bromide (11.4 mmol) in dry ether (25 ml) over a period of 35 min under a dry nitrogen atmosphere. The polymer was treated in a manner similar to that described for the synthesis of **5**, thus yielding the crude product (593 mg) as a syrup. Its NMR spectrum and thin-layer chromatogram showed the presence of **7** (~15%) and small amounts of benzoylformic acid and impurities, besides **6**.

In order to remove these undesirable acids, which were highly soluble in water, a carborundum[21] column (100 mesh, 2.8×19 cm) packed with cold water was used. A crude sample (530 mg) was dissolved in a small amount of ethanol, and the solution was put on the top of the column. After a few ml of water had been eluted, a few ml of cold water was added. The carborundum steeped with the ethanolic solution was stirred with a spatula so that the water-insoluble **6** could be precipitated. The column was then washed with cold water (125 ml), and the **6** was eluted with ethanol. The subsequent evaporation of the solvents gave a syrup, which was then decolorized with active charcoal in aqueous ethanol. The removal of the solvents afforded crystalline **6** (355 mg) after drying over KOH–P_2O_5 at room temperature for 2 days. Although a small amount of **6** was eluted while the column was being washed with water, **6** obtained was free from the water-soluble acids, judging from NMR spectroscopy and tlc analysis.

We wish to thank Dr. Haruo Homma and his staff for the elemental analyses, and Mr. Jun Uzawa and Mrs. Tamiko Chijimatsu for their measurements of the NMR spectra.

The Reaction of Sulfinic Acids with *N,N*-Dimethylaniline

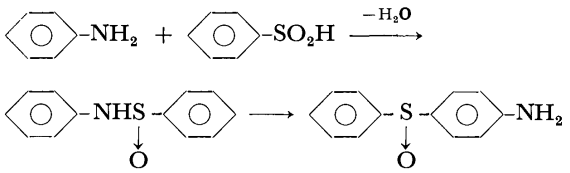
Shigeru OAE, Osamu YAMADA, and Tetsuya MAEDA

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka 558

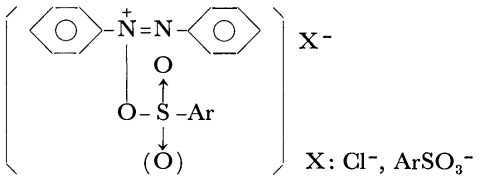
(Received July 13, 1973)

When *N,N*-dimethylaniline was allowed to react with *p*-toluenesulfinic acid, unusual demethylation products, *i.e.*, *p*-(*N,N*-dimethylamino)benzyl *p*-tolyl sulfone and *p*-(*N*-methylamino)benzyl *p*-tolyl sulfone were obtained. *N*-*p*-Toluenesulfonylmethyl-*N*-methylaniline was proposed to be a discrete intermediate, which undergoes intermolecular rearrangement in the presence of acid eventually to afford the above products. Similar results were obtained for the reaction of *N*-methylaniline with *p*-toluenesulfinic acid.

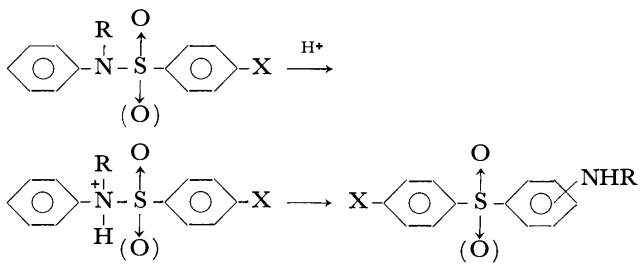
The reaction of benzenesulfinic acid with phenylhydrazine is known to give benzenesulfonyl phenylhydrazide,[1] presumably proceeding *via* a dehydrated intermediate, benzenesulfinyl phenylhydrazide. A similar reaction with aniline has also been suggested to proceed through sulfinamide to give a rearranged product of *p*-aminophenyl phenyl sulfoxide.[2]



This reaction is an example of sulfinyl migration from neutral nitrogen atom to the *para* position of the aniline ring, although the rearrangement may proceed after protonation of the nitrogen. A few reactions of sulfonyl and sulfonate migration, on the other hand, are known to proceed from the quartenary nitrogen atom. The reactions of azoxybenzene with arenesulfinyl chloride,[3] arenesulfonyl chloride,[4] and with arenesulfonic anhydride[5] are considered to proceed *via* either an intramolecular or intermolecular nucleophilic attack of sulfinate or sulfonate ion on the benzene ring to form the final products.



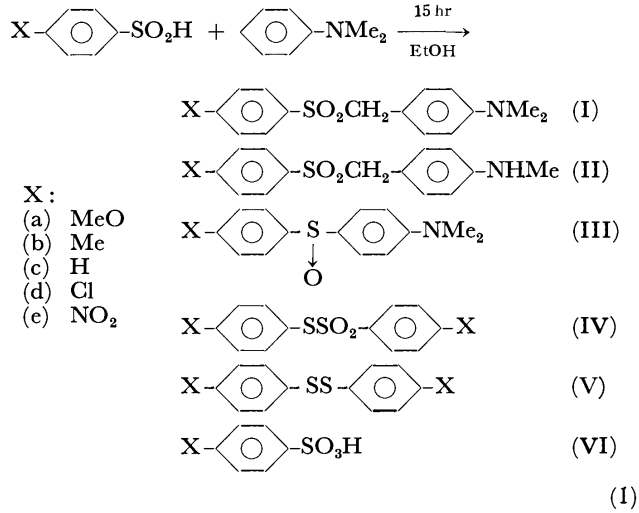
In contrast to the nucleophilic rearrangement of sulfinate or sulfonate groups, electrophilic rearrangements are well known. The rearrangement of benzenesulfinanilide to *p*-aminophenyl phenyl sulfoxide[6] and that of benzenesulfonanilide to *o*-aminophenyl phenyl sulfone[7] in concentrated sulfuric acid are considered to preceed *via* cationic rearrangement of sulfinyl or sulfonyl groups.



In order to clarify the ambiguity of the sulfinyl and sulfonyl rearrangements, we have reexamined the reaction of aniline with benzenesulfinic acid using *N,N*-dimethylaniline as a substrate. The neutral intermediate, sulfinanilide, can not be formed in this reaction as in the case of aniline. The reaction is expected to give *p*-aminophenyl phenyl sulfone by the nucleophilic attack of the sufinate on the *N,N*-dimethylanilinium ion, analogous to the reaction of azobenzene with benzenesulfinic acid to give *p*-benzenesulfonyl azobenzene.[8] However, we found that the reaction gave complex products, one of which was derived from the demethylation of the *N*-methyl group. In this paper, we deal with the reaction of *N,N*-dimethylaniline with benzenesulfinic acid, referring mainly to the intermediates of the reaction and also some other reactions with the related compounds.

Results and Discussion

N,N-Dimethylaniline was allowed to react with excess *p*-toluenesulfinic acid in refluxing ethanol for 15 hr. *p*-(*N,N*-Dimethylamino)benzyl *p*-tolyl sulfone (Ib) and *p*-(*N*-methylamino)benzyl *p*-tolyl sulfone (IIb) were found to be the major products and *p*-(*N,N*-dimethylamino)phenyl *p*-tolyl sulfoxide (IIIb) a minor product along with the disproportionation products of *p*-toluenesulfinic acid such as *p*-tolyl *p*-toluenethiolsulfonate (IVb), *p,p'*-ditolyl disulfide (Vb) and *p*-toluenesulfonic acid (VIb). Several *p*-substituted benzenesulfinic acids, allowed to react similarly, were found to give the



(I)

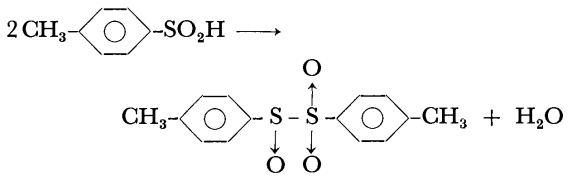
Table 1. Products of the reaction of *N,N*-dimethylaniline with excess arenesulfinic acid[a)]

X		Solvent	Yield of products (%)		
			I	II	III
a)	MeO	EtOH	32	3.4	3.6
b)	Me	EtOH	22	23	4.7
		CH_3CN	18	18	4
		Benzene	17	10	4.5
c)	H	EtOH	12	39	6
d)	Cl	EtOH	5	18	trace
e)	NO_2	EtOH	11	trace	9

a) Yields were obtained on the basis of the amount of *N,N*-dimethylaniline used.

corresponding products shown in Eq. (1). The yields except for those of the disproportionation products of the sulfinic acid are given in Table 1.

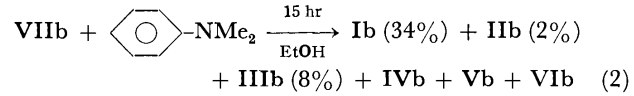
Products IV, V, and VI are considered to be formed by the disproportionation of the sulfinic acid.[9)] This was confirmed by an experiment involving the refluxing of the sulfinic acid alone in ethanol. The mechanism of the disproportionation of the sulfinic acid suggested by Kice *et al.* includes sulfinylsulfone (VII) as the intermediate[10)] which is known to be decomposed by the attack of a nucleophile.[11)]



(VIIb)

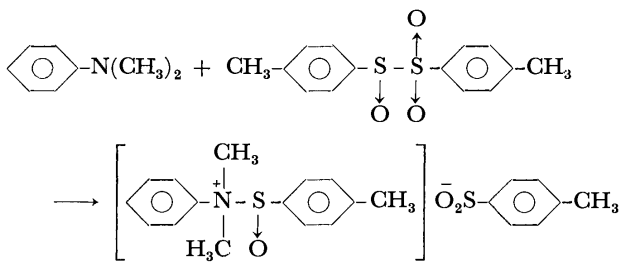
In the reaction of *N,N*-dimethylaniline with *p*-toluenesulfinic acid, the nucleophilic attack of aniline on the intermediate, VIIb is plausible.

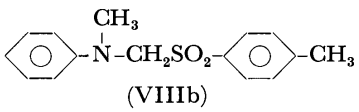
The reaction of *N,N*-dimethylaniline with an equimolar amount of *p*-tolyl *p*-toluenesulfinyl sulfone (VIIb) was carried out. As expected, *p*-(*N,N*-dimethylamino)-benzyl *p*-tolyl sulfone (Ib), *p*-(*N*-methylamino)benzyl *p*-tolyl sulfone (IIb) *p*-(*N,N*-dimethylamino)phenyl *p*-tolyl sulfoxide (IIIb) were obtained as the main products along with disproportionation products of the sulfinic acid as shown in the following.



+ IIIb (8%) + IVb + Vb + VIb (2)

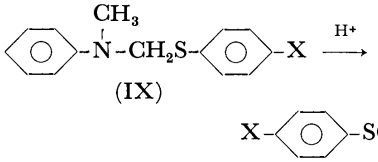
As to the mechanism of the reaction of the sulfinyl sulfone with *N,N*-dimethylaniline, the demethylation is considered to proceed through *N*-*p*-toluenesulfonyl-methyl-*N*-methylaniline (VIIIb) as an intermediate as in the case of similar Pummerer[12)] or Polonovski reactions.





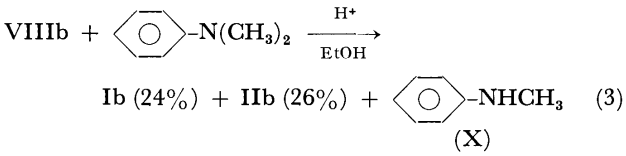
(VIIIb)

Succeeding rearrangements of VIIIb should proceed quite easily in view of the acid-catalyzed rearrangement of *N*-arenesulfenylmethyl *N*-methylaniline (IX).[13)]



(IX)

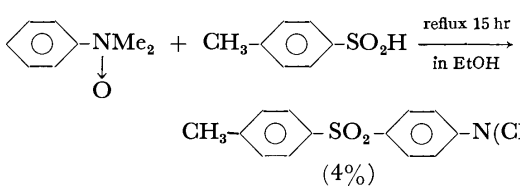
N-*p*-Toluenesulfonylmethyl-*N*-methylaniline (VIIIb) was prepared from *p*-toluenesulfinic acid, formaldehyde and *N*-methylaniline and was refluxed in ethanol with a trace amount of *p*-toluenesulfinic acid. *p*-(*N*-Methylamino)benzyl *p*-tolyl sulfone (IIb) was found as the product of the acid-catalyzed rearrangement of VIIIb. The rearrangement of VIIIb with an equimolar amount of *N,N*-dimethylaniline was found to give Ib, IIb, and *N*-methylaniline.



(X)

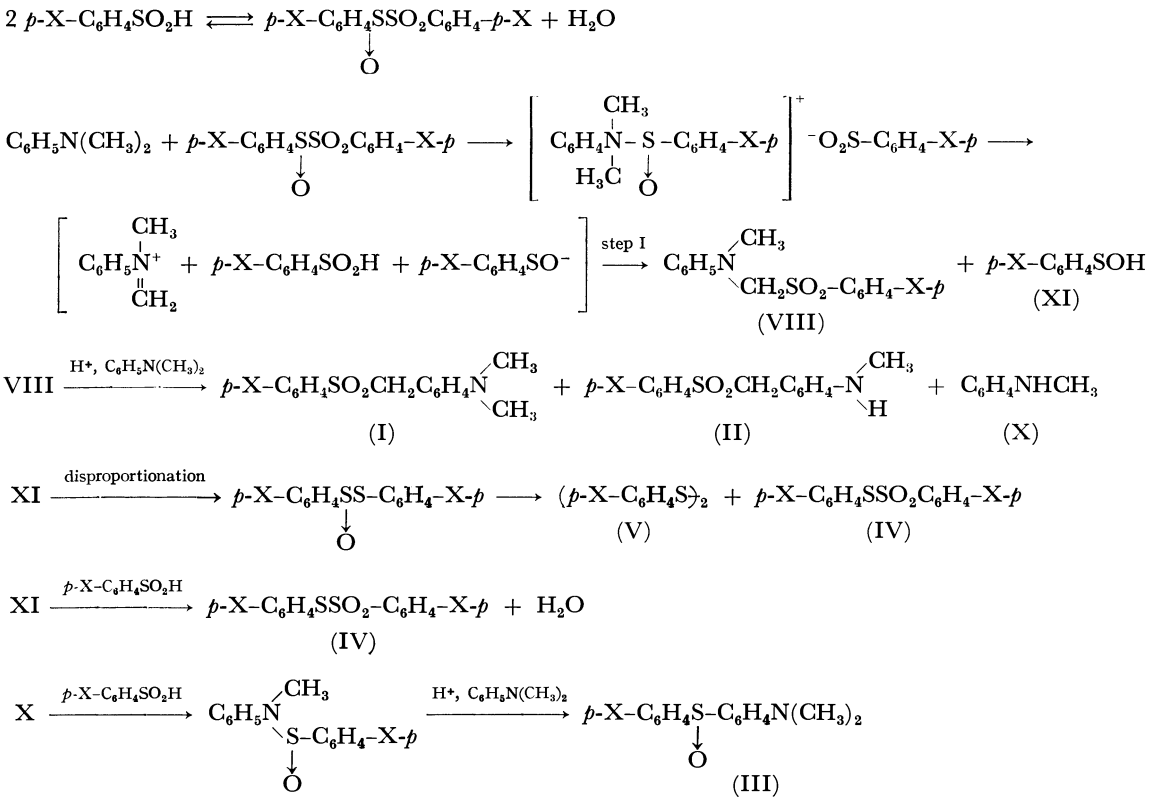
The formation of Ib and *N*-methylaniline indicates the reaction to be an intermolecular rearrangement of VIIIb to give IIb.

The overall processes of the reaction of *N,N*-dimethylaniline with arenesulfinic acid can thus be written as shown in Scheme 1. In relation to the reaction of *N,N*-dimethylaniline with *p*-toluenesulfinic acid, we examined the reaction of *N,N*-dimethylaniline *N*-oxide with *p*-toluenesulfinic acid. *p*-(*N,N*-Dimethylamino)-phenyl *p*-tolyl sulfone was isolated as follows. The sulfone is presumed to be formed *via* the Bamberger type rearrangement process.[14)]



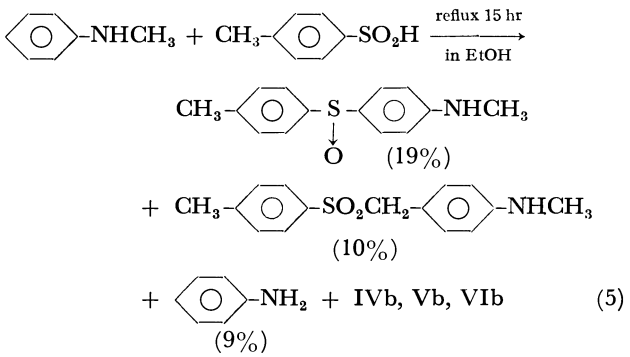
(4%)

We carried out the reaction of *N*-methylaniline with



Scheme 1.

p-toluenesulfinic acid under the same conditions and obtained *p*-(*N*-methylamino)phenyl *p*-tolyl sulfoxide and *p*-(*N*-methyl)aminobenzyl *p*-tolyl sulfone as follows.



However, *N*,*N*-dimethylbenzylamine and *N*-methylmorpholine did not undergo any demethylation reaction with arenesulfinic acid. This reaction apparently takes place only in the cases of *N*-methyl and *N*,*N*-dimethyl aromatic amines because of the formation of the stabilized anilinium ion formed in the reaction.

Experimental

Materials. *p*-Toluenesulfinic acid was prepared by the reduction of *p*-toluenesulfonyl chloride by the usual method.[15] *p*-Nitrobenzenesulfinic acid was prepared by the alkaline hydrolysis of *p*-nitrobenzenesulfinyl chloride which was synthesized by the oxidative chlorination of *p*,*p*'-dinitrodiphenyl disulfide by bubbling Cl_2 in methylene chloride.[16] Mp *p*-X-C_6H_4-SO_2H: X: OCH_3 97—98 °C, CH_3 85 °C, H 81 °C, Cl 92—93 °C, NO_2 135 °C. *p*-Tolyl *p*-toluenesulfinylsulfone was prepared from *p*-toluenesulfinyl chloride and sodium *p*-toluenesulfinate according to the process given by Bredereck *et al.*[17] *N*,*N*-Dimethylaniline *N*-oxide was prepared by the oxidation of *N*,*N*-dimethylaniline with H_2O_2.[18] *N*-*p*-Toluenesulfonylmethyl-*N*-methylaniline was prepared as follows: Formalin (1.04 g) was added to *p*-toluenesulfinic acid (2.0 g, 0.013 mol) in methanol (3 ml). An equimolar amount of *N*-methylaniline in 15 ml methanol was then added to the reaction mixture with stirring at room temperature. The white crystals precipitated were filtered off and washed with dilute Na_2CO_3. *N*-*p*-Toluenesulfonylmethyl-*N*-methylaniline was obtained. (2.7 g, mp 107—110 °C).

Reaction of N,N-*Dimethylaniline with Arenesulfinic Acid.* A typical run was carried out as follows: *N*,*N*-Dimethylaniline (0.5 g, 0.004 mol) was refluxed with *p*-toluenesulfinic acid (2 g, 0.013 mol) in absolute ethanol (1 ml) for 15 hr. After evaporation of the solvent, the residue was dissolved in $CHCl_3$ and the solution was extracted with water. *p*-Toluenesulfonic acid was obtained from the water layer. The compound was identified by comparison of the *S*-benzyl isothiouronium salt of the acid (mp 181—182 °C) with that of the authentic sample. The $CHCl_3$ layer was dried over Na_2SO_4 and chromatographed on silica gel with $CHCl_3$ as an eluent. *p*-(*N*,*N*-Dimethylamino)benzyl *p*-tolyl sulfone and *p*-(*N*-methyl)aminobenzyl *p*-tolyl sulfone were obtained. The former was identified by comparison of the physical properties with those of the authentic sample[19] and the structure of the latter was confirmed by IR, NMR, and elemental analysis. Found: C, 65.42; H, 6.22; N, 5.08%. Calcd for $C_{15}H_{17}NO_2S$: C, 65.26; H, 6.13; N, 5.01%.

p-(*N*,*N*-Dimethyl)aminophenyl *p*-tolyl sulfoxide was identified by comparison of the physical properties with those of the authentic sample prepared by the methylation of *p*-aminophenyl *p*-tolyl sulfoxide (mp 140—142 °C). Melting points of the products are given in Table 2.

Reaction of N,N-*Dimethylaniline with* p-*Tolyl* p-*Toluenesulfinyl Sulfone.* An ethanol solution of *N*,*N*-dimethylaniline

Studies on Reactions of the *N*-Phosphonium Salts of Pyridines. V. The Preparation of Carboxylic Amides and Esters by Means of the One-electron-transfer Oxidation of Phosphorous Acid and Its Esters in the Presence of Tertiary Amines

Noboru YAMAZAKI and Fukuji HIGASHI

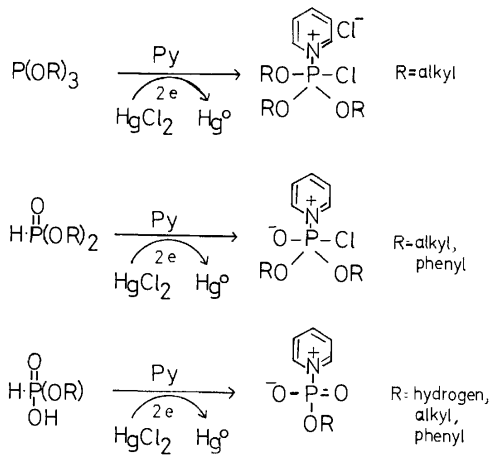
Department of Polymer Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received August 7, 1973)

The oxidation of phosphorous acid and its esters with an equimolar amount of mercurous chloride and half an equimolar amount of mercuric chloride was carried out in tertiary amines. On the treatment of the oxidation mixture with carboxylic acids, amines, and alcohols, followed by aminolysis, alcoholysis, or acidolysis, the corresponding carboxylic amides and esters were obtained in good yields, together with a nearly quantitative yield of metallic mercury. The yield was affected by the tertiary amines, the alkyl groups in the dialkyl phosphites, and the steric effect of the carboxylic acids. The reaction was proposed to proceed through the activation of carboxylic acids, amines, and alcohols *via* the *N*-phosphonium salts prepared by the oxidation. The electron-transfer processes involved in the oxidation were discussed on the basis of the yield of the amides obtained. These procedures were successfully extended to the preparation of peptides and active esters of amino acids, using diphenyl phosphite in pyridine.

In previous papers,[1-4] we showed a convenient method for the preparation of carboxylic amides and esters through the activation of carboxyl, amino, and hydroxyl groups by means of the *N*-phosphonium salts of pyridines given by the oxidation of phosphorous acid and its esters with mercuric salts in pyridines.

In these reactions, mercuric salts were used in amounts equimolar with the phosphorous compounds; the amount of liberated mercury after the reactions was nearly quantitative. Obviously, these facts show that the mercuric salts accepted two electrons from the phosphorous compounds, were changed into metallic mercury, and reversely oxidized the phosphorus(III) compounds into the phosphorus(V) compounds. Hence, the reactions can be described as the oxidation by a two-electron transfer:[1]



We have also found[5] that the oxidation products prepared from phosphorus compounds with an equimolar amount of mercurous chloride or half an equimolar amount of mercuric chloride in pyridine could cause coupling reactions between carboxylic acids and amines, and alcohols to produce the carboxylic amides and esters. It has been assumed[5] that the phosphorus (III) compounds are oxidized by an one-electron transfer to the corresponding phosphorus(IV) compounds, which then form the corresponding *N*-phosphonium salts of pyridine similar to those obtained by the two-electron-transfer oxidation

This paper will describe in detail the results of the oxidations of phosphorous acid and its esters with mercurous and mercuric chlorides in pyridines, and of application of the process to the syntheses of carboxylic amides and esters. It will also show a successful extension of this procedure to the preparation of peptides and active esters of amino acids.

Results and Discussion

Such as in the two-electron oxidation, phosphorous acid and its esters (25 mmol) was oxidized in refluxing pyridine with an equimolar amount of mercurous chloride (25 mmol) or half an equimolar amount of mercuric chloride (12.5 mmol). When the oxidation mixture (I) thus formed was treated with a carboxylic acid and then with aniline, the corresponding anilide was obtained in the yield shown in Table 1, together with a nearly quantitative yield of metallic mercury (Method A). In Method B, I was refluxed first with aniline and then acidolized with carboxylic acids.

Furthermore, the reaction of I with carboxylic acids and then with alcohols gave the corresponding carboxylic esters (Method C). The esters were also prepared by adding the two components in the reverse order, that is, by the reaction of I initially with alcohols and then with carboxylic acids (Method D). Several anilides and esters thus obtained are listed in Tables 1 and 2.

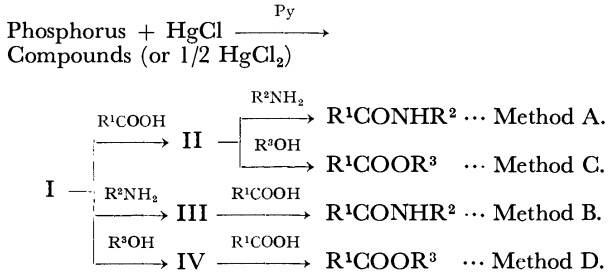


Table 1. Preparation of anilides by means of the one-electron oxidation of phosphorus compounds with mercurous and mercuric chlorides in pyridine

Phosphorus compounds	Yield of anilides obtained (%)			
	Method A		Method B	
	Acetanilide[a]	Pivalanilide	Acetanilide[a]	Pivalanilide
Phosphorous acid	79 (53)	0	61 (66)	9
Monophenyl ester	45 (51)	—	65 (61)	—
Diisopropyl ester	80 (81)	63	85 (93)	58
Triisopropyl ester	50 (48)	—	57 (58)	—

a) Values in the parentheses are those obtained by the oxidation with half an equivalent of mercuric chloride.

Table 2. Preparation of carboxylic esters by means of the one-electron oxidation of phosphorus compounds with mercurous chloride in pyridine

Phosphorus compounds	Carboxylic esters	Yield (%)	
		Method C	Method D
Phosphorous acid	Phenyl acetate	60	65
Diisopropyl ester	*n*-Butyl *n*-butyrate	59	56

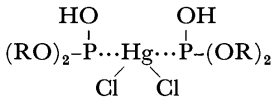
There are two possible ways of electron transfer, in principle, in the oxidation of the phosphorus(III) compounds with an equimolar amount of mercurous chloride or with half an equimolar amount of mercuric chloride. One is the one-electron-transfer oxidation of the phosphorus(III) compounds to yield the corresponding phosphorus(IV) compounds, and the other is two-electron transfer to the phosphorus(V) compounds.

The type of oxidation process involved in the oxidation of phosphorus(III) compounds was examined in terms of the yield of the acetanilide obtained (Table 1).

In the case of the oxidation of phosphorus(III) compounds with mercurous chloride, phosphorous acid and its diisopropyl ester gave acetanilide in excellent yields. The yields higher than 50% indicate that mercurous chloride can oxidize one equivalent of the phosphorus compounds by one-electron transfer to yield the corresponding active product (I), which could then condensate one equivalent of acetic acid and aniline to give the anilide in the high yields. The reactions with the monophenyl and triisopropyl esters, which gave yields of nearly 50% or more of acetanilide, possibly support the involvement of the one-electron-transfer oxidation in the reactions.

Similar situations were encountered in the oxidation with half an equivalent of mercuric chloride (Table 1). Especially, the diisopropyl ester gave acetanilide in a surprisingly high yield (93%). It is also the case with the reactions yielding carboxylic esters in yields higher than 50%.

In one-electron-transfer oxidation with mercuric chloride, the oxidation may not proceed step-by-step *via* one-electron oxidation, first with mercuric chloride and then with the resultant mercurous chloride, since mercuric chloride can undergo two-electron oxidation under these conditions. Therefore, the oxidation might take place between two moles of phosphorus(III) compounds and one mole of mercuric chloride *via* an intermediate, as is shown below;



The reaction producing amides by way of one-electron-transfer oxidation with mercurous chloride in pyridine was investigated in detail using phosphorous acid and its diesters. The reaction has been proposed[5] to proceed *via* the quaternary *N*-phosphonium salt of pyridine (I in the scheme), similar to that given by the two-electron oxidation, though the formation of quaternary phosphonium salts has been known only in the reactions of phosphorus(III) compounds with nucleophiles. If the *N*-phosphonium salt has a similar structure, the yield of anilides would be influenced by the alkyl groups of the phosphites, tertiary amines, and carboxylic acids, as in the cases of the two-electron-transfer oxidation.

Table 3. Effect of ester residues of the dialkyl and diphenyl phosphites upon the yield

Diester	Yield of acetanilide (%)
Dimethyl	33
Diethyl	75
Diisopropyl	80
Di-*n*-butyl	72
Diphenyl	79

Table 4. Effect of tertiary amines upon the yield

Tertiary amine	pK_a	Yield of acetanilide[a] (%)
Pyridine	5.23	79 (92)
3-Methylpyridine	5.52	50 (90)
2-Methylpyridine	5.97	39 (64)
4-Methylpyridine	6.02	45 (67)
2,6-Dimethylpyridine	6.99	30 (0)

a) Values in the parentheses are those obtained by two-electron oxidation[2].

The effect of alkyl groups upon the yield of acetanilide in the reactions using several dialkyl and diphenyl phosphites may be in the following order: methyl<ethyl≈*n*-butyl<isopropyl≈phenyl. This was similar to that observed in the reaction by two-electron oxidation. In addition, among the diesters of phos-

phorous acid examined, diphenyl phosphite with electron-attracting phenyl groups was found to be most effective for the reaction at low temperatures and so was used for peptide synthesis, as will be discussed below.

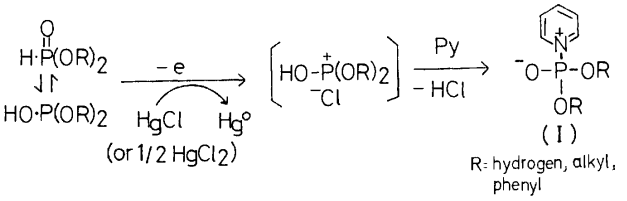
In Table 4 the effect of tertiary amines upon the reaction is compared with that in the two-electron oxidation. An increase in the basicity of amines decreases the yield of acetanilide, as in the latter case. However, the effect is not explicable only by the basicity, because a small difference in pK_a value between pyridine and other pyridine derivatives had an unexpectedly large effect upon the yield. The facts that the yield in 2-methylpyridine was nearly equal to that in 4-methylpyridine, and that even in 2,6-dimethylpyridine acetanilide was obtained in a 30% yield, suggested the presence of a slight steric effect.

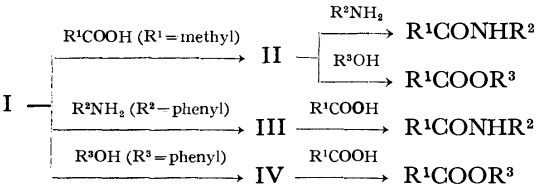
The steric effect of carboxylic acids upon the yield was reflected by the yields of pivalanilide, lower than those of acetanilide in both one- and two-electron oxidations.

The proposed reaction mechanism was investigated using diethyl phosphite, since the diester of phosphorous acid proceeded predominantly *via* one-electron-transfer oxidation, as has been discussed above. The salts, I, II, III, and IV, were separated according to previously described procedures,[1-4] though their amounts were not satisfactory.

The IR spectrum of I showed a band at 1630 cm^{-1} due to the $\nu_{C=N^+}$ of the *N*-phosphonium salts of pyridine.[1] II, III, and IV exhibited bands due to the $\nu_{C=O}$ of the acetoxy group, the $\nu_{C=C}$ of the anilino group, and the $\nu_{C=C}$ of the phenoxy group respectively, together with the band due to the $\nu_{C=N^+}$ of the *N*-phosphonium salt.

On the basis of the experimental results obtained, the reaction may be explained by assuming the initial formation of the *N*-phosphonium salt (I) by the one-electron-transfer oxidation of phosphorus compounds. Salt I reacts with carboxylic acids, amines, and alcohols to yield the corresponding products, II, III, and IV. The carboxyl, amino, and alkoxy groups carried by these products are activated enough to be converted into carboxylic amides and esters on further aminolysis, alcoholysis, and acidolysis (see the scheme).





Scheme

As has been discussed above, simple carboxylic amides and esters were synthesized by way of the one-electron-transfer oxidation of the phosphorus compounds with mercurous and mercuric chlorides in pyridines.

Then this method for the preparation of the amides and esters were applied in the syntheses of peptides and active esters of amino acids, using diphenyl phosphite in pyridine. The coupling reactions between carboxyl and amino components, and hydroxyl components were carried out at 45 °C by mixing the reactants with the oxidation product (I) obtained from diphenyl phosphite in order to prevent racemization.

Several peptides and an active ester were obtained in good yields without any detectable racemization within the limits of experimental error (see Table 5).

The presence of the free side chains of glutamic acid, glutamine, and methionine in the carboxyl component, and of tyrosine in the amino component, did not cause any difficulties in the reactions as have been observed in two-electron oxidation.[3] In the case of glutamic acid, the α-carboxyl group was activated in preference to the γ-carboxyl group, yielding the α-peptide in a good yield. Similarly, a peptide of glutamine was obtained without any accompanying side reactions such

Table 5. Preparation of peptides and an active ester by means of the oxidation of diphenyl phosphite with mercurous chloride in pyridine

a) Half an equivalent of mercuric chloride was used in the place of mercurous chloride.

as nitrile formation. In the reaction of ethyl tyrosinate, with both amino and hydroxyl groups, the amino group was preferably activated to produce the corresponding amide with the glycine.

Experimental

The salts (I, II, III, and IV), carboxylic amides and esters, peptides, and active esters were prepared according to previously reported procedures,[1-4] except for the use of one equivalent of mercurous chloride and half an equivalent of mercuric chloride in the place of one equivalent of mercuric chloride.

Kinetics of the Autoxidation of Substituted Anthranols to Anthraquinones in Buffered Aqueous Dioxane[1]

Yoshiro OGATA, Kazuo NATE, and Mitsuji YAMASHITA

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received March 2, 1973)

Autoxidation of 2-substituted anthranols to the corresponding anthraquinones in alkaline buffered aqueous dioxane (2:1 in vol) has been studied kinetically at 35 °C by means of the manometric method. The relative rate constants for the autoxidation of anthranyl oxide ions have been evaluated, in which dissociation of anthrones is taken into account. Application of substituent effect on the one-electron transfer to the oxide ion to the Hammett equation gives an average ρ-value of -1.5, which was little influenced by pH of the solution.

Anthrone is a tautometric compound which exists in most solvents predominantly in a keto form at room temperature, but the equilibrium is shifted much to the enol form at high pH.[2]

Anthranol is easily oxidized to anthraquinone by molecular oxygen in alkaline solutions. In a previous paper,[3] it was reported that the autoxidation rate of anthranol in alkaline buffered aqueous dioxane is expressed as: $v=k[\text{Anthrone}]_T[OH^-]_p$, where p is the partial pressure of oxygen and [ ]$_T$ the stoichiometric concentration. The results suggest a mechanism involving a rate-determining attack to form anthranyl oxide radical, which is rapidly oxidized to give anthraquinone.

The present study was undertaken to obtain further information on the mechanism of reaction, especially with respect to the substituent effect on anthranols. The experiments were carried out in alkaline buffered dioxane–water (2:1 in vol) under the conditions where anthraquinone was the only organic products; the product was confirmed by tlc (See Experimental).

Experimental

Materials. Purification of dioxane and preparation of anthrone were described previously.[3] 2-Methylanthrone[4] was prepared by the Friedel-Crafts condensation of phthalic anhydride and toluene followed by the reduction of formed 2-(4-methylbenzoyl)benzoic acid with zinc and ammonia and then cyclization of 4-methyldiphenylmethane-2′-carboxylic acid with concentrated H_2SO_4. Recrystallization from a mixture of benzene and petroleum ether (3:1 in vol) gave crystals of mp 98.5—99.5 °C (lit,[4] 99.5—100 °C). λ_{max} (log ε) 263 mμ (4.24).

2-Chloroanthrone,[5] 2-methoxyanthrone,[6] and 2-bromoanthrone[4] were prepared similarly by the reaction of 4-chloro, 4-methoxy, and 4-bromodiphenylmethane-2′-carboxylic acid with concentrated H_2SO_4, respectively, and then purified. 2-Chloroanthrone; mp 152—153 °C (lit,[5] mp 155 °C), λ_{max} (log ε) 264 mμ (4.23). 2-Methoxyanthrone; mp 92—93 °C (lit,[6] mp 94—95 °C), λ_{max} (log ε) 267 mμ (4.23). 2-Bromoanthrone; mp 157—158 °C (lit,[4] mp 160 °C), λ_{max} (log ε) 268 mμ (4.27).

2-Substituted anthraquinones[7] were prepared by the cyclization of 2-(4-substituted benzoyl)benzoic acids with fuming H_2SO_4 and recrystallized from ethanol. 2-Methylanthraquinone; mp 178 °C (lit,[5] mp 177—178 °C), λ_{max} (log ε) 255 mμ (4.68). 2-Chloroanthraquinone; mp 214 °C (lit,[8] mp 210 °C), λ_{max} (log ε) 256 mμ (4.67). 2-Methoxyanthraquinone; mp 194—196 °C (lit, mp 194.5 °C,[9a] 196 °C,[9b] 195—197 °C[9c]). 2-Bromoanthraquinone; mp 210—211 °C (lit,[10] mp 205—207 °C). Inorganic reagents were of commercial guaranteed grade.

Kinetic Procedure. The kinetic experiments were carried out by the manometric method.[11]

Reaction Products. The main products of autoxidation of anthranols under kinetic conditions were the corresponding anthraquinones, which were confirmed by tlc and melting points. Chloroform was used as an eluent for the tlc analysis with silica gel.

Hydroxylation of Nitrobenzene During Autoxidation of Anthranol. Nitrobenzene (1 g) was added to a solution of anthranol (10 g) which was treated under the same conditions as those for autoxidation. The resulting nitrophenols were identified and estimated by means of glc employing a Yanagimoto Model GCG 550F gas chromatograph with a flame ionization detector operated with a column of 15% Apiezone L grease using N_2 (15 ml/min) as a carrier with programming attachment (60—180 °C) and H_2 in a flow rate of 30 ml/min. Retention times were as follows: *o*-nitrophenol, 12 min; *m*-isomer, 19.3 min; *p*-isomer, 20.3 min. Authentic nitrophenols were used as reference compounds.

Spectroscopy. UV spectra were measured with an automatic recording spectrophotometer (Shimadzu SV-50A) equipped with quartz cells (light path of 10 mm). NMR spectra were measured with a Japan Electron Optics Laboratory NMR spectrometer C-60HL.

Determination of Dissociation Constant of Anthrones. The pK_a values of anthrones were measured by UV spectrophotometry in water at 25 °C using a H_3BO_3–KCl buffer solution. Determination of pK_a values in aqueous dioxane was unsuccessful, since the pH-meter was not stabilized in the solvent.

Keto-enol Equilibrium Constants. The anthrones–anthranols equilibrium constants were determined by means of NMR spectrometry in $CDCl_3$ at 35 °C,[12] and by iodometry[13,14] of anthranols in dioxane–water (2:1 in vol) according to Bansho *et al.* in the absence of oxygen.[15]

Results and Discussion

Effect of Substituent in Anthranol. The present reaction is of first-order in anthranols with large excess of oxygen and was carried out under vigorous stirring sufficient to avoid the rate-determining dissolution of gaseous oxygen. The observed pseudo-first-order rate constants at various pH were shown in Table 1, where [ ]$_0$ denotes the initial concentration. The k_{obsd} value varies little with different substituent, because it involves equilibrium and rate constants which are affected reversely by a substituent.

Effect of Acidity. The rates were measured at various pH values using H_3BO_3–KCl–NaOH buffer

Table 1. Effect of substituents on the rate of autoxidation of anthranols in $NaOH-H_3BO_3$ KCl buffered aqueous dioxane

Substituent in anthranol	$10^4 k_{obs}$ (s^{-1})			
	pH 10.31	pH 10.78	pH 11.20	pH 11.80
2-CH_3	0.690	2.74	7.64	14.3
H	1.01	3.18	11.7	17.8
2-CH_3O	0.725	2.69	8.95	15.9
2-Cl	0.644	2.26	7.67	14.0
2-Br	0.655	—	6.15	11.7

Initial concentration of anthranols: 1.4×10^{-2} M. Partial pressure of oxygen 600 mmHg at 35 °C.

solutions. A plot of pH *vs.* log k_{obsd} is shown in Fig. 1. where k_{obsd} is a pseudo-first-order rate constant.

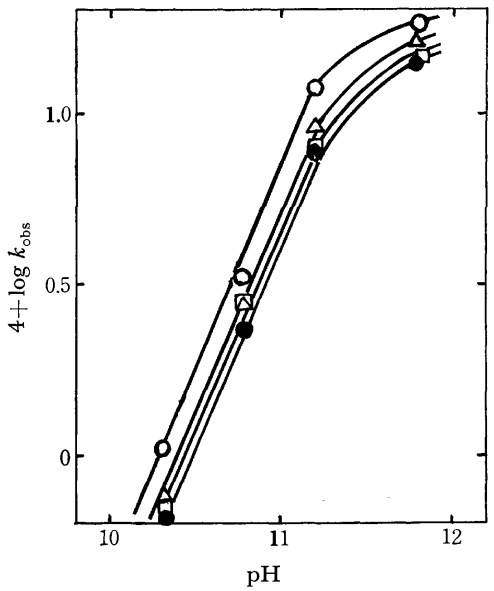

Fig. 1. Effect of pH of solution on the first-order rate constants for the autoxidation of anthranols in dioxane–water (2: 1) in Vol. at 35 °C.
○: H, □: 2-CH_3, △: 2-CH_3O, ●: 2-Cl

We see that straight lines with a slope of nearly unity were obtained at lower pH (pH<11.2), the lines tending to curve slightly at higher pH. This may be explained by the dissociation of anthranol to anthranyl oxide ion.

The pK_a values of anthranols were measured in water. In general, the strengths of acidity and basicity of the weak electrolytes are weakened in going from an aqueous solution to aquo-organic solutions. Hence, the observed pK_a values in the reaction solvent may be a little higher than those in water, and enable us to calculate the extent of ionization of anthranols at the respective pH values. For example, the ionization is over 90% complete when the difference of pH and pK_a is *ca.* unity.

The slope of the lines above pH 12 is much lower than unity (Fig. 1). Thus the dissociation of anthranols to the anions might be almost complete above this pH,

Dissociation Constant of Anthrones. The pK_a values of substituted anthrones containing anthranols were measured by UV spectrophotometry in water at 25 °C. Determination of pK_a values in dioxane–water was unsuccessful, since a pH meter was not stabilized in the aquo-organic solutions. The results are given in Table 2.

Table 2. Equilibrium constants for the dissociation of anthrones in water at 25 °C

Substituent in anthrone	$K_a\times10^{11}$	pK_a
2-CH_3	2.58	10.59
H	5.51	10.26
2-CH_3O	9.14	10.04
2-Cl	13.5	9.87
2-Br	10.7	9.97

A plot of log (K_a^x/K_a^H) *vs.* σ (Hammett's *meta*-value), where K_a^H and K_a^x denote the dissociation constants of unsubstituted and substituted 9-anthrones, respectively, gives an approximate ρ-value of 1.20 (r, 0.885), although the deviation is large. If the *para* σ values are used, the Hammett plot is less satisfactory ($\rho=0.730$, $r=0.578$). The reported ρ value for the dissociation constants of phenols is 2.091.[16]

Keto-Enol Equilibrium. The keto-enol equilibrium constants of anthrones–anthranols could be determined by NMR in $CDCl_3$.[12] However, they could not be determined in aqueous dioxane because of low solubility and the overlap of the peak of enolic proton with that of solvent. Thus, the equilibrium constants in dioxane–water (2: 1 in vol) were measured by iodometry[13,14] of anthranols in a similar way to that of Bansho *et al.*[15] The results are shown in Table 3.

Table 3. Keto-enol equilibrium constants for the reaction of Eq. (1) in dioxane–water (2: 1 in vol) at 35 °C

Substituent in anthranol	2-CH_3	H	2-CH_3O	2-Cl
K_1	0.0988	0.080	0.120	0.227

Effect of Temperature. The first-order rate constants were measured at 25, 35, and 45 °C. The Arrhenius plots giving energies and entropies of activation are given in Table 4.

In general, one-electron transfer reactions have low energy of activation and large negative entropy of

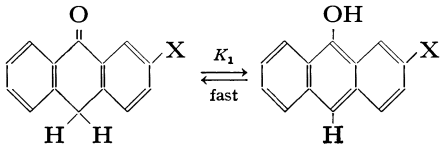
Table 4. Apparent energies and entropies of activation for the autoxidation of anthranols

Substituent in anthranol	$10^4 k_{obs}$ (s^{-1})			E_a (kcal mol^{-1})	$\Delta S^{\neq}$ at 35 °C (e.u.)
	25 °C	35 °C	45 °C		
2-CH_3	6.31	7.64	9.09	3.52	−63.6
H	10.2	11.7	14.0	2.86	−64.7
2-Cl	6.65	7.67	8.72	2.44	−67.1

Initial concentration of anthranols: 1.4×10^{-2} M. Partail pressure of oxygen: 600 mmHg at pH 11.2.

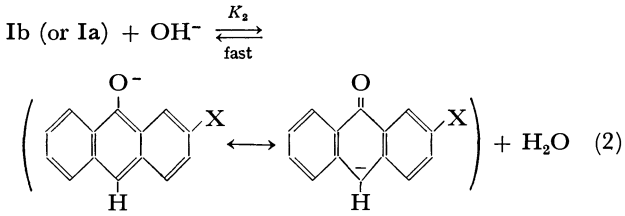
activation.[3,17] This was observed in the present case.

Mechanism. Our data support the following mechanism for the initial steps of autoxidation of substituted anthranols.[3]



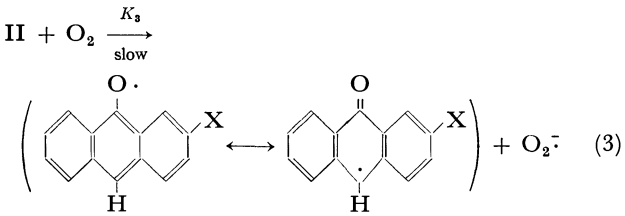
(1)

(Ia) (Ib)



(2)

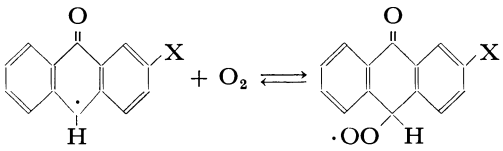
(II)



(3)

(III)

The formed anthranyl oxide radical (III) resonates as shown in Eq. (3), leading to the rapid reaction with molecular oxygen to form peroxy radical (IV).

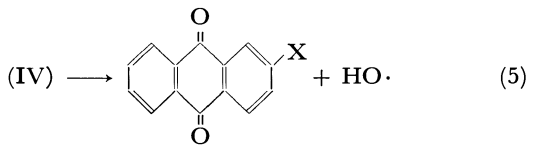


(4)

(III) (IV)

The reactions of carbanions with molecular oxygen to form peroxy radical as an initial step for the autoxilddation were reported.[17,18]

The peroxy radical may be rapidly converted into anthraquinone by expelling the hydroxy radical, which may couple to form hydrogen peroxide.



(5)

(V)

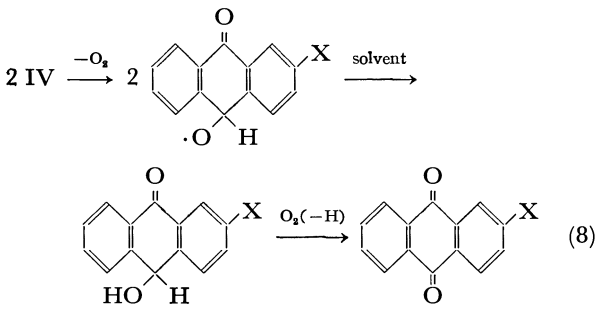
$$2HO\cdot \longrightarrow H_2O_2 \qquad (6)$$

Radical HO· may abstract a hydrogen atom from the solvent, but no product derived from the solvent radical could be detected, the chain length of the reaction being very short. Thus the main reaction seems to be the coupling of highly reactive HO· radicals (Eq. (6)).

The formation of H_2O_2 by a bimolecular reaction of IV

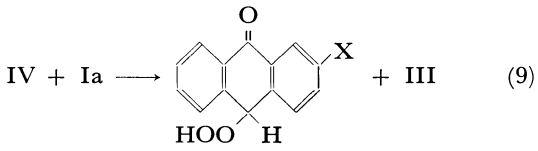
$$2\,IV \longrightarrow 2\,V + H_2O_2 \qquad (7)$$

is also conceivable, but the low concentration of IV and the high stability of anthraquinone make Eq. (5) preferable to Eq. (7) as in the case of the conversion of the cyclohexylperoxy radical into cyclohexanone. Another bimolecular reaction of IV, as in the case of the *t*-butylperoxy radical, leading to anthraquinone *via* 10-hydroxy-9-anthrone is less probable because of the necessity of many steps, *i.e.*, three hydrogen abstractions and two electron transfers to molecular oxygen.



(8)

Alternatively, radical IV may abstract a hydrogen atom from the substrate followed by the dehydration of 10-hydroperoxy-9-anthrone (VI), affording anthraquinone[19] as follows.



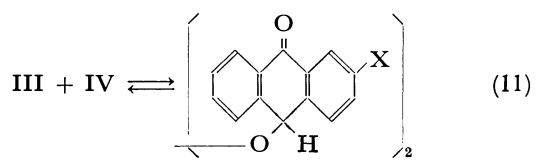
(9)

(VI)

$$VI \longrightarrow V + H_2O \qquad (10)$$

Although hydroperoxide VI was said to be prepared in the case of autoxidation of 10-phenylanthranol and even unsubstituted 9-anthranol,[20] our attempt to prepare VI under the reported conditions gave anthraquinone as the only isolable product. The crude product contained only a few percent peroxidic oxygen, which was detectable by iodometry. Radical initiators and metallic ions had no appreciable influence on the rate and no induction period was observed. Hence, the autoxidation seems to have no radical chain. In view of these facts, the chain mechanism involving Eqs. (4) and (9) is less probable. Hydroperoxide VI, if formed, should decompose rapidly *via* elimination of H_2O, which is unimportant.

Radical III in Eq. (3) might be consumed rapidly to react with peroxy radical IV.



(11)

(VII)

Scheme 11 is unfavorble, since no organic peroxide is detectable in the products and a large steric interaction is expected in peroxide VII.

Equation (5) indicates an intramolecular abstraction of a hydrogen atom by peroxy radicals (IV) to give anthraquinone and a hydroxy radical. Although the hydroxy radical is an energy-rich species, the reaction may occur fairly easily in view of the large heat of formation giving stable anthraquinone; this seems to

act as a driving force to accelerate the reaction.

It has been observed that nitrobenzene is hydroxylated at room temperature by a hydroxy radical produced by a mixture of H_2O_2–Fe(II) (Fenton's reagent).[21] This hydroxylation of nitrobenzene occurs during the autoxidation of anthranol, which supports the presence of hydroxy radical produced by Eq. (5), *i.e.*, glc analysis confirms that *o*-, *m*-, and *p*-nitrophenols were formed in the ratio 30: 35: 35. On the other hand, no nitrophenol was detected on addition of nitrobenzene to the autoxidation mixture of hydroquinone or pyrogallol, where $O_2^{\cdot-}$ and H_2O_2 are formed but no HO· radical.

Radical ion, $O_2^{\cdot-}$, formed in Eq. (3) is easily protonated in an aqueous solution to give hydroperoxy radical, HO_2·, which can then be converted into hydrogen peroxide[11] (Eq. (13)), and/or reacts with anthranol anion (II) (Eq. (14)).

$$O_2^{\cdot-} + H_2O \longrightarrow HO_2\cdot + OH^- \quad (12)$$

$$2HO_2\cdot \longrightarrow H_2O_2 + O_2 \quad (13)$$

$$HO_2\cdot + II \longrightarrow III + HO_2^- \quad (14)$$

The observed concentration of hydrogen peroxide (*ca.* 1—1/5) is less than that expected from the stoichiometry of Eqs. (5) and (6) at partial pressure of oxygen p of 113—620 mmHg and at pH of 10.41—11.60.[2] The change of concentration of hydrogen peroxide in the presence of anthranol in a dioxane–water (2: 1 in vol) buffer at 35 °C under nitrogen (spontaneous decomposition of H_2O_2) was negligible, while that under oxygen at higher pH (11.80), *ca.* 35% increase of the concentration of H_2O_2 after 15 min was observed.

The rate can be determined by Eq. (3) and expressed by the following equation, where p is the partial pressure of oxygen.

$$V = k_3[II]p \quad (15)$$

The measured dissociation constant, K_a, is equal to $[II][H_2O]/([I_a]+[I_b])\times[OH^-]$ or $[II][H_2O]/[I]\text{-}[OH^-]$, where $[I]=[I_a]+[I_b]$; the mechanism leads to the rate law:

$$v = k_3K_a[I]_T p \Big/ \left(\frac{[H_2O]}{K_a[OH^-]}+1\right)$$

$$= \frac{k_3K_a[I]_T[OH^-]p}{K_a[OH^-]+[H_2O]}$$

where $[\ \ ]_T$ denotes stoichiometric (total) concentration. The equation agrees with our results at pH 10.31—11.80 (Table 1).

Our estimation of the K_a value enables us to evaluate the rate constant k_3 for Eq. (3), *i.e.*, one-electron transfer to oxygen molecule from anthranyl oxide ion. The results for substituted anthrones are shown in Fig. 2 and Table 5. Application of the k_3 values for substituted anthranols to the Hammett equation using *meta* σ values gave a rough estimate of ρ-value of -1.5, which was little influenced by pH of the reaction medium (Table 5). The use of *para* σ value gave a poorer Hammett plot.

The one-electron transfer is accelerated by the introduction of electron-releasing groups. In the application of the Hammett rule to radical reactions, which were first attempted by Walling[22] and Swain[23] and reviewed by Otsu *et al.*,[24] fairly large negative ρ-values are sometimes reported in cases such as the reaction of peroxy radicals with phenols, -3.7,[25] autoxidation of phenylhydrazones, -1.7,[26] and autoxidation of phenylhydroxylamines, -1.6.[27] The effect of substituents for reduction of anthraquinones[28] was reported to afford a positive ρ-value of 1.11, which is convincing in view of the reverse of the present reaction (one-electron donation to quinones).

The present autoxidation of anthranols giving a ρ-value of -1.5 supports the mechanism which involves a rate-determining attack of molecular oxygen on anthranyl oxide ion to form anthranyl oxide radical by the one-electron abstraction from anthranyl oxide ion.

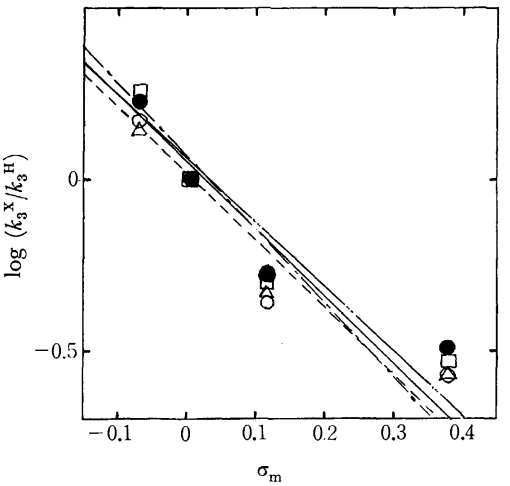


Fig. 2. Plots of σ_m (Hammett) *vs.* log (k_3^X/k_3^H) for the autoxidation of anthranols in alkaline buffered aqueous dioxane at p of 600 mmHg at 35 °C: —○—, pH 10.31; --×--, pH 10.78; -•-△-•-, pH 11.20; and -•••●-•••-, pH 11.80.

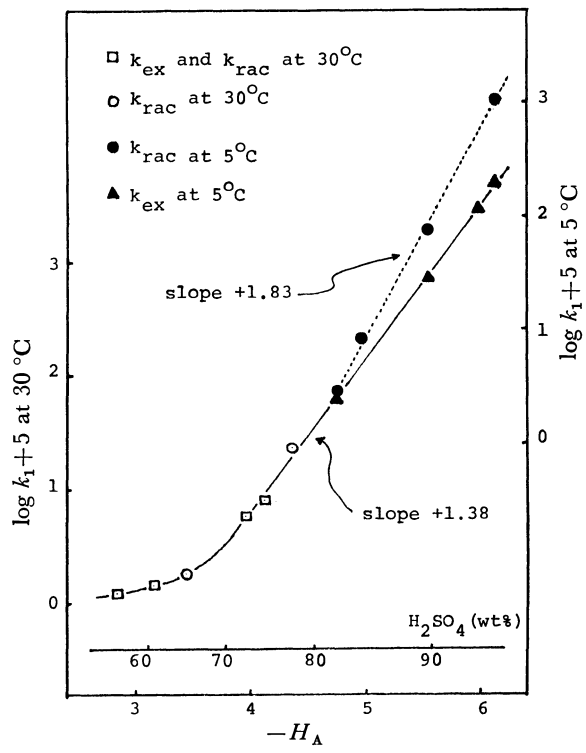

Fig. 1. Correlation between rate constant and acidity function H_A.

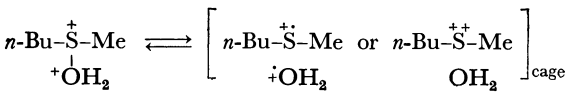
that the reaction is of the A-1-like mechanism according to the Zucker-Hammett hypothesis.[19] The energy and entropy of activation for the racemization in 82% acid are found to be 21.8 kcal/mol and −2.68 e.u., respectively (Table 2). The small negative value of entropy of activation also favors the rate-determining A-1-like S–O bond cleavage of sulfoxide.

TABLE 2. ACTIVATION PARAMETERS FOR RACEMIZATION OF (+)-*n*-BUTYL METHYL SULFOXIDE (**1**) IN SULFURIC ACID

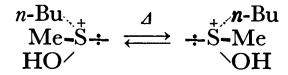
H_2SO_4 (wt%)	E_a (kcal/mol)	$\Delta S^{\neq}$ (e.u.)
89.7	17.3	−13.8
82.0	21.8	− 2.68
65.6	21.4	−11.7
56.1	16.7	−28.0

However, above 85% sulfuric acid, the racemization would be caused by both an A-1-like reaction and some other reaction without oxygen exchange. The following possibilities are considered for the racemization without oxygen exchange: 1) formation of an intimate ion pair produced by S–O bond fission of protonated sulfoxide followed by a fast internal return in solvent cage to afford the racemized sulfoxide; 2) a thermal racemization of protonated sulfoxide caused by a pyramidal inversion process; 3) a fast equilibrium of protonated sulfoxide and the corresponding ylide produced by abstraction of α-hydrogen of the protonated sulfoxide.

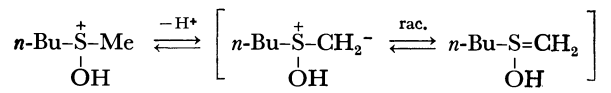
(1) Intimate ion-pair in solvent cage



(2) Pyramidal inversion



(3) Ylide-ylene intermediate



However, since the rate of racemization is so fast in concentrated sulfuric acid of around 95%, in which racemization without oxygen exchange takes place almost predominantly, its mechanism can not be visualized on the basis of kinetic observation alone.

The third possibility may be readily tested by using α-deuterium labeled sulfoxide. When *n*-butyl trideuteriomethyl sulfoxide (**1**—d_3) was dissolved in an excess non-labeled sulfuric acid, no detectable amount of H–D exchange was observed under both normal and drastic reaction conditions (See Experimental). It can thus be ruled out.

It is well known that a pyramidal inversion of an optically active trialkyl substituted sulfonium salt takes place slowly only on being heated around 50 °C,[20-22] while there is no thermal racemization without any oxygen exchange reaction of sulfoxides for both alkyl aryl and diaryl sulfoxides in the concentrated sulfuric acid.[10-12] Therefore the second possibility would not be significant.

Thus, the first possibility seems to be most favorable in view of the fact[23] that a highly concentrated sulfuric acid should have a larger solvent cage effect, because of the higher viscosity and a lower nucleophilicity of water molecules.

In order to clarify the mechanism, we have analyzed the data on the basis of the Φ parameter.[24] This is taken from the slope of the plots of log $[k_1+H_0]$ *vs.* $[H_0+\log[H^+]]$ and is an indication of the change in solvation from the initial to the transition states; namely, if Φ value is larger than 0.58, water is involved as a proton transfer agent in the rate-determining step; in the Φ range 0.22—0.56, water is involved as a nucleophile in the rate-determining step; while if the Φ value is smaller than zero, water is not involved in the rate-determining step.

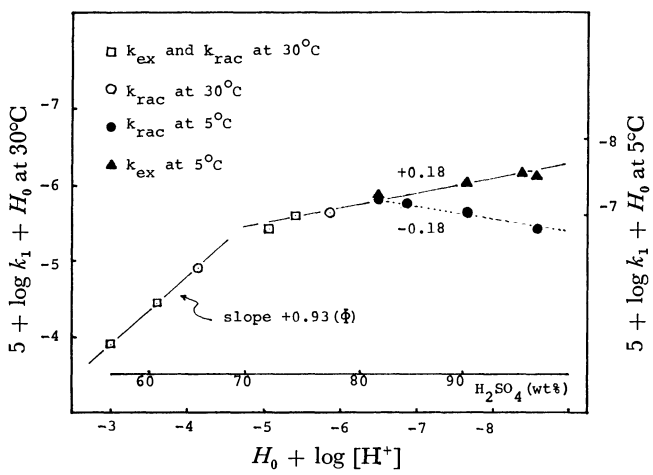


Fig. 2. Bunnett-Olsen plot of rate constant.

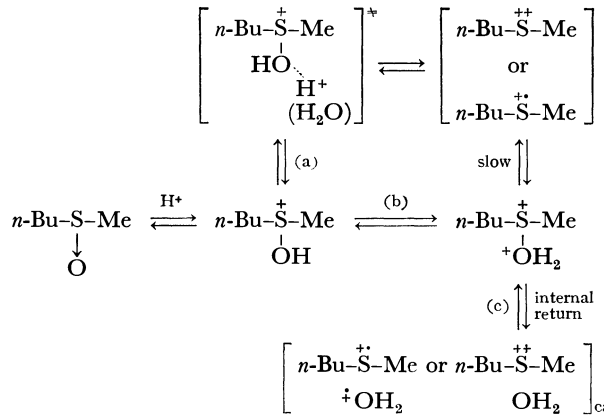
The plot, in which straight lines with slopes (Φ values) of +0.93 and +0.18 were obtained for below 70% and above 70% sulfuric acids, respectively, is shown in Fig. 2.

Thus, the oxygen exchange reaction below 70% sulfuric acid would proceed through the rate-determining A-1-like S–O bond cleavage in which water is involved as a proton transfer agent and the solvation in the transition state is markedly high from the data of Φ value. The unity of k_{ex}/k_{rac} and a large negative activation entropy ($\Delta S^{\neq} = -28.0$ e.u.) for racemization in 56.8% sulfuric acid also supported this (Tables 1 and 2). A similar mechanism was proposed in the A-1-like oxygen exchange reaction of sulfoxide with acetic acid and chloroacetic acids,[5] in which acetic acid acts as an acid-catalyst and the solvation is remarkably high at the transition state ($k_{ex}/k_{rac} = 1.01$, $\Delta S^{\neq} = -23.4 \sim -32.9$ e.u.).

An overall scheme for the oxygen exchange and racemization of *n*-butyl methyl sulfoxide (**1**) might be schematically drawn as shown below.



The reaction seems to proceed through path (a) below 70% acid, path (b) above 70% acid and paths (b) and (c) above 85% acid to afford the symmetrical dication ($-\overset{++}{S}-$) or cation radical ($-\overset{+\cdot}{S}-$) intermediate, while the subsequent attack of water should be very fast.

The labile symmetrical intermediate should be detected by the following ^{18}O tracer experiment by quenching the solution of the non-labeled sulfoxide with ^{18}O-enriched water. A small amount of incorporation of ^{18}O into the sulfinyl function of the recovered sulfoxide was observed by quenching the non-labeled sulfuric acid solution containing non-labeled sulfoxide (**1**) with a large amount of cold ^{18}O-labeled water (See Experimental).

Experimental

Materials. *Optically Active (+)n-Butyl Methyl Sulfoxide*, **(+)-1**, was prepared from the reaction of (−)menthyl (−)*n*-butanesulfinate with methylmagnesium iodide in ether according to the method of Andersen.[25] The optically active sulfoxide thus obtained was purified by the method of Mislow *et al.*[26] $[\alpha]_D$ +33.0° (*c* 1.20, $CHCl_3$) (lit,[27] +112° (*c* 1.02, isooctane, 94% optically pure)).

^{18}O-Labeled n-Butyl Methyl Sulfoxide, **1**, was prepared by the oxidation of *n*-butyl methyl sulfide with bromine in the presence of pyridine in acetic acid and $H_2{}^{18}O$, according to the usual procedure.[28] ^{18}O-Content was 1.70 atom %.

n-Butyl Trideuteriomethyl Sulfoxide, **1-d_3**, was prepared by treating *n*-butyl methyl sulfoxide with NaOD–D_2O at 60 °C for 14 hr. The deuterium content was determined by NMR measurement and the D content was found to be above 95%.

Sulfuric Acid. Concentrations of sulfuric acid were determined by titration with a standard alkali solution. H_A values are taken from reported tables[17,18] and H_0 values from the table prepared by Johnson *et al.*[16]

Test for H–D Exchange of Sulfoxide, **1-d_3**, *with Sulfuric Acid.* Deuterium labeled sulfoxide, **1-d_3**, (*ca.* 50 mg) was dissolved in 0.5 ml sulfuric acid and the sulfuric acid solution was introduced into an NMR tube. After being kept standing under three different conditions, *i.e.*, i) 92% sulfuric acid at room temperature for 240 hr; ii) 72.3% acid at room temperature for 50 hr; iii) 56.1% acid at 50 °C for 58 hr, ^1H-NMR spectra of the sulfoxide solution were measured. However, no detectable peak of methyl proton (CH_3SO; 3.3 ppm) appeared.

Trapping of the Dication or Cation Radical Intermediate by Quenching with $H_2{}^{18}O$. Non-labeled sulfoxide (**1**) was dissolved in non-labeled sulfuric acid and kept standing under appropriate conditions and then the sulfuric acid solution was quenched with a large excess of cold $H_2{}^{18}O$. The sulfoxide was recovered according to the procedure described below, and subjected to ^{18}O-analysis. The result is given in Table 3.

Table 3. ^{18}O-Contents of sulfoxide (**1**) recovered by quenching with $H_2{}^{18}O$ [a,b]

H_2SO_4 (wt%)	Time (hr)	Temperature (°C)	^{18}O-Content (atom%)[c]
56.1	24	30	0.204
72.3	1.5	30	0.214
96.8	0.7	25	0.244

a) Sulfoxide: 0.1 mol/l.
b) ^{18}O-Content of water used is 1.67 atom%.
c) Natural abundance: 0.204, accuracy of analysis of mass spectrum: ±0.005 atom%.

Kinetic Procedure. The rates of oxygen exchange and racemization were measured by the following two methods with a Yanagimoto OR-10 type polarimeter and a Hitachi RMU-6E mass spectrometer.

Method A (for Both Oxygen Exchange and Racemization). In order to compare the rate constants, both oxygen exchange and racemization reactions were carried out under identical conditions. An ^{18}O-labeled or optically active sulfoxide was dissolved in a sulfuric acid in such a way as to maintain the concentration of the sulfoxide at just about 0.1 mol/l at a given temperature. Five aliquot portions of the solution were removed from the constant temperature bath at appropriate time intervals and quenched with a large amount of ice-water. The sulfoxide was extracted from the solution with chloroform or dichloromethane by the salting-out technique, and the extract was washed with a 5% aqueous solution of sodium carbonate and water containing salt, and then dried over anhydrous sodium sulfate after which the solvent was distilled off. The resulting sulfoxide was subjected to both ^{18}O-analysis and specific rotation measurement. The ^{18}O-atom % was calculated from the mass peak heights of 44 and 46 according to the method of Samuel.[29]

Method B (for Racemization). A sulfuric acid solution containing an optically active sulfoxide of a set mol was placed in a square cell (5 cm). The rate was measured directly by checking the rotation α of the polarimeter, which

was connected with a constant temperature bath at the desired temperature.

Calculation of Pseudo first-order Rate Constant. For racemization, $\log[\alpha_0]-\log[\alpha_t]=kt/2.303$, where α_0 and α_t are the rotations at times 0 and t, respectively; and for oxygen exchange, $\log[\beta_0-\beta]-\log[\beta_t-\beta]=kt/2.303$, where β_0 and β_t are the atom% of ^{18}O at times 0 and t, respectively, and β is that of natural CO_2.

The Heck Reaction of 2-Vinylpyridine

Akira KASAHARA, Taeko IZUMI, Toru TAKEDA, and Hayao IMAMURA*

Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa, Yamagata 992
**Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152*

(Received August 6, 1973)

In the presence of lithium chloropalladite, 2-vinylpyridine reacted with phenylmercuric chloride to give di-μ-chloro-bis[2-phenyl-2-(α-pyridyl)ethyl]dipalladium(II). Similar complexes were obtained from *p*-tolyl-, *p*-anisyl-, or *m*-nitrophenylmercuric chloride. The σ-bonded structures of these complexes have been confirmed by a study of their absorption and of the NMR spectra.

We wish to report that 2-vinylpyridine (**1**) reacted with arylmercuric chloride in the presence of lithium chloropalladite(II) to give complexes (**2**) containing both a carbon-palladium σ-bond and an aryl group.

Experimental

Materials. All the melting points are uncorrected. The arylmercuric chlorides were prepared by the methods described in the literature: *p*-tolylmercuric chloride,[1] mp 232—233 °C; *p*-anisylmercuric chloride,[2] mp 173—174 °C; *m*-nitrophenylmercuric chloride,[3] mp 218—221 °C. Phenylmercuric chloride (mp 250—251 °C) was obtained from the commercially available phenylmercuric acetate by treating with alcoholic lithium chloride.

*The General Procedure for the Preparation of Di-μ-chloro-bis-[2-aryl-2-(α-pyridyl)ethyl]dipalladium(II) (**2a—d**).* A lithium chloropalladite solution was prepared by stirring 0.42 g (10 mmol) of anhydrous lithium chloride and 1.77 g (10 mmol) of anhydrous palladium chloride overnight at room temperature in 100 ml of acetonitrile. Into the lithium chloropalladite solution, arylmercuric chloride (10 mmol) was then stirred at room temperature for five minutes, after which 1.26 g (12 mmol) of **1** was added in one portion. After the mixture had then been stirred at room temperature for 6 hr, the product was isolated by filtration to remove a precipitated palladium and by distillation under reduced pressure to remove the solvent. The residue was dissolved in chloroform and chromatographed on neutral alumina. The first elution with chloroform and recrystallization from methanol afforded colorless crystals, which were identified as biphenyls (**3a—d**) by a comparison of the IR spectra and by a mixed-melting-point determination with an authentic sample. Further elution with chloroform and recrystallization from chloroform–cyclohexane afforded yellow products (**2a—d**). The results are summarized in Table 1.

*The Preparation of Chloro-[2-aryl-2-(α-pyridyl)ethyl]-pyridine-palladium Complexes (**4a—d**).* A solution of the chloro-bridged palladium complex (**4**) (0.10 g) in methylene chloride was treated with a solution of pyridine (5% excess) in ether. After 10 min, the solvent was removed under reduced pressure; the residue was then recrystallized from benzene–cyclohexane to give pale yellow crystals. The results are summarized in Table 1.

Results and Discussion

In the presence of lithium chloropalladite, **1** reacted with phenylmercuric chloride in acetonitrile to give a yellow crystal, di-μ-chloro-bis[2-phenyl-2-(α-pyridyl)-ethyl]dipalladium(II) (**2a**), accompanied by a small amount of biphenyl (**3a**). Similarly, *p*-tolylmercuric chloride, *p*-anisylmercuric chloride, and *m*-nitrophenylmercuric chloride all reacted with **1** to afford yellow complexes (**2b—d**).

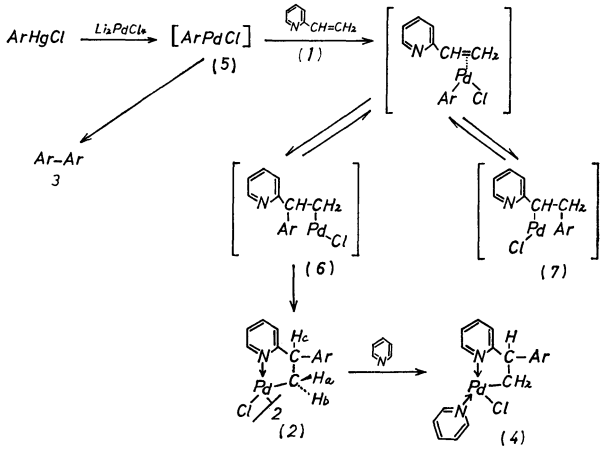

Fig 1.

The mechanism of the formation of **3a—d** as a by-product may involve a coupling reaction of aryl-palladium chloride (**5**), prepared *in situ* from arylmercuric chloride and lithium chloropalladite in acetonitrile. The σ-bonded structure for the yellow complexes (**2a—d**) was supported by the molecular-weight determinations and by the reaction with pyridine to give readily soluble monomeric derivatives (**4a—d**). Moreover, the far-infrared spectra of **2a—d** showed a bridged Pd–Cl stretching absorption at about 290 and 255 cm^{-1}. The NMR spectra of **2a—d** were in agreement with the proposed structures. For example, the NMR spectrum of **2a** consists of four resonances, at σ 3.48, 3.73 (the protons of the *N*-methylene group (H_a and H_b)), 4.55 (the methine proton H_c), and 7.05—8.52 ppm (the protons of the phenyl and pyridyl groups). The nonequivalence of the methylene protons (H_a and H_b) can most easily be explained in terms of a cyclic system in which nitrogen is coordinated to the metal. Similarly, in the NMR spectra of **2a—d**, all the resonances can be satisfactorily accounted for by the presence of the σ-bond and a cyclic system.

Recently, Heck[4] has reported that the arylation of olefin with **5** was stereospecific with internal olefin, giving products consistent with a *cis* addition of the organopalladium reagent to the olefin, followed by a *cis* elimination of a hydridopalladium(II) species. In

Synthesis of Furfuryl and Nitrofurfuryl Derivatives of Adenine and Uracil

Shunzo FUKATSU,* Aiko SAWA,** and Sumio UMEZAWA

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Yokohama 222

(Received September 19, 1973)

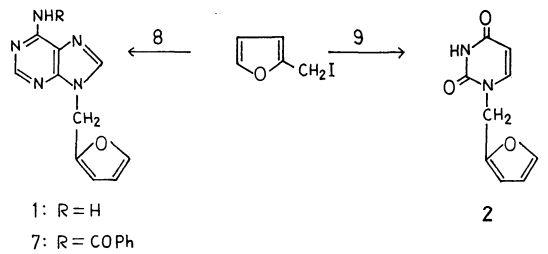
Condensation of 5-nitrofurfuryl iodide with uracil in dimethylformamide in the presence of lithium hydride gave 1-(5′-nitrofurfuryl)uracil. When the iodide was treated with adenine, 3-substituted adenine was mainly obtained, whereas the analogous reaction of benzamidopurine gave 9-substituted adenine. These compounds showed antitumor and broad antibacterial activity. Furfuryl derivatives were also described.

Since the introduction of nitrofurazone (5-nitrofurfural semicarbazone) as an antibacterial agent, many nitrofuran derivatives have been prepared in an effort to increase and to modify activity. Among the derivatives, 5-nitrofurfuryl derivatives of pyrazolopyrimidines have been prepared by Burch[1] and found to possess excellent antibacterial activity. Furthermore, the 5-nitrofurfuryl derivative of a tetrahydropyrimidine compound prepared by Hurst *et al.*[2] has been found to be antiviral but not antibacterial. On the other hand, a series of furfuryl pyrimidines and purines have been prepared by Hull[3] in connection with kinetine which is an adenine derivative and a cell division stimulator.

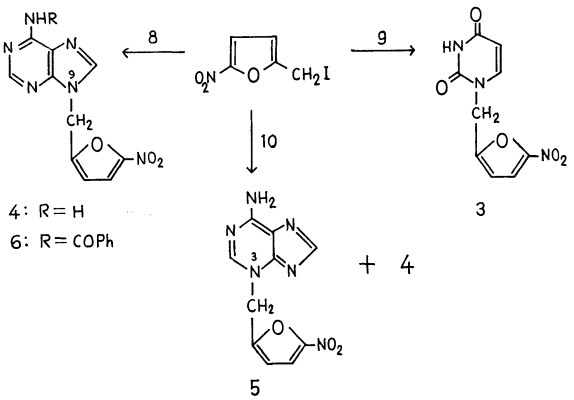
In the course of an investigation of the synthesis of nucleoside-related compounds, we have recently reported[4] the synthesis of some reversed nucleosides of pyrimidine and purine bases. As a part of this investigation, it seemed of interest to synthesize further nitrofurfuryl and furfuryl analogs in which the furanose structure is replaced by furan. This paper describes the preparation of 9-furfuryl-, 9-(5′-nitrofurfuryl)-, and 3-(5′-nitrofurfuryl)adenine(**1**, **4**, and **5**) and 1-furfuryl- and 1-(5′-nitrofurfuryl)uracil (**2** and **3**).

In the previous paper,[4] the authors have shown that the condensation of terminal iodo-sugars with pyrimidine bases in dimethylformamide smoothly occurred in the presence of lithium hydride or sodium hydride. This reaction was extended in the present synthesis, using furfuryl and 5-nitrofurfuryl iodide.

Furfuryl iodide, which was prepared by the reaction of triphenyl phosphate methiodide with furfuryl alcohol according to the method of Lanauer and Rydon,[5] was, *in situ*, condensed with 6-benzamidopurine (8) in the presence of sodium hydride to afford 6-benzamido-9-furfurylpurine (**7**) in 51% yield. Ammonolysis of the benzamido derivative with methanolic ammonia gave 9-furfuryladenine (**1**) (Scheme 1), which showed a melting point corresponding with that reported for the substance prepared by a entirely different method by Hull.[3] An analogous reaction of furfuryl iodide with uracil (9) in the presence of lithium hydride gave 1-furfuryluracil (**2**).



Scheme 1.



Scheme 2.

Likewise, 5′-nitrofurfuryl derivatives have been prepared from 5-nitrofurfuryl iodide[6] and uracil, adenine (10) and 6-benzamidopurine (Scheme 2).

The condensation of the iodide with uracil in the presence of lithium hydride afforded 1-(5′-nitrofurfuryl)uracil (**3**).

Analogous reaction of the iodide with adenine and 6-benzamidopurine (benzoyladenine) led to different derivatives. It has been found that the reaction using 6-benzamidopurine followed by hydrolysis gave 9-(5′-nitrofurfuryl)adenine (**4**), while the reaction using adenine mainly gave 3-(5′-nitrofurfuryl)adenine (**5**).

3- and 9-subsitutions on adenine and 1-substitution on uracil have been established by comparison of the ultraviolet spectra (Table 1) of the products with substituted adenines and uracils of known structure.[7-10] The structures of the above described products have further been supported by their IR and NMR spectra by reference to the compilations by Jackman[11] and Bhacca *et al.*[12]

In preliminary experiments to assess the biological activity of the above products, it has been observed that the nitrofurfuryl derivatives **3**, **4**, and **5** interestingly showed antitumor activity. All these compounds also

showed wide antimicrobial spectra against bacteria and fungi.

Experimental

9-Furfuryladenine (1). A solution of furfuryl alcohol (1.01 g, 10.3 mmol) and methyltriphenoxyphosphonium iodide (5.27 g, 11.6 mmol) in dry ether (15 ml) was stirred at room temperature for 1 hr. To the solution, a solution of 6-benzamidopurine (2.43 g, 10.2 mmol) and sodium hydride (270 mg, 11.3 mmol) in dry dimethylformamide (30 ml) was added and the mixture was heated at 80—83 °C (bath temperature) for 5 hr and evaporated to dryness at 40 °C. The residue was dissolved in chloroform (120 ml) and the solution was washed with two 40 ml portion of water, dried with sodium sulfate, filtered, and evaporated to sirup. The residue (6.4 g) was chromatographed on a short column (2.5×30 cm) of alumina (Merck, acid washed, 110 g) and eluted successively with benzene, benzene–ethyl acetate (1: 1), ethyl acetate, ethyl acetate–methanol (1: 1) and methanol. The condensation product (**7**) was eluted with ethyl acetate–methanol (1: 1), being recognized by ultraviolet absorption. The fractions were combined and evaporated to dryness. The residue was crystallized from ethanol, 1.64 g (51%) of needles of 6-benzamido-9-furfurylpurine (**7**), mp 192.5—193.5 °C, UV: λ_{max}^{MeOH} 331 mμ(ε 15000).

Found: C, 64.05; H, 4.33; N, 21.87%. Calcd for $C_{17}H_{13}N_5O_2$: C, 63.94; H, 4.10; N, 21.93%.

A sample of **7** (1.64 g) was dissolved in 40 ml of methanolic ammonia (saturated at 0 °C) and kept at 0 °C for 16 hr. The solution was evaporated *in vacuo* to dryness. The residue was crystallized from hot water to give 9-furfuryladenine (**1**), 0.48 g (21.5%) of needles, mp 193.5—194 °C (lit,[3] mp 191—192 °C), UV $\lambda_{max}^{0.1N\ HCl}$ 260 mμ (ε 17800), $\lambda_{max}^{H_2O}$ 261 mμ (ε 17700), $\lambda_{max}^{0.1N\ NaOH}$ 261 mμ(ε 18100).

Found: C, 56.30; H, 4.58; N, 31.93%. Calcd for $C_{10}H_9N_5O$: C, 55.81; H, 4.22; N, 32.54%.

1-Furfuryluracil (2). Uracil (0.810 g, 7.2 mmol) and lithium hydride (52 mg, 8.0 mmol) dissolved in 20 ml of dry dimethylformamide by heating to 120—130 °C was added to a solution of triphenyl posphate methiodide (3.61 g, 8.0 mmol) and furfuryl alcohol (0.70 g, 7.2 mmol) in ether (10 ml). After heating at 110—120 °C for 45 min, the solution was evaporated *in vacuo* and the dark sirup was extracted with hot water (40 ml). The extract was evaporated to dryness *in vacuo* and chromatographed over 80 g of silica gel (Mallineckrodt) using benzene–methanol (4: 1) to give crystals of **2**, 0.28 g (20.2%), which was recrystallized from water; colorless needles, mp 117—119 °C.

Found: C, 56.25; H, 4.20; N, 14.58%. Calcd for $C_9H_8N_2O_3$: C, 56.05; H, 4.64; N, 14.51%.

UV: $\lambda_{max}^{0.1N\ HCl}$ 266 mμ (ε 6860), $\lambda_{min}^{0.1N\ HCl}$ 238 mμ (ε 2250), $\lambda_{max}^{H_2O}$ 265 mμ (9800), $\lambda_{min}^{H_2O}$ 240 mμ (ε 2680), $\lambda_{max}^{0.1N\ NaOH}$ 264 mμ (ε 6840), $\lambda_{min}^{0.1N\ NaOH}$ 245 mμ(ε 4600).

1-(5′-Nitrofurfuryl)uracil (3). To a mixture of uracil (1.68 g, 15 mmol) and lithium hydride (0.12 g, 15 mmol) dissolved in dry dimethylformamide (100 ml) by heating to 80 °C, 5-nitrofurfuryl iodide (2.68 g, 10 mmol) was added and stirred at 80 °C for 80 min. The reaction mixture was condensed to 15 ml and filtered. To the filtrate, water (80 ml) was added and the mixture was shaken with benzene (50 ml×2). The benzene layer was evaporated to dryness *in vacuo* to give a dark residue which was chromatographed over silica gel (Mallineckrodt, 70 g) using benzene–methanol (9: 1) as the eluent. The main fractions were evaporated to dryness *in vacuo* to yield 0.447 g (20%) of crude 1-(5′-nitrofurfuryl)uracil. Recrystallization from ethanol or water–ethanol gave pale yellow needles. Mp 209—210 °C (decomp.).

Found: C, 45.74; H, 3.25; N, 17.30%. Calcd for $C_9H_7N_3O_5$: C, 45.57; H, 2.98; N, 17.72%.

IR: ν_{max}^{KBr} 1500, 1360 cm^{-1} (–NO_2). NMR (DMSO-d_6): δ 5.12 (2H singlet, –CH_2–), δ 5.74 (1H doublet, J=8 Hz, H_5), δ 6.90 and 7.74 (1H each doublet, J=4 Hz, H_3' and H_4'), δ 7.85 (1H doublet, J=8 Hz, H_6), δ 11.41 (1H, 3-NH).

9-(5′-Nitrofurfuryl)adenine (4). To a sample of **6** (116 mg) dissolved in hot methanol (40 ml) was added 2 M hydrochloric acid (40 ml) and the mixture was refluxed on boiling water bath for 2 hr. After concentration *in vacuo* to about 27 ml and subsequent washing with ethyl ether (20 ml×3), the solution was further concentrated to give fine needles of 9-(5′-nitrofurfuryl)adenine hydrochloride (82.5 mg, 88%). It decomposed at >216 °C.

Found: C, 40.03; H, 3.69; N, 27.90; Cl, 11.54%. Calcd for $C_{10}H_9N_6O_3Cl$: C, 40.49; H, 3.06; N, 28.32; Cl, 11.95%.

The crystals gave a single spot ($R_f \simeq 0.5$) (tlc with butanol saturated with water). IR: ν_{max}^{KBr} 1700, 1610 (–N=C=), 1510, 1350 (–NO_2), 1235, 1225 cm^{-1} (furan ring).

A sample of the hydrochloride (73.2 mg, 0.25 mmol) was dissolved in a mixture of hot water (45 ml) and methanol (5 ml) and the solution was cooled to room temperature. To the solution, sodium carbonate (14.5 mg, 0.13 mmol) was added to give pale yellow needles of **4** (51.7 mg, 80.5%). It decomposed at >235 °C.

Found: C, 46.66; H, 3.55; N, 32.65%. Calcd for $C_{10}H_8N_6O_3$: C, 46.16; H, 3.10; N, 32.30%.

IR: ν_{max}^{KBr} 1645, 1595 (–N=C=), 1500, 1350 (–NO_2), 1240 cm^{-1} (furan ring). NMR (DMSO-d_6): δ 6.56 (2H, –CH_2–), δ 7.34 (2H, –NH_2), δ 6.90 and 7.70 (each 1H, H_4' and H_3'), δ 8.27 and 8.34 (each 1H, H_2 and H_8).

3-(5′-Nitrofurfuryl)adenine (5). To a mixture of adenine (1.06 g, 8 mmol) and lithium hydride (64 mg, 8 mmol) dis-

solved in dry dimethylformamide (40 ml) by heating to 55 °C, 5-nitrofurfuryl iodide (2.14 g, 8 mmol) was added and the mixture was stirred at 50—55 °C for 2 hr. The mixture was concentrated and the dark residue was chromatographed on a column of silica gel (90 g, Mallineckrodt), being washed with benzene (300 ml) and eluted with ethyl acetate–methanol (4: 1). Evaporation of the initial fractions followed by crystallization from water–methanol gave 9-(5′-nitrofurfuryl)-adenine (**4**), 42.1 mg (2.2%). From the middle fractions, 3-(5′-nitrofurfuryl)adenine (**5**) was obtained, colorless crystals, 344 mg (16.5%), mp 214 °C (decomp.).

Found: C, 46.34; H, 3.31; N, 32.34%. Calcd for $C_{10}H_8N_6O_3$: C, 46.16; H, 3.10; N, 32.30%.

IR: ν_{max}^{KBr} 1495, 1345 cm^{-1} ($-NO_2$). MNR (DMSO-d_6): δ 5.77 (2H, $-CH_2-$), δ 6.99 and 7.68 (each 1H, H_4' and H_3'), δ 7.83 and 8.56 (each 1H, H_8 and H_2), δ 8.19 (2H, $-NH_2$).

6-Benzamido-9-(5′-nitrofurfuryl)purine (**6**). To a mixture of 6-benzamidopurine (2.524 g, 10.6 mmol) and lithium hydride (80 mg, 10.1 mmol) dissolved in dry dimethylformamide (100 ml) by heating to 80 °C, 5-nitrofurfuryl iodide (2.680 g, 10.6 mmol) was added and the mixture was heated at 78—85 °C for 3 hr. The reaction mixture was evaporated to dryness *in vacuo* and the residue was dissolved in methanol (10 ml). The solution was chromatographed on a column of silica gel (200 g, Mallineckrodt, 100 mesh), being washed with benzene (900 ml) and eluted with benzene–methanol (15: 1). The middle fractions gave crude 6-benzamido-9-(5′-nitrofurfuryl)purine (yield 24.6%). Analytical sample was obtained as colorless needles by recrystallization from 2-propanol. Mp 171—172.5 °C.

Found: C, 56.15; H, 3.63; N, 22.88%. Calcd for $C_{17}H_{12}N_6O_4$: C, 56.04; H, 3.32; N, 23.07%.

UV: λ_{max}^{MeOH} 282 mμ(ε 28000). IR: ν_{max}^{KBr} 1695 (C=O), 1500, 1360, 1330 ($-NO_2$), 1240 cm^{-1} (C–O–C). NMR (DMSO-d_6): δ 5.80 (2H, $-CH_2-$), δ 7.00 and 7.7 (H_4' and H_3'), δ 8.69 and 8.84 (each 1H, H_8 and H_2).

Bioassay. It is interesting that compounds **3**, **4**, and **5** showed significant antitumor activity against Yoshida *sarcoma ascites*. The inhibition % of **3**, **4**, and **5** at concentrations 10 mcg/ml and (100 mcg/ml) were 66.3 (83.0), 78.1 (78.7) and 75.7 (83.7) %, respectively. (Control: 6-mercapto-9-β-D-ribofuranosylpurine at 10 mcg/ml and (100 mcg/ml): 49.4 (77.8) %.

Compounds **3**, **4**, **5**, and **6** also showed broad antibacterial and antifungal activity. Their minimum inhibitory concentrations (mcg/ml) were 1.0—7.8 against Gram-positive bacteria tested, 31.2—62.4 against *E. coli* K-12 and 15.6—31.2 against some fungi tested.

Photolysis of 2,2-Diethoxy-2,3-dihydrophenalene-1,3-dione

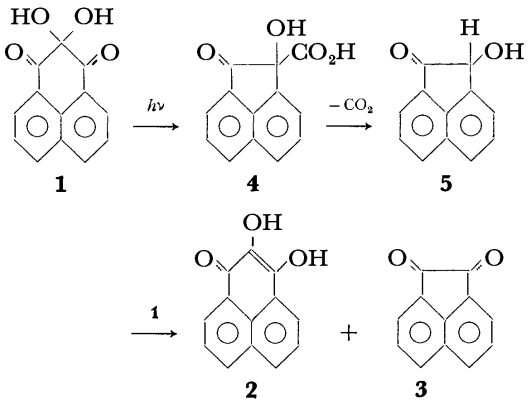
Yoshio Otsuji, Shigeo Wake, Eiichi Maeda, and Eiji Imoto

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai-shi, Osaka 591

(Received August 30, 1973)

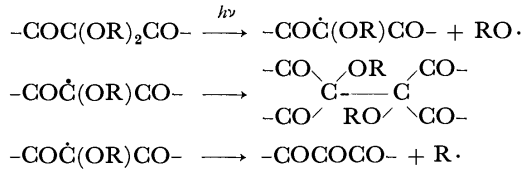
Irradiation of 2,2-diethoxy-2,3-dihydrophenalene-1,3-dione (**6**) with a pyrex-filtered high-pressure Hg arc lamp afforded acetaldehyde, 2-ethoxy-3-hydroxyphenalene-1-one (**7**) and bis-2-(2-ethoxy-1,3-dioxo-2,3-dihydro) phenalenyl (**8**). Mechanistic studies revealed that the first step of this photoreaction was a homolytic fission of the C–OC_2H_5 bond to 2-(2-ethoxy-1,3-dioxo-2,3-dihydro)phenalenyl radical (**9**) and ethoxyl radical. This homolytic fission occurred mostly from the triplet and in part from the singlet excited state of **6**. Dimerization of **9** gave **8** and the disproportionation between **9** and ethoxyl radical gave acetaldehyde and **7**. The photochemical behaviors of a variety of triketone derivatives were discussed.

In a separate paper,[1] we have reported that 2,2-dihydroxy-2,3-dihydrophenalene-1,3-dione (**1**) undergoes the redox disproportionation with elimination of CO_2 to 2,3-dihydroxyphenalene-1-one (**2**) and acenaphthene-1,2-dione (**3**) upon irradiation in organic solvents. A key step of this reaction was a rearrangement of **1** to 2-carboxy-2-hydroxyacenaphthene-1-one (**4**) from the singlet excited state of **1** (see Scheme 1).



Scheme 1

However, we have previously presented evidence supporting that 2,2-dihydroxy- or 2,2-dialkoxy-1,3-diketones such as alloxan monohydrate,[2] ninhydrin[2] or 5,5-dialkoxybarbituric acids[3] undergo the photoreaction involving an α-cleavage as illustrated in Scheme 2.



where R represents H or alkyl.

Scheme 2.

These diverse photochemical behaviors of triketone derivatives prompted us to study the photochemistry of 2,2-diethoxy-2,3-dihydrophenalene-1,3-dione (**6**). The specific effect such as an intramolecular hydrogen bonding, which is present between the hydroxyl and carbonyl groups of **1**, is absent in **6**. We observed that **6** undergoes the α-cleavage reaction upon irradiation, but the radical produced behaves differently from those represented in Scheme 2. In this paper, the results so far obtained are summarized and the mechanism of the photoreaction is discussed.

Results

Products. A Pyrex-filtered irradiation of a solution of **6** in benzene with a high-pressure Hg arc lamp under nitrogen at room temperature afforded acetaldehyde, 2-ethoxy-3-hydroxyphenalene-1-one (**7**) and bis-2-(2-ethoxy-1,3-dioxo-2,3-dihydro)phenalenyl (**8**). Acetaldehyde, which distilled out upon passing nitrogen into the reaction mixture, was identified as its 2,4-dinitrophenylhydrazone. The dimer **8** deposited on the bottom of the reaction vessel and it was easily separated from other products by filtration. The unreacted starting material and **7** were satisfactorily separated by a column-chromatography on silica gel.

The structure of **7** was confirmed by the analytical and spectral data. The NMR spectrum ($CDCl_3$) showed a triplet (J=7.5 Hz, 3H) at 1.40 ppm (–CH_2–CH_3), a quartet (J=7.5 Hz, 2H) at 4.42 ppm (–CH_2–CH_3), a broad singlet (1H) at 6.96 ppm (–OH), and the multiplet signal (6H) due to the aromatic protons from 7.28 to 8.47 ppm. The IR spectrum (KBr) exhibited a band at 3520 cm^{-1} due to the hydroxyl group and at 1630 cm^{-1} attributable to the carbonyl group. The mass spectrum displayed prominent peaks at m/e 240 (M^+), 212 (M^+—CO), and 196 (M^+—CH_3–CHO).

In support of the structure assignment of **8**, we observed the molecular weight to be 474 (calcd 478) by the Rast method. The IR spectrum (KBr) indicated a band at 1679 cm^{-1} due to the carbonyl group. The analytical data showed the molecular formula to be $C_{30}H_{22}O_6$.

The same sort of the products was also obtained when irradiation was carried out in acetonitrile and 2-propanol. The isolated yields are shown in Table 1.

A ratio of the yield of the dimer **8** to that of **7** was higher in the non-polar solvent, benzene, than in the polar solvents such as acetonitrile and 2-propanol.

Quantum Yields for the Formation of **7**. The photolysis of **6** was conducted in three solvents in a 1 cm optical cell under anaerobic conditions by irradiation of 313 nm light. As the reaction proceeded, an absorption of 320 nm band due to **6** decayed with

Table 1. Photolyses of **6**

Solvent	Recovered starting material %	Yields of products %[a]	
		7	**8**
C_6H_6[b]	36	21	14
CH_3CN[b]	28	61	1.5
2-PrOH[c]	20	66	5.0

a) The yields are based on the total amount of the starting material initially used.
b) A solution of 200 mg of **6** in 50 ml of the solvent in a quartz vessel was irradiated for 48 hr externally from the outside of the reaction vessel.
c) A solution of 200 mg of **6** in 200 ml of the solvent was irradiated for 6 hr employing an immersion-type apparatus.

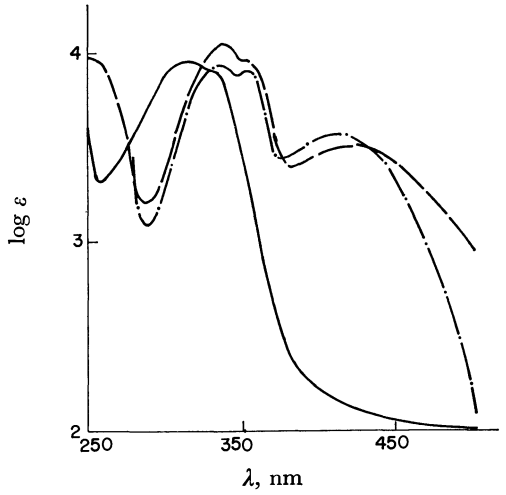


Fig. 1. Absorption spectra of 2,2-diethoxy-2,3-dihydrophenalene-1,3-dione (**6**) and 2-ethoxy-3-hydroxyphenalen-1,-one (**7**)
——, **6** in 2-PrOH; ——, **7** in 2-PrOH; —•—, **7** in C_6H_6 and CH_3CN. The stectra of **6** in C_6H_6 and CH_3CN were almost identical with that in 2-PrOH.

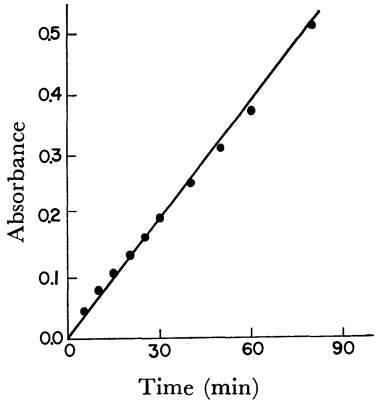

Fig. 2. Rate of appearance of the absorbance of 2-ethoxy-3-hydroxyphenalene-1-one (**7**) at 413 nm upon irradiation of 2,2-diethoxy-2,3-dihydrophenalene-1,3-dione (**6**) in C_6H_6.

appearance of 410—425 nm band due to **7** as shown in Fig. 1. The rates of the formation of **7** were followed by monitoring an appearance of the absorptions at 413 nm in benzene, at 410 nm in acetonitrile, and at 425 nm in 2-propanol. The amounts of **7** formed linearly increased with irradiation time in all solvents until more than 50% of **6** was consumed. In a typical example, the result of the photolysis of **2** in benzene is shown in Fig. 2. The rate data were then converted into the quantum yields by use of the ferric oxalate actinometer. The quantum yields obtained are summarized in Table 2.

Table 2. Quantum yields for the formation of **7** upon irradiation by 313 nm light

Concn. of **6**, M	Solvent	Φ
1.01×10^{-3}	C_6H_6	0.040
1.04×10^{-4}	CH_3CN	0.035
1.00×10^{-3}	CH_3CN	0.046
9.97×10^{-3}	CH_3CN	0.059
1.00×10^{-3}	2-C_3H_7OH	0.043

The results of Table 2 indicate that the quantum yield for the formation of **7** is not so much affected by the concentration of **6** present and not at all by the nature of solvents used.

Stern-Volmer Plots. In order to gain information on the nature of the excited state involved, quenching experiments were carried out. A 1.00×10^{-3} M solution of **6** in benzene was irradiated in the presence of various concentrations (0—0.01 M) of cyclohexadiene, a triplet quencher, and the quantum yield for the formation of **7** was measured as described above. In

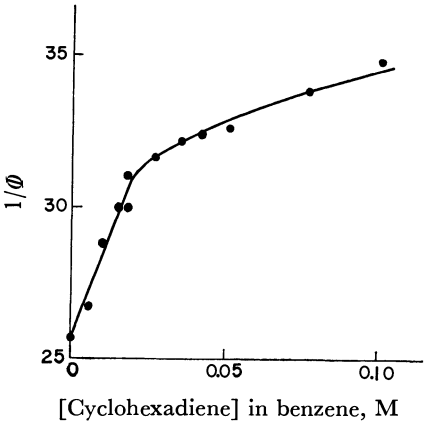

Fig. 3. Stern-Volmer plot for the formation of 2-ethoxy-3-hydroxyphenalene-1-one (**7**) by irradiation of 2,2-diethoxy-2,3-dihydrophenalene-1,3-dione (**6**) in C_6H_6.

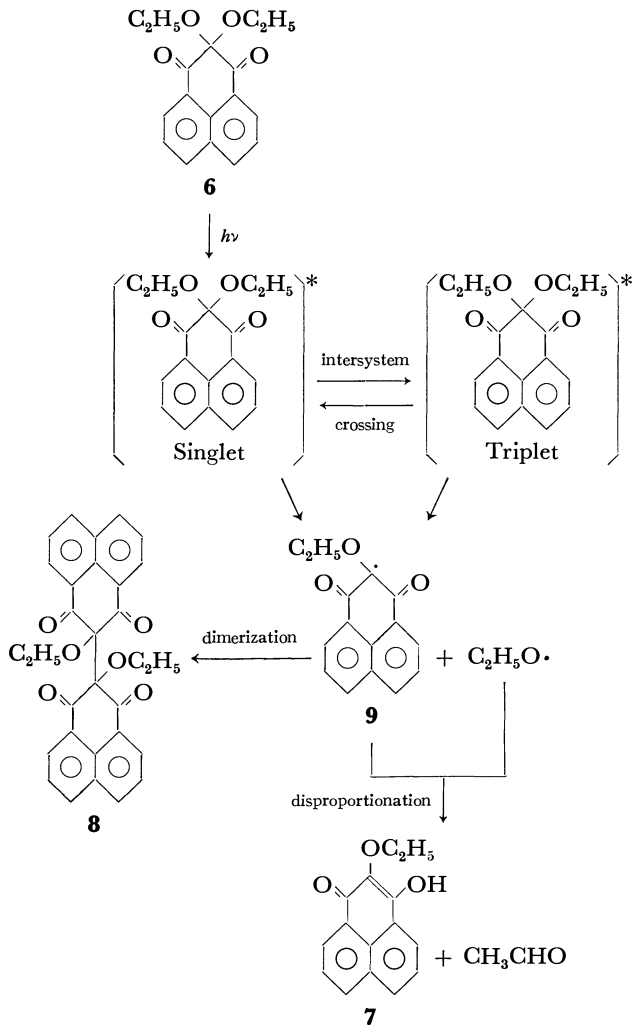
Fig. 3, the reciprocals of the quantum yields were plotted against the concentrations of cyclohexadiene added (Stern-Volmer plot). From Fig. 3, it can be seen that the quantum yield for the formation of **7** is reduced strongly by the presence of lower concentrations of cyclohexadiene, but weakly by the presence of higher concentrations of cyclohexadiene. This phenomenon suggests that **7** is formed mostly from a triplet

excited state and in part from a singlet excited state of **6**.[4]

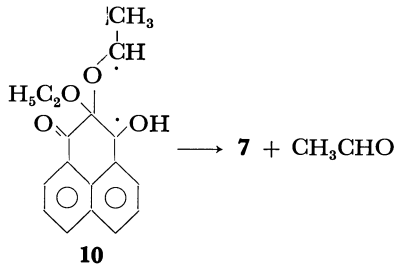
Discussion

A plausible mechanism which explains the results presented earlier is given in Scheme 3. The first step of the photoreaction is a homolytic cleavage of the C–OC_2H_5 bond in **6** to form the radical **9** and the ethoxyl radical. This cleavage reaction occurs mostly from a triplet excited state of **6** and in part from its singlet excited state. The radical **9** dimerizes to form the dimer **8**. On the other hand, the disproportionation between **9** and the ethoxyl radical gives **7** and acetaldehyde. The dimerization reaction is favored in non-polar solvent such as benzene, while the disproportionation reaction is favored in polar solvents such as acetonitrile and 2-propanol. The solvent effect of this sort in radical reactions has frequently been observed.[5]



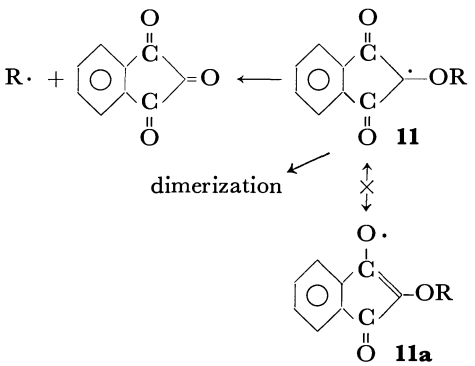
Scheme 3

The formation of **7** and acetaldehyde may also be explained by the other mechanism involving the 1,4-biradical intermediate **10** which can be formed *via* a γ-hydrogen abstraction by the excited carbonyl of **6**; a decomposition of **10** would lead to **7** and acetaldehyde. However, this possibility can be eliminated from the fact that the quantum yield for the formation of **7** was actually independent on the polarity of solvents used as shown in Table 2. If the biradical **10** participates as an intermediate of the photoreaction, then the quantum yield should become higher in the solvents of higher polarity, since the intermediate would be stabilized in polar solvents.[6] However, this was not the case.



Unfortunately, the systematic understanding on the diversity of the photochemical behaviors of triketone derivatives is not attained at present. However, it would be important to note that the ionic-type reaction of **1** takes place from its singlet excited state,[1] while the α-cleavage reaction of a radical-type as observed in **6** occurs mainly from a triplet excited state of the carbonyl group. An intramolecular hydrogen bonding between the hydroxyl and carbonyl groups of **1**, which was inferred from a broad hydroxyl band centered at 3200 cm^{-1} in the IR spectrum, may contribute at least in part to an exclusive formation of the singlet excited state.

A difference in the reactivity between the 1,3-dioxoradical generated from **6** and that from ninhydrin might be explained in terms of the stability of the radicals. The radical **9** generated from **6** can be stabilized by a conjugation with the vicinal carbonyl groups. In contrast, the radical **11** generated from ninhydrin would gain destabilization rather than stabilization by a conjugation with the vicinal carbonyl groups, since the structure of the type **11a** is of an anti-aromatic character.[7]



An odd electron in the radical **11** thus become fixed to a greater extent at the 2-position, and hence the radical is forced to undergo dimerization or cleavage reaction to indanetrione and the radical R·. On the other hand, the resonance-stabilized radical **9** undergoes dimerization or disproportionation if other radicals are present in the reaction mixture.

Experimental

All melting points are uncorrected. Electronic absorption spectra were recorded with a Hitachi EPS-3T recording spectrophotometer or a Hitachi Perkin-Elmer 139 spectrophotometer. IR spectra were obtained with a Hitachi 215 infrared spectrophotometer. NMR spectra were obtained on a Hitachi H-60 high resolution NMR spectrometer with tetramethylsilane as an internal standard. Microanalyses were performed with a Hitachi 026 CHN analyzer. Irradiations were carried out with a 100 W Ushio UM-102 high-pressure Hg arc lamp equipped with a Pyrex water-cooling jacket.

Materials. 2,2-Diethoxy-2,3-dihydrophenalene-1,3-dione (**6**) was prepared by the method of Regitz and Adolph[8] and purified by recrystallization from ethanol; mp 137—138 °C (lit,[8] mp 138—139 °C). Cyclohexadiene was prepared by the method of Blomquist and Kwiatek[9] and purified by distillation; bp 79—81 °C (lit,[9] bp 79—81 °C).

Photoreaction of 6. *(a) In Benzene*: A solution of 200 mg (0.704 mmol) of **6** in 50 ml of benzene was placed in a cylindrical quartz vessel. An outlet of the vessel was connected with a vinyl tubing to a flask containing a solution of 2,4-dinitrophenylhydrazine in an aqueous HCl. Nitrogen was introduced into the reactant solution for 30 min and then irradiation was carried out externally from the outside of the vessel at room temperature under bubbling nitrogen in the solution. After irradiation for 8 hr, nitrogen-bubbling was stopped and the outlet of the reaction vessel was sealed with a glass stopper. During this period, red precipitates appeared in the flask containing 2,4-dinitrophenylhydrazine. The precipitates, 20 mg, were separated by filtration. They melted at 146—147 °C and were identical with the authentic sample of 2,4-dinitrophenylhydrazone of acetaldehyde in every respect.

On the other hand, when the irradiation was continued for 48 hr, brown crystals appeared on the bottom of the reaction vessel. They were removed by filtration, and washed thoroughly with dioxane and then with chloroform. The crystals thus obtained were found to be 47 mg (14%) of **8**: mp 236—237 °C (decomp.). Found: C, 75.29; H, 4.65%. Calcd for $C_{30}H_{22}O_6$: C, 75.30; H, 4.63%.

Evaporation of the solvent from the filtrate, which was obtained after removal of **8**, under reduced pressure gave a brown oil. The oil was dissolved in benzene–chloroform (1 : 1) and chromatographed on a silica gel column using the same solvent as an eluent. Evaporation of the first eluent gave 73 mg (36%) of the unreacted starting material as light yellow crystals of mp 134—137 °C, which melted at 138—139 °C after recrystallization from ethanol.

Further elution with benzene–chloroform and evaporation of the eluent gave 35 mg (21%) of **7**. Recrystallization from methanol gave orange crystals: mp 125—126 °C. Found: C, 75.05; H, 4.94%. Calcd for $C_{15}H_{12}O_3$: C, 74.99; H, 5.03%.

(b) In Acetonitrile: A solution 200 mg (0.704 mmol) of **6** in 50 ml of acetonitrile was irradiated for 48 hr as described above. After irradiation, the reaction mixture was worked up in the manner similar to that described above. From the reaction mixture, 5 mg (1.5%) of **8**, 56 mg (28%) of the unreacted starting material and 103 mg (61%) of **7** were obtained. 2,4-Dinitrophenylhydrazone of acetaldehyde was also isolated.

(c) In 2-Propanol: A solution of 200 mg (0.704 mmol) of **6** in 200 ml of 2-propanol was placed in an immersion-type apparatus, and nitrogen was bubbled for 30 min. Irradiation was then carried out in a stream of nitrogen at room temperature for 6 hr. Treatment of the reaction mixture afforded 17 mg (5.0%) of **8**, 41 mg (21%) of the starting material and 111 mg (66%) of **7**. 2,4-Dinitrophenylhydrazone of acetaldehyde was also isolated in this photolysis.

Determination of Quantum Yields. The same apparatus and procedure as those described separately[1] were employed for determination of the quantum yields. The rates of the formation of **7** were followed by monitoring the absorbances at 413 nm in benzene, at 410 nm in acetonitrile and at 425 nm in 2-propanol. In quenching experiments, the rates of the formation of **7** were measured by monitoring the absorbances at the same wavelengths as described above.

N-Alkylideneanilines. III.[1] Behavior of *N*-Isopropylideneanilines in Methanol-d_4

Hiizu IWAMURA,* Michiko TSUCHIMOTO,** and Shigeo NISHIMURA**

**Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113*

***Department of Industrial Chemistry, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184*

(Received August 6, 1973)

When *N*-isopropylideneanilines are dissolved in methanol-d_4, three types of reactions, exchange of protons in isopropylidene moiety, formation of carbinolamine ethers, and liberation of anilines with formation of acetone dimethyl acetal take place as revealed by NMR spectra of the solutions. The H–D exchange reaction is favored by electron-releasing ring substituents and yet is considerably slower than the rates of the E–Z isomerization of the corresponding imines. The carbinolamine ethers are formed when the substituents are strongly electronegative. Formation of acetone dimethyl acetal occurs additionally with imines carrying halogen atoms as the ring substituents. The competitive reaction mechanism is proposed.

Recently Jennings and Boyd pointed out the intermediacy of enamine tautomers for the E–Z isomerization of imines containing HCC=N moiety.[2] To test the role of this mechanism in the E–Z isomerization of a series of *N*-isopropylideneanilines with various ring substituents, we have examined their rates of H–D exchange reaction by the NMR spectroscopy and found that the above mechanism is not operative in these imines and that they behave quite differently in methanol-d_4, depending on the nature of the ring substituents. Specifically the following three types of reactions were observed for *N*-isopropylideneanilines.

1) Exchange of protons in isopropylidene moiety.
2) Formation of adducts of *N*-isopropylideneanilines with methanol-d_4.
3) Liberation of anilines with formation of acetone dimethyl acetal-d_6.

Experimental

NMR spectra were obtained on a JEOL C-60 HL (Japan Electron Optics Lab. Co., Ltd.) high resolution NMR instrument (60 MHz). *N*-Isopropylideneanilines (0.25 mmol) were dissolved in 0.5 ml of CD_3OD (99.5%). The measurement was carried out at time intervals on the growth and decay of resonance signals by recorder integration (the accuracy of each integration is about ±4%). The chemical shifts were read relative to TMS as the internal reference at 25 °C.

General procedure of the preparation of *N*-isopropylideneanilines:[3] 30 g of molecular sieve 4A were added to a solution of 0.1 mol of acetone and 0.05 mol of aniline in anhydrous ether. The mixture was kept at 10 °C for 9 to 10 days, by renewing the molecular sieve 2—3 times. After removing the molecular sieve by filtration and the solvent by application of a rotary evaporator, the residue was fractionaly distilled.

N-Isopropylidene-*p*-iodoaniline was obtained as a yellow oil (bp 127 °C/8 mmHg, n_D^{25} 1.5732); NMR spectrum ($CDCl_3$, 25 °C): *syn* CH_3, s, 1.80 ppm; *anti* CH_3, s, 2.18 ppm;[4] 2,6 ring protons, d, 6.55 ppm; 3,5 ring protons, d, 7.66 ppm. Found: C, 41.67; H, 3.70; N, 5.37%. Calcd for $C_9H_{10}NI$: C, 41.72; H, 3.89; N, 5.41%.

N-Isopropylidene-*p*-fluoroaniline; a colorless oil (bp 54—56 °C/5 mmHg, n_D^{25} 1.5081; NMR spectrum ($CDCl_3$, 25 °C): *syn* CH_3, s, 1.80 ppm; *anti* CH_3, s, 2.18 ppm;[4] ring protons, centered at 6.88 ppm. Found: C, 71.34; H, 6.53; N, 9.34%. Calcd for $C_9H_{10}NF$: C, 71.50; H, 6.67; N, 9.27%.

N-Isopropylidene-*m*-trifluoromethylaniline: a yellow oil (bp 52 °C/5 mmHg, n_D^{25} 1.4712); NMR spectrum ($CDCl_3$, 25 °C): *syn* CH_3, s, 1.82 ppm; *anti* CH_3, s, 2.20 ppm;[4] 2,6 ring protons, d, 7.01 ppm; 3,4 ring protons, d, 7.42 ppm. Found: C, 59.73; H, 5.02; N, 7.14%. Calcd for $C_{10}H_{10}NF_3$: C, 59.70; H, 5.01; N, 6.96%.

Results and Discussion

The H–D Exchange Reaction. The isopropylidene methyl protons of *N*-isopropylideneanilines carrying electron-releasing *p*-substituents exchange with deuterium in methanol-d_4 solution at ambient temperature. The rate of the reaction can readily be followed by measuring the decrease of their proton signals or the

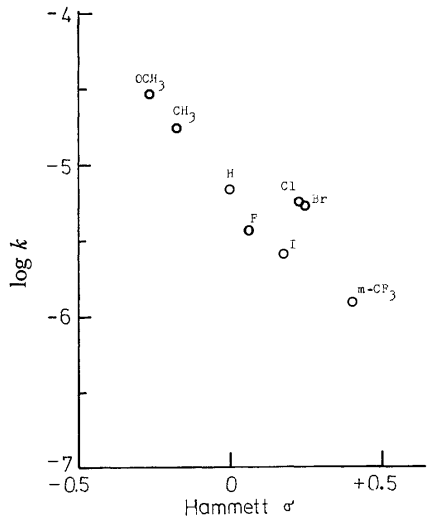

Fig. 1. The Hammett plots of the rates of H–D exchange reaction.

increase of the OH protons[5] due to CD_3OH produced. The pseudo-first-order rate constants for the exchange reaction in a large excess of CD_3OD are calculated and given in Table 1. Note that the rates of exchange increase with increasing electron-donating ability of the substituents. This relation is demonstrated more clearly by the Hammett expression as shown in Fig. 1. The trend indicates that the exchange reaction is nucleophilic and that protonation either to the imines or to the enamines is the rate-determining step. The values for *p*-Cl and *p*-Br deviate from the straight line. This might be due to inaccuracy of the determination of the rates because of the concurrent occurrence of the addition reaction (*vide infra*). In those having more electron-withdrawing substituents than the halogenes, the exchange is not observed to detectable extent and the addition reaction is the exclusive one.

We recall that the rates of E–Z isomerization [$k(s^{-1}) = 4.0\times10^{-2}$ for *m*-CF_3 and 2.5×10^{-3} for *p*-OCH_3 at 25 °C][6] are faster by order of magnitude than the rates of exchange in Table 1 and are subject to reverse substituent effects; the electron-withdrawing groups enhance while the electron-releasing substituents retard the isomerization. It is concluded from these results that formation of enamine is slower and cannot be the contributing mechanism for the E–Z isomerization.

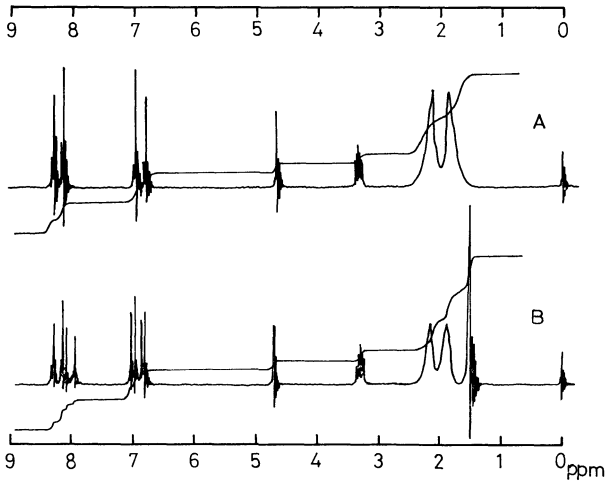

Fig. 2. NMR spectra of *N*-isopropylidene-*p*-nitroaniline (0.25 mmol) in CD_3OD (0.5 ml), 25 °C.
A: At the beginning of the reaction.
B: After 212 min with 32% adduct formation.

The Addition Reaction. When *N*-isopropylidene-*p*-nitroaniline is allowed to stand in CD_3OD, the signals due to the *syn*- and *anti*-methyl protons (δ 1.87 and 2.21) as well as A_2X_2 type aromatic protons (δ 6.93 and 8.23) diminish their intensity with a corresponding increase of a new singlet at δ 1.51, as shown in Fig. 2. The new A_2X_2 type multiplets start to develop in the aromatic region (δ 6.98 and 8.07). No increase in the OH proton signal was detected. The diamagnetic shift of the singlet signal suggests that the carbon atom to which the methyl groups are attached has changed its hybridization from sp^2 to sp^3. The chemical shifts of the aromatic protons are now more like those of *p*-nitroaniline.[7]

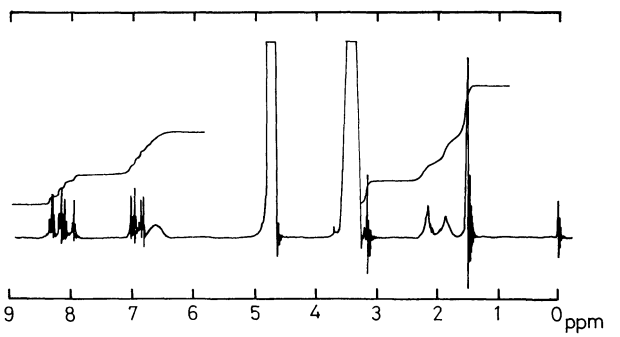

Fig. 3. NMR spectra of *N*-isopropylidene-*p*-nitroaniline (0.25 mmol) in CH_3OH (0.5 ml), 25 °C, taken at 300 min after the start of the reaction. 40% conversion.

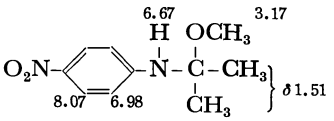
While we have not succeeded in isolating the product, these spectral changes can be fully explained in terms of the formation of the adduct of the *N*-isopropylidene-aniline with methanol. The carbinolamine ether structure is further supported by the change in the NMR signals when the *N*-isopropylidene-*p*-nitroaniline is dissolved in CH_3OH (Fig. 3). Thus the additional singlets at δ 6.67 and 3.17 are consistent with the NH and OCH_3 protons in structure



In Table 2 are given the equilibrium constants K_c, which are defined for the addition reactions by equation

$$K_c = X_e/[(a-X_e)(b-X_e)]$$

where *a* and *b* are the stoichiometric molar concentrations of *N*-isopropylideneanilines (2.50×10^{-4}) and CD_3OD (1.09×10^{-2}) and X_e is the molar concentration of the adduct in equilibrium. The pseudo-first-order rate constants for the addition reaction of various substituted *N*-isopropylideneanilines are also calculated

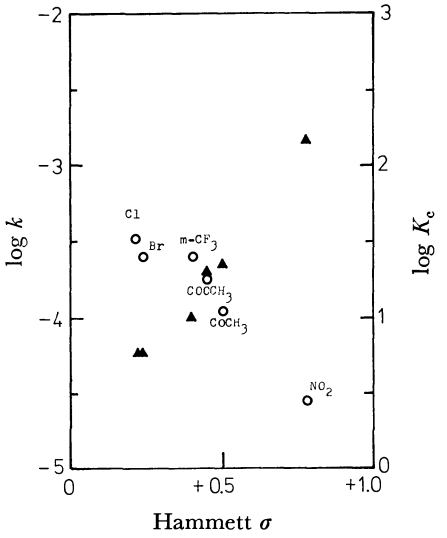


Fig. 4. The Hammett plots of the equilibrium constant K_c and the rate of adduct formation.
(○) for log *k*, (▲) for log K_c.

Table 2. Kinetic data of addition reactions

X in 	k/sec	X_e/%	X_e/mol	K_c	Time to equiribrium (min)

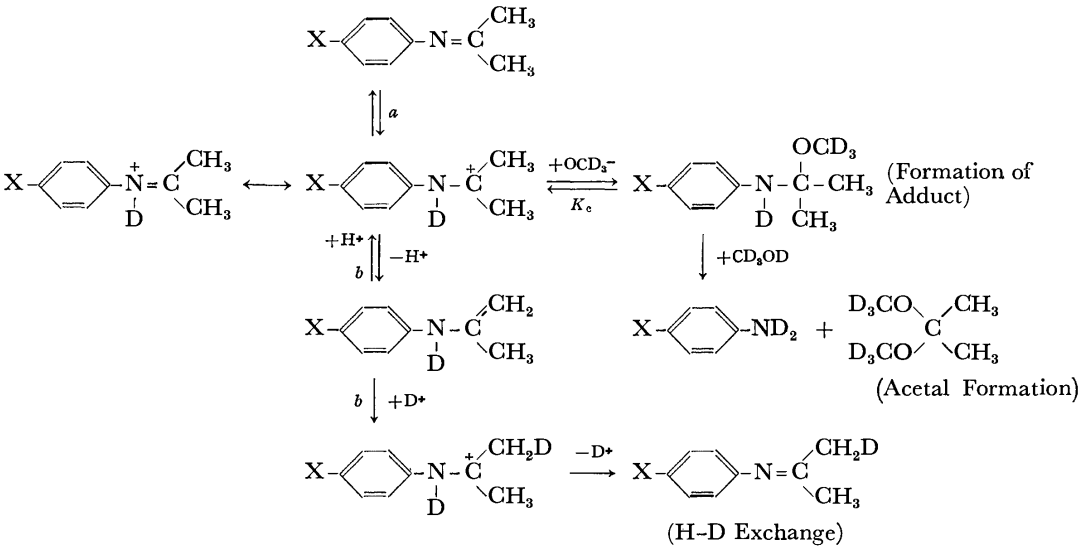
p-NO_2	3.20×10^{-5}	61.7	1.54×10^{-4}	1.49×10^{2}	24 hr



Scheme 1

and shown in the same Table. At 25 °C, the equilibrium is attained for the addition reaction in approximately 20—70 min. Especially *p*-NO_2 compound requires 24 hr before the equilibrium state is obtained. We note that, with increasing electronegativity of the ring substituents, the rate of formation of the adduct decreases, but the equilibrium constant for formation of the adduct increases. The effects of the ring substituents obey the Hammett relationship as shown in Fig. 4.

Relevant to the mechanism is the fact that there is no incorporation of deuterium observed in the methyl groups of the carbinolamine ether adducts.

The Acetal Formation. In the *N*-isopropylideneanilines having *p*-Cl, *p*-Br, *p*-I, and *m*-CF_3, it has been found that the formation of the carbinolamine ether is followed by the slow formation ($k\simeq10^{-6}$—10^{-7}) of acetone dimethyl acetal which is identified by the appearance of the signal at δ 1.30, independent of the ring substituents. The assignment is confirmed by comparison of the chemical shift with that of an authentic sample.[8] The reactions are practically complete in 2 weeks at ambient temperature with *ca.* 11% conversion.

It is of interest that the formation of the acetal is seen only in these *N*-isopropylideneanilines. In those having more electron-releasing substituents the formation of the intermediate adduct is very small, while in those having more electronegative substituents the intermediate adduct seems too stable to undergo further reaction into the acetal.

The Mechanism of the Reaction. As seen from the results described above, the course and rates of the reactions of *N*-isopropylideneanilines in CD_3OD are characteristically dependent on the nature of ring substituents. The reaction scheme and probable mechanisms for the whole reactions are summarized in Scheme 1.[9] Whereas the substituent effects on the rates of H–D exchange and formation of carbinolamine ethers have the same trend, the fact that the latter without H–D exchange has larger rate constants rules out the possibility that protonation or deuteration of the imines (step *a*) is rate-determining step in both cases. Step *a* may well be the rate-determining step for adduct formation, but protonation of enamines (step *b*) is more likely to be slower than step *a* and rate-determining for exchange reactions. The extent of formation of the carbinolamine ethers is governed by the electrophilicity of the conjugate acid of the imines.

Syntheses and Reactions of Optically Active Polymers. I. Syntheses and Polymerizations of *N*-Vinylbenzyl-L-amino Acid Derivatives

Mitsuaki NARITA and Masayasu AKIYAMA
Tokyo University of Agriculture and Technology, Koganei, Tokyo 184

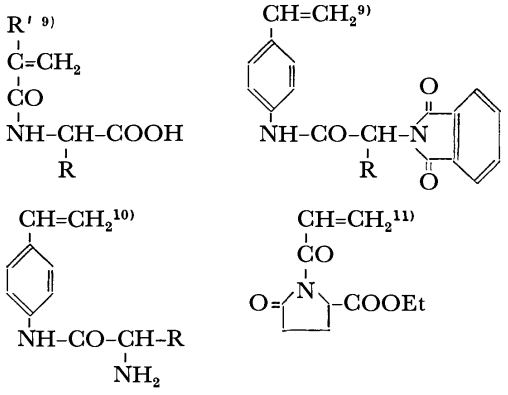
(Received July 16, 1973)

N-Vinylbenzyl-L-amino acids were synthesized by the reaction of L-amino acids with formylstyrenes and the subsequent reduction of the condensation products with sodium borohydride. The procedure was performed without protection of the various functional groups of amino acids and racemization was not accompanied by the above process. The method is useful for the synthesis of optically active vinyl monomers containing various amino acids with their intact functionality. As a representative L-amino acid, a variety of *N*-vinylbenzyl-L-leucine derivatives such as *N*-methyl-L-leucine, L-leucine ethyl ester, L-leucinol and *N*-formyl-L-leucine ethyl ester were prepared by means of chemical transformation. These optically active monomers of leucine derivatives were polymerized to optically active polymers.

Though considerable attempts were made to carry out asymmetric syntheses using optically active polymers as catalysts or reagents,[1-5] no clear asymmetric courses, as usually seen in the formation of low optically active products, have been established. Steric regulation for asymmetric induction would be better achieved by proper selection of a functional group responsible for the asymmetry in the reaction course.

We previously reported on the use of polymers as chemical reagents in amide group formation.[6] To extend the utility of reagents of this type, we have undertaken the investigation of syntheses and reactions of polymers containing optically active groups.

The groups of our primary concern are those derived from α-amino acids, which contain one asymmetric carbon and various functional groups. Some devices have been worked out for the preparation of synthetic polymers possessing α-amino acid residues. Most polymers were synthesized through polymer reactions by which α-amino acids were introduced into reactive polymers, such as chloromethylated polystyrene[7] polymethacroyl chloride.[8] A few polymers have also been obtained by polymerizations of vinyl monomers containing α-amino acids as shown below.[9-11]



In polymer reactions, undesirable side reactions are sometimes inevitable. As to the monomers hitherto prepared, either amino- or carboxyl-group was transformed into amide for introduction of the vinyl group.

In order to use optically active polymers as chiral components for asymmetric reactions, it is desirable that they are prepared by polymerization of optically active monomers. This paper describes a new convenient synthesis and polymerization of vinyl monomers which contain an optically active α-amino acid moiety.

Results and Discussion

Syntheses of N-*Vinylbenzyl-*L-*amino Acids.* Quitt *et al.*[12] reported a synthetic procedure of *N*-benzyl-L-amino acids, in which L-amino acids were allowed to react with benzaldehyde and be reduced subsequently with sodium borohydride.

This procedure was applied and a variety of *N*-vinylbenzyl-L-amino acids were prepared by the reaction of L-amino acids with *o*- or *p*-formylstyrene according to Scheme 1.

The reaction of sodium salt of L-amino acids, glycine, valine, leucine, tyrosine, histidine and glutamine, was carried out in methanol at room temperature. Intermediate (I') formed was not isolated but was reduced with sodium borohydride under cooling conditions to give *N*-vinylbenzyl-L-amino acids (II or III) as crystals after acidification of the reaction mixture. Vinyl monomers II and III were obtained in good yield without protection of the functional groups. The physical data of the monomers synthesized by the above procedure

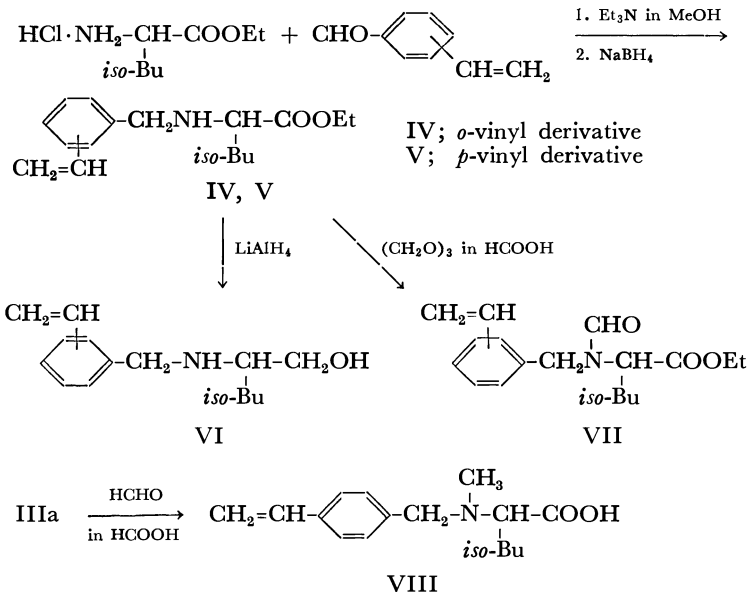

Scheme 2.

are given in Table 1. These amino acid derivatives are optically active and are insoluble in non-polar organic solvents. *o*-Vinyl derivatives are more soluble than *p*-vinyl derivatives in acetic acid, trifluoroacetic acid and formic acid.

Hydrogenolysis of compounds IIb and IIc with palladium-carbon catalyst produced the starting amino acids, L-valine and L-leucine. Optical rotations of the hydrogenolysis products coincided with those of the starting L-amino acids, indicating that the reactions according to Scheme 1 proceed without recemization.

Syntheses of N-*Vinylbenzyl-*L-*leucine Derivatives.* L-Leucine was selected as a representative, and several vinyl monomers carrying the derivatives of this amino acid were prepared according to Scheme 2.

The reaction of L-leucine ethyl ester with formylstyrenes gave *N*-vinylbenzyl-L-leucine ethyl esters IV and V. The reduction of IV with lithium aluminium hydride yielded *N*-*o*-vinylbenzyl-L-leucinol (VI). The reaction of IV with trioxane in formic acid did not give the *N*-methylated product but *N*-formyl-*N*-*o*-vinylbenzyl-L-leucine ethyl ester (VII). *N*-methylation of IIIa was carried out with formalin in formic acid to give *N*-methyl-*N*-*p*-vinyl-benzyl-L-leucine (VIII). The results are summarized in Table 2. The L-leucine derivatives are optically active. Vinyl monomers IV, V, VI and VII are easily soluble in almost all organic solvents, while the *N*-methylated amino acid(VIII) is soluble in acetone, methanol, chloroform and other polar solvents.

Optically active vinyl monomers containing various functional groups derived from α-amino acids were

prepared easily without protection of the functional groups (Schemes 1 and 2).

Polymerization of N-*Vinylbenzyl-*L-*leucine Derivatives.* Homo- and co-polymerizations of *N*-vinylbenzyl-L-leucine derivatives were carried out with the use of azobisisobutyronitrile (AIBN) as an initiator at 75—80 °C. The results are summarized in Tables 3 and 4.

Homopolymerization of IIIa in formic acid gave *N*-formylated homopolymer (IX). Homopolymer of V was gummy and became insoluble after a few weeks. Copolymerization of IIc, V, and VIII with styrene gave the corresponding copolymers, whose compositions coincided with mole ratios of the initial monomer mixtures. The inherent viscosities of copolymers were low, but the infrared absorption bands at 990 and 910 cm^{-1} (–CH=CH_2) disappeared virtually in the IR spectra of the products. The homo- and co-polymers shown in Table 4, are optically active. Cross-linking polymerization of L-leucine derivatives in the presence of divinylbenzene (DVB) was carried out with an AIBN initiator. Cross-linked insoluble polymers were obtained in good yield. Polymers IX and XI are soluble in formic acid, acetic acid, and trifluoroacetic acid and insoluble in other organic solvents. Polymers XII and XV are soluble in formic acid, trifluoroacetic acid, pyridine, and *N*,*N*-dimethylformamide and insoluble in ether and methanol. Polymers XIII and XIV are soluble in almost all organic solvents except methanol and ethanol.

These optically active functional polymers might be useful as adsorbents for the chromatographic resolution of amino acid racemates, or as chiral components for asymmetric syntheses.

Experimental

The melting points were uncorrected. The IR spectra were obtained as potassium bromide disks with a Jasco Model DS-403G grating infrared spectrophotometer. Optical rotations were determined with a Jasco Model ORD/UV-5 optical rotatory dispersion recorder. Formylstyrenes were prepared by Dale's method.[13]

Preparation of N-*vinylbenzyl-*L-*amino Acids.* The following is an example of the general procedure. L-Leucine, 3.93 g (0.03 mol), was dissolved in 30 ml of methanol containing 1.20 g (0.03 mol) of sodium hydroxide and 1.0 ml of water. To this solution was added 4.20 g (0.032 mol) of *o*-formylstyrene with stirring at room temperature. After 1 hr, 5 ml of water containing 0.75 g (0.02 mol) of sodium borohydride was added dropwise below 20 °C by cooling

TABLE 4. PHYSICAL PROPERTIES OF POLY-*N*-VINYLBENZYL-L-LEUCINE DERIVATIVES

a) Based on nitrogen analysis. b) $c=2.0$, in formic acid. c) $c=0.5$ g/dl, in formic acid. d) calculated for the *N*-formylated polymer ($C_{16}H_{21}O_3N$). e) $c=2.0$, in tetrahydrofuran. f) $c=0.5$ g/dl, in tetrahydrofuran. g) calculated for the initial copolymerization mixture.

with ice-cold water, and the solution was stirred for 1 hr under cooling. The pH was then adjusted to 5—6 with diluted hydrochloric acid. *N-o*-Vinylbenzyl-L-leucine was precipitated as white crystals and filtered and washed with acetone. The yield was 6.8 g (76%). Recrystallization from water-acetic acid gave a pure material, mp 196 °C (dec.).

N-p-Vinylbenzyl-L-leucine was prepared with *p*-formylstyrene instead of *o*-formylstyrene. The other *N*-vinylbenzyl-L-amino acids were similarly obtained by the reactions of L-amino acids with formylstyrenes. The results are summarized in Table 1.

IR absorption bands common to *N-o*-vinylbenzyl-L-amino acids are as follows: (cm^{-1}), 3200 (NH), 3080—3020 (aromatic CH), 1620—1550 (COO^-), 990, 910 (−CH=CH_2), 780 (*o*-substituted benzene), and those for *N-p*-vinylbenzyl-L-amino acids are 3200 (NH), 3080—3030 (aromatic CH), 1620—1550 (COO^{-1}), 990, 910 (−CH=CH_2), 850—800 (*p*-substituted benzene).

Hydrogenolyses of compounds (IIb) and (IIc) (1.0 g) with 10% palladium-carbon catalyst (0.5 g) were carried out in acetic acid (20 ml) at 80 °C and 100 atm for 10 hr. Palladium-carbon was filtered off. Acetic acid was then, evaporated under vacuum, and the residue was recrystallized from water. L-Leucine; yield 0.42 g, mp 293 °C (dec.), $[\alpha]_D^{27}$ −11.0 (*c* 2.0, H_2O). L-Valine; yield 0.37 g, mp 300 °C, $[\alpha]_D^{27}$ +6.3 (*c* 4.8, H_2O).

Preparation of N-*Vinylbenzyl-L-leucine Ethyl Ester.* L-Leucine ethyl ester hydrochloride, 19.5 g (0.10 mol), and triethylamine, 10.2 g (0.10 mol), were dissolved in 100 ml of methanol. *o*-Formylstyrene, 13.5 g (0.10 mol), was added to this solution at room temperature. After stirring for 1 hr, 30 ml of water containing 3.8 g (0.10 mol) of sodium borohydride was added dropwise below 20 °C by cooling with ice-cold water and stirring. The solution was stirred for 1 hr under cooling, and then 20 ml of 5% sodium carbonate solution was added. This solution was extracted three times with 150 ml of ether. The ether solution was dried with sodium sulfate, and concentrated. The residue was distilled in the presence of 0.5 g of cuprous chloride under vacuum to yield 18.2 g (66%) of *N-o*-vinylbenzyl-L-leucine ethyl ester, bp 129—131 °C/0.5 mmHg.

N-p-Vinylbenzyl-L-leucine ethyl ester was similarly obtained, bp 153—155 °C/1 mmHg. The yield was 70%.

IR data (cm^{-1}); 3080, 3070 (aromatic CH), 2980, 2880 (isobutyl), 1720 (COOEt), 1625 (−CH=CH_2), 1450, 1370 (isobutyl), 1170, 1150 (ester), 990, 910 (−CH=CH_2), 825 (*p*-vinyl compound), 775 (*o*-vinyl compound).

Preparation of N-o-*Vinylbenzyl-L-leucinol.* *N-o*-Vinylbenzyl-L-leucine ethyl ester, 16.0 g (0.058 mol), in 70 ml of ether was added dropwise with stirring to lithium aluminium hydride, 3.8 g (0.10 mol) in 80 ml of ether. After the mixture was stirred for 40 min and then diluted with ether, 10 ml of water was added with vigorous stirring. The ether solution was filtered, and the precipitate was washed with ether and with methanol. The washings were combined with the filtrate. The mixture was dried, and concentrated under vacuum to give crystals. Recrystallization from *n*-hexane gave a pure material in 70% (9.4 g) yield, mp 57—59 °C.

IR data (cm^{-1}); 3500 (OH), 3080—3000 (aromatic CH), 2990, 2920, 2880 (isobutyl), 1630 (−CH=CH_2), 1590, 1490, 1450 (benzene ring), 1100—1050 (−C−O−) 990, 910 (−CH=CH_2), 780 (*o*-substituted benzene).

Reaction of N-o-*Vinylbenzyl-L-leucine Ethyl Ester with Trioxane in Formic Acid.* *N-o*-Vinylbenzyl-L-leucine ethyl ester, 8.0 g, and trioxane, 1.0 g, were dissolved in 5 ml of formic acid. The solution was heated at 95—1000 °C for 2 hr, and then concentrated under vacuum. The residue was distilled under vacuum to give *N-o*-vinylbenzyl-*N*-formyl-L-leucine ethyl ester, bp 173—176 °C/1 mmHg. The yield was 5.1 g.

IR data (cm^{-1}); 3080, 3070 (aromatic CH), 2980, 2970 (isobutyl), 1730 (ester), 1670 (amide), 1625 (−CH=CH_2).

Preparation of N-p-*Vinylbenzyl-N-methyl-L-leucine.* *N-p*-Vinylbenzyl-L-leucine, 15.0 g (0.06 mol) was suspended in

the solution of formic acid (12 ml) and 40% formalin (9 ml; *ca.* 0.12 mol) and heated on a water bath for 30 min. *N-p*-Vinylbenzyl-L-leucine was gradually dissolved into the solution with vigorous carbon dioxide evolution. This solution was concentrated under vacuum. Water was added to the residue and then evaporated. The procedure was repeated three times. *N-p*-Vinylbenzyl-*N*-methyl-L-leucine, thus separated, was recrystallized from benzene two times. The yield was 12.2 g, mp 158—160 °C.

IR data (cm^{-1}); 1600 (COO^-), 1370 (CH_3), 990, 910 ($-CH=CH_2$), 845, 825 (*p*-substituted benzene).

Polymerization of N-*Vinylbenzyl-L-leucine Derivatives.* Homo- and co-polymerizations of *N*-vinylbenzyl-L-leucine derivatives were carried out with 5—10 mol% of azobisisobutyronitrile (AIBN) as an initiator at 75—80 °C. The amounts of monomers and solvents used are given in Table 3.

The polymerization tubes were sealed off under vacuum, and heated in a thermostated bath. After polymerization, the polymer solution was poured into a non-solvent and the polymer obtained as precipitates was purified by reprecipitation.

Cross-linked polymers (XVI—XVIII) were similarly prepared by polymerization in the presence of divinylbenzene, purified by washing with benzene and with methanol, respectively, in a Soxhlet extractor for 5 hr.

Non-solvents were acetone for IX, water for X, ether for XI and XV, and methanol for XII, XIII and XIV. Solvents were formic acid for IX and XI, and tetrahydrofuran for X, XII, XIII, XIV and XV.

In the IR spectra of homopolymers, the bands at 990 and 910 cm^{-1} ($-CH=CH_2$) disappeared completely. In the IR spectra of copolymers the bands at 1630, 990 and 910 cm^{-1} ($-CH=CH_2$) disappeared, and those at 1490, 750 and 690 cm^{-1} ($-CH=CH_2$) disappeared, and those at 1490, 750 and 690 cm^{-1} ($-CH_2-CH-C_6H_5$) appeared.

Synthesis of TACK, a New Chloromethyl Ketone Derivative of Arginine[1,2]

Ken INOUYE, Atsushi SASAKI, and Nobuo YOSHIDA

Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka 553

(Received September 7, 1973)

A synthesis is described of TACK, the chloromethyl ketone derivative of N^{α}-tosyl-L-arginine, in which a crystalline intermediate N^{G}-nitro-TACK is found to be converted into TACK with hydrogen fluoride without appreciable impairment of the chloromethyl ketone moiety.

TLCK is an active site-directed reagent for trypsin, first described by Shaw *et al.*[3] Their initial synthesis involves the hydrolytic removal of a benzyloxycarbonyl group from the N^{ε}-protected derivative to lead to the formation of TLCK in a rather low yield. Recently Shaw and Glover[4] have improved the yield greatly by the use of trifluoroacetic acid[5] in this deprotection step. A trifluoroacetic acid-hydrochloric acid mixture was also used by other authors.[6] For the same purpose we tried to use the hydrogen fluoride treatment[7] in which the treatment was found to cause no detectable damage in the chloromethyl ketone moiety of TLCK, affording the reagent in a good yield.[8] This finding prompted us to extend the use of hydrogen fluoride to the synthesis of N^{α}-tosyl-L-arginine chloromethyl ketone (TACK). The only chloromethyl ketone derivative of arginine ever known is *p*-nitrobenzyloxycarbonyl-L-arginine chloromethyl ketone (Z(NO_2)ACK) which has been prepared by Shaw and Glover.[4] Attempts we have made to obtain TACK are as follows:

$$\text{H-Arg(R)-OH} \xrightarrow{\text{Tos-Cl}} \text{Tos-Arg(R)-OH} \xrightarrow{PCl_5}$$

$$\text{Tos-Arg(R)-Cl} \xrightarrow{CH_2N_2} \text{Tos-Arg(R)-CHN}_2 \xrightarrow{\text{HCl}}$$

$$\text{Tos-Arg(R)-CH}_2\text{Cl} \xrightarrow{\text{HF}} \text{Tos-Arg-CH}_2\text{Cl (TACK)}$$

where R is either a tosyl or a nitro group, which is known to be split with hydrogen fluoride.[7,9] When R=NO_2, the penultimate compound Tos-Arg(NO_2)-CH_2Cl was crystalline and was found to be fairly stable. In the case of R=Tos, however, all the intermediates were amorphous and their purification seemed to be of trouble. In this communication we wish to report our TACK synthesis starting from nitroarginine.

TACK, prepared in the present work, was homogeneous in thin-layer chromatography. The chlorine content of TACK hydrochloride has remained unchanged at least for six months, provided that the preparation has been kept dry and refrigerated. The inhibition studies of enzymes with TACK will be described in a separate communication.[10]

Experimental

All melting points were uncorrected.

