(1) Dichloro(methanol)(hydroquinone)(2,2′-bipyridine)ruthenium(II), [$RuCl_2$(MeOH)(QH_2)bipy]: To a solution of 1 g of [RuO_4bipy]$\cdot 3H_2O$ or [$RuO_2(OH)_2$bipy]$\cdot 3H_2O$ in 150 ml of 0.1 M hydrochloric acid, 2 g of hydroquinone was added. The mixture was refluxed with occasional shaking on a water bath for about 2 hr until the solution turned orange-brown. The solution was then evaporated to dryness, and the residue was washed repeatedly with diethyl ether and then dissolved in methanol. An insoluble material was filtered off. The solution was concentrated, and the crystals which formed were recrystallized from methanol and dried *in vacuo*. Complex I which was derived from [RuO_4bipy] was stable in air, but complex II which was derived from [$RuO_2(OH)_2$-bipy] was slightly hygroscopic.

Found for complex I: Ru, 20.85; C, 43.55; H, 3.89; N, 5.36; Cl, 16.48; CH_3OH, 7.24%; mol wt, 510; yield 72.5%.

Found for complex II: Ru, 20.63; C, 43.00; H, 4.02; N, 5.22; Cl, 15.58; CH_3OH 7.49%; mol wt, 520; yield 90.1%. Calcd for [$RuCl_2(CH_3OH)(C_6H_6O_2)(C_{10}H_8N_2)$]: Ru, 21.49; C, 43.40; H, 3.83; N, 5.96; Cl, 15.10; CH_3OH, 6.80%; mol wt, 470.

Both complexes were insoluble in carbon tetrachloride, benzene, diethyl ether, ethyl acetate, chloroform and dioxane, but were slightly soluble in methanol, acetone, DMSO and DMF, and very slightly soluble in water. These complexes were green in methanol, but dark-brown in acetone, black in DMSO or DMF and pink in water, probably due to the replacement of coordinated methanol by the solvent molecules.

(2) Chloro(hydroquinonato)bis(2,2′-bipyridine)ruthenium(II), [RuCl(QH)$(bipy)_2$]: To a solution of 0.5 g of [$RuCl_2$(MeOH)-(QH_2)bipy] (complex I or II) in 250 ml methanol, 2 g of 2,2′-bipyridine was added. The mixture was refluxed with occasional shaking on a water bath for about 3 hr until the solution turned reddish-brown. The solution was then evaporated to dryness, and the residue was repeatedly washed with diethyl ether. The product was dissolved in methanol.

An insoluble material was filtered off. The solution was concentrated, and the crystals which formed were recrystallized from methanol and dried *in vacuo*. Yield: 89.5%. The complex was insoluble in carbon tetrachloride, benzene, diethyl ether, ethyl acetate, dioxane and chloroform, but soluble in water, methanol, ethanol, acetic acid, DMSO and DMF, and slightly soluble in acetone.

Found: Ru, 17.35; C, 57.89; H, 4.11; N, 10.39; Cl, 5.85%; mol wt, 585. Calcd for $[RuCl(C_6H_5O_2)(C_{10}H_8N_2)_2]$: Ru, 18.11; C, 55.96; H, 3.79; N, 10.04; Cl, 6.36%; mol wt, 558.

(3) Dihydroxobis(2,2'-bipyridine)ruthenium(II), $[Ru(OH)_2(bipy)_2]\cdot 1.5H_2O$: A solution of 0.5 g of $[RuCl(QH)(bipy)_2]$ in 150 ml of distilled water was refluxed with occasional shaking on a water bath for 3 hr. An insoluble material was filtered off. The solution was then evaporated to dryness, and the residue was repeatedly washed with diethyl ether. The product was recrystallized twice from water and dried *in vacuo*. Yield: 79.8%. The water content of the complex was determined by measuring the weight loss in the temperature range 100~130 °C with a thermobalance. The complex was insoluble in carbon tetrachloride, benzene, diethyl ether, ethyl acetate, dioxane and chloroform, but soluble in water, methanol, ethanol, acetic acid, acetone, DMSO and DMF.

Found: Ru, 20.15; C, 49.09; H, 4.39; N, 10.87; H_2O, 5.39%. Calcd for $[Ru(OH)_2(C_{10}H_8N_2)_2]\cdot 1.5H_2O$: Ru, 21.32; C, 50.62; H, 4.42; N, 11.81; H_2O, 5.69%.

(4) Chloro(hydroquinone)bis(2,2'-bipyridine)ruthenium(II) chloride, $[RuCl(QH_2)(bipy)_2]Cl$: To a solution of 0.2 g of $[RuCl_2(MeOH)(QH_2)bipy]$ (complex I) in 100 ml methanol containing 0.05 ml of conc. hydrochloric acid, 0.8 g of 2,2'-bipyridine was added. The mixture was refluxed with occasional shaking on a water bath for about 3 hr until the solution turned reddish-brown. Then we followed the procedure described in section (2). Yield: 94.3%. The solubility of the complex in the several solvents was similar to $[RuCl(QH)(bipy)_2]$, but the complex was slightly hygroscopic.

Found: Ru, 16.35; C, 53.78; H, 4.36; N, 10.41; Cl, 13.50%. Calcd for $[RuCl(C_6H_6O_2)(C_{10}H_8N_2)_2]Cl$: Ru, 17.00; C, 52.53; H, 3.73; N, 9.42; Cl, 11.93%.

(5) cis-*Dichlorobis(2,2'-bipyridine)ruthenium(II)*, cis-$[RuCl_2(bipy)_2]\cdot 0.5H_2O$: To a solution of 0.2 g of $[RuCl_2(MeOH)(QH_2)bipy]$ (complex II) in 100 ml methanol containing 0.05 ml of conc. hydrochloric acid, 0.8 g of 2,2'-bipyridine was added. The mixture was refluxed with occasional shaking on a water bath for 3 hr until the solution turned reddish-brown. The solution was slowly evaporated to dryness and the residue was repeatedly washed with diethyl ether. Then I followed the procedure in section (2). Yield: 75.6%. (Found: C, 50.49; H, 4.02; N, 11.11; Cl, 15.15%. Calcd for $[RuCl_2(C_{10}H_8N_2)_2]\cdot 0.5H_2O$: C, 48.72; H, 3.46; N, 11.36; Cl, 14.38%).

cis-$[RuCl_2(bipy)_2]$ was also obtained by heating $[RuCl(QH)(bipy)_2]$ and $[RuCl(QH_2)(bipy)_2]Cl$ in methanol containing hydrochloric acid. Then we followed the procedure in section (2). The product which was synthesized from $[RuCl(QH)(bipy)_2]$ was further recrystallized from chloroform according to the method reported by Liu *et al.*[6]

(6) Oxalatobis(2,2'-bipyridine)ruthenium(II), $[Ru(ox)(bipy)_2]\cdot 4H_2O$: To a solution of 0.5 g of $[Ru(OH)_2(bipy)_2]\cdot 1.5H_2O$ in 75 ml of methanol, 0.5 g of oxalic acid was added. The reaction mixture was refluxed with occasional shaking on a water bath for about 2 hr. The solution was then slowly evaporated to dryness and the residue was repeatedly washed with diethyl ether. The crystals were recrystallized from methanol and dried *in vacuo*. Yield: 86.7%. (Found: Ru, 18.26; C, 46.01; H, 3.89; N, 8.96%. Calcd for $[Ru(C_2O_4)(C_{10}H_8N_2)_2]\cdot 4H_2O$: Ru, 17.62; C, 46.07; H, 4.12; N, 9.76%).

(7) Trihydroxoaquo(1,10-phenanthroline)ruthenium(III), $[Ru(OH)_3(H_2O)phen]$: To a solution of 1 g of $[RuO_3phen]_2O$ or $[Ru(OH)_3phen]_2O$ in 150 ml of 0.1 M hydrochloric acid, 2 g of hydroquinone was added. Then we followed the procedure described in section (1). Yield: 79.3% and 83.5%, on the basis of $[RuO_3phen]_2O$ and $[Ru(OH)_3phen]_2O$, respectively. The complex was insoluble in carbon tetrachloride, benzene, chloroform, diethyl ether, ethyl acetate and dioxane, but soluble in methanol, acetone, DMSO, and DMF, and slightly soluble in water.

Found: Ru, 28.36; C, 40.47; H, 3.42; N, 8.07%; mol wt, 350. Calcd for $[Ru(OH)_3(H_2O)(C_{12}H_8N_2)]$: Ru, 28.94; C, 41.41; H, 3.71; N, 8.00%; mol wt, 350.

Measurements. Ruthenium in these complexes was determined spectrophotometrically by measuring the absorbance at 465 nm after thermal decomposition of the complexes at 350 °C followed by alkali fusion.[7] Chlorine was determined by use of micro-determing apparatus for halogens. The molecular weights of $[RuCl_2(MeOH)(QH_2)bipy]$ (complex I and II) and $[RuCl(QH)(bipy)_2]$, $[RuCl(QH_2)(bipy)_2]Cl$, $[Ru(OH)_3(H_2O)phen]$ were measured in DMSO at 40 °C and in CH_3OH at 45 °C, respectively, with a Shibayama Model S-601 Vapor Pressure Osmometer. NMR spectra could not be measured owing to the poor solubilities of the complexes I and II in DMSO-d_6 and CD_3OD. Methanol in the complexes was determined by measuring the β-activity of $[RuCl_2(^{14}CH_3OH)(QH_2)bipy]$ which was prepared using $^{14}CH_3OH$ (supplied by Daiichi Pure Chemical) with a liquid scintilator. Hydroquinone in the complexes was detected with a Shimadzu LKB-9000 GC-Mass spectrometor, but the amount could not be measured. The infrared absorption spectra were measured in KBr disks on a JASCO Model IR-S infrared spectrophotometer. In order to confirm the presence of coordinated water the complex was deuterated by standing at room temperature for two days in monodeuteriomethanol. Far infrared absorption spectra of the geometrical isomers (complex I and II) could not be obtained, because the two complexes did not mix well with Nujol. Visible and ultraviolet absorption spectra were measured with a Beckmann Model DU spectrophotometer. The magnetic susceptibility was measured by the Faraday method[8] at 25 °C with a Cahn R. G. electrobalance. Polarographic measurements were carried out at 25 °C with a Yanagimoto automatic recording polarograph (Type PA 101). A conventional H-type electrolytic cell was used with a saturated mercury(II) sulfate reference electrode, and an agar plug saturated with potassium sulfate was used for the junction. Lithium perchlorate was used as the supporting electrolyte. The measurements were performed in methanol as described previously.[4] The molar conductivity was measured at 25 °C with a Yanagimoto Model MY-7 conductivity outfit.

Results and Discussion

The ruthenium(II) and Ru(III) compounds obtained and the preparative pathways are summarized in Fig. 1. Two kinds of complex, I and II, of the same composition were formed by the reaction of $[RuO_4bipy]$ and $[RuO_2(OH)_2bipy]$, respectively, with hydroquinone in methanol. The compounds $[RuCl(QH)(bipy)_2]$ and $[RuCl(QH_2)(bipy)_2]Cl$ were derived

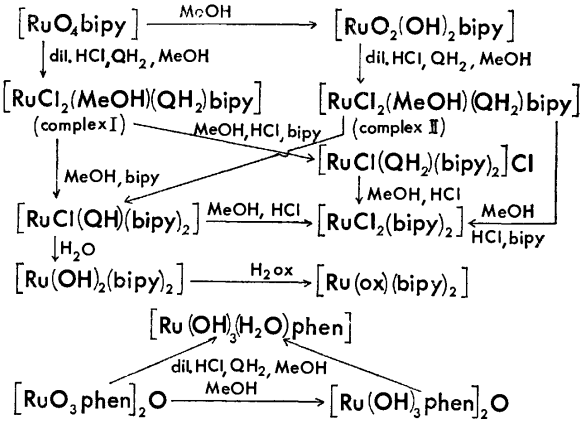

Fig. 1. Reduction and substitution reactions of [RuO_4-bipy] and [RuO_3phen]$_2$O.

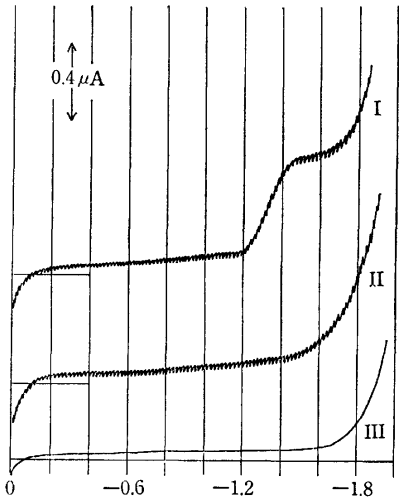

E, V *vs.* Hg, Hg_2SO_4(satd.) elec.

Fig. 2. Polarograms of the complexes.
I: 5×10^{-4} mol/l [$Ru(OH)_3(H_2O)$phen], II: 5×10^{-4} mol/l [$RuCl_2(MeOH)(QH_2)$bipy](complex I), III: 0.5 mol/l $LiClO_4$ in CH_3OH.

from the complex I and II, and the complex I, respectively. [$RuCl_2$(bipy)$_2$] could not be directly derived from complex I without passing [RuCl(QH)-(bipy)$_2$] or [RuCl(QH_2)(bipy)$_2$]Cl. This indicates that the methanol and hydroquinone ligands of the complex I are coordinated at the *trans* positions, assuming that the positions of the other ligands were not changed by the ligand substitution reactions. On the other hand, [$RuCl_2$(bipy)$_2$] was derived directly from complex II by a ligand substitution reaction. This indicates that the methanol and hydroquinone ligands of the complex II are coordinated at the *cis* positions. It was confirmed that three complexes with the same compostion, [$RuCl_2$(bipy)$_2$], which were derived from [$RuCl_2$(MeOH)(QH_2)bipy] (complex II), [RuCl(QH)(bipy)$_2$] and [RuCl(QH_2)(bipy)$_2$]Cl, all had *cis* configurations by comparing their spectra with the spectrum of *cis*-[$RuCl_2$(bipy)$_2$] which was reported by Bryant *et al.*[9] and Fergusson and Harris.[10] Since *cis*-[$RuCl_2$(bipy)$_2$] could be directly derived from the monochlororuthenium(II) complexes, [RuCl(QH)-(bipy)$_2$] and [RuCl(QH_2)(bipy)$_2$]Cl, the two complexes were both *cis* configurations. This difference in reactivity of the geometrical isomers indicates that complex I was *cis-trans*- and complex II was *cis-cis*-[$RuCl_2$(MeOH)(QH_2)bipy].

It was confirmed by elemental analyses by comparison of spectra that the same compound, [$Ru(OH)_3(H_2O)$-phen], was formed by the reaction of [RuO_3phen]$_2$O and [$Ru(OH)_3$phen]$_2$O.

Polarograms of [$RuCl_2$(MeOH)(QH_2)bipy] (complex I) and [$Ru(OH)_3(H_2O)$phen] are shown in Fig. 2. In the case of [$RuCl_2$(MeOH)(QH_2)bipy], no reduction wave was observed in 0.5 mol/l $LiClO_4$ methanol solution. The complex, [$Ru(OH)_3(H_2O)$phen], was reduced polarographically in one step. The half-wave potential of the reduction wave of [$Ru(OH)_3(H_2O)$-phen] was −1.33 V *vs.* Hg, Hg_2SO_4 (satd.) elec. in 0.5 mol/l $LiClO_4$ methanol solution. The height of the reduction wave corresponded to a gain of one electron, indicating a reduction from Ru(III) to Ru(II). It has been reported by Niedrach and Tevebaugh[11] that ruthenium(IV) undergoes a stepwise reduction through Ru(III) to Ru(II) in perchloric acid solution. It was therefore concluded that the oxidation number of ruthenium in [$Ru(OH)_3(H_2O)$phen] was 3. Since no reduction wave was obtained under the same experimental conditions as that of [$Ru(OH)_3(H_2O)$-phen], the oxidation number of ruthenium in [$RuCl_2$(MeOH)(QH_2)bipy] must be 2, indicating that

tetraoxo(2,2′-bipyridine)ruthenium(VIII) was reduced to Ru(II) complex in hydroquinone in hydrochloric acid solution.

Infrared Spectra. The characteristic infrared absorption bands of the present Ru(II) complexes with hydroquinone and 2,2′-bipyridine are shown in Table 1 together with those of free QH_2 and bipy ligands. In the two geometrical isomers of $[RuCl_2(MeOH)(QH_2)bipy]$, ν(O–H), ν(C–H), ν(C–O) and δ(C–H) vibrations of coordinated hydroquinone closely resembled those of the free ligand, and the bands due to the benzoquinone were not observed. This shows that the hydroquinone which was added in excess to the hydrochloric acid solution of $[RuO_4bipy]$ or $[RuO_2(OH)_2bipy]$ as a reducing agent was coordinated to the metal atom, and that benzoquinone which was formed by oxidation of hydroquinone with $[RuO_4bipy]$ or $[RuO_2(OH)_2bipy]$ was not coordinated. In the present complexes, $[RuCl_2(MeOH)(QH_2)bipy]$ (complexes I and II), $[RuCl(QH)(bipy)_2]$ and $[RuCl(QH_2)(bipy)_2]Cl$, characteristic absorption bands of the coordinated hydroquinone were clearly observed in the regions from 837 to 830 and from 1880 to 1868 cm^{-1}, probably due to the C–H bending vibrations and their overtones. These were all shifted to higher frequency by coordination. The absorption bands observed in the regions from 3400 to 3340 and from 1273 to 1197 cm^{-1} were assigned to the phenolic O–H and C–O stretching vibrations, respectively.[12,13]

In five present ruthenium-2,2′-bipyridine complexes, characteristic absorption bands of coordinated 2,2′-bipyridine were observed in the regions from 1605 to 1602, from 1590 to 1580 and from 737 to 730, probably due to the C=N, C=C stretching and C–H bending vibrations, respectively. The ν(C=N) and ν(C=C) vibrations were shifted to higher frequency on coordination, indicating that the bond orders of the carbon-nitrogen and carbon-carbon links were increased.[14,15]

The absorption band at 3420 cm^{-1} of $[Ru(OH)_3(H_2O)phen]$ was assigned to the coordinated OH and H_2O stretching vibrations, and the absorption band at 1635 cm^{-1} was assigned to the H_2O bending vibration. These two bands were shifted to 2460 and 1200 cm^{-1} by deuteration.

Electronic Absorption Spectra. The visible and ultraviolet absorption spectra of $[RuCl_2(MeOH)(QH_2)bipy]$, $[RuCl(QH)(bipy)_2]$, $[Ru(OH)_2(bipy)_2]$, $[RuCl(QH_2)(bipy)_2]Cl$ and $[Ru(OH)_3(H_2O)phen]$ were measured in methanol, and are shown in Figs. 3, 4 and 5. The absorption spectra of the complexes are summarized in Table 2.

The spectrum of complex II (Fig. 3, curve II) resembles that of complex I, but the CT bands of complex II are stronger than those of the complex I, while the order of the π–π^* bands is reversed. The spectrum of $[RuCl(QH_2)(bipy)_2]Cl$ resembles that of $[RuCl(QH)(bipy)_2]$ except in the vicinity of 520 nm.

The spectrum of $[Ru(OH)_3(H_2O)phen]$ resembles that of $[Ru(phen)_3]^{3+}$[16], but $[Ru(OH)_3(H_2O)phen]$ had the lower intensity in the vicinity of 450 nm than that $[Ru(phen)_3]^{3+}$. Fergusson and his co-workers[10,17] of attributed the absorption bands observed in the visible region for tervalent ruthenium-2,2′-bipyridine complexes to the charge-transfer transitions from ligand to metal.

Conductivity. The molar conductivity of

chloro(hydroquinone)bis(2,2′-bipyridine)ruthenium(II) chloride in methanol solution was 111.4 $ohm^{-1}\cdot cm^2\cdot mol^{-1}$ at 25 °C, showing that the complex was a 1 : 1 type electrolyte.

Magnetic Properties. The observed diamagnetism of the geometrical isomers of [$RuCl_2(MeOH)(QH_2)bipy$] indicated that the ruthenium atom has a spin-paired d^6 configuration.

[$Ru(OH)_3(H_2O)phen$] had a magnetic moment of 1.81 B.M., indicating that the ruthenium atom has a spin-paired d^5 configuration. The stereochemical configuration of [$Ru(OH)_3(H_2O)phen$] is not clear.

The structures thus proposed for the geometrical isomers of [$RuCl_2(MeOH)(QH_2)bipy$] are shown in Fig. 6.

Magnetic Circular Dichroism of $[Cr(CN)_5NO]^{3-}$

Hiroshi KOBAYASHI, Ken EGUCHI, and Youkoh KAIZU

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received July 27, 1974)

Magnetic circular dichroism (MCD) was observed in the region of the 22000 cm^{-1} band of $[Cr(CN)_5NO]^{3-}$. The absorption band was assigned to a charge-transfer transition linearly polarized in the direction of Cr–NO, while the MCD observed in the same region was assigned to B term extrema of the (d, d*) transitions hidden beneath the charge-transfer band. The charge-transfer transition gives rise to an absorption peak but no MCD, since the transition is polarized in the direction of the orbital angular momentum, even in the case where a degenerate excited state is involved.

The electronic structure of $[M(CN)_5NO]^{n-}$ complexes has been established on the basis of magnetic, spectroscopic and theoretical studies.[1-15] The weight of evidence shows a strong M–NO π-bonding.[16-21] However the important role of the π^*_{NO} orbital in the low-energy excitations had not been considered until Manoharan and Gray interpreted the electronic excitations of $[M(CN)_5NO]^{n-}$ in terms of self-consistent charge and configuration-molecular orbital (SCCC MO) calculations.[20]

According to the most recent suggestion,[22] the order of the orbitals responsible for the outer electronic configuration is: $1e < xy < 2e < x^2-y^2 < z^2$, where xy, x^2-y^2, and z^2 denote the molecular orbitals predominantly distributed on the metal d_{xy}, $d_{x^2-y^2}$, and d_{z^2} orbitals, and 1e and 2e are the highest occupied and the lowest vacant degenerate orbital pairs, which are mainly composed of metal d_{zx} and d_{yz} orbitals and the lowest nitric oxide antibonding π orbitals $\pi_x^*{}_{NO}$ and $\pi_y^*{}_{NO}$.

The ESR data for $[CrL_5NO]$ (L: CN^-, NH_3, OH_2) have been interpreted for the ground electronic configuration $(1e)^4(xy)$.[20,23,24] The unpaired electron relevant to an almost isotropic ESR signal is localized predominantly in the d_{xy} orbital. A characteristic absorption band observed around 22000 cm^{-1} is fairly constant both in position and intensity for L=CN^-, NH_3, H_2O and C_2H_5OH in $[CrL_5NO]$,[25] and has been assigned to the transition $^2B_2 \rightarrow {}^2B_2$ $((1e)^4(xy) \rightarrow (1e)^3(2e)(xy))$ which is linearly polarized in the direction of the Cr–NO bond.[20] In the present work, however, magnetic circular dichroism (MCD) was observed in the region of the 22000 cm^{-1} band of $[CrL_5NO]$.

Experimental

$K_3[Cr(CN)_5NO]\cdot H_2O$ was prepared by the method described in the literature.[26] The sample was recrystallized twice from water. The bright green crystals thus obtained were identified by elemental analysis.

Found: C, 17.2; H, 0.4; N, 24.5; Cr, 15.0%. Calcd for $K_3[Cr(CN)_5NO]\cdot H_2O$: C, 16.7; H, 0.6; N, 24.2; Cr, 15.0%.

$[Cr(NH_3)_5NO]Cl_2$ was prepared and purified by the method of Mori, Ueshiba and Kawaguchi.[27] The brown crystals thus obtained were identified by analysis for chromium.

Found: Cr, 22.1%. Calcd for $[Cr(NH_3)_5NO]Cl_2$: Cr, 21.8%.

A perchloric acid solution of $[Cr(OH_2)_5NO](ClO_4)_2$ was prepared by the method described in the literature.[25]

Our MCD measurement technique has been described elsewhere,[28] All the measurements were carried out on a JASCO Model ORD/UV-5 instrument with its electromagnet. The magnetic field was set at 10000 G The electronic absorption spectra of solutions and films were taken on a Shimadzu automatic recording spectrophotometer Model MPS-50. The instruments were furnished with a Dewar for low-temperature measurement. The polarizing microscope absorption spectrum of a single crystal was taken by courtesy of Professors Kondo and Nakahara, St. Paul's University, on a Hitachi automatic recording spectrophotometer Model EPS-3T equipped with a special microscope. A single crystal suitable for the measurement was selected on a polarizing microscope from crystals deposited on a clean glass plate by the spontaneous evaporation of an aqueous solution of $K_3[Cr(CN)_5NO]$. The extinction axis of the crystal was coincident with the direction of growth of the crystal needles (c axis).

The magnitude of MCD is reported here in terms of molar circular dichroism per unit external magnetic field, $(\varepsilon_l - \varepsilon_r)/H_z$, where ε_l and ε_r represent the molar absorption coefficients for left and right circularly polarized light, respectively, and H_z is the strength of external magnetic field.

The magnitude of molar circular dichroism per unit external magnetic field observed at a transition a→j is given by

$$(\varepsilon_l - \varepsilon_r)/H_z = -\left(\frac{16\pi}{3hc}\right)\frac{N}{10^3 \ln 10}\{f_1 A + f_2(B + C/kT)\},$$

where the function f_1 is a shape function of the sigmoidal dispersion at the position of the absorption maximum ν_{Ja}, the function f_2 is a shape function as approximated by a Gaussian with an extremum at the absorption maximum.[29-21]

The MCD and absorption spectra were measured with $[Cr(OH_2)_5NO]^{2+}$ in concd $HClO_4$ solution, $[Cr(NH_3)_5NO]^{2+}$ in 0.1 M HCl solution, and $[Cr(CN)_5NO]^{3-}$ in aqueous solution, in 2 : 1 mixture of propyleneglycol and water, and in a polyvinyl alcohol (PVA) film. The 2 : 1 mixture of propyleneglycol and water gave a transparent rigid glass dispersing an electrolyte such as $K_3[Cr(CN)_5NO]$ down to dry ice-methanol temperature (195 K). However the transparence of the rigid glass in the near-ultraviolet region became poor at dry ice-methanol temperature. The MCD spectrum of $[Cr(CN)_5NO]^{3-}$ in a PVA film was obtained at various temperatures down to liquid nitrogen temperature. A PVA film was made by spontaneous evaporation of an aqueous solution of PVA on a glass plate and then the film was heated up to 90 °C for 1 hr in order to increase its transparence. A transparent PVA film thus obtained was swelled a little in water and then dyed in an aqueous solution of $K_3[Cr(CN)_5NO]$. The dyed film was dried at room temperature for 24 hr over phosphorous pentoxide under reduced pressure. The spectrum of this yellow ochreous transparent film was in good agreement with the solution spectrum.

Results and Discussion

The visible and near-ultraviolet MCD and absorption spectra of $[Cr(CN)_5NO]^{3-}$ in aqueous solution and in a 2 : 1 mixture of propyleneglycol and water are shown in Fig. 1. The MCD and absorption spectra around 22000 cm^{-1} of $[Cr(CN)_5NO]^{3-}$ in PVA film were also measured at various temperatures down to liquid nitrogen temperature. The result is shown in Fig. 2.

An apparent dispersion of MCD was observed at 23700 cm^{-1}. An MCD maximum corresponds to the absorption peak at 22100 cm^{-1}, whereas no absorption maximum was observed corresponding to the MCD minimum at 25400 cm^{-1}. $[Cr(NH_3)_5NO]^{2+}$ and $[Cr(OH_2)_5NO]^{2+}$ also show a similar absorption band

around 22000 cm^{-1}, and their MCD extrema are also not coincident with their absorption maxima. The substitution of L in $[CrL_5NO]$ gives rise to a small but detectable shift of the 22000 cm^{-1} absorption maximum in the opposite direction to the shift of the MCD maximum. The MCD and absorption spectra of $[Cr(NH_3)_5NO]^{2+}$ in 0.1 M HCl solution and of $[Cr(OH_2)_5NO]^{2+}$ in concd $HClO_4$ solution are shown in Figs. 3 and 4 although the spectra of the latter are rather qualitative. The whole profile of the MCD spectra of $[Cr(NH_3)_5NO]^{2+}$ and $[Cr(OH_2)_5NO]^{2+}$ is similar to that of $[Cr(CN)_5NO]^{3-}$. It should be noted that the lowest energy MCD peak and its corresponding absorption maximum (at about 22000 cm^{-1}) show a shift opposite to the spectrochemical series upon substitution of L in $[CrL_5NO]$ whereas the other MCD extrema show a shift coincident with the spectrochem-

TABLE 1. THE MAGNETIC CIRCULAR DICHROISM EXTREMA AND ABSORPTION MAXIMA OF THE CHROMIUM NITROSYL COMPLEXES

ical series. The observed MCD extrema are summarized in Table 1. The 22000 cm^{-1} band of $[Cr(CN)_5NO]^{3-}$ in PVA does not show ripple structure even at 77 K, although the single crystal absorption spectrum at room temperature shows a trace of ripple structure. The corresponding band of $[Cr(NH_3)_5NO]^{2+}$, however, displays a remarkable ripple structure in 0.1 M HCl solution even at room temperature. On the other hand, the MCD spectrum of $[Cr(NH_3)_5NO]^{2+}$ around 22000 cm^{-1} does not show any indication of vibrational fine structure. The differences observed in the behavior of the MCD and absorption spectra around 22000 cm^{-1} indicate that MCD measurements can detect a ligand-field (d, d*) transition hidden in a characteristic absorption band arising from the charge-transfer transition 1e→2e in Cr–NO. This charge-transfer band is rather independent of the other ligands present in the complexes.

Since the molecular orbital pairs, both 1e and 2e, have a z component of orbital angular momentum $\Lambda_z=\pm1$, the charge-transfer excitation 1e→2e gives rise to $^2\Delta$ ($\Lambda_z=\pm2$) and $^2\Sigma$ ($\Lambda_z=0$) states. A transition from the ground $^2\Sigma$ state to the excited $^2\Sigma$ state is allowed, whereas the one to the excited $^2\Delta$ state is forbidden. The molar absorption coefficient of the band around 22000 cm^{-1} is about 130 in $[Cr(CN)_5NO]^{3-}$. If this band arises from a charge-transfer transition in Cr–NO, it should be assigned to a forbidden transition, $^2\Sigma\rightarrow{}^2\Delta$. The forbidden transition can borrow spectral intensity from the allowed transition $^2\Sigma\rightarrow{}^2\Sigma$ by a degenerate vibration which removes the degeneracy of the molecular orbital pairs and gives rise to a mixing between allowed and forbidden transitions. The participating vibration is either a degenerate bending vibration of the Cr–NO skeleton or, less possibly, a degenerate stretching vibration of the Cr–$(CN)_4$ skeleton in a plane perpendicular to the Cr–NO axis. In fact, a vibrational progression has been found on the low-energy side of the 22000 cm^{-1} band of $[(n\text{-}C_4H_9)_4N]_3[Cr(CN)_5NO]$ in EPA solution at 100 K.[20] The band around 22000 cm^{-1} in $[Cr(NH_3)_5NO]^{2+}$ is also accompanied by ripples spaced at about 480—490 cm^{-1} intervals. Bernal assumed a contribution of the Cr–$(NH_3)_4$ stretching vibration in a place perpendicular to the Cr–NO bond.[20] Kobayashi, Tsujikawa, Mori, and Yamamoto, suggested participation of the degenerate bending vibration of the Cr–NO skeleton which is observed at 531—535 cm^{-1} in the vibration spectrum.[24] However they assigned the 22000 cm^{-1} band to the ligand-field transition $^2B_2(xy)\rightarrow{}^2B_1(x^2-y^2)$ which should be coupled with a vibration of E symmetry in order to be allowed. Since no similar ripple structure had been found in the (d, d*) transitions of other chromium ammine complexes, a possibility of participation of the degenerate Cr–$(NH_3)_4$ stretching mode was eliminated. If the 22000 cm^{-1} band arises from a forbidden charge-transfer transition $^2\Sigma\rightarrow{}^2\Delta$ in Cr–NO, the transition can borrow intensity from the allowed $^2\Sigma\rightarrow{}^2\Sigma$ transition, coupled either with a degenerate bending vibration of the Cr–NO skeleton or much less possibly, with a degenerate stretching vibration in the Cr–$(NH_3)_4$ skeleton. In the case of $[Cr(NH_3)_5NO]^{2+}$ the bond between chromium and coordinated NH_3 has the nature of a σ coordination bond, whereas in the case of $[Cr(CN)_5NO]^{3-}$ the back-bonding character of the chromium–CN^- bond is appreciable. Thus, in $[Cr(CN)_5NO]^{3-}$, a small participation of the stretching vibration cannot always be eliminated.

The fact that the position of the 22000 cm^{-1} band is rather independent of other ligands present in the complex and the band has a ripple structure indicates a transition mainly localized in the Cr–NO bond. The charge-transfer excitations in Cr–NO, both allowed and forbidden, are polarized in the direction of the Cr–NO bond and do not have any appreciable transition dipole in the plane perpendicular to the bond axis. It was experimentally proved that a similar forbidden charge-transfer transition in $Na_2[Fe(CN)_5NO]$ is polarized in the direction of the Fe–NO bond.[20] Since a linear oscillator collinear with the orbital angular momentum shows no Zeeman splitting, a charge-transfer transition linearly polarized in the direction of the Cr–NO bond does not display any MCD.

A schematic energy diagram of the orbitals responsible for the outer electronic configuration is shown in Fig. 5. The order of orbitals $a_1(z^2)$ and $b_1(x^2-y^2)$ depends upon σ donations from coordinated NO^+ and CN^-, NH_3 or OH_2. The bonding molecular orbital pair 1e is appreciably lower than orbital $b_2(xy)$ for a π-bonding interaction between metal $d\pi$ orbitals

a) For the degenarate states, only one component of the wave functions is given.

zx and yz and NO antibonding orbitals π^*_{NO}. As ESR studies show, the ground state should be a ^2B state with electronic configuration $(1e)^4(b_2)$. The energy of the lowest one-electron excited doublets is obtained in terms of orbital energy parameters Δ, ε_1, and ε_2 and Racah's electrostatic parameter B as in Table 2. An empirical relationship $C=4.0B$ was assumed and the value of B was reduced for the delocalization in molecular orbital 1e following Koide and Pryce:[32] $B(e,e)=k^2B$, $B(e,b_2)=kB$, and $B(b_2,b_1)=B$.

The empirical values of Δ are 13900 cm^{-1} in $[Cr(OH_2)_6]^{2+}$ and 17400 cm^{-1} in $[Cr(OH_2)_6]^{3+}$.[33] Since the formal oxidation state of chromium in $[Cr(OH_2)_5NO]^{2+}$ is 1+, the value of Δ should be less than 13900 cm^{-1}. Furthermore an almost isotropic ESR signal indicates a large energy gap between 1e and b_2. The energies of ligand-field excited doublets were calculated for a variety of parameters Δ, ε_1, ε_2 in units of B. The lowest observed ligand-field bands in $[Cr(OH_2)_5NO]^{2+}$ and $[Cr(NH_3)_5NO]^{2+}$ are assigned to transitions to excited states $^2A_1$ ($b_2\rightarrow a_1$) and 1^2E ($1e\rightarrow b_2$). The next four ligand-field transitions above 20000 cm^{-1} are assigned to four ^2E states arising from excitations $1e\rightarrow b_1$ and $1e\rightarrow a_1$. In the case of $[Cr(CN)_5NO]^{3-}$, an increase in Δ gives rise to a blue-shift of the transitions to $^2B_1(b_2\rightarrow b_1)$ and to $^2A_1(b_2\rightarrow a_1)$. The back-bonding interactions of coordinated CN^- push down orbital b_2. This reduces the value of ε_2 and gives rise to a red-shift of the transition to $1^2E(1e\rightarrow b_2)$. As shown in Figs. 3 and 4, a red absorption band and its closely corresponding MCD maximum are observed in $[Cr(NH_3)_5NO]^{2+}$ and $[Cr(OH_2)_5NO]^{2+}$. Because insufficient sensitivity of our instrument, the MCD maximum of $[Cr(CN)_5NO]^{3-}$ in near-infrared region could not be detected. An MCD maximum, however, is expected at 13700 cm^{-1} corresponding to the absorption peak (Fig. 1). The lowest wave number band is red-shifted in the order

$$[Cr(CN)_5NO]^{3-} > [Cr(NH_3)_5NO]^{2+} > [Cr(OH_2)_5NO]^{2+}.$$
(13700 cm^{-1}) (17100 cm^{-1}) (17400 cm^{-1})

The absorption intensity of the lowest wave number band of $[Cr(NH_3)_5NO]X_2$ depends upon the outer sphere anions in the complex salts: the color of the complex salts varies from brown to green. Thus Kobayashi, Tsujikawa, Mori and Yamamoto have assigned the lowest wave number band to a charge-transfer excitation in the Cr–NO bond.[24] The observations in the present work, however, indicate that the red absorption band should be assigned to a (d, d*) transition rather than a charge-transfer transition. The red absorption band, however, should have two components corresponding to $^2B_1(b_2\rightarrow b_1)$ and $1^2E(1e\rightarrow b_2)$. In fact, the single crystal absorption spectrum of $K_3[Cr(CN)_5NO]\cdot H_2O$ exhibits two different peaks in the red band for polarized light $\parallel$ and $\perp$ to the c axis as shown in Fig. 6. The spectra polarized $\parallel$ and $\perp$ to the optically equivalent Cr–NO axis could not be obtained because of the crystal disorder, which had been revealed by X-ray crystallography.[34] Since the 22000 cm^{-1} absorption is linearly polarized along the Cr–NO axis, the fact that the absorption for the light polarized $\parallel$ to the c axis is a little more intense than that for the light polarized $\perp$ to the c axis indicates that a slightly higher number of complexes have their Cr–NO bonds $\parallel$ to the c axis. Thus the lower wavenumber component of the red absorption band (680 nm, 14700 cm^{-1}) is polarized more $\parallel$ to the Cr–NO axis and the higher wave number component (670 nm, 14900 cm^{-1}) is polarized more $\perp$ to the Cr–NO axis.

The excited states n^2E arising from the excitations $1e\rightarrow b_1$ and $1e\rightarrow a_1$ in $[Cr(CN)_5NO]^{3-}$ correspond well to

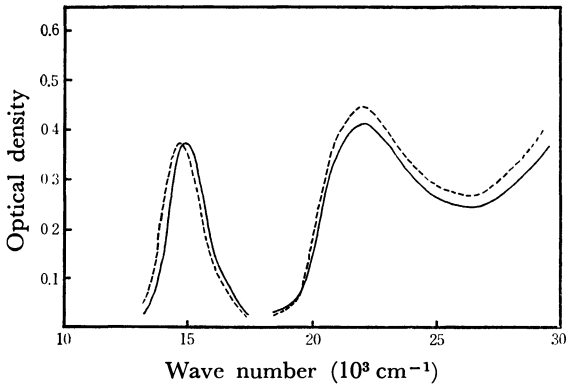

Fig. 6. The polarized single crystal absorption spectrum of $K_3[Cr(CN)_5NO]\cdot H_2O$.
——: polarized $\perp$ to c axis
----: polarized $\parallel$ to c axis

those in $[Cr(NH_3)_5NO]^{2+}$ and $[Cr(H_2O)_5NO]^{2+}$. The calculated energy of the lowest excited doublets is shown in Fig. 7. For a reasonable choice of parameters, theory can reproduce the ligand-field (d, d*) excited states which were detected by MCD spectra as in Fig. 8. The same parameters also predict that the ground state of $[CrL_5NO]$ is ^2B rather than ^6A, and that 1^4E arising from configurations $(1e)^3b_2b_1$ in $[Cr(CN)_5NO]^{3-}$ is higher than 1^2E, which arises from configuration $(1e)^3b_2^2$, whereas 1^4E is lower than 1^2E in $Cr(NH_3)_5NO]^{2+}$ and $[Cr(OH_2)_5NO]^{2+}$. In fact, the anisotropy of the g value for $[Cr(CN)_5NO]^{3-}$ is different from that of $[Cr(NH_3)_5NO]^{2+}$ and $[Cr(OH_2)_5NO]^{2+}$, *i.e.* the sign of $\Delta g_\perp$ ($\equiv g_\perp - 2.0023$) is reversed. The g values observed and calculated for $[CrL_5NO]$ are summarized in Table 3. The g values are given within

the first-order term of spin-orbit coupling parameter λ as follows:

$$g_\parallel = 2.0023 - 8\lambda/E(^2B_1),$$

$$g_\perp = 2.0023 + 2\lambda/E(1^2E) - \sum_m 2\lambda/E(m^4E_{1/2})\{(1/3)(c_1^m)^2+(c_2^m)^2\} + \sum_n 2\lambda/E(n^2E)\{-(3/2)(c_1^n)^2+(1/3)(c_2^n)^2 - (1/2)(c_3^n)^2 + (c_4^n)^2\},$$

where $E(\Gamma)$ denotes the energy of excitation to state Γ, c_i^m and c_j^n denote the coefficients in the state wave functions

$$\phi(m^4E_{1/2}) = \sum_i c_i^m \phi_i',$$

$$\phi(n^2E) = \sum_j c_j^n \phi_j,$$

$$\phi_1' = \{|\bar{\varepsilon}\zeta\xi\eta\bar{\eta}| + |\varepsilon\bar{\zeta}\xi\eta\bar{\eta}| + |\varepsilon\zeta\bar{\xi}\eta\bar{\eta}|\}/\sqrt{3},$$

$$\phi_2' = \{|\bar{\theta}\zeta\xi\eta\bar{\eta}| + |\theta\bar{\zeta}\xi\eta\bar{\eta}| + |\theta\zeta\bar{\xi}\eta\bar{\eta}|\}/\sqrt{3},$$

$$\phi_1 = \{|\theta\bar{\zeta}\xi\eta\bar{\eta}| - |\theta\zeta\bar{\xi}\eta\bar{\eta}|\}/\sqrt{2},$$

$$\phi_2 = \{2|\bar{\varepsilon}\zeta\xi\eta\bar{\eta}| - \varepsilon\bar{\zeta}\xi\eta\bar{\eta}| - |\varepsilon\zeta\bar{\xi}\eta\bar{\eta}|\}/\sqrt{6}\ ,$$

$$\phi_3 = \{|\varepsilon\bar{\zeta}\xi\eta\bar{\eta}| - |\varepsilon\zeta\bar{\xi}\eta\bar{\eta}|\}/\sqrt{2}\ ,$$

$$\phi_4 = \{2|\bar{\theta}\zeta\xi\eta\bar{\eta}| - |\theta\bar{\zeta}\xi\eta\bar{\eta}| - |\theta\zeta\bar{\xi}\eta\bar{\eta}|\}/\sqrt{6}\ ,$$

and ε, θ, ζ, ξ, and η denote x^2-y^2, z^2, xy, yz, and zx orbitals, respectively. This indicates that $\Delta g_\perp > 0$ when ^1E is higher than $^1A_2$ as in $[Cr(CN)_5NO]^{2-}$, whereas $\Delta g_\perp < 0$ when it is lower as in $[Cr(NH_3)_5NO]^{2+}$ and $[Cr(OH_2)_5NO]^{2+}$. The $g_\perp$ value was evaluated assuming $\lambda = 100\ cm^{-1}$ which correctly predicts the value of $g_\parallel$. The delocalization in molecular orbitals reduces the spin-orbit coupling effect in Cr and thus the value of λ in the complex should be smaller than that observed in the atomic spectrum. The calculated values are in good agreement with the observed values. This confirms the assignment of MCD extrema to the ligand-field excitations.

Plots of the ratio of $\int\left(\frac{\varepsilon_l-\varepsilon_r}{H_z}\right)\Big/\bar{\nu}\ d\bar{\nu}$ to $\int \varepsilon/\bar{\nu}\ d\bar{\nu}$ against $1/kT$ give a straight line. If an MCD maximum is assumed at 22000 cm^{-1}, apparent values of B/D and C/D in units of transition dipole strength D are obtained as $-0.11\times10^{-3}\beta/cm^{-1}$ and $-0.0059\,\beta$, respectively. Such a relatively temperature-independent MCD is seemingly consistent with the non-degenerate ground state $^2B_2$. These values, however, are less significant in this particular case, where the transition detected by MCD is not the transition detected by absorption in the same wave number region.

The authors would like to thank Dr. Hanako Kobayashi, Kyoto University, and Professor Masayasu Mori, Osaka City University, for more than useful comments. The authors wish to express their appreciation to Professors Yukio Kondo and Masayoshi Nakahara, St. Paul's University, for the measurements of polarizing microscope absorption spectrum. This work was supported by a grant from the Ministry of Education.

Metal Complexes of Amino Acids. VII.[1] The *trans*(*N*) and *cis*(*O*)*cis*(*N*) Isomers of the Type [Co(aa)$_2$phen]X and [Co(aa)$_2$dipy]X

Takaji YASUI

Faculty of Arts and Sciences, Kochi University, Asakura, Kochi 780

(Received September 9, 1974)

Fourteen complexes of the type [Co(aa)$_2$phen]X and [Co(aa)$_2$dipy]X (where aa is the anion of glycine, β-alanine, L-serine, or L-proline) were newly prepared. Two geometrical isomers (*trans*(*N*) and *cis*(*O*)*cis*(*N*)) for the glycinato and β-alaninato complexes, four geometrical and/or diastereomeric isomers ((+)$_D$- and (−)$_D$-*trans*(*N*) and -*cis*(*O*)*cis*(*N*)) for the L-serinato complexes, and two diastereomers ((+)$_D$- and (−)$_D$-*trans*(*N*)) for the L-prolinato complex were separated. These complexes were characterized by absorption, circular dichroism spectra, and ^{1}H and ^{13}C NMR spectra. The absolute configurations of the L-serinato and L-prolinato complexes were assigned as *Λ* and *Δ* for the (+)$_D$- and (−)$_D$-isomers, respectively.

In our previous study[2] one of the three possible geometrical isomers for the type [Co(aa)$_2$(diimine)]X (where aa is the anion of amino acid and diimine is 1,10-phenanthroline or dipyridyl) was separated. It was concluded that this isomer has the *trans*(*N*) (C_2 symmetry) structure with respect to the amino groups. Matsuoka and coworkers succeeded in separating the three geometrical isomers for [Co(gly)$_2$en]$^+$ and for [Co ox(gly)$_2$]$^-$ complex ions,[3] and the six geometrical and/or diastereomeric isomers for [Co ox(L-ser)$_2$]$^-$ complex ion[4] by a column chromatographic method. Analogous separations of the six geometrical and/or diastereomeric isomers for the [Co(L-aspH)$_2$en]$^+$ complex ion have been performed by Kojima and Shibata.[5]

In the present paper two geometrical isomers of the type [Co(aa)$_2$(diimine)]X which were newly separated are characterized on the basis of the absorption, ^{1}H and ^{13}C NMR, and circular dichroism (CD) spectra.

Experimental

Preparation and Separation of Four Isomers of the [Co(L-ser)$_2$phen]Br Complex. Four isomers were obtained by modifying the method reported in the previous paper.[2]

To an aqueous solution containing $CoCl_2 \cdot 6H_2O$ (4.8 g, 0.02 mol) and L-serine (4.2 g, 0.04 mol) in 50 ml of water was added PbO_2 (10 g, excess), and the mixture was stirred for about 15 min. To the mixture was added gradually 1,10-phenanthroline (3.9 g, 0.02 mol) with stirring, and the solution was heated at 65 °C for 15 min. The resulting purple solution was allowed to stand at room temperature overnight and filtered. The filtrate was diluted with 100 ml of water and poured into a column containing cation-exchange resin (Dowex 50W×8, 200—400 mesh, K-form, φ3.5 cm×60 cm). Purple and pink solutions (neutral complexes) were swept out with water in that order and then the purple solution of the bis(L-serinato)diaquo complex ions was swept out with a 0.025 M aqueous solution of KBr. The brownish-orange ((+)$_D$-*trans*(*N*)), the scarlet ((−)$_D$-*cis*(*O*)*cis*(*N*)), the brownish-orange ((−)$_D$-*trans*(*N*)), and the scarlet ((+)$_D$-*cis*(*O*)-*cis*(*N*)) bands were eluted with a 0.1—0.5 M aqueous solution of KBr in that order. Each eluate was concentrated at below 35 °C under reduced pressure, and a large amount of methanol was added to the concentrated solution. Each crude complex was recrystallized by dissolving it in a small amount of warm water, by adding methanol–acetone (1 : 2) mixture to the concentrated solution, and by keeping in a refrigerator overnight.

Four isomers ((+)$_D$- and (−)$_D$-*trans*(*N*) and -*cis*(*O*)*cis*(*N*)) of [Co(L-ser)$_2$dipy]Br and two geometrical isomers (*trans*(*N*) and *cis*(*O*)*cis*(*N*)) of [Co(gly)$_2$phen]Br, [Co(β-ala)$_2$phen]Br and [Co(gly)$_2$dipy]Br were obtained as described above for the [Co(L-ser)$_2$phen]Br. The *cis*(*O*)*cis*(*N*) isomers have lower solubility in water than the *trans*(*N*) isomers. Only two diastereomers ((+)$_D$- and (−)$_D$-*trans*(*N*)) were separated for the [Co(L-pro)$_2$phen]Br.

The elemental analyses for the newly prepared complexes are shown in Table 1.

Measurements. The absorption spectra were measured with a Hitachi Model EDS-3T spectrophotometer. The CD data were obtained by using a JASCO Model ORD/UV-5 spectrophotometer. The measurements of the ^{1}H and ^{13}C NMR spectra were made by a JEOL MH-100 spectrometer (with pulsed Fourier transform/proton noise decoupled mode for the ^{13}C NMR measurements) in D_2O solutions. DSS and cyclohexane were used as an internal standard for ^{1}H NMR and as an external standard for ^{13}C NMR, respectively. The chemical shifts of the carbon resonances are shown relative to TMS using the relation $\delta_{TMS} = \delta_{cyclohexane} - 27.5$.

Results and Discussion

For either [Co(L-aa)$_2$phen]X or [Co(L-aa)$_2$dipy]X, six geometrical and/or diastereomeric isomers (*Λ*- and *Δ*-*trans*(*O*) (C_2 symmetry), *Λ*- and *Δ*-*trans*(*N*) (C_2 symmetry), and *Λ*- and *Δ*-*cis*(*O*)*cis*(*N*) (C_1 symmetry)) are possible, as shown in Fig. 1. In our previous study[2] the *trans*(*N*) isomers for the [Co(aa)$_2$-(diimine)]X (where aa is the anion of glycine, L-alanine, L-hydroxyproline, or *allo*-L-hydroxyproline, and diimine is phen or dipy) complexes were separated and characterized. In this study the separations of the three geometrical isomers (six isomers for the L-amino acid) were tried repeatedly by the column chromatographic method, but unfortunately only two geometrical isomers were obtained. This result suggestes that the stereoselectivity of the two amino acidato

trans(*O*) (C_2) *trans*(*N*) (C_2) *cis*(*O*)*cis*(*N*) (C_1)

Fig. 1. Three possible isomers (all *Λ*) for the [Co(aa)$_2$(diimine)]$^+$ ion.

ligands for the complexes containing phen or dipy is different from that for the corresponding ethylenediamine and oxalato complexes.[3,4]

Absorption Spectra. The absorption curves of the two geometrical isomers of the $[Co(gly)_2phen]^+$ and $[Co(\beta\text{-ala})_2phen]^+$ ions are shown in Fig. 2. The new geometrical isomer (isomer eluted late) of the glycinato complex does not show any splitting in the first band as was also found[2] for the *trans(N)* isomer (complex eluted early). The *trans(O)* isomer is expected to show large splitting of the bands, as observed for other $trans(O)_2(N)_4$ type complexes.[3,5] The first band maximum ($\nu=19610\ cm^{-1}$, $\log\varepsilon=2.10$) of the new isomer has higher intensity and occurs at lower energy, as compared with that ($\nu=20660\ cm^{-1}$, $\log\varepsilon=2.02$) of the *trans(N)* isomer. The greater dipole strength and greater band width of the first band of the isomer eluted late are consistent with the lower symmetry (C_1) of the *cis(O)cis(N)* isomer in comparison to the *trans(N)* isomer. The sharpest bands are expected for the *trans(N)* isomer for which the effective field along each axial direction (amine *N*–amine *N* and two imine *N*–*O*) should be most nearly the same. For geometrical isomers one might expect a lower crystal filed strength, indicated by lower energy of the first band, and one might also expect a lower stability. In fact, the new isomer is easily decomposed in the aqueous solution on heating, as compared with the *trans(N)* isomer. Therefore, the geometrical structure of the new isomer is concluded to be *cis(O)cis(N)* (C_1 symmetry). This assignment agrees with the results of ^1H NMR (*vide infra*).

The geometrical structures of the isomers for the $[Co(\beta\text{-ala})_2phen]X$ (Fig. 2), $[Co(gly)_2dipy]X$ (not shown), $[Co(L\text{-ser})_2phen]X$ (Fig. 3), and $[Co(L\text{-ser})_2dipy]X$ (Fig. 4) are assigned by comparing their first bands with those of the *trans(N)* and *cis(O)cis(N)* isomers for the $[Co(gly)_2phen]X$ complex. The structural assignments of these complexes are indicated in Table 1. The absorption spectra of the diastereomeric L-prolinato complexes correspond to that of *trans(N)*-$[Co(gly)_2phen]X$ (Fig. 5).

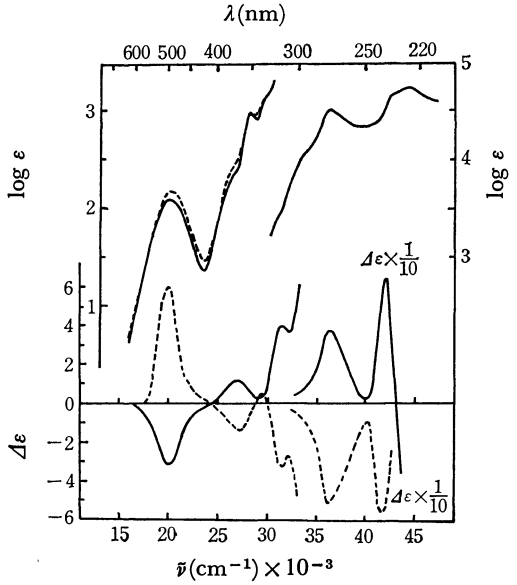

Fig. 5. Absorption and CD curves of (----) $(+)_D$- and (——) $(-)_D$-*trans*(*N*)-$[Co(L\text{-pro})_2phen]^+$ ions.

phen]$^+$ ions are quite similar to those of the corresponding $[Co(L\text{-ala})_2phen]^+$ ions reported in our previous paper.[2] The $(+)_D$- and $(-)_D$-*cis*(*O*)*cis*(*N*) isomers show also CD spectra of the same form as those of the corresponding *trans*(*N*) isomers, although the main CD peaks in the first band region shift to lower energy (Figs. 3 and 4). Therefore, the absolute configurations of these complexes can be assigned as *Λ* and *Δ* for the $(+)_D$- and $(-)_D$-*trans*(*N*) and -*cis*(*O*)*cis*(*N*) isomers, from the sign of the main CD band in the first band region.[6] The same comparisons can be made for the *trans*(*N*)- and *cis*(*O*)*cis*(*N*)-$[Co(L\text{-ser})_2dipy]^+$ ions (Fig. 4). The diastereomers of the *trans*(*N*)-$[Co(L\text{-pro})_2$-phen]$^+$ ion show also CD curves quite similar to those of the corresponding L-hydroxyprolinato complex previously reported.[2] The absolute configurations of these isomers can also be assigned as *Λ* and *Δ* to the $(+)_D$- and $(-)_D$-isomers, respectively. The same assignments of the absolute configuration can also be made from CD spectra in the region of the phen or bipy ligand π-π^* transition (ultraviolet).[2,7] In this case the *Λ*-configuration is assigned to the isomer having an intense negative CD peak in this region (*ca.* 37000 and 33000 cm^{-1} for the phen and bipy complexes, respectively).

^1H and ^{13}C NMR Spectra. The ^1H NMR spectra of two isomers for the $[Co(gly)_2phen]^+$ ion are shown in Fig. 6. The methylene proton resonance of the chelated glycinate ion for the isomer eluted early (*trans*(*N*)) shows a typical single AB pattern expected for the C_2 symmetry. On the other hand, the isomer eluted late shows the methylene resonances of two AB patterns in 3.2—4.2 ppm region. This split pattern is attributed to the low symmetry (C_1) and supports the conclusion that this isomer takes the *cis*(*O*)*cis*(*N*) structure, in agreement with the interpretation of the absorption spectra.

The ^{13}C NMR spectroscopy has been applied to

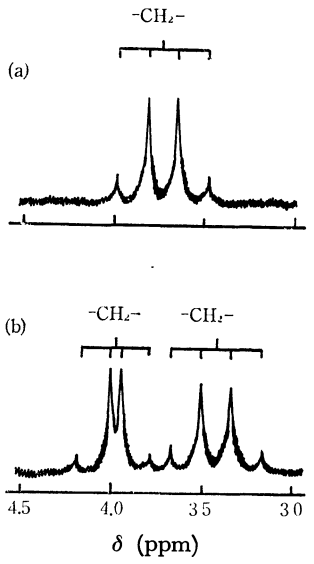

Fig. 6. ^1H NMR spectra of (a) *trans*(*N*)- and (b) *cis*(*O*)*cis*(*N*)-$[Co(gly)_2phen]^+$ ions in D_2O solutions.

the determination of the structure for a large number of organic compounds.[8,9] Recently, Fuhr and Rabenstein pointed out that ^{13}C NMR study is more useful than ^{1}H NMR for elucidating the binding of metal ions by peptides and proteins.[10]

The ^{13}C NMR spectra of two isomers of the $[Co(\beta\text{-ala})_2phen]^+$ ion are shown in Fig. 7. The sharp carbon resonances of ethylene and carboxyl groups of the chelated β-alaninate ions, and phenanthroline are observed in the ranges of 33—41, 128—155 and 182—185 ppm, respectively. The resonances of the *cis(O)-cis(N)* isomer show complicated patterns as compared with those of the *trans(N)* isomer, as expected from the symmetry. In particular, each signal for a single carbon resonance of the latter isomer (C_2 symmetry) appears as a doublet for the former isomer of lower (C_1) symmetry. This ascertainment of the geometrical structure of two isomers of $[Co(\beta\text{-ala})_2phen]^+$ ion from ^{13}C NMR spectra supports the conclusion which was obtained from their absorption spectra.

Formation Ratios of Isomers. Kojima and Shibata[5] separated six isomers for $[Co(L\text{-aspH})_2en]^+$ and $[Co(L\text{-aspH})_2(l\text{-pn})]^+$ using activated carbon in the preparation. They showed that the yields decrease in the order of *Λ-trans(O)>Λ-cis(O)cis(N)>Δ-trans(O)≃Λ-trans(N)>Λ-cis(O)cis(N)≫Δ-trans(N)* for the former complex and *Λ-trans(O)>Λ-cis(O)cis(N)>Δ-trans(O)>Λ-trans(N)=Λ-cis(O)cis(N)≫Δ-trans(N)* for the latter complex. These results suggest that the *trans(N)* isomer is less favored in this type of complex and for these preparative conditions. Similar results were obtained by Matsuoka *et al.* for the type $[Co(aa)_2en]^+$.[3,4]

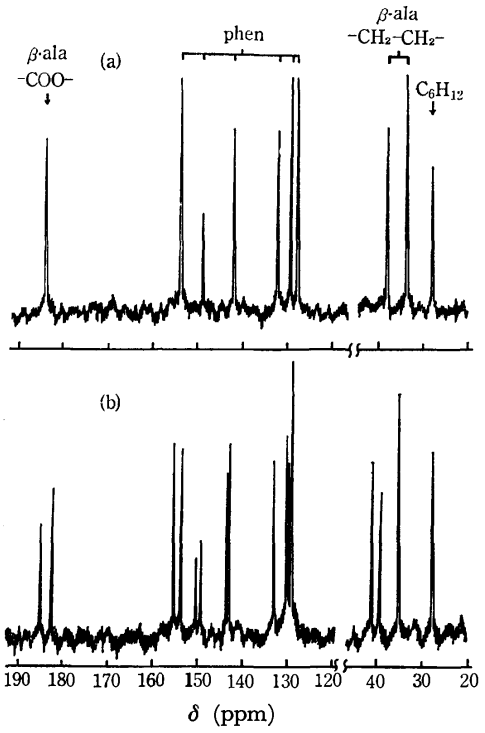

Fig. 7. ^{13}C NMR spectra of (a) *trans(N)*- and (b) *cis(O)cis(N)*-$[Co(\beta\text{-ala})_2phen]^+$ ions in D_2O solutions.

For the complexes reported here the formation ratios of *Λ-*, *Δ-trans(N)*, *Δ-* and *Λ-cis(O)cis(N)* isomers were 5.1 : 2.3 : 1.6 : 1.0 for $[Co(L\text{-ser})_2phen]^+$ ion, and 9.4 : 4.1 : 2.1 : 1.0 for $[Co(L\text{-ser})_2bipy]^+$ ion. On the other hand, the formation ratios of *trans(N)* and *cis(O)cis(N)* isomers were 2.6 : 1.0 for $[Co(gly)_2phen]^+$ and 4.4 : 1.0 for $[Co(gly)_2bipy]^+$, and these ratios also agree with those of the L-serinato complexes (2.8 : 1.0 for phen and 4.3 : 1.0 for bipy). From the preparation using activated carbon, however, only one geometrical isomer, *trans(N)* was identified. These results suggest that the *trans(N)* isomer in the phen and bipy complexes is more easily formed and more stable in aqueous solution than the *cis(O)cis(N)* and *trans(O)* isomers.

The author is grateful to Professor Bodie E. Douglas and Professor Y. Shimura for their valuable discussions and suggestions.

Studies of the Mixed Amino Acid Complexes of Cobalt(III). III.[1] Absorption and Circular Dichroism Spectra of Bis(amino acidato)ethylenediaminecobalt(III) and Bis(amino acidato)oxalatocobaltate(III) Complexes

Nobuko MATSUOKA, Jinsai HIDAKA, and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received October 7, 1974)

Three isomers of *cis(O)*-bis(L-alaninato)ethylenediaminecobalt(III) perchlorate, four isomers of potassium *cis(N)*-bis(L-alaninato)oxalatocobaltate(III) and two isomers of potassium *trans(N)*-bis(L-prolinato)oxalatocobaltate(III) have been prepared, and their configurations have been assigned by absorption and circular dichroism spectra. From analysis of the circular dichroism spectra of about 25 complexes of these types (the aminoacidato ligands are glycinato, L-alaninato, L-serinato and L-prolinato), the configurational and the vicinal circular dichroism curves have been separated and discussed. The vicinal circular dichroism curve shows a pattern characteristic of the absolute configuration of α-aminoacidato ligand and of the geometrical structure of the complex.

Three geometrical isomers, *trans*, C_2-*cis* and C_1-*cis*, exist for $[Co(amac)_2en]^+$ or $[Co(amac)_2ox]^-$ type complexes[1] (amac=aminoacidato, en=ethylenediamine, and ox=oxalato ligand). In earlier works, we reported the circular dichroism (CD) spectra of all the geometrical isomers of the glycinato and L-serinato complexes and of the *trans* isomers of the L-alaninato complexes.[2,3] Because more data are required to investigate the so-called vicinal effect displayed by the coordinated optically active α-aminoacidato ligand, we have prepared three *cis(O)* isomers of $[Co(L\text{-}ala)_2en]^+$ and four *cis(N)* isomers of $[Co(L\text{-}ala)_2ox]^-$ and two *trans(N)* isomers of $[Co(L\text{-}prol)_2ox]^-$. In the present paper, details are given for the preparation and separation of the isomers, the assignments of their geometrical structures and absolute configurations. The CD spectra of several complexes of the general types, $[Co(amac)_2en]^+$ and $[Co(amac)_2ox]^-$, are discussed and summarized.

Experimental

Preparation and Separation of Complexes. 1) Isomers of Bis(L-alaninato)ethylenediaminecobalt(III) Perchlorate. A solution of $[Co(L\text{-}ala)_2en]^+$ was prepared from cobalt(II) chloride hexahydrate, L-alanine and ethylenediamine by the method described in the previous paper,[3] and it was poured into a column (3 cm×90 cm) of cation-exchange resin (Dowex 50W-X8, 200—400 mesh, H^+ form). The neutral species, *mer*- and *fac*-$[Co(L\text{-}ala)_3]$, were swept out with water, and the two dark red species, *Δ*- and *Λ-trans(O)*-$[Co(L\text{-}ala)_2en]^+$, were eluted out with 0.02 M $NaClO_4$ solution. The separation and optical properties of these two *trans(O)* isomers have already been reported.[3] With further elution, three red bands appeared in the middle region of the column. The first red band was composed of $(-)_{546}$-isomers, which showed absorption maxima at 502 and 360 nm in the earlier eluted part and at 500 and 356 nm in the later eluted part. The second and the third red bands contained $(+)_{546}$-isomers. The species in the second band had absorption maxima at 503 and 360 nm, and that in the third band at 500 and 356 nm. By comparing the above experimental data with those of the corresponding glycinato and L-serinato complexes,[3] it was confirmed that the first band consisted of the two isomers, $(-)_{546}$-(*Δ*)-C_1-*cis(O)* and $(-)_{546}$-(*Δ*)-C_2-*cis(O)*, and that the second band contained $(+)_{546}$-(*Λ*)-C_1-*cis(O)* and the third band $(+)_{546}$-(*Λ*)-C_2-*cis(O)*.

$(-)_{546}$-C_1-cis(O)-$[Co(L\text{-}ala)_2en]ClO_4$: The earlier eluate of first red band was concentrated with a vacuum evaporator, and ethanol and ether were added to it. A large amount of white precipitate of sodium perchlorate deposited and it was filtered off. If an oily substance was formed, the supernatant was removed by decantation. The oil was treated with a little amount of water, and ethanol and ether were again added to it. After repeated precipitation and removal of sodium perchlorate by the same procedure, red crystals were deposited. They were isolated by using a centrifuge and recrystallized from water by adding ethanol and ether. Pure crystals (E–C–1) were filtered, washed with water–ethanol mixture and ethanol, and dried in air.

From the later eluate of the first red band, no pure complex could be obtained.

$(+)_{546}$-C_1-cis(O)-$[Co(L\text{-}ala)_2en]ClO_4$: This isomer (E–C–2) was obtained from the eluate of second red band by the same method used for the $(-)_{546}$-C_1-*cis(O)* isomer.

$(+)_{546}$-C_2-cis(O)-$[Co(L\text{-}ala)_2en]ClO_4$: The eluate of third red band was evaporated to dryness with a vacuum evaporator, and the red substance was extracted with methanol. When ether was added to the methanol solution a large amount of white sodium perchlorate precipitate was formed, which was filtered off. After repeated precipitation and removal of sodium perchlorate, red crystals began to deposit. They were isolated by using a centrifuge. The crude complex was dissolved in water, and a small amount of insoluble material was filtered off. The pure complex (E–C–3) was obtained by evaporating the mother liquor in a vacuum desiccator.