N^{α}-p-*Toluenesulfonyl*-N^{G}-*nitro*-L-*arginine (I).* Nitroarginine (5.50 g, 25 mmol) was dissolved in 2M sodium hydroxide (37.5 ml), and sodium carbonate (2.65 g, 25 mmol) and acetone (25 ml) were introduced. To this was then added dropwise a solution of *p*-toluenesulfonyl chloride (7.15 g, 37.5 mmol) in acetone (20 ml) at 0 °C. The mixture was stirred at 0 °C for 3.5 hr. After removal of acetone by evaporation *in vacuo*, the aqueous solution was acidified with 4 M hydrochloric acid. The crystalline precipitates which separated were filtered off, washed with water and dried *in vacuo* (8.16 g, 88%). Recrystallization from methanol–water gave the desired product in pure form; wt, 7.39 g (79%), mp 167—169 °C, $[\alpha]_D^{22}+23.6\pm0.7°$ (*c* 1.0, methanol).

Found: C, 42.05; H, 5.20; N, 18.74; S, 8.75%. Calcd for $C_{13}H_{19}N_5O_6S$: C, 41.82; H, 5.13; N, 18.76; S, 8.59%.

N^{α}-p-*Toluenesulfonyl*-N^{G}-*nitro*-L-*arginyl Diazomethane (III).* A solution of I (0.75 g, 2 mmol) in anhydrous tetrahydrofuran (10 ml) was chilled in an ice-salt bath and to this was added phosphorus pentachloride (0.84 g, 4 mmol) in several portions. The mixture was stirred for 60 min during which the temperature was allowed to rise to 0 °C. Anhydrous ether (80 ml) was then introduced to yield sirupy precipitates. The supernatant solution was removed by decantation and the residue was triturated with ether and dried *in vacuo* over sodium hydroxide pellets at 4 °C to give N^{α}-*p-toluenesulfonyl*-N^{G}-*nitro*-L-*arginyl chloride (II)* as amorphous solid (0.47 g, 60%); IR (Nujol) 1790 cm^{-1}. A small sample was dissolved in methanol and this was subjected to tlc (Silica gel GF, E. Mreck) in methanol–chloroform (2 : 8 by vol) to give a single component which was indistinguishable from the authentic methyl ester of I.

The chloride (II) obtained above was dissolved in anhydrous tetrahydrofuran (10 ml) and to this solution was added an ethereal solution of diazomethane at 0 °C until an yellow color persisted. The reaction mixture was stirred at 0 °C for 60 min, after which time anhydrous ether (80 ml) was introduced. The resulting precipitates were filtered off, washed with ether and dried *in vacuo* to give III; wt, 0.36 g (45%, as based on I used), IR (chloroform) 2145 cm^{-1}, $[\alpha]_D^{22}$ $-51.3\pm1.0°$ (*c* 1.0, methanol). The product was used for the subsequent reaction without further purification.

N^{α}-p-*Toluenesulfonyl*-N^{G}-*nitro*-L-*arginyl Chloromethane (IV).* To a 0.25 g-sample of III was added M hydrogen chloride in acetic acid (10 ml) to cause the reaction to occur with the instant evolution of nitrogen. The mixture was kept at room temperature for 60 min, followed by evaporation *in vacuo* at a bath temperature of 35 °C. The residue was then lyophilized from acetic acid. The resulting crude preparation of IV was submitted to a column of silica-gel (0.05—0.2 mm, E. Merck, 25 g) using a mixture of methanol–chloroform (1 : 9 by vol) as a solvent for elution. Tubes 17—30 (5 g/tube) containing the desired product as a main component (as examined by tlc) were collected and evaporated *in vacuo* to give a sirupy residue which crystallized upon addition of chloroform (0.12 g, 49%). Recrystallization from methanol yielded a pure and odorless preparation of IV in an 86% recovery; mp 165—167 °C decomp., $[\alpha]_D^{24}$ $-23.7\pm0.7°$ (*c* 1.0, dimethylformamide), IR (Nujol) 1745 cm^{-1}.

Found: C, 41.64; H, 5.11; N, 17.34; S, 8.02; Cl, 8.80%. Calcd for $C_{14}H_{20}N_5O_5SCl$: C, 41.43; H, 4.97; N, 17.26; S, 7.90; Cl, 8.74%.

N^{α}-p-*Toluenesulfonyl*-L-*arginyl Chloromethane* (N^{G}-*Tosyl*-L-*arginine Chloromethyl Ketone, TACK) Hydrochloride (V).* Compound IV (0.18 g) and anisole (0.2 ml) were put into a reaction vessel (made of fluorinated polyethylene) and hydrogen

fluoride (*ca.* 5 ml) was introduced into the vessel placed in a dry ice-acetone bath. The mixture was stirred at 0 °C for 30 min. After removal of hydrogen fluoride by evaporation *in vacuo* the residue was dissolved in water and the solution was, after washing with ethyl acetate, passed through a column (0.9×10 cm) of Amberlite CG-400 (acetate form); the column was washed with portions of water. The aqueous solutions were combined and M hydrochloric acid (0.5 ml) was added. Lyophilization of the resulting solution gave the desired TACK hydrochloride; wt, 0.18 g (98%), $[\alpha]_D^{25}$ $-21.2\pm0.6°$ (*c*, 1.0, 0.1 M hydrochloric acid), IR (KBr) 1737 cm^{-1}. Tlc revealed that the product was homogeneous to Sakaguchi reagent (Cellulose F, E. Merck, 1-butanol-acetic acid-water (18 : 2 : 5 by vol)).

Found: C, 40.95; H, 5.66; N, 13.13; S, 7.17; Cl, 17.95%. Calcd for $C_{14}H_{22}N_4O_3SCl\cdot HCl\cdot H_2O$: C, 40.48; H, 5.82; N, 13.49; S, 7.72; Cl, 17.07%.

The Photo-desulfurization of Crude Naphtha by UV Irradiation

Yoshio BABA

National Research Institute for Pollution and Resources, Kawaguchi, Saitama 332

(Received July 5, 1973)

The photolysis of crude naphtha in the presence of an oxidizing reagent was studied with a view to accomplishing the desulfurization of crude naphtha. The irradiation of crude naphtha consisting of 0.15% sulfur by means of a 200-W high-pressure mercury-vapor lamp, with the aeration of air or oxygen at the flow rates of 5—15 ml/min at 0 °C, resulted in an 80—90% photolysis of the principal mercaptans and sulfides in the crude naphtha within 20 min. The major photo-oxidation products were water-soluble oxygenated sulfur compounds; thus, this process resulted in 67.8% desulfurization when the irradiated naphtha was washed with water. The effects on the photolysis of the molecular weights and the structures of sulfur compounds were also examined with 11 mercaptans and 3 sulfides.

An alkali-sweetening process, *e. g.*, doctor sweetening, Merox process, the Unisol process, is a low-cost process to remove corrosive and malodorous mercaptans and to increase the lead susceptibility of gasoline, but it has several disadvantages: the susceptibility to the oxidation of the mercaptans by alkali solution is markedly influenced by the structural features of mercaptan, and thus the process is not effective for removing *tert*-mercaptans; desulfurization is usually low because sulfides in crude naphtha cannot be removed by this method, and this process produces a malodorous waste liquor.

In this paper a photo-desulfurization of light straight naphtha was studied on the basis of the fact that mercaptans and sulfides can be photolyzed by UV irradiation.

Although many reports on the photolysis of mercaptans and sulfides have been published, most of them have been focused on the reaction mechanism of the photolysis of these sulfur compounds,[1-10] and few works have been undertaken for the purpose of a practical application.[11-12] In related works, Murray[11] studied the photo-oxidation method as a possible means of controlling malodorous waste gases containing mercaptans and sulfides from a kraft pulp mill. In his study of the effects of UV light on the oxidation of methyl mercaptan (MM), dimethyl sulfide (DMS), and dimethyl disulfide (DMDS), Murray was able to demonstrate the photo-oxidation of these compounds at both 2537 and 3600 Å. By monitoring the disappearance of the starting materials, he showed that DMDS undergoes photo-oxidation most rapidly, while DMS was found to be the least reactive. In addition MM exposed to solar radiation was found to disappear with a half-life of approximately 7 days during a period with an average noon temperature of 10 °C.

Bentley[12] has reported that about a 7-hr irradiation of dimethyl sulfide in air with a 200-W high-pressure mercury-vapor lamp caused a more than 91% decomposition of the sulfide.

In this study 11 mercaptans, *i. e.*, ethyl-, *n*-propyl-, isopropyl-, *n*-butyl-, *sec*-butyl-, isobutyl-, *tert*-butyl-, *n*-amyl-, *sec*-isoamyl-, *tert*-amyl-, and *n*-hexyl-mercaptans and 3 sulfides, *i.e.*, diethyl-, di-*n*-butyl-, and diallyl-sulfides, were irradiated with a 100-W low-pressure mercury-vapor lamp at 0 °C to determine the effects of the molecular weights and structures of these sulfur compounds on the photolysis; further experiments were also performed in order to determine the rates of the photo-decomposition and photo-oxidation of important mercaptans and sulfides in crude naphtha by the irradiation of light straight naphtha with a bp 27—95 °C from Iranian heavy by means of a 200-W high-pressure mercury-vapor lamp at the temperatures of 0, 30, 50 °C, and by irradiation in the presence of oxidizing reagents, air, and oxygen at 0 °C.

The results showed that the irradiation of the crude naphtha consisting of 0.15% sulfur by means of a 200-W high-pressure mercury vapor lamp, with the aeration of air or oxygen at the flow rate of 5—15 ml/min and at 0 °C, resulted in an 80—90% photolysis of the major mercaptans and sulfides in the crude naphtha within 20 min; unlike the alkali-sweetening process, no difference in the reactivity of mercaptan due to its structural features has been observed. The principal photo-oxidation products were SO_2, SO_3, and sulfonic acids; the reaction afforded a 67.8% reduction of the total sulfur content in the photo-desulfurized naphtha.

Experimental

1. Materials and Apparatus. The mercaptans and sulfides used to determine the effects of thier molecular weights and structures on the photolysis, and used as the internal standards for the gas chromatography, were analytical-standard reagents (Poly Science Corp.).

The crude naphtha used for the photo-desulfurization study was a light straight naptha (bp 27—95 °C) from Iranian heavy.

The photolysis was conducted in a 200-ml round-bottom, Pyrex flask fitted with a water-cooled lamp housing, a thermometer, and a reflux condenser cooled with ice water.

The light sources were a 100-W low-pressure mercury-vapor lamp, which emits predominantly 2357 Å light, in the runs for determining the effects of the molecular weights and structures on the photolysis of mercaptans and sulfides, and a 200-W high-pressure mercury-vapor lamp with a predominant light of 3650 Å in the runs for the photo-desulfurization of crude naphtha.

Gas chromatography was done by means of Micro Tek Instruments Corp. Model 160 gas chromatograph equipped with a flame photometric detector and a 3 m×3 mm i.d. Teflon analytical column packed with 1,2,3-tris(cyanoethoxy)-propane on Shimalite 25%, 80/100 mesh.

2. Procedure. Each 100-ml portion of *n*-hexane solutions (100 ppm) of mercaptans and sulfides or the crude naphtha was placed in the flask, and the reaction solution

was irradiated with a mercury-vapor lamp at a constant temperature. One ml portions of the sample solution were taken off at discrete periods of irradiation time and mixed with the *n*-propyl sulfide standard solution (prepared by dissolving 10 μl of the sulfide in 5 ml of *n*-hexane and stored in a cooled dark place) to serve as internal standards for the gas chromatography.

The rates of the reaction of mercaptans and sulfides on the photolysis were determined by comparing the peak area of each sulfur compounds to be analyzed with that of the internal standard, calculated by means of a digital integrator; the relative amounts of sulfur compounds in the sample solutions were compared with those in the original solutions.

In the runs to study the effects of the molecular weights and structures of mercaptans and sulfides on the photolysis, the reactions were carried out at 0 °C; in the runs of the photo-desulfurization of the crude naphtha, the reaction temperatures of 0 °C, 30 °C, and 50 °C were used.

The experiments of the photo-oxidation of the crude naphtha were performed at 0 °C; with the aeration of air or oxygen at the flow rates of 5—30 ml/min. In these experiments, corresponding dark reactions under the same reaction conditions except for irradiation were done in order to check the amount of possible mechanical losses or chemical reactions.

The total sulfur contents in the crude and the photo-desulfurized naphtha were determined by the UOP oxygen-hydrogen combustion method (UOP 586—66); the reaction product was washed with distilled water, and a measured aliquot of the water solution was used for determining SO_2 and SO_3 by gravimetric $BaSO_4$ analysis.

The reaction product formed by UV irradiation was identified as higher-molecular-weight sulfides by gas chromatography utilizing a mercaptan-substracting column ($Hg(CN)_2$ 1% on Chromosorb).

Results and Discussion

The studies of the photolysis of organic sulfur compounds indicate that the photolysis of disulfide is initiated through –S–S– fission[1] rather than C–S fission,[2] while in the cases of monosulfides and mercaptans, the reactions are believed to occur through an initial cleavage of the C–S and S–H bonds respectively.[4,12]

In any case, however, the initial photo-decomposed reaction products are thinyl and alkyl radicals; these radicals are considered to produce hydrocarbons, mercaptans, and various sulfides by the following series of recombination reactions:

$$CH_3\cdot + \cdot CH_3 \rightarrow C_2H_6 \quad (1)$$

$$CH_3S\cdot + \cdot CH_3 \rightarrow CH_4 + CH_2{=}S \quad (2)$$

$$CH_3S\cdot + CH_3SCH_2R \rightarrow CH_3SH + CH_2{=}SCH_2R \quad (3)$$

$$CH_3S\cdot + CH_3S\cdot \rightarrow CH_3SSCH_3 \quad (4)$$

$$CH_3S\cdot + CH_2{=}S \rightarrow CH_3SCH_2S \xrightarrow{\cdot CH_3} CH_3SCH_2SCH_3 \quad (5)$$

The reaction becomes complex and produces oxygenated sulfur compounds (*i.e.*, sulfoxides, sulfones, sulfonic acids, SO_2 and SO_3) and oxygenated compounds (*i.e.*, alcohols, carboxylic acids, aldehydes, and esters) when an oxidizing reagent, such as air or oxygen is present in the reaction system.

A possible reaction mechanism for the formation of the oxygenated sulfur compounds, proposed by Bentley,[12] can be briefly described as follows:

$$CH_3S\cdot + O_2 \rightarrow CH_3SOO\cdot \xrightarrow{RH\ (e.g.,H_2O)} CH_3SOOH + R\cdot \quad (6)$$

$$\rightarrow SO_2 + \cdot CH_3 \quad (7)$$

$$CH_3SOOH \xrightarrow{h\nu} CH_3SO\cdot + \cdot OH \quad (8)$$

$$CH_3SO\cdot + RH \longrightarrow CH_3SOH + R\cdot \quad (9)$$

$$3\,CH_3SOOH \longrightarrow CH_3SOOSCH_3 + CH_3SO_3H \quad (10)$$

(1) Effect of the Molecular Weight on the Photolysis of Mercaptans. When the photochemical labilities of five mercaptans with a straight carbon chain (*i.e.*, ethyl-, *n*-propyl-, *n*-butyl-, *n*-amyl-, and *n*-hexyl-mercaptans) are compared, photochemical stability is found to increase with an increase in the carbon number of mercaptans.

As is shown in Fig. 1, with ethyl- and *n*-propyl-

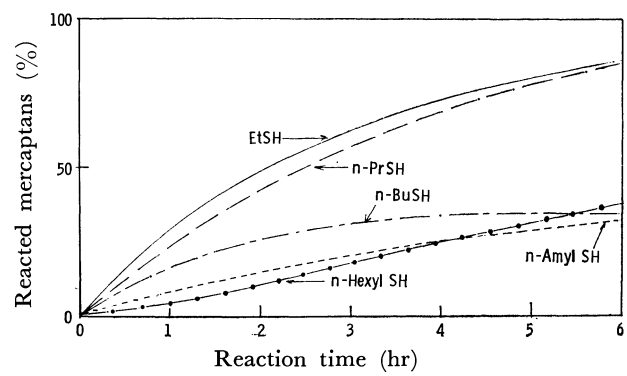

Fig. 1. Effect of molecular weight on photo-decomposition of mercaptans.

mercaptans a 3-hr irradiation of *n*-hexane solutions of these mercaptans at 0 °C with a low-pressure mercury-vapor lamp gave a more than 50% conversion, while with C_4–C_6 straight chain mercaptans the photolysis afforded only a 15—30% conversion under the same reaction conditions. Although a 6-hr irradiation caused an 85% decomposition with C_2 and C_3 mercaptans, C_4–C_6 mercaptans afforded only a 30—40% decomposition.

(2) Effect of the Molecular Structure on the Photolysis of Mercaptans and Sulfides. As the photolysis of mercaptans and sulfides is considered to be initiated through –S–S–, C–S, or S–H fission, the photochemical labilities were compared with *n*-propyl, isopropyl-, *n*-butyl-, *tert*-butyl-, *sec*-butyl, isobutyl, *n*-amyl-, *sec*-isoamyl-, and *tert*-amyl-mercaptane in order to examine the difference in photochemical stability with the structural features of the carbon atom attached to the –S– or –SH group.

In the cases of mercaptans with lower molecular weights, as is shown in Figs. 2 and 3, no difference in photochemical stability due to the change in the molecular structure was observed. With butyl mercaptan isomers, only a slight difference in the photochemical

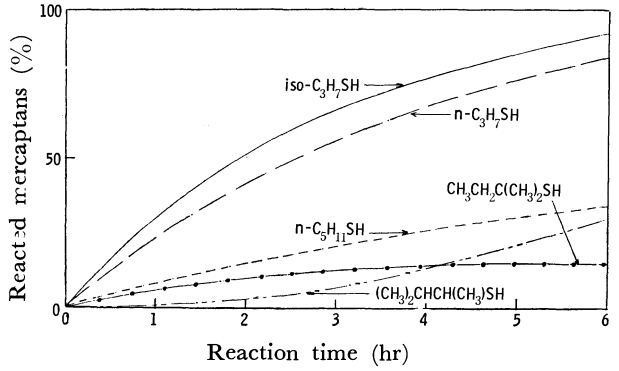

Fig. 2. Effect of molecular structure on photo-decomposition of mercaptans.
(Propyl mercaptans and amyl mercaptans)

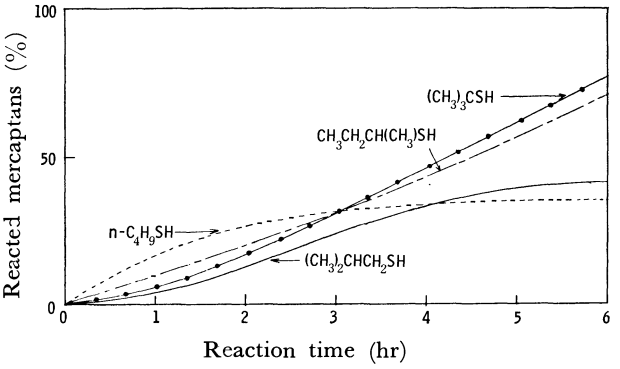

Fig. 3. Effect of molecular structure on photo-decomposition of mercaptans.
(Butyl mercaptans)

stability was observed at the beginning of the irradiation, but after a 6-hr irradiation *n*-butyl- and isobutyl-mercaptans, which have primary carbon atoms, were decomposed by 35—40%, while the irradiation of mercaptans containing secondary or tertiary carbon atoms (*i.e.*, *sec*-butyl- and *tert*-butyl-mercaptans) resulted in a 70—75% conversion.

It is, however, apparent from a comparison of the amyl mercaptan isomers with mercaptans of higher molecular weights, that the structural features of the carbon atoms attached to the –SH group slightly influence the photochemical stability.

Sulfides are more stable upon photolysis than the mercaptans, and Milligan[8] reported that, on the

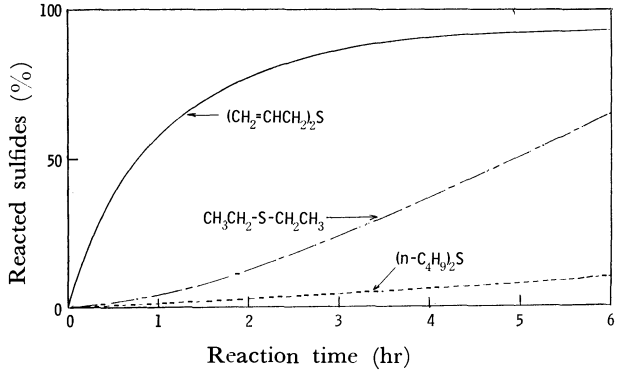

Fig. 4. Effect of molecular structure on photo-decomposition of sulfides.

photolysis of dialkyl polysulfides, no simple correlation of the stability of dialkyl polysulfides with the nature of the alkyl substituents was observed.

However, the presence of an unsaturated linkage in the carbon chain of the sulfide markedly reduces the photochemical stability of the sulfide. This fact can be demonstrated by comparing the rates of the photo-decomposition of three sulfides. As is shown in Fig. 4, a 2-hr irradiation of diethyl sulfide and di-*n*-butyl sulfide resulted in a 5—15% conversion, while diallyl sulfide, a typical unsaturated sulfide, afforded a 75% conversion, which corresponds to that of the photochemical labile mercaptans with lower molecular weights.

(3) Effect of the Reaction Temperature on the Photolysis of Mercaptans and Sulfides in Crude Naphtha. Inaba[4] reported that no temperature effect had been observed on the photolysis of methyl mercaptan in a gaseous phase because of the heat stability of the thinyl radical, formed as an initial photo-decomposition product of mercaptan.

In this study, UV irradiations of the crude naphtha were carried out at 0, 30, and 50 °C in order to examine the effect of the reaction temperature on the photolysis of the principal mercaptans and sulfide (*i.e.*, ethyl-,

isopropyl-, and *sec*-butyl-mercaptans and dimethyl sulfide) in the crude naphtha.

As is shown in Figs. 5 and 6, no influence of the reaction temperature was observed with any mercaptan or sulfide.

(4) Effect of an Oxidizing Reagent on the Photo-oxidation of Mercaptans and Sulfides in Crude Naphtha. Bentley[12] obtained CH_3SO_3H (21%) and SO_2+SO_3 (30%) as the principal photo-oxidation products on the photolysis of dimethyl sulfide in air, and he concluded that the presence of air had altered the mode of the photolysis of the sulfide.

In this study, photolysis in the presence of oxidizing reagent, air, and oxygen was undertaken with a view to accomplishing the desulfurization of the crude naphtha rather than to oxidize the mercaptans to the sulfides. As the irradiation was conducted with aeration, the reaction temperature was kept at 0 °C to prevent any possible mechanical losses or chemical reactions.

Figures 7 and 8 compare the rates of the photo-oxidation of several principal mercaptans and sulfides in crude naphtha. The presence of an oxidizing reagent markedly increases the rate of the photo-decomposition of mercaptans and sulfides, but the difference in either the nature or the flow rate of the oxidizing reagents resulted in no practical influence

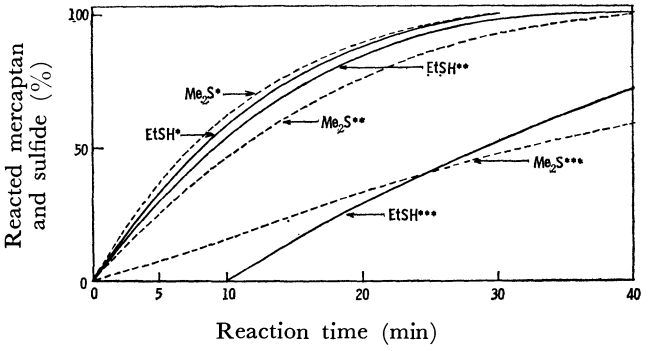

Fig. 7. Effect of oxidizing reagent on photo-decomposition of mercaptans and sulfides in crude naphtha.
* irradiated at 0°C with aeration (15 ml O_2/min)

*** irradiated at 0°C without aeration.

on the rate of the photo-oxidation (cf. Table 1). This suggests that the irradiation of crude naphtha by means of a high-pressure mercury-vapor lamp initiates the S–H and C–S fission of mercaptans and sulfides; thus, the formation of thinyl and alkyl radicals and the subsequent recombination reactions of free radicals (1—5), or the oxidation of these free radicals (6—10), takes place. In the presence of the oxidizing reagents, the oxidation of free radicals might occur in preference to the recombination reactions, but the former would not be accelerated by the presence of an excess of the oxidizing reagent.

The total sulfur content of the photo-desulfurized naphtha, obtained by washing the irradiated naphtha with water after a 40-min irradiation with aeration, decreased by 32.2%, and the sulfur compounds in the oil layer consisted mainly of higher-molecular-weight sulfides produced by the recombination reactions; 67.8% of the original sulfur compounds in the crude naphtha was converted into water-soluble oxygen-containing sulfur compounds, such as SO_2, SO_3, and sulfonic acids.

Unlike the results of the gas-phase photolysis of methyl mercaptan, dimethyl sulfide, and dimethyl disulfide, as reported by Rayner[11] and Haines,[7] or Milligans study[8] of the photolysis of several alkyl polysulfides, in this study no difference was observed in the rates of the photolysis of mrecaptans and sulfides in crude naphtha in either the presence or the absence of an oxidizing reagent.

Conclusion

Although a certain difference was observed in the rates of the photolysis of mercaptans due to their molecular weights and structural features, the UV irradiation of crude naphtha caused a rapid photolysis of the sulfur com ounds in it. This fact indicates the possibility of the practical application of this method for the desulfurization of the crude naphtha.

Thus, the irradiation of crude naphtha consisting of 0.15% sulfur by means of a 200-W high-pressure mercury-vapor lamp, with the aeration of air or oxygen at the flow rate of 5—15 ml/min and at 0 °C, resulted in an 80—90% photolysis of the principal mercaptans and sulfides in the crude naphtha within 20 min.

As the major photo-oxidation products were water-soluble oxygenated sulfur compounds, this process resulted in 67.8% desulfurization of the crude naphtha when the resultant UV irradiated naphtha was washed with water.

Effects of the Wavelength and the Matrix on the Photopolymerization of 2,5-Distyrylpyrazine and Its Related Compounds and on Their Photodepolymerization*

Yasuzo SUZUKI, Takashi TAMAKI, and Masaki HASEGAWA

Research Institute for Polymers and Textiles, Sawatari, Kanagawa-ku, Yokohama 221

(Received November 10, 1972)

The solution photopolymerization of 2,5-distyrylpyrazine (DSP) and its related compounds with the general formula of Ar–CH=CH–Ar′–CH=CH–Ar, where Ar and Ar′ represent aryl and arylene groups respectively, have been investigated. All diolefines were converted in good yields into amorphous oligomers with cyclobutane in the main chain on the exclusive excitation of the monomer molecules, while, in the crystalline state, only DSP and 1,4-bis[β-pyridyl-(2)-vinyl] benzene are known to yield highly crystalline oligomers under the same light. All the oligomers were found to be photodepolymerized to the original monomers in the solution on the excitation of the terminal groups of these oligomers. In consequence, a photoreverse scheme has been demonstrated between the diolefinic monomer and the oligomer, depending on the excitation wavelength. Poly-DSP was photodepolymerized into the monomer in trifluoroacetic acid solution, while amorphous poly-DSP in film was readily photooxidized in the air under sunlight. From the photochemical behavior of DSP, oligo-DSP, and poly-DSP, it was found that chemically the same substance, oligo-DSP, behaved in three ways, photopolymerization, photodepolymerization and no photoreaction, according to the physical state. Such a matrix effect is discussed from the point of view of topochemical reaction.

Various kinds of diolefinic compounds have been known to photopolymerize in the crystalline state into highly crystalline polymers with cyclobutane in the main chain.[1–3] Among a series of diolefinic compounds with the general formula of Ar–CH=CH–Ar′–CH=CH–Ar (where Ar and Ar′ represent aryl and arylene groups respectively), 2,5-distyrylpyrazine(DSP) and 1,4-bis-[β-pyridyl-(2)-vinyl]benzene (P2VB) have been reported to be photopolymerized in the crystalline state.[3] Furthermore, photooligomerization on DSP, P2VB, and other types of diolefinic compounds in the crystalline state has been reported in a preceding paper.[4]

On the other hand, the attempted solution photopolymerization of DSP has been reported in the earlier paper not to produce the polymer.[5] In the present work, it was found that the oligomer of DSP and other related diolefinic compounds were obtained by the irradiation of the light with a wavelength that excites monomer molecule exclusively.

Contrary to the exclusive monomer excitation, all the oligomers obtained were found to be photodepolymerized to the monomer in the solution when terminal groups of these oligomers were excited. In addition, a photooxidative degreadation which is not observed in the solution has been investigated preliminarily on amorphous film of poly-DSP.

In the present paper, the photooligomerization of DSP and related compounds and their photodepolymerization will be described. The results for these diolefinic monomers will be discussed in comparison with the reaction in the crystalline state and with reactivity of the corresponding monoolefines.

Experimental

Preparation of Monomers. DSP,P2VB, and three other monomers, 1,4-bis[β-pyridyl-(3)-vinyl] benzene (P3VB), 1,4-bis[β-pyridyl-(4)-vinyl]benzene(P4VB), and 1,4-distyrylbenzene(DSB), were prepared as has been described in an earlier paper.[3]

Preparation of Oligo-DSP in the Solution. DSP was dissolved in tetrahydrofuran(THF) which had been distilled over calcium hydride. The solution (1.41×10^{-2} mol/l, 50 ml) was irradiated with filtered light of a wavelength longer than 380 mμ for 48 hr at room temperature. The filtered light was produced by using a cut-off filter(Corning. 3—75) on a 500-W xenon lamp. After irradiation, the solvent was removed *in vacuo*; a pale yellow oil was thus obtained. A few milliliters of ethyl alcohol were added to the oil, the mixture was stirred overnight, and the precipitated powder was filtered off, and then dried *in vacuo*. The oligomer structure of the product with cyclobutane and a terminal olefinic double bond was confirmed by NMR and IR spectroscopies. The average molecular weight was about 900 (as determined by vapor-pressure osmometry). The final yield of oligo-DSP was 0.12 g (60%).

Preparation of Other Oligomers in the Solution. The oligomerization of other monomers was carried out in a similar way. However, a 0—51 filter was used in place of the 3—75 filter for the oligomerization of DSP in order to filter out the light shorter than 360 mμ. A mixture of petroleum ether and ethyl ether was used as a precipitant for the oily products. The final yield, the irradiation conditions, and the average molecular weight of the oligomers are summarized in Table 1.

The Attempted Dimerization of Stilbene and 2-Styrylpyridine in the Solution. Stilbene was dissolved in THF which had been distilled over calcium hydride. The solution (2.22×10^{-2} mol/l, 50 ml) was irradiated with filtered light of wavelengths longer than 300 mμ for 48 hr at room temperature. The filtered light was produced by using a cut-off filter(0—54) on a 500-W xenon lamp. After irradiation, the solvent was removed *in vacuo*; an oily product was thus obtained. The oil was dissolved in 0.8 ml of deuterochloroform and then submitted to NMR spectroscopy. Aromatic and vinyl-(*trans*- and *cis*-types) protons and the remaining THF were found in the NMR spectrum. The dimerization of 2-styrylpyridine was attempted under the same reaction conditions as were used in the stilibene. Only a *cis-trans* isomerization reaction was observed by NMR spectroscopy.

Photodepolymerization of the Oligomers. The oligomer

* A part of results were reported in This Bulletin, **43**, 3020 (1970).

was dissolved in chloroform or THF at a suitable concentration for UV measurement. The solution was then irradiated with the monochromatic light from a spectroirradiator(Jasco) equipped with a 2000-W xenon lamp as the light source and a gration monochromater. The reaction was followed by UV spectrometry.

Photodecomposition of Poly-DSP in the Solution and in Amorphous Film. Since crystalline poly-DSP is insoluble in the usual organic solvent, trifluoroacetic acid was used as the solvent of poly-DSP. The trifluoroacetic acid solution of poly-DSP (0.5 mg/40 ml) was irradiated with the light of 300 mμ from the spectroirradiator and the reaction was followed by UV spectrometry.

An amorphous poly-DSP film was made by casting on the glass plate from the trifluoroacetic acid solution. After the solvent had been removed *in vacuo*, the film was washed with triethylamine and then with ethyl alcohol. The poly-DSP film in the glass tube was degassed by means of a vacuum line and replaced by helium gas. After this procedure had been repeated three times, the tube was sealed. The tube was then exposed to sunlight through window glass for 80 days. The film sample thus exposed to the sunlight was subsequently compared with a sample which had been exposed to the sunlight in the air by means of IR spectroscopy. The sample stored in the dark in the air was prepared in a wrapped tube with aluminum foil. After 80 days, the contents were checked by studying the IR spectrum.

Results and Discussion

Solution Photooligomerization of DSP and Related Compounds. Figure 1 shows the UV spectral change in DSP when 0.5 ml of DSP in THF(6.09×10^{-3} mol/l) was irradiated by monochromatic light of 395 mμ. The absorption maximum of DSP at 385 mμ decreased gradually with the irradiation, and finally the absorption spectrum was changed to the f spectrum. This spectrum coincides with that of the oligo-DSP obtained by the photooligomerization of DSP in the crystalline state[4] when the remaining monomer of 19%, which was estimated from the absorption ratio of a and f 385 mμ, is subtracted from the f spectrum; then the concentration of the resulting spectrum was adjusted to the concentration at the spectral measurement of oligo-DSP(g) from the crystalline-state photoreaction. The NMR spectrum of the oligomer through solution photoreaction is shown in Fig. 2. A broad peak at 4.9 ppm due to the aryl cyclobutane[6] and a peak at 7.2—7.9 ppm of aromatic hydrogen-overlapping olefinic hydrogen may be seen in Fig. 2. Furthermore, terminal double bond in the oligomer chain was observed at both 970 and 1630 cm^{-1} in the IR absorption spectrum. From these spectral results, it was concluded that DSP was oligomerized in the solution by means of irradiation with the selected wavelength.

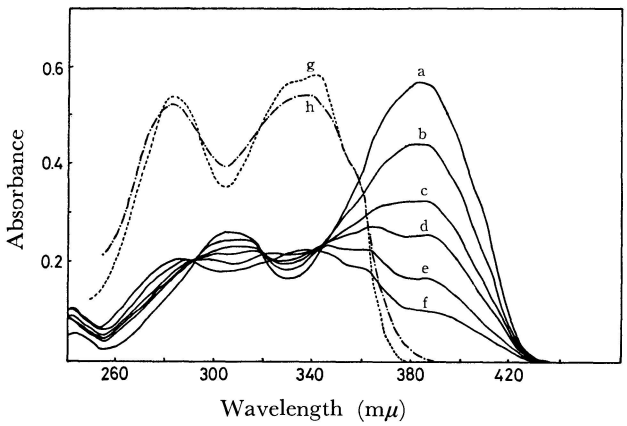

Fig. 1. UV spectral change during the oligomerization of DSP in THF by the irradiation with the light of 395 mμ. a: spectrum of DSP, b—f: after irradiation for 5, 10, 30, 45 and 60 min, respectively, g: oligo-DSP obtained from the crystalline photooligomerization in THF (1.07×10^{-2} g/l), h: spectrum of oligo-DSP estimated from f.

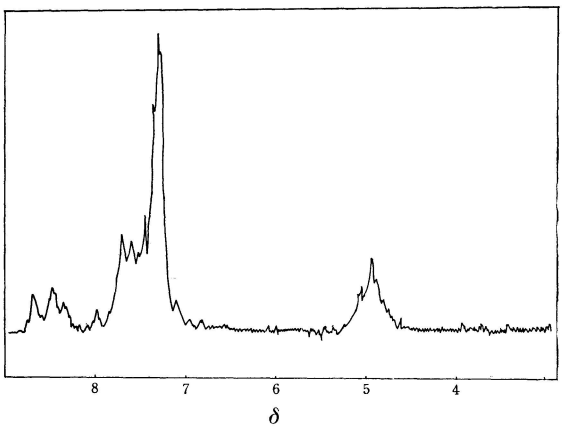

Fig. 2. NMR spectrum of oligo-DSP obtained from solution photooligmerization.

Oligo-DSP was obtained in a 60—80% yield in preparative scale and showed the average molecular weight of 600—900, corresponding to that of the dimer or trimer as is shown in Table 1.

The successful oligomerization of DSP can be explained in terms of two side reaction, the photoreaction of olefinic compound with the solvent[7] and the photocleavage of the resulting cyclobutane in the oligo-DSP, as will be discussed in a later section, being suppressed by interrupting the light shorter than 380 mμ. Another side reaction, the formation of phenanthrene- or azaphenanthrene-type derivatives as photoproducts, can be assumed because of their *cis*-form.[8,9] However, in the present work, such photoproducts were not detected in the oligomerization reaction of any diolefinic compound.

The wavelength of the light for the oligomerization reaction of DSP was chosen from the UV-absorption-spectrum difference between DSP and oligo-DSP. Since the longer-absorption end of oligo-DSP is 380 mμ in the THF solution, an irradiation wavelength longer than 380 mμ excites only DSP, not the terminal olefinic group of the oligomer.

The oligomerization technique of DSP was also extended to other diolefines, P2VB, P3VB, P4VB, and DSB. An irradiation wavelength longer than 360 mμ was decided on for the same reason as in the case of DSP. As a result, all the diolefines examined here gave the same type of oligomers as oligo-DSP, which has a structure with a cyclobutane ring in the main chain. The experimental conditions, the oligomer yield, and their average molecular weights are shown in Table 1.

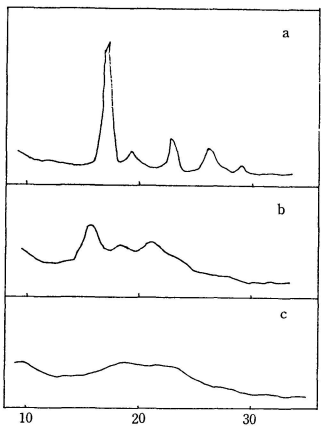
Table 1. Solution photooligomerization of DSP and its related compounds

Monomers Ar	Monomers Ar'		Irradiated wavelength (mμ)	Reaction time (hr)	Concentration of the monomers in THF (mol/l)	Yield of the oligomer (%)	Molecular weight
		DSB	≥360	48	1.42×10^{-2}	100	634
		DSP	≥380	48	1.40×10^{-2}	60	900
		P2VB	≥360	48	1.40×10^{-2}	29	814
		P3VB	≥360	48	1.40×10^{-2}	94	1074
		P4VB	≥360	48	1.40×10^{-2}	74	682

The degree of polymerization of the obtained oligomers ranges from 2 to 4, and the yields are relatively high except for the case of oligo-P2VB.

It should be noticed that all the diolefinic compounds attempted were converted to the oligomers, while among this type of compounds only DSP and P2VB are photo-oligomerized or photopolymerized in the crystalline state. These results indicate that the cycloaddition reaction ability on this type of diolefinic compound does not depend on its chemical structure.

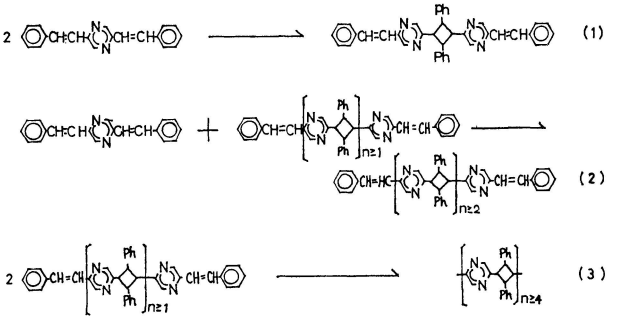
A study of the wavelength dependency on the photochemical behavior in solution was carried out for the corresponding to monoolefines, stilbene, and 2-stryl-pyridine for the sake of comparison. However, neither of these two compounds dimerized under experimental condition similar to those of the oligomerization; exclusive excitation of the monoolefines in the highly-concentrated solution suppressed the photocleavage of resulted cyclobutane and isomerization reaction. It can be assumed from the results that, in a solution, the ability of cyclobutane formation of the monoolefines is lower than that of the corresponding diolefines, although the formation of a small amount of a photodimer has been reported in the case of stilbene in benzene by means of long irradiation with an ultraviolet lamp.[6] Although such a difference in reactivity between mono- and di-olefines can not be explained at present, if a unimolecular side reaction, the *cis-trans* isomerization of monoolefines, is presumed to be more striking than that of diolefines, and if cyclobutane is presumed to be produced only from *trans*-olefines, the observed difference in reactivity may be understood.



2θ degree

Fig. 3. X-ray diffraction diagrams of oligo-DSP. a: as-polymerized oligomer, b: recrystallized oligomer, c: amorphous oligomer.

One of the most striking features of the step-by-step solution photooligomerization in the present work originates in the monomer structure, in which two reactive double bonds are mutually conjugated through the 1,4-position of an aromatic ring. In such a structure of the monomers, the photocycloaddition step consists of three kinds of addition, as is represented in the case of DSP below:



Under the reaction conditions where only the monomer is excited, only Steps(I) and (2) proceed in the solution. Furthermore, these two elementary processes do not proceed after the monomer has been exhausted. The average molecular weight of the oligomers should be determined by the reaction velocity ratio of the two elementary processes, Steps(I) and (2). The actual ratio does not take any extreme values(infinitude or zero), since more of the oligomer mixture than dimer is obtained in the preparative experiment. These are the reasons why all the monomers here can not grow into high polymers in a solution, whereas, for example, bismaleimide derivatives are polymerized by photocycloaddition into high polymers through a step-by-step photoreaction.[10]

Configuration of Oligomers. The oligomers obtained through the solution photooligomerization are distingunished from the oligomers of DSP and P2VB through crystalline-state photooligomerization, which established the following two points. First, the oli-

gomer from the solution is shown to be amorphous by x-ray analysis, as is shown in Fig. 3, while the oligomer obtained through crystalline-state oligomerization shows a high crystallinity. Second, the amorphous oligomers of DSP and P2VB in the solid state do not grow into high polymers on irradiation with the light of 340 mμ, which excites the terminal group of the oligomer.

The first difference suggests that the oligomers obtained through solution photooligomerization consist of mixed structures of cyclobutane units in the oligomers, while the as-polymerized oligomers of DSP are known from the results of x-ray crystal analysis to consist of a single steric configuration of 1,3-*trans*-type cyclobutane.[11,12] However, by NMR analysis, we could not observe the definite differences between these two types of oligomers because of poor spectrum resolution. The second difference in photoreactivity between amorphous and as-polymerized crystalline oligomers suggests that, in the case of the crystalline oligomer, residual terminal olefinic groups face each other in the crystal intermolecularly, but this is not the case with amorphous oligomers of DSP and P2VB.

Photodepolymerization of the Oligomers. In order to study further the photochemical behavior of the oligomers in a solution, a chloroform solution(1 mg/40 ml) of oligomer of DSP, which had been prepared by solution photooligomerization, was irradiated with the monochromatic light of 340 mμ and the reaction was monitored by UV spectroscopy, as is shown in Fig. 4. The peak which appeared at 385 mμ was identified with that of DSP by comparison with the UV spectrum (e in Fig. 4) in chloroform. When oligo-DSP in a chloroform solution (4.85×10^{-3} mol/l) is irradiated with a light longer than 340 mμ, the molecular weight of the oligomer is depressed from the 954 of the original to 475 after irradiation. Accordingly, in the solution unimolecular photodepolymerization reaction is considered to overcome a bimolecular-chain growth reaction(Step (3)), if any. Another type of oligo-DSP obtained through crystalline-state photooligomerization has been confirmed to be photodepolymerized in the solution in the same manner.

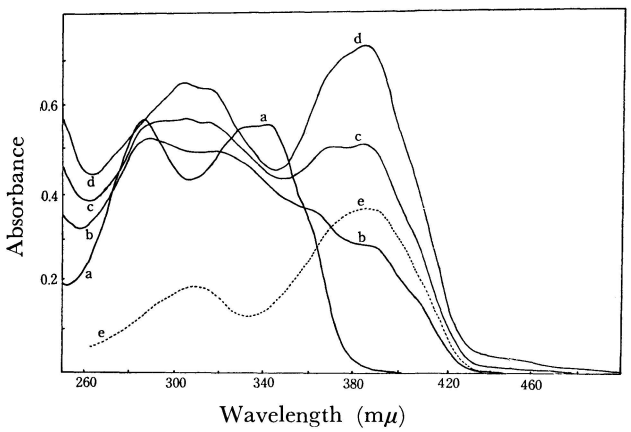


Fig. 4. UV spectral change during the photodepolymerization of oligo-DSP in chloroform by the irradiation with the light of 340 mμ. a: oligo-DSP, b—d: after irradiation for 15, 30 and 60 min, respectively, e: DSP (0.7×10^{-5} mol/l).

Other oligomers, oligo-DSB, -P2VB, -P3VB, and -P4VB, were also found to be photodepolymerized with oligo-DSP in a similar way, as is represented by oligo-DSB in Fig. 5. From these results, it may be concluded that these oligomers are photodepolymerized to the monomers when the terminal groups are excited in the solution. In consequence, a photoreverse scheme has been found between diolefinic monomers and the oligomers, depending on the different excitation wavelength. Such a photodepolymerization reaction results in the irradiation-wavelength effect of the solution oligomerization of these monomers.

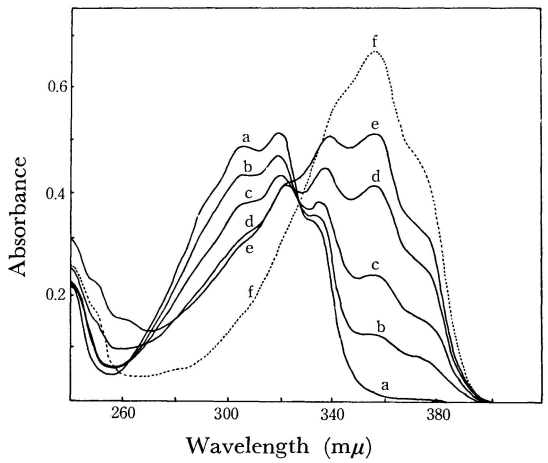

Fig. 5. UV spectral change during the photodepolymerization of oligo-DSB in THF by the irradiation with the light of 277 mμ. a: oligo-DSB, b—e: after irradiation for 1, 3, 12 and 40 min, respectively, f: DSB (1.2×10^{-5} mol/l).

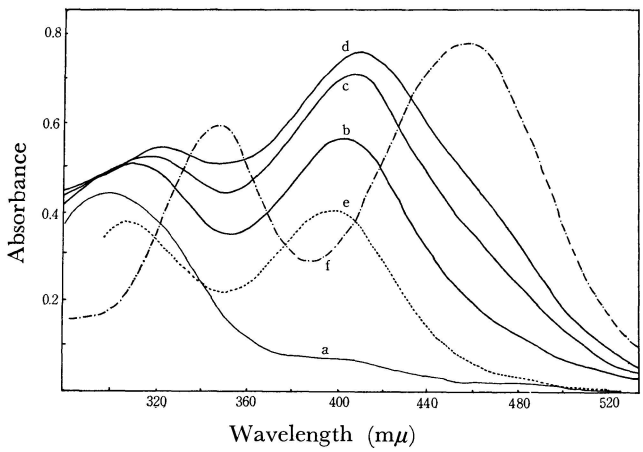

Fig. 6. UV spectral change during the photodepolymerization of poly-DSP in trifluoroacetic acid by the irradiation with the light of 300 mμ. a: poly-DSP, b—d: after irradiation for 20, 120 and 200 sec, respectively, e: oligo-DSP, f: DSP.

Photodegradation of Poly-DSP. In a previous paper, it has been reported that poly-DSP is thermally depolymerized to the monomer in a high yield.[1] In the course of the photochemical study of cyclobutane derivatives, the photodepolymerization of poly-DSP was also examined. Fig. 6 shows the UV spectral

change when the trifluoroacetic acid solution of poly-DSP was irradiated with the light of 300 mμ. In comparision with the spectra of DSP and oligo-DSP in the same solvent, the spectrum obtained was confirmed to be a mixture of the monomer and the oligomer of DSP. From these results, it may be concluded that the photodepolymerization of poly-DSP proceeds at random in the polymer chain under the present experimental conditions.

The photochemical behavior of poly-DSP was also examined in amorphous film. The poly-DSP film did not show any change in IR spectroscopically when the film was stored for eighty days in helium gas in the dark. On the other hand, hydroxy and carbonyl groups appeared vigorously in the IR spectrum when poly-DSP film was stored in the air under the sunlight, as is shown in Fig. 7. Moreover, the photoirradiation of the film by sunlight in helium resulted in little change in the IR spectrum. Although no photoproducts have been isolated from the degrated film, it is obvious that amorphous film of poly-DSP is photooxidized, while the poly-DSP in the solution is mostly photodepolymerized to the monomer. Such an extreme difference in the reactivities between amorphous and solution states of the same polymer is unique in polymeric materials.

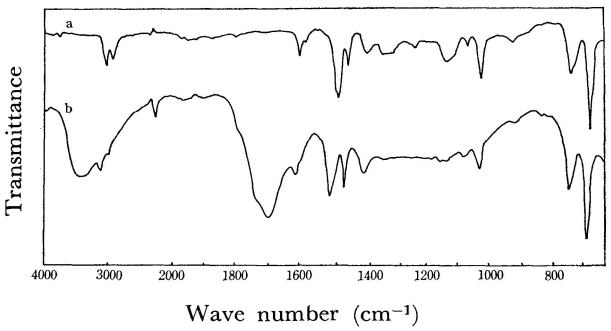

Fig. 7. IR spectra of poly-DSP(a) and the photooxidized poly-DSP(b) in film.

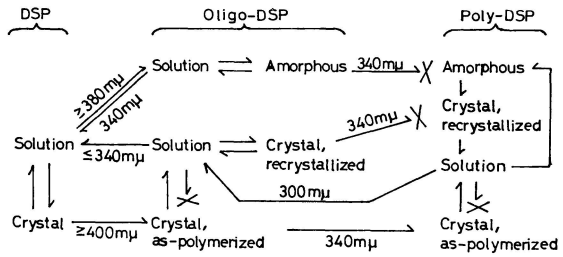
Characteristics of Photopolymerization of DSP. The photochemical interrelationship in DSP, oligo-DSP, and poly-DSP is summarized below:



This experiment demonstrates that the DSP molecule in the crystal reacts only with a intermolecularly-facing double bond under the steric control of the crystalline lattice (a topochemical process) to give a thermodynamically metastable polymer (as-polymerized crystalline polymer). As a matter of course, such a metastable polymer crystal can never be reproduced after it has been dissolved, but the thermodynamically-stable polymer crystal with a different form (a recrystallized crystalline polymer) is obtained from a polymer solution.[13]

According to the same explanation, oligo-DSP does not grow further into a high polymer without such topotactic assistance (crystal lattice control) as is presented in the case of the as-polymerized crystalline oligo-DSP. Therefore, the oligo-DSP retains two different reaction paths which are entirely the reverse of each other, cyclobutane formation in the crystalline state and its cleavage in the solution, under the same irradiation light. In other words, the direction of the reaction depends principally on its physical reaction states(matrix effect). Such a matrix effect is also revealed on amorphous and recrystallized oligo-DSP. That is, neither of the oligomers grows into a polymer in the solid state, while both are photodepolymerized to the monomer in a solution. It is interesting that chemically the same substance, the oligomer, behaves in three extremely different ways, photopolymerization, no photoreaction, and photodepolymerization, according to the physical state (in the as-polymerized, amorphous or recrystallized, and solution states). Such a multiplicity of reactivity is clear-cut example of a matrix effect originating in a topochemical process and has been demonstrated for the first time in the organic field.

Total Synthesis of Ferrichrome

Yoshikazu Isowa, Muneki Ohmori, and Hideaki Kurita

Sagami Chemical Research Center, Nishi-ohnuma, Sagamihara, Kanagawa 229

(Received March 31, 1973)

Two different sequence hexapeptides for the synthesis of ferrichrome were prepared using N^{δ}-tosyl-N^{δ}-benzyloxy-L-ornithine by means of *N*-hydroxysuccinimide plus *N,N*-dicyclohexylcarbodiimide or Woodward reagent K method. The linear hexapeptides (XII·HCl and XIX·HCl) were cyclized by excess *N,N*-dicyclohexylcarbodiimide to give cyclo-triglycyltri-N^{δ}-tosyl-N^{δ}-benzyloxy-L-ornithyl (XX). Detosylation, acetylation and successive reductive debenzylation of XX afforded deferri-ferrichrome (XXIV). Addition of ferric iron to XXIV gave ferrichrome, which had the same crystalline form, superimposable infrared and well-agreeing visible spectra and the same value in optical rotation compared with the data in the literature of natural product.

Ferrichrome (I), shown in Fig. 1, is one of a family of iron binding molecules[1] in nature and a representative of siderochrome.[2] It is an extremely powerful and relatively selective chelating agent for ferric iron[3] and it has been assumed this substance acts as a specific iron transport agent, a shuttle necessary for the permeation of the metal through the cellular membrane, or a coenzyme in heme biosynthesis.[4]

Neilands first actually isolated ferrichrome as a crystalline organo-iron pigment from the smut fungus, *Ustilago sphaerogena*, in 1952.[5] Subsequent study on the structure[6] of I showed that it binds a ferric iron mainly through ionic forces and that it is a cyclic hexapeptide built up from three residues of N^{δ}-acetyl-N^{δ}-hydroxy-L-ornithine together with three residues of glycine. The amino acid sequence within the peptide moieties of this naturally occurring ferric trihydroxamate was established by Neilands and collaborators in 1963 as cyclo-triglycyltri-N^{δ}-acetyl-N^{δ}-hydroxy-L-ornithyl.[7] Conformation in solution of I was recently studied by Llinas *et al.*[8]

The chemical synthesis of ferrichrome has been accomplished by Keller-Schierlein and Maurer[9] in 1969 using L-δ-nitronorvaline and glycine. The linear hexapeptide, *t*-butyloxycarbonylglycyltri-L-δ-nitronorvalylglycylglycine methyl ester, was prepared by means of mixed anhydride method using *t*-butyloxycarbonyl group as amino protecting group. The cyclization of the linear hexapeptide was carried out by the *p*-nitrophenyl ester method in pyridine. The reduction of the nitro group to hydroxyamino was accomplished with zinc in aqueous ammonium chloride.

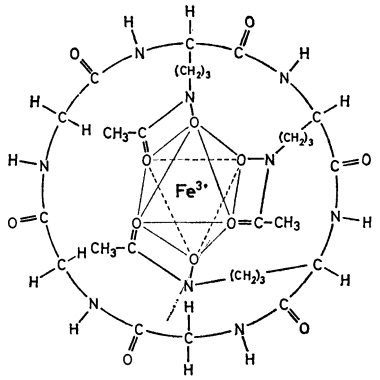

Fig. 1. Structure of ferrichrome (I).

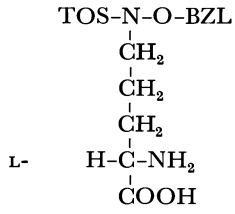
Without isolation of the product, acetylation was carried out with acetic anhydride in pyridine and *O*-acetyl group the removed by treatment of the product with methanolic ammonia. After addition of the ferric chloride, the product, ferrichrome, was purified by countercurrent distribution and crystallized from methanol.

In this paper we also describe the total synthesis of ferrichrome using N^{δ}-tosyl-N^{δ}-benzyloxy-L-ornithine (II), shown in Fig. 2, which has been reported in the paper from our laboratory.[10]



(II)

Fig. 2. N^{δ}-Tosyl-N^{δ}-benzyloxy-L-ornithine: TOS, *p*-toluenesulfonyl; BZL, benzyl.

II has a protected hydroxyamino group at δ-position of L-ornithine and therefore fulfils prerequisites for incorporation into peptides of more complex structures. The linear hexapeptides (XII·HCl and XIX·HCl) were prepared *via* two different routes, shown in Fig. 3 and Fig. 4, in order to ascertain whether or not the protected cyclic peptides obtained from the linear hexapeptides possess the same optical rotatory power. Figure 3 indicates the synthesis of glycyltri-N^{δ}-tosyl-N^{δ}-benzyloxy-L-ornithylglycylglycine hydrochride (XII·HCl), in which glycines are the *N*- and *C*-terminal amino acid residues to remove possible racemization at the step of the cyclization reaction. For a study of the relationship between the optical purity and the coupling method at the preparation of XII·HCl, the linear hexapeptide (XII·HCl) was prepared by a step-by-step elongation using *N*-hydroxysuccinimide plus *N,N*-dicyclohexylcarbodiimide[11] or Woodward reagent K[12] as a coupling reagent. The final product (XII·HCl), obtained by the different coupling methods, possessed the same specific rotation, $-8.1°$ and $-8.2°$ in chloroform each other, and its homogeneity was demonstrated by thin-layer chromatography.

It should be noted that hydroxyamino protecting tosyl and benzyl groups are stable to the reaction conditions employed in the peptide formation and in the deprotection of the α-position. Figure 4 indicates the synthesis of another linear hexapeptide, tri-N^{δ}-tosyl-

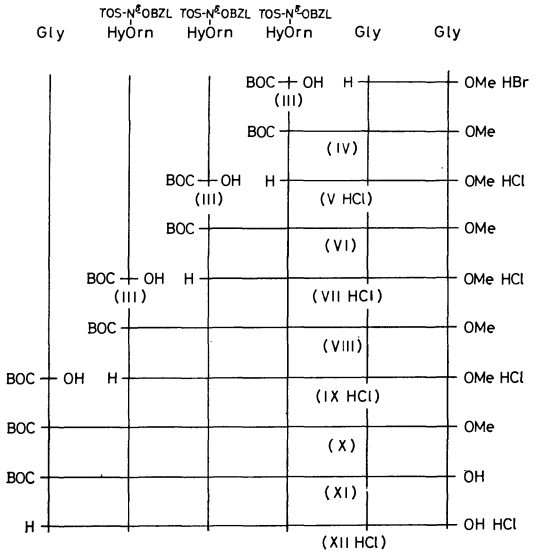


Fig. 3. Synthesis of glycyltri-N^{δ}-tosyl-N^{δ}-benzyloxy-L-ornithylglycylglycine hydrochloride (XII·HCl): HyOrn, N^{δ}-hydroxy-L-ornithine; Gly, glycine; BOC, *t*-butyloxycarbonyl.

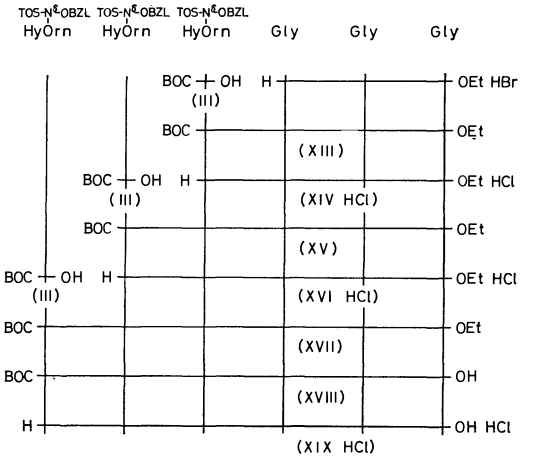

Fig. 4. Synthesis of tri-N^{δ}-tosyl-N^{δ}-benzyloxy-L-ornithyldiglycylglycine hydrochloride (XIX·HCl).

N^{δ}-benzyloxy-L-ornithyldiglycylglycine hydrochloride (XIX·HCl), in which II is *N*-terminal amino acid and glycine is *C*-terminal amino acid. XIX·HCl, prepared by a step-by-step elongation by means of *N*-hydroxysuccinimide plus *N,N*-dicyclohexylcarbodiimide method, possessed the specific rotation, +3.2° in chloroform.

Various methods for the cyclization of the linear hexapeptides (XII·HCl and XIX·HCl) were undertaken. Namely *N,N*-dicyclohexylcarbodiimide, water soluble carbodiimide (*N*-ethyl-*N'*-(3-dimethylaminopropyl)carbodiimide) or *N*-hydroxysuccinimide plus *N,N*-dicyclohexylcarbodiimide method were attempted to cyclize the linear hexapeptides. Since the *N,N*-dicyclohexylcarbodiimide method gave the pure cyclization product in the 41% yield, we describe in detail about the cyclization reaction using *N,N*-dicyclohexylcarbodiimide. The scheme for the cyclization reaction of XII·HCl or XIX·HCl is presented in Fig. 5.

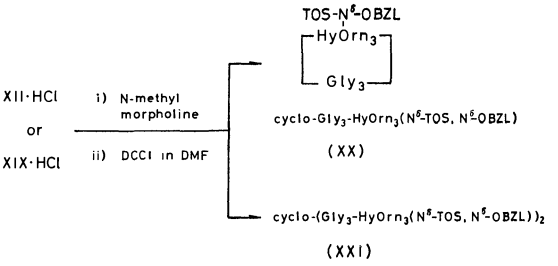

Fig. 5. Cyclization of linear hexapeptide (XII·HCl or XIX·HCl) using *N,N*-dicyclohexylcarbodiimide (DCCI).

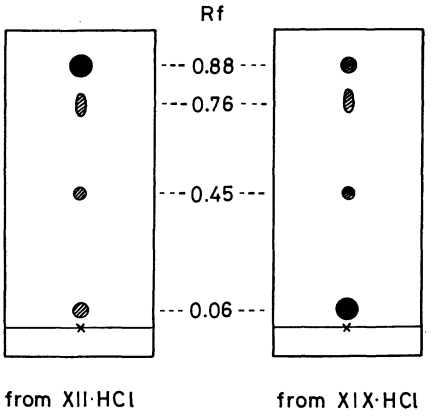

Fig. 6. Thin-layer chromatogram of the crude cyclization products obtained from XII·HCl or XIX·HCl; the R_f value of cyclic hexapeptide is 0.88 and that of dimerization product is 0.06.

The cyclization of XII·HCl using *N,N*-dicyclohexylcarbodiimide in a large amount of dimethylformamide gave a mixture of the desired monomerization product (XX), the dimerization substance (XXI), the unreacted linear hexapeptide (XII) and *N,N*-dicyclohexylurea, which were determined by thin-layer chromatography (Fig.. 6).

The R_f value of 0.06 was proved to be of the dimerization product (XXI), which was demonstrated by the molecular weight determination and elemental analysis, while that of 0.88 was of the desired protected cyclic hexapeptide (XX). The product indicating R_f 0.76 was considered to be a linear hexapeptide (XII) and R_f 0.45 was determined to be of dicyclohexylurea. For the removal of XXI, the reaction mixture was treated with hot methanol. After methanol-insoluble material (XXI) had been filtered off, the methanol solution was evaporated to dryness. Furthermore, for the removal of XII and dicyclohexylurea, the residue thus obtained was dissolved in a mixture of dimethylformamide and water (4 : 1) and passed successively through columns of CG-120 and CG-400; the yield of the crystalline XX from XII·HCl was found to be 41% after recrystallization from methanol. The molecular weight determination demonstrated that the molecular size of this compound was corresponded to that of XX. The cyclization reaction of another linear hexapeptide (XIX·HCl) gave the result indicated in Fig. 6. In this case, the main product, obtained in a *ca.* 40% yield, was found to be

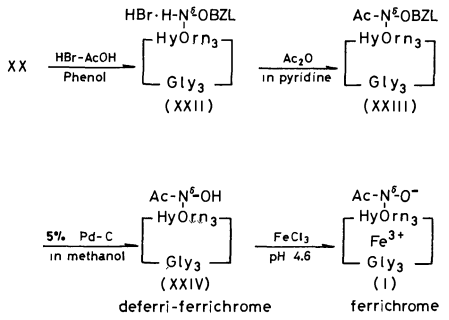

Fig. 7. Transformation of XX to deferri-ferrichrome XXIV and addition of ferric ion to XXIV.

a dimer (XXI). Not more than 7% of the starting material (XIX·HCl) was converted to the cyclic hexapeptide. Since the cyclic hexapeptide, thus obtained, possessed the same specific rotation with that of XX prepared from XII·HCl, the maintenance of optical purity was demonstrated.

The transformation of XX to deferri-ferrichrome (XXIV) and of XXIV to ferrichrome (I) are presented in Fig. 7.

The tosyl group of XX could be removed selectively on treatment with 36% hydrogen bromide in acetic acid in the presence of phenol. However, it was unsuccessful to isolate the detosylated product (XXII·3HBr) in the pure state. The removal of the tosyl group was confirmed by the lacking of the absorptions at 1350 and 1165 cm^{-1} in the infrared spectrum. Experiment in which the crude detosyl-compound was acetylated with acetic anhydride in pyridine, resulted acetyl-derivative (XXIII) in 47% overall conversion (XX to XXIII). On hydrogenation in methanol solution over 5% palladium on charcoal at room temperature under atmospheric pressure for 4 days, XXIII was almost quantitatively converted into XXIV (deferri-ferrichrome), which was ascertained by the comparison with the NMR spectrum obtained from natural product.[13] Figure 8 shows the NMR spectrum of XXIV, in which the characteristic signal of methyl protons in N^{δ}-acetyl group appears at δ 2.61 and the signals of benzyl group are not observable. Figure 9 shows the infrared spectrum of XXIV, in which the removal of the benzyl group is confirmed by the absence of the absorptions at 3025 and 698 cm^{-1}.

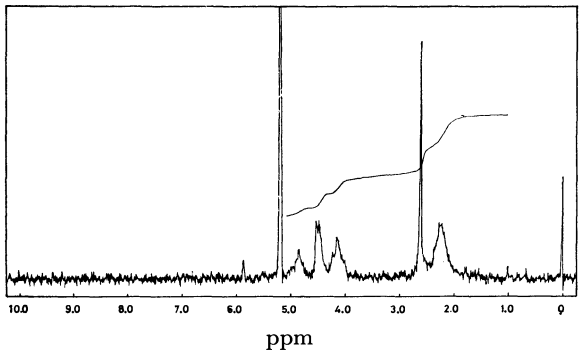

Fig. 8. NMR spectrum of synthetic deferri-ferrichrome (XXIV).

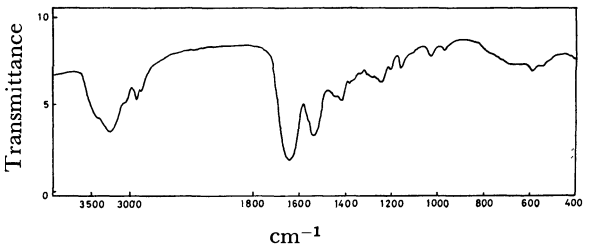

Fig. 9. Infrared spectrum of synthetic deferri-ferrichrome (XXIV).

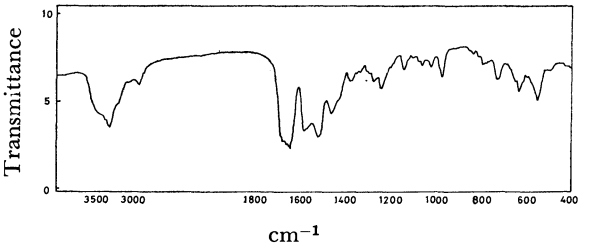

Fig. 10. Infrared spectrum of synthetic ferrichrome (I).

The synthetic ferrichrome (I) was obtained by the reaction of XXIV with three equivalents of ferric chloride in aqueous buffered solution of pH 4.6, at which re-addition of iron to deferri-ferrichrome obtained from naturally occurring ferrichrome was performed by Emery and Neilands.[6b] On recrystallizations from anhydrous methanol, pure synthetic ferrichrome (I) was obtained as long orange needles with the well-agreeing value of elemental analysis. The comparison with the data in the literatures of natural product was made of the melting point, optical rotation and absorptivity in visible absorption; mp 248—251 °C (decomp.) (lit.[5] 240—242 °C (decomp.)), $[\alpha]_D$ +304°± 10° (*c* 0.0425, water) (lit.[9b] +300° (*c* 0.04, water)) and $E_{1cm}^{1\%}$ (428 mμ 39.8 (water) (lit.[5] $E_{1cm}^{1\%}$ (425 mμ) 39.6 (water)). Furthermore, the infrared spectrum of synthetic I, as shown in Fig. 10, corresponded closely to that of natural product described in the literature.[13]

Experimental

All melting points were determined with a Yanagimoto electric micromelting point apparatus unless otherswie indicated and are uncorrected. Optical rotations were measured with a Yanagimoto automatic polarimeter OR-50. The nuclear magnetic resonance spectra were run on a Hitachi Perkin-Elmer R-20 High Resolution NMR spectrometer, using tetramethylsilane as an external or internal standard. Infrared spectra were recorded on a Hitachi G-3 spectrophotometer as KBr disk. Molecular weight was determined by the use of a differential vapor pressure osometer (Hitachi Perkin-Elmer 115 Molecular weight apparatus). The visible spectrum was taken on a Hitachi Recording Spectrophotometer EPS-3. The thin-layer chromatography was carried out on Merck silica gel F_{254} using the solvent system of *n*-butanol–acetic acid–pyridine–water (4 : 1 : 1 : 2 v/v). The paper chromatography was carried out on Toyo Roshi No. 50 using the solvent system of *n*-butanol–acetic acid–water (4 : 1 : 1 v/v).

N$^{\alpha}$-t-*Butyloxycarbonyl*-N$^{\delta}$-*tosyl*-N$^{\delta}$-*benzyloxy*-L-*ornithine (III)*.

This compound was prepared by the procedure described in the previous paper.[15]

N^{α}-t-Butyloxycarbonyl-N^{δ}-tosyl-N^{δ}-benzyloxy-L-ornithylglycylglycine Methyl Ester (IV).[16] *a*): To a stirred solution of *N^{α}-t*-butyloxycarbonyl-*N^{δ}*-tosyl-*N^{δ}*-benzyloxy-L-ornithine (III) (4.92 g, 10 mmol), glycylglycine methyl ester hydrobromide (2.27 g, 10 mmol), *N*-hydroxysuccinimide (2.3 g, 20 mmol) and *N*-methyl morpholine(1.21 ml, 11 mmol) in dimethylformamide (100 ml) was added a solution of dicylcohexylcarbodiimide (2.27 g, 11 mmol) in dimethylformamide (10 ml) at −10 °C. After stirring for 42 hr, the crystalline deposit was removed and the filtrate was evaporated *in vacuo*. The oily residue was dissolved in chloroform (150 ml) and washed successively with water, M sodium bicarbonate, 2 M hydrochloric acid and water. The organic layer was dried over magnesium sulfate and evaporated *in vacuo*. The oily residue was solidified with the aid of petroleum ether; 5.03 g (81%); mp 56—64 °C; $[\alpha]_D$ +6.8° (*c* 1, methanol).

Found: C, 56.35; H, 6.68; N, 8.91%. Calcd for $C_{29}H_{40}N_4O_9S$: C, 56.11; H, 6.50; N, 9.03%.

b): To a stirred suspension of III (9.86 g, 20 mmol) and Woodward reagent K (5.07 g, 20 mmol) in nitromethane (80 ml) was added triethylamine (2.93 ml, 21 mmol) at 5 °C. To the resultant clear solution was added glycylglycine methyl ester hydrobromide (4.5 g, 20 mmol) and triethylamine (2.93 ml, 21 mmol). The mixture was stirred at room temperature for 36 hr and then evaporated *in vacuo*. The oily residue was treated as described above; yield, 8.9 g (72%); mp 61—67 °C; $[\alpha]_D$ +7.0° (*c* 1, methanol).

N^{δ}-Tosyl-N^{δ}-benzyloxy-L-ornithylglycylglycine Methyl Ester Hydrochloride (V·HCl). *i*): To the cold solution of IV-a[17] (5.03 g) in ethyl acetate (20 ml) was added 6 M hydrogen chloride in ethyl acetate (30 ml). After stirring for 2 hr at room temperature, the mixture was evaporated *in vacuo*. The oily residue was crystallized from a small volume of ethyl acetate by addition of ether; yield, 4.30 g (95.5%); mp 108—121 °C; $[\alpha]_D$ +22.3° (*c* 1, ethanol).

Found: C, 51.24; H, 5.97; N, 10.06%. Calcd for $C_{24}H_{33}N_4O_7SCl$: C, 51.67; H, 6.09; N, 9.94%.

ii): The peptide hydrochloride (V·HCl) derived from IV-b[17]; mp 109—120 °C; $[\alpha]_D$ +22.1° (*c* 1, ethanol).

N^{α}-t-Butyloxycarbonyl-N^{δ}-tosyl-N^{δ}-benzyloxy-L-ornithyl-N^{δ}-tosyl-N^{δ}-benzyloxy-L-ornithylglycylglycine Methyl Ester (VI). a): To a stirred colorless solution of III (4.17 g, 8.47 mmol), V·HCl (4.72 g, 8.47 mmol), *N*-hydroxysuccinimide (1.96 g, 17.0 mmol) and *N*-methyl morpholine (1.00 ml, 9.00 mmol) in dimethylformamide (50 ml) was added a solution of dicyclohexylcarbodiimide (1.86 g, 9.00 mmol) in dimethylformamide (10 ml) at −15 °C. After stirring for 45 hr at room temperature, the crystalline deposit was removed by suction and the filterate was evaporated *in vacuo*. The oily residue was dissolved in ethyl acetate (200 ml) and washed successively with water, M sodium bicarbonate, water, 2 M hydrochloric acid and water. The organic layer was dried over anhydrous magnesium sulfate and evaporated *in vacuo*. The residual semi-solid was crystallized from ethyl acetate-ligroin (1 : 1) to give an amorphous powder; yield, 6.9 g (82%); mp 112—120 °C; $[\alpha]_D$ −2.8° (*c* 1, methanol). One more recrystallization from the same solvent raised the mp to 120—123 °C.

Found: C, 57.98; H, 6.10; N, 8.25%. Calcd for $C_{48}H_{62}N_6O_{13}S_2$: C, 57.93; H, 6.28; N, 8.45%.

b): The tetrapeptide ester (VI) was obtained by the same procedure employed for the preparation of IV-b; yield, 72.5 %; mp 118—122 °C; $[\alpha]_D$ −2.7° (*c* 1, methanol).

Di-N^{δ}-tosyl-N^{δ}-benzyloxy-L-ornithylglycylglycine Methyl Ester Hydrochloride (VII·HCl). *i*): Removal of the *t*-butyloxycarbonyl group from VI-a using the same reagent employed for the preparation of V·HCl gave VII·HCl; yield, 93.0%; mp 112—126 °C; $[\alpha]_D$ +16.4° (*c* 1, methanol).

Found: C, 55.22; H, 6.17; N, 8.92%. Calcd for $C_{43}H_{55}N_6O_{11}S_2Cl$: C, 55.44; H, 5.95; N, 9.02%.

ii): The tetrapeptide ester hydrochloride derived from VI-b; mp 110—123 °C; $[\alpha]_D$ +16.0° (*c* 1, methanol).

N^{α}-t-Butyloxycarbonyl-N^{δ}-tosyl-N^{δ}-benzyloxy-L-ornithyldi-N^{δ}-tosyl-N^{δ}-benzoyloxy-L-ornithylglycylglycine Methyl Ester (VIII). *a*): To a stirred colorless solution of III (3.19 g, 6.48 mmol), VII·HCl (6.04 g, 6.48 mmol) and *N*-hydroxysuccinimide 1.50 g, 13.0 mmol) in dimethylformamide (40 ml) was added *N*-methyl morpholine (0.77 ml, 7.0 mmol) at −15 °C. Thereafter dicyclohexlcarbodiimide (1.45 g, 7.0 mmol) in dimethylformamide (10 ml) was added at the same temperature. The mixture was stirred for 48 hr at room temperature. The crystalline deposit was removed and the pale yellow filtrate was evaporated *in vacuo*. The residual semi-solid was triturated several times with water and then the resultant solid was collected by suction. Recrystallization from ethyl acetate-ligroin (3 : 1) gave an amorphous powder; yield, 5.35 g (60.5%); mp 152—154 °C; $[\alpha]_D$ −3.1° (*c* 1, methanol).

Found: C, 58.68; H, 5.92; N, 8.12%. Calcd for $C_{67}H_{84}N_8O_{17}S_3$: C, 58.75; H, 6.18; N, 8.18%.

b) The pentapeptide ester (VIII) was obtained by the same method employed for the preparation of IV-b; yield, 49%; mp 154—156 °C; $[\alpha]_D$ −3.6° (*c* 1, methanol).

Tri-N^{δ}-tosyl-N^{δ}-benzyloxy-L-ornithylglycylglycine Methyl Ester Hydrochloride (IX·HCl). *i*): VIII was converted to the pentapeptide ester hydrochloride (IX·HCl) in the same manner as described above for V·HCl; yield, 91.5%; mp 126—135 °C; $[\alpha]_D$ +5.8° (*c* 1, methanol).

Found: C, 56.52; H, 6.05; N, 8.23%. Calcd for $C_{62}H_{77}N_8O_{15}S_3Cl$: C, 57.02; H, 5.94; N, 8.53%.

ii): IX·HCl from VIII-b by the same procedure employed for the preparation of V·HCl; yield, 96.5%; mp 123—135 °C; $[\alpha]_D$ +4.8° (*c* 1, methanol).

t-Butyloxycarbonylglycyltri-N^{δ}-tosyl-N^{δ}-benzyloxy-L-ornithylglycylglycine Methyl Ester (X). *a*): To a stirred solution of *t*-butyloxycarbonylglycine (0.43 g, 2.45 mmol), IX·HCl (3.2 g, 2.45 mmol) and *N*-hydroxysuccinimide (0.58 g, 5.0 mmol) in dimethylformamide (20 ml) was added *N*-methyl morpholine (0.30 ml, 2.7 mmol) at −15 °C. After stirring for 30 min at the same temperature, dicyclohexylcarbodiimide (0.56 g, 0.70 mmol) in dimethylformamide (5 ml) was added and the reaction mixture was stirred for 48 hr at room temperature. The crystalline deposit was removed and the yellow filtrate was evaporated *in vacuo*. The crude crystalline hexapeptide ester was collected with the aid of water (50 ml), washed successively with water and dried over phosphorus pentoxide under vacuum. Recrystallization from methanol treated with charcoal gave a colorless powder; yield, 3.0 g (86%); mp 170—172 °C; $[\alpha]_D$ +2.4° (*c* 1, chloroform): IR, 1740 cm^{-1} (-COOMe).

Found: C, 57.94; H, 6.11; N, 8.74%. Calcd for $C_{69}H_{87}N_9O_{18}S_3$: C, 58.08; H, 6.15; N, 8.84%.

b): The hexapeptide ester was obtained by the same procedure employed for the preparation of IV-b; mp 168—170 °C (from methanol); $[\alpha]_D$ +2.1° (*c* 1, chloroform).

t-Butyloxycarbonylglycyltri-N^{δ}-tosyl-N^{δ}-benzyloxy-L-ornithyl-glycylglycine (XI). *i*): To a stirred suspension of the hexapeptide methyl ester (X) (2.9 g, 2.0 mmol) in acetone (20 ml) was added M sodium hydroxide (4 ml) at room temperature. After 48 hr, resultant pale yellow clear solution was neutralized with citric acid and then evaporated *in vacuo*. Residual solid was collected with the aid of water and recrystallization from methanol gave a colorless powder; yield, 1.6 g (57%);

mp 138—143 °C; $[\alpha]_D$ +1.4° (*c* 1, chloroform); IR absorption of the ester group in X at 1740 cm^{-1} disappeared.

Found: C, 57.56; H, 5.88; N, 8.66%. Calcd for $C_{68}H_{85}N_9O_{18}S_3$: C, 57.81; H, 6.07; N, 8.92%.

ii): The ester-free hexapeptide derived from X-b; yield, 58%; mp 138—143 °C; $[\alpha]_D$ +1.5° (*c* 1, chloroform).

Glycyltri-N$^\delta$-tosyl-N$^\delta$-benzyloxy-L-ornithylglycylglycine Hydrochloride (XII·HCl). *i*): To a solution of XI-a (1.6 g, 1.1 mmol) in chloroform (30 ml) was added 6 M hydrogen chloride in ethyl acetate (20 ml) under ice cooling. The solution was then allowed to stand at room temperature for 4 hr and evaporated *in vacuo*. Crystalline deposit was collected with the aid of dry ether; yield, 1.4 g (92%); mp 131—138°C; $[\alpha]_D$ −8.1° (*c* 1, chloroform); R_f 0.75 (tlc).

Found: C, 55.94; H, 6.06; N, 9.10%. Calcd for $C_{63}H_{78}N_9O_{16}S_3Cl$: C, 56.09; H, 5.83; N, 9.35%.

ii) The hexapeptide hydrochloride (XII-HCl) derived from XI-b; mp 132—138 °C; $[\alpha]_D$ −8.2° (*c* 1, chloroform); R_f, 0.75 (tlc).

Glycyltri-N$^\delta$-tosyl-N$^\delta$-benzyloxy-L-ornithylglycylglycine (XII). XII was obtained by the treatment of XII·HCl with aqueous ammonia in dimethylformamide. Recrystallization from dimethylformamide-water gave a pure product (XII); mp 212—218 °C; $[\alpha]_D$ −4.2° (*c* 0.5, acetic acid); R_f, 0.76 (tlc).

Found: C, 57.34; H, 5.80; N, 9.30%. Calcd for $C_{63}H_{77}N_9O_{16}S_3$: C, 57.65; H, 5.91; N, 9.61%.

N$^\alpha$-t-Butyloxycarbonyl-N$^\delta$-tosyl-N$^\delta$-benzyloxy-L-ornithyldiglycylglycine Ethyl Ester (XIII). III and diglycylglycine ethyl ester hydrobromide were coupled by the same procedure employed for the preparation of IV-a to give a desired tetrapeptide ester; mp 98—102 °C (from ethyl acetate-ligroin); $[\alpha]_D$ +0.3° (*c* 1, acetic acid).

Found: C, 55.94; H, 6.43; N, 10.19%. Calcd for $C_{32}H_{45}N_5O_{10}S$: C, 55.55; H, 6.56; N, 10.12%.

N$^\delta$-Tosyl-N$^\delta$-benzyloxy-L-ornithyldiglycylglycine Ethyl Ester Hydrochloride (XIV-HCl). Removal of the *t*-butyloxycarbonyl group of XIII was carried out by the same procedure employed for the preparation of V·HCl to give the tetrapeptide ester hydrochloride; mp 115—128 °C; $[\alpha]_D$ +21.7° (*c* 1, methanol).

Found: C, 51.54; H, 5.90; N, 10.89%. Calcd for $C_{27}H_{38}N_5O_8SCl$: C, 51.63; H, 6.10; N, 11.15%.

N$^\alpha$-t-Butyloxycarbonyl-N$^\delta$-tosyl-N$^\delta$-benzyloxy-L-ornithyl-N$^\delta$-tosyl-N$^\delta$-benzyloxy-L-ornithyldiglycylglycine Ethyl Ester (XV). III and XIV·HCl were coupled by the same procedure employed for the preparation of IV-a to give a desired pentapeptide ester; mp 155—157 °C (from methanol); $[\alpha]_D$ −7.4° (*c* 1, acetic acid).

Found: C, 57.50; H, 6.05; N, 9.08%. Calcd for $C_{51}H_{67}N_7O_{14}S_2$: C, 57.45; H, 6.33; N, 9.20%.

Di-N$^\delta$-tosyl-N$^\delta$-benzyloxy-L-ornithyldiglycylglycine Ethyl Ester Hydrochloride (XVI·HCl). XVI·HCl was obtained by the same procedure employed for the preparation of V·HCl; mp 196—201 °C, $[\alpha]_D$ +17.9° (*c* 1, methanol).

Found: C, 54.78; H, 5.82; N, 9.42%. Calcd for $C_{46}H_{60}N_7O_{12}S_2Cl$: C, 55.10; H, 6.03; N, 9.78%.

N$^\alpha$-t-Butyloxycarbonyl-N$^\delta$-tosyl-N$^\delta$-benzyloxy-L-ornithyldi-N$^\delta$-tosyl-N$^\delta$-benzyloxy-L-ornithyldiglycylglycylglycine Ethyl Ester (XVII). III and XVI·HCl were coupled by the same procedure employed for the preparation of IV-a; mp 192—195 °C (from methanol); $[\alpha]_D$ −5.2° (*c* 1, acetic acid).

Found: C, 58.49; H, 6.09; N, 8.67%. Calcd for $C_{70}H_{89}N_9O_{18}S_3$: C, 58.35; H, 6.23; N, 8.75%.

N$^\alpha$-t-Butyloxycarbonyl-N$^\delta$-tosyl-N$^\delta$-benzyloxy-L-ornithyldi-N$^\delta$-tosyl-N$^\delta$-benzyloxy-L-ornithyldiglycylglycine (XVIII). Hydrolysis of the hexapeptide ester (XVIII) in acetone with M sodium hydroxide was carried out by the same method employed for the hydrolysis of X; mp 122—129 °C (from methanol); $[\alpha]_D$ −2.0° (*c* 1, acetic acid).

Found: C, 57.94; H, 6.09; N, 8.87%. Calcd for $C_{68}H_{85}N_9O_{18}S_3$: C, 57.81; H, 6.07; N, 8.92%.

Tri-N$^\delta$-tosyl-N$^\delta$-benzyloxy-L-ornithyldiglycylglycine Hydrochloride (XIX·HCl). XIX·HCl was obtained by the same procedure employed for the preparation of XII·HCl; mp 188—198 °C (from ethanol); $[\alpha]_D$ +3.2° (*c* 1, acetic acid).

Found: C, 56.18; H, 5.98; N, 9.13%. Calcd for $C_{63}H_{78}N_9O_{16}S_3Cl$: C, 56.09; H, 5.83; N, 9.34%.

cyclo-Triglycyltri-N$^\delta$-tosyl-N$^\delta$-benzyloxy-L-ornithyl (XX).

i) From XII·HCl: To a solution of XII·HCl (7.8 g, (5.8 mmol) in dimethylformamide (60 ml), *N*-methyl morpholine (0.66 ml), 6.0 mmol) was added at room temperature. After stirring for 3 hr, the solution was diluted with dimethylformamide to 2 l. The diluted solution of the free base of XII·HCl was added dropwise into a solution of dicyclohexylcarbodiimide (24 g, 115 mmol) in dimethylformamide (4 l) kept at 0—5 °C under stirring over a period of 48 hr. The solution was stirred for another 4 days at room temperature and then evaporated to 200 ml *in vacuo* at 40 °C. To the residual pale yellow solution was added 50% acetic acid (30 ml) under ice cooling to remove an excess of dicyclohexylcarbodiimide as dicyclohexylurea. After 2 hr, crystalline deposit was removed by filtration and the yellow filtrate was evaporated to dryness. Further the residual oil in dimethylformamide (100 ml) was treated wtih 50% acetic acid as described above and this procedure was repeated several times. The oily residue thus obtained was solidified by addition of water. The crude product was collected and dried; yield, 9.15 g. This was dissolved in 1 l of hot methanol and the insoluble substance (550 mg) was removed by filtration. The filtrate was evaporated to dryness and the residue was redissolved in 150 ml of a mixture of dimethylformamide and water (4 : 1). The solution was successively passed through columns (5×20 cm) of CG-120 (H^+ form) and CG-400 (OH^- form). The columns were then washed with the same solvent. The combined effluents were treated with charcoal and evaporated to dryness *in vacuo*. The residue was collected with the aid of water and dried; yield, 5.8 g. Recrystallization of the product from methanol gave the cyclic hexapeptide (XX); yield, 3.1 g (41%); mp 161—167 °C; $[\alpha]_D$ −3.0° (*c* 1, chloroform); R_f 0.88 (tlc); molecular weight, 1308 (calcd 1295) (dimethylformamide as solvent). Ninhydrin reaction was negative. Recrystallization three times from methanol raised the mp to 181—182 °C.

Found: C, 58.43; H, 5.89; N, 9.48%. Calcd for $C_{63}H_{75}N_9O_{15}S_3$: C, 58.45; H, 5.84; N, 9.74%.

Identification of the methanol-insoluble substance as the dimerization reaction product, i.e. cyclo-*(triglycyltri-N$^\delta$-tosyl-N$^\delta$-benzyloxy-L-ornithyl)$_2$.* Recrystallization from acetic acid gave an analytical sample; mp 246—251 °C; R_f 0.06 (tlc); molecular weight, 2603 (calcd 2589) (dimethylformamide as solvent); yield, 550 mg (7.3%).

Found: C, 58.51; H, 5.83; N, 9.98%. Calcd for $(C_{63}H_{75}N_9O_{15}S_3)_2$: C, 58.45; H, 5.84; N, 9.74%.

ii) From XIX·HCl: XIX·HCl was converted to the free base and allowed to cyclize in dimethylformamide using excess dicyclohexylcarbodiimide as a condensing reagent as has been described above; yield, 7%; mp 172—181 °C; $[\alpha]_D$ −2.8° (*c* 1, chloroform). Dimerization product was obtained as main product; yield, 40%; mp 244—250 °C.

cyclo-*Triglycyltri-N$^\delta$-benzyloxy-L-ornithyl Hydrobromide (XXII·3HBr).* To a solution of 36% hydrogen bromide in acetic acid (32 ml) and phenol (4.0 g) in a glass-stoppered bottle, XX (3.0 g, 2.3 mmol) was added. After stirring

for 42 hr at room temperature, the solution was evaporated *in vacuo* at 30 °C. The oily residue was solidified by adding ether. The crude product collected by suction with the aid of ether was dissolved in water (200 ml). After water-insoluble materials were filtered off, the solution was washed three times with ether, treated with charcoal and then evaporated to dryness *in vacuo*. To the residual oil, ethanol was added and evaporated *in vacuo* in order to remove a trace of water. After the residual oil was solidified by the addition of anhydrous ether and collected with the aid of ether, the product (XXII·3HBr) was obtained as a hygroscopic colorless powder. The removal of tosyl group was determined by Infrared absorption spectrum; absorptions at 1350 and 1165 cm^{-1} for tosyl group were absent.

cyclo-*Triglycyltri*-N$^{\delta}$-*acetyl*-N$^{\delta}$-*benzyloxy*-L-*ornithyl* *(XXIII)*. XXII·3HBr was dissolved in a mixture of pyridine (20 ml) and acetic anhydride (1.0 ml) at 5 °C. After stirring for 12 hr at room temperature, the reaction mixture was evaporated to a syrup *in vacuo*. The residue was evaporated twice with water in order to decompose an excess of acetic anhydride. The final residue was taken up in *n*-butanol (150 ml) and the solution was repeatedly washed with water. The organic layer was treated overnight with charcoal and evaporated to dryness *in vacuo*. The residue was triturated with ether to give an amorphous product (XXIII); the over-all yield in the conversion of XX into XXIII was 47%. NMR spectrum (CD_3OD, TMS-internal standard) indicates N^{δ}-acetyl protons at δ 2.04. The signal of *O*-acetyl derivative was not detected in NMR spectrum.

cyclo-*Triglycyltri*-N$^{\delta}$-*acetyl*-N$^{\delta}$-*hydroxy*-L-*ornithyl*; *deferriferrichrome (XXIV)*. A solution of XXIII (1.0 g) in methanol (40 ml) was hydrogenated in the presence of 5% palladium charcoal (2.0 g) for 4 days at room temperature. After the catalyst was filtered off, the filtrate was evaporated *in vacuo* at 25 °C. The residue was triturated with ether to give an amorphous XXIV; the yield of the dried product, 620 mg. NMR spectrum (D_2O, TMS-external standard) indicates N^{δ}-acetyl protons at δ 2.61, β,γ-methylene protons of N^{δ}-hydroxyornithine at δ 2.25, δ-methylene protons of that at δ 4.15, α-methyne proton of that at δ 4.86 and methylene protons of glycine at δ 4.49 respectively, as shown in Fig. 8. The signals of δ 5.87 and 4.53 are those of side bands of water.

Ferrichrome (I). To the colorless solution of XXIV (500 mg) in McIlvain buffer (pH 4.6) (25 ml), M ferric chloride (2.2 ml, ca. three equivalents) was added at room temperature under continuous stirring. On addition of the ferric chloride, the reaction mixture formed a reddish-violet solution. After stirring for an additional 2 hr, the solution was completely saturated with ammonium sulfate. This solution was extracted with benzyl alcohol (600 ml × 2) and the reddish-orange benzyl alcohol layer was washed with water (100 ml × 3). Diethyl ether (3.6 l) was added to the washed benzyl alcohol solution and then the solution extracted with water (200 ml × 3). The combined aqueous extract was shaken with diethyl ether (200 ml × 3) and the ether phase discarded. The fine red aqueous solution was then evaporated to dryness *in vacuo* at 28 °C. The residual product was scratched with acetone (50 ml) and acetone-insoluble substance was collected by suction. The reddish-brown powder obtained was briefly refluxed in anhydrous methanol (120 ml), filtered and the filtrate concentrated slightly on the oil-bath. The ferrichrome (I) began to crystallize at once in long orange needles, whoes paper chromatography gave a single spot (R_f 0.28) using the solvent system of *n*-butanol–acetic acid–water (4 : 1 : 1). The yield was 85 mg; mp 248—251 °C (decomp.) determined with Melting Point Apparatus MP-21 (Yamato Scientific Co., Ltd., open capillary in silicone oil) and uncorrected; $[\alpha]_D$ $+304° \pm 10°$ (*c* 0.0425, water); $E^{1\%}_{1cm}$ (428 mμ) 39.8 in water. For analysis, a part of the product was recrystallized three times from anhydrous methanol.

Found: C, 43.26; H, 5.69; N, 16.72%. Calcd for $C_{27}H_{42}N_9O_{12}Fe$: C, 43.79; H, 5.72; N, 17.02%.

16) This compound was prepared by two different methods described in the text; a) indicates *N*-hydroxysuccinimide plus *N,N*-dicyclohexylcarbodiimide method and b) indicates Woodward reagent K method. This is repeated in the preparations of VI, VIII and X.
17) The symbol, IV-a, indicates the peptide obtained by the *N*-hydroxysuccinimide plus *N,N*-dicyclohexylcarbodiimide method in the preparation of IV and IV-b indicates that obtained by the Woodward reagent K method. This is to be repeated in the following in order to ascertain whether or not the peptides obtained by the different methods possess the same optical rotation.

Studies of Peptide Antibiotics. XXXI.[1] Syntheses of *iso*-Gramicidin S and *iso*-[2,2′-Lysine]-Gramicidin S[2]

Hideo TAKIGUCHI and Nobuo IZUMIYA*

Department of Chemistry, Faculty of Science, Fukuoka University, Nanakuma, Fukuoka 814
**Laboratory of Biochemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka 812*

(Received September 17, 1973)

Structural isomers of gramicidin S and [2,2′-lysine]-gramicidin S, namely *iso*-gramicidin S and *iso*-[2,2′-lysine]-gramicidin S, were prepared to investigate the influence of the ring size for antibacterial activity and conformation of natural gramicidin S. Each isomer involves two peptide bonds between carboxyl group of valine residue and ω-amino group of ornithine or lysine residue. Two isomers showed no antibacterial activity toward several microorganisms. In the experiment of optical rotatory dispersion, two isomers showed similar shaped curves as gramicidin S in a solvent of ethanol. In 6 M urea, the trough of two isomers was moved significantly, whereas that of gramicidin S remained constant.

In studies of relationship between ring size and antibacterial activity of gramicidin S (GS), several analogs have been synthesized.[3] As one analog with a larger ring size than GS, [β-Ala$^{5,5'}$]-GS showed entirely different ORD[4] pattern compared with that of GS and possessed no activity.[5] Recently, two macro-ring analogs of GS, namely sesquiGS and diGS, were synthesized, and the analogs showed similar ORD patterns with GS in a solvent of ethanol and possessed weak activities.[6]

In order to determine further the influence of larger ring size on the activity and the conformation, we have designed the syntheses of *iso*-gramicidin S (*iso*-GS)[7] and *iso*-[2,2′-lysine]-gramicidin S (*iso*-[Lys$^{2,2'}$]-GS) which are the structural isomers of GS and [Lys$^{2,2'}$]-GS, respectively, as shown in Fig. 1. A related analog of GS, [Lys$^{2,2'}$]-GS, was already synthesized, and the analog showed the same ORD curve and antibacterial activity as GS.[8,9]

Among many natural antibiotics with a character of cyclic peptide, it has been reported that several antibiotics involve a peptide bond participating ω-amino group of ornithine or lysine. Tamura and his collaborators reported the structure of aspochracin as *cyclo*-[δ-(−*N*-Me−Val−*N*-Me−Ala)-Orn(α-octatrienoyl)-].[10]

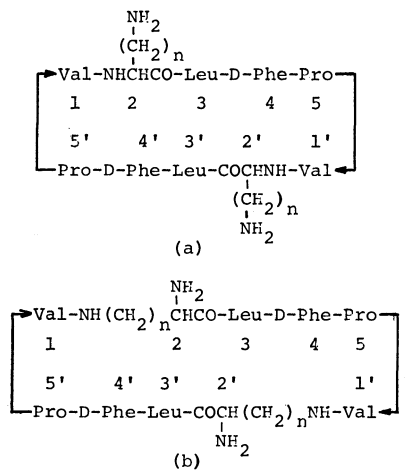

Fig. 1. Structure of gramicidin S (GS) and related peptides.
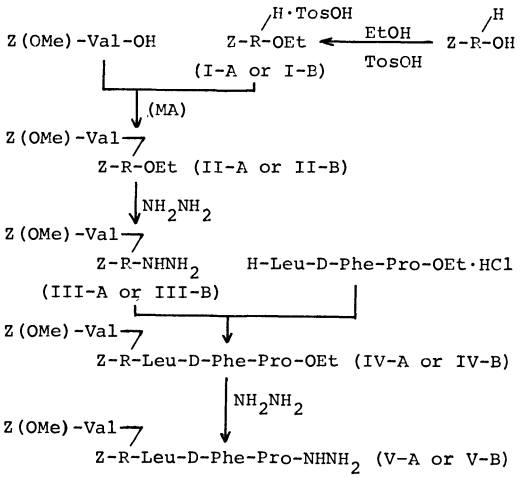
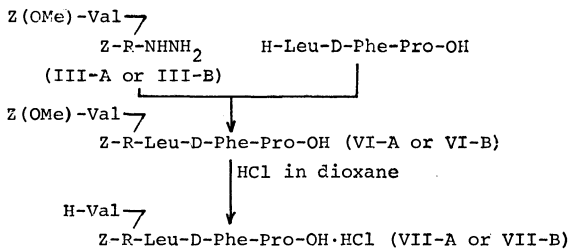
(a) GS (n=3) and [Lys$^{2,2'}$]-GS (n=4).
(b) *iso*-GS (n=3) *iso*-[Lys$^{2,2'}$]-GS (n=4).

Ressler and her collaborators presented a deduced structure of bacitracin; the antibiotic possesses a cyclic heptapeptide moiety as a partially sequence which involves a peptide bond between α-carboxyl group of asparagine residue and ε-amino group of lysine residue.[11] The present investigation would be worth as a model study to synthesize a natural antibiotic with peptide bond participating ω-amino group of α,ω-diamino acid.

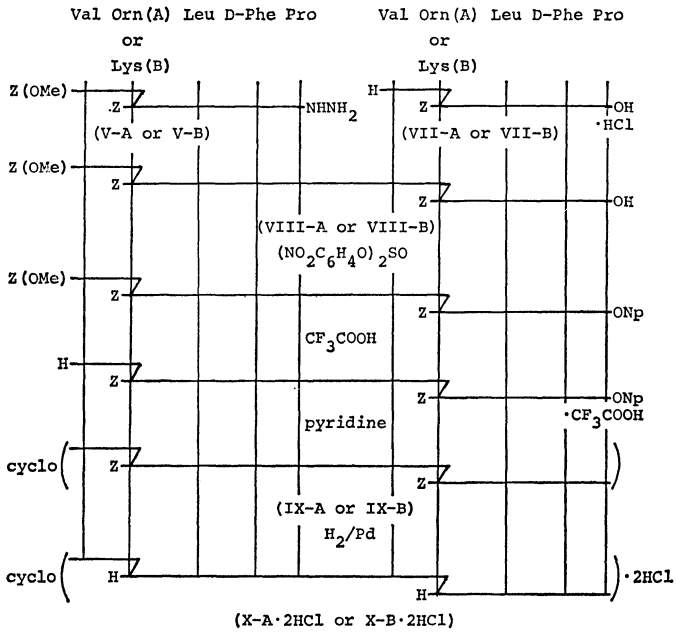
Scheme 1 indicates a route for syntheses of intermediate acylpentapeptide hydrazides (V-A and V-B). Acrylpentapeptide ethyl ester (IV) was prepared without any difficulties by condensation of the azide derived from acyldipeptide hydrazide (III) and a tripeptide ester. The ester (IV) was converted into the



Scheme 1. Syntheses of acylpentapeptide hydrazides. V-A (R=Orn), V-B (R=Lys).



Scheme 2. Syntheses of neutral pentapeptides. VII-A (R=Orn), VII-B (R=Lys).



Scheme 3. Syntheses of *iso*-GS (X-A) and *iso*-[Lys$^{2,2'}$]-GS (X-B).

hydrazide (V) by the usual way. Scheme 2 indicates a sequence of reaction employed for the syntheses of another intermediates, namely free pentapeptides (VII-A and VII-B).

Scheme 3 indicates a route for syntheses of the desired cyclic decapeptides (X-A and X-B). The azide derived from Z(OMe)-pentapeptide hydrazide (V) was condensed with a neutral pentapeptide (VII), and the resulting acyldecapeptide acid (VIII) was converted into Z(OMe)-decapeptide *p*-nitrophenyl ester by the action of di-*p*-nitrophenyl sulfite. Its Z(OMe) group was removed with trifluoroacetic acid, and the resulting decapeptide ester trifluoroacetate was treated with pyridine for the cyclization reaction. The reaction mixture yielded a pure Z-substituted cyclic decapeptide (IX-A or IX-B) which was hydrogenated to afford *iso*-GS (X-A) or *iso*-[Lys$^{2,2'}$]-GS (X-B) as a crystalline dihydrochloride. The homogeneity of these cyclic decapeptides was ascertained by paper and thin layer chromatography, paper electrophoresis, and elemental analysis.

The antibacterial activities toward several microorganisms were examined. Both synthetic isomers (X-A and X-B) showed no activity for any of the microorganisms even at 100 μg/ml of the assay medium, whereas minimum concentration of growth inhibition for *Bacillus subtilis* was found to be 1—2 μg/ml with GS as a reference compound.

The ORD curves measured in a solvent of ethanol are shown in Fig. 2-a. The synthetic isomers have similarly shaped curves with a negative trough at 234 nm as GS possesses the same. In 6 M urea solution in 50% ethanol which causes denaturation of some polypeptide, the troughs of two isomers were moved to 225 nm whereas that of GS remained constant (Fig. 2-b). The results indicate that a conformation of the synthetic isomers is unstable, whereas that of GS has the rigid β-pleated sheet structure with four

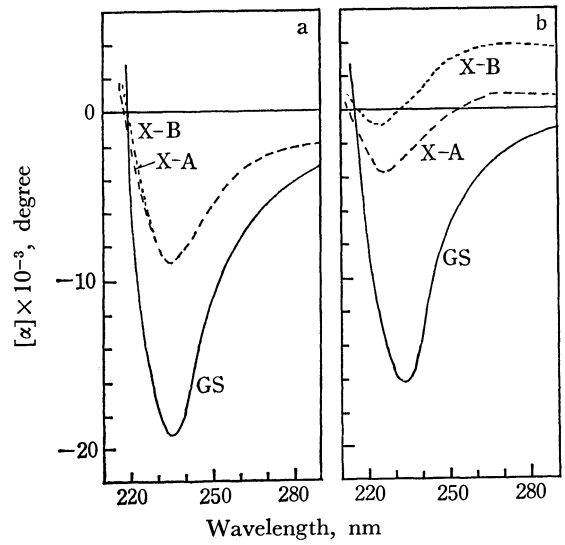


Fig. 2. ORD curves of GS and its isomers.
Solvent: a, ethanol; b, 6 M urea in 50% ethanol.

hydrogen bondings.[3] The isomers may have similar conformation as GS in a mild condition such as a solution in ethanol, but the conformation is transformed in such a urea solution. The fact that the isomers possess no antibacterial activity may be correlated to the unstableness of conformation in a certain medium.

Experimental

All melting points are uncorrected. Prior to analysis, the compounds were dried over phosphorus pentoxide to a constant weight at 80 °C and 2 mmHg except the cyclic peptides (IX-A, IX-B, X-A, and X-B). Thin layer chromatography was carried out on Merck silica gel G with the following solvent system; R_f^1, *n*-butanol-acetic acid-pyridine-water (4 : 1 : 1 : 2, v/v). Paper chromatography was carried out on Toyo Roshi No. 52 with the same solvent, R_f^2 being used.

α-Z-Orn-OEt·TosOH (I-A). This compound was prepared according to the general procedure of Kato *et al.*[12] A solution of α-Z-Orn-OH[13] (6.66 g, 25 mmol) and *p*-toluenesulfonic acid monohydrate (6.09 g, 32 mmol) in a mixture of ethanol (12 ml) and carbon tetrachloride (80 ml) was refluxed, and the water thus liberated was removed as an azeotropic mixture. The reaction mixture was concentrated *in vacuo*, and the residual oil was washed with ether and petroleum ether by decantation. The product was obtained as an oil; yield, 11.7 g (100%); R_f^1 0.77.

α-Z-Lys-OEt·TosOH (I-B). This compound was preparated from α-Z-Lys-OH[14] (5.60 g, 20 mmol) as described above. The product was recrystallized from acetone-ether; yield, 8.84 g (92%); mp 113—115 °C; $[\alpha]_D^{20}$ −7.8° (*c* 2, DMF); R_f^1 0.78.

Found: C, 57.23; H, 6.82; N, 5.77%. Calcd for $C_{23}H_{32}O_7N_2S$: C, 57.48; H, 6.71; N, 5.83%.

δ-[Z(OMe)-Val]-Orn(α-Z)-OEt (II-A). To a solution of Z(OMe)-Val-OH[15] (6.28 g, 22.3 mmol) and TEA (3.12 ml, 22.3 mmol) in tetrahydrofuran (70 ml) at −5 °C, was added isobutyl chloroformate (2.92 ml, 22.3 mmol). After 15 min, to the solution was added a mixture of I-A (10.4 g, 22.3 mmol) and TEA (3.12 ml) in chloroform (70 ml) at 0 °C. The reaction mixture was allowed to stand overnight at room temperature, and evaporated *in vacuo*. The residue was triturated with water and petroleum ether, and the

precipitate was collected by filtration. The product was washed successively with 4% sodium bicarbonate, 10% citric acid, and water. It was recrystallized from methanol-ether-petroleum ether; yield, 9.45 g (76%); mp 155—156 °C; $[\alpha]_D^{30}$ +2.4° (*c* 2, DMF); R_f^1 0.88.

Found: C, 62.83; H, 7.21; N, 7.41%. Calcd for $C_{29}H_{39}O_8N_3$: C, 62.46; H, 7.05; N, 7.54%.

ε-[Z(OMe)-Val]-Lys(α-Z)-OEt (II-B). This compound was obtained from Z(OMe)-Val-OH (4.50 g, 16 mmol) and I-B (7.69 g, 16 mmol) as described above; yield, 7.77 g (85%); mp 148—150 °C; $[\alpha]_D^{20}$ −2.1° (*c* 2, DMF); R_f^1 0.94.

Found: C, 62.72; H, 7.27; N, 7.16%. Calcd for $C_{30}H_{41}O_8N_3$: C, 63.03; H, 7.23; N, 7.35%.

δ-[Z(OMe)-Val]-Orn(α-Z)-NHNH$_2$ (III-A). A solution of II-A (7.81 g, 14 mmol) and hydrazine hydrate (13.6 ml, 280 mmol) in DMF (28 ml) was allowed to stand for 2 days at room temperature. The solution was concentrated *in vacuo* to a small volume. The hydrazide precipitated upon the addition of water (140 ml) was collected by filtration; yield, 5.81 g (76%); mp 162—165 °C; $[\alpha]_D^{31}$ −11.0° (*c* 1, AcOH).

Found: C, 59.40; H, 7.09; N, 13.29%. Calcd for $C_{27}H_{37}O_7N_5$: C, 59.66; H, 6.86; N, 12.88%.

ε-[Z(OMe)-Val]-Lys(α-Z)-NHNH$_2$ (III-B). II-B (5.15 g, 9 mmol) was converted to hydrazide (III-B) as described above; yield, 3.92 g (78%); mp 194—196 °C; $[\alpha]_D^{21}$ −13.2° (*c* 1, AcOH).

Found: C, 60.14; H, 7.32; N, 12.49%. Calcd for $C_{28}H_{39}O_7N_5$: C, 60.31; H, 7.05; N, 12.56%.

δ-[Z(OMe)-Val]-Orn(α-Z)-Leu-D-Phe-Pro-OEt (IV-A). III-A (2.17 g, 4 mmol), in a mixture of glacial acetic acid (48 ml) and N hydrochloric acid (8.8 ml), was treated with N sodium nitrite (4.4 ml) at −5 °C. After 6 min, cold water (200 ml) was added to the mixture. The azide was extracted with ethyl acetate, and the organic layer was washed with 4% sodium bicarbonate and water, and dried over sodium sulfate. The filtered solution was added to a solution of H-Leu-D-Phe-Pro-OEt·HCl[16] (1.76 g, 4 mmol) and TEA (0.56 ml) DMF (20 ml). The mixture was stirred for 3 days at 0 °C and evaporated *in vacuo* to a small volume. The precipitate which formed upon the addition of water was collected, washed with 4% sodium bicarbonate, 10% citric acid, and water, and dried. The product was recrystallized from dioxane-ether-petroleum ether; yield, 2.12 g (58%); mp 118—122 °C; $[\alpha]_D^{30}$ −18.0° (*c* 1, DMF); R_f^1 0.88.

Found: C, 64.01; H, 7.30; N, 9.16%. Calcd for $C_{49}H_{66}O_{11}N_6$: C, 64.31; H, 7.27; N, 9.18%.

ε-[Z(OMe)-Val]-Lys(α-Z)-Leu-D-Phe-Pro-OEt (IV-B). This compound was prepared from III-B (1.67 g, 3 mmol) and H-Leu-D-phe-Pro-OEt·HCl (1.32 g, 3 mmol) as described above; yield, 1.90 g (68%); mp 132—136 °C; $[\alpha]_D^{24}$ −23.6° (*c* 1, DMF); R_f^1 0.96.

Found: C, 64.42; H, 7.30; N, 9.20%. Calcd for $C_{50}H_{63}O_{11}N_6$: C, 64.64; H, 7.38; N, 9.05%.

δ-[Z(OMe)-Val]-Orn(α-Z)-Leu-D-Phe-Pro-NHNH$_2$ (V-A). A solution of IV-A (1.10 g, 1.2 mmol) and hydrazine hydrate (1.2 ml) in DMF (4.5 ml) was allowed to stand for 7 days at room temperature, and evaporated *in vacuo*. The hydrazide which precipitated upon the addition of water (40 ml) was collected and recrystallized from dioxane-ether; yield, 0.873 g (81%); mp 112—115 °C; $[\alpha]_D^{27}$ −31.4° (*c* 1, DMF).

Found: C, 62.24; H, 7.50; N, 12.13%. Calcd for $C_{47}H_{64}O_{10}N_8 \cdot 1/2H_2O$: C, 62.03; H, 7.20; N, 12.31%.

ε-[Z(OMe)-Val]-Lys(α-Z)-Leu-D-Phe-Pro-NHNH$_2$ (V-B). IV-B (1.47 g, 1.58 mmol) was converted to the hydrazide (V-B) as described above; yield, 1.23 g (85%); mp 118—120 °C $[\alpha]_D^{20}$ −28.2° (*c* 1, DMF).

Found: C, 63.25; H, 7.35; N, 12.50%. Calcd for $C_{48}H_{66}O_{10}N_8$: C, 63.00; H, 7.27; N, 12.24%.

δ-[Z(OMe)-Val]-Orn(α-Z)-Leu-D-Phe-Pro-OH (IV-A). III-A (1.63 g, 3 mmol) was converted to the azide as described for the preparation of IV-A. The azide solution in ethyl acetate was added to a solution of H-Leu-D-Phe-Pro-OH[17] (1.13 g, 3 mmol) and TEA (0.42 ml) in DMF (24 ml). The mixture was stirred for 3 days at 0 °C and evaporated *in vacuo*. To the concentrated solution was added 10% citric acid, and the oil separated was extracted with ethyl acetate. The organic layer was washed with 10% citric acid and water, and dried. The filtered solution was evaporated, and the precipitate which formed upon the addition of ether and petroleum ether was collected. It was recrystallized from ethyl acetate-petroleum ether; yield, 1.20 g (45%); mp 112—115 °C; $[\alpha]_D^{27}$ −27.8° (*c* 1, DMF); R_f^1 0.82.

Found: C, 63.34; H, 7.16; N, 9.17%. Calcd for $C_{47}H_{62}O_{11}N_6$: C, 63.64; H, 7.05; N, 9.47%.

ε-[Z(OMe)-Val]-Lys(α-Z)-Leu-D-Phe-Pro-OH (VI-B). This compound was prepared from III-B (1.95 g, 3.5 mmol) and H-Leu-D-Phe-Pro-OH (1.31 g, 3.5 mmol) as described above. The product was recrystallized from methanol-ether-petroleum ether; yield, 2.24 g (71%); mp 126—129 °C; $[\alpha]_D^{25}$ −14.6° (*c* 1, DMF); R_f^1 0.94.

Found: C, 63.53; H, 7.20; N, 9.55%. Calcd for $C_{48}H_{64}O_{11}N_6$: C, 63.98; H, 7.16; N, 9.33%.

δ-(H-Val)-Orn(α-Z)-Leu-D-Phe-Pro-OH·HCl (VII-A). To a solution of VI-A (887 mg, 1 mmol) in dioxane (10 ml), 4.8 N hydrogen chloride in dioxane (6.2 ml) was added at room temperature. After 3 hr, the solution was evaporated to dryness and the product was collected with the aid of ether; yield of a hydroscopic powder, 683 mg (90%); mp 157—164 °C; $[\alpha]_D^{20}$ −12.6° (*c* 1, DMF); R_f^1 0.71.

Found: C, 59.85; H, 7.54; N, 11.37%. Calcd for $C_{38}H_{55}O_8N_6Cl$: C, 60.11; H, 7.30; N, 11.07%.

ε-(H-Val)-Lys(α-Z)-Leu-D-Phe-Pro-OH·HCl (VII-B). VI-B (723 mg, 0.802 mmol) was converted to VII-B as described above; yield of a hygroscopic powder, 564 mg (91%); mp 137—140 °C; $[\alpha]_D^{28}$ +4.0° (*c* 0.5, DMF); R_f^1 0.73.

Found: C, 60.36; H, 7.65; N, 10.98%. Calcd for $C_{39}H_{57}O_8N_6Cl$: C, 60.57; H, 7.43; N, 10.87%.

δ-{δ-[Z(OMe)-Val]-Orn(α-Z)-Leu-D-Phe-Pro-Val}-Orn(α-Z)-Leu-D-Phe-Pro-OH (VIII-A). V-A (808 mg, 0.897 mmol) was converted to corresponding azide as described for the preparation of the azide from III-A. The azide in ethyl acetate was coupled with VII-A (681 mg, 0.897 mmol) in TEA (0.25 ml) and DMF (20 ml) as described for the preparation of VI-A. The product was recrystallized from dioxane-ether-petroleum ether; yield, 871 mg (61%); mp 150—153 °C; $[\alpha]_D^{17}$ −50.0° (*c* 0.5, DMF); R_f^1 0.80.

Found: C, 64.38; H, 7.42; N, 10.56%. Calcd for $C_{85}H_{114}O_{18}N_{12}$: C, 64.13; H, 7.22; N, 10.56%.

ε-{ε-[Z(OMe)-Val]-Lys(α-Z)-Leu-D-Phe-Pro-Val}-Lys(α-Z)-Leu-D-Phe-Pro-OH (VIII-B). This compound was prepared from V-B (641 mg, 0.7 mmol) and VII-B (541 mg, 0.7 mmol) as described above. The product was recrystallized from ethyl acetate-petroleum ether; yield, 952 mg (84%); mp 130—132 °C; $[\alpha]_D^{34}$ −34.6° (*c* 0.5, DMF); R_f^1 0.83.

Found: C, 64.35; H, 7.57; N, 10.63%. Calcd for $C_{87}H_{118}O_{18}N_{12}$: C, 64.51; H, 7.34; N, 10.38%.

cyclo-*{δ-[δ-(-Val)-Orn(α-Z)-Leu-D-Phe-Pro-Val]-Orn(α-Z)-Leu-D-Phe-Pro-} (IX-A).* To a solution of VIII-A

(637 mg, 0.4 mmol) in pyridine (8 ml), di-*p*-nitrophenylsulfite[18] (1.30 g, 4 mmol) was added. The reaction mixture was allowed to stand for 3 days at room temperature. After the solvent had been evaporated, the oily product was triturated with petroleum ether, washed repeatedly with a mixture of ether and petroleum ether (1 : 1) by decantation, and the residual solid was collected. To the solid (the *p*-nitrophenyl ester) were added anisole (0.4 ml) and trifluoroacetic acid (4 ml) at −5 °C. After 30 min, the solution was evaporated at 0 °C, and the residue was triturated with ether. A decapeptide *p*-nitrophenyl ester trifluoroacetate was collected in a cold room, washed with ether, and dried. The trifluoroacetate was dissolved in DMF (10 ml) containing acetic acid (0.4 ml), and the solution added to pyridine (200 ml) which had been kept at 60 °C over a period of 1 hr. The stirring was continued for additional 2 hr. After the solvent had been evaporated, the residue was dissolved in a mixture of methanol (150 ml) and water (50 ml). The solution was passed successively through the columns (2.5 × 12 cm, each) of Dowex 1 (OH^- form) and Dowex 50 (H^+ form). The columns were washed with the same solvent (600 ml), and the effluent was evaporated to dryness. The residual product was collected with the aid of water, and recrystallized from methanol-water; yield, 121 mg (21% from VIII-A); mp 160—163 °C; $[\alpha]_D^{10}$ −68.7° (*c* 0.3, DMF); R_f^1 0.96.

Found: C, 62.86; H, 7.75; N, 11.28%; mol wt, 1420.[19] Calcd for $C_{76}H_{104}O_{14}N_{12}\cdot 2H_2O$: C, 63.14; H, 7.53; N, 11.63%; mol wt, 1446.

Found: C, 56.48; H, 8.31; N, 12.61%. Calcd for $C_{62}H_{98}O_{10}N_{12}Cl_2\cdot 4H_2O$: C, 56.65; H, 8.13; N, 12.79%.

Electrophoresis. Electrophoresis on Toyo Roshi No. 50 paper was carried out with a solvent system, formic acid-acetic acid-methanol-water (1 : 3 : 6 : 10, v/v; pH 1.8) for 3 hr at 500 V/30 cm. Figure 3 shows that mobilities of X-A and X-B were comparable with that of GS.

ORD Measurement. The measurements were performed with a Jasco Model ORD/UV 5 spectropolarimeter. Cell of path length 0.2 cm was used and the runs were made at ambient temperature. In Fig. 2 are reported the ORD curves (range 220—300 nm) of the isomers (X-A and X-B) and GS in ethanol or 6 M urea solution in 50% ethanol[20] (*c* 0.1, each).

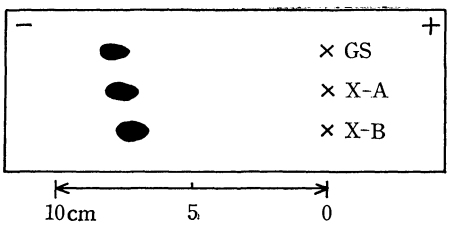

Fig. 3. Paper electrophoresis of GS and its isomers.
GS, gramicidin S; X-A, *iso*-GS; X-B, *iso*-[Lys$^{2,2'}$]-GS.

Microbiological Assays.[21] The microorganisms employed are *Escherichia coli*, *Proteus vulgaris*, *Staphylococcus aureus*, and *Bacillus subtilis*. The minimum amount of the compounds necessary for the complete inhibition of growth was determined by a dilution method in both Bouillon agar medium and synthetic medium. GS was examined as a reference compound. X-A and X-B exhibited no antibacterial activity against the microorganisms tested even at 100 μg/ml, whereas minimum concentration of GS for inhibition were 2—5 μg/ml on *S. aureus* and 1—2 μg/ml on *B. subtilis*.

The authors wish to express their thanks to Drs. T. Kato, M. Waki, and S. Matsuura of Kyushu University for helpful discussions and ORD measurements.

The Allylic Rearrangement of Linalyl Acetate in the Medium of Acetic Acid, Propionic Acid, or Acetic Acid Containing Dioxane or Sulfuric Acid

Kunio KOGAMI and Ju KUMANOTANI

T. Hasegawa Co., Ltd, Nihonbashi, Chuo-ku, Tokyo 103

Engineering Research Institute, Faculty of Engineering, The University of Tokyo, Yayoi, Bunkyo-ku, Tokyo 113

(Received May 9, 1973)

The mechanism of the allylic rearrangement of linalyl acetate in the medium of acetic acid, propionic acid, or acetic acid containing dioxane or sulfuric acid has been investigated. The nature of the carbonium-ion pairs generated from linalyl acetate in low-dielectric-constant solvents or in strong acids, and the behavior of the active intermediate in the transition state were postulated from the kinetic data as well as from the physicochemical properties and distributions of the products.

It has been well known that linalyl acetate (designated as LA), an ester of tertiary monoterpene alcohols, is isomerized through allylic rearrangement. Young and Webb[1] isomerized LA to geranyl acetate in acetic acid (designated as HOAc) containing phosphoric acid (0.1 mol H_3PO_4), and Crabalona[2] to geranyl- and terpinyl acetate, geraniol, terpineol, and terpene hydrocarbons in HOAc containing 5 volume percent of water.

The foregoing studies gave qualitative results, but no quantitative data relating to the mechanism of the rearrangement or to the product distribution are available. In order to clarify the reactivity of LA in non-aqueous solvents containing HOAc, we have investigated rearrangements in the medium of HOAc, propionic acid, and HOAc containing dioxane or sulfuric acid.

The present paper discloses how the rearrangement of LA in the medium of HOAc or HOAc–dioxane has been found to be an S_N1-type solvolytic reaction[3] accompanied by both allylic rearrangement[4] and the common ion effect of the acetate anion.[5] In the case of propionic acid, the rearrangement followed a pseudo-first-order condition. An internal return[6] was postulated from the formation of racemized linalyl propionate *via* an intimate ion pair[7] which had formed among a carbonium ion, an acetate anion, and a propionic acid molecule. A typical acid-catalyzed A1 reaction[8–10] was found in the medium of HOAc containing sulfuric acid.

Experimental

Materials. LA prepared by the acetylation of linalool with ketene[11,12] was supplied by T. Hasegawa Co., Ltd; its purity was analyzed by gas-liquid chromatography (designated as glc and found to be 100%: n_D^{30} 1.4501, d_{30}^{30} 0.9050, bp 88—89 °C/4 mmHg, $[\alpha]_D^{25}$ −7.6° (optical purity 96%). Commercially-available reagents of a chemical pure grade were used in this study. HOAc free from moisture was obtained by the Noyce method[13] (bp 119 °C). Dioxane, which had been refluxed with metallic sodium for 8 hr beforehand, was rectified (bp 101 °C). Sodium acetate was dehydrated by the usual method. *o*-Nitroaniline was recrystallized from ethanol (mp 71 °C).

Measurement of the Acidity Function H_0. The acdity function, H_0, was estimated by spectrophotometry for each medium–LA–HOAc, HOAc–dioxane, and HOAc–sulfuric acid; we then calculated according to the following equation:

$$H_0 = \log (C_B/C_{BH^+}) + pk_a$$

where C_B and C_{BH^+} are the concentrations of the indicator used, *o*-nitroaniline ($pk_a = -0.17$, $\varepsilon = 5000$), and the conjugated acid respectively, both of which values were obtained at 412 mμ.[14] The measurements were carried out at 30 °C, and the density of HOAc was found to be d_{30}^{30} 1.0380.

Estimation of the Reaction Rate. *1) Rearrangement in HOAc*: A mixture (20 ml) of LA and HOAc in a given ratio (10 : 90, 20 : 80 or 30 : 70 vol%) was ampouled in cleaned glass tubes (30 ml) and then dipped at once into an oil bath kept at a desired temperature (80, 100, or 120 °C). At prescribed intervals an ampoule was taken off from the bath and cooled to room temperature with water. The reaction product was poured into 200 ml of ice water, neutralized with a 10% aqueous solution of sodium carbonate, saturated with sodium carbonate, saturated with sodium chloride, and then extracted several times with 100-ml portions of ether. The extracts were then put together and dried over sodium sulfate. An oily matter obtained after the removal of the ether was weighed, and the composition was analyzed by glc using an internal standard method using methyl caprylate. In order to determine the amount of polymeric material present, oily products simultaneously collected from several amouples were distilled *in vacuo* by means of a micro Claisen flask.

The rate constant (k) of the rearrangement was calculated according to the following equation:

$$k = 2.303 \log (a/(a-x))/t$$

where a is the initial concentration of LA and where a–x is the concentration at time t.

2) Rearrangement in the Medium of HOAc Containing Dioxane: A mixture (50 ml) of HOAc and dioxane in a given ratio (90 : 10, 80 : 20, or 70 : 30 vol%) containing 1 ml of LA (0.0046 mol) was ampouled in a glass tube (60 ml) and then placed in a thermostated oil bath at a desired temperature (80, 90, or 100±0.1 °C).

3) Rearrangement in Propionic Acid: LA and propionic acid were ampouled in glass tubes (60 ml) in a given ratio 10 : 90 vol%). The ampoules were kept in a thermostat (100±0.1 °C) for a precribed time.

4) Rearrangement in the Medium of HOAc Containing Sulfuric Acid: A mixture (50 ml) of 90% HOAc and sulfuric acid, the acidity function of which is known,[14] containing 1 ml of LA was put into a 100-ml Erlenmeyer flask. The flask was then closed with a stopper, placed in a thermostat regulated at 0±0.01 °C, and reacted while being stirred with a magnetic stirrer.

Identification of Products. The reaction products, such as LA, *d*-α-terpinyl,[15] neryl- and geranyl acetates, racemized linalool, and linalyl propionates, were separated by distillation with a spinning-band-type column (dia. 6 mm; length 1.5 m) and by preparative gas liquid chromatography

Inscriptions for terpene hydrocarbons (TH): Myrcene-M, limonene-L, ocimene-O, terpinolene-T; for acetate: Linalyl acetate-LA, terpinyl acetate-TA, neryl acetate-NA, geranyl acetate-GA. Product distributions at 100 °C and in 80 vol% of HOAc are abbreviated owing to the same tendency as the others.

according to demand; they were identified by comparing the NMR, IR, and mass spectra with those of an authentic sample.[11,12] Terpene hydrocarbons, such as myrcene, limonene, β-trans-ocimene,[16] and terpinolene, were identified by comparing the mass spectra and the retention times on gas chromatography with those of the authentic samples described in the previous paper.[11,12]

Analyses of Composition. The composition of the rearrangement products of LA obtained in the prescribed medium were analyzed by glc by the internal standard method using methyl caprylate. The calibration curves of components were obtained in the usual way. Thus, LA, for instance, was analyzed within the relative experimental error of ±0.5%, and the other components, within ±1.0% A 2-m stainless steel column (dia. 3 mm) packed with Rac-2R-446 (10 wt%) on Celite 545 sk of 60—80 mesh was used. The operating conditions of the gas chromatograph (Kotaki GU-21): column temperature, 150 °C; flash evaporator, 220 °C; carrier gas, (helium); flow rate, 22 ml/min. In the case of the medium of propionic acid or HOAc containing sulfuric acid, only LA was analyzed by the internal standard method, using methyl caprylate and other components and the area ratio method.

Calculation of the Total Energy of Carbonium Ions. The total energy was calculated for a few typical carbonium ions by Hoffmann's Extended Hückel Molecular Orbital Method.[17] In determining the geometry, the following assumptions were used:

1) *Bond Length*: C–C (1.541 Å), C–C, adjacent to double bond (1.53 Å), C=C (1.337 Å), C–H, monosubstituted (1.101 Å), C–H, disubstituted (1.073 Å), C–H, trisubstituted (1.070 Å), C–H, olefinic (1.071 Å).

2) *Bond Angle*: The bond angle between C=C and C–C is 120 °C; the one between two C–C, 109.5 °C; the one of a charged C atom in the plane sp^2 hybrid structure, 120 °C.

A method of charge iteration was incorporated in the Kikuchi-Konakahara-Ishihara EHMO (Extended Hückel Molecular Orbital) program.[18] For the calculation, a HITAC 5020 computer at the Tokyo University Computer Center was used.

Results and Discussion

Previously we reported that LA prepared by acetylation with acetic anhydride, using sodium acetate or phosphoric acid as a catalyst, is rearranged with ease, and that the rearrangement proceeds from HOAc originating in the acetylation and is accompanied by various by-products as well.[11] The latter fact led us to study the preparation of LA as pure as possible. Thus, it has been found that a method of acetylating linalool with ketene in the presence of phosphoric acid gives neither HOAc nor by-products.[11] In order to reveal the mechanism of rearrangement in LA, the following Reactions (1)—(4) were examined.

Table 2. Rate constants k_1 (1/s) of rearrangement of LA in HOAc

HOAc	80 °C	100 °C	120 °C
90 vol%	2.82×10^{-4}	9.58×10^{-4}	2.57×10^{-3}
80 vol%	1.26×10^{-4}	4.37×10^{-4}	1.45×10^{-3}
70 vol%	4.81×10^{-5}	1.50×10^{-4}	5.89×10^{-4}

Remarks: HOAc 90 vol% (15.57 mol)-LA 10 vol% (0.5 mol)
HOAc 80 vol% (13.84 mol)-LA 20 vol% (1.0 mol)
HOAc 70 vol% (12.11 mol)-LA 30 vol% (1.5 mol)

(1) Rearrangement of LA in HOAc. The results obtained under controlled conditions were as follows. The rates of rearrangement in HOAc were found to be of the first order in any of the concentrations examined on LA (Table 1). The rate contant increased with an increase in both the concentration of HOAc and the reaction temperature (Table 2). Ratios of logarithm of the rate constant against that of the molar concentration of HOAc yield straight lines, with the slope varying from 5.0 to 7.0 (order of solvent participation).[3] This fact proves that the rearrangement of LA in HOAc is an S_N1-type solvolytic reaction. The ionization of LA to carbonium-ion pairs is assumed to result from a solvation due to the formation of hydrogen bonds among a carbonium ion, and an acetate anion and some HOAc molecules. The Arrhenius plots of log k_1 *versus* $1/T$ gave straight lines. The estimated activation energy ranged from 15.00 to 17.20 kcal/mol, and the entropy of activation, from −34.8 to −31.5 e.u. As the concentration of HOAc increases, both the activation energy and the entropy decrease as follows:

HOAc vol%	LA vol%	ΔE kcal/mol	ΔS^* (e.u.) 120 °C	100 °C	80 °C
70	30	17.20	−34.7	−32.4	−31.9
80	20	16.65	−31.9	−31.7	−31.5
90	10	15.00	−34.8	−34.6	−34.6

The results indicate that the carbonium-ion pairs are easily formed in the transition state, and that the formation of a solvent shell due to the surrounding acetic acid molecules diminishes the degree of freedom to react.

The above discussion is based on the apparent kinetical data; however, the product distribution in the rearrangement should be considered as well. The compositions of the rearrangement products were analyzed by glc by the internal standard method using methyl caprylate. The calibration curves of the components,

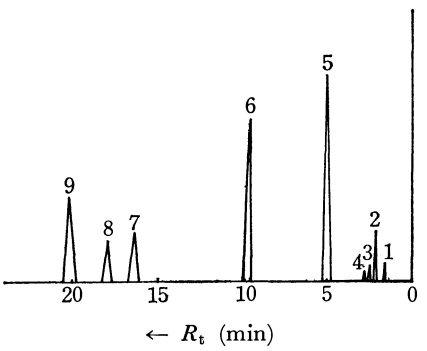

Fig. 1. A typical gas chromatograms of the products in a rearrangement.
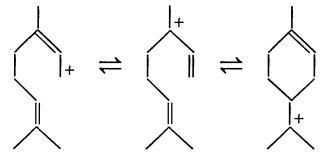
1: myrcene, 2: limonene, 3: ocimene, 4: terpinolene, 5: methyl caprylate, 6: LA, 7: terpinylacetate, 8: neryl acetate, 9: geranyl acetate.

such as LA, terpinyl-, neryl-, geranyl acetates and terpene hydrocarbons (the mixture of myrcene, limonene, ocimene and terpinolene was found to have the ratio of 1 : 2 : 1 : 0.2), were obtained by the usual way. All the curves referring to the area ratio against the weight ratio of these compounds to methyl caprylate showed a linear relationship. The products estimated from the gas chromatograms (Fig. 1) were as follows: partially racemized (10—15%) LA, acetates of geranyl, neryl, and the more racemized (65—70%) *d*-α-terpinyl, myrcene, limonene, β-*trans*-ocimene and terpinolene. The degrees of racemization in the LA and terpinyl acetate separated by preparative glc were estimated by the loss of optical purity (Table 1). The partial racemization of LA suggests a much higher stereospecificity for the return from the carbonium-ion pair to LA than for the solvent (HOAc) collapes.[4] On the other hand, the remarkable racemization of terpinyl acetate ($[\alpha]_D^{25}$ of pure acetate, +52.5°) shows a preferential collapse of the terpinyl-carbonium ion with the solvation shell of HOAc.

The amounts of acetates resulting from the allylic rearrangement were found to be in the following order:

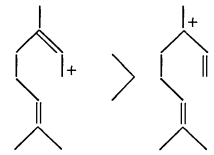
geranyl > neryl > linalyl > terpinyl

The acetates of geranyl (*trans*) and neryl (*cis*) were considered to be derived from the primary terpenoid carbonium ion and the *d*-α-terpinyl acetate, from the tertiary terpenoid carbonium ion. The product distribution is proportional to the instability of the following carbonium ions, disclosing that the labile carbonium ions are more reactive:[19]



carbonium ion geranyl linalyl terpinyl

As the terpinyl carbonium ion is considered to be the most stable one of the four, the total energies of the other two typical carbonium ions (geranyl and linalyl) were calculated by Hoffmann's EHMO Method (Figs. 2—3). The instability of these carbonium ions was found to be in the following order;



carbonium ion	geranyl	linalyl
eV	−983.724	−984.322

This order well agrees with the results mentioned above.

The acetates of geranyl, neryl, and terpinyl obtained were not further isomerized in HOAc under the same conditions (Table 1, Remarks column). This indicates that; 1) these acetates are directly formed by the alkyl fission of LA *via* carbonium ions, and 2) the rearrangement of LA may be promoted by the delocalization of the tertiary carbonium ions due to the allyl group.

An E_1-type elimination was found to be accompanied

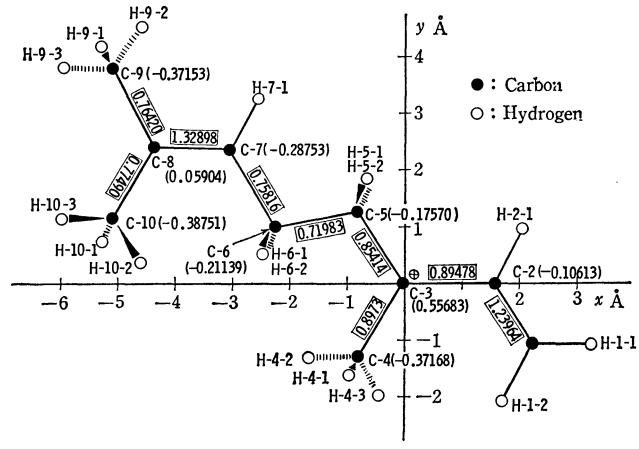


Fig. 2. Calculation on the total energy of a linalyl carbonium ion.
Total energy: −984.3220 eV.
Numerals in ( ) refer to formal charge and those in ▭ to bond population.

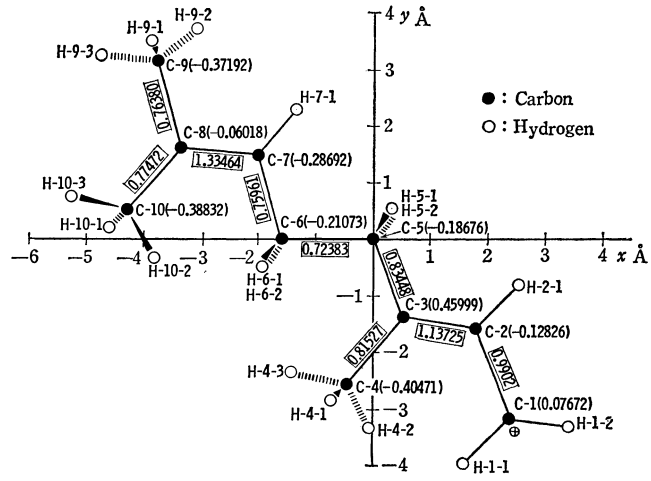

Fig. 3. Calculation on the total energy of a geranyl carbonium ion.
Total energy: −983.7244 eV.

by a S_N1-type solvolytic reaction. The elimination products amounted to as much as 20% of the total. They were terpene hydrocarbons, such as myrcene, limonene, ocimene, and terpinolene, which were also considered to be derived from the above carbonium ions. Even at relatively lower concentrations of HOAc as well as at lower reaction temperatures and in the eary stages of the rearrangement, a great deal of myrcene was found, together with a small amount of limonene, ocimene, and terpinolene. However, the amount of limonene nearly increased with the concentration of HOAc as well as with the advance of the reaction. As a result, the main product under the conditions of an S_N1-type solvolytic reaction was found to be the above-described primary acetates (geranyl and neryl), while the main products of an E_1-type elimination was myrcene. The latter result agrees well with the fact that acetates of geranyl and neryl are broken down to form myrcene in an electron-impact elimination.[12]

For studying the common ion effect charcteristic of the S_N1-type solvolytic reaction, LA was isomerized

Table 3. Rearrangement of LA in the medium of HOAc containing sodium acetate

in the medium of HOAc containing sodium acetate, and was estimated by glc on the basis of the product distribution. The effect seems to suppress the ionization of LA to carbonium ion pairs qualitatively. Table 3 shows the results obtained. The optical purity of LA was almost the same before and after the reaction. It may be postulated that nucleophilic acetate anions dissociated from sodium acetate are attracted to coordinate intimately with the carbonium ion of LA, resulting in the prevention of coordination with the neutral HOAc molecules.

(2) Rearrangement of LA in the Medium of HOAc containing Dioxane. It is well known that a carbonium ion is coordinated from the back with a dioxane molecule.[3] Consequently, dioxane is considered to be a suitable solvent for studying the specific solvation of HOAc. The rearrangement of LA in the medium of HOAc containing dioxane was found to be of the first order with respect to the concentration of LA. The rates constants and the product distributions estimated in the same manner as (1) are summarized in Tables 4 and 5. In the straight lines giving the correlation between the logarithm of the concentration of HOAc and that of the rate constant, the slopes of the lines ranged from 7.3 to 7.5 (the value corresponds to the order of solvent participation).[3] Thus, the rearrangement in this case can be classified as an S_N1-type solvolytic reaction. The plots of the Arrhenius equation relating to log k_1 and $1/T$ gave straight lines. The estimated activation energy changed from −15.41 to −20.63 kcal/mol; however, no linearity was found with the concentration of HOAc as follows:

HOAc vol%	Dioxane vol% (mol. fr.)	ΔE kcal/mol	ΔS^* (e.u.) 100 °C	90 °C	80 °C
45	5 (0.07)	15.41	−34.1	−34.5	−33.7
40	10 (0.14)	20.63	−22.1	−21.7	−21.9
35	15 (0.21)	19.67	−25.7	−26.2	−25.6

LA, 1 vol%, 0.0046 mol.

The value increased nearly parallel with the increase in the molar fraction (up to 0.14) of dioxane, and then decreased. This may be explained in terms of the specific solvation of a polar solvent, HOAc, in the mixed system.[4] In spite of the presence of an actual rearrangement, the well reservation in the optical purity of LA proves that the coordination of dioxane to a carbonium ion eventually occurred from the back alone (Table 4). The entropy of activation, which ranged from −34.5 to −21.7 e.u., also discloses that the solvation of HOAc to a carbonium ion is much stronger than that of dioxane. The smaller effect of dioxane on the solvation in the medium of HOAc containing dioxane resulted also in a product distribution similar to that in the medium of HOAc (Table 4).

(3) Rearrangement of LA in Propionic Acid. There is no available means to prove the reverse reaction, in which a LA molecule returns *via* the carbonium ion or the ion pairs to the original LA in the foregoing system (1)—(2). Thus, the rearrangement of LA in propionic acid was examined. Table 6 gives the results obtained. The kinetics of the rearrangement were found to follow the first-order rate law with respect to the concentration of LA. As products, not only propionates of linalyl, geranyl, neryl, and terpinyl, but also acetates of the same terpene alcohol, were obtained, together with some terpene hydrocarbons. Among the products, only linalyl

40	13.84	10	2.27	1	0.0046	5.48×10^{-5}	1.40×10^{-4}	2.60×10^{-4}
35	12.11	15	3.40	1	0.0046	3.40×10^{-5}	5.64×10^{-5}	1.50×10^{-4}

propionate was found to be racemized. This fact suggests that a leaving-group acetate anion was rather closely associated with a carbonium ion (linalyl) to form an intimate ion pair, and that a selective internal return[6] resulted in the products obtained. This interesting finding reflects the structure of the intimate ion pairs as well as the varieties of the activated intermediate in the transition state.

The same phenomenon can be expected to occur in the rearrangement of LA in the medium of HOAc, because the former system has a dielectric constant and pk_a similar to those in the medium of propionic acid.

Based on the preceding results, the kinetic and mechanism of the rearrangement of LA in HOAc can be postulated to be as follows (Fig. 4):

$$v = k_1(C)^x(A)k_2(C)/(k_{-1}+k_2(C)+k_E)$$

k_{-1} or k_E = very small $\ll k_2(C)$.

$$v = k_1(C)^x(A).$$

(4) Rearrangement of LA in the Medium of HOAc Containing Sulfuric Acid, The rearrangement was found to follow the first-order rate law with respect to the concentration of LA. It corresponds to a typical acid-catalyzed A1 reaction, because it shows such a linearity as gives a slope of 1.0 based on the correlation of log k_1 against H_0.[8-10] The following products were obtained: racemized linalool ($[\alpha]_D^{25}$ = 0°), *d*-α-teripneol ($[\alpha]_D^{25}$ = +12.9°), acetates of linalyl, terpinyl, neryl and geranyl, myrcene, limonene, ocimene, and terpinolene (Tables 7, 8, and Fig. 5). The amount of cyclized products, such as terpinyl acetates, terpineol, limonene, and terpinolene, which are considered to be derived *via* a cyclized tertiary carbonium (terpinyl), exceeded that obtained in other solvents. The results agree with the fact that monoterpenoids are readily cyclized in a strong acid.[20,21] No primary terpene alcohols, such as geraniol or nerol, could be found. This proves that the behavior of carbonium ions in a strong acid undoubtedly differs from that in a weak acid, and that a tertiary carbonium ion in a strong acid medium is more stable and reactive than in a weak one.

Lately, Winstein *et al.*[22] reported that the solvolysis of optically-active linalyl *p*-nitrobenzoate in 70% aqueous acetone at 50, 75, and 100 °C was accompanied by a S_N2' reaction to geranyl *p*-nitrobenzoate, neryl *p*-nitrobenzoate, and *d*-α-terpinyl *p*-nitrobenzoate (50—90% optical active, temperature-dependent) as well as terpene hydrocarbons (myrcene, limonene, γ-terpinene, and terpinolene), and that the linalool formed during the solvolysis of the optical active ester was *ca.* 20% active.

However, it might have been expected that the S_N1-type rearrangement of linalyl esters would have been favored over S_N2' reaction because of ability of the intermediates, the carbonium ions, to dissociate favorably in acidic media.

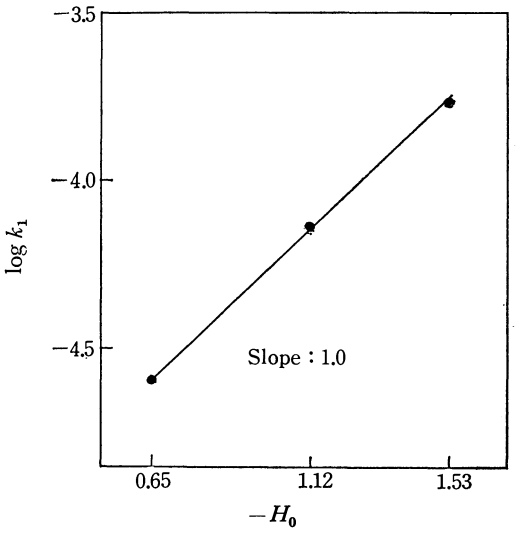

Fig. 5. Effect of the acidity function on the rearrangement rate constant of LA in the medium of HOAc containing sulfuric acid.

Table 8. Rate constants k_1 (1/s) of rearrangement of LA in the medium of HOAc containing sulfuric acid

HOAc-H_2SO_4	H_0	Reaction temperature, 0 °C k_1 (1/s)
90% HOAc-0.8 mol H_2SO_4	−1.53	1.67×10^{-2}
90% HOAc-0.6 mol H_2SO_4	−1.12	7.35×10^{-3}
90% HOAc-0.4 mol H_2SO_4	−0.65	2.45×10^{-3}

The present authors produced racemized linalyl propionate ($[\alpha]_D^{25}=0°$), together with myrcene, ocimene, limonene, and terpinolene, in the rearrangement of LA in propionic acid, and racemized linalool ($[\alpha]_D^{25}=0°$) in that of LA in the medium of HOAc containing sulfuric acid. In addition to these facts, the aforementioned kinetic and product data for the allylic rearrangement of LA in the medium of acetic, propionic acid, or acetic acid containing dioxane or sulfuric acid indicate that intermediate carbonium ions occupy a pivotal position in the rearrangements.