2) Isomers of Potassium Bis(L-alaninato)oxalatocobaltate(III). A solution of $[Co(L\text{-}ala)_2ox]^-$ was prepared from cobalt(II) chloride hexahydrate, L-alanine and potassium oxalate by the method described in the previous paper.[4] From a column (3 cm×90 cm) of anion-exchange resin (Dowex 1–X8, 200—400 mesh, Cl^- form) the upper layer (about 4 cm) of resin was sucked out by a syringe, and stirred in a separate beaker with a saturated potassium acetate solution. It was again stirred with the solution of $[Co(L\text{-}ala)_2ox]^-$ and the resulting resin which adsorbed several isomers of the complex ion returned to the top of the column. By elution with 0.02—0.01 M KCl solution, a colored band was progressively separated into the three bands which were, in order of elution, blue-violet, red-violet and blue-violet. From their visible and ultraviolet absorption spectra, CD and ORD curves, these bands were assigned as follows. The first blue-violet band consisted of two species, $(-)_{546}$-(*Δ*)-*trans(N)*- and $(+)_{546}$-(*Δ*)-*trans(N)*-$[Co(L\text{-}ala)_2ox]^-$, which were eluted in this order. In the second red-violet band there were also two species, $(-)_{546}$-(*Λ*)-C_1-*cis(N)*- (eluted earlier) and $(+)_{546}$-(*Δ*)-C_1-*cis(N)*-$[Co(L\text{-}ala)_2ox]^-$ (eluted later), both of which showed absorption maxima at 542 and 386 nm. The last

blue-violet band was further separated into two bands. The species in the earlier eluted band was $(+)_{546}$-(*Δ*)-C_2-*cis*(*N*)-[Co(L-ala)$_2$ox]$^-$ which had absorption maxima at 548 and 381 nm, and the species in the later eluted band was $(-)_{546}$-(*Λ*)-C_2-*cis*(*N*)-[Co(L-ala)$_2$ox]$^-$ which had absorption maxima at 551 and 381 nm.

$(-)_{546}$-(*Λ*)- and $(+)_{546}$-(*Δ*)-trans(N)-*K*[*Co(L-ala)$_2$ox*]: The $(-)_{546}$- and $(+)_{546}$-isomers in the first blue-violet band were identical to the less soluble and the more soluble isomers, respectively, in the earlier paper.[4] Therefore the isolation and purification were carried out as before.

$(-)_{546}$-(*Λ*)- and $(+)_{546}$-(*Δ*)-C_1-cis(N)-*K*[*Co(L-ala)$_2$ox*]: The eluate of the second red-violet band was concentrated with a vacuum evaporator. By adding a limited amount of ethanol in portions to the concentrated solution, several fractions of the complex were obtained, after the white precipitates of potassium chloride formed at first had been removed. By measurement of their ORD, these fractions were divided into two groups, $(-)_{546}$- and $(+)_{546}$-fractions. It was found that the isomer in the $(-)_{546}$-fraction (O-C-1) was less soluble and the one in $(+)_{546}$-fraction (O-C-2) more soluble. Both isomers were independently recrystallized from water by adding ethanol (and ether too for the $(+)_{546}$-isomer), and they were filtered, washed with ethanol and dried in a desiccator. The $(-)_{546}$-isomer was also isolated by adding ethanol to the earlier eluted part of the second band.

$(+)_{546}$-(*Δ*)-C_2-cis(N)-*K*[*Co(L-ala)$_2$ox*]: The earlier eluted part of the third blue-violet band was evaporated to dryness with a vacuum evaporator. The complex was extracted with methanol, and then ether was added to this methanol solution. The crude complex deposited was recrystallized from water by adding ether. Pure violet crystals (O-C-3) were filtered, washed with ether and dried in a vacuum desiccator.

$(-)_{546}$-(*Δ*)-C_2-cis(N)-*K*[*Co(L-ala)$_2$ox*]: This isomer (O-C-4) was obtained from the later eluted part of the third band by the same method used for the $(+)_{546}$-isomer.

3) Trans(N) *Isomers of Potassium Bis(L-prolinato)oxalatocobaltate(III).* A solution of 4.7 g (0.02 mol) of cobalt (II) chloride hexahydrate in 20 ml of water was mixed with a solution of 4 g (0.02 mol) of potassium oxalate and 5 g (0.04 mol) of L-proline in 40 ml of water. The resulting solution was mechanically stirred with 5 g of lead dioxide and a small amount of active charcoal at 60 °C for about 40 min, and cooled to room temperature. After standing overnight, insoluble material was removed. The resin which adsorbed the resulting complex ion was prepared by the method described for [Co(L-ala)$_2$ox]$^-$, and it was transferred into the top of a 3 cm×90 cm column packed with anion-exchange resin (Dowex 1-X8, 200—400 mesh, Cl^- form). The adsorbed complexes were progressively separated into two bands colored blue-violet and violet, by elution with about 0.05 M KCl solution. From the absorption and CD spectra, it was shown that the blue-violet band contained two isomers of *trans(N)*-[Co(L-prol)$_2$ox]$^-$, which was the *Δ*-isomer in the earlier eluted fraction and the *Λ*-isomer in the later eluted fraction. Similarly, the violet band was shown to contain *cis(N)*-[Co(L-prol)$_2$ox]$^-$ isomer.

Only two *trans* isomers have been successfully isolated as follows.

$(+)_{546}$-(*Δ*)-trans(N)-*K*[*Co(L-prol)$_2$ox*]: The earlier eluted fraction of the blue-violet band was evaporated to dryness with a vacuum evaporator, and then the violet substance was extracted with methanol. An insoluble mixture of white precipitate (potassium chloride) and reddish violet solid (*Λ-trans* isomer) was filtered off, and then ether was added to the mother liquor. Violet crystals were deposited. They were recrystallized from methanol by adding ether. After repeated recrystallizations, pure crystals (P-T-1) were filtered, washed with ether and dried in a desiccator.

$(+)_{546}$-(*Λ*)trans(N)-*K*[*Co(L-prol)$_2$ox*]: The later eluted fraction of the blue-violet band was concentrated with a vacuum evaporator. By adding ethanol to the concentrate, a large amount of pinkish violet crystals was deposited. If a precipitate of potassium chloride was formed prior to precipitating the complex, it was removed, and ethanol was again added to the mother liquor. The crude complex was recrystallized from water by adding ethanol. The pure crystals (P-T-2) were filtered, washed with ethanol-water mixture and then with ethanol and dried in air.

Measurements. The electronic absorption spectra were measured with a Shimadzu UV-200 spectrophotometer. The CD spectra were recorded with a JASCO Model MOE-1 spectropolarimeter or with a Roussel-Jouan Dichrograph. The ORD curves were recorded with a Yanagimoto Model-185 spectropolarimeter. All measurements were made in aqueous solutions at room temperature.

Results and Discussion

The three newly obtained isomers of *cis(O)*-[Co(L-ala)$_2$en]$^+$ were labeled as E-C-1, E-C-2 and E-C-3, the four isomers of *cis(N)*-[Co(L-ala)$_2$ox]$^-$ as O-C-1, O-C-2, O-C-3 and O-C-4, and the two isomers of *trans(N)*-[Co(L-prol)$_2$ox]$^-$ as P-T-1 and P-T-2, in the order of elution. The analytical data for these complexes are presented in Table 1, together with

those of the two isomers of *trans*(*N*)-[Co(L-ala)$_2$ox]$^-$ (O-T-1 and O-T-2).

The sample of *Δ-trans*(*N*)-K[Co(L-ala)$_2$ox] prepared in the present work (O-T-2) had 2.5 mol of water of crystallization (*cf.* Table 1), although the sample prepared in the earlier paper[4] was anhydrous. The optical purity of the present sample is greater than that of the previous one. It seems that the sample in the earlier work was partly racemic, *i.e.* it was mixed with a little of the *Λ-trans*(*N*) isomer. The E-C-3 isomer of [Co(L-ala)$_2$en]$^+$ and O-C-3 and O-C-4 isomers of [Co(L-ala)$_2$ox]$^-$ are contaminated with small amounts of sodium perchlorate or potassium chloride. However, further purifications have not been carried out, because of the low yields of the complexes.

Structural Assignments of Isomers. The geometrical structures of [Co(amac)$_2$en]$^+$ or [Co(amac)$_2$ox]$^-$ complexes can be determined from their absorption spectra in the d-d transition region. Thus the O-T-1, O-T-2, P-T-1 and P-T-2 isomers are easily identified as *trans*-(*N*) structures from the large splitting of their first absorption bands[1] (*cf.* Fig. 1).

The absorption spectra of the C_2-*cis* and C_1-*cis* isomers of the present complexes are similar in appearance in the d-d transition region, as seen in Figs. 2 and 3. However, we have found previously some regular differences in the absorption maxima between the C_2-*cis* and the C_1-*cis* isomers in both series of [Co(gly)$_2$en]$^+$ and [Co(gly)$_2$ox]$^-$. The geometrical structures of these bis(glycinato) isomers were determined unambiguously from their NMR spectra.[1] For instance, the C_2-*cis*(*O*) isomer of [Co(gly)$_2$en]$^+$ shows a second absorption maxima at a higher energy than that of the corresponding C_1-*cis*(*O*) isomer. The same behavior has also been observed for the [Co(L-ser)$_2$en]$^+$ isomers. The data are presented in Table 2 together with those of the [Co(L-ala)$_2$en]$^+$ isomers,

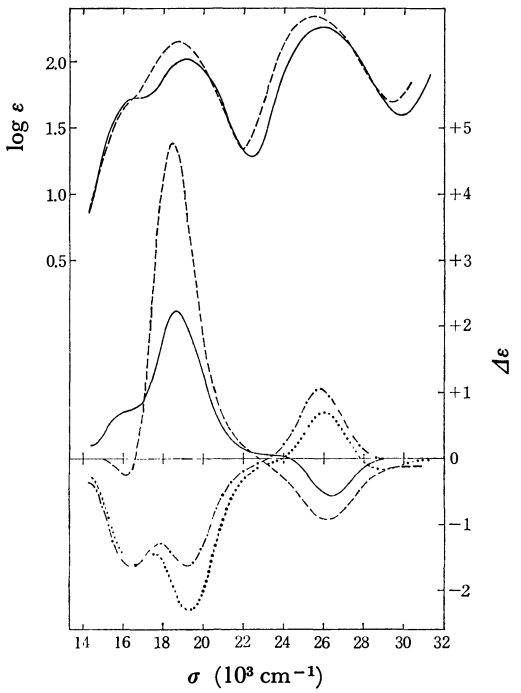

Fig. 1. Absorption and CD spectra of *trans*(*N*)-[Co(L-amac)$_2$ox]$^-$.
——: *Λ*-L-alaninato complex (O-T-1), ----: *Δ*-L-alaninato complex (O-T-2), ——: *Δ*-L-prolinato complex (P-T-1), ——: *Λ*-L-prolinato complex (P-T-2).

——: *Δ*-C$_1$-*cis*(*O*) isomer (E-C-1), ——: *Λ*-C$_1$-*cis*(*O*) isomer (E-C-2), ——: *Λ*-C$_2$-*cis*(*O*) isomer (E-C-3).

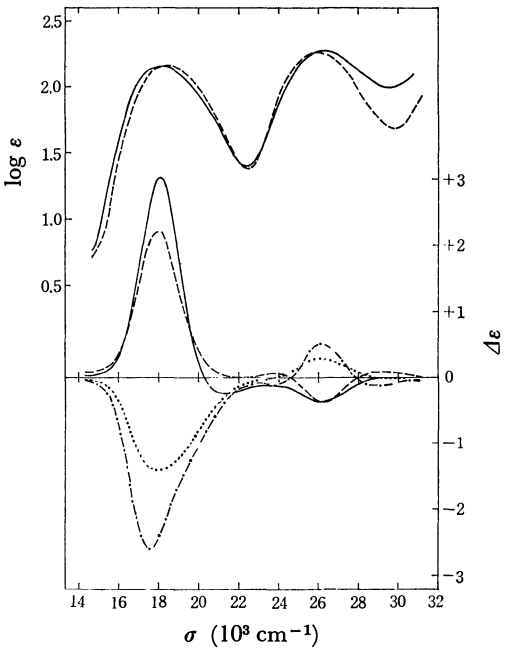

Fig. 3. Absorption and CD spectra of *cis*(*N*)-[Co(L-ala)$_2$ox]$^-$.
——: *Λ*-C$_1$-*cis*(*N*) isomer (O-C-1); ——: *Δ*-C$_1$-*cis*(*N*) isomer (O-C-2); ----: *Δ*-C$_2$-*cis*(*N*) isomer (O-C-3); ——: *Λ*-C$_2$-*cis*(*N*) isomer (O-C-4).

E–C–1, E–C–2, and E–C–3. By comparing these values, the geometrical structures of E–C–1 and E–C–2, both of which have their second absorption maxima at 27800 cm^{-1}, are assigned to C_1-*cis*(*O*), and E–C–3, which has a second absorption maximum at 28200 cm^{-1}, to C_2-*cis*(*O*). In the oxalato complexes such as $[Co(gly)_2ox]^-$ and $[Co(L\text{-}ser)_2ox]^-$, the C_2-*cis*(*N*) isomer has its first absorption maximum at a lower energy and the second absorption maximum at a higher energy than the C_1-*cis*(*N*) isomer, as seen in Table 2. Therefore, the geometrical structures of O–C–1 isomer (absorption maxima at 18500 and 25900 cm^{-1}) and the O–C–2 isomer (maxima at 18400 and 25900 cm^{-1}) are assigned as C_1-*cis*(*N*), while the structures of O–C–3 (maxima at 18200 and 26200 cm^{-1}) and O–C–4 isomers (maxima at 18200 and 26300 cm^{-1}) are assigned as C_2-*cis*(*N*).

The absolute configurations of all the isomers were assigned from the sign of major CD band in the region of the first absorption band.[5] It has been confirmed that the absolute configurations derived from this CD method agree with conclusions from PMR studies, which were reported for several mixed aminoacidatocobalt(III) complexes including *trans*(*O*)-$[Co(L\text{-}ala)_2en]^+$ and *trans*(*N*)-$[Co(L\text{-}ala)_2ox]^-$.[6,7] Since the E–C–2, E–C–3, O–C–1, O–C–4, and P–T–2 isomers have a positive major CD band in the region of the first absorption band (Figs. 2 and 3), these isomers are assigned to the *Λ*-configuration. The other four complexes have a negative major CD band, and they are assigned to the *Δ*-configuration. Consequently, the nine newly obtained complexes are characterized as follows: in the $[Co(L\text{-}ala)_2en]^+$ series, E–C–1 is *Δ*-C_1-*cis*(*O*), E–C–2 *Λ*-C_1-*cis*(*O*), and E–C–3 *Λ*-C_2-*cis*(*O*); in the $[Co(L\text{-}ala)_2ox]^-$ series, O–C–1 is *Λ*-C_1-*cis*(*N*), O–C–2 *Δ*-C_1-*cis*(*N*), O–C–3 *Δ*-C_2-*cis*(*N*), and O–C–4 *Λ*-C_2-*cis*(*N*); in the $[Co(L\text{-}prol)_2ox]^-$ series, P–T–1 is *Δ*-*trans*(*N*), and P–T–2 *Λ*-*trans*(*N*). We have failed in isolation of the *Δ*-C_2-*cis*(*O*) isomer in the $[Co(L\text{-}ala)_2en]^+$ series, though it has been confirmed that this isomer certainly exists in a fraction eluted from the column after the E–C–1 fraction.

Absorption Spectra. The absorption spectra of the complexes in the $[Co(amac)_2en]^+$ and $[Co(amac)_2ox]^-$ series are summarized in Table 2. As mentioned above, the second absorption band maximum of

a) In the unit of 10^3 cm^{-1}.

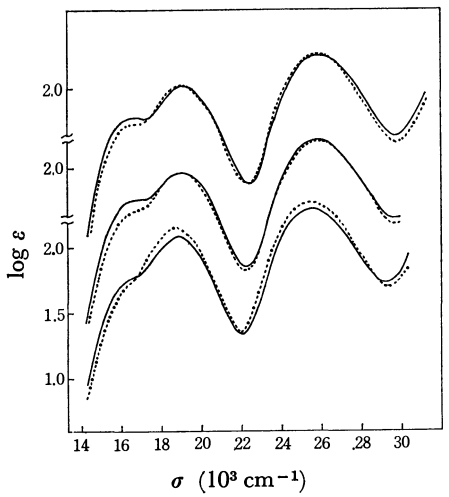

Fig. 4. Absorption spectra of *trans*(*N*)-[Co(L-amac)$_2$ox]$^-$. {L-amac=L-ala (upper); L-ser (middle); L-prol (lower)}: ——: *Δ*-isomer, ----: *Λ*-isomer

C_2-*cis* isomer is generally at a higher energy than that of the corresponding C_1-*cis* isomer.

For the *trans*(*N*)-[Co(amac)$_2$ox]$^-$ complexes, the position of the first absorption band maximum shifts to higher energies in the order of aminoacidato ligands: L-prolinato, glycinato, L-serinato and L-alaninato. The same order is also observed for the C_2-*cis*(*O*)-[Co(amac)$_2$en]$^+$ and C_2-*cis*(*N*)-[Co(amac)$_2$ox]$^-$ complexes. This spectrochemical series for aminoacids agrees with that observed for the [Co(amac) $(NH_3)_4]^{2+}$ complexes.[8] In Fig. 4, it is interesting to note that the intensity of the longer wavelength component of the first absorption band is always stronger in the *Δ* diastereomer of the *trans*(*N*)-[Co(L-amac)$_2$ox]$^-$ complex than in the corresponding *Λ* one.

Configurational Circular Dichroism. The observed CD data for the [Co(L-amac)$_2$en]$^+$ and [Co(L-amac)$_2$ox]$^-$ complexes are summarized in Table 3. By applying the following relations,[2,3] the configurational (Figs. 5 and 6) and the vicinal (Fig. 7) curves have been derived from the observed curves.

$$\Delta\varepsilon(2L) = 1/2\{\Delta\varepsilon(\Lambda_{2L}) + \Delta\varepsilon(\Delta_{2L})\}$$
$$\Delta\varepsilon(\Delta) = 1/2\{\Delta\varepsilon(\Delta_{2L}) - \Delta\varepsilon(\Lambda_{2L})\}$$
$$\Delta\varepsilon(\Lambda) = 1/2\{\Delta\varepsilon(\Lambda_{2L}) - \Delta\varepsilon(\Delta_{2L})\}$$

where $\Delta\varepsilon(\Delta_{2L})$ and $\Delta\varepsilon(\Lambda_{2L})$ are the observed CD for the *Δ* and *Λ* diastereomers, respectively, of the [Co(L-amac)$_2$en]$^+$ or [Co(L-amac)$_2$ox]$^-$ complex, and $\Delta\varepsilon(\Delta)$ and $\Delta\varepsilon(\Lambda)$ the configurational CD, and $\Delta\varepsilon(2L)$ the vicinal CD of the two mol of L-aminoacidato ligands.

The configurational CD curves agree well with the observed ones of the corresponding glycinato isomers, as seen in Figs. 5 and 6. Each configurational curve is quite characteristic of its geometrical structure irrespective of the kind of aminoacidato ligand. This means that the configurational chiralities of these complexes are almost identical regardless of the sub-

stituent on the α carbon atom of the aminoacidato chelate ring. The configurational CD of the *trans* isomers show two bands of the same sign in the first absorption band region. On the other hand, those of the C_2-*cis* and C_1-*cis* isomers show a single main band in this region. A clear difference between the C_2-*cis* and C_1-*cis* isomers appears in the second absorption band region. The C_1-*cis* isomer shows three bands whose signs are positive, negative and positive (for the Λ isomer) from lower energy side, while the C_2-*cis* isomer shows one (or two) negative band (for the Λ isomer), in the second absorption band region. This behavior of the C_1-*cis* and C_2-*cis* isomers is common to both the [Co(amac)$_2$en]$^+$ and [Co(amac)$_2$ox]$^-$ complexes.

a) In the unit of 10^3 cm^{-1}.

The extrema in the calculated configurational CD curves are listed in Table 4. In general, the positions of the CD extrema in the calculated configurational CD curves coincide closely with those of the absorption maxima in the first absorption band region. However, in C_1-*cis* isomers of both types, $[Co(amac)_2en]^+$ and $[Co(amac)_2ox]^-$, the configurational CD extrema are 500—1000 cm^{-1} lower in energy than the absorption maxima.

Vicinal Circular Dichroism. The calculated vicinal CD curves also show systematic patterns characteristic of the geometrical structures, as seen in Fig. 7. The vicinal CD curve of C_2-*cis*(*O*)-$[Co(L\text{-}ala)_2en]^+$ has been drawn by subtracting the configurational curve of Λ-C_2-*cis*(*O*)-$[Co(L\text{-}ser)_2en]^+$ from the observed curve of Λ-C_2-*cis*(*O*)-$[Co(L\text{-}ala)_2en]^+$, because neither Δ-C_2-*cis*(*O*)-$[Co(L\text{-}ala)_2en]^+$ nor optically active C_2-*cis*(*O*)-$[Co(gly)_2en]^+$ has been isolated. The three bands whose signs are negative, positive and negative from lower energy side are observed for the *trans* isomers of $[Co(L\text{-}ala)_2en]^+$, $[Co(L\text{-}ala)_2ox]^-$ and $[Co(L\text{-}ser)_2ox]^-$ complexes. In these three bands, the highest energy band of $[Co(L\text{-}amac)_2en]^+$ and the lowest energy band of $[Co(L\text{-}amac)_2ox]^-$ appeared in the region of the shoulder of the first absorption band. Thus the vicinal CD in these *trans* type complexes, which contain L-aminoacidato ligands, may be summarized as follows: the $A_{2g}(D_{4h})$ transition has a negative CD component and the $E_g(D_{4h})$ splits into two CD components with opposite signs, by lowering the molecular symmetry. Hawkins has proposed an empirical rule for the vicinal effects of aminoacidato ligands: "In tetragonal or rhombic complexes, amino acids with the L configuration impose a negative Cotton effect on the transition with $A_{2g}(D_{4h})$ parentage and give rise to two nondegenerate transitions of opposite sign corresponding to the $E_g(D_{4h})$ band".[9] This is just the case for the present *trans* type complexes. The $E_g(D_{4h})$ component of $[Co(L\text{-}prol)_2ox]^-$ does not appear split. The strong positive intensity of this component may be related to the existence of asymmetric (S) nitrogen atoms of the coordinated L-prolinate ligands.

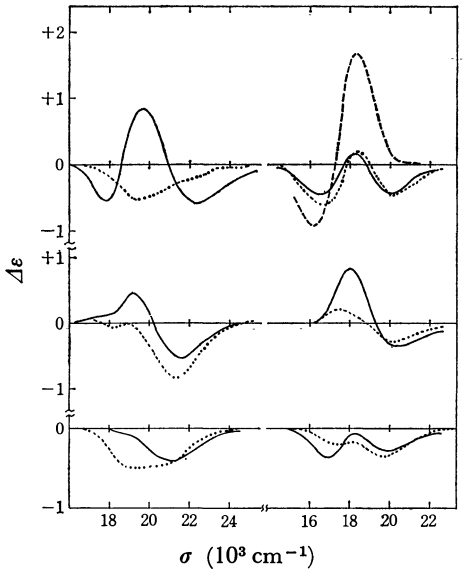

Fig. 7. Vicinal CD curves of $[Co(L\text{-}amac)_2en]^+$ (left) and $[Co(L\text{-}amac)_2ox]^-$ (right), for *trans* (upper), C_2-*cis* (middle) and C_1-*cis* (lower) isomers.
——: L-alaninato complexes; ----: L-serinato complexes; ———: L-prolinato complex.

The vicinal CD curves of the C_2-*cis*(*O*) isomers of $[Co(L\text{-}ala)_2en]^+$, $[Co(L\text{-}ala)_2ox]^-$ and $[Co(L\text{-}ser)_2ox]^-$ have two bands, whose signs are positive and negative from lower energy side, while those of all the C_1-*cis* isomers have two (or one in appearance) negative bands. It is interesting that the same pattern is observed in both types of complex, C_2-*cis*(*O*)-$[Co(L\text{-}amac)_2en]^+$ and C_2-*cis*(*N*)-$[Co(L\text{-}amac)_2ox]^-$, because the order of the energies of their $A_{2g}(D_{4h})$ and $E_g(D_{4h})$ transitions are reversed.

The vicinal CD curves of *trans*(*O*)- and C_2-*cis*(*O*)-$[Co(L\text{-}ser)_2en]^+$ deviate from the ordinary patterns. A molecular model examination indicates that an intramolecular hydrogen-bond is possible for the Λ-isomers of these two complexes: a hydrogen-bond is possible between two L-serinato ligands for the Λ-*trans*(*O*) isomer, and two hydrogen-bonds between an L-serinato and an ethylenediamine ligand for the Λ-C_2-*cis*(*O*) isomer. Such hydrogen-bond interactions may more or less fix the conformation of chelate ring or restrict the internal rotation of the substituent group on the α-carbon atom, and thus be responsible for the anomalous vicinal CD.

Magnetic Circular Dichroism of Dicyanobis(2,2′-bipyridine)iron(II)

Hiroshi KOBAYASHI, Badri Vishal AGARWALA,* and Youkoh KAIZU

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received October 19, 1974)

Magnetic circular dichroism (MCD) of *cis*-dicyanobis(2,2′-bipyridine) iron(II) was measured for a variety of solvents. The visible absorption band is assigned to the lowest "iron(II) to bipyridine" charge-transfer transition. The complex exhibits a significant MCD in its lowest charge-transfer absorption band. The transition shows a shift to higher wave number with an increase in the proton-donating power of solvent. This spectral shift is attributed to hydrogen-bonding interactions of protolytic solvent molecules. In H_2SO_4 this dibasic complex is subjected to stepwise protonations. The complex is diamagnetic in protolytic solvents, and even in conc H_2SO_4 the diprotonated complex formed is mostly present in the diamagnetic state.

Schilt has described the mixed-ligand complex of iron(II) with cyanide and 2,2′-bipyridine.[1] The neutral complex $[Fe(CN)_2(2,2'\text{-bipyridine})_2]$ was found to be especially interesting because of its unique property. It gives violet, blue, red, orange and yellow colors depending upon the nature of the solvent. Concentrated sulfuric acid dissolves large amounts without decomposition. The compound shows dibasic character and reacts reversibly with acids to form stable protonated species.[2] $[Fe(2,2'\text{-bipyridine})_3]^{2+}$ is stable against oxidation, but $[Fe(CN)_2(2,2'\text{-bipyridine})_2]$ is rather readily oxidized. It has been employed as nonaqueous acid-base and aqueous oxidation-reduction indicators.[3]

A change between high-spin $^5T_2$ and low-spin $^1A_1$ ground states has been established within the series of *cis*-$[FeX_2(2,2'\text{-bipyridine})_2]$ complexes. Considerable efforts have been achieved in the synthesis and physical measurements of the complexes with ligands X covering a wide range of ligand field strengths.[4] Only when X=CN, a stable diamagnetic complex is obtained. In the present work, the magnetic circular dichroism (MCD) spectra of *cis*-$[Fe(CN)_2(2,2'\text{-bipyridine})_2]$ (abbreviated to $[Fe(CN)_2(bipy)_2]$) in a variety of solvents were measured for understanding of the lowest electronic excitations.

Experimental

Materials. *cis*-Dicyanobis(2,2′-bipyridine)iron(II) trihydrate was prepared by the method of Schilt[1] and identified by elemental analysis.

Found: C, 55.66; H, 4.44; N, 17.37%. Calcd for $C_{22}H_{16}N_6Fe\cdot 3H_2O$: C, 55.70; H, 4.68; N, 17.72%. By means of Sasse's method, 4,4′-dimethyl- and 5,5′-dimethyl-2,2′-bipyridine (abbreviated to 4 dmbip and 5 dmbip, respectively) were prepared.[5,6] The dimethyl bipyridine analogs of dicyanobis(2,2′-bipyridine)iron(II) were also prepared by the method of Schilt:[1]

Found: C, 63.30, H, 5.24, N, 16.96%. Calcd for $C_{26}H_{24}N_6$ (4 dmbip) $Fe\cdot H_2O$: C, 63.17; H, 5.30; N, 17.00%.

Found: C, 59.12; H, 5.28; N, 15.93%. Calcd for $C_{26}H_{24}N_6$ (5 dmbip) $Fe\cdot 3H_2O$: C, 58.88; H, 5.70; N, 15.85%. The 4 dmbip complex was dried over silicagel prior to the elemental analysis.

All solvents including C_2H_5OH and $CHCl_3$ were commercially available and purified by distillation except H_2SO_4.

Measurements. MCD spectra were recorded on a JASCO ORD/UV-5 spectropolarimeter with its CD attachment and electromagnet. The measurement technique had been described earlier.[7] The magnetic field was set at 10,000 G. The visible and ultraviolet absorption spectra were taken on a Shimadzu automatic recording spectrophotometer Model MPS-50. The NMR spectra were taken on a 60 MHz Varian T-60 NMR spectrometer using sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) as an internal standard.

Results and Discussion

The MCD and absorption spectra of $[Fe(CN)_2(bipy)_2]$ in $CHCl_3$, C_2H_5OH, H_2O and H_2SO_4 are shown in Figs. 1 and 2. The prominent maxima are summarized in Table 1. The electronic transitions which give rise to the MCD extrema and absorption maxima in 15000—30000 cm^{-1} are assigned to the lowest "iron to bipyridine" charge-transfer excitations. The lowest wave number absorption peak exhibits a blue shift in the order bipy<4 dmbip<5 dmbip and the second peak shows a blue shift in the order 4 dmbip<5 dmbip≤bipy. Such spectral shifts for the dimethyl substitutions in coordinated bipyridine have been observed in the lowest and the second "metal to

bipyridine" charge-transfer excitations in 2,2'-bipyridine tetracarbonylchromium, -molybdenum, and -wolfram.[8] The ultraviolet peak shows a shift for dimethyl substitutions in the order 5 dmbip<bipy≤4 dmbip. This indicates that the ultraviolet peak arises from the lowest (π, π^*) excitation in coordinated bipyridine.[8]

The nature of MCD and absorption spectra does not change in different solvents. However a shift observed in different solvents should be noted. With an increase in the proton-donating power of solvent, the absorption band shifts to higher wave number : chloroform<ethanol<water. Figure 3 shows a linear relationship obtained between the first and second absorption peaks for a variety of proton-donating power

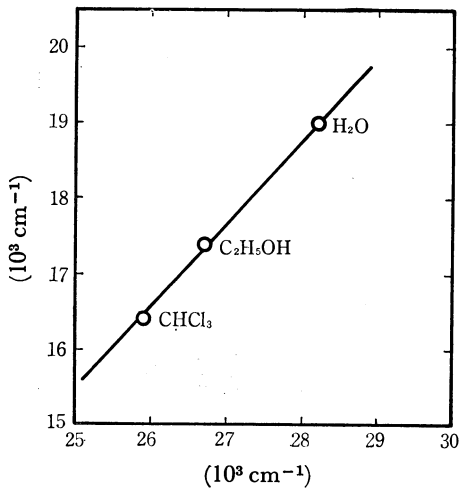

Fig. 3. A linear relationship between the first and second charge-transfer bands.

of solvents. In a protolytic solvent, a hydrogen-bonding interaction of the solvent molecules arises on coordinated cyano groups. The coordinated cyano group is a σ-donor but a π-acceptor. The iron dπ electrons even in the ground state migrate into the lowest vacant π^* molecular orbitals which delocalize not only over coordinated bipyridines but also over coordinated cyano groups. Thus the hydrogen-bonding interaction of protolytic solvent molecules with coordinated cyano groups encourages the migration of iron dπ electrons into the coordinated cyano groups. This gives rise to a blue-shift of the "iron to bipyridine" charge-transfer excitations in protolytic solvents. In conc H_2SO_4, the lowest wave number absorption peak appears at 25000 cm^{-1}. This blue-shift, however, should be attributed to the protonations in conc H_2SO_4 since the effect is greater than expected for the hy-

drogen-bonding interactions in protolytic solvents. Hamer and Orgel have suggested the protonation of the complex in conc H_2SO_4.[9] The MCD and absorption spectra measured for a variety of concentrations of H_2SO_4 in solution are presented in Figs. 4 and 5. These stepwise spectral changes for an increase in the concentration of H_2SO_4 indicate the stepwise protonation toward two coordinated cyano groups. The straight line with a slope of 1.00 in Fig. 3 predicts the second peak in conc H_2SO_4 at 34200 cm^{-1} for the first peak at 25000 cm^{-1}. Since the second band as well as the first band is not so intense as the bipyridine (π, π^*) band, the second band of the complex in conc H_2SO_4 must be present beneath the ligand (π,π^*) band.

The energy of the ground state of *cis*-$[FeA_4B_2]$ complex is given as follows:

$^5\Gamma(^5T_2$ in Oh symmetry: $(xy)^2(yz)(zx)(z^2)(x^2-y^2))$
$2\{\Delta-(X_A-X_B)\}+15A-35B+7C$
$^1\Gamma_1(^1A_1$ in Oh symmetry: $(xy)^2(yz)^2(zx)^2)$
$15A-30B+15C$,

where Δ is the cubic ligand field parameter of $[FeA_6]$, (X_A-X_B) is a correction for the ligand field of ligand B at *cis*-positions (X_B is defined as a one third of the cubic ligand field parameter of $[FeB_6]$ as well as $X_A=\Delta/3$), and A, B, and C are Racah's interelectronic electrostatic energy parameters. Provided that $3(X_A-X_B)=x\Delta$ and $4B=C$, an energy difference between the quintet and singlet ground states is given by $2(1-x/3)\Delta-37B$. Since the ground state of $[Fe(bipy)_3]^{2+}$ ($x=0$) is singlet, $\Delta>(37/2)B$. In fact, the d-d transition $^3T_1\leftarrow{}^1A_1(\Delta-12B)$ in $[Fe(bipy)_3]^{2+}$ is observed at 12000 cm^{-1},[10] which indicates that $\Delta=24B$ if $B=1000$ cm^{-1}. The energy diagram of the ground state of $[FeA_4B_2]$ is shown in Fig. 6. When the value of x increases, the ligand field of B decreases. For high values of x, the ground state of $[FeA_4B_2]$ should be quintet even for a fairly high value of Δ which gives the singlet ground state for $[FeA_6]$. In fact, the ground states of $[FeX_2(bipy)_2]$ are mostly quintet, whereas the ground

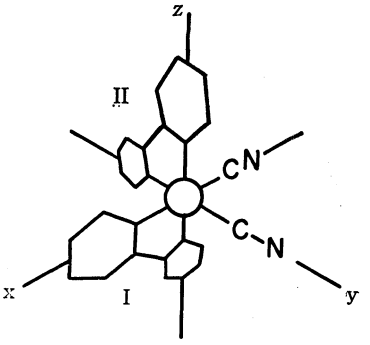

Fig. 7. Molecular coordinate.

state of $[Fe(bipy)_3]^{2+}$ is singlet.[4] A decrease in x, which is revealed by a greater value of Δ in $[Fe(CN)_6]^{4-}$, gives rise to diamagnetic $[Fe(CN)_2(bipy)_2]$. The vacant antibonding π^* orbitals of coordinated bipyridines and cyano groups accept iron $d\pi$ electrons, and thus an enhancement of the ligand field splitting in diamagnetic $[Fe(CN)_2(bipy)_2]$ should be attributed partly to the back-donation effect. The back donation also gives rise to a splitting in $d\pi$ orbitals: d_{xy} is a little more stabilized than d_{yz} and d_{zx} orbitals in $[Fe(CN)_2(bipy)_2]$ (Fig. 7).

The lowest "metal to bipyridine" charge-transfer transitions borrow their intensity from the allowed (π, π^*) transitions localized in coordinated bipyridines I and II, $1/\sqrt{2}\{(j\rightarrow k)_I\pm(j\rightarrow k)_{II}\}$.[11] Among possible six charge-transfer excitations $d\pi\rightarrow k_I$, k_{II}, $1/\sqrt{2}\{(xy\rightarrow k_I)\pm(xy\rightarrow k_{II})\}$ and $1/\sqrt{2}\{(yz\rightarrow k_I)\pm(zx\rightarrow k_{II})\}$ can borrow the intensity. Since d_{xy} orbital is lower than d_{yz} and d_{zx} orbitals, the charge-transfer transitions arising from the d_{xy} orbital must be in a wave number higher than those from the d_{yz} and d_{zx} orbitals. The MCD spectra indicate separate four B peaks with alternating sign corresponding to two components of the charge-

transfer transitions to the lowest and the second lowest vacant π^* orbitals. Since the plus and minus combinations in $1/\sqrt{2}\{(xy\rightarrow k_I)\pm(xy\rightarrow k_{II})\}$ and $1/\sqrt{2}\{(yz\rightarrow k_I)\pm(zx\rightarrow k_{II})\}$ form a degenerate pair, an *A*-term dispersion is expected in the corresponding absorption peak. However the expectation value of angular momentum between the wave functions within the degenerate pair is vanished and thus the *A*-term dispersion does not appear. On the other hand, a non-zero value of angular momentum comes out between the wave functions of different degenerate pairs and gives rise to a magnetic-field induced mixing between different degenerate excited states.[12,13] The MCD spectra thus exhibit *B*-term extrema with alternating sign.

The blue shift of the lowest charge-transfer transitions in conc H_2SO_4 is as great as 5000 cm^{-1}. This spectral blue shift is attributed to protonation rather than hydrogen-bonding. Since the character of the lowest charge-transfer transition is still conserved even in conc H_2SO_4, the complex is mostly in the diamagnetic state. The ionization potential of $d\pi$ orbitals is dependent upon the spin state of iron(II) in complex. The values given in Table 2 were obtained by the procedure described in Griffith's book.[14] In the high spin state, only an electron pair in d_{xy} orbital shows a higher tendency of back donation. In the diamagnetic state, all $d\pi$ electrons equally show an enhanced tendency of back donation. If a change of the spin state of the complex comes out upon protonation, the charge-transfer transition should exhibit a more drastic red shift or blue shift since the ionization potential of $d\pi$ electrons in the high spin state is very different (more than 10000 cm^{-1}) from the corresponding ionization potential of diamagnetic iron(II) as shown in Table 2. The spectral intensity of the complex in conc H_2SO_4 is almost reproducible within experimental error, however, the spectral intensity depends on somewhat how to prepare the solution. The high spin complex must be labile, and thus the high spin species, if it is formed upon protonation, suddenly dissociates ligands and/or is oxidized. The NMR spectrum of the complex in conc H_2SO_4 shows, in fact, a significant line broadening which indicates the presence of some high spin species. One of the authors (B.V.A.) wishes to express his gratitude to the Japanese Government for a UNESCO fellowship.

Reaction of Cupric Ion Fixed on the Ion Exchange Resin with Acetylacetone

Takashi Okamura, Kunio Ohzeki, and Tomihito Kambara
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received November 19, 1974)

It was found that the cupric ions fixed on the resin are removed by acetylacetone(Hacac) to form bisacetylacetonatocopper(II), $Cu(acac)_2$. By the addition of a small amount of pyridine-water mixture to the copper(II) form resin in acetylacetone milieu, the cupric ions are quantitatively removed from the resin in the form of pyridine adduct, and the pyridinium ions are adsorbed on to the resin in place of the cupric ions. The reaction was successfully applied to the synthesis of $Cu(acac)_2$.

Recently, the conversion of a metal ion fixed on the ion exchanger to a chelate compound based on the ion exchange reaction in organic medium[1,2] has been studied. Higgins[1] developed the new preparation method of cesium lanthanoids hexafluoroacetylacetonates by treating the rare earth ion fixed on Dowex 50 with 0.4 mol/l of cesium hexafluoroacetylacetonate in 50% ethanol.

The authors[2] have reported the quantitative removal of iron(III) ions fixed on Amberlyst 15 by Hacac with the aid of the addition of a small amount of pyridine-water mixture. In this work, the reaction of the cupric ions fixed on Amberlyst 15 resin with Hacac is investigated and the conditions of the quantitative removal of the cupric ions are discussed. The reaction of Cu(II)-form resin with Hacac is shown by

$$(RSO_3)_2Cu + 2\,Hacac = 2\,RSO_3H + Cu(acac)_2 \qquad (1)$$

where R denotes the resin matrix.

Experimental

Apparatus and Reagents. A Hitachi 356 two-wavelength double beam spectrophotometer with 10-mm cells was used for the absorption measurement. A Hitachi 508 atomic absorption spectrophotometer was used for the copper absorption measurement at 324.8 nm in air-acetylene flame. Acetylacetone and pyridine, both of analytical grade (Wako Pure Chemical Inc.), were used without further purification.

Preparation of Copper(II)-Form Resin. The resin used is the sulfonic acid cation exchanger, Amberlyst 15, with a macroreticular structure. The commercially available Amberlyst 15 is crushed and sieved to a fraction of 60—80 mesh. The resin was converted to Cu(II)-form by treatment with 0.1 mol/l solution of cupric nitrate. The Cu(II)-form resin was washed with water, dried at 110 °C and then stored in a desiccator over phosphorus pentoxide.

Determination of Cupric Ions on the Resin. The cupric ions on the dried Cu(II)-form resin were eluted by 2 mol/l hydrochloric acid solution and determined by EDTA titration. It was found that 3.90 ± 0.13 meq of cupric ions were adsorbed onto 1 g of the dried Cu(II)-form resin.

Water Associated with Cu(II)-form Amberlyst Resin. It was pointed out that the water plays an important role in the reaction of β-diketone with metal ion fixed on the resin,[2] and so it is necessary to determine the water content in the oven-dried cupric form resin. The air-dried H-form resin is weighed in a glass filter and dried at 110 °C in oven until a constant weight, and then the resin is converted into cupric form and washed with deionized water, and the resulting resin is dried at 110 °C until a constant weight. Cupric ions fixed on the resin are eluted by 2 mol/l hydrochloric acid and determined by EDTA titration. The data obtained are summarized in Table 1. The ratio of exchange capacity of cupric ion to proton was 1.03. When the H-form resin is converted to Cu(II)-form, the increase in weight is expected, but as is shown in Table 1, the weight increase is larger than that of copper determined by titration. It may be safe to say that the difference is caused by water coordinated to the copper ion on the resin. Consequently, it is supposed that one molecule of water is coordinated to a copper(II) ion on the resin, such as $(RSO_3)_2Cu\cdot H_2O$.

Reaction of Cu(II)-Form Resin with Hacac. A portion of 3 ml of Hacac was poured onto the 40 mg of dried Cu(II)-form resin in a test tube and shaked by hand for 10 min. at room temperature (around 22 °C). After the filtration, the resin was washed with ethyl alcohol and water. The cupric ions remaining on the resin were eluted by 2 mol/l hydrochloric acid solution, and determined by atomic absorption spectrophotometry.

Results and Discussion

Effect of Pyridine. The reaction of $Cu(acac)_2$ with pyridine(py) has been investigated and the adduct formation of $Cu(acac)_2\cdot py$ has been reported.[3] Upon addition of pyridine to Hacac in contact with Cu(II)-form resins, the color of the solution turned from pale blue to green, indicating the formation of $Cu(acac)_2\cdot py$.

Table 1. Water associated with Cu(II)-form resin

Weight of H-form resin, taken (g)	Weight of resin converted into Cu-form, found (g)	Increase in weight (g)	Cu on resin, found by titration (mmol)	Weight increase calculated[a] (g)	Coordinated water estimated[b] (mmol)	Mole ratio H_2O/Cu
0.8146	0.9667	0.1521	1.83	0.1145	2.09	1.14
0.7366	0.8740	0.1374	1.71	0.1066	1.71	1.00
0.7273	0.8634	0.1361	1.74	0.1089	1.51	0.87

a) Provided that the non-hydrated cupric ion is adsorbed on the resin. b) If two mmol hydrogen ions on the resin are replaced by one mmol copper(II) ion, the increase in resin weight should be $(63.54-1.008\times2)$ mg, provided that no water molecule is coordinated to the cupric ion on the resin.

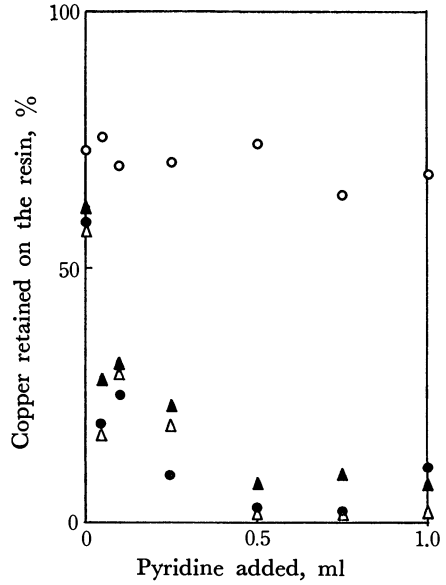

Fig. 1. Effect of pyridine and water.
The pyridine and water were added to 3 ml of Hacac in contact with 40 mg of Cu(II)-form resin. Water added, μl, 0(○), 10(▲), 25(●), 50(△).

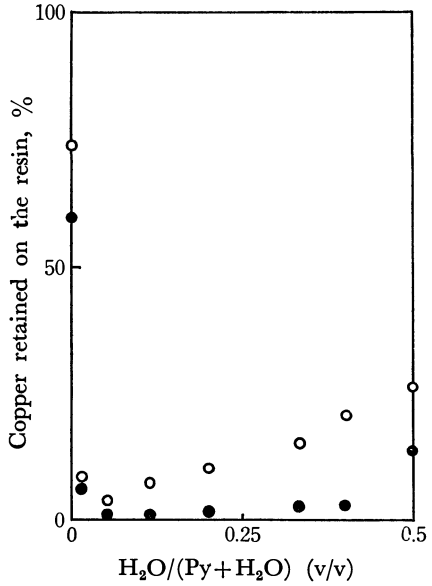

Fig. 2. Effect of the pyridine-water mixture with various ratios on the removal of the copper(II) from 40 mg of the Cu(II)-form resin with 3 ml of Hacac. The pyridine-water mixture added, 0.5 ml (○), 1 ml (●).

Nevertheless, the amount of the copper removed from the resin is hardly affected by the addition of pyridine to Hacac as shown in Fig. 1.

Effect of Pyridine and Water. The separate addition of pyridine or water does not effect remarkably, but the coexistence of them in Hacac is found highly effective for adduct formation, as shown in Fig. 2. More than 99% of copper ions are removed from the resin by addition of *ca.* 30 : 1 pyridine–water mixture to the extent of one-third of the volume of Hacac employed.

The dissociation of the Hacac is accelerated in the presence of pyridine–water mixture as shown by equations (2) and (3).

$$py + H_2O = pyH^+ + OH^- \quad (2)$$

$$Hacac + OH^- = acac^- + H_2O \quad (3)$$

Acetylacetonate anion withdraws the copper ion from the resin and pyridinium ion is adsorbed on the resin instead of monoaqua cupric ion and the resulting $Cu(acac)_2$ coordinates the excess pyridine to form $Cu(acac)_2 \cdot py$. The total reaction can be written as follows.

$$(RSO_3)_2Cu + 2\,Hacac + 3\,py \xrightarrow{H_2O} Cu(acac)_2 \cdot py + 2\,RSO_3Hpy \quad (4)$$

The air-dried Cu(II)-form resin, one gram of which contains 3.64±0.16 meq copper, has an appropriate amount of water, namely, around 10% by weight. Thus, there may occur the reaction shown by equation (4) even without addition of water. The various amounts of pyridine are added to 10 ml of Hacac containing 40 mg of air-dried Cu(II)-form resin. After the reaction, the resin is separated by filtration. The absorbance measurement of the filtrate at 655 nm *vs.* Hacac clearly reveals that the amount of copper liberated from the resin increases with increasing amount of pyridine added, as shown in Fig. 3.

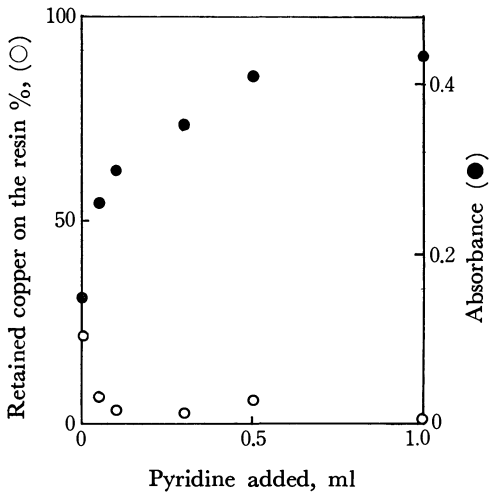

Fig. 3. Effect of pyridine on the air-dried resin.
The absorbance mesurement of the filtrate (●), and copper retained on the resin (○).

Application to the Synthesis of Chelate Compound. Treat 500 mg of air-dried Cu(II)-form resin with 10 ml of Hacac and add 3 ml of pyridine. After the reaction, separate the resin by filtration and wash it with Hacac containing appropriate amount of pyridine until the filtrate shows no color of $Cu(acac)_2 \cdot py$. Boil off the excess Hacac and pyridine by bubbling the nitrogen gas into the filtrate at 130 °C. In the course of this procedure, the adduct $Cu(acac)_2 \cdot py$ is decomposed to $Cu(acac)_2$, which is confirmed by color change of the chelate compound. The crude $Cu(acac)_2$ is purified

by sublimation at 175 °C under 1 mmHg. One obtains 0.209 g of $Cu(acac)_2$ in 85% yield. The result of elementary analysis was: Found: C, 45.84; H, 5.35%. Calcd for $Cu(acac)_2$: C, 45.89; H, 5.39%.

We wish to thank the Ministry of Education for financial support granted to this research.

Metal Complexes Containing Six-membered Chelate Rings V. Preparation and Structure of Oxalato Complexes of Cobalt(III) with Substituted 3,7-Diaza-1,9-nonanediamine Derived from 2,4-Pentanediamine[1]

Fujio MIZUKAMI*

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received July 10, 1974)

The syntheses, resolution and structure of three oxalato complexes of cobalt (III) with tetramine ligand, *R*(4), *R*(6)- and *R*(4), *S*(6)-4,6-dimethyl-1,9-nonanediamine (*RR*- and *RS*-2,3'', 2-tet), and *R*(6), *S*(8)-6,8-dimethyl-2,5,9,12-tetraazatridecane (*N,N'*-Me_2-*RS*-2,3'',2-tet) are reported. Only one geometrical isomer (*cis* β) was isolated for each complex, [Co(ox)(*N,N'*-Me_2-*RS*-2,3,'',2-tet)]$^+$, [Co(ox)(*RS*-2,3'',2-tet)]$^+$ and [Co(ox)(*RR*-2,3'',2-tet)]$^+$. The central six-membered chelate rings of $(-)_{546}$-*cis* β-[Co(ox)(*N,N'*-Me_2-*RS*-2,3'',2-tet]$^+$ and $(-)_{546}$-*cis* β-[Co-(ox)(*RS*-2,3'',2-tet)]$^+$ take a chair conformation with two equatorial methyl groups, and that of $(-)_{546}$-*cis* β-[Co-(ox)(*RR*-2,3'',2-tet)]$^+$ a chair conformation with an axial and equatorial methyl group.

Studies have been carried out on cobalt(III) complexes of 2,4-pentanediamine, a β-diamine with a methyl group on each α-carbon atom of trimethylenediamine.[2-5] Transition metal complexes containing 3,7-diaza-1,9-nonanediamine (2,3,2-tet) were investigated by Hamilton and Alexander and others.[6-14] However, few stereochemical studies have been carried out on the cobalt(III) complexes of tetramine involving a substituted trimethylenediamine part.[15] Complexes of cobalt(III) with 2,3,2-tet derivatives containing 2,4-pentanediamine part were prepared in order to elucidate the correlations between the configuration of asymmetric carbon and nitrogen atom, the conformation of the chelate ring, and the configuration about metal ion.

Only one isomer (*trans*) was isolated for each dichloro complex of cobalt(III) with tetramine ligand, *R*(4), *R*(6)- and *R*(4), *S*(6)-4,6-dimethyl-3,7-diaza-1,9-nonanediamine (*RR*- znd *RS*- 2,3'',2-tet) and *R*(6), *S*(8)-6,8-dimethyl-2,5,9,12-tetraazatridecane (*N,N'*-Me_2-*RS*-2,3'',2-tet).[1] This paper deals with the preparation of *cis* oxalato complexes of cobalt(III) each with tetramine, *N,N'*-Me_2-*RS*-2,3'',2-tet, *RS*-2,3'',2-tet and *RR*-2,3'',2-tet, and their stereochemistry on the basis of CD and PMR spectra.

Experimental

R(4),R(6)-, and *R(4),S(6)-4,6-dimethyl-3,7-diaza-1,9-nonanediamine* (RR-*2,3'',2-tet and* RS-*2,3'',2-tet)* and *R(6),S(8)-6,8-dimethyl-2,5,9,12-tetraazatridecane* (N,N'-*Me_2*-RS-*2,3'',2-tet)*: Prepared according to the method described previously.[1]

trans-[*$CoCl_2$*(RR-*2,3'',2-tet)*]*ClO_4*, trans-[*$CoCl_2$*(RS-*2,3'',2-tet)*]*ClO_4* *and* trans-[*$CoCl_2$*(N,N'-*Me_2*-RS-*2,3'',2-tet)*]*ClO_4*: Prepared according to the reported method.[1]

$(-)_{546}$-cisβ-[*Co(ox)*(RR-*2,3'',2-tet)*]*ClO_4*: A solution containing 0.7 g of *trans*-[$CoCl_2$(*RR*-2,3'',2-tet)]ClO_4 and 0.4 g of sodium oxalate in 40 ml of water was warmed at 65—70 °C for 2 hr. After being cooled to room temperature, the red crystals (I) were filtered off and washed with a small amount of cold water. The filtrate and washing were combined and concentrated to 10 ml in a vacuum desiccator over phosphorus pentoxide. A second crop of red crystals (II) was filtered off and washed with a small amount of cold water. Crystal II was found to be the same as crystal I on the basis of absorption, CD and PMR spectra. The crystals were recrystallized by evaporating the aqueous solution in a vacuum desiccator over phosphorus pentoxide. Yield: 0.6 g. Found: C, 30.44; H, 5.82; N, 12.91%. Calcd for $C_{11}H_{24}N_4ClO_8Co$: C, 30.39; H, 5.56; N, 12.89%.

Racemic-cisβ-[*Co(ox)*(RS-*2,3'',2-tet)*]*$ClO_4 \cdot H_2O$*: This was prepared from *trans*-[$CoCl_2$(*RS*-2,3''-2-tet)]ClO_4 (1.5 g) and sodium oxalate (0.5 g) by a similar method to that for corresponding *RR*-2,3,2-tet complex described above. Yield: 1.15 g. Found: C, 29.17; H, 6.24; N, 12.82%. Calcd for $C_{11}H_{26}N_4ClO_9Co$: C, 29.18; H, 5.79; N, 12.38%.

$(-)_{546}$-cisβ-[*Co(ox)*(RS-*2,3'',2-tet)*]$^+$ *Complex*: To a stirred solution of racemic-*cis*β-[Co(ox)(*RS*-2,3'',2-tet)]$ClO_4 \cdot H_2O$ (1 g) in 100 ml of water at 70 °C was added slowly 0.9 g of sodium hydrogen dibenzoyltartrate in 50 ml of hot water. After *ca.* two hr, the solution was evaporated to 50 ml at 70 °C under reduced pressure and cooled to room temperature. A deposited pink powder was filtered off. The powder was suspended in 50 ml of water at 60 °C, stirred for 30 min, and then filtered off. The insoluble material was treated further twice with warm water in the same way. The residue was dissolved in an appropriate amount of 10% perchloric acid, and gradually evaporated to remove less soluble dibenzoyltartaric acid and racemic-*cis*β-[Co(ox)(*RS*-2,3'',2-tet)]$ClO_4 \cdot H_2O$ which were filtered off occasionally. Evaporation was continued until the ratio of $\Delta\varepsilon$ and ε values of the filtrate became constant. More soluble, optically active, crystalline perchlorate was obtained from the final filtrate. However, it was contaminated with dibenzoyltartaric acid which could not be removed completely. Thus, the quantitative CD curve of $(-)_{546}$-*cis*β-[Co(ox)(*RS*-2,3'',2-tet)]$^+$ was determined by the aid of the ε values of racemate.

Racemic-cisβ-[*Co(ox)*(N,N'-*Me_2*-RS-*2,3'',2-tet)*]*$ClO_4 \cdot H_2O$*: A solution containing 1.2 g of *trans*-[$CoCl_2$(*N,N'*-Me_2-*RS*-2,3'', 2-tet)]ClO_4 and 0.36 g of sodium oxalate was warmed at 70 °C for 6 hr, and filtered while hot. The filtrate was cooled to room temperature and evaporated to 4 ml under reduced pressure in a vacuum desiccator over phosphorus pentoxide. The deposited crystals were filtered off, washed with a small amount of cold water and ethanol, and air-dried. The crystals were recrystallized from a small amount of hot water. Yield: 1.1 g. Found: C, 32.79; H, 6.56; N, 11.41%. Calcd for $C_{13}H_{30}N_4ClO_9Co$: C, 32.48; H, 6.29; N, 11.65%.

$(-)_{546}$- *and* $(+)_{546}$-cisβ-[*Co(ox)*(N,N'-*Me_2*-*RS-2,3'',2-tet)*]-*ClO_4*: Half a gram of racemic-*cis*β-[Co(ox)(*N,N'*-Me_2-2,3'', 2-tet)]$ClO_4 \cdot H_2O$ was dissolved in 70 ml of water at 70 °C. To the solution was added slowly 1 g of sodium hydrogen

* Present Address, National Chemical Laboratory for Industry (Tokyo Kogyo Shikensho), 1-1-5, Honmachi, Shibuya-ku, Tokyo 151.

dibenzoyltartrate in 50 ml of hot water and stirred for 1 hr. After being cooled to room temperature, a pink powder was filtered off to give crude dibenzoyltartrate salt of $(-)_{546}$-isomer. The filtrate was stored to obtain $(+)_{546}$-isomer. The powder dissolved in an appropriate amount of 10% perchloric acid at 65 °C and cooled to room temperature. The deposited crystals of dibenzoyltartaric acid were filtered off and the filtrate was allowed to stand for a while. The crude perchlorate of $(-)_{546}$-isomer was filtered off and recrystallized from water fractionally until the CD showed a constant curve. The filtrate free of pink powder was evaporated to 50 ml at 60 °C. To the solution was added slowly an appropriate amount of 60% perchloric acid and cooled to room temperature. The deposited crystals of dibenzoyltartaric acid were filtered off and the filtrate was allowed to stand for a while. The crude perchlorate of $(+)_{546}$-isomer was filtered off and recrystallized from water fractionally until the CD of $(+)_{546}$-isomer became constant. The pure optically active perchlorate is less soluble in water than the racemate. Found: C, 33.56; H, 6.59; N, 11.78%. Calcd for $C_{11}H_{24}N_4ClO_8Co$: C, 33.74; H, 6.10; N, 12.11%.

Measurements. Visible and ultraviolet absorption spectra were obtained with a Hitachi 124 recording spectrophotometer. The CD curves were recorded with a Model ORD/UV-5 JASCO spectrophtometer with a CD attachment. PMR spectra in D_2O were obtained with a Varian T-60 spectrometer using Na–TMS as an internal standard. The perchlorate salts of $(-)_{546}$-*cisβ*-[Co(ox)(*RR*-2,3″,2-tet)]$^+$ and $(-)_{546}$-*cisβ*-[Co(ox)(*N,N'*-Me_2-*RS*-2,3″,2-tet)]$^+$ were converted into chloride salts by use of the anion exchanger Dowex 1-X4 in chloride form. $(-)_{546}$-*cisβ*-[Co(ox)(*RS*-2,3″,2-tet)]$ClO_4 \cdot H_2O$ was converted into sulphate by treating with potassium sulphate, because of poor solubility of these complexes in D_2O. All the measurements were carried out at room temperature.

Results and Discussion

Structures of Complexes. Two geometrical isomers are possible for the oxalatotetramine complexes of cobalt(III). In the present study, however, only one could be isolated for [Co(ox)(*N,N'*-Me_2-*RS*-2,3″,2-tet)]$^+$, [Co(ox)(*RS*-2,3″,2-tet)]$^+$, and [Co(ox)(*RR*-2,3″,2-tet)]$^+$. Each complex was fractionally crystallized as a perchlorate salt, all the fractions being spectrophotometrically identical and giving the same pattern in the PMR spectra. Accordingly, the geometrical configuration for [Co(ox)(*N,N'*-Me_2-*RS*-2,3″,2-tet)]$^+$, [Co(ox)(*RS*-2,3″,2-tet)]$^+$ and [Co(ox)(*RR*-2,3″,2-tet)]$^+$ should be assigned to *cisα* or *cisβ*.

For [Co(ox)(*N,N'*-Me_2-*RS*-2,3″,2-tet)]$^+$, molecular models indicate that *cisα* isomer is a less stable form than *cisβ* in which the two *C*-methyl groups locate in the equatorial orientation and the central chelate ring takes a chair conformation (Table 1). For the *cisβ* form, four isomers can exist with respect to the orientation of the two *N*-methyl groups. Of the isomers, the form in which one methyl group on the in-plane nitrogen atom takes an axial orientation to the terminal five-membered chelate ring and the other on the out-plane nitrogen atom exists in an equatorial position to another terminal five-membered chelate ring, seems to involve smaller steric interaction than the other forms. Accordingly, [Co(ox)(*N,N'*-Me_2-*RS*-2,3″,2-tet)]$^+$ seems to be assigned to an enantiomeric pair of the structure (Fig. 1-a). The PMR spectrum of $(-)_{546}$-[Co(ox)(*N,N'*-Me_2-*RS*-2,3″,2-tet)]$^+$ is consistent with this assignment since two doublets at 1.2—2.2 ppm and two singlets at 2.2 ppm and 3.2 ppm are assigned to two kinds of *C*-methyl group and two kinds of *N*-methyl group, respectively (Fig. 3-b).

Table 1. Conformations of 2,4-pentanediamine part in tetramines

Ligand	Conformation		
	Chair	δ-skew-boat	λ-skew-boat
RR-2,3″,2-tet	a, e	a, a	e, e
RS-2,3″,2-tet	a, a e, e	a, e	a, e
N,N'-Me_2-*RS*-2,3″,2-tet	a, a e, e	a, e	a, e

a: methyl axial e: methyl equatorial.

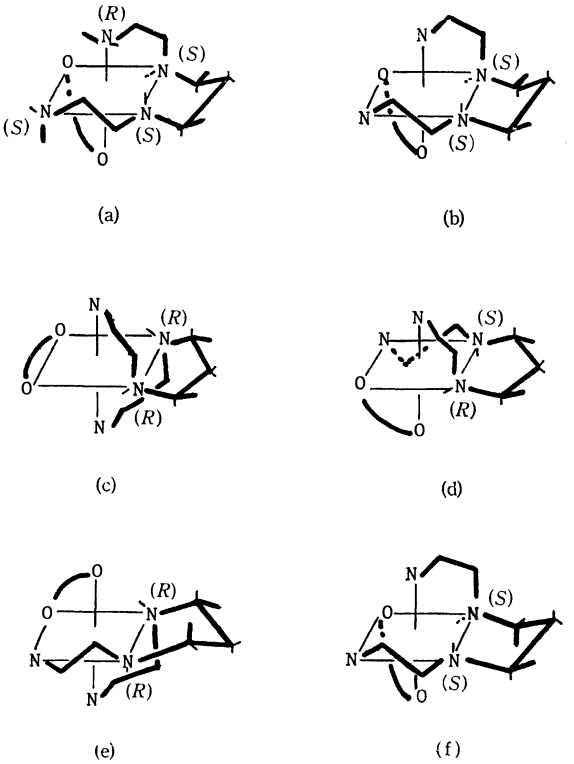

Fig. 1. Schematic structures of *cis*-[Co(ox)(2,3″,2-tet)]$^+$
(a) *Λ-cisβ-N(S),N(S),N(S),N(R)*-[Co(ox)(*N,N'*-Me_2-*RS*-2,3″,2-tet)]$^+$
(b) *Λ-cisβ-N(S),N(S)*-[Co(ox)(*RS*-2,3″,2-tet)]$^+$
(c) *Λ-cisα-N(R),N(R)*-[Co(ox)(*RR*-2,3″,2-tet)]$^+$
(d) *Λ-cisβ-N(R),N(S)*-[Co(ox)(*RR*-2,3″,2-tet)]$^+$
(e) *Λ-cisβ-N(R),N(R)*-[Co(ox)(*RR*-2,3″,2-tet)]$^+$
(f) *Λ-cisβ-N(S),N(S)*-[Co(ox)(*RR*-2,3″,2-tet)]$^+$

The CD spectra of the complexes prepared here are similar to the spectrum of $(+)_{546}$-*cisβ*-[Co(ox)(2,3,2-tet)]$^+$ which is assiged *Λ* configuration and in which the central six-membered chelate ring takes a chair conformation[9–11] (Fig. 2, Table 2). Similarity between the CD spectra of the four complexes strongly suggests that these complexes belong to the same chilarity. Thus, $(-)_{546}$-[Co(ox)(*N,N'*-Me_2-*RS*-2,3″,2-tet)]$^+$ should be assigned to the structure, *Λ-cisβ-N(S), N(S), N(S), N(R)*-[(*δ-gauche*)(chair)(*δ-gauche*)] (Fig.

(——) $(-)_{546}$-*cisβ*-[Co(ox)(*RR*-2,3″,2-tet)]ClO_4
(----) $(-)_{546}$-*cisβ*-[Co(ox)(*RS*-2,3″,2-tet)]$ClO_4\cdot H_2O$
(—·—) $(-)_{546}$-*cisβ*-[Co(ox)(*N,N′*-Me_2-*RS*-2,3″,2-tet)]-ClO_4 in H_2O.

l-a). This was substantiated by X-ray analysis of the crystalline $(-)_{546}$-[Co(ox)(*N,N′*-Me_2-*RS*-2,3″,2-tet)]ClO_4.[16]

$(-)_{546}$-[Co(ox)(*RS*-2,3″,2-tet)]$^+$ gives a CD curve similar to that of *Λ*-$(-)_{546}$-*cisβ*-[Co(ox)(*N,N′*-Me_2-*RS*-2,3″,2-tet)]$^+$ (Fig. 2). The *RS*-2,4-pentadiamine part of *RS*-2,3″,2-tet tends to take a chair conformation in the complex of cobalt(III) because of the steric regulation coming from the methyl groups in the six-membered chelate ring (Table 1).[1-5] The PMR spectrum of $(-)_{546}$-[Co(ox)(*RS*-2,3″,2-tet)]$^+$ is shown in Fig. 3-a. Two doublets at 1.4 ppm are assigned to two kinds of methyl signal. This seems to support the view that [Co(ox)(*RS*-2,3″,2-tet)]$^+$ takes *cisβ* configuration. Thus, $(-)_{546}$-[Co(ox)(*RS*-2,3″,2-tet)]$^+$ is assigned to the structure, *Λ-cisβ-N(S)*, *N(S)*-[(*δ-gauche*)(chair)-(*δ-gauche*)] (Fig. 1-b).

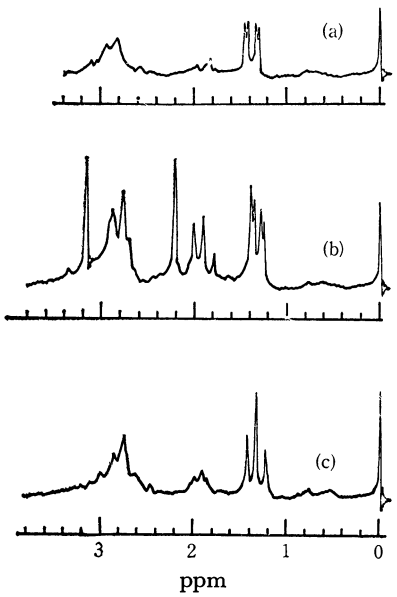

Fig. 3. PMR spectra of
(a) $(-)_{546}$-*cisβ*-[Co(ox)(*RS*-2,3″,2-tet)]$_2SO_4$
(b) $(-)_{546}$-*cisβ*-[Co(ox)(*N,N′*-Me_2-*RS*-2,3″,2-tet)]Cl
(c) $(-)_{546}$-*cisβ*-[Co(ox)(*RR*-2,3″,2-tet)]Cl in D_2O.