The authors wish to express their gratitude to Mr. Shozo Hasegawa, the president of T. Hasegawa, Co., Ltd. for his permission to publish this paper. One of the authors (Kunio Kogami) would also like to thank Assistant Professor Kazutoshi Yamada, Chiba University, for his guidance in the computer calculation. The authors also wish to thank Professor Kunio Okamoto, Kyoto University, for his valuable suggestions and comments.

Comparison of the Catalytic Activities of Metal Oxides for Hydrogen-Deuterium Equilibration and Ortho-Parahydrogen Conversion

Kiyoshi Otsuka and Tominaga Kei

Department of Chemical Engineering, Tokyo Institute of Technology, Ookayama Meguroku, Tokyo 152

(Received April 5, 1972)

Synopsis. The corrected activities, rates divided by square of spin magnetic moment of a metal ion, in ortho-parahydrogen conversion on first series transition metal oxides at 77 K were shown to give a very similar activity pattern to that obtained in hydrogen-deuterium equilibration.

In order to find the relation between catalytic activity and the character of the catalysts, considerable work has been done to examine the activities of the first series transition metal oxides in reactions such as hydrogen-deuterium equilibration,[1] dehydrogenation and disproportionation of cyclohexene,[2] dehydrogenation of propane,[3] hydrogenation of ethylene,[4] isotopic mixing in ethylene[5] and dehydrogenation of cyclohexane.[6] It is noteworthy that a similar activity pattern was obtained in the above reactions.

Systematic studies have not yet been carried out on the activities in ortho-parahydrogen conversion, one of the simplest of catalytic reactions. We thought it of interest to see if an activity pattern similar to that in the above reactions also holds in this conversion. In the present work, we show the activity sequences of the first series transition metal oxides in ortho-parahydrogen conversion at 77 K, and in hydrogen-deuterium equilibration at 178 K.[7]

Experimental

Preparation of Oxides. V_2O_5 was prepared by the decomposition of NH_4VO_3 at 773 K in an oxygen flow. V_2O_3 was obtained by the reduction of V_2O_5 with hydrogen at 873 K. Cr_2O_3, Mn_2O_3, Fe_2O_3, Co_3O_4, NiO, CuO, ZnO, and CdO were prepared by the calcination of the respective hydroxide at 773 K for 5 hr in air. The hydroxide was precipitated with ammonia from the aqueous solution of the corresponding nitrate. Mn_3O_4 was prepared similarly and calcined at 1223 K. FeO was prepared by the reduction of Fe_2O_3 at 1473 K with an equimolar mixture of hydrogen and carbon dioxide. CoO was prepared by the decomposition of Co_3O_4 at 1073 K. SiO_2 and Al_2O_3 were prepared by the calcination of the corresponding hydroxide obtained by the hydrolysis of ethyl-ortho-silicate and that of alminum isopropoxide, respectively. MoO_3 was obtained by the oxidation of ammonium molybdate with the addition of concd. HNO_3. TiO_2 and CrO_3 were obtained from Wako Pure Chemical Industries, Ltd. The oxides, TiO_2 (anatase), V_2O_3, $Cr_2O_3(\alpha)$, Mn_2O_3, Mn_3O_4, $Fe_2O_3(\alpha)$, FeO, Co_3O_4, CoO, NiO, and CuO were confirmed to be well crystallized from X-ray diffraction patterns.

Materials. Hydrogen gas was purified by diffusion through a heated palladium thimble. Deuterium gas (D_2 99.3%, HD 0.7%, Takachiho Chemical Co.) was used without further purification.

Apparatus and Procedure. The reactor attached to the glass-made gas circulation system capable of achieving a vacuum to 10^{-6} Torr was used. The rates of the conversion and the equilibration were measured at temperatures 77—90 K and 77—300 K, respectively, under the total pressure of 100 Torr. Prior to individual runs, the catalyst in the reactor was outgassed at high temperature for more than 4 hr *in vacuo* below 5×10^{-5} Torr. The catalyst thus treated was cooled down to room temperature in herium gas, and the reaction vessel was immersed in a coolant to establish the required temperature for the reaction. The catalyst after being used once for the reaction was substituted by a fresh one before each run.

Results and Discussion

Both the conversion and the equilibration obeyed first order kinetics in the whole temperature range for all the oxides studied. The reaction rate, R_m, was calculated from the first order rate constant k_e to be

$$R_m = k_e N/S \quad \text{molecule}\cdot\text{s}^{-1}\cdot\text{cm}^{-2} \qquad (1)$$

where N is the number of molecules in the reaction system and S the surface area of the catalyst. The rates of conversion at 77 K over paramagnetic oxides and diamagnetic ones are shown in Tables 1 and 2, respectively. The former oxides have magnetic moment due to free spins in their metal ions, but the latter none. The rates of equilibration at 178 K are also shown in Table 3. In the temperature range 77—90 K, the conversion over paramagnetic oxides proceeds rapidly with a small apparent activation energy. However, the equilibration does not take place except over Co_3O_4 in this temperature range. The rates of the conversion over paramagnetic oxides are greater than those over diamagnetic oxides by a factor of $\sim10^3$. This shows that the low-temperature conversion proceeds *via* a paramagnetic mechanism.

Activity Order in the Equilibration and Conversion. The activity order in the equilibration at 178 K is seen from Table 3 to be

$$Co_3O_4 > CoO > NiO > Cr_2O_3 \gg ZnO > V_2O_3,\ Mn_2O_3,\ Mn_3O_4,\ Fe_2O_3,\ FeO,\ CuO.$$

A similar activity sequence was presented in the same reaction[1] and many other different types of reaction.[2-6]

The activity order of the paramagnetic oxides for the conversion at 77 K is seen from Table 1 to be

$$Co_3O_4 > Cr_2O_3 \simeq Mn_3O_4 > CoO > NiO > Fe_2O_3 > V_2O_3 > FeO > Mn_2O_3 > CuO.$$

Table 1. Rates of conversion over paramagnetic oxides

Oxides	Outgassing Temp. (K)	Surface area (m^2/g)	Activation energy at 77—90 K (kcal/mol)	$R_m \times 10^{-14}$ (molecule·$s^{-1}\cdot cm^{-2}$) 77K, 100 Torr

ZnO	5.9	0.03

As in the usual paramagnetic mechanism, the conversion proceeds by the interaction of adsorbed hydrogen molecules with the inhomogeneous magnetic field of a metal ion on the surface. The rate of the conversion can be given by

$$R_m = k \cdot f_a \cdot f_m \cdot n_a \qquad (2)$$

where f_a is a measure of the interaction strength of a catalyst with hydrogen molecule, f_m a measure of the strength of the magnetic field of a metal ion on an oxide, n_a the number of active sites per surface area of an oxide and k the transition probability of hydrogen from para- to ortho-hydrogen or *vice versa*, which is constant over various oxides. It was shown that the probability of the transition depends on the square of the spin magnetic moment of an ion or molecule.[8] The rate of the low temperature conversion on the rare earth metal oxides was confirmed to increase in proportion to the square of the spin magnetic moment of a metal ion in the corresponding metal oxides.[9] Thus, we assume here that f_m can be substituted by μ_M^2 in Eq. (2).[10] The corrected rates of the conversion, *i.e.*, R_m divided by the square of the spin magnetic moment of a metal ion in the corresponding metal oxide, are shown in Fig. 1. The rates of the conversion thus eliminated by the magnetic field contribution give a very similar activity pattern to that obtained in the equilibration.

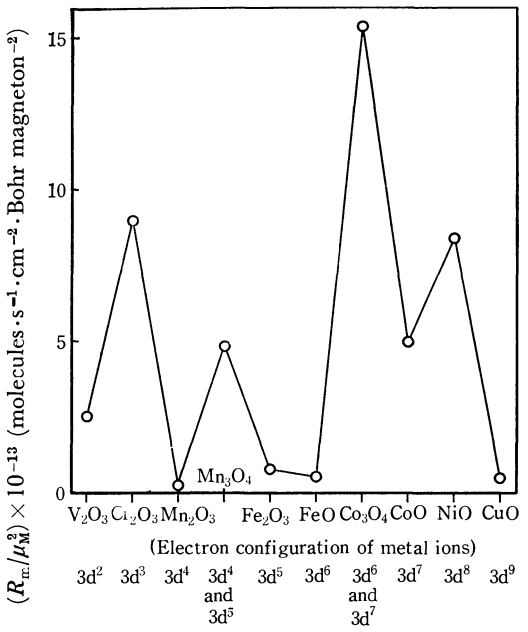

Fig. 1. Comparison of R_m/μ_M^2 for the paramagnetic oxides of the first series transition metal elements.

The Decomposition of Nitrous Oxide in the Radiolysis of *n*-Hexane Solutions

Yoshihiko HATANO[1] and José-Luis ABBOUD[2]

Laboratory of Physical Chemistry, Tokyo Institute of Technology, Meguro-ku, Tokyo 152

(Received May 25, 1973)

Synopsis. The effect of the addition of N_2O (10^{-2}—10^{-4} mole fraction) in the radiolysis of liquid *n*-hexane has been examined. The oxygen-containing products such as water and alcohols have been detected. The number of nitrogen molecules produced per an electron scavenged by N_2O exceeds unity even at the lowest concentration.

Nitrous oxide has been widely used as an electron scavenger in radiation chemistry. The mechanism of its decomposition when dissolved in saturated hydrocarbons, however, is not yet fully understood.[3,4]

In this work, the γ-radiolysis of liquid *n*-hexane containing N_2O has been carried out in order to establish the quantitative relationship between the nitrogen yield and the decrease in the hydrogen yield as well as the stoichiometry[4] of the decomposition of N_2O.

Experimental

The *n*-hexane was a Phillips research-grade material. The gas-chromatographic analysis using a dimethylsulfolane column operated at 30 °C showed the main impurities to be methylcyclopentane and 3-methylpentane for a total amount of 0.015%. No unsaturates were detected. The nitrous oxide (>99%), supplied by the Takachiho Shoji Co., was degassed and stored under a vacuum through a −120 °C cold trap.

A given amount (2 or 10 ml) of *n*-hexane was transferred into a tube containing a liquid potassium–sodium alloy freshly distilled *in vacuo*. The tube, fitted with a break-off tip, was stored for one week with frequent shaking. The dried sample was then transferred *in vacuo* into a irradiation cell previously baked and sparkled under a vacuum. The irradiation cells were glass tubes 10 mm in o.d., 7 mm i.d., and 15 mm in o.d., and 12 mm in i.d., with break-off tips. The dead space over the solutions was, at the most, 10% of the total volume.

The samples were irradiated in a ^{60}Co facility at a dose rate of 5.50×10^{19} eV g^{-1} h^{-1}.

After the irradiation, non-condensable gases at the temperature of liquid nitrogen were collected and measured by means of a Toepler pump-gas buret device. The hydrogen was removed by pumping the gaseous mixture into a copper oxide furnace at 250—270 °C. The relative amounts of nitrogen and methane were determined by means of a Hitachi RMU-5 mass spectrometer. The total yield of water and alcohols was determined by the sodium-potassium method.[4,5] The alcohols were identified gas-chromatographically.

Results and Discussion

The sodium-potassium treatment not only dehydrates the *n*-hexane but also eliminates micromolar amounts of CO_2 and O_2, initially dissolved in the *n*-hexane, which may act as electron scavengers.

The radiolysis of pure *n*-hexane at different total doses was undertaken. The dose dependence of the hydrogen yield from pure *n*-hexane closely resembles that reported previously,[6] but the extrapolated initial *G*-value, 5.79 ± 0.05, is the highest ever reported for *n*-hexane and compares well with the recent data on cyclopentane[7] and cyclohexane.[4] This large *G*-value may be due to the removal of the scavengers initially dissolved in *n*-hexane.

b) Not measured.

The experimental results on *n*-hexane–N_2O systems are collected in Table 1 as a function of the N_2O mole fraction, N_{N_2O}. The oxygen-containing-products detected here are water and small amounts of 2-hexanol and 3-hexanol. The total *G*-value of alcohols is small, 0.1 at $N_{N_2O}=2\times10^{-3}$. The relative amount of 3-hexanol is *ca.* 50% higher than that of 2-hexanol. The formation of water in this system has already been reported.[8] Alcohols have not yet been detected. As is shown in Table 1, the total yield of the oxygen-containing-products denoted ROH is in good agreement with that of N_2, within the limits of experimental error. This finding shows that the decomposition of N_2O in liquid *n*-hexane finally leads to N_2 and ROH in the ratio of one-to-one. The following possible schemes of ROH formation through ionic processes may be deduced:

$$n\text{-}C_6H_{14} \longrightarrow C_6H_{14}^+ + e^- \quad (1)$$

$$e^- + N_2O \longrightarrow N_2O^- \quad (2)$$

$$N_2O^- + C_6H_{14}^+ \longrightarrow N_2 + OH + C_6H_{13} \quad (3a)$$

$$\searrow\ N_2 + H_2O + C_6H_{12} \quad (3b)$$

$$N_2O^- + n\text{-}C_6H_{14} \longrightarrow N_2 + OH^- + C_6H_{13} \quad (4)$$

$$OH + n\text{-}C_6H_{14} \longrightarrow H_2O + C_6H_{13} \quad (5)$$

$$OH^- + C_6H_{14}^+ \longrightarrow H_2O + C_6H_{13} \quad (6)$$

$$OH + C_6H_{13} \longrightarrow C_6H_{13}OH \quad (7a)$$
$$\searrow C_6H_{12} + H_2O \quad (7b)$$

Since the selective C–H bond scission in both the 2 and 3 positions of *n*-hexane has already been described,[9] the alcohols detected here may be produced *via* Reaction (7a). The above scheme may at least explain the yields of N_2 and ROH arising from the electron scavenging, but not their yields in excess of the expected yield of the electron. The excess yields of N_2 and ROH may be interpreted effectively as:

$$N_2O + X \xrightarrow{n\text{-}C_6H_{14}} N_2 + ROH \quad (8)$$

where X may be intermediates other than N_2O^- or an electron which is captured by N_2O, as is shown in Reaction (2). The intermediate, X, is not determined here, but it must finally lead to the formation of N_2 and ROH again in the ratio of one-to-one. To compare the relative importance of Reactions (2) and (8) as a function of N_{N_2O}, the following attempt has been made.

Let $G(H_2)_0$ be the hydrogen yield in the absence of N_2O corrected for the ionic part of the dose effect on the hydrogen yield.[10] The quantity $\Delta G(H_2)=G(H_2)_0-G(H_2)$ is a measure of the decrease in the hydrogen yield resulting from the interruption of the ion-electron recombination processes by N_2O according to the following reactions:

$$e^- + C_6H_{14}^+ \longrightarrow f'H_2$$
$$e^- + N_2O \longrightarrow N_2O^-$$
$$N_2O^- + C_6H_{14}^+ \longrightarrow f''H_2$$

in which f' and f'' are the efficiencies of hydrogen formation. According to Schuler *et al.*,[11] the efficiency $f'-f''$ for hydrogen formation from *n*-hexane is 0.9. The ratio $\gamma=0.9G(N_2)/\Delta G(H_2)$ is approximately the yield of N_2 formed per electron scavenged. If only the above processes (1)—(7b) were to be taken into account, we should expect the value $\gamma\sim1$. As is shown in Fig. 1, though, the value of γ systematically exceeds 1. This can not be explained solely by Processes (1)—(7b), although this conclusion seems to be less rigorous at very low concentrations because of the large experimental errors. A satisfactory explanation of the excess nitrogen, that is, an intermediate X in Reaction (8), seems to be required.

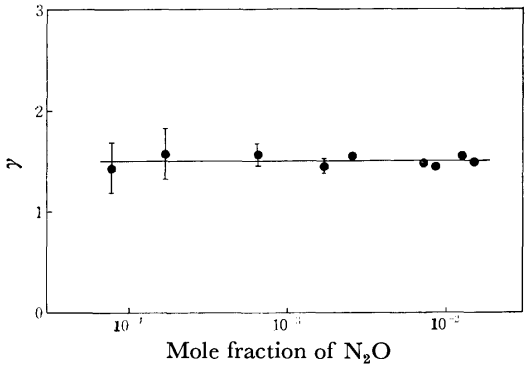

Fig. 1. The ratio γ as a function of the mole fraction of nitrous oxide.

Nitrous oxide appears to be inert towards thermal hydrogen atoms and alkyl radicals. The possibility of a reaction between hydroxyl radical and N_2O is also unlikely.[4] The decomposition of N_2O *via* energy transfer from an excited *n*-hexane molecule does not seem a significant process at least at the lower solute concentrations used here. The same reasoning can be appplied to the proposed[3] secondary reaction between N_2O and its negative ion. If such a reaction had to take place even at the lower concentrations as a significant competing process with Reaction (4), its rate constant would have to be exceedingly high. Among other possibilities deserving further study, the reactions with slow electrons not captured by N_2O or with positive ions may be the most promissing.

Photochemical Reaction of Halo-1,3,5-triazines: Photo-triazinylation

Hideo YAMADA, Haruo SHIZUKA, Shizen SEKIGUCHI, and Kohji MATSUI

Department of Chemistry, Gunma University, Kiryu, Gunma 376

(Received July 12, 1973)

Synopsis. Chloro-*s*-triazines or bromo-*s*-triazines containing halogen and/or methoxy substituents in the *s*-triazine nucleus gave the corresponding phenyl-*s*-triazines upon irradiation at 2537 Å in benzene.

It is known that some aryloxy-*s*-triazines rearrange photochemically to give *ortho* or/and *para* hydroxyaryl-*s*-triazines (photo-Fries rearrangement),[1] while aryloxy-*s*-triazines containing an *ortho* amino group give *ortho*-hydroxyarylamino-*s*-triazines on irradiation (photo-Smiles rearrangement);[2] these photochemical reactions are known to occur from the lowest excited singlet states of the corresponding molecules.

Recently, the photochemical reactions of haloarenes have been studied extensively; the photochemical primary processes in halobenzenes involve the fission of the C–Hal bond to give the phenyl radical and the halogen atom.[3] The photolysis of chlorobenzene in the gas phase orginates from the excited singlet state.[4] The photoarylations of aromatic compounds with haloarenes, such as halobenzenes[5-7] and *p*-halophenols,[8,9] proceed *via* a radical process. As for haloheteroaromatics, such as 2-iodothiazole,[10,11] 3-iodothiophen,[12] 3-iodobenzo[*b*]-thiophen,[13] and 3-iodopyridine,[14] similar photochemical reactions take place. However, no photochemical study of halo-*s*-triazine has yet been reported.

In the case of the *s*-triazine derivative, the photo-*s*-triazinylation of aromatic compounds with the halo-*s*-triazines was of interest from two points of view: the influence of the presence of three ring nitrogen atoms and the substituent effect upon the reaction. In addition, the photo-*s*-triazinylation of aromatic compounds with chloro-*s*-triazines will provide a useful and convenient method for the synthesis of aryl-*s*-triazines, since chloro-*s*-triazines containing various substituents in the *s*-triazine nucleus can readily be obtained from cyanuric chloride. This paper will report on the photo-*s*-triazinylation of benzene with halo-*s*-triazines.

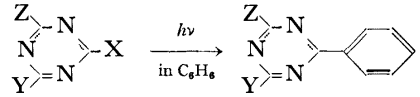
Experimental

A low-pressure mercury lamp was used as the 2537 Å radiation source. Table 1 lists the halo-*s*-triazines employed as the starting materials (No. 1—6).

After a long irradiation of benzene solutions of halo-*s*-triazines at 2537 Å, the reaction mixtures were evaporated, after which the photoproducts were separated and purified by column or thin-layer chromatography. The photoproducts were identified by means of elemental analyses, by a study of the IR, UV, and NMR spectra, and by a mixed-melting-point test with an authentic sample in some cases.

Results

In every case, the main product was found to be a phenylated *s*-triazine derivative, showing that the photoarylation of aromatic compound can be carried out using halo-*s*-triazine; Table 1 lists the photoproducts thus obtained (No. 6—9). The photoreaction of halo-*s*-triazines in benzene can be represented by the following general formula:



X=-Cl, -Br, Y, Z=-Cl, -Br, $-OCH_3$

Thus, chloro- and bromo-*s*-triazines containing one, two, and three halogen atoms, and halo-*s*-triazines containing methoxyl groups in the *s*-triazine nucleus reacted photochemically with benzene to give the corresponding phenyl-*s*-triazines. However, when a phenyl group or an amino group, such as the *N*-methylanilino- or dimethylamino group, is present in the *s*-triazine nucleus, it was found to be very difficult for the photoreaction of halo-*s*-triazine to take place; therefore, derivatives containing more than two phenyl groups could not be obtained by the photoreaction of dihalo- or trihalo-*s*-triazines with benzene.

Generally, the progresses of these photoreactions were slow compared with those of photo-Fries rearrangements of aryloxy-*s*-triazines or photo-Smiles rearrangements of *O*-*s*-triazinyl-2-aminophenols; for example, the quantum yield for the product formation in the reaction of 2-chloro-4,6-dimethoxy-*s*-triazine with benzene was found to be 0.03 at the concentration of 3×10^{-3} M in benzene. In addition to the photoproducts mentioned above, the formation of hydrogen halide was observed, for example, in the photo-phenyldechlorination of chloro-dimethoxy-*s*-triazine, and the chemical yields of phenylated products in the photoreactions of 2-bromo-4,6-dimethoxy-*s*-triazine, 2-chloro-4,6-dimethoxy-*s*-triazine, 2,4-dichloro-6-methoxy-*s*-triazine, and cyanuric chloride were 21, 22, 20, and 19% respectively, at the concentration of 2×10^{-2} M in benzene at 2537 Å for 24 hr.

The reactive state in the reaction may originate from the excited singlet state of halo-*s*-triazine, judging from the following reasons:

(1) The incident light at 2537 Å is absorbed by benzene (>99%), not by halo-*s*-triazine, under the experimental conditions described above. Therefore, the excited halo-*s*-triazine should be formed by the energy transfer from the excited benzene. The singlet-singlet energy transfer from the excited benzene to halo-*s*-triazine was confirmed by the measurements of the fluorescence quenching of benzene by halo-*s*-tri-

azine; the intensity of the fluorescence decreased considerably with an increase in the concentration of halo-*s*-triazine.

(2) Very little effect of dissolved oxygen on the product formation was observed. This fact supports the singlet mechanism in the reaction, although an extremely fast triplet reaction can not be excluded.

When a solution of 2-bromo-4,6-dimethoxy-*s*-triazine in cumene was irradiated, dicumyl was obtained as a photoproduct, while the formation of acetone was observed when it was irradiated in 2-propanol, suggesting that the photoreaction of halo-*s*-triazines proceeded *via* a radical process involving an α-bond dissociation (C–X) into the halogen atom and the *s*-triazinyl radical. The triazinyl radical produced by the dissociation of excited singlet halo-*s*-triazine may attack the benzene molecule to give the final product *via* the intermediate, M. Figure 1 shows the schematic reaction mechanism of the photo-triazinylation of benzene by halo-*s*-triazine at 2537 Å, where B and B* are the ground and the

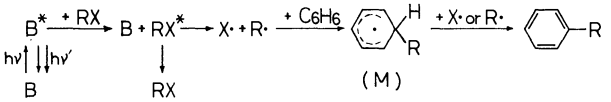

Fig. 1. Schematic reaction mechanism at 2537 Å.

lowest singlet excited states of benzene respectively, where RX and RX* denote the ground and the excited ($^1\pi\pi^*$) singlet states of halo-*s*-triazine respectively, and where X· and R· indicate the ground states of the halogen atom and the *s*-triazinyl radical respectively.

The susbtituent effects on the reaction may suggest that the electronic structures in the excited states of halo-*s*-triazines (the $n\pi^*$ and $\pi\pi^*$ energy levels and the character of the lowest excited state) play an important role in the dissociation of the C–X bond Similar substituent effects were also observed in the case of the photo-Fries rearrangement of *s*-triazine derivatives.[15]

The Photo-Fries Rearrangement of Bis(methoxymethoxy)-phenyl Cinnamates

Jun-ichi ONODERA and Heitaro OBARA

Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa 992

(Received August 1, 1973)

Synopsis. The irradiation of bis(methoxymethoxy)-phenyl cinnamates in benzene solution gave 2'-hydroxy-bis-(methoxymethoxy)chalcones in 5.4—7.6% yields and 2',3',4'-, 2',3',5'-, and 2',4',6'-trihydroxychalcone were obtained by the hydrolysis of the resulting chalcones.

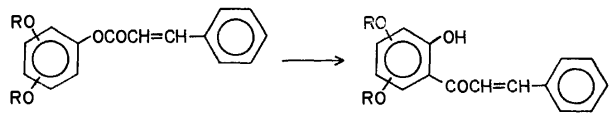
In previous papers,[1,2] we have reported the formation of hydroxychalcones by the photo-Fries rearrangement of phenyl cinnamate and hydroxyphenyl cinnamate. Further, we have attempted the photo-irradiation of 2,3- and 3,5-dihydroxyphenyl cinnamate (I and III); however, the isolation of the corresponding trihydroxy-chalcones (X and XII) was very difficult.[3]

In this note we wish to report the photo-Fries rearrangement of dihydroxyphenyl cinnamates protected their hydroxyl groups with methoxymethyl groups.

2,3-,[3] 2,4-, and 3,5-[3] Dihydroxyphenyl cinnamate (I, II, and III) were isolated from the reaction mixture obtained by the acylation of pyrogallol, 1,2,4-trihydroxybenzene, and phloroglucinol with cinnamoyl chloride in pyridine.

The structure of II was confirmed by a comparison of the melting points of the 2,4-dimethoxyphenol obtained by the hydrolysis of the dimethylether of II and its benzoate with those of authentic samples.[4,5]

2,3-, 2,4-, and 3,5-Bis(methoxymethoxy)phenyl cinnamate (IV, V, and VI) were obtained from the corresponding dihydroxyphenyl cinnamate by treatment with sodium amide, followed by that of chloromethyl ether in a tetrahydrofuran–benzene solution; these bis(methoxymethoxy)phenyl cinnamates were then purified by means of silica gel column chromatography.



I, IV (2,3-) VII, X (3',4'-)
II, V (2,4-) VIII, XI (3',5'-)
III, VI (3,5-) IX, XII (4',6'-)

I ~ III X ~ XII : R=H IV ~ IX : R=CH_3OCH_2

The irradiation was carried out in a benzene solution under a nitrogen atmosphere and at room temperature using a high-pressure 100 W mercury arc. After irradiation, the benzene was evaporated *in vacuo*, and the residue was chromatographed on a column of silica gel. By the irradiation of IV and VI, 2'-hydroxy-3',4'- and 2'-hydroxy-4',6'-bis(methoxymethoxy)chalcones (VII and IX) were obtained, in 7.6 and 6.0% yields; they were converted into 2',3',4'- and 2',4',6'-trihydroxy-chalcones respectively (X and XII) by heating with methanolic hydrochloric acid. The structures of X and XII were identified by comparing their melting points and IR spectra with those of authentic samples.[6,7]

Similarly, 2'-hydroxy-3',5'-bis(methoxymethoxy)-chalcone (VIII) was obtained in a 6% yield by the irradiation of V; it was then converted into 2',3',5'-trihydroxychalcone (XI) (mp 174—175 °C). The structure of this new chalcone was identified by the elemental analysis and by a study of its UV and IR spectra.

From these results, it may be thought that the protection of the hydroxyl groups of dihydroxyphenyl cinnamate with methoxymethyl group can be used in obtaining trihydroxychalcones by photo-Fries rearrangement.

Experimental

All the melting points are uncorrected.

The 2,3-dihydroxyphenyl cinnamate (I, mp 172—174 °C) and the 3,5-dihydroxyphenyl cinnamate (III, mp 188—189 °C) were prepared according to the method of a previous report.[3]

2,4-Dihydroxyphenyl Cinnamate (II). To a stirred solution of 2.2 g of 1,2,4-trihydroxybenzene in 20 ml of pyridine, there was slowly added 5.2 g of cinnamoyl chloride at 8—12 °C; then the mixture was stirred at 45 °C over a period of about 1 hr. The reaction mixture was then poured into 150 ml of cold 3 M hydrochloric acid and extracted with ethyl acetate; the ethyl acetate layer was washed with water. The ethyl acetate solution was evaporated *in vacuo*, and the residue was chromatographed with benzene–ether (2:1) on a column of silica gel.

From the last elution, II was obtained as light yellow crystals. Yield, 1.2 g (26%); mp 144—145 °C (from benzene). IR (KBr): 3430, 3240 (ν OH) and 1700 cm^{-1} (ν CO). UV: λ_{max}^{EtOH} 283 mμ(log ε=4.44). Found: C, 70.42; H, 4.94%. Calcd for $C_{15}H_{12}O_4$: C, 70.30; H, 4.72%. Dimethyl ether, mp 104—105 °C (colorless prisms from ethanol). NMR ($CDCl_3$): δ 3.80 (-OMe), 6.61, 7.84 (-CH=CH-, J=16.0 Hz). Found: C, 71.66; H, 5.75%. Calcd for $C_{17}H_{16}O_4$: C, 71.82; H, 5.67%.

The hydrolysis of this dimethylether with an aqueous sodium hydroxide solution gave 2,4-dimethoxyphenol (mp 25—27 °C) (lit, mp 28 °C,[4] benzoate, mp 88—89 °C (lit, mp 89 °C[5])).

2,3-Bis(methoxymethoxy)phenyl Cinnamate (IV). To a solution of 1.0 g of I in 10 ml of dry tetrahydrofuran and 30 ml of dry benzene, there was added 2.0 g of sodium amide; after the mixture had then been stirred for 30 min, 3.2 g of monochloromethyl ether was added to the reaction mixture, drop by drop, over a period of about 30 min at room temperature. The reaction mixture was then poured into a cold, dilute, aqueous sodium carbonate solution and extracted with ether. The ether layer was washed with water and dried over anhydrous sodium sulfate. The ether was evapolated

in vacuo, and the resulting crude oil was chromatographed on a column of silica gel. 2,3-Bis(methoxymethoxy)phenyl cinnamate (IV) was obtained as colorless crystals from the second elution with benzene–ether (20: 1). Yield, 0.50 g (37%); mp 75—77 °C (from petroleum ether). IR (KBr): 1730 cm^{-1} (ν CO). NMR ($CDCl_3$): δ 3.49, 3.52 (-OMe), 5.18, 5.12 ($-CH_2-$), 6.67, 7.89 (-CH=CH-, J=16.0 Hz).

3,5-Bis(methoxymethoxy)phenyl Cinnamate (VI). This compound was prepared from III by the method described above. The crude VI was purified by silica-gel-column chromatography with benzene–ethyl acetate (5: 1). Yield, 35%; pale yellow oil. IR ($CHCl_3$): 1725 cm^{-1} (ν CO). NMR ($CDCl_3$): δ 3.44 (-OMe), 5.11 ($-CH_2-$), 6.56, 7.80 (-CH=CH-, J=16.0 Hz).

2,4-Bis(methoxymethoxy)phenyl Cinnamate (V). This compound was prepared from II by the method described above. The crude V was purified by silica-gel-column chromatography with benzene–ethyl acetate (20: 1). Yield, 31%; pale yellow oil. IR (neat): 1730 cm^{-1} (ν CO). NMR ($CDCl_3$): δ 3.44 (-OMe), 5.12 ($-CH_2-$), 7.81, 6.56 (-CH=CH-, J=16.0 Hz).

Irradiation of 2,3-Bis(methoxymethoxy)phenyl Cinnamate (IV). A solution of 500 mg of IV in 300 ml of dry benzene was irradiated under a nitrogen atmosphere at room temperature by means of a high-pressure 100 W mercury arc for 20 hr. After irradiation, the benzene was evapolated *in vacuo*, and the resulting crude mixture was chromatographed on a column of silica gel. 2′-Hydroxy-3′,4′-bis(methoxymethoxy)-chalcone (VII) was obtained as yellow needles from the second elution with petroleum ether–ether (2: 1). Yield, 38 mg (7.6%); mp 95—96 °C (from ligroin). Found: C, 66.26; H, 5.64%. Calcd for $C_{19}H_{20}O_6$: C, 66.27; H, 5.85%. UV: λ_{max}^{EtOH} 336 mμ(log ε=4.47). NMR ($CDCl_3$): δ 3.15, 3.66 (-OMe), 5.22, 5.29 ($-CH_2-$), 7.52, 7.89 (-CH=CH-, J= 16.0 Hz), 13.24 (-OH). A solution of 40 mg of VII in 1.5 ml of methanol containing 0.3 ml of 6 M hydrochloric acid was refluxed for 5 min. After cooling, 2′,3′,4′-trihydroxychalcone (X) was obtained as yellow needles. Yield, 20 mg (67%); mp 164—165 °C (lit, mp 166 °C[6]). The structure of this trihydroxychalcone was identified by comparison with that of an authentic sample.[6]

Irradiation of 3′,5′-Bis(methoxymethoxy)phenyl Cinnamate (VI). A solution of 600 mg of VI in 400 ml of dry benzene was irradiated for 20 hr as has been described above. Subsequent elution with petroleum ether–ether (2: 1) gave 2′-hydroxy-4′,6′-bis(methoxymethoxy)chalcone (IX) as yellow prisms. Yield, 36 mg (6.0%); mp 89—92 °C (from ligroin). Found: C, 66.32; H, 6.01%. Calcd for $C_{19}H_{20}O_6$: C, 66.27; H, 5.85%. NMR ($CDCl_3$): δ 3.49, 3.53 (-OMe), 5.18, 5.29 ($-CH_2-$), 7.76, 7.90 (-CH=CH-, J=16.0 Hz), 13.74 (-OH). The hydrolysis of IX gave 2′,4′,6′-trihydroxychalcone (XII) as yellow needles; mp 176—178 °C (from benzene). The structure of XII was identified by a comparison of its IR spectrum with that of an authentic sample.[7]

Irradiation of 2,4-Bis(methoxymethoxy)phenyl Cinnamate (V). A solution of 820 mg of V in 400 ml of dry benzene was irradiated for 42 hr as has been described above. 2′-Hydroxy-3′,5′-bis(methoxymethoxy)chalcone (VIII) was obtained as orange red crystals from the third elution with benzene–ethyl acetate (20: 1). Yield, 44 mg (5.4%); mp 122—124 °C (from ligroin). Found: C, 66.13; H, 5.98%. Calcd for $C_{19}H_{20}O_6$: C, 66.27; H, 5.85%. UV: λ_{max}^{EtOH} 328 mμ(log ε= 4.40). NMR ($CDCl_3$): δ 3.50, 3.53 (-OMe), 5.12, 5.22 ($-CH_2-$), 7.52, 7.89 (-CH=CH-, J=16.0 Hz), 13.78 (-OH).

2′,3′,5′-Trihydroxychalcone (XI). To a solution of 20 mg of VIII in 0.5 ml of methanol, there was added 0.1 ml of 6 M hydrochloric acid, after which the mixture was boiled for 5—6 min. After cooling, 2 ml of a saturated aqueous sodium chloride solution was added to the mixture, and then the mixture was extracted with ether. The ether layer was dried over anhydrous sodium sulfate, and the ether was evaporated *in vacuo*. The resulting residue was crystalized by the addition of petroleum ether to give 2′,3′,5′-trihydroxychalcone (XI). Yield, 10 mg (65%); mp 174—176 °C (from benzene). Found: C, 70.00; H, 4.68%. Calcd for $C_{15}H_{12}O_4$: C, 70.30; H, 4.72%. UV: λ_{max}^{EtOH} 330 and 440 mμ(log ε= 4.44 and 3.43).

The authors wish to thank Messrs. Hiromichi Hirano, Norio Tanaka, Yasuo Sugawara, and Yutaka Kikuchi for their technical assistances.

Estimation of Chlorine Content in Single Crystals of Chromium Chalcogenide Spinels by Atomic Absorption Spectrophotometry

Kohei AMETANI

RCA Research Laboratories, Inc., Zushi-machi, Machida-shi, Tokyo 194-02

(Received September 13, 1973)

Synopsis. Analyses using the silver atomic absorption indicated that all the crystals grown by the vapor transport method were contaminated with chlorine. Particularly in crystals containing copper, a large amount of chlorine was incorporated. In crystals with an intended composition $CuCr_2S_3Cl$, the chlorine content was much higher than the expected amount.

Single crystals of chromium chalcogenide spinels such as $CuCr_2S_3Cl$, $CdCr_2S_4$, and $CdCr_2Se_4$, are usually grown by the chemical vapor transport method, using chlorine gas as a transport agent.[1] It is known that the chlorine is incorporated as either a major or minor component in the grown crystals[1,2] and affects the magnetic and electrical properties.[1,3,4] The chlorine content as the major component is commonly determined by Vegard's law comparing the lattice constant of single crystals with that of polycrystals having a known composition.[3] Sleight and Jarrett[4] used a chemical analysis to determine the chlorine content of $CuCr_2S_{4-x}Cl_x(0\leq x\leq 1)$, where the maximum chlorine expected is 11.85 wt%. However, they did not discuss their method of analysis. Similarly, for a chlorine content of less than 0.02 wt% in $CdCr_2Se_4$ crystals, Harbeke and Pinch[5] did not report the details of their chemical analysis. In both cases one must assume that a large number of samples are necessary for the chlorine analysis since the crystals are, at most, 3 mm on edge and weigh only several mg. In the present paper we describe an indirect method, using 10 mg samples, to estimate the chlorine content in some single crystals by atomic absorption spectrophotometry.

The sample is dissolved in nitric acid containing a known amount of silver ions and the chlorine is simultaneously precipitated as AgCl. After filtration, the chlorine content is determined either from the AgCl precipitate dissolved in the ammoniacal solution[6] or the excess silver ions in the filtrate.[7] For the measurement of silver atomic absorption and the precipitation of AgCl, the effects of the constituent elements in the materials are examined.

Experimental

Reagents. (1) Standard chlorine solution: Sodium chloride dried at 110 °C was accurately weighed and dissolved in deionized water. (2) Standard silver solution: Silver nitrate dried at 110 °C was accurately weighed and dissolved in a minimum amount of deionized water, and then diluted with concentrated nitric acid. (3) Other solutions: Metal nitrates and sodium sulfate were dissolved in deionized water and selenium metals were dissolved in nitric acid and then diluted with deionized water. Reagents used were of analytical reagent grade.

Measurement of Silver Atomic Absorption. The silver atomic absorption was measured at 328.1 nm in an acetylene-air flame using a Hitachi Model 208 atomic absorption spectrophotometer and a hollow cathode lamp HLA-3. For the measurement of silver concentrations up to 2 ppm, the nitric acid concentration was adjusted to 0.05 M, taking into account the stability of the dilute silver solution. For this condition, the silver atomic absorption was not affected by 2 ppm Cu^{2+}, Fe^{3+}, and In^{3+}, 3—400 ppm Cr^{3+}, 200—400 ppm Cd^{2+}, 12—1200 ppm SO_4^{2-} and 1000 ppm SeO_3^{2-}. For the measurement from the ammoniacal solution, it was necessary to use at least a 3% ammonia concentration, since the silver atomic absorption remained nearly constant above this concentration.

Precipitation of Silver Chloride. We successfully precipitated more than 10 μg of chlorine as AgCl using a standard chlorine solution. The nitric acid concentration was adjusted to about 1.5 M for this examination. The results suggested that 5 mg of silver was necessary to capture about 1 mg of chlorine and 1 or 0.5 mg of silver was suitable for less than 100 μg of chlorine. Several diverse ions did not interfere with the precipitation of AgCl. Table 1 shows the recovery of chlorine in the presence of diverse ions. The amount of

Table 1. Recovery of chlorine in the presence of diverse ions

Elements[a] added	Cl added	From precipitate		From filtrate	
		Cl found	error	Cl found	error
Cu 2.0 mg	0.500 mg	0.481 mg	−3.8%	0.503 mg	+0.6%
Cr 3.0	1.000	1.000	0	0.985	−1.5
S 3.5	1.500	1.488	−0.8	1.508	+0.5
Cd 3.0 mg	10 μg	9.5 μg	−5.0%	10.8 μg	+8.0%
Cr 3.0	25	24.1	−3.6	26.9	+7.6
	50	51.6	+3.2	51.8	+3.6
S 4.0	100	99.4	−0.6	103.8	+3.8

a) Cu, Cr, and Cd were added as nitrates, and S as sodium sulfate.

added elements was nearly equivalent to the sample weight of 10 mg. The values given on the same line in Table 1 for the precipitate and filtrate were obtained from the same starting solution. The results obtained from both the precipitate and the filtrate are in agreement each other. This indicates that the chlorine can be determined either from the AgCl precipitate dissolved in the ammoniacal solution or the excess silver ions in the filtrate. Considering the simplicity of the experimental procedure, the latter technique seems to be more practical than the former. However, for analyses of the actual samples, both techniques were usually used to attain a satisfactory result as described below.

Analysis of Single Crystals. Ten mg of the sample (usually 5—6 crystals) was dissolved in nitric acid containing excess silver ions of a known quantity and the chlorine was simultaneously precipitated as AgCl to prevent the escape of chlorine from the system during the dissolution.[8] For a sample containing about 1 mg of chlorine, 5 ml of nitric acid containing 1 mg Ag/ml was used, and the solution was then diluted to about 50 ml. However, if the expected chlorine content in the sample was less than 100 μg, 2 ml of nitric acid containing 0.5 or 0.25 mg Ag/ml was used and the solution was then diluted to about 20 ml. The solutions were aged for 30 min over a water bath. After the solution was cooled in ice water, the precipitated AgCl was filtered and washed with six 5 ml portions of cold nitric acid (1: 50), and dissolved in an aqueous ammonia solution. After the dilution of both the ammoniacal solution and the filtrate to an appropriate silver concentration, chlorine was usually determined indirectly from the silver content in both solutions. The results obtained were corrected by the blank test.

Table 2. Results of single crystal analysis

Sample Intended composition	Cl found, wt% From precipitate	From filtrate
$CuCr_2S_3Cl$ (1)	13.2	12.9
$CuCr_2S_3Cl$ (2)	13.8	13.6
$CuCr_2S_3Cl$ (3)	14.1	13.8
$Cu_{0.5}In_{0.5}Cr_2S_4$	2.39—3.56	—
$Fe_{1-x}Cu_xCr_2S_4$ (x=0.4—0.6)	4.52—8.32	—

a) Annealed in vacuum at 500—600 °C for 2—15 days.

The results of the analyses are given in Table 2. The chlorine content determined from both the precipitate and the filtrate are in good agreement each other. In the case of crystals with an intended composition $CuCr_2S_3Cl$, the chlorine content was much higher than the 11.85 wt% expected for the intended composition while Sleight and Jarrett obtained crystals containing a nearly stoichiometric amount of chlorine.[4] In a separate experiment, however, it was found that the sulfur content in our crystals was consistently lower than the stoichiometric amount.[9] Such deviations from the stoichiometric composition would strongly affect the magnetic and electric properties of the crystals.[9] For the other crystals, Table 2 also indicates that all the single crystals grown by the vapor transport method using chlorine gas as a transport agent, were always contaminated with chlorine. Particularly in crystals containing copper, a large amount of chlorine was incorporated.

The author thanks Professor Katsumi Yamamoto of Ibaraki University, Drs. Fumio Okamoto and Yasuo Wada of this laboratories for their helpful suggestions, and Messrs. Katsuhiro Kato and Takao Oka of this laboratories for providing the samples.

The Structure of the Pechmann Condensation Product of *p*-Orsellinic Acid with Ethyl Acetoacetate

Toshifumi HIRATA and Takayuki SUGA*

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received September 10, 1973)

Synopsis. The product obtained by the Pechmann condensation, followed by the decarboxylation, of *p*-orsellinic acid with ethyl acetoacetate has been established not to be such 4,5-dimethyl-7-hydroxycoumarin as previously reported, but to be 2,5-dimethyl-7-hydroxychromone.

In the course of the structural determination of aloenin,[1] a new bitter glucoside isolated from Aloe species, we carried out the Pechmann condensation of *p*-orsellinic acid (I) with ethyl acetoacetate, followed by the decarboxylation, with a view to obtaining 4,5-dimethyl-7-hydroxycoumarin (II) following the method in a literature.[2] However, all physico-chemical and chemical examinations indicated the product to be 2,5-dimethyl-7-hydroxychromone (III), but not the coumarin. We now wish to describe evidences leading to the chromone structure (III) for the product.

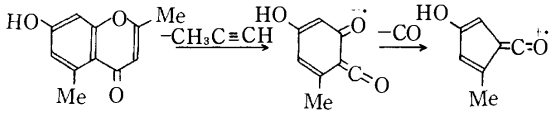
VII: $R_1=COOMe$, $R_2=Me$

VIII: $R_1=H$, $R_2=Ac$

Results and Discussion

We repeated the treatment of *p*-orsellinic acid (I) with ethyl acetoacetate in the presence of sulfuric acid, followed by the decarboxylation, in accordance with Sethna's report[2] and obtained an *O*-heterocyclic compound (III), $C_{11}H_{10}O_3$, whose properties are identical with those reported by Sethna and Shah. The compound exhibited the IR and UV spectra characteristic of a chromone;[3,4] ν_{max} (dioxane) 1663 cm^{-1} (C=O) and λ_{max} (EtOH) 291 nm (log ε 4.08), 250 (4.31), and 241 (4.22). The alkaline degradation of its monomethyl ether (IV) yielded 2-hydroxy-4-methoxy-6-methylacetophenone (V). As the formation of the acetophenone derivative by such a degradation is also characteristic of a chromone,[5] the heterocyclic compound (III) appeared to be 2,5-dimethyl-7-hydroxychromone.

The chromone structure was proved by the mass spectrum, which exhibited a base peak of the parent ion at *m/e* 190 and two significant peaks capable of demonstrating the chromone skeleton at *m/e* 150 and 122. As shown in Scheme 1, the occurrence of the *m/e* 150 peak is caused by the retro-Diels-Alder cleavage, which has not been observed for coumarin derivatives yet,[6,7] with loss of acetylene and retention of the charge on the fragment. The fragment of mass 122 is formed by the sequential loss of a CO molecule from the *m/e* 150 ion. These fragments were completely characterized by high-resolution mass spectrum measurements.



III, *m/e* 190 (M^+) *m/e* 150 *m/e* 122

Scheme 1.

The NMR spectrum of the monomethyl ether (IV) in a deuterochloroform solution showed signals of two methyl (at 2.25 and 2.77 ppm), one methoxy, two aromatic, and one ethylenic protons. The signal at 2.77 ppm was assigned to the C(5)-methyl group, because it is strongly deshielded by the adjacent carbonyl group.[8] This assignment was proved by the benzene-induced downfield shifts[9] ($\Delta\delta=-0.16$ ppm) observed only for the C(5)-methyl group. No such chemical shift and solvent effect in the NMR spectrum can be explained for 4,5-dimethyl-7-hydroxycoumarin (II) proposed previously by Sethna and Shah.[2] Thus, all evidences have established the condensation product (III) to be 2,5-dimethyl-7-hydroxychromone. Such a formation of the chromone is a unique example in the Pechmann condensation in the presence of sulfuric acid, although Simonis and Remmert[10] have described the formation of chromones in the presence of phosphorus pentoxide.

Experimental

The NMR spectra were recorded on a Hitachi Perkin-Elmer R-20 spectrometer. Mass spectral analyses were performed on a Hitachi RMU-7L high-resolution mass spectrometer and a Hitachi RMS-4 mass spectrometer, ionizing at the order of 70 eV.

The Condensation of p-*Orsellinic Acid (I) with Ethyl Acetoacetate.* Following the method in a literature,[2] *p*-orsellinic acid (I) (800 mg; mp 166—167 °C; prepared[11] from orcinol) was stirred with ethyl acetoacetate (640 mg) at 65—70 °C for 4 hr in the presence of sulfuric acid (8.4 ml) and the reaction mixture was poured into water to give a solid product, which then was ground up with a 5% sodium bicarbonate solution. The solution, on acidification, gave 2,5-dimethyl-7-hydroxychromone-8-carboxylic acid (VI) (342 mg): mp 222—225 °C (effervescence); IR (Nujol): 3500—2500 (OH and COOH), 1650 (C=O) and 1580 cm^{-1} (C=C); UV (EtOH): 304 nm (log ε 3.94), 282 (4.03), and 248 (4.41); MS: *m/e* (rel. intensity) 234 (M^+, 64), 216 (94), 190 (18), 188 (18), 160 (100), and 120 (28).

* To whom all inquiries regarding this paper should be addressed.

Found: C, 61.38; H, 4.51%. Calcd for $C_{12}H_{10}O_5$: C, 61.54; H, 4.30%.

The Dimethyl Derivative (VII). The treatment of the acid (VI) with diazomethane as usual gave the dimethyl derivative (VII): mp 147—148 °C; IR (Nujol): 1730 (COOMe), 1650 (C=O), and 1600 cm^{-1} (C=C); NMR ($CDCl_3$): δ 2.30 (s, C(2)-Me), 2.83 (s, C(5)-Me), 3.91 (s, COOMe), 3.94 (s, OMe), 6.01 (s, C(3)-H), and 6.69 ppm (s, C(6)-H); (C_6H_6) δ 1.52 (s, C(2)-Me), 2.97 (s, C(5)-Me), 3.18 (s, COOMe), 3.67 (s, OMe), 5.80 (s, C(3)-H), and 6.19 ppm (s, C(6)-H); MS: *m/e* (rel. intensity) 262 (M^+, 94), 230 (100), and 191 (51).

The Decarboxylation of the Acid (VI). The acid (VI) (100 mg) was maintained at 230 °C for 10 min, melting with the effervescence. The crystalline mass obtained after cooling was crystallized from ethanol to give the heterocyclic compound, 2,5-dimethyl-7-hydroxychromone (III) (48 mg): mp 245 °C (decomp.); IR (Dioxane): 1663 (C=O), 1615 and 1585 (C=C); UV (EtOH), described above; NMR (C_5H_5N): δ 2.06 (s, C(2)-Me) and 2.97 ppm (s, C(5)-Me); MS: *m/e* (rel. intensity) 190 (M^+, 100), 175 (3), 162 (33), 161 (43), 150 (18), and 122 (23); High-resolution MS: *m/e* 190.0636 (calcd for $C_{11}H_{10}O_3$: 190.0630), 162.0654 ($C_{10}H_{10}O_2$: 162.0680), 161.0594 ($C_{10}H_9O_2$: 161.0601), 150.0299 ($C_8H_6O_3$: 150.0316), and 122.0361 ($C_7H_6O_2$: 122.0366).

The Acetyl Derivative (VIII). Mp 117—118 °C; IR (Nujol): 1765, 1659, 1630, and 1615 cm^{-1}; ($CHCl_3$) 1769, 1654, and 1611 cm^{-1}; NMR ($CDCl_3$): δ 2.30 (s, C(2)-Me and OAc), 2.83 (s, C(5)-Me), 6.07 (s, C(3)-H), 6.83 (d, J=2.0 Hz, C(6)-H), and 7.06 ppm (d, J=2.0 Hz, C(8)-H).

The Monomethyl Ether (IV). The treatment of the chromone (III) with diazomethane gave the ether (IV): mp 116—117 °C (recrystallized from ethyl acetate); IR (KBr): 3050, 1655, 1628, 1610, and 1569 cm^{-1}; ($CHCl_3$) 1657, 1612, and 1570 cm^{-1}; NMR ($CDCl_3$): δ 2.25 (s, C(2)-Me), 2.77 (s, C(5)-Me), 3.81 (s, OMe), 5.95 (s, C(3)-H), 6.60 (s, C(6)- and C(8)-H); (C_6H_6) δ 1.64 (s, C(2)-Me), 2.93 (s, C(5)-Me), 3.24 (s, OMe), 5.84 (s, C(3)-H), 6.40 (d, J= 2.5 Hz, C(8)-H), and 6.51 ppm (d, J=2.5 Hz, C(6)-H); MS: *m/e* (rel. intensity) 204 (M^+, 100), 189 (2), 176 (9), 175 (10), 164 (7), and 161 (31).

The Alkaline Degradation of the Monomethyl Ether (IV). The monomethyl ether (IV) (36 mg) was refluxed in a mixture of 50% potassium hydroxide (4 ml) and ethanol (2 ml) for 2 hr in a current of nitrogen. The reaction mixture, after acidification, was extracted with ether and the ether extract was washed with a 5% sodium bicarbonate solution. Removal of the solvent afforded 2-hydroxy-4-methoxy-6-methylacetophenone (V) (25 mg): mp 78.0—78.5 °C (lit,[12] mp 79 °C); IR ($CHCl_3$): 1610 and 1585 cm^{-1}; UV (EtOH): 279 nm (log ε 4.13) and 231 (4.05); NMR ($CDCl_3$): δ 2.53 (s, C(6)-Me), 2.58 (s, $COCH_3$), 3.77 (s, OMe), 6.25 (s, aromatic 2H), and 13.48 ppm (s, phenolic OH); MS: *m/e* (rel. intensity) 180 (M^+, 28) and 165 (100); High-resolution MS: *m/e* 180.0779 (calcd for $C_{10}H_{12}O_3$: 180.0785) and 165.0532 ($C_9H_9O_3$: 165.0550).

Found: C, 66.53; H, 6.58%. Calcd for $C_{10}H_{12}O_3$: C, 66.65; H, 6.71%.

Double Tridentate Complex of Triquinoyl with Boric Acid

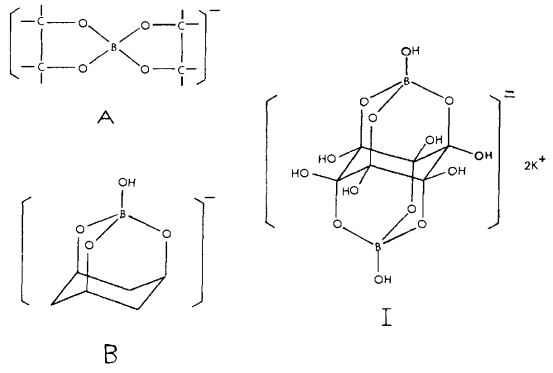
Toshio Goto* and Masanori NAGAO**

Chemical Institute, Faculty of Science, Nagoya University, Nagoya 464

(Received August 25, 1973)

Synopsis. Triquinoyl forms with boric acid a strongly acid double-tridentate complex, dipotassium salt of which is almost insoluble in water. The formation of this complex supports dodecahydroxycyclohexane structure for triquinoyl.

It is well known that some polyol compounds form borate complexes,[1-3] which cause the increased acidity and conductivity of boric acid solutions after the addition of the polyols.[4] There are two types of the borate complexes. One type (**A**), which is usually called as Böeseken complex, is believed to involve *cis*-1,2-diol structures[2] and the borate-polyol reactions forming this type of complexes are usually reversible. Another type is seen in some borate–cyclitol complexes. Cyclitols having three *cis*-1,3,5-hydroxyl groups form complexes by a three-point attachment as in **B**, which are referred to as tridentate complexes.[5,6] The complexes are usually stable and strong acids.[5] *cis*-Phloroglucitol makes tridentate complex (**B**) from its less stable chair form. *cis*-Inositol with three axial hydroxyl groups on the same side of the ring in either chair form, forms by far the firmest complex. Scyllitol in its all equatorial conformation cannot form a tridentate complex and hence forms no borate complex under mild conditions,[5] but under forced conditions it could form a double tridentate complex with borate.[7]



A B I

We found that triquinoyl also forms a stable complex with borate in a 1:2 ratio. When 1 M KCl solution (10 ml) was added to an aqueous 0.5 M boric acid solution (20 ml) of triquinoyl (60 mg) white precipitate appeared immediately, which was collected by centrifugation and washed with water (pH of the supernatant was 2.4). When the borate solution of triquinoyl was slowly titrated with 0.1 M KOH solution two equivalents of KOH per 1 mol of triquinoyl were consumed and crystalline precipitate was formed. The precipitate shows no definite mp, no UV absorption, and apparent pK_a at *ca.* 2.6, and is almost insoluble in water and usual organic solvents, but soluble in conc. HCl; IR spectrum is shown in Fig. 1.

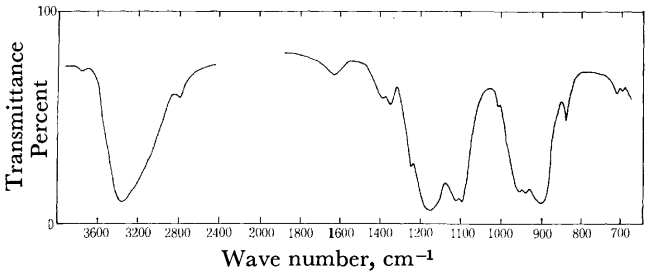


Fig. 1. Infrared spectrum of I.

Found: B, 5.20; K, 19.3%. Calcd for $C_6H_8O_{14}B_2K_2$: B, 5.36; K, 19.35%. The complex is assigned to have the double tridentate structure (**I**) from its elemental analysis, titration equivalent, apparent pK_a, and by analogy from other tridentate complexes.[8]

Böeseken and Meuwissen[9] observed that triquinoyl increases the electronic conductivity of boric acid. They had suggested the structure of triquinoyl as the completely hydrated form, dodecahydroxycyclohexane $[C_6(OH)_{12}\cdot 2H_2O]$, which was later confirmed by IR spectroscopic analysis.[10] The formation of the double tridentate borate complex supports this structure.

Vapor-Liquid Equilibrium in the 2-Butanol-Water System and the Effect of Uranyl Nitrate

Norio Yui, Yōichi Kurokawa, and Hiroyuki Ōtsuki

Department of Applied Science, Faculty of Engineering, Tohoku University, Aramaki, Sendai 980

(Received April 13, 1973)

Synopsis. Vapor-liquid equilibrium have been investigated by a modified Randall's method. The activities of solvents showed positive deviation from Raoult's law. There was a sign of salting effect on 2-butanol by addition of uranyl nitrate hexahydrate.

When the solute is non-volatile, the activity of the solvent or the behavior of the solute can be obtained from measurements of the change in the vapor pressure caused by the presence of the solute. Therefore, vapor-liquid equilibrium data for both 2-butanol–water and 2-butanol–water–uranyl nitrate systems have been determined at atmospheric pressure and 25 °C by a modification of Randall's method.

Experimental

Reagents: 2-Butanol and Uranyl Nitrate Hexahydrate. Reagent-grade chemicals were used without further purification. The conductivity water was prepared by the passage of the distilled water through mixed-bed ion-exchange resins.

Procedure. The vapor pressures of the 2-butanol and water system have been determined by a modification of Randall's method, as is shown in Fig. 1.[1,6]

Analysis. The condensates in the high butanol range remaining in a single phase and the aqueous solution containing a large proportion of water were analyzed by means of an Abbe refractometer. Most of the condensates separated into two phases upon standing at room temperature. They were diluted with sufficient *tert*-butyl alcohol to produce a homogeneous solution, and then the solutions were analyzed by gas chromatography.[6]

Results and Discussion

2-Butanol–Water System. The results of the experimental vapor-liquid equilibrium measurements are given in Fig. 2. The experimental value is the mean of two or three runs determined in each experiment. Assuming that the vapor phase obeys the ideal gas law over the complete concentration range, then the activity in the solution is given by $p/p°$. The saturated vapor pressure of a solvent at 25 °C was taken from Ref. 6 ($p°_1$: 23.7, $p°_2$: 17.1 mmHg). Activities are shown in Fig. 3. A positive deviation from Raoult's law, which is represented by the straight line, occurs as predicted. A discontinuous portion of the curve is not realized except in the two-phase region. The activity of the solvent must be the same in the two phases, which are in equilibrium with each other, because the chemical potential of the solvent is the same in each phase. Therefore, the dashed line, which indicates the region of the two phases, parallels the abscissa in the figures. However, in Fig. 3 the axes in water-rich region are magnified so as to be observed easily, and so the discontinuous portion is not shown clearly.

The values are comparable to those of the isomeric butanols.[1,2] Palit has attributed the difference in the solubility of isomeric alcohol in water to the difference in the effects of the hydroxyl group upon electron displacement in the hydrocarbon chain.[3] Paterson reported that the rate of proton exchange increased linearly with the water concentration, and that the τ (s) value for the attachment of the proton in the alcoholic OH group increased in this sequence; n-<

Slant dotted line: 2-butanol–water–uranyl nitrate

iso-<*sec*-<*tert*-butyl alcohol.[4,5] This is the same order as those of the increasing proton-accepting facility and of the deviation from Raoult's law. Positive deviations from Raoult's law are favored differences in the internal pressure or in the molecular-attractive forces, and therefore the activity coefficient, γ, yields much information on the nature of the latter. The increase in γ can bring about a separation into two liquid phases because the two components have their own attractive forces, dissimilar to one another.

The van Laar equation was found to fit the data for the system more closely than the Margules equation, much as in the case of the 1-butanol–water system.[6] The separation of γ into the enthalpy and entropy terms is quite general; they can not be exactly separated. In general, the contribution of the entropy term to γ is larger than that of the enthalpy. Isomeric butanols have almost equal molal volumes. Therefore, the entropy terms may not be so different. Consequently, it seems that the difference in γ of the isomeric butanols must be due to the enthalpy term.

Effect of Uranyl Nitrate on the Vapor-Liquid Equilibrium. The effect of the addition of $UO_2(NO_3)_2 \cdot 6H_2O$ on the 2-butanol–water system was determined, also the behavior of the distribution of the salt in the region of the liquid-liquid distribution was discussed. The addition of a salt to an aqueous solution of a non-electrolyte has a marked effect upon the vapor-liquid equilibrium; may either raise or lower the relative volatility of the non-electrolyte, or in an extreme case, cause the formation of two liquid phases. Various experimental studies of the salt effect on the vapor-liquid equilibrium have been reported.[7] However, these investigations have dealt almost exclusively with the equilibrium either at the boiling point or with a saturated salt concentration. On the other hand, only a few investigations at 25 °C have been performed. The knowledge of the vapor-liquid equilibrium accounts for the behavior of the salt in the range of the two liquid distribution. Each solvent for the liquid sample was determined by means of a refractometer after the salt has been removed by distillation.

The experimental data are shown graphically in Fig. 2 (slant dotted line). The liquid compositions were plotted on a salt-free basis. The addition of uranyl nitrate to the system resulted in an increase in the partial pressures of both water and 2-butanol above *ca.* a 0.5 mol fraction of water, while below that fraction it resulted in a decrease in both. As is shown in Fig. 4, there is a considerable salting-out of 2-butanol. This may be interpreted as being due to a breaking up or a loosening of the interaction between 2-butanol and water molecules. Consequently, the salting-out should largely be due to a preferential attraction between water molecules and uranyl nitrate. Whether uranyl nitrate with a net hydration of six water molecules appears in the butanol phase must depend largely on the competitive strength of the butanol and water molecules with respect to coordination with the uranyl nitrate. However, in this case, 2-butanol may not replace the water molecules as other solvents do.[8] Katzin *et al.* inspected the phase diagram in the region of the liquid-liquid distribution and found that the uranyl nitrate was extracted into the 2-methylpropanol phase with four water molecules coordinated.[6] Considering this result, in the 2-butanol phase it probably takes either $UO_2^{2+}\text{-}(NO_3^-)_2 \cdot (H_2O)_4 \cdot 2H_2O$ form just as in the aqueous phase, or $UO_2^{2+}(NO_3^-)_2 \cdot (H_2O)_4 \cdot x\text{BuOH}$ form and the former joins the water molecules by hydrogen bonding, thus forming the second solvation shell. This can also be suggested on the basis of spectrophotometric measurements with IR and UV.

The Electrodepositions of Copper and Nickel from Their Trifluoroacetate-Formamide Baths

Tatsuko TAKEI

The Faculty of Engineering, Shinshu University, Wakasato, Nagano 380

(Received March 9, 1973)

The present author has been studying the electrodeposition of metals from non-aqueous solutions of metal trifluoroacetates. In the present study, the properties of the $Cu(CF_3COO)_2$–$HCONH_2$ bath and the $Ni(CF_3COO)_2$–$HCONH_2$ bath, and the mechanism of the electrodeposition of copper and nickel from these baths, were studied. Both $Cu(CF_3COO)_2$ and $Ni(CF_3COO)_2$ were easily dissolved in formamide. The specific conductance of these solutions was high. Satisfactory electrodeposits are obtained from these solutions, with a high current efficiency. The cross-section of the electrodeposits showed a granular structure. The rate of the electrodeposition of copper from the $Cu(CF_3COO)_2$–$HCONH_2$ bath and that of nickel from the $Ni(CF_3COO)_2$–$HCONH_2$ bath were controlled by the charge-transfer reaction at low current densities. The activation overvoltage of the hydrogen-evolution reaction for the electrolysis of the CF_3COOH–$HCONH_2$ bath was higher than that for the electrolysis of the CF_3COOH–H_2O bath.

Menzies *et al.*[1] and Brenner[2,3] pointed out the importance of the study of the electrodeposition of metals from non-aqueous solutions. Studies[2–5] have already been made of various metals.

However, none has thus far been used industrially. In the deposition of metals from non-aqueous solutions, it is hard to find metal salts that are readily soluble in an organic solvent or a solvent which forms a complex ion in a suitable strength with metal ions in the solutions. Moreover, little is known about the properties of the solutions and the mechanism of the electrodeposition of metals.

The present author has been studying the electrodeposition of metals from non-aqueous solvents by the use of metal salts of trifluoroacetic acid. In the present study, examinations were made into the nature of the $Cu(CF_3COO)_2$–$HCONH_2$ bath and that of the $Ni(CF_3COO)_2$–$HCONH_2$ bath, which dissolve $Cu(CF_3COO)_2$ or $Ni(CF_3COO)_2$ respectively, using formamide. Formamide has a high boiling point and a high dielectric constant and readily forms complex ions with metal ions. Electrodeposition was performed in these baths in order to examine the effect of the condition of electrolysis on the current efficiency and on the electrodeposit. The overvoltages were measured by the interrupter method in order to analyze the electrodeposition reactions. Measurements were also made on the hydrogen overvoltage in the formamide bath.

The deposition of copper from the $Cu(CF_3COO)_2$–$HCONH_2$ bath was compared with that of nickel from the $Ni(CF_3COO)_2$–$HCONH_2$ bath.

Experimental

Reagent. *Formamide*: For the measurement of the conductance, the solubility, and the viscosity, guaranteed reagent-grade formamide containing about 0.02% moisture was used. For the electrodeposition and the measurement of the overvoltage, commercial first-grade reagent formamide containing about 0.12% moisture was used.

$Cu(CF_3COO)_2$ and $Ni(CF_3COO)_2$: These substances were prepared by the neutralization method from copper hydroxide and nickel hydroxide with trifluoroacetic acid. The purities of the corresponding products were 99.4 and 99.8% respectively.

Other Chemicals: Phosphoric acid and acetic acid of the first-grade reagent were used. Sulfuric-, nitric-, and hydrochloric acids of a special grade were used.

Measurement of the Solubility. The solubility of $Cu(CF_3COO)_2$ in formamide was measured by the gravimetric determination of copper in a definite amount of a saturated solution obtained by dissolving $Cu(CF_3COO)_2$ in formamide at 20 °C. The gravimetric determination of copper was done by the use of oxine.

Measurement of the Conductance. The electrolytic conductance of $Cu(CF_3COO)_2$–$HCONH_2$ and $Ni(CF_3COO)_2$–$HCONH_2$ solutions was determined by the use of a Yanagimoto electrolytic conductometer MY-7. Before the measurement the solutions to be measured were kept for about an hour at 30, 40, and 50 °C in a thermostat.

Viscosity Measurement. The viscosity of the $Ni(CF_3COO)_2$–$HCONH_2$ solutions was measured by means of an Ostwald viscosimeter at 30.0±0.1 °C.

Density Measurement. The densities of the formamide and $Ni(CF_3COO)_2$–$HCONH_2$ solutions were determined by the use of a Springel densimeter at 30.0±0.1 °C.

Electrodeposition. The electrodeposition was performed by the use of the apparatus shown in Fig. 1. In the case of

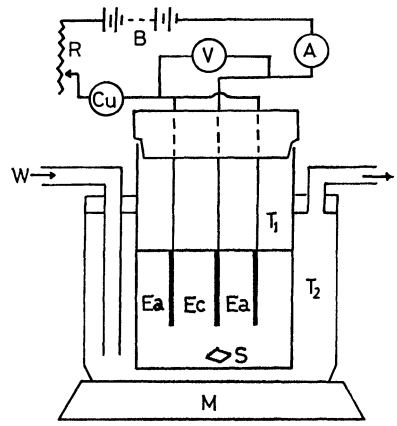

Fig. 1. Apparatus for metal plating.
A: Ammeter, B: Battery, Cu: Copper coulometer, Ea: anode, Ec: cathode, M: Magnetic stirrer, R: Slide rheostat, S: Stirrer, T_1: Electrolysis cell, T_2: Thermostat, V: Voltmeter, W: Water (const. temp.)

copper electrodeposition, two copper plates and one iron plate were used as anode and cathode respectively. For nickel deposition, two nickel plates and one copper plate were used as anode and cathode respectively. These electrodes were pretreated by the usual method as indicated.[6] Nitrogen was passed through formamide for about 30 minutes. A definite amount of the $Cu(CF_3COO)_2$ or $Ni(CF_3COO)_2$ was dissolved in the formamide solution to give a bath used for the electrodeposition. The bath was stirred at a definite rate. The electrodeposition was carried out at a current density of 0.5—15.0 A/dm² at 30—70 °C.

The thickness of the electrodeposited layer was about 5 μ, the thickness being calculated from the amount electricity used for the deposition.

Observation of the Electrodeposited Surface and the Electrodeposited Layer. For these observations, a metallurgical microscope was used.

The specimen with an electrodeposited layer, about 30 μ thick, was mounted in resin and etched.

Analysis of Gases and Electrolytic Solutions. During the electrolysis, a slight evolution of gases from the cathode and the anode was noticed. Therefore, the gases and the electrolytic solution were analyzed by gas-chromatography in order to examine the composition of the gases and the mechanism of the reaction. For the measurement, a gas-chromatograph, Type GCG-220, made by the Yanagimoto Manufacturing Co., Ltd, was used. The packing materials of the column were silicon DC 550 at 53 °C and 100 °C, and active carbon at 33 °C, used for the analysis of the electrolytic solution and of the gas respectively.

Measurement of the Overvoltage. The overvoltage of the copper electrodeposition was measured at 30, 40, and 50 °C for the baths containing 100, 200, and 400 g $Cu(CF_3COO)_2$ per liter respectively. The overvoltage of nickel deposition was measured at 50, 60, and 70 °C for the baths containing 50, 100, 150 g $Ni(CF_3COO)_2$ per liter respectively. The measuement was made by the current-interrupter method, with stirring at a definite rate.

The measurement of the overvoltage of hydrogen evolution was made by the same method as above at 50 °C, in a 0.1 N CF_3COOH–H_2O bath and also in a 0.1 N CF_3COOH–$HCONH_2$ bath.

A platinized-platinum electrode (length, 3 mm; diameter, 0.3 mm) was used as a reference electrode for the measurement of the overvoltage.

A current-interrupter, Type CI-2515, made by the Hokuto Electric Works Co., Ltd., was used.

Results and Discussion

The Properties of Formamide Solutions. Solvolysis: According to Röhler, solvolysis takes place in formamide solutions of copper sulfate and nickel chloride.[7] Therefore, solvolysis can be expected to take place in formamide solutions of $Cu(CF_3COO)_2$ and $Ni(CF_3COO)_2$ by means of the following reaction:

$$M(CF_3COO)_2 + 4HCONH_2 \rightarrow M(HCONH)_2 \cdot 2HCONH_2 + 2CF_3COOH \quad (1)$$

where M represents copper or nickel.

Actually, a light yellow-green precipitate is formed in the $Ni(CF_3COO)_2$–$HCONH_2$ solution by the reaction of $Ni(CF_3COO)_2$ with formamide. This reaction becomes more remarkable with a rise in the bath temperature and with an increase in the $Ni(CF_3COO)_2$ concentration.

When the reaction product was filtered, an almost colorless filtrate was obtained. The gas-chromatographic analysis of this solution showed the presence of CF_3COOH. The precipitate was washed, dried, and then gravimetrically analyzed with dimethyl glyoxime in order to determine the nickel content in the precipitate. The nickel content was about 96.8% of the theoretical amount of Ni in $Ni(HCONH)_2 \cdot 2HCONH_2$. It was found by these results that the reaction shown in Eq. (1) takes place in the $Ni(CF_3COO)_2$–$HCONH_2$ solution.

CF_3COOH was also detected in the $Cu(CF_3COO)_2$–$HCONH_2$ solution. Therefore, it is likely that the reaction shown by Eq. (1) also takes place in this bath.

Solubility. At 20 °C, 182 g $Cu(CF_3COO)_2$ was dissolved in 100 g of formamide. Consequently, the solubility of $Cu(CF_3COO)_2$ in formamide is larger than those in methanol and acetonitrile[8]. The solvolysis takes place very easily in a formamide solution with a high concentration of $Ni(CF_3COO)_2$. Therefore, the solubility of $Ni(CF_3COO)_2$ in formamide could not be determined.

Specific Conductance. Figure 2 shows the specific conductance of the $Cu(CF_3COO)_2$–$HCONH_2$ solution. The specific conductance of the $Cu(CF_3COO)_2$–$HCONH_2$ solution was almost the same as that of the $Ni(CF_3COO)_2$–$HCONH_2$ solution and about 1.5 times that of the $Cu(CF_3COO)_2$–MeOH solution.[8]

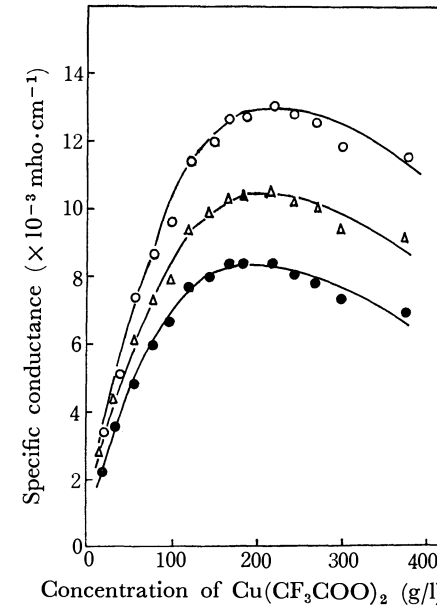

Fig. 2. Specific conductance of $Cu(CF_3COO)_2$–$HCONH_2$ solutions.
-●-: 30 °C, -△-: 40°C, -○-: 50°C

The specific conductance approached a definite value when the $Cu(CF_3COO)_2$ concentration reached about 200 g/l at any temperature. In the solutions containing more than 200 g of $Cu(CF_3COO)_2$, copper trifluoroacetate does not seem to dissociate any more; on the contrary, it seems that the movement of ions in the solutions is interfered with by the presence of non-dissociated salts.

Viscosity. The viscosity of the $Ni(CF_3COO)_2$–

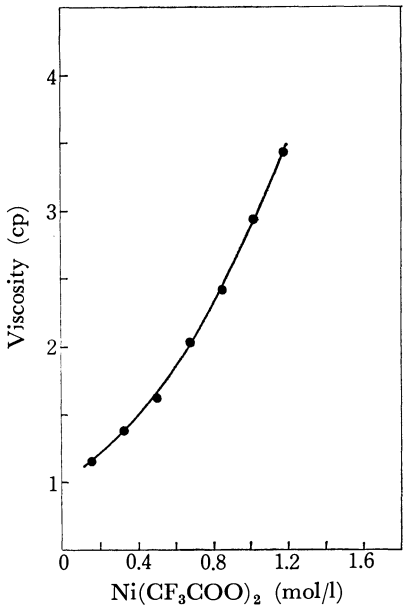

Fig. 3. Relationship between viscosity and concentration of $Ni(CF_3COO)_2$ in $Ni(CF_3COO)_2$–$HCONH_2$ solutions at 30°C.

$HCONH_2$ solution as a function of the concentration of $Ni(CF_3COO)_2$ is shown in Fig. 3. It may be seen in Fig. 3 that the viscosity increases almost linearly with the increase in the $Ni(CF_3COO)_2$ concentration. It thus appears that the viscosity of the $Cu(CF_3COO)_2$–$HCONH_2$ solution increases with the increase in the $Cu(CF_3COO)_2$ concentration, like that of the Ni-$(CF_3COO)_2$–$HCONH_2$ solution.

Electrodeposition. Copper Electrodeposition: Figure 4 shows an example of the current density-current

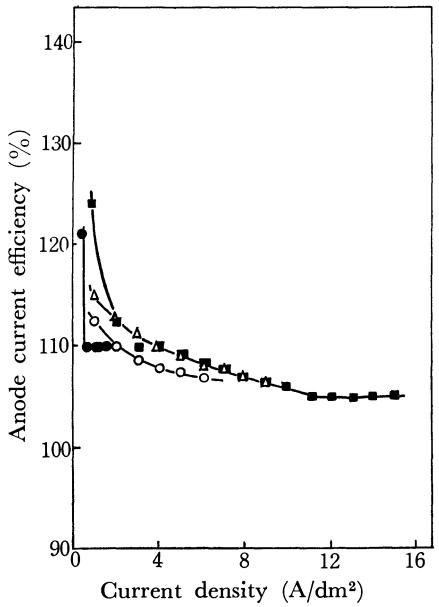

Fig. 4—2. Anode current efficiency as a function of current density at 40 °C.
-●-: $Cu(CF_3COO)_2$ 20 g/$HCONH_2$ 1 l
-○-: $Cu(CF_3COO)_2$ 100 g/$HCONH_2$ 1 l
-△-: $Cu(CF_3COO)_2$ 200 g/$HCONH_2$ 1 l
-■-: $Cu(CF_3COO)_2$ 400 g/$HCONH_2$ 1 l

efficiency curve of copper deposition from the Cu-$(CF_3COO)_2$–$HCONH_2$ bath.

The cathodic current efficiency was close to 100% irrespective of the $Cu(CF_3COO)_2$ concentration. However, the efficiency tends to decrease with the rise in the bath temperature.

It was noticed that a very small amount of hydrogen gas evolved from the cathode during the electrolysis. The lowering of the cathodic current efficiency is attributable to this evolution of hydrogen gas. The evolution of hydrogen gas is attributable to the discharge of hydrogen ions formed by the dissociation of CF_3-COOH, which was itself derived from the reaction shown in Eq. (1).

On the other hand, the anodic current efficiency was found to be more than 100% irrespective of the concentration of $Cu(CF_3COO)_2$ and of the bath temperature. The efficiency even exceeded 110% at a low current density. This efficiency is attributable to the chemical reaction of copper with the CF_3COOH formed by the reaction given by Eq. (1).

No gases evolved from the anode.

Figure 5 shows the current density region in which bright and smooth deposits are obtained. At any temperature, bright and smooth deposits were observed over a wide range of current density when the concentration of $Cu(CF_3COO)_2$ was high.

From the results mentioned above, it was confirmed that bright and smooth deposits of copper are obtained with a high efficiency over a wide region of current density from the $Cu(CF_3COO)_2$ 400 g/l–$HCONH_2$ bath at 40 °C.

Electrodeposition of Nickel: An example of the current density-current efficiency curve for the nickel deposition from $Ni(CF_3COO)_2$–$HCONH_2$ bath is shown

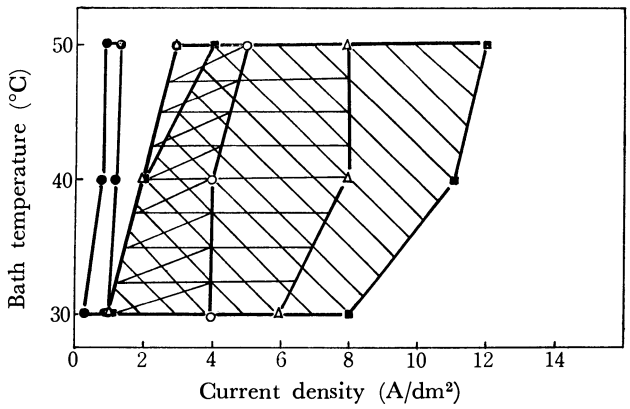

Fig. 5. The range of current density for bright and smooth copper deposit.
●: $Cu(CF_3COO)_2$ 20 g/$HCONH_2$ 1 l
○: $Cu(CF_3COO)_2$ 100 g/$HCONH_2$ 1 l
△: $Cu(CF_3COO)_2$ 200 g/$HCONH_2$ 1 l
■: $Cu(CF_3COO)_2$ 400 g/$HCONH_2$ 1 l

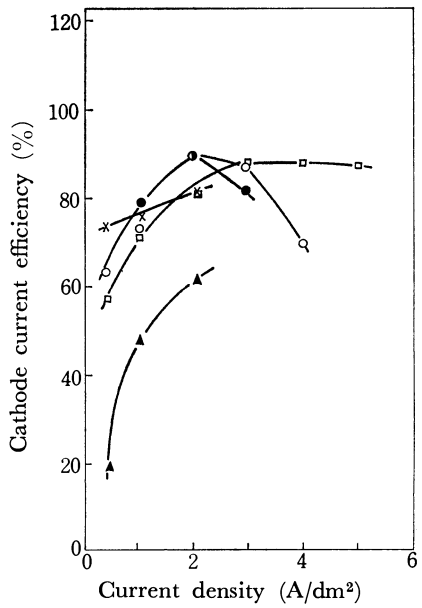

Fig. 6—1. Cathode current efficiency as a function of current density for $Ni(CF_3COO)_2$-$HCONH_2$ baths at 50 °C.
-▲-: $Ni(CF_3COO)_2$ 20 g/$HCONH_2$ 1 l
-□-: $Ni(CF_3COO)_2$ 80 g/$HCONH_2$ 1 l
-○-: $Ni(CF_3COO)_2$ 100 g/$HCONH_2$ 1 l
-✳-: $Ni(CF_3COO)_2$ 150 g/$HCONH_2$ 1 l
-●-: $Ni(CF_3COO)_2$ 200 g/$HCONH_2$ 1 l

in Fig. 6.

With the increase in the $Ni(CF_3COO)_2$ concentration, the cathodic current efficiency increased, but the anodic current efficiency tended to decrease.

When the $Ni(CF_3COO)_2$ concentration was 80—100 g/l, the anodic current efficiency was close to 100% irrespective of the bath temperature. However, the cathodic current efficiency was low at 50 °C and 70 °C when the current density was high. Only at 60 °C was the efficiency about 90% at a high current density.

The discharge of the H^+ formed by the dissociation

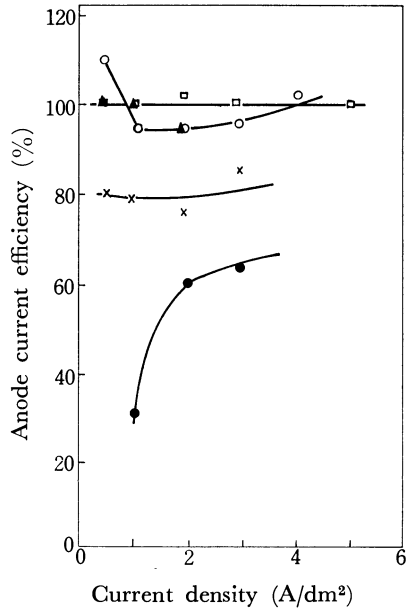

Fig. 6—2. Anode current efficiency as a function of current density for $Ni(CF_3COO)_2$-$HCONH_2$ baths at 50 °C.
-▲-: $Ni(CF_3COO)_2$ 20 g/$HCONH_2$ 1 l
-□-: $Ni(CF_3COO)_2$ 80 g/$HCONH_2$ 1 l
-○-: $Ni(CF_3COO)_2$ 100 g/$HCONH_2$ 1 l

-●-: $Ni(CF_3COO)_2$ 200 g/$HCONH_2$ 1 l

of CF_3COOH in the bath occurred on the cathode during the electrolysis in the $Ni(CF_3COO)_2$-$HCONH_2$ bath, as in the case of the $Cu(CF_3COO)_2$-$HCONH_2$ bath, resulting in the evolution of a small amount of hydrogen. From the $Ni(CF_3COO)_2$-$HCONH_2$ bath, the evolution of carbon dioxide gas occurred from the anode. However, the amount of carbon dioxide evolved was much smaller than that of the gas evolved from the cathode.

The deposits from the $Ni(CF_3COO)_2$-$HCONH_2$ bath were easily peeled off from the substrate when the $Ni(CF_3COO)_2$ concentration or the bath temperature was low. Table 1 shows the current-density region in which a lustrous and adherent nickel deposit is obtained.

From the results mentioned above, it was confirmed that the conditions which give a lustrous and adherent deposit from the $Ni(CF_3COO)_2$-$HCONH_2$ bath with a high efficiency are: $Ni(CF_3COO)_2$ concentration,

TABLE 1. THE RANGE OF CURRENT DENSITY FOR BRIGHT AND ADHERENT NICKEL DEPOSIT IN $Ni(CF_3COO)_2$-$HCONH_2$ BATH
(unit of current density : A/dm²)

Bath temp. (°C)	$Ni(CF_3COO)_2$ (g/l)			
	80	100	150	200
40	1.0—2.0		0.5—1.0	
50	1.0—2.0	1.0—2.0	0.5—2.0	1.0—2.0
60		0.5—2.0		
70		0.5—4.0		

80—100 g/l; bath temperature, 60 °C; and current density, 0.5—2.0 A/dm².

It will be possible to widen the current-density region which gives satisfactory deposits if the adherence of the deposits to the substrate is improved by the addition of an appropriate additive to the $Ni(CF_3COO)_2$–$HCONH_2$ bath.

Appearance on Deposited Surface and the Structure of the Deposited Layer. An example of the deposited surface and the deposited layer of nickel and copper is shown in Photograph 1. The deposited surfaces of copper and nickel are very smooth and consist of very fine grains when the deposition has been made at a low current density. The grains on the electrodeposited surface of nickel were especially fine. With the increase in the current density, all the deposits tended to show round blocks and cracks.

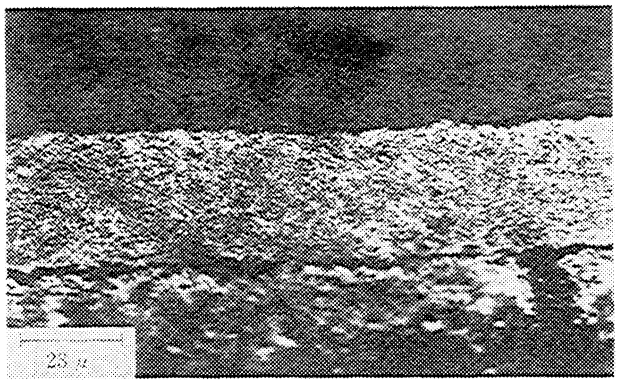

Photo. 1—2. Cross-section of copper deposit obtained from $Cu(CF_3COO)_2$ (400 g)/$HCONH_2$ (1 l) bath at 4.0 A/dm² at 30 °C.

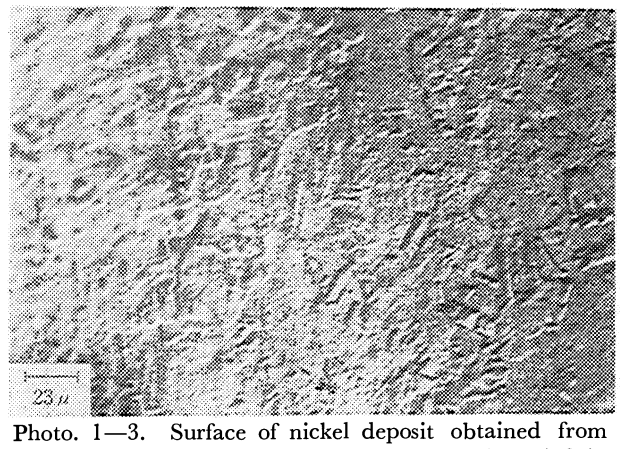

Photo. 1—3. Surface of nickel deposit obtained from $Ni(CF_3COO)_2$ (100 g)/$HCONH_2$ (1 l) bath at 1.0 A/dm² at 60 °C.

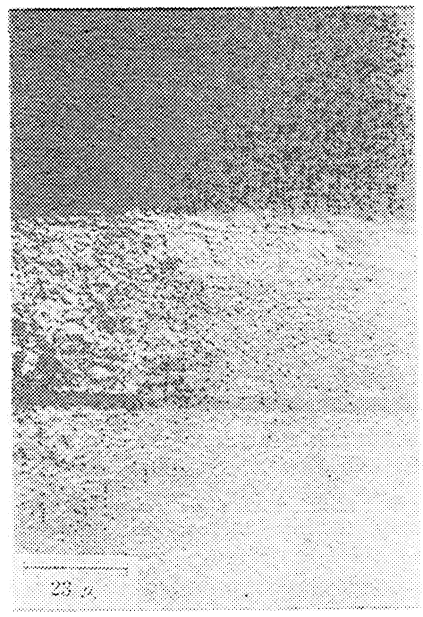

Photo. 1—4. Cross-section of nickel deposit obtained from $Ni(CF_3COO)_2$ (100 g)/$HCONH_2$ (1 l) bath at 1.0 A/dm² at 50 °C.

It was possible to obtain dense deposits when the bath temperature was high.

The structures of the deposits of copper and nickel were granular. The copper- and nickel- ions in the $HCONH_2$ baths form complex ions. The ligands which are adsorbed on the electrode during electrodeposition, suppress any surface diffusion of the adatom and prevent the growth of the nucleus in the vertical direction. Therefore, the frequency of the nucleus formation increases. It appears that the fine grains are produced to form a granular structure.

Activation Overvoltage. From the decay curve of the overvoltage 4 ms after the interruption of the electrolytic current, the resistance polarization was subtracted. The remainder was assumed to be the activation overvoltage.

The Relation between the Current Density (i_c) and the Activation Overvoltage (η_c) of the Electrodeposition of Copper or Nickel: The electrodeposition of metals from the solvated metal complex ions is [11] generally complicated.

This experiment was based upon the thought that the charge-transfer reaction is rate-determining within the range of current density (*i.e.* the Tafel region) with a straight-line relation between the current density and the activation overvoltage. According to the present experiment, the Tafel region was found to be in the range of current density, of 0.7—1.5 A/dm² at a bath temperature of 30 °C, in that of 0.8—2.0 A/dm² at 40 °C, and in that of 0.9—3.5 A/dm² at 50 °C for copper deposition. The ranges of the current density were 0.9—2.3 A/dm² at 50 °C, 0.9—4.4 A/dm² at 60 °C, and 0.9—4.8 A/dm² at 70 °C for nickel

deposition.

The Apparent Exchange Current Density (i_{oc}) of the Copper and Nickel Depositions: The apparent exchange current density of copper and nickel depositions was obtained by extrapolating the η_c in the relation of $\eta_c - i_c$ to 0. The apparent exchange current density was thus determined at various temperatures and various salt concentrations. The results are shown in Tables 2 and 3.

The values of the i_{oc} of the copper and nickel depositions tended to increase with the salt concentration in the bath and with the bath temperature.

It was noticed that the i_{oc} of the nickel deposition was smaller than that of the copper deposition.

The Apparent Transfer Coefficient (α_c) and the Apparent Valence (n) of Copper and Nickel Depositions: On the Tafel curves, Eqs. (2) and (3) hold among n, α_c, i_{oc}, the apparent standard rate constant (K_{SR}), and the concentration of Cu^{2+} or Ni^{2+}, C_0 mol/l:

$$i_c = i_{oc} \exp(-\alpha_c F n \eta_c / RT) \quad (2)$$

$$i_{oc} = nFK_{SR}C_0^{(1-\alpha_c)} \quad (3)$$

If the plot of log i_{oc}—log C_0 becomes linear in Eq. (3), its slope is equal to $(1-\alpha_c)$. This relation is shown in Fig. 7 for the deposition of copper from the $Cu(CF_3COO)_2$-$HCONH_2$ bath as an example. Similar results were obtained for the deposition of nickel from the $Ni(CF_3COO)_2$-$HCONH_2$ bath. The relation was approximately linear. Therefore, α_c was determined from the slope. On the other hand, the slopes of the Tafel line are equal to $2.303 \times RT/\alpha_c nF$ as is given by Eq. (2). Therefore, $\alpha_c n$ was determined from this relationship. Tables 2 and 3 show α_c, $\alpha_c n$, n and the slopes of the Tafel lines.

As an average of these results, the following relations were found for copper deposition:

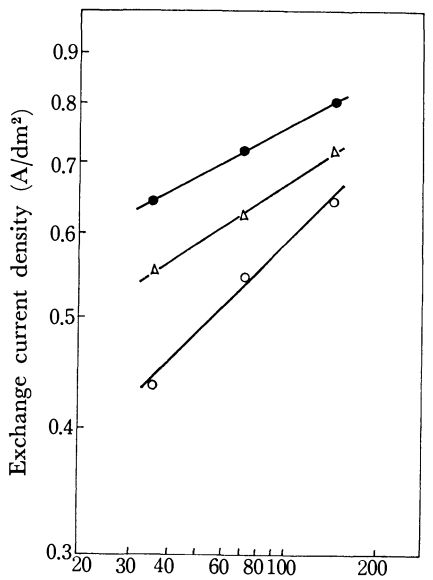

Fig. 7. Relationship between exchange current density and concentration of copper ion.
-○-: 30 °C, -△-: 40 °C, -●-: 50 °C

$\alpha_c = 0.78$ (namely, dlog i_{oc}/dlog $C_0 = 0.22$)

$n = 0.77$

The slope of the Tafel line $(b_c) = -0.113$ V. For nickel deposition:

$\alpha_c = 0.66$ (namely, dlog i_{oc}/dlog $C_0 = 0.34$)

$n = 1.00$

$b_c = -0.102$ V.

Therefore, it may be concluded that the reaction proceeds as is shown in Eqs. (4) and (5) within the

range of 0.7—3.5 A/dm² for copper deposition from the $Cu(CF_3COO)_2$–$HCONH_2$ bath and within that of 0.9—4.8 A/dm² for nickel deposition from the $Ni(CF_3COO)_2$–$HCONH_2$ bath.

$$M^{2+} + e^- \rightarrow M^+ \quad (4)$$

$$M^+ + e^- \rightarrow M \quad (5)$$

where M is Cu or Ni.

It may also be concluded that the reaction of Eq. (4) is rate-determining, because the effect of the potential (current density) on the electrodeposition is relatively slight at low current densities, which give satisfactory deposits.

It seems that the solvation[11] has some effect on the deposition of metals.

The Apparent Activation Energy of Copper and Nickel Depositions: The relation between i_{oc} and the bath temperature (T) is given by the Arrhenius equation. Thus,

$$i_{oc} = K \exp(-E_c/RT) \quad (6)$$

where E_c: the apparent activation energy of the deposition of metals. K: a constant.

Figure 8 shows the relation between the apparent exchange current density and the bath temperature (namely, $\log i_{oc} - 1/T$) for the copper deposition. This relation is approximately shown by a straight line. The same relation also holds for the nickel deposition. The apparent activation energies of the deposition of copper and nickel were determined from the slopes of these curves.

It was thus found that the apparent activation energies were 3.50 kcal/mol, 2.86 kcal/mol, and 2.46 kcal/mol for the deposition of copper from the baths containing 100, 200, and 400 g $Cu(CF_3COO)_2$ per liter respectively. For the deposition of nickel, the activation energies were 8.85 kcal/mol, 8.03 kcal/mol, and 6.31 kcal/mol for the baths containing 50, 100, 150 g $Ni(CF_3COO)_2$ per liter respectively.

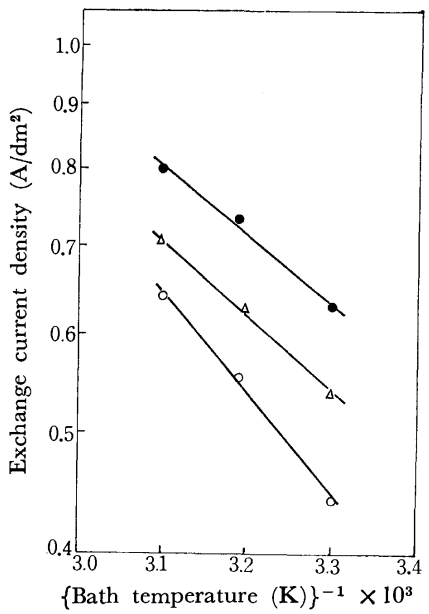

Fig. 8. Relationship between exchange current density and bath temperature.
-●-: concentration of copper ion 140×10^{-2} mol/l
-△-: concentration of copper ion 70×10^{-2} mol/l
-○-: concentration of copper ion 35×10^{-2} mol/l

That is, the activation energy of the copper deposition from the $Cu(CF_3COO)_2$–$HCONH_2$ bath was 2.9 kcal/mol on the average, while that of the nickel deposition from the $Ni(CF_3COO)_2$–$HCONH_2$ bath was 7.7 kcal/mol on the average. In the high-concentration solutions of $Cu(CF_3COO)_2$ or $Ni(CF_3COO)_2$, the true concentration of Cu^{2+} or Ni^{2+} is lower than that of $Cu(CF_3COO)_2$ or $Ni(CF_3COO)_2$. Therefore, it is likely that the true activation energy is larger than those values.

The activation energy of the direct deposition of Cu^{2+} from a copper borofluoride bath is estimated to be about 11—12 kcal/mol.[9] The activation energy as determined by the present study is lower than this value. It may be concluded, in view of the activation energy, that the deposition of copper from the $Cu(CF_3COO)_2$–$HCONH_2$ bath takes place through Cu^+ and that the deposition of nickel takes place through Ni^+.

The Electrodeposition of Metals from a Metal Trifluoroacetate-$HCONH_2$ Bath. It is not sufficient to discuss the deposition of metals from a metal trifluoroacetate–$HCONH_2$ bath from the viewpoint of copper deposition and nickel deposition only. However, the following tendencies were noticed:

(1) Formamide well dissolves metal trifluoroacetate. In this solution, metal-complex ions are formed.

(2) The i_{oc} value of the deposition of metals from a formamide bath is larger than that from an aqueous solution. However, the metals which show large i_{oc} values in aqueous solutions also show large i_{oc} values in formamide baths. Those which show small i_{oc} values in aqueous solutions also show small i_{oc} values in formamide baths.

(3) When the i_{oc} values are large, metals are easily deposited and the deposits are apt to be coarse.[10] In formamide baths, a metal-complex are formed. Therefore, the growth in the perpendicular direction is suppressed, resulting in an increase in the frequency of nucleation. Therefore, a smooth deposited surface with small crystallites is obtained.

(4) In the formamide bath, the i_{oc} values of metal deposition are larger than in aqueous baths. The values of i_{oc} vary little with the kind of metal. It is, therefore, possible to accelerate the deposition of metals, which are hardly deposited at all from aqueous solutions.

Activation Overvoltage of Hydrogen Evolution. When the electrolysis was performed in the CF_3COOH–$HCONH_2$ bath, hydrogen gas evolved from the cathode. However, no gases evolved from the anode.

The activation overvoltage of hydrogen evolution from the CF_3COOH–$HCONH_2$ bath is higher than that from an aqueous solution. Therefore, hardly any evolution of hydrogen takes place in formamide baths because of the activation overvoltage.

The author wishes to express her deep gratitude to Professor Rimpei Kojima for his kind direction and encouragement throughout this work.

The Electrodepositions of Copper and Nickel from Their Trifluoroacetate–*N*,*N*-Dimethylformamide Baths

Tatsuko TAKEI

The Faculty of Engineering, Shinshu University, Wakasato, Nagano 380

(Received August 2, 1973)

This paper will deal with the electrodepositions of copper and nickel from $Cu(CF_3COO)_2$–$HCON(CH_3)_2$, $Cu(CF_3COO)_2$–$HCON(CH_3)_2$–citric acid, $Ni(CF_3COO)_2$–$HCON(CH_3)_2$, and $Ni(CF_3COO)_2$–$HCON(CH_3)_2$–additives baths. The properties of these baths and the mechanism of the electrodeposition of copper from the $Cu(CF_3COO)_2$–$HCON(CH_3)_2$–citric acid bath were studied. The solubility of $Cu(CF_3COO)_2$ in 100 g of $HCON(CH_3)_2$ was 180 g at 20 °C. The specific conductances of the $Cu(CF_3COO)_2$–$HCON(CH_3)_2$ and $Ni(CF_3COO)_2$–$HCON(CH_3)_2$ baths were lower than those of the $Cu(CF_3COO)_2$–$HCONH_2$ and $Ni(CF_3COO)_2$–$HCONH_2$ baths. Cu_2O was electrodeposited at the cathode, while copper was not easily obtained from the $Cu(CF_3COO)_2$–$HCON(CH_3)_2$ bath. By dissolving citric acid in the bath, copper electrodeposition was made easier. Bright and smooth copper deposits were obtained at current densities in the range of 2.0—11.0 A/dm² from the $Cu(CF_3COO)_2$ 500 g/l–$HCON(CH_3)_2$–citric acid 200 g/l bath at 60 °C, the current efficiencies for cathode and anode being about 75% and above 100% respectively. The cross-section of the copper deposits showed that the deposits have a granular structure. The rate of the electrodeposition of copper from the $Cu(CF_3COO)_2$–$HCON(CH_3)_2$–citric acid 200 g/l bath at current densities ranging from 1.0 to 3.5 A/dm² was found to be controlled by the charge-transfer reaction. A black powder nickel deposit was obtained from the $Ni(CF_3COO)_2$–$HCON(CH_3)_2$ bath. By dissolving NH_4Cl, H_3BO_3, sulfamic acid or CCl_3COOH in the bath, adherent bright and smooth nickel deposits were obtained. While the cathode current efficiency was lower in the bath containing sulfamic acid, the anode current efficiency was lower in the bath containing H_3BO_3 or CCl_3COOH. NH_4Cl and $AlCl_3$ have the disadvantage that they are dissolved in $HCON(CH_3)_2$ only with difficulty. Since the bond between the metallic ion and the solvent in the $HCON(CH_3)_2$ bath is stronger than that in the $HCONH_2$ bath, and since dielectric constant of the solvent in the former is lower than that in the latter, metal electrodeposition from the former is more difficult.

Few fundamental data have been reported on the metallic electrodeposition from non-aqueous solutions, in addition, the electrode reaction is not clear in many respects.

The present author previously described[1] the electrodeposition of copper and nickel from the $HCONH_2$ bath, a polar proton solvent.

On the other hand, $HCON(CH_3)_2$ is a polar aprotic solvent; it has a comparatively low melting point and a comparatively high boiling point among the amide solvents. It can be expected that this solvent would also be useful for the electrodeposition of very base metals, because the solvent, lacking in active hydrogen, does not evolve H_2 simultaneously with the metallic electrodeposition from this solution.

The electrodeposition of metal from the $HCON(CH_3)_2$ solution has,. however been investigated only by Baba *et al.*,[2] and the present author cannot find any data fully examining the influence of the electrolysis conditions on the electrodeposit, the mechanism of the electrodeposition reaction, or the properties of the solution.

In the present experiment, the author investigated the properties of the $Cu(CF_3COO)_2$–$HCON(CH_3)_2$ bath and the $Ni(CF_3COO)_2$–$HCON(CH_3)_2$ bath, the electrodepositions of copper and nickel from these baths, and the mechanism of the electrodeposition of copper from the former bath. The author then compared the previously described electrodepositions,[1] of copper and nickel from the $HCONH_2$ bath with those in the present experiment from the $HCON(CH_3)_2$ bath.

Experimental

Reagents. *$HCON(CH_3)_2$*: A reagent grade containing about 0.003% moisture was used.

$Cu(CF_3COO)_2$ and $Ni(CF_3COO)_2$: These were[1] prepared by the neutralization method from $Cu(OH)_2$ and $Ni(OH)_2$ with CF_3COOH.

Other Chemicals: Phosphoric acid and acetic acid of the reagent grade were used. Citric acid (anhydride) and other chemicals of a special grade were used.

Electrodeposition. The electrodepositions of copper and nickel from the $Cu(CF_3COO)_2$–$HCON(CH_3)_2$ and $Ni(CF_3COO)_2$–$HCON(CH_3)_2$ baths, or from these baths with additives, were carried out at a current density of 0.5—14.0 A/dm², using an apparatus already described,[1] at 40—60 °C, while the bath was being stirred at a definite rate.

The thickness of the electrodeposited layer was made about 5 μ, this thickness being calculated from the amount of electricity consumed during the deposition.

Observation of the Electrodeposited Surface and the Electrodeposited Layer. The electrodeposited surfaces and electrodeposited layers were observed by means of a metallurgical microscope. To observe the layers in particular, their thickness was made about 30 μ and they were buried in resin and etched.

Measurement of the Solubility. The solubility of $Cu(CF_3COO)_2$ in $HCON(CH_3)_2$ was obtained by determining quantitatively with oxine (gravimetric method) the copper in a definite amount of a saturated solution of $Cu(CF_3COO)_2$ at 20 °C.

Measurement of the Electrolytic Conductance. The $Cu(CF_3COO)_2$–$HCON(CH_3)_2$, $Cu(CF_3COO)_2$–$HCON(CH_3)_2$–citric acid, and $Ni(CF_3COO)_2$–$HCON(CH_3)_2$ baths were kept at 50 °C for about one hour before the measurement, and

their electrolytic conductance was measured by means of a Yanagimoto electrolytic conductometer Model MY-7.

Measurement of the Ultraviolet Absorption Spectrum. A sample of a 0.10 mol/l $Cu(CF_3COO)_2$–$HCON(CH_3)_2$– 0 to 0.30 mol/l citric acid bath was placed in a quartz cell with a 2-mm light-pass length, and the ultraviolet absorption spectrum was measured by means of Hitachi recording spectrophotometer, Model EPS-3.

Analysis of Gas and Bath. The composition of the gas evolved during the electrolysis of a 100 g/l $Cu(CF_3COO)_2$–$HCON(CH_3)_2$–0 to 200 g/l citric acid bath and the change in the composition of the bath itself were determined by a method previously described.[1)]

Polarography. With a Yanagimoto polarograph, Model PA-102, DC and AC polarograms of a 1.0×10^{-2} mol/l $Cu(CF_3COO)_2$–$HCON(CH_3)_2$–0 to 3.0×10^{-2} mol/l citric acid bath were recorded at 25 °C, using 0.1 M sodium perchlorate as the supporting electrolyte.

Elementary Analysis. Elementary analyses were carried out on the yellowish brown substance produced at theca thode by the electrolysis of a 100 g/l $Cu(CF_3COO)_2$–$HCON(CH_3)_2$ bath and on the precipitate produced after the heating, at about 90 °C for 2 hr, of a 0.1 mol/l $Cu(CF_3COO)_2$–$HCON(CH_3)_2$–0.2 mol/l citric acid bath. H and C were determined by the Pregl method for microanalysis, N, by the Dumas method, and Cu, by the oxine method (gravimetric method).

X-ray Diffraction. The yellowish-brown substance produced at the cathode by the electrolysis of the $Cu(CF_3COO)_2$–$HCON(CH_3)_2$ bath was X-ray diffractometrically determined by means of a Geiger-Flex Model CN2035 manufactured by Rigaku Denki Co. Ltd., using copper as the target.

Measurement of the Overvoltage. The overvoltage of the copper electrodeposition from a $Cu(CF_3COO)_2$–$HCON(CH_3)_2$–200 g/l citric acid bath was measured at 40, 50, and 60 °C by the current interruptor method[1)] for baths containing $Cu(CF_3COO)_2$: 100 g/l (35×10^{-2} mol/l), 150 g/l (52×10^{-2} mol/l), and 200 g/l (70×10^{-2} mol/l) respectively.

Results and Discussion

Electrodeposition. *Nickel Electrodeposition*: Table 1 shows some results obtained on nickel deposition from $Ni(CF_3COO)_2$–$HCON(CH_3)_2$ baths with additives. The additives chosen were such that could dissolve the anode (Ni plate) and/or form a metal complex ion with the metal ion in the bath.

The deposit obtained from the $Ni(CF_3COO)_2$–$HCON(CH_3)_2$ bath was a black powder; bright and smooth nickel deposits were obtained from this bath containing NH_4Cl, $AlCl_3$, H_3BO_3, sulfamic acid, H_3BO_3–NH_4Cl, saccharin–NH_4Cl, CCl_3COOH, hydroxylamine hydrochloride, glycolic acid, H_2SO_4, or phthalic acid. The deposit obtained from the solution containing $AlCl_3$ was particularly bright.

Among these baths, those containing NH_4Cl, H_3BO_3, sulfamic acid, H_3BO_3-NH_4Cl, saccharin-NH_4Cl, or CCl_3COOH gave adherent nickel deposits.

While the cathode current efficiency was lower in the bath containing H_3BO_3 or CCl_3COOH, NH_4Cl and $AlCl_3$ have the disadvantage that they are dissolved in $HCON(CH_3)_2$ only with difficulty.

From these results it is apparent that the nickel electrodeposition from a $Ni(CF_3COO)_2$–$HCON(CH_3)_2$ bath is promoted by adding NH_4Cl, sulfamic acid, H_3BO_3, or CCl_3COOH to the bath. It would improve not only the anode current efficiency but also the adhesion of electrodeposit on the substrate if we could find a chloride highly soluble to $HCON(CH_3)_2$.

Table 1. Electrodeposition of nickel from $Ni(CF_3COO)_2$ 20.0 g/l–$HCON(CH_3)_2$ bath with additives at 40 °C

Additive (g/l)	Current density (A/dm²)	Current efficiency (%)		Deposit
		Cathode	Anode	
No addition	0.5—1.0	56—95	12—65	black
NH_4Cl 4.0	0.5—2.0	28—78	100—110	bright
H_3BO_3 4.0 —22.0	1.0	92—42	31—62	bright
Sulfamic acid 4.0—16.0	1.0	17—9.7	16—18	bright
Citric acid 4.0	0.5—1.0	10—16	5.6—3.1	grey
Tartaric acid 4.0	0.5—1.0	3.6—22	3.6—4.3	grey
LiCl 4.0	0.5—1.0	60—6.3	104—103	black
$AlCl_3$ 4.0	0.5—2.0	59—91	105—107	bright
CCl_3COOH 2.0—6.0	0.5—2.0	65—63	6.7—12	bright
Salicylic acid 2.0	2.0	67	3.0	black

Glycolic acid 2.0	0.5—1.0	41—63	6.1—4.2	bright
Phthalic acid 2.0	1.0	41	10	bright
H_2SO_4 10 ml	1.0—2.0	27—51	23—23	bright

It appears that, on the anode in the $Ni(CF_3COO)_2$–$HCON(CH_3)_2$ baths containing additives (except chloride), another reaction occurs (such as the electrolysis of the solvent).

It can be concluded that chloride is dissolved in $HCON(CH_3)_2$ with more difficulty than in $HCONH_2$: also, both nickel deposition and anode dissolution are more difficult in a $HCON(CH_3)_2$ bath than in a $HCONH_2$ bath.

Copper Electrodeposition: A bright and smooth copper deposit can be obtained from the $Cu(CF_3COO)_2$–$HCON(CH_3)_2$ bath only if the electrodeposition is carried out in a 20 g/l $Cu(CF_3COO)_2$ concentration at 60 °C for a 1.0 to 3.0 A/dm² current density. Under such electrolysis conditions, the anode current efficiency is about 100%, while the cathode current efficiency is about 75%.

Figure 1 shows an example of the anode and cathode current efficiencies for copper deposition from the $Cu(CF_3COO)_2$–$HCON(CH_3)_2$ bath.

The anode current efficiency was always about 100%, irrespective of the $Cu(CF_3COO)_2$ concentration and the bath temperature. On the other hand, while the cathode current efficiency was also scarcely affected

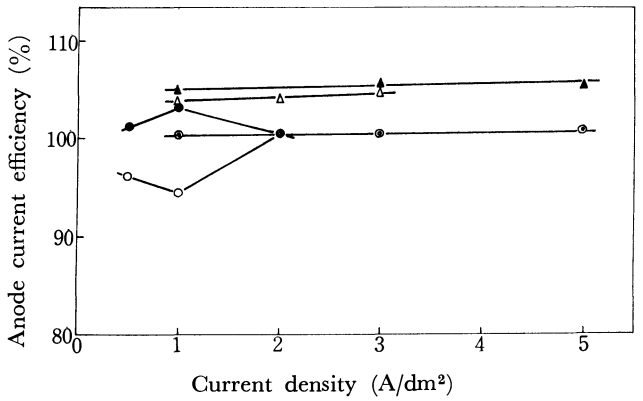

Fig. 1-1. Anode current efficiency as a function of current density for $Cu(CF_3COO)_2$-DMF bath
$Cu(CF_3COO)_2$ 20 g/l, —○—: 40 °C, —●—: 50 °C, —△—: 60 °C
$Cu(CF_3COO)_2$ 100 g/l, —◎—: 40 °C, —▲—: 60 °C

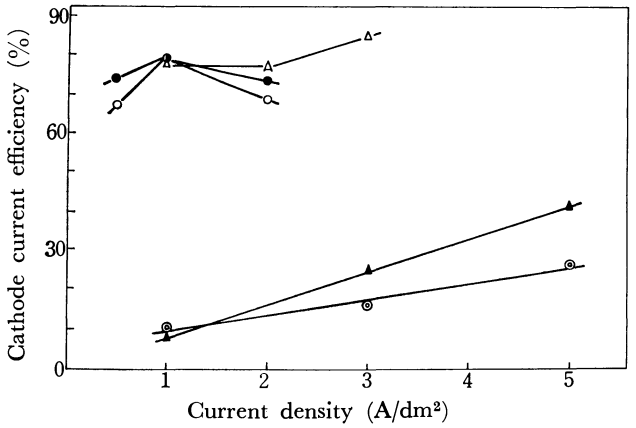

Fig. 1-2. Cathode current efficiency as a function of current density for $Cu(CF_3COO)_2$-DMF bath
$Cu(CF_3COO)_2$ 20 g/l, —○—: 40 °C, —●—: 50 °C, —△—: 60 °C, $Cu(CF_3COO)_2$ 100 g/l, —◎—: 40 °C, —▲—: 60 °C

by the bath temperature, it was decreased down to about 10% at a low current density with an increase in the $Cu(CF_3COO)_2$ concentration.

No gases evolved from the anode and cathode, but during electrolysis a yellowish-brown precipitate was produced at the cathode. Elementary analysis of this precipitate showed C: 6.89%, H: 1.56%, N: 0.88%, and Cu: 55.0%; X-ray diffraction showed that it was mainly composed of Cu_2O.

Moreover, gas chromatographic analysis of the cathode solution proved the existence of $(CF_3CO)_2O$.

Therefore, the following reaction (1) can be said to have occurred at the cathode, resulting in a decrease in the cathode current efficiency:

$$2Cu(CF_3COO)_2 + 2e^- \rightarrow Cu_2O + 2(CF_3CO)_2O + 2CF_3COO^- \quad (1)$$

In view of this fact, it seems that it is difficult for copper electrodeposition to occur from a $Cu(CF_3COO)_2$–$HCON(CH_3)_2$ bath because the copper ion forms a stable complex with $HCON(CH_3)_2$ if the $Cu(CF_3COO)_2$ concentration is high.

The present author has assumed that, if this stable copper complex were broken or if such a substance as forms a more unstable copper complex than the above-mentioned complex were added to the $HCON(CH_3)_2$ bath, it would be possible to facilitate the copper electrodeposition from the bath; the author thus tentatively added citric acid, a complexing agent, to the bath.

Fig. 2 shows an example of the influence of citric acid addition on the anode and cathode current efficiencies. The increased addition of citric acid increases the cathode current efficiency.

While the copper electrodeposition from the $Cu(CF_3COO)_2$–$HCON(CH_3)_2$ bath is difficult because of the strong bond between the copper ion and $HCON(CH_3)_2$, it appears that the addition of citric acid fa-

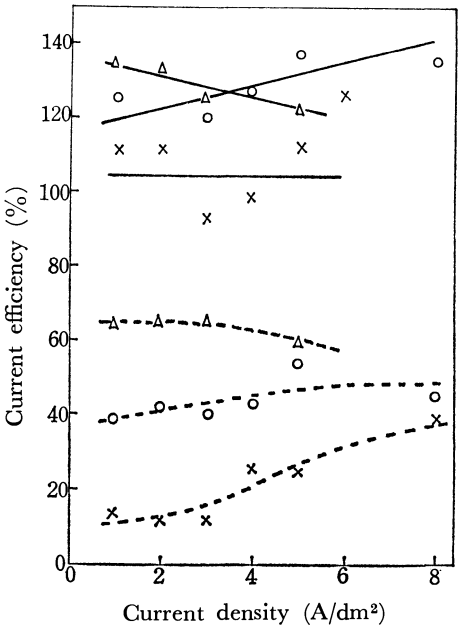

Fig. 2-1. Cathode and anode current efficiencies as a function of current density for $Cu(CF_3COO)_2$ 100 g/l-DMF-citric acid baths at 50 °C
Anode: ——, Cathode: ——,
—×—: citric acid 20 g/l,
—○—: citric acid 100 g/l,
—△—: citric acid 200 g/l

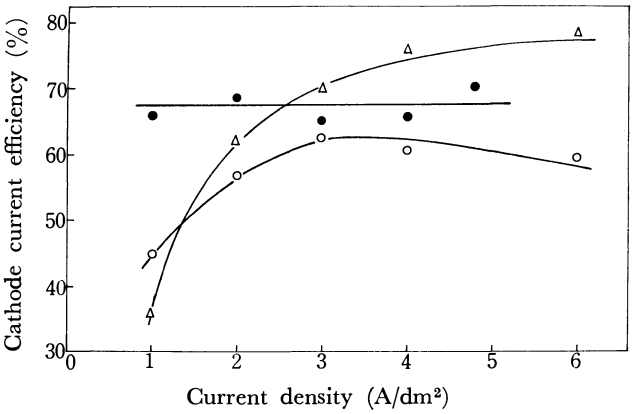

Fig. 2-2. Cathode current efficiency as a function of current density for $Cu(CF_3COO)_2$ 300 g/l-DMF-citric acid 200 g/l bath
—○—: 40 °C, —●—: 50 °C, —△—: 60 °C

cilitates the copper electrodeposition because it alters, as will be described later, the solution's property to weaken the influence of the solvent on the copper ion.

While the anode current efficiency was higher than 100% irrespective of the $Cu(CF_3COO)_2$ concentration and the bath temperature, the cathode current efficiency was affected by the $Cu(CF_3COO)_2$ concentration; it amounted to 75% in 100 to 500 g/l $Cu(CF_3COO)_2$ baths and to 85% in the bath with a $Cu(CF_3COO)_2$ concentration lower than 100 g/l at 60 °C for a high current density.

It seems that the anode current efficiency exceeds 100%, because the anode is also chemically dissolved in the bath's acid (citric acid). The evolution of hydrogen gas from the cathode lowered its current efficiency.

Figure 3 shows the range of current density within which a bright and smooth copper deposit can be obtained from a $Cu(CF_3COO)_2$–$HCON(CH_3)_2$–200 g/l citric acid bath. At each bath temperature, an increase in the $Cu(CF_3COO)_2$ concentration contributes to the tendency for good deposits to be obtained within a wider range of current densities.

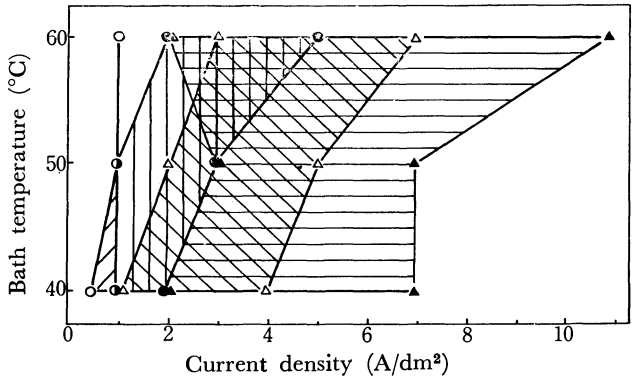

Fig. 3. The range of current density for bright and smooth copper deposit from $Cu(CF_3COO)_2$–DMF–citric acid 200 g/l bath
○: $Cu(CF_3COO)_2$ 20 g/l, ●: $Cu(CF_3COO)_2$ 100 g/l,
△: $Cu(CF_3COO)_2$ 300 g/l, ▲: $Cu(CF_3COO)_2$ 500 g/l

These ranges are remarkably wider than those in the case of the bath without citric acid and are almost equal to those in the case of the formamide bath[1] with the same $Cu(CF_3COO)_2$ concentration.

From the above-mentioned results, it is apparent that the addition of citric acid is effective on the copper electrodeposition from the $Cu(CF_3COO)_2$–$HCON(CH_3)_2$ bath, while the anode-current efficiency in the bath containing citric acid exceeds 100%. The cathode current efficiency reaches a remarkable level of 90% at 50 °C if more than 100 g/l of citric acid is added to a 20 g/l $Cu(CF_3COO)_2$ bath, and it is about 75% at 60 °C if 200 g/l of citric acid is added to a 100—500 g/l $Cu(CF_3COO)_2$ bath. Moreover at 60 °C from a 500 g/l $Cu(CF_3COO)_2$–$HCON(CH_3)_2$–200 g/l citric acid bath, a bright and smooth deposit can be obtained within a current density range of 2.0 to 11.0 A/dm².

Appearance of the Deposited Surface and the Structure of the Deposited Layer. *Nickel Deposit*: A representative nickel deposited surface is shown in Fig. 5. The deposited surfaces obtained from all the baths investigated in the present experiment consist of fine grains; those obtained from the baths containing H_2SO_4, $AlCl_3$, or hydroxylamine hydrochloride consist of very fine grains. A cracked deposited surface is obtained from the bath containing $AlCl_3$ or CCl_3COOH.

Since the deposited surfaces consist of grains, it can be assumed that the deposited layer has a granular structure.

Copper Deposit: Figure 6 shows as an example of the deposited surface and the deposited layer of the copper deposit obtained from the bath containing citric acid.

The deposited surface consists of fine grains, and the deposit becomes more compact for higher concentrations of the copper salt and at high bath temperatures. Moreover, the deposited layers have a granular structure irrespective of the bath temperature, the current density, and the $Cu(CF_3COO)_2$ concentration.

It appears that, since the copper and nickel ions form a complex in the $HCON(CH_3)_2$ bath, the ligands are adsorbed on the electrode during electrodeposition, thus suppressing any surface diffusion of the adatom; the growth in the vertical direction is thus prevented, increasing the frequency of nucleus formation, and fine grains are produced to form a granular structure.

Solubility. In 100 g of $HCON(CH_3)_2$, 180 g of $Cu(CF_3COO)_2$ were dissolved at 20 °C.

After several days, crystals were precipitated in an $Ni(CF_3COO)_2$–$HCON(CH_3)_2$ saturated solution at 20 °C.

The solubility of $HCON(CH_3)_2$ in $Cu(CF_3COO)_2$ is lower than that of $HCONH_2$.

Specific Conductance. Figure 4 shows the specific conductance of the $Cu(CF_3COO)_2$–$HCON(CH_3)_2$ bath. The specific conductance of the $Cu(CF_3COO)_2$–

(|——|: 23 μ).

$HCON(CH_3)_2$ bath was almost the same as that of the $Ni(CF_3COO)_2$–$HCON(CH_3)_2$ bath. They are both about 1/4 of those [1] of the $Cu(CF_3COO)_2$–$HCONH_2$ bath and the $Ni(CF_3COO)_2$–$HCONH_2$ bath.

It seems that more viscous $HCONH_2$ bath has a higher electrolytic conductance than the less viscous

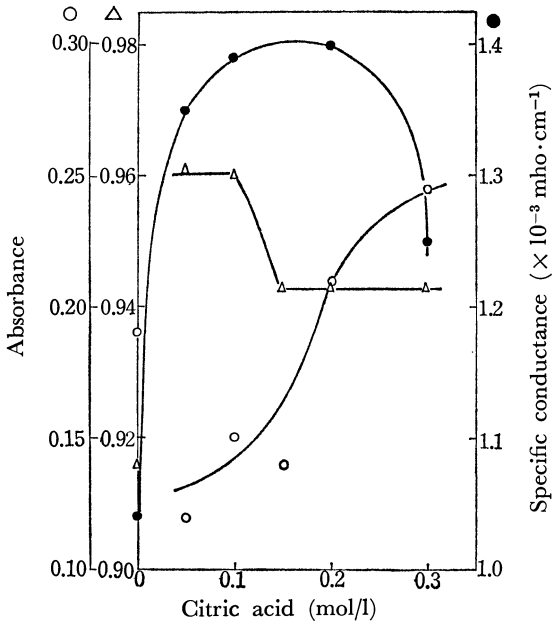

Fig. 7. The properties of $Cu(CF_3COO)_2$ 0.1 mol/l-DMF-citric acid solutions
—○—: absorbance at 1950 mμ
—△—: absorbance at 810 mμ
—●—: specific conductance at 50 °C

$HCON(CH_3)_2$ bath, mainly because the dielectric constant of $HCONH_2$, 110, is about three times that of $HCON(CH_3)_2$, 37.

$Cu(CF_3COO)_2$–$HCON(CH_3)_2$–Citric Acid Solution. Figure 7 shows the specific conductance of a 0.10 mol/l $Cu(CF_3COO)_2$–$HCON(CH_3)_2$– 0 to 0.30 mol/l citric acid bath and the absorbance of its ultraviolet absorption spectrum.

At citric acid concentrations of from 0.1 to 0.2 mol/l the conductance has its maximum, while inflexion points appear at the absorbances of 810 and 1950 mμ. It appears that these inflexion points change the condition of the solution surrounding the copper ion. The present author believes that, in the $Cu(CF_3COO)_2$–$HCON(CH_3)_2$–citric acid bath, coordination perhaps occurs in a ratio of 1 mol of $Cu(CF_3COO)_2$ to 1 mol of citric acid.

Both AC and DC polarograph of 1.0×10^{-2} mol/l $Cu(CF_3COO)_2$–$HCON(CH_3)_2$–0 to 3.0×10^{-2} mol/l citric acid baths show a reduction wave at −0.20 V *vs.* Hg A and −0.36 V *vs.* Hg B of the average half-wave potential. A wave is a clear peak in the AC polarogram, but an ill-defined wave in the DC polarogram.

The following results were obtained by AC polarography. While the wave height of A is increased with an increase in the amount of citric acid added, it becomes constant at amounts more than 2.0×10^{-2} mol/l. On the other hand, the wave height of B is constant, irrespective of the amount of citric acid added. Moreover, the wave heights of A and B coincide with each other for amounts of more than 2.0×10^{-2} mol/l.

It appears that the A wave is a reduction wave corresponding to the valency decrease of the copper–

citric acid complex from 2 to 1, while the B corresponds to the reduction of the latter to copper. Moreover, judging from the wave height, it is apparent that the addition of citric acid is effective for efficient copper electrodeposition in the $Cu(CF_3COO)_2$–$HCON(CH_3)_2$ bath and that the best amount of citric acid to be added is in a ratio of 1 mol of $Cu(CF_3COO)_2$ to more than 2 mol of citric acid rather than in a ratio of 1 mol of $Cu(CF_3COO)_2$ to 1 mol of citric acid, which corresponds to the amount of citric acid necessary for the formation of a copper-citric acid complex. This fact coincides well with the results of electrodeposition.

Activation Overvoltage of Copper Electrodeposition from the $Cu(CF_3COO)_2$–$HCON(CH_3)_2$–Citric Acid Bath. From the decay curve of the overvoltage 4 ms after the interruption of the electrolytic current, the resistance polarization was subtracted. The remainder was assumed to be the activation overvoltage. Figure 8 shows an example of the current density-activation overvoltage relation during the deposition of copper from the $Cu(CF_3COO)_2$–$HCON(CH_3)_2$–citric acid 200 g/l bath. Such ranges of current density as to make

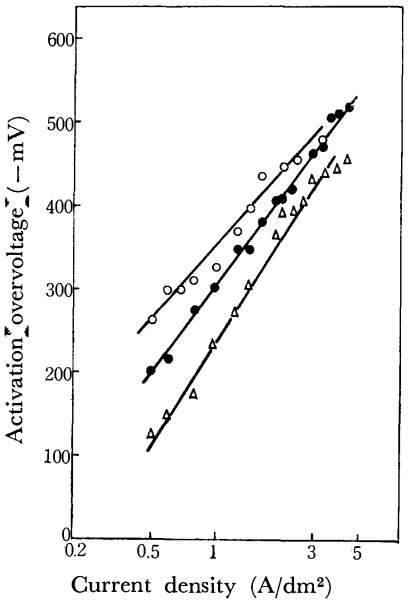

Fig. 8. Current density-activation overvoltage relation during the deposition of copper from $Cu(CF_3COO)_2$ 100 g/l–DMF–citric acid 200 g/l bath
—○—: 40 °C, —●—: 50 °C, —△—: 60 °C

the activation overvoltage, η_c, related to the logarithm of the current density, log i_c, in a direct proportionality are 1.0 to 3.0 A/dm² at a bath temperature of 40 °C, 1.0 to 3.5 A/dm² at 50 °C, and 1.0 to 4.1 A/dm² at 60 °C; it appears that in such ranges of current density Tafer's formula is valid—in other words, the charge-transfer process is rate-determining.

This η_c value is very much larger than that[1] in the $Cu(CF_3COO)_2$–$HCONH_2$ bath.

Table 2 shows the apparent exchange-current density, i_{oc}, the apparent transfer coefficient, α_c, and the apparent valency, n, for copper deposition, all obtained by a method previously described.[1]

While the obtained value of i_{oc} is higher than that[2] obtained by measuring the polarization potential with a potentiometer in a 0.1 M $CuSO_4$–$HCON(CH_3)_2$–0.1 M $NaClO_4$ bath, the former is slightly lower than that[1] obtained from the $Cu(CF_3COO)_2$–$HCONH_2$ bath.

Also, the obtained values of α_c, n and the slope of the Tafel line, b_c, are, in the average, as follows:

$$\alpha_c = 0.20,\ n = 0.960 \text{ and } b_c = -0.336 \text{ V}.$$

Within a range of current density of about 1.0 to 3.5 A/dm², the copper electrodeposition reaction from the $Cu(CF_3COO)_2$–$HCON(CH_3)_2$–200 g/l citric acid bath proceeds as in the following equations:

$$Cu^{2+} + e^- \rightarrow Cu^+ \quad (2)$$

$$Cu^+ + e^- \rightarrow Cu^0 \quad (3)$$

Moreover, it appears that Reaction (2) is rate-determining.

On the assumption of a linear relation between log i_{oc} and the reciprocal of the bath temperature, T, that is, $1/T$, the apparent activation energy, E_c of copper electrodeposition is calculated from the relation's slope; this results in values of 8.45, 8.61, and 9.10 kcal/mol E_c for the baths, the $Cu(CF_3COO)_2$ concentrations of which are 100, 150, and 200 g/l respectively.

Comparison between the Properties of a $Cu(CF_3COO)_2$–$HCONH_2$ or $Ni(CF_3COO)_2$–$HCONH_2$ Bath and a $Cu(CF_3COO)_2$–$HCON(CH_3)_2$ or $Ni(CF_3COO)_2$–$HCON(CH_3)_2$ Bath and between Copper and Nickel Electrodepositions from Those Baths. 1) While solvolysis occurs in the $HCONH_2$ bath, it does not occur in the $HCON(CH_3)_2$ bath. A complex is formed in each bath.

2) Since the bond between the metallic ion and the solvent in the $HCON(CH_3)_2$ bath is stronger than that

Table 2.

$Cu(CF_3COO)_2$ (mol/l) $\times 10^{-2}$	Bath temp. (°C)	i_{oc} (A/dm²)	α_c	$\alpha_c n$	n	b_c (−V)	Current density of linear part (A/dm²)
35	40	0.120	0.194	0.189	0.975	0.330	0.9—2.6
	50	0.170	0.201	0.179	0.890	0.360	0.9—2.8
	60	0.285	0.215	0.168	0.782	0.395	0.9—3.5
52	40	0.162	0.194	0.164	0.850	0.380	1.0—3.0
	50	0.240	0.201	0.172	0.859	0.375	1.1—3.5
	60	0.380	0.215	0.222	1.03	0.300	1.0—4.0
70	40	0.200	0.194	0.223	1.15	0.280	1.2—3.2
	50	0.320	0.201	0.214	1.07	0.300	1.2—4.0
	60	0.490	0.215	0.222	1.03	0.300	1.2—5.0

in the $HCONH_2$ bath, and since the dielectric constant of the solvent in the former is also lower than that in the latter, is difficult to electrodeposit metal and Cu_2O is formed at cathode in the $Cu(CF_3COO)_2$–$HCON(CH_3)_2$ bath.

3) The specific conductance in the $HCON(CH_3)_2$ bath is lower than that in the $HCONH_2$ bath.

4) It is possible to obtain a better copper electrodeposit over a wider range of current density in the $Cu(CF_3COO)_2$–$HCON(CH_3)_2$ bath containing citric acid than in the same bath containing no citric acid. This range almost coincides with that in the $Cu(CF_3COO)_2$–$HCONH_2$ bath.

While it is possible to obtain better nickel electrodeposit in $Ni(CF_3COO)_2$–$HCONH_2$ and $Ni(CF_3COO)_2$ $HCON(CH_3)_2$ baths containing appropriate additives, the range of current density which permits one to obtain a superior electrodeposit in the latter bath is narrower.

The electrodeposit of nickel or copper obtained from the $HCONH_2$ and $HCON(CH_3)_2$ baths has a granular structure.

5) The values of η_c, E_c, and b_c in the copper-electrodeposition reaction from the $Cu(CF_3COO)_2$–$HCON(CH_3)_2$–200 g/l citric acid bath are higher than those in the same reaction from the $Cu(CF_3COO)_2$–$HCONH_2$ bath, while the values of i_{oc} and α_c are lower, so the electrodeposition of copper from the former can be said to be more difficult. On the other hand, the value of n is always about 1 for both the baths.

The author wishes to express her deep gratitude to Professor Rimpei Kojima for his kind direction and encouragement throughout this work.

(Received July 23, 1973)

Treatments of the normal coordinate and the elastic constant were undertaken for two calcium carbonate crystals. By the use of the least-squares technique, we obtained sets of the force constants which reproduce satisfactorily both the observed vibrational frequencies and the macroscopic elastic constants. The intermolecular interactions, the elastic strains of the internal coordinates, and the nature of the splitting of the normal frequencies in these crystals were briefly discussed.

The vibrational spectra of molecular crystals and ionic crystals have been studied by many investigators. Some of them have performed normal coordinate analyses, and the force fields of many crystals have been determined. Recently more rigorous treatments of the lattice dynamics, such as those based on the rigid-ion model[2)] or on the shell model,[3)] have been made for relatively simple crystal systems mainly by physicists.[4)] Presumably the impracticability of these treatments arises in part from the difficulties in the reasonable estimation of the potential parameters. The results of these treatments are quite suggestive for the analysis of the crystal vibration in a complex crystal system, though the application of the above models to actual complex crystals is difficult at the present time.

Generally, in contrast to the treatment of isolated free molecules, many restrictions which are characteristic of the solid state make it difficult to determine the force fields from only the vibrational spectra. These restrictions are caused by the experimental limitations, the complicated crystal structures, the strong intra- or inter-molecular interactions, and so on. The short-range interaction, intramolecular or intermolecular, is considered to dominate the crystal vibration and the elastic deformation, at least in molecular crystals or in predominantly covalent crystals. Therefore, it is necessary, for the determination of the force fields in the successional models, to ascertain the fundamental short-range force fields.

The present investigations of the short-range force fields of two calcium carbonates, and of sodium nitrate and sodium nitrite in the low-temperature ferroelectric phase[1)] were undertaken not only in order to check the reasonability of the vibrational force fields, but also to determine those force fields which interpret both the observed vibrational frequencies and the elastic constants.

Methods of Calculation

Crystal Structure. According to the X-ray diffraction analyses,[5,6)] the Bravais unit cells of calcite and aragonite belong to the rhombohedral space group D_{3d}^{6}—$R\bar{3}c$, with Z=2, and the orthorhombic D_{2h}^{16}—Pmcn, with Z=4 respectively. The cell constants are a_{rh}=6.3753 Å and α=46°4.6′ in calcite and a=4.9614 Å, b=7.9671 Å, and c=5.7404 Å in aragonite. Figures 1 and 2 show the structures of calcite and aragonite respectively. The structure of calcite may be regarded as a sodium chloride arrangement

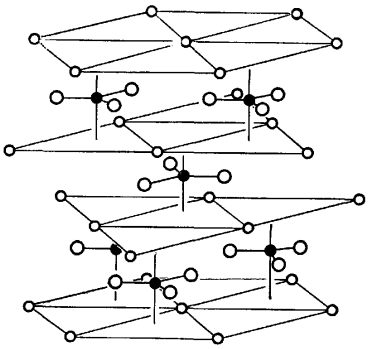

Fig. 1. Crystal structure of calcite.
●: carbon, ○: calcium, ○: oxygen.

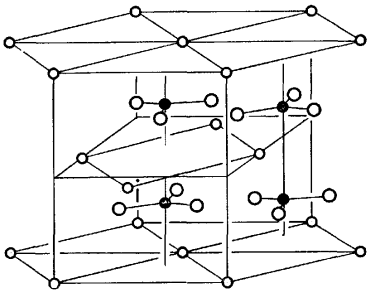

Fig. 2. Crystal structure of aragonite.
●: carbon, ○: calcium, ○: oxygen.

distorted by the introduction of disk-shaped carbonate groups. Each calcium atom is coordinated by six oxygen atoms, each belonging to a different carbonate group, and such oxygen atom is bound to two calcium atoms. On the other hand, the orthorhombic structure of aragonite is related to that of nickel arsenide. Each calcium atom is now surrounded by nine neighbors, each of which is, in its turn, bound to three calcium atoms.

Normal Coordinate Treatment. The application of the *GF*-matrix method[7)] to the analysis of optically-active crystal vibrations was reported previously by Shimanouchi, Tsuboi, and Miyazawa.[8)] The modified Urey-Bradley force field[9)] was applied to the intramolecular vibrations in carbonate groups, the correction terms of which were the bond interaction term, p, for the adjacent C–O bond pairs and the angle interaction term, n, for the adjacent O–C–O angle pairs in a single carbonate group. On the other hand, the central force field, which is based on the two-body interaction, was used for the intermolecular vibrations.

----, calcium···carbon; ———, calcium···oxygen; ————————, oxygen···oxygen.

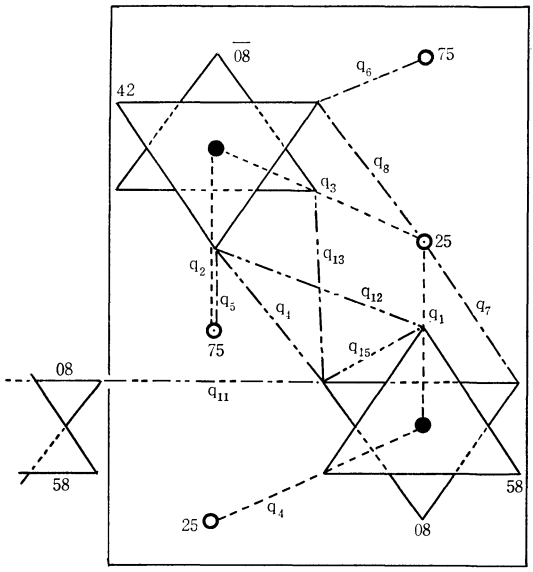

Fig. 4. Short-range interactions in aragonite viewed along the z axis. Other descriptions are the same to Fig. 3.

In this study, only those pairs that lie within 3.5 Å were taken into consideration. As is illustrated in Figs. 3 and 4, there are six different kinds of these pairs in calcite and fifteen in aragonite respectively. The corresponding atomic separations are also listed in Table 3.

In many cases, group theoretical considerations, such as the site-group analysis[10] or the factor-group analysis,[11] have been found to be useful for the analysis of crystal vibrations. The factor-group analysis of these crystals was once performed by Bhagavantam and Venkatarayudu;[11] their results are summarized in Tables 1 and 2. It is obvious from these tables that, of the twenty-seven degrees of freedom for genuine vibrations eight modes are infrared-active, and five, Raman-active, in calcite, and that, of the fifty-seven degrees, twenty-seven are infrared-active, and thirty, Raman-active, in aragonite. The selection rules for the optically-active vibrations are followed under the mutual exclusion rule, since each crystal has a center of symmetry.

a) Unit of distances is in Å. b) Fixed force constants.
c) Units of n and α are in mdyn·Å.

Treatment of the Elastic Constant. When a crystal is subjected to homogeneous deformation, the elastic constant of the crystal can be calculated in accordance with the method established by Shiro.[12] The course of the calculation is outlined below. In the first place, by the use of the resulting matrices of the preceding section, *i.e.*, $\boldsymbol{F}_0^{\mathrm{R}}$ and $\boldsymbol{B}_\rho$, and of the external strain matrix, $\boldsymbol{D}$, the (6×6) elastic constant matrix is derived as:

$$\boldsymbol{C}=1/v\tilde{\boldsymbol{H}}\boldsymbol{F}_0^{\mathrm{R}}\boldsymbol{H}, \tag{1}$$

where a tilde denotes a transposed matrix, where v is the unit cell volume, and where

$$\boldsymbol{H}=(\boldsymbol{E}-\boldsymbol{B}_\rho(\tilde{\boldsymbol{B}}_\rho\boldsymbol{F}_0^{\mathrm{R}}\boldsymbol{B}_\rho)^{-1}\tilde{\boldsymbol{B}}_\rho\boldsymbol{F}_0^{\mathrm{R}})\boldsymbol{D}. \tag{2}$$

The Jacobian matrix with respect to the elastic constant, $(\partial C_i/\partial K_h)$, and the contribution of the h-thp otential term to the i-th elastic constant, $(PED)_{ih}$, are also given:

$$J_{ih}^{\mathrm{E}}=(\partial C_i/\partial K_h)=1/v(\tilde{\boldsymbol{H}}\boldsymbol{A}_h\boldsymbol{H})_{ii}, \tag{3}$$

$$(\mathrm{PED})_{ih}=J_{ih}^{\mathrm{E}}K_h/C_i, \tag{4}$$

respectively, where $\boldsymbol{A}_h$ is the coefficient matrix of the k-th term in the potential energy matrix. Furthermore, the change in the internal coordinates due to the elastic stress, $\Delta\boldsymbol{S}$ is calculated as:

$$\Delta\boldsymbol{R}_0=\boldsymbol{H}\boldsymbol{C}^{-1}\Delta\boldsymbol{S}. \tag{5}$$

The change, $\Delta\boldsymbol{R}_0$, is found to be useful for the analysis of the elastic strains.

Refinement of the Force Constant. The Jacobians with respect to the optically-active vibrations, $\boldsymbol{J}^\lambda$, and to the elastic constants, $\boldsymbol{J}^{\mathrm{E}}$, are derived independently from the treatments of the preceding sections. The force constants of the force fields were refined by the least-squares method:

$$\Delta\boldsymbol{K}=(\tilde{\boldsymbol{J}}^\lambda\boldsymbol{W}_\lambda\boldsymbol{J}^\lambda+\tilde{\boldsymbol{J}}^{\mathrm{E}}\boldsymbol{W}_{\mathrm{E}}\boldsymbol{J}^{\mathrm{E}})^{-1}\times(\tilde{\boldsymbol{J}}^\lambda\boldsymbol{W}_\lambda\Delta\lambda+\tilde{\boldsymbol{J}}^{\mathrm{E}}\boldsymbol{W}_{\mathrm{E}}\Delta\boldsymbol{C}), \tag{6}$$

where $\boldsymbol{W}^\lambda$ and $\boldsymbol{W}^{\mathrm{E}}$ are diagonal weight matrices for the observed vibrational frequencies and elastic constants respectively, where $\Delta\lambda$ is a deviation column matrix of the calculated frequencies from the corresponding observed ones, and where $\Delta\boldsymbol{C}$ is that of the elastic constants.

Results and Discussion

Optically-active Vibrations. The vibrational spectra of calcite and aragonite have been reported by several authors.[13–19] However, it seems likely that the observed resonance frequencies will deviate slightly from the corresponding eigenfrequencies[20] when one come to think of the ionic properties of the two crystals. In our normal coordinate treatments, we postulated an equilibrium crystal field, *i.e.*, any dynamical effects are frozen out, since only the short-range interactions were taken into consideration. Consequently, the eigenfrequencies in the idealized equilibrium field should generally deviate from those in the actual dynamical lattices. We have, however, regarded the observed resonance frequencies as the eigenfrequencies without any correction, because the appropriate estimation of the shifts is impracticable, especially for a complex crystal system. Provided that the shifts are brought about through interactions among the vibrating dipoles, the observed frequencies of the g-symmetric vibrations are found to be approximately equal to those in the equilibrium crystal field.[21] Therefore, we have given some priority to the g-symmetric vibrations over the u-symmetric ones in the course of the refinement of the force constants in calcite.

Ramdas'[13] and Tsuboi's data[14] were adopted as the observed frequencies for the intramolecular vibrations of the carbonate groups and for the (intermolecular) lattice vibrations respectively. In the case of aragonite, though few data are available, Couture's data,[13] which were obtained from the depolarization study of Raman scattering, are noteworthy. Hence, only Couture's data were taken as the observed data, the remaining data[16–19] other than Couture's amounted to no more than supplimentary references.

Intramolecular Vibration of the Carbonate Groups: Carbonate groups in calcite occupy a site, the symmetry of which is D_3, while it is C_s in aragonite. Because of the lowering of the site symmetry, more numbers of the optically-active frequencies are to be observed in aragonite than in calcite. The intramolecular vibrations in these crystals may, in principle, be explained in terms of the force field of an isolated free carbonate group, since the observed intramolecular frequencies of these crystals show much similarity. The results on force constants are shown in Table 3. The observed and calculated frequencies in calcite and aragonite are also compared in Tables 4 and 5 respectively. It

a) See Ref. 15. b) See Ref. 11.

is obvious from these tables that the large splittings of the frequencies between g-symmetric and u-symmetric C–O stretching vibrations cannot be explained on the basis of the short-range interaction model. Not only the coupling of the motion of the carbonate groups, but also the interaction between the vibrating dipoles would cause these large splittings. These consideration have been made by Haas and Ketelaar,[21] Decius,[22] and Ishigame *et al.*[23] Their results are quite suggestive, but they give only qualitative explanations for complicated crystal systems. These models will actually be applied in our subsequent papers.