For the complex of $(-)_{546}$-[Co(ox)(*RR*-2,3″,2-tet)]$^+$, the central six-membered chelate ring adopts *λ* skew-boat conformation (Table 1) as long as the two methyl groups locate in the equatorial orientation. In this case, the probable structure of $(-)_{546}$-[Co(ox)(*RR*-2,3″,2-tet)]$^+$ are *Λ-cisβ-N(R)*, *N(S)* and *Λ-cis α-N(R)*, *N(R)* form (Figs. 1-c and 1-d). In the former structure, the two methyl groups are non-equivalent to each other, whereas, in the latter structure, they are equivalent to each other. If the central six-membered chelate ring forms a chair conformation, one methyl group locates in the equatorial orientation and the other takes axial position (Table 1). In this case, both structures *Λ-cisβ-N(R)*, *N(R)* and *Λ-cisβ-N(S)*, *N(S)* are possible for [Co(ox)(*RR*-2,3″,2-tet)]$^+$ (Figs. 1-e and 1-f). In these structure, the two methyl groups are non-equivalent to each other.

The CD spectrum of $(-)_{546}$-[Co(ox)(*RR*-2,3″,2-tet)]$^+$ is similar to that of *Λ*-$(-)_{546}$-*cisβ*-[Co(ox)(*N,N′*-Me_2-

RS-2,3″,2-tet)]$^+$ whose absolute configuration was determined by the X-ray method (Fig. 2).[16] Thus, [Co(ox)(*RR*-2,3″,2-tet)]$^+$ should be assigned to *Λ-cisα-N(R)*, *N(R)* or *Λ-cisβ-N(S)*, *N(S)* structure. The PMR spectrum of $(-)_{546}$-[Co(ox)(*RR*-2,3″,2-tet)]$^+$ gives a triplet signal which seems to be an accidental overlapping of two doublet signals due to the two methyl groups (Fig. 3-c). Thus, $(-)_{546}$-[Co(ox)(*RR*-2,3″,2-tet)]$^+$ is assigned to the structure, *Λ-cisβ-N(S)*, *N(S)*-[(*δ-gauche*)(chair)(*δ-gauche*)] (Fig. 1-f). The validity of this assignment was established by the X-ray method.[17]

The [Co(ox)(*RR*-2,3″,2-tet)]$^+$ was prepared by the reaction of $[Co(ox)_3]^{3-}$ and *RR*-2,3″,2-tet. The obtained crystals also have *Λ*-$(-)_{546}$-*cisβ-N(S)*, *N(S)* form as assigned above. These results lead to the conclusion that the *Λ*-$(-)_{546}$-*cisβ-N(S),N(S)* -[Co(ox)(*RR*-2,3″,2-tet)]$^+$ could be prepared stereospecifically.

Absorption Spectra. The absorption spectra of three oxalatotetramine cobalt(III) complexes are compared in Table 2 and Fig. 2. The absorption bands including the first and second band are shifted from longer to shorter wavelength, *i.e.* in the order $(-)_{546}$-*cisβ*-[Co(ox)(*N,N′*-Me_2-*RS*-2,3″,2-tet)]$^+$ $(-)_{546}$-*cisβ*-[Co(ox)(*RR*-2,3″,2-tet)]$^+$ and $(-)_{546}$-*cisβ*-[Co(ox)(*RS*-2,3″,2-tet)]$^+$. This is in line with the fact that the absorption bands of *trans*-[$CoCl_2$(*N,N′*-Me_2-*RS*-2,3″,2-tet)]$^+$ are shifted to longer wavelength compared with those *trans*-[$CoCl_2$(*RR*-2,3″,2-tet)]$^+$ and *trans*-[$CoCl_2$(*RS*-2,3″,2-tet)]$^+$.[1] At present, it is difficult to explain why the absorption bands of $(-)_{546}$-*cisβ*-[Co(ox)(*RR*-2,3″,2-tet)]$^+$ are shifted to longer wavelength than those of $(-)_{546}$-*cisβ*-[Co(ox)(*RS*-2,3″,2-tet)]$^+$. However, this result seems to be related to the structural stabilities of these complexes, since *Λ*-$(-)_{546}$-*cisβ-N(S)*, *N(S)*-[Co(ox)(*RR*-2,3″,2-tet)]$^+$ with an axial and equatorial methyl group is less stable than *Λ*-$(-)_{546}$-*cisβ-N(S)*, *N(S)*-[Co(ox)-(*RS*-2,3″,2-tet)]$^+$ with two equatorial methyl groups.

The author thanks Drs. S. Yano and M. Saburi for their valuable suggestions. Expenses for the work were defrayed by a grant-in-aid from the Ministry of Education.

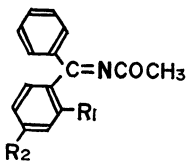
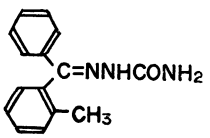
Photochemical Deuteration of *ortho*-Substituted *N*-(Diphenylmethylene)acetamides[1]

Masaru SAEKI, Naoki TOSHIMA, and Hidefumi HIRAI
Department of Industrial Chemistry, Faculty of Engineering
The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received April 15, 1974)

The alkyl hydrogens of *N*-(2-alkyldiphenylmethylene)acetamides were found to be readily replaced with deuterium on irradiation in deuteriomethanol (CH_3OD). It is proposed that the deuteration proceeds *via* an enamide isomer produced by intramolecular hydrogen transfer from the *o*-alkyl group to the excited C=N double bond. An intermolecular hydrogen atom abstraction pathway was excluded because neither *N*-(4-methyldiphenylmethylene)acetamide in deuteriomethanol(CH_3OD) nor diphenylmethane in deuteriomethanol(CH_3OD) in the presence of *N*-(diphenylmethylene)acetamide was deuterated. Intramolecular hydrogen abstraction is essential for the deuteration, because no deuteration occurs on irradiation of 2-methylbenzophenone semicarbazone which undergoes no photoreduction. The difference in reactivities of the *ortho*-substituted imines between in solution and in a rigid matrix is discussed from the viewpoint of *syn-anti* isomerization.

In previous papers we have reported that the imine **1** which has a C=N double bond conjugated with a carbonyl group undergoes photochemical reduction in hydrogen-donating solvents such as alcohol or ether,[2] and reduction and reductive addition in alkyl benzenes or aliphatic olefins.[3] In spite of the recent accumulation of reports of the photoreduction of simple imines,[2-5] its reduction pathway has not yet been unambiguously characterized. Fischer[4] and Padwa and others[6,7] have proposed that the reactive intermediates in these reactions are exclusively the excited states of the carbonyl compounds contained as impurities in the reaction mixtures. The lack of reactivity of the excited states of imines was explained by a feasible deactivation *via* *syn-anti* isomerization.[7] Nevertheless, it is still open to question whether this interpretation is applicable to different kinds of imine, *e.g.*, **1**.





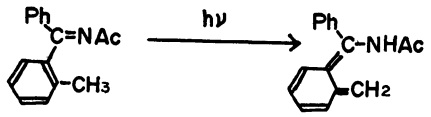
1; R_1=H, R_2=H **4**
2a; R_1=CH_3, R_2=H
2b; R_1=$CH_2C_6H_5$, R_2=H
3; R_1=H, R_2=CH_3

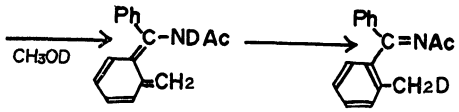
We expected that participation of an impurity in the hydrogen abstraction reaction could be prevented by setting the hydrogen-accepting imino group and the hydrogen-donating alkyl group in one molecule. *N*-(2-Methyldiphenylmethylene)acetamide (**2a**), *N*-(2-benzyldiphenylmethylene)acetamide (**2b**), and *N*-(4-methyldiphenylmethylene)acetamide (**3**) were prepared and the photogenerated intermediates were detected by the exchange of hydrogen in the alkyl group with deuterium in deuteriomethanol (CH_3OD). Changes in the absorption spectra during irradiation and the photochemical behavior of 2-alkylbenzophenone semicarbazone (**4**) were investigated as well.

Results and Discussion

Deuteration. The 2- (**2a**) and 4-methyl (**3**) substituted *N*-(diphenylmethylene)acetamides were prepared and photochemically deuterated at the 2- and 4-methyl positions. A solution of each compound in a deuteriomethanol(CH_3OD)–benzene mixed solvent was irradiated with light of wavelength longer than 320 nm at room temperature for 8 hr. After irradiation, the solvent was removed and the NMR spectrum of the recovered imine was measured. The spectrum of the recovered **2a** revealed that 0.30±0.09 atoms of deuterium per molecule were incorporated in the 2-methyl group of **2a**, while no deuteration was observed in **3**. This striking contrast is apparently due to the difference between the geometrical positions of the hydrogen-donating methyl groups. In other words, this is an example of the *ortho*-effect. It is also noteworthy that the acetyl hydrogens in **2a** or **3** remained undeuterated throughout the above irradiations.

Mechanism of Deuteration. The lack of deuteration of **3** indicates that some intramolecular interaction between the *N*-acetylimino group and the 2-methyl group of **2a**, possibly intramolecular hydrogen atom abstraction *via* a six-membered cyclic transition state formation, is involved in the photodeuteration of **2a**.





The following experiment showed that the deuteration of **2a** does not proceed *via* an intermolecular hydrogen atom abstraction. Thus diphenylmethane and imine **1** were used as a hydrogen donor and an acceptor, respectively, for a typical intermolecular reaction. When a solution of diphenylmethane and **1** in deuteriomethamol(CH_3OD)–benzene was irradiated at room temperature, even after irradiation for 86 hr NMR and mass spectra showed no evidence of deuteration. This shows that the deuteration of **2a** must proceed *via* an intramolecular hydrogen abstraction pathway.

Furthermore, the participation of the hydrogen abstraction in the deuteration was confirmed by studying the photochemical behavior of 2-methylbenzophenone semicarbazone (**4**). Generally, it is known that irradiation of *N*-acylimines in hydrogen donors results in reduction of the C=N double bond, but no photoreductions of semicarbazones have been reported yet. In fact, semicarbazone **4** gave no photoreduction product. As might have been expected from the inability of semicarbazones to abstract a hydrogen atom photochemically, no deuteration of **4** was observed after irradiation for 20 hr in deuteriomethanol(CH_3OD). This result indicates that the deuteration of **2a** results from hydrogen abstraction in its excited state.

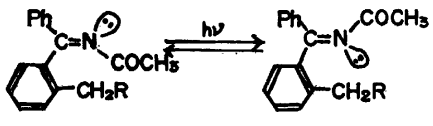
Attempts of Spectrophotometrical Detection of Intermediate. 2-Methylbenzophenone (**5a**) isoelectronic with the imine **2a**, is known to undergo photochemical deuteration, which has been interpreted as the consequence of the hydrogen-deuterium exchange between deuteriomethanol(CH_3OD) and the enol isomer of **5a** generated by the intramolecular hydrogen atom transfer.[8,9] This photoenol was detected spectrophotometrically as a colored species which was stable only at low temperature. It was, therefore, expected that upon irradiation at 77 K the imine **2a** would also produce the corresponding enamide which might be detected as a colored species in a rigid matrix. Since it was not possible to eliminate the impurity **5a** completely from the liquid **2a**, the crystalline 2-benzyl derivative **2b** was used for measuring the absorption spectra of the reaction system. The imine **2b** was carefully recrystallized several times from dry cyclohexane. 2-Benzylbenzophenone (**5b**), as well as **5a**, has also been reported to generate a colored species at low temperature and to undergo deuteration upon irradiation.[9]

A solution of **2b** in an alcoholic solvent was irradiated and the change in the absorption spectrum of the reaction mixture was followed. At room temperature no color change was observed. At 77 K in the matrix, the colored enol of the impurity **5b** was often observed (λ_{max} 430—480 nm) when insufficiently purified **2b** was used. However more careful purification removed the coloration completely. When a small amount of water was added to the purified sample which was subsequently allowed to stand at room temperature for 48 hr, coloration due to **5b** produced by the hydrolysis of **2b** was again observed at 77 K. Furthermore, a solution of unpurified **2a** in an alcoholic solvent gave a colored species (λ_{max} 405 nm and 430 nm) on irradiation at 77 K, but the coloration was removed by addition of phenylhydrazine to the system. Phenylhydrazine would react with the impurity **5a** to give a less reactive species, phenylhydrazone. As described above, it was concluded that the observed colorations were due to the photoenols of impurities.[10] An attempt to detect the intermediate enamide spectroscopically was unfortunately unsuccessful. This observation, however, is not in conflict with the contention that the enamides are involved in deuteration, as discussed in the next section.

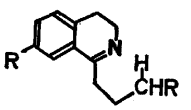
In order to examine the influence of impurities, the deuteration of the impurity-free **2b** was rigorously checked. A solution of impurity-free **2b** in a deuteriomethanol(CH_3OD)–toluene solvent was first irradiated at 77 K to check the absence of the coloration due to the impurity. Then the irradiation was continued at room temperature for 20 hr. The amount of deuterium contained in the recovered **2b** was found by NMR spectroscopy to be 0.3 atom per molecule in good agreement with the figure determined by mass spectroscopy. The deuterium atom was found to be located at the benzylic position. It was, therefore, concluded that the deuteration of the *ortho*-substituted imines **2** proceeded indeed *via* the excited states of **2** and that the impurity, a ketone, did not participate in the deuteration *via* a chemical sensitization mechanism.

Intramolecular Hydrogen Atom Abstraction and Molecular Geometry of 2. Padwa and Dharan[6] claimed that irradiation of simple imines resulted in isomerization about the C=N double bond which dissipated the excitation energy and resulted in inhibition of hydrogen abstraction by the excited imine. The results of the present study, however, showed that hydrogen abstraction is indeed able to proceed when the hydrogen-donating alkyl group is located at a geometrically and consequently kinetically preferable position within the molecule. Moreover it has been found in our laboratory and will be reported in a separate paper[11] that the excited state of imine **1** also underwent hydrogen abstraction to a considerable extent even without any chemical sensitizers. The deuteration of the *ortho*-alkyl groups in **2** provided strong evidence for the participation of the excited states of these imines (**1** and **2**) in the hydrogen abstraction.

It was necessary to consider the molecular geometry of **2** to discuss the geometrical features of the hydrogen abstraction. Several reports on the *syn-anti* isomerization of asymmetric benzophenone imines in solution showed that the *para*-substituted derivatives[12] mostly undergo rapid isomerization at room temperature whereas the *ortho*-substituted ones[13] exist exclusively in the *syn*(*Z*)-form. This would be the case in *ortho*-substituted **2a** and **2b**, shifting the equilibrium to the *syn(Z)*-form. The fact that the intermediate enamide was not detected even at low temperature can be reasonably explained as follows. Because the lone pair of the nitrogen atom in *syn(Z)*-**2** is in position opposite to the *ortho*-alkyl group and also the isomerization of *syn(Z)*-**2** to the *anti(E)*-isomer is prevented at



syn(*Z*)-**2** *anti*(*E*)-**2**



6

77 K in a rigid matrix, the excitation energy is dissipated by radiative or radiationless processes without hydrogen abstraction.[14] In fact, no deuteration could be detected on irradiation of **2a** at 77 K, which is consistent with the absence of coloration of the pure imine.[15] On the contrary, irradiation of **2** at room temperature in solution results in the formation of the *anti(E)*-isomer by rotation about the C=N double bond.[16] The excited state of the *anti(E)*-isomer is supposed to be the active species in the hydrogen abstraction and the photochemical deuteration. In fact, Ogata[17] and Stermitz[18] reported that azomethine **6** undergoes photochemical intramolecular hydrogen abstraction.

Experimental

General. Ultraviolet spectra were recorded on a Shimadzu MPS-50L spectrophotometer. Infrared spectra were taken as liquid film or in Nujol mulls on a Jasco IR-E spectrophotometer. Nuclear magnetic resonance spectra were taken on a Japan Electron Optics Laboratory Model PS-100 spectrometer using tetramethylsilane as the internal standard. The mass spectra were recorded on a Hitachi RMS-4 mass spectrometer, in which the ionization energy was 80 eV. The samples were injected directly at 120 °C or injected through a Hitachi 063 gas chromatograph (SE30, 3 mmϕ × 2 m, 225 °C). Melting points were determined with a Yanagimoto micro melting point apparatus. All irradiations were carried out in a quartz reactor equipped with a Ushio type 501C 500W ultrahigh pressure mercury lamp through a glass filter transparent to wavelengths longer than 320 nm.

Materials. Monodeuteriomethanol(CH_3OD) was obtained from Merck. Benzene, toluene, and cyclohexane were dried over metallic sodium, methanol over magnesium, and 2-propanol over barium oxide, and distilled. Diphenylmethane was recrystallized from petroleum ether.

N-(Diphenylmethylene)acetamide (***1***) was prepared in the usual way.[19] *N*-Acetylation was carried out with acetic anhydride.

N-(2- or 4-Methyldiphenylmethylene)acetamide (***2a*** *or* ***3***) was prepared by the coupling of benzonitrile with the Grignard reagent of the corresponding bromotoluene,[19] followed by *N*-acetylation with acetic anhydride. **2a**: bp, 152 °C (1 mmHg); IR (liquid film): 1690(C=O), 1640(C=N) cm^{-1}; NMR(CCl_4): δ 1.9(acetyl CH_3), 2.2(CH_3), 7.1—7.8 (9H, aromatic ring protons). **3**: IR(liquid film): 1690(C=O), 1640(C=N) cm^{-1}; NMR(CCl_4): δ 1.9 (acetyl CH_3), 2.3(CH_3), 7.0—7.6(9H, aromatic).

*N-(2-Benzyldiphenylmethylene)acetamide(**2b**).* The Grignard coupling of bromobenzene and 2-chlorobenzyl chloride gave 2-chlorodiphenylmethane.[20] 2-Chlorodiphenylmethane was refluxed in pyridine in the presence of cuprous cyanide to give 2-benzylbenzonitrile.[21] A solution of 20 g of 2-benzylbenzonitrile in 50 ml of dry diethyl ether was added to the Grignard reagent prepared from 15.7 g of bromobenzene and 2.5 g of magnesium in 100 ml of diethyl ether. The reaction mixture was refluxed for 6 hr, cooled, decomposed with 100 ml of methanol, and filtered. The solvent was evaporated and the residue was distilled under reduced pressure to give 2-benzyldiphenylmethyleneimine; 22% yield; bp, 200 °C(1 mmHg); IR(liquid film): 3240(NH), 1605(C=N) cm^{-1}; NMR(CCl_4): δ 3.8(CH_2), 6.9—7.7(14H, aromatic), 8.6(NH); Anal.: Found: C, 86.65; H, 6.00; N, 4.94%. Calcd for $C_{20}H_{17}N$: C, 88.52; H, 6.32; N, 5.16%.[22] This imine was easily acetylated with acetic anhydride to give *N*-(2-benzyldiphenylmethylene)acetamide. Careful recrystallization from cyclohexane was repeated several times until impurity-free white crystals were obtained: bp, 205 °C (1 mmHg); mp, 100—101 °C; Mass: m/e=313; IR(Nujol mull): 1690(C=O), 1640(C=N) cm^{-1}; λ_{max}^{MeOH} (log ε_{max}):

Table 1. Results of the photodeuteration in deuteriomethanol(CH_3OD)

Compound	Irr. time (hr)	Analysis: Method	Analysis: Observed value (Calcd value)	Deuterium content (%)

a) The NMR spectra were taken in CCl_4 at room temperature. b) Recovered diphenylmethane (**Dm**) was analyzed in this run. c) The figure in the parentheses is the ratio calculated from the natural isotope abundance. d) Toluene was used in this run instead of benzene as a solvent. e) The corresponding ketone was completely eliminated from the starting material and dry toluene was used instead of benzene in this case.

215(4.54), 234(4.40), 253(4.40), 372(sh)(0.97), 382(0.66), 392(0.66)nm; NMR(CCl_4): δ 1.8(acetyl CH_3), 3.8(CH_2), 6.9—7.6(14H, aromatic). Anal.: Found: C, 84.48; H, 6.09; N, 4.44%. Calcd for $C_{22}H_{19}NO$: C, 84.31; H, 6.11; N, 4.47%.

2-Methylbenzophenone Semicarbazone(4) To a solution of 1 g of semicarbazide hydrochloride and 1.5 g of sodium acetate in 10 ml of water was added 10 ml of ethanol containing 1 g of 2-methylbenzophenone. Ethanol was added until the mixture became transparent. The solution was heated for half an hour and allowed to stand at room temperature over a period of several days. A new crystalline compound **4** was separated from the reaction mixture and recrystallized from ethanol: mp, 156—157 °C; Mass: *m/e*= 253; IR(Nujol mull): 3300(NH), 1680(C=O)cm^{-1}; NMR (CCl_4): δ 2.2(CH_3), 6.0(NH, NH_2), 7.5(9H, aromatic). Anal.: Found: C, 71.19; H, 5.92%. Calcd for $C_{15}H_{15}N_3O$: C, 71.11; H, 5.98%.

Deuterium Exchange. Usually 2 ml of a deuteriomethanol (CH_3OD)-benzene solvent containing 100—500 mg of an imine was degassed and pure nitrogen was introduced until the system reached atmospheric pressure for experimental convenience. After being irradiated at room temperature in a quartz tube, the starting material was recovered and analyzed by NMR and mass spectroscopy. The results are summarized in Table 1.

Irradiation at Low Temperature. Unless otherwise mentioned, an oxygen-free 10^{-1} mol/l solution of the substrate in 4 ml of a methanol-2-propanol (1 : 1) solvent was irradiated at 77 K in a quartz cell with light of wavelengths longer than 320 nm. Changes in the absorption spectra were measured at 77 K in a quartz Dewar filled with liquid nitrogen.

16) The preceding discussion was developed on the assumption that the n-orbital on the nitrogen atom is operative in the hydrogen abstraction. The participation of the n-orbital on the oxygen atom could not be eliminated by the present study. In this case, hydrogen abstraction must proceed *via* an eight-membered cyclic transition state and the lack of coloration in the matrix must be interpreted as due to the loss of flexibility of the C=N-C=O chromophore to form an eight-membered cyclic transition state.

22) Since this imine is easily hydrolyzed, it contains 2-methylbenzophenone inevitably. This causes the discrepancy of the elemental analysis.

Reactions of Sulfenes with Schiff Bases. The Stereochemistry and Thermal Fragmentation of Thiazetidine 1,1-Dioxide

Tetsuo HIRAOKA and Takeo KOBAYASHI

Central Research Laboratories, Sankyo Co., Ltd. Hiromachi, Shinagawa-ku, Tokyo 140

(Received April 17, 1974)

Phenylsulfene (II) generated from benzylsulfonyl chloride (I) and triethylamine, reacted with *N*-(*p*-substituted)-benzylidene-methylamine to give 2-methyl-4-phenyl-3-(*p*-substituted-phenyl)-1,2-thiazetidine 1,1-dioxide whose *cis* and *trans* isomers were separated. Both *cis* and *trans* 3,4-diphenyl-2-methyl-1,2-thiazetidine 1,1-dioxide (IV and V) afforded *trans* stilbene and benzaldehyde on pyrolysis. This new fragmentation reaction could be explained by a stepwise decomposition because of its non-stereospecificity.

Although heterocyclic four-membered ring compounds have been well investigated,[1] little is known about 1,2-thiazetidine 1,1-dioxide due to the scarcity of synthetic examples. Whereas thermal [2+2] cycloaddition reactions for the synthesis of this four-membered saltam have been reported,[2] no stereochemical aspects are known. This report deals with reactions of sulfenes with Schiff bases and the synthesis of 1,2-thiazetidine 1,1-dioxide derivatives which sheds light on the stereochemistry and a thermal fragmentation.

Phenylsulfene (II) generated from benzylsulfonyl chloride (I) and triethylamine in tetrahydrofuran was treated with *N*-benzylidene-methylamine (III) to give 3,4-diphenyl-2-methyl-1,2-thiazetidine 1,1-dioxide whose *cis* (IV) and *trans* (V) isomers were separated by silica gel chromatography. This is the first instance of isolation of the both stereoisomers in thiazetidine 1,1-dioxide system. The other components of the reaction mixture were the starting Schiff base and stilbene which has been known to be derived from phenylsulfene.[3] Similarly substituted *N*-benzylidene-methylamine afforded the desired four-membered saltams, whose physical data are summarized in Table 1. The determination of the structures was made on the basis of NMR data which showed a typical AB type quartet due to hydrogens at 3 and 4 positions. The assignment of *cis* and *trans* isomers was also based on the coupling constants between C^3-H and C^4-H. The difference between J_{cis} and J_{trans} is relatively small (1.5—2.0 Hz), leaving the possibility of a misassignment which was pointed out by Fleming and Williams[4] in four-membered carbocyclic ring systems. The validity of these *cis* and *trans* assignments is supported by the following chemical interconversions. Heating the *cis*

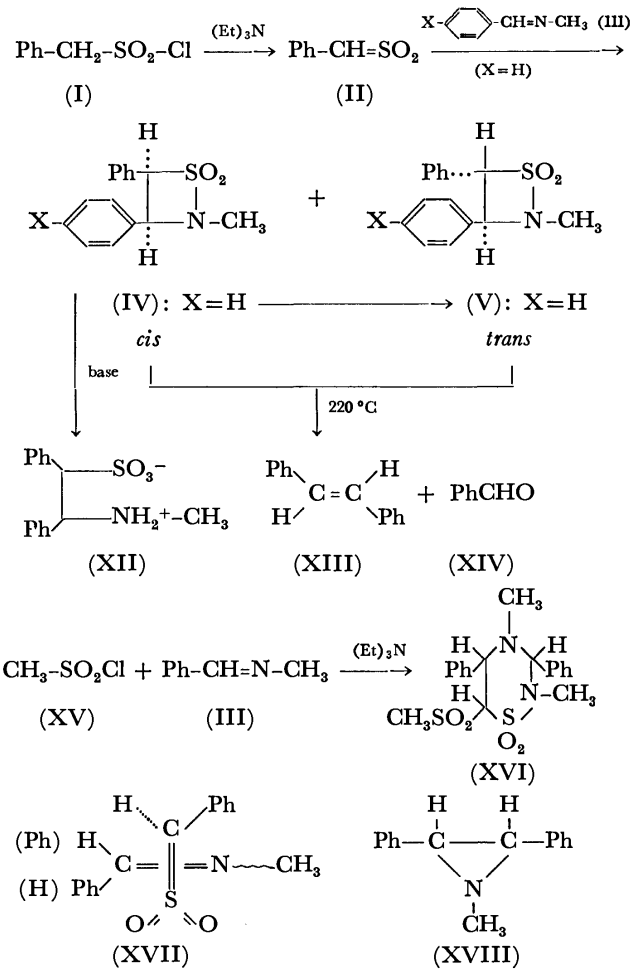

Chart 1.

TABLE 1. 1,2-THIAZETIDINE 1,1-DIOXIDE

Compound X			NMR spectra[a]					
			Mp (°C)	N-CH_3	C_3-H	C_4-H	$J_{3,4}$(Hz)	aromatic H

isomer(IV) in tetrahydrofuran in the presence of triethylamine for 15 hr gave a mixture of the *cis* (IV) and *trans* isomer (V) in a ratio of 4 : 1, whereas the same treatment of the *trans* compound (V) afforded the unchanged starting material together with a trace amount of the *cis* isomer (IV).

The yields of these 1,2-thiazetidine 1,1-dioxides changed significantly depending on the reaction conditions. The best result was obtained when two equivalents of Schiff base and one equivalent of benzylsulfonyl chloride were used without triethylamine or another base (Table 2).

Table 2. Formation of 1,2-thiazetidine 1,1-dioxides from benzylsulfonyl chloride and Schiff bases in THF

Schiff base	Reaction conditions	Yield[c]	Ratio[d] *cis* : *trans*
Ph-CH=N-CH_3	A[a]	17.5%	64 : 36
	B[b]	80.0%	61 : 39
p-Cl-Ph-CH=N-CH_3	A	14.6%	62 : 38
	B	88.3%	58 : 42
p-CH_3O-Ph-CH=N-CH_3	A	16.7%	68 : 32
	B	79.7%	64 : 36
p-NO_2-Ph-CH=N-CH_3	A	12.3%	60 : 40
	B	51.7%	52 : 48

a) Molar ratio of benzylsulfonyl chloride-Schiff base-triethylamine=1 : 1 : 1, −78 °C, 5 hr, then, allowed to warm slowly to room temperature and kept at this temperature overnight. b) Molar ratio of benzylsulfonyl chloride-Schiff base=1 : 2, room temperature, 42 hr. When the reaction was stopped after 18 hr, 10—30% decrease of yields was observed. c) Otained from NMR data. The reactions were carried out using 0.05 equivalents of hexamethylbenzene as an internal standard for NMR analysis. The isolated yields were given in experimental part. d) Calculated from NMR data.

The preferred formation of the *cis* isomer over the *trans* isomer in the reaction of the sulfene with the Schiff base suggests that the reaction would be a concerted [$_\pi 2_s + _\pi 2_a$] cycloaddition (depicted as XVII) with some secondary effects.[5]

Treatment of the saltam (IV) with sodium methoxide in methanol and subsequent work-up with hydrochloric acid gave 1,2-diphenyl-2-methylamine-ethanesulfonic acid (XII). This ring cleavage presents a striking contrast with a base-catalyzed ring opening of four-membered saltam, in which 2—3 bond fission took place.[2b,2c]

According to the literature[3] the structures of the products obtained by the reactions of sulfene with Schiff bases have not been established. In our experiments only phenylsulfene afforded a four-membered sulfonamide, and alkyl sulfenes gave many products whose structures could not be clarified at this time. In the case of unsubstituted sulfene the reaction proceeded in a different way. Methanesulfonyl chloride was treated with *N*-benzylidene-methylamine in tetrahydrofuran in the presence of triethylamine to yield a crystalline substance, mp 181—182 °C. The NMR spectrum of this compound exhibited peaks at 1.87 (3H, singlet), 2.84 (3H, singlet), 2.85 (3H, singlet), 4.39 (1H, doublet, J=9.0Hz), 4.83 (1H, doublet, J=9.0Hz), and 5.30ppm (1H, singlet), in addition to aromatic hydrogen peaks (10H, multiplet). This fact suggests that 2 mol of sulfene and 2 mol of Schiff base were incorporated into the product. The molecular ion peak at *m/e* 394 in the mass spectrum supported this inference. When this reaction was carried out in acetonitrile instead of tetrahydrofuran the yield of the product increased appreciably, suggesting the involvement of a dimeric sulfene: similarly Optiz[6] observed O_2S=CH-SO_2-CH_3 was formed from methanesulfonyl chloride and triethylamine in acetonitrile. Degradation of this product with hydrochloric acid gave methylamine hydrochloride, and treatment with sodium hydroxide afforded benzylalcohol, which was not helpful in the elucidation of the structure. From these facts we propose the structure (XVI) *i.e.* 2,4-dimethyl-3,5-diphenyl-6-methylsulfonyl-tetrahydro-1,2,4-thiadiazine 1,1-dioxide for the reaction product from methanesulfonyl chloride and *N*-benzylidene-methylamine. The measurement of nuclear Overhauser effect of XVI in NMR also suported this structure. This NOE results are shown in Fig. 1, together with the stereochemistry.

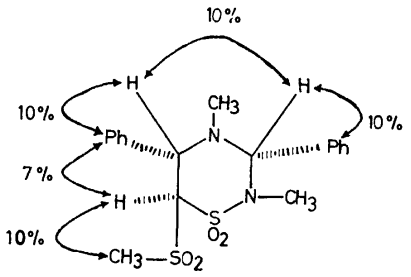

Fig. 1. Nuclear Overhauser effect of XVI.

Next our attention was directed towards thermal fragmentation reaction of such four-membered saltams. Pyrolysis of the *cis* saltam (IV) at 220 °C in nitrogen atmosphere yielded *trans*-stilbene (XIII) (37% yield) and benzaldehyde (XIV) (5% yield) together with the unchanged starting material (*ca* 10%). Analogously heating the *trans* isomer (V) at the same temperature afforded also *trans*-stilbene (XIII) and benzaldehyde (XIV) in 7% and 8% yield, respectively, in addition to the starting *trans* compound (V) (*ca* 7%) and polymeric substance. Recovery of a part of the unchanged *cis* (IV) and the *trans* saltam (V) indicates no interconversions between the two isomers during pyrolysis. Under these reaction conditions (220 °C, 2 hr) *cis*-stilbene gave a mixture of *cis* and *trans* stilbene (3 : 2), whereas *trans*-stilbene isomerized to a negligible amount of *cis*-stilbene (vpc analysis). Thus the formation of *trans*-stilbene from both *cis*-and *trans*-thiazetidine dioxide took place non-stereospecifically. This thermal fragmentation exhibits a striking contrast to that of β-lactams wherein cleavage leading to an olefinic compound proceeded with total retention of stereochemistry.[7] The concerted fragmentation of a four membered ring is only symmetry allowed in the case of [$_\sigma 2_s + _\sigma 2_a$] pathway,[5] which is not apparently applicable to the present cleav-

age reaction. A mechanistic possibility might be the extrusion of sulfur dioxide from the four-membered saltam to give an aziridine derivatives, which will subsequently afforded stilbene by a cheletropic reaction.[5] This route seems reasonable since thietane has been known to lose sulfur dioxide to give a cyclopropane derivatives.[8] However, to our knowledge, no aziridine derivative produces an olefinic compound without its conversion to the corresponding *N*-oxide.[9] In order to clarify this point *cis*-2,3-diphenyl-1-methylaziridine (XVIII) was prepared according to the literature.[10] The compound (XVIII) was pyrolyzed under the same conditions as in the case of IV and V to afford an unidentified mixture with a trace amount of *trans*-stilbene (XIII), thus excluding the intermediacy of XVIII. At present, the fragmentation of IV and V could be explained by a stepwise decomposition as in the case of cyclobutane derivatives.[11] An intermediate leading to benzaldehyde is not clear at present time.

The mass spectra of IV and V are interesting in connection with their thermal reactions. The peak due to (M^+–SO_2) appeared in medium intensity, and (M^+–SO_2–H) peak constituted a base peak. A fragment corresponding to stilbene was not observed, whereas a peak assignable to Ph–C≡N^+–CH_3 was very strong.

Experimental

All melting points were determined in open capillaries and are uncorrected. IR spectra were measured with a Hitachi IRA-2 spectrophotometer. NMR spectra were recorded on a Varian D-60 spectrometer.