For the observed Raman frequency shifts at 1415 cm^{-1} and around 1460 cm^{-1} in aragonite, there are two ways of interpretation. Krishnan[16] regarded only the shift at 1463 cm^{-1} as the fundamental band and assigned the shift at 1415 cm^{-1} to the overtone band of the fundamental band at 707 cm^{-1} on the basis of his second-order Raman scattering study. On the other hand, Krishnamurti[17] considered all these shifts to be fundamental bands. In this study, we have regarded the shift at 1415 cm^{-1} as the fundamental band, with reference to the spectra of carbonate or nitrate crystals.

Lattice Vibration: Normal coordinate treatments of calcite have been performed by Venkateswarlu and Ramaswamy,[24] Tsuboi,[14] Shiro,[25] and Plihal and Schaack;[26] however, no treatment of aragonite has been reported. Though only the short-range interactions were taken into consideration in both Tsuboi's[14] and Shiro's[25] treatments, their results are satisfactory for at least the factor-group vibrations. Assuming an idealized simpler unit cell which contains only four ions, Plihal and Schaack[26] took the long-range Coulomb interaction of vibrating dipoles and the influence of the electronic polarizability of the component ions as well as the short-range interaction; thus they explained fairly well the observed TO–LO splittings of the optically-active lattice vibrations in the calcite-form crystals. A detailed analysis based on the rigid ion model is now in progress; the results will be published in time.

Therefore, we have determined the short-range fields, which reproduce both the observed vibrational frequencies and the elastic constants, and have also improved the previous treatment.[25] Tables 4 and 5 show the observed and calculated frequencies and the tentative assignments of the observed fundamental bands. The contributions of all the potential terms to the calculated vibrational frequencies are also given in Tables 6 and 7. The results of the calculation imply that certain lattice modes in the same symmetry species are fairly well coupled with each other, but that the couplings between an intramolecular mode and lattice modes are negligibly smal, except for the out-of-plane angle deformation modes in carbonate groups. As is shown in Tables 4 and 5, the calculated frequencies of aragonite agree less well with the observed ones than that of calcite, particularly in the B_{2g} and B_{3u} symmetric vibrations. Our resulting force field for calcite is substantially that obtained by Tsuboi.[14] The interatomic force constants will be discussed briefly in a later section.

Elastic Constants. The elastic constants of these crystals have previously been determined [27,28] and tabulated in the "Landolt-Börnstein Phys. Chem. Tables."[29] However, only a few attempts at theoretical calculation have yet been reported. For example, calculations of the two particular constants were performed by Oke[30,31] on the basis of the electrostatic theory of crystal lattices. We have ourselves calculated the elastic constants by the method described above; the calculated elastic constants are compared

Notations are the same to Tables 3 and 8.

with the observed ones in Table 8. It is obvious from these results that a good agreement was obtained for calcite, while only a rough fit was obtained for aragonite. Particularly, the agreement of the elastic constants related to the shear strains, *i.e.*, C_{44}, C_{55}, and C_{66}, is relatively poor in aragonite because of the lack of effective oblique interaction terms compared with those in calcite. The contributions of all the potential terms to the calculated elastic constants are also listed in Table 9. This table shows that the elastic constants have a strong dependence on the following potential terms; f_1, f_2, f_4, and f_5 in calcite, and f_2, f_6, f_8, f_{13}, f_{14}, and f_{15} in aragonite. It is likely that these contributions are partly dependent on the spatial orientation of the internal coordinates. These contributions are considered to be independent of those to the vibrational frequencies, as is shown in Tables 6 and 7; therefore the determination of the interatomic force constants becomes more meaningful.

Interatomic Force Constants. The resulting interatomic force constants are plotted as functions of the interatomic distance in Fig. 5. As this figure illustrates, three steep curves can be drawn through the points of the same pairs, and the distances of their burst upbreaks approximately correspond to the sums of the van der Waals radii or of the Pauling's ionic radii[32] of the constituent atoms, as shown in Fig. 5: $R_{Ca}+R_O=2.39$ Å, $R_{Ca}+R_C=2.69$ Å, and $2R_O=2.80$ Å. Since these interatomic interaction force constants should be derived from the appropriate interatomic potentials, we began to estimate them with simple Lennard-Jones 6-9 type potentials[33] determined for some purely ionic crystals and noble gas crystals; however, we thus obtained unreasonable results except

for a few cases. We inevitably chose several trial sets of them which reproduced the observed values as well as possible, and then refined by the least-squares method.[12] As is shown in Fig. 5, some plots were found to deviate from the corresponding curves. This must mainly be because of the uncertainty of the experimental frequencies and/or elastic constants, and the incompleteness of the force fields. The former is considered to have an appreciable influence on the force constants in aragonite, while both the observed frequencies and elastic constants were found to be fairly reliable in calcite. The results listed in Tables 6 and 9 suggest that the force constant, f_1, of calcite contributes particularly to certain lattice modes and to all the elastic constants except C_{33}. If this force constant is reduced to the value on the curve, less agreement will be obtained. Therefore, the large deviation of the closed triangle must arise mainly from the incompleteness of the force field. The incompleteness of the force field can be improved by the rigid ion treatment or by the polarizable ion treatment; these treatments are now in progress. As to the open circles in Fig. 5, f_{11} was found to contribute in particular to C_{11} (see Table 9), and f_{12}, to almost all the lattice modes in aragonite. Therefore, the incompleteness must exert an appreciable influence on the force constants, above all, the force constants which are closely related to the lattice vibrations in aragonite.

The force constants obtained would be useful as the initial values of the force constants in the normal coordinate treatments of similar crystals, though it is meaningless to discuss certain fundamental properties of the solid state on the basis of only these data.

Analysis of Elastic Strain. Table 10 shows the change in the internal coordinates due to unit elastic stress in calcite. We can see from this table that the q_5 coordinate is sensitive to the S_{xx} applied stress, the q_3, q_5, and q_6 coordinates, to the S_{zz} stress, and the q_3, q_4, and q_5 coordinates, to the S_{yz} stress. The internal coordinates of calcite, therefore, can be changed by the applied stress along the direction z. For aragonite, Table 11 suggests that the q_4, q_6, q_{14}, and q_{15} coordinates a strong dependence on the appropriate stresses. As well as in calcite, it seems that calcium atoms in aragonite would be easy to displace in the directions to the adjacent carbonate groups, and that the carbonate would be susceptible to certain deformations along the

(Received August 2, 1973)

Tetraarylallyl-type radicals are stable radicals. In these series, TPA is obtained as radical crystals. However, BDA, BDAA and DDA are obtained as diamagnetic dimerized substances. These are partially dissociated in solution. These can be detected in solution by ESR and optical spectra measurements of these radicals about the equilibrium between the radical monomer and its dimer. The equilibrium constants and the energy of the formation of the dimer are thus determined. The order of the magnitudes of the dimer's formation energies can be explained in terms of the frontier electron densities of the bond-forming positions of radicals.

In a previous paper,[1] hereafter referred as I, we reported that abnormal hyperfine splittings in the ESR spectra of tetraarylallyl-type radicals had been observed, and that the splitting can be explained on the basis of the "twisted allyl" model. Another feature of the tetraarylallyl-type radicals is the existence of an equilibrium between the radical monomer and its diamagnetic dimer in solution.[2-4] $\alpha,\alpha,\gamma,\gamma$-Tetraphenylallyl(TPA) is a stable radical in solution and is also obtained as pure radical crystals.

However, $\alpha,\alpha,\gamma,\gamma$-bisdiphenyleneallyl(BDA), $\alpha,\alpha,\gamma,\gamma$-bisdiphenylene-$\beta$-azoallyl(BDAA), and α,α-diphenyl-γ,γ-diphenyleneallyl(DDA)(Fig. 1) are partially dimerized in solution, as is triphenylmethyl. These substances can be detected in solution by ESR and optical spectra measurements of these radicals about the equilibrium between the radical monomer and its dimer, carried out at various temperatures. The equilibrium constants and the enthalpy of the formation of the dimer are determined. In the following section, some factors for stabilizing the radical will be considered.

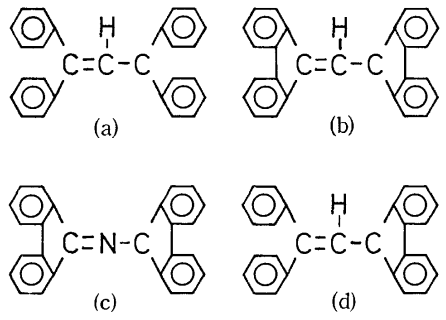

Fig. 1. Tetraarylallyl-type radicals.
(a) TPA (b) BDA (c) BDAA (d) DDA

As is shown in Fig. 1, these radicals resemble one another closely in structure. However, BDA has no degree of free rotation of the four phenyl rings attached to the α and the γ carbons after the partially-hindered DDA, by comparison with the TPA radical which has the degree of free rotation of the four phenyl rings. A comparison of the structures of BDA and DDA shows that DDA has more steric hindrance of phenyl groups than that of BDA. On the other hand, BDAA is an azoallyl which is replaced by a nitrogen at the β-position of the allyl group of BDA. By a comparison of BDA and BDAA, which have the same structures, one can ascertain the influence of the distribution of electron densities. These differences reflect the relative factor of the radical stabilities, which will be discussed in the following section.

Experimental

The samples were prepared following the processes described in Refs. 2, 3, 4 and 5. Their physical constants and the results of the elemental analyses are shown in Table 1.

Table 1. Physical constants and elemental analyses

	Mp[a] (°C)	Obsd / Calcd	C	H	N

	235—237[4]	Calcd	94.42	5.58	

a) Melting points are not corrected.

For the observation of the ESR spectra in solution, the solvents were well purified, dehydrated, and degassed by the usual methods.[6] The ESR signal intensity (I) was measured at various temperatures in the usual way (amplitude of magnetic field modulation: 8 G). The logarithm of the intensity (I) *vs.* the reciprocal of the temperature(T) plot gives directly the association energy of the two radical monomers to the dimer (Fig. 2). Mn^{2+} in MgO was used as the standard for the ESR signal intensity. All the ESR measurements were carried out with an X-band ESR spectrometer, JES-ME3, equipped with a 100 KHz field modulation, while the integration of the signal intensity was carried out by the use of a spectrum computer, EC-5, of the JEOL. Co.

The optical spectra were also measured at various temperatures and at several concentrations with an evacuated quartz cell with a path length of 1 cm, using a MPS-50-type spectrophotometer of the Shimadzu Co. The solvents used were treated in the afore-mentioned way.

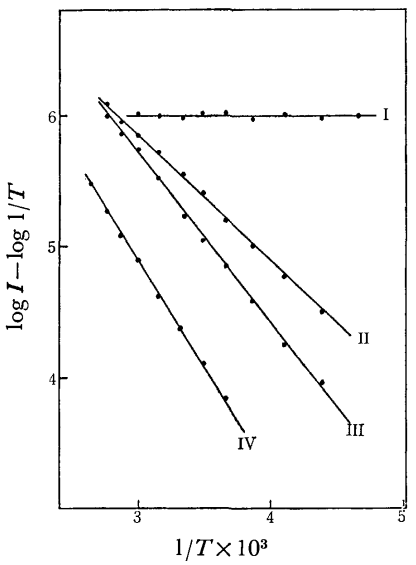

Fig. 2. Temperature dependence of integrated ESR signal intensity (I) TPA (II) BDAA (III) BDA (IV) DDA.

Results and Discussion

The ESR hyperfine structures of TPA, BDA, and BDAA have been reported elsewhere.[1] The ESR hyperfine spectrum of DDA observed in a diluted benzene solution at 60 °C is shown in Fig. 3 with the spectrum reconstructed by the ESR-spectrum computer using the hyperfine coupling constants given in Table 2. Those of the other radicals are also tabulated in Table 2. The values of A_β^H reflect the degree of twisting of the allyl skeleton, because the value of A_β^H is represented by the function of a twisted angle around the bond-axis and the spin densities on the carbons of the allyl skeleton.[1] Furthermore, the fact that the values of the twisted angles around the bond-axis of each allyl skeleton tabulated in Table 2 are in order of BDA→DDA→TPA can be well understood by a comparison with the molecular structure of each.

Now, in order to compare the relative stability among these radicals, each association energy from the two radical monomer to a dimer was determined by measuring the ESR and optical spectra at various temperatures. The equilibrium between a radical monomer (S·) and a dimer (S-S) can be quantitatively explained by the following equations:[9]

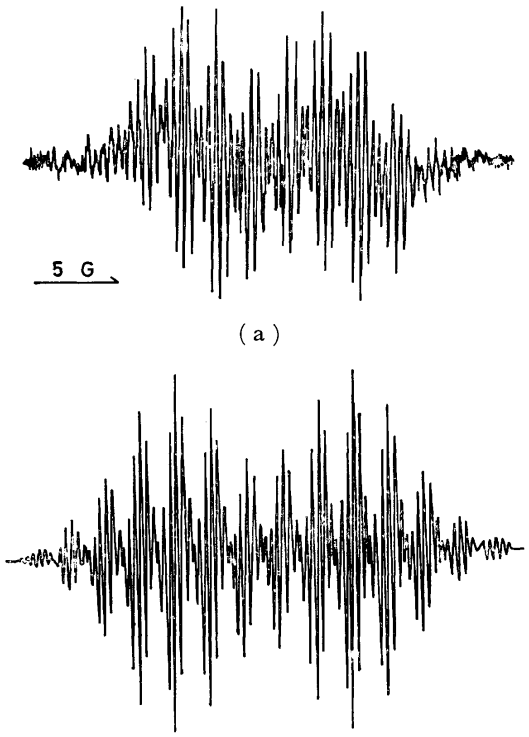

Fig. 3. ESR spectrum of DDA.
(a) Observed spectrum (b) Calculated spectrum

$$2S\cdot \rightleftharpoons S\text{-}S$$
$$K = [S\text{-}S]/[S\cdot]^2, \quad (1)$$

where K is the equilibrium constant expressed by;

$$K = A\exp(-\Delta H/RT), \quad (2)$$

A: proportionality constant
ΔH: association energy
R: gas constant
T: temperature

Hence,

$$\ln K = (-\Delta H/R)(1/T) + \ln A. \quad (3)$$

On the other hand, the intensity of the ESR signal (I) is simply expressed as a function of the radical concentration divided by the temperature, provided that I follows the Curie law in a dilute solution; thus,

$$I = B(1/T)[S\cdot], \quad (4)$$

where B is a proportionality constant. From Eqs. (1)

Table 2. Hyperfine coupling constants of tetraarylallyl-type radicals (in G) and twisted angle of allyl group

	A_β	A_1^H	A_2^H	A_3^H	A_4^H	A_5^H	A_6^H	A_7^H	Twisted angle of allyl group
TPA	8.90[a]	1.95	1.30	0.65					≃26°
BDA	13.4[a]	1.99	1.99	0.46	0.1>				≃37°
(Ref. 7)	13.2[a]	1.92	1.86	0.48	0.36				
(Ref. 8)	13.2[a]	1.89	1.89	0.42	0.06				
BDAA	3.38[b]	1.69	1.69	0.30	0.14				
DDA	9.57[a]	2.45	2.45	2.45	2.45	0.46	0.1>	0.1>	≃32°

a) A_β^H. b) A_β^N.

and (2),

$$I = B(1/T)([\text{S-S}]/K)^{1/2}$$
$$= B(1/T)\{[\text{S-S}]/(A\exp(-\Delta H/RT))\}^{1/2}, \quad (5)$$

Hence,

$$\ln I = 1/2(\Delta H/R)(1/T) + \ln(1/T) + \ln B + 1/2\ln[\text{S-S}] - 1/2\ln A. \quad (6)$$

In the limiting case of a low concentration of the radical monomer, the equilibrium lies so much to the side of the dimer that we finally have:

$$\ln I - \ln(1/T) = 1/2(\Delta H/R)(1/T) + C, \quad (7)$$

where C is a constant which involves $\ln B$, $\ln A$, and $\ln[\text{S-S}]$. The slopes of $\log K$ *vs.* $1/T$(Fig. 4) and $\log I$ *vs.* $1/T$(Fig. 2) enable us to calculate the values of the association energy.

The optical spectra of BDA and BDAA are shown in Figs. 5 and 6, the maximum absorptions being $\lambda_1=750$, $\lambda_2=488(\varepsilon_{max}=2119)$, $\lambda_3=422$ and $\lambda_1=775$, $\lambda_2=466(\varepsilon_{max}=2560)$, $\lambda_3=435$, $\lambda_4=404$, respectively. It may be seen in Figs. 5a(488 nm and 335 nm) and 6a(466 nm and 325 nm) that these dimers dissociate

completely into monomers in the concentration of 10^{-6} M. at 20 °C. In this concentration, then, the spectra do not show the temperature dependence explicitly. From the radical concentration obtained from the ε_{max}, the equilibrium constants, K, can be enumerated at each temperature. Log I *vs.* $1/T$ and log K *vs.* $1/T$ are shown in Figs. 2 and 4 respectively, while the association energies thus obtained are tabulated in Table 3. Table 3 shows that TPA is very stable as a radical molecule and that the two values determined by different measuring methods coincide fairly well. Thus, the approximate equations, (3) and (7), have been shown to be correct.

Table 3. Association energy from radicals to dimer (kcal/mol)

	From ESR	From optical spectra
TPA	$\simeq 0$	
BDA	11.9	12.6
(Ref. 2)		($\simeq 13$)
BDAA	8.7	9.2
DDA	14.7	

On the other hand, the reactivity from the radicals to the dimer may be explained by the "frontier electron" theory,[10] where the frontier electron density plays an important role. The frontier electron density of a neutral radical is approximately equal to its odd-electron density. Thus, the odd-electron density in each radical will reflect directly the reactivities of the radicals.

On the other dimerizable radicals, such as triphenylmethyl and phenoxyl, their bond formations do not all occur at the same position. For example, two triphenylmethyls form a bond between the center carbon of one radical and the *para*-position of one phenyl group of the other radical.[11] Of these tetraarylallyl-type radicals, TPA itself is not dimerized, but BDA, BDAA, and DDA are dimerized. According to the IR spectra of these dimerized substances, the bond formation of these dimerized radicals must occur at the α or the γ position of the allyl group.[12]

Table 4 shows the values of the frontier electron densities on the allyl group of each radical, as calculated by the McLachlan method on the basis of the "twisted allyl" model.[1] As has been mentioned above, TPA has never been dimerized in spite of possessing the largest frontier electron density on the possible position of the bond formation in this radical. This fact can be considered as showing that two TPA radicals are difficult of access to each other because of the steric hindrance of the four phenyl rings on the α or the γ position of the allyl group.

On the other hand, since two phenyl groups at one or both ends of the allyl group in DDA, BDA, and BDAA are fixed to each other, these radicals can approach each other and be dimerized in such a manner as to form a bond at the positions with the largest frontier electron densities in the radical molecules. From the values of these densities of the bond-forming position, which are the α or the γ carbon atoms of the allyl groups, one can expect that DDA associates more easily to form a dimer than do BDA and BDAA. This expectation shows a good parallelism to the results of Figs. 2 and 4.

Table 4. Frontier electron densities on allyl group

	α	β	γ	$(\alpha+\gamma)/2$
TPA[a]	+0.318	−0.097	+0.318	+0.318
BDA[b]	+0.260	−0.086	+0.260	+0.260
BDAA[b]	+0.253	−0.051	+0.253	+0.253
DDA[c]	+0.285	−0.067	+0.270	+0.277

a) Each phenyl group is rotated by 30° as that of triphenylmethyl and allyl group is also twisted by 26°. b) Allyl group is twisted by 37°. c) Diphenyl fitt to α position, Phenyl groups are rotated as TPA and allyl group is twisted by 32°.

In general, the stabilization of the radical is mainly affected by the following two factors: the magnitude of the delocalization of an odd-electron, and the magnitude of the steric repulsion around the bond-forming position in the radical molecular frame. For the case of TPA, the latter is the predominant factor, and it is well known to be the predominant factor in the association of the triphenylmethyl derivatives.[13] In the other tetraarylallyl-type radicals, however, the former must be the dominant factor, because the magnitude of the steric repulsion of DDA may be larger than those of BDA and BDAA, judging from the molecular structure of each radical.

On the other hand, the molecular structures of BDA and BDAA are similar except that either a carbon atom or a nitrogen atom occupies the β-position of the allyl group. Then, one may assume that this difference in the occupied atom will not affect the magnitude of steric repulsion, but the magnitude of the delocalization of the odd-electron. In fact, the difference in the magnitudes of the association energy of BDA and of BDAA may be found in Table 3.

It can be concluded that the TPA radical is the most stable radical in these series, since no indication of dimerization has so far been experimentally observed for this radical.

The authors wish to thank Professor Kazuhiko Ishizu, Mr. Osamu Takizawa, and their collaborators for their helpful discussions. They are also indebted to Professors Hideo Takaki and Toshio Takada for their encouragement during this work.

The Fractionation of Tritiated Water in an Equilibrium between Organic Hydrates and Their Aqueous Solutions

Haruhiko TANAKA*, Tsutomu KADO, and Hisao NEGITA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received August 6, 1973)

The fractionation of the tritiated water (HTO) was examined during the crystallization of hydrates, such as $(COOH)_2\cdot 2H_2O$, $(COOK)_2\cdot H_2O$, $Cu(HCOO)_2\cdot 4H_2O$, and $Sr(HCOO)_2\cdot 2H_2O$. The dilution of HTO in the organic salts was found to be comparable to that in inorganic salts observed previously. The fractionation of HTO was explained on the basis of an ionic process in an aqueous solution, and the crystal growth mechanism, in a way similar to that described in a previous paper. On the contrary, a considerable dilution was observed for oxalic acid dihydrate. The proton effect on the fractionation in both the ionic and dehydration processes was also discussed.

It has been reported by many workers that the fractionation of deuterated water occurs during the crystallization of various hydrated inorganic salts from aqueous solutions.[1] A similar fractionation of tritiated water (HTO) has been investigated for a number of metal sulfates[2,3] and chlorides[4] by the present authors. It has been found that a dilution of HTO of a few percent occurs in the water of crystallization of these inorganic salts. From these studies, some information has been derived concerning the kinetics of the deposition of the hydration water on the crystal from an aqueous solution.

In order to study the dilution in a more systematic way, it seems worthwhile to determine the separation factor, S, of metal organic salts and to compare it with those of inorganic salts. For this purpose, copper formate tetrahydrate and strontium formate dihydrate have been examined. It may also be quite interesting to examine the fractionation in an organic acid hydrate, *e.g.*, oxalic acid dihydrate, since the acid contains hydrogen atoms besides those of the hydration water. For the estimation of the proton effect in the carboxyl groups on the fractionation, the S value for the hydration water in the metal salt of the acid can properly be used. Potassium oxalate monohydrate has been chosen as the salt in the present study.

Experimental

Strontium formate was prepared by adding strontium carbonate to formic acid. The other samples were obtained from a commercial source and purified by recrystallization. The solvent consisted of twice-distilled water containing a trace of tritiated water (HTO). A large well-developed single crystal of the hydrate was grown from a very slightly supersaturated solution by lowering the temperature gradually within a narrow range. The temperature ranges were 32.5—29.0 °C, 33.0—32.1 °C, 36.3—34.3 °C, and 29.8—28.8 °C for $Sr(HCOO)_2\cdot 2H_2O$, $Cu(HCOO)_2\cdot 4H_2O$, $(COOK)_2\cdot H_2O$, and $(COOH)_2\cdot 2H_2O$ respectively.

Water from both the mother liquid and the hydration water of the single crystal was recovered by dehydrating them *in vacuo* at 45 °C. The β-activity of the dehydrated water was measured with a liquid scintillation counter, a Packard Model 2002 Tri-Carb Scintillation Spectrometer. Besides, the activity due to the tritium in the dihydrate was directly measured by dissolving it in a scintillant in the case of the oxalic acid dihydrate, $(COOH)_2\cdot 2H_2O$. As a scintillant we used a solution composed of toluene, ethylene glycol monomethyl ether, 2,5-diphenyloxazole (PPO), and 1,4-bis-2′-(5′-phenyloxazolyl)benzene (POPOP).

Results and Discussion

The separation factor, S, of HTO for the crystallization of a hydrated salt from an aqueous solution can be given as $S=N_s/N_l$, where N_s and N_l are the mole fractions of HTO in the solid and liquid phases respectively. Table 1 shows the observed fractionation of HTO, together with the average net cpm for 0.1 g of water, which is proportional to the fraction of HTO. We see in copper formate tetrahydrate a very slight dilution of HTO and no practical fractionation, whereas appreciable dilutions are found in the other hydrates, particularly in the oxalic acid dihydrate.

Table 1. The separation factor, S, of HTO for organic hydrates

Crystal	Net cpm of HTO[a]		$S(N_s/N_l)$
	N_s	N_l	
$Sr(HCOO)_2\cdot 2H_2O$	22248±168	23329±157	0.954±0.010
$Cu(HCOO)_2\cdot 4H_2O$	21570±83	21640±91	0.997±0.006
$(COOK)_2\cdot H_2O$	20326±125	20837±92	0.976±0.007
$(COOH)_2\cdot 2H_2O$	25324±152	29278±177	0.865±0.007

a) Averaged for 6—8 measurements with a counter of 35% efficiency.

The HTO Fractionation in the Water of Crystallization. It has been reported that HTO is diluted in the water of crystallization during the crystal growth from a solution if a surface-diffusion mechanism in which the growth unit diffuses over a wide range of the crystal surface before integrating into the kink controls the crystal growth.[2] The R_{HTO}/R_{H_2O} ratio has been approximately derived for the free water on the crystal growth of a hydrated salt *via* surface diffusion:

$$R_{HTO}/R_{H_2O} = (m_{H_2O}/m_{HTO})^{1/2}=0.949, \quad (1)$$

where R_{HTO}/R_{H_2O} is the ratio of integration of HTO into the crystal to that of H_2O and where m_{H_2O}/m_{HTO}

* Present address; Shinonome Branch School, Faculty of Education, Hiroshima University, Shinonome, Hiroshima 734.

is the molecular weight ratio of H_2O to HTO. It can be assumed that minimum S value becomes *ca.* 0.95 when the free water integrates into the crystal from the solution.

In the hydration water of cations in the solution, the fractionation of HTO from the bulk water, if any, has been disregarded in a previous work.[4] Although such a simplification can be justified in the cases of Na^+ and K^+, which exert weak hydration, it may not be justified in the cases of most of the other cations.[5] It seems that HTO should be slightly enriched in the hydration water if the hydration water is held more rigidly in the sphere than in the solvent water itself, as can be seen from the theory of the isotope effect in the exchange reaction.[5,6] Such an ion is frequently referred to as a structure-former. As for the anion, the hydration water can be assumed to exert no considerable effect on the fractionation in the present case. Accordingly, it can be suggested that the more free water molecules and the less hydration water molecules of a structure-former ion there are, in the solution, the more dilution of HTO in the crystal hydrates should result.

In the case of $Sr(HCOO)_2 \cdot 2H_2O$, the hydration water of a Sr^{2+} ion in the solution is taken to become free in order to be integrated into the crystal,[4] since the lifetime of the hydrated cation is extremely short.[7] It can thus be expected that a considerable dilution of HTO occurs for the salt, *i.e.*, the S value becomes close to 0.95.

As for $Cu(HCOO)_2 \cdot 4H_2O$, half of the hydration water of a Cu^{2+} ion in the solution can be assumed to become free to be integrated, because half of the water of crystallization is not coordinated to the Cu^{2+} ion in the crystal.[8] On the other hand, the remaining half, which is coordinated to the cation in the crystal, seems to come from the hydration water in the aqueous solution.

It follows that HTO is diluted in the former according to Eq. (1), whereas a slight enrichment of HTO results in the latter since the Cu^{2+} ion is known to be a structure-former. In these estimations, we assume that no exchange of the proton in the $HCOO^-$ ion with others occurs.[9]

For $(COOK)_2 \cdot H_2O$, the S value can be estimated to be nearly equal to that of $Sr(HCOO)_2 \cdot 2H_2O$, because the lifetime of the hydrated K^+ ion is also very short; *ca.* 10^{-9} s.[7] However, the observed S value was found to be a little larger than the estimated one. The cause of the disagreement is not clear at this stage. A small deviation of the estimated value from the observed value seems to be inevitable, as was the case with a few other salts.[4] It appears, at least qualitatively, that the present treatment is still applicable. The S value for $(COOK)_2 \cdot H_2O$ will help to estimate the value for $(COOH)_2 \cdot 2H_2O$.

It can be seen that, in general, the degree of dilution of HTO in the water of crystallization of the metal organic salts is a few percent or so, comparable to that in the metal inorganic salts. It can thus be suggested that the former dilution can also be explained on the basis of an ionic process in an aqueous solution and the crystal growth mechanism, as is the case with the latter.

The HTO Fractionation in the Oxalic Acid. It is worth noting that a considerable dilution is found to occur in the oxalic acid dihydrate. In order to estimate the fractionation in the carboxyl groups, $(COOH)_2$, we assume that the partial dilution due to the water of crystallization in $(COOH)_2 \cdot 2H_2O$ is nearly equal to be dilution for $(COOK)_2 \cdot H_2O$, 0.976.

The dilution resulting from the others is considered to come from the following three steps: (1) the proton-exchange reaction in an aqueous solution, (2) the proton integration into the crystal from an aqueous solution, and (3) the proton-exchange reaction between $(COOH)_2$ and the hydration water during the course of the vacuum dehydration.

It is well known that deuterium is slightly diluted in the hydronium ion in the exchange reaction:[10]

$$H_2O + H_2DO^+ \rightleftharpoons HDO + H_3O^+. \quad (2)$$

The same process should proceed in the case of tritium, *i. e.*; $H_2O + H_2TO^+ \rightleftharpoons HTO + H_3O^+$.
The HT_2O^+ and T_3O^+ ions can be neglected as a source of tritium, since the mother liquid used contains only a trace of tritium.

For the other species containing hydrogen atoms, $(COOH)_2$ and $C_2O_4H^-$, we can infer that tritium should be diluted, because the bond energy of the hydrogen atoms of H_2O is larger than those of $(COOH)_2$ and $C_2O_4H^-$, as can be seen from the proton level given by Gurney.[11,12] In fact, the dilution of deuterium in $(COOH)_2$ was evidenced by the work of Okazaki and Takemura.[13]

Consequently, tritium should be diluted in all the species in the aqueous solution of oxalic acid. Moreover, these species are subjected to further dilution to a small extent during the integration into the crystal according to the surface-diffusion mechanism. The possible dilution estimated above for the $(COOH)_2$ groups of the crystal can be confirmed by measuring the tritium concentration in the oxalic acid dihydrate, $(COOH)_2 \cdot 2H_2O$.

It is well known that a labeled organic compound containing a weak β-emitter, *e. g.*, tritium, causes a quenching in the liquid scintillation counting. The quenching of the oxalic acid was, therefore, corrected according to the method of Peng.[14] The tritium concentration ratio in the $(COOH)_2 \cdot 2H_2O$ crystal to the mother liquid was thus found to be 0.876 ± 0.009. It can thus be concluded that tritium is diluted in the $(COOH)_2$ groups of the crystal by *ca.* 0.676, assuming the S value of 0.976 for the hydration water, as has been described above.

Tritium Fractionation during the Dehydration. It is generally accepted that hydrogen atoms directly bonded to oxygen atoms are labile and can be exchanged with other hydrogen atoms.[9] In the case of oxalic acid dihydrate, it is likely that there occurs a ready exchange of protons between $(COOH)_2$ and H_2O by mere shifts of protons through the hydrogen bonds in the crystal.[15] The ready exchange under a vacuum dehydration was confirmed using deuterium by Okazaki and Takemura.[13]

In the exchange reaction, the hydrogen isotope effect

can also occur. Okazaki and Takemura reported that deuterium is slightly enriched in the water molecules, as is the case with the aqueous solution of oxalic acid.[13] According to the study, we can assume that tritium is slightly enriched in the water molecules relative to the carboxyl groups during the dehydration. It can be considered qualitatively that the small S value observed for the dehydrated water of $(COOH)_2 \cdot 2H_2O$, 0.865, should result from the fact that the dilution of tritium in the water due to the proton exchange between $(COOH)_2$ and H_2O surpasses the enrichment through the proton exchange during the dehydration.

Although the present discussion is somewhat qualitative, it seems worthwhile to examine the HTO fractionation in the hydrated crystal containing hydrogen atoms other than those of the hydration water, because a very large fractionation may be possible. Such an examination can also contribute to a better understanding of the proton exchange in the solution and/or in the dehydration.

The authors wish to express their thanks to Dr. Osamu Yamamoto for his help in analyzing the activity of tritium.

Spectral Intensities of Some Er^{3+} β-Diketonate Complexes

Toshiyuki Isobe and Seizo Misumi

Inorganic Chemistry Laboratory, Faculty of Science, Kyushu University, Fukuoka 812

(Received August 10, 1973)

The oscillator strengths of the absorption bands of Er^{3+} acetylacetonate, thenoyltrifluoroacetate, and dibenzoylmethide in methanol and dimethylformamide were determined and discussed in terms of the Judd-Ofelt's theory. It was possible to use the Judd-Ofelt parameters for the evaluation of the spectral intensities. The oscillator strength of the hypersensitive transition $^2H_{11/2}\leftarrow{}^4I_{15/2}$ of Er^{3+} complexes, $P(^2H_{11/2})$, was indicated by the $P(^2H_{11/2})\approx\tau_{2\mathrm{comp}}\,\nu_{\mathrm{comp}}\,U(2)/2J+1$ and it is demonstrated that "hypersensitivity" may be explained only by the τ_2 parameter of each complex, originating from the forced electric dipole transition.

The intensities of the solution spectra of the most lanthanoid(III) have been interpreted by the Judd-Ofelt's theory.[1,2] It should be noticed that the oscillator strengths of the certain transitions in lanthanoid(III) complexes are greater than those of the same transitions in the lanthanoid(III) aquo ions. These are known as "hypersensitive transitions"[3] and have hitherto been characterized by the selection rule $\Delta J\leqq 2$ and by relatively larger values of the matrix elements of $U^{(2)}$ in comparison with those of other transitions. However, no satisfactory explanation of hypersensitivity has yet been given. Some possible mechanisms involved in the appearance and the intensity of *f-f* transition have been reported, namely, (a) inhomogeneous dielectric,[3] (b) forced electric dipole transitions,[4] and (c) vibronic mechanism[5]+covalency.[6] In this paper, the Judd-Ofelt's theory was applied to the intensities of the spectra of some erbium(III)[7] β-diketonate complexes[8,9] in methanol and dimethylformamide(DMF).

Theoretical and Calculations

In Judd-Ofelt's theory, the *f-f* transitions (except those involving an allowed magnetic dipole mechanism) are assumed to be forced electric dipole in nature, occurring by the mixing of a higher energy configuration (or configurations) of opposite parity with the $4f^N$ configuration *via* the odd terms in the ligand field. The equation derived for the oscillator strengh (P) of a transition between a ground state ($|f^N\psi_J|$ and an excited state $|f^N\psi'_{J'}\rangle$ of the lanthanoid(III) in solution is given by

$$P=\sum\tau_\lambda\nu U(\lambda)/(2J+1) \qquad (1)$$

$$\lambda=2,\ 4,\ 6$$

$$U(\lambda)=(f^N\psi_J\|U^{(\lambda)}\|f^N\psi'_{J'})^2$$

where ν is the energy of the transition $\psi'_{J'}\leftarrow\psi_J$, *i. e.*, the baricentre of the absorption band in cm^{-1}, $U(\lambda)$ is the reduced matrix elements of the unit tensor operators $U^{(\lambda)}$ concerning the initial and final states of the transition, and the τ_λ vaules are usually treated as empirical parameters in cm. Reduced matrix elements for all the lanthanoids(III) have been published.[10] By using the experimental oscillator strength P_{exp}, ν, and $U(\lambda)$ values in Eq. (1) and carrying out an analysis by least-squares, an optimum set of three parameters, τ_λ, are obtained. The τ_λ parameters were, in turn, used to obtain "calculated oscillator strengths". The root-mean-square (rms) deviations between the calculated and experimental oscillator strengths were also calculated. All calculations were made with a FACOM 230-60 computer of Kyushu University.

Experimental

The absorption measurements were carried out with a Hitachi EPS-2 spectrophotometer and a Jasco ORD/UV-5 recorder by scale expansion. The solvents used were "spec-pure" absolute methanol and DMF. The erbium(III) β-diketonate complexes do not dissociate in these two solvents. The erbium(III) acetylacetonate(AA), thenoyltrifluoroacetonate(TTA), and dibenzoyl methide(DBM) were prepared by using ordinary methods.[11-13] The absorption intensities were determined by measuring the area on the experimental absorption curves with planimeter, and the oscillator strengths were calculated by using the reduced Eq. (2)

$$P_{\mathrm{exp}}=4.318\times10^{-9}\frac{9\eta}{(\eta^2+2)^2}\int\varepsilon(\nu)\mathrm{d}\nu \qquad (2)$$

where η in the refractive index of the solution and $\varepsilon(\nu)$ is the molar extinction coefficient at wave number ν. Refractive indices values of 1.32652 and 1.42817 were used for methanol and DMF, respectively, in calculation. These intensities were reproducible within $\pm0.2\times10^{-6}$ oscillator strength unit.

Results and Discussion

The experimental(P_{exp}) and calculated(P_{calc}) values of oscillator strengths of the absorption bands have been collected in Table 1—3. The τ_λ parameters are given in Table 4. The root-mean-square (rms) deviations obtained are very small in calculating four separated J'-bands ($^4F_{9/2}$, $^4S_{3/2}$, $^2H_{11/2}$, and $^4F_{7/2}$), containing only the hypersensitive $^2H_{11/2}$ band. As far as all four J'-bands are concerned, Judd-Ofelt's theory could be reasonably applied. But, the intensity of another hypersensitive transition $^4G_{11/2}\leftarrow{}^4I_{15/2}$ of Er(III) complex could not be adopted to the experimental oscillator strength, due to UV cut-off caused by intense absorption of the β-diketone ligands except acetylacetone, for calculation of the set of τ_λ parameters.

The results show that the effect of solvent and ligand on spectral intensity of Er(III) is very small for all the bands except for those in the region 18500—20000 cm^{-1}, which are known to be due to the hypersensitive transitions. Figure 1 shows the variation of the τ_λ parameters of Er(III) β-diketonate complexes in meth-

anol and DMF. The τ_2 parameter in the complex, τ_{2comp}, is the most sensitive to the environment, with marked differences in relative magnitudes of other τ_λ. (Refer to Table 4). The ratios of the experimental intensities (P_{comp}/P_{aquo}) at each J'-band and those of the calculated τ_λ parameters ($\tau_{\lambda comp}/\tau_{\lambda aquo}$) of Er(III) β-diketonate complexes are shown in Table 5. Table 5 seems to indicate that in the case of hypersensitive transition, the increase in the intensity is due to the solvent or ligand, and that it may be correlated with the marked increase in the value of τ_2 parameter.[6-7] This is shown more clearly in Fig. 2, by plotting of τ_λ values of the complexes *vs.* oscillator strength of the hypersensitive band ($^2H_{11/2}$) in the complexes. It may be pointed out that approximately τ_2 value of complex is linear to the intensity of the hypersensitive

	2	19.74	21.39	26.24	26.22	32.04	35.04
	4	0.84	1.43	0.70	1.46	0.73	0.63
	6	1.16	0.65	1.50	1.17	1.84	1.55
$\frac{P(2)_{comp}}{\sum P(\lambda)_{comp}}$ ($^2H_{11/2}$) $\lambda=2,4,6$		0.96	0.94	0.97	0.95	0.97	0.98

band. The values in the last row of Table 5 are those of

$$\frac{P(2)_{\text{comp}}}{\sum P(\lambda)_{\text{comp}}}, \quad \lambda = 2, 4, 6$$

$$\{P(\lambda) = \tau_\lambda \nu U(\lambda)/2J+1, P = \sum P(\lambda)\} \quad \lambda = 2, 4, 6$$

and this term expresses clearly contribution of τ_2 value to the intensity of the observed hypersensitive band($^2H_{11/2}$). Thus, it is concluded that $P(^2H_{11/2} \leftarrow {}^4I_{15/2})$ is approximately equal to the value of $\tau_{2\text{comp}} \cdot \nu_{\text{comp}} U(2)/2J+1$.

Therefore, this fact seems to support the result that the intensities of hypersensitive transitions are characterized by the magnitude of the τ_2 parameter, in three parameters of the Judd-Ofelt's theory.

The authors wish to thank to Mr. Hideto Yamashita for his kind experimental help.

(Received August 20, 1973)

The proton NMR absorption spectra from 1.3 to 77 K in two organic free radicals, BDPA-Bz and *p*-Cl-BDPA, have been measured on powder samples which undergo a magnetic phase transition from a paramagnetic to an antiferromagnetic state at the temperatures of 1.695 and 3.25 K respectively. The behavior of the NMR absorption spectra associated with the magnetic phase transition has been studied for the first time in the organic free radicals and interpreted in terms of the hyperfine interaction. These results are then compared with those of the TANOL radical, which is a linear antiferromagnet with no magnetic phase transition down to 1.3 K.

Since the original preparation of an organic free radical BDPA (1,3-bisdiphenylene-2-phenyl-allyl) by Koelsch,[1] the magnetic properties of this radical and its derivatives have been studied on powder samples by several authors. For these radicals, especially in the cases of BDPA–Bz (the complex of 1,3-bisdiphenylene-2-phenyl-allyl with benzene) and *p*-Cl-BDPA (1,3-bisdiphenylene-2-[*p*-chloro-phenyl]-allyl), static magnetic susceptibility, magnetic resonance absorption, and specific heat measurements have been carried out.[2–7]

Anderson *et al.*[2] have observed the magnetic susceptibility from the paramagnetic shift, which exhibited a broad maximum at about 6 K. Hamilton and Pake[3] have pointed out the possibility of a long-range magnetic ordering of BDPA–Bz below 1.73 K, judging from the results of the specific heat and ESR measurements. One of the present authors (J.Y.)[4] has measured the magnetic susceptibility and ESR spectra of BDPA–Bz and *p*-Cl-BDPA. A broad maximum in the magnetic susceptibility was observed for both radicals at 5.6 K and a minimum for *p*-Cl-BDPA at 2.8 K; a divergence of the linewidth of the ESR absorption was also observed for BDPA-Bz and *p*-Cl-BDPA at 1.78 and 2.8 K respectively. Recently, Duffy *et al.*[5] have measured the specific heat of BDPA-Bz and observed a sharp peak in the magnetic contribution part at 1.695 K, while Yamauchi *et al.*[6,7] have observed a sharp peak in the magnetic specific heat of *p*-Cl-BDPA at 3.25 K and have also measured the antiferromagnetic resonance spectra below that temperature. Thus, it has become clear that BDPA-Bz and *p*-Cl-BDPA undergo a magnetic phase transition from a paramagnetic to an antiferromagnetic state at the Néel temperatures of 1.695 and 3.25 K respectively.

The behavior associated with the magnetic phase transition of the two BDPA derivatives is as follows: 1) a minimum in the magnetic susceptibility at the Néel temperature, 2) an abrupt increase in the ESR absorption linewidth and in the *g*-value in the vicinity of the Néel temperature, 3) an observation of the antiferromagnetic resonance absorption, and 4) an anomaly in the magnetic specific heat at Néel temperature. The behavior of the NMR absorption spectra associated with the magnetic phase transition, however, has not yet been clarified in organic free radicals. In this paper we would like to demonstrate the behavior associated with both the short-range and the long-range ordering of unpaired electron spins in these radical solids, whose molecular structures are as is shown in Fig. 1.

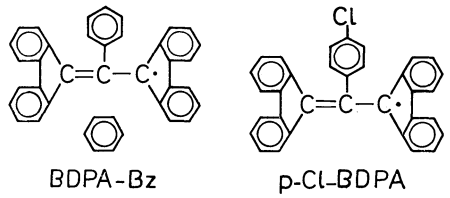

Fig. 1. The molecular structures of the radicals studied.

Experimental

The samples of BDPA-Bz and *p*-Cl-BDPA were prepared according to the procedure of Kuhn and Neugebauer[8] and were recrystallized from a benzene solution. The melting points and the results of the elementary analyses of carbon and hydrogen are in good agreement with those in the literature.

The proton NMR measurements were carried out using Pound-Watkins-type[9] and Robinson-type[10] spectrometers at the oscillation frequency, ν, of 18.0 MHz and at 27.0, 30.0, and 35.0 MHz. During the measurements the oscillation frequency and power level were kept constant. The magnetic field was modulated at 80 Hz, and the phase-sensitive detection was employed following the use of a narrow-band amplifier.

An ordinary cryostat was utilized, and the thermometer, an Allen-Bradley carbon resistor, was calibrated against the vapor pressures of liquid helium, hydrogen, and nitrogen.

Results

The proton NMR spectra of a powder sample of BDPA-Bz at 18.0 MHz are shown in Fig. 2. In addition to the central unshifted line, one more absorption line, shifted to the upper magnetic field and with a relatively small intensity, was observed from the temperature of liquid nitrogen down to about 2 K. The resonance field of the unshifted line corresponded to the magnetic field where the resonance of a free proton occurs at that frequency. The shift of the absorption line which appears at the high field

† Present address: Research Laboratories, Kawasaki Steel Corporation, 1, Kawasaki-cho, Chiba 280.

†† To whom all correspondences should be addressed.

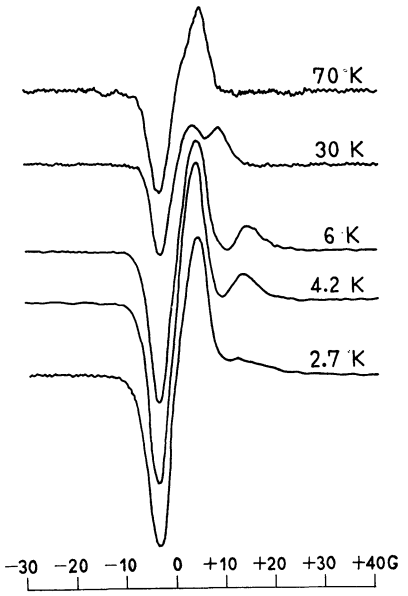

Fig. 2. NMR spectra of BDPA-Bz measured at 18.0 MHz.

is attributed to the paramagnetic shift of some protons attached to the carbon atoms with positive spin densities. The paramagnetic shift can be evaluated from the spacing between the unshifted and shifted absorption lines. Although these two resonance lines are not highly resolved, one may regard the resonance position of the shifted line as the center of the two peaks of the shifted absorption line. Thus, the paramagnetic shift, δH, the peak height of the unshifted line, h, and the half-width between the maximum slopes of the unshifted line, ΔH, were defined as is shown in Fig. 3. As the temperature was lowered to about 2 K, the shifted line became too broad to evaluate the δH, and the peak height of the unshifted line, h, decreased abruptly from 2.2 to 1.5 K, much as in the case of the spectra measured at 30.0 MHz. The curve of Fig. 4 indicates the temperature dependence of h for BDPA-Bz, which is normalized to 100% at 4.2 K.

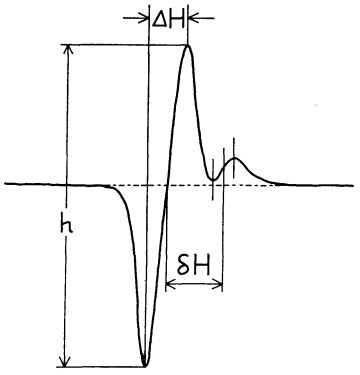

Fig. 3. Definition of δH, h and ΔH in the NMR spectra of the free radicals studied here. The δH stands for the paramagnetic shift to the high field. h and ΔH mean the peak height and the peak-to-peak linewidth of the unshifted absorption line respectively.

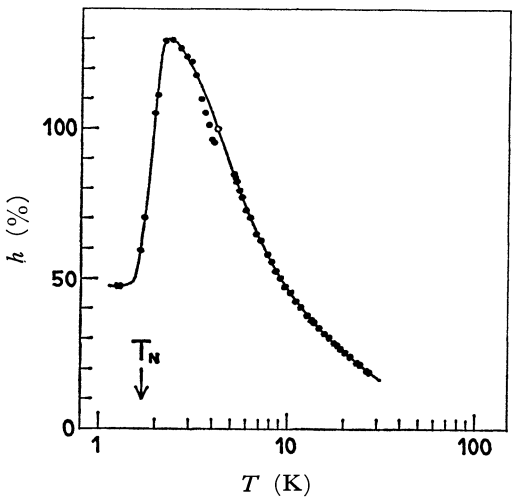

Fig. 4. Peak height of the unshifted line, h, of BDPA-Bz *vs.* temperature measured at 18.0 MHz. h is normalized to 100% at 4.2 K. T_N is the Néel temperature of this radical.

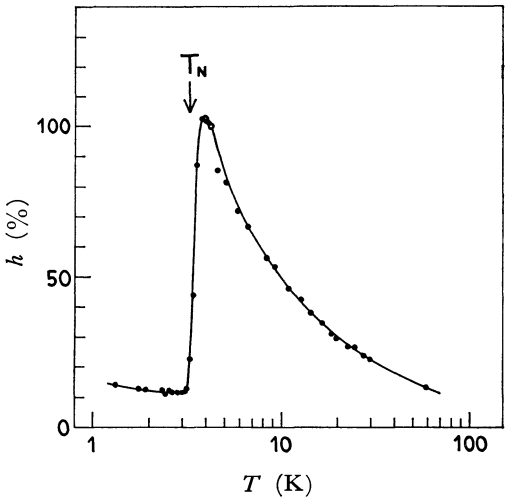

Fig. 5. h of p-Cl-BDPA *vs.* temperature measured at 18.0 MHz.

For the measurements of p-Cl-BDPA, spectra similar to those of BDPA-Bz were obtained except for one or two shifted lines observed above 4 K. The peak height, h, exhibited an abrupt decrease from 3.8 to 3.2 K, as is shown in Fig. 5.

For the sake of comparison, as will be discussed later, the temperature dependence of h for a powder sample of TANOL (2,2,6,6-tetramethyl-4-piperidinol-1-oxyl) was also obtained.

Discussion

Each proton in a radical molecule interacts with an unpaired electron which spreads over a whole molecular framework. In general, the Hamiltonian in the system where such a proton is located in a static magnetic field, H_0, along the z-axis may be given by:

$$\mathcal{H} = \mathcal{H}_{\text{Zeeman}} + \mathcal{H}_{\text{iso}} + \mathcal{H}_{\text{dip}}. \quad (1)$$

Here, $\mathcal{H}_{\text{Zeeman}}$ is the nuclear Zeeman term:

$$\mathcal{H}_{\text{Zeeman}} = -g_N\beta_N H_0 I_z. \quad (2)$$

$\mathcal{H}_{iso}$ and $\mathcal{H}_{dip}$ denote the hyperfine interaction; the former is the isotropic term, and the latter, the anisotropic dipolar term. $\mathcal{H}_{Zeeman}$ decides the free proton resonance field, and $\mathcal{H}_{iso}$ and $\mathcal{H}_{dip}$ contribute to a shift from that field.

Paramagnetic Region. The electron spins fluctuate rapidly as a result of the exchange interaction between the unpaired electrons on neighboring radical molecules. Hence, a small time-averaged local magnetic field acts on a proton.[11] In a powder sample, therefore, the dipolar term does not contribute to the paramagnetic shift, and the isotropic hyperfine term is given by:

$$\mathcal{H}_{iso} = a\boldsymbol{I}_z\langle\delta\boldsymbol{S}_z\rangle. \tag{3}$$

where a is the isotropic hyperfine coupling constant and is proportional to the spin density on the carbon atom adjacent to the proton according to McConnell's relation,[12] and where $\langle\delta\boldsymbol{S}_z\rangle$ denotes the z-component of a time-averaged value of an electron spin which is induced by the external magnetic field, H_0. The relation between $\langle\delta\boldsymbol{S}_z\rangle$ and H_0 is:

$$\chi_M H_0 = -Ng\beta\langle\delta\boldsymbol{S}_z\rangle. \tag{4}$$

where χ_M is the molar static magnetic susceptibility and N, Avogadro number. From Eqs. (2) and (3) the paramagnetic shift, expressed in Gauss, is obtained as:

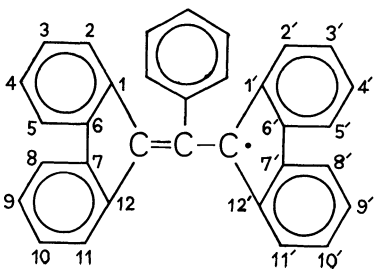
$$\delta H = \frac{a\langle\delta\boldsymbol{S}_z\rangle}{g_N\beta_N}. \tag{5}$$

From Eq. (4) and the resonance condition ($h\nu = g_N\beta_N H_0$), we obtain:

$$\delta H = \frac{a\chi_M h\nu}{Ng\beta(g_N\beta_N)^2}. \tag{6}$$

Thus, δH is proportional to the hyperfine coupling constant (or the spin density on the adjacent carbon atom), the static magnetic susceptibility, and the resonance frequency.

According to McConnell's relation, a is negative for a proton attached to the carbon atom with a positive spin density. From the results of a simple molecular orbital calculation for BDPA, it is considered that the absorption line shifted to the high field is attributable to eight protons attached to the carbon atoms, with positive spin densities, situated at the 2-, 4-, 9-, and 11-positions on two diphenylene groups in a radical molecule. Since BDPA-Bz is a one-to-one complex of benzene, the absorption intensity ratio of the unshifted line to the shifted line should be 13+6 : 8 (observed 70 : 30). Hence, the line shape of BDPA-Bz in Fig. 3 is valid and also corresponds well with the results by Anderson *et al.* Since the intensity ratio for *p*-Cl-BDPA should be 12 : 8 (observed 60 : 40), the line shape of this radical is also valid.



One can recognize the frequency dependence of δH in Fig. 6 and can see quite a good agreement of the temperature dependence curve of δH with that of χ_M as is shown in Fig. 7.

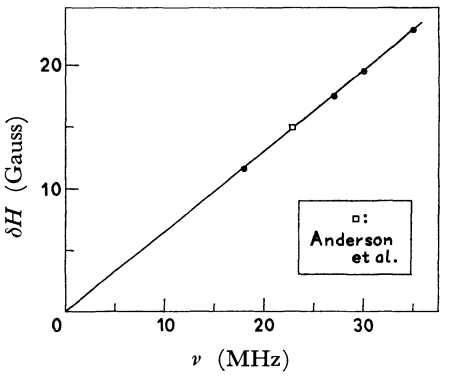


Fig. 6. Paramagnetic shift, δH, of BDPA-Bz *vs.* resonance frequency, ν, measured at 4.2 K. The value by Anderson *et al.* is also plotted for comparison.

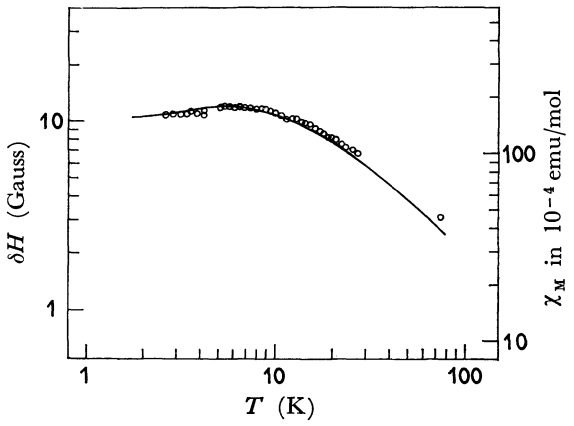

Fig. 7. δH of BDPA-Bz *vs.* temperature. The solid line is the curve of the molar magnetic susceptibility, χ_M, by Yamauchi[4] fitted at the maximum point.

As it is known that the width of the shifted line depends upon $\langle\delta\boldsymbol{S}_z\rangle$,[13] Fig. 2 shows a broadening of that line associated with a rise in the paramagnetic susceptibility.

Critical Region and Antiferromagnetic Region. The electron spins do not fluctuate rapidly any longer. Hence, a spontaneous magnetization of the electron spins occurs and a large time-averaged local field acts on a proton, which is specified as:

$$\mathcal{H}_{iso} = a\boldsymbol{I}_z\langle\boldsymbol{S}_z\rangle. \tag{7}$$

where $\langle\boldsymbol{S}_z\rangle$ denotes the time average of the z-component of the effective spontaneous magnetization of the electron spins which acts on that proton. In the paramagnetic state, $\langle\boldsymbol{S}_z\rangle$ is nonvanishing only in a finite applied field. Though it would be difficult to express $\mathcal{H}_{dip}$ in a simple form for a system where the electron spins are widely delocalized, it can be easily understood that this term also involves $\langle\boldsymbol{S}_z\rangle$. Both the hyperfine terms contribute to the

striking increase in the width of the shifted line shown in Fig. 2. The unshifted line originally consists of the absorption of each proton which is coupled weakly with the unpaired electron (or attached to the carbon atom with a very small spin density). The occurrence of the spontaneous magnetization, therefore, shifts the resonance field of each proton to a point far from the free-proton resonance field.

The temperature dependence of h can be regarded as that of the absorption intensity of the unshifted line, for ΔH does not show a large temperature dependence, as is shown in Fig. 8, and no saturation of the unshifted line[3] was observed. The rapid decrease in h near Néel temperature can, therefore, be ascribed to the long-range ordering of the unpaired electron spins in BDPA-Bz and *p*-Cl-BDPA. In TANOL a short-range ordering occurs, with a maximum susceptibility at 6.5 K,[4,14,15] but a long-range ordering does not occur down to 1.3 K; this radical is believed to be a good linear antiferromagnet.[4] Hence, h (or the absorption intensity) for TANOL is approximately inversely proportional to the temperature, as is shown in Fig. 9, and it may be considered that the absorption intensity is proportional to the "nuclear magnetic susceptibility" in the absence of a long-range ordering. On the other hand, in the presence of a long-range ordering, the absorption intensity of the unshifted line decreases abruptly in the critical temperature region, as is shown for BDPA-Bz and *p*-Cl-BDPA in Figs. 4 and 5 respectively, because of the spontaneous sublattice magnetization, which acts as a large local field on protons through the hyperfine interaction.

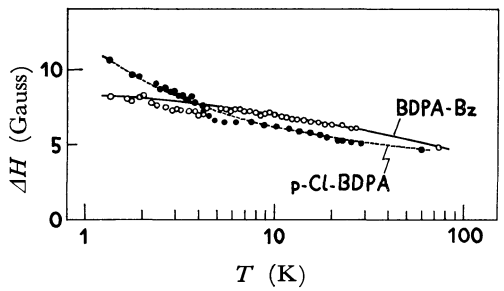

Fig. 8. Linewidth of the unshifted line, ΔH, of BDPA-Bz and *p*-Cl-BDPA *vs.* temperature measured at 18.0 MHz.

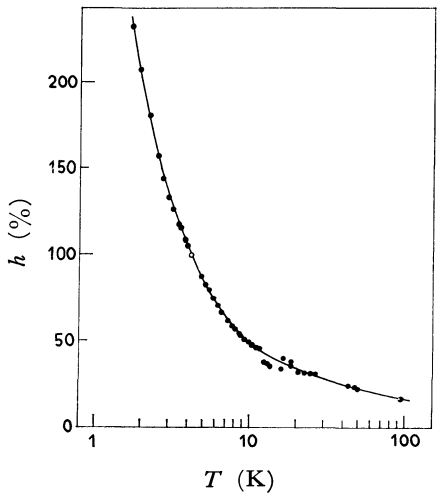

Fig. 9. h of TANOL *vs.* temperature measured at 30.0 MHz.

Thus, the results of the proton NMR measurements are consistent with the other information about the magnetic susceptibility, the ESR, and the specific heat measurements.

The shifted absorption lines in the antiferromagnetic region could not be found for powder samples of the two radicals. It is hoped that the magnetic properties of these radicals will be studied with single crystals in the future.

Conclusion

The proton NMR of the organic free radicals was studied in the paramagnetic and antiferromagnetic regions. The results are consistent with the other information on their magnetic properties; especially, it may be concluded that the intensity of the proton NMR absorption line decreases abruptly in the vicinity of the Néel temperature. This phenomenon illustrates the behavior associated with the long-range magnetic ordering of the two organic free radicals, BDPA-Bz and *p*-Cl-BDPA. Moreover, it may be concluded that the transition temperature in the organic free radicals can be foretold on the basis of the results of the proton NMR measurements of powder samples.

The authors would like to express their sincere thanks to Messrs. Teruaki Fujito and Toshio Yoshioka for their help in the measurements and also to Mr. Kohji Watanabe for his advice on the sample preparation.

Kinetic Studies of the Reaction between Sodium Dodecyl Sulfate and Pinacyanol Chloride

Nobuhide TATSUMOTO, Kunio TAKEDA, Shunji ISSHIKI, and Tatsuya YASUNAGA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received September 10, 1973)

Below the critical micelle concentration, a kinetic study of the aggregate formation reaction of sodium dodecyl sulfate and pinacyanol chloride was made by means of a stopped-flow system combined with a rapid scanning spectrophotometer. The process involves the following four steps and a precipitate whose composition ratio was dodecyl sulfate : pinacyanol = 1 : 1 was obtained as the final product:

$$\frac{1}{2}D_2 \longleftrightarrow D \underset{S}{\rightleftharpoons} DS \longleftrightarrow DS' \longrightarrow (ppt)$$

where D and S are the dye and detergent molecules respectively. The forward rate constants have been calculated to be 6×10^5 $(M\ s)^{-1}$ for $[S]_0=0.05$—0.1 mM in the second step and 1.2×10^2—3.9×10^{-3} s^{-1} for $[S]_0=$ 0.05—1.0 mM in the third step.

Above the critical micelle concentration (CMC), the color of a mixed solution of sodium dodecyl sulfate (SDS) and pinacyanol chloride is characterized by two absorption bands, α at 615 nm and β at 570 nm.[1] These characteristic absorptions have been attributed to the incorporation of dye into the micelles.[1] In a kinetic study of that incorporation by the stopped-flow method, the absorption at the γ band, 480 nm, which is associated with dye-detergent salt,[1] appeared and reached its maximum within 1 ms. Its absorption gradually decreased with the time, while the absorption at the α band increased. From these results it was nearly proved that the dye is incorporated into micelles through an intermediate, dye-detergent salt. In view of the above considerations, the process of the dye-detergent salt formation should be observed by the stopped-flow method at lower concentrations of SDS. As a preliminary test, the dynamic behavior of the absorption spectrum over a wide range of wavelengths was observed using the stopped-flow system combined with a rapid scanning spectrophotometer. The change in the absorption at the γ band with the time could be observed as expected. Moreover, the absorption at the γ band decreased gradually with the time, while the absorption at 520 nm appeared and subsequently increased. Finally, this new absorption disappeared completely within one or two days.

The purpose of the present investigation is to study the kinetics of the overall reaction in which the salt precipitates after the solutions of pinacyanol chloride and SDS have been mixed below CMC, paying attention to the absorptions at the γ band 520 nm.

Experimental

Materials. The SDS and the pinacyanol chloride were obtained from Nikko Chemicals Co. and Eastmann Organic Chemicals Co. respectively. These reagents were used without further purification. The CMC of SDS was measured to be 7.6, 7.1, and 7.0 mM by the electrical conductivity, surface tension, and viscosity methods respectively, and was measured to be 5.7 mM in 0.02 mM of pinacyanol chloride by the spectral method at 20 °C.

Method. The dynamic spectra were measured by means of a stopped-flow system combined with a rapid scanning spectrophotometer, JASCO, RSP-1D, whose scanning speed was 400 nm/ms. This spectrophotometer, moreover, was also used as a fixed-wavelength monochromator. The dead time of the stopped-flow system was less than 2 ms.[2] All the experiments were performed at 25 °C.

Results and Discussion

The dependence of the static spectrum on the concentration of SDS was measured in a 0.04 mM solution of pinacyanol chloride, and very complex spectra were observed, as can be seen in Fig. 1. In the range of 0.1—3 mM of SDS, the absorption changed with the time, and a precipitate was observed on standing for a long time. Therefore, the measurement was done within one hour after mixing the pinacyanol chloride with the SDS. In the higher concentration range of SDS, no absorption change was observed even after 16 hours.

The stable peaks of absorption due to the incorporation of dye into the micelles were observed at the α and β bands, above the CMC. On the other hand, the quite stable peak of absorption, whose half-life period is greater than 6 hours, associated with the

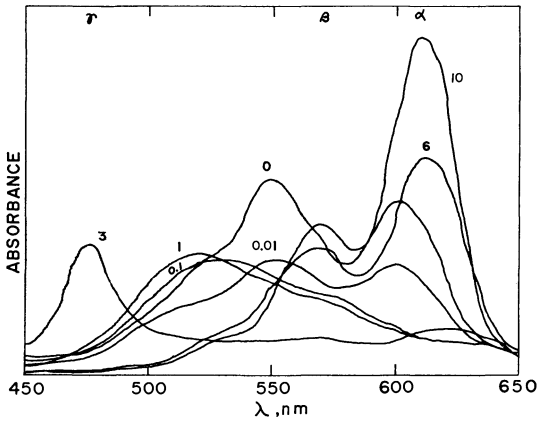

Fig. 1. Change in absorption spectrum with concentration of SDS in 0.04 mM pinacyanol chloride. Numbers in this figure refer to concentration of SDS, mM unit.

dye-detergent salt was observed at the γ band in about 3 mM of SDS. Further, in the lower range (0.1—1 mM) of SDS an unaccountable peak of absorption was observed at 520 nm. Below 0.1 mM of SDS, the characteristic absorptions of pinacyanol chloride were observed at 550 and 600 nm.

In the measurement of the dynamic spectrum, the characteristic absorptions of pinacyanol chloride at 550 and 600 nm in 0.1 mM of SDS decreased with the time, while that at the γ band increased after mixing, as is shown in Fig. 2. Subsequently, the absorption at the γ band gradually decreased with the time, while an unaccountable one at 520 nm appeared and increased. Finally, this absorption at 520 nm disappeared completely and the precipitate settled within one or two days. At a higher concentration, 0.25 mM, of SDS, the absorptions at 550 and 600 nm could not be observed, and that at the γ band reached its maximum within 1 ms after mixing, as is shown in Fig. 3. Subsequently, those at the γ band and 520 nm changed with the time in a manner similar to that in 0.1 mM of SDS. The above results lead us to presume that the species associated with the absorption at 520 nm is produced through the intermediate, the dye-detergent salt. In the meantime, at a lower concentration, 0.025 mM, of SDS, the absorptions at 550 and 600 nm gradually decreased with the time, while the absorption at 520 nm increased after mixing without any appearance of the absorption at the γ band, as can be seen from Fig. 4. These facts indicate that

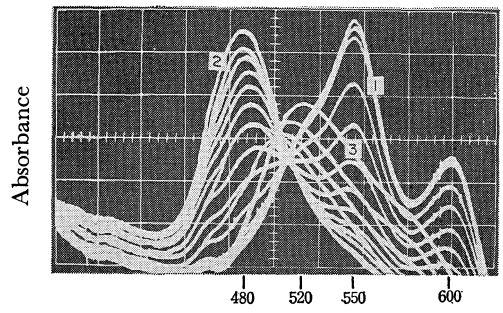

Fig. 2. Change in absorption spectrum with time. $[S]_0=0.1$ mM. $[D]_0=0.04$ mM. Time after mixing, 1 : 1 ms, 2 : 80 ms, 3 : 28 s.

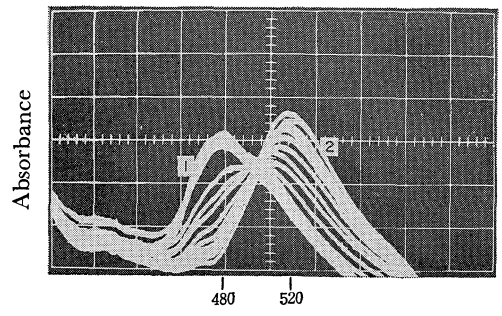

Fig. 3. Change in absoption spectrum with time. $[S]_0=0.25$ mM. $[D]_0=0.04$ mM. Time after mixing, 1 : 1 ms, 2 : 205 s.

the formation rate of dye detergent salt is less than or equal to that of species associated with the absorption at 520 nm.

Then, the changes in the absorptions at the γ band, 520, 550, and 600 nm with the time were measured in further detail at four fixed wavelengths by the stopped-flow method in 0.05 and 0.1 mM of SDS in order to study the overall reaction. The absorbances at 550 and 600 nm changed with the time after the mixing of 0.08 mM of pinacyanol chloride with 0.2 mM of SDS, as is shown in Fig. 5. Here, the dead time was 4 ms, since the mixing-flow time had to be lowered because the sample was a foamy liquid. As can be seen from Fig. 5, the variations in the absorbances at 550 and 600 nm with the time differ from each other in shape. In order to examine the above phenomenon in detail, the concentration dependences of absorptions at 550 and 600 nm were measured in an aqueous solution of dye alone. The plots of the absorbances at both wavelength *vs.* the total concentration of the dye are not linear, as can be seen from Fig. 6.

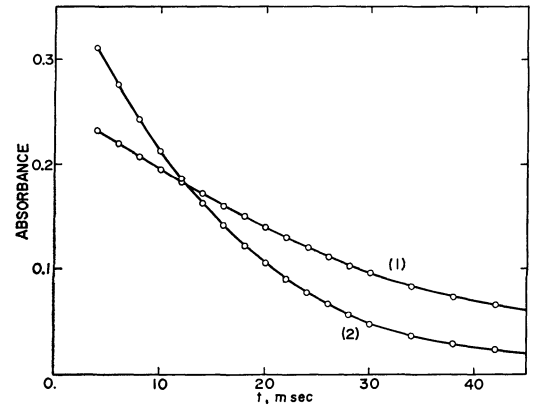

Fig. 5. Changes in absorbance with time. $[S]_0=0.1$ mM. $[D]_0=0.04$ mM. (1) : 550 nm, (2) : 600 nm.

It has been reported that, in a certain range of concentrations, a cationic dye is in equilibrium between the monomer and dimer.[3] Therefore, the following equilibrium for the present system can be assumed:

$$D_2 \rightleftharpoons 2D \qquad (1)$$

where D is the dye molecule. Then, the equilibrium

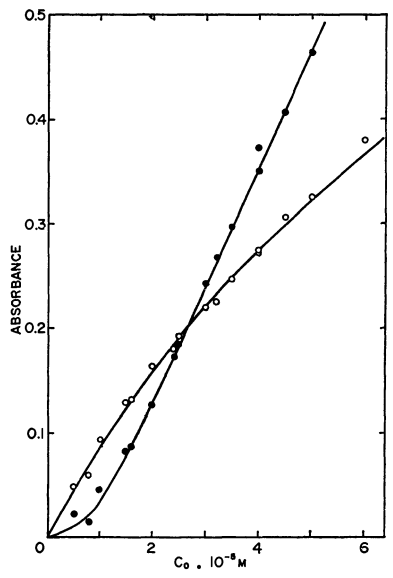

Fig. 6. Changes in absorbance with concentration of pinacyanol chloride. ●: 550 nm, ○: 600 nm.

constant K_1 is given by:

$$K_1 = 2\delta^2 C_0/(1-\delta) \tag{2}$$

where C_0 is the total concentration of dye in the monomer unit and δ, the dissociation degree. On the other hand, the absorbances, A, at the two absorption bands are given by:

$$A_D = \varepsilon_D C_D l = \varepsilon_D(1-\delta)C_0 l/2 \tag{3}$$

$$A_M = \varepsilon_M C_M l = \varepsilon_M \delta C_0 l \tag{4}$$

where ε is the molar absorption coefficient, l, the pass length of the cell, and the subscripts, D and M, refer to the dimer and the monomer respectively. The values of K_1, ε_D, and ε_M were determined so as to obtain the best fit of the data to the theoretical curves calculated by Eqs. (2)—(4). The theoretical curves, which are characterized by $K_1=2\times10^4$ M, $\varepsilon_D=\varepsilon_{550}=3.8\times10^5$ M^{-1} cm^{-1}, and $\varepsilon_M=\varepsilon_{600}=4.5\times10^4$ M^{-1} cm^{-1}, are shown in Fig. 6, along with the experimental data. The good fitting of the experimental and theoretical values indicates that the equilibrium of $D_2 \rightleftharpoons 2D$ is varied for the present system. The kinetic study for this step might be made by the chemical relaxation method.

Assuming that the dye-detergent salt is produced from SDS and the monomer of pinacyanol which is more reactive than the dimer, the formation of salt may be represented by:

$$mD + n_1S \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} X \tag{5}$$

where S is the detergent; X, salt; m and n_1, stoichiometric constants, and k_2 and k_{-2}, forward and backward rate constants respectively. Therefore, the formation rate of X is given by:

$$\frac{d[X]}{dt} = k_2[D]^m[S]^{n_1} - k_{-2}[X] \tag{6}$$

$$m[X] = [D]_0 - \left([D]+\frac{1}{2}[D_2]\right) \tag{7}$$

$$[S] = [S]_0 - n_1[X] \tag{8}$$

In an earlier stage of the reaction

$$\frac{d[X]}{dt} = k_2[D]^m[S]^{n_1} \tag{9}$$

and

$$\int_{[X]_i}^{[X]_t} d[X] = k_2 \int_i^t [D]^m[S]^{n_1} dt \tag{10}$$

where i is the dead time. The two integers, m and n_1, were determined so as to obtain the best linear plot of the integration on the left *vs.* that on the right of Eq. (10). In both cases of $[S]_0=0.05$ and 0.1 mM, the assumption of $m=n_1=1$ was sufficient to give the best straight line, whose slope gave $k_2=6\times10^5$ $(M\,s)^{-1}$. Therefore, X can by represented by DS. In practice, the integration on the right was performed by the graphical method. The plot is shown for $[D]_0=0.04$ mM and $[S]_0=0.1$ mM in Fig. 7. The value of k_{-2} can be calculated theoretically from the deviation of the integration on the left-hand side of Eq. (10) from the straight line at the final stage of the reaction, but it could not be determined in practice because the values of [X] were not very accurate there.

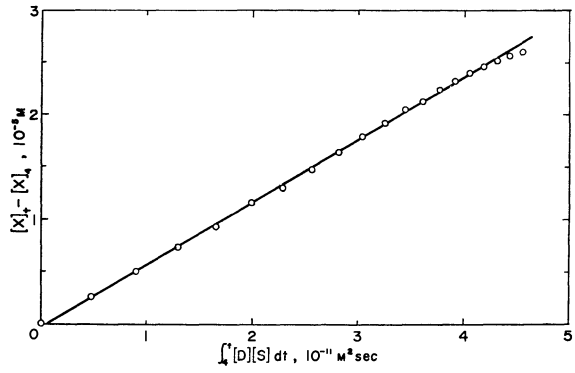

Fig. 7. A plot of $[X]_t-[X]_4$ *vs.* $\int_4^t [D][S]\,dt$. $[S]_0=$ 0.1 mM. $[D]_0=0.04$ mM.

Since the species, Y, associated with the absorption at 520 nm must be produced through the DS associated with that at the γ band, the formation of the former may be represented by:

$$n_2(DS) \underset{}{\overset{k_3}{\rightleftharpoons}} Y \tag{11}$$

where k_3 is a forward rate constant and n_2, a stoichiometric constant. In an earlier stage of the reaction

$$-\frac{d[DS]}{dt} = k_3[DS]^{n_2} \tag{12}$$

$$[DS] = \beta A_\gamma \tag{13}$$

and

$$\log(-dA_\gamma/dt) = \log(k_3\beta^{n_2-1}) + n_2 \log A_\gamma \tag{14}$$

where A_γ is an absorption coefficient at the γ band and β, a constant. All the plots of $\log(-dA_\gamma/dt)$ *vs.* $\log A_\gamma$ were linear, and their slopes, n_2, were nearly equal to unity, as can be seen from Fig. 8. Therefore, the forward process may be described by an equation of a first-order reaction and the product, Y, can be represented by DS′:

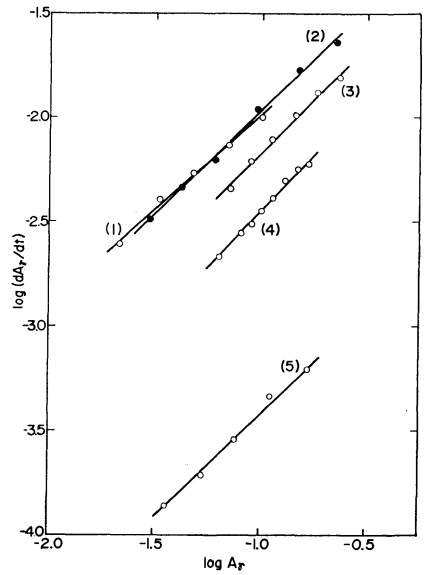

Fig. 8. Plots of $\log(dA_T/dt)$ *vs.* $\log A_T$. $[S]_0=0.05$—1.0 mM. $[D]_0=0.04$ mM. (1) : 0.05 mM, (2) : 0.1 mM, (3) : 0.2 mM, (4) : 0.5 mM, (5) : 1.0 mM.

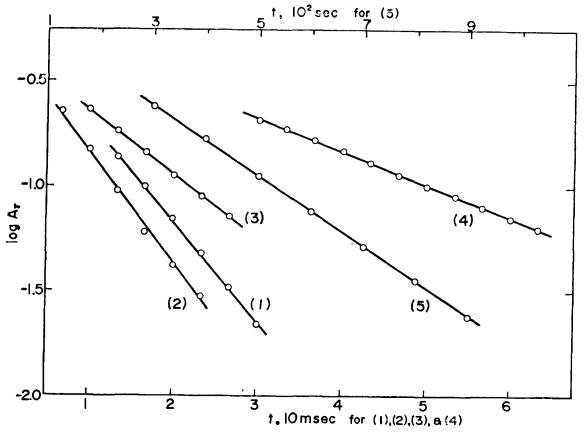

Fig. 9. Changes in $\log A_T$ with time. $[S]_0=0.05$—1.0 mM. $[D]_0=0.04$ mM. (1) : 0.05 mM, (2) : 0.1 mM, (3) : 0.2 mM, (4) : 0.5 mM, (5) : 1.0 mM.

$$DS \xrightarrow{k_3} DS' \tag{15}$$

$$\ln A_T = -k_3 t + \ln A_{T0} \tag{16}$$

The values of k_3 were obtained from the slope of the plots of $\ln A_T$ *vs.* t shown in Fig. 9; they are listed in Table 1.

When the absorption at 520 nm can be observed, as in the case described above, the salt precipitated completely within one or two days. The precipitate was recrystallized from ethanol to form large monoclinic needles, blue-violet in color. Microanalysis gave the results listed in Table 2 for both the recrystallized and unrecrystallized precipitates. Considering that both the analytical values are in good agreement with the theoretical ones calculated by assuming that the ratio of SDS and pinacyanol chloride is unity, the precipitate might be an aggregate of DS′ associated with the absorption at 520 nm:

$$n_3 DS' \rightleftharpoons (DS')_{n_3} \tag{17}$$

where n_3 is a stoichiometric constant. Consequently, the overall reaction may be given by:

$$\frac{1}{2}D_2 \longleftrightarrow D \underset{S}{\overset{}{\rightleftharpoons}} DS \longleftrightarrow DS' \longleftrightarrow \frac{1}{n_3}(DS')_{n_3} \tag{18}$$

Finally, although it should be noted that the forward rate constant in the third process decreases with the concentration of SDS except in 0.1 mM, no definitive conclusion can be drawn on the basis of the above experimental results alone. However, it may be presumed that the stability of DS increases with the concentration of SDS, while that of DS′ increases with the concentration of water. This, moreover, leads us to question whether DS is different from DS′ in the chemical bonding between D and S or is conformational isomers with DS′, which has a steric structure stabilized by a hydrophobic bonding.

Table 1. FORWARD RATE CONSTANTS FOR THE THIRD STEP REACTION

(Received September 12, 1973)

The kinetics of hydrogen-deuterium exchange in sperm whale metmyoglobin has been followed in aqueous solutions of various pD values (5.6—7.7) and at various temperatures (0—55 °C) by an infrared absorption measurement. At pD=5.6 and at 0 °C, 117 out of the total 148 peptide hydrogen atoms exchange relatively slowly with a rate of an apparent first-order reaction for one hour of the reaction time. This number (117) is almost equal to the sum of the number of peptide NH-groups (108~111) which are found to be involved in hydrogen bonds with the carbonyls of other peptide groups and those (8) which are in hydrogen bonds with oxygen atoms of some sidechains in the myoglobin molecule in the crystalline state. At higher temperatures and/or at higher pD's, however, only 109 peptide NH groups (assignable to those involved in the peptide-peptide hydrogen bonds) are found to exchange relatively slowly. The kinetics of the exchange reactions of these 109 peptide NH groups are explained by assuming that the fluctuation amplitude (*i.e.*, the probability of finding the peptide-peptide hydrogen bonds broken) becomes lower on going from the terminus towards the inner portion in each of the eight α-helices involved in the myoglobin structure.

In our previous works[1-3] it has been shown that a kinetic study of the hydrogen-deuterium exchange reaction of a protein in aqueous solution can provide useful information on the fluctuation of the protein structure. The kinetic data have been connected with the fluctuation of the protein structure through the following two assumptions: (1) The exchange reaction of a peptide NH group is distinctively slow when it is involved in a peptide-peptide hydrogen bonds. (2) The rate constant of such a slow exchange reaction is proportional to the chance of finding the hydrogen bond broken. These assumptions are essentially based upon the reaction scheme proposed by Hvidt[4] many years ago, and by our recent experiments good pieces of evidence have been found for the validity of these assumptions in the case of lysozyme.[1]

In this work myoglobin is the subject of our kinetic measurement. On the hydrogen exchange in myoglobin, Englander and Staley[5] and Abrash[6] made detailed studies. In the former work, special attention was paid to the estimation of the free and hydrogen-bonded peptide NH groups. While, in the latter work the effect of the pH-induced denaturation was intensively examined. Both of the results are interpretable by considering that the assumptions given above are valid. We have extended the hydrogen-exchange measurement into the temperature range of 0 to 55 °C and attempted to discuss a detail of the fluctuation of the structure of this protein in solution.

Experimental

Crystalline sperm whale myoglobin was obtained from Miles-Seravac, Ltd., Maidenhead, Berkshire, England (Batch 57A). The hydrogen-deuterium exchange reaction was followed by infrared absorption measurements according to the method described by Blout, de Lozé and Asadourian.[7] The experimental procedure is the same as given in our previous papers.[1,2,8] The concentration of myoglobin was kept at 3.3%. The solvent was 0.1 M phosphate buffer. The amount of undeuterated peptide group was taken as proportional to the ratio of the absorbance of amide II (at 1550 cm^{-1}) to that of amide I (at 1650 cm^{-1}) bands, A(amide II)/A (amide I). In the absorbance measurements, the baseline for the amide I band was drawn parallel to the 100% transmittance line from the transmittance at 1800 cm^{-1}, and the baseline of the amide II band was taken as the absorption of a solution of the completely deuterated myoglobin. The latter was obtained by keeping the solution of the exchanging protein at pD≒10 and at 45—50 °C for several hours, and then by bringing the pD and temperature of the solution into proper values.

Results and Interpretations

(a) General Features of the Exchange Kinetics. The hydrogen-deuterium exchange reaction was followed for myoglobin in D_2O solutions of pD 5.6, 6.3, 7.0, and 7.7 at 15, 25, 35, 45, and 55 °C. For solution of pD 5.6, the observation was made also at 0 °C and 5 °C. The results are shown in Figs. 1 and 2. As may be seen in these figures, the reaction rate is higher

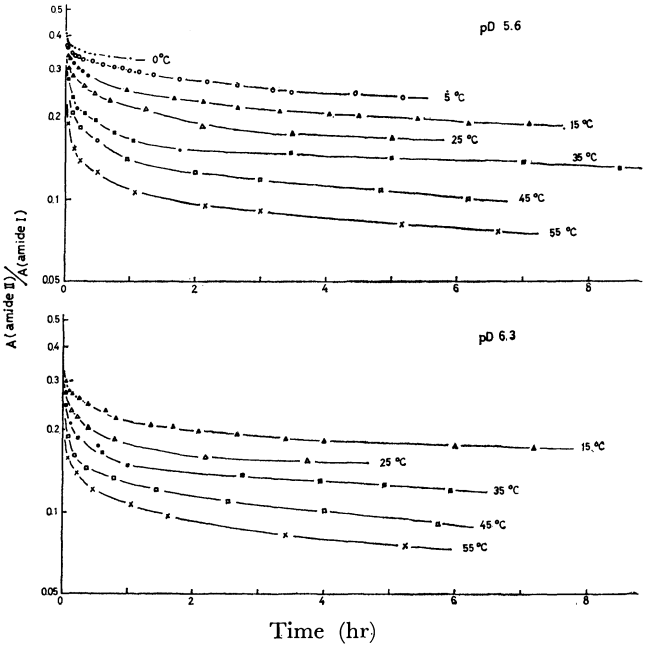

Fig. 1. Semilogarithmic plots of deuterium exchange of myoglobin in D_2O solutions of pD 5.6 (upper) and of pD 6.3 (lower) at various temperatures.

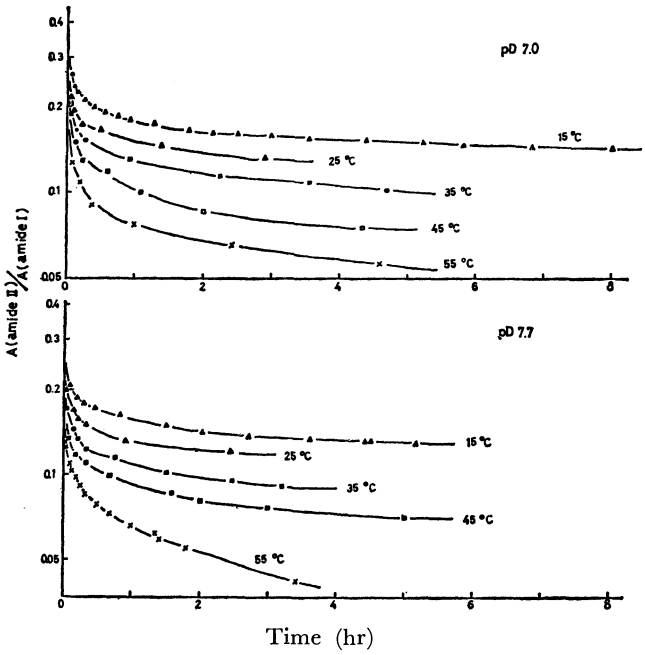

Fig. 2. Semilogarithmic plots of deuterium exchange of myoglobin in D_2O solutions of pD 7.0 (upper) and of pD 7.7 (lower) at various temperatures.

at higher temperatures and in solutions with higher pD's. Under any of these conditions the reaction does not proceed as a simple first-order reaction. This is in contrast to the case of lysozyme,[1,2] where the peptide hydrogen atoms exchange with a rate of an apparent first-order reaction except in an early stage of the reaction. This fact indicates that the peptide NH group in the myoglobin molecule should be classified into a number of categories with different kinetic behaviors from one another.

(b) Measurement of the Free and Hydrogen-bonded Peptide NH Groups. At 0 °C the reaction proceeds so slowly that we can estimate the A(amide II)/A(amide I) value at time zero by an extrapolation (Fig. 3, upper portion). The value is found to be 0.450. This value is equal to what are determined in a less ambiguous for lysozyme[1,2] and α-lactalbumin.[3] The reaction

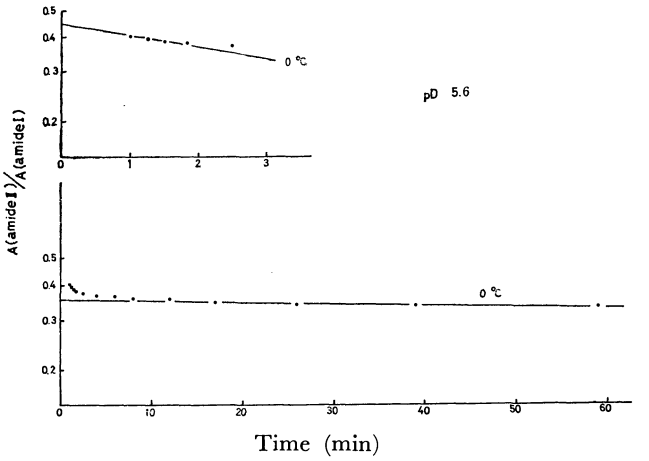

Fig. 3. Semilogarithmic plots of an early stage of the deuterium exchange reaction of myoglobin in a D_2O solution of pD 5.6 at 0 °C.

proceeds rather rapidly in the period of 0 to 10 minutes, and suddenly at about 10 minutes it slows down (see Fig. 3, lower portion). In the period of 17—60 min the exchange proceeds apparently as a simple first-order reaction. The extrapolation of the straight line obtained in the semilogarithmic plots for this stage of the reaction gives an A(amide II)/A(amide I) value of 0.355 at the zero time. This fact indicates that we can divide the peptide NH groups in myoglobin into two main classes; $(0.450-0.355)/0.450=21._0\%$ of them exchange rapidly and the rest $0.355/0.450=79._0\%$ do slowly. Because there are 148 peptide NH groups in the myoglobin molecule, the former corresponds to 31 and the latter 117 in the actual number. According to the crystallographic study of Kendrew *et al.*,[9] 108~111 peptide NH groups in the myoglobin molecule are involved in intramolecular peptide-peptide hydrogen bonds, 8 NH's are involved in intramolecular hydrogen bonds with oxygen atoms in sidechains, and 29—32 are free from such intramolecular hydrogen bonds.[10] Therefore, it is probable that the slowly exchanging 117 peptide NH groups found in our experiment correspond to the $(109+8)\pm2$ peptide NH groups involved in hydrogen bonds in the myoglobin molecule in its crystalline state.

Similar estimation of the free and hydrogen-bonded amides of myoglobin was made by following the tritium exchange by Englander and Staley.[5] Our result is practically equal to theirs. It may be pointed out here, however, that we can extract only the behavior of the peptide NH groups in this protein molecule by the infrared absorption measurement, while in the measurement of ^3H radioactivity one needs to take, in principle, all the exchangeable hydrogen atoms into account.

As may be seen in Fig. 1 (upper), the exchange reaction at 5 °C and at pD=5.6 proceeds as a simple first-order reaction from 18 to 100 minutes. In the semilogarithmic plot, the straight line which corresponds to this part of the reaction intersects the ordinate (A(amide II)/A(amide I)) at 0.330. At 15 °C a straight line in the semilogarithmic plot occurs for the 0~20 minutes period. This also intersects the ordinate at 0.330. This value of A(amide II)/A(amide I) corresponds to 109 peptide NH groups. This is equal to the number of peptides NH groups involved in the peptide-peptide hydrogen bonds. This fact therefore may be interpreted as indicating that, at temperatures higher than 5 °C, only the peptide NH groups involved in the peptide-peptide hydrogen bonds should be classified as the "slowly exchanging peptide NH groups", and those involved in the peptide-sidechain hydrogen bonds are to be classified as the "fast" NH groups. Such an interpretation has been found to be valid for lysozyme[1,2] and for α-chymotrypsin.[11]

(c) Hvidt's "Relaxation Spectra" and the "Fluctuation Amplitude" γ. On the basis of the interpretation just described, we now attempt an analysis of the hydrogen-deuterium exchange reaction with special attention on the 109 peptide NH groups involved in the peptide-peptide hydrogen bonds. For such an analysis, Willumsen[12,13] and Hvidt and Wallevik[14] proposed to display the kinetic data as plots of the number of

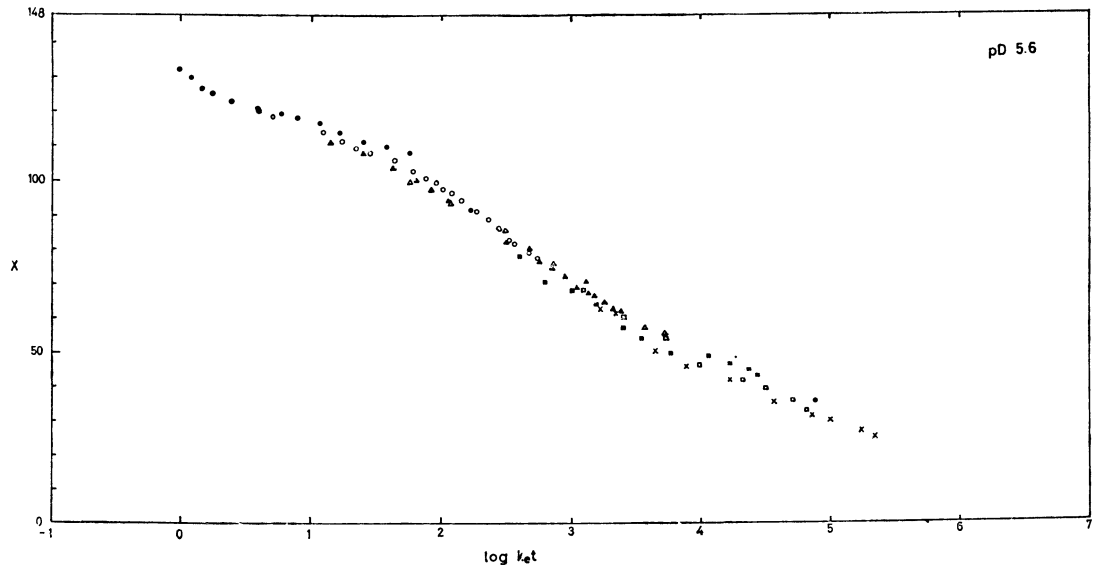

Fig. 4. A re-plotting of the experimental data given in Fig. 1 (upper). X is the number of unexchanged peptide NH groups at time t, and k_e is the rate constant of peptide hydrogen atoms free from hydrogen bonds, calculated according to equation (1). ●, at 0 °C; ○, at 5 °C; ▲, at 15 °C; △, at 25 °C; ■, at 35 °C; □, at 45 °C; and ×, at 55 °C. pD=5.6.

unexchanged peptide hydrogen atoms (X) at a given time (t) *versus* $\log_{10}(k_e t)$, where k_e is the exchange rate constant of solvent-exposed peptide groups. They mentioned such plots as "relaxation spectra". We have re-plotted our kinetic data according this proposal. For k_e at various pD's and temperatures (θ °C), we have adopted, according to Hvidt and Nielsen,[15] the values given by the following formula:

$$k_e = 50(^{0.3-pD} + 10^{pD-6.3})10^{0.05(\theta-20)}\text{min}^{-1} \quad (1)$$

(We have neglected here the primary-structure effects discussed by Molday, Englander and Kallen.[16]) In Fig. 4, an example of the "relaxation spectra" is shown for the peptide NH groups of myoglobin in the solution of pD 5.6; this is obtained by re-plotting the data given in Fig. 1 (upper).

Hvidt and Nielsen[15] showed that most studies of the hydrogen exchange led to the conclusion that the so-called EX_2 reaction mechanism offers the simplest, and the most likely explanation of the slow exchange of the hydrogen-bonded peptide NH groups. Let us consider i-th peptide NH group. The exchange takes place as follows:

$$N_i \underset{k_{2i}}{\overset{k_{1i}}{\rightleftharpoons}} D_i \xrightarrow{k_e} \text{exchange}, \quad (2)$$

where N_i means a state of the i-th NH group involved in a hydrogen-bond and D_i is that after the hydrogen-bond is broken so that it is now ready to exchange with the rate costant k_e. The EX_2 mechanism corresponds to the case of

$$k_e \ll k_2, \quad (3)$$

and in this case X_i (fraction remaining unchanged) is given as

$$X_i = \exp(-\gamma_i k_e t), \quad (4)$$

where

$$\gamma_i = [D_i]/([N_i]+[D_i]) \quad (5)$$

is the probability of finding the particular peptide-peptide hydrogen bond broken so as to be ready to exchange with the rate constant k_e. If the NH group now in question is intrinsically free from hydrogen bond, $\gamma_i \fallingdotseq 1$. While, if it is involved in a peptide-peptide hydrogen bond in the "intact" form of the myoglobin molecule, the γ_i value is very small (in comparison with 1), and such γ_i value may be taken as a measure of the "fluctuation amplitude" of the local structure around the i-th peptide NH group.

Now, according to Eq. (4), the plot of X_i *versus* $\log_{10}(k_e t)$ for a fixed γ_i value should result in a curve whose slope is everywhere independent of the γ_i value, because $dX_i/d\log(k_e t)=2.30X_i \ln X_i$. Therefore, the curves corresponding to different γ values have the same shape but are mutually displaced along the abscissa. The amount of displacement of each curve from that with $\gamma_i=1$ is equal to $-\log_{10}\gamma_i$. The ordinate X in the observed plot such as shown in Fig. 4 should correspond to the sum of X_i at every $\log_{10}(k_e t)$.

$$X = \sum_i \exp(-\gamma_i k_e t) \quad (6)$$

Thus, Hvidt's "relaxation spectrum", *i.e.*, the X *versus* $\log_{10} k_e t$ plot, is considered to be a so-to-say "spectrum" of γ, the probability of finding each NH group free from a hydrogen bond so that it is ready to exchange with the rate constant k_e. In other words, it is a "spectrum" of the amplitude of local fluctuation of the protein structure.

(d) Effects of Temperature and pD *on the Local Fluctuation.* In Fig. 4, observed X *versus* $\log_{10} k_e t$ curves at different temperatures are found to be nearly superposed on one another, although a little more detailed inspection indicates a probably significant tendency that a curve for higher temperature is shifted very slightly towards leftside direction (*i.e.*, towards higher γ value) from a curve for lower temperature. This

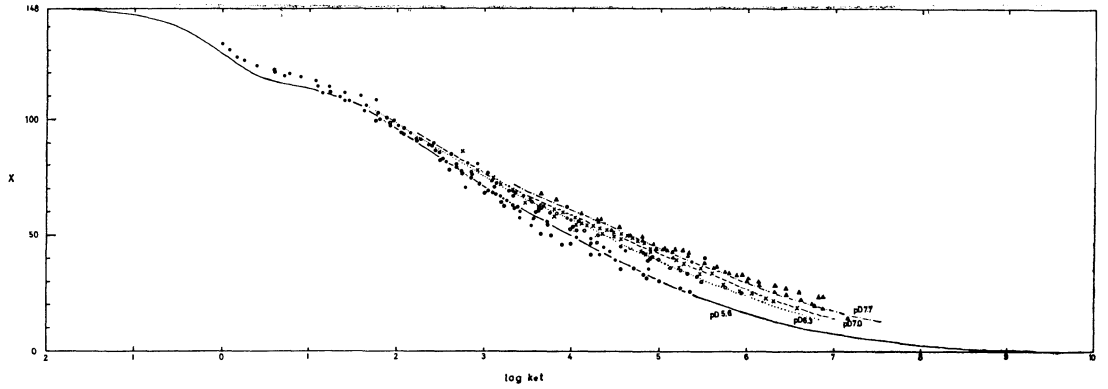

Fig. 5. Observed and calculated "relaxation spectra" of myoglobin. X is the number of unexchanged peptide NH groups at time t. k_e is the rate constant of solvent-exposed peptide hydrogen atoms (free from hydrogen bonds). Points are obtained by re-plotting the experimental data given in Figs. 1 and 2. ●, at pD=5.6 (at various temperatures in the range of 0—55 °C); ○, at pD=6.3; ×, at pD=7.0; ▲, and at pD=7.7. Continuous lines are obtained by calculation on equation (6), and by assigning the γ_i values to the 148 peptide NH groups as shown in Table 1. ——, for pD=5.6; ·····, for pD=6.3; ----, for pD=7.0; and —·—, for pD=7.7.

was found to be the case not only for the plot at pD=5.6 but also for plots at pD=6.3, 7.0, and 7.7. This fact may be taken as indicating that the observed temperature effect on the exchange kinetics is mostly attributable to the temperature effect on k_e, and that γ_i value of every NH group is almost independent of temperature in the range of 0—55 °C, although it becomes very slightly higher on raising the temperature of the solution. This is quite similar to what we found for lysozyme[2] and α-lactalbumin[3] as long as the temperature was kept by 20—25 °C lower than the thermal transition point.

In Fig. 5, we have re-plotted our kinetic data given in Figs. 1 and 2 in the form of X *versus* $\log_{10} k_e t$ curve. On the basis of what has just been stated, no distinction is made here between the points for different temperatures, but different marks are given to points for different pD's. As may be seen in the figure, the "relaxation spectrum" depends slightly but appreciably upon pD. Every γ_i value is considered to become lower as pD of the solution increases from 5.6 to 7.7.

Discussion

The denaturation of sperm whale myoglobin was extensively investigated by Acampora and Hermans[17] as a function of pH and temperature. In Fig. 6, transition temperatures found by them are shown as a function of pH of the solution. The area with hatching corresponds to the native form region. All the place within this region are considered to be similar as far as the optical density and/or optical rotation measurements are concerned. In the manner of fluctuation of the structure, however, there may be a variety even within the native region, and this is just the subject of our study. In this respect, we have examined in the present work the region surrounded by the rectangle in Fig. 6. Within this region, the fluctuation has been found to be greater for lower pH than that for higher pH, while it is almost independent of the temperature of the solution.

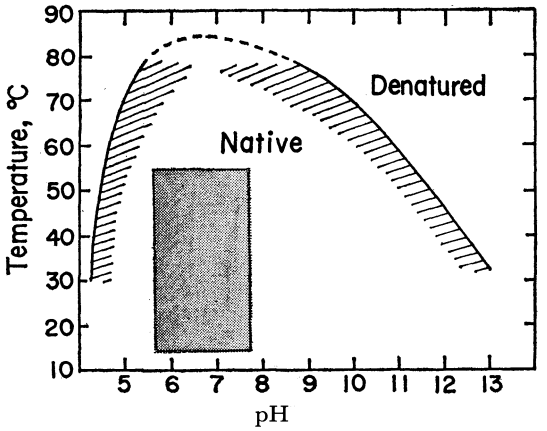

Fig. 6. An equilibrium diagram between the native and denatured forms of myoglobin given by Acampora and Hermans[17]. The rectangular region is what we have examined as to the fluctuation of the structure.

In addition, we have been able to go into some details of the fluctuation of the local structures within the molecule. Some experiments are yet to be designed for determining the rate of hydrogen exchange reaction of every particular NH group, so that the fluctuation amplitude of the structure can be mapped at every exact locus within the molecule. Even by our present study, however, it has been indicated that the map of the local fluctuation is different in myoglobin from that in lysozyme. In the latter, all of the 44 peptide-peptide hydrogen bonds have nearly equal chances of cleavage to one another, while in the former, 109 peptide-peptide hydrogen bonds have various chances, greatly different from one another.

At present, we have no unique solution as for the assignment of each γ_i value to a particular peptide NH group in the molecule. It is not improbable, however, that a peptide NH in a central portion of an α-helix has a lower γ value than that of a peptide NH around the terminal portion of the α-helix. This is just what has often been postulated for explaining various be-

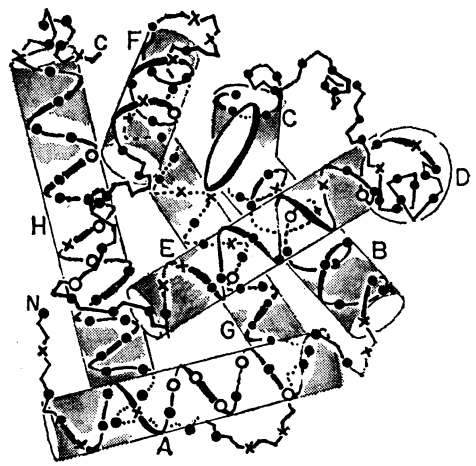

Fig. 7. A schematic drawing of a model of the fluctuation of the myoglobin structure, *i.e.*, a model of the distribution of the γ value in the molecule. γ is the probability of finding each NH···OC hydrogen bond broken, and this is considered to be greater at the terminal portions of each α-helix, and becomes smaller on going towards the central portion. This model is considered to be supported to some extent by a recent neutron diffraction study by Schoenborn.[20] Black and white circles in the figure indicate the deuterated and undeuterated peptide NH groups found by them in a partially deuterated myoglobin crystal. × denotes the absence of any indication for H or D.

haviors of α-helices of synthetic polypeptides.[8,18,19] We found, for example, that the hydrogen-deuterium exchange reaction is slower for longer α-helix of poly-L-glutamic acid.[8] In addition, recent neutron diffraction study of myoglobin by Schoenborn[20] may be taken as supporting the above idea to some extent. By soaking a myoglobin crystal in a solvent with 75% D_2O, they obtained a partially deuterated crystal, and then they located the hydrogen and deuterium atoms in the myoglobin molecule. As may be seen in Fig. 7, the undeuterated peptide groups found by them are mostly located in the central portions of eight α-helices in the molecule.

On the basis of what has just been described, we attempted to construct a tentative model in which the γ value of the peptide NH becomes lower on going from the terminus into the inner portion of each α-helix. The γ value should be proportional to $\exp(-\Delta F_1/kT)$ where ΔF_1 is the effective free energy change caused by the N_i—D_i transition, k the Boltzmann constant, and T the absolute temperature. Let us postulate that the free energy difference ΔF_n for the n-th residue from the terminus is given as

$$\Delta F_n = \Delta F_t + (n-1)\Delta F_s. \quad (7)$$

This is based upon the assumptions that the terminus peptide NH group has the free energy change ΔF_t and that the breaking of every peptide-peptide hydrogen bond in an α-helix takes place always after the next-door peptide-peptide hydrogen bond which is nearer to the terminus has been broken, with an additional free energy change of ΔF_s. After a few trials, we found that the following set of the values for the two parameters fits the observed relaxation spectra: $\Delta F_t=2.86$ and $\Delta F_s=0.82$ kcal/mol at pD=5.6 (25 °C), 3.00 and 0.93 at D=6.3, 3.00 and 0.98 at D=7.0, and 3.13 and 1.02 at pD=7.7. This set of values of ΔF_t and ΔF_s corresponds to a set of γ values given in Fig. 8 and Table 1. The calculated X *versus* $\log_{10}(k_e t)$

Molecular Structures of Hydrogen Cyanide and Acetonitrile as Studied by Gas Electron Diffraction

Ken-ichi KARAKIDA, Tsutomu FUKUYAMA, and Kozo KUCHITSU

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received October 27, 1973)

The structures of HCN and CH_3CN have been determined by gas electron diffraction for a critical comparison between diffraction and spectroscopic data. For HCN, the r_g(C≡N), determined by gas electron diffraction, 1.158±0.003 Å, is consistent within the estimated limit of experimental error with that calculated from the spectroscopic r_e structure and the harmonic and anharmonic force constants by a perturbation procedure, 1.158_8 Å. For CH_3CN, electron diffraction intensities have been analyzed jointly with the rotational constants for the normal and three deuterated species determined by microwave spectroscopy by Kessler *et al.* and Thomas *et al.* The isotopic difference in the average C–H distance, $\delta r = r_{av}$(C–H) − r_{av}(C–D), has also been treated as one of the independent parameters. The analysis has led to the following structure: r_g(C≡N) = 1.159±0.002 Å, r_g(C–C) = 1.468±0.002 Å, r_g(C–H) = 1.107±0.004 Å, ∠C–C–H (r_{av}) = 109.7±0.2° and δr = 0.001±0.002 Å.

The purpose of the present determination of the r_g structures of hydrogen cyanide and acetonitrile is twofold. First, a comparison of the structures is made with those of analogous molecules with conjugated multiple bonds in pursuit of a systematic variation in the C–C and C≡N bond lengths with environment.[1,2] Second, a comparison is made of the structures determined by electron diffraction (ED) with those determined by spectroscopic (SP) methods, since these molecules are suitable examples for a critical check of SP and ED structures.

For HCN the equilibrium (r_e) structure[3] and the potential constants (up to the quartic)[4] have been determined by infrared spectroscopy with such precision that the r_g structure can be calculated purely from spectroscopic data by a perturbation procedure.[5] A comparison of ED and SP structures should then afford a direct test of the experimental accuracy and the theory of ED[5-7] on which our method is founded. Our attention has primarily been called to the C≡N distance, since the accuracy of the C–H distance determined by ED is not sufficient for such a critical comparison. Similar studies have already been made for a number of molecules, for which r_e structures and potential constants are well known by spectroscopy (diatomics, CO_2, CS_2, NH_3, CH_4, *etc.*), and in all cases the structures are reported to be fully consistent.[2] However, there still remain unsolved problems important for the application of the method to more complicated systems. For instance, for diacetylene[8] the bond lengths, mean amplitudes and rotational constants derived from ED appeared to be slightly different from those determined by SP, and the small discrepancies were tentatively ascribed to a cubic potential term representing bending-stretching interactions.

Furthermore, the hydrogen-deuterium isotope effect on the average structure is another important problem, which has by no means been settled, for a combined analysis of ED and SP measurements. Acetonitrile was selected in this study because of its simplicity, high symmetry, well-defined quadratic force field, and the absence of low frequency motions such as internal rotation.

The ED structure of CH_3CN was reported to be[9] r(C–C) = 1.54±0.02 Å and r(C≡N) = 1.16±0.02 Å, or[10] r(C–C) = 1.49±0.03 Å and r(C≡N) = 1.16±0.03 Å, where the C–H distance and CCH angle were assumed. The r_0 structure was determined from ten rotational constants for eight isotopic species determined by microwave spectroscopy.[11-14] Besides the C–H, C≡N, C–C distances and CCH angle, r_0(C–D) and the CCD angle were taken as independent parameters.[14] The isotope effects on the r_0 structure were: r_0(C–H) − r_0(C–D) = 0.0048 Å and ∠CCH − ∠CCD = 0.1°. The isotopic rotational constants were used by Costain[15] and Matsumura *et al.*[16] to determine the r_s structure by Kraitchman's equations. The r_s and r_0 structures are compared with the r_g structure determined in the present analysis in a later section.

Experimental

A sample of hydrogen cyanide (bp 26 °C) was prepared by adding sulfuric acid to sodium cyanide. The vessel was filled with dry nitrogen and the product was trapped in ice-cold water. The crude product containing water was purified by passing it through a tube heated to about 40 °C packed with calcium chloride. Acetonitrile was obtained from a commercial source (purity 96%, bp 81 °C) and used after distillation. The infrared spectra of HCN gas and CH_3CN liquid showed no band that could be assgined to impurities.

Electron diffraction photographs were taken with an apparatus equipped with an r^3-sector[17] at camera lengths of 107.8 and 243.2 mm. The electron wavelength was about 0.06 Å. The sample gases were maintained in thermal equilibrium with their liquid phase at 0 °C for HCN and at room temperature for CH_3CN. The pressures of the samples were about 250 and 70 Torr for HCN and CH_3CN, respectively. The exposure time for the shorter camera length was about 40 s for each sample, while that for the longer camera length was about one-third of that. Other experimental details are described elsewhere.[17,18]

The scale factor was calibrated with reference to the r_a(C=O) distance (1.164_6 Å) of carbon dioxide measured with the identical camera geometry. The accelerating voltage was monitored during photographic exposures. The observed r_a(C=O) distance and its standard deviation were 1.1649±0.0004 Å. Besides this calibration, the r_a(N≡N) of nitrogen (theoretical, 1.100_7 Å[19]) was also measured, and it was confirmed that carbon dioxide and nitrogen gave consistent scale factors.

Observed molecular intensities covering the range s = 3.5—37.7 Å^{-1} were used in the analysis. The data taken with

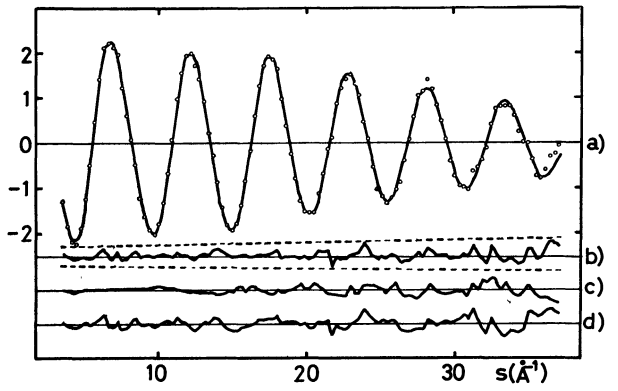

Fig. 1. a) Experimental and best-fit molecular intensities for HCN shown in dots and solid curves, respectively.

b) Experimental minus best-fit theoretical. The broken curve represents the estimated limit of random error in the molecular intensity (corresponding to a relative error of 1×10^{-3} in the original photocurrent).

c) Typical difference between two molecular intensity data used in the analysis illustrating the degree of reproducibility.

d) The observed minus theoretical molecular intensity calculated from spectroscopic parameters.

b) See caption b) of Fig. 1.

the short and long camera lengths were linked at $s=13.8$ and 11.9 Å^{-1} for HCN and CH_3CN, respectively.[20] The elastic and inelastic scattering factors and the phase shifts were taken from the tables prepared by Bonham *et al.*[21] The molecular intensities are illustrated in Figs. 1 and 2 for HCN and CH_3CN, respectively, and the corresponding radial distribution curves are given in Figs. 3 and 4. For a representation of the reproducibility of the molecular intensity data, a difference between two intensities for HCN selected arbitrarily is shown in Fig. 1 (c). The level of random scatter is similar to that of the residuals (observed minus calculated intensities) derived from a least-squares analysis.

Analysis and Discussion

HCN. A linear equilibrium structure was assumed. A least-squares analysis was carried out with an empirical diagonal weight matrix.[22] The asymmetry parameters κ[19] for the C–H and C≡N bonds

r(C-H)	−13	−63	52	−13	11	74	
r(C≡N)	−35	−54	−48	−9	−12	−21	15

a) Units ($\times 10^{-4}$) for the distances are Å, those for the indices are dimensionless. b) Index of resolution for the long-camera region, 0.87±0.03. c) Index of resolution for the short-camera region, 0.98±0.05.

were estimated to be 1.7×10^{-5} and 0.5×10^{-6} Å^3 from the anharmonicity parameter a_3 for the diatomic molecules CH and CN,[23] 1.98 and 2.27 Å^{-1}, respectively. The κ parameter for the nonbonded N–H pair was ignored. The vibrational corrections for the shrinkage effect[24] and the mean amplitudes of vibration ($d=r_a-r_\alpha$ and l_{calcd}, listed in Table 1) were calculated from the force constants.[4] The most probable r_g distances and mean amplitudes are shown in Table 1 with their limits of error estimated from random and systematic uncertainties.[25] The error in the r_g(C≡N) distance originates mainly from the standard deviation in the least-squares analysis (0.0015 Å), and the uncertainties in the scale factor and in the shrinkage corrections (about 0.0006 Å and 0.0003 Å, respectively) are relatively unimportant. A slight discrepancy between the observed and calculated l(C≡N) may be ascribed to a systematic error in the observed mean amplitude due to extraneous scattering observed in large scattering angles. However, the r_g(C≡N) distance is not influenced significantly by this extraneous scattering. A typical error matrix is given in Table 2.

In order to compare the r_g structure with the r_e structure determined by infrared spectroscopy, the values of $r_g-r_e=\langle\Delta r\rangle$ were calculated by use of the anharmonic force constants[4] and perturbation theory.[5,26,27] Mean values of the internal coordinates are calculated from those of the normal coordinates (Table 3). Then thermal averages were taken with the Boltzmann factors, and corrections for centrifugal distortion[28] were included. In the present case, however, the normal frequencies are so high that the temperature corrections are negligible. The results are compared in Table 4 with those estimated by a diatomic approximation,[6,23] $\langle\Delta r\rangle=(3/2)a_3\langle\Delta r^2\rangle$. The $\langle\Delta r\rangle$ values calculated by perturbation theory are estimated to be accurate to about 0.0001 Å, and hence, the diatomic approximation is valid to the order of 0.002 Å (see Table 4). The r_g structure calculated from the spectroscopic equilibrium structure are compared in Table 1 with those determined by electron diffraction. They are consistent with each other within the experimental error of the latter. This situation is illustrated in Fig. 1 (d) as a difference curve between the observed molecular intensity and that calculated from the spectroscopic parameters. The fluctuations of the difference curve are random and similar in magnitude to those of the least-squares residuals.

Table 3. Mean values of the normal coordinates for HCN[a]

$\langle Q_1\rangle$	0.00988	$\langle Q_1Q_2^2\rangle$	0.00032
$\langle Q_3\rangle$	−0.00638	$\langle Q_3Q_2^2\rangle$	−0.00088
$\langle Q_1^2\rangle$	0.00801	$\langle Q_1^2Q_2^2\rangle$	0.00039
$\langle Q_2^2\rangle$	0.04851	$\langle Q_3^2Q_2^2\rangle$	0.00025
$\langle Q_3^2\rangle$	0.00525	$\langle Q_2^4\rangle$	0.00471

a) The normal coordinates are in (amu)$^{1/2}$Å.

a) Derived from the r_{av} structure determined in the present study. b) Refs. 15, 16. No estimates of uncertainties are given. c) Ref. 14. No estimates of uncertainties are given. d) r_{av} structure. e) Isotopic differences based on the r_{av} structure. f) Assumed value.

to vary δr as one of the parameters. Hence, a major part of the uncertainties resulting from the assumptions about unknown isotopic differences are eliminated, and the precision of these parameters is thereby improved by nearly an order of magnitude.

The r_g structure derived from the r_{av} structure determined in the present study is compared with the r_s[15,16] and r_0 structures[14] in Table 9.* Particularly significant is the discrepancy of about 0.01 Å observed in the r_g(C–C) and $r_s(r_0)$(C–C) distances. The r_g(C≡N) and r_g(C–C) bond distances in acrylonitrile,[35] cyanogen,[36] acetonitrile and hydrogen cyanide are compared in Table 10. The r_g(C≡N) in acrylonitrile is longer than those in the other molecules. The r_g(C–C) in acetonitrile is significantly longer than those in acrylonitrile and cyanogen.

* **Note added in proof**: A more precise r_0 structure of acetonitrile has recently been determined: J. L. Duncan, D. C. McKean, and N. D. Michie, *J. Mol. Structure*, **23** (1974), in press.

Determination of the Number of Hydrogen-Bonds in a Protein Molecule

Mamoru NAKANISHI and Masamichi TSUBOI

Faculty of Pharmaceutical Sciences, University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received October 27, 1973)

By means of an infrared-spectroscopic observation of the hydrogen-exchange reaction, the number of peptide-peptide hydrogen-bonds involved in a given protein molecule in its aqueous solution can be determined.

Every globular protein is considered to involve a proper set of intra-molecular hydrogen-bonds in its native form, both in its crystalline state and in its aqueous solution. Such a proper set of the hydrogen-bonds seems to keep a proper rigidity and at the same time a proper flexibility of the protein molecule, both of which are essential for playing its biological role.

We propose here a simple and reliable method of determining the number of the peptide-peptide hydrogen bonds in a given protein molecule in its aqueous solution. The method is based on a hypothesis, which is supported by our recent experiments,[1-3] that the slowly exchanging peptide hydrogen atoms are assignable to those involved in such hydrogen bonds. Similar but slightly different hypotheses on the slowly exchanging hydrogen atoms in proteins seem to have for long been kept in minds by a number of investigators.[4-7] Until recently, however, they were not used for obtaining useful pieces of information of the protein structure. A tritium-gel filtration study recently made by Englander and Staley[8] demonstrated, for example, that the amount of slowly exchanging hydrogens found in myoglobin matched the known number of hydrogen-bonded amides.[9] While, in the measurement of ^3H radioactivity, one needs to take, in principle, all the exchangeable hydrogen atoms in the protein molecule in question into account, we can extract only the behavior of the peptide NH groups by an absorption measurement.[5] This is what we propose here to adopt.

The proposed method is as follows. Dissolve, at time zero, a protein into D_2O in 2~3% in concentration, and place the solution into a sealed cell with CaF_2 windows and of 50 μ in optical path length. Measure the time-dependent decrease in the ratio of the peak intensity of amide II band around 1540 cm^{-1} to that of amide I band at about 1650 cm^{-1} (A(amide II)/A(amide I)) (see Fig. 1). In the intensity measurements, the baseline for the amide I band is drawn parallel to the 100% transmittance line from the transmittance at 1800 cm^{-1}, and the baseline of the amide II band is taken as the absorption of a solution of the completely deuterated protein. Com lete deuteration is achieved by heating the solution of the exchanging protein to a proper temperature, or by elevating the pH of the solution to 10 or so. Figure 2 illustrates a set of semilogarithmic plots of such a hydrogen→deuterium exchange reaction. The protein here is bovine pancreatic α-chymotrypsin. As may be seen in the Figure, two kinds of peptide hydrogen atoms are readily found: those which exchange quickly and those which do slowly. At 25 °C and at a proper pH, the exchange reaction of the former usually completes within three hours or so and that of the latter usually takes place

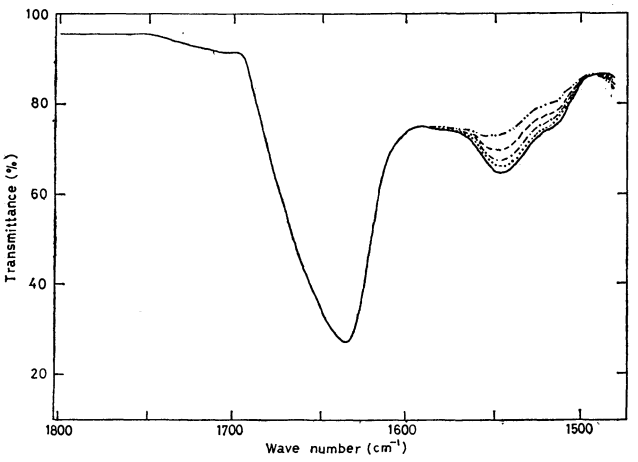

Fig. 1. Infrared absorption curves of bovine pancreatic α-chymotrypsin in D_2O solution of pH 3.5 at 35°C. —— 10 min, ····· 19 min, —·—·— 55 min, ——— 170 min, —···—··— 20 hr.

for one day or so. The semilogarithmic plot corresponding to the latter forms usually a straight line at least for first several hours or at least for first several points of measurement. Extend, then, this straight line till the ordinate axis and find the ordinate value for slowly exchanging peptide NH groups at time zero. Repeat similar kinetic measurements at different temperatures (from 10 °C to denaturation temperature, for example), at different pH's (from 4 to 8, for example), and/or with different concentrations of a denaturation agent (LiCl, for example, from 0

TABLE 1. DETERMINATION OF THE NUMBER OF PEPTIDE-PEPTIDE HYDROGEN-BONDS IN PROTEIN MOLECULES

Protein	Intensity ratio Amide II/Amide I at time zero		Ratio of NH···OC / total peptide NH's (a_i/a_t)	Total peptide NH's (N_t)	Peptide NH's involved in peptide-peptide hydrogen bonds	
	Total peptides (a_t)	Slowly exchanging peptides (a_i)			Hydrogen exchange experiment (N_i)	Found in X-ray analysis
Lysozyme	0.450	0.155[1,2]b)	34.4%	126[10]b)	44[1,2]	44[18]
Myoglobin	0.450	0.335[3]	74.4	148[11]	109[3]	108[9]
α-Chymotrypsin	0.450	0.235	52.2	229[12]	120	121[19]
Bovine pancreatic trypsin inhibitor	(0.450)a)	0.170	37.8	53[13]	20	20[20]
Concanavalin A	(0.450)a)	0.175	38.9	226[14]	88	(86)c)
α-Lactalbumin	0.450	0.130	28.9	120[15]	35	
Soy-bean trypsin inhibitor (Kunitz)	(0.450)a)	0.220	48.9	170[16]	83	
Streptomyces subtilisin inhibitor (17)	(0.450)a)	0.140	31.1	104[17]	33	

a) The a_t value was not determined for this protein. The value was assumed to be 0.450. b) The numbers in these parentheses indicate references. c) Counted on the basis of the description of Edelman *et al.* in the Ref. 14.

to 8 M). It is essential to confirm that the straight lines corresponding to the slowly exchanging hydrogen atoms converge into the same point on the ordinate axis (see Fig. 2). Record the ordinate value of this point as $[\text{A(amide II)/A(amide I)}]_i=a_i$ (given in the third column of Table 1). Next, the A(amide II)/A(amide I) value for the total peptide NH groups of this protein is to be determined. This is done by following very slow hydrogen→deuterium exchange reaction of the protein at pH=3 and/or at a low temperature (0~5 °C). Obtain the ordinate value at time zero by an extrapolation (see Fig. 2), and let it be $[\text{A(amide II)/A(amide I)}]_t=a_t$. For every protein so far examined, the a_t value has been found to be 0.450 (the second column of Table 1). From the result of amino acid analysis of the protein in question, find the total number N_t of peptide NH groups in the molecule. Then, $N_i=N_t(a_i/a_t)$ is considered to be equal to the number of peptide NH groups involved in peptide-peptide (NH···O=C) hydrogen bonds.

The method has been tested for five proteins, for which X-ray crystallographic analyses have been made. The results are shown in Table 1. As may be seen here the N_i values obtained by the proposed method are in accord with the numbers of peptide-peptide hydrogen bonds found by the X-ray analyses within ±1. The method has also been applied to bovine α-lactalbumine, soy-bean trypsin inhibitor (Kunitz), and Streptomyces subtilisin inhibitor. The N_i value found here (respectively 35, 83, and 33) are considered to be predicted numbers of peptide-peptide hydrogen bonds in these proteins.

The method involves an assumption that the contributions of various undeuterated peptide groups in the protein molecule to the A(amide II)/A(amide I) value are equal. This assumption is justified to some extent by our finding[21] that the intensity ratio now in question is practically independent of the helix content for poly-L-glutamic acid in an aqueous system. The assumption is all indirectly supported by our test for five proteins already mentioned.

It is well known that the position of the amide II band is slightly different for different polypeptide conformations (at 1535 cm^{-1} for the random conformation, at 1546 cm^{-1} for the α-helix, and at 1530 cm^{-1} for the β-structure). The amide I band also appears at different frequencies according to the conformations[22] (between 1650 and 1655 cm^{-1} for random, at 1650 cm^{-1} for the α-helix, and at 1630 cm^{-1} for the β structure; for a deuterated polypeptide each of three frequencies is lower than what is given here by about 10 cm^{-1}). In principle, therefore, integrated intensities of the I and II bands should always be measured at each time to determine the number of peptide groups remained undeuterated. Sometimes, this is certainly found to be necessary. Quite often, however, the band widths of both amide I and II do not appreciably all over the reaction time (see Fig. 1, for example). In such a case, a simple measurement of the peak intensities can give an accurate enough kinetic data.

One of the merits of this method is its simplicity. In addition, the reliability of this method is rather easily judged by examining how good is the convergence of the several straight lines corresponding to the kinetic measurements of the slowly exchanging peptide NH groups under several different conditions (in temperature, pH, and/or LiCl concentration).

The peptide NH groups involved in the peptide-sidechain hydrogen-bonds (instead of the peptide-peptide hydrogen bonds) seem to escape completely to be counted in the proposed method.[1,3] By a proper adjustment of the pH and temperature of the solution, however, the number of the peptide NH groups in this category may also be determined by a similar kinetic method.[3] Sometimes, a further classification of the peptide-peptide hydrogen bonds may also be made by a kinetic study by means of an infrared absorption measurement similar to what is described above.

We thank Dr. A. Ikegami for discussions.

The Kinetics and Mechanisms of the Reactions of Nitric and Nitrous Acids with Hexaaquochromium(II) Ions

Hiroshi OGINO, Keiichi TSUKAHARA, and Nobuyuki TANAKA

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received August 23, 1973)

Stoichiometric and kinetic investigations of reactions of the nitric and nitrous acids with hexaaquochromium(II) ions have been carried out in acidic media. The stoichiometries of these reactions found in this work were consistent with the mechanisms proposed by Swaddle,[1] in which one mole of nitric acid reacts with four moles of chromium(II) and one mole of nitrous acid reacts with two moles of chromium(II). For the former reaction, it was found that the two-electron reduction of nitric acid by chromium(II) is rate-determining and that the rate constant was 2.2×10^{2} M^{-1} s^{-1} at 25 °C and at an ionic strength of 1.0 ($NaClO_4$). For the latter reaction, it was found that the one-electron reduction of nitrous acid by chromium(II) is rate-determining and that the rate constant was 4.5×10^{3} M^{-1} s^{-1} at 25 °C and at an ionic strength of 1.0 ($NaClO_4$). The rates of the reactions of chromium (II) with anionic species of the parent acids, NO_3^- and NO_2^-, were too slow to be detected under the present experimental conditions.

Ardon and Herman[2] demonstrated that the reaction products of nitrate with hexaaquochromium(II), Cr^{2+}, in acidic media were $Cr(NO)(H_2O)_5^{2+}$, $Cr(H_2O)_6^{3+}$ and $(H_2O)_4Cr(OH)_2Cr(H_2O)_4^{4+}$ and succeeded in isolating a nitrosyl complex, $[Cr(NO)(H_2O)_5]SO_4$. Swaddle[1] suggested, on the basis of the product ratios, that the reduction of the nitrate ion by Cr^{2+} in an acidic solution proceeds through the following reaction paths:

$$Cr^{2+} + NO_3^- + 2H^+ \longrightarrow Cr(IV) + NO_2^- + H_2O \quad (1)$$

$$Cr(IV) + Cr^{2+} \xrightarrow{H_2O} (H_2O)_4Cr(OH)_2Cr(H_2O)_4^{4+} \quad (2)$$

$$Cr^{2+} + NO_2^- + 2H^+ \xrightarrow{H_2O} Cr(H_2O)_6^{3+} + NO + H_2O \quad (3)$$

$$Cr^{2+} + NO \xrightarrow{H_2O} Cr(NO)(H_2O)_5^{2+} \quad (4)$$

Mori *et al.*[3] prepared several salts of $[Cr(NO)(NH_3)_5]^{2+}$ by the reaction of chromium(II) in an ammoniacal solution with sodium nitrite or nitrate. The chloride salt was prepared also by Griffith by the reaction of chromium(II) with NO in liquid ammonia.[4] In early works[2,3] on nitrosyl chromium complexes, the formulation Cr(III)–(NO^-) has been used. Later it was reported,[4,5] however, that the formulation Cr(I)–(NO^+) was more feasible.

In order to ascertain the kinetic and mechanistic details of these interesting reactions, the reactions of nitrate and nitrite with chromium(II) in acidic media have been dealt with in this study.

Experimental

Reagents. All the solutions were prepared with redistilled water. The acidic solution of hexaaquochromium(III) perchlorate was prepared by the reduction of sodium dichromate in perchloric acid with hydrogen peroxide. The chromium(II) perchlorate solutions were prepared by the reduction of hexaaquochromium(III) perchlorate with a zinc amalgam under an atmosphere of nitrogen. The chromium(II) solutions thus obtained contained known amounts of sodium perchlorate and perchloric acid. The concentration of the hydrogen ion was determined by the method reported in the literature.[6,7] A sodium perchlorate solution was prepared by the neutralization of sodium bicarbonate of a primary standard reagent grade with perchloric acid. All the other chemicals were of an analytical reagent grade and were used without further purification.

Kinetic Measurements and Apparatus. For the reaction of nitrate with Cr^{2+}, kinetic measurements were carried out by a conventional method similar to that reported previously.[8] The change in the absorbance with the time was followed at 422 nm with a Hitachi EPS-3 pen-recording spectrophotometer. Solutions containing $NaNO_3$, $NaClO_4$ and $HClO_4$ were added to the optical cell, which was then sealed with a serum cap. After the solution had been purged with nitrogen gas, chromium(II) was added with a syringe.

As the rate of the reaction of HNO_2 with Cr^{2+} was too fast to be measured by a conventional method, the stopped-flow method was employed by the use of a Hitachi EPS-2 rapid-scanning spectrophotometer which was equipped with two syringes as reactant containers. One of the syringes was filled with a deoxygenated $NaNO_2$ solution, and the other, with a solution containing Cr^{2+}, $NaClO_4$ and $HClO_4$. The change in the transmittance at 443 nm was recorded on a storage-type oscilloscope (Hitachi V-018 Memoriscope) as a function of time after the mixing of the two reactant solutions.

In the kinetic measurements, the temperature was controlled at 25 °C and the ionic strength was adjusted to 1.0 with sodium perchlorate.

Product Analyses. The chromium species in the reaction products were separated by SP-Sephadex C-25 (Pharmacia, Sweden) column chromatography. The column used was 2.5 cm^2 in cross-section and 4 cm in height. The separation of the products with the Sephadex column was much more convenient than that with Dowex 50W used by previous workers.[1,2]

After the completion of the reaction between nitrate and Cr^{2+}, the reaction mixture was passed through the column. When the initial concentration of Cr^{2+} was smaller than that of nitrate, the chromium species were adsorbed in three bands···brown at the bottom, bluish-violet in the middle, and green at the top. The brown-colored species was eluted with a 0.1 M $HClO_4$–0.1 M $NaClO_4$ solution and was identified as $Cr(NO)(H_2O)_5^{2+}$ ($CrNO^{2+}$) spectrophotometrically. The bluish-violet species was eluted with a 0.1 M $HClO_4$–0.5 M $NaClO_4$ solution and was identified as $Cr(H_2O)_6^{3+}$ (Cr^{3+}). The green species was eluted with a 0.1 M $HClO_4$–0.9 M $NaClO_4$ solution and was identified as $(H_2O)_4Cr(OH)_2$–$Cr(H_2O)_4^{4+}$ ($Cr(OH)_2Cr^{4+}$). When the initial concentration of Cr^{2+} exceeded that of nitrate, the column gave four bands···of brown, bluish-violet and two kinds of green··· from the bottom to the top of the column. The lower three

products were identified as $CrNO^{2+}$, Cr^{3+}, and $Cr(OH)_2Cr^{4+}$ respectively. The uppermost green species was considered to be produced by the reaction between $CrNO^{2+}$ and Cr^{2+}. Sephadex column chromatography revealed that this green species moves slightly slower than $Cr(OH)_2Cr^{4+}$. This species has not been identified, but the spectrum shows absorption maxima at 584 nm and 422 nm which are very close to those of $Cr(OH)_2Cr^{4+}$.[9]

In the nitrous acid system, the chromium species produced during the reaction were adsorbed on the Sephadex column in two bands···an upper bluish-violet band and a lower brown band, unless the initial concentration of nitrous acid was smaller than that of Cr^{2+}. The brown species was eluted with a 0.1 M $HClO_4$–0.1 M $NaClO_4$ solution and was identified as $CrNO^{2+}$. The bluish-violet species was eluted with a 0.1 M $HClO_4$–0.5 M $NaClO_4$ solution and was identified as Cr^{3+}. Under these experimental conditions the formation of $Cr(OH)_2Cr^{4+}$ was not observed. The chromium content in each effluent was determined spectrophotometrically as CrO_4^{2-} after oxidation with alkaline peroxide.

Results

Reaction of $CrNO^{2+}$ with Cr^{2+}. Stoichiometric and kinetic studies of this reaction were reported by Armor and Buchbinder very recently.[10] According to their results, the stoichiometry is:

$$4Cr^{2+} + 2CrNO^{2+} + 6H_2O + 2H^+ \longrightarrow 3Cr(OH)_2Cr^{4+} + 2NH_3OH^+ \quad (5)$$

The present authors have also investigated the reaction between $CrNO^{2+}$ and Cr^{2+} and found that the rates of the reaction were in agreement with those reported by Armor and Buchbinder. However, a green species which is different from $Cr(OH)_2Cr^{4+}$ and which can not be expected from the stoichiometry of Eq. (5) was found in this work. From the chromatographic behavior described in the Experimental section, the positive charge of this species seems not to be smaller than 4. Further extensive work has not been made of this system, however.

Reaction of Nitrate with Cr^{2+}. The results of the product analyses are summarized in Table 1. If the initial concentration of nitrate is higher than that of Cr^{2+}, nitrate is found to react with four equivalents of Cr^{2+} to produce $CrNO^{2+}$, Cr^{3+}, and $Cr(OH)_2Cr^{4+}$ in the ratio of 1 : 1 : 1. The overall reaction of nitrate with Cr^{2+} is expressed by Eq. (6), which is the same as that reported by Swaddle:[1]

$$NO_3^- + 4Cr^{2+} + 2H^+ \longrightarrow CrNO^{2+} + Cr^{3+} + Cr(OH)_2Cr^{4+} \quad (6)$$

When the initial concentration of nitrate is smaller than that of Cr^{2+}, the yield of $CrNO^{2+}$ is much lower than those of Cr^{3+} and $Cr(OH)_2Cr^{4+}$, as is shown in Table 1. This can be understood in view of the fact that there is a slow reaction between the $CrNO^{2+}$ produced by Reaction (6) and the Cr^{2+} remaining in excess.

The kinetics for the reaction of nitrate with Cr^{2+} were studied under second-order conditions. If it is assumed that the rate equation (7) is valid for this system:

$$\text{Rate} = k[NO_3^-][Cr^{2+}] \quad (7)$$

Eq. (8) is then derived:

$$\log \frac{4\varepsilon_{app}[NO_3^-]_0 - D_t}{D_\infty - D_t} = \frac{4[NO_3^-]_0 - [Cr^{2+}]_0}{4\times 2.303} kt + \log \frac{4[NO_3^-]_0}{[Cr^{2+}]_0} \quad (8)$$

where $[NO_3^-]_0$ and $[Cr^{2+}]_0$ indicate the initial concentrations of nitrate and Cr^{2+} respectively. D_t is the absorbance measured at time t, and D_∞ is the final absorbance. The symbol, ε_{app}, is the apparent extinction coefficient of the products at 422 nm, which was determined from the absorbance after the completion of the reaction. The plots of the left-hand side of Eq. (8) *vs.* t gave a good linear relation for three half-lives. The second-order rate constant, k, was determined from the slope of this straight line. The kinetic results under the experimental condition of nitrate in excess of Cr^{2+} are given in Table 2. The rate constants were independent of the initial concentrations of both nitrate and Cr^{2+} at a given hydrogen-ion concentration. Therefore, the reaction is strictly second-order. Under the condition of Cr^{2+} in excess of nitrate, the second-order rate constants are very different from the values given Table 2. This can be attributed to the fact that the $CrNO^{2+}$ produced reacts further with the Cr^{2+} remaining in the solution. The observed second-order rate constants were considerably dependent on the hydrogen-ion concentrations, as is shown in Table 2. This dependency can be explained by considering the following mechanism:

$$HNO_3 \overset{K_a}{\rightleftharpoons} H^+ + NO_3^- \quad (9)$$

$$NO_3^- + Cr^{2+} \xrightarrow{k_1} \text{products} \quad (10)$$

$$HNO_3 + Cr^{2+} \xrightarrow{k_2} \text{products} \quad (11)$$

On the basis of this mechanism, the following rate law was derived:

$$\text{Rate} = \frac{k_1 + k_2 K_a^{-1}[H^+]}{1 + K_a^{-1}[H^+]}[NO_3^-]_T[Cr^{2+}] \quad (12)$$

where

$$[NO_3^-]_T = [NO_3^-] + [HNO_3]$$

$$K_a = \frac{[H^+][NO_3^-]}{[HNO_3]}$$

Many values for the dissociation constant, K_a, of nitric acid have been reported.[11,12] They are in good agreement with each other, almost all of the values ranging from 15 to 34 M at 25 °C and at an ionic strength of zero. Of them, the value of 15.4 which was revised by Davis and de Bruin[13] was used for the analysis of the rate constants without any correction of the ionic strength. The plots of $k(1+K_a^{-1}[H^+])$ *vs.* $[H^+]$ show a linear relation, which is given in Fig. 1. The value of the intercept is practically zero. This means that the contribution of Reaction (10) is negligible and that the whole reaction proceeds almost entirely through the path represented by Eq. (11). The rate constant, k_2, is $2.2\times10^2\ M^{-1}\,s^{-1}$, and the value of k_1 is less than $0.2\ M^{-1}\,s^{-1}$.

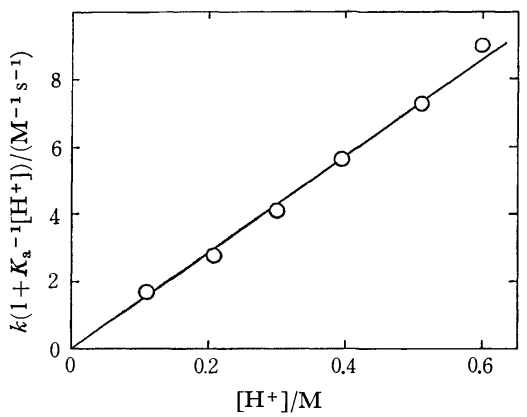

Fig. 1. The plots of $k(1+K_a^{-1}[H^+])$ *vs.* $[H^+]$ at 25 °C. and at an ionic strength of 1.0.

Reaction of Nitrous Acid with Cr^{2+}. Nitrous acid was found to react with two equivalents of Cr^{2+} to produce $CrNO^{2+}$ and Cr^{3+} in the ratio of 1 : 1 under the condition of a higher concentration of nitrous acid than of Cr^{2+}. Therefore, the overall reaction of nitrous acid with Cr^{2+} is as follows:

$$HNO_2 + 2Cr^{2+} + H^+ \longrightarrow CrNO^{2+} + Cr^{3+} + H_2O \quad (13)$$

In order to avoid the interference of the reaction between $CrNO^{2+}$ and Cr^{2+}, the kinetics of the reaction of nitrous acid with Cr^{2+} were studied under the condition that the concentration of nitrous acid exceeded that of Cr^{2+}. When the second-order rate equation:

$$\text{Rate} = k[HNO_2][Cr^{2+}] \quad (14)$$

holds in this case, Eq. (15) is derived:

$$\log\frac{2\varepsilon_{app}[HNO_2]_0 - D_t}{D_\infty - D_t} = \frac{2[HNO_2]_0 - [Cr^{2+}]_0}{2\times2.303}kt + \log\frac{2[HNO_2]_0}{[Cr^{2+}]_0} \quad (15)$$

where $[HNO_2]_0$ and $[Cr^{2+}]_0$ are the initial concentrations of HNO_2 and Cr^{2+} respectively. The symbol, ε_{app} is the apparent extinction coefficient of the products at 443 nm. The plots of the left-hand side of Eq. (15) *vs.* t gave a good linear relation for three half-lives. The second-order rate constant, k, was obtained from the slopes of the plots. The results are given in Table 3. The rate was independent of the hydrogen-ion concentration. The pK_a value of nitrous acid has been reported to be 2.8.[11,12] HNO_2 is the predominant species under the present experimental conditions where the hydrogen-ion concentrations were varied from 0.10 to 0.65 M. Therefore, the mechanism of the reaction can be expressed as:

$$HNO_2 + Cr^{2+} \xrightarrow{k} Cr^{3+} + NO + OH^- \quad (16)$$

$$Cr^{2+} + NO \xrightarrow{\text{fast}} CrNO^{2+} \quad (17)$$

The second-order rate constant, k, was determined to be $(4.5\pm0.3)\times10^3\ M^{-1}\,s^{-1}$. The analysis of the data given in Table 3 revealed that the rate constant of NO_2^- with Cr^{2+} was less than $5\times10^4\ M^{-1}\,s^{-1}$.

Table 3. Rate constants of the reaction between HNO_2 and Cr^{2+} at 25 °C and at an ionic strength of 1.0

$[Cr^{2+}]_0$/mM	$[HNO_2]_0$/mM	$[H^+]$/M	k/($10^3\ M^{-1}\,s^{-1}$)

4.4	6.0	0.30	4.7
4.3	6.0	0.50	4.9
5.8	6.0	0.65	4.4

Discussion

It is known that the reactions of Cr^{2+} with Tl(III) and O_2 produce $Cr(OH)_2Cr^{4+}$.[9] In the Tl(III) system, the following mechanism has been proposed:

$$Cr^{2+} + Tl(III) \longrightarrow Cr(IV) + Tl(I)$$

$$Cr(IV) + Cr^{2+} \longrightarrow Cr(OH)_2Cr^{4+}$$

A kinetic study of the reaction of molecular oxygen with Cr^{2+} showed that the reaction rate is of the second-order in Cr^{2+} and of the first-order in O_2.[14] From these results, the formation of a μ-peroxo dimer was suggested. In the reaction of HNO_3 with Cr^{2+}, however, the reaction rate is of the first-order in both reactants. Product analysis revealed that $CrNO^{2+}$, Cr^{3+}, and $Cr(OH)_2Cr^{4+}$ were produced in the ratio of 1 : 1 : 1. In the reaction of HNO_2 with Cr^{2+}, only $CrNO^{2+}$ and Cr^{3+} were produced, in the ratio of 1 : 1. Therefore, it is considered that $Cr(OH)_2Cr^{4+}$ is produced in the first step of the reaction between HNO_3 and Cr^{2+}. The experimental results lead to the conclusion that the mechanism expressed by Eqs. (1) to (4) is effective in the reaction between HNO_3 and Cr^{2+} when the contribution of the reaction between $CrNO^{2+}$ and Cr^{2+} is negligibly small.

Table 4 summarizes the rate constants obtained or estimated in this work. It is interesting to note that Cr^{2+} reacts with HNO_3 but not the NO_3^- ion, which is the predominant species under the present experimental conditions. Swaddle reported that $[Co(NO_3)(NH_3)_5]^{2+}$ was reduced by Cr^{2+}.[1] Thirty-three percent of the reaction proceeds through the reduction of the central cobalt(III) ion to the cobalt(II) ion, while the remaining sixty-seven percent of the reaction proceeds through the reduction of the coordinated nitrato ligand instead of the central cobalt(III) ion. Therefore, when the NO_3^- ion is bound to the proton or is coordinated to the pentaamminecobalt(III) ion, which is a Lewis acid, the reduction of nitrate by Cr^{2+} is accelerated.

Table 4. Rate constants of the reactions of Cr^{2+} with some reactants obtained in this work at 25 °C and at an ionic strength of 1.0 ($NaClO_4$)

Reactant	Rate constant/(M^{-1} s^{-1})
HNO_3	2.2×10^2
NO_3^-	<0.2
HNO_2	$(4.5\pm0.3)\times10^3$
NO_2^-	$<5\times10^4$
NO	$>4.5\times10^3$

It was found in this work that the rates of the reactions of Cr^{2+} with HNO_3, HNO_2, and NO are in the following order: $HNO_3<HNO_2<NO$.

The authors wish to thank Professor Kahei Takase in this department for allowing us to use a rapid-scanning spectrophotometer. They also wish to thank the Ministry of Education for the financial support granted for this research.

Factors Affecting the Line-width of Nitrogen Superhyperfine Structure in the ESR Spectra of Copper(II) Complexes

Yasuomi NONAKA, Tadashi TOKII* and Sigeo KIDA

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received August, 13, 1973)

ESR spectra were measured for several series of copper(II) complexes in an attempt to find the best-observable condition for ^{14}N-superhyperfine structure. It was demonstrated that in addition to the temperature and the dilution factors the line-width of ^{14}N-superhyperfine structure is broadened out by the following factors; 1) deviation from square planar configuration around a copper ion, *i. e.*, deformation to elongated octahedron or square pyramid due to weak bonding along the tetragonal axis and/or distortion of coplanality of the coordination bond effected by some steric condition, and 2) the presence of protons that can couple with an unpaired electron and ^{14}N-nuclei.

Although variable informations of coordination bonds are obtainable from an observation of ^{14}N-superhyperfine structure (=^{14}N-shfs) in ESR spectra of copper(II) complexes, there are known rather few examples which give ESR spectra with well-resolved ^{14}N-shfs useful for the discussion of nature of coordination bond. In this study, therefore, it was attempted to investigate under what condition ^{14}N-shfs is observed with a good resolution.

It has been known that broadening of ESR line-width is effected mainly by 1) spin-lattice interaction and 2) spin-spin interaction.[1] Since the spin-orbit coupling plays an essential role at the mechanism, 1), the spin-lattice relaxation time depends very markedly on the energy separation between the ground state and the first excited state capable of coupling with the ground state *via* spin-orbit interaction.[2] Among the various symmetries of copper(II) complexes, the separation between the ground and the first excited states is largest for a square planar complex. Accordingly, deformation of square planar structure to eleongated octahedron, square pyramid or flattered tetrahedron should cause broadening of ESR line-width.

For the mechanism, 2), there are two kinds of spin-spin interactions, that is, intermolecular interaction between paramagnetic ions and interaction between an unpaired electron and nuclear spins. The effect due to the former interaction can be reduced by diluting a sample in diamagnetic host lattice or solvent. The latter interaction sometimes gives a hyperfine or superhyperfine structure with many sharp lines, but when there are so many nuclear spins to interact with an electron spin and line-width are not narrow enough to separate each line, the lines are superposed on each other, making the line-width of the original spectrum broader. Therefore, the effect of ligand protons may play an important role for the resolution of ^{14}N-shfs of copper(II) complexes.

Among the various factors on which ESR line-width is dependent, the two effects, *i. e.*, the effect of deviation from square planar configuration around copper ion and the effect of protons in the ligand capable of coupling with an electron spin, are mainly investigated in the present study.

Experimental

Bis(*N*-alkylsalicylaldiminato)copper(II),[3] bis(*N*,*N*-dialkylglycinato)copper(II),[4] sodium bis(*N*,*N'*-dialkyloxamidato)-cuprate(II),[5] *N*,*N'*-bis(2-aminoethyl)malonamidatocopper-(II),[6] bis(2-hydroxyacetophenone)ethylenediiminatocopper-(II)[7] and bis(salicylaldehyde)ethylenediiminatocopper(II)[7] were prepared according to the methods described in the literatures.

The ESR spectra were measured with a JEOL ESR-apparatus model JES-ME-3X at 130 K and at room temperature using the X-band, DPPH being used as a standard marker.

Absorption and reflectance spectra in the visible region were measured with Hitachi EPS-2 and EPS-3T spectrophotometers, respectively.

Abbreviations of the compounds are tabulated in Table 1.

1) 1,1,2,2-tetrachloroethane, 2) water+ethanol (1 : 1), 3) methanol, 4) corresponding nickel(II) complex, 5) reflectance spectrum

The spectra of a series of bis(*N*-alkylsalicylaldiminato)copper(II), (where, alkyl=methyl, ethyl, *i*-propyl, and *t*-butyl) are shown in Fig. 1. For the methyl homologue ^{14}N-shfs was observed in a perpendicular component of the spectra, though the resolution was rather poor. With the increase of bulkiness of the alkyl group ^{14}N-shfs becomes unresolved as seen in Fig. 1. This is compatible with the trend[10] that the increase of the size of a substituent on the imine nitrogen sterically effects a distortion of the planar configuration around the copper ion. On the contrary to the above results, as shown in Fig. 2, the resolution of ^{14}N-shfs becomes better with the increase of bulkiness of alkyl group for the series of bis(*N*,*N*-dialkylglycinato)copper(II), (where, alkyl=H, methyl, ethyl, and *n*-propyl). Since in these compounds the alkyl groups block the axial coordination sphere from the attack of solvent molecules, the increase of the size of alkyl group reduces the axial perturbation, effecting a good resolution of the ESR line-width. As shown in Table 2, frequency of visible absorption band increases with the increasing order of bulkiness of alkyl groups *i.e.*, H<CH_3<C_2H_5<*n*-C_3H_7. This fact is supporting the above discussion, since it is well known that d-d band of a copper complex shifts to higher frequency with the change from elongated octahedron to square planar configuration.

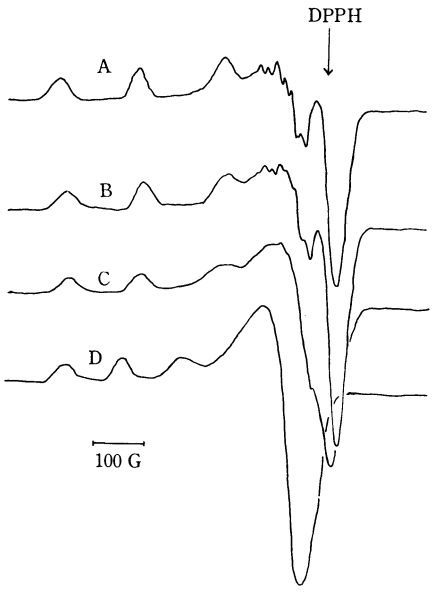

Fig. 1. ESR spectra of bis(*N*-alkylsalicylaldiminato)-copper(II) in 1,1,2,2-tetrachloroethane at room temperature
A: methyl, B: ethyl, C: *i*-propyl, D: *t*-butyl

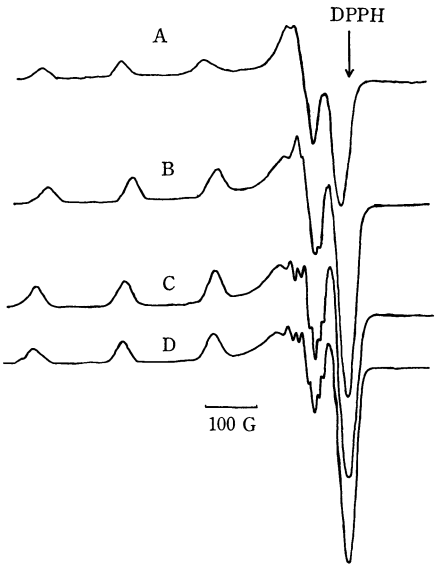

Fig. 2. ESR spectra of bis(*N*,*N*-dialkylglycinato)-copper(II) in water-ethanol (1 : 1) at 133 K
A: H, B: methyl, C: ethyl, D: *n*-propyl

In the series of bis(*N*,*N'*-dialkyloxamidato)copper(II) complexes, frequency of visible band of powder reflectance spectrum decreases with the increase of bulkiness of alkyl group, *i.e.*, $H > CH_3 > C_2H_5$, (*cf.* Table 2), quite reverse to the bis(*N*,*N*-dialkylglycinato)copper(II) series. This fact implies that in this case the alkyl groups function as to twist the planar configuration around the copper ion by steric hindrance.

Accordingly, one might expect that the resolution of ^{14}N-shfs becomes poor with the increase of the size of the substituent. This is true for the methyl and the ethyl derivatives, as obviously seen in Fig. 3. However, the oxamidato complex shows much poorer

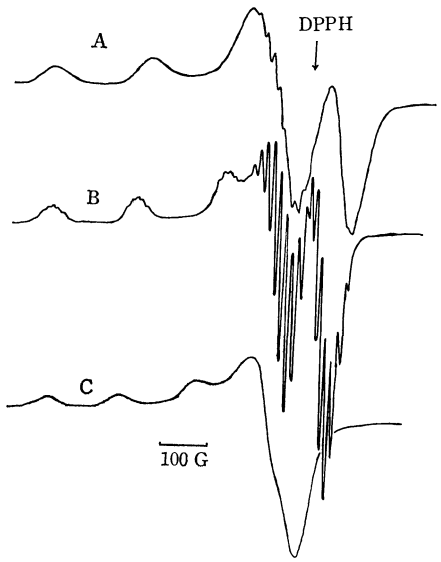

Fig. 3. ESR spectra of sodium bis(*N*,*N'*-dialkyloxamidato)cuprate(II) doped in the corresponding nickel(II) complexes at 130 K
A: H, B: methyl, C: ethyl

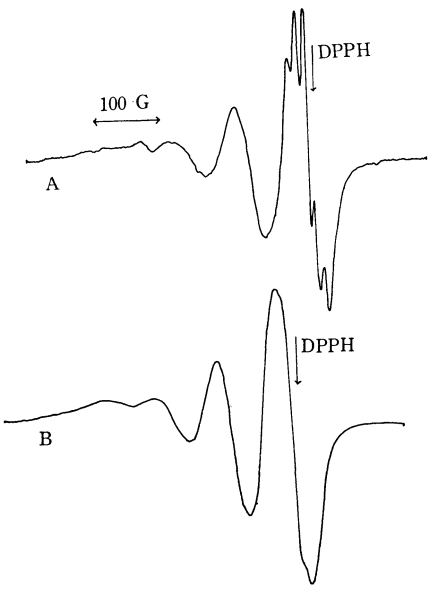

Fig. 4. ESR spectra of bis(salicylaldehyde)ethylenediiminatocopper(II) (B) and its methyl derivative (A) in 1,1,2,2-tetrachloroethane at room temperature.

^{14}N-shfs than the methyl derivative (Fig. 3). This rather complex result seems to be only interpretable in terms of the line-broadening effect of protons on nitrogen atoms of oxamide, *i. e.*, further coupling with the hydrogen nucleus tends to increase the number of ESR lines,[11] but line-width is not so sharp as to separate each line, and as a result, smoothening out the original ^{14}N-shfs.

A similar effect is seen in bis(salicylaldehyde)ethylenediminatocopper(II) (=[Cu salen]) and its methyl derivative (=[Cu oapen]). As evidently seen in Fig. 4, the ^{14}N-shfs was much better resolved in the methyl homologue than that in [Cu salen]. This is also attributed to the line-broadening effect of methine protons which are very close to the C═N═Cu π-bond system.

The effect of protons on ^{14}N-shfs is clearly elucidated by comparison of the spectra of *N*,*N'*-bis(2-aminoethyl)-malonamidatocopper(II) (= [Cu malen]) in methanol and D_2O. As shown in Fig. 5, ^{14}N-shfs was observed in D_2O solution,[12] but hardly observable in methanol solution. This is because the spin-spin interaction between electron and nucleus is much weaker for $^2H(\mu_I=0.857)$ compared to that for ^1H $(\mu_I=2.793)$ and therefore, ^{14}N-shfs of [Cu malen] was observed only in D_2O, where the amino hydrogens are substituted with deuterium.

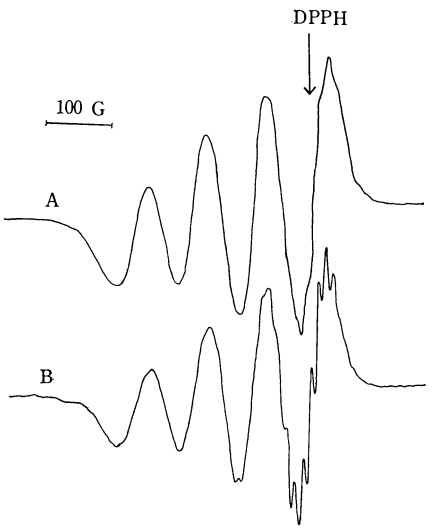

Fig. 5. ESR spectra of *N*,*N'*-bis(2-aminoethyl)malonamidatocopper(II) in methanol (A) and in D_2O (B) at room temperature.

All the above facts support our initial assumption that a deviation from square planar configuration and a presence of protons to couple with an unpaired electron spin are both important factors for the interference of observation of well-resolved ^{14}N-shfs.

Methylene Analogs of Cyclobutenedione. VIII.[1] The Oxidation of 1-Halo- and 1,2-Dihalo-3,4-bis(diphenylmethylene)cyclobut-1-enes

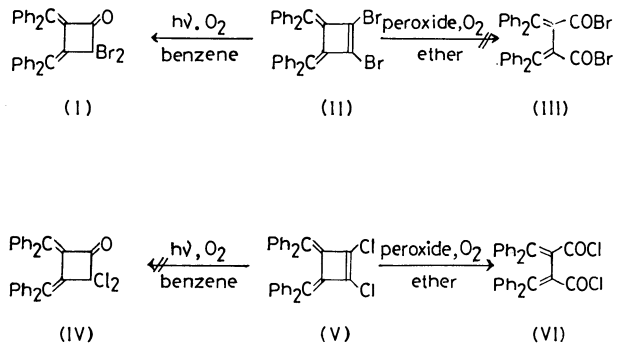
Fumio TODA, Fumio MONDEN, and (in part) Mitsuru OHI

Department of Industrial Chemistry, Faculty of Engineering, Ehime University, Matsuyama 790

(Received July 26, 1973)

The ether peroxide-catalyzed oxidation of 1-chloro- (X) and 1,2-dichloro-3,4-bis(diphenylmethylene)cyclobut-1-enes (V) afforded two ring-opened products, XI and VI respectively. However, neither X nor V was oxidized by photooxidation. By the photooxidation, 1-bromo- (XVI) and 1,2-dibromo-3,4-bis(diphenylmethylene)cyclobut-1-enes (II) were converted to cyclobutanones, XIII and I respectively. Although II was inert to the peroxide-catalyzed oxidation, XVI was oxidized by this procedure. Nevertheless, the main product of the latter reaction was the cyclobutanone (XIII). The mechanisms of these reactions were described.

We have previously reported[2] a photooxidation of 1,2-dibromo-3,4-bis(diphenylmethylene)cyclobut-1-ene (II) in benzene affording 2,2-dibromo-3,4-bis(diphenylmethylene)cyclobutane-1-one (I) in a 78% yield. It was found, however, that the dichloro-analog of II (V) was inert to the photooxidation and did not afford the dichloro-analog of I (IV). On the other hand, V was oxidized in ether containing its peroxide to afford 2,3-bis(diphenylmethylene)succinoyl chloride (VI), while the ether peroxide-catalyzed oxidation of II did not afford any product, II being recovered (Scheme 1).

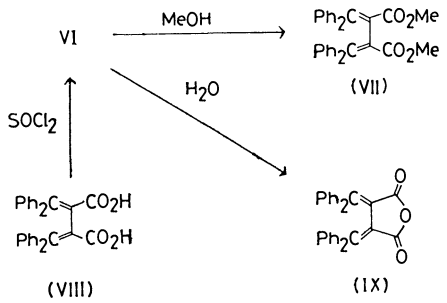


Scheme 1.

These facts suggest that the behavior in response to oxidation reactions varies with the halogen bonded to the 1,2-positions of 3,4-bis(diphenylmethylene)cyclobut-1-ene (XXII). The study was extended to the oxidations of 1-monohalo derivatives of XXII and the Br-Cl-analog (XIX).

The stirring of a solution of V in commercial ether under an oxygen atmosphere at room temperature for 3 hr afforded VI in a 62% yield. The structure of VI was determined by studying its reactions with methanol and with water, which afforded dimethyl 2,3-bis(diphenylmethylene)succinate (VII) and 3,4-bis(diphenylmethylene)succinic anhydride (IX) respectively. Finally VI was identified by a comparison of its spectral data with those of an authentic sample prepared by the reaction of 2,3-bis(diphenylmethylene)succinic acid (VIII) with $SOCl_2$ (Scheme 2).

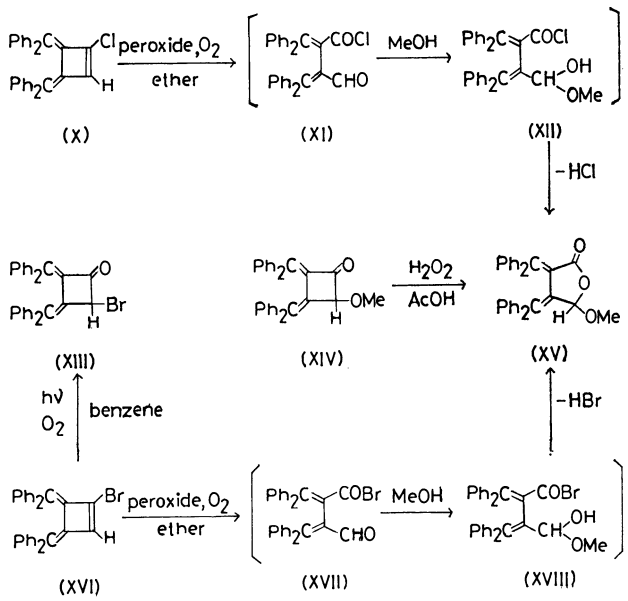
Although X was inert to the photooxidation in benzene, it underwent the peroxide-catalyzed oxidation; 5-methoxy-3,4-bis(diphenylmethylene)-γ-butyrolactone (XV) (33%) was isolated after the treatment of the



Scheme 2.

reaction mixture with MeOH. The structure of XV was identified by a comparison of its spectral data with those of an authentic sample prepared by the oxidation of 2-methoxy-3,4-bis(diphenylmethylene)-cyclobutane-1-one (XIV) with H_2O_2 in AcOH. The formation of XV can be interpreted in terms of an intramolecular esterification of the hemiacetal (XII) produced by the reaction of the oxidation product (XI) with MeOH (Scheme 3).

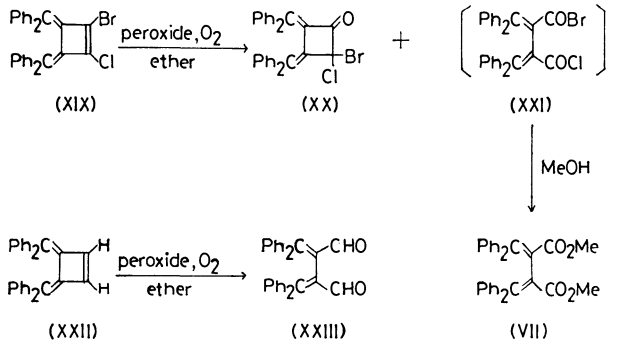
The photooxidation of XVI afforded 2-bromo-3,4-bis(diphenylmethylene)cyclobutane-1-one (XIII) in an 81% yield. XVI was also oxidized by the peroxide-



Scheme 3.

catalyzed method to afford, after treatment with MeOH, XIII and XV in 48 and 15% yields respectively. Since the same result was obtained when the oxidation was carried out in the dark, the pathway of the formation of XIII may not be a photochemical one. The mechanism of the formation of XV is probably the same as that of the conversion of X to XV (Scheme 3).

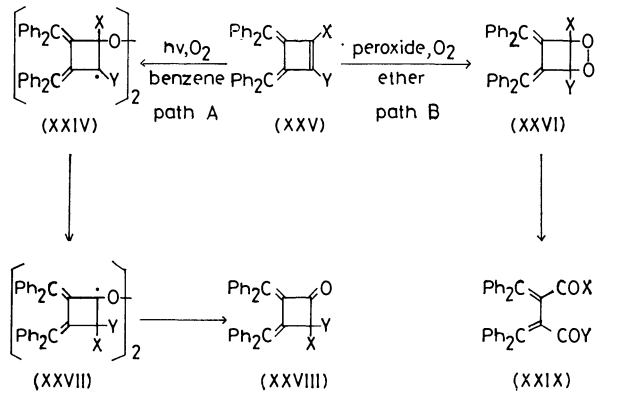
The chloro-derivatives (V and X) were oxidized by the peroxide-catalyzed procedure, but not photochemically. On the contrary, the bromo-derivative (II) was oxidized by the photochemical procedure, but not by the peroxide-catalyzed one. This rule, however, was not applicable to the peroxide-catalyzed oxidation of XVI, even though the main product (XIII) was the same as the photooxidation product of XVI.



Scheme 4.

The photooxidation of XIX[1] afforded only a resinous material. The peroxide-catalyzed oxidation of XIX afforded, after treatment with MeOH, 2-bromo-2-chloro-3,4-bis(diphenylmethylene)cyclobutane-1-one (XX) and VII in 24 and 12% yields respectively. The acid halide (XXI) may be an initial oxidation product and a precursor of VII (Scheme 4). The peroxide-catalyzed oxidation of XXII in ether afforded 2,3-bis(diphenylmethylene)butanedial (XXIII) in a quantitative yield, whereas the photooxidation of XXII in benzene did not afford any product, XXII being recovered.[3]

Both the photochemical and peroxide-catalyzed oxidations are undoubtedly radical reactions, because they were inhibited by hydroquinone. Nevertheless, the type of oxidation reaction differs widely depending on



Scheme 5.

whether the halogen bonded to the cyclobutene is Br or Cl. The reason for the difference is not clear, but one plausible interpretation is as follows: the photooxidation proceeds *via* Path A, which includes a 1,2-shift of the halogen atom (X·) in the intermediate (XXIV) initially produced by an intermolecular oxygenation of XXV. The ketonization of XXVII affords XXVIII. The peroxide-catalyzed oxidation proceeds *via* Path B, which includes the ketonization of XXVI initially produced by an intramolecular oxygenation of XXV (Scheme 5). It is understandable that only the cyclobutenes containing Br can be oxidized to cyclobutanone derivatives, because the elimination of the Br atom from a radical species is easier than that of the Cl atom.[4] The formation of XX, which was not contaminated with its dibromo-(I) and/or dichloro-analog (IV), in the oxidation of XIX suggests that the 1,2-shift of X· is an intramolecular one. Because it has been established that 1,2-shifts of hydrogen do not occur to any detectable extent during the lifetime of radicals,[4] the oxidation reaction of XXII to afford XXIII, but not any cyclobutanone derivative, is also understandable. An intermediate similar to XXVI has been postulated for the reaction of tetraphenylcyclobutadiene with oxygen to afford dibenzoyl-*cis*-stilbene.[5]

Experimental

All the melting points are uncorrected. Photooxidation was carried out at room temperature under an oxygen atmosphere in purified dry benzene, using 100-W high-pressure mercury lamp (Riko Kagaku Sangyo Co.). Peroxide-catalyzed oxidation was carried out at room temperature under an oxygen atmosphere in commercial ether. The IR, UV, and NMR spectra were measured in Nujol mull, $CHCl_3$, and $CDCl_3$ respectively.

Peroxide-catalyzed Oxidation of V. A solution of V (0.2 g) in ether (30 ml) was stirred under an oxygen atmosphere at room temperature for 3 hr. The recrystallization from dry AcOEt of the crystals formed when the reaction mixture was allowed to stand for 10 hr afforded VI as pale yellow prisms; 0.133 g (62%); mp 164—165 °C. IR: 1790 and 1770 (C=O) and 1540 cm^{-1} (C=C); λ_{max}: 356 (14000), 306 (13000), and 249 nm (ε, 20000); NMR: 2.8 τ (m, Ph).

Found: C, 74.88; H, 4.09%. Calcd for $C_{30}H_{20}O_2Cl_2$: C, 75.00; H, 4.17%.

Reactions of VI with MeOH and H_2O. A solution of VI (0.1 g) in MeOH (30 ml) was heated under reflux for 1 hr. The subsequent evaporation of the solvent left crude crystals. Recrystallization from AcOEt afforded VII as yellow needles; 0.095 g (97%); mp 233—234 °C (lit,[6] mp 233—234 °C).

A solution of VI (0.1 g) in wet THF (5 ml) was heated under reflux for 1 hr. Recrystallization from AcOEt of the crude crystals obtained by the evaporation of the solvent afforded IX as red rhombs; 0.08 g (90%); mp 230 °C (lit,[2] mp 230 °C).

Preparation of an Authentic Sample of VI. A mixture of VIII (1 g) and $SOCl_2$ (5 ml) was heated at 70 °C for 5 hr. The residue left after the evaporation of the excess $SOCl_2$ was recrystallized from dry AcOEt to afford VI; 0.42 g (38%); mp 164—165 °C.

Peroxide-catalyzed Oxidation of X. A solution of X (0.49 g) in ether (50 ml) was stirred under an oxygen atmosphere at room temperature for 3 hr. The oily material left by the

evaporation of the solvent was crystallized by the addition of MeOH. Recrystallization from AcOEt afforded XV as orange prisms; 0.17 g (33%); mp 212.5—214 °C. IR: 1770 (C=O), 1550 (C=C), and 1080 cm^{-1} (MeO-); λ_{max}: 380 (9600) and 258 nm (ε, 21600); NMR: 3.0 (m, Ph, 20 H), 4.7 (s, CH, 1H), and 6.5 τ (s, OCH_3, 3H).

Found: C, 83.63; H, 5.30%. Calcd for $C_{31}H_{24}O_3$: C, 83.76; H, 5.40%.

Preparation of an Authentic Sample of XV. A solution of XIV[2] (0.1 g) and 30% H_2O_2 (0.4 ml) in AcOH (40 ml) was heated at 60 °C for 7 hr. The subsequent evaporation of the solvent left crude crystals. Recrystallization from AcOEt afforded XV; 0.047 g (45%); mp 212.5—214 °C.

Photooxydation of XVI. A solution of XVI (1 g) in benzene (100 ml) was irradiated under an oxygen atmosphere at room temperature for 3 hr. The subsequent evaporation of the solvent left crude crystals. Recrystallization from AcOEt afforded XIII as orange red hexagonals; 0.84 g (81%); mp 202—203 °C (lit,[2] mp 202—203 °C).

Peroxide-catalyzed Oxidation of XVI. A solution of XVI (0.193 g) in ether (30 ml) was stirred for 3 hr under the same conditions as were used for X. The subsequent evaporation of the solvent left crude oil. Treatment with a small amount of MeOH afforded a mixture of orange red and orange crystals, which were then separated mechanically. The recrystallization of the former from AcOEt afforded XIII; 0.085 g (48%). The recrystallization of the latter from AcOEt afforded XV; 0.027 g (15%).

Peroxide-catalyzed Oxidation of XIX. A solution of XIX (1 g) in ether (100 ml) was stirred for 5 hr under the same conditions as were used for X. The subsequent evaporation of the solvent left an oil, which was crystallized by the addition of a small amount of MeOH to afford a mixture of red prisms and yellow prisms. They were separated mechanically. The recrystallization of the red prisms from AcOEt afforded XX; 0.248 g (24%); mp 169.5—171 °C. IR: 1775 (C=O) and 1540 cm^{-1} (C=C); λ_{max}: 463 (15600), 344 (9200), and 273 nm (ε, 20200).

Found: C, 70.68; H, 3.63%. Calcd for $C_{30}H_{20}OBrCl$: C, 70.40; H, 3.94%.

The recrystallization of the yellow prisms from AcOEt afforded VII; 0.119 g (12%).

Peroxide-catalyzed Oxidation of XXII. A solution of XXII (1 g) in ether (100 ml) was stirred for 3 hr under the same conditions as were used for X. The subsequent evaporation of the solvent left crude crystals. Recrystallization from AcOEt afforded XXIII as pale yellow rhombs; 1.08 g (100%); mp 208.5 °C (lit,[3] mp 208.5 °C). The spectral data were identical with those recorded for XXIII.[3]

Photocycloaddition of Thiocarbonyl Compounds to Multiple Bonds. X. Photocycloaddition of *O*-Alkyl Thiobenzoates to Olefins

Atsuyoshi OHNO, Tamotsu KOIZUMI, and Yutaka AKASAKI

Sagami Chemical Research Center, Nishiohnuma, Sagamihara-shi, Kanagawa 229

(Received September 10, 1973)

Photochemical reactions of *O*-ethyl and *O*-methyl thiobenzoates with various olefins have been studied. Some olefins afford ketones, others yield thietanes, and in some cases both products are obtained. Thiobenzoate *O*-esters in the n,π^* triplet state are the reacting species. The mechanism of the reaction has been elucidated: photocycloaddition of a thioester to an olefin results in the formation of a thietane. Photosensitized decomposition of the thietane yields an α,β-unsaturated ether, which is converted to a ketone by general acid-catalyzed hydrolysis.

Photochemistry of carbonyl compounds has been received intensive attention for many decades. In contrast, the photochemical behavior of thiocarbonyl compounds has generated little interest. Although several groups have recently published in this area, almost all the studies dealt with aromatic and alicyclic thioketones.[1-7]

This study was initiated to determine the substituent effects on either the reactivity of photo-excited thiocarbonyl compounds or the transient intermediates in photocycloaddition to olefins, and to synthesize multifunctional compounds that may have synthetic utility.

Results and Discussion

Products. The reaction of *O*-alkyl thiobenzoates (**1**) with some olefins afforded ketone, **3** or **4** or both (Eq. 1), whereas with other olefins thietane derivative, **5** or **6** or both, or **7** or **8** or both, were obtained (Eq. 2). In some cases ketones and thietanes were obtained.

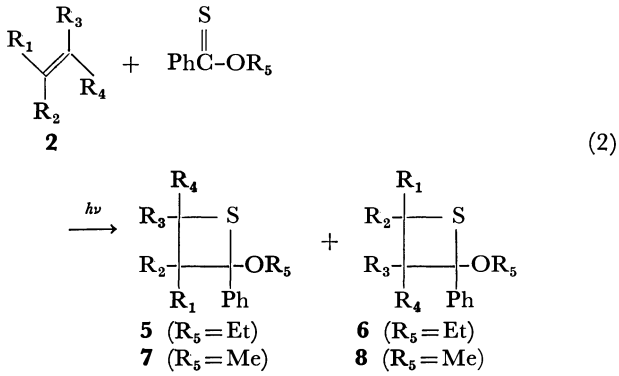
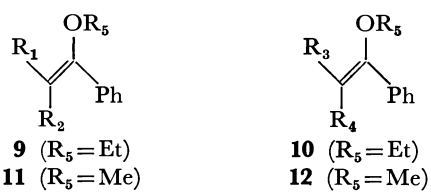
(1)



(2)

The unified designation used for compounds **2**—**8** is shown in Table 1 and the reactions are summarized in Tables 2 and 3.

Generally, the reaction mixture was subjected to column chromatography on silica gel and the yield of the isolated products were calculated from their weights. When the reaction mixture was analyzed by vpc before it was subjected to the column chromatography, the yields of ketones were surprisingly lower than those determined after column chromatography, as shown by parenthesized numbers in Tables 2 and 3. However, the vpc analysis indicated that the deficit of ketones was compensated by the presence of corresponding amounts of α,β-unsaturated ethers, **9** or **10** or both, or **11** or **12** or both.



(R_i's are those defined in Table 1)

a) See footnotes in Table 2.

Some of these ethers were isolated by subjecting the reaction mixture to column chromatography on neutral alumina. This surprising observation was explained when an authentic sample of the ether was quantitatively converted into the corresponding ketone by the treatment with silica gel—apparently an effective catalyst for this transformation.

Reacting Species. *O*-alkyl thiobenzoates have absorption maxima at around 290 nm ($\varepsilon \approx 12000$) and 420 nm ($\varepsilon \approx 120$) that are attributable to π,π^* and n,π^* transitions, respectively.[8] Excitation at either transition was found to bring about the reaction.

As shown in Fig. 1, when a mixture of *cis*- or *trans*-2-pentene and **1a** in *n*-dodecane was photo-irradiated, *cis-trans* isomerization of the olefin took place and the thermodynamically equilibrated composition of 75% *trans*- and 25% *cis*-2-pentene[9-11] was asymptotically attained.

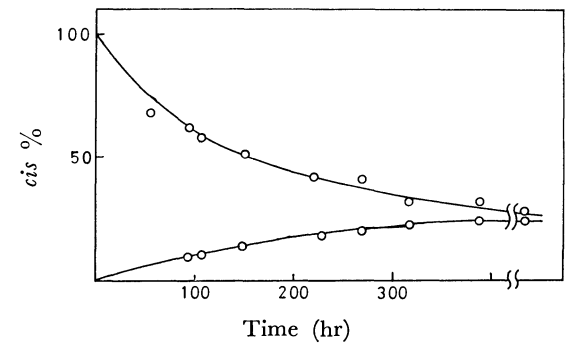

Fig. 1. Photo-initiated isomerizations of *cis*- and *trans*-2-pentene in the presence of *O*-ethyl thiobenzoate.

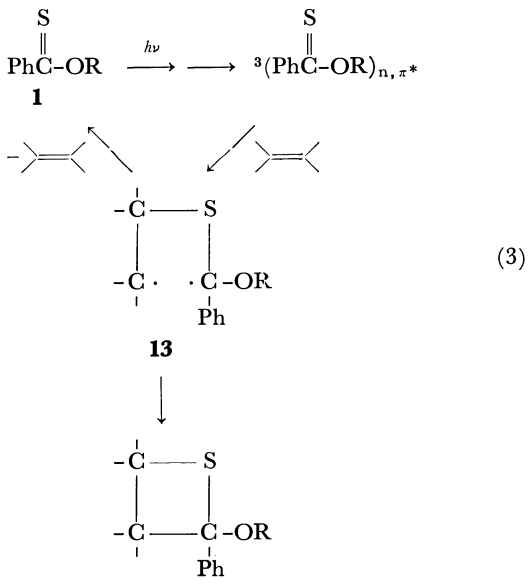
It is known that thiobenzophenone in the n,π^* triplet state behaves like a thiyl radical, *i. e.*, it attacks an olefin reversibly.[3a] The reactivities of benzophenone in the n,π^* triplet state and an alkoxy radical have also been compared.[12] The *cis-trans* isomerization of 2-pentene reported here suggests that photo-activated **1** is also in the n,π^* triplet state.

Further evidence of the multiplicity of the excited state responsible for the reaction was obtained from the photosensitized reaction of **1a** (E_T=57—58 kcal/mol)[13] with allylbenzene in the presence of Michler's ketone (λ_{max}=370 nm, ε=31000, E_T=62 kcal/mol).[14] Under the condition that more than 99% of the irradiated light was absorbed by Michler's ketone, the reaction was found to proceed similarly to that effected by direct photo-irradiation. However, quantitative observations were precluded by the fact that the quantum yield of the reaction is too low to be measured accurately (as is recognized from the reaction time). The observed effect of the photosensitizer together with the physico-chemical data on thiobenzoate *O*-esters[13] provide additional support for the electronic configuration and state of the reacting **1**.

Since the lowest triplet energies of simple alkenes (74—82 kcal/mol)[15] and substituted styrenes (60—70 kcal/mol)[16] are higher than that[13] of **1**, it is not necessary to take into account the energy transfer from **1** to olefins.

Mechanism of the Reaction. As discussed above,

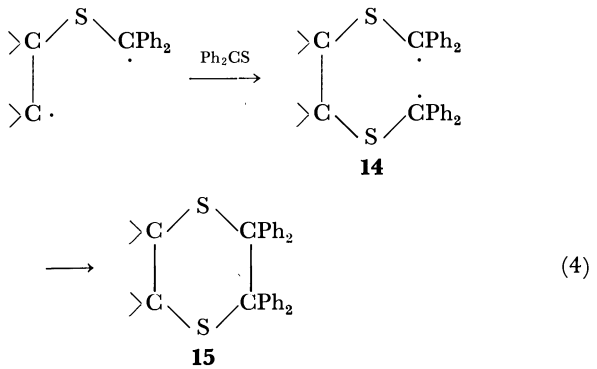


(3)

there is strong indication to propose that the reaction initiated by the attack of **1** in the *n,π* triplet state* on an olefin yielding a composite biradical **13** (Eq. (3)), which may regenerate ground-state **1** and the olefin, or cyclize into a thietane.[17]

The product distribution reveals that the attack of photo-excited **1** on an olefin takes place so as to form the more stable radical. However, when the olefin has a bulky substituent, attack on the less-hindered side is favored (Runs 3, 8, 12, 16, and 20). This observation is consistent with the general trend found in the chemistry of thiyl radicals.[18] In this connection, it is noteworthy that photo-excited **1** reacts with equal facility with tri-, di- or mono-substituted olefins, whereas the addition of thiyl radicals to tri-substituted olefins (compared to di- and mono-substituted olefins) proceeds slower and with increasing amounts of side products.[18]

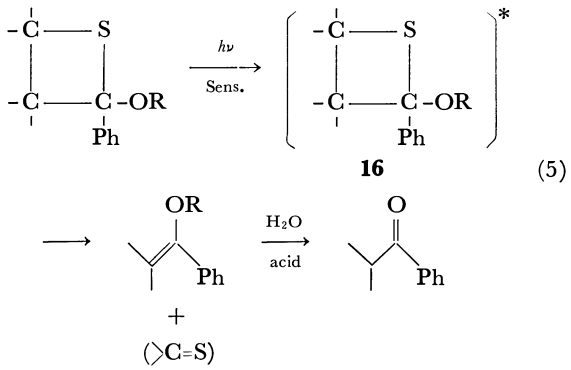
In the reaction of thiobenzophenone with alkenes the **13**-type biradical, formed as an intermediate, reacted with another molecule of thiobenzophenone giving **14**, then **15**.[3a] This reaction occurred with thiobenzophenone because it is a powerful scavenger of free radicals.[19] In contrast, since **1** has no tendency to react with free radicals,[20] the reactions described here do not afford 1,4-dithiane derivatives.



(4)

Again, in the reaction of thiobenzophenone a 1,3-dithiane is the proposed precursor of a thietane.[4b] Although we do not have proof that a 1,3-dithiane derivative is intermediary in the formation of a thietane, it should be noted that 2,4-diphenyl-2,4-diethoxy-1,3 dithiadecalin was obtained in 27% yield by the reaction of **1a** with cyclohexene.[21]

Unsubstituted and alkyl-substituted thietanes are known to be photolyzed into olefins.[22-24] However, there is no evidence for the photochemical transformation of alkoxythietanes into corresponding α,β-unsaturated ethers. Therefore, we studied the photolysis of an alkoxythietane (**7g**) as a controlled experiment. When a benzene solution of **7g** was irradiated with light from a high-pressure mercury lamp (315 and 366 nm), the majority of the products was tarry polymer. The vpc analysis showed that the yield of the ketone, **3g**, was only 7% and the ether, **11g**, was absent. On the other hand, in the presence of a large excess (about 9 equivalents) of **1b**, yields of **3g** and **11g** were improved to 59 and 16.5%, respectively. The present result reveals that α,β-unsaturated ethers are afforded by photosensitized decomposition of alkoxythietanes (Eq. (5)), although detailed mechanism is not known.



(5)

The fact that irradiation with wavelengths longer than 390 nm is effective in producing the ether (*e.g.*, **2a**+**1a**→**9a**) also supports the idea that the decomposition of the thietane is a photosensitized process. Based on the results reported by Barton and co-workers,[13] **16** is supposed to be in the triplet state. Photochemical reactions of alkoxy- and hydroxyoxetanes leading to the formation of an α,β-unsaturated ether and a ketone, respectively, have also been proposed.[25,26]

As described above, it is confirmed that the α,β-unsaturated ether is easily hydrolyzed into corresponding ketone in the presence of an acid like silica gel or hydrogen chloride.[27]

Experimental

Materials. As previously reported,[28] *O*-alkyl thiobenzoates (**1**) were prepared from the corresponding orthoesters[29] or imido ethers.[30,31] Olefins **2c** and **2l** were prepared according to Klages.[32] A mixture of **2b** and **2d**, obtained by the reaction of phenylmagnesium bromide and 1-chloro-2-butene,[33] was fractionally distilled by a Podbielniak Model 3475 apparatus yielding **2b** and **2d** of 70 and 90% purities, respectively. Other olefins were commercially available. An α,β-unsaturated ether, **11g** (a mixture of *cis*- and *trans*-isomers), was synthesized by refluxing a mixture of α-methylvalerophenone (1.7 g), trimethyl orthoformate (2.4 g), and *p*-toluenesulfonic acid (5 mg) in absolute methanol (8 ml) for 4 hr, followed by fractional distillation under a reduced

a) Chemical shifts are expressed by δ from TMS in CCl_4 and coupling constants, J, have the unit of Hz.

pressure: bp 85 °C/2 Torr; NMR (δ from TMS, CCl_4) 0.60—1.75 (m), 1.57 (s), 1.71 (s), 1.75—2.35 (m), 3.19 (s), and 7.20 (s); IR 3070—3000, 2900—2800, 1440, 1135, 1070, 770, and 700 cm^{-1}.

Found: C, 81.90; H, 9.31%. Calcd for $C_{13}H_{18}O$: C, 82.06; H, 9.54%.

Purities of materials were confirmed by NMR, IR, and vpc.

General Procedure. Reaction solutions were prepared in a dry box under an atmosphere of CO_2 by placing 0.5 g of **1**, 2.5 g of **2** and 2 ml of benzene in a Pyrex vessel.[34] Photoreactions were carried out by external irradiation method with a 400 W high-pressure mercury lamp (Toshiba H-400P) at a temperature of running water. Some reactions were carried out with a Toshiba UV-39 filter (transparent for >390 nm), and it was found that application of the filter did not alter the product distribution.

Photo-irradiation was continued until **1** disappeared completely. At the end of the reaction, products were analyzed directly by vpc (Hitachi K-53, TCD or FID, 20% XF-1150, 1 m, 140 °C for thietanes and **1**; 20% XF-1150, 1 m, 120 °C for alkyl aryl ketones and corresponding ethers; 5% XF-1150, 1 m, 140 °C for aralkyl aryl ketones and corresponding ethers) or, after evaporation of benzene and excess olefin, by column chromatography on silica gel with appropriate compositions of *n*-hexane-benzene mixtures.

cis-trans *Isomerization of 2-Pentene (**2f**).* A mixture of *trans*-2-pentene (578.4 mg, 8.26 mmol) and **1a** (1.0104 g, 6.09 mmol) in *n*-dodecane was irradiated. At an appropriate interval, aliquots were taken out from the mixture with a syringe and compositions of isomers were analyzed by vpc (40% $AgNO_3$/PEG, 1 m, room temperature). Similar experiments were also done with the *cis*-isomer. Results are shown in Fig. 1.

*Photosensitized Reaction of O-Ethyl Thiobenzoate (**1a**) with Allylbenzene (**2a**).* A mixture of **1a** (100.6 mg, 0.606 mmol), **2a** (495.2 mg, 4.20 mmol), and Michler's ketone (164.0 mg, 0.612 mmol) in acetonitrile (15 ml) was irradiated. A filter solution of aqueous 2,3-dihydro-5,7-dimethyl-1,4-diazepine perchlorate[35] (400 mg/l) was circulated through the outer shell of the reaction vessel. Under the condition, more than 99% of the irradiated light (366, 405/408, and 436 nm)[36] was absorbed by Michler's ketone. After 9 days, when no **1a** remained, the reaction mixture was worked-up and subjected to column chromatography on silica gel and the ketone, **3a**, was isolated in quantitative yield.

*Photolysis of 2-Methoxy-2-phenyl-3-methyl-3-propylthietane (**7g**).* A solution composed of **7g** (40 mg, 0.169 mmol) and **1a** (226.7 mg, 1.49 mmol) in 4 ml of benzene was irradiated for 13 days until **7g** had disappeared completely. The

a) Molecular Weight: Calcd for $C_{19}H_{22}OS$; 298. Found; 300.7.

vpc analysis of the reaction mixture showed that **3g** and **11g** were afforded in 59 and 16.5% yields, respectively. However, in the absence of **1a**, the reaction afforded large amount of tarry polymer and the yield of **3g** was only 7% after 21 days. Although aliquots were analyzed by vpc every day, no indication was obtained for the formation of **11g** from this reaction solution.

*Hydrolysis of 1-Methoxy-1-phenyl-2-methyl-1-pentene (**11g**).* A CCl_4 solution (5 ml) of **11g** (190 mg, 1 mmol) containing catalytic amount of silica gel was stirred at room temperature and aliquots were analyzed by vpc. After 2 weeks almost all **11g** was converted into **3g**. When a drop of hydrochloric acid was added to the solution in place of silica gel, the ether transformed into the ketone within a day. Furthermore, a solution of **11g** in benzene was passed through a column of silica gel and the ketone, **3g**, was obtained in quantitative yield. However, a column of neutral alumina did not catalyze this transformation.

Characterization of Products. Ketones and ethers were identified by comparing their NMR, IR spectra, and vpc with those of authentic samples. All thietanes described here are new compounds. Their NMR, IR, and mass spectral data are summarized in Tables 4, 5, and 6, respectively. Since the thietanes are unstable oily materials,[37] most efforts to purify them were not successful and only limited numbers of compounds gave satisfactory results on elemental analyses (Table 7).

Structures of thietanes were determined by NMR: a ring proton bound to a carbon adjacent to the sulfur appears more down-field than that of the other isomer.[3a] Mass spectra provided another support for the structures. Photochemical conversion of **7g** into **3g** and **11g** also confirmed the structure of this thietane.

(Received August 6, 1973)

In order to evaluate the contribution of a hydroxyl group to the degree of sweetness of aspartyl dipeptides, we have synthesized a number of α-L-aspartyl dipeptides, such as the esters of α-L-aspartyl-L-hydroxynorleucine (**16** and **17**), -*O*-acyl-L-serine (**18**—**21**), -D-serine (**22**—**28**), -D-threonine (**30**—**36**), and -D-allothreonine (**37**—**43**); their sweetness potencies were compared with those of the corresponding dipeptides without a hydroxyl group. It has been found that a hydroxyl group makes a major contribution to the sweetness of the α-L-aspartyl dipeptide esters. The introduction of a hydroxyl group into the L–L peptides gave compounds with reduced potency. However, no such regularity was observed in the L–D peptides; the esters of α-L-aspartyl-D-serine (**22**—**28**) and -D-threonine (**30**—**36**) were sweeter than the corresponding esters of α-L-aspartyl-D-alanine and -D-α-amino-*n*-butyric acid respectively, while the esters of α-L-aspartyl-D-allothreonine (**37**—**43**) were less sweet than the corresponding esters of α-L-aspartyl-D-α-amino-*n*-butyric acid. The enzymatic resolution of *N*-acetyl-*erythro*- and -*threo*-β-hydroxy-DL-norleucine is also described.

The pronounced sucrose-like sweetness of α-L-aspartyl-L-phenylalanine methyl ester (APM) was reported by Mazur *et al.*[1] At that time, L-aspartic acid seemed to be necessary for sweetness, but the phenylalanine part could be modified considerably.[1,2] A number of sweet dipeptide esters related to APM have been synthesized by several groups,[3] according to the generalization made by Mazur *et al.*[1,2] Recently, however, Briggs and Murley described that the aspartic acid part could be replaced by amino malonic acid without losing its sweetness.[4] Furthermore, Lapidus and Sweeney reported that an *N*-protected APM, *N*-trifluoroacetyl-L-aspartyl-L-phenylalanine methyl ester, was 120 times as sweet as sucrose,[5] though the free amino group of L-aspartic acid had been considered to be necessary for sweetness.[1]

APM appears attractive as a low-calorie sweetener, but it is somewhat unstable in an aqueous solution, in which APM spontaneously cyclizes to cyclo-L-aspartyl-L-phenylalanyl, which lacks sweetness. In order to obtain more stable sweeteners than APM and, in particular, to draw on for more definite structure-taste relationships of aspartyl dipeptides, we synthesized a number of aspartyl dipeptide derivatives, including D-amino acids and L- and D-hydroxy amino acids, and tasted them.

During the replacement of the phenylalanine part of APM by other amino acids, it was found that α-L-aspartyl-L-norvaline methyl ester (**1**) was somewhat sweet, about 4 times sucrose, while α-L-aspartyl-L-α-amino-*n*-butyric acid methyl ester (**2**) was devoid of sweetness. Mazur *et al.* reported that the methyl esters of α-L-aspartyl-L-valine, -L-leucine, and -L-isoleucine were bitter.[1] The results show that, in the cases of the aspartyl dipeptides with the L–L configuration, L-norvaline seems to be the smallest amino acid to give a sweet derivative; they also show that the substitution of a methyl group for a hydrogen on the β- or γ-carbon of the amino acid results in a bitter taste (Table 2). A similar relationship was found to hold for the methyl esters of α-L-aspartyl-*O*-acyl-L-threonine, -*O*-acyl-L-allothreonine, and -D-alanylsarcosine (*vide post*). α-L-Aspartyl-β-alanine methyl ester (**6**) and -β-alanine *i*-propyl ester (**7**) lacking an asymmetric carbon were sweet, about equal to sucrose and 7 times sucrose respectively. α-L-Aspartyl-DL-β-amino-*n*-butyric acid methyl ester (**4**) and -γ-amino-*n*-butyric acid methyl ester (**5**) were similar in potency to sucrose. α-L-Aspartyl-L-lysine methyl ester (**8**) was bitter, while α-L-aspartyl-N^{ε}-acetyl-L-lysine methyl ester (**9**) as well as α-L-aspartyl-N^{δ}-acetyl-L-ornithine methyl ester (**10**) was sweet, about equal to sucrose. α-L-Aspartyl-DL-(α-methyl)phenylalanine methyl ester (**11**) and -DL-(α-methyl)glutamic acid dimethyl ester (**12**) were sweet, 5 times sucrose and 8 times sucrose respectively. The results show that the α-hydrogen is not necessary for sweetness, but can be replaced by a methyl group without losing sweetness. α-L-Aspartyl-D-alanylglycine methyl ester (**13**), a tripeptide, was 3 times as sweet as sucrose, and the replacement of the glycine by sarcosine resulted in a bitter taste. They are reasonable results if the D-alanylglycine methyl ester is considered as approximately equivalent to an L-2-amino-alkane such as L-2-amino-octane,[2] and if the replacement of the glycine by sarcosine is also considered as approximately equivalent to the introduction of a methyl group into the γ-position of alkyl amines (*e.g.*, L-1,3-dimethylbutylamine[2]) or amino acids (*e.g.*, L-Leu-OMe in Table 2). Therefore, the former is sweet and the latter is bitter. No compound sweeter than APM was found. The results are summarized in Table 1.

At the present time, the phenomenon of a sweet taste seems best explained by the hydrogen bond between receptor site of the "sweet-sensitive protein" and the sweet unit of the chemical compound. Therefore, we are interested in the contribution of a hydroxyl group to the degree of sweetness, since there has been no systematic and thorough study of the evaluation of a hydroxyl group, though the introduction of hetero-atoms, including a hydroxyl group, resulted in the diminution of the potency.[1,2] In order to evaluate the contribution of a hydroxyl group, we intended to introduce a hydroxyl group into the β-position of the norleucine of α-L-aspartyl-L-norleucine methyl ester (**15**) with a sweetness potency of 45 times sucrose. When *erythro*- and *threo*-β-hydroxy-L-norleucine were substituted for the norleucine, the sweetness fell off

a) Abbreviations according to IUPAC-IUB Commission on Biochemical Nomenclature, *Arch. Biochim. Biophys.*, **150**, 1 (1972). b) Number times sweeter than sucrose. In addition, + = 1—2 times sucrose (5% sucrose level).

rapidly; α-L-aspartyl-*erythro*-β-hydroxy-L-norleucine methyl ester (**16**) was 18 times as sweet as sucrose, and the corresponding *threo*-isomer (**17**) was 7 times sucrose (Table 3). It seems to be true that the introduction of a hydroxyl group into a dipeptide with the L–L configuration results in a diminution in the potency.

Next, we synthesized the esters of α-L-aspartyl-*O*-acyl-L-serine (**18**—**21**). α-L-Aspartyl-*O*-acetyl-L-serine methyl ester (**18**), as well as the *O*-*n*-propionyl (**19**), *O*-*n*-butyroyl (**20**), and *O*-*i*-butyroyl (**21**) analogs, was sweet (Table 3). From an examination of a model, this is a reasonable result if the *O*-acylated part is considered as approximately equivalent to the *n*-butyl part of norleucine of **15** (Table 3). The replacement of the methyl ester group by the ethyl ester gave compounds with reduced potency; α-L-aspartyl-*O*-acetyl-L-serine ethyl ester was slightly sweet, about equal to sucrose, the *O*-*n*-butyroyl analog was 10 times as sweet as sucrose, and the *O*-*i*-butyroyl analog was 3 times sucrose. The replacement of the serine by L-threonine or by L-allothreonine resulted in bitter compounds; the methyl esters of α-L-aspartyl-*O*-acyl-L-threonine and -*O*-acyl-L-allothreonine (acyl: *n*-butyroyl and *i*-butyroyl) were bitter (Table 2). These results support the idea that the substitution of a methyl group for a hydrogen on the β-carbon of amino acids may result in a bitter substance (Table 2 and see also Ref. 1).

In order to find out more information about hydroxyl function, α-L-aspartyl-D-serine esters (**22**—**28**) were synthesized. α-L-Aspartyl-D-serine methyl ester (**22**), as well as the ethyl (**23**), *n*-propyl (**24**), *i*-propyl (**25**), *n*-butyl (**26**), *i*-butyl (**27**), and cyclohexyl (**28**) esters, was found to have an intensely sweet taste (Table 3). It was surprising to us that α-L-aspartyl-D-serine esters, in spite of having a hydroxyl group, were sweeter than α-L-aspartyl-D-alanine esters[3g] without a hydroxyl group; *e.g.*, α-L-aspartyl-D-serine *n*-propyl ester (**24**) was 320 times as sweet as sucrose, while the corresponding α-L-aspartyl-D-alanine *n*-propyl ester (**29**) was 125 times sucrose. The increased sweetness of the peptides

a) See Table I for abbreviations. b) Number times sweeter than sucrose (5% sucrose level).

(**22**—**28**) would not have been predicted from the previous results, since the replacement of the amino acids or amines by those with a hydroxyl group always resulted in the diminution of the potency;[1,2] *e.g.*, α-L-aspartyl-L-amphetamine is 50 times as sweet as sucrose, while α-L-aspartyl-1-hydroxymethyl-2-phenylethylamine is only 1—2 times sucrose in sweetness[2] (Table 2).

This finding led us to synthesize the esters of α-L-aspartyl-D-threonine (**30**—**36**) and -D-allothreonine (**37**—**43**). It was found that they all have an intensely sweet taste (Table 3). It is very interesting to note that the esters of α-L-aspartyl-D-threonine (**30**—**36**) were sweeter than the esters of α-L-aspartyl-D-α-amino-*n*-butyric acid,[3g] which lacks a hyrdoxyl group of the D-threonine, as in the case of the esters of α-L-aspartyl-D-serine and -D-alanine. The replacement of the D-threonine by D-allothreonine resulted in a significant diminution of the potency; *e.g.*, α-L-aspartyl-D-α-amino-*n*-butyric acid *n*-propyl ester (**44**) was 95 times as sweet as sucrose, α-L-aspartyl-D-threonine *n*-propyl ester (**32**) was 150 times sucrose, and α-L-aspartyl-D-allothreonine *n*-propyl ester (**39**) was 40 times sucrose. With an increase in the size of the ester, the potency increased peaking at the chain length of three carbons, such as the *n*-propyl and *i*-butyl esters (Table 3). It is also of interest to note that the configurational change in the hydroxyl group results in a change in the potency, as is shown in Table 3 (**16** and **17**, and **30**—**36** and **37**—**43**). In the cases of the peptides with the L-D configuration, the *threo*-isomers were sweeter than the corresponding *erythro*-isomers, in contrast to the cases of the L-L peptides. In the cases of the L-L peptides, the *erythro*-isomers were sweeter than the corresponding *threo*-isomers, as has been described in the case of α-L-aspartyl-β-hydroxy-L-norleucine methyl ester (**16** and **17**). The results (Table 3) indicate that the introduc-

a) See Table 1 for abbreviations. b) Number times sweeter than sucrose (5% sucrose level).

tion of a hydroxyl group into the L–D peptides does not always result in a diminution of their potencies, but sometimes increase their potencies, in contrast to the cases of the L–L peptides. In the cases of the L–L peptides, the potencies always decreased when a hydroxyl group was introduced, as has been described above and as has been reported by Mazur *et al.*[1,2] The contribution of a hydroxyl group to the L–D peptides seems to differ significantly from that to the L–L peptides. These results would appear to hold considerable promise for clarifying the interaction between the receptor site and the sweet unit. More detailed studies concerning this problem are now in progress.

Experimental

All the melting points are uncorrected. The optical rotations were measured with a visual polarimeter. All the compounds reported here were homogeneous on thin-layer chromatography on silica. Spots were detected first by the ninhydrin method and then by the starch-iodide method, as modified by one of us.[6] The acylated NH groups, if any, can be detected at the 0.1—0.25 μg level after chromatography by the latter method.

Starting Materials. L- and D-α-Amino-*n*-butyric acid, L-norvaline, L-norleucine, D-serine, and D-allothreonine were obtained without any difficulty *via* the L-directed asymmetric hydrolytic action of the mold acylase on their *N*-acetyl racemates by the usual procedure.[7] L-α-Amino-*n*-butyric acid: $[\alpha]_D^{21}$ +20.5° (*c* 2, 5 M HCl). lit,[7] $[\alpha]_D^{25}$ +20.6° (*c* 2, 5 M HCl). D-α-Amino-*n*-butyric acid: $[\alpha]_D^{21}$ −20.5° (*c* 2, 5 M HCl). lit,[7] $[\alpha]_D^{25}$ −20.7° (c 2, 5 M HCl). L-Norvaline: $[\alpha]_D^{26}$ +24.3° (*c* 2, 5 M HCl). lit,[7] $[\alpha]_D^{25}$ +24.9° (*c* 2, 5 M HCl). L-Norleucine: $[\alpha]_D^{25}$ +24.0° (*c* 1, 6 M HCl). lit,[8] $[\alpha]_D^{23}$ +23.3° (*c* 4.15, 6 M HCl). D-Serine: $[\alpha]_D^{19}$ −15.8° (*c* 2, 6 M HCl). lit,[7] $[\alpha]_D^{25}$ −15.0° (*c* 2, 5 M HCl). D-Allothreonine: $[\alpha]_D^{26}$ −9.6° (*c* 4, water). lit,[7] $[\alpha]_D^{25}$ −9.6° (*c* 4, water). D-Threonine, which had been resolved by the preferential crystallization, was left over from a previous investigation.[9] $[\alpha]_D^{29}$ +28.7° (*c* 2, water). lit,[7] $[\alpha]_D^{25}$ +28.5° (c 2, water). *threo*- and *erythro*-β-Hydroxy-L-norleucine: β-Hydroxynorleucine was resolved *via* the asymmetric synthetic action of papain on *N*-benzoyl-β-methoxynorleucine by Adams and Niemann.[10] We will now describe a more convenient method of resolving the two diastereoisomeric racemates of β-hydroxynorleucine *via* the L-directed asymmetric hydrolytic action of a mold acylase on their *N*-acetyl derivatives. β-Hydroxynorleucine was prepared by the condensation of copper glycinate with *n*-butyraldehyde according to the method described by Mix[11] and was then separated into the two diastereoisomeric racemates through their tetrachlorophthalic acid salts according to the method previously reported by one of the present authors.[12] *N*-Acetyl-*threo*- and -*erythro*-β-hydroxy-DL-norleucine were obtained by the usual acetylation of *threo*- and *erythro*-β-hydroxy-DL-norleucine with acetic anhydride. *N*-Acetyl-*threo*-β-hydroxy-DL-norleucine: yield, 82%; mp 149—150.5 °C (decomp.). Found: C, 50.86; H, 8.08; N, 7.40%. Calcd for $C_8H_{15}O_4N$: C, 50.78; H, 7.99; N, 7.40%. *N*-Acetyl-*erythro*-β-hydroxy-DL-norleucine: yield, 82%; mp 137—138 °C. Found: C, 50.97; H, 8.02; N, 7.35%. The optical resolution of *N*-acetyl-*threo*- and -*erythro*-β-hydroxy-DL-norleucine was not easily accomplished because the rate of the hydrolysis was found to be considerably lower than those observed with other amino acids, such as norvaline and serine.

Incubation with Enzyme. A solution of *N*-acetyl-*threo*-β-hydroxy-DL-norleucine (18.4 g) in water (1800 ml) was adjusted to pH 7.0 with an aqueous sodium hydroxide solution. To the solution, there were then added cobaltous chloride hexahydrate (0.43 g) and the mold acylase (0.36 g).[13] The solution was incubated at 38 °C for 8 days. During the incubation, an additional acylase (0.18 g) was added every other day to the solution.

Isolation of threo-*β-Hydroxy-*D*-norleucine.* In order to separate the free L-amino acid and *N*-acetyl-D-amino acid, the solution was passed through a column (3×50 cm) of Diaion SK 1B[14] (H-form) and the column was washed with water. The fractions containing the *N*-acetyl-D-amino acid were combined and concentrated *in vacuo* to dryness. The residue was dissolved in water and decolorized with charcoal. The solution was concentrated *in vacuo* until the crystals appeared. After storage in a refrigerator overnight, the crystals of *N*-acetyl-*threo*-β-hydroxy-D-norleucine thus formed were collected by filtration; yield, 8.3 g (89%); mp 136—138 °C. Found: C, 50.85; H, 7.95; N, 7.40%.

A solution of *N*-acetyl-*threo*-β-hydroxy-D-norleucine (8.3 g) in 3 M hydrochloric acid (83 ml) was heated under reflux for 6 hr and then concentrated *in vacuo* to dryness. The residue was dissolved in water, and the solution was adjusted to pH 6.0 with an aqueous sodium hydroxide solution and poured onto a column (3×50 cm) of Diaion SK 1B (H-form). The column was washed with water, and then the D-amino acid was eluted with 1.5 M ammonium hydroxide. The eluate was concentrated *in vacuo* to a small volume, and then a sufficient amount of ethanol was added to the concentrate to give 5.7 g (88%) of crystals (*threo*-β-hydroxy-D-norleucine), which were subsequently recrystallized from water–ethanol; yield, 4.8 g (74%); mp 222—224 °C (decomp.); $[\alpha]_D^{25}$ −4.8° (*c* 2, water) and −18.5° (*c* 2, 5 M HCl); $[M]_D^{25}$ −7.0° (*c* 2, water) and −27.2° (*c* 2, 5 M HCl). lit,[10] mp 185—188 °C (decomp.); $[\alpha]_D^{25}$ −4.6° (*c* 3.50, water) and −18.5° (*c* 2.28, 6.03 M HCl). Found: C, 49.40; H, 8.79; N, 9.44%. Calcd for $C_6H_{13}O_3N$: C, 48.96; H, 8.90; N, 9.52%.

Isolation of threo-*β-Hydroxy-*L*-norleucine.* The column, adsorbing the free L-amino acid, was washed with water (200 ml) to remove completely the trace amount of the *N*-acetyl-D-amino acid from the column. The L-amino acid was eluted with 1.5 M ammonium hydroxide. The eluate was concentrated *in vacuo* to a small volume, and then a sufficient amount of ethanol was added to the concentrate to give 5.8 g (89%) of the L-amino acid, which was subsequently recrystallized from water–ethanol; yield, 5.0 g (70%); mp 222—223 °C (decomp.); $[\alpha]_D^{25}$ +4.5° (*c* 2, water) and +18.5° (*c* 2, 5 M HCl); $[M]_D^{25}$ +6.6° (*c* 2, water) and +27.7° (*c* 2, 5 M HCl). lit,[10] mp 184—188 °C (decomp.); $[\alpha]_D^{25}$ +4.6° (*c* 3.46, water) and +18.6° (*c* 2.42, 6.07 M HCl). lit,[15] $[M]_D^{25}$ 6.8° (*c* 2, water) and +27.4° (*c* 2, 5 M HCl). Found: C, 48.80; H, 8.63; N, 9.40%.

The resolution of the racemic *erythro*-isomer was carried out by the manner described in the resolution of the racemic *threo*-isomer, except that the *N*-acetyl-D-amino acid was obtained as an oil; it was subjected to acid hydrolysis without further purification.

erythro-β-Hydroxy-D-norleucine: yield, 76%; mp 241—242 °C (decomp.); $[\alpha]_D^{25}$ +2.3° (*c* 2, water) and −28.3° (*c* 2, 5 M HCl); $[M]_D^{25}$ +3.4° (*c* 2, water) and −41.6° (*c* 2, 5 M HCl). lit,[10] mp 198—202 °C (decomp.); $[\alpha]_D^{26}$ +2.0° (*c* 8.81, water) and $[\alpha]_D^{25}$ −27.4° (*c* 2.63, 6.07 M HCl). Found: C, 48.99; H, 8.72; N, 9.57%.

erythro-β-Hydroxy-L-norleucine: yield, 89%; mp 240.5—241.5 °C (decomp.); $[\alpha]_D^{25}$ −2.3° (*c* 2, water) and +28.3°

(*c* 2, 5 M HCl); $[M]_D^{25}$ −3.4° (*c* 2, water) and +41.6° (*c* 2, 5 M HCl). lit,[10] mp 203—205 °C (decomp.); $[\alpha]_D^{22}$ −2.0° (*c* 5.87, water) and $[\alpha]_D^{25}$ +27.1° (*c* 2.47, 6.07 M HCl). lit,[15] $[M]_D^{25}$ −2.9° (*c* 2, water) and +39.9° (*c* 2, 5 M HCl). Found: C, 48.96; H, 8.63; N, 9.45%.

Hydrochlorides of Amino Acid Esters. In a typical procedure (D-serine *i*-propyl ester hydrochloride), into a suspension of D-serine (10.5 g) in *i*-propyl alcohol (200 ml) was bubbled dry hydrogen chloride gas without external cooling. After the crystals had gone into solution, the reaction mixture was boiled under reflux for 5 hr and then concentrated *in vacuo*. Benzene (100 ml) was added to the residue; the solution was then evaporated *in vacuo* to remove the trace amount of water, and then the esterification procedure was repeated. The reaction mixture was concentrated *in vacuo* to give the crude ester, which was recrystallized from *i*-propyl alcohol–ether; yield, 13.7 g (75%); mp 145—146 °C.

The other amino acids were esterified with an appropriate alcohol by the same procedure, and the resulting hydrochlorides of amino acid esters were recrystallized from the appropriate alcohol and ether. When *n*-butanol, *i*-butyl alcohol and cyclohexanol were employed, the reaction temperature was maintained at 100 °C.

*α-L-Aspartyl-O-acyl-L-serine Esters (**18**—**21**).* In a typical procedure (**21** in Table 3), β-benzyl-*N*-carbobenzoxy-L-aspartyl-L-serine methyl ester[16] (4.6 g) was dissolved in pyridine (50 ml) and cooled in an ice bath, and then *i*-butyric anhydride (3.2 g) was stirred in. After stirring for 3 hr at room temperature, the reaction mixture was stirred into 500 ml of water containing ice flakes. The crystals thus formed were collected by filtration and washed with 0.7 M hydrochloric acid and then water; yield, 5.1 g (98%). Recrystallization from ethyl acetate–petroleum ether gave 4.7 g (91%) of β-benzyl-*N*-carbobenzoxy-L-aspartyl-*O*-*i*-butyroyl-L-serine methyl ester; mp 95—96 °C. Found: C, 61.58; H, 6.16; N, 5.31%. Calcd for $C_{27}H_{32}O_9N_2$: C, 61.35; H, 6.10; N, 5.30%.

A solution of the dipeptide derivative (4.0 g) in 90% methanol (50 ml) was hydrogenated in the presence of 5% palladium on charcoal (0.4 g) for 5 hr. After the removal of the catalyst by filtration, the filtrate was concentrated *in vacuo* to give a crystalline residue. Recrystallization from aqueous methanol gave 1.3 g (54%) of α-L-aspartyl-*O*-*i*-butyroyl-L-serine methyl ester.

The results are shown in Table 3.

*The Esters of α-L-Aspartyl-*erythro- *and* -threo-*β-hydroxy-L-norleucine (**16** and **17**), -D-serine (**22**—**28**), -D-threonine (**30**—**36**), and -D-allothreonine (**37**—**43**).* In a typical procedure (**25** in Table 3), β-benzyl-*N*-carbobenzoxy-L-aspartate[17] (7.2 g) was dissolved in chloroform (50 ml) and cooled in an ice bath, and then *N,N'*-dicyclohexylcarbodiimide (4.3 g) was added. After 20 mins' stirring in the ice bath, a solution of *i*-propyl D-serinate hydrochloride (4.0 g) and triethylamine (2.3 g) in chloroform (50 ml) was added to the reaction mixture. After stirring for 6 hr at room temperature, a few drops of acetic acid were added to the reaction mixture. After the removal of *N,N'*-dicyclohexylurea by filtration, the filtrate was concentrated *in vacuo*. The residue was dissolved in ethyl acetate and washed successively with 1 M hydrochloric acid, a 5% sodium bicarbonate solution, and water, and finally dried over sodium sulfate. After filtration, the filtrate was concentrated *in vacuo* to give 7.6 g (78%) of β-benzyl-*N*-carbobenzoxy-L-aspartyl-D-serine *i*-propyl ester; mp 80.5—81.5 °C. Found: C, 61.35; H, 6.16; N, 5.65%. Calcd for $C_{25}H_{30}O_8N_2$: C, 61.71; H, 6.22; N, 5.76%.

A solution of the protected dipeptide derivative (5.0 g) in 75% acetic acid (100 ml) was hydrogenated in the presence of 5% palladium on charcoal (0.5 g) at room temperature for 5 hr. After the removal of the catalyst by filtration, the filtrate was concentrated *in vacuo* to give crystals, which were subsequently recrystallized from aqueous methanol; yield, 2.2 g (82%). Recrystallization from water gave 1.5 g of α-L-aspartyl-D-serine *i*-propyl ester.

The results are shown in Table 3.

Sweetness Evaluation. The sweetness values of the dipeptide derivatives were organoleptically determined by panel evaluation, with ten to fifteen people per panel, in our Foodstuff Development Laboratory. In a series of tests with aqueous solutions, samples of the peptides and samples of various levels of sucrose (3—8%) were compared for relative sweetness. The tests were carried out at concentrations higher than threshold in order to provide a comparison at a practical level. In a typical comparison test, an aqueous solution of α-L-aspartyl-D-serine *n*-propyl ester containing 0.02% was rated in between a 6.08 and a 7.00% sucrose solution, putting it in the 305—350 sweetness range. Therefore, the compound was assumed about 320 times as sweet as sucrose.

The results are shown in Tables 1, 2, and 3.

The authors wish to express their thanks to Mr. Fusayoshi Kakizaki and Miss Yuki Nakakouji for their skillful technical assistances and to Miss Sachiko Suzuki and Miss Harue Yamada for their evaluations of sweetness.

The Photochemical and the Thermal Reaction of Dimethyl *trans*-Spiro[2.6]nona-4,6,8-triene-1,2-dicarboxylate[1]

Katsuhiro SAITO, Takashi TODA, and Toshio MUKAI

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received August 13, 1973)

The irradiation of dimethyl *trans*-spiro[2.6]nona-4,6,8-trien-1,2-dicarboxylate (I) with a low-pressure mercury lamp afforded two tricyclic valence isomers (II and III). Upon heating, II and III were converted into dimethyl *trans*-indan-1,2-dicarboxylate (IV), which was also obtained by the thermolysis of I. In order to elucidate the reaction mechanism for the formation of IV from I, we studied the thermal reaction using a deuterium-labelled compound (V).

Dimethyl *trans*-spiro[2.6]nona-4,6,8-trien-1,2-dicarboxylate (I)[2,3] is an interesting unsaturated cyclic compound; it possesses both a cycloheptatriene and a cyclopropane ring, like the spiro system. Therefore, it seems that it would be interesting to study the thermal photochemical reactions of I to distinguish whether such a compound behaves as a spiro compound,[3-8] as a cyclopropane derivative, or as a cycloheptatriene derivative. It has already been reported by Jones and Ennis[3] and by our group[2] that I, when heated over 150 °C, easily rearranged to dimethyl *trans*-indan-1,2-dicarboxylate (IV). On the other hand, however, no photochemical study of I has ever been reported. We investigated the photoreaction of I and found that I exhibited the photochemical valence isomerization characteristic of the cycloheptatriene moiety.[9-14] In addition, the reaction mechanism of the thermolysis of I leading to IV was studied using a deuterized spiro compound (V). In this paper, we wish to report the results obtained concerning the photoreaction and the reaction mechanism of the thermolysis of I.

The irradiation of I, which has an absorption maximum at 263 nm (log ε, 3.52) and a tailing around 350 nm (log ε, ca 2.5), using a high-pressure mercury lamp, did not cause any photoreaction, but resulted in the recovery of I in a quantitative yield. The benzophenone-sensitized photoreaction of I also resulted in the recovery of I. On the other hand, when the irradiation of I was carried out in a quartz vessel using a low pressure mercury lamp, a crystalline material (II) (mp 105.5 °C), and an oily substance (III) were obtained in 23 and 22% yields respectively. When methanol, ether and *n*-hexane were used as the solvents, no solvent effect was observed. Under these irradiation conditions, no interconversion between II and III was detected; this fact indicated that II and III were the primary photoproducts.

The two products, II and III, have the same molecular formula, $C_{13}H_{14}O_4$, and the same molecular ion peak (M^+, 234) in their mass spectra. In addition, they possess almost the same spectral properties: IR ($CHCl_3$), 1720, 1440, 1340, and 1160 cm^{-1}; UV (methanol), 225 nm (log ε, 3.39). Their NMR spectra are shown in Table 1, while the coupling constants as determined by the double and triple resonance techniques are shown in Table 2. These data support the idea that II and III are isomers of I, and that they are stereoisomers with relation to each other. In addition, the chemical shifts and coupling constant of the H_c–H_h protons of II and III are similar to those of the corresponding protons of the bicyclo[3.2.0]hept-2,5-diene derivatives.[10-14] The H_a and H_b protons are assigned to the cyclopropane protons which are located in the *trans*-configuration on the basis of the chemical shifts, which are coincident with those of the cyclopropane protons of I, and the coupling constant (5.5 Hz).[15] Thus, the structure shown in Fig. 1 are proposed for II and III.

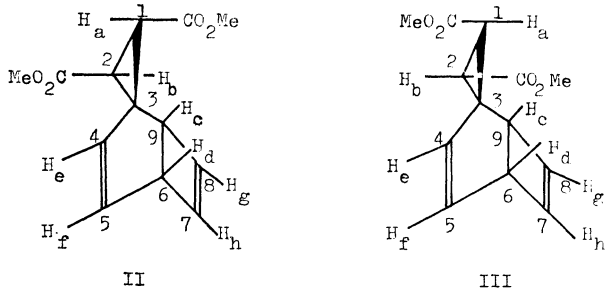

Fig. 1.

The configuration of the two ester groups of II and III could be deduced from the chemical shifts of their H_c and H_g values. The signals of the H_c of II appear at a higher field than those of the H_c of III, and the signals of the H_g of II come at a lower field than those of the H_g of III, while the chemical shifts of the other hydrogens of II and III do not differ very much from each other. By an investigation of the Dreiding models of II and III, the ester group at C_1 of II is found to be closer to H_c; also the H_g of III is closer to the ester group at C_2. Furthermore, by the repulsion between the ester group at C_1 and the cyclopropane protons, the conformation in which the sp^2 plane of the ester carbonyl group is set over to H_c is the most stable form of II; also, for the same reason, in the case of III H_g is

TABLE 1. CHEMICAL SHIFTS OF II AND III (δ ppm) (100 MHz, in $CDCl_3$)

	H_a	H_b	H_c	Ester Me	H_d	H_e	H_f	H_g	H_h
II	2.45	2.57	3.19	3.64, 3.66	3.73	5.61	5.97	6.16	6.40
III	2.43	2.54	3.36	3.67, 3.69	3.80	5.56	6.05	5.78	6.39

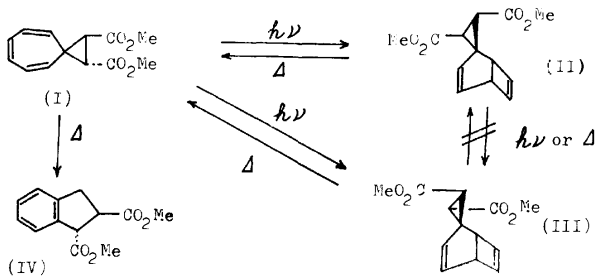
Table 2. Coupling constants of II and III (Hz)

	J_{ab}	J_{cd}	J_{df}	J_{dh}	J_{ef}	J_{gh}	J_{ce}
II	5.5	3.5	2.5	~1	5.5	3.0	~1
III	5.5	3.5	2.5	~1	5.3	3.0	1.0

covered by the sp^2 plane of the ester group at C_2. Thus, considering the anisotropic effect of the ester groups, the differences in the chemical shifts of H_c and H_g in II and III can be reasonably explained by those models.

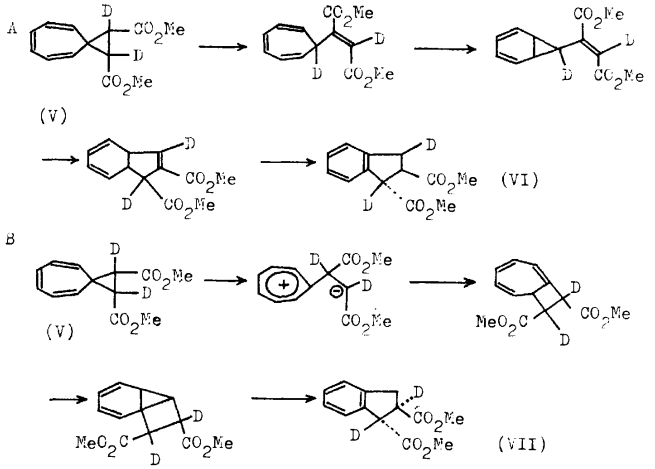
The results obtained above make it clear that the irradiation of I did not undergo a reaction involving the cyclopropane ring; instead, the cycloheptatriene ring dominated its photoreaction. The fact that this photoreaction was not sensitized by benzophenone is compatible with the fact that the photovalence isomerization of the cycloheptatriene derivatives proceeds *via* singlet excited states.[11,12] In addition, it should be noted that both ring-closure products, II and III, were formed in almost the same yield, the yields being 22 and 23% respectively. This seems to prove that the ester groups located near the reaction center do not have any effect on the photochemical ring closure of I, either stereochemically or electronically.

The photoproducts, II and III, were fairly stable to heat, and they were recovered when the thermolysis was attempted by a flow method by heating about 350 °C. Above 400 °C, however, both II and III gave the same pyrolyzate, dimethyl *trans*-indan-1,2-dicarboxylate (IV), in good yields. Since I is transformed thermally to IV under less severe pyrolyzing conditions (about 150 °C), it is most probable that II and III, upon heating, are converted first into I by the ring opening and are then rearranged to IV (Scheme 1).



Scheme 1.

Previously, Mukai, Nakazawa, and Isobe suggested the possibility of two reaction paths for the rearrangement of I to IV.[2] Recently, Jones and Ennis also investigated this rearrangement; they pointed out that the rate of the rearrangement depended on the nature of the solvents, and proposed an ionic mechanism resembling the mechanism of Mukai *et al.*[3] Therefore, the following two mechanisms (A and B shown in Scheme 2) are proposed for the rearrangement of I to IV. In order to investigate the adequacy of the mechanisms, A and B, we did the same thermolysis using a dideuterized spiro compound (V), which had been synthesized by the addition reaction of dideuterized dimethyl maleate with cycloheptatrienylidene.[2,3]



Scheme 2.

As Scheme 2 exhibits, if the reaction proceeds *via* Mechanism A, dimethyl *trans*-1,3-dideuteroindan-1,2-dicarboxylate (VI) will be formed, whereas if Mechanism B occurs, 1,2-dideuteroindane derivative (VII) is formed. On the basis of the NMR spectral data, the indane derivative obtained here found to be VII, not VI. That is, in the NMR spectrum of IV, the methylene protons at the C_3-position and the two methine protons at the C_1- and C_2-positions show their signals at δ 3.1, 3.9 and 4.6 respectively, whereas the indane derivative obtained from V exhibits peaks of the methylene protons at δ 3.1, but does not show any peak ascribed to the methine protons. These results fit VII and confirm that the thermal rearrangement of I proceeds *via* Mechanism B.

Experimental[16]

Photoreaction of I. A solution of I (1.50 g) in *n*-hexane (1.5 l) was irradiated with a low-pressure mercury lamp (Rayonet 2537 Å) in a quartz vessel for 44 hr under a nitrogen atmosphere. After the removal of the resinous substances (100 mg), a yellow oily product (1.4 g) was obtained and subsequently chromatographed on alumina (50 g). A crystalline product (A)(400 mg) was eluted with petroleum ether–benzene (4 : 1); 261 mg of an oily product (B) with petroleum ether–benzene (7 : 3); 174 mg of the starting substance with benzene, and 475 mg of a tarry material with methanol. The crystalline product (A) was found to contain II (60%) and III (40%) by vpc analysis (20% Ucon 50 LB; Chromosorb W; temp. 150 °C). In the same way, the oily product (B) was found to contain II, III, and the starting material in percentages of 18, 42, and 40% respectively. The total yields of II and III were 287 mg and 270 mg (23 and 22%) respectively. Both products were purified by recrystallization from methanol and by distillation. II, mp 104.5—105.5 °C. Found: C, 66.43; H, 6.09%. Calcd for $C_{13}H_{14}O_4$: C, 66.65; H, 6.02%. IR(KBr); 1720, 1440, 1340, and 1160 cm^{-1}. Mass; M^+, 234 at 70 eV. III, oil bp 105 °C/1 mm Hg. Found: C, 66.51; H, 5.92%. Calcd for $C_{13}H_{14}O_4$; C, 66.65; H, 6.02%. IR ($CHCl_3$); 1720, 1440, 1340, and 1160 cm^{-1}. Mass; M^+, 234 at 70 eV.

Thermal Rearrangement of II and III. We attempted to pyrolyze a solution of II (34 mg) in benzene (20 ml) by passing it under a nitrogen stream (30 ml/min) through a quartz tube (9 mm × 45 cm) preheated at 350 °C which

contained quartz pieces. After the removal of the solvent, a white crystalline product was obtained. NMR and vpc studies of the obtained product showed that the crystalline product contained IV and the starting substances in 2.6 and 97.4% yield respectively.

The pyrolysis at a higher temperature (420 °C) resulted in the formation of IV and the recovery of II in 82% and 18% yields respectively. The NMR spectrum and the retention time of the vpc of IV were in accordance with those of an authentic sample of dimethyl *trans*-indan-1,2-dicarboxylate.[2]

By the same procedure at 400 °C, III gave IV in an 80% yield, accompanied by the recovery of III in a 20% yield.

Preparation and Thermal Rearrangement of Dimethyl trans-*1,2-dideuterospiro[2.6]nona-4,6,8-trien-1,2-dicarboxylate (V).* V was formed from the addition reaction of dimethyl dideuteromaleate with troponetosylhydrazone sodium salt by the methods of Jones and Ennis[3] and Mukai *et al.*[2] The thermolysis of V was carried out under the same conditions as were used by Mukai *et al.*[2] Mass; M^+, 236 at 70 eV.

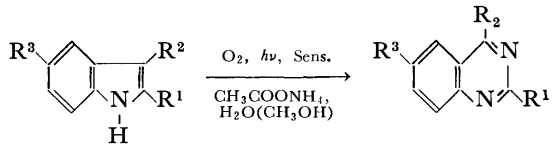
(Received August 14, 1973)

2,4-Di- and 2,4,6-trisubstituted quinazolines (II) were prepared from 2,3-di- and 2,3,5-trisubstituted indoles (I) respectively by the sensitized photo-oxygenation in aqueous methanol in the presence of ammonium acetate or by fusion with ammonium acetate after the photo-oxygenation. Chemical evidences that II was produced *via* the hydroperoxide (III) of the indole and then the dicarbonyl compound (IV) were provided.

In our previous paper[2] we reported that 2,4,6-triaryl-*s*-triazines were produced from 2,4,5-triarylimidazoles by the sensitized photo-oxygenation in methanol in the presence of ammonium acetate and the reaction proceeded *via* the hydroperoxides which afforded the triazines by the reaction with ammonium acetate. Although the formation of 2,4-dioxo-1,2,3,4-tetrahydroquinazoline from indole and that of 2-phenyl-4-oxo-3,4-dihydroquinazoline from 2-phenylindole, similar to that of triaryl-*s*-triazine from triarylimidazole, on irradiation with sunlight in ethanol in the presence of oxygen and ammonia have been reported,[3] no investigations have been carried out similar reactions for 2,3-di- and 2,3,5-trisubstituted indoles. The present paper deals with the formation of 2,4-di- and 2,4,6-trisubstituted quinazolines from the corresponding 2,3-di- and 2,3,5-trisubstituted indoles by sensitized photo-oxygenation in the presence of ammonium acetate and the reaction mechanism of the ring enlargement.

Results and Discussion

Indoles (Ia, Ib, Ic, Id listed in Table 1) were transformed to quinazolines (IIa, IIb, IIc, IId) respectively by sensitized photo-oxygenation in aqueous methanol in the presence of ammonium acetate. The reaction was carried out at room temperature and completed by boiling the methanolic solution. The procedure was similar to that for the formation of trisubstituted triazines from trisubstituted imidazoles.[2] The time-course of the ring enlargement was followed by UV spectrum and thin layer chromatography. The spectrum and chromatogram changed with the formation of the quinazoline (II) *via* the hydroperoxide (III) and the dicarbonyl compound (IV). Indoles (Ie and If) which have phenyl groups at the 2- and 3-positions did not give quinazolines by the same procedure as that for Ia—Id. These quinazolines (IIe and IIf), however, were obtained by fusion of the solid residue after removal of the solvent from the reaction mixture of the sensitized photo-oxygenation of Ie and If, with ammonium acetate at about 180 °C, respectively.



(I) (II)

When about 20 vol% of water was added into methanol, the reaction rate from I to II was increased because of the acceleration of the formation of IV from III. The short reaction time was convenient to avoid a formation of fair amounts of brown oily products by prolonged heating of the reaction mixture in a methanolic solution containing trace amounts of water after the formation of III from I. The yields and melting points of II are shown in Table 1. Ethanol, *n*-propyl alcohol and acetone which contained water were also usable as the solvent.

a) In methanol containing 20 vol% of water. Reaction conditions are shown in the experimental part.

It was reported[8,9] that several substituted indoles including Ia, Ib and Ic exhibited chemiluminescence on oxidation in basic solutions and the mechanism of the chemiluminescence reaction involved the primary formation of radicals of the indoles and then oxygenation of the radicals to hydroperoxides by molecular oxygen. The mechanism of the chemiluminescence is similar to that of imidazole derivatives.[10] Similarities between indoles and imidazoles in both ring enlargement reaction and mechanism of chemiluminescence reaction suggested that in the ring enlargement reaction of the indole (I) hydroperoxides are also intermediates. Hydroperoxides (IIIa—IIIf in Table 2) (2,3-di- and 2,3,5-trisubstituted-3-hydroperoxy-

indolenins) were prepared to examine the reaction with ammonium acetate in aqueous methanol. Hydroperoxides (IIIa—IIId) were prepared by autoxidation or by sensitized photo-oxygenation of indoles (Ia—Id) whereas IIIe and IIIf were obtained only by sensitized photo-oxygenation of Ie and If. Hydroperoxide (IIIf) was also obtained by reaction of If and singlet oxygen prepared from hydrogen peroxide and sodium hypochlorite.[11] These facts suggested that singlet oxygen was probably involved in oxygenation of Ie and If.

N-Methyl-2,3-diphenylindole which did not transform to a quinazoline derivative by the same procedure as that for Ie and If did not give a hydroperoxide by the sensitized photo-oxygenation. This result shows that hydrogen on nitrogen of the indole (I) is necessary for the oxygenation and also for the ring enlargement.

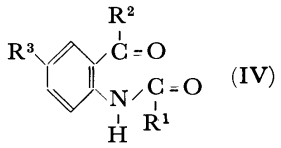
A: Autoxidation, B: Sensitized photo-oxygenation

By treatment of IIIa, IIIb and IIId with ammonium acetate in aqueous methanol at room temperature or under reflux IIa, IIb and IId were produced respectively (Table 3). Hydroperoxides IIIe and IIIf did not give the corresponding quinazolines by the same procedure, but produced dicarbonyl compounds, 2-benzamidobenzophenone (IVe) and 2-benzamido-5-methylbenzophenone (IVf) as shown in Table 4, respectively, which were transformed to IIe and IIf by fusion with ammonium acetate at about 180 °C. The method of preparation of quinazoline derivatives from dicarbonyl compounds (VI, R^1, R^2, R^3: H, alkyl, aryl) by heating with ammonia in ethanol under pressure or fusion with ammonium acetate is known as Bischler's method.[6,15] When the sensitized photo-oxygenation of Ia and Id in aqueous methanol containing ammonium acetate was stopped before the reaction was completed, dicarbonyl compounds IVa and IVd (Table 4) were isolated with a small amount of IIa and IId, respectively. These facts suggested that dicarbonyl compound (IV) was probably formed from the hydroperoxide (III) and then transformed to the quinazoline (II) by ring closure with ammonia. In order to confirm this reaction process, IIIa, IIIb, IIId, IIIe and IIIf were heated in aqueous methanol and IVa, IVb, IVd, IVe and IVf (Table 4) were obtained. Water was necessary for the transformation of the hydroperoxides to the dicarbonyl compounds. The reaction rate was accelerated with increasing amounts of water in methanol and was very fast on boiling in water. The need of water in methanol for the ring enlargement of the indole (I) to the quinazoline (II) is considered to be associated with the formation of the dicarbonyl compound (IV) by hydrolytic reaction of hydroperoxide (III).

Table 4. Dicarbonyl compounds (IV) from hydroperoxides (III)



(IV)

	R^1	R^2	R^3	Mp °C	Yield (%)
IVa	CH_3	CH_3	CH_3	123—124 (123—124)[16]	84
IVb	CH_3	CH_3	Cl	133—134 (134—134.5)[12]	70
IVd	C_6H_5	CH_3	H	93.5— 95 (98)[14]	76
IVe	C_6H_5	C_6H_5	H	81— 82 (80.5)[13]	64
IVf	C_6H_5	C_6H_5	CH_3	114—116 (114—117)[16]	92

As shown in Table 5, IIa, IIb and IId were obtained by treating IVa, IVb and IVd, respectively, with ammonium acetate in methanol or aqueous methanol at room temperature or under boiling, whereas IIe and IIf which were not obtained by the same procedure were obtained by fusion of IVe and IVf with ammonium acetate at about 180 °C. Quinazolines (IIa, IIb and IId) were also obtained by fusion of IVa, IVb and IVd with ammonium acetate.

From these results the mechanism of the ring enlargement reaction of 2,3-di- and 2,3,5-trisubstituted in-

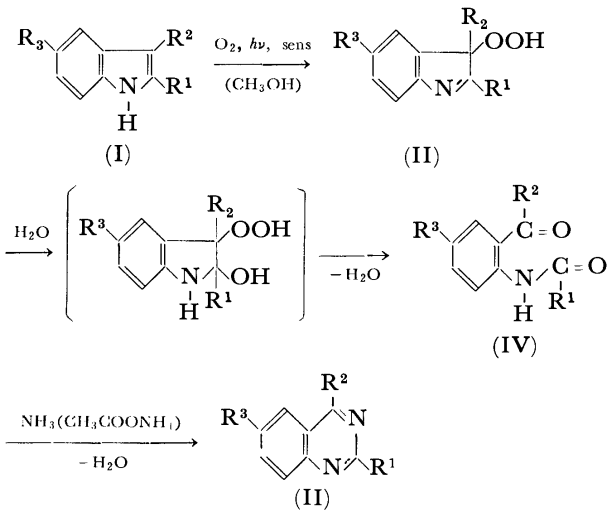
doles (I) to 2,4-di- and 2,4,6-trisubstituted quinazolines (II) by sensitized photo-oxygenation in the presence of ammonium acetate is concluded to be shown by the following scheme:



In the transformation of triphenylimidazole to triphenyl-*s*-triazine the carbonyl compound, *N*,*N'*-dibenzoylbenzamidine, did not give the triazine by the reaction with ammonium acetate in a methanolic solution and even by fusion with ammonium acetate at about 180 °C. These results seem to show that the process of the ring enlargement of substituted indoles differs in part from that of substituted imidazoles.

Experimental

All the melting points are uncorrected. The IR spectra were obtained in a JASCO IR-G spectrophotometer. The UV spectra were measured by a Hitachi 124 spectrophotometer.

Preparation of Substituted Indole (I). All the indoles examined were prepared by the method described in the literatures.[14,17,18,19]

2,3,5-Trimethylindole (Ia)[17]: Colorless plates (from ethanol-water), mp 118—119 °C. Found: C, 82.91; H, 8.23; N, 8.58%. Calcd for $C_{11}H_{13}N$: C, 82.97; H, 8.23; N, 8.80%.

2,3-Dimethyl-5-chloroindole (Ib)[17]: Colorless plates with luster (from benzene), mp 142—144 °C. Found: C, 66.94; H, 5.56; N, 7.86; Cl, 19.64%. Calcd for $C_{10}H_{10}NCl$: C, 66.86; H, 5.61; N, 7.80; Cl, 19.73%.

2,3-Dimethyl-5-methoxyindole (Ic)[17]: Colorless needles (from ethanol and then from petroleum ether), mp 104—106 °C. Found: C, 75.76; H, 7.43; N, 8.05%. Calcd for $C_{11}H_{13}NO$: C, 75.48; H, 7.48; N, 7.99%.

2-Phenyl-3-methylindole (Id)[14]: Pale brown prisms (from benzene), mp 88—90 °C. Found: C, 87.28; H, 6.51; N, 6.71%. Calcd for $C_{15}H_{13}N$: C, 86.92; H, 6.32; N, 6.76%.

2,3-Diphenylindole (Ie)[18]: Colorless prisms (from benzene ligroin), mp 123.5—124 °C. Found: C, 89.33; H, 5.64; N, 5.11%. Calcd for $C_{20}H_{15}N$: C, 89.19; H, 5.61; N, 5.20%.

2,3-Diphenyl-5-methylindole (If)[18]: Colorless needles (from acetone-ligroin), mp 158—159 °C. Found: C, 89.10; H, 6.06; N, 5.00%. Calcd for $C_{21}H_{17}N$: C, 89.01; H, 6.05; N, 4.94%.

N-Methyl-2,3-diphenylindole: Colorless needles (from acetic acid), mp 135—136 °C (137 °C[19]). Found: C, 88.99; H, 6.06; N, 4.82%. Calcd for $C_{21}H_{17}N$: C, 89.01; H, 6.05; N, 4.94%. This compound did not give a hydroperoxide and also a quinazoline derivative by the same procedure as those for the other indoles.

Formation of the Quinazoline (II) by Sensitized Photo-oxygenation of the Indole (I) in the Presence of Ammonium Acetate. General Procedure. An aqueous methanolic solution (containing 20 vol% of water) of indoles (Ia, Ib, Ic, Id) which contained ammonium acetate and methylene blue as a sensitizer was irradiated with two incandescent lamps (300 W) for 1—10 hr under bubbling oxygen at room temperature or was refluxed for 1 hr after the irradiation. The solvent was removed under reduced pressure and the residue was extracted with ether. The ether extracts were washed with aqueous sodium carbonate and with water for removing methylene blue and dried over sodium sulfate. Quinazolines IIe and IIf were formed by fusion of the products obtained by sensitized photo-oxygenation with ammonium acetate at about 180 °C.

2,4,6-Trimethylquinazoline (IIa): Ammonium acetate (5 g) was added to the aqueous methanolic solution (300 ml) of Ia (600 mg). The mixture was irradiated for 10 hr at room temperature or for about 1 hr and then refluxed for 1 hr. The brown residue after removal of ether from ether extract was chromatographed on an alumina column with benzene and *n*-hexane (1 : 1). The elute was evaporated and the remaining product was recrystallized from petroleum ether. Colorless prisms. Found: C, 76.72; H, 7.05; N, 16.30%. Calcd for $C_{11}H_{12}N_2$: C, 76.70; H, 7.02; N, 16.28%. λ_{max}^{EtOH} nm (ε): 227 (1.56×10^4), 259 (1.0×10^3), 315 (7.0×10^2). IR(KBr): 1625, 1570, 1560, 1510, 1498, 880, 827 cm^{-1}.

2,4-Dimethyl-6-chloroquinazoline (IIb): Ammonium acetate (5 g) was added to the aqueous methanolic solution (300 ml) of Ib (500 mg) and the resulting solution was irradiated for 7 hr. The product obtained by removal of the solvent from ether extract was recrystallized from ethanol. Colorless needles. Found: C, 62.38; H, 4.89; N, 14.51; Cl, 17.69%. Calcd for $C_{10}H_9N_2Cl$: C, 62.33; H, 4.71; N, 14.55; Cl, 18.41%. λ_{max}^{EtOH} nm (ε): 227 (9.1×10^3), 256 (2.2×10^3), 315 (1.4×10^3). IR(KBr): 1570, 1550, 1480, 865, 835, 805, 670 cm^{-1}.

2,4-Dimethyl-6-methoxyquinazoline (IIc): The aqueous methanol solution (300 ml) of Ic (600 mg) was treated by the same procedure as that in the case of formation of IIa. IIc was obtained as colorless needles by recrystallization from a mixture of ether and acetone. Found: C, 69.82; H, 6.42; N, 14.89%. Calcd for $C_{11}H_{12}N_2O$: C, 70.18; H, 6.43; N, 14.89%. λ_{max}^{EtOH} nm (ε): 232 (2.1×10^4), 247 (2.6×10^3), 256 (2.3×10^3), 318 (1.9×10^3), 335 (1.9×10^3). IR(KBr): 1625, 1572, 1560, 1500, 845, 835 cm^{-1}.

2-Phenyl-4-methylquinazoline (IId): The aqueous methanol solution (200 ml) of Id (200 mg) was treated by the same procedure as that in the case of formation of IIa. IId was obtained as colorless plates by recrystallization from ethanol. Found: C, 81.58; H, 5.49; N, 12.33%. Calcd for $C_{15}H_{12}N_2$: C, 81.79; H, 5.49; N, 12.72%. λ_{max}^{EtOH} nm (ε): 260 (2.9×10^4), 280 (1.0×10^4), 317 (3.4×10^3). IR(KBr): 1620, 1575, 1500, 1495, 780, 750, 704 cm^{-1}.

IId was also prepared by using acetone containing 20 vol % of water with 40% yield.

2,4-Diphenylquinazoline (IIe): Ammonium acetate (5 g) was added to the aqueous solution (300 ml) of Ie (500 mg) and the resulting solution was irradiated for 1 hr and then refluxed for 1 hr. The residue obtained by removal of the solvent

was heated at 180 °C for 1.5 hr and then extracted with ether. The residue obtained by evaporation of the solvent was recrystallized from ethanol. Colorless prisms. Found: C, 85.00; H, 5.05; N, 9.81%. Calcd for $C_{20}H_{14}N_2$: C, 85.07; H, 5.00; N, 9.93%. λ_{max}^{EtOH} nm (ε): 224 (1.36×10^4), 248 (1.27×10^4), 3.08 (9.6×10^3). IR(KBr): 1615, 1560, 1539, 1489, 770, 750, 695 cm^{-1}.

IIe was also obtained in *n*-propyl alcohol containing 20 vol% of water. The alcoholic solution of Ie (200 mg in 200 ml) was irradiated for 5 hr in the presence of methylene blue as a sensitizer under a stream of oxygen. After the solvent was removed from the solution, ammonium acetate (5 g) was added to the residue. The mixture was heated at 180 °C for 1.5 hr and IIe was obtained with 67% yield by the same procedure as that in the methanolic solution.

2,4-Diphenyl-6-methylquinazoline (IIf): The aqueous methanol solution (300 ml) of If (500 mg) was treated by the same procedure as that in the case of formation of IIe. IIf was obtained as colorless prisms by recrystallization from ethanol. Found: C, 85.02; H, 5.50; N, 9.41%. Calcd for $C_{21}H_{16}N_2$: C, 85.11; H, 5.44; N, 9.45%. λ_{max}^{EtOH} nm (ε): 266 (1.37×10^4), 335 (1.3×10^3), 352 (1.3×10^3). IR-(KBr): 1624, 1560, 1540, 1492, 840, 790, 770, 705 cm^{-1}.

IIf was also obtained with 55% yield in *n*-propyl alcohol containing 20 vol% of water.

Preparation of the Hydroperoxide (III). The hydroperoxide (III) was prepared by autoxidation (Method A)[12,13] or by sensitized photo-oxygenation (Method B). The yields and melting points of III are shown in Table 2.

Method A: A trace amount of benzoyl peroxide was added to a warm solution of indole (I) (200—300 mg in 60—80 ml of petroleum ether). Crystalline hydroperoxide began to deposit from the solution after about 1 hr. The solution was left to stand for 4 hr in a refrigerator, and the crystalline hydroperoxide was obtained. These hydroperoxides liberated iodine from potassium iodide and showed an IR absorption at near 2800 cm^{-1} due to a stretching vibration of -OOH.

Method B: A methanolic solution of the indole (I) was irradiated with two incandescent lamps (300 W) in the presence of methylene blue as a sensitizer under oxygen stream at 5—10 °C for 1 hr. The residue obtained by removing the solvent was extracted with ether. The ether solution was washed with water to remove methylene blue. The solution was dried over sodium sulfate. Crude hydroperoxide obtained by removing the solvent under reduced pressure. Although it was reported[13] that indole derivatives having phenyl group at the 3-position resist to the action of oxygen, IIIe and IIIf were obtained by sensitized photo-oxygenation.

IIIa, IIIe and IIIf were also obtained in ethanol.

2,3,5-Trimethyl-3-hydroperoxyindolenin (IIIa): Colorless prisms (from ethyl acetate-petroleum ether). Found: C, 69.07; H, 6.81; N, 7.32%. Calcd for $C_{11}H_{13}NO_2$: C, 69.09; H, 6.85; N, 7.32%. λ_{max}^{EtOH} nm (ε): 217 (2.57×10^4), 222 (2.68×10^4), 261 (6.0×10^3).

2,3-Dimethyl-5-Chloro-3-hydroperoxyindolenin (IIIb): Colorless needles (from ethyl acetate-petroleum ether). Found: C, 56.93; H, 4.79; N, 6.41; Cl, 17.44%. Calcd for $C_{10}H_{10}NO_2Cl$: C, 56.75; H, 4.76; N, 6.62; Cl, 16.75%. λ_{max}^{EtOH} nm (ε): 216(1.14×10^4), 219 (1.18×10^4), 261 (3.2×10^3).

2,3-Dimethyl-5-methoxy-3-hydroperoxyindolenin (IIIc): Pale gray prisms (from ethyl acetate-petroleum ether). Found: C, 63.92; H, 6.30; N, 6.81%. Calcd for $C_{11}H_{13}NO_3$: C, 63.76; H, 6.32; N, 6.76%. λ_{max}^{EtOH} nm (ε): 232 (1.13×10^4), 277 (4.4×10^3), 311 (2.4×10^3).

2-Phenyl-3-methyl-3-hydroperoxyindolenin (IIId): Colorless needles (from ethyl acetate-petroleum ether). Found: C, 74.93; H, 5.53; N, 5.77%. Calcd for $C_{15}H_{13}NO_2$: C, 75.30; H, 5.48; N, 5.85%. λ_{max}^{EtOH} nm (ε): 238 (1.3×10^4), 245 (1.2×10^4), 314 (1.0×10^4).

2,3-Diphenyl-3-hydroperoxindolenin (IIIe): Colorless prisms (from acetone-ligroin). Found: C, 79.72; H, 5.08; N, 4.53%. Calcd for $C_{20}H_{15}NO_2$: C, 79.72; H, 5.02; N, 4.65%. λ_{max}^{EtOH} nm (ε): 222 (9.0×10^3), 250 (8.7×10^3), 317 (6.13×10^3).

2,3-Diphenyl-5-methyl-3-hydroperoxyindolenin (IIIf): Colorless prisms (from acetone-ligroin). Found: C, 79.88; H, 5.50; N, 4.36%. Calcd for $C_{21}H_{17}NO_2$: C, 79.98; H, 5.43; N, 4.44%. λ_{max}^{EtOH} nm (ε): 254 (5.6×10^3), 330 (4.0×10^3).

The hydroperoxide (IIIf) was also obtained by reaction of If with singlet oxygen which was produced by the method of Foote and Wexler.[11] To a methanolic solution (180 ml) of If (1.08 g) hydrogen peroxide (30%, 20 ml) was added. The solution was stirred in nitrogen atmosphere at about 10 °C, and 150 ml of 0.3 M sodium hypochlorite solution was added in 90 min. After the solution was left to stand for 1 hr at 0—5 °C, the solution was diluted with water and extracted with ether. The ether solution was dried over sodium sulfate. Yellowish oil remained by removing ether under reduced pressure was recrystallized from a mixture of ether and ethyl acetate.

Influence of an Amount of Water in Methanol for the Reaction Rate from IIIa to IVa. When a solution of IIIa (100 mg in 40 ml) in dehydrated methanol was allowed to stand for 20 hr and then refluxed for 5 hr, no change was observed by UV spectrum and thin layer chromatogram. In a methanolic solution containing about 1% of water, IIIa was changed to IVa in part by refluxing the solution for 8 hr. In an aqueous methanolic solution containing 20 vol% of water, IIIa was changed to IVa by refluxing for 0.5 hr. In boiling water, the change of IIIa to IVa came to an end in a few minutes.

Preparation of the Dicarbonyl Compound (IV). A methanolic solution (containing 20 vol% of water) (40 ml) of the hydroperoxide (III) (100 mg) was heated on a water bath for 0.5 hr. The solvent was removed under reduced pressure and the brown oily residue was recrystallized from *n*-hexane (in the case of IVa) or ethanol (in the cases of IVb, IVd, IVe, IVf). Their analytical values were satisfactory for the formulas corresponding to the dicarbonyl compounds. The yields and melting points are shown in Table 4.

The authors wish to express their gratitude to Professor Michio Shiota of Ochanomizu University and Dr. Hiroshi Midorikawa of the Institute of Physical and Chemical Research for their kind advice and encouragement in the course of this investigation.

proposal[5] regarding the ring opening of the aziridinium compound. The process for the formation of aziridinium bromide (**B**) probably involves the initial attack of diazomethane at the higher electrophilic carbimino position of the iminium bromide, and the subsequent ring closure to the aziridinium bromide (**B**), as is shown in Chart 3. It seems likely that this aziridinium bromide (**B**) is very unstable because of its highly strained structure, and that ring opening takes place spontaneously by the fission of the 1,3-bond to give carbonium ion (**C**), which may then afford a bromide (**D**). Since the presence of the nitrogen atom (at the 4-position) apparently effects the dissociation of the bromide (**D**) to the carbonium ion (**C**), the bromide (**D**) must be in equilibrium with the carbonium ion (**C**); therefore, the ethanolysis of the carbonium ion (**C**) results in the formation of **14**.

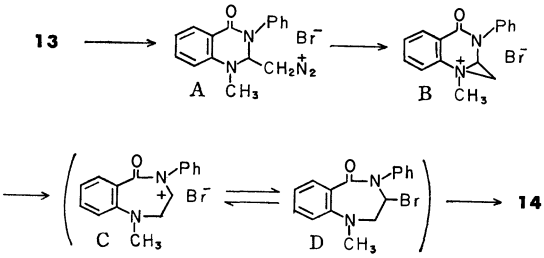

Chart 3.

Treatment of **13** with phenyldiazomethane in EtOH at room temperature afforded a product possessing the benzodiazepine ring system in a moderate yield. The structure was identified as 1-methyl-2,4-diphenyl-3-ethoxy-1,4-benzodiazepin-5(*H*)-one (**16**) on the basis of the elemental analysis and the spectral data, though the stereochemistry of compound **16** remained unclarified. The UV spectrum [maximum at 226 nm (ε 33400), 265 (sh), 334 (4300)] corresponded closely to the data for **14**. The NMR spectrum showed the signals of an ethoxy group in the usual region, a methyl singlet at δ 2.77, and an AB quartet at δ 4.85 and 5.08 (J=6 Hz) assignable to the methine protons in the seven membered ring.

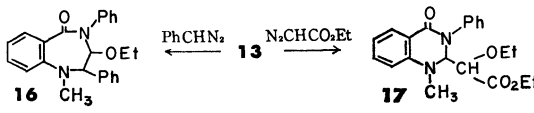

Chart 4.

Reaction of **13** with ethyl diazoacetate in EtOH did not occur even under reflux. On the other hand, reaction with ethyl diazoacetate in the presence of $CuSO_4$ at 65—70 °C gave an oily product which was shown to be homogeneous by the criteria of the glc and tlc. It has been established[9] that the $CuSO_4$-catalyzed decomposition of ethyl diazoacetate results in the formation of the carbene-copper complex, which then reacts with olefins to give cyclopropanes, but which does not undergo insertion into carbon-hydrogen bonds. Therefore, a carbene addition to the $>C=\overset{+}{N}<$ bond may be considered in the present case, though to our knowledge, no addition of a carbene at the positively-charged double bond is yet known. The planar structure of the product was shown to be 1-methyl-2-(1-ethoxy-1-ethoxycarbonylmethyl)-3-phenyl-4-oxo-1,2,3,4-tetrahydroquinazoline (**17**) by the spectral data. The mass spectrum showed a molecular ion peak (*m/e* 368) and a base peak (*m/e* 237) which must have arisen by the loss of the substituent at the 2-position. It has been reported by Bogentoft and Danielsson[10] that this type of cleavage is a main pathway in the mass fragmentation of 4-oxo-1,2,3,4-tetrahydroquinazolines. The structural assignment was also supported by the UV spectrum. The spectrum [maximum at 228 nm (ε 31000), 251 (sh), 354 (3000)] was similar to those of 4-oxo-1,2,3,4-tetrahydroquinazoline compounds and was distinctly different from those of benzodiazepines **14** and **16**. The two singlets due to the *N*-methyl groups in the NMR spectrum of **17** suggested that the product consisted of a 21 : 13 mixture of two isomers. Since no change in the signal pattern was observed at elevated temperatures, the product **17** must be a mixture of diastereoisomers. No further study on the separation of the isomers was attempted.

To evaluate the synthetic utility of this ring expansion reaction, the extension to the synthesis of the 1-dialkylaminoalkyl derivatives of 1,4-benzodiazepine is now in progress.

Experimental

Melting points are uncorrected and were determined on a Yamato apparatus MP-1. The NMR spectra were determined on a Hitachi Perkin-Elmer R-20A instrument (Me_4Si). Mass spectra were measured on a Hitachi RMS-4 spectrometer. IR spectra were determined on a Shimadzu IR-27G spectrometer, and UV spectra on a Hitachi EPS-2U spectrometer.

2-(N-methylbromoacetamido)benzanilide (8). To a stirred solution of 2-(*N*-methylamino)benzanilide (**7**) (4.52 g, 0.02 mol) and pyridine (2.4 g, 0.03 mol) in benzene (120 ml) was added dropwise bromoacetylbromide (2.4 g, 0.022 mol) at room temperature, and the mixture was stirred for 1 hr. The solvent was evaporated under reduced pressure and the residue was dissolved in $CHCl_3$. The chloroform layer was washed with H_2O, dried (Na_2SO_4), and concentrated to dryness. The residual oil was triturated with a mixture of *i*-Pr_2O-EtOH (1 : 1) to afford an almost pure crystalline product (5.8 g, 83%), mp 185—187 °C. An analytical sample was obtained as colorless needles by recrystallization from EtOH; mp 185—187 °C. Found: C, 55.43; H, 4.35; N, 7.72%. Calcd for $C_{16}H_{15}O_2N_2Br$: C, 55.34; H, 4.35; N, 8.07%.

1-Methyl-2-bromomethyl-3-phenyl-4-oxo-3,4-dihydroquinazolinium Perchlorate (9). A solution of **8** (5.0 g) and an excess of 60% $HClO_4$ in EtOH was refluxed for 3 min and the precipitates were collected by filtration and washed with EtOH to give pure **9** (5.6 g, 90.3%); mp 251—253 °C (decomp.). IR ν_{max}^{Nujol} cm^{-1}: 1723, 1625, 1594, 1563, 1490. Found: C, 44.96; H, 3.29; N, 6.30%. Calcd for $C_{16}H_{14}O_5N_2BrCl$: C, 44.72; H, 3.28; N, 6.52%.

1-Methyl-2-bromomethyl-3-phenyl-4-oxo-1,2,3,4-tetrahedroquinazoline (10). To a suspension of **9** (5.0 g, 0.012 mol) in EtOH (200 ml) was added dropwise a solution of $NaBH_4$ (0.46 g, 0.012 mol) in EtOH (20 ml) at 0—5 °C over a 1.5-hr period. The mixture was then concentrated under reduced pressure, and the residue was dissolved in $CHCl_3$.

The chloroform layer was washed with H_2O, dried (Na_2SO_4), and concentrated under reduced pressure. The residue was crystallized by trituration with *i*-Pr_2O and the crystals were collected by filtration to give crude **10** (3.4 g, 88.4%); mp 108—110 °C. Recrystallization from *i*-PrOH gave a pure sample as colorless prisms (3.1 g, 80.0%); mp 108—110 °C. UV λ_{max}^{EtOH} nm ($\varepsilon \times 10^{-3}$): 229 (33.2), 252 (sh), 356 (2.9). NMR ($CDCl_3$) δ: 3.25 (3H, s), 3.53 (1H, d.d, J=11 Hz, J=5 Hz), 3.76 (1H, d.d, J=11 Hz, J=7 Hz), 5.17 (1H, d.d, J=7 Hz, J=5 Hz), 6.15—7.65 (3H, m), 7.37 (5H, s), 8.00 (1H, d.d, J=8 Hz, J=2 Hz). Found: C, 57.99; H, 4.63; N, 8.38%. Calcd for $C_{16}H_{15}ON_2Br$: C, 58.01; H, 4.56; N, 8.45%.

Reaction of ***10*** *with* $AgClO_4$ *in EtOH.* A mixture of **10** (0.5 g 0.0015 mol), $AgClO_4$ (0.31 g, 0.0015 mol), and EtOH (30 ml) was stirred at room temperature for 1.5 hr and at 50—60 °C for 8 hr. The insoluble solid that had formed was then filtered off, and the filtrate was concentrated under reduced pressure. The residue was dissolved in $CHCl_3$ and the solution was washed with aqueous 5% K_2CO_3 solution, dried (K_2CO_3), and concentrated. The residual oil was chromatographed on silica gel (20 g, solvent $CHCl_3$) to give 2-[*N*-methyl-*N*-(1,2-diethoxyethyl)amino]benzanilide (**11**) as an oil (0.3 g, 58.5%). NMR ($CDCl_3$) δ: 1.08 6H, t, J=7 Hz), 2.80 (3H, s), 3.29 (2H, d, J=6 Hz), 3.49 (2H, q, J=7 Hz), 3.55 (2H, q, J=7 Hz), 4.60 (1H, t, J=6 Hz), 7.0—8.3 (9H, m), 11.25 (1H, br.s). Mass *m/e*: 324 (M^+). Found: C, 70.10; H, 7.58; N, 8.44%. Calcd for $C_{20}H_{16}N_2O_3$: C, 70.15; H, 7.65; N, 8.18%.

*2-(N-methylformamido)benzanilide (****12****).* To a mixture of formic acid (20 g) and acetic anhydride (5.0 g) was added 2-(*N*-methylamino)benzanilide (**7**, 10 g) and the reaction mixture was stirred at room temperature for 4 hr. The solution was poured into H_2O and extracted with $CHCl_3$. The chloroform layer was washed, dried (Na_2SO_4), and concentrated. The residual oil was triturated with Et_2O and the solid was collected by filtration to give almost pure **12** (10.0 g, 88.9%), mp 141—142 °C. Recrystallization from benzene gave a pure sample as colorless prisms, mp 141—142 °C. NMR ($CDCl_3$) δ: 3.12 and 3.24 (3H, two singlets in a ratio of 17 : 11), 6.9—7.75 (9H, m), 8.04 and 8.09 (1H, two singlets in the same ratio), 8.73 (1H, br.s). Found: C, 70.63; H, 5.63; N, 10.76%. Calcd for $C_{15}H_{14}O_2N_2$: C, 70.85; H, 5.55; N, 11.02%.

*1-Methyl-3-phenyl-4-oxo-3,4-dihydroquinazolinium Bromide (****13****).* To a solution of **12** (10 g) in EtOH (50 ml) was added an excess of 47% HBr and the solvent was evaporated. The residue was triturated with EtOH to afford crude **13**; mp 222—223 °C (decomp.). Recrystallization from EtOH gave a pure sample (10.5 g, 84.0%); mp 225—227 °C (decomp.). IR ν_{max}^{Nujol} cm^{-1}: 1745, 1730, 1715, 1660, 1600, 1569, 1490. Found: C, 56.43; H, 4.16; N, 8.62%. Calcd for $C_{15}H_{13}ON_2Br$: C, 56.79; H, 4.13; N, 8.83%.

*1-Methyl-3-ethoxy-4-phenyl-1,2,3,4-tetrahydro-1,4-benzodiazepin-5(H)-one (****14****). A)*: To a solution of **13** (1.9 g, 0.006 mol) in EtOH (100 ml) was added dropwise a solution of CH_2N_2 in Et_2O (freshly prepared from 12.9 g of *p*-TsN(NO)-CH_3) at 0—5 °C during 1 hr and the mixture was stirred for 4 hr at the same temperature. After standing overnight, the solvent was evaporated and the residue was poured into aqueous K_2CO_3 solution. The oil was extracted with $CHCl_3$ and the chloroform layer was washed with H_2O, dried (K_2CO_3) and concentrated to dryness. The residue was crystallized by trituration with *i*-Pr_2O and the crystals were collected by filtration to give almost pure **14** (1.2 g, 67.6%); mp 86—88 °C. Recrystallization from *i*-Pr_2O gave a pure sample as colorless prisms; mp 89—90 °C. UV λ_{max}^{EtOH} nm ($\varepsilon \times 10^{-3}$): 225 (24.3), 262 (sh), 352 (2.0). NMR ($CDCl_3$) δ: 0.90 (3H, t, J=7 Hz), 2.90 (3H, s), 3.15—3.85 (4H, m), 4.97 (1H, t, J=5 Hz), 6.8—7.8 (4H, m), 7.36 (5H, s). Found: C, 72.55; H, 6.95; N, 9.38%. Calcd for $C_{18}H_{20}O_2N_2$: C, 72.95; H, 6.80; N, 9.45%.

B): A mixture of 3-ethoxy-4-phenyl-1,2,3,4-tetrahydro-1,4-benzodiazepin-5(*H*)-one[1] (**15**, 5.65 g, 0.02 mol), 37% HCHO (2.5 g, 0.03 mol) and EtOH (200 ml) was warmed at 50—60 °C for 1 hr. The mixture was then hydrogenated with 5% Pd/C (2.5 g) under 2.5 kg/cm². The theoretical volume of H_2 was absorbed in 4 hr on warming. The catalyst was filtered off and the filtrate was concentrated under reduced pressure. The residue was triturated with *i*-Pr_2O and the crystals were collected by filtration to give almost pure **14** (4.9 g, 82.4%); mp 87—88 °C. The product was identical with the sample (**14**) obtained from **13**.

*1-Methyl-2,4-diphenyl-3-ethoxy-1,2,3,4-tetrahydro-1,4-benzodiazepin-5(H)-one (****16****).* To a stirred suspension of **13** (1.0 g) was added dropwise a solution of $PhCHN_2$ in Et_2O [freshly prepared from *N*-nitroso-*N*-benzyl-*p*-toluenesulfonamide (5.8 g) by the method of Oberberger[11]] at room temperature during 1 hr. Stirring was continued overnight. The solvent was evaporated and the residue was poured into 5% aqueous K_2CO_3 solution. The oil was extracted with $CHCl_3$ and the extract was washed with H_2O, dried (K_2CO_3), and concentrated under reduced pressure. This residue was chromatographed on silica gel (100 g, solvent $CHCl_3$) to give a crystalline product **16** (350 mg, 29.8%); mp 182—184 °C (decomp.). Recrystallization from EtOH gave a pure sample colorless prisms (300 mg); mp 184—186 °C (decomp.). UV λ_{max}^{EtOH} nm ($\varepsilon \times 10^{-3}$): 226 (33.4), 265 (sh), 334 (4.3). NMR ($CDCl_3$) δ: 0.81 (3H, t, J=7 Hz), 2.77 (3H, s), 3.05—3.85 (2H, m), 4.85 (1H, d, J=6 Hz), 5.08 (1H, d, J=6 Hz), 6.8—7.85 (14H, m). Found: C, 77.43; H, 6.65; N, 7.69%. Calcd for $C_{23}H_{22}O_2N_2$: C, 77.39; H, 6.50; N, 7.52%.

*1-Methyl-2-(1-ethoxy-1-ethoxycarbonylmethyl)-3-phenyl-4-oxo-1,2,3,4-tetrahydroquinazoline (****17****).* To a stirred suspension of **13** (3.0 g) and $CuSO_4$ (0.6 g) in EtOH (100 ml) was added dropwise a solution of $N_2CHCOOEt$ (3.0 g) in EtOH (50 ml) at 70—75 °C during 3 hr. The insoluble solid was filtered off and the filtrate was concentrated under reduced pressure. The residue was shown by tlc to be a mixture of a major product and three minor products. This residue was chromatographed on silica gel (180 g, solvent $CHCl_3$) to give an oil (600 mg) which was shown to be homogeneous by the criteria of the glc and tlc. IR ν_{max}^{neat} cm^{-1}: 1740, 1660, 1619, 1498. UV λ_{max}^{EtOH} nm ($\varepsilon \times 10^{-3}$): 228 (31.0), 251 (sh), 354 (3.0). NMR (CCl_4) δ: 1.01, 1.10 (6H, two triplets in a ratio of 21 : 13, J=7 Hz), 3.06, 3.13 (3H, two singlets in the same ratio), 3.2—4.3 (5H, m), 5.24, 5.26 (1H, two doublets, J=5 Hz), 6.45—8.05 (9H, m). Mass *m/e*: 368 (M^+), 237 (base peak). Found: C, 65.62; H, 6.54; N, 7.06%. Calcd for $C_{21}H_{24}O_4N_2 \cdot H_2O$: C, 65.27; H, 6.78; N, 7.25%.

We wish to express our gratitude to Mr. T. Takayanagi, Senior Managing Director of our Company, Dr. I. Chibata, Director of our Laboratory, Dr. K. Okumura and Dr. M. Miyoshi for their encouragement. Thanks are due to the members of the analytical center for elemental analyses.

Reaction of 1-Methyl-4-phenylquinazolinium Salts with Diazomethane

Yoshihisa YAMADA, Toyonari OINE, and Ichizo INOUE

Research Laboratory of Applied Biochemistry, Tanabe Seiyaku Co., Ltd., Kashima-cho, Higashiyodogawa-ku, Osaka 532

(Received August 17, 1973)

For the synthesis of 5-phenyl-1,4-benzodiazepines, reaction of quinazolinium salts with diazomethane was studied. In the course of the study, it was found by NMR spectroscopy that the starting materials (**2**) reacted even with a slight amount of water present in the solvent to give hydrates **5**. Treatment of **2c** with diazomethane at 10 °C under absolute anhydrous conditions gave quinazoline **8c** and benzodiazepines **9** and **10c** in about the same ratio. In the reactions at lower temperatures, the distribution of the products varied markedly, and the ring expansion product **10c** was obtained in an improved yield. The mechanism for the formation of **8**, **9**, and **10** was discussed.

Within the past decade the synthesis of the 1,4-benzodiazepines has attracted considerable attention since the advent of chlorodiazepoxide and diazepam as tranquilizers,[1] and a number of synthetic approaches[2] to 1,4-benzodiazepine derivatives have been developed. In a previous paper,[3] we have reported that reaction of 1-methyl-3-phenyl-4-oxo-3,4-dihydroquinazolinium bromide with diazomethane in ethanol gave 1-methyl-3-ethoxy-4-phenyl-1,2,3,4-tetrahydro-1,4-benzodiazepin-5*H*-one. We considered that this ring expansion reaction could become a new approach to the preparation of 5-phenyl-1,4-benzodiazepine derivatives from 1-methyl-4-phenylquinazolinium salts (**2**). We present results concerning the ring-expansion reaction of **2** with diazomethane.

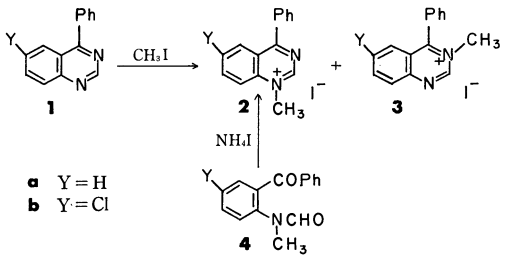

Chart 1.

The starting material, 1-methyl-4-phenylquinazolinium iodide (**2a**), has already been reported by Ott and Denzer.[4] They have observed that treatment of 4-phenylquinazoline (**1a**) with methyl iodide gave a mixture of the 1-methiodide (**2a**) and the 3-methiodide (**3a**) in a 7 : 1 ratio,[5] and that the two methiodides could not be separated by the usual purification technique because of their very similar physical properties. We reexamined the reaction thereby and found that the 1-methiodide could be easily isolated by washing with chloroform. The NMR spectrum of the product in DMSO-d_6 showed a couple of singlet at δ 3.80 and 4.60 (an intensity ratio of 1 : 10) assignable to two different *N*-methyl protons. The presence of the two *N*-methyl signals suggested an incomplete purification. However, since another set of two singlets (at δ 3.08 and 4.14[6]) observed in the spectrum of the original mixture has disappeared, we considered that one of the singlets might be due to the *N*-methyl protons of a contaminant. To ascertain this point, an unequivocal preparation of the 1-methiodide (**2a**) was attempted. Thermal cyclization of 2-(*N*-methylformamido)benzophenone (**4a**) with NH_4I in ethanol gave a product, albeit in a very low yield (4.3%), which showed an NMR spectrum identical with that of the purified 1-methiodide (**2a**) obtained according to Ott's procedure. Consequently, we concluded that the purified 1-methiodide (**2a**) was free from the 3-isomer and that, accordingly, one of the singlets was attributable to the *N*-methyl protons of the contaminant.

Quarternization of 4-phenyl-6-chloroquinazoline (**1b**) with methyl iodide also gave a mixture of a 1- and a 3-methiodide. The purified 1-methiodide (**2b**) exhibited a similar spectral pattern in its NMR spectrum. A presumption that the contaminant was the hydrated form of the 1-methiodide (**2b**) was proved by NMR spectroscopy (see Fig. 1 a, b, c). The hydration reaction of **2b** in DMSO-d_6 was carried out in an NMR sample tube. With an increase in the quantity of the additive water, the intensity of the

Fig. 1. NMR spectral change on hydration of **2b**.
- a The spectrum of **2b** (0.2 mmol) in DMSO-d_6 (0.6 ml).
- b The spectrum of **2b** (0.2 mmol) in DMSO-d_6 (0.6 ml) containing H_2O (0.056 mmol).
- c The spectrum of **2b** (0.2 mmol) in DMSO-d_6 (0.6 ml) containing H_2O (0.224 mmol).
- d The spectrum of **2b** (0.2 mmol) in DMSO-d_6 (0.6 ml) containing D_2O (0.1 ml).

singlet at δ 4.60 varied inversely; on the contrary, the methyl signal at δ 3.78 increased. Simultaneously, the signal at δ 10.20 assignable to $>\overset{+}{N}=CH-$ decreased an intensity in the same ratio, followed with enhancement of the signal at δ 8.91. The other important spectral feature was the disappearance of the doublet at δ 8.43 (J=2 Hz) corresponding to the aromatic proton on the 5-position in **2b** and the appearance of a new doublet at δ 7.05 (J=2 Hz). These high-field shifts was probably caused by the remission of the strong positive charge on the quinazolinium ring and the anisotropic effect of the benzene ring on the sp^3-C(4) formed upon hydration. Preferential occurrence of hydration at C(4) was supported by the absence of the coupling[7] between the hydroxy proton (δ 8.22) and the methine proton (δ 8.91) in the NMR spectrum in DMSO-d_6. The position of hydration may also be explained by a mechanistic consideration of the same type of reaction.[8] The methiodides (**2a-b**) were converted to 1-methyl-4-hydroxy-4-phenyl-1,4-dihydroquinazoline (**6**) and 1-methyl-4-hydroxy-4-phenyl-6-chloro-1,4-dihydroquinazoline (**7**) respectively under mild alkaline conditions. This conversion was found to be reversible. Thus, treatment of **6** and **7** with excess HBr afforded the corresponding quinazolinium bromides (**2c-d**) in a high yield.

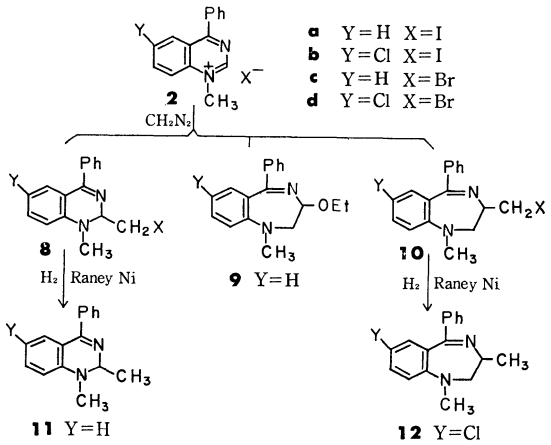
Chart 2.

Reaction of **2a-d** with diazomethane was carried out under absolute anhydrous conditions, because the nucleophilic attack of diazomethane to form an aziridinium compound can take place only at the imminium carbon.[9] Treatment of **2c** with diazomethane in anhydrous CH_2Cl_2 at 10 °C gave three major products in about the same ratio. The first product was characterized as a picrate; the structure was chemically confirmed as 1-methyl-2-bromomethyl-4-phenyl-1,2-dihydroquinazoline (**8c**) by hydrogenation with Raney nickel. The NMR spectrum of the hydrogenation product was consistent with 1,2-dimethyl-4-phenyl-1,2-dihydroquinazoline (**11**), exhibiting a doublet at δ 1.46 (J=6 Hz) assignable to the methyl group at the 2-position and an absence of any signals attributable to methylene protons. Two other products, 1-methyl-3-ethoxy-5-phenyl-2,3-dihydro-1*H*-1,4-benzodiazepine (**9**) and 1-methyl-3-bromomethyl-5-phenyl-2,3-dihydro-1*H*-1,4-benzodiazepine (**10c**) were isolated from the mother liquor by column chromatography. The structure of **9** was established by the presence of the characteristic absorption of 4-phenyl-2,3-dihydro-1*H*-1,4-benzodiazepine[10] at 242 nm (ε 22000) and at 346 (1700) in the UV spectrum and by the signal of an ethoxy group in the NMR spectrum. The structure of **10c** was tentatively assigned on the basis of the spectral data. The UV spectrum [242.5 nm (ε 23000) and 346 (2900)] corresponded to the datum for **9**. The bromomethyl group was indicated by the molecular ion peak (*m/e* 330 and 328) and the base peak (*m/e* 249) in the mass spectrum, and by a multiplet at δ 3.4—3.9 which overlapped with the endocyclic methylene and methine protons in the NMR spectrum. There remained a little ambiguity as to the position of the bromomethyl group.



a Y=H X=I
b Y=Cl X=I
c Y=H X=Br
d Y=Cl X=Br

Chart 3.

Since the results of the preliminary reaction presented about was not necessarily satisfactory for our present purposes because of the low yield and the multiple product formation, we attempted to improve the reaction by changing the factors (the anion species, the

Table 1. Products in reaction of **2** with CH_2N_2

a) As the picrate. b) The tlc showed the presence of the compounds. However, since it seemed that the yields were very low, isolation was not attempted. c) As the picrolonate. d) 207—208 °C (decomp.). e) Nil.

substituent on the benzene ring, and the reaction conditions). Thus, the reactions of the quinazolinium salts (**2a–d**) with diazomethane were examined under various conditions. The results are shown in Table 1.

The reaction of 6-chloroquinazolinium iodide (**2b**) with diazomethane at −30——40 °C gave 1-methyl-2-iodomethyl-4-phenyl-6-chloro-1,2-dihydroquinazoline (**8b**) and 1-methyl-3-iodomethyl-5-phenyl-7-chloro-2,3-dihydro-1*H*-1,4-benzodiazepine (**10b**) in a ratio of about 1 : 2. The structure of **10b** was confirmed by its chemical transformation to a known compound, 1,3-dimethyl-5-phenyl-7-chloro-2,3-dihydro-1*H*-1,4 benzodiazepine (**12**).[11] Hydrogenation of **10b** with Raney nickel afforded **12** in a good yield. These results gave conclusive evidence for the tentative assignment of the structure of **10c**.

The change of the halide ion in the quinazolinium salt did not affect the product ratio. However, the reaction at low temperature showed a tendency to increase markedly the ratio of 3-halomethylbenzodiazepine. We will now attempt to explain the formation of **8**, **9**, and **10** (Chart 4). The process probably involves an initial attack of diazomethane to give an adduct (**A**) and a subsequent ring closure to the aziridinium halide (**B**). According to Crist and Leonard,[12] two pathways, a solvolysis-type reaction at the more substituted ring carbon and a nucleophilic displacement at the less hindered, less substituted ring carbon, are possible for the ring opening of an aziridinium compound. The product (**8**) would then be obtained by SN2-like ring opening with the halide ion at the less hindered methylene. However, an alternate route involving the displacement of the diazo group in (**A**) with the halide ion might be considered.

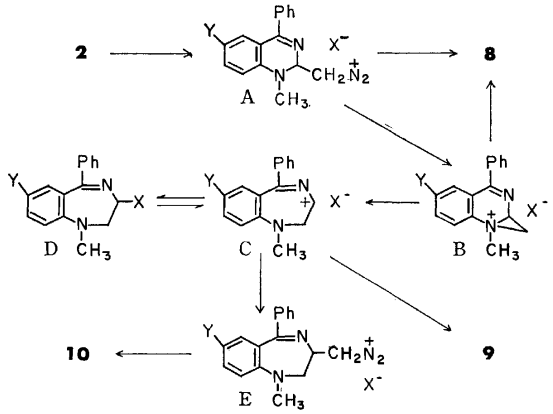

Chart 4.

The ring enlargement to **9** would be due to an *S*N1-type reaction of the most stable carbonium ion, which could arise *via* the ionic cleavage of the aziridinium intermediate (**B**), with the ethanol present in the ethereal diazomethane solution.[13] It seems that the formation of **10** was due to the participation of two equivalents of diazomethane. Bernhard and Snieckus[14] reported the formation of a benzazocine in addition to a seven-membered ring product in the reaction of 3,4-dihydro-2-methylisoquinolinium perchlorate with diazomethane. They explained the benzazocine formation by the second addition of diazomethane to the benzazepinium compound, which could arise from the aziridinium compound. However, the formation of our compound (**10**) could not be explained by their mechanism. Therefore, a different machanism must be operative in our case. Our failure to isolate the aziridinium compound (**B**) suggested that the intermediate (**B**) would be very unstable due to its own nature to afford smoothly the resonance-stabilized carbonium ion (**C**). This carbonium ion would react competitively with diazomethane and with the halide ion to give the adduct (**E**) and the halide (**D**) respectively. However, in view of the allylic nature of the C(3), the halide (**D**) would be amenable to equilibrium with the carbonium ion. Ultimately, the product (**10**) which could be formed *via* the displacement of the diazo group with the halide ion would become an end product.

The reaction of quinazolinium perchlorate with diazomethane was also attempted; however, it resulted only in the recovery of the starting material.

Experimental

Melting points are uncorrected and were determined on a Yamato apparatus, MP-1. The NMR spectra were determined on a Hitachi Perkin-Elmer R-20A instrument (Me_4Si). Mass spectra were measured on a Hitachi RMS-4 spectrometer. IR spectra were determined on a Shimadzu IR-27G spectrometer, and UV spectra, on a Hitachi EPS-2U spectrometer.

1-Methyl-4-phenyl-quinazolinium Iodide (2a). A): A mixture of 4-phenylquinazoline (**1**, 20.0 g) and methyl iodide (50 ml) was refluxed for 6 hr. The precipitates that had formed were collected by filtration and washed with Et_2O to give a crude product (21.0 g); mp 175—177 °C. In the NMR spectrum (DMSO-d_6), four singlets attributable to four different methyls (at δ 3.08, 3.80, 4.14, and 4.60) were observed.[6] The crude product was washed with $CHCl_3$ (300 ml) to give pure **2a** as an orange powder (15.5 g, 44.3%); mp 196—198 °C. IR ν_{max}^{Nujol} cm^{-1}: 1610, 1590, 1520. NMR (DMSO-d_6) δ: 3.80 and 4.60 (3H, two singlets in the ratio of 1 : 10), 7.0—8.7 (9H, m), 8.86 and 10.15 (1H, two singlets in the ratio of 1 : 10). Found: C, 51.85; H, 3.77; N, 7.74%. Calcd for $C_{15}H_{13}N_2I$: C, 51.74; H, 3.76; N, 8.05%.

B): A mixture of 2-(*N*-methylformamido)benzophenone (**4a**, 0.5 g), NH_4I (0.5 g), and EtOH (10 ml) was heated in a sealed tube at 150—160 °C for 10 hr. The mixture was then concentrated to dryness, and the residue was triturated with AcOEt to give a crystalline material. The crystals were extracted with CH_2Cl_2 and the extract was concentrated. The residue was triturated with AcOEt to give **2a** (30 mg, 4.3%). The NMR spectrum of this compound was identical with that of **2a** prepared by Method A.

C): A mixture of 1-methyl-4-hydroxy-4-phenyl-1,4-dihydroquinazoline (**6**, 0.2 g), an excess of 57% HI (*ca.* 0.2 ml) and *i*-PrOH (10 ml) was warmed until it became a clear solution. After cooling, the precipitates were collected by filtration to give almost pure **2a** as orange leaflets (0.25 g, 89%); mp 195—197 °C (decomp.). The NMR spectrum and IR spectrum of this compound were identical with those of **2a**.

1-Methyl-4-phenyl-6-chloroquinazolinium Iodide (2b). A): A mixture of 4-phenyl-6-chloroquinazoline (**1b**, 11.0 g) and methyl iodide (30 ml) was heated in a sealed tube at 100—110 °C for 20 hr. The precipitates were collected by filtration and washed with Et_2O to give a crude product

(15.8 g, 97.7%); mp 204—205 °C (decomp.). NMR (DMSO-d_6) δ: 3.10 and 4.17 (two singlets, N^3-CH_3), 4.63 (s, N^1-CH_3) (3H, the ratio of 3 : 7),[15] 7.0—8.75 (8H, m), 8.99 and 9.95 (two singlets), 10.20 (s), (1H, the ratio of 3 : 7). This product was recrystallized from a mixture of DMF (100 ml) and AcOEt (50 ml) to give pure **2b** as dark red leaflets (8.6 g, 49.4%); mp 211—213 °C (decomp.). IR ν_{max}^{Nujol} cm^{-1}: 1595, 1590, 1521. NMR: The spectrum is shown in Fig. 1. Found: C, 47.06; H, 3.10; N, 7.34%. Calcd for $C_{15}H_{12}N_2ClI$: C, 47.08; H, 3.17; N, 7.32%.

B): A mixture of 2-(*N*-methylformamido)-5-chlorobenzophenone (**4b**, 2.0 g), NH_4I (4.0 g), and EtOH (30 ml) was heated in a sealed tube at 150 °C overnight. The mixture was then concentrated to dryness, and the residue was triturated with AcOEt. The solid was collected by filtration and extracted with CH_2Cl_2 (100 ml). The extract was concentrated to give a crystalline residue (200 mg). A mixture of the residue (100 mg), three drops of 47% HI, and *i*-PrOH (5 ml) was warmed to give a clear solution. After cooling, the crystals which had formed were collected by filtration to give pure **2b** as red leaflets (50 mg, 3.5%); mp 212—213 °C (decomp.). The NMR spectrum of this compound was identical with that of **2b** prepared by Method A. **4b** (1.1 g, 55%) was recovered from the AcOEt filtrate.

*1-Methyl-4-hydroxy-4-phenyl-1,4-dihydroquinazoline (**6**).* To a suspension of **2a** (1.0 g) in H_2O (20 ml) was added $NaHCO_3$ (1.5 g), and the mixture was stirred at room temperature for 1 hr. The crystals were collected by filtration to give almost pure **6** (0.65 g, 95%); mp 135—136 °C (decomp.). Recrystallization from DMF-EtOH gave an analytical sample colorless leaflets; mp 141—143 °C (decomp.). IR ν_{max}^{Nujol} cm^{-1}: 1640, 1600, 1570. NMR (DMSO-d_6) δ: 3.30 (3H, s), 6.22 (1H, br.s), 6.8—7.55 (10H, m). Found: C, 75.65; H, 5.92; N, 11.82%. Calcd for $C_{15}H_{14}ON_2$: C, 75.60; H, 5.92; N, 11.76%.

*1-Methyl-4-hydroxy-4-phenyl-6-chloro-1,4-dihydroquinazoline (**7**).* To a suspension of **2b** (9.0 g) in H_2O (200 ml) was added a small excess of 5% $NaHCO_3$ solution, and the mixture was stirred overnight. The crystals were collected by filtration to give almost pure **7** (6.0 g, 98%); mp 170—172 °C. Recrystallization from dioxane gave a pure sample as colorless leaflets; mp 176—178 °C (decomp.). IR ν_{max}^{Nujol} cm^{-1}: 1640, 1600, 1570, 1513. NMR (DMSO-d_6) δ: 3.31 (3H, s), 6.6—7.6 (10H, m). Found: C, 65.93; H, 4.88; N, 10.26%. Calcd for $C_{15}H_{13}ON_2Cl$: C, 66.05; H, 4.80; N, 10.27%.

*1-Methyl-4-phenylquinazolinium Bromide (**2c**).* **2c** (2.7 g, 78.0%) was prepared from **6** (4.0 g) and excess 47% HBr (8 ml) in *i*-PrOH. Recrystallization from DMF–AcOEt gave an analytical sample as pale yellow leaflets; mp 243—244 °C (decomp.). IR ν_{max}^{Nujol} cm^{-1}: 1610, 1590, 1520. NMR (DMSO-d_6) δ: 3.81, 4.65 (3H, two singlets), 7.35—8.75 (9H, m), 8.97, 10.27 (1H, two singlets). Found: C, 59.80; H, 4.42; N, 9.07%. Calcd for $C_{15}H_{13}N_2Br$: C, 59.81; H, 4.35; N, 9.30%.

*1-Methyl-4-phenyl-6-chloroquinazolinium Bromide (**2d**).* To a suspension of **7** (5.0 g) in *i*-PrOH (50 ml) was added an excess of 25% HBr/AcOH (*ca.* 30 ml) and the mixture was warmed until it became clear. After cooling, the yellow leaflets which had precipitated were collected by filtration and washed with *i*-PrOH (5.0 g, 81.2%); mp 230—231 °C (decomp.). IR ν_{max}^{Nujol} cm^{-1}: 1596, 1528, 1486. NMR (DMSO-d_6) δ: 3.82, 4.67 (3H, two singlets), 7.0—8.8 (8H, m), 9.06, 10.31, (1H, two singltes). Found: C, 53.45; H, 3.64; N, 8.12%. Calcd for $C_{15}H_{12}N_2BrCl$: C, 53.67; H, 3.60; N, 8.34%.

*Reactions of Quinazolinium Salts (**2a—d**) with CH_2N_2.* *1)*: To a stirred suspension of **2a** (1.05 g) in THF (100 ml) was added dropwise a freshly-prepared ethereal solution of CH_2N_2 (from 4 g of *p*-TsN(NO)CH_3) at 10 °C over a 1-hr period. After standing for 15 min, the mixture was concentrated to dryness and the residual oil was crystallized as a picrate (1.2 g, 69.4%); mp 162—164 °C. Recrystallization from a mixture of DMF and EtOH gave 1-methyl-2-iodomethyl-4-phenyl-1,2-dihydroquinazoline (**8a**) picrate as dark red prisms; mp 163—165 °C. NMR (DMSO-d_6) δ: 3.33 (3H, s), 3.45—3.75 (2H, m), 5.79 (1H, d.d, J=10 Hz, J=6 Hz), 6.8—8.0 (9H, m), 8.62 (2H, s). Found: C, 44.53; H, 3.21; N, 11.82%. Calcd for $C_{22}H_{18}O_7N_5I$: C, 44.68; H, 3.07; N, 11.84%.

2): To a stirred suspension of **2c** (0.9 g) in CH_2Cl_2 (100 ml) was added a freshly-prepared ethereal solution of CH_2N_2 (from 6.0 g of *p*-TsN(NO)CH_3) at 10 °C over a 1-hr period. After standing for 1 hr, the mixture was washed with aqueous 5% $NaHCO_3$ solution, dried (Na_2SO_4) and concentrated to dryness. The residual oil was crystallized as a picrate (0.3 g, 28.3%), mp 130—132 °C (decomp.). A pure sample of 1-methyl-2-bromomethyl-4-phenylquinazoline (**8c**) picrate was obtained as red prisms by recrystallization from EtOH; mp 133—135 °C (decomp.). Found: C, 49.75; H, 3.52; N, 13.48%. Calcd for $C_{22}H_{18}O_6N_5Br$: C, 50.01; H, 3.43; N, 13.25%.

The mother liquor from the crystallization of the picrate was concentrated, and the residue was poured into aqueous 5% LiOH solution. The oil was extracted with benzene, and the benzene layer was dried (K_2CO_3) and concentrated to dryness. Tlc of the residual oil indicated the presence of two major products. This was chromatographed on silica gel (30 g, solvent $CHCl_3$–EtOH, 200 : 1). The first fraction (110 mg, 11.0%) was crystallized from *n*-hexane. Recrystallization from petroleum ether gave 1-methyl-3-bromomethyl-5-phenyl-2,3-dihydro-1*H*-1,4-benzodiazepine (**10c**) as colorless prisms, mp 81—83 °C. IR ν_{max}^{Nujol} cm^{-1}: 1614, 1595, 1580, 1563, 1492. UV λ_{max}^{EtOH} nm ($\varepsilon\times10^{-3}$): 242 (23.0), 346 (2.9). NMR ($CDCl_3$) δ: 2.79 (3H, s), 3.4—3.9 (5H, m), 6.9—7.75 (9H, m). Mass *m/e*: 330, 328 (M^+), 249 (M^+-81, M^+-79). Found: C, 61.85; H, 5.34; N, 8.53%. Calcd for $C_{17}H_{17}N_2Br$: C, 62.01; H, 5.21; N, 8.51%.