General Procedure for Reactions of Sulfonyl Chlorides with N-p-*substituted-Benzylidene-methylamine.* A stirred solution of 0.01 mol of the *N-p*-substituted-benzylidene-methylamine and 0.01 mol of triethylamine in 25 ml of a dry solvent, under slight pressure of dry nitrogen, was maintained at −78 °C while a solution of 0.01 mol of a sulfonyl chloride in 5 ml of a dry solvent was slowly added over a period of 30 min. Usually triethylamine hydrochloride separated immediately. The resulting suspension was allowed to warm slowly to room temperature and was then stirred overnight. The solid (triethylamine hydrochloride) was removed by filtration and washed with a small amount of a solvent. The filtrate and washings were combined and concentrated under reduced pressure. The residue, oil or crystals, was purified by column chromatography using silica gel or alumina. Recrystallization from a suitable solvent gave a desired compound.

*2-Methyl-3,4-diphenyl-1,2-thiazetidine 1,1-Dioxide (*cis *IV and* trans *V).* Under the general procedure with THF as solvent, *N*-benzylidene-methylamine (1.19 g) and benzylsulfonyl chloride (1.91 g) in the presence of triethylamine (1.01 g) gave a mixture of IV and V. The mixture was purified by column chromatography using silica gel (solvent: benzene) to give 222 mg (after recrystallization from isopropyl ether) of *cis*-isomer IV and 70 mg (after recrystallization from ethanol) of *trans*-isomer V; 10.7% yield, *cis*-isomer (IV): mp 147—148 °C; IR (Nujol) 1142 and 1303 (SO_2) cm^{-1}; NMR see Table 1. (Found: C, 65.78; H, 5.59; N, 5.21; S, 11.67%. Calcd for $C_{15}H_{15}NO_2S$: C, 65.91; H, 5.53; N, 5.12; S, 11.73%), *trans*-isomer (V): mp 81—82 °C; IR (Nujol) 1160 and 1303 (SO_2) cm^{-1}; NMR see Table 1. (Found: C, 66.11; H, 5.52; N, 5.29; S, 11.76%. Calcd for $C_{15}H_{15}NO_2S$: C, 65.91; H, 5.53; N, 5.12; S, 11.73%).

*3-*p*-Chlorophenyl-2-methyl-4-phenyl-1,2-thiazetidine 1,1-Dioxide (*cis *VI and* trans *VII).* Analogously *N-p*-chlorobenzylidene-methylamine (1.54 g) and benzylsulfonyl chloride (1.91 g) in THF with triethylamine (1.01 g) gave a mixture of VI and VII. The mixture was purified by column chromatography using silica gel (solvent: benzene) to give 199 mg (after recrystallization from isopropyl ether) of *cis*-isomer VI and 117 mg (after recrystallization from ethanol) of *trans*-isomer VII; 10.2% yield, *cis*-isomer (VI): mp 154—155 °C; IR (Nujol) 1120 and 1308 (SO_2) cm^{-1}; NMR see Table 1. (Found: C, 58.77; H, 4.54; N, 4.67; S, 10.51; Cl, 11.58%. Calcd for $C_{15}H_{14}NO_2SCl$: C, 58.53; H, 4.58; N, 4.55; S, 10.42; Cl, 11.52%), *trans*-isomer (VII): mp 89—90 °C; IR (Nujol) 1092 and 1298 (SO_2) cm^{-1}; NMR see Table 1. (Found: C, 58.73; H, 4.58; N, 4.78; S, 10.56; Cl, 11.64%. Calcd for $C_{15}H_{14}NO_2SCl$: C, 58.53; H, 4.58 N, 4.55; S, 10.56; Cl, 11.64%).

*3-*p*-Methoxyphenyl-2-methyl-4-phenyl-1,2-thiazetidine 1,1-Dioxide (*cis *VIII and* trans *IX).* According to the general procedure, *N-p*-methoxybenzylidene-methylamine (1.49 g) and benzylsulfonyl chloride (1.91 g) with triethylamine (1.01 g) afforded a mixture of VIII and IX. The mixture was purified by column chromatography using silica gel (solvent: benzene) to give 204 mg (after recrystallization from isopropyl ether) of *cis*-isomer VIII and 115 mg (oil) of *trans*-isomer IX; 10.5% yield, *cis*-isomer (VIII): mp 132—133 °C; IR (Nujol) 1142 and 1320 (SO_2) cm^{-1}; NMR see Table 1. (Found: C, 63.85; H, 5.60; N, 4.69; S, 10.74%. Calcd for $C_{16}H_{17}NO_3S$: C, 63.34; H, 5.65; N, 4.62; S, 10.57%), *trans*-isomer (IX): oil; IR (Nujol) 1160 and 1302 (SO_2) cm^{-1}; NMR see Table 1. (Found: C, 63.72; H, 5.82; N, 4.55; S, 9.94%. Calcd for $C_{16}H_{17}NO_3S$: C, 63.34; H, 5.65; N, 4.62; S, 10.57%).

*2-Methyl-3-*p*-nitrophenyl-4-phenyl-1,2-thiazetidine 1,1-Dioxide (*cis *X and* trans *XI).* As described in the general procedure, *N-p*-nitrobenzylidene-methylamine (1.64 g) and benzylsulfonyl chloride (1.91 g) in the presence of triethylamine (1.01 g) in THF gave a mixture of X and XI. The mixture was purified by column chromatography using silica gel (solvent: benzene) to give 114 mg (after recrystallization from ethanol-ethyl acetate) of *cis*-isomer X and 73 mg (after recrystallization from ethanol) of *trans*-isomer XI; 5.9% yield, *cis*-isomer (X): mp 179—180 °C; IR (Nujol) 1142 and 1309 (SO_2), 1346 and 1520 (NO_2) cm^{-1}; NMR see Table 1. (Found: C, 56.53; H, 4.36; N, 8.86; S, 10.27%. Calcd for $C_{15}H_{14}N_2O_4S$: C, 56.59; H, 4.43; N, 8.80; S, 10.07%), *trans*-isomer (XI): mp 170—171 °C; IR (Nujol) 1162 and 1315 (SO_2), 1350 and 1512 (NO_2) cm^{-1}; NMR see Table 1. (Found: C, 56.68; H, 4.40; N, 8.81; S, 10.27%. Calcd for $C_{15}H_{14}N_2O_4S$: C, 56.59; H, 4.43; N, 8.80; S, 10.07%).

2,4-Dimethyl-3,5-diphenyl-6-methylsulfonyl-tetrahydro-1,2,4-thiadiazine 1,1-Dioxide (XVI). Under the general procedure with THF as solvent, *N*-benzylidene-methylamine (1.19 g) and methanesulfonyl chloride (1.15 g) in the presence of triethylamine (1.01 g) gave a solid. The solid was purified by column chromatography using alumina (solvent: benzene-ethyl acetate 7 : 1) to give 378 mg (after recrystallization from ethyl acetate-ethanol) of XV; 19.3% yield. When the reaction was carried out in acetonitrile 28.0% yield of XV was obtained: mp 181—182 °C; IR (Nujol) 1140 and 1300 (SO_2) cm^{-1}; NMR ($CDCl_3$) δ 1.87 (3H, s, N-C**H**$_3$), 2.84 (3H, s, SO_2-C**H**$_3$), 2.85 (3H, s, SO_2-N-C**H**$_3$), 4.39 (1H, d, Ph-C**H**-N, J=9.0 Hz), 4.83 (1H, d, SO_2-C**H**-SO_2, J=9.0 Hz), 5.30 (1H, s, Ph-C**H**(N)-N), 7.21-7.83 (10H, m, aromatic H). (Found: C, 54.88; H, 5.51; N, 7.17; S, 16.32%. Calcd for $C_{18}H_{22}N_2O_4S_2$: C, 54.80;

H, 5.62; N, 7.10; S, 16.26%).

1,2-Diphenyl-2-methylamino-ethanesulfonic Acid (XII). A stirred suspension of compound IV (136 mg, 0.0005 mol) in 5 ml of 1 M-sodium methoxide-methanol was heated under reflux in an atomosphere of nitrogen. The solution was allowed to cool to room temperature and then treated with 1M-aqueous hydrochloric acid solution until the pH reached 1.0. The separated white solid was collected by filtration and recrystallized from acetone-water to give 104 mg (yield 60.9%) of 1,2-diphenyl-2-methyl-amino-ethanesulfonic acid (XII).: mp >300 °C: IR (Nujol) 2750 and 2520 (N^+H_2), 1618 (benzene), 1249 and 1050 (SO_3^-) cm^{-1}; NMR (DMSO-d_6) δ 2.46 (3H, s, N-C**H**$_3$), 4.56 (1H, d, C**H**-SO_3^- or C**H**-NH_2^+, J=11.0 Hz), 4.98 (1H, d C**H**-SO_3^- or C**H**-NH_2^+, J=11.0 Hz), 6.99—7.54 (10H, m, aromatic H). (Found: C, 61.92; H, 5.65; N, 5.06; S, 11.06%. Calcd for $C_{15}H_{17}NO_3S$: C, 61.83; H, 5.88; N, 4.81; S, 11.00%).

Isomerization of cis- *and* trans-*2-Methyl-3,4-diphenyl-1,2-thiazetidine 1,1-Dioxide (IV and V).* *cis-* or *trans*-2-Methyl-3,4-diphenyl-1,2-thiazetidine 1,1-dioxide (IV or V, 91.0 mg, 0.3 m mol) was dissolved in 10 ml of dry THF, followed by the addition of 10 ml (0.14 mol) of triethylamine. The solution was heated on an oil bath (80 °C) for 3 hr under dry nitrogen. Thin layer chromatography indicated no interconversion between *cis*-isomer IV and *trans*-isomer V. Then the solution was further refluxed for 15 hr. The resulting solution was evaporated under reduced pressure. The residue was dissolved in deuteriochloroform and examined by NMR. In the case of the *cis* compound IV, 80% *cis*-20% *trans* mixture was established, whereas *trans*-isomer V was unchanged under these reaction conditions.

Thermal Fragmentation of cis- *and* trans-*2-Methyl-3,4-diphenyl-1,2-thiazetidine 1,1-Dioxide (IV and V).* *cis-* or *trans*-2-Methyl-3,4-diphenyl-1,2-thiazetidine 1,1-dioxide (IV and V, 100 mg) was placed in a 30 ml flask equipped with a Dimroth-type condenser. A stirred sample was then heated at 220 °C under slight pressure of dry nitrogen for 3 hr. The cooled sample was dissolved in 10 ml of chloroform which was washed with 5 ml of water. The organic layer was evaporated under reduced pressure and the residue was checked by VPC and NMR.

Similarly *cis-* and *trans*-stilbene were heated at 220 °C for 3 hr and analysis of the products was carried out using VPC.

The compound IV was completely recovered on heating at 200 °C for 2 hr.

We wish to thank Mr. H. Kuwano for NOE measurement.

Formation of Phosphate Derivatives by the Reaction of Propyl and Allyl Halides with Phosphorus Trichloride and Oxygen

Yoshiki Okamoto, Toshihiro Okada, and Hiroshi Sakurai

The Institute of Scientific and Industrial Research, Osaka University, Yamada-kami, Suita-shi, Osaka 565

(Received April 22, 1974)

In addition to phosphonyl dichlorides, a significant amount of phosphoryl dichlorides was obtained by the reaction of propyl and allyl halides with phosphorus trichloride in oxygen atmosphere. Formation of the P–O–C bond can be explained by a scheme involving a preferential reaction of the bridged intermediate radical with oxygen.

The reaction of hydrocarbons with phosphorus trichloride and oxygen provides a convenient route to alkylphosphonyl dichloride derivatives (P–C bond formation). Phosphoryl compounds occur only as minor products under high pressure of oxygen.[1] Boyce and Webb found that the reaction of 1,2-dichloroethylene with phosphorus trichloride–oxygen gives 1,2,2-trichloroethyl phosphate as the major product (*ca.* 40% yield) despite the fact that oxygen was used at atmospheric pressure.[2] No further investigations were made.

We have found that phosphoryl dichlorides are obtained from propyl and allyl halides in various yields under atmospheric pressure conditions of oxygen. The formation of phosphoryl dichloride was more remarkable in bromine-substituted hydrocarbon. The mechanism of the formation of phosphoryl dichloride will be discussed.

Results and Discussion

In a typical run, 0.1 mol of alkyl halide and 0.5 mol of phosphorus trichloride were placed in a 200 ml-cylindrical flask, fitted to a drying tube. Dried oxygen gas was bubbled into the mixture at a 50 ml/min rate for 3 hr. After the removal of phosphorus oxychloride and unreacted material at reduced pressure, the residue was distilled. The products were esterified with excess absolute ethanol, and analyzed by glc.

Chlorophosphonation of n-, *Isopropyl Chlorides, and the Same Bromides.* The yields and compositions of the products from these halides are given in Tables 1 and 3, respectively.

Table 1. Products from *n*- and isopropyl chlorides and the same bromides

Alkyl halide	Component (relative ratio %)	
n-Propyl chloride	$CH_3CH_2CHClPO(OC_2H_5)_2$	(14)
	$CH_3CH[PO(OC_2H_5)_2]CH_2Cl$	(44)
	$CH_2[PO(OC_2H_5)_2]CH_2CH_2Cl$	(32)
	$CH_3CH[OPO(OC_2H_5)_2]CH_2Cl$	(10)
Isopropyl chloride	$CH_3CHClCH_2PO(OC_2H_5)_2$	
n-Propyl bromide	$CH_3CH_2CHBrPO(OC_2H_5)_2$	(23)
	$CH_3CH[PO(OC_2H_5)_2]CH_2Br$	(34)
	$CH_3CH[OPO(OC_2H_5)_2]CH_2Br$	(7)
	$CH_3CHBrCH_2OPO(OC_2H_5)_2$	(7)
	$CH_2[PO(OC_2H_5)_2]CH_2CH_2Br$	(29)
Isopropyl bromide	$CH_3CH[PO(OC_2H_5)_2]CH_2Br$	(47)
	$CH_3CH[OPO(OC_2H_5)_2]CH_2Br$	(33)
	$CH_3CHBrCH_2OPO(OC_2H_5)_2$	(20)

n-Propyl chloride and bromide gave 10% and 14% of phosphate in composition, respectively. In the case of isopropyl bromide, the content of phosphate increased up to 53%.

The following facts suggest that the formation of a phosphoryl structure proceeds *via* a bridged intermediate radical. 1) In all the phosphoryl products, the P–O–C bonds are only at the β-position of halogen atom. 2) 1,2-Rearrangment of bromine atom occurs at the same time. 3) Phosphoryl dichloride production from the bromide is much greater than that from the chloride. It is well-known that bromine atom is more favorable in the formation of a symmetrical and stabilized bridged radical than chlorine atom.[3] 4) The phosphoryl dichloride production from the alkanes with other substituents (CN, COCl, Ph, and $OCOCH_3$) could not be observed under the same conditions.[4]

The bridged radical seems to be the more resonance-stabilized radical by means of delocalization of unpaired electron than the unbridged β-haloalkyl radical. The great reactivity of stable radical $Ph_3C\cdot$ with oxygen is well-known.[5] However, the stable radicals $(CH_3)_2\dot{C}CN$ and $Ph_3C\cdot$ were found to be unreactive toward phosphorus trichloride.[6] The bridged radical is therefore preferentially scavenged with oxygen to form the alkyl peroxide radical.

The subsequent process of the phosphoryl dichloride production can be explained by the mechanism represented by reactions (1)—(5).

$$R\cdot + O_2 \longrightarrow ROO\cdot \quad (1)$$

$$ROO\cdot + PCl_3 \longrightarrow RO\cdot + OPCl_3 \quad (2)^{6}$$

$$RO\cdot + PCl_3 \longrightarrow RO\dot{P}Cl_3 \quad (3)$$

$$RO\dot{P}Cl_3 + O_2 \longrightarrow ROPCl_3OO\cdot \quad (4)$$

$$ROPCl_3OO\cdot + PCl_3 \rightarrow ROPOCl_2 + OPCl_3 + Cl\cdot \quad (5)$$

In order to explain phosphate production from alkanes, Mayo, Durham, and Griggs suggested a heterolytic reaction (7) between phosphorus oxychloride and the alcohol produced by reaction (6).[1]

$$RO\cdot + RH \longrightarrow ROH + R\cdot \quad (6)$$

$$ROH + POCl_3 \longrightarrow ROPOCl_2 + HCl \quad (7)$$

The alkoxy radical appears to be the hydrogen-abstracting species. However, the isomer distributions of these reaction products differ from those of the reaction in which hydrogen abstraction by the alkoxy radical is operative, eliminating the possibility of mechanisms (6) and (7).[8]

Chlorophosphonation of Allyl Chloride and Bromide. Olefin also reacts with phosphorus trichloride–oxygen to give β-chloroalkylphosphonyl dichloride. The formation is explained by the following sequences of reactions.[9]

$$RCH{=}CHR' + Cl\cdot \rightarrow R\dot{C}HCHClR' \quad (I) \qquad (8)$$

$$R\dot{C}H\text{-}CHClR' + PCl_3 \rightarrow RCH(PCl_3\cdot)\text{-}CHClR' \qquad (9)$$

$$RCH(PCl_3\cdot)\text{-}CHClR' + O_2 \rightarrow RCH(PCl_3OO\cdot)\text{-}CHClR' \qquad (10)$$

$$RCH(PCl_3OO\cdot)\text{-}CHClR' + PCl_3 \rightarrow RCH(POCl_2)CHClR' + POCl_3 + Cl\cdot \qquad (11)$$

In the case of allyl halide, the intermediate radical (I, R=CH_2X, R'=H) has two halogen atoms on both sides and the bridging effect thus seems to be more enhanced. The results obtained from allyl chloride and bromide are given in Table 2.

Table 2. Products from allyl chloride and allyl bromide

Allyl halide	Component (relative ratio mol %)	
Allyl chloride	$CH_2ClCH[PO(OC_2H_5)_2]CH_2Cl$	(19)
	$CH_2ClCH[OPO(OC_2H_5)_2]CH_2Cl$	(79)
	$CH_2ClCHClCH_2OPO(OC_2H_5)_2$	(2)
Allyl bromide	$CH_2ClCH[PO(OC_2H_5)_2]CH_2Cl$	(3)
	$CH_2ClCH[OPO(OC_2H_5)_2]CH_2Cl$	(22)
	$CH_2ClCHClCH_2OPO(OC_2H_5)_2$	(1)
	$CH_2ClCH[OPO(OC_2H_5)_2]CH_2Br$	(25)
	$CH_2BrCH[OPO(OC_2H_5)_2]CH_2Br$	(49)
	$CH_2BrCHBrCH_2OPO(OC_2H_5)_2$	(trace)
	$CH_2ClCHBrCH_2OPO(OC_2H_5)_2$	(trace)
(and/or	$CH_2BrCHClCH_2OPO(OC_2H_5)_2$)	

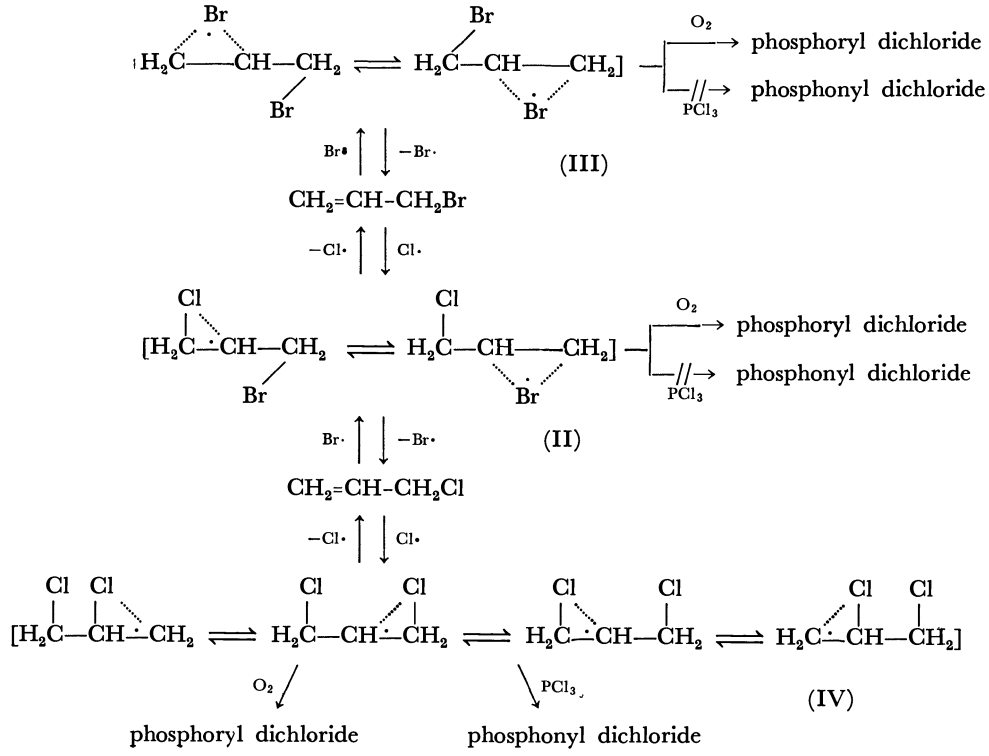
In the case of allyl bromide, the content of phosphate in the product exceeds 97%, halogen exchange occurring at the same time. The formations are illustrated by Scheme 1.

The addition of chlorine atom to the double bond of allyl bromide gives 1-chloromethyl-2-bromoethyl radical (II), which reacts only with oxygen to give phosphate. On the other hand, elimination of bromine atom from II gives allyl chloride. The resulting bromine atom reacts with allyl bromide to give 1-bromomethyl-2-bromoethyl radical (III), which is the most resonance-stabilized radical by bridging with either of bromine atom in both sides. III also reacts with oxygen to give the phosphate. Addition of chlorine atom to allyl chloride gives 1-chloromethyl-2-chloroethyl radical (IV), which is best described as an unsymmetrically bridged radical.[4] IV seems to be less resonance-stabilized than radicals II or III. It therefore reacts not only with oxygen but also phosphorus trichloride to give both phosphoryl and phosphonyl dichlorides.

Experimental

All the boiling points are uncorrected. NMR spectra were obtained at 100 MHz on a JNM-100 spectrometer with TMS as an internal reference in CCl_4 solution. The mass spectra were obtained on a Hitachi RMU-6 or RMU-7 spectrometer with a direct inlet. GC-MS were obtained on a Hitachi RMS-4 spectrometer.

Glc analyses were carried out with a Shimadzu GC-3AF on a 3 m×3 mmφ column packed with 5% Ucon LB 550X on Shimalite W. Preparative work was carried out with a



Scheme 1.

Hitachi 023 on a 1 m×12 mmϕ column with the same packing.

All the reagents were prepared by purifying commercial products. Vacuum distillation was carried out under nitrogen.

General Procedure of Chlorophosphonation. Oxygen was bubbled for 3 hr into a mixture of phosphorus trichloride (1.0 mol) and halide (0.2 mol) cooled in a bath at −15—0 °C at such a rate (50 ml/min) that the temperature of the mixture did not rise above 0 °C. After removal of a large portion of unreacted material and phosphorus oxychloride, the residue was vacuum-distilled yielding a colorless liquid. The yields and boiling points of the products from *n*-, isopropyl chlorides, *n*-, isopropyl bromides, allyl chloride, and allyl bromide are given in Table 3.

Table 3. Yields in the chlorophosphonation of the halides

Halide	Yield (g)	Bp °C/mmHg
n-Propyl chloride	7.5	55—83 /1
Isopropyl chloride	5.7	58—78 /1
n-Propyl bromide	4.0	85—123/7
Isopropyl bromide	2.1	65—75 /1
Allyl chloride	35.0	68—84 /0.5
Allyl bromide	34.8	70—95 /0.5

Ethanolysis of the Reaction Products. The above reaction product (2.0 g) was stirred and cooled at −5 °C and a stream of dry nitrogen was passed through it. Absolute ethanol (20 ml) was then added dropwise for 2 hr. The mixture was stirred at 0—5 °C for 3 hr and then at room temperature overnight. Glc analysis of residue after removal of ethanol *in vacuo* was carried out.

Analysis. The products were identified by comparison of their retention times with those of authentic samples prepared by the methods described below. The other products were identified by elemental analysis, NMR, and mass spectra after being fractionated by preparative glc.

Authentic Sample. Diethyl 3-chloropropylphosphonate (bp 78—80 °C/1 mmHg)[10] and diethyl 3-bromopropylphosphonate (bp 94—95 °C/2 mmHg)[10] were prepared by Arbuzov reactions of 3-chloropropyl bromide and trimethylene dibromide with triethyl phosphite respectively. Diethyl 1-chloropropylphosphonate (bp 53—54 °C/0.1 mmHg)[4] was prepared by chlorination of diethyl 1-hydroxypropylphosphonate with thionyl chloride. Diethyl 2-chloropropylphosphonate(bp 77—79 °C/1 mmHg)[10] was prepared by the ethanolysis of 2-chloropropylphosphonyl dichloride, obtained by the reaction of propylene with phosphorus pentachloride.[10] Diethyl 2-bromopropyl phosphate (bp 95—97 °C/2 mmHg, Found: C, 30.41; H, 5.88%. Calcd for $C_7H_{16}O_4PBr$: C, 30.56; H, 5.86%), diethyl 2,3-dichloropropyl phosphate (bp 123—125 °C/4 mmHg).[10] Diethyl 1-chloromethyl-2-chloroethyl phosphate (bp 112—114 °C/2 mmHg)[10] were prepared from the corresponding alcohols and diethyl phosphorochloridate.[10] Diethyl 2,3-dibromopropyl phosphate (bp 122—123 °C/10^{-3} mmHg, Found: C, 23.61; H, 4.30%. Calcd for $C_7H_{15}O_4PBr_2$:C, 23.75; H, 4.27%.) were prepared by the addition of bromine to diethyl allyl phosphate.[11]

The following products were identified by means of the data of NMR, mass spectra and elementary analysis. Diethyl 1-methyl-2-chloroethylphosphonate; NMR: δ 1.05 (d, 3H, J_{HH} 7.0 Hz, CH-C$\underline{H}_3$), 1.35(t, 6H, J_{HH} 7.5 Hz, CH_2-C$\underline{H}_3$), 1.5—2.0(m, 1H, -C$\underline{H}$-CH_3), 3.65(d, 2H, J_{HH} 5.0 Hz, -C$\underline{H}_2$Cl), and 4.10(q-d, 4H, J_{POCH} 7.4 Hz, -OC$\underline{H}_2$-). Found: C, 39.08; H, 7.48%. Calcd for $C_7H_{16}O_3PCl$: C, 39.17; H, 7.51%. Diethyl 1-methyl-2-chloroethyl phosphate;[11] NMR: δ 1.40(d, 3H, J_{HH} 7.2 Hz, -CH-C$\underline{H}_3$), 1.44(t, 6H, J_{HH} 7.5 Hz, CH_2C$\underline{H}_3$), 3.54(d, 2H, J_{HH} 7.2, CH_2Cl), 4.05(q-d, 4H, J_{POCH} 7.5 Hz, -OC$\underline{H}_2$-), and 4.3—4.6 (m, 1H, OCH-CH_3). Diethyl 1-bromopropylphosphonate; NMR δ 1.12(t, 3H, J_{HH} 7.0 Hz, CH-C$\underline{H}_3$) 1.34(t, 6H, J_{HH} 7.0 Hz, OCH_2-C$\underline{H}_3$), 2.00(m, 2H, C$\underline{H}_2$-CH), 3.62(d-t, 1H, J_{HH} 10 Hz, J_{PCH} 5.0 Hz, C$\underline{H}$Br-P), and 4.12(qui, 4H, J_{POCH} 7.0 Hz, -C$\underline{H}_2$-CH_3). Found: C, 32.64; H, 6.18%. Calcd for $C_7H_{16}O_3PBr$: C; 32.45; H, 6.23%. Diethyl 1-methyl-2-bromoethylphosphonate; NMR δ 1.30(d-d, 3H, J_{HH} 7.0 Hz, J_{PCCH} 15 Hz, CH-C$\underline{H}_3$), 1.33(t, 6H, J_{HH} 7.0 Hz, -CH_2C$\underline{H}_3$), 2.04(m, 1H, P-C$\underline{H}$-), 3.20(t-d, 1H, J_{HH} 5.0 Hz, $J_{H_aH_b}$ 11.0 Hz, J_{PCCH} 11.0 Hz, -C$\underline{H}_a$$H_b$Br), 3.76(t-d, 1H, J_{HH} 5.0 Hz, J_{PCCH} 11.0 Hz, -$CH_a$$\underline{H}_b$Br), and 4.06 (qui, 4H, J_{POCH} 0.7 Hz, -OC$\underline{H}_2$-). Found: C, 32.40; H, 6.33%. Calcd for $C_7H_{16}O_3PBr$: C, 32.45; H, 6.23%. Diethyl 1-methyl-2-bromoethyl phosphate; NMR δ 1.41(t, 6H, J_{HH} 7.0 Hz, -CH_2C$\underline{H}_3$) 1.44(d, 3H, J_{HH} 7.0 Hz, -CH-C$\underline{H}_3$), 3.46 (d, 2H, J_{HH} 5.0 Hz, C$\underline{H}_2$Br), and 4.06(q-d, 4H, J_{POCH} 7.4 Hz, -OC$\underline{H}_2$-), Found: C, 29.87; H, 5.80%. Calcd for $C_7H_{16}O_4PBr$: C, 30.56; H, 5.86%. Diethyl 1-chloromethyl-2-chloroethylphosphonate; NMR δ 1.36(t, 6H, J_{HH} 7.0 Hz, CH_2C$\underline{H}_3$), 2.48(m, 1H, P-C$\underline{H}$-), 3.90(d-d, 4H, J_{HH} 5.0 Hz, J_{PCCH} 14.5 Hz, -C$\underline{H}_2$Cl), and 4.08(qui, 4H, J_{POCH} 7.0 Hz, -C$\underline{H}_2$-). Found: C, 34.21; H, 6.12%. Calcd for $C_7H_{15}O_3PCl_2$: C, 33.75: H, 6.07%. Diethyl 1-chloromethyl-2-chloroethyl phosphate;[10] NMR δ 1.36(t, 6H, J_{HH} 7.0 Hz, -CH_2C$\underline{H}_3$), 3.78(d, 4H, J_{HH} 4.0 Hz, -C$\underline{H}_2$Cl), 4.08(qui, 4H, J_{POCH} 7.0 Hz, -OC$\underline{H}_2$-), and 4.60(m, 1H, P-OC$\underline{H}$-). Diethyl 1-chloromethyl-2-bromoethyl phosphate; NMR δ 1.36(t, 6H, J_{HH} 7.0 Hz, CH_2C$\underline{H}_3$), 3.62(d, 2H, J_{HH} 5.0 Hz, -C$\underline{H}_2$Br), 3.78(d, 2H, J_{HH} 5.0 Hz, -C$\underline{H}_2$Cl), 4.08 (qui, 4H, J_{POCH} 7.0 Hz, -OC$\underline{H}_2$-), and 4.20(m, 1H, -OC$\underline{H}$-). Found: C, 27.04; H, 4.90%. Calcd for $C_7H_{15}O_4PBrCl$: C, 27.16; H, 4.88%. Diethyl 1-bromomethyl-2-bromoethyl phosphate; NMR δ 1.36(t, 6H, J_{HH} 7.0 Hz, CH_2C$\underline{H}_3$), 3.63(d, 4H, J_{HH} 5.0 Hz, -C$\underline{H}_2$Br), 4.08(qui, 4H, J_{POCH} 7.0 Hz, -OC$\underline{H}_2$-), and 4.48(m, 1H, OC$\underline{H}$-). Found: C, 23.65; H, 4.21%. Calcd for $C_7H_{15}O_4PBr_2$: C, 23.75; H, 4.27%.

A strong ion peak of *m/e* 99($P(OH)_4^+$) was observed in the mass spectra of all the phosphate components, not of the phosphonate components. Diethyl 1(2)-bromo-2(1)-chloropropyl phosphate was identified by comparison of its relative retention time in glc. The mass spectrum of this fraction showed no molecular ion peak but strong peaks at *m/e* 229 and 231 (M^+–Br) and at *m/e* 81 and 79 ($^{81}Br^+$ and $^{79}Br^+$). A significant amount of allyl chloride was detected in the chlorophosphonation of allyl bromide.

A Synthesis of 3-Hydroxy-5-methoxyphenanthro[4,5-*bcd*]furan

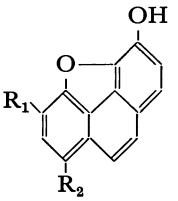
Takaaki HORAGUCHI and Takahachi SHIMIZU

Department of Chemistry, Faculty of Science, Niigata University, Igarashi, Niigata 950–21

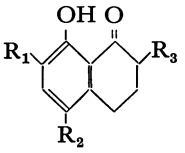
(Received May 1, 1974)

3-Hydroxy-5-methoxyphenanthro[4,5-*bcd*]furan (Ia) was synthesized by the dehydrogenation of 5-methoxy-3-oxo-1,2,3,8,9,9a-hexahydrophenanthro(4,5-*bcd*)furan (IVa), starting from 8-hydroxy-7-methoxy-1-tetralone (IIb).

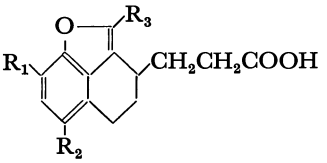
In previous papers,[1,2] the first synthetic route to phenanthro[4,5-*bcd*]furans which contain a ring strain[3] has been reported; by this method Ib and Ic (morphenol) were prepared starting from 8-hydroxy-1-tetralones (IIe and IIf respectively). In the syntheses, however, the yields were not satisfactory in two kinds of cyclization reactions, the formation of naphtho[1,8-*bc*]furans (IIIb and IIIc) from 8-hydroxy-1-tetralones (IIe and IIf) and ethyl bromoacetate, and the intramolecular cyclization of naphtho[1,8-*bc*]furans (IIIb and IIIc) to the corresponding phenanthro[4,5-*bcd*]-furans (IVb and IVc); on the other hand, a methoxyl group on the benzene ring in IIe and IIf served to increase the yield in the latter cyclizations (IIe,f→IIIe,f) and did not have any effect on the yield in the other cyclizations (IIIe,f→IVb,c). These results have required us to make a further attempt to prepare 3-hydroxy-5-methoxyphenanthro[4,5-*bcd*]furan (Ia), an isomer of Ib, starting from a 8-hydroxy-1-tetralone derivative (IId), which has a substituent at the *ortho*-position to the hydroxyl group.