The second fraction (110 mg, 13.1%) was crystallized from petroleum ether; subsequent recrystallization from petroleum ether gave 1-methyl-3-ethoxy-5-phenyl-2,3-dihydro-1*H*-1,4-benzodiazepine (**9**) as colorless prisms; mp 90—92 °C. IR ν_{max}^{Nujol} cm^{-1}: 1603, 1595, 1564. UV λ_{max}^{EtOH} nm ($\varepsilon\times10^{-3}$): 242 (22.0), 346 (1.7). NMR ($CDCl_3$) δ: 1.29 (3H, t, J=7 Hz), 2.80 (3H, s), 3.25—4.3 (4H, m), 4.73 (1H, q, J=5 Hz), 6.9—7.8 (1H, m). Mass *m/e*: 280 (M^+). Found: C, 76.89; H, 7.11; N, 9.88%. Calcd for $C_{18}H_{20}ON_2$: C, 77.11; H, 7.19; N, 9.99%.

3): The reaction of **2c** (18 g) with CH_2N_2 in CH_2Cl_2 (200 ml) was carried out at −18—−20 °C to obtain **10c** picrolonate (2.7 g, 74%); mp 128—131 °C (decomp.). The crystals were dissolved in $CHCl_3$ and passed through alumina (50 g). The product was identified as **10c**.

4): 1-Methyl-3-iodomethyl-5-phenyl-7-chloro-2,3-dihydro-1*H*-1,4-benzodiazepine (**10b**, 500 mg) was obtained from **2b** (1.0 g) as colorless prisms (*i*-PrOH); mp 145—147 °C. Yield, 46.6%. IR ν_{max}^{Nujol} cm^{-1}: 1615, 1595, 1555, 1490. UV λ_{max}^{EtOH} nm ($\varepsilon\times10^{-3}$): 233 (26.0), 250 (21.0), 358 (1.2). NMR ($CDCl_3$) δ: 2.77 (3H, s), 3.2—3.9 (5H, m), 6.8—7.8 (8H, m). Mass *m/e*: 410 (M^+), 283 (M^+-127). Found: C, 49.55; H, 3.99; N, 6.72%. Calcd for $C_{17}H_{16}N_2ClI$: C, 49.72; H, 3.93; N, 6.82%.

From the mother liquor, 1-methyl-2-iodomethyl-4-phenyl-7-chloro-1,2-dihydroquinazoline (**8b**) picrate (400 mg) was obtained as dark red prisms (DMF–EtOH); mp

156—158 °C. Yield, 24.5%. NMR (DMSO-d_6) δ: 3.30 (3H, s), 3.45—3.95 (2H, m), 5.65—5.95 (1H, m), 7.0—8.0 (9H, m), 8.60 (2H, s). Found: C, 41.95; H, 2.52; N, 11.30%. Calcd for $C_{22}H_{17}O_7N_5ClI$: C, 42.23; H, 2.74; N, 11.19%.

5): 1-Methyl-3-bromomethyl-5-phenyl-7-chloro-3,4-dihydro-1*H*-1,4-benzodiazepine (**10d**, 600 mg) was obtained from **2d** (1.0 g) as colorless prisms (Et_2O-*n*-hexane); mp 140—142 °C. Yield, 55.3%. IR ν_{max}^{Nujol} cm^{-1}: 1615, 1575, 1555, 1490. UV λ_{max}^{EtOH} nm ($\varepsilon \times 10^{-3}$): 233 (26.0), 250 (24.0), 358 (1.0). NMR ($CDCl_3$) δ: 2.78 (3H, s), 3.35—4.0 (5H, m), 6.8—7.8 (8H, m). Mass *m/e*: 364, 362 (M^+), 283 (M^+-81, M^+-79). Found: C, 55.98; H, 4.49; N, 7.68%. Calcd for $C_{17}H_{16}N_2BrCl$: C, 56.14; H, 4.43; N, 7.70%.

*Reduction of 1-Methyl-2-iodomethyl-4-phenyl-1,2-dihydroquinazoline (**8a**) with Raney Ni.* A mixture of **8a** picrate (0.5 g) and aqueous 5% LiOH solution (10 ml) was extracted with benzene and the extract was dried (K_2CO_3). The solution was hydrogenated with 2 ml of Raney Ni under 2.5 kg/cm² (30 min). The catalyst was removed by filtration and the filtrate was washed with aqueous 5% $NaHCO_3$ solution, dried (Na_2SO_4) and concentrated under reduced pressure. The residue was crystallized from EtOH as a picrate and recrystallization from EtOH gave 1,2-dimethyl-4-phenyl-1,2-dihydroquinazoline (**11**) picrate as red needles (0.2 g, 50%); mp 160—163 °C (decomp.). NMR (DMSO-d_6) δ: 1.46 (3H, d, J=6 Hz), 3.20 (3H, s), 5.61 (1H, q, J=6 Hz), 6.75—8.0 (9H, m), 8.60 (2H, s). Found: C, 56.30; H, 4.20; N, 14.78%. Calcd for $C_{22}H_{19}O_7N_5$: C, 56.77; H, 4.12; N, 15.05%.

*Reduction of 1-Methyl-3-iodomethyl-5-phenyl-7-chloro-2,3-dihydro-1H-1,4-benzodiazepine (**10b**) with Raney Ni.* A mixture of **10b** (1.8 g), KOH (300 mg), and EtOH (50 ml) was hydrogenated with 1.5 ml of Raney Ni under 2.5 kg/cm². The catalyst was removed by filtration, and the filtrate was concentrated to dryness. The residue was dissolved in $CHCl_3$, and the solution was washed with H_2O, dried (K_2CO_3), and concentrated. The residue was crystallized from *n*-hexane, and the crystals were collected by filtration. Recrystallization from ether-*n*-hexane gave pure 1,3-dimethyl-5-phenyl-7-chloro-2,3-dihydro-1*H*-1,4-benzodiazepine (**12**, 0.5 g, 40.5%); mp 101—102 °C. IR ν_{max}^{Nujol} cm^{-1}: 1607, 1570, 1490. UV λ_{max}^{EtOH} nm ($\varepsilon \times 10^{-3}$): 231 (23.9), 250 (20.3), 356 (1.1). NMR ($CDCl_3$) δ: 1.42 (3H, d, J=6 Hz), 2.75 (3H, s), 3.4—4.0 (3H, m), 6.75—7.75 (8H, m). Found: C, 71.97; H, 6.06; N, 9.77%. Calcd for $C_{17}H_{17}N_2Cl$: C, 71.69; H, 6.02; N, 9.84%. The IR spectrum of this compound was identical with that of the authentic sample.[11,12] Treatment of the mother liquor from crystallization of crude **12** with MeOH/HCl gave **12**·HCl (0.5 g, 35.5%); mp 231—232 °C. Found: C, 63.88; H, 5.67; N, 8.47%. Calcd for $C_{17}H_{18}N_2Cl_2$: C, 63.55; H, 5.65; N, 8.72%.

Reduction of 1-Methyl-3-bromomethyl-5-phenyl-7-chloro-2,3-dihydro-1H-1,4-benzodiazepine with Raney Ni. **10d** was hydrogenated in the same way, and the product was identified as **12**.

We are indebted to Dr. R. I. Fryer for kindly providing us with the sample. We wish to express our gratitude to Mr. T. Takayanagi, Senior Managing Director of our Company, Dr. I. Chibata, Director of our Laboratory, Dr. K. Okumura and Dr. M. Miyoshi for their encouragement. Thanks are due to the members of the analytical center for elemental analyses.

The Oxidation of 1,3-Butadienes with Nitric Acid into 2,5-Dihydrofurans

Fumio Toda and Eishiro Todo

Department of Industrial Chemistry, Faculty of Engineering, Ehime University, Matsuyama 790

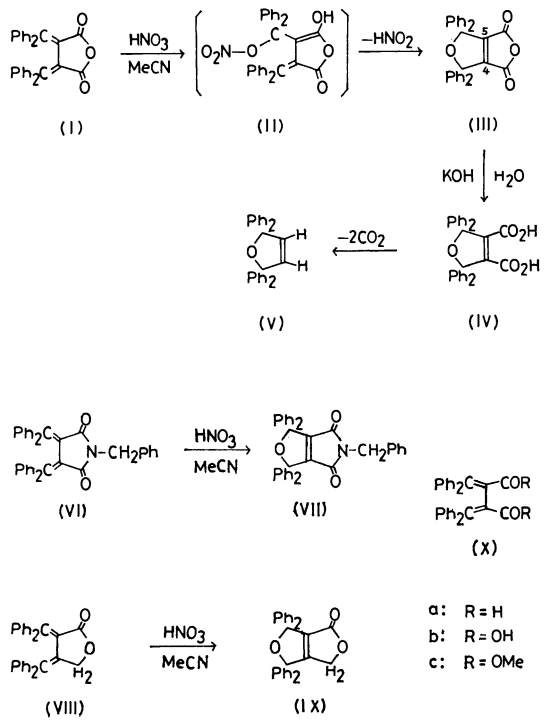
(Received September 17, 1973)

The oxidation of 3,4-bis(diphenylmethylene)-succinic anhydride (I), -1-benzylsuccinimide (VI), and -γ-butyrolactone (VIII) with nitric acid afforded the corresponding 2,5-dihydrofuran derivatives, III, VII, and IX respectively. The same oxidation of 3,4-bis(diphenylmethylene)cyclobutane-1,2-dione (XI) afforded 3,4-bis(diphenylhydroxymethyl)cyclobut-3-ene-1,2-dione (XIII), probably *via* the bicyclic cyclobutenedione intermediate (XII).

No one-step oxidation of buta-1,3-diene into dihydrofuran has yet been reported. We have now performed the oxidation of the buta-1,3-diene group of I, VI, VIII, and XI with HNO_3 into dihydrofuran.

When a solution of 3,4-bis(diphenylmethylene)succinic anhydride (I)[1] and concd HNO_3 in MeCN was heated under reflux for 10 min, 6,6,8,8-tetraphenyl-2,7-dioxabicyclo[3.3.0]oct-4-ene-1,3-dione (III) was obtained in an 89% yield. The structure of III was identified by the decarboxylation of the 2,2,5,5-tetraphenyl-3,4-dicarboxy-2,5-dihydrofuran (IV) initially produced by the hydrolysis of III; this afforded 2,2,5,5-tetraphenyl-2,5-dihydrofuran (V).[2] The same treatment of 3,4-bis(diphenylmethylene)-1-benzylsuccinimide (VI)[3] and -γ-lactone (VIII)[4] afforded 6,6,8,8-tetraphenyl-2-benzyl-2-aza-7-oxabicyclo[3.3.0]oct-4-ene-1,3-dione (VII) (85%) and 6,6,8,8-tetraphenyl-2,7-dioxabicyclo[3.3.0]oct-4-en-1-one (IX) (51%) respectively.

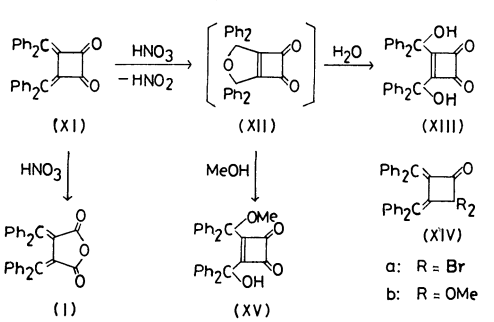
However, 2,3-bis(diphenylmethylene)-butane-1,4-dial (Xa), -succinic acid (Xb), and its dimethyl ester (Xc) were not oxidized with concd HNO_3. This shows that a fixed s-*cis* configuration of the buta-1,3-diene moiety is essential for the oxidation. Since I was not oxidized with concd $HClO_4$, HBF_4, and H_2SO_4, concd HNO_3 may be a characteristic reagent for the oxidation reaction. A possible pathway of the oxidation of I is illustrated in Scheme 1, *i. e.*, the elimination of HNO_2 from the II initially formed by the 1,4-addition of HNO_3 to the enone group of I.



Scheme 1.

The same treatment of 3,4-bis(diphenylmethylene)-cyclobutane-1,2-dione (XI) with concd HNO_3 in MeCN afforded I and 3,4-bis(diphenylhydroxymethyl)cyclobut-3-ene-1,2-dione (XIII)[5] in 37 and 17% yields respectively. Since the oxidation of XI with 30% H_2O_2 or with concd $HClO_4$ to afford I has been reported,[1] I may be produced by a similar Baeyer-Villiger-type oxidation of XI. When the reaction of XI with concd HNO_3 was carried out in a non-poalr solvent such as CCl_4, this Baeyer-Villiger oxidation was inhibited, and XIII was obtained in a 64% yield as the sole isolable product. A possible precursor of XIII is the bicyclic cyclobutenedione (XII), which can be produced by the oxidation of XI *via* a pathway similar to that described for the formation of III.

In order to prove the intermediacy of XII, XI was allowed to react with concd HNO_3 in MeOH, in the expectation of isolating 3-diphenylhydroxymethyl-4-diphenylmethoxymethylcyclobut-3-ene-1,2-dione (XV). The reaction, however, afforded only 2,2-dimethoxy-3,4-bis(diphenylmethylene)cyclobutan-1-one (XIVb),[1] no XV. Nevertheless, when MeOH was added to a reaction mixture of XI, concd HNO_3, and CCl_4, soon the green color of XI disappeared and XV was isolated in a 54% yield. Since XIII did not react with MeOH in the presence of concd HNO_3 at an elevated temperature, the possibility that XIII is a precursor of XV can be ruled out. A plausible pathway of the formation of XV is an acid-catalyzed methanolysis of XII (Scheme 2). Unfortunately, however, all attempts to isolate XII failed.



Scheme 2.

The reaction of 2,2-dibromo-3,4-bis(diphenylmethylene)cyclobutan-1-one (XIVa) with concd HNO_3 in MeCN for 2 min afforded I in a 52% yield. The same treatment of XIVb as for XIVa for 2 min afforded XI in a 45% yield.

Experimental

All the melting points were uncorrected. The IR, UV, and NMR spectra were measured in Nujol mull, $CHCl_3$, and $CDCl_3$ respectively, unless otherwise noted. The mass spectra were measured with an ionization energy of 75 eV.

Oxidation of I. A solution of I (1.2 g) and concd HNO_3 (0.8 ml) in MeCN (100 ml) was heated under reflux for 10 min. Crude crystals left by the evaporation of the solvent were recrystallized from MeCN to afford III as colorless needles; 1.0 g (89%); mp 196—197 °C. IR: 1850 and 1780 (C=O), 1670 (C=C), and 1020 cm^{-1} (C–O–C); λ_{max}: 264 (ε, 4700) and 280 nm (4700); NMR: 2.78 τ (s, Ph); MS: *m/e* (rel intensity) 444 (M^+, 30), 323 (100), 289 (80), and 218 (55).

Found: C, 79.81; H, 4.68%. Calcd for $C_{30}H_{20}O_4$: C, 81.06; H, 4.54%.

Hydrolysis of III. A solution of III (0.19 g) and KOH (0.2 g) in MeOH (30 ml) was heated under reflux for 2 hr. The crude crystals which had been separated out by the addition of dil HCl to the reaction mixture were recrystallized from MeCN to afford IV as colorless needles; 0.16 g (74%); mp 204—205 °C. IR: 1740 and 1720 (unsplit doublet, C=O), 1650 (C=C), and 1030 cm^{-1} (C–O–C); λ_{max}^{EtOH}: 240 sh (ε, 10500), 258 sh (5100), and 216 sh nm (3700). MS: *m/e* (rel intensity) 323 (100) and 218 (40).

Found: C, 77.69; H, 4.78%. Calcd for $C_{30}H_{22}O_5$: C, 77.91; H, 4.80%.

Decarboxylation of IV. A mixture of IV (0.104 g), Cu-powder (0.05 g) and quinoline (3 ml) was heated under reflux for 4 hr. The cooled reaction mixture was then diluted with ether (100 ml). The ethereal solution was washed successively with dil HCl and water, and then dried over anhydrous Na_2SO_4. The crude crystals left after the evaporation of the solvent were recrystallized from MeCN to afford V as colorless needles; 0.012 g (14%); mp 179—181 °C (lit,[2] mp 180—183 °C). IR: 1010 cm^{-1} (C–O–C); λ_{max}: 250 sh (ε, 900), 253 (1100), 260 (1200), and 266 nm (1000); NMR: 2.82 (s, Ph, 20H) and 3.52 τ (s, =CH, 2H).

Oxidation of VI. VI (0.1 g) was treated with concd HNO_3 (0.08 ml) in MeCN (10 ml) under the same conditions as were used for I. The crude crystals left by the evaporation of the solvent were recrystallized from MeCN to afford VII as colorless needles; 0.087 g (85%); mp 178—179 °C. IR: 1775 and 1715 (C=O), 1435 (CH_2), and 1010 cm^{-1} (C–O–C); λ_{max}: 252 (ε, 14200) and 295 sh nm (5100); NMR: 2.4—3.2 (m, Ph, 25H) and 5.29 τ (s, CH_2, 2H).

Found: C, 83.15; H, 4.83%. Calcd for $C_{37}H_{27}O_3N$: C, 83.28; H, 5.10%.

Oxidation of VIII. VIII (0.1 g) was treated with concd HNO_3 (0.08 ml) in MeCN (10 ml) under the same conditions as were used for I. The crude crystals left after the evaporation of the solvent were recrystallized from MeCN to afford IX as colorless needles; 0.053 g (51%); mp 227—228 °C. IR: 1770 (C=O), 1675 (C=C), and 1010 cm^{-1} (C–O–C); λ_{max}: 260 sh (ε, 4100), 263 sh (3100), and 270 sh nm (1800); NMR: 2.3—3.2 (m, Ph, 20H) and 4.95 τ (s, CH_2, 2H).

Found: C, 83.55; H, 4.95%. Calcd for $C_{30}H_{22}O_3$: C, 83.70; H, 5.15%.

Oxidation of XI in MeCN. XI (0.1 g) was allowed to react with concd HNO_3 (0.05 ml) in MeCN (20 ml) under the same conditions as were used for I. The evaporation of the solvent gave a mixture of red and colorless crystals. The subsequent recrystallization of this mixture from AcOEt afforded I as red rhombs; 0.038 g (37%); mp 230 °C (lit,[1] mp 230 °C). The AcOEt solution left after the separation of I was evaporated to dryness, and the residue was recrystallized from MeOH to afford XIII as colorless prisms; 0.018 g (17%); mp 205—206 °C (lit,[5] mp 205—206 °C). The IR spectra of I and XIII were identical with those of the authentic samples.

Oxidation of XI in CCl_4. XI (0.1 g) was oxidized with concd HNO_3 (0.05 ml) in CCl_4 (20 ml) by the procedure used for MeCN. The crude crystals left by the evaporation of the solvent were recrystallized from MeOH to afford XIII; 0.069 g (64%).

Oxidation of XI in CCl_4. XI (0.1 g) was oxidized with concd HNO_3 (0.05 ml) in CCl_4 (20 ml) by the procedure used for MeCN. The crude crystals left by the evaporation of the solvent were recrystallized from MeOH to afford XIII; 0.069 g (64%).

Isolation of XV. A solution of XI (0.1 g) and concd HNO_3 (0.07 ml) in CCl_4 (20 ml) was heated under reflux until the green color of XI almost disappeared (*ca.* 7 min). MeOH (10 ml) was then immediately added to the reaction mixture, and it was heated under reflux for 5 min. The crude crystals left by the evaporation of the solvent were recrystallized from MeOH to afford XV as colorless needles; 0.06 g (54%); mp 138—140 °C. IR: 3580 and 3300 (OH), 1790 sh and 1780 (C=O), 1560 (C=C), and 1070 cm^{-1} (C–O–C); λ_{max}^{EtOH}: 241 sh (ε, 13500) and 274 sh nm (6500); NMR: 2.70 (s, Ph, 20H), 3.22 (s, OH, 1H), and 7.04 τ (s, OCH_3, 3H).

Reaction of XI with Concd HNO_3 in MeOH, A solution of XI (0.1 g) and concd HNO_3 (0.07 ml) in MeOH (20 ml) heated under reflux for 2 hr. The crude crystals left by the evaporation of the solvent were recrystallized from AcOEt to afford XIVb as orange red needles; 0.074 g (67%); mp 191—192 °C (lit,[1] mp 191—192 °C). The IR spectrum was identical with that previously-recorded for XIVb.[1]

Reaction of XIVa with Concd HNO_3. A solution of XIVa (0.1 g) and concd HNO_3 (0.04 ml) in MeCN (15 ml) was heated under reflux for 2 min. The crude crystals left by the evaporation of the solvent were recrystallized from AcOEt to afford I as red rhombs; 0.04 g (52%).

Reaction of XIVb with Concd HNO_3. When XIVb (0.1 g) was treated with concd HNO_3 (0.04 ml) in MeCN (15 ml) for 2 min by the procedure used for XIVa, XI was obtained as green prisms; 0.04 g (45%); mp 206—207 °C (lit,[1] mp 206—207 °C). The IR spectrum was identical with that previously-recorded for XI.[1]

Total Synthesis of Natural Acetylenic Analogues of Isorenieratene and Renieratene[1]

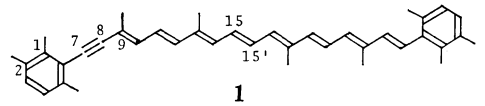
Tetsuji IKE,[2] Junji INANAGA, Akio NAKANO, Nobuhisa OKUKADO, and Masaru YAMAGUCHI

Department of Chemistry, Faculty of Science, Kyushu University, Higashi-ku, Fukuoka 812

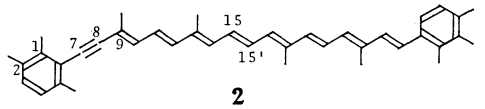
(Received September 19, 1973)

The total synthesis of two natural acetylenic aromatic carotenoids, 7,8-didehydroisorenieratene (**1**) and 7,8-didehydrorenieratene (**2**), was carried out. Although the condensations involving C_{15}-acetylenic ylids (derived from the phosphonium salts **7**, and **8**) as the intermediates gave only 9-*cis* isomers of **1** and **2**, low-temperature condensations of C_{25}-hexaene yield (derived from **19** and **28**) with C_{15}-acetylenic aldehyde (**12a**) led to all-*trans* **1** and **2**, which were identical with natural specimens.

It has recently been shown that two minor carotenoid constituents, mp 194—194.5 °C and mp 204—205 °C, isolated from a sea sponge "*Reniera japonica*" ("*Halichondria japonica*") have the acetylenic aromatic structures of **1** and **2**,[3] which correspond to those of the 7,8-didehydro derivatives of isorenieratene[4] and renieratene[5] respectively. The present work has been



1



2

undertaken to verify these structures by synthesis. Analogous syntheses have already been done on several alicyclic acetylenic carotenoids by Weedon.[6] In the present work, a similar construction principle, $C_{15}+C_{10}\rightarrow C_{25}$, $C_{25}+C_{15}\rightarrow C_{40}$, has been used.

Results and Discussion

Synthesis of 7,8-Didehydroisorenieratene (1). The first synthesis, which led to the 9-*cis* isomer (**22**) of **1**, was started with 2,3,6-trimethylbenzoic acid,[7] which was converted into the acetylenic alcohol (**5**) through **3** and **4**. The treatment of **5** with triphenylphosphonium bromide gave a sole product, which was later proved to be the *cis* salt (**7**) by comparing its NMR spectrum with that of **8** to be described below. The condensation of the ylid from **7** with the C_{10}-dialdehyde

(**17**)[8] afforded the acetylenic aldehyde (**20**) as the major product (25% yield), besides 9,9′-di-*cis*-7,7′,8,8′-tetradehydroisorenieratene (**21**). The condensation of 2,3,6-trimethylbenzalacetone with ethoxycarbonylmethylenetriphenylphosphorane gave, after saponification, a mixture of the *trans* (**14a**) and the *cis* acid[9] (**14b**) (3 : 1), which were then separated by fractional crystallization. The *trans* acid (**14a**) was converted into the phosphonium bromide (**16**) *via* the corresponding alcohol (**15**). The Wittig reaction of the ylid of **16** with the C_{25}-acetylenic aldehyde (**20**) gave the 9-*cis*-didehydroisorenieratene (**22**) as reddish-orange needles in a 51% yield.

The pigment (**22**) thus obtained exhibited λ_{max} at wavelength locations about 8 nm shorter than those of **1**, and showed a distinct *cis*-peak at 356 nm (Fig. 1).

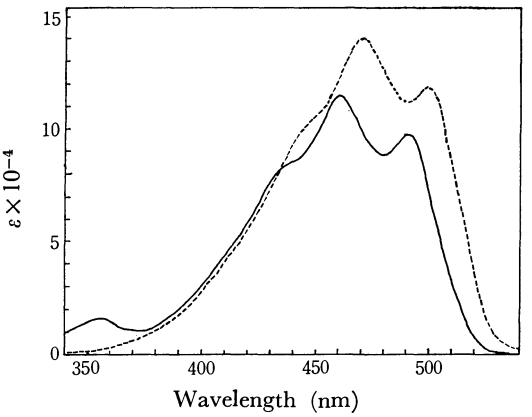

Fig. 1. Absorption spectra of **1** (natural, mp 194—194.5 °C, ——) and its 9-*cis* isomer (**22**, ——) in benzene.

On isomerization (iodine and light[10]), however, both the pigments gave the same absorption curve, which was essentially identical with that of **22**. This means that the 9-*cis* isomer (**22**) is the most stable one among the stereoisomers, including all-*trans* **1**, and that **22** is the major constituent of the equilibrium mixture, which is to be expected in view of the small steric

requirement of the triple bond.

B. C. L. Weedon reported that *trans*-[5-(4-hydroxy-2,2,6-trimethyl-6-cyclohexen-1-yl)-3-methyl-2-penten-4-ynyl]-triphenylphosphonium salt gave an all-*trans* Wittig condensation product when the reaction was conducted in the dark.[6b] In our second synthesis, therefore, *trans*-C_{15}-phosphonium salt (**8**) was prepared in the hope that its configuration would be retained during the condensation, thus leading to the predominant formation of **1**.

A mixture of the *trans* and the *cis* ester (1 : 3), prepared from **4** through **6**, was saponified and separated by fractional crystallization into the corresponding acids (**9a** and **9b**). In contrast to the fact that the base treatment of the ester mixture did not change the isomeric ratio, the *cis* acid seemed to be less stable than the *trans* isomer in an alkaline medium, and the former was converted into the latter by heating with an aqueous-methanolic potassium hydroxide solution. The *trans* acid (**9a**) was converted into the *trans* phosphonium salt (**8**) by the usual procedures. The condensation of the ylid from **8** with the all-*trans* C_{25}-aldehyde (**18**), prepared by the condensation of **16** with C_{10}-dialdehyde (**17**), proceeded smoothly under various reaction conditions, but the product was always predominantly the 9-*cis* isomer (**22**), even when the reaction was run in the dark. The isolation of the *trans* pigment (**1**) was practically impossible, though a very faint zone corresponding to **1** was observed on the chromatographic column.

In order to circumvent the lability of the 2-double bond in the ylid, a reversed combination of ylid and aldehyde was then undertaken. The *trans* C_{15}-aldehyde (**12a**), obtained by the manganese dioxide oxidation of **10a**, seemed to be stable, at least at room temperature, for several days. When **12a** was condensed with C_{25}-ylid (prepared from **19**) at room temperature, however, the predominant product was again **22**. When the reaction was run at a low temperature, on the other hand, the yield of the condensation product was very low, though the product contained a substantial amount of **1**, which could be purified and which was proved to be identical with a natural specimen in every respect.

*Synthesis of 7,8-Didehydrorenieratene (**2**).* 9-*cis*-7,8-Didehydrorenieratene (**23**) was synthesized by a route analogous to that of the first synthesis of **1**. The absorption maxima of the isomer were about 8 nm shorter than those of natural **2**, but both the pigments gave the same absorption curve after isomerization. The all-*trans* **2** was also synthesized in a way corresponding to that used for all-*trans* **1**; it was identical with the natural specimen in every detail examined.

Experimental

All the Wittig condensations were carried out under an atmosphere of nitrogen. The phosphonium salts were dried under a vacuum for several hours just before use. Anhydrous sodium sulfate was used for drying the solutions. The melting or boiling points were uncorrected. Unless otherwise mentioned, the IR spectra were taken in potassium bromide pellets. The NMR spectra were taken in a deuterochloroform solution. Benzene solutions were used for the UV determination.

*2,3,6-Trimethylacetophenone (**3**).* It was prepared from 2,3,6-trimethylbenzoyl chloride (prepared from 2,3,6-trimethylbenzoic acid and thionyl chloride by heating at 60 °C for 12 hr; bp 80—81 °C/6 mmHg) and methyl magnesium iodide in a way similar to that reported for 2,4,6-trimethylacetophenone.[11] A colorless oil;[12] bp 99—101 °C/6 mmHg, IR (liquid film) 1690 cm^{-1}.

2,3,6-Trimethyl-α-chlorostyrene. The method for the synthesis of 2,4,6-trimethyl-α-chlorostyrene[13] was modified because of the very low yield of the product (less than 10%). To a mixture of **3** (30 g) and phosphorus pentachloride (50 g) in benzene (50 ml), we added a portion (10 ml) of a solution of collidine (25 g) in dry benzene (50 ml). After the mixture had been heated at 80 °C for 24 hr with occasional additions of the remainder of the collidine solution, it was cooled and poured into ice water. The organic layer was worked up in a usual way. A colorless liquid (21 g); bp 68—70 °C/5 mmHg; IR (liquid film) 1630, 888 cm^{-1}.

*2,3,6-Trimethylphenylacetylene (**4**).* 2,3,6-Trimethyl-α-chlorostyrene (18 g) was heated (160—180 °C) with sodium amide (12 g) in mineral oil (30 ml) for 3 hr, after which the crude product was fractionally distilled. A fragrant mobile liquid[12] (9.4 g); bp 54—55 °C/5 mmHg. IR (liquid film) 3295, 2090 cm^{-1}.

*3-Methyl-1-(2,3,6-trimethylphenyl)-4-penten-1-yn-3-ol (**5**).* The magnesium derivative was prepared from **4** (5.7 g), isopropyl magnesium bromide (0.04 mol), and a catalytic amount of cuprous chloride in ether (50 ml) in the usual way. A solution of methyl vinyl ketone (2.8 g) in dry ether (20 ml) was stirred into this over a period of 1 hr at room temperature. After refluxing for 3 hr, the reaction mixture was poured into cold water and treated with saturated aqueous ammonium chloride. The organic layer was then washed, dried, and distilled. A viscous oil[12] (3 g); bp 86—87 °C/0.024 mmHg; IR(liquid film) 3370, 2220, 925 cm^{-1}.

*[3-Methyl-5-(2,3,6-trimethylphenyl)-*cis*-2-penten-4-yn-1-yl]triphenylphosphonium Bromide (**7**).* A solution of **5** (1.09 g) and triphenylphosphonium bromide (1.71 g) in dichloromethane (25 ml) was stirred for 20 hr at room temperature. The subsequent evaporation of the solvent gave a solid, which was recrystallized from dichloromethane-ethyl acetate. Colorless needles[12] (2.4 g); mp 211—212 °C; NMR δ 1.97 (3H, d, J=6.0 Hz; 3-methyl).

*2,7,11-Trimethyl-13-(2,3,6-trimethylphenyl)-2,4,6,8,*cis*-10-tridecapentaen-12-yn-1-al (**20**) and 9,9'-Di-*cis*-7,7',8,8'-tetradehydroisorenieratene (**21**).* To a stirred suspension of **7** (0.432 g) in dry ether, we added an ethereal phenyl lithium solution (0.2 mol, 4 ml); the mixture was stirred for 1 hr at room temperature, and then a dichloromethane-ether mixture (2 : 1, 3 ml) was added. The resulting deep red solution of the ylid was added, drop by drop, to a solution of the C_{10}-dial[8] (**17**, 0.256 g) in dichloromethane (20 ml). The mixture was refluxed with stirring for 3 hr, poured into water, and extracted with ether. The extract was dried and evaporated. The reddish-brown residue was chromatographed on neutral alumina [Merck, deactivated by the addition of water (5%)] with a benzene-petroleum benzine mixture (1 : 19) as a developer; this gave two main zones; i) a reddish-orange zone (upper) and ii) a yellow zone (lower). The elute (benzene-methanol, 9 : 1) of i) gave a crude product (63 mg) on evaporation; this product was recrystallized from dichloromethane-methanol. Orange needles[12] (**20**); mp 129—130 °C; λ_{max} 421 nm ($\varepsilon=5.96\times10^4$); IR 1660, 1605 cm^{-1}; NMR δ 9.69 (1H, s; 1-proton).

The elute of ii) gave crude **21** (14 mg), which, on recrystal-

lization, gave red thick plates;[12] mp 174—175 °C; λ_{max} 462 nm ($\varepsilon=10.1\times10^4$); IR 2920, 1455, 1435, 1365, 970, 960, 800 cm^{-1}; NMR δ 1.96 (6H, s), 2.09 (6H, s), 2.25 (6H, s), 2.44 (12H, s), 5.9—6.9 (14H, m).

Ethyl 3-Methyl-5-(2,3,6-trimethylphenyl)-trans-*2*, trans-*4-pentadienoate (**13a**) and Its 2*-cis *Isomer (**13b**).* A mixture of 4-(2,3,6-trimethylphenyl)-3-buten-2-one[14] (3.3 g, bp 127—132 °C/6 mmHg) and ethoxycarbonylmethylenetriphenylphosphorane (7.0 g) was heated at 150 °C for 4 hr with stirring. After cooling, the mixture was extracted with petroleum ether. The extract was then distilled to give a mixture of *trans* and *cis* esters (**13a** : **13b**=3 : 1, NMR) as a colorless oil (3.4 g); bp 156—160 °C/1 mmHg.

3-Methyl-5-(2,3,6-trimethylphenyl)-trans-*2*, trans-*4-pentadienoic Acid (**14a**) and Its 2*-cis *Isomer (**14b**).* A mixture of the above esters (6.7 g) and a 40% aqueous potassium hydroxide solution (10 ml) was stirred at 110 °C for 4 hr, washed with ether, acidified, and extracted with ether. The extract was then dried and evaporated to give a white crystalline solid (5.7 g, *trans* : *cis*=3 : 1), which was separated by fractional crystallization from ethyl acetate. The *trans* acid[12] (**14a**): mp 170—172 °C[9]; IR 2940, 1670, 1600 cm^{-1}; NMR δ 5.85 (1H, s; 2-proton), 6.26 and 7.07 (2H, ABq, J=16.3 Hz; 4,5-protons).

Methyl ester (diazomethane), mp 42 °C.

The *cis* acid[12] (**14b**): mp 173—174 °C,[9] colorless needles; NMR δ 5.76 (1H, broad s; 2-proton), 7.01 and 7.76 (2H, ABq, J=16.7 Hz; 4,5-protons).

*3-Methyl-5-(2,3,6-trimethylphenyl)-2,4-pentadien-1-ol (**15**).* To a cold (0 °C) suspension of lithium aluminium hydride (93.7 mg) in dry ether (15 ml), we added a solution of the methyl ester of **14a** (547 mg) in ether (5 ml) over a 15-min period, after which the mixture was stirred for 20 min at room temperature. After working-up in the usual way, the product was distilled to give an oil (**15**, 387 mg); bp 140—145 °C/0.9 mmHg; NMR δ 4.32(2H, d, J=6.9 Hz; 1,1-protons). This oil was employed for the next step without further purification.

*[3-Methyl-5-(2,3,6-trimethylphenyl)-2,4-pentadien-1-yl]triphenylphosphonium Bromide (**16**).* A mixture of **15** (232 mg), triphenylphosphonium bromide (377 mg), and dichloromethane (3 ml) was stirred at room temperature for 48 hr. The solvent was then removed, and the residue was washed with dry ether. A glass-like white solid (540 mg); NMR δ 4.83 (2H, dd, J=8.0, J=14.2 Hz; 1,1-protons).

*9-cis-7,8-Didehydroisorenieratene (**22**).* To a solution of the ylid of **16** (65 mg), prepared in a way similar to that described in **20**, we added a solution of **20** (10.4 mg) in dry dichloromethane (7 ml). After refluxing for 4 hr, the reaction mixture was treated in the usual way and the product was chromatographed on alumina (containing 5% water) from a benzene-petroleum benzine (1 : 9) solution. The residue (8 mg, 51%) of the elute of the main orange zone gave, on recrystallization from dichloromethane-methanol, reddish-orange needles[12] (**22**); mp 173 °C; λ_{max} 491.5, 462 ($\varepsilon=11.6\times10^4$), (435), 356 nm; IR 3040, 2920, 1590, 1560, 1460, 1440, 1380, 1368, 1035, 1000, 965, 960, 810, 795 cm^{-1}; NMR δ 1.96 (6H, s), 2.08 (6H, s), 2.28 (12H, s), 2.48 (6H, s), 6.1—7.2 (16H, m).

Both **22** and the natural pigment (mp 194—194.5 °C) were isomerized with iodine under diffused daylight in benzene for 1 hr.[10] They gave the same UV curves, with maxima at 490.5, 462, (435), and 357 nm.

4-(2,3,6-Trimethylphenyl)-3-butyn-2-ol. Acetaldehyde (3.0 g) was treated at 0 °C with a solution of the Grignard reagent prepared from **4** (4.0 g, 28 mmol), isopropyl magnesium bromide (30 mmol), and a catalytic amount of cuprous chloride in ether (40 ml). After working-up in the usual manner, the distillation of the product gave colorless crystals[12] (3.3 g); bp 125 °C/1 mmHg, mp 42—44 °C.

*4-(2,3,6-Trimethylphenyl)-3-butyn-2-one (**6**).* A mixture of the above acetylenic alcohol (13 g) and active manganese dioxide[15] (50 g) in dry dichloromethane (100 ml) was stirred overnight at room temperature, after which the reaction mixture was filtered through celite. The evaporation residue (12.5 g) of the filtrate was purified by sublimation; mp 39—40 °C.[12]

3-Methyl-5-(2,3,6-trimethylphenyl)-trans-*2-penten-4-ynoic Acid (**9a**) and Its 2*-cis *Isomer (**9b**).* The condensation reaction and the separation of isomeric acid after hydrolysis were carried out in a manner similar to those used for **13a**, **13b**, **14a**, and **14b**. The ratio of the *trans* and *cis* esters in the mixture was 1 : 3 (NMR). The *trans* acid[12] (**9a**): mp 158—159 °C, colorless prisms; IR 2190, 1680, 1600 cm^{-1}; NMR δ 6.18(1H, q, J=1.6 Hz; 2-proton). Methyl ester (diazomethane); mp 45—46 °C.

The *cis* acid[12] (**9b**): mp 163.5—165.5 °C, white needles; NMR δ 6.03 (1H, q, J=1.5 Hz; 2-proton). Methyl ester (diazomethane); mp 67—68 °C.

*Isomerization of **9b**.* A mixture of the *cis* acid (**9b**, 400 mg), potassium hydroxide (5 g), methanol (2.5 ml), and water (2.5 ml) was stirred at 80 °C for 2 days. After the methanol had been removed, the reddish-brown solution was washed with ether and then acidified with aqueous hydrochloric acid to give a solid (200 mg), which was proved to be the *trans* acid (**9a**) from its NMR spectrum. No *cis* acid was recovered.

3-Methyl-5-(2,3,6-trimethylphenyl)-trans-*2-penten-4-yn-1-ol (**10a**) and Its 2*-cis *Isomer (**10b**).* To a cold (0 °C) suspension of aluminium hydride, prepared from lithium aluminium hydride (11.4 mg) and aluminium chloride (13.3 mg) in dry ether (5 ml), we added a solution of the methyl ester of **9a** (48.4 mg) in ether (5 ml); the mixture was then stirred for 1 hr at room temperature. The reaction mixture was then worked-up in the usual way. A colorless oil (**10a**, 33.3 mg); IR (liquid film) 3350, 2190, 1625 cm^{-1}; NMR δ 6.08 (1H, qt, J=1.7 Hz, J=6.8 Hz; 2-proton). This oil was used for the next step without purification, since the distillation of the alcohol caused a partial isomerization to the *cis* isomer.

The *cis* alcohol (**10b**) was also obtained from the corresponding *cis* ester as a solid[12]: mp 73—75 °C; NMR δ 5.90(1H, qt, J=1.2 Hz, J=6.8 Hz; 2-proton).

3-Methyl-5-(2,3,6-trimethylphenyl)-trans-*2-penten-4-yn-1-yl Bromide (**11a**) and Its 2*-cis *Isomer (**11b**).* To a solution of **10a** (33.3 mg) in ether (6 ml) containing a catalytic amount of pyridine, we added phosphorus tribromide (25 mg), after which the mixture was stirred for 1 hr at room temperature. The reaction mixture was washed with a 5% aqueous sodium hydroxide solution and water, dried, and evaporated to give a viscous oil (32.3 mg); IR (liquid film) 2190, 1450, 1195, 800 cm^{-1}; NMR δ 6.66 (1H, qt, J=1.4 Hz, J=8.6 Hz; 2-proton). It was used for the next step without purification, since distillation caused partial isomerization.

The *cis* bromide (**11b**) was also obtained from **10b** as a viscous oil;[12] bp 80 °C (bath)/5—6 mmHg; NMR δ 5.97 (1H, qt, J=2.0 Hz, J=8.0 Hz).

[3-Methyl-5-(2,3,6-trimethylphenyl)-trans-*2-penten-4-yn-1-yl]triphenylphosphonium Bromide (**8**).* To a solution of **11a** (22.4 mg) in ether (2 ml), we added triphenylphosphine (21.3 mg), after which the mixture was stirred for 14 hr at room temperature. The precipitate was recrystallized from dichloromethane-carbon tetrachloride to give the *trans* salt

(**8**, 25.1 mg); mp 196—199 °C (decomp.); NMR δ 1.65 (3H, d, J=4.4 Hz; 3-methyl).

*2,7,11-Trimethyl-13-(2,3,6-trimethylphenyl)trideca-2,4,6,8,10,12-hexaen-1-al (**18**).* The operations were similar to those described in **20**. The condensation of **16** (540 mg) with the C_{10}-dial (**17**, 450 mg) gave all-*trans* C_{25}-aldehyde (**18**, 8 mg) as reddish-orange needles;[12] mp 126 °C; λ_{max} 426 nm (ε=6.90×10^4); IR 2920, 1655, 1610, 1595, 1550, 1355, 1210, 1185, 970, 960, 810 cm^{-1}; NMR δ 9.52(1H, s; 1-proton).

A mixture of **13a** and **13b** (1.082 g) gave a mixture of *cis* and *trans* **18** (197 mg) in a similar way. This was isomerized by iodine and light in benzene for 3 hr and purified by alumina chromatography and recrystallization to give a further amount of *trans* **18** (134 mg).

*Wittig Reaction of **18** with the Ylid from **8**.* 1) The condensation was carried out in a way similar to that used for the synthesis of **22**. Starting with **8** (58 mg), the main product (6.2 mg) was obtained as reddish-orange needles; it was completely identical with **22**. The elute of the faint orange zone, which moved just above the main orange zone of **22**, gave λ_{max} 500, 470, and 442 nm, values which were very similar to those of **1**,[3] but the amount was too small to be worked out further.

The following three experiments also gave the *cis* pigment (**22**) almost exclusively:

2) Base, sodium methylsulfinylmethide: solvent, benzene–DMSO(1 : 11): 1 hr at room temperature and 2 hr at 35—45 °C.

3) Base, sodium methoxide: solvent, methanol–pyridine (5 : 2): 1 hr at room temperature and 2 hr at 35—45 °C.

4) Base, sodium methoxide: solvent, methanol: 20 hr at room temperature in the dark.[6b]

2,7,11-Trimethyl-13-(2,3,6-trimethylphenyl)-2,4,6,8,10,12-tridecahexaen-1-ol. To a cold (0 °C) suspension of aluminium hydride prepared from lithium aluminium hydride (38 mg) and aluminium chloride (42 mg) in dry ether (30 ml), we added a solution of **18** (116 mg) in dry benzene (10 ml), and the subsequent mixture was stirred for 30 min. The mixture was then treated in the usual way to give a canary yellow solid (114 mg); mp 106—107 °C; λ_{max} 404, 387, 366 nm; IR 3400, 1080, 970 cm^{-1}; NMR δ 4.09 (2H, s; 1,1-protons).

*[2,7,11-Trimethyl-13-(2,3,6-trimethylphenyl)-2,4,6,8,10,12-tridecahexaen-1-yl]triphenylphosphonium Bromide (**19**).* A mixture of the above C_{25}-alcohol (14 mg), triphenylphosphonium bromide (14 mg), and dry dichloromethane (10 ml) was stirred at room temperature for 72 hr under nitrogen in the dark. After the removal of the solvent, the resulting solid (**19**) was dried under a vacuum.

*3-Methyl-5-(2,3,6-trimethylphenyl)-*trans*-2-penten-4-yn-1-al (**12a**) and Its 2-*cis* Isomer (**12b**).* A mixture of **10a** (214 mg), active manganese dioxide[15] (2 g), and dry dichloromethane (10 ml) was stirred at 0 °C for 1 hr, after which the reaction mixture was filtered quickly. The filtrate was then evaporated to dryness at 0 °C to give a solid (214 mg); mp 67 (sinter)—77 °C; λ_{max} 337, 327 nm; IR 2180, 1660, 1595, 853 cm^{-1}; NMR δ 6.32 (1H, qd, J=1.2 Hz, J=8.0 Hz; 2-proton), 10.8 (1H, d, J=8.0 Hz; 1-proton). This was stored in a refrigerator under nitrogen and used without further purification. On sublimation at 60 °C, most of the aldehyde changed into its *cis* isomer (**12b**). In solution in deuterochloroform for NMR measurement, it also changed completely into the *cis* isomer within 12 hr. In the crystalline state, however, it seemed to be stable for more than a week at room temperature.

The *cis* aldehyde (**12b**) was obtained from **10b** and purified by sublimation: mp 89—91 °C;[12] λ_{max} 323 nm; NMR δ 6.19(1H, qd, J=1.6 Hz, J=8.1 Hz; 2-proton), 10.20 (1H, d, J=8.1 Hz; 1-proton).

*7,8-Didehydroisorenieratene (**1**).* A solution of the ylid was prepared from **19** (60 mg) in a way similar to that described in **20**. A solution of **12a** (30 mg) in dichloromethane (2 ml) was added to this on cooling at −78 °C. The mixture was stirred at −78 °C for 3 hr, then at −20 °C for 20 hr, at 0 °C for 4 hr, and at room temperature for 1 hr. Cold water was added to the deep red mixture. The product was extracted with ether, washed with water, dried, and evaporated below 40 °C. The dark red residue was chromatographed on alumina (5% water) with a benzene–petroleum benzine (1 : 9) mixture, thus giving two main zones: a reddish-orange zone (upper) and an orange zone (lower). The upper zone gave, after rechromatography on alumina, crude **1**, which was then recrystallized three times from a dichloromethane–methanol mixture. Red needles (**1**, 0.3 mg, 1% based on the C_{25}-alcohol); mp 196 °C, undepressed by admixture with a natural specimen. A mixed chromatography of the synthetic and the natural pigment showed no separation. The spectral properties (UV, NMR, and mass) were also identical with those reported previously.[3]

In an experiment carried out at room temperature, the product was essentially **22**. A very small amount of **1** was also observed on the column.

All the 2,3,4-trimethylphenyl derivatives necessary for the synthesis of **2** or its *cis* isomer (**23**) were prepared in essentially the same manners as were used for the corresponding compounds described in the syntheses of **1** or **22**.

*Methyl 3-Methyl-5-(2,3,4-trimethylphenyl)-*trans*-2,*trans*-4-pentadienoate (**24a**) and Its 2-*cis* Isomer (**24b**).* 4-(2,3,4-Trimethylphenyl)-3-buten-2-one[16] (4.5 g) was condensed with ethoxycarbonylmethylenetriphenylphosphorane to give a mixture of 2-*trans* and 2-*cis* isomers of the ethyl ester (1 : 1) (6.2 g, bp 100 °C (bath)/5 mmHg). The ester mixture was then saponified, and the acids (5.5 g) were separated by fractional crystallization.

The *trans* acid[12] (mp 214—215 °C) was treated with diazomethane to give the methyl ester (**24a**). Colorless prisms;[12] mp 84—86 °C; bp 80 °C (bath)/4—5 mmHg; IR 1710 cm^{-1}; NMR δ 5.87 (1H, s; 2-proton).

The *cis* acid,[12] mp 183—186 °C. Methyl ester (**24b**): mp 57—59 °C; NMR δ 5.71 (1H, broad s; 2-proton).

*3-Methyl-5-(2,3,4-trimethylphenyl)-2,4-pentadien-1-ol (**25**).* Aluminium hydride reduction of **24a** (531 mg) gave the *trans* alcohol (**25**) (442 mg); mp 56.5—58.5 °C; IR 3370, 1625 cm^{-1}.

*[3-Methyl-5-(2,3,4-trimethylphenyl)-2,4-pentadien-1-yl]triphenylphosphonium Bromide (**26**).* This was obtained from **25** (442 mg) and triphenylphosphonium bromide (700 mg): a glassy solid (900 mg); NMR (90 Mc) δ 4.86 (2H, dd, J=8.5 Hz, J=16.0 Hz; 1,1-protons).

*9-cis-7,8-Didehydrorenieratene (**23**).* The condensation of the ylid from **26** (630 mg) with **20** (10 mg) gave **23** as deep red needles (6.9 mg); mp 170.5 °C; λ_{max} 503.5, 472.5 (ε=11.0×10^4), (445), 369, (353) nm; IR 3030, 2915, 1477, 1460, 1440, 1361, 960, 800 cm^{-1}; NMR δ 1.95(6H, s), 2.05 (6H, s), 2.25 (12H, s), 2.45 (6H, broad s), 6.20—7.50 (16H, m). Mass (*m/e*) 526 (M), 434, 420, 393, 328, 133. Found: C, 90.27[17]; H, 8.87%. Calcd for $C_{40}H_{46}$: C, 91.20; H, 8.80%. The natural pigment (**2**) (mp 204—205 °C) and **23** were isomerized with iodine and light in benzene for 1 hr. Both the isomerized solutions gave the same UV curve, with maxima at 501, 470.5, (444), 370, and (354) nm. From the lower part of the chromatogram, a pigment which melted at 164—164.5 °C was obtained besides **23**; red needles [λ_{max} 498, 467, (439), 372, (354) nm]. It was considered to be

9,11′-di-*cis*-7,8-didehydrorenieratene from the mode of its formation.

*2,7,11-Trimethyl-13-(2,3,4-trimethylphenyl)-2,4,6,8,10,12-tridecahexaen-1-al (**27**).* The condensation of **26** (1 g) and the C_{10}-dial (**17**, 900 mg) gave **27** as red needles (23 mg); mp 161—162 °C; λ_{max} 444 nm ($\varepsilon=6.9\times10^4$); IR 3050, 2925, 1665, 1615, 1540, 1190, 970, 965 cm^{-1}; NMR δ 9.46 (1H, s; 1-proton). Mass (m/e) 346(M), 278, 262, 219, 210, 133, 29. Found: C, 85.86[17]; H, 8.69%. Calcd for $C_{25}H_{30}O$: C, 86.65; H, 8.73%.

From the reaction mixture, the 8-*cis* isomer of **27** was also obtained as red needles; mp 141—142 °C; λ_{max} 440 nm.

*[2,7,11-Trimethyl-13-(2,3,4-trimethylphenyl)-2,4,6,8,10,12-tridecahexaen-1-yl]triphenylphosphonium Bromide (**28**).* The aluminium hydride reduction of **27** (46.8 mg) gave the corresponding alcohol as a canary-yellow solid (46 mg). The crude alcohol [mp 116—126 °C; λ_{max} 432, 409, 389 nm; IR 3350, 1025, 1015, 965 cm^{-1}] (23 mg) was converted into the phosphonium salt (**28**) with triphenylphosphonium bromide (23 mg); this crude salt was used without purification.

*7,8-Didehydrorenieratene (**2**).* The condensation of the ylid of **28** (44 mg) with **12a** (20 mg) was carried out under a low temperature in the way described in the recipe for **1**. The crude product was chromatographed on 5% aqueous alumina with a benzene-petroleum benzine (1 : 4) mixture. After rechromatography and recrystallization (dichloromethane-methanol), **2** was obtained as purplish-red needles (0.05 mg); mp 205—206 °C, undepressed by admixture with a natural specimen. A mixed chromatography of the synthetic and the natural pigment showed no separation. The spectral properties (UV and mass) also agreed with those reported previously.[3]

17) Because the amount available for elementary analysis was too small, a larger deviation from the calculated value was recorded for the carbon content.

Fundamental Studies on Palladium Catalysts. IX. Characteristics of Hydrogen Sorption and Hydrogenation Activity of Supported Palladium Catalysts[1)]

Tsunekichi YAMABE, Katsuhiro SHIRONO, Masaru UEHARA, and Sadao SUZUKI

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received February 27, 1973)

The sorption of hydrogen and the hydrogenation of ethylene on palladium/silica-alumina catalysts with palladium contents of 0.58—4.5 wt% were investigated. It was found that V_x (the amount of molecularly-adsorbed hydrogen) and V_z (that of dissociatively-adsorbed hydrogen) increase, while V_y (that of dissolved hydrogen) decreases, with the increase in the specific surface area of palladium, and that the saturated value of V_z is proportional to the amount of chemisorbed carbon monoxide. It was also shown that the increase in the palladium content results in a growth of the palladium crystallites, their number staying approximately constant. The rate of ethylene hydrogenation was found to be first-order with respect to hydrogen and zero-order with respect to ethylene over the temperature range of −20—20 °C. The activity was proportional to the surface area of palladium, and the activation energy was almost constant for these catalysts.

It has previously been demonstrated[2)] that the equilibrium amount of hydrogen in the first ascending part of the sorption isotherm is expressed by the sum of the amounts of two hydrogen species, that is, molecularly-adsorbed hydrogen and dissolved hydrogen in the case of palladium-black with a surface area of less than 15 m^2/g. However, another species of dissociated hydrogen strongly adsorbed on palladium has been revealed as a result of an investigation[1,3)] using supported catalysts with a large surface area of palladium (>100 m^2/g).

In this investigation, we have studied the effects of the specific surface area of palladium on the equilibrium amount of each hydrogen species and on the hydrogenation of ethylene.

Experimental

Materials and Catalyst Preparation. The palladium/silica-alumina catalyst was prepared by immersing silica-alumina (Neobead D from the Mizusawa Industrial Chemicals, Ltd.) in a hydrochloric acid solution of $PdCl_2$ for a few weeks at room temperature until the solution became almost colorless. The catalyst, after having been washed with ion-exchanged water, was dried by evacuating it in the reaction cell and then reduced with hydrogen at 200 °C for 2 hr. Before each run, the catalyst was evacuated for 10 hr at 200 °C to arrive at a residual pressure of less than 1×10^{-4} Torr. The palladium-black/silica-alumina mixed catalyst was prepared by the Willstätter method[4)] in the presence of silica-alumina, followed by the same pretreatment as in the case of the supported catalyst. The palladium content was determined by the EDTA titration method. The hydrogen was purified by passage through a palladium thimble. The ethylene contained less than 0.3% methane and a trace amount of ethane as impurities. The purity of the carbon monoxide used for the determination of the palladium surface area was more than 99.8%.

Apparatus and Procedure. Our measurements of the sorption isotherms and the desorption rate were carried out in a conventional static-sorption apparatus incorporating a rotary MacLeod gauge, as has been described in Ref. (3). The catalytic activity was estimated by measuring the rate of ethylene hydrogenation in a batch recirculation system. The amounts of ethylene and ethane were monitored by the measurement of the pressure change in the total gas and checked by a chromatographic analysis of the gas mixture at appropriate intervals.

Results

Relation between the Specific Surface Area of Palladium S and the Amount of Each Type of Hydrogen. As has already been indicated in a previous paper,[1)] the amount of dissociatively-adsorbed hydrogen, V_z, is expressed as follows:

$$V_z = b_3\sqrt{K_3P}/(1+\sqrt{K_3P}) \quad (1)$$

where b_3, K_3 and P represent the site number per atom of palladium (H/Pd), the equilibrium constant, and the equilibrium hydrogen pressure respectively. The assumption that the dissociated hydrogen atoms combine with exposed palladium atoms in the ratio of 1 to 1 makes it possible to calculate the specific surface area of palladium S (m^2/g-Pd) from the b_3 values. Thus, S is determined by assuming that the number of palladium atoms per square meter is 1.2×10^{19}; this is the mean value for the crystallographic planes (100), (110), and (111).

$$S = 472b_3 \quad (2)$$

On the other hand, Scholten and his co-workers have proposed a method of determining the surface area of supported palladium from the chemisorbed amount of carbon monoxide.[5)] Therefore, we have also examined the adsorption of carbon monoxide on a series

		20	22.7		1.03×10^{-3}	
		35	15.9		2.25×10^{-3}	

of catalysts at 20 °C and calculated the S values according to their procedure. The relation between b_3 and S obtained by means of carbon monoxide chemisorption (S_{CO}) is presented in Fig. 1; it suggests the validity of Eq. (2). In Fig. 1, we also show the results obtained with a palladium-black/silica-alumina mixed catalyst, assuming that the amount of residual hydrogen after 1 hr's evacuation at 20 °C is equal to b_3. In addition, we calculated the heat of dissociative adsorption from the temperature dependency of K_3; we thus obtained approximately 7.5 kcal/mol (see Table 1).

Then we have investigated the desorption process of hydrogen taken up at 20 °C, 100 Torr according to the procedure described in Ref. 1. We first determined V_z; then we estimated the amount of molecularly-adsorbed hydrogen, V_x, and that of hydrogen dissolved in the lattice, V_y, assuming that the molecularly-adsorbed hydrogen had just been desorbed by the 30-second's evacuation to the residual pressure of 1×10^{-1}—8×10^{-2}, and that the dissolved hydrogen is not desorbed under the above conditions. The relation between V_x and b_3 (or S) as well as V_y and b_3 (or S) is illustrated in Fig. 2. It is demonstrated in Fig. 2 that V_x increases proportionally, while V_y decreases, with the increase in S.

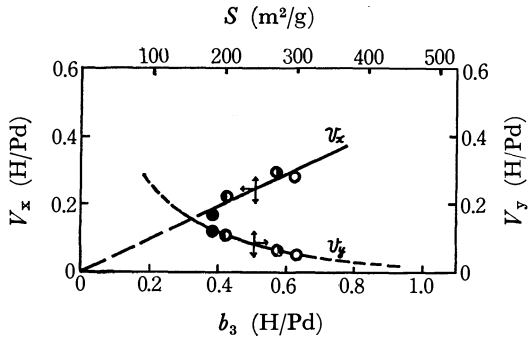

Fig. 2. Relation between (V_x, V_y) and (b_3, S) at 20 °C, 100 Torr.
Pd content (wt%); ●: 4.5, ◐: 2.1, ◑: 0.81, ○: 0.58

In addition, it was found that values of k_3' (the desorption rate constant of dissociatively-adsorbed hydrogen) for the catalysts with the palladium contents of 0.81 wt% and 2.1 wt% were almost identical and that the activation energies calculated from the temperature dependency of k_3' were about 8.7 kcal/mol in both cases (see Table 1).

Hydrogenation of Ethylene. The hydrogenation of ethylene was studied over the temperature range from −20 °C to 20 °C. The circulation velocity of the reactant gas does not influence the kinetics under the standard conditions: the initial pressures of hydrogen and ethylene are around 25 Torr, and no diluent is used. Since the activity was found to decrease slightly with the progress of the reaction, a fresh catalyst was used for each run. The reaction rate, R, was proved to be as follows:

$$R=kP_hP_e^0 \quad (3)$$

where k is the rate constant and where P_h and P_e denote the partial pressures of hydrogen and ethylene respectively. The rate constants[6] per gram of palladium in the catalyst were calculated; they are plotted against b_3 and against S_{co} in Fig. 3. The linear relationship indicates that the hydrogenation activity is proportional to the specific surface area of palladium. The activation energies were about 2.5 kcal/mol for all the catalysts used.

Discussion

As for dissociatively-adsorbed hydrogen, the validity of the assumption that the hydrogen atoms combine strongly with the palladium atoms exposed in 1-to-1 ratio is supported by Fig. 1. Since b_3 can be easily determined by means of Eq. (1), Eq. (2) may be thought to be very convenient for the estimation of the palladium surface area. In Scholten's method, the modes

of the binding of carbon monoxide on palladium, namely, linear type and bridged type, must be considered in contrast to the method described above, in which only one hydrogen species is concerned. Furthermore, Dorling and Moss have reported[7] that the ratio of linear bonding to bridge bonding varies according to the metal crystallite size in the case of platinum/silica catalysts, so the surface area calculated from b_3 may be thought to be more precise than that determined by means of carbon monoxide chemisorption. This can be seen from Fig. 3, which illustrates better the linearity in the plot of k *vs.* b_3 than in that of k *vs.* S_{co}.

The dependency of V_x on S is similar to the results in Ref. 2. At present, we may suppose that the two surface species are adsorbed on different sites of the palladium, but the situation has not yet been ascertained in detail.

V_y decreases with an increase in S, probably because the number of sites in the lattice decreases with a decrease in the crystallite size of the palladium. In the case of $b_3=1.0$, it can be expected that each palladium atom is exposed to gaseous hydrogen and V_y becomes zero. Thus, b_3 means not only the total site number of the Langmuir isotherm, but also the proportion of palladium atoms exposed.

It may be concluded from the above results that the main role of the support is to disperse palladium, and that the spillover phenomenon reported by Boudart[8] in supported platinum catalysts does not take place in this system.

The increase in the palladium content resulted in a reduction of S, thus suggesting the growth of palladium crystallites. We have examined the relation between the total surface area of palladium per unit of weight of the support, S_t, and its weight, W, by plotting S_t *vs.* $W^{2/3}$ in Fig. 4. The linear relationship shows that the number of crystallites per gram of support is unchanged, irrespective of the palladium content. If the palladium crystallites are regarded as spheres, the number of crystallites per gram of support is calculated to be approximately 3.7×10^{17}; the diameter of the crystallites is considered to change over the range from 10 Å to 30 Å.

It may be concluded from the results obtained by ethylene hydrogenation that all sites are of the same quality in these catalysts, and that their difference in number per unit weight of palladium is reflected in the difference in catalytic activity. However, further

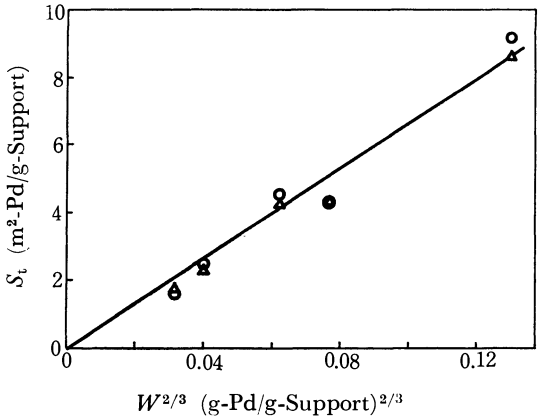

Fig. 4. S_t *vs.* $W^{2/3}$.
S_t: Determined by CO and H_2 adsorption
○: CO, △: H_2

research employing the catalysts with palladium crystallites larger than 30 Å is needed to characterize the catalytic behavior. The results of the present study give no information about the active species of hydrogen, because both V_x and V_z are proportional to S. Nevertheless, the b_3 value appears to be a useful parameter for the activity as long as the reaction in question is "facile". Which of the two surface species of hydrogen contributes to ethylene hydrogenation is an interesting subject for further study.

New Photochemical Reactions of 9-ω-Bromoacetylanthracene. I

Tamotsu MATSUMOTO, Masanori SATO, and Satoshi HIRAYAMA

Faculty of Textile Science, Kyoto Technical University, Matsugasaki, Sakyo-ku, Kyoto 606

(Received April 9, 1973)

New photochemical reactions were found on 9-ω-bromoacetylanthracene. The main photo-products were 1-aceanthrenone and 9-bromoanthracene. Their formation was not appreciably affected by the presence of oxygen. Other products such as anthracene, 9-acetylanthracene and anthraquinone were also detected and their yields greatly depended on the reaction conditions. From the low temperature experiments, it was made clear that 9-bromoanthracene and 1-aceanthrenone were formed *via* different mechanisms. A rather stable intermediate, which was not a radical but presumably an intramolecular adduct, was detected spectroscopically. 1-Aceanthrenone was formed from the intermediate both photochemically and thermally with liberation of hydrogen bromide. In the absence of oxygen both the thermal and photochemical reactions of the intermediate yielded almost the same amount of 1-aceanthrenone. The reaction mechanisms were considered in reference to the photochemical reactions of 9-nitroanthracene and sodium 9-anthroate. The relation between these reactions and the radiationless transition processes of carbonyl derivatives of anthracene was also discussed.

Anthracene and its derivatives which have been studied extensively are known to undergo a wide variety of photochemical reactions.[1—4] In most cases, however, they are simple and detailed investigations have been made into their primary photochemical and photophysical processes. It has been made clear that with the anthracene derivatives the radiationless transition processes which sometimes profoundly affect primary photochemical processes are entirely different from those of other organic compounds. The difference is believed to originate from the fairly large energy gap between the lowest excited singlet and the lowest triplet states of these compounds.[5,6]

Recently the substituent effect on the radiationless transition processes has been investigated, valuable results being obtained.[7,8] A detailed investigation we have made of the carbonyl derivatives of anthracene has revealed the existence of interesting relations between the position of a substituent, photochemical reactivity, fluorescent property and the life-times of their triplet state.[9] As regards the fluorescent property, these derivatives are unusual. A typical compound is 9-acetylanthracene (9-CH_3CO-A),[9,10] which is non-fluorescent in various solvents and becomes fluorescent only at temperatures near 77 K. This phenomenon was interpreted in terms of the temperature effect on the intersystem crossing process of $S_{\pi\pi^*} \rightsquigarrow T_{n\pi^*}$.[9,10]

The intersystem crossing process of 9-CH_3CO-A is expected to be perturbed by certain substituents.[11] In order to see what occurs when a hydrogen atom of the acetyl group of 9-CH_3CO-A is substituted by a bromine atom, 9-ω-bromoacetylanthracene (9-CH_2BrCO-A) was synthesized. In contrast to 9-CH_3CO-A, 9-CH_2BrCO-A underwent quite remarkable intramolecular reactions. These new photochemical reactions seem to be useful for clarifying the intramolecular energy dissipation processes of carbonyl derivatives of anthracene and are reported herewith.

Experimental

9-CH_2BrCO-A was synthesized from 9-CH_3CO-A.[13] Commercial solvents of guaranteed grade were used for photochemical reactions without further purification. For spectroscopic measurements, solvents of spectrograde supplied by Nakarai Chemical Co. Ltd. were used.

Absorption spectra were recorded on a Hitachi Spectrophotometer Model 124. The relative yields of the photoproducts were determined spectrophotometrically. Fluorescence and excitation spectra were recorded on a Shimadzu Corrected Recording Spectrofluorophotometer Model RF 502. Fluorescence spectra at low temperature were measured with a modified Beckmann type spectrophotometer equipped with an EMI 9558 QB photomultiplier.

An Ushio 500 W high-pressure mercury-arc lamp was used as an irradiation source. To isolate suitable excitation lines Toshiba glass filter UV-DIB (isolated lines: 313, 334 and 366 nm) or UV-39 (isolated lines: 366 nm and longer ones) was used with a solution filter containing distilled water. A reaction cell was either an ordinary optical cell of 1×1 cm or a cylindrical cell of 3 cm diameter and 3 cm length, each of which was made of quartz and had a side arm for evacuation. Solutions were degassed by repeating freeze-pump-thaw cycles with an oil diffusion pump. When degassing was not necessary, an ordinary optical rectangular cell of 1×1 cm with a ground-glass joint was used.

Irradiation at dry ice-ethanol temperatures (−74——80 °C) was carried out in a Pyrex cylindrical cell of 1.2 cm diameter, which was dipped into a transparent Dewar vessel containing dry ice-ethanol mixture.

Preparative photolysis was carried out in an Ushio photochemical reaction vessel Model UM 103B. A 100 W medium-pressure mercury-arc lamp was immersed in a water-cooled jacket made of Pyrex glass, the outside of which was surrounded by a window glass pipe of 1 mm thickness. Cyclohexane solution of 9-CH_2BrCO-A (*ca.* 1 g/300 ml) was irradiated at 7—10 °C[14] for about 4 hr by bubbling nitrogen gas gently through the solution. After the reaction the solvent was evaporated with a rotary evaporator. The residue was then dissolved in an appropriate amount of ethanol and was allowed to stand for a while to complete the reaction. The solvent was again evaporated and the residue was separated by column chromatography on silica gel. Elution with benzene gave 9-bromoanthracene (9-Br-A) and *ca.* 300 mg of crude 1-aceanthrenone as main photo-products. The latter was identified by means of IR, NMR, mass spectra and elemental analysis. The UV absorption spectrum of photochemically synthesized 1-aceanthrenone agreed with that of the authentic sample synthesized chemically.[15] Recrystallization from acetone and then twice from benzene gave pure 1-aceanthrenone, for which the molar extinction coefficient

was determined.

Electric conductivity measurements were made on a Yanagimoto Conductivity Outfit Model MY-7.

Result

The UV absorption spectrum of 9-CH_2BrCO-A is similar to that of 9-CH_3CO-A, but shifts to the red *ca.* 2 nm and is slightly broader. As regards fluorescence, 9-CH_2BrCO-A also resembles 9-CH_3CO-A,[10] which is non-fluorescent at room temperature and becomes fluorescent at temperatures near 77 K. In spite of these similarities, both compounds differ completely in their photo-reactivity. Only 9-CH_2BrCO-A undergoes photochemical intramolecular reactions, yielding mainly 1-aceanthrenone and 9-Br-A.

Irradiation at Room Temperature. The change in absorption spectra when the aerated cyclohexane solution of 9-CH_2BrCO-A was irradiated at room temperature through the filter UV-39 for about 20 min is shown in Fig. 1. The absorption band assignable to the p-band of anthracene disappears with irradiation and a large new band appears at about 315 nm (curve b). This band is attributed to the intermediate, which reacts both thermally and photochemically to give 1-aceanthrenone. At least two separate reactions seemed to proceed at different rates in cyclohexane so that no isosbestic point was observed.[16] The absorption spectrum (curve c) was observed after standing the solution showing the absorption spectrum b for about 40 hr without irradiation at room temperature. The absorption spectrum with a band maximum at 414 nm is due to 1-aceanthrenone.

The rate of decrease of the intermediate and that of increase of 1-aceanthrenone were obtained by measuring the changes in the optical densities at 315 nm and 414 nm, respectively. Both rates were found to follow the same first order equation with the opposite sign. This means that the intermediate at 315 nm turns unimolecularly into 1-aceanthrenone. It was also ascertained that the rate of the reaction was accelerated as temperature increased. The half life of the intermediate was of the order of several hours in cyclohexane.

Similar experiments were carried out in the deaerated solutions. Almost the same results as those in the presence of oxygen were obtained.

These photochemical reactions did not show any appreciable concentration dependence in the range 5×10^{-6}—2×10^{-4} M in cyclohexane, proceeding likewise in various solvents. Thus the main photochemical reactions of 9-CH_2BrCO-A are considered to be intramolecular.

The stable intermediate observed in cyclohexane could not be detected in alcoholic solutions at 30—35 °C because of its instability. The result obtained in the ethanol solution by irradiation through the filter UV-39 is shown in Fig. 2. There is no absorption attributable to the intermediate. Instead, the isosbestic points are seen at 322 nm and 392 nm, indicating that the final products are formed simultaneously with irradiation.[16]

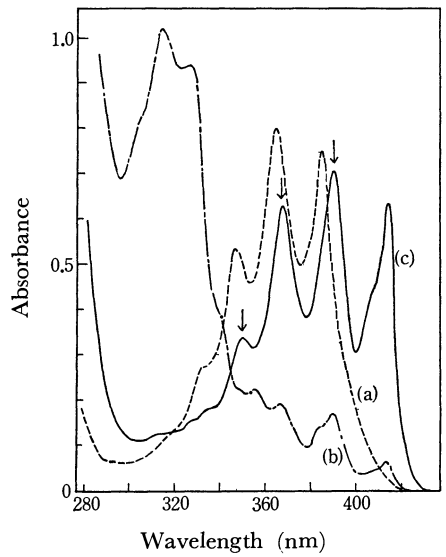

Fig. 1. Change in the absorption spectra of the aerated cyclohexane solution of 9-CH_2BrCO-A caused by irradiation.
(a) ——: 9-CH_2BrCO-A (1.0×10^{-4} M)
(b) ——: the spectrum of the intermediate obtained after 20 min irradiation through the filter UV-39.
(c) ——: final products obtained by the dark reaction of the intermediate (see the text).
The arrows indicate that the absorptions at these wavelength are partly due to 9-Br-A.

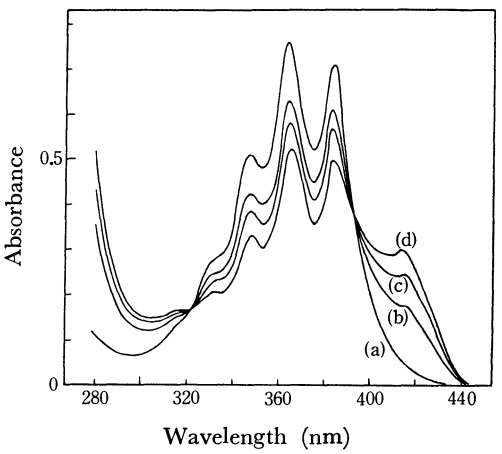

Fig. 2. Change in the absorption spectra of the aerated ethanol solution of 9-CH_2BrCO-A caused by irradiation.
(a) reactant, (b) after 5 min, (c) after 10 min, (d) after 25 min (final products).
The solution was irradiated through the filter UV-39 at 30—35 °C. No absorption attributable to the intermediate is observable and the isosbestic points are seen at 322 nm and 392 nm.

The absorption spectra of 1-aceanthrenone in cyclohexane and in ethanol are shown in Fig. 3. A comparison of the absorption spectrum in cyclohexane with that given in Fig. 1 shows that the increment of the absorption indicated by the arrows is due to 9-Br-A. The yield of each compound can thus be easily calculated from its molar extinction coefficient. The values obtained in this way are given in Table 1.

Table 1. Yields of photo products

Reaction conditions[a]			Yield (%)		Other products[b]
Solvent	Temperature	Presence of oxygen	1-Aceanthrenone	9-Br-A	
Cyclohexane	Room temp.	Yes	71	9	anthraquinone (UV) (425 nm)
Cyclohexane	Room temp.	No	77	11	9-CH_3CO-A (UV, IR) anthracene (Fl, Ex)
Ethanol	Room temp.	Yes	52	14	9,10 di-Br-A (UV) anthraquinone (UV)[c] (387 nm, 425 nm)
Ethanol	Dry ice-ethanol temp.	Yes	58	32	anthraquinone (UV)
Ethanol	Dry ice-ethanol temp.	No	59	36	9-CH_3CO-A (UV) anthracene (Fl, Ex)

a) The yields were obtained in the reactions of dilute solutions (*ca.* 10^{-4} M).
b) Method of detection is given in parentheses in abbreviated form; Fl: fluorescence spectrum, Ex: excitation spectrum. The longest wavelengths of the absorption spectra observed in cyclohexane after separation by column chromatography are also given in parentheses.
c) Prolonged irradiation of a more concentrated solution gave anthraquinone and 9,10-di-Br-A in high yields.

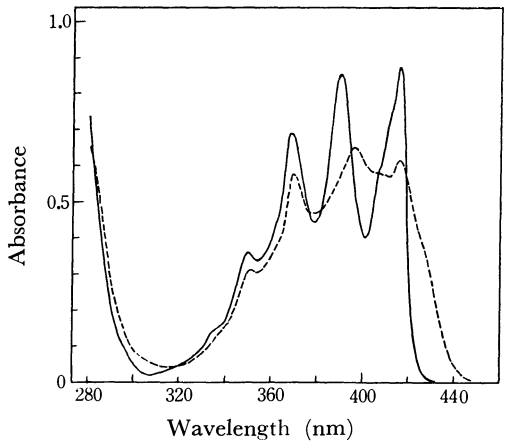

Fig. 3. Absorption spectra of 1-aceanthrenone (1.0×10^{-4} M) in cyclohexane (——) and in ethanol (----).

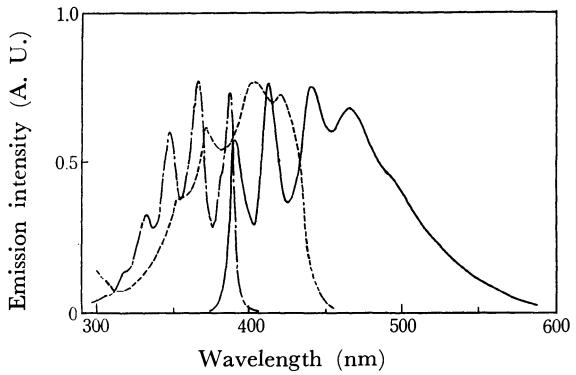

Fig. 4. Fluorescence and excitation spectra of the photoproducts in ethanol. The solution shows the absorption spectrum represented by Fig. 2d.
——: fluorescence spectrum,
– – –: excitation spectrum observed at 412 nm,
----: excitation spectrum observed at 500 nm.
The emission at the shorter wavelength region is not due to 9-Br-A.[17]

The fluorescence and excitation spectra of the solution having the absorption spectrum shown in Fig. 2d are given in Fig. 4. The emission band at the longer wavelength is due to 1-aceanthrenone, judging from the excitation spectrum. The component at the shorter wavelength is not assignable to 9-Br-A and is due to some other unidentified product.[17] The absorption spectrum of this compound overlaps that of 9-Br-A. The yields were thus determined spectrophotometrically after separation by column chromatography.

Irradiation at Dry Ice-Ethanol Temperatures. When the degassed *n*-hexane solution of 9-CH_2BrCO-A was irradiated through the filter UV-39 at dry ice-ethanol temperatures, the absorption spectrum given by curve a in Fig. 5 was obtained. *n*-Hexane was used because of high freezing point of cyclohexane. At these temperatures the reaction of the intermediate to form 1-aceanthrenone is completely retarded. Thus no absorption can be seen at 414 nm (curve a, Fig. 5). There is a small absorption peak at 388 nm where 9-Br-A shows absorption. After temperature was raised to room temperature and the reaction was completed, the yield of 9-Br-A was determined from the difference of the absorbances at 388 nm and at 414 nm. The yield of 9-Br-A obtained in this way agreed well with that gained before temperature was raised. This fact makes it clear that 9-Br-A is not formed by a thermal reaction after irradiation and that only 1-aceanthrenone is formed from the intermediate.

When the solution at the state shown by curve a (Fig. 5) was irradiated further through the filter UV-DIB, photochemical reactions occurred as indicated by curves b-f, the final state being shown by curve f. As seen from the absorption spectrum, 1-aceanthrenone was produced. In the absence of oxygen, the yields obtained by the photochemical and thermal reactions of the intermediate were almost the same. In the presence of oxygen, however, the yield for the former procedure was lower than that for the latter by about 60%. The irradiation of the intermediate seems to produce other compounds than 1-aceanthrenone.

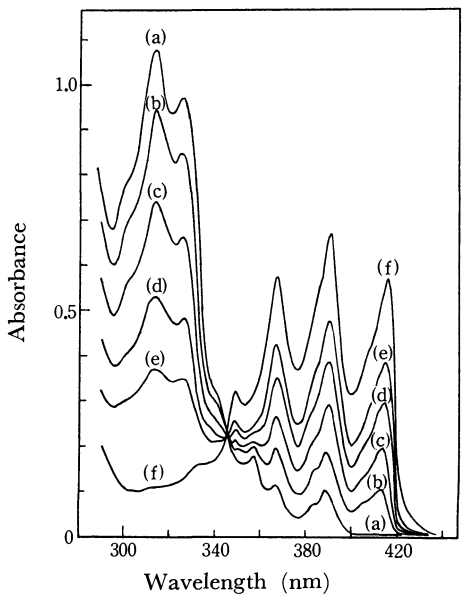

Fig. 5. Photochemical reactions of the intermediate in the degassed *n*-hexane solution.
(a) before the second irradiation, (b) after 30 s (c) after 90 s, (d) after 180 s, (e) after 300 s, (f) final products
Curve a was observed after 30 min irradiation through the filter UV-39 at dry ice-ethanol temperatures. The second irradiation was carried out through the filter UV-DIB at room temperature. The absorption spectrum f did not change by further irradiation.

Their compositions are not identified.

Even in ethanol it was confirmed that the intermediate could exist stably at temperatures as low as dry ice-ethanol temperature in the following way. After sufficient irradiation of the ethanol solution of 9-CH_2BrCO-A at dry ice-ethanol temperatures through the filter UV-39, the reaction cell was dipped into a transparent Dewar vessel containing liquid nitrogen and the fluorescence spectra were measured. The only emissive species was 9-Br-A. When temperature was raised to room temperature, a new fluorescence band due to 1-aceanthrenone appeared. This indicates that the intermediate can exist stably at low temperatures and only 1-aceanthrenone is formed from the intermediate.

Miscellaneous. Measurements of electric conductivity enabled us to elucidate the intermediate. The cyclohexane solution of 9-CH_2BrCO-A (*ca.* 10^{-3} M) which had been irradiated through the filter UV-39 and enriched with the intermediate was shaken well with distilled water. This operation did not appreciably affect the stability of the intermediate. The water layer was separated and its electric conductivity was measured. After this, the aqueous solution was again combined with the cyclohexane layer. The above operation was repeated several times at certain time intervals. The electric conductivity of the water layer was found to increase as the intermediate decreased by the thermal reaction. This shows that the reaction of the intermediate to form 1-aceanthrenone is accompanied by the elimination of a certain molecule which can dissociate into ions. Hydrogen bromide is the most probable candidate, judging from the structures of the reactant and the product and from the reaction mechanisms.

On the irradiation of a completely degassed solution of 9-CH_2BrCO-A, an appreciable amount of 9-CH_3CO-A and a small amount of anthracene were formed as minor photo-products. In an aerated solution, anthraquinone was formed instead of these two compounds. The formation of other minor photo-products depends on reaction conditions. A detailed description is given in Table 1.

1-Aceanthrenone was rather photo-stable in cyclohexane, but in ethanol its absorption spectrum gradually changed with irradiation. The products in this reaction were not identified.

Heating an *o*-dichlorobenzene solution of 9-CH_2BrCO-A to *ca.* 135 °C for 2 hr was unsuccessful to produce 9-Br-A or 1-aceanthrenone, for no UV absorption change was observed.

A preliminary experiment on 9-ω-chloroacetylanthracene showed that it underwent photochemical reactions analogous to those of 9-CH_2BrCO-A.

Discussion

If we neglect the photodimerization of 9-CH_2BrCO-A in the low concentration range 5×10^{-6}—2×10^{-4} M, the photochemical reaction mechanisms of 9-CH_2BrCO-A can be given as shown in Fig. 6. The reactions are noteworthy particularly as regards the following three points: (i) The main photochemical reactions proceed in various solvents in the presence or in the absence of oxygen, *i. e.*, paths (1), (2) and (3) do not seem to be affected greatly by the presence of oxygen. In contrast, oxygen completely suppresses path (4). (ii) With an appropriate choice of excitation wavelength and reaction temperature, the reaction intermediate can be produced stably and can be detected by its UV absorption spectrum. The intermediate gives 1-aceanthrenone by either the dark reaction or the photochemical reaction. (iii) It can be shown that 9-Br-A and 1-aceanthrenone are produced *via* two different processes.

The structure of the intermediate (Fig. 6) has been

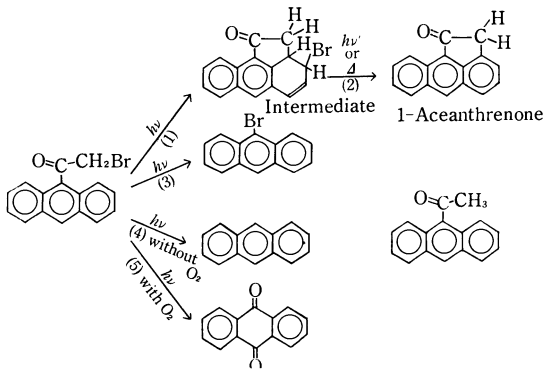

Fig. 6. Mechanisms of the photochemical reactions of 9-CH_2BrCO-A. Only the identified products are shown. For further detailed descriptions on the other products, see Table 1.

proposed on the basis of the following: The intermediate eliminates a hydrogen bromide in path (2). The absorption spectrum of the intermediate can be most reasonably interpreted by assigning it to a derivative of naphthalene. The intermediate has a long half life at room temperature in cyclohexane and shows no ESR signal. Thus it is probably not a free radical. The solvent itself is not involved in the formation of the intermediate.

The thermal and photochemical reaction mechanisms of the intermediate could be reconciled by considering the photochemical reaction of the intermediate to occur at vibrationally excited states, *i. e.*, vibrational excess energy supplied by direct photo-excitation or by a succeeding radiationless transition process would facilitate the liberation of a hydrogen bromide molecule. The structure of the intermediate we proposed seems to be pertinent to this interpretation.

The primary process of the photochemical reactions of 9-nitroanthracene (9-NO_2-A) and sodium 9-anthroate (9-COONa-A) to produce anthraquinone in the presence of oxygen is analogous to that of 9-CH_2BrCO-A. For 9-NO_2-A and 9-COONa-A, the most relevant primary process is considered to be not the dissociation and recombination of the substituent but the intramolecular rearrangement at the $n\pi^*$ states.[18-20] In the ground states of these compounds the plane containing the three atoms of each substituent makes almost a right angle to the anthracene ring[21,22] owing to the steric hindrance by *peri* hydrogen atoms. Thus, in the $n\pi^*$ excited state populated either by direct photo-excitation or by intersystem crossing process, an unpaired electron in the n-orbital of the oxygen atom can just interact attractively with an electron in the p-orbital of the carbon atom at 9-position. As a result, the intramolecular photochemical reactions take place. Experimental evidence for the above supposition, however, has not yet been obtained.

If we take into account the structure of 9-CH_3CO-A, the substituent of 9-CH_2BrCO-A can be considered to be perpendicular to the anthracene ring[9] in the ground state. Although we have no experimental evidence at present with regard to the nature of reactive excited states, a change in the electronic state of the anthracene ring or the carbonyl group on photo-excitation seems to make the lone pair of electrons of the bromine atom interact with a p-orbital electron of the carbon atom at 9- or 2-position. As a result, 9-Br-A or the intermediate will be formed. In the case of 9-NO_2-A and 9-COONa-A, rotation of the substituents on excitation is not taken into account. An unpaired n-orbital electron of these compounds interacts with a p-orbital electron solely at 9-position. In this respect 9-CH_2BrCO-A differs from these compounds. Considering its reaction products, the interactions both at 9- and 2-positions should exist. This leads to the occurrence of rotation of the substituent on photo-excitation.

A change in interaction between a substituent and an anthracene ring caused by photo-excitation has been proposed by Werner and Hercules[23,24] in the case of 9-anthroic acid. They attributed its abnormally large Stokes shift of the fluorescence to the conformational change in the excited state, where the carbonyl group rotates into a co-planar configuration, forming a hydrogen bond with a hydrogen atom at a *peri* position. The photochemical formation of 1-aceanthrenone would verify the existence of such interaction.

Thus it is expected that the relative yield of 9-Br-A and 1-aceanthrenone would be affected by the kind of solvent, viscosity and temperature, which would influence the ease of the rotation of the substituent on photo-excitation. The values cited in Table 1 seem to indicate such a tendency.

It is worthwhile to consider the relation between these new photochemical reactions of 9-CH_2BrCO-A and its relaxation processes of excitation energy.[9,10,12]

With regard to the reactive excited state of 9-CH_2BrCO-A, one possible candidate is the singlet $\pi\pi^*$ state where the change in the π-electron density at 9- or 2-position causes the attractive interaction between the bromine atom and the carbon atom at 9- or 2-position, leading to the bond formation between them. If this is the case, only the existence of a bromine atom is indispensable for the progress of similar intramolecular photochemical reactions and it may be unnecessary for a substituent to have a carbonyl group.

Another possibility is to relate these photochemical reactions to the characteristic radiationless transitions of carbonyl derivatives of anthracene. The non-fluorescent property of the majority of these compounds reflects the existence of the efficient intersystem crossing process of $S_{\pi\pi^*} \rightsquigarrow T_{n\pi^*}$.[9,10,12] 9-$CH_2$BrCO-A is expected to behave as 9-CH_3CO-A and thus the effective intersystem crossing process of $S_{\pi\pi^*} \rightsquigarrow T_{n\pi^*}$ is thought to be working also in this molecule. If this is the case, photo-excitation will mainly produce the triplet $n\pi^*$ state and some highly vibrationally excited states which are produced from the triplet state by radiationless transitions. In the triplet $n\pi^*$ state, excitation is localized to the carbonyl group, so in the vibrationally excited states formed from that state, the excess vibrational energy would be localized also to the bromoacetyl group. In the triplet $n\pi^*$ state itself or in the vibrationally excited state, the bromoacetyl group is supposed to interact strongly with the anthracene ring, or the excess vibrational energy would aid in breaking the C–C and C–Br bonds. As a result, the photochemical reactions including the C–C and C–Br bond rupture are considered to proceed. In the sense that the occurence of the efficient $S_{n\pi^*} \rightsquigarrow T_{n\pi^*}$ intersystem crossing results in the activation of the bromoacetyl group, the photochemical reactions of 9-CH_2BrCO-A is correlated to non-fluorescent property of carbonyl derivatives of anthracene.

Of the two possibilities, the latter is more interesting, since it takes into consideration the role of the carbonyl group and can interpret more reasonably the production of anthracene and 9-CH_3CO-A. However, neither has experimental evidence at present.

Phase Diagrams of YCl_3–KCl, YCl_3–NaCl, and YCl_3–KCl·NaCl Systems, and Densities of Their Molten Mixtures

Junichi Mochinaga and Kyozan Irisawa

Department of Synthetic Chemistry, Faculty of Engineering, Chiba University, Yayoi-cho, Chiba 280

(Received June 7, 1973)

YCl_3 has been prepared with Y_2O_3 and NH_4Cl, and the optimum conditions for chlorination have been determined. The YCl_3 salt obtained was purified to a pure YCl_3 crystal by sublimation. Phase diagrams of binary YCl_3–KCl and YCl_3–NaCl system, and liquidus curve diagram of quasi-binary YCl_3–KCl·NaCl system have been determined with the use of the purified YCl_3 crystal. Densities of YCl_3 and the mixtures in molten state were measured dilatometrically, and represented by empirical formulas as a function of temperature. From the results thermal expansion coefficients and molar expansibilities of the molten YCl_3 and the molar volumes of molten mixtures were calculated.

YCl_3 can be prepared by heating a mixture of Y_2O_3 and NH_4Cl:

$$Y_2O_3 + 6NH_4Cl = 2YCl_3 + 6NH_3 + 3H_2O \quad (1)$$

Since the product contains H_2O owing to the hygroscopic property of YCl_3, if the reaction temperature is too high, yttrium oxychloride is produced by the reaction of YCl_3 and H_2O, thus reducing the yield of YCl_3. In the present experiment the optimum conditions for the chlorination were determined. The YCl_3 salt was purified to a pure YCl_3 crystal by sublimation. This was used for the determination of phase diagrams and the measurement of densities of the YCl_3 and the mixture systems in molten state. Measurements of melting and transition points were carried out by differential thermal analysis. The dilatometer method was used in the measurements of densities.

Experimental

Preparation of YCl_3. A mixture of Y_2O_3 and NH_4Cl in a glass test tube of standard size was heated for a certain time in an electric furnace. The yields of YCl_3 were determined by chemical analysis of reaction products obtained under various conditions of temperature, time, and mixing ratio of Y_2O_3 and NH_4Cl. When the reaction product is treated with water purified by ion-exchange resins, YCl_3 only is dissolved in the water, but not yttrium oxychloride and Y_2O_3. The precipitate obtained by filtration of the solution was separately dissolved in the hot dilute hydrochloric acid. The amounts of Y^{+3} ions contained in both solutions were determined by the titration with EDTA solution. The yield of YCl_3 can be obtained by

$$\eta = [A/(A+B)] \times 100 \quad (\%)$$

where A is the amount of YCl_3 contained in the filtrate, and B the amount of YCl_3 contained in the solution from the filter cake. The Y_2O_3 used as starting material was 99.9% in purity (Shin-Etsu Chem. Ind. Co. Ltd., Japan: Found: Tb_4O_7, <0.003; Dy_2O_3, 0.030; Fe, 0.0003; Cu, 0.00002%). NH_4Cl(A.R. grade) was dried at about 120 °C for several hours.

Purification of YCl_3. Purification of YCl_3 is necessary since it still contains a small amount of water and NH_4Cl. Purification was carried out by sublimation in a vacuum.

Differential Thermal Analysis. Measurements were carried out from the cooling curve of the molten sample in demoistured argon gas, α-Al_2O_3 powder being used as a reference material. The cooling rates were 15 °C/min at 800 °C and 13 °C/min at 500 °C.

Measurements of Densities. The densities of the liquid chlorides were measured dilatometrically with a transparent silica dilatometer. The meniscus of molten salt was read with a cathetometer. This method was checked by measuring the densities of KCl and NaCl, the result being in good agreement with the data in literature.[1]

Results and Discussion

Preparation of YCl_3. The high yield of YCl_3 in the chlorination of Y_2O_3 makes it necessary to add an excess amount of NH_4Cl as compared with the theoretical amount in Eq. (1). The dependence of reaction time for the yield of YCl_3 at 300 °C is shown in Fig. 1, in which the curves a, b, and c are the results for the reactions with the mixtures of 1.32, 1.72, and 2.13 times the theoretical amount of NH_4Cl in Eq. (1), respectively. For curve a (1.32 times theoretical amount of NH_4Cl), the yield of YCl_3 was less than about 70%, but in the others very high yields were obtained. In cases where a more excess amount of NH_4Cl was contained the reaction rates were greater.

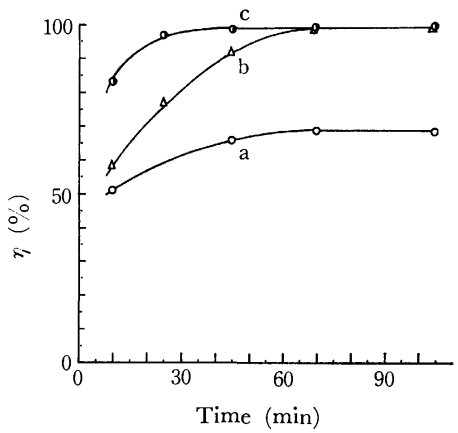

Fig. 1. Dependences of reaction time for the yield of YCl_3 at 300 °C; a: reaction of mixture containing 1.32 times of NH_4Cl, b: 1.72 times, c: 2.13 times.

The dependence of reaction temperature for the yield of YCl_3 in the reaction with 1.72 times the theoretical amount of NH_4Cl is shown in Fig. 2, in which the curves A, B, C, D, and E are the results for the reactions at 200, 250, 300, 350, and 400 °C, respectively. In the reaction at 200 °C, YCl_3 was not formed. The reactions at 350 and 400 °C proceeded rapidly,

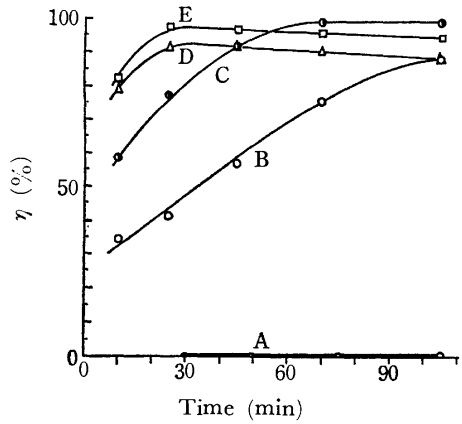

Fig. 2. Dependences of reaction temperature for the yield of YCl_3 in reactions of mixtures containing 1.72 times of NH_4Cl; A: reaction at 200 °C, B: 250 °C, C: 300 °C, D: 350 °C, E: 400 °C.

but the yields of YCl_3 decreased a little after a longer reaction time than 30 min. The tendency might indicate that the yttrium oxychloride was produced from YCl_3 and H_2O in the reaction product due to the high reaction temperature. This was also anticipated by Wendlandt[2] from the results of thermal analysis for YCl_3 containing H_2O.

It is preferable to carry out the reaction under the following optimum conditions for the chlorination of Y_2O_3 with NH_4Cl: reaction temperature 300 °C; addition to Y_2O_3 of 1.7 times or more the theoretical amount of NH_4Cl in Eq. (1); reaction time 70 min or more.

Purification of YCl_3. The maximum yield of YCl_3 crystal in sublimation, obtained when the sublimation temperature was 950—1050 °C, was about 50% after 7 hours. The purified YCl_3 crystal was completely soluble in water, the atomic ratio of Y and Cl being 1 : 3.01. The mp of this crystal was 714 and 717 °C in cooling and heating measurements, respectively, by DTA analysis. The contents of metallic impurities in this crystal are given in Table 1.

Table 1. Contents of metallic impurities in YCl_3 crystal[a]

Element	Content (ppm)	Element	Content (ppm)
La	5	Yb	< 1
Ce	<30	Lu	<10
Pr	<10	Mg	< 1
Nd	<10	Al	< 5
Sm	<10	Si	50
Eu	< 1	V	< 5
Gd	<10	Mn	< 1
Tb	< 5	Fe	5
Dy	60	Ni	< 5
Ho	<10	Cu	< 1
Er	< 5	Sn	< 5
Tm	< 5		

a) Method of analysis: Spectrographic; M. Sato, H. Matsui, and T. Matsubara, *Bunseki Kagaku*, **20**, 215 (1971).

Phase Diagram. Phase diagrams of YCl_3–KCl, YCl_3–NaCl systems and the liquids curve diagram of quasi-binary YCl_3–KCl·NaCl system are shown in Figs. 3, 4, and 5, respectively. In the YCl_3–KCl system, two intermediate compounds ($3YCl_3$·KCl and YCl_3·3KCl), one peritectic point(552 °C, 74 mol% YCl_3), 2 eutectic points(435 °C, 44 mol% YCl_3 and 685 °C, 15 mol% YCl_3), and a polymorphic transition point(367 °C) in solid range between the intermediate compounds were observed.

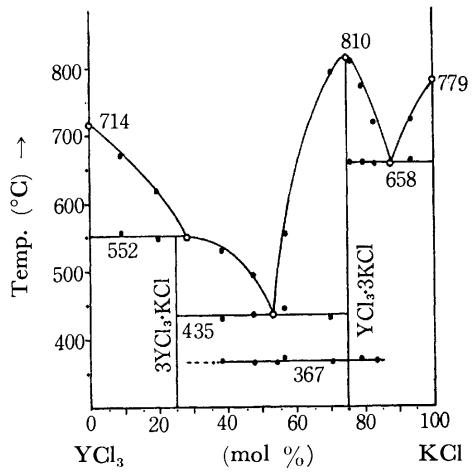

Fig. 3. Phase diagram of YCl_3-KCl system.

This is in fairly good agreement with the diagram given by Korshunov and Drobot,[3] but not with that by Su and Ch'iu.[4] In the YCl_3–NaCl system, one intermediate compound (YCl_3·3NaCl), one peritectic point (556 °C, 33 mol% YCl_3), and one eutectic point (389 °C, 50 mol% YCl_3) were observed. In this system, the intermediate compound NaCl·$9YCl_3$ reported by Su and Ch'iu[4] was not observed.

We see in Fig. 5 that the YCl_3–KCl·NaCl system has 2 minimum points (409 °C, 57 mol% YCl_3 and 600 °C, 86 mol% YCl_3), and one maximum point (632 °C, 76 mol% YCl_3).

Density of Molten YCl_3. The measurement of density of the molten YCl_3 was performed in the range

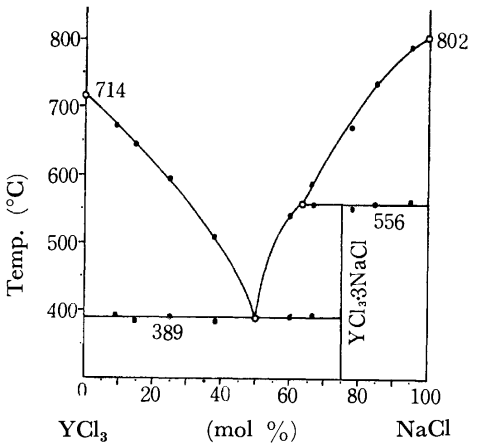

Fig. 4. Phase diagram of YCl_3-NaCl system.

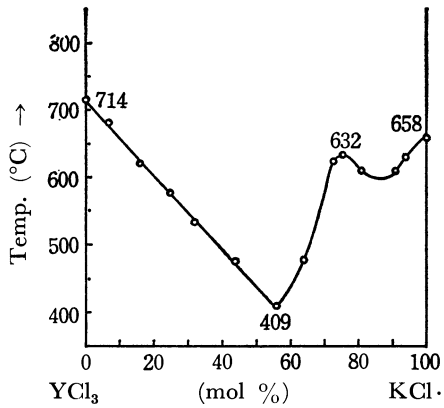

Fig. 5. Liquidus curve diagram of YCl_3-KCl·NaCl (e.m.) system.

809—1005 °C with the use of the method of least squares. The following empirical formula was obtained as a function of temperature;

$$d = 2.9226 - 4.594\times10^{-4}\,t,$$

where d is the density of molten YCl_3 in g/cm³, and t the temperature in °C. Since the density change of the molten salt with temperature is linear, the density of the molten YCl_3 at a mp of 714 °C could be calculated by extrapolation. The density of the molten YCl_3 at mp is 2.595 g/cm³. The volume change of YCl_3 on melting, calculated from the density data at room temperature (2.61 g/cm³), since the thermal expansion of the solid is much smaller than that of the liquid, was +0.594% for the solid volume. This is much smaller than the given values of $PrCl_3$, $NdCl_3$, and $GdCl_3$.[5]

Coefficients of Thermal Expansion of Molten YCl_3.
The expansivity and molar expansibility of molten YCl_3 under atmospheric pressure were calculated by combining the formula with the equation

$$\alpha = -(1/d)(\partial d/\partial t)_p \qquad (2)$$

where α is the expansivity in /°C under the pressure p. The molar expansibility is equal to αV, where V is the molar volume of molten YCl_3. The values of the expansivity and molar expansibility are given in Table 2.

TABLE 2. EXPANSIVITY AND MOLAR EXPANSIBILITY OF MOLTEN YCl_3

Temp. (°C)	Expansivity (/°C)	Molar expansibility (cm³/mol °C)
750	1.782×10^{-4}	1.350×10^{-2}
800	1.798×10^{-4}	1.374×10^{-2}
850	1.814×10^{-4}	1.399×10^{-2}
900	1.831×10^{-4}	1.425×10^{-2}
950	1.848×10^{-4}	1.451×10^{-2}
1000	1.865×10^{-4}	1.479×10^{-2}

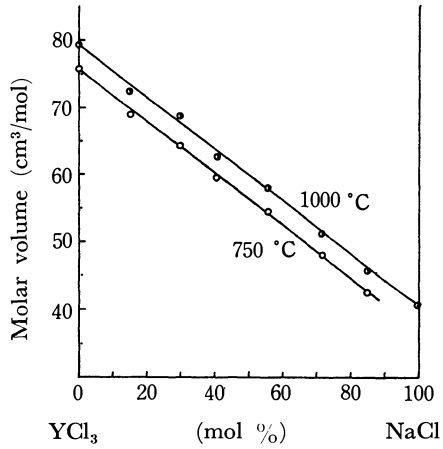

Fig. 7. Molar volume isotherm of molten YCl_3-NaCl system.

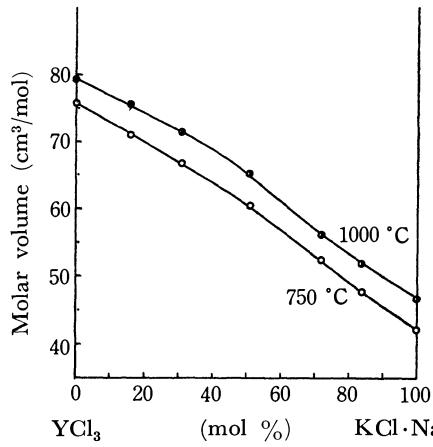

Fig. 8. Molar volume isotherm of molten YCl_3-KCl·NaCl (e.m.) system.

Densities of the Molten Mixtures. The densities of molten mixtures were measured for the various compositions in YCl_3-KCl, YCl_3-NaCl, and YCl_3-KCl·NaCl systems. The density data were treated then by the method of least-squares and represented by the empirical formulas as functions of temperature. The formulas are given in Table 3.

Molar Volume Isotherms. From the formulas in Table 3, the molar volumes of the molten mixtures were calculated by the following equation.

$$V_{mix} = \sum (X_i M_i)/d_{mix},$$

where V_{mix} is the molar volume of molten mixture in cm^3/mol, X_i the mole fraction of component i in the mixture, M_i the molecular weight of the component i in the mixture in g/mol, and d_{mix} the observed density of the molten mixture in g/cm^3. The molar volume isotherms of three molten mixture systems are shown in Figs. 6, 7, and 8.

The authors wish to thank Mr. Matsuji Sato, Shin-Etsu Chem. Ind. Co., for assistance in the analysis of materials.

Formation of Charge-transfer Complexes by Solid State Reaction; Electronic Spectra and Relative Reactivity

Hiroyasu SATO and Tamiharu YASUNIWA

College of Liberal Arts, Kagoshima University, Kamoike, Kagoshima 890

(Received July 13, 1973)

Formation of charge-transfer complexes by solid state reaction was studied for 16 donors and 10 acceptors. The relative reactivity of 160 pairs was determined by the presence or absence of the charge-transfer band on grinding the component pairs of the same concentration (diluted with sodium chloride) for the same length of time. Equilibrium was not reached within the grinding time. This relative reactivity was compared with and found to have a parallel relationship with the relative ease of formation of the charge-transfer complex on evaporating a mixture of the solutions of components, indicating that the relative reactivity is related to an apparent equilibrium established on the grain surface. Relative reactivity was found to be largely dependent on molecular size and geometry. Smaller molecules were more reactive. For molecules with the same number of rings, those with compact structure were more reactive. Most of the new bands given by the reaction were CT bands of microcrystals. They were very broad. A fairly good linear relationship was found between the transition energies of the CT bands and the ionization potentials of the donors or the electron affinities of the acceptors.

A considerable amount of information has been accumulated on the equilibria of charge-transfer (CT) complexes in solutions, but very little is known about those in solid phase. Hammick and Hutchison[1] discussed the free energy of formation of solid CT complexes (from the solid components) from their solubility measurements of trinitrobenzene- or trinitrotoluene-aromatic hydrocarbon systems. Suzuki and Seki[2] calculated the heats of formation of crystalline CT complexes (from the crystalline components) on the basis of their measurements of heat of solution for trinitrobenzene-aromatic hydrocarbon systems. They noted that the relative magnitudes of the thermodynamic data differ from those in solutions. Braun and Kortüm[3] studied CT equilibria of some trinitrobenzene complexes formed by solid state reaction by means of diffuse reflection spectra (DRS). However, very little is known about the relative ease of CT complex formation by solid state reaction. We have carried out a qualitative study of relative reactivity choosing 16 donors and 10 acceptors.

Experimental

Materials. The chemicals used are given in the following with their abbreviations and code numbers or symbols. Donors: (a) *N,N,N′,N′*-tetramethyl-*p*-phenylenediamine (TMPD), (b) hexamethylbenzene, (c) 1,2,4,5-tetramethylbenzene, (d) 1,5-dimethylnaphthalene, (e) naphthalene, (f) *N,N,N′,N′*-tetramethylbenzidine, (g) diphenyl, (h) phenanthrene, (i) anthracene, (j) *p*-terphenyl, (k) pyrene, (l) triphenylene, (m) chrysene, (n) tetracene, (o) *p*-quaterphenyl, (p) perylene. Acceptors: (**1**) tetracyanoethylene (TCNE), (**2**) 7,7,8,8-tetracyano-*p*-quinodimethane (TCNQ), (**3**) 1,2-dichloro-4,5-dicyano-*p*-benzoquinone (DDQ), (**4**) *p*-chloranil, (**5**) 2,5-dichloro-*p*-benzoquinone, (**6**) *p*-benzoquinone, (**7**) α-naphthoquinone, (**8**) anthraquinone, (**9**) pyromellitic anhydride (PMDA), (**10**) tetrachlorophthalic anhydride (TCPA) All of these were commercial products. G.R. reagents (c, d, f, k, l, m, o, p, **4**, **5**, **6**, and **10**) were used without further purification. The others were purified by vacuum sublimation or recrystallization.

Procedure. *(I) Grinding Two Components Only (a preliminary test)*: Appropriate amounts (*ca.* 10 mg each) of two components were ground on a glass plate with a stainless spatula. The formation of CT complexes was monitored visually by color. In some cases (*e.g.* a-**1**, a-**3**) colored products appeared immediately after mixing (before any grinding) the two components together. In most cases (*e.g.* a-**4**), a few seconds of grinding was necessary for obtaining the colored products. In some cases (*e.g.* i-**4**), no color of CT complexes appeared even on prolonged grinding.[4]

(II) Grinding Two Components with NaCl: The measurement of DRS was carried out to follow the CT complex formation.[5] In order to obtain good DRS by minimizing the effect of total reflection, it is necessary to disperse the sample in a white non-absorbing material used as a standard substance, which should neither react with the sample nor affect the CT equilibria. Braun and Kortüm[3] measured DRS of some CT complexes in sodium chloride, which was found not to cause dissociation of the complexes. Thus, sodium chloride was used as the white standard substance. Two components (10^{-4} mol each) and 5 g of sodium chloride were ground together manually in a porcelain mortar, 7.5 cm in diameter, for 30 s at room temperature. Sodium chloride was dried at 150 °C for 2 hours and stored in a desiccator.[6] Another 5 g of sodium chloride, ground in the same manner, was used as a reference. Measurement of DRS was then made quickly on a Shimadzu MPS-50 recording spectrophotometer with a reflection attachment. When a new DRS band or bands appeared, the measurement was repeated for some time to follow the spectral change after the sample was set in the reflection attachment. Values for $-\log R$ were measured rather than those for R. (For the definition of R, see footnote 7.) A very slight change in the spectra can thus be detected. The values for $f(R)$ in the Kubelka-Munk formula[7] were calculated from the measured values for $(-\log R)$, since the $f(R)$ value is proportional to absorbance on the assumption that the scattering coefficient is independent of wavelength. The value $-\log R=0.01$ was detectable in this measurement. This corresponds to $f(R)=2.65\times10^{-4}$. If no new band appeared, another sample was ground for 300 s at room temperature.[8]

(III) Evaporating the Mixture of Dichloromethane Solutions of Each Component: Dichloromethane solutions (10^{-2} mol/l) of a donor and an acceptor were prepared separately. Dichloromethane (Wako, G.R. reagent) was used without further purification. An aliquot (0.1 ml) of the donor solution and that (0.1 ml) of the acceptor solution were mixed. The resulting mixture was then evaporated on a glass plate at room temperature. For sparingly soluble compounds (*i.e.* **9**, **10**, n, o, and p) solutions of smaller concentration were

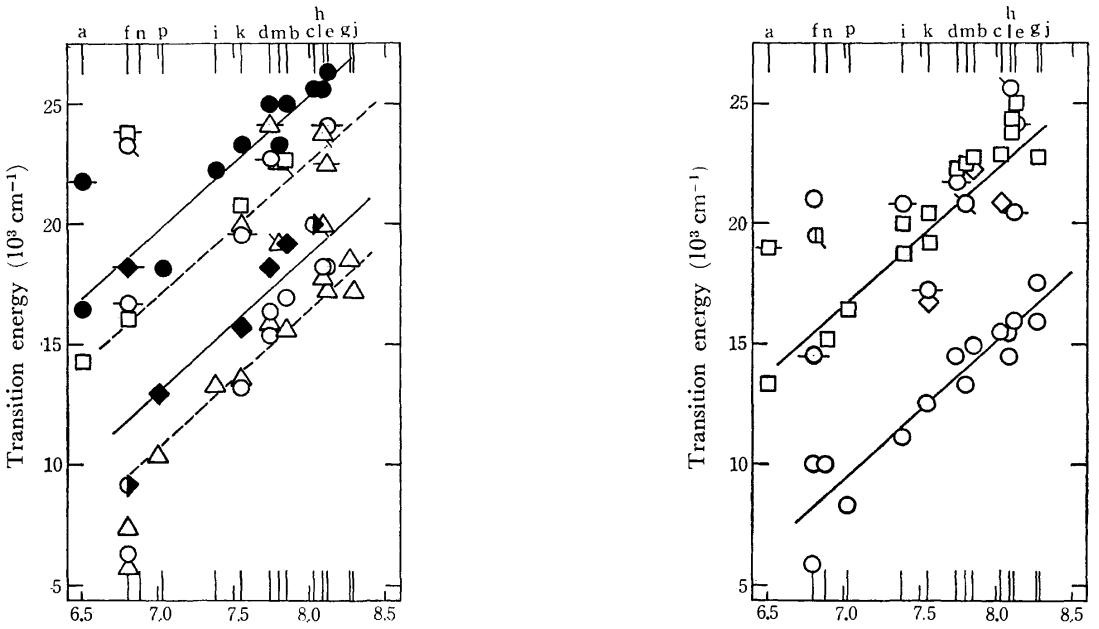

Fig. 1. Transition energies of observed new bands *vs.* ionization potential of donors.[25] The symbols of donors are shown on the upper abscissa.
Acceptors: (a) ○ 1, △ 2, ◆ 4, □ 6, ● 10.
(b) ○ 3, ◇ 5, □ 9.
A short line (horizontal) shows that the band can be assigned to the second CT band.[26] A short oblique line shows that the assignment of the band is uncertain. Such a band was considered as due to "the other product" in the text. Long straight lines in the figure show the approximate linear relationship of the CT transition energies *vs* ionization potentials of the donors. For TMPD complexes, only those bands which can be assigned to outer-complexes are given. For TCNE complexes, those bands attributable to the 1,1,2,3,3-pentacyanopropenide ion are not given.

prepared. An aliquot including 10^{-6} mol of substance was used in one experiment. Whether the solid residue is mostly (a) a CT complex, or (b) a mixture of donor and acceptor crystals, was judged from the color of the residue after evaporation.

Results

Nature of the Product. The positions of observed new DRS bands are shown in Figs. 1 and 2. Most of these bands can be considered as CT bands of minute crystals of CT complex, since their positions essentially coincide with the data of 15 crystalline CT complexes,[9-17] and solution data.[18-20] A few remarks are given here.

(i) TMPD Complexes (Figs. 1 and 2.): For a-**1**, the spectrum of the ion-pair was obtained with a CT band at 850 nm. For a-**3**, the CT band at 800 nm decreased in intensity, with an increase in intensity of the ion-pair bands (at 400, 573, and 625 nm). For a-**2**, **4**, and **5**, the presence of a band in the near infrared can be related to the inner-complex nature of the complexes.[14,17] For a-**9** and a-**10**, the bands can be attributed to outer complexes (Fig. 1a, b.). For a-**6**, the band was very broad. The presence of an apparent peak at 620 nm and a broad shoulder at 1100 nm would be associated with an inner-complex (Fig. 2), while a smaller peak at *ca.* 700 nm indicates

that an outer complex is also present (Fig. 1a).

(ii) N,N,N′,N′-*Tetramethylbenzidine Complexes (Fig. 1)*: Most of the observed bands are found near those of single crystals.[13,16] Additional bands in the case of f-**3** (near 500 and 1000 nm) would be related to the cation of the donor, considering that benzidine cation has absorption bands near 450, 760, and 850 nm.[21,22] It is striking that no complex formation was found for f-**4** or f-**5** while the corresponding benzidine complexes were formed under the same conditions. Crystals of these two complexes can be formed by mixing the solutions of the components (experiment III, *cf.* Ref. 13.). These findings can be attributed to the smaller rate of complex formation due to the steric hindrance of the dimethylamino-groups.

Relative Reactivity in the Solid State. The results are summarized in Table 1. Symbols A, B, C, and D are given for those pairs which gave DRS bands not attributable to either parent molecule on 30 s grinding. The symbols A, B, C, and D denote new DRS bands as follows. (A) the CT complex only, (B) the CT complex with a small amount of another product, (C) a small amount of the CT complex and more of an other product, and (D) an other product only. The distinction was made on the criteria of CT bands given above. The symbols in parentheses are given for the pairs which gave such DRS bands not on 30 s grinding but on 300 s grinding. Those which gave no new DRS bands on 300 s grinding are denoted by the symbol — . The relative reactivity in experiment (I) showed similar features to the result given here, though comparison is possible only when the resulting CT complexes are colored, thus confirming that the presence of NaCl did not cause any change in, at least qualitatively, the relative reactivity of CT complex formation. Pairs C and D are excluded from the following discussion of relative reactivity.

Change in f(R) with Time. Although fast reaction was observed during the process of grinding, a very slow reaction continued to take place after grinding was stopped, for most component pairs studied. This is shown in Fig. 3, **k-4** being taken as an example.

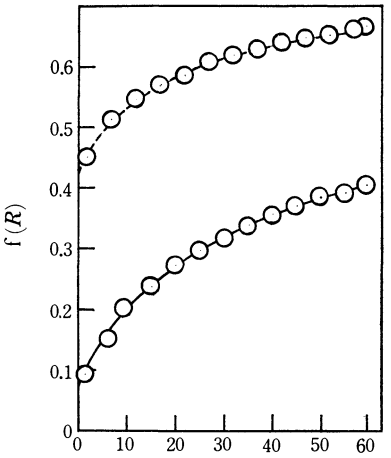

Fig. 3. The change of f(*R*) after grinding is ceased in the measurement of pyrene-*p*-chloranil (at 655 nm).
—— grinding for 30 s.
---- grinding for 300 s.

Time $t=0$ on the abscissa shows the time when the grinding (30 or 300 s) was stopped. Values for f(*R*) are plotted on the ordinate. The value of $[f(R)]_{t=0}$ corresponds to the total amount of the complex given in the process of grinding. Concentration-time curves could not be obtained due to the lack of information concerning (1) whether or not only one type of CT complex contributes, and (2) the molar extinction coefficient. Very few data are available so far on the molar extinction coefficients of solid CT complexes. When grinding was done for a longer time (*i.e.* 300 s), $[f(R)]_{t=0}$ became larger. Thus, the reaction is far from complete by grinding for 30 s. The leveling-off in the f(*R*)-*t* curve is only an apparent one. Only the region near the grain surface seems to have attained equilibrium. To bring the reaction completely up to true equilibrium, much more time will be needed. For a few component pairs, f(*R*) decreases with time because of a further reaction *via* the CT complex. This

is the case for a-**1**, a-**3**, a-**5**, j-**1**, and k-**1**.

Evaporating the Dichloromethane Solution. The results are given in Table 2, in which the symbol + denotes the appearance of a new color. The color obtained for each pair was in line with that obtained in the solid state reaction with a few exceptions. The symbol − denotes only the color of parent compounds shown by the remaining solid. Since judgement was made only from color change, none can be made when little color change is expected on CT complex formation, *i.e.*, when the CT complex to be obtained (if any) for the given pair is either colorless or in a very close color to that of parent compounds (*i.e.* $\lambda_{CT}<500$ nm). No symbol is given in the Table for these cases.

Discussion

Shape and Position of CT Bands. Most of the new bands can be considered as CT bands of microcrystals. In crystal, the single band in solution splits into several bands, each of which has a peculiar polarization *vs.* crystal axes. In the microcrystalline sample, these bands are amalgamated into a very broad band. Most of the CT bands were very broad, making it sometimes very difficult to find absorption maxima. Nevertheless, a fairly good linear relationship was found between transition energy and ionization potential of the donor (I_D) or the electron affinity of the acceptor (E_A), in most of the cases (Figs. 1 and 2).

Relative Reactivity. The observed difference in chemical reactivity can be interpreted as resulting, mainly from the difference in (i) chemical equilibria or (ii) reaction rates. An important factor in the former is the difference in lattice energy, while in the latter it is the molecular diffusion through the grain boundary. The "relative reactivity" in this study is judged by whether or not the CT band is found on grinding for 30 (or 300) s. The reaction does not proceed to equilibrium for most of the component pairs. Experiment (III) was carried out to see what the relative order of chemical equilibria is like. The chemical equilibrium between complex and component molecules is established in the dichloromethane solution. On evaporating, crystals of DADA··· and/or DD··· plus AA··· were formed. The crystals thus obtained should give information on the equilibrium in solid phase, when the process of crystallization is assumed to be slow enough to establish the equilibrium. The assumption seems to be valid in this experiment. There is generally a good parallelism between the solid state reactivity and the formation of the CT complexes in evaporating the dichloromethane solution (Tables 1 and 2). This shows that an apparent (false) equilibrium was established on the grain surface. This is not the true equilibrium, since a slow reaction (probably by slow diffusion through the grain boundary) still continues.

The relative reactivity should be interpreted in terms of molecular and/or crystal structure (Table 1). Taking the molecular structure into consideration, we make the following qualitative conclusions. (1) The reactivity depends largely on molecular size and structure (Table 1). Smaller molecules are more reactive. (2) For the molecules with the same number of rings, those with compact structure are more reactive (*i.e.* h>i>j, k>l>m>n>o).
(3) For the molecules with similar molecular size and structure, the pairs which have smaller I_D-E_A values are more reactive.

The importance of molecular geometry in determining molecular properties in solid phase is sometimes mentioned. Matsunaga[23] has found the "size and shape effect" in the ionic character of solid molecular compounds. Such an effect will play an important role also in the chemical reactivity in solid phase. The higher selectivity in chemical reaction might thus be expected in solid state rather than in solution.

The observed order of reactivity in solid phase are not in line with that of equilibrium constants in fluid solution. Similar findings are also reported by Hammick and Hutchison,[1] and by Suzuki and Seki[2] for

trinitrobenzene or trinitrotoluene complexes. For h-**4** and i-**4**, the former has greater reactivity in solid phase, though the equilibrium constant in fluid solution[24] is in the reverse order. This is also the case for k-**4** and l-**4**.

The origin of such a difference in reactivity cannot be understood only by means of molecular structure. The difference in crystal structure (space group and dimension of unit cell) undoubtedly plays an important role. In the solid state reaction in the system of mixed microcrystals, the reformation of the crystal on the grain boundary should occur during the course of reaction. If the crystal structure of the resulting CT complex is similar to that of at least one of the component molecules, the reformation will occur with a smaller activation energy. In order to confirm this hypothesis, however, the crystal data are necessary for the CT complex and for the parent molecules. Very few data of CT complexes are available at present to make such a discussion.

Thanks are due to Miss Yumiko Masumitsu and Mr. Shun-ichi Horai for their assistance in the measurement.

25) Ionization potentials are taken from: J. B. Birks, "Photophysics of Aromatic Molecules," Wiley-Interscience, New York (1970), Table 9.5. The ionization potential of a was assumed to be 6.5 eV after Briegleb (Ref. 18, p. 183). That of f was assumed to be 6.8 eV after Y. Matsunaga and G. Saito (Ref. 16).
26) Assignment to the second CT band was made according to Ref. 9, 13, 16, and 20 (for k-**1**, f-**4** and f-**6**, f-**1**, and d-**1**, respectively); compare the spacing between the band in question and the first CT band for a pair with that between the first and second CT bands for another pair composed of the same donor and a different acceptor, when both bands are reported for the latter pair and when the second CT band is associated with the second highest molecular orbital of the donor (for d-**2**, d-**3**. f-**3**, k-**2**, k-**3**); compare with d-**1**—d-**3** (for e-**1**—e-**3**). The band at 20800 cm^{-1} for i-**3** was assigned to the second CT band since the difference in transition energy of this band and that of the first CT band is close to the difference of the first and second ionization potentials of π-electron system in anthracene (P.A. Clark, F. Brogli and E. Heilbronner, *Helv. Chim. Acta*, **55**, 1415 (1972); See also, J. Aihara and H. Inokuchi, *Chem. Lett.*, **1973**, 421). For a-**9** and a-**10**, the bands at 18900 and 21700 cm^{-1}, respectively, were tentatively assigned to the second CT bands from the relationship shown in Fig. 2.

The Crystal and Molecular Structure of Tris(π-cyclopentadienyl nickel)tertiary-butylammonium

Nagao KAMIJYO and Tokunosuké WATANABÉ*

Government Industrial Research Institute, Osaka, Midorigaoka, Ikeda, Osaka 563

** Faculty of Science, Kwansei Gakuin University, Nishinomiya 665*

(Received July, 30, 1973)

The crystal structure of tris(π-cyclopentadienylnickel)tertiary-butylammonium, t-$C_4H_9N(\pi$-$C_5H_5Ni)_3$, has been determined from single crystal X-ray diffractometer data. The space group is C2/c and the lattice constants are $a=28.40$ Å, $b=9.16$ Å, $c=15.28$ Å, $\beta=100°30'$, and $Z=8$. The refinement was carried out using block-diagonal least-squares calculation including anisotropic temperature factors for the three nickel atoms. The final R index for 1620 reflections is 0.138. The molecule is of approximately a trigonal pyramidal structure with an apical nitrogen atom on a triangle of the nickel atoms. The interatomic distances are 2.33—2.39 Å for nickel to nickel, 1.93—1.98 Å for nickel to nitrogen. The distances between a nickel atom and a centroid of a cyclopentadienyl ring are 1.74—1.81 Å. The three cyclopentadienyl rings are inclined to the nickel triangle plane at 68°—69°.

Tris(π-cyclopentadienylnickel)tertiary-butylammonium, t-$C_4H_9N(\pi$-$C_5H_5Ni)_3$, synthesized by a reaction of $(t$-$C_4H_9N)_2S$ with $(\pi$-$C_5H_5)_2Ni$ or with $(\pi$-$C_5H_5Ni(CO))_2$ in heptane solution, is reported to be paramagnetic (1.68 B.M., $g=2.035$).[1] IR, UV, and EPR spectra suggest that the molecule has a pyramidal structure with an apical nitrogen atom on a triangle of the nickel atoms.[1]

We have carried out a crystallographic study of the title substance in order to confirm the suggested structure, special attention being paid to the Ni-Ni distances because of their bondings including one unpaired electron.

Experimental

Crystals obtained from a heptane solution[1] were blue-black irregular platelets. Some effort was required for selecting a suitable specimen, and a platelet $0.4\times0.4\times0.2$ mm was used. Weissenberg photographs showed the crystal to be monoclinic and the systematically absent reflections, hkl for $h+k=2n+1$ and $h0l$ for $l=2n+1$, indicated the space group to be Cc or C2/c. The space group was assumed to C2/c on the evidence of a centric distribution of the three-dimensional intensities.[2] The unit cell dimensions were measured on a Hilger and Watts linear diffractometer using Mo$K\alpha$ radiation ($\lambda=0.7107$ Å). Intensity data were collected with a linear diffractometer using monochromatic Mo$K\alpha$ radiation. The crystal was oriented about the b-axis, ten layers being recorded. There were 2170 independent reflections, of which 550 with $\sin\theta/\lambda\geq0.59$ Å^{-1} were too weak to be observed and were neglected for the structure determination. The intensity data were corrected for Lorentz and polarization factors and placed on an approximately absolute scale by Wilson's method. The crystal data are as follows.

Tris(π-cyclopentadienylnickel)tertiary-butylammonium; t-$C_4H_9N(\pi$-$C_5H_5Ni)_3$; MW=442.1.

Monoclinic: Space group C_{2h}^6—C2/c; $a=28.40\pm0.03$ Å, $b=9.16\pm0.02$ Å, $c=15.28\pm0.02$ Å, $\beta=100°30'\pm10'$; $Z=8$. $D_x=1.48$ g·cm^{-3}, $D_m=1.5$ g·cm^{-3} (flotation method).

The linear absorption coefficient of the substance is 28.0 cm^{-1} for Mo$K\alpha$ radiation. Thus the absorption parameter μR_{max} was 0.6, and no correction for absorption was made.

† $P(U,V,W)=\sum\sum\sum|F(hkl)|^2(1-\exp(-Q\sin^2\theta/\lambda^2))^2\cos(2\pi(hU+kV+lW))$ with $Q=30$.[3]

Determination of the Structure

Appoximate positional parameters of the three Ni atoms were determined from a modified three-dimensional Patternson function.† From a Fourier synthesis calculated with all terms phased by the Ni atoms, twelve out of the twenty non-hydrogen light atoms of the whole molecule were located. Ten of these twelve atoms were easily assigned to the carbon atoms of two cyclopentadienyl rings, and the remaining two were inferred to two carbon atoms of the t-butyl group. Further Fourier syntheses did not reveal the remaining light atoms. The coordinates of eight atoms were assumed with the use of conventional bond distances and angles. By repeating diagonal least-squares refinement with isotropic temperature factors and Fourier syntheses, all the positions of non-hydrogen atoms were obtained. Several cycles of block-diagonal least-squares refinement, minimizing the function $\sum w(k|F_o|-|F_c|)^2$, were carried out with anisotropic temperature factors for the nickel atoms and isotropic ones for all the remaining non-hydrogen atoms. A weighting scheme, $w=1$ if $F_o\geq14.0$, otherwise $w=0.2$, was used. The R index for 1620 reflections ceased to decrease at 13.8%. The final positional and temperature parameters are shown in Tables 1 and 2. The atomic numbering system is shown in Fig. 1. The temperature factors of the carbon atoms of the cyclopentadienyl groups and of the end-members of the t-butyl group are considerably large, especially for C(2), C(3), C(4), C(15), C(16), C(17), C(18) and C(19). The atomic scattering factors were taken from the International Tables for X-ray Crystallography,[5] the contribution of hydrogen atoms being disregarded. Anomalous dispersion corrections of the scattering factors were not made.

The initial solution of the structure and preliminary refinement were made with the program written by one of us (N.K.). The final refinement was performed with the program HBLS-IV[4] written by Dr. T. Ashida for HITAC-5020E computer. The table of the observed and calculated structure factors is preserved by The Chemical Society of Japan. (Document No. 7402).

Description of the Structure and Discussion

The molecular structure is shown in Fig. 1. The three nickel atoms almost form an equilateral triangle. The *t*-butylamine group is situated perpendicularly to this triangle and the three cyclopentadienyl groups are disposed symmetrically. The molecule thus takes approximately a trigonal pyramidal structure with a symmetry C_{3v}–3m. The suggested structure for this molecule by IR, UV, and EPR studies[1] has now been confirmed.

The bond distances and bond angles associated with the nickel atoms are given in Table 3. Not much can be said about the C–C and C–N bond distances and the corresponding bond angles, since the temperature factors of the carbon atoms are large. The cyclopentadienyl groups are essentially planar, the mean deviations of atoms from the least-squares planes of these rings being 0.07, 0.04 and 0.05 Å. The average distance of the C–C bonds in the rings is 1.46 Å, though the maximum deviation amounts to 0.15 Å. The three cyclopentadienyl planes are inclined to the Ni_3 plane by amounts 68°—69° as measured from the opposite direction of the *t*-butyl group. The distances between nickel atoms and centroid of cyclopentadienyl rings are 1.81, 1.80 and 1.74 Å. The

perpendicular distance between the apical nitrogen atom and the nickel triangle is 1.40 Å. The distance of the N–C bond is 1.18(4) Å and the mean angle N–C(1)–C is 118°(3), the numbers in parentheses being the standard deviations. The three end-carbon atoms of the t-butyl group lie almost parallel to the Ni_3 cluster plane. The Ni–N bond roughly makes a tetrahedral angle with the bonds of nickel-to-cyclopentadienyl ring. This situation is in contrast to the cases of the three congeneric complexes, $(C_5H_5Ni)_3(CO)_2$,[7] $(C_5H_5Co)_3S_2$[8] and $(C_5H_5Ni)_3S_2$,[6] where the cyclopentadienyl rings are at right angles to the metallic cluster plane. The mean value of the metal-metal distances, 2.364 Å, found in the present analysis can be compared to the value 2.39 Å, reported for $(C_5H_5Ni)_3(CO)_2$, but is considerably shorter than the values reported for $(C_5H_5Ni)_3S_2$, 2.801 Å, and for $(C_5H_5Co)_3S_2$, 2.691 Å.

A simple M.O. scheme of the metal-metal bondings based upon Cotton-Haas' calculation[9] about the $(Re_3Cl_{12})^{3-}$ ion can be used to account for the Ni–Ni distances of these compounds. Each nickel atom is bonded to the nitrogen atoms as well as to a cyclopentadienyl ring through four electron pair bonds tetrahedrally, 4s $4p^3$. The nickel-to-nickel bonding can be interpreted in terms of the interactions of the electrons. One of the five d-orbitals for each nickel atom may act as non-bonding and the remaining twelve orbitals of the three nickel atoms may form six bonding and six anti-bonding orbitals. There are 49 electrons available for the formation of the molecule; 30 from the three nickel atoms, 15 from the three cyclopentadienyl groups and 4 from the nitrogen atom. Twenty-four of these are used for the bondings for Ni-N's and Ni-cyclopentadienyl groups. Six of these enter the non-bonding orbitals. Thus the remaining 19 electrons interact between the Ni–Ni bondings. Twelve of these will occupy the bonding orbitals and seven the anti-bonding levels giving the molecule the paramagnetic character. The electronic configuration of the nickel-nickel interaction in this complex is, therefore, close to that of $(C_5H_5Ni)_3(CO)_2$ which also has 19 electrons in the nickel-nickel orbitals. With this crude scheme one may understand the close resemblance of the intermetallic distances of these two complexes. The congeneric complexes, $(C_5H_5Ni)_3S_2$ and $(C_5H_5Co)_3S_2$, have much longer intermetallic distances, having four more electrons and one more electron respectively, in the anti-bonding orbitals. The Ni–N interatomic distances as observed in the present compound, 1.93, 1.95 and 1.98 Å, are considerably longer than the sum of the covalent radii of N and Ni atoms, 1.85 Å. In $(CH_3N)_2Fe_3(CO)_9$[10] and $((C_6H_5)_2CNN)_2Fe_3(CO)_9$[11] also, the metal-nitrogen distances 1.93 and 1.95 Å are greater than the sum of the covalent radii, 1.87 Å. The mean distances between a nickel atom and the five carbon atoms of a cyclopentadienyl group are 2.20, 2.14 and 2.15 Å, which can be compared with the value 2.20 Å, reported for nickelocene.[12]

The molecular arrangement in the crystal, projected along the b-axis, is shown in Fig. 2. There are no special short intermolecular contacts in the crystal.

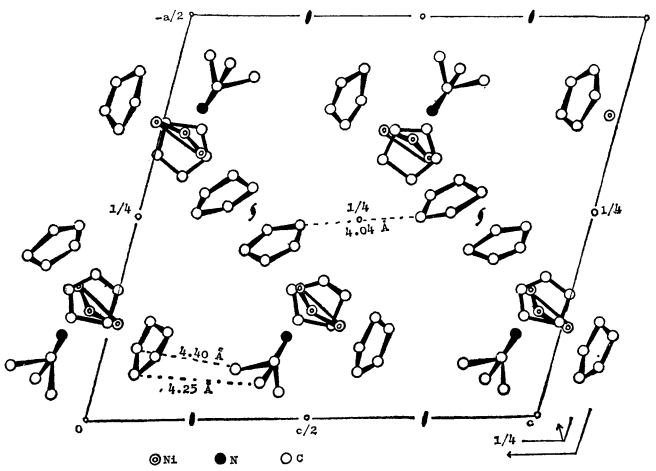

Fig. 2. Projection of the crystal structure along the b-axis (b-axis upwards).

We are indebted to Prof. S. Otsuka, Osaka University, for his interest in this work and for the supply of the sample. We are also indebted to Takeda Chemical Industries Ltd. for use of the Hilger and Watts linear diffractometer. We thank Dr. K. Ogawa and Mrs. H. Tamura, Osaka University, for their discussions.

(Received August 6, 1973)

Using the modified CNDO MO method, the electronic structures of Pd(II)- and Hg(II)-ethylene complexes have been studied successfully. Our MO calculations have shown that the nucleophilic attack of OH^- on ethylene was accelerated by Pd(II) and Hg(II), and that the acceleration by Hg(II) was larger than that by Pd(II), these results agree well with those of the experiments. The *cis*-attack of OH^- in the oxymercuration has also been discussed by the use of the results obtained by the MO calculations. The mechanism of the *cis*-type four-center addition of OH^- to ethylene in the Wacker reaction, which was supposed by Henry and Jira *et al.* in spite of any direct evidence, has been supported by the MO calculations. Our calculations have been able to explain the Markovnikoff rule in the Wacker reaction and in the oxymercuration of propylene.

A number of reactions of nucleophilic attack on olefins coordinated to a metal ion are well known.[1-3] Complex formation reduces the electron density between the carbon atoms of double bond, rendering the double bond more susceptible to nucleophilic attack. This must be the first requisite for the catalytic ability of transition metal ions in nucleophilic reactions. It is, therefore, interesting from the viewpoint of catalytic chemistry to investigate the electronic structures of olefins coordinated to transition-metal ions. There have, though, been few MO studies[4,5] of such transition-metal olefin complexes supposed to be intermediates in catalytic reactions.

The Wacker reaction[1-3] and the oxymercuration[6,7] are known as nucleophilic reactions onto a coordinated olefin; in them Pd(II)- and Hg(II)-olefin complexes are considered to be reaction intermediates. We carried out MO calculations of Pd(II)- and Hg(II)-olefin complexes in order to investigate the electronic structures of the coordinated olefins and discussed the catalytic activities of Pd(II) and Hg(II). Also, using the MO method, we studied whether the *cis*-addition occurs in the oxymercuration, or whether the *trans*-addition does, and whether or not the *cis*-addition of OH^- in the Wacker reaction is a reasonable mechanism; these problems have never been discussed theoretically. Since some work[8,9] using the Iterative Extended Hückel MO method has been done to investigate the catalytic reactions, it is also our object to examine the possibility of applying the more accurate semi-empirical SCF-MO method to studies in the field of catalytic chemistry.

Calculation and Models

Calculation. All the valence orbitals, including the 5d-atomic orbitals of the Hg atom, were considered explicitly. The modified CNDO-type approximation was used; the Hartree-Fock matrix elements have been given in our previous papers.[10] The resonance integral, H_{rs} $(r \neq s)$, was calculated according to the Wolfsberg-Hermholz approximation:[11]

$$H_{rs} = -kS_{rs}(I_r+I_s) \quad (1)^{12}$$

In order to determine the value of k, the MO's of ethylene, propylene, methane, carbon monoxide, and formaldehyde were calculated using various values of k. That is, as to the MO energies of ethylene and the ionization potentials of these compounds, the best-fitting value of k was 0.40.[13] Hereafter, the value of k will be taken as 0.40 for all s and p orbitals. For the AO pair including the d-orbital, the value of k was determined to be equal to 0.50, thus the calculated first and second d-d transitions of $PdCl_4^{-2}$ coincide with the experimental results, as is shown in Table 1.

TABLE 1. THE FIRST AND SECOND d-d TRANSITION ENERGIES OF $PdCl_4^{-2}$

k	0.55	0.50	Obsd	
$^1A_{2g}$	2.62 (eV)	2.54 (eV)	2.62 (eV)[a]	2.48 (eV)[b]
^1E_g	3.40	3.44		2.80

a) Ref. 15. b) Ref. 16.

The values of the ionization potentials, I_r, and the one-center Coulomb repulsion integrals, γ_{rr}, of ligand atoms were taken from Jaffé *et al.*,[16] while those values of the Pd atom were taken from Di Sipio *et al.*[17] Since those values of the Hg atom were not given in the paper of Di Sipio *et al.*, the values of I_r were taken from Bach's paper[18] and those of γ_{rr} were estimated as follows;

$$\gamma_{rr}(6)_{\text{semi-emp}}/\gamma_{rr}(5)_{\text{semi-emp}} = \gamma_{rr}(6)_{\text{nonemp}}/\gamma_{rr}(5)_{\text{nonemp}} \quad (2)$$

where $\gamma_{rr}(5)$ and $\gamma_{rr}(6)$ represent the one-center Coulomb repulsion integrals of a fifth-row element and a sixth-row element, which belong to the same group in the periodic table, respectively. The subscripts "semi-emp" and "nonemp" indicate the semi-empirical value and the nonempirical value of γ_{rr} respectively. $\gamma_{rr}(N)_{\text{nonemp}}$ $(N=5$ or $6)$ was calculated using Clementi's AO,[19] and $\gamma_{rr}(5)_{\text{semi-emp}}$ was taken from Di Sipio's paper.[17] Then the γ_{rr} (6) values used in this work were obtained from the values of $\gamma_{rr}(6)_{\text{semi-emp}}$ by applying the least-squares method and by imposing the restrictive condition[17] that the values of $\gamma_{rr}(6)$ varied linearly with the atomic number. In order to calculate the overlap integrals, a single Slater-type orbital[19,20] was used for all the s- and p-orbitals; the

Table 2. Orbital exponent (ζ_r), valence state ionization potential (I_r), and one-center Coulomb repulsion integral (γ_{rr}) of Pd and Hg atoms

Atom	AO	ζ_r[a]	C[b]	I_r	γ_{rr}

		3.032	0.5401		
	6s	2.649		10.44	7.40
	6p	2.649		5.00	6.31

a) The double-ζ form AO's are used only for d orbitals (Ref. 21). b) Because we neglect the contribution of the 3d orbital in the case of the Pd atom and the contributions of the 3d and 4d orbitals in the case of the Hg atom, the 4d orbital of the Pd atom and the 5d orbital of the Hg atom are renormalized in this work. c) Ref. 17. d) Ref. 18. e) The estimated values.

double-ζ-form orbital[21] was used only for the d-orbitals of metal atoms. The values of the AO exponents, ζ_r, I_r and γ_{rr} of the Pd and Hg atoms are listed in Table 2.

We discussed the bond strength in terms of E_{AB},[22-24] the contribution of the interaction between A and B atoms to the total energy; it is written, using the approximations used in this work, as follows;

$$E_{AB} = E_{AB}^{(1)} + E_{AB}^{(2)} + E_{AB}^{(3)} \quad (3)^{12}$$

$$E_{AB}^{(1)} = 2\sum_r^A \sum_s^B P_{rs}H_{rs} \quad (4)^{12}$$

$$E_{AB}^{(2)} = -0.5\sum_r^A \sum_s^B P_{rs}^2(rr|ss) \quad (5)^{12}$$

$$E_{AB}^{(3)} = \sum_r^A \sum_s^B (N_r - P_{rr})(N_s - P_{ss})(rr|ss) \quad (6)^{12}$$

where $\sum^A$ represents the summation on the A atom.

Geometries of Pd(II)- and Hg(II)-Olefin Complexes. Because of the lack of knowledge of the accurate configurations of these compounds, the configurations of the olefin moieties in these complexes were assumed to be the same as those of the corresponding free olefins.[25] The distances between the metal atom and the center of the double bond were fixed as 2.31 Å for Pd(II) Complexes[25] and as 2.34 Å for the Hg(II) complexes.[4] The metal-olefin coordination bond was assumed to intercept the double bond perpendicularly at its center. The coordinate systems for these complexes are given in Fig. 1.

Models for the Oxymercuration and the Wacker Reaction. In the oxymercuration, both *cis*- and *trans*-addition products were formed from the strained olefins, such as norbornene and bicyclo-[2,2,2]-oct-2-ene,[7,26-29] although only a *trans*-addition product was formed from nonstrained olefins.[6] Therefore, it is meaningful to shed some light on the course of the addition using an MO method. Since mercurinium ions have been postulated as intermediates in oxymercurations of olefins,[6,30] we assumed both *cis*- and *trans*-oxymercurials were derived from a common mercurinium ion, and calculated the MO's of the models for *cis*- and *trans*-addition (cf. Fig. 2). In order to ascertain the effects of reactants and ligands, we calculated the MO's of reaction systems, such as $Hg(C_2H_4)^{+2}\leftarrow OH^-$, $HgCl(C_2H_4)^{+}\leftarrow OH^-$, $HgCl(C_3H_6)^{+}\leftarrow OH^-$, $HgCl(cis\text{-}2\text{-}C_4H_8)^{+}\leftarrow OH^-$, and $HgCl(trans\text{-}2\text{-}C_4H_8)^{+}\leftarrow OH^-$, in which OH^- was assumed to approach olefin in the *trans* position of Hg(II) (see Fig. 3.), since the *trans*-oxymercurials were formed in general.

In the case of the Wacker reaction, an oxypalladate intermediate has not been observed. However, its existence has been postulated on the basis of kinetic studies[31-35] and the step of its formation from Pd(II)-olefin complex has been considered to be the rate-

determining step. The models for these intermediates are shown in Fig. 3.

In order to investigate the selectivity in the Wacker reaction[34] and the oxymercuration,[6] we carried out the MO calculation of the models described in Fig. 4.

Results and Discussion

Pd(II)- and Hg(II)-ethylene Complexes. The electron densities, the π-bond order, P_π,[37] the π^*-bond order, P_{π^*},[37] the quantities of transferred electrons from ethylene to metal-ligand part, ΔQ, are shown in Table 3. The electron densities on the Pd and Hg atoms increase with the decrease in the electron negativity of the halogen atom, except in the case of $HgCl(C_2H_4)^+$ or $HgBr(C_2H_4)^+$. The electron density on the C atom is decreased by the coordination as follows; free ethylene>ethylene coordinated to Pd(II)>ethylene coordinated to Hg(II). It is notable that this decreasing order agrees with the increasing reactivity for the nucleophile; *i.e.*, the nucleophilic attack of OH^- in the Wacker reaction slowly proceeds,[31–35] and that in the oxymercuration proceeds very fast,[38] while the reaction can not occur in the absence of Pd(II) and Hg(II).