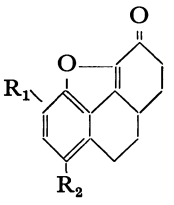
Ia: R_1=OMe, R_2=H
Ib: R_1=H, R_2=OMe
Ic: R_1=H, R_2=H



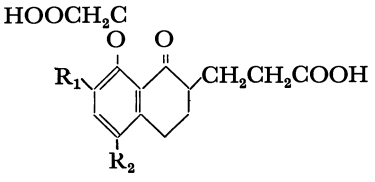
IIa: R_1=OMe, R_2=Cl, R_3=H
IIb: R_1=OMe, R_2=H, R_3=H
IIc: R_1=OMe, R_2=H, R_3=CHO
IId: R_1=OMe, R_2=H, R_3=CH_2CH_2COOH
IIe: R_1=H, R_2=OMe, R_3=CH_2CH_2COOMe
IIf: R_1=H, R_2=H, R_3=CH_2CH_2COOH



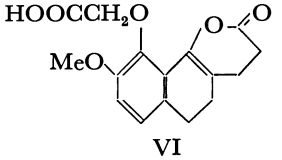
IIIa: R_1=OMe, R_2=H, R_3=COOH
IIIb: R_1=H, R_2=OMe, R_3=COOH
IIIc: R_1=H, R_2=H, R_3=COOH
IIId: R_1=OMe, R_2=H, R_3=H
IIIe: R_1=H, R_2=OMe, R_3=H
IIIf: R_1=H, R_2=H, R_3=H



IVa: R_1=OMe, R_2=H
IVb: R_1=H, R_2=OMe
IVc: R_1=H, R_2=H



V: R_1=OMe, R_2=H



VI

Fig. 1.

Results and Discussion

The tetralone (IId) was prepared from 3-(3,4-dimethoxybenzoyl)propionic acid through a series of intermediates (IIa), (IIb), and (IIc), as will be described in the Experimental section.

When IId was treated with ethyl bromoacetate at 170 °C, followed by hydrolysis, the expected di- and monocarboxylic acids, 3-(2-carboxy-8-methoxy-4,5-dihydro-3*H*-naphtho[1,8-*bc*]furan-3-yl)propionic acid (IIIa) and 3-(8-methoxy-4,5-dihydro-3*H*-naphtho[1,8-*bc*]furan-3-yl)propionic acid (IIId), were obtained in 39 and 1.5% yields respectively. An attempt to prepare IIId from V by treating it with a mixture of acetic anhydride and sodium acetate was unsuccessful; the reaction mixture gave a crystalline product. The infrared absorption spectrum of the product, unlike that of V, shows no bands corresponding to the conjugated-carbonyl group near 1660 cm^{-1} and to the carboxyl group of the propionic acid near 1700 cm^{-1}; instead, it has a new band at 1756 cm^{-1} which is characteristic of a γ,δ-unsaturated δ-lactone ring. Therefore, the compound is believed to have the lactone structure (VI).

The monocarboxylic acid (IIId), which was also obtained from the dicarboxylic acid (IIIa) by decarboxylation (58%), was subjected to a polyphosphoric acid-catalyzed intramolecular cyclization to give 5-methoxy-3-oxo-1,2,3,8,9,9a-hexahydrophenanthro[4,5-*bcd*]furan (IVa) in a 59% yield. For the aromatization of IVa to the phenol (Ia), palladium on charcoal was used as the catalyst; the yield was 10%.

The yields of the di- and monocarboxylic acids

(IIIa and IIId) were comparable to those of the corresponding carboxylic acids (IIIc and IIIf) from IIf in the synthesis of Ic (34 and 2%).[2] The results, combined with previously reported,[1,2] seem to indicate that the methoxyl groups of IId and IIe have no effect on the yields of the cyclizations. The yield of the ketone (IVa) was almost the same as that of IVb (67%)[1] and better than that of IVc (45%).[2] The results indicate that the methoxy groups of IIId and IIIe serve to increase the yields in the cyclizations. As the IVa–c are obtained in fairly good yields from IId–f under mild conditions, no large strain is introduced into the reactions. If the strain is present in phenanthro[4,5-*bcd*]furan derivatives (IV),[3] it is mainly present in the naphtho[1,8-*bc*]furan ring. The problem of the strain in naphtho[1,8-*bc*]furan derivatives will be further investigated later.

Experimental

All the melting points are uncorrected. The column chromatography was performed on silica gel (WAKOGEL C-200). The polyphosphoric acid was prepared from 85% phosphoric acid (100 ml) and phosphorus pentoxide (123 g) by heating them at 160—165 °C for 5 hr. Unless otherwise stated, anhydrous sodium sulfate was employed as the drying agent. The infrared absorption spectra were determined with a JASCO Model DS 402 G infrared spectrophothometer. The ultraviolet absorption spectra were determined with a Shimadzu Model UV-200 spectrophothometer. The nuclear magnetic resonance spectra were determined at 100 MHz with a JEOL Model 4H-100 NMR spectrometer, using tetramethylsilane as the internal standard.

4-(3,4-Dimethoxyphenyl)butyric Acid. A mixture of 3-(3,4-dimethoxybenzoyl)propionic acid (40 g) in acetic acid (150 ml), palladium chloride (520 mg) in 0.1M hydrochloric acid (30 ml), and charcoal (10 g) was shaken under a hydrogen atmosphere at room temperature.[4] After the usual treatment, the recrystallization of the resulting solid from chloroform-petroleum ether gave 30.3 g (85%) of 4-(3,4-dimethoxyphenyl)butyric acid as colorless plates; mp 60—61 °C (lit,[5] 58—59 °C).

4-(2-Chloro-4,5-dimethoxyphenyl)butyric Acid. This acid was prepared according to the method of Brown *et al.*[6] Colorless prisms; mp 106—108 °C (lit,[5] 112 °C).

5-Chloro-8-hydroxy-7-methoxy-1-tetralone (IIa). A mixture of 4-(chloro-4,5-dimethoxyphenyl)butyric acid (30.0 g) and polyphosphoric acid (390 g) was heated with stirring at 90 °C for 7 hr. The deep red mixture was decomposed with ice water, and the resulting precipitates were extracted with ether. The ethereal layer was washed with 1M potassium carbonate and then water, dried, and evaporated. The recrystallization of the residue from ethanol gave 22.7 g (86%) of IIa as yellow needles; mp 102—103 °C (lit,[5] 104—105 °C).

8-Hydroxy-7-methoxy-1-tetralone (IIb). A mixture of charcoal (4.0 g), palladium chloride (500 mg) in 0.1 M hydrochloric acid (20 ml), and ethanol (50 ml) was shaken under a hydrogen atmosphere at room temperature until no hydrogen was consumed. After adding of IIa (30 g) in ethanol (200 ml), the mixture was then shaken at 40 °C until 2.3 l of hydrogen had been consumed.[6,7] After the usual subsequent treatment, the recrystallization of the resulting solid from hexane gave 15.2 g (60%) of IIb as yellow plates; mp 76—77 °C. IR(KBr): 1625 (C=O), 829 (OH), and 811 cm^{-1} (two adjacent aromatic hydrogen atoms). NMR(CD_3COCD_3): δ 12.67 (s, OH), 3.82 (s, OCH_3), 7.15 (d, 1H, J=8 Hz, Ar–H), and 6.70 (d, 1H, J=8 Hz, Ar–H).

Found: C, 68.81; H, 6.28%. Calcd for $C_{11}H_{12}O_3$: C, 68.74; H, 6.29%.

8-Hydroxy-2-hydroxymethylidene-7-methoxy-1-tetralone (IIc). To a mixture of sodium methoxide (8.0 g, from 4.3 g of sodium and absolute methanol) and benzene (50 ml), we added ethyl formate (14.5 ml) under a nitrogen atmosphere at room temperature, after which the mixture was stirred for 30 min. To the mixture we then added IIb (8 g) in benzene (50 ml), drop by drop, over a 30min period under cooling with ice water, after which the mixture was stirred for an additional 4 hr at room temperature. The resulting green-yellow mixture was decomposed with 1 M sulfuric acid (120 ml) and extracted with benzene. The benzene layer was extracted with a 1 M potassium carbonate solution. The alkaline solution thus obtained was acidified with 6 M hydrochloric acid, and the resulting precipitates were recrystallized from 60% aqueous ethanol to give 7.7 g (84%) of IIc as yellow plates; mp 110—111 °C. IR(KBr): 1625 (C=O), 832 (OH), and 800 cm^{-1} (two adjacent aromatic hydrogen atoms). NMR(CD_3COCD_3): δ 13.36 (broad s, Ar–OH+ =C–OH), 11.98 (s, –C–OH), 2.00 (broad s, =CH–O–), 2.43 (broad s, =CH–O–), 7.10 (d, 1H, J=8 Hz, Ar–H), 6.68 (d, 1H, J=8 Hz, Ar–H), and 3.84 (s, OCH_3). UV(EtOH): λ_{max} 225 (ε 14500) and 315—356 nm, (10500).

Found: C, 65.33; H, 5.54%. Calcd for $C_{12}H_{12}O_4$: C, 65.45; H, 5.49%.

3-(Hydroxy-7-methoxy-1-oxo-1,2,3,4-tetrahydro-2-naphthyl)-propionic Acid (IId). A mixture of IIc (15.0 g), methyl acrylate (75.0 g), triethylamine (7.5 g), and 80% aqueous methanol (120 ml) was refluxed at 115 °C for 1 hr. The reaction mixture was then concentrated under reduced pressure, and the resulting oil was extracted with ether. The ethereal layer was washed with 2 M hydrochloric acid, a 1 M potassium carbonate solution, and then water, and dried, after which the ether was evaporated. The residue was heated in a water-bath under reduced pressure to remove any unreacted methyl acrylate. The residue was then dissolved in a small amount of ethanol and hydrolyzed with a 3 M potassium hydroxide solution. The alkaline solution was acidified with 6M hydrochloric acid. The resulting precipitates were collected and recrystallized from 70% aqueous ethanol to give 15.2 g (85%) of IId as orange yellow needles; mp 157—158.5 °C. IR(KBr): 1708 (COOH), 1625 (C=O), and 812 cm^{-1}, (two adjacent aromatic hydrogen atoms). NMR(CD_3COCD_3): δ 12.67 (s, OH), 7.14 (d, 1H, J=8 Hz, Ar–H), and 6.70 (d, 1H, J=8 Hz, Ar–H). UV (EtOH): λ_{max} 227 (ε 16300), 267 (10200), and 353 nm (3100).

Found: C, 63.66; H, 6.13%. Calcd for $C_{14}H_{16}O_5$: C, 63.63; H, 6.10%.

3-(2-Carboxy-8-methoxy-4,5-dihydro-3H-naphtho[1,8-bc]furan-3-yl)propionic Acid (IIIa) and 3-(8-Methoxy-4,5-dihydro-3H-naphtho-[1,8-bc]furan-3-yl)propionic Acid (IIId). A mixture of IId (2.0 g), ethyl bromoacetate (18.6 g), and potassium carbonate (12.8 g) was gradually heated to 170 °C and then refluxed for an additional 6 hr at this temperature. The dark brown mixture was extracted with hot acetone, and then the acetone was evaporated. The residue was dissolved in a small amount of ethanol and hydrolyzed with a 3 M potassium hydroxide solution. The alkaline solution was acidified with 6M hydrochloric acid, and the resulting precipitates were extracted with ether. The ethereal solution was washed with water and dried, and then the solvent was evaporated. The residue was divided into soluble and insoluble portions with benzene. The benzene-insoluble portion (0.9 g, 39%) was recrystallized from 60% aqueous

ethanol to give IIIa as colorless needles; mp 213—214 °C. IR(KBr): 1705 and 1690 cm^{-1} (COOH). UV(EtOH): λ_{max} 234 (ε 22500) and 277 nm (14500).

Found: C, 63.20; H, 5.37%. Calcd for $C_{16}H_{16}O_6$: C, 63.15; H, 5.30%.

The benzene-soluble portion was chromatographed on silica gel and eluted with benzene–ether (9 : 1). A yellow fraction was collected to give crystals. Recrystallization from benzene–*n*-hexane gave 30 mg (1.5%) of IIId as colorless plates; mp 136—138 °C. IR(KBr): 1705 cm^{-1} (COOH). NMR(CD_3COCD_3): δ 7.60 (d, 1H, J=1 Hz, furan H), 6.91 (d, 1H, J=8 Hz, Ar–H), 6.76 (d, 1H, J=8 Hz, Ar–H), and 5.97 (s, OCH_3). UV(EtOH): λ_{max} 216 (ε 30700), 247 (10000), 255 (9200), 280 (1900), and 290 nm (1700).

Found: C, 69.22; H, 6.22%. Calcd for $C_{15}H_{16}O_4$: C, 69.92; H, 6.20%.

Decarboxylation of IIIa. A mixture of IIIa (1.0 g), copper powder (1.0 g), and quinoline (10 g) was heated at 160 °C for 1 hr. The reaction mixture was extracted with ether and acidified with 2M hydrochloric acid. The ethereal layer was washed with 2M hydrochloric acid and then water, dried, and then evaporated. The residue was chromatographed on silica gel and eluted with benzene–ether (9 : 1). A yellow fraction was collected, and after the removal of the solvent the residue was recrystallized from benzene–*n*-hexane to give 500 mg (58%) of IIId as colorless plates; mp 137—138 °C.

5-Methoxy-3-oxo-1,2,3,8,9,9a-hexahydrophenanthro[4,5-bcd]-furan (IVa). A mixture of IIId (2.0 g) and polyphosphoric acid (260 g) was heated while being stirred at 80 °C for 4 hr. The green reaction mixture was then decomposed with ice water, and the resulting precipitates were extracted with ether. The ethereal layer was washed with a 1M potassium carbonate solution and then water, and dried. The ether was evaporated, and the residue was recrystallized from ethanol to give 1.1 g (59%) of IVa as colorless needles; mp 161—162 °C. IR(KBr): 1659 cm^{-1} (C=O). NMR ($CDCl_3$): δ 6.97 (d, 1H, J=8 Hz, Ar–H), 6.86 (d, 1H, J=8 Hz, Ar–H), and 4.06 (s, OCH_3). UV(EtOH): λ_{max} 240 (ε 16500) and 294 nm (20200).

Found: C, 74.06; H, 5.85%. Calcd for $C_{15}H_{14}O_3$: C, 74.36; H, 5.82%.

3-Hydroxy-5-methoxyphenanthro[4,5-bcd]furan (Ia). A mixture of IVa (200 mg), 20% palladium on charcoal (400 mg), and α-methylnaphthalene (3.5 g) was heated under a nitrogen atmosphere at 240 °C for 30 hr.[8,9] The reaction mixture was then filtered, and the filtrate was extracted with ether. The ethereal layer was extracted with a 1 M potassium hydroxide solution. The alkaline solution thus obtained was washed with carbon tetrachloride and then acidified with 6M hydrochloric acid. The resulting precipitates were extracted with ether. The ethereal layer was washed with water, dried, and then evaporated. The residue was chromatographed on silica gel and eluted with benzene–ether (9 : 1). A yellow fraction was collected, and after the removal of the solvent the residue was recrystallized from benzene to give 40 mg (10%) of Ia as colorless needles; mp 127—128 °C. IR(KBr): 3250 (Ar–OH) and 816 cm^{-1} (two adjacent aromatic hydrogen atoms). NMR(CD_3COCD_3): δ 9.61 (s, OH), 7.75 (s, 2H, Ar–H), 2.25—2.60 (m, 6H, Ar–H), and 5.65 (s, OCH_3). UV(EtOH):[10] λ_{max} 232 (ε 38200), 245 (48300), 258 (25300), 268 (24600), 315 (14000), 327 (14100), and 356 nm (23000).

Found: C, 75.76; H, 4.25%. Calcd for $C_{15}H_{10}O_3$: C, 75.62; H, 4.23%.

3-(8-Carboxymethoxy-7-methoxy-1-oxo-1,2,3,4-tetrahydro-2-naphthyl)propionic Acid (V). A mixture of IId (1.0 g), ethyl bromoacetate (3.7 g), potassium carbonate (6.0 g), and dioxane (15 ml) was refluxed for 6.5 hr at 115 °C. The reaction mixture was then extracted with acetone, and the acetone was evaporated. The residue was dissolved in ethanol and hydrolyzed with a 3M potassium hydroxide solution. The alkaline solution was acidified with 6M hydrochloric acid, and the resulting precipitates were extracted with ether. The ethereal layer was washed with water, dried, and then evaporated. The residue was washed with benzene to give 650 mg (53%) of V; mp 183—185 °C. Recrystallization from acetone–tetrahydrofuran gave colorless prisms; mp 185—187 °C. IR(KBr): 1750 (COOH), 1698 (CO-OH), 1658 (C–O), and 815 cm^{-1} (two adjacent aromatic hydrogen atoms). UV(EtOH): λ_{max} 219 (ε 18700), 253 (6000), and 320 nm (2300).

Found: C, 59.62; H, 5.63%. Calcd for $C_{16}H_{18}O_7$: C, 59.53; H, 5.82%.

Lactone (VI). A mixture of V (1.0 g), sodium acetate (4.6 g), and acetic anhydride (15 ml) was heated for 1 hr at 145 °C and then for 5 min at 150 °C. The reaction mixture was poured into water to decompose the acetic anhydride and then extracted with ether. The ethereal layer was washed with water, dried, and then evaporated. The residue was washed with benzene to give 500 mg (53%) of VI; mp 168—169 °C. Recrystallization from acetone gave colorless needles; mp 169—170 °C. IR(KBr): 1756 (lactone), 1736 (COOH), and 816 cm^{-1} (two adjacent aromatic hydrogen atoms).

Found: C, 62.97; H, 5.34%. Calcd for $C_{16}H_{16}O_6$: C, 63.15; H, 5.30%.

The authors wish to thank Mr. Hideo Saisu for the infrared analyses and Mr. Hideo Ōno for the nuclear magnetic resonance analyses.

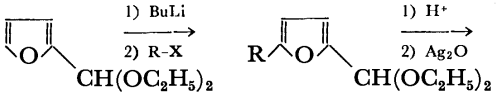
A Convenient Synthesis of 5-Substituted-2,5-dihydro-2-furoic Acids

Tadashi MASAMUNE, Mitsunori ONO, and Hajime MATSUE
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received May 17, 1974)

Nine 5-alkyl- and 5-aryl-2-furoic acids were reduced under controlled Birch conditions and then esterified with acidic methanol. 2-Furoic acids with 5-alkyl groups gave good yields of methyl 5-alkyl-2,5-dihydro-2-furoates, which were obtained as mixtures of *cis*- and *trans*-diastereoisomers. These 2,5-dihydrofuroates revealed interesting spectroscopic properties; (1) large long-range coupling constants, 5—7 and 3—4 Hz, between protons at C_2 and C_5 were observed in the NMR spectra of *cis*- and *trans*-diastereoisomers, respectively, and (2) two high absorption maxima due to the ester carbonyl group of each furoate appeared near 1750 and 1730 cm^{-1} in the IR spectrum. On the other hand, the furoic acids with 5-aryl substituents afforded 5-arylpentanoate or 5-arylpent-3-enoate as main products. These esters would be produced as a result of reductive cleavage at C_5 of 5-aryl-2,5-dihydrofuroates formed as intermediates.

In connection with a study aimed at the total synthesis of laurencin[1] with a tetrahydrooxocin skeleton, we have been in search of a facile method for preparation of the titled furoic acids, because an elegant synthesis[2] of the skeleton involved a 3-oxagranatanine derivative[3] as a key intermediate, which had been prepared by the Robinson-Schöpf condensation starting from 3-oxaglutaraldehyde. Only a few papers have been reported of syntheses of 2,5-dihydrofurans.[4] The reduction of furans with dissolving metals seems to be highly dependent on the reaction conditions and gives many products.[5] However, it has been reported recently that 2-furoic acid is reduced efficiently to the 2,5-dihydro derivative under the controlled Birch conditions.[6] We have developed the method for 5-alkyl- and 5-aryl-furoic acids. The present paper describes the reduction result and the spectroscopic properties of resulting 5-alkyl-2,5-dihydro-2-furoic acids. In view of the occurrence of natural products containing this moiety, such as carotenoids,[7] sesquiterpenoids[8] and antibiotics,[9] this result would be useful for synthesis of some of these compounds.

Nine 5-substituted furoic acids (**1a**—**1i**) were used as starting materials. All these compounds are known but were not always obtained under the reported processes or conditions. The first three acids **1a**, **1b** and **1c** (R=CH_3, C_2H_5 and n-C_3H_7) were prepared more readily and/or in better yields according to a modified process (Scheme 1). This method, however, was not available for preparation of two other alkyl acids **1d** and **1e** (R=i-C_3H_7 and t-C_4H_9) with 5-branched alkyl substituents. These two acids and two 5-benzylfuroic acids **1f** and **1g** (R=$C_6H_5CH_2$ and p-$CH_3OC_6H_4CH_2$) were synthesized by Friedel-Crafts alkylation of methyl furoate followed by hydrolysis. Two 5-phenylfuroic acids **1h** and **1i** (R=C_6H_5 and p-$CH_3OC_6H_4$) were not prepared by the reported methods;[10,11] after careful examination of the reaction process and conditions, the latter **1i**, mp 186—187 °C, was obtained by the Meerwein reaction of p-anisidine and 2-furoic acid under the limited conditions, and the former **1h**, mp 150—150.5 °C, by the Vilsmeyer reaction of 2-phenyl-



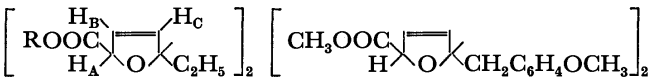
1

Scheme 1.

1 2

furan followed by oxidation

The reductions of 2-furoic acids (**1**) to the 2,5-dihydro derivatives (**2**) were searched under various Birch reductions, using 5-ethyl-2-furoic acid (**1b**). (1) Reduction of **1b** in liquid ammonia with sodium (3 mol) and subsequent addition of methanol afforded, as a main product, a nicely crystalline acid (**3**, R=H) mp 229—230 °C, which was converted into the methyl ester (**3**, R=CH_3), mp 88—89 °C, having a molecular formula of $C_{16}H_{22}O_6$ corresponding to a dihydro dimeric compound; Mass, m/e 310 (M^+) and IR, ν_{max} 1760 and 1740 cm^{-1}. The (planar) formula was assigned on the basis of the NMR spectrum; each of two protons (H_A), on the carbon flanked by a double bond, an oxygen atom and a carbomethoxy group, appeared at low field, δ 5.20, as a double doublet with coupling constants of 2.6 (J_{AB}) and 1.5 Hz (J_{AC}) with olefinic protons (H_B and H_C). On the other hand, (2) treatment of **1b** in both liquid ammonia and methanol with sodium or lithium (3 mol) followed by esterification produced good yields of a 1 : 1 mixture of diastereoisomeric methyl 5-ethyl-2,5-dihydro-2-furoates (**2b**), bp 88—89 °C/13 mmHg. Thus, the reductions of all other furoic acids (**1**) were carried out under these conditions. The products were separated and purified by distillation, gas (glc), thin layer (tlc) and/or column chromatographies, and identified on the spectral data. The results are summarized in Table 1.



3 4

One example of the structure elucidations of the 2,5-dihydro products (**2**) will be illustrated by the 5-ethyl derivative (**2b**). This compound **2b** proved to be obtained as a 1 : 1 mixture of diastereoisomers by glc, though isolation of each isomer (*cis* and *trans*) was not attempted. The elemental analysis and the Mass [m/e 156 (M^+), 127 (M^+–C_2H_5) and 97 (M^+–$COOCH_3$)] and IR spectra (ν_{max} 1768 and 1743 cm^{-1}) confirmed the molecular formula $C_8H_{12}O_3$, and indicated **2b** to be a dihydro methyl ester of **1b**. In accordance

Table 1. The Birch reduction of 5-substituted 2-furoic acids

Compound (R′=H)	Substituent	Metal	Yield[a] Product[b]	1 (R′=CH_3)[c]
1a	CH_3	Na	**2a** (1:1); 70 (80)	(10)

a) The figures in parentheses denote yields estimated by glc. b) The figures in parentheses following **2a** to **2g** denote ratios of *cis*- and *trans*-diastereoisomers estimated by glc. c) Recovered acid methyl esters.

with this assigned structure, the NMR spectrum exhibited two triplets (total 3H, J=7 Hz) at δ 0.88 and 0.91, a multiplet (2H) centered at 1.57, two singlets (3H) at 3.64 and 3.66, a multiplet (2H) centered at 4.90, and a double quartet (2H) centered at 5.88, which were attributed to ethyl CH_3, ethyl CH_2, and $COOCH_3$ protons, two protons at C_2 and C_5 (H_A and H_B), and two olefinic protons at C_3 and C_4. Irradiation at both δ 1.57 and 5.88 collapsed a H_A and H_B multiplet into two simple AB-type quartets, indicating that H_A and H_B protons in one of the diastereoisomers absorbed at δ 4.91 and 4.62, respectively, with coupling constant of 3—4 Hz, and these protons in the other at δ 4.96 and 4.77 with coupling constant of 5—6 Hz. The latter isomer would be oriented *cis* and the former *trans*, as discussed later. These large, long-range coupling constants and also the two absorption maxima due to a carbomethoxy group in each of compounds **2** are listed in Table 2.

As shown in Table 1, all alkylfuroic acids (**1a**—**1e**) produced the corresponding dihydro methyl esters

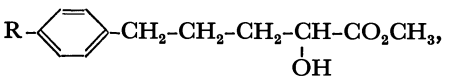
Table 2. The IR and NMR spectra of methyl 5-alkyl-2,5-dihydro-2-furoates

Compound	Absorption maximum[a] (cm^{-1})	Coupling constant[b] (Hz) *cis*	*trans*
2a	1768, 1743	5—6	3—4
2b	1768, 1743	5—6	3—4
2c	1755, 1725	5—6	3
2d	1755, 1725	6	3—4
2e	1755, 1725	7	4
2f	1756, 1735	5—6	3—4
2g	1745, 1735	5—6	3—4

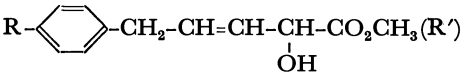
a) Absorption due to the ester carbonyl group in chloroform. b) Coupling constant between protons at C_2 and C_5 in deuterochloroform.

(**2a**—**2e**) in good yields, only about 10% of the starting acid methyl esters being identified by glc. However, two benzylfuroic acids (**1f** and **1g**) gave only moderate yields (ca. 50%) of the expected dihydro esters (**2f** and **2g**) and most of the remaining esters consisted of the unreacted acid esters and, in case of **1g**, a small amount of the dimer (**4**), mp 210—211 °C. The structure of **4** was determined in the same manner as that of **3**. The lower yields of **2f** and **2g** would be explained well if some sodium metal would be consumed for partial reduction of the phenyl ring followed by dehydrogenation during work-up.

The reductions of 5-phenylfuroic acids (**1h** and **1i**) proceeded in different way. Two products, methyl 2-hydroxy-5-phenylpentanoate (**5**) and the corresponding *cis*-pent-3-enoate (**6**), were identified along with the unreduced methyl esters, the main product from **1h** being pentanoate **5h** and that from **1i** pentenoate **6i**. These compounds would be resulted from facile reductive cleavage at C_5, the carbon atom adjacent to both phenyl and vinyl groups, of the 2,5-dihydro derivative, which would be formed in the same manner as other alkyl- and benzyl-furoic acids. The structure determination of **6i** will be discussed as a representative of these esters. Compound **6i**, oil, was hydrolyzed to give the acid (**6i**, R′=H), mp 101—102 °C, in good yield. The Mass [m/e 222 (M^+) and 121 (base peak, $M^+-C_6H_5CH_2$)] and IR spectra (ν_{max} 3648 and 1738 cm^{-1}) suggested this formula, which was confirmed by the NMR spectrum; a doublet (2H) at δ 3.52, a doublet (1H) at 5.12, a triplet (1H) at 5.52 and a double triplet (1H) at 5.92 were assigned to protons at C_5, C_2, C_3, and C_4, respectively. A broad peak centered at δ 6.42 disappeared on addition of D_2O. The signal at δ 5.92 was simplified to a doublet (J=11 Hz) by irradiation at δ 3.52, and that at 5.52 to a doublet (J=11 Hz) by irradiation at δ 5.12. These double resonance experiments were consistent with the assigned



5h R=H
5i R=OCH_3



6h R=H
6i R=OCH_3

structure.

In summary, the present result indicates that the relevant Birch reductions under controlled conditions are generally available for the synthesis of methyl 5-alkyl-2,5-dihydro-2-furoates, which will be derived into 2,5-unsymmetrically substituted 2,5-dihydrofurans not readily accessible. The spectroscopic properties of these 2,5-dihydrofuroates deserve some comments. (1) Extremely large long-range coupling constants were demonstrated between two protons (H_A and H_B) at C_2 and C_5 of the dihydrofurans, irrespective of their configurations, *cis* and *trans*. Usually, homoallylic coupling constants fall in a range of 1—3 Hz.[12] On the other hand, large coupling constants as shown by these compounds have also been observed between protons across five single bonds.[13] In general, these large values have been interpreted as a result of the transmission through the double "zig-zag" paths of the bonds between the two protons.[14] 2,5-Dihydrofuroates with *cis*-configuration would readily take this "zig-zag" type of conformation,[9] whereas those with *trans*-configuration would not be able to adopt such conformations. However, in view of the variety of the coupling constants in question in other 2,5-dihydrofurans,[15] no definite configurational assignment could not be made to each of the diastereoisomers **2**. Now we only tentatively assign the larger constants (5—7 Hz) to the *cis*-isomers and the smaller (3—4 Hz) to the *trans*-isomers, and point out that both the intervending double bond and oxygen atom would probably play a significant role for this noteworthy finding. (2) Two high absorption maxima due to the ester carbonyl groups were observed near 1750 and 1730 cm^{-1} in the IR spectra. It would not be reasonable to ascribe these two absorptions to the existence of two diastereoisomers, because such two bands have appeared in the spectra of methyl 2,5-dihydro-2-furoate[6] and ethyl tetrahydro-2-furoate and 2,3-dimethyl-2,3-epoxybutanoate.[16] This would result from the presence of two conformers caused by rotation of the carbomethoxy group around the bond between the epoxy carbon and carbonyl carbon. Further investigations concerning these bands by the CMR are now in progress.

Experimental

All the mps and bps were uncorrected. The homogenity of each compound was always checked by tlc over silica gel (Wakogel B-5) and/or by glc (Hitachi K-53) over 10% SE-30. Column chromatographies were carried out over silicic acid (Merck, Kieselgel 60 or Mallinckrodt, silicic acid 100 mesh). The IR spectra were taken in chloroform, unless otherwise stated. The NMR spectra were obtained in deuterochloroform, unless otherwise stated, at 100 MHz, and the chemical shifts were given in δ-values, TMS being used as an internal reference. The abbreviations "s, d, t, q, m, and br" in the NMR spectra denote "singlet, doublet, triplet, quartet, multiplet, and broad", respectively.

*5-Methyl-2-furoic Acid (**1a**).* 2-Furfural diethyl acetal was prepared by a modified method;[17] a solution of furfural (96 g) and triethyl orthoformate (165 ml) in ethanol (150 ml) containing ammonium chloride (1.5 g) was refluxed for 3 hr and then distilled fractionally to give the acetal (134 g), bp 77—79 °C/20 mmHg.

To a suspended mixture of lithium (3.0 g), finely cut, in dry tetrahydrofuran (THF, 90 ml) cooled at −25 °C with Dry Ice-ethanol, was added dropwise *n*-butyl chloride (18.5 g) in THF (90 ml) under stirring and under a stream of nitrogen. When the reaction had started as indicated by the appearance of cloudiness after addition of a small volume of the chloride solution, the remaining solution was further added at −30 °C to −35 °C during 45 min to the mixture, which was then stirred at −25 °C (bath temp) for 4 hr. To this mixture was added dropwise the afore-mentioned acetal (18 g) at this temperature, and the whole mixture was again stirred at −15 °C (bath temp) for 4 hr, forming the 5-furyllithium derivative.[18] A solution of methyl iodide (28.4 g) in THF (equal weight, 28.4 g) was added to the mixture, which was further stirred at −15 °C (bath temp) for 1 hr and allowed to stand overnight at room temperature. The reaction mixture was poured into cracked ice and water, forming two layers. After separation of the THF layer, the aqueous solution was extracted with ether (3×150 ml). The THF and ether solutions were combined, dried over sodium sulfate and evaporated to leave resinous oil, which was distilled fractionally under reduced pressure to give 5-methyl-2-furfural diethyl acetal (10.3 g), bp 84—85 °C/9 mmHg; NMR (CCl_4), δ 1.15 (6H, t, J=7 Hz, acetal CH_3), 2.23 (3H, s, 5-CH_3), (4H, q, J=7 Hz, acetal CH_2), 5.34 (1H, s, acetal CH), 5.80 and 6.12 (each 1H, ABq, J=3.5 Hz, 3- and 4-H).

To the acetal (10.25 g) was added 2 M hydrochloric acid (6 ml), and the mixture was stirred at room temperature for 25 min. After addition of water (10 ml) the mixture was extracted with ether (5×10 ml), and the ether solution was washed with 5% sodium hydrogen carbonate solution (2× 10 ml) and water (2×10 ml), dried and distilled to give 5-methyl-2-furfural[19] (3.1 g), bp 75—76 °C/15 mmHg (lit,[19] 72—73 °C/11 mmHg).