Table 3. The electronic structures of Pd(II)- and Hg(II)-ethylene complexes

Compound	Electron density: Metal *d*	Metal *sp*	Carbon	P_π[a]	P_{π^*}[b]	ΔQ[c]

$HgBr(C_2H_4)^+$	0.074	0.104	0.370	0.344

a) $P_{d\pi-\pi^*}$ represents the bond order matrix element between d_π orbital of metal and π^*-MO of ethylene, and the others such as $P_{d\sigma-\pi}$, *etc.*, represent similar bond order matrix elements.

The values of ΔQ in the Hg(II)-complexes are larger than those in the Pd(II)-complexes, while the values of P_π and P_{π^*} are smaller than those in the Pd(II)-complexes. The coordination bond orders are shown in Table 4. The π-acceptor bond orders, $P_{d\pi-\pi^*}$, in the Pd(II)-complexes are greater than those in the Hg(II)-complexes; this agrees with the larger values of P_{π^*} in the Pd(II)-complexes relative to those values in the Hg(II)-complexes. While in Pd(II)-complexes the contributions of the d-orbitals are remarkably large, their contributions are very small in the Hg(II)-complexes, in which the 6s and 6p orbitals of Hg(II) mainly contribute to the coordination bond. The small contribution of the 5d atomic orbitals of Hg(II) is considered to be due to the $5d^{10}$ configuration of Hg(II) as well as Ag(I)-ethylene complexes.[10b,39]

The Oxymercuration. The results are given in Fig. 2. It may be seen from a comparison of the total energy that the *cis*-attack system is more stable than the *trans*-attack system. The absolute value of E_{C-O} in the *cis*-attack system is smaller than that in the *trans*-attack system, probably because of the interaction of the O atom with the Hg atom in the *cis*-attack system, while there is no interaction between the O and Hg atoms in the *trans*-attack system. On the other hand, the bonding interaction between the O and Hg atoms contributes to the larger stabilization of the *cis*-attack system, suggesting that the mercurinium ion is stabilized by the coordination of the nucleophile. Our results agree with the mechanism proposed by Bach *et al.*:[29] (a) if the concentration of the nucleophile is sufficient, or if the solvent coordinates to Hg(II) to interfere with the coordination of the nucleophile, the *trans*-attack may occur, since the nucleophile in the *trans*-position interacts with the C atom of olefin more strongly than that in the *cis*-position; and (b) the mercurinium ion which is formed from a strained olefin, such as norbornene, is relatively short-lived and is

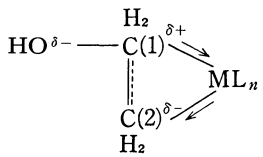
a) See Fig. 3—c. b) The E_{AB} value of bond C(1)-O (eV unit). c) The relative position of OH^- to ethylene is the same as that in $Hg(C_2H_4)^{2+} \leftarrow OH^-$ system.

likely to react with the intimate nucleophile coordinated the mercurinium ion nearest to the olefin, since there is a remarkable bonding interaction between the C and O atoms, though this interaction is weak relative to that in the *trans*-attack system. In this case, the *cis*-attack may occur preferably.

The calculated results of the models in Fig. 3 are given in Table 5, together with the results on the interaction of OH^- with free ethylene and on the interaction of OH^- with the ethylene coordinated to the $PdCl_3^-$ anion.[40] The values of E_{C-O}[41] are negative in all cases, suggesting a bonding interaction between the C atom of ethylene and the O atom of OH^-. The absolute values of E_{C-O} increase in the following order; free ethylene$<PdCl_3(C_2H_4)^-<HgCl(C_2H_4)^+<Hg(C_2H_4)^{+2}$. Those results suggest that the nucleophilic attack of OH^- on ethylene is accelerated by Pd(II) and Hg(II), and that the acceleration by Hg(II) is larger than that by Pd(II), which agrees well with the catalytic behaviour of Hg(II)[38] and Pd(II).[35] Compared with the absolute values of $E_{C-O}^{(1)}$, $E_{C-O}^{(2)}$, and $E_{C-O}^{(3)}$ in $C_2H_4 \rightarrow OH^-$ system, those of $E_{C-O}^{(1)}$ and $E_{C-O}^{(3)}$ are largely increased in the $PdCl_3(C_2H_4)^- \leftarrow OH^-$ system, and the values of $E_{C-O}^{(1)}$ and $E_{C-O}^{(2)}$ are also increased in the $Hg(C_2H_4)^{+2} \leftarrow OH^-$ and $HgCl(C_2H_4)^+ \leftarrow OH^-$ systems. Since $E_{AB}^{(1)}$ and $E_{AB}^{(2)}$ indicate approximately the contribution of covalent interaction to the total energy, the existence of Hg(II) and Pd(II) may cause an increase in the covalent bonding ability of ethylene with OH^-. From the results that the electron density on the C atom in ethylene complexes decreases in the following order; free ethylene $> PdX_3(C_2H_4)^- > HgX(C_2H_4)^+ > Hg(C_2H_4)^{+2}$, the absolute values of $E_{C-O}^{(3)}$ can be effected to this order, since $E_{C-O}^{(3)}$ represents approximately the electrostatic energy and since the O atom has a negative charge. However, the absolute values of $E_{C-O}^{(3)}$ increase in the following order: $Hg(C_2H_4)^{+2} \leftarrow OH^- < C_2H_4 \leftarrow OH^- < HgCl(C_2H_4)^+ \leftarrow OH^- < PdCl_3(C_2H_4)^- \leftarrow OH^-$; this trend disagrees with the decreasing trend of electron density on the ethylene carbon atom in the Hg(II)- and Pd(II)-ethylene complexes. This disagreement is a result of the difference in the polarization of the ethylene part between the Pd(II)- and Hg(II)-systems (see Table 5). The π-acceptor bond contributes to the coordination bond in the Pd(II)-ethylene complex, while it scarcely contributes in the Hg(II)-ethylene complex. Therefore, the electron transfer shown in Scheme 1 is more feasible in Pd(II)-complexes than in Hg(II)-complexes, which leads to a higher polarization, a smaller electron density on the C(1) atom, and a larger absolute value of $E_{C-O}^{(3)}$ in the Pd(II)-complexes than in the Hg(II)-complexes. Therefore, the trend of $E_{C-O}^{(3)}$ the is not same as that of the electron density of the C atom in the Pd(II)- and Hg(II)-complexes. That is, the high catalytic activity of Hg(II) is not due to the electrostatic energy, while it is probably important in the long-range interaction.



Scheme 1

In the above Scheme, M and L represent a metal and ligand respectively and "→" indicates the direction of electron transfer.

The absolute value of $E_{C-O}^{(3)}$ in the $HgCl(2\text{-}C_4H_8)^+$ system is remarkably large, probably because of the larger positive charge on the olefinic carbon atom of butene coordinated to Hg(II).[42] In these cases, the polarization is small.

When the mercurinium ion has an anion ligand, the absolute value of E_{C-O} is smaller than that of the system containing no anion ligand.

The absolute values of E_{C-O} for various reactants increase in the following order (Table 5, 8); C(β) atom of $CH_3CH{=}CH_2 < C_2H_4 < trans\text{-}2\text{-}C_4H_8 < cis\text{-}2\text{-}C_4H_8 <$ C(α) atom of $CH_3CH{=}CH_2$ in $HgCl(olefin)^+ \leftarrow OH^-$ system. The rate constants for the oxymercuration have been reported to increase in the following order;[38] $trans\text{-}2\text{-}C_4H_8 < C_2H_4 < cis\text{-}2\text{-}C_4H_8 < CH_3CH{=}CH_2$. Our results do not agree with this order. However, it has been shown by our calculation that the reactivity of *cis*-2-C_4H_8 is higher than that of *trans*-2-C_4H_8.

The results given in Table 5 reveal the following aspect of the structure of the intermediate in the oxymercuration; (1) The electron density on the C(1) atom is larger than that on the C(2) atom except in the case of $Hg(C_2H_4)^{+2} \leftarrow OH^-$. (2) The absolute value of $E_{Hg-C(1)}$ is larger than that of $E_{Hg-C(2)}$. These situations are shown in the following Scheme, which agrees well with the situation usually assumed.[7]

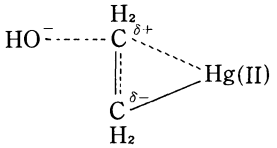
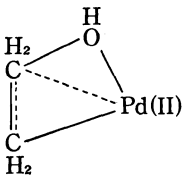


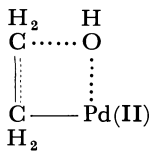
Scheme 2

In the above Scheme, "——" and "----" represent the strong interaction and the weak one respectively.

Wacker Reaction. The calculated results on intermediate models **1**—**5** are given in Table 6. From the intermediate **1** to the intermediate **5**, the values of E_{total} and E_{C-O} decrease gradually; this shows the increases in the stability of the intermediate models and in the strength of the C(1)–O bond. These results suggest that this reaction model is reasonable for the Wacker reaction. The electron densities on the Pd and C(1) atoms decrease in the course of this, while that of the C(2) atom increases. From the above results, ethylene can be said to be polarized by the approach of OH^-. Proceeding from the intermediate **1** to the intermediate **5**, the absolute values of $E_{Pd-C(1)}$, E_{Pd-O}, and P_π decrease, whereas that of $E_{Pd-C(2)}$ increases; *i.e.*, the bonds of C(1)–O and Pd–C(2) become stronger, although the bonds of Pd–C(1), Pd–O, and C–C become weaker, relative to those of the **1** intermediate. These results, pictured in Scheme 3, agree with the *cis*-type four-center reaction speculated by Henry[32] and Jira *et al.*[33] (see Scheme 4.)



Scheme 3



Scheme 4

The results for the intermediate models **5**—**8** (Fig. 3) are given in Table 7. The bending of protons about C(1) makes the total energy more negative, suggesting that the system is more stabilized and that the C(1) atom changes from sp^2 to sp^3. Also, this bending brings about decreases in the absolute values of $E_{Pd-C(1)}$ and

TABLE 7. THE *cis*-BENDING OF PROTONS OF INTERMEDIATES[a] IN THE WACKER REACTION OF $PdCl_2(C_2H_4)OH$

Intemediate	5	6	7	8

$E_{C(1)-O}$[b]	−11.22	−12.59	−13.68	−13.89
$E_{Pd-C(1)}$[b]	−1.94	−1.87	−1.83	−1.74
$E_{Pb-C(2)}$[b]	−6.38	−6.43	−6.14	−6.87
E_{Pd-O}[b]	−12.34	−12.26	−11.92	−12.00
P_π	0.513	0.491	0.475	0.443

a) See Fig. 3. b) eV unit.

P_π and increases in the absolute values of $E_{C(1)-O}$ and $E_{Pd-C(1)}$, which reveal that the reaction more proceeds from the intermediate **5**. However, the bending of the C(2)–H bond destabilizes the system, whereas the absolute values of $E_{C(1)-O}$ and $E_{Pd-C(2)}$ are increased and those of $E_{Pd-C(1)}$ and P_π are decreased. Therefore, any *cis*-bending of the protons about the C(2) atom hardly occurs. These results are considered to be due to the polarization of ethylene, which is expected to be enhanced by the π-acceptor bond with Pd(II), as has been shown in Scheme 1; the C(2) atom should have sp^2 character to obtain the electron through the π-acceptor bond, leading to no *cis*-bending of its proton.

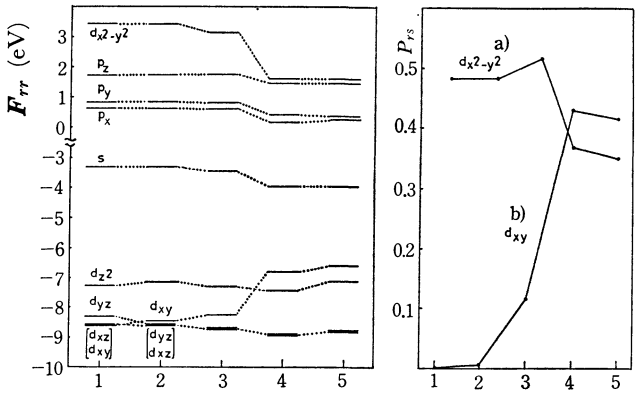

Fig. 5. The changes of values of F_{rr} and bond order. a) The sum of bond orders between $d_{x^2-y^2}$ of Pd atom and s, p_x, p_y orbitals of O atom. b) The sum of bond orders between d_{xy} of Pd atom and s, p_x, p_y orbitals of O atom.

Then, the changes from the intermediate **1** to the intermediate **5** were investigated in detail. The values of the Fock-matrix elements, F_{rr}, are shown in Fig. 5-A, together with the sum of the values of the density matrix elements between the $d_{x^2-y^2}$ orbital of the Pd atom and the s, p_x and p_y orbitals of the O atom, and those between the d_{xy} orbital and the s, p_x, and p_y orbitals of these atoms (Fig. 5-B). There is a remarkable increase in the value of $F_{d_{xy}d_{xy}}$ and a decrease in the value of $F_{d_{x^2-y^2}d_{x^2-y^2}}$, while there are few changes in the other F_{rr}. These remarkable changes are due to the moving of OH^- in the xy plane and suggest the change in the Pd–O bonding character. As is shown in Fig. 3-B, the contribution of the d_{xy} orbital to the Pd-O bond increases, although that of $d_{x^2-y^2}$ decreases in the reaction course. In other words, OH^- attacks the C(1) atom, interacting with the d_{xy} orbital, as has been proposed by Cossee *et al.*[9,43]

Markovnikoff Rule in These Reactions. We calculated the MO's of the models for the nucleophilic attack on propylene; the results are given in Fig. 4 and Table 8. In both the Pd(II)- and Hg(II)-systems, attack on the C(1) atom gives a lower total energy than the attack on the C(2) atom, which reveals that the former attack is superior to the latter attack. Also,

Table 8. Nucleophilic attack of OH^- to propylene

State[a]	$PdCl_2(OH)(C_3H_6)^-$		$HgCl(C_3H_6)^+ \leftarrow OH^-$	
	A	B	C	D
E_{total}[b]	−2426.6	−2426.3	−2353.0	−2352.6
E_{C-O}[b]	−5.596	−4.756	−5.545	−4.528
$E_{C-O}^{(1)}$[b]	−3.674	−3.793	−3.063	−2.923
$E_{C-O}^{(2)}$[b]	−0.618	−0.660	−1.175	−1.185
$E_{C-O}^{(3)}$[b]	−1.305	−0.303	−1.307	−0.420
P_π	0.669	0.718	0.531	0.535

a) See Fig. 4. b) eV unit.

the absolute values of $E_{C(1)-O}$ of models [A] and [C] are greater than those of models [B] and [D]. It is obvious from Table 8 that this difference is a result of the difference of $E_{C-O}^{(3)}$, suggesting that this selectivity is determined by the electrostatic energy. The carbon atom attacked by OH^- is positively charged in both Pd(II)- and Hg(II)-systems(see Tables 5 and 6 and Fig. 4), and the propylene is polarized by the hyperconjugation of the methyl group, as follows,

$$CH_3\text{-}\overset{\delta+}{C}H=\overset{\delta-}{C}H_2$$

Scheme 5

Therefore, the attack on the C(α) atom is superior to the attack on the C(β) atom, since the former attack causes the same polarization, while the latter attack causes an inverse polarization.

As has been described above, the semi-empirical SCF-MO method using the modified CNDO approximation gives fruitful results; this encourages us to apply this method to studies of the other catalytic reactions.

The calculations were carried out by means of the FACOM 230—60 Computer in the Data Processing Center at Kyoto University.

The authors are grateful to Dr. Hideyuki Konishi for his help with these calculations. They also wish to thank Professor Dr. Katsuhiko Ichikawa for his instructive suggestions.

The viscosity *B* coefficients for the three homologous series of sodium alkane carboxylates (acetate to butyrate), sodium *n*-alkyl sulfonates (methyl to hexyl), and *n*-alkylammonium chlorides (methyl to hexyl) in aqueous solutions at 25 °C have been determined. The *B* values increase linearly with the number of carbon atoms in the alkyl chains for each homologous series studied in this work, as well as for a homologous series of *n*-alkyl sulfate ions previously studied. In the case of the three kinds of organic anions with the same alkyl groups, the *B* values increase in the order: $-COO^- \gg -SO_3^- > -OSO_3^-$. The ion-solvent interaction effect, as estimated by the combination of the *B* values with the molal volume at an infinite dilution for ions, is positive for each carboxylate ion; however, it is negative for the lower alkyl sulfonate, alkyl sulfate and alkylammonium ions. From these facts, $-COO^-$ may be classified as an "electrostrictive structure-maker," whereas, $-SO_3^-$, $-OSO_3^-$, and $-NH_3^+$ are "electrostrictive structure-breakers." In this connection, the reported specific interactions of these ionic parts with simple counter-ions on the activity coefficients of organic electrolytes, the counter-ion binding of polyelectrolytes, and the effect of counter-ions on the critical micelle concentrations of long-chain electrolytes are briefly discussed on the basis of the change in water structure induced by both cations and anions in water.

A series of measurements of viscosity *B* coefficients for organic electrolytes in aqueous solutions has been performed in this laboratory in order to elucidate the behavior of organic ions in water. In a previous paper,[1] the results for a homologous series of sodium *n*-alkyl sulfates were reported. This paper will describe the experimental results for the three homologous series of sodium alkane carboxylates, sodium *n*-alkyl sulfonates, and *n*-alkylammonium chloride.

The behavior of ions in water has generally been attributed to the structural change in water upon the introduction of ions into water.[2] In solutions of electrolytes with large ions, such as K^+, Cl^-, and Br^- ions, these ions will decrease the extent of intermolecular hydrogen-bonding of water in the vicinity of ions; thus, they are "electrostrictive structure-breakers."[2] On the other hand, in solutions of salts with small ions, such as Li^+, Na^+, and F^- ions, these ions will promote the water structure in the vicinity of ions; thus, they are "electrostrictive structure-makers."[2] As a third possibility, nonpolar groups are "hydrophobic structure-makers"[2] in water; that is, the water molecules will form "icebergs" around nonpolar molecules or groups in water.[3] As amphiphilic organic ions generally consist of both nonpolar and ionic parts, the behavior of these organic ions in water may be interpreted approximately by the balance of two different modes of interaction, namely, hydrophobic hydration due to nonpolar parts and electrostrictive hydration due to ionic parts. The main object of this paper is to discuss the role of ionic parts on the structural influence in water on the basis of the experimental results of the effect of ionic groups on the viscosity *B* coefficients.

Experimental

Sodium acetate and *n*-butyrate were from Wako Pure Chemical Industries, and all the other organic substances were from Tokyo Kasei Kogyo Co. Sodium propionate and *n*-butyrate were recrystallized from ethanol. All the sodium carboxylates were dried at 100 °C. Sodium methyl and ethyl sulfonates were prepared by the neutralization of the corresponding sulfonic acids with a 2 M solution of sodium hydroxide, and then the water was evaporated to dryness. The sodium salts were twice recrystallized from ethanol-water solutions (80% for methyl salt and 90% for ethyl salt). The other sodium alkyl sulfonates were synthesized by a modification[4] of Strecker method. The *n*-alkyl bromides were added, drop by drop, to the saturated solutions of sodium sulfite at 100 °C, and then the mixtures were dried in air. The sodium salts were extracted with ethanol and were further twice purified by recrystallizing them from ethanol. All the products of sodium alkyl sulfonates were dried *in vacuo* at 100 °C. All the *n*-alkylammonium chlorides except pentyl salt were recrystallized from suitable solvents—*i.e.*, ethanol for methyl salt and an ethanol-benzene solution for the other salts. Pentylammonium chloride was prepared by the neutralization of pentylamine with gaseous hydrogen chloride in benzene; the salt thus prepicitated was recrystallized from an ethanol-benzene solution. All the alkylammonium chlorides were dried in a vacuum desiccator. Water was obtained by redistillation from an alkaline permanganate solutions.

The viscosities were measured at 25 °C by a method similar to that described in a previous paper.[1] Ubbelohde-type viscosimeters with flow times for water of 800—1200 s were used. The densities were measured in Ostwald pycnometers.

Results and Discussion

The B Values for the Organic Ions. The viscosity of aqueous electrolyte solutions can be expressed by the Jone-Dole equation:[5]

$$\eta = \eta_0(1 + AC^{1/2} + BC) \quad (1)$$

where η and η_0 are the viscosity of the solution and of the water respectively; C, the concentration (molarity); A, the constant relating to the ion-ion interaction, and B, the viscosity B coefficient. The viscosity B coefficients can be obtained as slopes of $(\eta/\eta_0 - 1)/C^{1/2}$ *versus* $C^{1/2}$ plots. In this work generally, the viscosity measurements were made at five different concentrations up to about 0.15 M for each salt; the B values thus obtained are summarized in Table 1. The B value for sodium acetate is slightly higher than that reported by Padova.[6] The B values for sodium hexanoate[7] and octanoate[8] calculated from the re-

sults published by Campbell *et al.* are included in Table 1.

The viscosity *B* coefficients of electrolytes are considered to be determined by adding the individual contribution of the solute constituent ions.[9] Adopting the convention of Gurney[9] that the ionic *B* values for K^+ and Cl^- ions are equal, the ionic *B* values for Na^+ and Cl^- ions become 0.086 and −0.007 respectively.[10] The ionic viscosity *B* coefficients, B_{ion}, for the series of alkane carboxylate, alkyl sulfonate, and alkylammonium ions thus calculated are listed in Table 2. The *B* values for the alkylammonium ions are in fairly good agreement with those calculated from the results for alkylammonium bromides by Desnoyers, Arel and Leduc,[11] assuming that the B_{ion} value for Br^- ion[10] is −0.032. The data for a series of alkyl sulfate ions reported in the previous paper[1] are included in Table 2.

The *B* values for homologous electrolytes are found to increase with the chain length. Fig. 1 shows the relationship between the B_{ion} values of the organic ions and the number of carbon atoms in the alkyl chains. It can be seen in Fig. 1 that the linear relation between the B_{ion} values and the number of carbon atoms holds for each series of homologous electrolytes and that the slopes are nearly equal. If the role of the interaction of the organic ion with water could be separated into the effect of the nonpolar part and that of the ionic part, nearly the same strength of interaction for the nonpolar alkyl group with water could be anticipated for all the homologous organic electrolytes. If this assumption is valid, the difference in the B_{ion} values for the organic ions with the same alkyl groups may be attributed to the interaction of the ionic parts

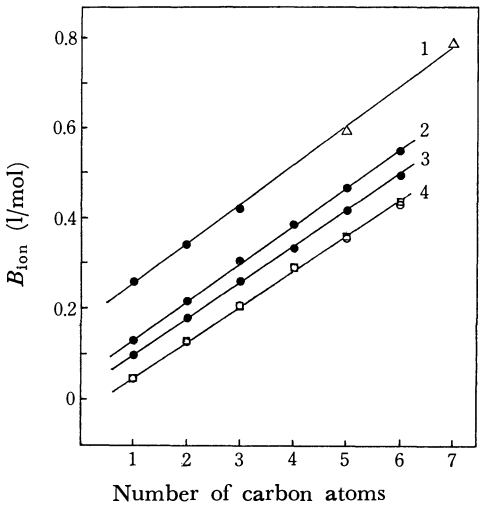

Fig. 1. Plots of viscosity *B* coefficients for organic ions against number of carbon atoms in the alkyl group. 1: alkane carboxylate ions, 2: alkyl sulfonate ions, 3: alkyl sulfate ions, 4: alkylammonium ions, ●, ○: present work, △: Refs 8 and 9, □ Ref. 11.

with water. As is evident in Fig. 1, the B_{ion} values for the four types of homologous organic ions with the same alkyl groups are larger in the order: alkane carboxylate ions≫alkyl sulfonate ions>alkyl sulfate ions>alkylammonium ions. However, there remains some uncertainty as to the comparison of the absolute B_{ion} values between the alkylammonium cations and the three other kinds of the organic anions, because the values depend on the convention used in splitting the *B* values for an electrolyte into the individual values of a cation and an anion. Nevertheless, in the case of the three kinds of organic anions, *i.e.*, alkane carboxylate, alkyl sulfonate, and alkyl sulfate ions, the above sequence of the B_{ion} values is independent of the convention adopted.

The Behavior of $-COO^-$, $-SO_3^-$ and $-OSO_3^-$ in Water. The viscosity *B* coefficient has been interpreted in terms of the size of the solute or the ion (Einstein effect) and in terms of the solute or ion-solvent interaction.[9,10] For a comparison of the size of the solutes, the partial molal volumes at an infinite dilution of the electrolytes in water, $\overline{V}°$, are listed in Table 3. The data for alkane carboxylates,[12,13,14] and some for sulfonates[14] and sulfates[15] are cited from the literature. Because of the incompleteness of data in the liter-

ature, the $\overline{V}°$ values for alkyl sulfonates and sulfates are calculated from the present density data by the use of the standard procedure.[16] Our density measurements are not very accurate, as they were for the calculation of the viscosity. However, these volume data are still instructive for the following discussion. The $\overline{V}°$ values of electrolytes are also composed of the sum of the contributions from both cations and anions. Unfortunately, there has been some controversy about the absolute values of ions, $\overline{V}°_{ion}$.[16] If we use −5.4 cm^3/mol as the $\overline{V}°_{ion}$ value of H^+ ion at 25 °C, recommended by Millero,[16] the $\overline{V}°_{ion}$ values of Na^+ and Cl^- ions become −6.6 and 12.4 cm^3/mol respectively.[16] The $\overline{V}°_{ion}$ values thus calculated are listed in Table 4. Figure 2 represents an approximate linear relation between the B_{ion} values and the $\overline{V}°_{ion}$ values. A similar relation has frequently been reported.[11,15,17]

The viscosity of a dilute suspension of spherical colloids is given by the Einstein equation:[18]

$$\eta = \eta_0(1+2.5\phi) \quad (2)$$

where ϕ is the volume fraction of colloids. Though the coefficient of 2.5 in Eq. (2) becomes slightly varied in the case of elongated solutes,[19] an approximate attempt assuming the spherical form will be made in this paper. For the solution, the B coefficient can be related to $\overline{V}°$ expressed in cm^3/mol:

$$B = 0.0025\,\overline{V}° \quad (3)$$

Thus, the contribution from the Einstein effect in the B_{ion} values is equal to $0.0025\,\overline{V}°_{ion}$. Desnoyers and Perron[20] showed that the values, $B-0.0025\,\overline{V}°$, is a measure of the solute-solvent interation. Similarly, the ion-solvent interaction effect, Δ, for organic ions can be derived by the equation:[20]

$$\Delta = B_{ion} - 0.0025\,\overline{V}°_{ion} \quad (4)$$

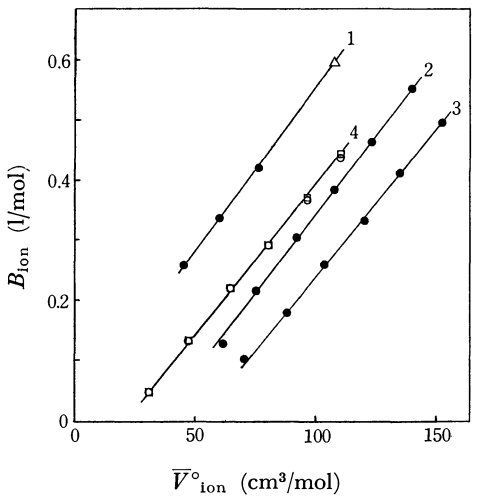

Fig. 2. Plots of viscosity B coefficients for organic ions against molal volumes for ions at infinite dilution.
1: alkane carboxylate ions, 2: alkyl sulfonate ions, 3: alkyl sulfate ions, 4: alkylammonium ions, ●, ○ present work, △: Ref. 8, □: Ref. 11.

It may be noted that the Δ values are of a semi-quantitative nature, because the absolute values of Δ depend on the two conventions adopted for splitting the B values and the $\overline{V}°$ values into the respective ionic B_{ion} and $\overline{V}°_{ion}$ values.

As is indicated in Table 4, the Δ values are positive for all the carboxylate ions. Further, it has been reported that alkane carboxylic acids have rather small B values, those for acetic, propionic, and butyric acids being 0.117, 0.190, and 0.250 respectively.[21] The large difference in the B values between carboxylic acids and carboxylate ions may be interpreted in terms of the strong tendency of the carboxylate anion to

orientate the water molecules around the ions.[9] Therefore, it may be concluded that the $-COO^-$ ionic part acts as an "electrostrictive structure-maker" in the water phase.

On the other hand, the $-SO_3^-$ ionic part and the $-OSO_3^-$ ionic part have quite small B values. With the lower members of sulfonates and sulfates, the Δ values are negative, as is shown in Table 4. Therefore, it may be assumed that these two anionic parts are "electrostrictive structure-breakers" in water. The structure-breaking properties of sulfonate ions have been discussed by Uedaira and Uedaira[22] on the basis of their conductivity measurements, and by Katayama *et al.*[23] on the basis of their partial molal measurements.

The Behavior of $-NH_3^+$ in Water. The $\overline{V}^\circ$ values for alkylammonium chlorides and the $\overline{V}^\circ_{ion}$ values for alkylammonium ions are listed in Tables 3 and 4 respectively. Table 4 indicates a negative Δ value for methylammonium ion. From this fact, the $-NH_3^+$ ionic part is considered to be an "electrostrictive structure-breaker." This is probably supported by the fact that simple ammonium ion has a net structure-breaking effect.[9]

Specific Interactions of the $-COO^-$, $-SO_3^-$, $-OSO_3^-$ and $-NH_3^+$ Ionic Parts with Other Simple Counter-ions. There are several phenomena which indicate the characteristic behavior of the $-COO^-$, $-SO_3^-$, $-OSO_3^-$ and $-NH_3^+$ ionic parts in water, particularly with regard to the interaction of these ionic parts with other simple counter-ions. The mean ionic activity coefficients, γ, for the alkali metal salts of acetic acid for a given concentration decrease in the order: $Li^+<Na^+<K^+$.[24] On the other hand, the γ values for the salts of *p*-toluensulfonic acid[24] as well as the salts of methyl and ethyl sulfonic acids[25] in dilute solutions increase in the order: $Li^+>Na^+>K^+$. The variation in the order of the ionic activity coefficients has been discussed by Gurney[9] and by Frank.[26] The theory of Gurney and Frank implies that an anion and a cation with similar structural influences—both being structure-makers or both structure-breakers—will attract each other, whereas if an anion and a cation have different structural tendencies, they will repel each other. Among the cations, Li^+ is a strong, and Na^+, a weak structure-maker, while K^+, slightly structure-breaking. As has been explained above, the $-COO^-$ ionic part is believed to be a structure-maker, while the $-SO_3^-$ ionic part, a structure-breaker. Therefore, the lithium salt of carboxylic acid, a "maker-maker" salt, and the potassium salt of sulfonic acid, a "breaker-breaker" salt, will give lower-lying activity coefficient *versus* concentration curves because of the tendency toward more attraction between cations and anions. At the opposite extreme, the potassium salt of carboxylic acid, a "breaker-maker" salt, and the lithium salt of sulfonic acid, a "maker-breaker" salt, will give higher-lying curves because of the greater escaping tendency between cations and anions. Steigman and Dobrow[27] also discussed the ionic activity coefficients along the same lines.

With polyelectrolytes, the counter-ions are bound to poly-ions because of the strong electrostatic potential of poly-ions.[28] This phenomenon is called "counter-ion binding". There are characteristic sequences of simple counter-ions with regard to the degree of binding to the poly-ions. In the case of the alkali metal salts of polyacrylic acid, the degree of binding decreases with the size of the counter-ion: $Li^+>Na^+>K^+$.[29] With polyvinyl- and polystyrenesulfonates, on the other hand, the degree of binding increases with the size of the ion: $Li^+<Na^+<K^+$.[24] This characteristic feature may also be interpreted in terms of the structural influences by ions in water. In the case of the "like-like" combinations in the structural influences of both cations and anions, such as lithium polyacrylate and potassium polyvinyl- and polystyrenesulfonates, cations and anions will attract each other more. Conversely, in the case of the incompatible combinations in the structural influences of cations and anions, such as potassium polyacrylate and lithium polyvinyl- and polystyrene-sulfonates, the resultant phenomenon will result in a stronger repulsive force.

The amphiphilic salts containing an alkyl group, higher than octyl, have a tendency to form micelles in aqueous solutions. The critical micelle concentration (CMC) is a measure of the solute-solvent interaction. The CMC value depends mainly on the oleophilic group. However, there are some specific effects of ionic species. In the case of the alkali metal salts of dodecyl sulfuric acid, the CMC values decrease with size of the cations: $Li^+>Na^+>K^+$.[30] In the case of the alkali metal salts of long-chain carboxylic acid, the CMC values are in the order: $Li^+<Na^+<K^+$.[31] Further, the CMC values for dodecylammonium halides are in the order: $I^-<Br^-<Cl^-$.[32] In view of the structural influences in water induced by both cations and anions, the degree of counter-ion binding at the surface of ionic micelles will be in the order of $Li^+<Na^+<K^+$ in the case of the alkali metal salts of dodecyl sulfuric acid, whereas the order will be reversed in the case of the alkali metal salts of alkane carboxylic acid: further, it will be in the order of $I^->Br^->Cl^-$ in the case of dodecylammonium halides. With increased binding of counter-ions the contribution of the electric free energy in the micelle formation per monomer will be reduced, thus resulting in the easier formation of the aggregates at lower concentrations.

Electron-transfer Kinetics of Transition-metal Complexes in Lower Oxidation States. Part II.[1] The Electrochemical Electron-transfer Rate of the $Cr(bipy)_3^+/Cr(bipy)_3$ System as Measured by the Galvanostatic Double-pulse Method[2]

Tetsuo SAJI and Shigeru AOYAGUI

Faculty of Engineering, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo 152

(Received August 10, 1973)

The kinetic parameters of the electron-transfer reaction, $Cr(bipy)_3^+ + e \rightleftharpoons Cr(bipy)_3$, were measured by the galvanostatic double-pulse method at a dropping mercury electrode in *N*,*N*-dimethylformamide. The apparent and the corrected standard rate constants were 1.0 ± 0.2 and 0.3 cm s^{-1} respectively, and the transfer coefficient was 0.6 ± 0.1 at 25 °C. These rate constants were discussed in comparison with the corresponding homogeneous rate constant on the basis of the theoretical equation of Marcus. They were quite inconsistent with the value, 10^3 cm s^{-1}, predicted from the corresponding homogeneous rate constant.

The polarograms of $Cr(bipy)_3^+$ and $Cr(bipy)_3$ exhibited three waves with half-wave potentials of -0.21, -0.65 and -1.19 V *vs.* a cationic glass electrode. The diffusion coefficients of these complexes, as determined polarographically, were identical: 3.2×10^{-6} cm^2 s^{-1} at 25 °C.

The theory of Marcus has been successfully applied to a number of electron-transfer reactions[3,4] in order to make the theoretical predictions of (1) the rate constants for the homogeneous and the electrochemical electron-transfer reactions, (2) the transfer coefficients for them, and (3) the correlation between the rate constants for the homogeneous electron-exchange reaction, $A^z + A^{z-n} \rightleftharpoons A^{z-n} + A^z$, and the corresponding electrochemical electron-transfer reaction, $A^z + ne \rightleftharpoons A^{z-n}$. Here, z is the number of the ionic charge, and n, the number of electrons transferred. This paper is concerned with the third aspect: the rate constants of these two types for the $Cr(bipy)_3^+/Cr(bipy)_3$ system are compared and discussed in the light of the theory of Marcus.

According to this theory, the homogeneous electron-exchange rate constant, k_{ex}, is related to the corresponding electrochemical electron-transfer rate constant, k_{el}, by the following simple relationship:[5]

$$(k_{ex}/Z_{hom})^{1/2} = k_{el}/Z_{el} \quad (1)$$

where Z_{hom} is the hypothetical collision number of two uncharged species in a solution when they have a unit concentration, and where Z_{el} is the collision number of an uncharged species with a unit area of the electrode when it has a unit concentration. An electron-transfer reaction with which this relationship is to be tested must have such a large rate constant that the rates of other possible coupled processes, *e.g.*, the bond-rupture, bond-formation, and atom-transfer processes, can be neglected, as this theory is based on the assumption that the reaction proceeds through an outer-sphere mechanism. With the Z values of 10^{11} M^{-1} s^{-1} for Z_{hom} and 10^4 cm s^{-1} for Z_{el}, the (1) relation holds fairly well in the reactions with a rather small rate constant,[5-7] *e.g.*, V^{3+}/V^{2+}, Eu^{3+}/Eu^{2+}, Tl^{3+}/Tl^+, and $Co(phen)_3^{3+}/Co(phen)_3^{2+}$, but it is insufficient in those with a large rate constant,[5] *e.g.*, Fe^{3+}/Fe^{2+}, $Fe(CN)_6^{4-}/Fe(CN)_6^{3-}$, and MnO_4^{2-}/MnO_4^-. According to recent investigations, however, it is quite probable that the reactions of aquo-complexes proceed through a mechanism other than the outer-sphere mechanism.[8] The reaction of $Co(phen)_3^{3+}$-$(t_{2g}^6)/Co(phen)_3^{2+}(t_{2g}^5 e_g^2)$ is also inappropriate for the present purposes, because the two reactants are in different spin states.[8] Consequently, the excellent agreement between the theoretical prediction and experimental results found for these reactions cannot be a support for the validity of Eq. (1) Unfortunately, there are not many homogeneous electron-exchange reactions that have been confirmed to proceed through an outer-sphere mechanism, and even the concept of outer- and inner-sphere mechanisms has never been established in electrochemical electron-transfer reactions. Therefore, we recommend a system with a sufficiently large homogeneous electron-exchange rate constant for testing Eq. (1), for the same reasons as were discussed in a previous paper treating the potential dependence of the transfer coefficient.[9]

Generally an electron-exchange reaction is very fast if it satisfies the following two conditions:[8] (1) the reactants have "conducting" unsaturated ligands, such as cyanide, phenanthroline, bipyridine, and cyclopentadienyl, that is, the reactants are characterized by a highly delocalized π-electron distribution, and (2) the reactants are a pair of complexes differing by one in the number of electrons in the lower orbitals not used in ligand bondings. The electron-exchange reaction between $Fe(phen)_3^{3+}(t_{2g}^5)$ and $Fe(phen)_3^{2+}$-(t_{2g}^6) is a reaction satisfying these conditions; its second-order rate constant[10] is larger than 3×10^7 M^{-1} s^{-1} and some 10^7 times as large as that of the $Co(phen)_3^{3+}/Co(phen)_3^{2+}$ system.[6,7]

It should be borne in mind that Eq. (1) has been derived by neglecting the contribution to the activation free energy from the free energy required to bring the reactant(s) and the product(s) to the positions where electron-transfer takes place. This contribution is referred to as a "work term" in the Marcus theory. The work term may reasonably be neglected in a homogeneous electron-exchange reaction where one of the reactants is uncharged. Our choice of the $Cr(bipy)_3^+(t_{2g}^5)/Cr(bipy)_2(t_{2g}^6)$ system is based partly on this reasoning and partly on its electronic configuration, which is analogous to that of the $Fe(phen)_3^{3+}/Fe(phen)_3^{2+}$ system, thus promising a large electron-transfer rate

constant. Recently we have measured the rate constant of the homogeneous electron-transfer reaction between $Cr(bipy)_3^{+}$ and $Cr(bipy)_3$ in *N,N*-dimethylformamide (DMF) by the electron spin resonance method using the line-broadening procedure.[1] The observed second-order rate constant was 1.5×10^9 M^{-1} s^{-1} at 25 °C. This was in good agreement with the rate constant calculated non-empirically according to the theory of Marcus, with the inner-sphere reorganization energy neglected. Furthermore, the oxidation-reduction potential of the $Cr(bipy)_3^{+}/Cr(bipy)_3$ system is negative *vs.* the oxidation potential of mercury, so the Frumkin correction can be applied, if necessary, to this system. According to Eq. (1), the predicted value for the standard rate constant of this system should be larger than 10^3 cm s^{-1}, beyond the upper limit accessible by existing techniques. In this experiment measurements are made by the galvanostatic double-pulse method; the standard rate constant obtainable by this method is 10 cm s^{-1} at most.

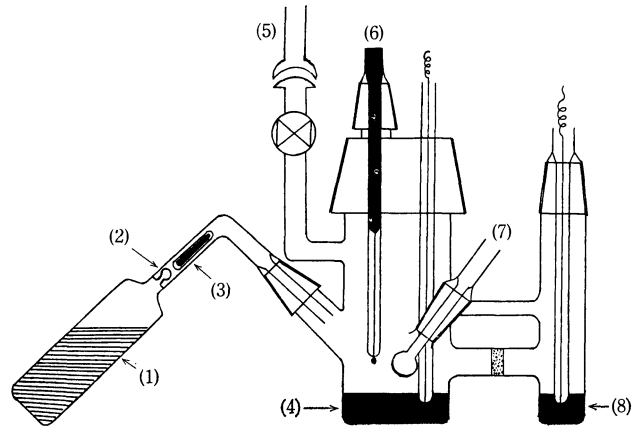

Fig. 1. Electrolysis cell: (1) electrolytic soln, (2) breakable seal, (3) hammer, (4) mercury pool A, (5) joint to vacuum line and inlet for nitrogen gas, (6) working electrode, (7) cationic glass electrode, (8) mercury pool B.

Experimental

Complexes. Both complexes, tris-(2,2′-bipyridine)-chromium(I) perchlorate and tris-(2,2′-bipyridine)-chromium (0), are very sensitive to oxygen. They were prepared and handled in a vacuum or in a nitrogen atmosphere. The preparation and analysis of these complexes were described in a previous paper.[1]

Reagents. Lithium perchlorate (Yoneyama Chemical Industries) and DMF(Wako Pure Chemical Industries) were used as the supporting electrolyte and the solvent, respectively. The former was recrystallized from an oxygen-free aqueous solution under a nitrogen atmosphere and then dried *in vacuo*. The latter was purified in a way described previously.[1]

Solutions. The $Cr(bipy)_3ClO_4$ and $Cr(bipy)_3$ solutions were prepared by dissolving the required amounts of lithium perchlorate and one of the complexes in DMF so that their concentrations might be 0.5 M and of the order of 10^{-3} M with respect to the supporting electrolyte and the complexes. The solutions were then stored in evacuated glass ampoules fitted with breakable-seals. The solution ampoule was connected with the cell *via* a tapered joint. Each aliquot was about 25 ml. All operations in preparing the solutions were performed *in vacuo*, with the subsidiary use of nitrogen. The electrolytic solution used in the double-pulse measurement must contain both the oxidant and the reductant.[11] It was prepared within the cell by the partial electrolytic reduction of a $Cr(bipy)_3ClO_4$ solution at a controlled potential. The concentrations of both species were determined polarographically.

Cell. The Pyrex-glass electrolysis cell shown in Fig. 1 was used. After the cell had been evacuated, nitrogen gas was introduced into it until an atmospheric pressure was reached. The electrolytic solution was then transferred into the cell through the broken breakable-seal by the appropriate rotation of the ampoule around the tapered joint. A cation-permiable glass electrode (CGE) served as a reference electrode in the polarographic measurements and controlled potential electrolyses. Its e.m.f. was −50 mV *vs.* SCE, as measured by the use of a conventional agar bridge; this was sufficiently reproducible within the limits of accuracy of this experiment, *i.e.*, 2 mV. The cell was evacuated easily and completely by the use of this reference electrode. Besides the CGE, a dropping mercury electrode (DME) and two mercury pool electrodes were fitted in the cell. The DME, the CGE, and the mercury pool electrode, A, were used in the polarographic measurements. The apparent area of the mercury pool A was about 10 cm^2. The two mercury electrodes, A and B, served as the working and the couter electrodes respectively in the controlled potential electrolyses. The compartment of the latter electrode was separated by a fritted glass from that of the former electrode. The progress of the controlled potential electrolysis was followed polarographically. A controlled current double-pulse was applied between the DME and the mercury pool electrode A.

Procedure and Devices. A controlled current double-pulse was applied to each drop of DME 3.0 s after the birth of the drop. The controlled current double-pulse generator equipped with an ohmic-drop compensating unit,[13] the synchronizing and timing circuit for DME,[14] and the potentiostat[15] which were used in this experiment have all been described elsewhere. Measurements were made at room temperature maintained at 25 °C.

Results and Discussion

A typical polarogram taken in a 0.3 mM solution of $Cr(bipy)_3$ is shown in Fig. 2. It exhibits three oxidation waves, with half-wave potentials of −0.21, −0.65, and −1.19 V *vs.* CGE respectively. The waves at −0.65 and −1.19 V are reversible, and their wave-heights are identical when corrected for the drop area. Two oxidation waves and a reduction wave with half-wave potentials of −0.20, −0.64, and −1.17 V *vs.* CGE appeared in a polarogram taken in a 0.5 mM solution of $Cr(bipy)_3^{+}$. After the $Cr(bipy)_3^{+}$ had been reduced completely to $Cr(bipy)_3$ by the controlled-potential electrolysis at −1.5 V, the polarogram was exactly the same as that of $Cr(bipy)_3$. On the basis of these experimental results and the proportionality between the wave-height and the concentration of $Cr(bipy)_3ClO_4$, the half-wave potential of −1.19 V *vs.* CGE can be assigned to the following redox system:

$$Cr(bipy)_3^{+} + e \rightleftharpoons Cr(bipy)_3 \qquad (2)$$

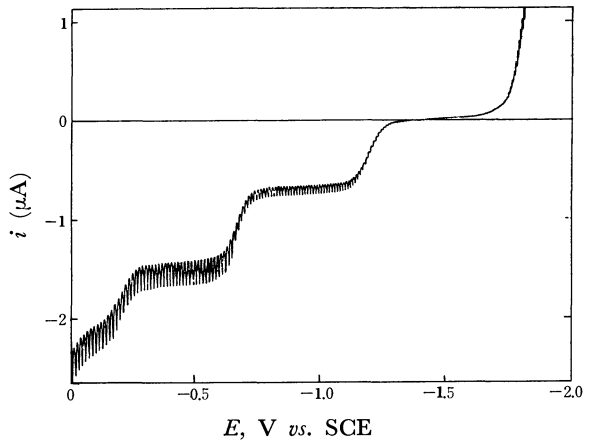

Fig. 2. Polarogram of 0.3 mM $Cr(Bipy)_3$ in a DMF soln containing 0.5 M $LiClO_4$.

There have been several polarograms of $Cr(bipy)_3^{3+}$ reported.[16] They were measured in solvents other than DMF, but in these polarograms one can find a wave corresponding to each wave in Fig. 2.

The diffusion coefficients of $Cr(bipy)_3^+$ and $Cr(bipy)_3$ were identical; they were determined to be 3.2×10^{-6} $cm^2\,s^{-1}$ at 25 °C.

The results obtained by the galvanostatic double-pulse measurement were analyzed according to the following equation:

$$\log(I_0/nFC_O) = \log k_s + \alpha\log(C_R/C_O) \qquad (3)$$

where I_0 is the exchange current density; k_s, the standard rate constant; α, the transfer coefficient, and the C's, the concentrations of the oxidant, O, and the reductant, R. An experimental plot in accordance with Eq. (3) is shown in Fig. 3. The standard rate constant and the transfer coefficient were determined to be 1.0 ± 0.2 cm s^{-1} and 0.6 ± 0.1 respectively. Such a large apparent standard rate constant approaching 1 cm s^{-1} has rarely been reported for the electrochemical electron-transfer reactions of transition-metal complexes.

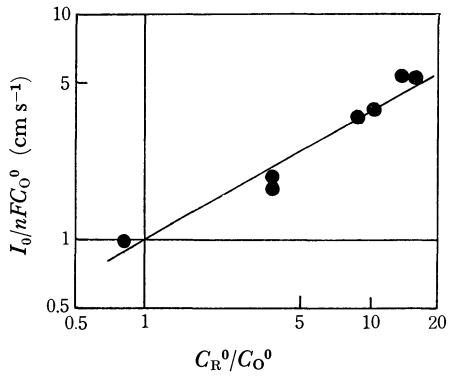

Fig. 3. Plot of $\log(I_0/nFC_O^0)$ *vs.* $\log(C_R^0/C_O^0)$.

Thus, we have found that the rate constants for the homogeneous and the electrochemical electron-transfer reactions of the $Cr(bipy)_3^+/Cr(bipy)_3$ system are both sufficiently large; this system is now considered to be appropriate for testing Eq. (1). Its electrochemical rate constant, however, is quite inconsistent with the value predicted by Eq. (1), *i.e.*, 10^3 cm s^{-1}.

Table 1. The observed, the corrected and the calculated rate constants for the $Cr(bipy)_3^+/Cr(bipy)_3$ system at 25°C

k_{el} (cm s^{-1})		
Observed	Corrected	Calculated
1.0 ± 0.2	0.3	10^3

If the positions occupied by the reactant and the product in their respective activated complexes are located within the diffuse double-layer, the work term for $Cr(bipy)_3^+$ in the electrochemical reaction should not be neglected, whereas this term may reasonably be neglected in the homogeneous electron-transfer of this system. These positions are referred to as the sites of the pre-electrode. The electrical potential at the pre-electrode site must be known in order for the work term to be evaluated. However, this is rather a difficult task. Assuming that the double-layer structure is of the Gouy-Chapman type and that both pre-electrode sites are located on the outer Helmholtz plane, the work term correction can be made according to the Frumkin procedure. Although the validity of the latter assumption is not quite certain, a Frumkin correction is applied as a trial to the electrochemical rate constant obtained above.

The data of the ϕ_2-potential in a DMF solution of lithium perchlorate are not available, but the electrocapillary curves for several electrolytes in this solvent have been reported.[17] The extent of the specific adsorption of perchlorate ions may be seen to be the least of all the anions studied. The electrocapillary curves were analyzed on the assumption that neither the anions nor the cations were specifically adsorbed on the electrode. The ϕ_2-potential at -1.19 V *vs.* CGE was obtained as -76 mV. The corrected standard rate constant was 0.3 cm s^{-1}. The corrected rate constant does not agree with the predicted value better than the apparent rate constant.

The original theory of Marcus regarding the electrochemical reaction does not state anything explicitly about the location of pre-electrode sites. The experimental results show, though, that the corrected rate constant cannot be larger than the observed one, wherever the pre-electrode site is located. Consequently, it is evident that Eq. (1) cannot hold unless the apparent electrochemical rate constant is immeasurably large. The same situation can be expected for a system satisfying the following conditions: (1) the number of electrons transferred is one; (2) k_{ex} is larger than 10^8 $M^{-1}\,s^{-1}$; (3) either species of the system is positively (or negatively) charged, or both species are, and (4) the standard electrode potential is negative (positive) *vs.* the zero-charge potential. Equation (1) has been applied exclusively to systems these conditions are not satisfied.

Polymerization of Vinyl Compounds with Hydridodinitrogentris(triphenylphosphine)cobalt(I)

Yoichiro KUBO, Akio YAMAMOTO, and Sakuji IKEDA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, O-okayama, Meguro, Tokyo 152

(Received March 14, 1973)

The kinetics of polymerization of vinyl compounds (acrylonitrile, methacrylonitrile, and methyl methacrylate) with hydridodinitrogentris(triphenylphosphine)cobalt(I), $CoH(N_2)(PPh_3)_3$ **1** (PPh_3: triphenylphosphine) was studied. By comparison with previous studies on the decomposition of **1** in the presence of vinyl compound a polymerization mechanism involving slow initiation followed by rapid propagation and unimolecular termination was proposed. The effects of concentration of monomer and of added triphenylphosphine on the molecular weight of the polymer were studied. The result of copolymerization was explained by the competitive coordination between the monomers involved. Poly(methyl methacrylate)s obtained by **1** in bulk and the solvent were all rich syndiotactic fraction.

Many investigations on the mechanisms of coordination polymerization by Ziegler type mixed catalysts have been made. However, a clear understanding of the polymerization mechanism by kinetic approaches[1] has been hindered by the complexity and instability of the mixed catalyst systems. By studying the polymerization kinetics with an isolated transition metal complex capable of initiating the polymerization, more information on the mechanism with Ziegler type catalysts might be expected. Employment of isolated transition metal complexes will make it possible to discover new catalysts so far unavailable with the mixed systems, where the reaction of the monomer with a catalyst component often invalidates the catalyst system. Examples of successful polymerization of vinyl monomers with Ziegler type catalysts, previously considered unpolymerizable, are increasing.[2] Recently some isolated transition metal allyls[3] and alkyls[4] have been reported to initiate the vinyl polymerization, detailed kinetic studies being made. Transition metal hydrides are also expected to initiate it, but few studies using the isolated transition metal hydrides have been made so far. We have continued our studies[5] on the reactions of hydridodinitrogentris(triphenylphosphine)-cobalt(I) $CoH(N_2)(PPh_3)_3$[6] and $CoH(CO)(PPh_3)_3$ with olefins, and report in this paper the vinyl polymerization with $CoH(N_2)(PPh_3)_3$ together with information obtained on the polymerization kinetics.

Results and Discussion

Kinetics of Polymerization. The polymerization conditions, polymer yields, and molecular weights of polymers obtained with $CoH(N_2)(PPh_3)_3$ are summarized in Table 1. For cases where the olefins were not polymerized and olefin-coordinated complexes were obtained, the compositions of the complexes are included in the table. The synthesis and characterization of the olefin-coordinated cobalt complexes have been reported.[7] It was confirmed that triphenylphosphine alone does not initiate the polymerization. Nitrogen was released from $CoH(N_2)(PPh_3)_3$ with the polymerization of the vinyl monomers, but no hydrogen was evolved.

Figure 1 shows a typical time-conversion curve in the polymerization of methacrylonitrile by $CoH(N_2)(PPh_3)_3$. Polymerization starts after an induction period of about 2 minutes and the conversion approaches a certain maximum value with time. The induction period does not change with the concentra-

TABLE 1. REACTIVITIES AND POLYMERIZATION ACTIVITIES OF $CoH(N_2)(PPh_3)_3$ TOWARD SUBSTITUTED OLEFINS

Monomer	*e* value	Time	Polymer Yield	Mol. wt.	Complex Isolated

Reaction temp: room temperature; −20°C for acrolein and methyl vinyl ketone. a) Poly(methacrylonitrile) produced by $CoH(N_2)(PPh_3)_3$ was soluble in acetone.

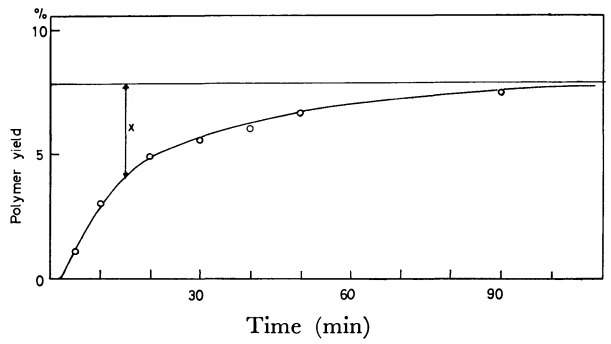

Fig. 1. Time-conversion curve of the polymerization of methacrylonitrile with $CoH(N_2)(PPh_3)_3$ at 25 °C. Yield against time. Methacrylonitrile, 10 ml; toluene, 20 ml; $CoH(N_2)(PPh_3)_3$, 2.28×10^{-3} mol/l.

tions of free triphenylphosphine and of $CoH(N_2)(PPh_3)_3$. The reason for the presence of the induction period remains unexplained. Since the polymer yield is low, concentration of methacrylonitrile can be regarded as constant during the course of polymerization.

The molecular weight of the polymer is independent of time and conversion having a value of 1.5×10^5. The reactions of $CoH(N_2)(PPh_3)_3$ with olefins are of first order in the concentration of $CoH(N_2)(PPh_3)_3$ under the conditions where the olefin concentrations can be regarded invariant,[5] and can be expressed as follows.

$$R_{N_2} = -d[CoH(N_2)(PPh_3)_3]/dt = k_{N_2}[CoH(N_2)(PPh_3)_3] \quad (1)$$

where R_{N_2} denotes the rate of change of $CoH(N_2)(PPh_3)_3$ under nitrogen. Thus, the concentration of $CoH(N_2)(PPh_3)_3$ decreases with time in the presence of an olefin and should markedly decrease in the time scale shown in Fig. 1. It can be concluded that the molecular weight of the polymer is independent also of the concentration of $CoH(N_2)(PPh_3)_3$. This is supported by experimental results showing the invariance of the molecular weights of the polymers with varying initiator concentrations over a three-fold range. Since the molecular weights of the polymers obtained at different conversions are almost constant, the yield of the polymer can be regarded as proportional to the number of polymer chains produced. This suggests that the polymerization process of the vinyl monomer consists of a slow initiation step followed by rapid propagation and termination steps as in the polymerization with dialkylbis(dipyridyl)iron[4] or dihydridotetrakis(triphenylphosphine)ruthenium.[8] Features common to the polymerization by the transition metal complexes are the strong inhibition effects of ligands. As was done previously[4] the logarithm of the value x(=the maximum yield (Y_∞)—the yield at time t(Y_t)) is plotted against time. Except for the induction period the straight lines having the slope $\bar{k}$ are obtained indicating the relationship

$$\log(Y_\infty - Y_t) = -\bar{k}t + \text{const.} \quad (2)$$

The change of slope $\bar{k}$ against the methacrylonitrile concentration is plotted in Fig. 2. The value $\bar{k}$ increases with the increase in methacrylonitrile concentration,

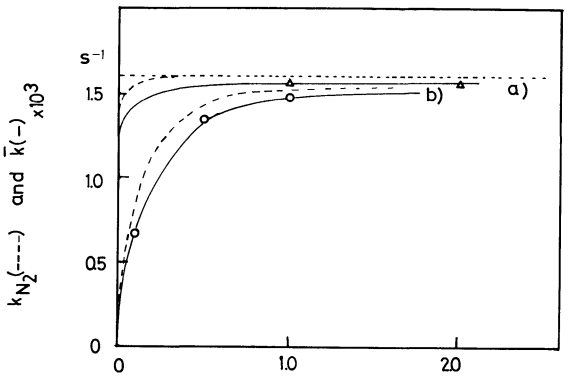

Fig. 2. Plots of pseudo-first-order rate constants, k_{N_2} and $\bar{k}$, against the concentration of methacrylonitrile, a) in the absence of triphenylphosphine; b) Concentration of triphenylphosphine, 8.50×10^{-2} mol/l. Solvent: toluene; $CoH(H_2)(PPh_3)_3$, 3.40×10^{-3} mol/l. Polymerization temperature: 25 °C.
k_{N_2} (·····): pseudo-first-order rate constants obtained by a spectroscopic method.[5]
$\bar{k}$ (——): pseudo-first-order rate constants obtained from the time-conversion curve.

approaching a limiting value of $1.60\times10^{-3}\,s^{-1}$. We proposed the following mechanism of the decomposition of the cobalt complex.[5]

$$CoH(N_2)(PPh_3)_3 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} CoH(N_2)(PPh_3)_2 + PPh_3$$
$$\Big\| \begin{matrix} k_{-2} \uparrow \\ \downarrow k_2 + \text{olefin} \end{matrix}$$
$$CoH(N_2)(\text{olefin})(PPh_3)_2$$
$$\Big\| \begin{matrix} k_{-3} \uparrow \\ \downarrow k_3 \end{matrix}$$
$$CoH(\text{olefin})(PPh_3)_3 + N_2$$
$$\Big\downarrow k_4$$
$$\text{decompsition} \quad (3)$$

The pseudo-first-order rate constant k_{N_2} in Eq. (1) can be expressed as follows.

$$\frac{1}{k_{N_2}} = \frac{1}{k_1} + \frac{k_{-1}}{k_1 k_2 k_3}\frac{[PPh_3]}{[\text{olefin}]}\left\{(k_{-2}+k_{-3}) + \frac{k_{-2}k_{-3}}{k_4}[N_2]\right\} \quad (4)$$

The limiting value of $\bar{k}$, $1.60\times10^{-3}\,s^{-1}$ in Fig. 2 is in agreement with the k_1 value corresponding to the rate constant for the dissociation of a triphenylphosphine ligand from the cobalt complex. The whole feature of the curves (Fig. 2) obtained from the time-conversion curves agrees with the decomposition pattern of $CoH(N_2)(PPh_3)_3$. The results suggest a relationship between the decomposition rate of the cobalt complex and the polymerization rate. If we assume that the cobalt complex initiates the polymerization with initiator effeciency f by insertion of one monomer into the Co–H bond followed by insertion of monomers into the Co–C bonds, and that the growth of the polymers is terminated spontaneously after reaching a certain degree of polymerization $\overline{DP}$, which is constant, the polymerization rate can be expressed as follows:

$$R_p = \frac{d[Y]}{dt} = f \cdot \overline{DP} \cdot \left\{ - \frac{d[CoH(N_2)(PPh_3)_3]}{dt} \right\} \quad (5)$$

Substituting Eq. (1) into Eq. (5), we have

$$\log (Y_\infty - Y_t) = -k_{N_2} t + \log \{ f \cdot \overline{DP} \cdot [CoH(N_2)(PPh_3)_3]_0 \} \quad (6)$$

where $[CoH(N_2)(PPh_3)_3]_0$ is the initial concentration of the cobalt complex. Equation (6) is identical in form with Eq. (2). There is a reasonable agreement between $\bar{k}$ derived from the time-conversion curve, and k_{N_2} rate constant of the decomposition of $CoH(N_2)(PPh_3)_3$ measured by the spectroscopic method (Fig. 2). The results support our assumption that the initiation process, which probably proceeds *via* the insertion of the monomer into the Co–H bond, is the rate-determining step followed by rapid propagation and termination process by which the complex is eventually destroyed.

Table 2. Effects of concentration of added triphenylphosphine on the molecular weight of poly(methacrylonitrile)

$[PPh_3]$ mmol	Yield %	Mol. wt.
0	60	5.71×10^5
1.29	50	2.65×10^5
6.85	30	5.79×10^4
43.8	0	—

Polymerization time, 1 day; Temp., 25°C
[MAN]: 2.00 mol/l; $[CoH(N_2)(PPh_3)_3]$: 0.34 mmol/l

The yield and molecular weight of the polymer are affected by the monomer concentration, the concentration of the added triphenylphosphine and the solvent. The polymer yields and the decrease in molecular weight by the increase of the concentration of the added triphenylphosphine are given in Table 2. If we assume the initiation process to be formulated in Eq. (3) involving the dissociation of triphenylphosphine from $CoH(N_2)(PPh_3)_3$, the inhibition effect of triphenylphosphine can be readily explained. The effects of monomer concentration and the added triphenylphosphine on the molecular weight of the polymer can be explained by assuming a competitive coordination between the monomer, the solvent and the ligand toward the growing polymer chain end with a cobalt-carbon bond as in the polymerization with the alkyliron complex.[4] When the growing polymer end is coordinated by a monomer molecule, the monomer can be inserted between the metal-carbon bond with a certain probability, whereas the coordination of the solvent and the triphenylphosphine may cause the termination of the polymer growth with different probabilities. The effect of solvent is particularly marked in the polymerization of a monomer, such as methyl methacrylate, having a weaker coordinating ability toward the complex. The polymerization of methyl methacrylate, given in Table 3, is retarded in solution, being severely hindered in solvents of stronger coordinating power, such as tetrahydrofuran and dimethylformamide.

Table 3. Effects of solvents on the yield of poly(methyl methacrylate)

MMA	Solvent	Time	Yield %
8 ml	none	1 day	17
5 ml	Toluene	7 days	5
5 ml	Benzene	7 days	0.2
5 ml	Tetrahydrofuran	7 days	trace
5 ml	Dimethylformamide	7 days	trace

$[CoH(N_2)(PPh_3)_3]$: 4—5 mmol/l 25°C

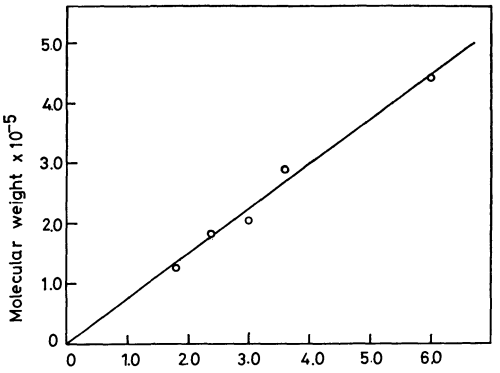

Fig. 3. The effect of concentration of methacrylonitrile on the molecular weight of poly(methacrylonitrile).

The molecular weight of poly(methacrylonitrile) increases linearly with increasing monomer concentration(Fig. 3). This supports our assumption that the coordination of the monomer to the complex with a growing polymer chain leads to the insertion of the monomer between the M–C bond. If we assume the following propagation and termination reactions

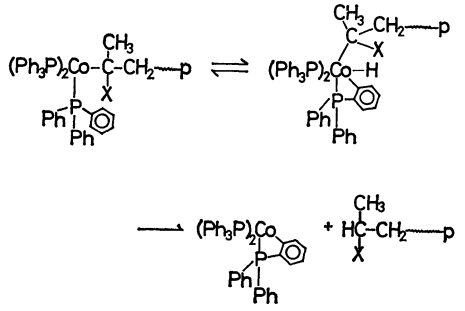
$$R_p = k_p[M][C^*]$$
$$R_t = k_t[C^*],$$

where [C*] represents the concentration of the catalyst with a growing polymer chain, the degree of polymerization of the polymer can be given by

$$\overline{DP} = (k_p/k_t)[M],$$

in agreement with the experimental result.

We showed that at least a part of the termination process takes place by hydrogen abstraction from the



X=CN for methacrylonitrile
$COOCH_3$ for methyl methacrylate
Termination mechanism

Scheme 1.

β-position of the polymer chain bonded to the metal with the polymer end bearing the substituents.[9] If a similar β-hydrogen abstraction takes place also in this case, it would regenerate an active cobalt hydride species to initiate the polymerization again. That the initiator efficiency is lower than unity is not compatible with such a chain transfer mechanism. A possible termination mechanism is the one which involves the participation of ortho hydrogens of the triphenylphosphine ligand (Scheme 1).

The formation of a cobalt complex $Co(styrene)(C_6H_4PPH_2)(PPh_3)_2$,[8] in which cobalt is bonded with an *ortho* carbon of the triphenylphosphine ligand in the reaction of $CoH(N_2)(PPh_3)_3$ with styrene, supports the feasibility of the above mechanism.

TABLE 4. STEREOREGULARITY OF POLY(METHYL METHACRYLATE)

No.	Solvent	Triad[a]			Pm[b]
		mm	mr	rr	
1	—	10	25	65	0.23
2	Toluene	9	32	59	0.27
3	DMF	3	24	73	0.15

a) Triad tacticities: mm, isotactic; mr, heterotactic; rr, syndiotactic; peak areas determined by NMR spectra measured in nitromethane at 120°. b) Probability of *meso* placement; Average values calculated from triad are shown. Catalyst: $CoH(N_2)(PPh_3)_3$ at room temparature.

It was observed that the stereoregularity of poly(methyl methacrylate) obtained by the alkyl iron complex is affected by solvents, an acetone-soluble polymer rich in syndiotactic fraction, and an acetone-insoluble stereoblock type polymer being obtained.[10] The methyl methacrylate polymers obtained by the cobalt complex in toluene, dimethyl formamide and in the absence of solvent were soluble in acetone. The triad tacticities determined by NMR spectroscopy are given in Table 4. The polymers are all rich in syndiotactic fraction. The polymerization process appears to obey the Bernoulli trial with the probability of *meso* placement Pm[11] ranging from 0.15 to 0.27 depending on the solvent employed. The main factor in determining the stereoregularity of the polymer may be the mutual electrostatic and steric interactions between the substituents of the coordinating monomer and those of the polymer end attached to cobalt.

In order to obtain further information on the propagation mechanism, the copolymerization of methyl methacrylate (M_1) with methacrylonitrile (M_2) was studied. The results indicate that the copolymerization curve differs distinctly from that of free radical polymerization,[12] being somewhat similar to that of anionic polymerization.[13] The copolymer produced by the present catalyst, however, contains more methacrylonitrile units than those obtained by the conventional anionic initiators. The monomer reactivity ratios determined by an intersection method[14] for the copolymerization by $CoH(N_2)(PPh_3)_3$ were 0.20 ± 0.05 (r_1), 7.50 ± 0.40 (r_2), and $r_1 \times r_2 = 1.5\pm0.5$. A preferential introduction of methacrylonitrile to methyl methacrylate into the copolymer may be caused by the stronger coordinating ability of methacrylonitrile than methyl methacrylate in the compeptitive coordination of the monomers toward the complex with the growing polymer chain.[4]

In conclusion, the overall feature of the polymerization of vinyl monomers with the cobalt hydride complex is quite similar to that with the alkyliron[4] and ruthenium hydride[8] complexes: (i) the rate-determining initiation process involves the dissociation of the ligand for making a coordination site available toward the incoming monomer which enters into the metal–hydrogen or metal–carbon bond; (ii) the compeptitive coordination process is important in regulating the molecular weight and copolymer composition; (iii) the termination process is probably a spontaneous unimolecular process without involving a chain transfer process.

Experimental

General. Hydridodinitrogentris(triphenylphosphine)-cobalt was prepared as reported.[6] Monomers and solvents were purified by the usual methods and stored under nitrogen.

Polymerization. Polymerization was mostly carried out in a sealed ampoule in which the catalyst, monomer and solvent were transferred in a nitrogen stream or by a trap-to-trap distillation *in vacuo*. The ampoule was opened after the set time of polymerization and the content was poured into acidic methanol. The polymer was filtered, washed with methanol and dried. Kinetic study was carried out with a Schlenk type flask in a thermostatted water bath, the monomer being added with a pipette into the Schlenk type flask containing the catalyst solution. The yield was measured by weighing the polymer obtained after a set interval.

Copolymerization Experiment. Compositions of the copolymers between methyl methacrylate and methacrylonitrile were determined from the microanalysis of carbon, hydrogen and nitrogen.

Molecular Weight. The molecular weights of polymers were measured by a viscocity method using the following equations: for poly(methyl methacrylate),[15] $[\eta]=3.80\times10^{-5}M^{0.79}$; for poly(acrylonitrile),[16] $[\eta]=1.66\times10^{-4}M^{0.8}$; for poly(methacrylonitrile),[17] $[\eta]=9.55\times10^{-4}M^{0.56}$.

NMR Spectra. Proton magnetic resonance spectra of poly(methyl methacrylate) were obtained at 100 °C with a JEOL PS-100 Spectrometer at 100 MHz by using the sample solutions in nitromethane (*ca.* 10% W/V) containing a few per cent of tetramethylsilane as an internal standard.

Tri(hetero)substituted Carbonium Ions. VII.[1] Effect of the Ring System on the Ambident Reactivity of Cyclic Dithiocarbamidium Ions[2]

Takeshi NAKAI, Kazuhisa HIRATANI, and Makoto OKAWARA

Reserach Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro, Tokyo 152

(Received June 20, 1973)

In order to study the effect of structure on the ambident reactivity of cyclic dithiocarbamidium ions, two *endo*-iminium type cations, 2-methylthio-3-methyl-4,5-dihydrothiazolium ion (**5**) and 2,3,5,6-tetrahydrothiazolo-[2,3-*b*]-thiazolium ion (**6**) were prepared. Their electrophilic reactivities were studied and compared with those of the *exo*-iminium type cations, 2-dimethylamino-1,3-dithiolan-2-ylium ion (**1**) and its ring analogues. 3-Dimethylamino-2,4-benzodithiepan-3-ylium ion (**7**) was prepared and its ambident reactivity was studied. Examination of the products obtained from their reactions with various nucleophiles revealed that the three cation have two reactive sites, *i.e.*, the central (sp^2) carbon (site *a*) and the *S*-methylene (or *S*-methyl) (sp^3) carbon atoms (site *b*). Significant differences in the electrophilic behavior of the *endo*- and *exo*-iminium type cations were observed. They were discussed in terms of the structures as estimated from the spectra. Kinetic experiments showed that the reactivities at site *a* of these cations with hydroxide ion, relative to that of **1**, are 22.5 (**5**): 16.6 (**6**): 27.2 (**7**), and at site *b* with *N*,*N*-dimethyldithiocarbamate ion are 3.3 : 282 : $>10^4$. The reactivity order suggests that the reactivities at the two sites, especially at site *b*, are very sensitive to a change in the ring system of the cations.

In previous papers of this series,[3–6] the electrophilic behaviors of various dithiocarbamidium ions[7] including 2-dimethylamino-1,3-dithiolan-2-ylium ion (**1**), its ring analogues (**2** and **3**), and an open-chain analogue (**4**) were reported. It was shown that (a) the carbonium ions have two reactive sites, *a* and *b* in the formula shown below, (b) the reaction course is determined by both the nature of the attacking reagent employed and the structure of the cation and (c) the electrophilic reactivities at both sites depend markedly upon the the ring-size of the cation.

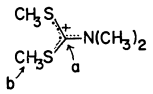
2: $n=1$
3: $n=2$



4

In order to obtain further information on the relationship between the structure and reactivity of dithiocarbamidium ions, the electrophilic behavior of 2-methylthio-3-methyl-4,5-dihydrothiazolium ion (**5**) and 2,3,5,6-tetrahydrothiazolo[2.3-*b*]thiazolium ion (**6**) has been investigated and compared with that of cation **1** having the same ring-size as **5** (and **6**). While the cyclic cations such as **1** and **2** are tentatively classified as *exo*-iminium type, **5** and **6** can be classified as *endo*-iminium type. The electrophilic reactivity of another *exo*-iminium type cation, 3-dimethylamino-2,4-benzodithiepan-3-ylium ion (**7**), was studied and compared with that of monocyclic **3** having the same ring-size as **7**.

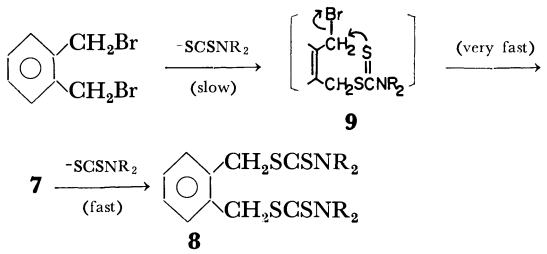
7

Results

Preparation of Carbonium Salts. Cations **5** and **6** were obtained as the iodide (**5a**)[8] and the chloride (**6a**)[9] by the methods in literature. Perchlorate (**5b**) was prepared by methylation of 3-methylthiazolidine-2-thione with dimethyl sulfate followed by treatment with sodium perchlorate. Treatment of **6a** with sodium perchlorate gave perchlorate (**6b**). Cation **7** was obtained as perchlorate by the reaction of *o*-xylylene dibromide with sodium *N*,*N*-dimethyldithiocarbamate followed by treatment with sodium perchlorate. Even under equimolar conditions, the disubstituted product, *o*-xylylene bis(dithiocarbamate) (**8**), was formed in considerable yields together with **7** and the product ratio varied with the solvent used. This suggests that, as in the reactions of 1,2-dichloroethane and 1,3-dichloropropane with the dithiocarbamate anion,[3,5,10] neighboring-group participation of the dithiocarbamate function accelerates the second substitution process, **9**→**8**, through the intermediacy of the isolated anchimeric cation (**7**), as illustrated below.



All carbonium salts thus obtained were identified by means of NMR spectroscopy and elemental analyses. The spectral data for the cations are given in Table 1 together with those for **1** and **3** as references.

Reactions with Various Nucleophiles. In order to demonstrate the ambident character of the cations, the reactions of **5** and **6** with a variety of nucleophiles were studied. The products thus obtained are given in Table 2. They were identified by IR, NMR and UV spectroscopy and/or comparison of their physical properties with those of authentic samples (see Experimental). All the products except for **10**, **11**, and the 2-imino-thiazolidines are known compounds,

The NMR spectrum of **10** showed only one slightly split singlet signal at δ 3.77 (Fig. 1) and the IR spectrum an absorption band at 2200 cm^{-1} due to the cyano group. The NMR spectrum of **11**, on the other hand, showed several signals which were assigned as shown in Fig. 1 through comparison with spectra of 3-methylthiazolidine-2-thione and methyl *N*,*N*-dimethyldithiocarbamate. The structure of **11** was further confirmed by the identity of its UV spectrum with that of an equimolar mixture of the two references.

It was found that **7** reacted with hydroxide and *N*,*N*-dimethyldithiocarbamate ions to yield *o*-mercaptomethylbenzyl thiolcarbamate (**12**) and the bis(dithiocarbamate) (**8**), respectively. The formation of **12** and **8** is best explained as a result of the attack of the nucleophile on the central carbon and on the *S*-methylene carbon, respectively.

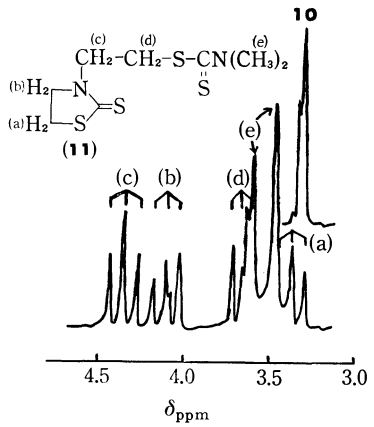

Fig. 1. NMR spectra of **10** and **11** ($CDCl_3$).

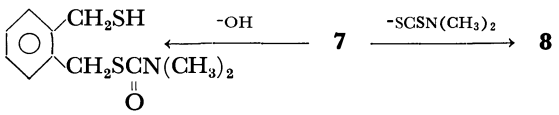

12

Kinetic Studies. The reaction at site *a* is kinetically controlled (mode A) whereas the reaction at site *b* or *c* is thermodynamically controlled (mode B).[3,4] In order to estimate the reactivity of modes A and B of the cation, the rates of reactions of the carbonium perchlorates with hydroxide and *N,N*-dimethyldithiocarbamate ions were measured, according to the procedures previously reported.[5]

The reaction of the cation with hydroxide ion was carried out in buffer solutions at 30 °C under pseudo-first-order conditions. Plots of the observed pseudo-first-order rate constants (k_{obs}) against the hydroxide concentrations were linear in the pH ranges studied for the cations (Fig. 2). The values of the second-order rate constants (k_a) for the reactions with hydroxide ion were obtained from the slopes of the straight lines obtained. The reaction of the cation with the dithiocarbamate ion was studied in dimethylformamide (DMF) at 30 °C. The values of the second-order rate constants (k_b) for the reaction with the dithiocarbamate ion were obtained from the slopes of the second-order rate plots (Fig. 3). The reaction of **7** with the anion

TABLE 3. RELATIVE REACTIVITIES OF MODE A AND B FOR THE CARBONIUM IONS (30°C)

Cation	Mode A Rel. k_a	Mode B[a] Rel. k_b
1[b]	1.0[c]	1.0[d]
5	22.5	3.3[e]
6	17.6	282
7	27.2	Very fast ($>10^4$)[f]
3	32.5	23.8

a) Unless otherwise stated, the reaction proceeded at site *b*. b) Ref. 5. c) $k_a=5.1\times10^{-1}$ M^{-1} s^{-1}. d) $k_b=1.30\times10^{-3}$ M^{-1} s^{-1}. e) At site *c*. f) See text.

was too fast to be measured by the present method. The value of k_b for **7** was found to be at least 10 M^{-1} s^{-1}. Table 3 shows the relative values of k_a and k_b for the cations.

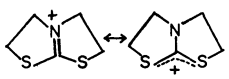
Discussion

Spectra and Relative Stabilities of the Carbonium Ions. The extent of stabilization of tri(hetero)carbonium ions depends upon the electron-donating power of the hetero-substituents directly adjoining the electron-deficient carbon atom. However, for the series of cyclic dithiocarbamidium ions we studied the extent of stabilization is expected to depend upon other structural factors, *e.g.*, the ring-size and the ring system, which enhance or diminish the internal dissipation of the positive charge.

On the other hand, it has been established[11] that the relative stability of a series of open-chain tri(hetero)-carbonium ions is linearly correlated with the transition energy ($1/\lambda_{max}$) in the electronic spectra; *the more stabilized the tri(hetero)carbonium ion, the shorter (higher energies) the wavelengths to which the maximum absorption band (λ_{max}) shifts.*[12] The linear correlation has not only been confirmed by simple HMO calculation[11] but also accepted experimentally for a series of cyclic dithiocarbamidium ions of *exo*-iminium type.[5,13]

Thus, the UV spectral data (Table 1) indicate that the stability of **5** (*endo*-iminium) is comparable to that of **1** (*exo*-iminium) and that both cations are more stabilized than open-chain **4** (λ_{max} 276 mμ[5]) presumably due to the more developed 1,3-overlapping in the ring system. The former is of particular interest since it could be expected that **5** is more stabilized than **1** if the formal ring-closures leading to the *endo*- (**5**) and *exo*-iminium type (**1**) increase the conjugative (stabilizing) effect of a combination of the nitrogen and sulfur atoms and of the two sulfur atoms in each ring *by the same factor*.[14] This would imply that participation of the nonbonding electron pair on the nitrogen in **5** is less fully involved in the 1,3-overlap seemingly due to twisting of the axis of symmetry of the nitrogen p orbital out of parallel with that of the vacant pπ orbital of the sp^2 carbon.

Another interesting fact obtained from UV spectral comparison is that bicyclic **6** is less stable than **1** and **5**. This suggests that the contribution to stabilization from the iminium structure (**6'**) is to a greater extent reduced by steric requirement presumably due to a larger twisting of the nitrogen p orbital described above, thus making the contribution from the sulfonium structure (**6''**) relatively more favored.[15] This is supported by the unusual observation that the NMR spectrum of **6** showed only singlet at δ 4.18, indicating that the *N*-methylene protons of **6** are more shielded than those of **5** (δ 4.55) while the *S*-methylene protons of **6** (δ 4.18) are much more deshielded than those of **5** (δ 3.82) and **1** (δ 3.61). The spectral observation also indicates a structure with all eight skeletal atoms nearly in one plane for **6**.[15]



6' **6''**

Comparison of λ_{max} between the two seven-membered cations shows that **7** is more stabilized than **3**; this suggests that the seven-membered ring of **7** is undoubtedly constrained to a near-planar configuration by the fused benzene ring, so that the 1,3-overlap in **7** is more effective.

It can be said that the stabilities of the cyclic dithiocarbamidium ions depend markedly not only on the ring-size but also on the ring system, and decrease in the order: **1**≈**5**>**6**>**2**>**7**>**3**≈**4**.

Effect of Ring System on the Ambident Reactivity

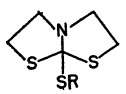
The stability of the tri(hetero)carbonium ion plays an important role in determining both the reaction course and the dual reactivities at the two sites.[4,5]

Let us discuss the effect of the ring system on the course of reaction of the cations with nucleophiles. An examination of the structures of the products given in Table 2 shows that the cations have two electrophilic sites and that the course of reaction with nucleophiles follows the selectivity rule[4]; hard bases, *e.g.*, OH^-, react at site *a* (mode A) while soft bases, *e.g.*, R_2NCSS^-, and bulky bases react at site *b* or *c* (mode B). However, the following significant differences in the reaction course of the *endo*- and *exo*-iminium types were observed: (a) the *endo*-iminium **5** directs the attack of CN^- to site *c* (mode B) while the *exo*-iminium **1** (and **6**) directs it to site *a* (mode A); (b) the bicyclic *endo*-iminium **6** directs the attack of RS^- to site *a* while **1** directs it to site *b*.

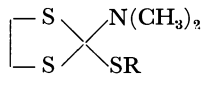
Case (a) is not well understood at the present stage. A possible factor responsible for the difference might be steric hindrance by the *N*-methyl of **5** arising from twisting of the nitrogen to attack CN^- at site *a*.

Case (b), on the other hand, is essentially the same as in the course of reaction with RS^- observed between **1** and open-chain **4** which has been best explained in terms of the difference in stability between **1** and **4**.[6] Thus, a similar argument is possible.

The major factor deciding the reaction course is the energy gap between the cation and its kinetically controlled (mode A) product.[4,16] In view of the fact that **6** is less stable than **1**, the energy gap between **6** and its mode A product (**13**) might be larger than that between **1** and its mode A product (**14**) since the process from **6** to **13** would result in the release of energy of both charge neutralization and twisting (ring strain) while the process from **1** to **14** would result in the release of only charge neutralization. As



13

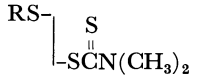


14

a result, the position of the equilibrium in Eq. 1 shifts to the right leading to the formation of the kinetic adduct (**13**), whereas that in Eq. (2) shifts to the left leading to the formation of the thermodynamically stable product (**15**) *via* mode B.

$$\mathbf{6} + RS^- \rightleftharpoons \mathbf{13} \quad (1)$$

$$\mathbf{1} + RS^- \rightleftharpoons \mathbf{14} \quad (2)$$



15

Let us now discuss the effect of ring system on the reactivities of both modes of the cations on the basis of the kinetic data given in Table 3. Figure 4 shows plots of the relative reactivities of mode B against those of mode A for the cations of *endo*- and *exo*-iminium types.

It has been suggested[5,16] that the reactivity of modes A and B depends, respectively, upon the energy gap between the cation and the kinetic adduct (the carbinol in this case) and between the cation and the transition state. If the energy contents of the carbinols for mode A and of the transition states for mode B were nearly constant, irrespective of changes in structures of the cations, that is, the rates of reactions were determined solely or at least favorably by the stability of the cations themselves, the rates of reactions of both modes would increase with a decrease in stability of the cation. This is the case for a series of the cations of *exo*-iminium type (Fig. 4). Thus, in view of the stability order of the cations, a similar argument is possible in explaining the observation qualitatively that

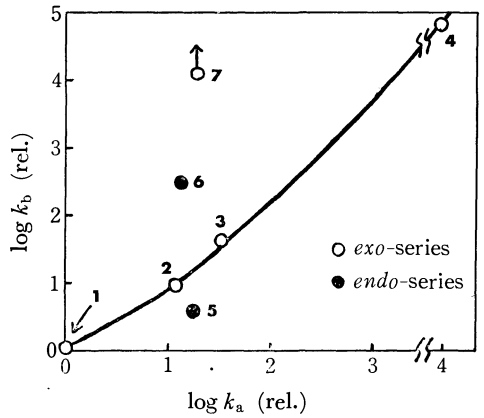


Fig. 4. Plots of log k_b *vs.* log k_a.

the k_a-value for **6** is larger than that for **1** and that the k_a-value for **7** is smaller than that for **3**.

It is obvious, however, that the stability order cannot account for the following observations; (a) mode A reactivity of **5** is larger than that of **1**, (b) mode B reactivity of **6** is much higher than not only that of **1**, but that of the six-membered **2** although **2** is less stable than **6**, and (c) mode B reactivity of **7** is much larger than that of **3** even though **7** is more stable than **3**. Thus, we should consider the unusual observations which are connected purely with the effect of ring system on the reactivity.

Observation (a) cannot be explained at the present stage. The higher reactivity of mode B of **6**, compared with that of the less stable cation **2**, indicates that **6** should represent the transition state of lower energy, *i.e.*, $\Delta F_B^{\neq}$ for **6** $<\Delta F_B^{\neq}$ for **2** in the schematic energy profile (Fig. 5). In view of the structural aspects for **6** it seems that the following factors are operative in activating the reaction center (site *b*); a more favorable contribution to stabilization from the sulfonium structure (**6″**) by steric requirement and a relief of the ring strain. Similarly, the higher reactivity of **7** indicates that $\Delta F_B^{\neq}$ for **7** is smaller than that for **3** in the energy profile even though the energy level for **7** is lower than that for **3**. It appears that the enhanced reactivity of **7** can be ascribed to two factors; the constrained near-planar configuration and the electronic effect of the fused benzene nucleus on the benzylic carbon atom.

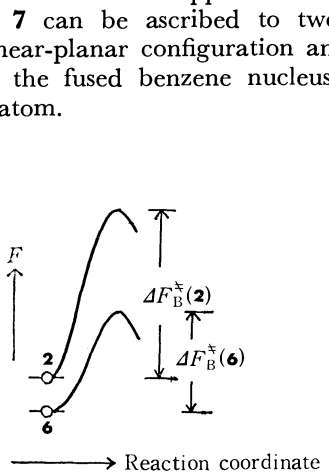

Fig. 5. Schematic ene gy profiles for mode B.

Experimental

General. Melting and boiling points are uncorrected. IR and UV spectra were recorded with Hitachi EPI-S2 and EPS-2 spectrometers. NMR spectra were obtained with a Japan Electron Optics C-100 spectrometer. Chemical shifts are reported in terms of δ ppm downfield from tetramethylsilane as an internal standard.

Materials. 3-Methylthiazolidine-2-thione was obtained in 65% yield from *N*-methylethanol amine and carbon disulfide by a modification of the method reported previously.[8] Bis(β-chloroethyl)amine hydrochloride and *o*-xylylene dibromide were prepared according to the procedure in literature.[9,17] Commercial reagents and solvents were used after purification by standard methods.

*2-Methylthio-3-methyl-4,5-dihydrothiazolium Salts (**5**).* 3-Methylthiazolidine-2-thione (7.5 g) was dissolved in 6.3 ml of methyl iodide. The mixture was heated at 40 °C for 30 min giving precipitates of the carbonium iodide (**5a**) quantitatively. Recrystallization of the precipitates from ethanol gave yellowish crystals; mp 132—135 °C (lit,[8] 132—135 °C).

Perchlorate (**5b**) was obtained as follows. 3-Methylthiazolidine-2-thione (2.7 g) was dissolved in 2.5 g of dimethyl sulfate. A vigorous exothermic reaction occurred when the mixture was heated up to 60 °C. The reaction temperature was kept below 100 °C. After the exothermic reaction was over, the mixture was stirred at 90 °C for 30 min. The mixture was poured into a saturated aqueous solution of sodium perchlorate giving 5.0 g (85%) of a pale yellowish precipitate, which was washed several times with ether and dried over phosphorous pentoxide *in vacuo*. The precipitate was so hygroscopic that its mp could not be determined. The structure of the salt was confirmed by its NMR spectrum (Table 1).

*2,3,5,6-Tetrahydrothiazolo[2.3-b]thiazolium Salts (**6**).* Carbonium chloride (**6a**) was prepared by the method in literature.[9] Bis(β-chloroethyl)amine hydrochloride (7.14 g) was dissolved in a solution of pyridine (10 ml) and water (4 ml). Carbon disulfide (2.4 ml) was added dropwise into the mixture with stirring for one hour; the mixture was kept below 10 °C. The white turbid solution thus formed was stirred at room temperature for 45 min, and warmed at 40 °C for 20 min. The reaction mixture was cooled in an ice box giving 7.9 g (90%) of a colorless precipitate. The precipitate was then dissolved in a minimum amount of water and reprecipitated by addition of ethanol giving colorless crystals; mp 93—95 °C (lit.,[9] 95 °C).

Treatment of **6a** with saturated aqueous solution of sodium perchlorate gave a colorless precipitate; mp 158—159 °C (recrystallized from acetonitrile).

Found: C, 24.40; H, 3.26; N, 5.70%. Calcd for $C_5H_8ClNO_4S_2$: C, 24.57; H, 3.36; N, 5.61%.

*3-Dimethylamino-2,4-benzodithiepan-3-ylium Perchlorate (**7**).* *o*-Xylylene dibromide (5.3 g) was added to a suspension of sodium *N,N*-dimethyldithiocarbamate (3.6 g) in 50 ml of dioxane. The mixture was stirred at 60 °C for 5 hr, then poured onto cold water (*ca.* 150 ml) giving 2.0 g of a white precipitate of *o*-xylylene bis(dithiocarbamate) (**8**); mp 124.5—125.5 °C (recrystallized from benzene); UV (EtOH): λ_{max} 250 and 275.5 mμ. The IR spectrum showed several absorption bands due to –S–CS–N<.

Found: C, 48.84; H, 5.86; N, 8.14%. Calcd for $C_{14}H_{20}N_2S_4$: C, 48.79; H, 5.85; N, 8.13%.

The filtrate was extracted with benzene and the aqueous solution was treated with an excess of sodium perchlorate giving 2.5 g (40%) of a white precipitate. Recrystalliza-

tion of the precipitate from ethanol and benzene gave colorless needles (**7**); mp 205—207 °C (dec.).

Found: C, 41.13; H, 4.24; N, 4.46%. Calcd for $C_{11}H_{14}ClNO_4S_2$: C, 40.80; H, 4.36; N, 4.33%.

Reaction of ***5a*** *with Sodium Methoxide.* **5a** (2.9 g) and sodium methoxide (1.1 g) were added to 25 ml of dioxane. The mixture was stirred at 100 °C for 3 hr and then poured into water. The mixture was extracted with ether. The ethereal layer was dried over anhydrous sodium sulfate, and the solvent evaporated *in vacuo*. Distillation of the residue gave 0.70 g (70%) of 3-methylthiazolidine-2-one; bp 85—87 °C/0.3 mmHg (lit,[18] 84—85 °C/0.2 mmHg); IR (neat): 1665 cm^{-1} (C=O). The IR spectrum of the product was in agreement with that of an authentic sample.

Hydrolysis of ***5a***. **5a** (0.02 mol) was dissolved in 20 ml of water. The mixture was heated at 60 °C for 3 hr and then extracted with ether. The ethereal solution was dried over anhydrous sodium sulfate and the solvent evaporated, giving 1.0 g of a yellowish oily residue. The IR spectrum of the residue was essentially the same as that of 3-methylthiazolidine-2-thione.

Reaction of ***5a*** *with Aniline.* **5a** (0.01 mol) and aniline (0.01 mol) were dissolved in 40 ml of acetic acid. The mixture was heated at 100 °C for 1 hr. The solvent was removed under reduced pressure giving a solidified residue. Recrystallization of the residue from acetonitrile gave crystals of the hydroiodide of 2-phenylimino-3-methylthiazolidine in 58% yield; mp 215—220 °C.

Found: N, 8.60%. Calcd for $C_{10}H_{13}IN_2S$: N, 8.75%.

An aqueous solution of the hydroiodide was treated with sodium methoxide giving the precipitate of 2-phenylimino-3-methylthiazolidine; mp 90—92 °C (recrystallized from methanol); IR (KBr): 1610 cm^{-1} (C=N).

Found: C, 61.97; H, 6.49; N, 14.63%. Calcd for $C_{10}H_{12}N_2S$: C, 62.48; H, 6.29; N, 14.58%.

Reaction of ***5a*** *with Tosylhyrdazine.* Tosylhydrazine (3.7 g) was suspended in a solution of **5a** (0.02 mol) in 40 ml of ethanol. The suspension was stirred at 55—60 °C for 4 hr. The reaction mixture turned into a clear solution. The resulting mixture was cooled in an ice box giving 2.7 g (62%) of a precipitate of the hydrazone. Recrystallization of the precipitate from ethanol gave colorless needles; mp 215 °C (dec.); IR (KBr): 1590 cm^{-1} (C=N).

Found: C, 46.08; H, 5.29; N, 15.06%. Calcd for $C_{11}H_{15}N_3O_2S_2$: C, 46.31; H, 5.30; N, 14.73%.

Reaction of ***5a*** with Triethylamine. **5a** (0.01 mol) was dissolved in a solution of triethylamine (1.0 g) in 20 ml of DMSO. The mixture was heated at 80 °C for 4 hr and then poured onto cold water giving 0.70 g (52%) of the precipitate of 3-methylthiazolidine-2-thione. The IR and UV spectra of the product were in agreement with those of an authentic sample.

Reaction of ***5a*** *with Sodium* N,N-*Dimethyldithiocarbamate.* **5a** (0.01 mol) was dissolved in a solution of sodium dimethyldithiocarbamate (3.0 g, 0.015 mol) in 40 ml of DMF. The reaction mixture was heated at 70 °C for 5 hr and then poured onto cold water. The mixture was extracted with benzene. The benzene layer was dried over anhydrous sodium sulfate and the solvent evaporated *in vacuo* giving a half-solid residue (1.3 g). Thin layer chromatography (tlc) was applied to separation and identification of the residue. The chromatogram was developed over silica gel (G. E. Merck Ag., Darmstadt) by dipping the top end of the glass plate in anhydrous ether. The plate was then exposed to iodine vapor showing two spots which were found to be those of methyl *N,N*-dimethyldithiocarbamate (R_f=0.98) and 3-methylthiazolidine-2-thione (R_f=0.46). The result was confirmed by UV spectroscopy.

Reaction of ***6b*** *with Sodium Cyanide.* **6b** (5.4 g, 0.02 mol) and sodium cyanide (1.0 g) were dissolved in 30 ml of DMF. The mixture was heated at 50—60 °C for 6 hr giving the precipitate of sodium perchlorate which was then filtered off. The filtrate was concentrated under reduced pressure and cooled in an ice box giving 3.2 g (93%) of a pale yellowish precipitate. Recrystallization of the solid from ethanol gave colorless crystals (**10**): mp 72—73 °C; IR (KBr): 2260 cm^{-1}(C≡N); NMR ($CDCl_3$): δ 3.37.

Found: C, 42.62; H, 4.61; N, 16.44%. Calcd for $C_6H_8N_2S_2$: C, 41.86; H, 4.68; N, 16.28%.

Reaction of ***6b*** *with Sodium* N,N-*Dimethyldithiocarbamate.* **6b** (5.4 g) and sodium *N,N*-dimethyldithiocarbamate (3.6 g) were dissolved in 20 ml of DMF. The mixture was heated at 60 °C for 2 hr, then poured onto cold water giving 4.4 g (83%) of a white precipitate. Recrystallization of the precipitate from ethanol and acetonitrile gave colorless needles (**11**); mp 142—143 °C. The IR spectrum of the product showed several absorption bands due to -S-CS-N<. The UV spectrum was in agreement with that of an equimolar mixture of methyl *N,N*-dimethyldithiocarbamate and 3-methylthiazolidine-2-thione.

Found: C, 36.28; H, 5.22; N, 10.18%. Calcd for $C_8H_{14}N_2S_4$: C, 36.10; H, 5.26; N, 10.52%.

The reaction of **6b** (0.01 mol) with sodium *N,N*-diethyldithiocarbamate (0.01 mol) carried out as in the case of sodium *N,N*-dimethyldithiocarbamate gave *N*-(*β*-*N'*,*N'*-diethyldithiocarbamoyl)ethylthiazolidine-2-thione in 80% yield; mp 74—75 °C (recrystallized from ethanol).

Found: C, 40.74; H, 6.21%. Calcd for $C_{10}H_{18}N_2S_4$: C, 40.81; H, 6.17%.

Hydrolysis of ***7***. Perchlorate **7**(0.01 mol) was dissolved in 10 ml of water. The mixture was heated at 60 °C for 3 hr and then extracted with benzene. The benzene layer was dried over anhydrous sodium sulfate and the solvent evaporated *in vacuo* giving a small amount of a yellowish oil; IR (neat): 1650 cm^{-1}(C=O). The oil discolored an aqueous solution of iodine and gave the mercury mercaptide on treatment with mercuric chloride indicating the presence of the mercapto group.

Reaction of ***7*** *with Sodium* N,N-*Dimethyldithiocarbamate.* **7** (0.3 g) and sodium dimethyldithiocarbamate (0.5 g) were dissolved in 20 ml of DMF. The mixture was stirred at 60 °C for 30 min and then poured onto cold water giving 0.35 g (98%) of a white precipitate. The product was identical with *o*-xylylene bis(dithiocarbamate) (**8**).

Kinetic Measurements. Hydrolyses (Mode A). The equipment and procedures were the same as those employed previously.[5] The rates of hydrolyses of the carbonium perchlorates were spectrometrically measured at 30 °C by following the disappearance of the cation. Pseudo-first-order rate constants (k_{obs}) were calculated from the plots of 2.303 log $(OD)_0/(OD)_t$ *vs.* time. The plots of k_{obs} against [OH^-] for the cations were linear in the pH range 7.5—9.0. The second-order rate constant (k_a) for reaction with hydroxide ion was calculated from the slopes of plots of k_{obs} *vs.* [OH^-] (Fig. 2).

Reactions with Sodium N,N-*Dimethyldithiocarbamate (Mode B).* The procedures were the same as those employed previously.[3,5] The rates of reactions with the dithiocarbamate anion were measured at 30 °C by following the disappearance of the anion. All reactions were carried out in DMF under equimolar conditions. At various time intervals the dithiocarbamate ion was gravimetrically determined from the quantity of the nickel chelate precipitated by treatment of the aqueous solution of the sample with an excess of a sa-

turated aqueous solution of nickel chloride. The second-order rate constants (k_b) were calculated from the slopes of plots of $1/a-x$ *vs.* time (Fig. 3).

Synthetic Studies by the Use of Carbonates. I. The Nucleophilic Substitution Reaction of Ethylene Carbonate with Amine Hydrohalides

Teruo YOSHINO, Shigeru INABA, Hajime KOMURA, and Yoshiharu ISHIDO

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, O-okayama, Meguro, Tokyo 152

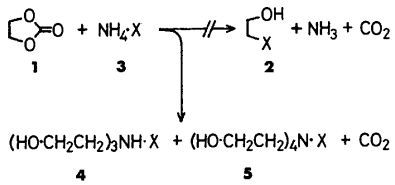
(Received July 25, 1973)

The reaction of ethylene carbonate with various amine hydrohalides gave the corresponding quaternary ammonium salts of β-hydroxyethylamines in good yields.

The nucleophilic substitution reactions of ethylene carbonate(**1**) with metal halides, such as potassium fluoride, lithium chloride, and sodium bromide, accompanied by the evolution of carbon dioxide gas, have been shown to give the corresponding ethylene halohydrins, and the reaction with potassium iodide has been shown to give ethylene oxide exclusively.[1] In view of these facts, the present authors attempted the reaction of **1** by ammonium halides and various amine hydrohalides. The results thus obtained will be described in this paper.

Results and Discussion

On the basis of the idea that the application of ammonium halides to the reaction of **1** in place of the above metal halides may bring about the formation of ethylene halohydrins(**2**), with a concomitant evolution of ammonia and carbon dioxide gas, ammonium bromide(**3**) was allowed to react with three moles of **1** at 145 °C. This reaction, however, afforded no ethylene bromohydrin, but only tri-(**4**) and tetra-β-hydroxyethylammonium bromides(**5**) in 54 and 45% (raw sirup) yields (Scheme 1). The structural assignment of **5** was accomplished by converting it into the corresponding perchlorate of the tetra-*O*-acetate.



Scheme 1

In addition, the reactions of an equimolar portion and two moles of **1** with **3** afforded **4** in 28 and 36% yields, besides the recovered **3** in 13 and 5% yields, respectively; no formation of *N*-mono-, -di-, and -tetra-β-hydroxyethylammonium bromides could be detected. Ammonium chloride and iodide also provided no halohydrin, but only unseparable mixtures of the corresponding tri- and tetra-β-hydroxyethylammonium halides, in reactions with **1**. Accordingly, such a comparative investigation of the reaction of **1** with these ammonium halides was abandoned. These results, however, led us to the assumptions regarding the reaction that halohydrins and ammonia are generated in the initial stage of the reaction, and that they react with each other successively to afford the products described above.

On the basis of these results, various amine hydrohalides were allowed to react with **1**, assuming that this reaction might be a general method for the preparation of β-hydroxyethylamine hydrohalides. Prior to the extention, the difference in the reactivity arising from the nature of halide ions was examined by heating an equimolar mixture of **1** and triethylamine hydrohalides (**6**) at 145 °C (Scheme 2). Volumes of the concomitantly-evolved gas were measured with a gas buret at room temperature under atmospheric pressure. In the cases of **6** (X=Br and I), the evolution of *ca.* 95% of the theoretical amount of carbon dioxide gas was observed within 1 hr; a steady state was thus obtained. In the case of **6**(X=Cl), on the other hand, the volume of evolved gas reached *ca.* 130% of the theoretical yield in the reaction with an equimolar **1**.[2] Such an unusual phenomenon may coincide with the exceedingly lowered yield (5%) of triethyl-β-hydroxyethylammonium halide(**7**) (X=Cl) in contrast with those of **7**(X=Br, 90%; X=I, 91% yield). In these experiments, the bromide (**7**, X=Br) was proved to be more easily crystallized from ethanol than the chloride and the iodide. Consequently, amine hydrobromides were used in the following experiments. The results thus obtained are summarized in Table 1, while the UV absorption spectral data of aromatic amine derivatives are listed in Table 2. The hydrobromides of tertiary amines, such as trimethylamine, pyridine, 2-(**8**), 4-aminopyridine(**9**), quinoline, 8-quinolinol, and nicotinamide(**10**), gave the corresponding mono-β-hydroxyethylammonium bromides in good yields. Moreover, the hydrobromides of primary and secondary amines, such as ethylamine, cyclohexylamine, and morpholine hydrobromides, afforded the corresponding mono-β-hydroxyethylammonium bromides selectively; this was in contrast with the corresponding free amines, which have well been known to afford the corresponding β-hydroxyethylcarbamates[3] selectively in reactions with **1**. The structural assignments of these products were accomplished on the basis of their UV and NMR spectral data. The structures of **11** and **12**, which were obtained from the reaction of **1** with **8**, and with **9**, were examined, since **8** and **9** have

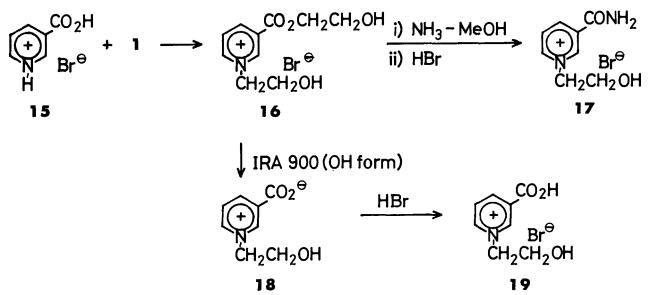
$N_{(1)}$-β-Hydroxyethylnicotinium (**19**)	266 (3800)		260 (3150),	272 (3200)

a) All the spectra were taken in distilled water. b) Numbers in parentheses are molar extinction coefficient (ε). c) The data are of the minimum absorption. d) In the vicinity of this peak, fine structures were observed at 235, 235.5, 237, and 238.5 nm. d) *cf.* Gol'farb, O. N. Setkina, and Y. L. Danyushevskii, *Zh. Obshch. Khim.*, **18**, 124 (1948); *Chem. Abstr.*, **38**, 4137 (1949). e) This is not bromide but inner salt.



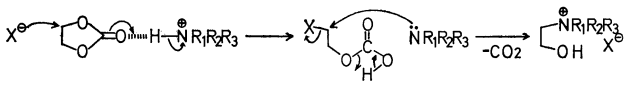
Scheme 4

two potential sites susceptible to the β-hydroxyethylation. Compound **11** was identified with the product of the reaction of **8** with ethylene bromohydrin,[4] and an apparent difference (*ca.* 4.5 Hz) between the $\equiv\overset{+}{N}-CH_2-$ NMR signals of **11** (δ 4.32 ppm) and $N_{(1)}$-β-hydroxyethyl-2-aminopyridinium chloride[5] (δ 3.57 ppm) in their chemical shifts was observed. The esterification of **11** with acetic anhydride–trifluoroboron diethyl etherate afforded the corresponding mono-*O*-acetate. Thus, the structure of **11** was identified as $N_{(1)}$-β-hydroxyethyl-2-aminopyridinium bromide. The structure of **12**($\equiv\overset{+}{N}-CH_2-$ NMR signal: δ 4.32 ppm) was similarly concluded to be $N_{(1)}$-β-hydroxyethyl-4-aminopyridinium bromide. On the other hand, picolinic acid hydrobromide(**13**) and nicotinic acid hydrobromide(**15**) gave $N_{(1)}$-β-hydroxyethylpicolinolactononium bromide(**14**) [IR 1735 cm^{-1} (six-membered

lactone)] and β-hydroxyethyl $N_{(1)}$-β-hydroxyethylnicotinium bromide(**16**) respectively. The treatment of **16** with methanolic ammonia, followed by treatment with aqueous hydrobromic acid, gave $N_{(1)}$-β-hydroxyethylnicotiamidium bromide(**17**), which was identical with the product from the reaction of **1** with **10**; its treatment with Amberlite IRA-900 (OH form) and then with aqueous hydrobromic acid gave $N_{(1)}$-β-hydroxyethylnicotinium bromide(**19**) *via* the zwitter ion, *i.e.*, $N_{(1)}$-β-hydroxyethylnicotinate(**18**).

It can thus be stated, in view of the above results, that this reaction is synthetically advantageous from the following standpoints: 1) The corresponding mono-*N*-β-hydroxyethylated ammonium halides can be prepared in a fairly good yield without regard to whether the amine is aliphatic or aromatic, in contrast with the reactions of **1** with free amines.[3] 2) The process of the reaction can easily be checked by measuring the volume of the carbon dioxide gas evolved in the course of the reaction; this is easier than the procedures involving the reaction of free amines with ethylene halohydrins or those with ethylene oxide in the presence of hydrogen halides or perchloric acid.[6]

The reaction can be assumed to proceed *via* a two-step mechanism; *i.e.*, the first step may be induced by the nucleophilic attack of the halide ion on the methylene carbon atom of **1** to afford an ethylene halohydrin, accompanied by the evolution of carbon dioxide gas; subsequently the resultant amine may attack the methylene carbon, to which the halogen atom is linked, to afford mono-*N*-β-hydroxyethylated ammonium halide, as is shown in Scheme 5.[7]



Scheme 5

Experimental

All the melting points are uncorrected. The IR spectra were determined in potassium bromide disks or neat liquid on a Hitachi EPI-S2 spectrophotometer. The NMR spectra were taken with a Varian T-60 spectrometer, in deuterium oxide as the solvent; the chemical shifts were recorded in δ values relative to sodium 2,2-dimethyl-2-silapentanesulfonate (DSS) as the internal standard, unless otherwise noticed.

*Reaction of Ethylene Carbonate(**1**) with Ammonium Bromide (**3**).* A mixture of **1**(2.7 g, 30 mmol) and **3**(0.9 g, 10 mmol) was heated at 145 °C for *ca.* 1.5 hr until the evolution of carbon dioxide gas has ceased. After the mixture had cooled to room temperature, acetone(30 ml) was added to the mixture. The resultant crystals were filtered and recrystallized from ethanol to give triethanolaminehydrobromide[tri-β-(hydroxyethyl)ammonium bromide](**4**) (2.3 g, 54% yield). Mp 187—189 °C. Found: C, 31.44; H, 6.82; N, 6.18%. Calcd for $C_6H_{16}O_3NBr$: C, 31.31; H, 7.00; N, 6.08%. NMR: δ 3.50 (6H, $-CH_2-\overset{+}{N}\equiv$) and 3.99 (6H, $-CH_2-O-$) ppm.

The evaporation of the above filtrate *in vacuo* gave the raw sirup of tetra-β-hydroxyethylammonium bromide(1.1 g, 45% yield). The sirup(2.7 g, *ca.* 10 mmol) was then treated with 1 M sodium ethoxide solution(10 ml), and the mixture was concentrated *in vacuo* to dryness. The residue was treated with anhydrous ethanol(10 ml), and the resultant crystals of sodium bromide were removed by filtration. The solution was neutralized with a 60% aqueous perchloric acid solution and then concentrated *in vacuo* to afford a sirup(1.9 g); this sirup was treated with acetic anhydride(8 ml) in the presence of trifluoroboron diethyl etherate(5 drops) at room temperature and then stirred with methanol(50 ml) for 2 hr, with evaporations *in vacuo* repeated 3 times after the addition of each 20-ml portion of benzene-ethanol(1 : 1 v/v), to give a sirup. The sirup was crystallized in a refrigerator, and the crude crystals were recrystallized from ethanol to give tetra-β-acetoxyethylammonium perchlorate. Mp 103.5—105.5 °C. Found: C, 41.87; H, 6.07; N, 3.21%. Calcd for $C_{16}H_{28}O_{12}NCl$: C, 41.60; H, 6.11; N, 3.03%. NMR-(DMSO-d_6, DSS): δ 2.10(12H, -OAc), 4.00(8H, $-CH_2-\overset{+}{N}\equiv$) and 4.60 (8H, $-CH_2-O-$) ppm.

On the utilization of an equimolar amount and 2 mol of **1** to **3**, tetra-β-hydroxyethylammonium bromide was not obtained, but tri-β-hydroxyethylammonium bromide was obtained in 28 and 36% yields respectively. Moreover, 13 and 5% recoveries of **3** were observed in these two cases.

*Reaction of **1** with Triethylamine Hydrohalides(**6**). The Measurement of the Velocity of Carbon Dioxide Gas Evolution.* The

The reaction vessel used for the measurements was a three-necked, 100-ml, round-bottomed flask fitted with an air-tight stirrer and an Allihn condenser. The top of the condenser was attached to a gas buret. The flask, containing **1**(1.76 g, 20 mmol) and triethylamine hydrohalides (**6**)(20 mmol), was immersed in a constant-temperature bath held at 145±0.2 °C. For the isolation of the products, the reaction mixtures were treated with dried acetone(50 ml); the resulting crystals were filtered and recrystallized from ethanol to give the corresponding triethyl-β-hydroxyethylammonium halides.

The Chloride was obtained as an equimolar mixture with triethylamine hydrochloride; its yield was calculated as 5% by means of the NMR spectrum of the mixture. NMR: δ 1.28 (9H, 3Me), 3.29(6H, $CH_3-CH_2-\overset{+}{N}\equiv$), and 3.38(2H, $HOCH_2-CH_2-\overset{+}{N}\equiv$), and 3.94(2H, $-O-CH_2-$) ppm.

The Bromide: Mp>230 °C. Found: C, 42.74; H, 8.82; N, 6.46%. Calcd for $C_8H_{20}ONBr$: C, 42.48; H, 8.82; N, 6.19%. NMR: δ 1.27(9H, 3Me), 3.29(6H, $CH_3-CH_2-\overset{+}{N}\equiv$), 3.38(2H, $HOCH_2-CH_2-\overset{+}{N}\equiv$), and 3.94(2H, $-CH_2-O-$) ppm.

The Iodide: Mp>230 °C. Found: C, 33.68; H, 7.26; N, 5.03%. Calcd for $C_8H_{20}ONI\cdot 1/2H_2O$: C, 34.05; H, 7.14; N, 4.96%. NMR: δ 1.28(9H, 3Me), 3.40(6H, $CH_3-CH_2-\overset{+}{N}\equiv$), 3.37(2H, $HOCH_2-CH_2-\overset{+}{N}\equiv$), and 3.98(2H, $-CH_2-O-$) ppm.

*Reaction of **1** with Ethylamine Hydrobromide.* Compound **1**(2.7 g, 30 mmol) and ethylamine hydrobromide(3.7 g, 30 mmol) were heated together for 1 hr at 155—160 °C to evolve carbon dioxide gas almost quantitatively. After cooling, the mixture was treated with acetone(30 ml); the resulting crystals were then filtered and recrystallized from ethanol–acetone to give ethyl-β-hydroxyethylammonium bromide(1.7 g, 32% yield). Mp 40—45 °C(hygroscopic). Found: C, 28.34; H, 7.15; N, 8.13%. Calcd for C_4H_{12}-ONBr: C, 28.25; H, 7.11; N, 8.23%. NMR: δ 1.32-(3H, Me), 3.08(2H, $-CH_2-\overset{+}{N}\equiv$), 3.35(2H, $HOCH_2-CH_2-\overset{+}{N}\equiv$), and 3.90(2H, $-CH_2-O-$) ppm. The concentration of the mother liquor of the recrystallization gave a sirup(2.0 g) which was deduced to be a carbamate from its IR spectrum (1688 cm^{-1}).

*Reaction of **1** with Cyclohexylamine Hydrobromide.* The reaction of **1**(2.0 g, 22 mmol) with cyclohexylamine hydro-

bromide(3.6 g, 20 mmol) was carried out in a manner similar to that described above to give cyclohexyl-β-hydroxyethylammonium bromide(3.1 g; 70% yield). Mp 124—126 °C. Found: C, 43.09; H, 9.93; N, 6.5%. Calcd for $C_8H_{18}ONBr$: C, 42.87; H, 9.99; N, 6.25%. NMR: δ 1.2—2.1 (10H, m, ring proton), 3.21(2H, $HOCH_2$-CH_2-$\overset{+}{N}\equiv$), and 3.88 (2H, -CH_2-O-) ppm.

Reaction of ***1*** *with Morpholine Hydrobromide.* Compound **1**(4.8 g, 55 mmol) and morpholine hydrobromide(8.4 g, 50 mmol) were heated together at 155—160 °C for about 1.5 hr. After cooling, ethanol(50 ml) was added to the mixture, and the resulting mixture was treated with a 1 M methanolic sodium methoxide solution to remove the hydrobromic acid. The solvent was vaporated *in vacuo*, and the residue was treated with acetone(80 ml) to remove the sodium bromide by filtration. After the evaporation of the solvent *in vacuo*, the resultant sirup was distilled to give *N*-β-hydroxyethylmorpholine(4.1 g, 61% yield). Bp 61—63 °C/0.5 mmHg. Found: C, 54.64; H, 9.93; N, 10.69%. Calcd for $C_6H_{13}O_2N$: C, 54.94; H, 9.99; N, 10.68%. NMR-($CDCl_3$-TMS): δ 2.51—2.56(6H, -CH_2-$\overset{+}{N}\equiv$) and 3.67-(6H, -CH_2-O-) ppm.

Reaction of ***1*** *with Pyridine Hydrobromide.* Compound **1**(2.7 g, 30 mmol) and pyridine hydrobromide(3.3 g, 20 mmol) were heated together for 50 min at 140—145 °C. After cooling, ethanol(40 ml) was added to the mixture, it was treated with active charcoal, and acetone(50 ml) was added. The resulting crystals were filtered and found to be pure enough for elemental analysis. The yield of *N*-β-hydroxyethylpyridinium bromide was 3.3 g(81%). Mp 104—105 °C. Found: C, 40.81; H, 4.91; N, 6.41%. Calcd for $C_7H_{10}ONBr$: C, 41.19; H, 4.94; N, 6.86%. NMR: δ 4.17 (2H, -CH_2-O-), 4.86(2H, -CH_2-$\overset{+}{N}\equiv$), 8.23(2H, H_β), 8.70 (1H, H_γ), and 9.00(2H, H_α) ppm. UV: $\lambda_{max}^{H_2O}$ 260 nm(ε 4500) and $\lambda_{shoulder}^{H_2O}$ 254 and 266 nm(ε 3400 and 3400 respectively).

Reaction of ***1*** *with Hydrobromides of Trimethylamine, 2-(****8****), 4-Aminopyridine(****9****), Quinoline, 8-Quinolinol, and Nicotinamide (****10****).* These reactions were carried out in almost the same way as has been described in the preceding reactions.

N-β-*Hydroxyethyltrimethylammonium Bromide*: The crystals resulting from the addition of acetone to the ethanolic solution of the resulting reaction mixture were recrystallized from ethanol to give a product(4.1 g, 74% yield). Mp >230 °C. Found: C, 32.71; H, 7.76; N, 7.64%. Calcd for $C_5H_{13}ONBr$: C, 32.62; H, 7.66; N, 7.61%. NMR: δ 3.25(8H, 3Me), 3.53(2H, -CH_2-$\overset{+}{N}\equiv$), and 4.05(2H, -CH_2-O-) ppm.

$N_{(1)}$-β-*Hydroxyethyl-2-aminopyridinium Bromide (****11****)*: The crystals obtained in the way described in the preceding experiment were recrystallized from ethanol to give the product(1.8 g; 79% yield). Mp 129—131.5 °C. Found: C, 38.48; H, 5.36; N, 13.10%. Calcd for $C_7H_{11}ON_2Br$: C, 38.37; H, 5.06; N, 12.78%. NMR: δ 4.05(2H, -CH_2-O-), 4.32(2H, -CH_2-$\overset{+}{N}\equiv$), and 6.8—8.1(4H, m, ring protons) ppm. UV: $\lambda_{max}^{H_2O}$ 232 and 302 nm (ε 7700 and 5700 respectively), and $\lambda_{min}^{H_2O}$ 251 nm (ε 220).

$N_{(1)}$-β-*Hydroxyethyl-4-aminopyridinium Bromide (****12****)*; The crystals obtained in the same way were recrystallized from ethanol to give a product(2.3 g; 99% yield). Mp 130—131 °C. Found: C, 38.60; H, 4.78; N, 13.10%. Calcd for $C_7H_{11}ON_2Br$: C, 38.37; H, 5.06; N, 12.78%. NMR: δ 4.00(2H, -CH_2-O-), 4.32(2H, -CH_2-$\overset{+}{N}\equiv$), 6.92(2H, H_β), and 8.06(2H, H_α) ppm. UV: $\lambda_{max}^{H_2O}$ 269 nm (ε 21000).

Acetylation of ***11*** *and* ***12***: Compounds **11** and **12**(920 mg, 4 mmol) were treated with acetic anhydride(3 ml) and trifluoroboron diethyl etherate(3 drops) respectively at room temperature overnight. After the addition of methanol (50 ml), the mixture was stirred for 3 hr at room temperature and the solvent was evaporated *in vacuo* to dryness. The resultant crystals were recrystallized from ethanol to give colorless crystals.

$N_{(1)}$-β-*Acetoxyethyl-2-aminopyridinium Bromide*: Yield, 1.14 g(81%). Mp 164—166 °C. Found: C, 41.55; H, 5.18; N, 10.58%. Calcd for $C_9H_{13}O_2N_2Br$: C, 41.45; H, 5.02; N, 10.73%. NMR: δ 2.17(3H, -OAc), 4.61(2H, -CH_2-OAc), 4.70(2H, -CH_2-$\overset{+}{N}_{(1)}\equiv$), 6.9—8.1(4H, m, ring protons) ppm.

$N_{(1)}$-β-*Acetoxyethyl-4-aminopyridinium Bromide*: Yield, 0.63 g(67%). Mp 208—209 °C. Found: C, 41.41; H, 4.91; N, 10.87%. Calcd for $C_8H_{13}O_2N_2Br$: C, 41.45; H, 5.02; N, 10.73%. NMR: δ 2.30(3H, -OAc), 4.03(2H, -CH_2-OAc), 4.58(2H, -CH_2-$N_{(1)}\equiv$), 8.10(2H, H_β), and 8.60(2H, H_α) ppm.

N-β-*Hydroxyethylquinolinium Bromide.* The crystals obtained in the same way as in the reaction of **1** with pyridinium bromide were recrystallized from acetonitrile-acetone to give a product(2.24 g; 71% yield). Mp 139—139.5 °C. Found: C, 51.30; H, 4.52; N, 5.31%. NMR: δ 4.38(2H, -CH_2-O-), 5.38(2H, -CH_2-$\overset{+}{N}\equiv$), 7.9—8.7(5H, m, ring protons), 9.28(1H, H-4), and 9.59(1H, H-2) ppm. UV: $\lambda_{max}^{H_2O}$ 236 and 316 nm(ε 54000 and 12500 respectively) and $\lambda_{min}^{H_2O}$ 258 nm(ε 280).

N-β-*Hydroxyethyl-8-quinolinolium Bromide.* The crystals obtained as in the above cases were recrystallized from ethanol-acetone to give a product(3.90 g; 73% yield). Mp 182.5—183.5 °C. Found: C, 48.99; H, 4.54; N, 5.26%. Calcd for $C_{11}H_{12}O_2NBr$: C, 48.90; H, 4.48; N, 5.19%. NMR: δ 4.30(2H, -CH_2-O-), 5.53(2H, -CH_2-$\overset{+}{N}\equiv$), 7.4—8.2(4H, m, ring protons), 9.03(1H, H-4), and 9.15(1H, H-2) ppm. UV: $\lambda_{max}^{H_2O}$ 256 nm(ε 35400), $\lambda_{shoulder}^{H_2O}$ 275 nm(ε 2950), and $\lambda_{min}^{H_2O}$ 363 nm(ε 150).

$N_{(1)}$-β-*Hydroxyethylnicotinamidium Bromide (****17****)*. The crystal obtained in the same way as above were recrystallized from ethanol to give a product(4.9 g; 100% yield). Mp 153—154 °C. Found: C, 38.78; H, 4.40; N, 11.60%. Calcd for $C_8H_{11}O_2N_2Br$: C, 39.04; H, 4.10; N, 11.40%. NMR: δ 4.17(2H, -CH_2-O-), 4.90(2H, -CH_2-$\overset{+}{N}\equiv$), 8.30(1H, H-5), 9.00(1H, H-6), and 9.39(1H, H-2) ppm. UV: $\lambda_{max}^{H_2O}$ 265 nm(ε 3800), $\lambda_{shoulder}^{H_2O}$ 259 and 272 nm(ε 3100 and 3200 respectively).

Reaction of ***1*** *with Picolinic Acid Hydrobromide (****13****).* Compound **1**(1.8 g, 20 mmol) and picolinic acid hydrobromide (2.04 g, 20 mmol) were heated together at 152 °C for 40 min, after which the mixture was treated with acetone-ethanol (1 : 3 v/v, 100 ml). The filtration of the resultant yellow granular crystals gave *N*-β-hydroxyethylpicolinolactononium bromide(2.8 g; 61% yield), which was analytically pure enough. Mp 225 °C. Found: C, 42.06; H, 3.68; N, 6.20%. Calcd for $C_8H_8NO_2Br$: C, 41.77; H, 3.50; N, 6.09%. NMR: δ 5.15(4H, -CH_2-), 8.3—9.0 (3H, ring protons), and 9.15(1H, H-6) ppm. IR: 1735 cm^{-1} (six-membered lactone). UV: $\lambda_{max}^{H_2O}$ 265 nm (ε 7700), $\lambda_{shoulder}^{H_2O}$ 259 and 272 nm (ε 3100 and 3200 respectively).

Reaction of ***1*** *with Nicotinic Acid Hydrobromide (****15****).* Compound **1**(8.8 g, 100 ml) and nicotinic acid hydrobromide (**15**)(4.2 g, 20 mmol) were heated together at 150 °C for 40 min. The resultant red-brown sirup was treated with dioxane-ethanol(1 : 1 v/v, 80 ml) to give colorless crystals of β-hydroxyethyl *N*-β-hydroxyethylnicotinatonium bromide (**16**) (5.07 g, 87% yield). Found: C, 40.97; H, 5.21;

N, 4.69%. Calcd for $C_{10}H_{14}O_4NBr$: C, 41.40; H, 4.83; N, 4.80%. NMR: δ 4.00 and 4.14(2H and 2H respectively, $-CH_2OH$), 4.60(2H, $-CH_2-O-CO-$), 4.88(2H, $-CH_2-\overset{+}{N}\equiv$), 8.29(1H, H-5), 9.11(1H, H-2) ppm.

Treatment of ***16*** *with Methanolic Ammonia.* Compound **16**(290 mg) was treated with methanolic ammonia saturated at 0 °C(50 ml) in a stoppered flask in a refrigerator overnight. The subsequent evaporation of the solvent *in vacuo* gave orange scaly crystals (290 mg); the residue was dissolved in ethanol (30 ml) followed by treatment with 10% aqueous hydrobromic acid, with the pH adjusted at about 5. After the evaporation of the solvent *in vacuo*, the residue was dissolved in ethanol (30 ml), treated with active charcoal, and then filtered. To the filtrate, we added *n*-hexane until the turbidity was noticed; the mixture was then allowed to stand in a refrigerator. The resultant scaly crystals were filtered to afford $N_{(1)}$-β-hydroxyethylnicotinamidium bromide(250 mg; 100% yield). Mp 153—154 °C. The product was identified with **17** by examining the mixed melting point.

Treatment of ***16*** *with Amberlite IRA-900.* Compound **16** (1.0 g) was treated with Amberlite IRA-900(OH form, 20 ml) in methanol(100 ml) under stirring overnight; the resin was then filtered and the solvent was evaporated to about 30 ml to give pale yellow crystals of $N_{(1)}$-β-hydroxyethylnicotinate (**18**) (0.4 g, 72% yield). Mp 230—231 °C. Found: C, 57.58; H, 5.87; N, 8.68%. Calcd for $C_8H_9O_2N$: C, 57.48; H, 5.43; N, 8.38%. NMR δ 4.19(2H, $-CH_2-O-$), 4.80(2H, $-CH_2-\overset{+}{N}\equiv$), 8.14(1H, H-5), 8.90(1H, H-4), and 9.19(1H, H-2) ppm.

Treatment of ***18*** *with Aqueous Hydrobromic Acid.* Compound **18**(167 mg) was dissolved in methanol (30 ml); the mixture was treated with 10% aqueous hydrobromic acid, with the pH adjusted at about 5 by the use of a pH test paper. After the evaporation of the solvent, the residue was recrystallized from ethanol to give $N_{(1)}$-β-hydroxyethylnicotinium bromide (**19**) (140 mg, 57% yield). Mp 107—109 °C. Found: C, 38.44; H, 3.94; N, 5.87%. Calcd for $C_8H_{10}O_3NBr$: C, 38.73; H, 4.06; N, 5.64%. NMR: δ 4.16(2H, $-CH_2-O-$), 4.89(2H, $-CH_2-\overset{+}{N}\equiv$), 8.29(1H, H-5), 9.10(1H, H-4), 9.12(1H, H-6), and 9.47(1H, H-2) ppm. UV: $\lambda_{max}^{H_2O}$ 266 nm(ε 3800) and $\lambda_{shoulder}^{H_2O}$ 260 and 272 nm(ε 3150 and 3200 respectively).

The authors wish to thank to the members of the Laboratory of Elemental Analysis, Department of Chemistry, Tokyo Institute of Technology, for the elemental analyses. They are also grateful to the Ministry of Education, for a Scientific Research Grant-in-Aid, and to the Kurata Foundation for a grant.

Substituent Effects on the ^{13}C and ^{1}H Chemical Shifts of 1-Phenyl-1,3-butadiene and Phenylallene

Tadashi Okuyama, Kunisuke Izawa, and Takayuki Fueno

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received, August 6, 1973)

CMR and PMR spectra of *trans*-1-phenyl-1,3-butadiene (PBD) and phenylallene (PA) and their ring-substituted derivatives (*p*-CH_3, *m*-CH_3, *p*-Cl, and *m*-Cl) have been measured. The chemical shifts of side-chain carbons and protons were treated with a Hammett-type relationship. The carbon chemical shifts of the side chain gave alternately opposite sign of ρ values while those of PA showed little dependence on the ring substitution. The ^{1}H chemical shifts showed behavior different from that of the ^{13}C shifts. The mode of electron polarization along the side-chain of PBD and PA was discussed to interpret the observations.

It is well known that the efficiency of a C=C double bond in transmitting electronic effects is greater than that of a saturated CH_2 group.[1] The π-bond polarization may contribute to the greater transmission efficiency of double bond. Kajimoto and Fueno[2] have recently found that the alternation of substituent effects on the ^{13}C chemical shifts occurs along the conjugated framework of 1-substituted 1,3-butadienes. The electronic effects are transmitted mainly through successive π-bond polarization.

$$X \leftarrow \overset{\delta-}{C}=\overset{\delta+}{C}-\overset{\delta\delta-}{C}=\overset{\delta\delta+}{C}$$

However, because of direct substitution at the 1-carbon' additional factors may have contributed to the chemical shifts of unsaturated carbons. To avoid this complexity, we have measured CMR spectra of ring-substituted 1-phenyl-1,3-butadienes.

On the other hand, opposite polarization of π-electrons in the orthogonal p-orbitals of the acetylenic bond has recently been considered in an attempt to interpret the substituent effects on the ^{13}C chemical shift of 1-phenylpropyne.[3] In this connection, it is interesting to examine the mode of bond polarization of allene which has cumulative orthogonal π-bonds. Thus, we have measured CMR spectra of some ring-substituted phenylallenes.

Proton chemical shifts have also been measured for the sake of comparison.

Results

The ^{13}C NMR spectra of *trans*-1-phenyl-1,3-butadiene (PBD) and phenylallene (PA) and their derivatives were measured as a neat liquid or a 50% solution in carbon disulfide. The observed signals were assigned by comparison with the partially proton-decoupled spectra and by the aid of the additivity rule[4] in the same way as described previously.[2,3] The chemical shifts of side-chain carbons are listed in Tables 1 and 2 for PBD's and PA's, respectively, in ppm downfield from tetramethylsilane.

Proton spectra were recorded with a 10% solution in carbon tetrachloride at the frequency of 100 MHz. The assignment of signals was accomplished through the analysis of their mode of coupling. The ^{1}H chemical shifts assigned are included in Tables 1 and 2.

Discussion

Butadiene System. Figure 1 shows plots of the chemical shifts of various side-chain carbons of PBD's against Hammett's σ values. It clearly exhibits that the sign of slope changes alternately from the α- to δ-carbon. That is, ρ values for the α- and γ-carbons are negative while those for the β- and δ-carbons are positive as are given in Table 1. These results apparently show the alternation of polar effects in the conjugated system. An electron-donating group on the phenyl ring increases the electron densities at the β- and δ-carbons (unfield shift) while it does decrease the electron densities at the α- and γ-carbons (downfield shift) of PBD.

Another interesting finding is that the ρ values are essentially equal for the β- and δ-carbons, 5.07 and 4.74. That is, the attenuation factor of C=C double bond in transmitting the substituent effects is close to unity (0.93) in the conjugated system. These ρ values are comparable with the value for the β-carbon of

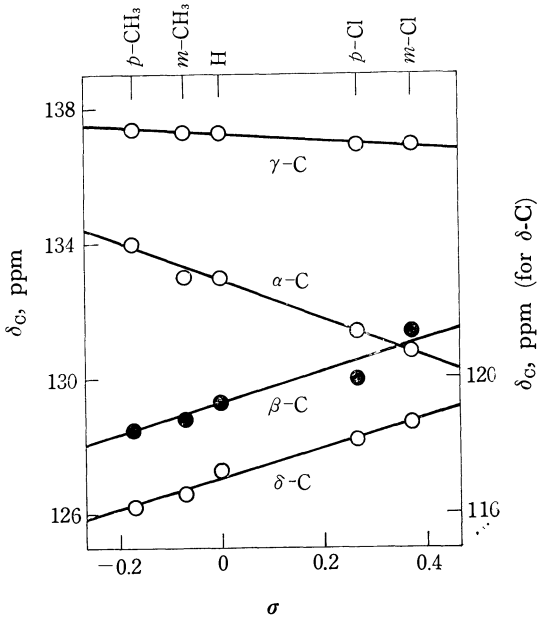

Fig. 1. Hammett-type plots of the ^{13}C chemical shifts of the side-chain carbons of *trans*-1-phenyl-1,3-butadienes.

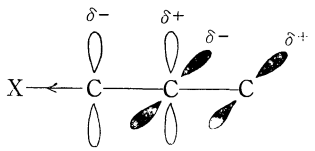
styrene (4.73).[5]

As for the PMR data, a fairly good linear correlation was obtained between the *trans*-δ-proton chemical shifts and Hammett's σ values with $\rho = 0.162$ ppm/σ. The sign is the same as that for the δ-carbon shift. The attenuation factor of the $C_\gamma = C_\delta$ bond is, however, *ca.* 0.5; the ρ value for the *trans*-β-proton shift of styrene is 0.335.[6]

The different efficiencies of the carbon chain in transmitting the substituent effects on the ^{13}C and ^{1}H chemical shifts contradict the earlier suggestion that ^{1}H shift mainly reflects the electron density of the attached carbon.[7] The ^{13}C shift was concluded on a sound basis to be determined predominantly by the electron density on the carbon atom of question.[8] Therefore, it is very likely that some other factors contribute to the determination of ^{1}H shift. Kajimoto and Fueno[9] pointed out that ^{1}H chemical shift is influenced by electron densities on both the hydrogen atom in question and the carbon atom directly bonded to it and that they very often show different dependence on a structural perturbation. This type of anomaly between ^{13}C and ^{1}H chemical shifts is becoming apparent as CMR data are accumulated.

Allenic System. The chemical shifts of side-chain carbons of PA's summarized in Table 2 show little dependency on the ring substitution. The ρ values were calculated and included in Table 2. The ρ values for the α-, β-, and γ-carbons are negative, nearly zero, and slightly positive, respectively.

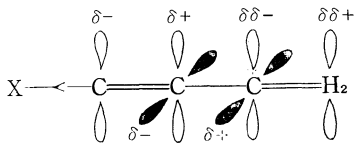
These observations might be explained by considering the polarization of π-electrons like



The opposite sign of ρ values between the α- and γ-carbons is understandable by this polarization. The net change in the electron density at the β-carbon would be very small owing to the cancellation of contributions from two orthogonal p-orbitals. This could be a reason for the low ρ value for the β-carbon shift.

On the other hand, chemical shifts of the γ-protons of PA show a fairly good linear correlation with Hammett's σ values. The ρ value is not very small (0.151 ppm/σ), being comparable with that for the δ-proton of PBD.

This distinctive difference between ^{13}C and ^{1}H shifts at the γ-position of PA seems to suggest that some special mechanism of electron polarization is operative in the side-chain bonds of PA. One possible explanation is a hyperconjugative model like



That is, electrons in the orbitals parallel to α-β π-orbitals are alternately polarized like conjugated diene, using the pseudo π-orbital of the γ-hydrogens. This may also explain the small ρ value for the γ-carbon shift. The hyperconjugative interaction may be effective because of the rigid structure of allene with favorable orientation of the γ-hydrogens.

Experimental

Materials. Preparations of *trans*-1-phenyl-1,3-butadiene (PBD) and phenylallene (PA) and their ring-substituted derivatives were described previously.[10,11]

NMR Measurements. The CMR spectra of a neat liquid of PBD derivatives and of a 50% solution in CS_2 of PA derivatives were recorded at 24 °C on a JEOL C-60 HL spectrometer with a 15.09 MHz RF unit as described previously.[2,3]

The PMR spectra were obtained on a JNM 4H-100 spectrometer at room temperature (~22 °C). A 10% solution of a sample in CCl_4 was used for the measurement. TMS was used as internal standard.

The authors wish to thank Messrs. Y. Terawaki and H. Okuda for recording the spectra.

Codimerization of Ethylene and Styrene Catalyzed by Bis(triphenylphosphine)-σ-Arylnickel(II) Halide–Trifluoroboron Etherate

Noboru KAWATA, Ken-ichi MARUYA, Tsutomu MIZOROKI, and Atsumu OZAKI

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received November 15, 1972)

The codimerization of styrene with ethylene was studied using the catalyst system composed of bis(triphenylphosphine)σ- aryl(bromo)nickel(II) and trifluoroboron etherate in methylene dichloride. The codimerization takes place readily at 0 °C under atmospheric pressure to give 3-phenyl-1-butene selectively. The reaction scheme was discussed on the basis of the product distribution during the course of reaction and its kinetics.

Many catalyst systems have been reported for dimerization of olefins and dienes since transition metal complexes, especially the VIII subgroup, were found to have a significant effect on selective dimerization. Attention has been paid to the active species of the catalyst, which is accepted to be a hydro metal complex. Its activity and selectivity, however, depend considerably on its metal and ligands (including solvent) as well as the olefin specified. During the course of our study on the activity and selectivity of the catalyst composed of nickel(II) compound and a Lewis acid for the ethylene dimerization, it was found that the bis(triphenylphosphine)σ-arylnickel(II) halide–trifluoroboron etherate catalyst system significantly enhanced the rate of ethylene dimerization to give butene selectively.[1] This catalyst system is less active for the dimerization of propylene or its codimerization with ethylene, but highly active and selective for the codimerization of styrene with ethylene.[2]

Rhodium(II) chloride[3] and palladium(II) chloride[4,5] catalyze the codimerization of ethylene and styrene even in the absence of Lewis acid. The former gives 2-phenyl-2-butene under a high pressure of ethylene(100 atm) and the latter 1-phenyl-butenes. Codimerization of styrene with ethylene was studied with two nickel complexes as the catalyst, one consisting of nickel diacetylacetonate, trialkylaluminium and trialkylphosphite, which gave cyclic oligomers of ethylene and styrene and only a small amount of their codimer,[6] and the other consisting of tetrakis(trichlorophosphine)-nickel, aluminium bromide and butyl lithium, which gave a mixture of 3-phenyl-1-butene, 2-phenyl-2-butene and 2-phenyl-1-butene.[7] The present catalyst system, however, gives 3-phenyl-1-butene selectively without being accompanied by 1-phenyl-butenes. This paper deals with the mechanism of the selective formation of 3-phenyl-1-butene.

Experimental

Materials. Dibromobis(triphenylphosphine)nickel(II)[8] and bis(triphenylphosphine)σ-aryl(bromo)nickel(II)[9] were prepared according to the methods given in literature. The results of elemental analysis of the carbon and hydrogen of these nickel complexes were as follows; bis(triphenylphosphine)dibromonickel(II) (Calcd: C, 58.2; H, 4.1%. Found: C, 58.2; H, 4.0%), bis(triphenylphosphine)-1-naphthyl-(bromo)nickel(II) (Calcd. C, 69.9; H, 4.7. Found: C, 69.9; H, 4.5%), bis(triphenylphosphine)-*o*-tolyl(bromo)-nickel(II) (Calcd: C, 68.5; H, 4.9%. Found: C, 67.1; H, 4.6%) and bis(triphenylphosphine)mesityl(bromo)nickel(II) (Calcd: C, 69.1; H, 5.3%. Found: C, 69.1; H, 4.7%). Commercial styrene, α- and ω-methyl styrene, ω-bromo styrene and *o*-, *m*-, and *p*-chlorostyrenes were dried under nitrogen with a molecular sieve before use. *o*-, *m*-, and *p*-Methyl styrene were prepared according to the literature[10] and purified by vacuum distillation. Small amounts of air and water in commercial ethylene were separated by means of a liquid nitrogen trap. Benzene and diethyl ether were well dried with metallic sodium before being purified by distillation, while methylene dichloride was dried with the molecular sieve. Trifluoroboron etherate was also purified by distillating its diethyl ether solution under nitrogen.

Procedure. All experiments were operated under nitrogen atmosphere. To a well dried methylene dichloride solution of bis(triphenylphosphine)σ-aryl(bromo)nickel(II) in a two necked flask(50 ml in vol.) were added trifluoroboron etherate, followed by adding a given amount of styrene. The nitrogen gas in the flask was evacuated at the temperature of liquid nitrogen, and the flask was kept in an ice-water bath before introducing ethylene gas at 0 °C with vigorous stirring. The gaseous pressure inside the flask was kept constant(±1 cmHg) during the course of reaction by adjusting the supply of ethylene with a fine needle valve. After a specified period of time, the reaction was terminated by adding an aqueous sodium hydroxide solution(1 M, 5 ml). Volatile substances such as ethylene, butenes and the solvent had been transferred to another flask by means of a liquid nitrogen trap before non-volatile materials were well extracted with *n*-hexane. They were quantitatively determined by a gaschromatography equipped with an FID detector.

Identification and Analysis. A VZ-7 column (4 mmφ, 8 m) was used at room temperature with nitrogen as a carrier gas for the quantitative dtermination of butenes. A DC-550 column (4 mmφ, 4 m) was used at 120 °C for the styrene-ethylene codimers. Most products were isolated by preparative gas-chromatography to be identified by NMR spectroscopy. Some of them were also checked by IR and mass spectroscopy when necessary.

3-phenyl-1-butene (CH_3– 8.70τ(d) 3H, –CH– 6.60τ(qui) 1H, CH_2=CH– 4.96τ and 4.00τ(m) 3H, and C_6H_5– 2.74τ(m) 5H): *trans*-2-phenyl-2-butene (CH_3– 8.54τ(s) 3H, CH_3–CH= 8.12τ(d) 3H, –CH= 4.48τ(m) 1H, and C_6H_5– 2.79(m) 5H): *cis*-2-phenyl-2-butene (CH_3– 8.16τ(s) 3H, CH_3–CH– 8.40τ(d) 3H, –CH= 4.23τ(m) 1H, and C_6H_5– 2.77τ(m) 5H). These phenyl butenes were all hydrogenated with Raney nickel catalyst to give 2-phenyl butane (CH_3–CH_2– 9.22τ(t) 3H, –CH_2– 8.45τ(qui) 2H, –CH– 7.50τ(m) 1H, CH_3–CH– 8.82 (d) 3H, and C_6H_5– 2.78τ(m) 5H). 3-methyl-3-phenyl-1-pentene (CH_3–CH_2– 9.30τ(t) 3H, –CH_2– 8.32τ(qua) 2H, CH_3–C– 8.75τ(s) 3H, CH_2–CH– 5.0 and 3.95τ(m) 3H, and C_6H_5–, 2.70 (m) 5H), the parent peak of its mass spectrum being 160: 3-(*p*-chlorophenyl)-1-butene (CH_3– 8.73τ(d) 3H, –CH– 6.63 (qiu) 1H, CH_2=CH– 5.00 and 4.14(m) 3H,

TABLE 1. EFFECT OF σ-ARYL LIGAND

No.	Cat.	Styrene consumed (mmol)	3-Phenyl-1-butene formed (mmol)	Select. (%)	Butenes

(σ-aryl)NiBr($P\phi_3$)$_2$, 1 mmol; $BF_3\cdot OEt_2$, 1 mmol; styrene employed, 174 mmol (2 ml); CH_2Cl_2, 30 ml; $P_{C_2H_4}$ 45—50 cmHg; temp. 0°C; time, 15 min.

and Cl–C_6H_4– 2.92τ(m) 4H): 2,3-diphenyl-1-butene (CH_3– 8.83τ(d) 3H, –CH– 6.50τ(qua) 1H, CH_2=C– 3.65τ(s) 2H, and C_6H_5– 2.77τ(m) 10H). The other products were estimated by the relative retention time on their gas chromatograms.

Results

Effect of σ-aryl Ligand: A methylene dichloride solution (30 ml) of bis(triphenylphosphine)σ-aryl(bromo)-nickel(II) (1.0 mmol), trifluoroboron etherate (1.0 mmol) and styrene (17.4 mmol) was treated at 0 °C with ethylene under about 70 cmHg for 15 min. The results are given in Table 1. Bis(triphenylphosphine)-σ-aryl(bromo)nickel(II) (No. 1,2,3) is highly active for codimerization to give 3-phenyl-1-butene selectively. In this case, small amounts of butenes were formed, while only trace amounts of isomers of 3-phenyl-1-butene were detected. Bis(triphenylphosphine)dibromonickel(II) (No. 4) has no activity for the codimerization, where the consumption of some amount of styrene seems to be caused by its polymerization with trifluoroboron etherate. The selectivity to 3-phenyl-1-butene decreases in the order, mesityl> naphthyl>o-tolyl.

Figure 1 shows the variation in the amounts of products during the codimerization of styrene with ethylene under the specified conditions. The results were ob-

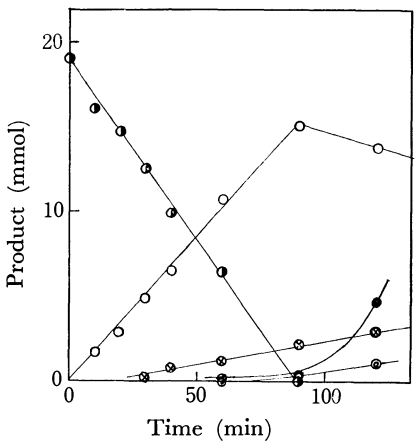

Fig. 1. Product distribution during the course of codimerization.
(1-naphthyl)NiBr($P\phi_3$)$_2$, 0.5 mmol; $BF_3\cdot OEt_2$, 0.5 mmol; styrene 19.1 mmol; CH_2Cl_2, 30 ml; $P_{C_2H_5}$, 50 cmHg; temp. 0°C. ◑: styrene, ○: 3-phenyl-1-butene, ⊗: 3-methyl-3-phenyl-1-pentene, ◎: 2-phenyl-2-butene, ●: butenes.

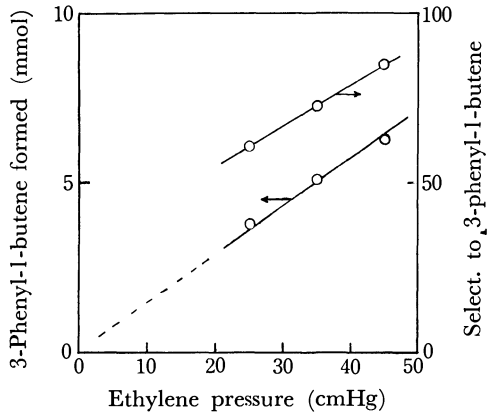

Fig. 2. Effect of ethylene pressure on the rate of codimerization; (1-naphthyl)NiBr($P\phi_3$)$_2$, 0.5 mmol; $BF_3\cdot OEt_2$, 0.5 mmol; styrene, 19.1 mmol; CH_2Cl_2, 30 ml; temp. 0°C; time. 30 min.

tained from repeated runs of the codimerization under the same conditions. It is shown that the reaction rate is independent of the concentration of styrene and that practically no dimerization of ethylene takes place until most of the styrene is consumed. It is to be noted that the ethylene dimerization as well as isomerization of 1-butene formed is accelerated when most of the styrene is consumed, and also that 3-methyl-3-phenyl-1-pentene given by the reaction of ethylene with 2-phenyl-2-butene formed from the isomerization of 3-phenyl-1-butene, is gradually formed during the course of codimerization. The effect of ethylene pressure was examined on the amount of 3-phenyl-1-butene formed. The amount is plotted against the partial pressure of ethylene in Fig. 2, where the vapour pressure of methylene dichloride is 15 cmHg at 0 °C. The amount of 3-phenyl-1-butene increases linearly with the partial pressure of ethylene, indicating that the reaction rate is first order in ethylene

Effect of Concentration of Catalyst Components: The effect of trifluoroboron etherate was examined on the rate of codimerization under a constant pressure(partial pressure of ethylene, 35 mmHg), where the amount of bis(triphenylphosphine)-1-naphthyl(bromo)nickel(II) was kept constant (0.5 mmol). The rate can be shown by the amount of 3-phenyl-1-butene formed for a specific period of reaction time, since the rate is independent of the amount of styrene(Fig. 1). The amount of 3-phenyl-1-butene (mmol) formed for 15 min. is plotted against the mole ratio, trifluoroboron etherate to the nickel complex(Fig. 3). The result at the mole ratio 2.5 was estimated from the amount

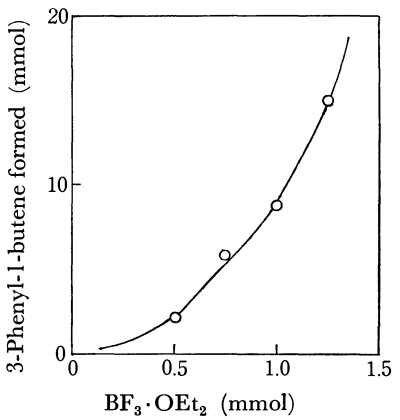

Fig. 3. Effect of the amount of $BF_3 \cdot OEt_2$. (1-naphthyl)NiBr($P\phi_3$)$_2$, 0.5 mmol; styrene, 19.1 mmol; CH_2Cl_2, 30 ml; $P_{C_2H_4}$, 35 cmHg; temp. 0°C; time 15 min.

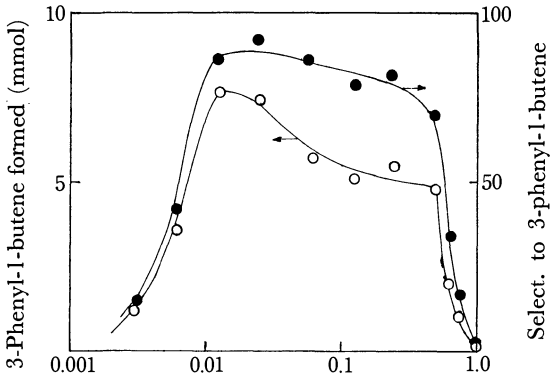

Fig. 4. Effect of the amount of (1-naphthyl)NiBr($P\phi_3$)$_2$ $BF_3 \cdot OEt$, 0.5 mmol; Styrene, 19.1 mmol; $P_{C_2H_4}$, 35 cmHg; CH_2Cl_2, 30 ml; temp. 0°C; time 30 min.

of 3-phenyl-1-butene formed for 10 min., since the reaction rate was too rapid. The rate seems to increase approximately in the second order with respect to the mole ratio of trifluoroboron etherate to bis(triphenylphosphine)-1-naphthyl (bromo) nickel (II). In this case, the amount of butene formed was less than 1% based on that of ethylene consumed. The effect of the amount of bis(triphenylphosphine)-1-naphthyl(bromo)nickel(II) on the codimerization rate and the selectivity to 3-phenyl-1-butene is shown in Fig. 4, where the amount of trifluoroboron etherate is kept constant (0.5 mmol). The rate increases with the amount of nickel complex and reaches maximum at about 0.0125 mmol (the mole ratio of $BF_3 \cdot OEt_2$/Ni-complex=40). Above the maximum, it gradually decreases in the range 0.02~0.5 mmol, within which the selectivity of 3-phenyl-1-butene is fairly high, while the rate rapidly decreases with increasing the amount of nickel complex more than 0.5 mmol (the mole ratio, less than 1).

Codimerization with Styrene Derivatives: The codimerization of ethylene with styrene catalyzed by the present catalyst system was extended to the codimerization with styrene derivatives such as *o*-, *m*-, and *p*-methylstyrene, *o*-, *m*-, and *p*-chlorostyrene, α- and ω-methylstyrene and ω-bromostyrene. The results are summarized in Table 2. *o*-, *m*-, and *p*-Methyl styrenes are also codimerized with ethylene to give the corresponding 2-(chloro- or methyl-phenyl)butenes under the conditions given in Table 2. There is no significant difference between methylstyrene and chlorostyrene in their conversion, while the selectivity of their codimers depends considerably on the position of chloro or methyl substituted on the phenyl. The selectivity increases on the order *ortho*<*meta*<*para* in methyl styrene as well as in chlorostyrene. On the other hand, α- and ω-methyl styrene are less reactive and a considerable amount of ethylene is consumed in the formation of butene (Table 2). No codimer was detected from the reaction of vinyl chloride with ethylene in the presence of this catalyst system. ω-Bromostyrene, however, gave a small amount of its codimers with ethylene consisting of two isomers, both in nearly the same amount.

Discussion

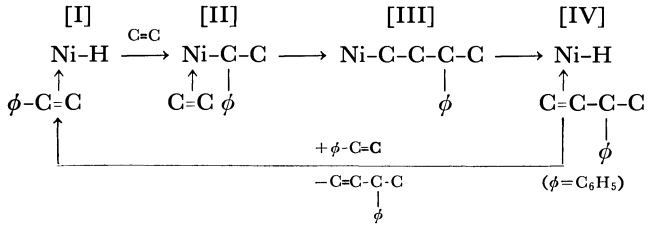
Course of Codimerization of Styrene with Ethylene. It was reported in a previous paper that the active species of the present catalyst system is a nickel hydride complex fromed from dissociative addition of ethylene to σ-aryl nickel(II) compound.[11] This has been clarified by the dimerization of deuteroethylene and its isotopic mixing with ethylene catalyzed by the present catalyst system.[12] From the product distribution of C_2H_4-C_3H_6 codimerization catalyzed by the present catalyst

Table 2. Codimerization of styrene derivatives with ethylene

Styrene derivatives (mmol)	Styrene consumed (mmol)	Codimer formed (mmol)	Select. to codimer (%)	Butenes (mmol)
p-Methylstyrene (15.2)	5.8	4.3	75	0.04
m-Methylstyrene (15.5)	6.0	4.3	72	0.05
o-Methylstyrene (15.1)	2.7	0.6	22	0.03
p-Chlorostyrene (15.1)	5.0	4.9	98	0.12
m-Chlorostyrene (15.0)	5.9	3.1	53	0.19
o-Chlorostyrene (15.0)	5.0	0.7	14	0.16
α-Methylstyrene (15.4)	1.4	0.9	67	7.3
ω-Methylstyrene (15.4)	2.4	1.7	70	2.1
ω-Bromostyrene (15.5)	1.5	0.4	26	0.31

(1-naphthyl)NiBr($P\phi_3$)$_2$, 0.5 mmol; $BF_3 \cdot OEt_2$, 0.5 mmol; CH_2Cl_2, 30 ml; $P_{C_2H_4}$, 35 cmHg; temp. 0° C; time, 30 min.

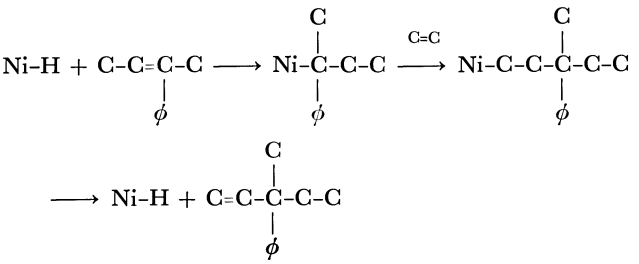
system, the nickel hydride is considered to be catalytically recycled in the course of the reaction and the reductive coupling processes of the intermediate nickel complexes can be excluded.[13] Thus selcetive formation of 3-phenyl-1-butene can also be understood in terms of the nickel hydride. Styrene reacts with the nickel hydride (Ni–H) to give σ-(1-phenylethyl)nickel intermediate(II), followed by the insertion of ethylene-(III) and elimination of its β-hydrogen to give 3-phenyl-1-butene and regenerate Ni-H. It has not been clarified whether the nickel hydride is formed by dissociative addition of ethylene or styrene.



In this scheme, 3-phenyl-1-butene should be readily replaced by styrene, because the codimerization rate is independent of the concentration of styrene. This is consistent with the fact that only a trace amount of butenes and 2-phenyl-2-butene is formed before most of the styrene is consumed(Fig. 1). This might be one reason for 3-phenyl-1-butene being selectively formed. The sterically most crowded complex, [mesityl]Ni($P\phi_3$)$_2$Br, gives the highest selectivity of codimerization (Table 1). This suggests that the aryl ligand remains on the nickel atom. Homodimerization of styrene and its codimerization with its derivatives are probably affected by a steric hindrance of the aryl ligand of the nickel complex. Styrene derivatives having a chloro or methyl substituent on the phenyl also give their codimers fairly selectively, except for *o*-chloro and *o*-methylstyrene (Table 2). Chloro and methyl substituents on the ortho position of phenyl seems to exhibit a sterically unfavorable effect for the reaction with ethylene. On the other hand, a considerable amount of butene is formed in the case of codimerization with α- or ω-methylstyrene. This suggests that the coordination of styrene is weakened by the methyl group.

It should be noted here that 3-phenyl-3-methyl-1-pentene is gradually accumulated during the course of codimerization of ethylene with styrene(Fig. 1). No other path can be considered for the formation of this product than the codimerization of ethylene with 2-phenyl-2-butene. This means that 2-phenyl-2-butene, once it is formed, is also readily codimerized with ethylene, though the isomerization rate of 3-phenyl-1-butene into 2-phenyl-2-butene is very small. However, the difference in their reactivities between 2-phenyl-2-butene and α-(or ω-)methylstyrene remains to be clarified(Table 2).

Role of Trifluoroboron Etherate: In the previous paper[12] dealing with ethylene dimerization catalyzed by present catalyst system, two functions of trifluoroboron etherate were discussed, its contribution as a ligand, where trifluoroboron is in contact with the nickel complex through the bromide ligand, and its removal of



the triphenylphosphine coordinated to the nickel complex to offer a vacant site avairable for the coordination ethylene. It can thus be expected that the codimerization rate increases approximately in the second order with respect to the amount of trifluoroboron etherate as shown in Fig. 3. However, the result shown in Fig. 4 is not obtained only by these two functions. Side reactions of styrene should be taken into account. Preliminary experiments showed that styrene is readily oligomerized in the absence of ethylene by this catalyst system and the oligomerization is highly accelerated by increasing the amount of trifluoroboron etherate, which probably gives rise to a cationic polymerization of styrene. This might be the reason why the selectivity to 3-phenyl-1-butene based on the amount of styrene consumed decreases in the presence of a large amount of trifluoroboron etherate. On the other hand, a decrease in its amount would be more disadvantageous the coordination of ethylene than that of ethylene. This is consistent with the decrease in selectivity to 3-phenyl-1-butene with the decrease in partial pressure of ethylene(Fig. 2). Accordingly, the selectivity to the codimer becomes low again when the amount of trifluoroboron etherate added is less than that of the nickel complex. We thus see why the present catalyst system is active and selective for the codimerization of styrene with ethylene over a range of mole ratio of trifluoroboron etherate to the nickel complex (Fig. 4).

8,5′-*O*-Cyclonucleosides of Tubercidin

Kentaro ANZAI and Masanao MATSUI

The Institute of Physical and Chemical Research, Wako-shi, Saitama 351

(Received June 21, 1973)

On treatment with NBS, 2′,3′-*O*-benzylidenetubercidin (**1**) and its isopropylidene analogue (**6**) afforded the 8,5′-*O*-cyclonucleosides **2** and **7** respectively. Catalytic hydrogenation of **2** and **7** afforded the dehalogenated compounds, **9** and **12**.

Conversion of tubercidin[1] to 5′-deoxytubercidin[2] has already been accomplished by the present authors, and 3′-deoxytubercidin has also been synthesized by Robins and his coworkers.[3] We wish to report here the reaction of NBS with 2′,3′-*O*-benzylidenetubercidin (**1**). This work was initially attempted to obtain the 2′(or 3′)-bromo derivative of 3′(or 2′)-*O*-benzoyltubercidin, which might be used as an intermediate in the synthesis of 2′(or 3′)-deoxytubercidin. Ponpipom and Hanessian have already succeeded[4] in the conversion of 2′,3′-*O*-benzylideneuridine into 3′-*O*-benzoyl-5, 2′-dibromo-2′-deoxyuridine; analogously, we carried out the reaction on **1**.

2′,3′-*O*-Benzylidenetubercidin (**1**), shown to be a diastereomeric mixture by a study of its NMR spectrum, was treated with 1.5 equivalent mol of NBS in a mixture of carbon tetrachloride and tetrachloroethane (1 : 1) under reflux. The reaction seemed to proceed with serious decomposition, and from the reaction mixture two products were isolated in low yields. The minor one was identified as 7-bromo-2′,3′-*O*-benzylidenetubercidin (**5**), obtained as a mixture of diastereomers.

The main product, which was obtained in a 36% yield, was identified as 8,5′-*O*-anhydro-7-bromo-8-hydroxy-2′,3′-*O*-benzylidenetubercidin (**2**). Though the isolated sample showed a single spot on tlc, it was found to be a diastereomeric mixture as shown by the NMR spectrum; we succeeded in obtaining one diastereomer by careful crystallization.

The molecular formula, $C_{18}H_{15}N_4O_4Br$, suggested that the substitution with two bromine atoms, followed by the loss of one mole of hydrogen bromide, afforded the product. In the IR spectrum no absorption was observed in the range of 1660—2900 cm^{-1}, showing that it was not a benzoyl ester as had first been expected. Moreover, it was stable in *n*-propanol–1 M NaOH (4 : 1) on prolonged heating; thus, the benzoyl-ester structure is also unlikely. The NMR spectrum exhibited signals of the ABX type assignable to two hydrogens at C–5′ (δ 4.04 and δ 4.54, $J_{gem}=12$ Hz, $J_{4',5'a}=1$ Hz, $J_{4',5'b}=2$ Hz), showing that it was a cyclonucleoside. A signal corresponding to a hydrogen at C–8 in the starting material was lacking. The mass spectrum showed the parent peaks at *m/e* 432 ($C_{18}H_{15}N_4O_4{}^{81}Br$) and *m/e* 430 ($C_{18}H_{15}N_4O_4{}^{79}Br$) as well as four intense peaks corresponding to the ion species, **3b** (*m/e* 230), **4b** (*m/e* 229), **3a** (*m/e* 228) and **4a** (*m/e* 227).

Catalytic reduction of **2** afforded the dehalogenated compound **9**. The mass spectrum of **9** showed the parent peak at *m/e* 352 as well as two intense peaks at *m/e* 150 and *m/e* 149 corresponding to the ion species **10** and **11**.

2′,3′-*O*-Isopropylidenetubercidin (**6**) similarly reacted with NBS to give 8,5′-*O*-anhydro-7-bromo-8-hydroxy-2′,3′-*O*-isopropylidenetubercidin (**7**). When the reaction was carried out at room temperature in a mixture of acetone and methylene chloride (1 : 1), with the molar ratio of NBS to **6** being 1.1, the product was a gummy material, from which **7** was isolated in a 7% yield. The formation of 7-bromo-2′,3′-*O*-isopropylidenetubercidin was also observed, though it was difficult to purify (See Exp). A few further attempts to improve the yield of **7** were made (See Exp.), but we now feel that it is a fruitless work.

The reaction path to give **7** may involve the dibromide **14** and the 3,5′-*O*-cyclonucleoside **15** as the intermediates (Scheme 1). In connection with this mechanism, conversion of adenine 3*N*-oxide and their xanthine and guanine analogues into the 8-oxygenated purines in acetic anhydride has been reported.[5] However, another possible path, which does not involve **15**, can not be excluded (Scheme 2).

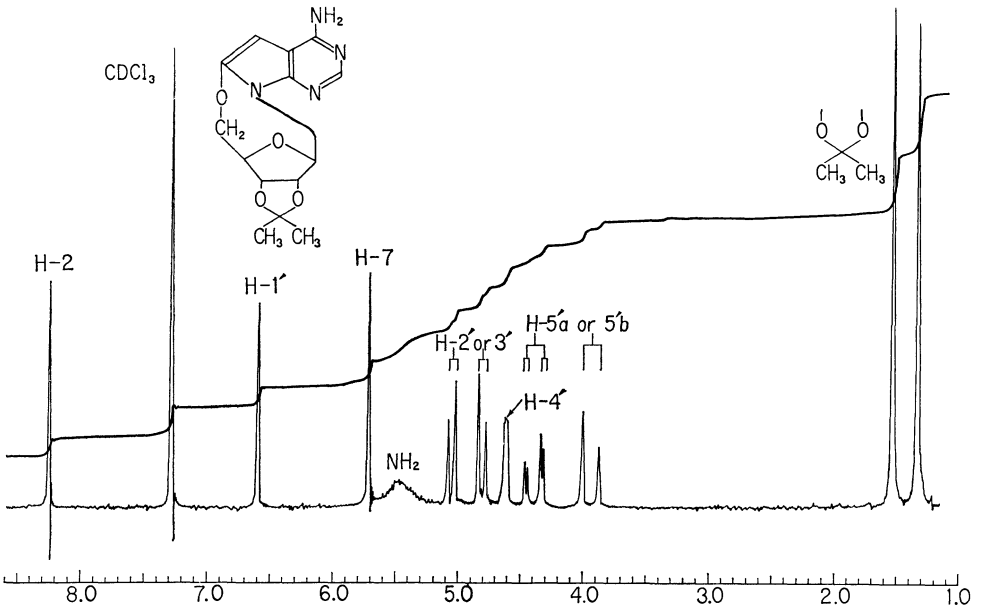

Fig. 1. The NMR spectrum of 8,5′-O-anhydro-2′,3′-O-isopropylidenetubercidin (**12**): 100 MHz, $CDCl_3$.

Catalytic reduction of **7** afforded the dehalogenated compound **12**, the structure of which was also supported by its NMR spectrum (Fig. 1).

Treatment of **12** with excess *p*-toluoyl chloride afforded the di-*p*-toluoyl derivative, **13**, the NMR spectrum of which exhibited a six-proton singlet at δ 2.32 corresponding to two methyls of *p*-toluoyl groups and a pair of four-proton doublets at δ 7.24 and δ 7.67 (J=8 Hz), supporting the N^6,N^6-diacyl structure[6] in **13**.

When 2′,3′-*O*-isopropylideneadenosine[7] (**16**) was treated with NBS under analogous conditions, the only product, which was isolated in a low yield, was 8-bromo-2′,3′-*O*-isopropylideneadenosine (**17**).

Experimental

*Reaction of NBS with 2′,3′-O-Benzylidenetubercidin (**1**).* NBS (700 mg, 3.94 mmol) and 2′,3′-*O*-benzylidenetubercidin (1) (700 mg, 2.68 mmol) were dissolved in a mixture of carbon tetrachloride and tetrachloroethane (1 : 1) (100 ml), and then $BaCO_3$ (500 mg) was added. The solution was refluxed for 2 hr. After cooling, $(NH_4)_2SO_4$ (1 g) was added, and the solution was stirred for 1 hr. It was then washed with an aqueous solution of sodium bicarbonate and concentrated to dryness. Tlc showed that the residue contained three UV-absorbing compounds; they were separated by silica gel chromatography. The least polar compound was eluted with a mixture of benzene and ethyl acetate (1 : 1); it was thus obtained as a crystalline powder from ethyl acetate and *n*-hexane; yield, 412 mg (36%); mp 201—203 °C. NMR (100 MHz, $CDCl_3$) suggested that it was a 1 : 1 mixture of diastereomers of 8,5′-*O*-anhydro-7-bromo-8-hydroxy-

2′,3′-*O*-benzylidenetubercidin (**2**); δ 5.84 and 6.22 (two s, $C_6H_5CH\langle$), 6.79 and 6.82 (two s, H-1′), 8.23 and 8.25 (two s, H-2). Mass *m/e*: 432.0245 (M^+, $C_{18}H_{15}N_4O_4$ ^{81}Br gives 432.0256), 430 (M^+, $C_{18}H_{15}N_4O_4$ ^{79}Br), 360 and 358 (M^+–OCH_2CHO), 326 and 324 (M^+ –C_6H_5CHO), 283 and 281 (M^+ –C_6H_5CHO–CH_2CHO), 230 (**3b**) (observed 229.9648, $C_6H_5N_4O^{81}Br$ gives 229.9626), 229 (**4b**), 228 (**3a**), 227 (**4a**), 202 (**4b**-*HCN*), 200 (**4a**-*HCN*).

Found: C, 50.24; H, 3.50; N, 13.22; Br, 18.41%. Calcd for $C_{18}H_{15}N_4O_4Br$: C, 50.13; H, 3.51; N, 12.99; Br, 18.53%.

One of the diastereomers was separated as crystals from benzene at room temperature; mp 197—199 °C(dec), $\lambda_{max}^{H_2O}$ 280 nm (ε 12300), $[\alpha]_D^{24}$ −1.5 (*c* 1.5, $CHCl_3$); NMR (100 MHz, $CDCl_3$) δ: 4.04 (dd, 1H, H-5′$_a$, J_{gem}=12 Hz, $J_{4',5'a}$= 1 Hz), 4.54 (dd, 1H, H-5′$_b$, J_{gem}=12 Hz, $J_{4',5'b}$=2 Hz), 4.81 (broad, 1H, H-4′), 4.90 and 5.15 (two d, 2H, H-2′ and H-3′, $J_{=2',3'}$=5.5 Hz), 5.84 (s, 1H, $C_6H_5CH\langle$), 5.95 (broad s, 2H, NH_2, disappeared on the addition of D_2O), 6.79 (s, 1H, H-1′), 8.23 (s, 1H, H-2).

Found: C, 53.94; H, 3.86; N, 12.06; Br, 17.10%. Calcd for $C_{18}H_{15}N_4O_4Br$ 1/2 C_6H_6: C, 53.63; H, 3.86; N, 11.92; Br 16.99%.

Next, a compound, which was identified as 7-bromo-2′,3′-*O*-benzylidenetubercidin (**5**), was eluted from the column using ethyl acetate as the developing solvent; it was obtained as a syrup by partial precipitation from ethyl acetate and *n*-hexane; yield, 226 mg; λ_{max}^{MeOH} 282 nm (ε 11000), M^+ 434 ($C_{18}H_{17}N_4O_4{}^{81}Br$) and 432($C_{18}H_{17}N_4O_4{}^{79}Br$).

Found: C, 49.19; H, 3.82; N, 12.53%. Calcd for $C_{18}H_{17}O_4N_4Br\cdot 1/2H_2O$: C, 48.88; H, 4.10; N, 12.67%.

The most polar compound eluted from the column with a mixture of ethyl acetate and methanol (9 : 1) was found to be the starting material.

*Reaction of NBS with 2′,3′-O-Isopropylidenetubercidin (**6**).* NBS (3.1 g, 17.4 mmol) and 2′,3′-*O*-isopropylidenetubercidin (**6**) (4.8 g, 15.6 mmol) were dissolved in a mixture of acetone and methylene dichloride (1 : 1) (200 ml); after the solution had been stirred at room temperature overnight, it was poured into a cold solution of sodium bicarbonate. The products were extracted with chloroform, and the organic phase was washed with an aqueous solution of sodium thiosulfate and then with water. Two main UV absorbing spots were shown on tlc, and each corresponding compound was separated on a silica gel column. 8,5′-*O*-anhydro-7-bromo-8-hydroxy-2′,3′-*O*-isopropylidenetubercidin (**7**) was first eluted from the column, using ethyl acetate as the developing solvent; yield, 389 mg. An analytical sample was obtained on crystallizing it first from benzene and then from ethanol and water; mp 215—218 °C (dec), λ_{max}^{MeOH} 280 nm (ε 12000), $[\alpha]_D^{23}$ +87.0 (*c* 1 : 1 $CHCl_3$); NMR (100 MHz, $CDCl_3$) δ: 1.37 and 1.57 (two s, 6H, two isopropylidene methyls), 4.03 (dd, 1H, H-5′$_a$, J_{gem}=13 Hz, $J_{3',5'a}$=1 Hz), 4.52 (dd, 1H, H-5′$_b$, J_{gem}=13 Hz, $J_{4',5'b}$=2 Hz), 4.66 (broad, 1H, H-4′), 4.82 and 5.19 (two d, 1H, H-2′ and H-3′, $H_{2',3'}$= 5 Hz), 5.76 (broad s, 1H, NH_2), 6.63 (s, 1H, H-1′), 8.24 (s, 1H, H-2); Mass *m/e*: 384 ($C_{14}H_{15}N_4O_4{}^{81}Br$) and 382 ($C_{14}H_{15}N_4O_4{}^{79}Br$) ($M^+$), 230 (**3b**), 229 (**4b**), 228 (**3a**), 227 (**3b**).

Found: C, 43.84; H, 3.79; N, 14.66; Br, 20.85%. Calcd for $C_{14}H_{15}N_4O_4Br$: C, 43.88; H, 3.95; N, 14.62; Br, 20.85%.

The more polar compound was eluted from the column with a mixture of ethyl acetate and methanol (9 : 1); the subsequent evaporation of the solvent afforded 712 mg of a syrup. The mass spectrum suggested that the product was 7-bromo-2′,3′-*O*-isopropylidenetubercidin (**8**), showing the parent peaks at 386 ($C_{14}H_{17}N_4O_4{}^{81}Br$) and 384 ($C_{14}H_{17}N_4O_4{}^{79}Br$). However, attempts to obtain an analytically pure sample by repeated precipitation from benzene and *n*-hexane were unsuccessful, possibly because of the contamination of the unreacted starting material, which showed an R_f value close to that of **8** on tlc.

When a 4.28 g portion of **6** (14.0 mmol) was treated with 2.0 g of NBS (10.6 mmol) under comparable conditions, 550 mg of **7** and 1.37 g of the starting material were obtained.

The molar ratio of NBS to **6** was then increased to 2.5, and the reaction was carried out in a mixture of carbon tetrachloride and tetrachloroethane (1 : 1) under reflux. In this case, a serious decomposition seemed to proceed and the reaction mixture darkened markedly. No UV absorbing spot could be detected on tlc.

*8,5′-O-Anhydro-8-hydroxy-2′,3′-O-benzylidenetubercidin (**9**).* One diastereomer of **2** (350 mg), obtained in the crystalline state, was catalytically hydrogenated over 10% Pd-C(50 mg) in a mixture of ethanol (50 ml) and 10% CH_3COONa (3 ml) for 3 hr. After the catalyst had been removed by filtration through a Celite pad the ethanol was evaporated. The product was extracted with ethyl acetate and was crystallized from ethyl acetate and carbon tetrachloride; yield, 270 mg, mp 227—228 °C (dec) λ_{max}^{MeOH} 272 nm (ε 16400), $[\alpha]_D^{24}$ −48.7 (*c*, 1.3 $CHCl_3$); Mass *m/e*: 352 (M^+), 150 (**10**), 149 (**11**); ($CDCl_3$, 100 MHz) δ: 4.02 (dd, 1H, H-5′$_a$, J_{gem}=12 Hz, $J_{4',5'a}$=1 Hz), 4.48 (dd, 1H, H-5′$_b$, J_{gem}= 12 Hz, $J_{4',5'b}$=2 Hz), 4.81 (broad, 1H, H-4′), 4.94 and 5.15 (two d, 2H, H-2′ and H-3′, $J_{2',3'}$=6 Hz), 5.86 (s, 2H, C_6H_5-$CH\langle$ and H-7), 6.80 (s, 1H, H-1′), 8.26 (s, 1H, H-2). The assignement of a two-proton singlet at δ 5.86 to a benzylidene methine proton and H-7 was confirmed by the spectrum in CD_3COCD_3, which exhibited two one-proton singlets at δ 5.92 and δ 6.06.

Found: C, 61.37; H, 4.58; N, 15.57%. Calcd for $C_{18}H_{16}N_4O_4$: C, 61.36; H, 4.58; N, 15.90%.

*8-5′-O-Anhydro-8-hydroxy-2′,3′-O-isopropylidenetubercidin (**12**).* Compound **7** (500 mg) was catalytically hydrogenated over 10% Pd-C (100 mg) for 4 hr in a mixture of ethanol (50 ml) and 10% CH_3COONa (2 ml). The reaction mixture was then filtered through a Celite pad, and the ethanol was evaporated. The product was extracted with chloroform and was thus obtained as a powder from benzene and *n*-hexane; yield, 350 mg; mp 107—113 °C, λ_{max}^{MeOH} 272 nm (ε 13900); $[\alpha]_D^{23}$ +86.0 (*c* 0.6 $CHCl_3$); Mass m/e: 304 (M^+), 150 (**10**), 149 (**11**); NMR (100 MHz, $CDCl_3$) δ: 1.36 and 1.56 (two s, 6H, two isopropylidene methyls), 3.96 (broad d, 1H, H-5′$_a$, J_{gem}=13 Hz), 4.40 (dd, 1H, H-5′$_b$, $J_{=gem}$ 13 Hz, $J_{4',5'b}$=2 Hz), 4.62(broad, 1H, H-4′), 4.82 and 5.04 (two d, 2H, H-2′ and H-3′, $J_{2',3'}$=5 Hz), 5.46 (broad s 2H, $-NH_2$, disappeared on the addition of D_2O), 5.72 (s, 1H, H-7), 6.60(s, 1H, H-1′), 8.26 (s, 1H, H-2).

Found: C, 54.45; H, 5.26; N, 17.91%. Calcd for $C_{14}H_{16}N_4O_4\cdot 1/2H_2O$: C, 53.84; H, 5.17; N, 17.94%.

*8-5′-O-Anhydro-8-hydroxy-N^6,N^6-p-toluoyl-2′,3′-O-isopropylidenetubercidin (**13**).* Into a stirred solution of **12** (152 mg) in pyridine (20 ml), *p*-toluoyl chloride (0.5 ml) was added at 0 °C, after which the solution was left in a refrigerator overnight. The reaction mixture was then poured into an ice-cooled solution of sodium bicarbonate, and the product was extracted with chloroform. After evaporation of the solvent to dryness, the residue was washed with a small amount of hot ethyl acetate; it was obtained as a powder; yield, 190 mg; mp 273—273.5 °C (dec); λ_{max}^{MeOH} nm (ε): 305 (12500) 253 (28000); Mass *m/e*: 540 (M^+), 512 (M^+-CO), 484 (M^+-2CO), 421 (M^+-$CH_3C_6H_4CO$), 393 (M^+-$CH_3C_6H_4CO$-CO); NMR (100 MHz, DMSO-*d*) δ: 1.31 and 1.50 (two s, 6H, two isopropylidene methyls), 2.32 (s, 6H, 2*p*-$CH_3C_6H_4$-CO), 5.80 (s, 1H, H-7), 6.42 (s, 1H, H-1′), 7.24 and 7.67 (two d, 8H, 2*p*-$CH_3C_6H_4CO$, J=8 Hz), 8.48 (s, 1H, H-2).

Found: C, 66.34; H, 5.19; N, 9.98%. Calcd for $C_{30}H_{28}N_4O_6$: C, 66.65; H, 5.22; N, 10.37%.

*8-Bromo-2',3'-O-isopropylideneadenosine (**17**).* A solution of 2',3'-O-isopropylideneadenosine (**16**) (1.6 g, 5.2 mmol), NBS (2 g, 11.2 mmol), and $CaCO_3$ (1 g) in acetone (50 ml) was stirred overnight at room temperature and then poured into a cold solution of sodium bicarbonate. The chloroform extract was washed with an aqueous solution of sodium thiosulfate and then with water.

Silica gel chromatography on developing with a mixture of ethyl acetate and methanol (9 : 1) afforded two compounds, the more polar one being the starting material (720 mg). The less polar one, identified as **17**, was crystallized from ethyl acetate; yield, 267 mg; mp 229 °C; λ_{max}^{MeOH} 264 nm (ε 18900); $[\alpha]_D^{23}$ −37.0 (*c* 1.1 DMSO); Mass *m/e*: 387 (M^+, $C_{13}H_{14}N_5O_4{}^{81}Br$), 385 ($M^+$, $C_{13}H_{14}N_4O_5{}^{79}Br$), 214 and 212 (base peak, base moiety of **17**): NMR (100 MHz, DMSO-*d*) δ: 1.34 and 1.56 (two s, 6H, two isopropylidene methyls), 3.50 (m, 2H, H-5'), 4.18 (m, 1H, H-4'), 5.04 (q, 1H, H-3', $J_{3',4'}$=3 Hz, $J_{2',3'}$=6 Hz), 5.67 (q, 1H, H-2', $J_{2',3'}$=6 Hz, $J_{1',2'}$=3 Hz), 6.04 (d, 1H, H-1', $J_{1',2'}$=3 Hz), 7.55 (broad s, 2H, NH_2) 8.16 (s, 1H, H-2).

Found: C, 40.44; H, 4.18; N, 18.57; Br, 20.61%. Calcd for $C_{13}H_{14}N_5O_4Br$: C, 40.43; H, 4.18; N, 18.14; Br, 20.69%.

Under altered conditions, the yield of **17** was not improved; *e.g.*, when **16** (5.47 g) was treated with NBS (3.5 g) in a mixture of tetrachloroethane (75 ml) and carbon tetrachloride (25 ml) in the presence of $CaCO_3$ (5 g) under reflux for 4 hr, the yield of **17** was 257 mg, and 1.13 g of **16** was recovered. An extended reaction time or the use of an increased amount of NBS resulted in a darkening of the reaction mixture and a decreased yield of **17**.

Effect of pH on the Circular Dichroism(CD)-sensitive Transitions of Some Lanthanoid(III) Complexes and "Pseudo CD-sensitive Transitions" of Europium(III) and Terbium(III) Complexes

Seizo MISUMI, Toshiyuki ISOBE, and Haruko FURUTA

Inorganic Chemistry Laboratory, Faculty of Science, Kyushu University, Fukuoka 812

(Received May 23, 1973)

The effect of pH on the CD-sensitive transitions of lanthanoid(III) complexes with *l*-propylenediaminetetraacetic acid(*l*-PDTA) and L-ethylenediaminedisuccinic acid(L-EDDS) was studied. The relation between the cross-over pH where the CD pattern changes or sign of CD reverses and the number of 4f-electrons in lanthanoid(III) complexes with L-EDDS showed a tetrad curve. A strong evidence for coordination of hydroxide ions was suggested. "Pseudo CD-sensitive bands" in the spectra of the complexes of europium(III) and terbium(III) which do not obey the selection rule $\Delta J \leq 1$ were found, and the mechanisms of these transitions were elucidated.

The circular dichroism (CD)-sensitive band has been observed on the J'-band of magnetic dipole character for some lanthanoid(III) complexes with optically active ligands. The experimental result was in accordance with the theory proposed previously.[1,2] It was observed that intensities and patterns of CD-sensitive bands of lanthanoid(III) complexes vary remarkably with pH of solutions, especially with high pH's. This phenomenon in the lanthanoid(III) complexes with *l*-PDTA or L-EDDS was studied in detail. The work has revealed some new information on the coordination bonds of the lanthanoid(III) complexes.

The pseudo CD-sensitive bands in the spectra of europium(III) and terbium(III) complexes were found and the mechanism of these bands which do not obey the selection rule $\Delta J \leq 1$, was discussed.

Experimental

Materials. All lanthanoid(III) perchlorates were prepared by dissolving lanthanoid oxides of 99.9% purity in perchloric acid and their concentrations were standardized by EDTA titration using xylenol orange as an indicator. *l*-PDTA was synthesized by Dwyer's method[3] and L-EDDS by the method of Neal and Rose[4] from 1,2-dibromoethane and L-aspartic acid, respectively. The sample solution was prepared by mixing lanthanoid(III) perchlorate with the ligand at 1 : 1 mole ratio (practically 10% excess of the ligand for *l*-PDTA and 5% excess for L-EDDS). The final concentration of lanthanoid(III) in complex was made to be 0.1 mol/l. The pH of the solution of *l*-PDTA complex was adjusted by 5 M NaOH and that of L-EDDS complex by aqueous ammonia. H[Pr(L-EDDS)]·$2H_2O$ and H[Dy(L-EDDS)]·$2H_2O$ were prepared by Moeller's method[5] and CD spectra of these complexes were measured at various pH values.

Measurements. Absorption and CD spectra of the complexes were measured with a JASCO model ORD/UV-5 optical rotatory dispersion recorder with a CD attachment, a 10 mm cell, at room temperature. It was found more convenient to use a 50 mm cell for H[Pr(L-EDDS)]·$2H_2O$ and H[Dy(L-EDDS)]·$2H_2O$ at various pH values in aqueous solutions. A Hitachi-Horiba model F-5 pH meter was used for pH measurements.

Results

The CD spectra of lanthanoid(III) complexes with *l*-PDTA and L-EDDS were measured at various pH values in aqueous solutions. In a strongly alkaline region, it was found that the patterns of CD-sensitive bands of these complexes vary remarkably with increasing pH value. The changes in the patterns and

intensities of the CD spectra of samarium(III) complexes with *l*-PDTA are shown in Fig. 1. The pH values plotted against $\Delta\varepsilon(=\varepsilon_l-\varepsilon_r)$ for CD components of $^4G_{5/2}\leftarrow{}^6H_{5/2}$ transition are shown in Fig. 2. The same features were observed also in the case of the Eu(III), Dy(III), Ho(III), Er(III), and Tm(III) complexes with *l*-PDTA. In order to confirm the phenomena observed for lanthanoid(III) complexes with *l*-PDTA, the CD spectra of Pr(III), Nd(III), Sm(III), Eu(III), Gd(III), Tb(III), Dy(III), Ho(III), Er(III), and Tm (III) complexes with L-EDDS were recorded more precisely by using the chart scales of 4 or 2 nm /cm. The following CD-sensitive and other transitions of the lanthanoid(III) complexes with L-EDDS were studied: Pr(III) complex, $^3P_2\leftarrow{}^3H_4$; Nd(III) complex, $^4G_{9/2}\leftarrow{}^4I_{9/2}$; Sm(III) complex, $^4H_{5/2}\leftarrow{}^6H_{5/2}$; Eu(III) complex, $^5D_0\leftarrow{}^7F_1$ and $^5G_2\leftarrow{}^7F_1$; Gd(III) complex, hardly any change observed in CD spectra in the pH range 9~11.5; Tb(III) complex, $^5G_6\leftarrow{}^7F_6$; Dy(III) complex, $^4I_{15/2}\leftarrow{}^6H_{15/2}$; Ho(III) complex, $^3K_8\leftarrow{}^5I_8$; Er(III) complex, $^2K_{15/2}\leftarrow{}^4I_{15/2}$; and Tm(III) complex, $(^3F_3, {}^3F_2)\leftarrow{}^3H_6$. A few examples are shown in Figs. 3(a) and 3(b). Similar features were observed for the other lanthanoid(III) complexes with L-EDDS. The cross-over pH values, where intensity of CD spectrum of L-EDDS complex changes suddenly, are plotted against the number of 4f-electrons (Fig. 4).

The CD spectra of H[Pr(L-EDDS)]·$2H_2O$ and H[Dy(L-EDDS)]·$2H_2O$ in aqueous solutions coin-

cide with those at neutral pH region in the mixed solutions of the lanthanoids(III) and L-EDDS. By increasing the pH of these solutions, similar changes of patterns took place, but they were not so remarkable as those of a mixed solution of lanthanoids(III) and L-EDDS.

Similar to the band (660 nm) of Tm(III) complex with *l*-PDTA,[2] other bands of the same kind which do not obey the selection rule $\Delta J \leq 1$, were also observed in europium(III) and terbium(III) complexes with L-EDDS. We will call these bands "pseudo CD-sensitive bands". The excited levels of such newly located "pseudo CD-sensitive transitions" are the group of bands at 386, 388, 392, and 410 nm of Eu(III) complex and a band at ~370 nm of Tb(III) complex (Figs. 5 and 6).

Discussion

We have reconfirmed that the "CD-sensitive bands",[2] where magnetic dipole transitions are allowed, always show marked intense bands. In Fig. 4, the cross-over pH values where CD pattern changes or sign of CD reverses, are plotted against the number of 4f-electrons. The curve shows a tetrad-type curve. In view of the coordination number of the lanthanoid(III) ion, *l*-PDTA or L-EDDS chelates may be possibly coordinated by hydroxide ions in strongly alkaline solutions.

According to Condon,[6] the rotational strength $\mathbf{R}_{ab}$ is determined by $\mathbf{R}_{ab}=(e^2/2mC)\mathbf{I}_m\langle a\mathbf{Q}b\rangle\langle b\mathbf{L}a\rangle$, where a and b are the wave functions of states a and b of the molecule or ion, $e\langle a\mathbf{Q}b\rangle$ and $e/2mC\cdot\langle b\mathbf{L}a\rangle$ are the induced electric and magnetic moments, respectively, of an electronic transition $b\leftarrow a$, and $\mathbf{I}_m$ is the imaginary part of the scalar product of these two moments. In general, a more simplified and practical expression of the rotational strength is $\mathbf{R}_{ab}=\rho\mu\cos\theta$, where ρ and μ are the real electric and magnetic dipole moments of the transition, respectively, and θ is the angle between the directions of the two moments. Thus, the following interpretation is acceptable for the changes of CD spectra. Coordination of hydroxide ions at the innersphere might perturb the surroundings of the lanthanoid(III) ion, and the magnitude and direction of induced electric dipole moment are forced to change, the intensity and sign of CD changing remarkably at a certain high pH. However, other methods such as pH titration and absorption spectrum could not detect the variation owing to low sensitivity. This was successfully found by means of the "CD-sensitive band". Thus, the variation was examined all over the bands again and "pseudo CD-sensitive bands" in the spectra of the complexes of Eu(III) and Tb(III), not obeying the selection rule $\Delta J \leq 1$, were found. The α $(=\Delta\varepsilon/\varepsilon)$ values of their dissymmetry ratio were estimated to be in the order of 10^{-2}. The phenomena could be elucidated by taking into consideration, transitions not only from the ground state, but also those from some higher excited states (Figs. 5 and 6). For Eu(III) complex, transitions from the first excited state $^7F_1$ and the second excited state $^7F_2$ have been reported.[7] The corresponding "pseudo CD-sensitive transition" of $^5G_2\leftarrow{}^6F_1$ and $^5G_2\leftarrow{}^7F_2$ of Eu(III) complex could be observed at 386 and 396 nm, respectively. The former band could immediately be assigned to the transition $^5G_2\leftarrow{}^7F_1$ on the basis of CD intensity and dissymmetry ratio. However, for the latter band, by overlapping of the band of a transition of $^5L_6\leftarrow{}^7F_0$ at 394 nm, the value of α remains in the order of 10^{-3}. A similar consideration accounted for the intensity of the CD band at 392 nm, superimposed on a band arising from the transition of $^5G_3\leftarrow{}^7F_2$.

By assuming that a transition from the third excited state $^7F_3$ takes place, the intensities of the CD components of the transition $^5G_2\leftarrow{}^7F_3$ for 410 nm and the transition $^5D_4\leftarrow{}^7F_3$ for 388 nm could be explained as due to the "pseudo CD-sensitive transition".

The unexpected intense CD bands at 370 nm of Tb(III) complex could be explained similarly by assuming the corresponding transition from the first excited state, ~2.1 kK higher than the ground level, *i.e.* the transition $^5L_6\leftarrow{}^7F_5$. It is impossible to do more accurate work on account of lack of detailed information on these mechanisms in atomic spectroscopy. However, the CD-sensitivity seems to be easily contained in the formal mechanism already developed for CD intensity of the lanthanoid(III) complex with optically active ligand in solution. It is difficult to study this phenomenon in aqueous solution at a low temperature. Though there is no experimental evidence of this mechanism, it is supposed that the origin of the "pseudo CD-sensitivity" in some europium(III) and terbium(III) complexes lies in the transition from some higher excited levels, satisfying the selection rule $\Delta J \leq 1$.

Financial support was given for this research by the Ministry of Education.

Dehydration of Secondary Alcohols Catalyzed by Solid Acids

Tsutomu YAMAGUCHI and Kozo TANABE

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received June 29, 1973)

In order to examine the correlation between the acidic properties of catalysts and their activity or selectivity and to elucidate the reaction mechanism, dehydration reactions of 4-methyl-2-pentanol and 2-butanol over Al_2O_3, SiO_2, SiO_2–Al_2O_3, ZnS, $NiSO_4$, $Al_2(SO_4)_3$ or Al_2O_3 poisoned with basic compounds were carried out at 80—250 °C by means of the conventional flow method or a thermal desorption method. The following results were obtained. 1) Both Brönsted and Lewis acids are active, the latter being so to a greater extent. 2) Even relatively weak acid catalysts of acid strength $H_0=4.8$—6.8 are active, the catalytic activity being correlated with the number of effective acid sites. 3) The selectivity of 4-methyl-1-pentene/4-methyl-2-pentene and 4-methyl-*cis*-2-pentene/4-methyl-*trans*-2-pentene is lower for Brönsted acids than for Lewis acids and higher for weaker Lewis acid strengths. 4) The composition of butene isomers varies greatly with changes in desorption temperature and the amount of adsorbed 2-butanol in the case of Al_2O_3, but not much for SiO_2–Al_2O_3. 5) The ratios of *cis*-2-butene/*trans*-2-butene and 1-butene/2-butene over Al_2O_3 are remarkably increased by poisoning with pyridine. A reaction mechanism including a new reaction path has been proposed.

The dehydration of secondary alcohols is found to be useful for investigating the properties of catalysts since the selectivity of the catalysts is indicated by the formation of 1-olefins, *cis*-2-olefins and *trans*-2-olefins and the ratios of 1-olefins/2-olefins and *cis*-2-olefins/*trans*-2-olefins.

The dehydration of alcohols is known to be catalyzed by solid acids[1] and it has been pointed out that the basic properties of some solid acids play an important role in dehydration reactions.[2-4] Some problems concerning the effective acid strength of catalysts[5,6] and the nature of reaction intermediates[7] have also been studied. However, the catalysts used for the dehydration of secondary alcohols are limited to several kinds, including alumina. No systematic work has been done on the correlation between acidic properties (the amount, strength and type —Brönsted or Lewis— of the acid sites) of catalyst surfaces and catalytic activity or selectivity.

In the present work, we examined the correlation by employing aluminum sulfate,[8] nickel sulfate,[8] zinc sulfide,[9] silica[10] and silica-alumina[10] in addition to alumina as catalysts whose acidic nature is fairly well understood. From the secondary alcohols, 4-methyl-2-pentanol was selected because of the importance of its main product, 4-methyl-1-pentene, as a synthetic material in surface active agents and perfumes. 2-Butanol was used as another secondary alcohol since it is the simplest secondary alcohol and is suitable for thermal desorption experiments which provide data on dehydration with a known amount of adsorbed alcohol without being accompanied by the isomerization of product olefins.

The dehydration mechanism of secondary alcohols and the catalytic action of solid acids are discussed in the light of the observed results.

Experimental

Catalysts and Reagents. Three kinds of alumina were used. Al_2O_3-I (Kishida Chemicals and Co. Ltd.) was calcined in air at 500 °C for 3 hr (specific surface area: 382 m^2/g). Al_2O_3-II was prepared by the hydrolysis of aluminum isopropoxide and calcination in air at 800 °C for 3 hr. Al_2O_3-III, an alkali-poisoned catalyst, was prepared by immersing Al_2O_3-I in NaOH solution for 24 hr, drying at 120 °C for 24 hr and calcining in air at 500 °C for 3 hr. For thermal desorption experiments, Al_2O_3-I was evacuated at 450 °C for 3 hr. For poisoning experiments, pyridine was adsorbed on the catalyst in a vacuum system. Silica (Kishida Chemicals and Co., Ltd.) was calcined in air at 720 °C for 2.5 hr. Silica-alumina (Shokubai Kasei Co., 25% Al_2O_3, specific surface area: 514 m^2/g) used for thermal desorption experiments was calcined in a vacuum at 450 °C for 3 hr. Nickel and aluminum sulfate catalysts were prepared by heating guaranteed reagents of the heptahydrate (Kanto Chemical Co.) and the octadeca-hydrate(Wako Pure Chemical Industries) respectively in air at various temperatures for 3 hr. The 16—24 mesh powders were stored in sealed ampoules. Zinc sulfide (guaranteed reagent of Kanto Chemical Co.) was calcined in air at 400 °C for 2.5 hr.

4-Methyl-2-pentanol (Tokyo Kasei Kogyo Co.) was purified by fractional distillation. 2-Butanol (guaranteed reagent of Wako Pure Chemical Industries) was distilled over sodium metal and dehydrated and degassed by repeated freeze-thaw cycles after distillation over Molecular Sieve 3A *in vacuo*.

Measurement of Catalyst Acidity. The acid amounts at various strengths for the catalysts were measured by titrating with *n*-butylamine[10,11] using various indicators; benzalacetophenone ($pK_a=-5.6$), dicinnamalacetone (−3.0), benzeneazodiphenylamine(+1.5), *p*-dimethylaminoazobenzene (+3.3), methyl red (+4.8) and neutral red (+6.8).

Reactions and Thermal Desorption. The dehydration of 4-methyl-2-pentanol was carried out by the conventional flow method using nitrogen as carrier gas at temperatures 150—200 °C. The alcohol vapor, whose pressure (25 mmHg) was kept constant in an alcohol saturator, was passed together with nitrogen through a reaction tube containing 1—2 g of catalyst. In order to prevent the condensation of alcohol and its products, the necessary parts of the apparatus were heated by resistance wires. The reaction products were collected in a liquid nitrogen trap and analyzed by gas chromatography. A one meter column of 30% TCP on Kacelite was used for the analysis of olefins and unreacted alcohol, and a 10 m column of Silicone DC-550/Bentone 34/Celite 545 for that of olefins alone. Catalytic activity was obtained from the linear plot of conversion percentage against contact time (W/F, W: catalyst weight, F: flow rate of alcohol).

The thermal desorption experiments of 2-butanol were carried out with a vacuum apparatus in the following way. After alcohol was introduced over 100—200 mg of evacuated catalyst at room temperature, the gas phase and weakly adsorbed alcohol were removed by condensation in a liquid

nitrogen trap, and the amount of irreversibly adsorbed alcohol at room temperature was measured as follows. The temperature of the system was elevated and the system kept at this temperature for 1.5 hr. All the species desorbed by the temperature elevation were collected in a liquid nitrogen trap and dried over Molecular Sieve 3A. The amount of each constituent was determined from the total pressure and gas chromatography analysis (1 m column of TCP for the analysis of alcohol-olefins and 5 m of VZ-7 for olefins).

The dehydration of 2-butanol over poisoned catalysts was carried out at 180 °C with a closed circulation apparatus. The initial pressure of alcohol was 12.5±0.3 mmHg. The catalysts were poisoned with pyridine or ammonia in a vacuum apparatus equipped with Tefron greaseless stopcocks. The amount of poisoning was estimated from the values obtained under the same condition as in the following adsorption-desorption experiments. Pyridine or ammonia was adsorbed at 100 °C for 1 hr on 30 mg of Al_2O_3-I which had been calcined *in vacuo* at 500 °C for 5 hr. After the catalyst was evacuated at 100 °C, the amount of adsorbed pyridine or ammonia was obtained by measuring the increase in catalyst weight with a microbalance (sensitivity: 3.4—3.5 mm/mg). The catalyst temperature was then elevated and the amount of pyridine or ammonia remaining on the catalyst was determined from its weight.

Results

Dehydration of 4-Methyl-2-pentanol. The reaction products were only olefins; 4-methyl-1-pentene, 4-methyl-*cis*-2-pentene and 4-methyl-*trans*-2-pentene.

Acidity and Activity of Catalysts: The acid amounts at various strengths of Al_2O_3-I, Al_2O_3-II, SiO_2, ZnS, $NiSO_4$ and $Al_2(SO_4)_3$ are shown in Table 1 and Fig. 1 and their catalytic activities for dehydration are shown in Table 2 and Fig. 1.

The acid strength of Al_2O_3-II was very weak, but its activity fairly high. This is considered to be due to the large number of acid sites having acid strength H_0=4.8—6.8. On the other hand, SiO_2, which has much stronger acid sites H_0=−3, showed relatively low activity. This is partly due to the small total acid amount (only 0.20 mmol/g at $H_0 \leqq +6.8$) and partly due to the fact that the acid sites on SiO_2 are of Brönsted type whose activity is less than that of Lewis type sites. The smaller activity of ZnS than that of Al_2O_3-II is also explained by the smaller total acid amount. In the case of metal sulfates calcined at various tem-

a) Calcination temperature (°C).

peratures, the activities were roughly correlated with total acid amount as seen in Fig. 1 and Tables 1 and 2. The activity of Al_2O_3-III decreased with increasing sodium hydroxide, but the catalyst poisoned with 1.75 mmol/g of NaOH which has no acid sites of $H_0 = +3.3$ did not completely lose activity.

These results indicate that the acidic properties of the catalysts are an important factor in activity, and even weak acid sites are active in the dehydration of 4-methyl-2-pentanol. This is in good agreement with the result observed by Misono *et al.*[5] that weak acid sites on silica-alumina poisoned with pyridine were active for the dehydration of tertiary butanol.

The number of acid sites on $NiSO_4$ calcined at 300 °C was large, but activity was very low (Fig. 1). However, the acid amount gives the sum of the amount of Brönsted and Lewis acid sites. According to the infrared study of pyridine adsorbed on nickel sulfate,[12] the maximum amount of Brönsted acid is observed on the sulfate calcined at 250—300 °C, and that of Lewis acid on the sulfate calcined at 400 °C. Since the Lewis acidity change caused by calcination is similar to the activity change, Lewis acid sites are believed to be more active than Brönsted acid sites of the same acid strength.

Since it is known by infrared study that a Lewis acid site can be converted into a Brönsted acid site in the presence of a water molecule,[13] the effect of water formed by the dehydration reaction on the type of acid site should be taken into consideration. However, a comparison of activity and acidity in Fig. 1 shows that the Lewis acid sites which might interact with water molecules differ entirely from the Brönsted acid sites originally present on the catalyst. The same kind of difference was also found for the vapor phase hydrolysis of methylene chloride catalyzed by various solid acid.[14] Matsuzaki *et al.*[15] showed that the acid strength of silica-alumina does not change with the adsorption of water when the temperature of adsorption is high. If a conversion of Lewis sites into Brönsted sites occurred, the acid strength should have changed. These facts indicate that Lewis sites are not converted into Brönsted sites at high temperatures, or that Lewis sites, even if they interact with water molecules, are distinguished from the original Brönsted sites.

Acidity and Selectivity of Catalysts: The ratios of 4-methyl-1-pentene/4-methyl-2-pentene (abbreviated as 1-P/2-P) and 4-methyl-*cis*-2-pentene/4-methyl-*trans*-2-pentene (*cis*-P/*trans*-P) for each catalyst are shown in Table 3. The 1-P/2-P ratio decreased in the order Al_2O_3-II > Al_2O_3-I > ZnS > $NiSO_4$ > $Al_2(SO_4)_3$ > SiO_2. In the case of Al_2O_3-III, the ratio increased with an increase in the amount of NaOH added as shown in Fig. 2. The lowest ratios were found for SiO_2, a well-known Brönsted acid,[16] while the higher ratios were found mainly for Lewis acids such as Al_2O_3-II, Al_2O_3-I, ZnS and $NiSO_4$ calcined at 400 °C. The selectivity of the latter catalysts changed with the Lewis acid strength and the basic properties. The Al_2O_3 catalysts which have basicity[10,17] together with Lewis acidity showed a high selectivity. Among aluminas, Al_2O_3-II which has the weakest acid strength showed the highest selectivity. An intermediate selectivity was found for

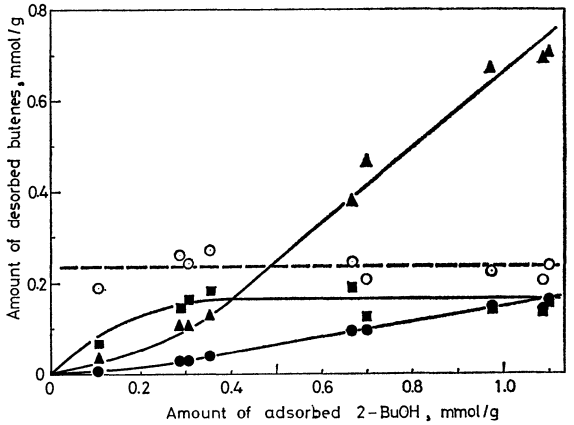

Fig. 4. Amounts of butenes desorbed up to 350 °C *vs.* amount of 2-butanol adsorbed on Al_2O_3-I: (●) 1-B, (▲) *cis*-B, (■) *trans*-B, (○) ratio of 1-B/*cis*-B.

being observed at the lower desorption temperature (Fig. 3 (b)). In Fig. 4, the amount of each butene isomer desorbed up to 350 °C is plotted against the amount of adsorbed alcohol in the case of Al_2O_3. The amount of *trans*-2-butene formed was almost constant independent of the amount of adsorbed alcohol, while that of 1-butene and *cis*-2-butene increased with the amount of adsorbed alcohol. In the case of SiO_2–Al_2O_3 catalyst, both ratios were very close to the equilibrium ratio independent of the amount of adsorbed alcohol, except that a higher *cis*-B/*trans*-B

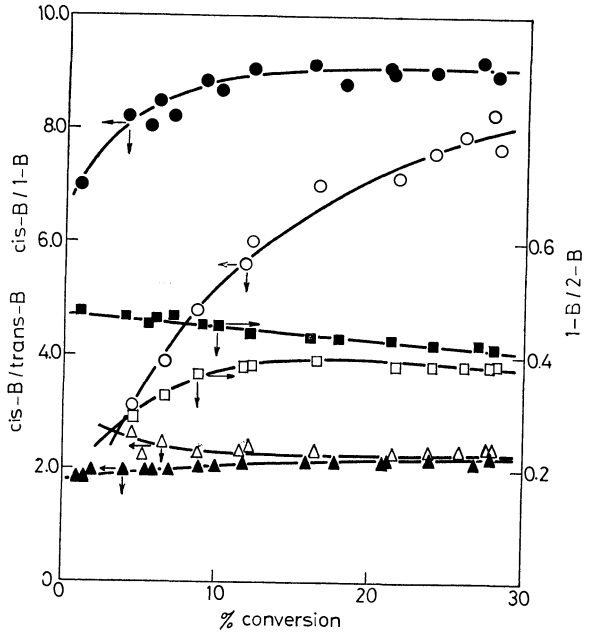

Fig. 5. Poisoning effect of pyridine on dehydration of 2-butanol.
Reaction temperature: 180 °C, Al_2O_3-I without poisoning, (○) *cis*-B/*trans*-B, (□) 1-B/2-B, (△) *cis*-B/1-B. Al_2O_3-I poisoned with 0.11 mmol g^{-1} pyridine, (●) *cis*-B/*trans*-B, (■) 1-B/2-B, (▲) *cis*-B/1-B.

ratio was observed below 160 °C.

The fact that SiO_2–Al_2O_3 which has only high acid strength gives low selectivity, while Al_2O_3 which has different acid strengths gives different kinds of selectivity, depending on the amount of adsorbed alcohol, is discussed later.

The effect of pyridine poisoning on the dehydration of 2-butanol over an alumina catalyst is shown in Fig. 5, where the ratios of butene isomers formed are plotted against the % conversion of 2-butanol. The ratios of *cis*/*trans* and 1-B/2-B over the poisoned catalyst were high compared to the unpoisoned ones at low % conversion. The ratios for the two catalysts approached the same value as the % conversion increased, while the ratio of *cis*/1-B over both catalysts was almost the same and remained nearly constant. Since no isomerization takes place under the present reaction conditions,[18] the results indicate that the formation of *trans*-2-butene was strongly retarded by the poisoning of the catalyst with pyridine. The poisoning effect of ammonia on selectivity was similar to that of pyridine, but the degree of retardation for the formation of *trans*-2-butene was lower. In the case of pure alumina, the ratios were approximately equal to the equilibrium value at low % conversions, but increased with increasing % conversion (Fig. 5). These phenomena are believed to be due to *trans* isomer formation being retarded by poisoning with water molecules formed by the dehydration reaction.

Discussion

The reaction mechanism is discussed in the light of the observed catalyst selectivity. The following

two are well-known mechanisms of olefin formation from alcohol; one includes oxonium ion and carbonium ion as reaction intermediates[19] (type El mechanism) represented by Scheme (A), and the other is an acid-base concerted mechanism[2] (type E2 mechanism), represented by Scheme (B), taking the dehydration of 2-butanol as an example.

$$C_4H_9OH \xrightarrow{H^+} C_4H_9OH_2^+ \xrightarrow{-H_2O} C_4H_9^+ \xrightarrow{-H^+} C_4H_8 \quad (A)$$

$$C_4H_9OH \xrightarrow{-H^+,\ -OH^-} C_4H_8 \quad (B)$$

Scheme (A) includes an alkoxonium ion $C_4H_9OH_2^+$ and carbonium ion $C_4H_9^+$ and the reaction is catalyzed only by Brönsted acid. In Scheme (B), the fissions of C–O and C–H bonds of alcohol occur simultaneously to eliminate a hydroxyl ion and a proton. The latter is effectively catalyzed by solid catalysts such as Al_2O_3 which has both Lewis acidity and basicity.

All the results can not be fully explained only by the above two mechanisms. In particular, it is difficult to explain the effect of Lewis acid strength on catalyst selectivity. We therefore propose a dehydration mechanism of secondary alcohols shown in Fig. 6, which presents a new route for the formation of carbonium ion from alcohol on a Lewis acid catalyst.

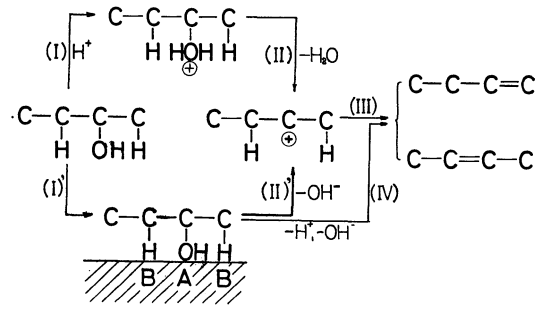

Fig. 6. Reaction paths of dehydration of secondary alcohols.
A: Lewis acid site, B: basic site.

The reaction path (I)-(II)-(III) is an alkoxonium-carbonium ion mechanism catalyzed by Brönsted acid. The dehydration of secondary alcohols over SiO_2 proceeds by this path. Since carbonium ion is formed in this case, the ratio 1-B/2-B tends to approach the equilibrium value. The ratio *cis*-B/*trans*-B also tends to approach the equilibrium value because of free rotation about the C–C bond. The observed selectivity of SiO_2 showed this tendency.

The reaction path (I)'-(IV) is a concerted mechanism, where H^+ and OH^- are eliminated simultaneously for either *cis*-elimination (Fig. 6) or *trans*-elimination. In this case, high ratios of 1-B/2-B and *cis*-B/*trans*-B are usually observed.[2]

A third reaction path (I)'-(II)'-(III) consists of adsorption of alcohol on Lewis acid sites A, the formation of carbonium ion by elimination of OH^- and the formation of an olefin by the elimination of a proton. This mechanism is possible when the Lewis acid strength is so high that the C–O bond is easily broken. Since a carbonium ion is formed as in the case of a Brönsted acid catalyst, both ratios 1-B/2-B and *cis*-B/*trans*-B approach the equilibrium values. Thus the stronger the Lewis acidity, the larger the possibility of reaction path (II)' and the lower the selectivity for 1-olefin and *cis*-2-olefin. On the other hand, as the strength of the Lewis acid becomes weaker, the fission of the C–O bond becomes harder and comparable to that of C–H bond. Thus, the probability that the dehydration proceeds *via* path (IV) becomes large and the selectivity for 1-olefin and *cis*-2-olefin increases. In the case of Al_2O_3, the formation of an alkoxide from an alcohol molecule and an aluminum atom on the surface has been reported,[7,20] but does not affect the conclusion of the above discussion concerning selectivity and reaction mechanism.

Now let us discuss the observed selectivity of various catalysts. Since the acid strength of Al_2O_3-I is higher than that of Al_2O_3-II, the probability that the dehydration proceeds *via* path (II)' becomes larger in Al_2O_3-I and hence the ratios of 1-olefin/2-olefin and *cis*-2-olefin/*trans*-2-olefin over Al_2O_3-I are higher than those of Al_2O_3-II (Table 3). However, since both Al_2O_3-I and Al_2O_3-II have basic properties as well as acidic properties, the probability of the concerted mechanism (IV) over alumina is large and the selectivity is higher than that of SiO_2 over which the dehydration takes place only *via* path (I)-(II)-(III). The selectivity of $Al_2(SO_4)_3$ is low compared with that of $NiSO_4$, because of the higher acid strength of $Al_2(SO_4)_3$. However, since both metal sulfates have no basic properties, the selectivity is low compared with Al_2O_3. Zinc sulfide which has no basicity,[9] but weak acidity (Table 1) shows an intermediate selectivity between Al_2O_3 and sulfates. The decrease in selectivity with increase of the amount of NaOH poisoning over Al_2O_3 is interpreted by assuming that path (IV) is favored over path (II)', because the acid strength is weakened by the poisoning.

In thermal desorption experiments, the fact that the ratio of desorbed butenes is close to the equilibrium value over SiO_2–Al_2O_3, but deviates from the equilibrium value over Al_2O_3 at low temperatures or for large amounts of adsorbed alcohol, is also explained by the scheme shown in Fig. 6. Reaction paths (I)'-(II)'-(III) and (I)-(II)-(III) are favored over SiO_2–Al_2O_3, since the catalyst has high acid strength and contains Brönsted acid sites.[10] In the case of Al_2O_3, the path (I)'-(IV) becomes preferred due to the concerted action of acid sites of weaker Lewis acid strength and basic sites. However, the high selectivity is lowered at higher temperatures, since the C–O bond is more readily broken so that path (II)' is favored. The high selectivity also decreases with decreasing amounts of adsorbed alcohol, since the fraction of adsorbed alcohol reacting with strong acid sites becomes large and path (II)' is thus also favored. The participation of basic sites on Al_2O_3 in the dehydration of secondary alcohols was verified by experimental results in which the isotope effects of the β-hydrogen of 2-propanol[21] and 2-butanol[4] were 4.1 and 2.3 at 160 °C, respectively.

The high ratios 1-B/2-B and *cis*/*trans* observed with Al_2O_3 poisoned with pyridine are explained by the disappearance or the weakening of strong acid sites with pyridine.

The Proton Magnetic Resonance in the DPPH–Benzene Complex

Toshio Yoshioka, Hiroaki Ohya-Nishiguchi, and Yasuo Deguchi*

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606
**College of Liberal Arts and Science, Kyoto University, Kyoto 606*

(Received July 23, 1973)

The proton magnetic resonance in single crystals of the DPPH-benzene complex has been measured around three Cartesian axes. All the spectra are highly complex, but some lines are clearly identified around all axes. The principal values of their anisotropic hyperfine tensors have been evaluated, in addition to the isotropic hyperfine coupling constants. In the crystalline state, the unpaired electron-spin distributions of one phenyl group is almost twice as large as that of the other phenyl group, as is to be expected from the crystal structure. Besides, the unpaired electron-spin delocalization is larger in the crystalline state than that in solution, particularly on the picryl group and on one phenyl group.

In the proton NMR spectra of some organic free radicals in polycrystalline states, some lines have been shifted from the free-proton position because of the exchange-narrowed hyperfine interaction.[1-5]

Anderson *et al.* have observed the proton resonance of a polycrystalline sample of the 1 : 1 DPPH–benzene complex at 4.2 K.[3] By deuterium substitution, the large central component and the largest downfield-shifted component were attributed to the benzene protons and to the picryl group protons respectively, but the other three components were not identified. Moreover, they reported that the single crystal spectrum is highly complex, containing as many as 15 resolvable peaks in certain orientations.

On the other hand, the ESR spectra of DPPH in mixed organic solvents have been measured, and the high resolution of the Electron-Nuclear Double Resonance (ENDOR) technique has been utilized to obtained precise values for the twelve proton hyperfine couplings of DPPH in a mineral oil solution.[6,7,8] Those results indicate that the unpaired electron-spin distributions of the two phenyl groups are equal in solution.

Recentyl the crystal structure of the 1 : 1 DPPH–benzene complex has been determined by Williams.[9] He reported that the molecular configuration around the α-nitrogen is approximately trigonal planar, with the phenyl groups twisted at angles of 49 and 22°. From his results, the unpaired electron-spin distribution of the two phenyl groups can be expected to be different in the crystalline state. In order to obtain more information about the unpaired electron-spin distribution in the crystalline state and the contribution of the anisotropic hyperfine interaction to the proton resonance shift, we have measured the NMR of protons in the DPPH–benzene complex single crystal around three Cartesian axes at 4.2 K, employing a higher frequency of 40.0 MHz. We have evaluated the principal values of the anisotropic hyperfine tensors for the identified lines. The single crystal and polycrystalline NMR data show that the unpaired electron-spin distribution of one phenyl group is almost twice as large as that of the other phenyl group.

Experimental

α,α-Diphenyl-β-picryl hydrazyl (DPPH) was prepared by the oxidation of commercially-obtained α,α-diphenyl-β-picryl hydrazine ($DPPH_2$) with PbO_2 and was recrystallized several times from a benzene solution. The single crystals of the DPPH–benzene complex used in the measurements was grown by the slow evaporation of the solvent from the benzene solution and had the dimensions of $10\times5\times4$ mm^3.

An x, y, z Cartesian axis system was defined for convenience from its shape. The x-axis was selected parallel to the long edge, and the z-axis, normal to the metallic lustrous face containing the long edge. All the NMR measurements were carried out using a Robinson-type spectrometer[10] at 40.0 MHz, with an 80-Hz field modulation and a field sweep. The angular dependence of the NMR spectra was obtained by rotating the magnet around the x, y, and z axes, with the magnet set perpendicular to the magnetic-field direction.

Results and Discussion

The 4.2 K proton resonance spectrum of a polycrystalline DPPH-benzene complex agrees well with the results reported by Anderson *et al.*,[3] as is shown in Fig. 1(a). Figs. 1(b) and (c) present relatively well-resolved spectra of the single crystal of the DPPH–benzene complex in a certain orientation, measured at 4.2 K and 1.5 K respectively. The angular dependences around the x, y, and z axes measured at 4.2 K are shown in Figs. 2(a), (b) and (c) respectively. The crystal structure obtained by Williams shows that

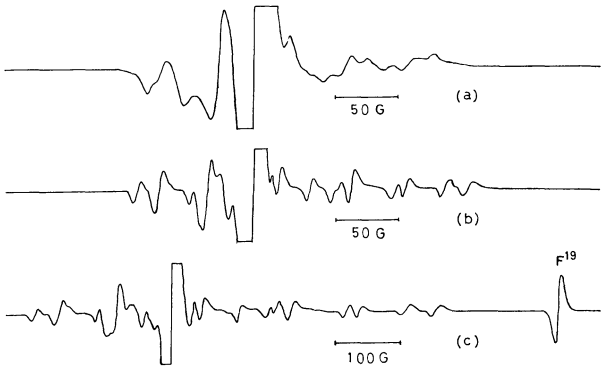

Fig. 1. Proton magnetic resonance absorption derivative curves (a) of the polycrystalline DPPH-benzene complex at 40.0 MHz, 4.2 K, (b), (c) of the single crystal of DPPH-benzene complex at 40.0 MHz, 4.2 K and 1.5 K. The static magnetic field is lying in the xy-plane and makes an angle 20° with the x-axis.

there are two DPPH molecules with unequivalent orientations in the crystal unit cell.[9] If the spectrum of the single crystal is completely resolved, 24 lines will be observed at most because of the anisotropic hyperfine interaction, except for the unshifted benzene proton lines. Around any axis we could identify six upfield-shifted lines and one downfield-shifted line, whose intensity is twice as strong as the others. In addition, two downfield-shifted lines can be partially identified around some axes.

The spin Hamiltonian for a free radical in which one proton interacts with one unpaired electron is:

$$\mathscr{H} = -g_N\beta_N\mathbf{H}\cdot\mathbf{I} + \mathbf{S}\cdot\mathbf{T}\cdot\mathbf{I}$$

in which the hyperfine term, $\mathbf{S}\cdot\mathbf{T}\cdot\mathbf{I}$, consists of an isotropic part, $a_H\mathbf{S}\cdot\mathbf{I}$, arising from the Fermi contact interaction and an anisotropic part, $\mathbf{S}\cdot\mathbf{D}\cdot\mathbf{I}$, due to the electron-nuclear dipolar interaction. Here, $\mathbf{T}$, a_H, and $\mathbf{D}$ are the total coupling tensor, the isotropic hyperfine coupling constant, and the traceless dipolar

coupling tensor respectively. The other symbols are used with their conventional significances. If the electron-spin relaxation, T_e, satisfies the condition of $|a_H T_e| \ll 1$, $\mathbf{S}=(\langle S_\alpha\rangle, 0, 0)$, which leads to the following equation: $\chi H=-g\beta\langle S_\alpha\rangle$. Here, $\langle S_\alpha\rangle$ is the α component of a vector **S** (parallel to the magnetic field, **H**) and χ is the static magnetic susceptibility per molecule, formulated by $\chi=g^2\beta^2S(S+1)/3k(T-\theta)$, provided that it obeys the Curie-Weiss law. The other symbols have their usual significances. To first order, therefore, the nuclear resonance signal shifts from the free-proton position to the high field by this amount:

$$\Delta H = -(\chi H/g\beta g_N\beta_N)T_{\alpha\alpha}$$

where $T_{\alpha\alpha}$ is the $\alpha\alpha$ component of the total tensor, **T**.

We reported in the previous paper[11] that, at 4.2 K, the static magnetic susceptibility per molecule of the DPPH–benzene complex obeys the Curie-Weiss law, with the Weiss constant $\theta=-0.5$ K. Although the anisotropy of the ESR g-value becomes larger as the temperature is lowered, it can be neglected in comparison with the magnitude of the anisotropic hyperfine interaction.[12] Consequently, from the angular variation of $T_{\alpha\alpha}$ around three Cartesian axes, it is possible to determine **T**. The tensor components with respect to the xyz-system were determined by the least-square method. Then, the **T**-tensor was diagonalized to obtain the principal values. The isotropic hyperfine coupling constant and the principal values, A, B, and C, of the anisotropic tensor, **D**, for each identified lines are summarized in Table 1, together with the direction cosines of the tensor. The isotropic hyperfine coupling constants of the six lines resemble each other and agree approximately with those obtained from the polycrystalline NMR spectrum, as will be shown afterwards. Using the results for the α-proton tensor in $CH(COOH)_2$,[13] we expect the anisotropic principal values to be $+1.35$, -0.03 and -1.32 for $a_H=-2.60$, and to be -0.84, $+0.02$ and $+0.82$ for $a_H=+1.62$. Those values do not agree well with the measured values listed in Table 1, especially in the case of the latter. Probably the anisotropic term does not depend only upon the spin density on the carbon atom adjacent to the proton, but also upon those on the second-nearest carbon atoms and the nitrogen atoms. Such an effect is serious in the case of the latter, for the positive spin densities on the second-nearest carbon atoms are larger than the negative ones on the carbon atom adjacent to the proton, as will be shown afterwards.[14] The direction of the principal hyperfine axes deviates considerably from that of the

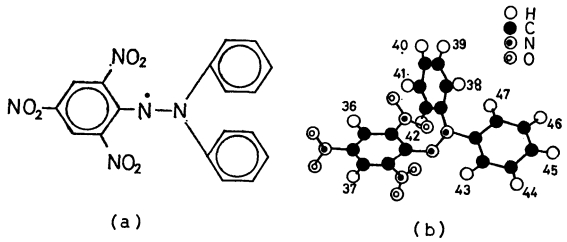

Fig. 3. (a) Molecular structure of DPPH (b) the shape of the DPPH molecule in the DPPH-benzene crystal. Williams' notation is used for the protons.

α-proton tensor. This cannot be explained by the experimental error. The relation between the directions of the principal hyperfine axes and the molecular structure was not discussed in this paper. Figs. 3(a) and (b) present the molecular structure of DPPH and the shape of the DPPH molecule in the DPPH–benzene crystal respectively. Williams' notation is used for the protons.

Now let us assign the proton resonance signals to the protons of the DPPH molecule. As there are two DPPH molecules with unequivalent orientations in the crystal unit cell, the six upfield-shifted lines are reduced to three for one molecule. In considering the theoretical results, we can expect the isotropic hyperfine coupling constants of two *ortho* protons to be approximately equal to that of one *para* proton.[2,15] Therefore, the three lines are attributable to two *ortho* protons and one *para* proton of the phenyl group twisted at an angle of 22°. These protons correspond to the largest upfield-shifted component in the polycrystalline spectrum. The downfield-shifted lines are assigned to *meta* protons of the picryl group, as has been determined by Anderson *et al.*[3] Another upfield-shifted component in the polycrystalline spectrum is probably due to two *ortho* protons and one *para* proton of the phenyl group twisted at an angle of 49°, and the other two downfield-shifted components (partially resolved), to the *meta* protons of two phenyl groups.

On the basis of the assignment of the polycrystalline NMR spectrum, the isotropic hyperfine coupling constants have been evaluated. The results are tabulated, together with the ESR[7] and ENDOR[8] results of DPPH in the solution state, in Table 2. The results in Table 2 indicate that the unpaired electron-spin distribution of one phenyl group is almost twice as large as that of the other phenyl group in the crystalline state. Further, in spite of the nonplanarity of the hydrazyl skeleton, the unpaired electron-spin delocalization is larger in the crystalline state than in solution, particularly on the picryl group and on one of the two phenyl groups. This fact may be related to the high stabilization of this radical in the crystalline state, in addition to the steric hindrance of the *o*-nitro groups reported by Williams.[9] In the case of a solution, a DPPH molecule may undergo dynamical changes in the hydrazyl skeleton and in the twist angle of the rings.

Pressure Effect on the Absorption Spectra of Iron Compounds

Yoji HARA, Ichimin SHIROTANI, Nobuko SAKAI, Saburo NAGAKURA, and Shigeru MINOMURA

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106

(Received September 1, 1973)

The effect of pressures up to 50 kbar has been measured on the absorption spectra in five ferric compounds, two ferrous compounds, and one mixed valence compound. In six compounds, but not in basic ferric acetate and soluble prussian blue, we observed pressure-induced bands which were assigned to the d-d transition of the converted Fe(II) for the ferric compounds and to the spin-forbidden d-d transition for the ferrous compounds. The absorption spectra for single crystals of potassium ferri- and ferrocyanide were studied at hydrostatic pressures up to 5 kbar. The band-peak intensity decreased with an increase in the pressure in both cases. The charge-transfer band from Fe(II) to Fe(III) of soluble prussian blue showed a blue shift (69 cm^{-1}/kb) at hydrostatic pressures up to 7.2 kbar.

A great deal of knowledge on the pressure-induced electronic transitions of iron compounds has been accumulated from measurements of the Mössbauer effect and of optical absorptions. Drickamer *et al.*[1] first observed that electronic transitions involving the reduction of ferric ions or the spin flip of ferrous ions are induced with various iron compounds by applying a wide range of pressures.

The reduction or spin flip initially increases with the increase in the pressure and exhibits a reversible process, sometimes with hysteresis. This behavior can be explained in terms of such basic effects of the pressure on the electronic structures as the increasing overlap and the relative displacement between adjacent electronic orbitals. In this paper, we wish to present data on the effects of pressures up to 50 kbar on the absorption spectra of some ferric, ferrous, and mixed-valence iron compounds.

The changes in the oxidation states of ferric and ferrous ions with pressure are discussed in connection with the results of the Mössbauer effect reported by Drickamer *et al.*

Experimental

The ferric and ferrous compounds used in this experiment were all of a commercially-available, reagent-grade quality. The absorption spectra were measured as a function of the pressure. The pressures were generated by means of an intensifier using a white gasoline medium up to 8 kbar and a high-pressure optical bomb using a NaCl medium up to 50 kbar.[2] The optical measurements were performed with a Shimadzu double-beam spectrometer and also with a Bausch-Lomb grating spectrometer.

The materials studied are listed in Table 1.

TABLE 1. MATERIALS STUDIED

Compounds	
Potassium ferricyanide	$K_3Fe(CN)_6$
Potassium ferrocyanide	$K_4Fe(CN)_6$
Ferric phosphate hydrate	$FePO_4 \cdot nH_2O$
Basic ferric acetate	$Fe_3(CH_3CO_2)_6(OH)_2 \cdot CH_3CO_2 \cdot H_2O$
Ferric citrate	$Fe(C_6H_5O_7) \cdot 3H_2O$
Ferric chloride	$FeCl_3$
Ferrous chloride hydrate	$FeCl_2 \cdot nH_2O$
Soluble prussian blue	$KFeFe(CN)_6$

Results and Discussion

Potassium Ferricyanide. Potassium ferricyanide and ferrocyanide are low-spin complexes. Figure 1 shows the pressure effect on the absorption spectra with a single crystal of potassium ferricyanide at hydrostatic pressures up to 4.5 kbar. Basu *et al.* assigned the broad band to the charge transfer from a ligand to the central metal ion.[3] The absorption intensity decreases with the increase in the pressure. This behavior was reproducible. Gardiner *et al.* have examined the visible spectrum of a $K_3Fe(CN)_6$ (potassium ferricyanide) solution in water under hydrostatic pressures up to 2 kbar.[4] They found no measureable change (>1/2%) in the absorbance.

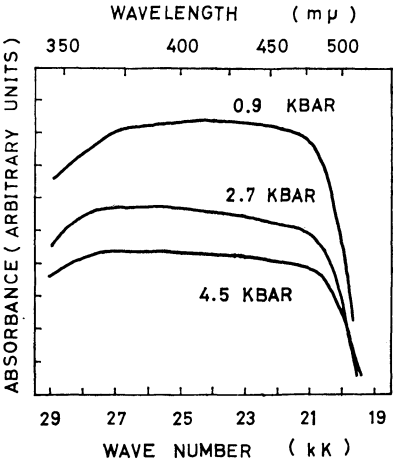

Fig. 1. Absorption spectra of a single crystal of potassium ferricyanide at various hydrostatic pressures.

In our experiment, however, a decrease of about 25% in the band peak intensity was observed upon a change from 0.9 kbar to 4.5 kbar. The decrease was over twice as much as that expected from the Mössbauer data of Champion and Drickamer.[5] This discrepancy may be interpreted as showing the remarkable dependence of the reduction on the samples. Therefore, in the first place, a reduction of the central $Fe(CN)_6^{3-}$ seems to be closely related to the direct interaction with the surrounding K^+ ions and $Fe(CN)_6^{3-}$. In the second place, the reduction can be explained in terms of the influence of the lattice distortion introduced by a kind of increasing local deformation with pressure near vacancies or dislocations in the

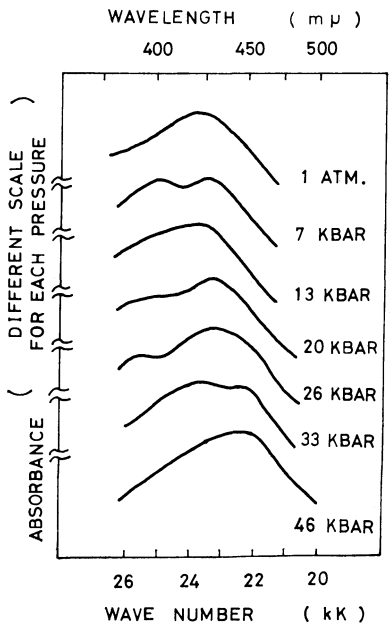

Fig. 2. Absorption spectra of polycrystalline potassium ferricyanide at various pressures.

crystal. The relationship between the reduction and the shearing stress of the sample has already been pointed out.[4,6] The absorption spectrum of a polycrystalline $K_3Fe(CN)_6$ sample diluted with NaCl was measured up to 46 kbar under quasi-hydrostatic pressure. The results are shown in Fig. 2. When the pressure was released, the original spectrum was obtained again. The band at 23.8 kK was assigned to the charge transfer from (CN^-) to the central Fe(III).[7] The intensity of the peak was found to decrease gradually up to 33 kbar, but was found to increase a little at 39 kbar. At 7 kbar, a doublet band appeared. The pressure-induced band at 25 kK exhibited a shift to the higher frequencies (blue shift) of about 500 cm^{-1} at 26 kbar, decreasing in intensity with pressure. By 33 kbar this band has been almost swamped by the lower energy bands. Another pressure-induced band was observed around 22.5 kK at 20 kbar; it was found to swamp the charge-transfer band at 46 kbar, increasing in intensity. These two pressure-induced bands seem to be due to the converted Fe(II).

Potassium Ferrocyanide. Figure 3 shows the pressure effect on the absorption spectra of a single crystal of potassium ferrocyanide at hydrostatic pressures up to 4.5 kbar. In an octahedral environment, the five d orbitals of the metal split into a threefold degenerated t_{2g} level and a doubly-degenerated e_g with the t_{2g} lying lowest.

In a low-spin case such as ferrocyanide, the six d electrons are in the t_{2g} orbital, with their spins paired; this is the ground state $^1A_{1g}$. The spectral assignment $K_4Fe(CN)_6$ in an aqueous solution shows that the band can be assigned to the expected d-d transition, $^1A_{1g} \rightarrow {}^1T_{1g}$.[8] The absorption peak showed a definite blue shift with an increase in the pressure, at the rate of 83 cm^{-1}/kb. The band-peak intensity decreased about 28% upon the pressure change from 0.9 kbar to 4.5 kbar.

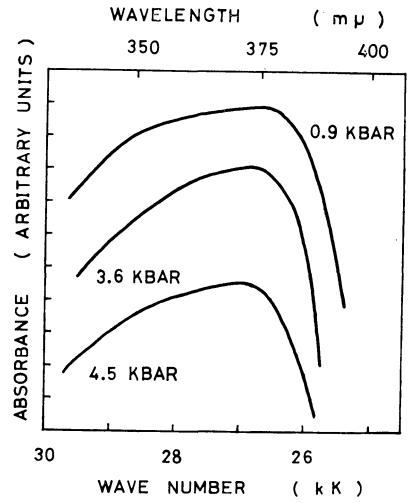

Fig. 3. Absorption spectra of a single crystal of potassium ferrocyanide at various hydrostatic pressures.

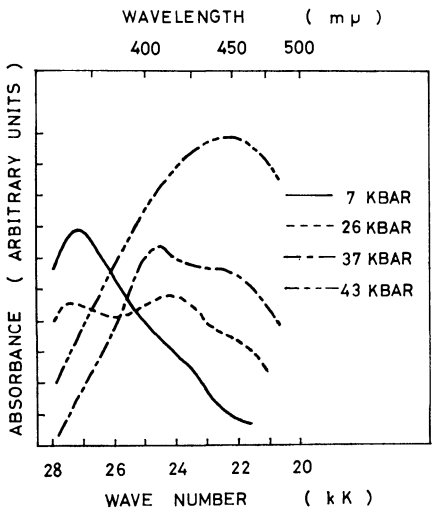

Fig. 4. Absorption spectra of polycrystalline potassium ferrocyanide at various pressures.

The blue shift and the decrease in the intensity continue at higher pressures, as is illustrated in Fig. 4, where the fade-out of the band is exhibited at 37 kbar. A reasonable explanation for the decrease from 2.7 kbar to 4.5 kbar in the absorbance around 27 kK of the single crystal $K_3Fe(CN)_6$, as is illustrated in Fig. 1, presents itself when one considers the decrease in the band intensity due to the converted Fe(II), as is shown in Fig. 3.

The pressure effect on the absorption spectra at quasi-hydrostatic pressures up to 50 kbar was measured. The results are shown in Fig. 4. The band around 24 kK at 7 kbar which appears as a shoulder showed a blue shift, about 500 cm^{-1} in 37 kbar, increasing in intensity drastically with pressure. At 26 kbar, another pressure-induced band was observed around 22 kK. This band also exhibited a blue shift, increasing in intensity drastically with pressure. This behavior was reproducible. The electronic spectrum of $Fe(CN)_6^{4-}$ shows a very weak band at 23.7 kK; this band can be assigned to the first spin-forbidden transition, $^1A_{1g} \rightarrow {}^3T_{1g}$.[8] Thus, the band at 21~26 kK which increased in intensity drastically

seem to be related to this transition. We obtained samples after 50 kbar and measured their infrared with a KBr pellet. No reasonable spectral change in the Fe(II)–C stretching frequency was observed.

Ferric Phosphate Hydrate. The absorption spectra of ferric phosphate hydrate at various pressures are given in Fig. 5. The spectra at 1 atmosphere and 6.3 kbar were measured with a KBr pellet under hydrostatic pressures. When the spectrum at 6.3 kbar was compared with that at 1 atmosphere, a swelling around 24 kK due to a pressure-induced band was found. The band peak at 1 atmosphere showed a red shift, about -700 cm^{-1} at 38 kbar. In 13 kbar a definite pressure-induced band around 24 kK was observed. This band increased in intensity relatively with that at higher wave numbers, exhibiting a slight shift. The spectra were reversible with some hysteresis. The electronic spectrum of ferrous phosphate, $Fe_3(PO_4)_2$, shows a band at about 23 kK at 1 atmosphere. This band corresponds to the pressure-induced band in ferric phosphate hydrate.

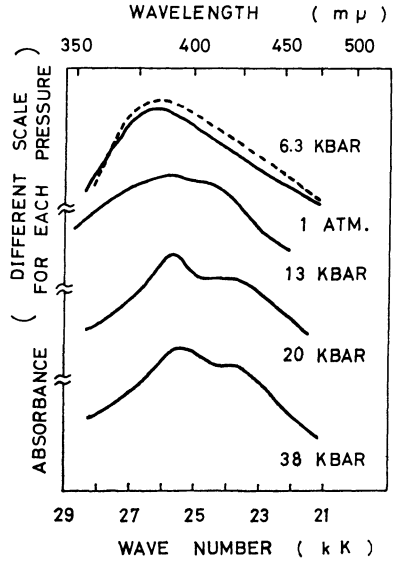

Fig. 5. Absorption spectra of polycrystalline ferric phosphate hydrate at various pressures; The spectra at 1 ATM. and 6.3 KBAR are at hydrostatic pressures.

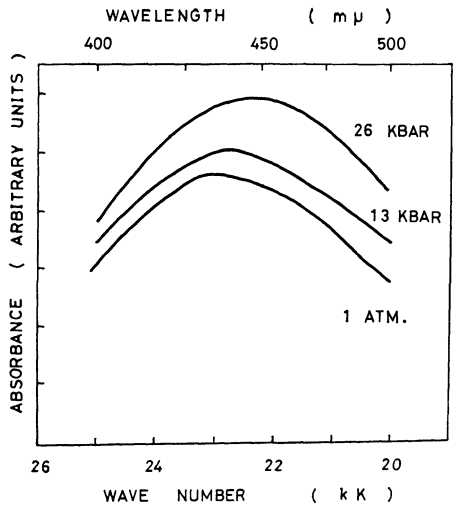

Fig. 6. Absorption spectra of polycrystalline basic ferric acetate at various pressures.

Basic Ferric Acetate. Figure 6 shows the absorption spectra measured with basic ferric acetate at various pressures up to 26 kbar. The measurement of the Mössbauer by Drickamer *et al.* showed evidence of only a trace of any reduction up to 150 kbar.[9,10] The band peak showed a red shift of -1100 cm^{-1} in 26 kbar, increasing in peak intensity about 30%. Basic ferric acetate is a tri-nuclear complex of ferric ions which are joined with each other by a strong linkage of the ($CH_3CO_2^-$) ions.[11]

Therefore, it may be inferred that the complex is difficult either to distort and to reduce because of less influence of a vacany and/or a dislocation.

Ferric Citrate. Figure 7 shows the effect of the hydrostatic pressure on the absorption spectra of ferric citrate with the KBr pellet. The band-peak intensity decreased by about 17% upon the pressure change from 0.9 to 5.4 kbar. This behavior was reproducible. The band shift may be small. According to the experiment which was carried out under quasi-hydrostatic pressures up to 26 kbar, this band shows a red shift, at the rate of -15 cm^{-1}/kb. At about 21.5 kK, a pressure-induced band was observed at 7 kbar, showing a blue shift, at the rate of 37 cm^{-1}/kb up to 26 kbar.

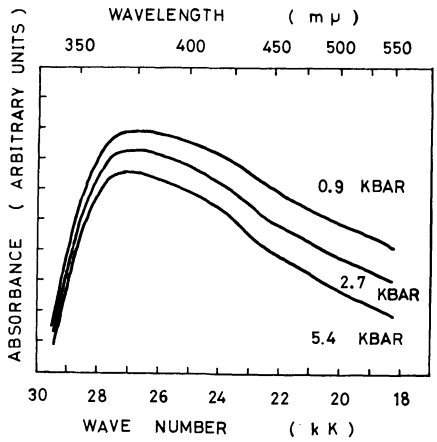

Fig. 7. Absorption spectra of polycrystalline ferric citrate at various hydrostatic pressures.

Ferric Chloride. The pressure effect on the absorption spectra of ferric chloride up to 46 kbar is illustrated in Fig. 8. The absorbance of the peak maximum decreased about 30% up to 46 kbar. The maximum of the broad band is 22.6 kK at 1 atomosphere. Pressure-induced bands were observed around 24.1 and 22 kK in 13 kbar. Judging from the results for ferrous chloride hydrate, these two bands should be assigned to the spin-forbidden bands of Fe(II). The peak around 23 kK due to Fe(III) was left. The band at 24.1 kK was swamped by the lower-energy bands by 20 kbar but was found to appear again at 39 kbar. The shift was approximately 200 cm^{-1} up to 39 kbar. The maximum absorption irregularly exhibited a red shift of about -800 cm^{-1} from 26 to 33 kbar; this is too great to be ascribed to the normal absorption due to Fe(III). A possible explanation of the irregular shift is that a pressure- induced band around 22 kK increases

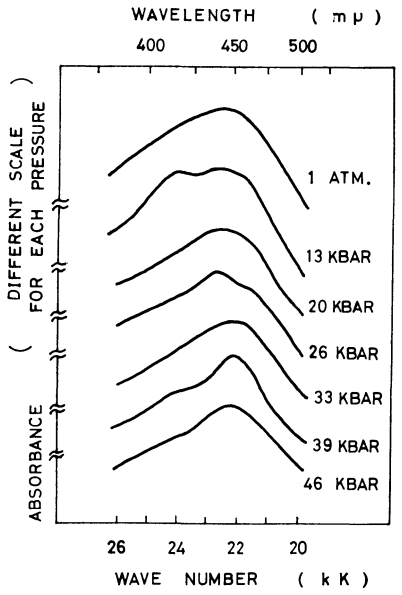

Fig. 8. Absorption spectra of polycrystalline ferric chloride at various pressures.

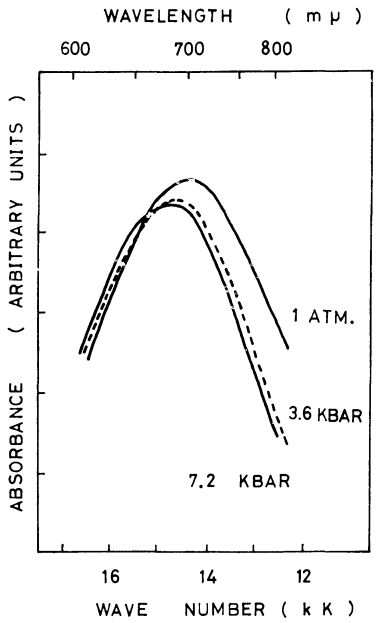

Fig. 10. Absorption spectra of polycrystalline soluble prussian blue at various hydrostatic pressures.

in intensity relative to the band which corresponds to Fe(III), located around 23 kK.

Ferrous Chloride Hydrate. Four d electrons are in the t_{2g} orbital and two are in the e_g orbital, which is the ground state $^5T_{2g}$. The two spin-forbidden d-d bands, $^5T_{2g} \rightarrow {}^3T_{1g}$ and $^5T_{2g} \rightarrow {}^3T_{2g}$, may be expected in the visible region. Figure 9 shows the pressure effect on the absorption spectra of ferrous chloride hydrate up to 36 kbar. No band was found in the 21~25 kK region of the spectrum at 1 atm. At 7 kbar, pressure-induced bands were observed, increasing in intensities drastically with pressure. The shifts of the two bands from 13 to 36 kbar were small. The spin-forbidden bands generally show a slight shift upon pressure.[12] Therefore, these new pressure-induced bands should be assigned to the expected d-d spin-forbidden transition.

Soluble Prussian Blue. The absorption spectra of polycrystalline soluble prussian blue at hydrostatic pressure are shown in Fig. 10. The structure of prussian blue has been elucidated by Robin.[13] A low-spin Fe(II) is coordinated to the carbon, and a high-spin Fe(III) to the nitrogen. The intermetallic charge-transfer band from the Fe(II) to the Fe(III) site assigned to $t_{2g}(\pi) \rightarrow t_{2g}(\pi)$ appears at 14.3 kK for the soluble prussian blue. The band exhibited a shift to higher frequencies of about 69 cm^{-1}/kb with pressure.

The absorbance at the band decreased by about 5% up to 7.2 kbar. This value is almost the same as that (about 5%) extrapolated from the result for $Fe[Fe(CN)_6]_3$ given by Mössbauer measurements by Drickamer *et al.*[14] who measured the transference of an electron from a low-spin Fe(II) site to a high-spin Fe(III) site at low pressure. The decrease in the absorbance at high pressure might be related to results of the Mössbauer spectra.

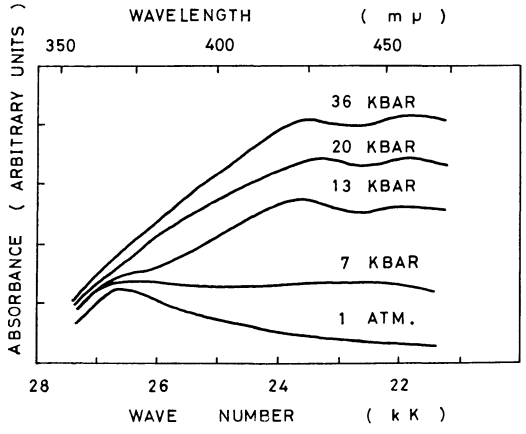

Fig. 9. Absorption spectra of polycrystalline ferrous chloride hydrate at various pressures.

(Received September 10, 1973)

We measured the polarized absorption spectra of the γ-hydroquinone and 1,4-dimethoxybenzene crystals in the wave number region between 30000 cm^{-1} and 65000 cm^{-1}. The dichroic ratios determined for the spectra of both crystals show that the bands at ~290 nm and at ~220 nm are polarized parallel with the short and long molecular axes, respectively; these support the assignment that they correspond to the L_b and L_a bands of benzene, respectively. The dichroic ratios and intensities determined for the bands in the vacuum ultraviolet region show that they do not simply correspond to the $B_{a,b}$ bands of benzene and that mixing among appropriate excited states occurs in both crystals.

The measurements of polarized electronic absorption spectra have played an important role in the studies of the electronic structures of molecules and molecular crystals.[1–5] Most of the studies made hitherto have, however, been concerned with polarized spectra in the wavelength regions longer than 250 nm; polarized absorption measurements in the vacuum ultraviolet region are rather scanty because of their experimental difficulties.[6]

In the present study, we have extended the polarized absorption measurements of single crystals to the vacuum ultraviolet region and have studied the electronic structures of the γ-hydroquinone and 1,4-dimethoxybenzene crystals from both theoretical and experimental points of view.

Experimental

Commercially-available (G. R. Grade) hydroquinone and 1,4-dimethoxybenzene were purified by repeated recrystallizations from water and by repeated sublimations in a vacuum, respectively. Single crystals used for the polarized absorption measurements were prepared by sublimation.

Polarized absorption spectra in the wave number region from 30000 cm^{-1} to 65000 cm^{-1} were measured by a vacuum ultraviolet microspectrophotometer constructed in our laboratory, the details of which were described in a previous paper.[7] Sample crystals were sandwiched between two quartz plates (optically flat) and were then put on the stage of the microscope of the spectrophotometer. The polarized absorption measurements were made along the b and c axes on the (100) surface and along the a and b axes on the (001) surface for the γ-hydroquinone and the 1,4-dimethoxybenzene crystals, respectively. The crystal surfaces were determined by comparing the crystal habits observed with the help of an orthonoscope with the crystal structure data obtained by Maartmann-Moe[8] and by Goodwin *et al.*[9] We could not measure the absorption at wavelengths shorter than 180 nm for the 1,4-dimethoxybenzene crystal because of the quick sublimation of the sample due to temperature elevation by the irradiation of the vacuum ultraviolet light.

The absorption spectrum of hydroquinone in the gaseous state was measured by the spectrophotometer used for the polarized absorption measurement, a microscope attached to the instrument being replaced by a gas cell.

Results and Discussion

Absorption Spectrum of Gaseous Hydroquinone and the Band Assignment. An absorption spectrum measured with gaseous hydroquinone is shown in Fig. 1. It consists of three bands with maxima at 34600, 45200, and 53300 cm^{-1}. Judging from their positions and intensities, they correspond to the $^1B_{2u} \leftarrow {}^1A_{1g}$ (L_b), $^1B_{1u} \leftarrow {}^1A_{1g}$ (L_a), and $^1E_{1u} \leftarrow {}^1A_{1g}$ ($B_{a,b}$) transition bands of benzene, respectively. In order to certify these assignments, the π-electron structure of hydroquinone was calculated by the Pariser-Parr-Pople SCF MO method[10] including the configuration interaction. The calculated and observed transition energies and oscillator strengths are given in Table 1. The calculated wave functions and polarizations are also shown in this table. The wave functions of the respective excited states show that the above-mentioned assignments are correct.

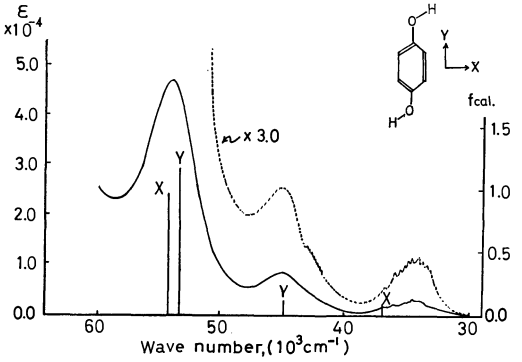

Fig. 1. The absorption spectrum of hydroquinone in the gaseous state. The vertical lines show the band positions and oscillator strengths calculated by the Pariser-Parr-Pople method: x and y indicate the polarization directions.

Polarized Absorption of the γ-Hydroquinone Crystal. The polarized absorption spectrum of the γ-hydroquinone crystal (monoclinic ($P2_1/c$)) is shown in Fig. 2. The projection of the four molecules within a unit cell of the crystal on the (100) face is shown in Fig. 3. Maartmann-Moe[8] reported that hydroquinone crystallizes in the γ-form upon sublimation.

Table 1. Observed and theoretical transition energies (ΔE) and oscillator strengths (f) of hydroquinone

Band	Experimental		Theoretical		Polarization	Configurations mainly contributed to each state[b]
	$\Delta E(\times 10^3\ cm^{-1})$	f[a]	$\Delta E(\times 10^3\ cm^{-1})$	f		
	34.6	0.040	36.9	0.092	x	$0.879\phi(5\rightarrow6)$, $-0.476\phi(4\rightarrow7)$
	45.2	0.097	44.8	0.130	y	$0.863\phi(5\rightarrow7)$, $0.503\phi(4\rightarrow6)$
	53.3	1.330	53.3	1.222	y	$-0.503\phi(5\rightarrow7)$, $0.864\phi(4\rightarrow6)$
			54.2	0.970	x	$0.477\phi(5\rightarrow6)$, $0.879\phi(4\rightarrow7)$

a) The f values of the first and second bands were obtained from the absorption spectrum in cyclohexane. Concerning the third band, f was obtained from the absorption spectrum in gas phase, the molar extinction coefficient (ε) of which was normalized by the absorption spectrum in cyclohexane.

b) $\phi(i\rightarrow j)$ represents the electron configuration in which one electron is excited from the i-th MO to the j-th MO. The coefficient of each configuration is that in the state wave function. ϕ_4, ϕ_5, ϕ_6, and ϕ_7 are as follows:

	a_1	a_2	a_3	a_4	a_5	a_6	a_7	a_8
ϕ_4		0.500	0.500		−0.500	−0.500		
ϕ_5	−0.497	−0.301	0.301	0.497	0.301	−0.301	0.269	−0.269
ϕ_6		0.500	−0.500		0.500	−0.500		
ϕ_7	0.576	−0.265	−0.265	0.576	−0.265	−0.265	−0.167	−0.167

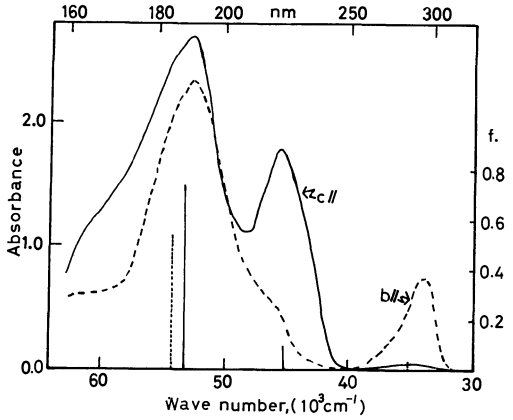

Fig. 2. The polarized absorption spectrum observed with the γ-hydroquinone crystal. The vertical full and broken lines show the absorption intensities estimated for the c- and b-polarized bands by the aid of the oriented gas model, respectively.

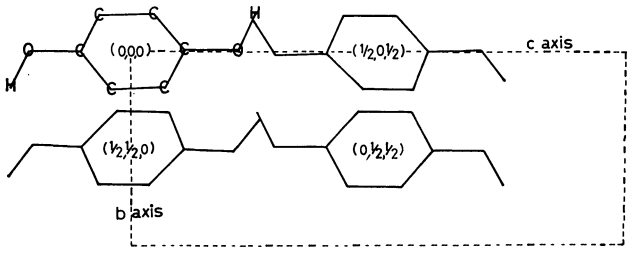

Fig. 3. Projection of the four site molecules on the bc plane of the γ-hydroquinone crystal.

As is clearly seen in Fig. 2, the polarized absorption spectrum of the γ-hydroquinone crystal has four peaks at 34500, 45500, 52000, and 60600 cm^{-1}. The dichroic ratios (D_b/D_c) are 20 : 1 and 1 : 4 for the first and the second bands, respectively, D_b and D_c being the absorbancies observed for each band along the b and c crystal axes, respectively. From the dichroic ratio observed with the crystal and from the orientations of the four site molecules in a unit cell, the molecular dichroic ratio, D_x/D_y, was obtained for the bands at 34500 and 45500 cm^{-1} as shown in Table 2. Here,

Table 2. The dichroic ratios observed for the first and second bands of γ-hydroquinone and 1,4-dimethoxybenzene

	γ-Hydroquinone	
	$D_b : D_c$	$D_x : D_y$
290 nm band	20 : 1	1 : 0
220 nm band	1 : 4	1 : 2.6
	1,4-Dimethoxybenzene	
	$D_b : D_a$	$D_x : D_y$
295 nm band	2 : 1	3 : 1
220 nm band	5 : 1	1 : 8

the x and the y axes are taken to be perpendicular and parallel to the molecular axis connecting the two oxygen atoms on the molecular plane.

Table 2 shows that the band of the crystal at 34500 cm^{-1} is polarized parallel with the x molecular axis and thus corresponds to the 34600 cm^{-1} band of the molecule in the gaseous state, which is expected from theoretical considerations to be polarized in the x-direction. The 45500 cm^{-1} band of the γ-hydroquinone crystal is polarized almost parallel with the y molecular axis; it corresponds to the 45200 cm^{-1} band of the molecule.

Let us turn to polarized absorption bands in the vacuum ultraviolet region. The spectra of the crystal polarized parallel with the b and c crystal axes show the intense absorption peaks at 52000 cm^{-1} and also have shoulders at around 60600 cm^{-1}.[11] As is seen in Fig. 3, the molecular x axis of each molecule in the crystal is almost parallel with the b crystal axis and the y molecular axis with the c crystal axis. Therefore, it is reasonable to assign the b-polarized band at 52000 cm^{-1} of the crystal to the x-polarized component of the intense absorption band of the molecule at 53300 cm^{-1}. The c-polarized absorption of the crystal with a peak at 52000 cm^{-1} can be assigned to the y-polarized absorption of the molecule, which is thought, from theoretical considerations, to overlap with the x-polarized component.

The intensities of the bands polarized parallel with the b and c crystal axes can be obtained on the as-

sumption of the oriented gas model from the experimental values of the oscillator strengths given in Table 1.[12] The results are shown by the vertical lines in Fig. 2. From this figure, it is seen that the polarized absorption spectra observed with the γ-hydroquinone crystal can be explained qualitatively by the oriented gas model. From the quantitative point of view, however, the observed intensity ratios of the 52000 cm^{-1} bands to the first and second bands are much smaller than those to be expected from the oriented gas model. For instance, the intensity ratio of the c axis polarized bands at 52000 cm^{-1} and at 45500 cm^{-1} is observed at 2 : 1 taking the integrated intensities; in case of the oriented gas model, the corresponding value is 7.5 : 1. This discrepancy is beyond the limitations of experimental error and may be due to the fact that the 53300 cm^{-1} band of the molecule in the gaseous state decreases its intensity in the crystalline state because of the intensity borrowing.

In the case of strong coupling, the intensity borrowing among the different excited states of the molecule may occur through the configuration interaction; consequently, the dichroic ratios of the crystal become different from those of the free molecule. Organic molecular crystals have many excited states including a continuous state (excitation from the valence band to the conduction band), so the intensity-borrowing effect may be significant for the exciton bands in this region. Tanaka and Tanaka[13] explained the spectrum of the anthracene crystal by considering the interaction among different exciton configurations. The observed decrease in the intensity of 52000 cm^{-1} bands polarized along the b and c axes of the γ-hydroquinone crystal may be due to the above-mentioned effect.

1,4-Dimethoxybenzene. The crystal of 1,4-dimethoxybenzene is orthorhombic (Pbca) and contains four molecules per unit cell. The polarized absorption spectrum was measured with the (001) plane of the single crystal prepared by sublimation; the results are shown in Fig. 4. The projection of the four molecules within a unit cell of the crystal on the (001) plane is shown in

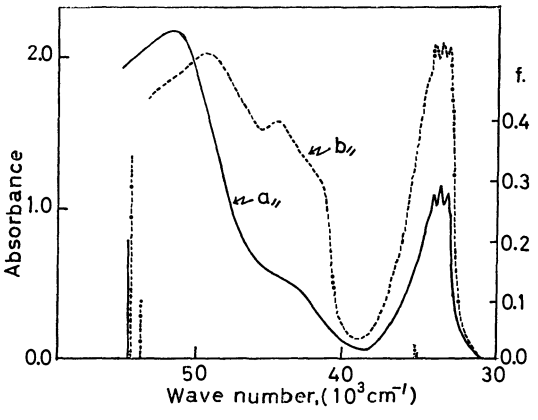

Fig. 4. The polarized absorption spectrum observed with the 1,4-dimethoxybenzene crystal. The vertical full and broken lines show the absorption intensities estimated for the a- and b-polarized bands by the aid of the oriented gas model, respectively.

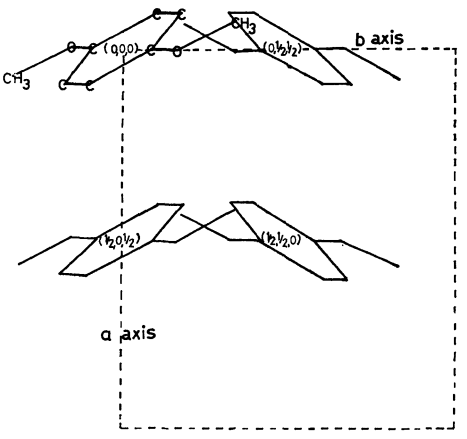

Fig. 5. Projection of the four site molecules on the ab plane of the 1,4-dimethoxybenzene crystal.

Fig. 5. The first and second bands at 295 nm and at 220 nm are polarized along the x and y axes, respectively, as is seen in Table 2. This result which is consistent with that by Albercht and Simpson[14] shows that the 295 nm and 220 nm bands correspond to the L_b and L_a bands of benzene.

In addition to the above-mentioned bands, we succeeded in observing the two absorption peaks at 49500 c n^{-1} and 51800 cm^{-1} polarized along the b and a axes, respectively. From the crystal structure data and the assumption of the oriented gas model, we can expect that the components polarized parallel with the a and b axes are 0.5 and 13.0 percent for the y-axis polarized band, respectively, and that they are 30.0 and 61.4 percent for the x-axis polarized one, respectively. Furthermore, the absorption intensities are almost equal for the bands polarized parallel with the x and y axes. Therefore, the two absorption peaks at 49500 cm^{-1} and 51800 cm^{-1} polarized along the b and a axes, respectively, are interpreted to correspond to the x-polarized band (B_b band for benzene), which is expected to show the Davydov splitting in the crystal. The splitting was calculated for the x-polarized transition by taking the dipole-dipole interaction between molecules within a sphere with a radius of 50 Å. The theoretical result that the a-axis spectrum shifts to higher frequencies than the b-axis one is consistent with the observation. The calculated value of the splitting, 480 cm^{-1} is, however, smaller than the observed value, 2300 cm^{-1}.

A small shoulder at 52200 cm^{-1} in the b axis spectrum may be assigned to the y-polarized transition band (the B_a band of benzene).

The relative intensities of the bands observed with the 1,4-dimethoxybenzene crystal are abnormal compared with those of the free molecule. This may be explained in terms of the interaction among various configurations in the crystals, as was done in the case of the γ-hydroquinone crystal.

Our thanks are due to Professor Ryumyo Onaka, Tokyo University of Education, for his kind suggestions and discussions regarding the design of the vacuum ultraviolet monochromator. We are also indebted to

Mr. Masaki Noma and Mr. Ichiro Sawamura, Olympus Optical Co., Ltd., for their kind help in constructing the reflection-type microscope used for the vacuum ultraviolet absorption measurements.

(Received September 3, 1973)

The emission spectrum of an organic charge transfer salt, 2,4,6-triphenylthiopyrylium-1,1,3,3-tetracyanopropenide, was studied in solutions of various solvents as well as in the solid state. A charge transfer fluorescence was observed both in the solid state and in non-polar rigid solution at 77 K, but not in fluid solution. In rigid solution, as the polarity of solvent increases, the charge transfer fluorescence shows a blue shift of its maximum wavelength and a remarkable decrease in intensity, the phosphorescence of a dissociated cation appearing predominantly. The strong dependence of the emission spectrum on the solvent polarity was explained in terms of the dissociation of the salt and the insufficient reorientation of solvent molecules around the salt in the excited charge transfer state.

An organic salt in which a charge-transfer (CT) interaction is present between an anion and a cation, which we have called an organic CT salt, has a predominantly ionic ground state and an excited state consisting of two neutral radical species. A report was given[2] on the CT absorption spectra of some new organic salts consisting of a pyrylium or thiopyrylium cation and a polycyanoacid anion(Fig. 1). The CT absorption spectra of these salts in solution were found to be very solvent sensitive due to two factors. With an increase in solvent polarity (i) the intensity of the CT band decreases by the dissociation of the salt into component ions, and (ii) the CT absorption peak shows a remarkable blue shift, which can be explained by Kosower's theorem.[3-5]

Although extensive studies have been carried out on the absorption spectra of organic CT salts,[2-11] few have been made on the emission spectra.[12] It seems that the solvent effect on the emission spectrum has not yet been elucidated in a wide range of solvent polarity. Of the salts we prepared, 2,4,6-triphenylthiopyrylium (TPT, Fig. 1 (2))-1,1,3,3-tetracyanopropenide (TCP, Fig. 1 (5)) is fairly soluble in various solvents including non-polar ones such as toluene or 1,4-dioxane, and with this we could investigate the solvent effect of the emission spectrum of an organic CT salt in detail. In addition to the temperature dependence of the absorption spectrum of TPT-TCP, we have also examined the emission spectrum of this salt in the solid state and in solutions of various solvents. TPT-TCP in the solid state shows exclusively a CT fluorescence, the emission from the component ion being completely quenched. This is the first example of the CT fluorescence of an organic CT salt in a crystalline solid state. In rigid solution of non-polar solvent at 77 K, the salt also shows a CT fluorescence. The CT fluorescence at 77 K shows a remarkable solvent effect both in intensity and energy. These solvent effects should be understood in terms of the dissociation of the salt in rigid solution and the relaxation behavior of solvent molecules around the CT excited state. In contrast to the case of a rigid solution, TPT-TCP does not show a CT fluorescence when dissolved in fluid solution irrespective of the solvent.

Experimental

The preparation of TPT-TCP and other salts used here have been reported.[2] For the measurement of the emission spectrum in the solid state, the microcrystalline sample was sealed in a pyrex tube (2 mm diameter) under vacuum. Each sample in solution having an appropriate concentration was degassed and sealed in a pyrex tube. All solvents used were purified according to the usual purification method.[13] Emission spectra were recorded on a Hitachi model MPF-3 spectrophotofluorometer equipped with a Xe excitation lamp and an R-446 photomultiplier tube, delayed emissions being measured with a delayed emission accessory including a cylindrical chopper to eliminate prompt emission. The spectra obtained were not corrected both for the excitation source and for the photomultiplier response. Phosphorescence lifetimes were estimated from the decay curves on an oscilloscope. Fluorescence lifetimes were measured by the pulse method with an N_2 gas laser excitation (337 nm, 5 nsec half-width). Absorption spectra were measured with a Hitachi EPS-3 UV spectrophotometer or a Cary model 14 spectrophotometer.

Results and Discussion

Absorption Spectrum. The absorption spectrum of TPT-TCP in a chloroform solution and the diffuse reflectance spectrum of the salt in the solid state are shown in Figs. 2a and 2b, respectively. These spectra are compared with sodium-TCP and TPT-perchlorate salts in methanol solution and TPT-perchlorate salt in the solid state. The absorption spectrum of TPT-TCP in solution consists mainly of three bands with the maximum wavelength at 350, 390 and 595 nm (Fig. 2a). The 350 and 390 nm bands correspond to the sum of the absorptions of TCP anion and TPT cation, and are assigned to the locally excited (LE) absorption bands of the component ions of the salt. Another absorption band at 595 nm is assigned to an interionic CT band, since it does not appear either in sodium-TCP or TPT-perchlorate salts where a CT interaction is absent between the cation and the anion. In the solid state, the corresponding CT absorption band is observed near 540 nm (Fig. 2b).

In order to understand the low temperature emission spectrum, the absorption spectrum was studied at low temperatures. The CT band shows a considerable blue shift as the temperature is lowered. The absorption spectra of TPT-TCP in 2-methyltetrahydrofuran (2MTHF)-toluene (9 : 1) solution at various temperatures are shown in Fig. 3. At 77 K, the LE bands of the component ions become sharp, but show no shift in maximum wavelength as compared with that at room temperature. The CT absorption maximum, however, shows a blue shift of 45 nm at 227 K and 120 nm at 77 K from the position of this band at room temperature. A consiberable decrease in absorbance of the CT band occurs together with the blue shift. Such a shift was observed in dichloromethane solutions of some alkylpyridinium-halide salts by Brinen *et al.*,[12] but they did not discuss the reason for this. We conclude that the blue shift is due to the increase of solvent polarity at low temperatures.

The maximum wavelength (λ_{max}) and the apparent molar extinction coefficients (ε_{app}) of the CT band of TPT-TCP in various solvents *at room temperature* are given in Table 1. With the increase of solvent polarity, the CT band shows a remarkable blue shift of λ_{max} and a decrease in ε_{app}. Since the energy of the CT band maximum shows a linear dependence on the

1,2-Dichloroethane	10.37	62.7	568	70
Benzyl alcohol	13.6	—	—[a]	—
Isopropyl alcohol	16.3	76.3	—[a]	—

a) The CT absorption band did not appear appreciably in this solvent.

Z-value of the solvent, or the empirical parameter of the solvent polarity,[3-5] the shift can be explained on the basis of Kosower's theorem. On the other hand, the decrease in ε_{app} is caused by the dissociation of an ion-pair, $D^-A^+ \rightarrow D^- + A^+$, where D^-A^+ is an ion-pair and D^- and A^+ are dissociated component ions. ε_{app} is more closely related to the dielectric constant (D) of solvent than to the Z-value (Table 1). The CT absorption peak is not conspicuous in the solvents with $D>10$ at room temperature, probably due to the almost complete dissociation of the ion-pair. Thus, the temperature dependence of the CT band shown in Fig. 3 can be understood phenomenologically in terms of the change in the solvent polarity with temperature.

It is known that the polarity of solvent increases with the lowering of temperature because of the enhanced orientation of the solvent dipole. Furutsuka *et al.* reported that the value of D of 2MTHF at 298, 223, just above the glass transition temperature (108 K), and below 108 K are 7.0, 9.0, 18.0, and 3.5, respectively.[14] Thus, the dielectric constant increases with the lowering of temperature down to the glass transition temperature. Even near the glass transition temperature of 2MTHF–toluene (9 : 1), the solvent molecules around the salt are expected to be in a well-oriented state. Although the D value of solvent is very small below glass transition temperature, the local solvent orientation around the salt may be kept even in the frozen state. The Z-value of the solvent, therefore, may increase with the lowering of temperature, and may not decrease even in a glass. From the result shown in Fig. 3, the Z-value of 2MTHF–toluene (9 : 1) at room temperature, 223, and 77 K can be estimated to be about 64, 72, and 88 kcal/mol. Thus the blue shift and the decrease of absorbance of the CT band can be accounted for by the increase of solvent polarity in a low temperature region.

Emission Spectrum in the Cyrstalline State. Although sodium–TCP gives no emission, TPT–perchlorate salt shows an emission both in solution and in the solid state. The emission and excitation spectra of TPT–TCP and TPT–perchlorate salts in the solid state at room temperature are given in Fig. 4. The emission of the perchlorate salt in the solid state is also found in fluid solution. This is assigned to the fluorescence of TPT cation by its lifetime in solution (a few ns), the mirror image relationship between the absorption and emission bands of the cation, and the excitation spectrum which approximately agrees with the absorption spectrum.

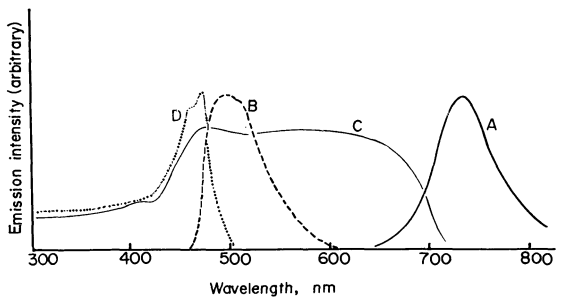

Fig. 4. Emission spectra of TPT-TCP and TPT-perchlorate salts in the crystalline state.
(A) emission spectrum of TPT-TCP, (B) emission spectrum of TPT-perchlorate, (C) excitation spectrum of the emission of TPT-TCP at 740 nm, (D) excitation spectrum of the emission of TPT-perchlorate at 500 nm.

In TPT–TCP in the solid state, the fluorescence of TPT cation was not found, and a new emission was observed at 740 nm which can be assigned to an interionic CT fluorescence for the following reasons: (i) the mirror image relationship with CT absorption holds, (ii) the emission can be found by irradiation not only in the LE band but also in the CT absorption band, (iii) the lifetime is much shorter than 100 μsec. The excitation spectrum of the emission (Fig. 4) does not coincide with the diffuse reflectance spectrum in Fig. 2b. This might be due to the insufficient transmission of the incident light into the microcrystalline sample.

The above assignment is confirmed by the fact that such an emission band is also found in the solid state of other organic CT salts (Fig. 1). The maximum wavelengths of the CT absorption and CT fluorescence bands of these salts are given in Table 2. An approximately parallel relationship is found between the energies of the absorption and emission bands. Thus, when a CT interaction is present, the fluorescence of the component ion is completely quenched and a CT fluorescence is observed in the solid state.

Emission Spectrum in Fluid Solution. The emission spectrum of TPT–TCP in fluid solution was measured at room temperature in various solvents in various concentrations. In all cases, the fluorescence of TPT cation was observed, but not CT fluorescence. The intensity of the fluorescence of the cation was very sensitive to the solvent polarity, becoming weak with the decrease of the solvent polarity (Fig. 5). This suggests that the fluorescence of the cation is emitted only from the free TPT cation present in solution, and that the amount of the free cation produced by the dissociation of the ion-pair becomes small in a less polar solvent. This is supported by the fact that the excitation spectrum of this emission agrees with the absorption of TPT cation.

Thus, in fluid solution TPT–TCP shows only the fluorescence of the free TPT cation and no emission from the undissociated ion-pair. This is in sharp contrast to the observation of the CT fluoerscence of

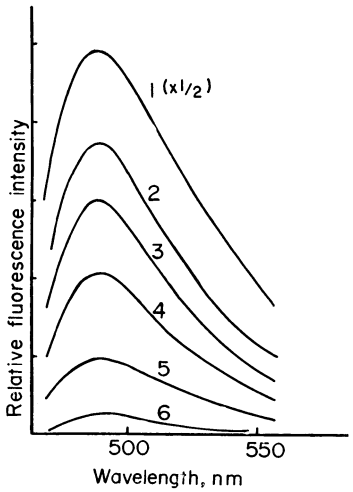

Fig. 5. Solvent effect of the emission spectrum of TPT-TCP salt in fluid solution at room temperature. (1) 2MTHF-C_2H_5OH (2 : 1), (2) 2MTHF, (3) 2MTHF-toluene (9.8 : 0.2), (4) 2MTHF-toluene (9.5 : 0.5), (5) 2MTHF-toluene (8 : 2), (6) 1,4-dioxane.

TPT-TCP in the solid state. In fluid solution the CT excited energy can be deactivated without radiation because of the interionic CT interaction.[15] Similarly, an ordinary molecular CT complex does not show a CT fluorescence even in non-polar solvents except for a few rare cases. This could be understood in terms of an extremely low transition probability of a CT complex in fluid solution.[16–18]

It should be noted that with TPT-TCP the following case is also conceivable: A CT fluorescence emitted near the IR region could not be observed because of the limitation of the spectrofluorometer in the wavelength region longer than 800 nm. In *s*-tetracyanobenzene-polymethylbenzene complexes in which a CT fluorescence can be found in fluid solution, the Stokes shift of the CT transition at room temperature is 8000—12000 cm^{-1}, which is much larger than that in rigid solution at 77 K (4500—8300 cm^{-1}).[17,18] In TPT-TCP the Stokes shift in 2MTHF-toluene (9 : 1) rigid solution at 77 K is estimated to be 4200 cm^{-1}. If the Stokes shift at room temperature were greater than 6000 cm^{-1} as in tetracyanobenzene complexes, the CT fluorescence would have its maximum above 800 nm, which could not be detected by our apparatus.

Emission Spectrum in Rigid Solution at 77 K. The emission spectrum of TPT-TCP in rigid solution is also affected by the nature of the solvent. In a polar solvent, methanol-ethanol(1 : 1), it is essentially the same as that of TPT-perchlorate under the same conditions (Fig. 6). The emission band at 460 nm is the fluorescence of the cation. An emission band at 540 nm is assigned to the phosphorescence of TPT cation, since it is found as a delayed emission of the perchlorate salt at 77 K, its lifetime being about 30 ms. Since in this solvent TPT-TCP dissociates completely into two component ions, the two emissions originate from the free TPT cation present in rigid solution.

The emission spectra of TPT-TCP in a less polar 2MTHF-toluene (9 : 1) solution are shown in Fig. 7.

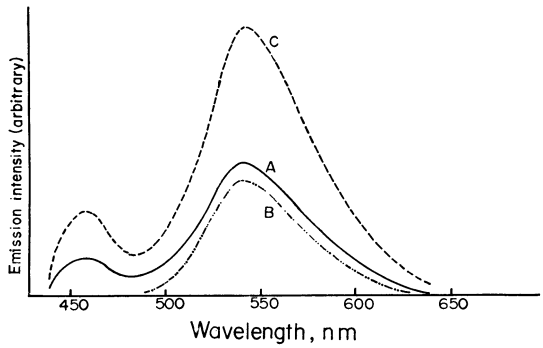

Fig. 6. Emission spectra of TPT-TCP and TPT-perchlorate salts in CH_3OH-C_2H_5OH (1 : 1) rigid solution at 77 K.
(A) total emission of TPT-TCP at 77 K, (B) delayed emission of TPT-TCP, (C) total emission of TPT-perchlorate.

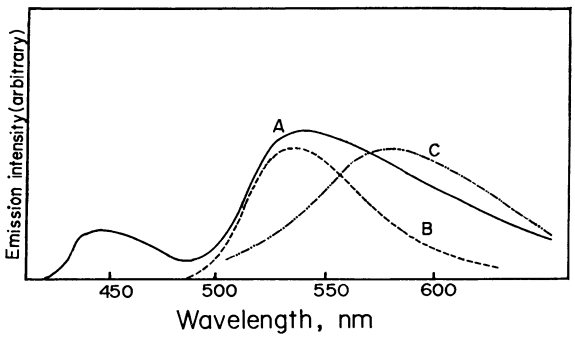

Fig. 7. Emission spectrum of TPT-TCP salt in 2MTHF-toluene (9 : 1) solution at 77 K.
(A) total emission by excitation at 420 nm, (B) delayed emission by excitation at 420 nm, (C) total emission by excitation at 470 nm.

In the case of the excitation of the LE band of the cation, the emission band at 540 nm becomes broad with a new emission around 600 nm. On the excitation of the CT band in rigid solution (at 470 nm), only the new emission was observed at 585 nm. The band can be assigned to the interionic CT fluorescence of TPT-TCP for the following reasons; (i) the lifetime is about 170 ns, (ii) a mirror image relationship holds between this emission band and the CT absorption band shown in Fig. 3, (iii) the Stokes shift of this transition, about 4200 cm^{-1}, is comparable with that of ordinary molecular CT complexes in rigid solution.[19]

The relative intensities of the three emission bands, the fluorescence and phosphorescence of the cation and the CT fluorescence, are very sensitive to solvent polarity. The total emission spectra of TPT-TCP by 420 nm excitation are shown in Fig. 8 for various compositions of 2MTHF-toluene solvent system. In a more polar solvent the phosphorescence of the cation is predominant over the CT fluorescence, while in a less polar solvent the CT fluorescence predominates. The relative intensity of the phosphorescence of the cation is plotted against the solvent composition in Fig. 9. The intensity of the phosphorescence is reduced strikingly with the addition of toluene, its lifetime remaining almost unchanged. Upon direct excitation of the CT absorption band, no phosphores-

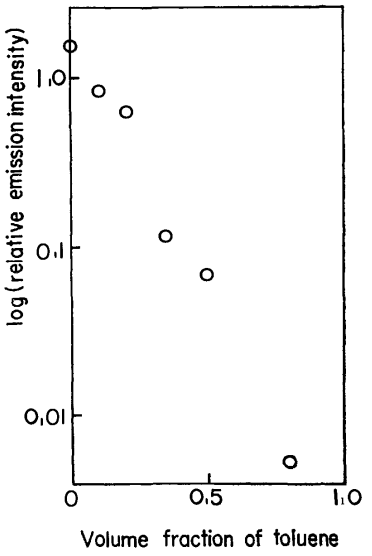

Fig. 9. Relative phosphorescence intensity of TPT cation against the solvent composition of 2MTHF-toluene.

cence of the cation be can observed. This indicates that even in a non-polar solvent the phosphorescence of the cation is emitted only from the dissociated free cation. Thus the dependence of the emission spectrum on the solvent polarity shown in Fig. 8 can be accounted for by the variation of the relative amount of the free TPT cation due to dissociation. This shows that the solvent polarity similar to that of 2MTHF-toluene (9 : 1) is required for the dissociation of the salt in rigid solution. This appears to correspond to the fact that in solution at room temperature the salt dissociates almost completely into two component ions in the solvent with $D>10$.

In the case of some molecular CT complexes, phosphorescence emission often occurs from the lowest CT triplet state which is generated by the intersystem-crossing *via* the CT singlet excited state. CT phosphorescence in particular which is similar to that of the component molecule, is observed in some complexes such as *s*-tetracyanobenzene–naphthalene complex.[20] In TPT-TCP, however, this is not possible since the energy of the phosphorescence is much higher than that of the CT fluorescence.

The solvent polarity is a very important factor in determining the emission spectrum of the interionic CT salt, the degree of dissociation of the salt being primarily determined by this factor. The solvent polarity also has an effect on the maximum wavelength and the lifetime of the CT fluorescence. The maximum wavelengths and lifetimes of the CT fluorescence, and the maximum wavelengths of the CT absorption in various solvents are listed in Table 3. Accurate determination of the maximum of the CT fluorescence is difficult with the excitation in the LE bands, since both the CT fluorescence and the phosphorescence of the cation are observed simultaneously. Thus, the maximum wavelengths given in Table 3 were determined by the excitation of the CT absorption band. The fluorescence lifetimes, however, were measured on the excitation at 337 nm of an N_2 gas laser.

TABLE 3. MAXIMUM WAVELENGTH (λ^{F}_{max}) AND LIFETIME (τ_F) OF CT FLUORESCENCE AT 77 K AND MAXIMUM WAVELENGTH (λ^{A}_{max}) OF THE CT ABSORPTION BAND IN VARIOUS SOLVENTS

Solvent	λ^{F}_{max} [a] (nm)	τ_F [b] (ns)	λ^{A}_{max} at 70 K (nm)	λ^{A}_{max} at 293 K (nm)
2MTHF	585	150	460(S) [c]	585

The increase of solvent polarity causes a blue shift of the CT fluorescence. Its amount is comparable with that of the CT absorption maximum resulting from the increase of the solvent polarity in solution at room temperature. A CT fluorescence of organic CT salts in rigid solution has been reported by Brinen *et al.* on some alkylpyridinium–halide salts.[12] They observed the CT fluorescence of the salts in three solvents, *i.e.*, water, methanol–ethanol (1 : 4), and dichloromethane, and found no solvent effect on the energy of the CT fluorescence. Thus, our result is quite different from that for alkylpyridinium salts.

As a CT salt has an ionic ground state, an ion-pair is strongly solvated in the ground state. Even in Franck-Condon state, the salt is still strongly solvated, despite the fact that the components of the salt are neutral in the excited state. Brinen *et al.* suggested that the solvent-solute reorientation occurs during the relaxation of the excited state from the Franck-Condon state to a fluorescent CT state even in rigid solution. However, Kobayashi *et al.* have shown that in *s*-tetracyanobenzene complexes this kind of reorientation

does not occur sufficiently during the relaxation in rigid solution at 77 K.[18] Our present observation of the blue shift of the CT fluorescence also suggests that the reorientation of the solvent molecules is insufficient at 77 K, and that the salt in the CT fluorescent state is still solvated in a similar fashion to that in the ground state. If the CT fluorescence of this salt could be observed in fluid solution, the energy would remain constant independent of the solvent polarity, since the reorientation of the solvent molecules would occur sufficiently in fluid solution.

The lifetime of the CT fluorescence becomes long with the decrease of solvent polarity. The increase of lifetime may be caused by the decrease of the radiative transition probability or the decrease of the radiationless transition probability of the excited ion-pair. If the emission probability decreases, the quantum efficiency of the CT fluorescence would show a considerable decrease corresponding to the increase of the fluorescence lifetime. Although the quantum efficiency of the CT fluorescence cannot be determined, since the concentration of the undissociating ion-pair in rigid solution is unknown, such a decrease of intensity of the CT fluorescence was not observed. This suggests that the dependence of the fluorescence lifetime is attributable to the decrease of the radiationless transition probability of the excited ion-pair in a less polar solvent.

(Received September 17, 1973)

The photoconductive and semiconductive properties of some organic charge-transfer (CT) salts consisting of a pyrylium or thiopyrylium cation and a polycyanoacid anion were investigated in single crystals. The salts are poor semiconductors with a resistivity of $10^{10}-10^{12}$ ohm·cm at room temperature, but show relatively large photoconduction when irradiated with monochromatized light in the interionic CT absorption band. There is a strong possibility that the photocarrier is intrinsic in nature, being generated spontaneously from the excited CT state. A weak ESR signal observed originally in these salts increased on the CT band or near IR excitation. From the relationship between the darkcarriers, photocarriers, paramagnetic species and the excited CT state, a mechanism of electrical conduction is proposed in which the carrier generation by the CT interaction and the carrier migration by trapping conduction are involved.

Organic charge-transfer (CT) salts are a class of ionic compounds consisting of organic cation and anion, having CT interaction between the component ions. In order to elucidate the role of the interionic CT interaction in them, we have studied the physical properties[1,2] of new organic CT salts consisting of a pyrylium or thiopyrylium cation and a polycyanoacid anion (Fig. 1). We have investigated the photoconductive and semiconductive properties as well as the magnetic properties.

Although photoconduction has been found in several weak molecular CT complexes having low dark conductivity,[3-6] the photocarrier generation in most cases has been considered to be extrinsic in nature, an intrinsic carrier generation not being proved in any of the cases. With weak molecular CT complexes, Akamatu and Kuroda discussed the relationship between the conduction state and the excited CT state.[3] They suggested that a difference of energy equivalent to that necessary for the separation of the excited CT state into free ions, that is, the separation of a D^+A^- ion-radical pair into two charge carriers might prevent the intrinsic carrier generation. However, in the case of an interionic CT salt, the excited CT state might consist of two neutral radical species, D·A·, and the carrier separation from the CT state would be easier than in the case of a weak molecular CT complex. Thus, in an organic CT salt, the possibility of intrinsic carrier generation by the CT excitation is expected.

Actually, all the CT salts studied showed a photocurrent about ten times larger than the dark current on irradiation at the CT absorption band. A weak ESR signal, which seems to originate from the charge carriers in the dark conduction, was enhanced on the CT and near IR excitations. From the results obtained on the electrical and magnetic properties, we will discuss the mechanism of electrical conduction and the possibility of the intrinsic carrier generation in organic CT salts.

Experimental

Materials. Crystals of the organic CT salts(Fig. 1) were prepared as described previously.[2] The salt was purified by recrystallization at least three times. Vacuum sublimation or zone refining could not be used because of decomposition of the salt. Single crystals of the CT salts, dimensions about $2\times1\times0.5$ mm, were grown from methanol–water (4 : 1) or methanol solution. However, except for TPT-perchlorate, single crystals of the perchlorate salts of other cations could not be obtained.

Conductivity Measurement. The apparatus for the measurement of the dark- and photo-conduction is shown in Fig. 2. The DC conductivity was measured with a Takeda-Riken vibrating reed electrometer, type TR-81. Temperature was controlled by passing cold nitrogen gas or heated air around a single crystal sample, and was monitored with a thermocouple. The light from a 500 W Xe lamp, arc current 20 A, was monochromatized with a monochromator. The energy distribution and the absolute light intensity of the Xe lamp were shown previously.[7] In order to investigate

the light intensity dependence of the photocurrent, neutral filters of known transmittance were inserted between a sample and a monochromator. A single crystal was placed on a quartz plate with Ag paste, which was used as electrodes (Fig. 2). In the case of TPP-perchlorate, a compressed pellet of powder crystals was used. The voltage-current characteristics were ohmic in all samples up to 200 V applied voltage, no photovoltaic current being observed when no voltage was applied. This indicates that the choice of electrode is adequate, and carrier injection from or to the Ag paste electrode is negligible. All conductivity measurements were performed both in dry air at one atmosphere and in a vacuum at 10^{-4}—10^{-5} mmHg.

ESR Measurement. The electron spin resonance measurement was carried out with an X band, JES-ME2X type spectrometer (Japan Electron Optics Laboratory Co. Ltd.) with a double mode cavity. A microcrystalline sample was packed in a quartz tube in air and in a vacuum at 10^{-2} mmHg. The concentration of unpaired spins of a salt was estimated by comparing its intensity with that of a DPPH sample. DPPH(Wako, pure grade) was purified by repeated recrystallizations from CS_2 or petroleum ether (a fraction of bp< 40 °C) solutions. The benzene solution or the powder sample dispersed in KCl (Merck, ultra pure grade, dried over 2 days at 200 °C in vacuum) was used as a reference substance of known concentration of unpaired spins. Temperature was varied by passing cold nitrogen gas or heated air into the cavity, and was monitored with a thermocouple attached around a sample tube in the cavity. The *g*-value of the unpaired spins in a salt was determined from the *g*-value of Mn^{2+} in a MgO sample.[8] For the measurement of photo-ESR absorption, a 500 W Xe lamp of 20 A was used. The spectral dependence of photo-ESR absorption was roughly estimated by combining several color glass filters of known transmittance at various wavelengths, since the light from a monochromator was too weak for observation of ESR absorption change.

Results

Dark Conductivity and Photoconductivity. The organic CT salts are semiconducting with resistivity in the range 10^{10}—10^{12} ohm·cm at room temperature. On irradiation with a visible light, a photocurrent of *ca.* 10 times greater magnitude than the dark current was observed.

The light intensity dependence of the photocurrent obeyed $i_{ph}=a\cdot L^n$, where L is the incident light intensity, a and n are the constants. This relation is given in Fig. 3 and the results in Table 1. The value of n appears to be independent of the presence of air, being

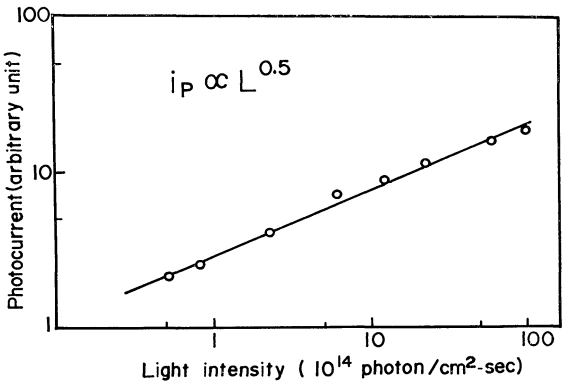

Fig. 3. Light intensity dependence of photocurrent at 650 nm of TPT-TCP salt.

Table 1. Light intensity dependence of photocurrent of organic CT salts

Salts	n in $i_{ph}=a\cdot L^n$		λ_{ex} (nm)[a]
	in vacuum	in air	
TPP-TCP	0.5	0.5	600
TPT-TCP	0.6	0.5	650
TPP-TCM	0.6	0.8	600
TPT-TCM	0.7	0.7	650

ADPP-TCM	—	0.5	600
TPT-ClO_4	0.4	0.4	500

a) wavelength of illuminating light.

0.5 for all salts.

The spectral dependence of the photoconduction is shown in Figs. 4 (a—d) for several salts, together with the corresponding absorption spectra. Large absorption bands near 400 nm are the locally excited (LE) bands of the component ions.[2] A relatively weak and broad absorption band observed near 550 nm in each CT salt but not in the corresponding perchlorate salt of the cation is assigned to the interionic

Table 2. Specific resistivity (ρ_d) in the dark at room temperature, photoconduction maximum wavelengths (λ_{max}^{ph}) and absorption maximum wavelengths (λ_{max}^{ab}) of organic CT salts

Salts	ρ_d (ohm·cm)	λ_{max}^{ph} (nm)	λ_{max}^{ab} (nm) CT band[a]	LE band[b]
TPP-TCP	10^{11}	640, 500	565	410
TPT-TCP	10^{11}	640, 500	540	390
TPP-TCM	10^{10}	580	530	410