To a semisolid mixture prepared from silver nitrate (12.75 g) in water (30 ml) and sodium hydroxide (5.0 g) in water (30 ml), was added dropwise 5-methyl-2-furfural (3.1 g) under cooling with ice. The mixture was stirred at room temperature for 12 hr and then filtered to remove silver oxide. The separated precipitate was washed with hot water repeatedly, and these washings and the filtrate were combined, acidified to pH 3 with concd hydrochloric acid, and extracted with ethyl acetate (3×20 ml). The acetate solution afforded crude acid (3.0 g), which was recrystallized from ethyl acetate to give **1a**[19] (2.14 g), mp 107—108 °C (lit,[19] 107—108 °C); NMR, δ 2.42 (3H, s, 5-CH_3), 6.21 and 7.28 (each 1H, ABq, J=3 Hz, 3- and 4-H), and 12.68 (1H, s, COOH).

*5-Ethyl-2-furoic Acid (**1b**).* A mixture of 2-diethoxylmethyl-5-furyllithium, prepared from 2-furfural diethyl acetal (13.6 g), lithium (3.0 g), and *n*-butyl chloride (18.5 g) in THF (180 ml), was treated with ethyl bromide (21.8 g) in THF (21.8 g) in the same manner as with methyl iodide and gave 5-ethyl-2-furfural diethyl acetal (9.7 g), bp 103—106 °C/15 mmHg. The acetal (9.5 g) was hydrolyzed with acid (2M HCl, 4 ml) for 30 min and gave the aldehyde[19] (4.32 g),

bp 88—89 °C/14 mmHg (lit,[19] 82—83 °C/11 mmHg); NMR (CCl_4), δ 1.24 (3H, t, J=7.5 Hz, ethyl $C\underline{H}_3$), 2.68 (2H, q, J=7.5 Hz, ethyl $C\underline{H}_2$), 6.14 and 7.06 (each 1H, ABq, J=3.5 Hz, 3- and 4-H), and 9.42 (1H, s, C$\underline{H}$O). This aldehyde (7.15 g), when oxidized with silver oxide, prepared from silver nitrate (24.3 g) and sodium hydroxide (11.4 g) in water (86 ml), afforded crude acid (6.3 g), mp 89—90 °C, which was recrystallized from ethyl acetate to give **1b**[19] (5.1 g), mp 91—92 °C (lit,[19] 93.5—94.5 °C).

*5-Propyl-2-furoic Acid (**1c**).* A mixture of 2-diethoxymethyl-5-furyllithium, prepared from 2-furfural diethyl acetal (13.6 g), lithium (3.0 g), and *n*-butyl chloride (18.5 g) in THF (180 ml), was treated with propyl bromide (24.4 g) in THF (24.4 g) in the same manner as with methyl iodide and gave 5-propyl-2-furfural diethyl acetal (4.76 g), bp 104—106 °C/15 mmHg. Found: C, 67.63; H, 9.70%. Calcd for $C_{12}H_{20}O_3$: C, 67.89; H, 9.50%.

The acetal (4.65 g) was hydrolyzed with acid (2M HCl, 4 ml) for 15 min to the aldehyde[20] (3.0 g), which was oxidized immediately with silver oxide, prepared from silver nitrate (9.35 g) and sodium hydroxide (4.4 g) in water (22 ml), and gave crude acid (2.97 g), mp 57—58 °C, which was recrystallized from ethyl acetate to give **1c**[20] (2.3 g), mp 63—64 °C (lit.,[20] 63—63.5 °C).

*5-Isopropyl-2-furoic Acid (**1d**), 5-tert-Butyl-2-furoic Acid (**1e**), and 5-Benzyl-2-furoic Acid (**1f**).* These acids were prepared according to the reported procedures.[21,22] Methyl 2-furoate was converted by the Friedel-Crafts reactions into methyl 5-isopropyl-2-furoate, bp 103—106 °C/14 mmHg (lit.,[21] 110—112 °C/20 mmHg), and methyl 5-*tert*-butyl-2-furoate, bp 95—97 °C/14 mmHg (lit,[21] 110—114 °C/15 mmHg), and methyl 5-benzyl-2-furoate, mp 41—41.5 °C and bp 187—189 °C/7 mmHg (lit,[22] 41—42 °C and 157—160 °C/3 mmHg). These esters were hydrolyzed to the corresponding acids **1d**, mp 65—65.5 °C (lit,[21] 65—66 °C), and **1e**, mp 104—105 °C (lit,[21] 104—105 °C), and **1f**, mp 106—107 °C (lit,[22] 105—105.5 °C).

*5-p-Methoxybenzyl-2-furoic Acid (**1g**).* To a mixture of methyl 2-furoate (17 g) in carbon disulfide (26 ml) containing anhydrous zinc chloride (1.45 g) was added dropwise *p*-methoxybenzyl chloride[23] in carbon disulfide (26 ml) under stirring at 0 °C. The mixture was kept for 30 min at 0 °C and further for 45 min at room temperature. It was poured onto crushed ice and the resulting two layers were separated. The aqueous phase was extracted with ether (50 ml). The carbon disulfide and ether layers were combined, washed with 5% sodium carbonate solution (2×50 ml) and water (50 ml), dried and distilled to give methyl *p*-methoxybenzyl-2-furoate (4.0 g), bp 166—167 °C/5 mmHg; IR, ν_{max} 1720, 1595, and 1030 cm^{-1}; NMR, δ 3.76 (3H, s, OCH_3), 3.84 (3H, s, $COOC\underline{H}_3$), 3.96 (2H, s, $C\underline{H}_2$), 6.08 and 7.14 (each 1H, ABq, J=3 Hz, 3- and 4-H), 6.88 and 7.22 (each 2H, ABq, J=7.5 Hz, $CH_3OC_6\underline{H}_4CH_2$).

A mixture of the ester (4.0 g) and 10% sodium hydroxide solution (40 ml) was boiled under reflux for 1 hr, when it became homogeneous. The solution was poured onto ice and water, acidified to pH 1 with concd hydrochloric acid, and extracted with ethyl acetate (3×50 ml). The acetate solution, after being washed with water, dried and evaporated, gave crude acid (3.1 g), mp 116—120 °C, which on recrystallization afforded **1g**[22] (2.6 g), mp 124—124.5 °C (lit,[22] 123—124 °C). Found: C, 66.82; H, 5.25%. Calcd for $C_{13}H_{12}O_4$: C, 67.23; H, 5.21%.

*5-Phenyl-2-furoic Acid (**1h**).* 2-Phenylfuran was prepared according to the procedure by Johnson;[24] a fraction boiling at 107—109 °C/15 mmHg (lit.,[24] 92—95 °C/10 mmHg) was further separated by column chromatography (Merck, benzene) into 3-phenylfuran,[25] mp 53—54 °C, and 2-phenylfuran, bp 107—109 °C/15 mmHg; NMR, δ 6.38 (1H, double d, J=3.5 and 1.7 Hz, 4-H), 6.60 (1H, d, J=3.5 Hz, 3-H), 7.36 (5H, m, $C_6\underline{H}_5$), and 7.61 (1H, d, J=1.7 Hz, 5-H).

To a mixture of dry dimethylformamide (1.9 g) and phosphorus oxychloride (3.96 g), which had been kept at 0 °C for 20 min, was added freshly distilled 2-phenylfuran (2.4 g) under stirring below 20 °C.[19] The whole mixture was kept at 0—5 °C for 1 hr and then at room temperature for 1.5 hr, and poured into ice water. The resulting mixture was neutralized with 5% sodium carbonate solution and allowed to stand for 16 hr, forming two layers. The organic layer was separated and the aqueous was extracted with ether (3× 60 ml). The organic and the ether solutions were combined, dried and evaporated to leave crude 5-phenyl-2-furfural, (2.86 g), ν_{max} 1660 and 1593 cm^{-1}, which was used for the next oxidation without further purification.

The aldehyde (2.56 g) was added into a semisolid mixture, prepared from silver nitrate (5.03 g) and sodium hydroxide (2.37 g) in water (20 ml) cooled with a ice bath, under vigorous stirring. The whole mixture was stirred at room temperature overnight and worked up as usual to give crude acid (2.20 g), mp 126—130 °C, which was recrystallized from chloroform to give **1h** (1.6 g), mp 150—150.5 °C (lit,[10] no mp, bp 120—122 °C/30 mmHg); IR, ν_{max} 3400, 1695, and 1195 cm^{-1}; NMR, δ 6.76 and 7.80 (each 1H, ABq, J=3.5 Hz, 3- and 4-H), 7.40 (5H, m, $C_6\underline{H}_5$), and 10.20 (1H, br s, COO$\underline{H}$). Found: C, 70.00; H, 4.16%. Calcd for $C_{11}H_8O_3$: C, 70.21; H, 4.29%.

*5-p-Methoxyphenyl-2-furoic Acid (**1i**).* This compound was not prepared by the reported method.[10] *p*-Anisidine (12.0 g) was dissolved in boiling 25% hydrochloric acid (40 ml) and cooled, when the hydrochloric acid salt precipitated. To the mixture were added crushed ice (30 g) and then rapidly sodium nitrite (8.0 g) in water (30 ml) under stirring, when the mixture became homogeneous. A saturated sodium acetate solution was added to the solution, until the pH value became 1.0, during which the temperature was kept at 0—10 °C. The solution was added dropwise under cooling to a mixture of 2-furoic acid (11.2 g) in water (100 ml) containing sodium acetate (32.0 g), which had been homogeneous on warming. The resulting mixture was mixed with an aqueous solution (10 ml) containing cupric chloride (4.0 g as $CuCl_2 \cdot 2H_2O$), and the whole mixture was stirred below 15 °C for 5 hr and then at room temperature for 60 hr. After removal of resinous material by filtration and evaporation of volatile substance by steam distillation, the solution became heterogeneous and, after being cooled, was filtered. The precipitate was treated with saturated sodium hydrogen carbonate solutions (3×100 ml). The carbonate extracts and the filtrate were combined, acidified with concd hydrochloric acid, and extracted with ethyl acetate (3× 100 ml). The acetate solution was washed with water (100 ml) and a saturated sodium chloride solution (100 ml), dried and evaporated to leave crude acid (4.5 g), mp 166—167 °C. This was recrystallized from 20% ethanol to give **1i** (2.9 g), mp 187—188 °C; IR (Nujol), ν_{max} 1670, 1265, and 1028 cm^{-1}; NMR, δ 3.80 (3 H, s, $OC\underline{H}_3$), 6.62 and 7.38 (each 1 H, ABq, J=3.5 Hz, 3- and 4-H), 6.94 and 7.74 (each 2 H, ABq, J=8 Hz, $CH_3OC_6\underline{H}_4$), and 8.84 (1 H, br s, COO$\underline{H}$). Found: C, 66.03; H, 4.64%. Calcd for $C_{12}H_{10}O_4$: C, 66.05; H, 4.62%.

*2,2'-Diethyl-2,2',5,5'-tetrahydro[2,2'-bifuran]-5,5'-dicarboxylic Acid (**3**).* To a mixture of 5-ethyl-2-furoic acid (**1b**) (0.3 g, 0.045 mol) in refluxing ammonia (300 ml) was added sodium (3.1 g, 0.145 mol), when the blue color appeared.

The mixture was stirred for 20 min and, when methanol (4.64 g, 0.145 mol) was added, became colorless and was further stirred for 3 hr. After removal of ammonia, the residue was diluted with water (20 ml), acidified with 2M hydrochloric acid, and extracted with ether (3×20 ml). The ether solution, on being dried and evaporated, gave crude acid (2.85 g), mp 210—215 °C, which was recrystallized from benzene to yield **3** (2.1 g), mp 229—230 °C; IR (Nujol), ν_{max} 1728, 1708, 1108, and 1060 cm^{-1}; NMR (C_6D_5N), δ 0.92 (6 H, t, J=6.5 Hz, $2C\underline{H}_3$), 2.20 (4 H, m, $2C\underline{H}_2$), 5.54 (2 H, double d, J=2.6 and 1.5 Hz, 5- and 5′-H), 6.03 (2H, double d, J=4.6 and 1.5 Hz, 3- and 3′-H), 6.60 (2H, double d, J=4.6 and 2.6 Hz, 4- and 4′-H), and 13.62 (2H, s, COO$\underline{H}$).

Compound **3** (243 mg) in ether was converted with diazomethane to the methyl ester (268 mg), which was recrystallized from ethanol to give **3** (R=CH_3) (215 mg), mp 88—89 °C; Mass, *m/e* 310 (M^+) and 155 (base); IR, ν_{max} 1760, 1740, 1278, and 1105 cm^{-1}; NMR (the text). Found: C, 62.22; H, 7.12%. Calcd for $C_{16}H_{22}O_6$: C, 61.92; H, 7.15%.

*Methyl 5-Ethyl-2,5-dihydro-2-furoates (**2b**).* To a refluxing ammonia (49 ml) containing 5-ethyl-2-furoic acid (**1b**, 3.5 g, 0.025 mol) dissolved in dry methanol (12 ml, 0.38 mole) was added lithium (0.53 g, 0.075 mol) during 15 min. The mixture was stirred under reflux for 30 min and, after removal of the ammonia, was mixed with dry methanol (35 ml). Into the solution was passed hydrogen chloride gas, until the pH value became 1 (universal test paper), when salts precipitated and were removed off by filtration. The mother liquors were refluxed for 4 hr, evaporated to remove methanol, diluted with water (30 ml), and then extracted with ether (3×20 ml). The ether solution was dried and evaporated to leave oily substance, which proved to contain a small amount of the unreacted acid methyl ester (**1b**, R′=CH_3) by glc, as shown in Table 1. The oil was distilled fractionally and a fraction (3.3 g), boiling 88—89 °C/13 mmHg, was collected. This was identified as a 1 : 1 mixture of diastereoisomers **2b**; Mass (the text); IR, ν_{max} 1768, 1743, 1270, and 1125 cm^{-1}; NMR (the text). Found: C, 61.47; H, 7.97%. Calcd for $C_8H_{12}O_3$: C, 61.52; H, 7.75%.

*Methyl 5-Methyl-, 5-Propyl-, 5-Isopropyl-, 5-*tert*-Butyl-, and 5-Benzyl-2,5-dihydro-2-furoates (**2a**, **2c**, **2d**, **2e**, and **2f**).* These compounds were produced from the corresponding furoic acids essentially in the same manner as the 5-ethyl derivatives (**2b**) and their physical constants are described in the following.

Compounds **2a**, bp 74—75 °C/15 mmHg; Mass, *m/e* 142 (M^+) and 83 (base, $M^+-COOCH_3$); NMR, δ 1.28 and 1.32 (total 3H, two d J=6 Hz, $C\underline{H}_3$), 3.68 (3H, s, $COOC\underline{H}_3$), 5.16 (2H, br m, 2- and 5-H), and 5.90 (2H, m, 3- and 4-H). Found: C, 58.81; H, 7.36%. Calcd for $C_7H_{10}O_3$: C, 59.14; H, 7.09%.

Compounds **2c**, bp 80—82 °C/13 mmHg; Mass, *m/e* 170 (M^+), 127 ($M^+-C_3H_7$) and 111 (base, $M^+-COOCH_3$); NMR, δ 0.90 (3H, br t, $CH_2CH_2C\underline{H}_3$), 1.48 (4H, br m, $C\underline{H}_2C\underline{H}_2CH_3$), 3.64 (3H, s, $COOC\underline{H}_3$), 5.15 (2H, m, 2- and 5-H), and 5.89 (2H, m, 3- and 4-H). Found: C, 63.19; H, 8.11%. Calcd for $C_9H_{14}O_3$: C, 63.51; H, 8.29%.

Compounds **2d**, bp 90—91 °C/15 mmHg; Mass, *m/e* 170 (M^+), 127 ($M^+-C_3H_7$) and 111 ($M^+-COOCH_3$); NMR, δ 0.90 (6H, m, isopropyl $C\underline{H}_3$), 1.74 (1H, septet, J=7.5 Hz, isopropyl C$\underline{H}$), 3.63 (3H, s, $COOC\underline{H}_3$), 4.60 (0.5 H, m, 5-H of *trans*-**2d**), 4.84 (0.5H, s, 5-H of *cis*-**2d**), 5.16 (1H, m, 2-H), and 5.88 (2H, br s, 3- and 4-H). Found: C, 63.35; H, 8.48%. Calcd for $C_9H_{14}O_3$: C, 63.51; H, 8.29%.

Compounds **2e**, bp 102—103 °C/15 mmHg; Mass, *m/e* 184 (M^+), 127 ($M^+-C_4H_9$), 125 ($M^+-COOCH_3$), and 57 (base, $C_4H_9^+$); NMR, δ 0.84 and 0.86 (total 9H, each s, $3C\underline{H}_3$), 3.65 (3H, s, $COOC\underline{H}_3$), 4.54 (0.5H, br d, J=4 Hz, 5-H of *trans*-**2e**), 4.72 (0.5H, br d, J=7 Hz, 5-H of *cis*-**2e**), 5.22 (1H, m, 2-H), and 5.92 (2H, br s, 3- and 4-H). Found: C, 65.02; H, 8.71%. Calcd for $C_{10}H_{16}O_3$: C, 65.19; H, 8.75%.

Compounds **2f**, oil, were separated from the unreacted acid methyl ester (**1f**, R=CH_3) and purified by repeated column chromatographies (Merck, benzene); Mass, *m/e* 218 (M^+) and 91 ($C_7H_7^+$); NMR, δ 2.86 and 3.04 (1.2 and 0.8H, each d, J=7 Hz, $C_6H_5C\underline{H}_2$), 3.64 and 3.66 (total 3H, each s, $COOC\underline{H}_3$), 5.12 (2H, m, 2- and 5-H), 5.90 (2H, br s, 3- and 4-H), and 7.25 (5H, m, $C_6\underline{H}_5CH_2$). Found: C, 71.50; H, 6.59%. Calcd for $C_{13}H_{14}O_3$: C, 71.54; H, 6.47%.

*Methyl 5-*p*-Methoxybenzyl-2,5-dihydro-2-furoates (**2g**) and Dimethyl 2,2′-*p*-Methoxybenzyl-2,2′,5,5′-tetrahydro[2,2′-bifuran]-5,5′-dicarboxylate (**4**).* 5-*p*-Methoxybenzyl-2-furoic acid (**1g**, 1.1 g) in ammonia (15 ml) and methanol (6 ml) was treated with sodium (0.33 g) in the same manner as **1b** and worked up as usual to give oily product (1.05 g), which on standing crystallized partially. The whole components were checked by glc (Table 1) and separated by column chromatography (Merck a 2 : 1 mixture of benzene and chloroform). Fractions with high R_f afforded oil (0.4 g), which was identified as the unreacted acid methyl ester (**1g**, R′=CH_3). Middle fractions gave **2g** (0.45 g), oil, Mass, *m/e* 248 (M^+) and 121 ($CH_3OC_7H_6^+$); NMR, δ 2.88 (2H, m, $CH_3OC_6H_4C\underline{H}_2$), 3.70 (3H, s, $C\underline{H}_3OC_6H_4CH_2$), 3.76 (3H, s, $COOC\underline{H}_3$), 5.12 (2H, m, 2- and 5-H), 5.84 (2H, m, 3- and 4-H), 6.81 and 7.10 (4H, br d, J=8 Hz, $CH_3OC_6\underline{H}_4CH_2$). Found: C, 66.75; H, 6.79%. Calcd for $C_{14}H_{16}O_4$: C, 66.73; H, 6.50%.

Fractions with low R_f gave crystalline material **4** (50 mg), mp 120—121 °C, which was recrystallized from chloroform for analysis; Mass, *m/e* 494 (M^+) and 247 (base); IR ν_{max} 1748, 1738, 1280, and 1215 cm^{-1}; NMR, δ 3.26 (4H, m, $2C\underline{H}_2$), 3.68 (6H, s, $2C\underline{H}_3O$), 3.76 (6H, s, $2COOC\underline{H}_3$), 4.56 (2H, m, 2×5-H), 5.40 and 5.56 (each 1H, m, 2×4-H), 5.96 and 6.04 (each 1H, m, 2×3-H), 6.74 and 7.12 (each 4H, ABq, J=8 Hz, 2×$C_6\underline{H}_4$). Found: C, 68.21; H, 6.08%. Calcd for $C_{28}H_{30}O_8$: C, 68.00; H, 6.12%.

*Methyl 2-Hydroxy-5-phenylpentanoate (**5h**).* 5-Phenyl-2-furoic acid (**1h**, 1.08 g) in ammonia (15 ml) and methanol (3 ml) was treated with sodium (0.41 g) in the same manner as **1b** and worked up as usual to give oily product (0.99 g), which consisted of two main components (by glc) and was separated by column chromatography (Merck, a 7 : 2 mixture of benzene and chloroform). Fractions eluted early afforded crystalline material (270 mg), which was recrystallized from ethanol to yield an unreacted acid methyl ester (**1h**, R′=CH_3) (245 mg), mp 90—91 °C; IR, ν_{max} 1730 (shoulder), 1715, 1591 (shoulder), 1575, 1273, and 1075 cm^{-1}. The remaining fractions (580 mg) were combined and separated by chromatography under the same conditions, giving small amounts of crude **1h** (R′=CH_3) (50 mg) and an unidentified oil (60 mg). After removal of these materials, the residual fraction (390 mg) was again submitted to column chromatography (a 3:1 mixture of benzene and hexane) to yield a colorless main product (200 mg), showing a single spot on tlc, along with an oily mixture (75 mg). The latter was presumed to consist mainly of methyl 2-hydroxy-5-phenylpent-3-enoate (**6h**) on the NMR spectrum but was not further purified. A part of the main product was purified by preparative tlc (benzene) for analysis to give **5h** in pure state; Mass, *m/e* 208 (M^+), 131 ($M^+-C_6H_5$), 117 ($M^+-C_6H_5CH_2$), 91 (base, $C_6H_5CH_2^+$), 77 ($C_6H_5^+$), and 59 ($COOCH_3^+$); IR, ν_{max} 3600, 1743, 1608, 1258, 1093, and 1070 cm^{-1} (shoulder); NMR δ 1.74 (4H, m,

3- and 4-H), 2.68 (3H, m, OH and 5-H), 3.76 (3H, s, CO-OCH$_3$), 4.20 (1H, t J=7 Hz, 2-H), and 7.16 (5H, s, C$_6$H$_5$). Found: C, 68.96; H, 7.68%. Calcd for $C_{12}H_{16}O_3$: C, 69.21; H, 7.74%.

*Methyl 2-hydroxy-5-p-methoxyphenylpent-3-enoate (**6i**).* 5-*p*-Methoxyphenyl-2-furoic acid (**1i**, 2.50 g) in ammonia (20 ml) and methanol (6 ml) was treated with sodium (0.80 g) in the same manner as **1b** and gave an oily product (2.56 g), which proved to consist of two main components by glc and tlc. This reaction product was separated by column chromatography (Merck, a 1 : 1 mixture of chloroform and hexane) into 3 parts. The most mobile fractions gave colorless oil (870 mg), which was further purified by column chromatography (a 2 : 1 mixture of benzene and ethyl acetate) to yield crystalline substance (560 mg), which on recrystallization from ethanol afforded the unreacted acid methyl ester (**1i**, R'=CH$_3$) (500 mg), mp 83—83.5 °C; Mass, *m/e* 232 (M$^+$), 201 (M$^+$—CH$_3$O) and 145 (base); IR, ν_{max} 1738 (shoulder), 1723, 1610, 1253, and 1073 cm^{-1}.

The middle fractions consisted mainly of the main product (**6i**), but resisted further purification. A part (100 mg) of these fractions was hydrolyzed with 5% potassium hydroxide in boiling methanol for 30 min to give crystalline acid (70 mg), mp 90—94 °C, which was recrystallized from chloroform to yield **6i** (R'=H), mp 101—102 °C; Mass (the text); IR (Nujol), ν_{max} 3468, 3030, 1738, 1611, and 1098 cm^{-1}; NMR (the text). Found: C, 64.57; H, 6.28%. Calcd for $C_{12}H_{14}O_4$: C, 64.85; H, 6.35%.

The least mobile fractions gave oily substance (206 mg), which was further purified by chromatography (a 10 : 1 mixture of benzene and ethyl acetate) to give colorless oil (110 mg), identified as methyl 2-hydroxy-5-*p*-methoxypentanoate (**5i**); Mass, *m/e* 238 (M$^+$) and 121 (base, CH$_3$OC$_6$H$_4$-CH$_2^+$); IR, ν_{max} 3368, 1743, 1723 (shoulder), 1608, and 1248 cm^{-1}; NMR, δ 1.73 (4H, m, 3- and 4-H), 2.57 (2H, m, 5-H), 2.84 (1H, br, s, OH), 3.75 (3H, s, CH$_3$O), 3.77 (3H, s, CO-OCH$_3$), 4.17 (1H, br t, J=6 Hz, 2-H), 6.80 and 7.08 (each 2H, ABq, J=8.5 Hz, C$_6$H$_4$). Found: C, 65.70; H, 7.79%. Calcd for $C_{13}H_{18}O_4$: C, 65.53; H, 7.61%.

Hetera-*p*-carbophanes. III. Conformation of Amide Groups in and Internal Rotation of Diaza[*n*]paracyclophanes with Two Alkoxy Groups at the Benzene Ring[1]

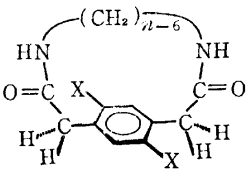
Kazuhiko SAKAMOTO and Michinori ŌKI*

Department of Chemistry, Faculty of Science, The University of Tokyo, Tokyo 113

(Received May 27, 1974)

A series of diazadioxo[*n*]paracyclophane derivatives with two alkoxy groups at the benzene ring were prepared. The conformation of amide groups in these compounds were studied by infrared, PMR, and ^{13}C NMR spectra to draw a conclusion that both amide groups are *s-trans*. Thus the infrared absorptions at 3430 and 3405 cm^{-1} are attributed to N—H···π interacting and N—H···O bonded *trans* forms, respectively. NCH_2 protons, which are separated by 5 bonds from the asymmetric center, as well as benzylic protons, were found to be non-equivalent when the rotation of the aromatic ring was slow. PMR spectra of the compounds studied at various temperatures indicate that introducing alkoxy groups in place of methyls at the benzene ring increases the barrier to rotation of the aromatic ring to a great extent.

In a recent paper, preparation and internal rotation of diaza[*n*]paracyclophane derivatives ($\mathbf{1}_n$ and $\mathbf{2}_n$, n=12—16) were reported.[2] Two amide groups in these compounds were suggested to take single conformation. From the infrared N—H stretching (ν_{NH}) absorptions, there were two possibilities: *s-cis* or *s-trans* with N—H···π interaction. From the scale model of the molecule, single absorption due to N—H stretching at the lower region, and PMR results which showed a single signal for NCH_2 protons, *s-cis* conformation was considered favorable.



$\mathbf{1}_n$: X=H, n=12—16
$\mathbf{2}_n$: X=CH_3, n=11—16
$\mathbf{3}_n$: X=OCH_3, n=11—16 and 18
$\mathbf{4}_{18}$: X=OC_2H_5, n=18

Further evidence will be needed to confirm the conformation of the amide group, because formation of N—H···π bond will lower the ν_{NH} frequency to the region of ν_{NH} absorption due to *s-cis* conformation and PMR data themselves can not rule out the *s-trans* conformation. Furthermore, the scale model of a molecule may not be taken as decisive evidence. Introduction of methoxy groups to the benzene ring will increase electron density on the benzene ring to favor the N—H···π bond.[3] Thus investigation on diaza[*n*]paracyclophane with methoxy groups will lend help in interpretation of the conformation of the amide groups.

The purpose of this paper is four fold. The first is to report results of preparation and characterization of $\mathbf{3}_n$ and $\mathbf{4}_{18}$ which carry alkoxy groups at the benzene ring, the second is finding of N—H···π and N—H···O bondings in these compounds, the third is establishment of *s-trans* conformation of the amide group by various means, and the fourth is barriers to rotation of the dialkoxybenzene rings. A part of the results on the last item was reported briefly in a short communication.[1]

Experimental

The syntheses of $\mathbf{3}_n$ and $\mathbf{4}_{18}$ were accomplished by condensation of α,ω-diamines with 2,5-dialkoxy-1,4-phenylenediacetyl dichloride under high dilution conditions. The latter compounds were prepared from 1,4-dialkoxybenzene according to the previously reported scheme.[2]

2,5-Dimethoxy-1,4-bis(chloromethyl)benzene. A mixture of 46 g(0.33 mol) of 1,4-dimethoxybenzene, 70 g(0.87 mol) of 37% formalin, 350 ml of concd. hydrochloric acid, and 300 ml of glacial acetic acid was warmed at 50—60 °C for 7 hr with stirring and introducing dry hydrogen chloride. The resulting solid was collected by filtration and was washed with water. Recrystallization from chloroform gave 58 g (yield, 74%) of pure compound, mp 163—164 °C (lit,[4] mp 165 °C).

2,5-Diethoxy-1,4-bis(chloromethyl)benzene was obtained similarly in a 60% yield, mp 148—151 °C (from chloroform). IR: 1225 and 1055 (ν_{C-OEt}), 700(ν_{C-Cl}) cm^{-1}. NMR ($CDCl_3$,δ): 1.42(6H, t, J=8 Hz), 4.04(4H, q, J=8 Hz), 4.62(4H, s), 6.92(2H, s). This compound was directly used for the next reaction.

2,5-Dimethoxy-1,4-bis(cyanomethyl)benzene. A suspension of 35 g(0.15 mol) of the above dichloride in 400 ml of dimethyl sulfoxide was slowly added to a stirred solution of 26 g(0.53 mol) of sodium cyanide in 300 ml of dimethyl sulfoxide at room temperature during a period of 1.5 hr. After the addition, the reaction mixture was warmed at 50—60 °C for 2 hr with stirring. The reaction mixture was poured into ice-water (*ca.* 3 l) and the resulting solid was collected by filtration. Recrystallization from chloroform gave 28 g(85%) of pure compound, mp 191—192 °C. IR: 2250($\nu_{C\equiv N}$), 1225 and 1045(ν_{C-OMe}) cm^{-1}. NMR($CDCl_3$, δ): 3.70(4H, s), 3.85(6H, s), 6.93(2H, s).

Found: C, 66.41; H, 5.36; N, 13.05%. Calcd for $C_{12}H_{12}N_2O_2$: C, 66.65; H, 5.39; N, 12.96%.

2,5-Diethoxy-1,4-bis(cyanomethyl)benzene was prepared similarly in a 90% yield, mp 177.5—178.5 °C (from hexane-ether). IR: 2250($\nu_{C\equiv N}$), 1230 and 1050(ν_{C-OEt}) cm^{-1}. NMR ($CDCl_3$, δ): 1.42(6H, t, J=8 Hz), 3.50(4H, s), 4.05(4H, q, J=8 Hz), 6.91(2H, s). This compound was directly used for the next reaction.

2,5-Dimethylphenylacetonitrile was obtained similarly from 2,5-dimethylbenzyl chloride[5] in an 86% yield, mp 29.5—31.0 °C (from hexane) (bp 126—128 °C/11—12 mmHg). IR (neat): 2250($\nu_{C\equiv N}$) cm^{-1}. NMR($CDCl_3$, δ): 2.28(3H, s), 2.32(3H, s), 3.60(2H, s), 7.07(2H, s), 7.16(1H, s).

Found: C, 82.88; H, 7.64; N, 9.65%. Calcd for $C_{10}H_{11}N$: C, 82.72; H, 7.64; N, 9.65%.

2,5-Dimethoxy-1,4-phenylenediacetic acid, mp 232—235 °C (decompn.), was prepared from the corresponding dicyanide by the previously reported method[2] in a 77% yield. IR: 1710($\nu_{C=O}$), 1230 and 1045(ν_{C-OMe}) cm^{-1},

2,5-Diethoxy-1,4-phenylenediacetic acid, mp 218—221 °C (decompn.), was prepared similarly in a 70% yield. IR: 1710($\nu_{C=O}$), 1220 and 1045(ν_{C-OEt}) cm^{-1}.

2,5-Dimethylphenylacetic acid, mp 124.5—126.0 °C (from chloroform), was prepared similarly in a 74% yield. IR: 1700($\nu_{C=O}$) cm^{-1}.

Found: C, 73.07; H, 7.07%. Calcd for $C_{10}H_{12}O_2$: C, 73.20; H, 7.37%.

2,5-Dimethoxy-1,4-phenylenediacetyl dichloride was obtained by the action of thionyl chloride in absolute ether in an 81% yield, mp 141.0—143.0 °C (from ether). IR: 1800($\nu_{C=O}$), 1220 and 1040(ν_{C-OMe}) cm^{-1}. NMR($CDCl_3$, δ): 3.78(6H, s), 4.11(4H, s), 6.71(2H, s).

2,5-Diethoxy-1,4-phenylenediacetyl dichloride, mp 110—112 °C (from ether), was prepared similarly in an 82% yield. IR: 1800($\nu_{C=O}$), 1225 and 1045(ν_{C-OEt}) cm^{-1}. NMR($CDCl_3$, δ): 1.39(6H, t, J=8 Hz), 4.00(4H, q, J=8 Hz), 4.10(4H, s), 6.73(2H, s).

2,5-Dimethylphenylacetyl chloride, yellowish oil, was prepared similarly in an almost quantitative yield. IR(neat): 1800 ($\nu_{C=O}$) cm^{-1}. NMR(CCl_4, δ): 2.26(3H, s), 2.31(3H, s), 4.02(2H, s), 7.00(3H, s).

Syntheses of Diaza[n]*paracyclophanes.*

Synthetic method will be described by taking the case of 13,16-dimethyl-3,9-diaza-2,10-dioxo[11]paracyclophane ($\mathbf{2}_{11}$) as an example.

A solution of 1.3 g(*ca.* 5 mmol) of 2,5-dimethyl-1,4-phenylenediacetyl dichloride in 100—150 ml of tetrahydrofuran was slowly added to a vigorously stirred and refluxing mixture of 2.0—3.0 g of potassium carbonate and 0.5 g (*ca.* 5 mmol) of pentamethylenediamine in 800 ml of tetrahydrofuran over a period of 26 hr, employing a high-dilution appratus. After filtration, the solvent was evaporated *in vacuo* to give a yellow solid. This solid was chromatographed on silica-gel (25 g). The fraction eluted with dichloromethane gave 370 mg(25%) of $\mathbf{2}_{11}$, mp 199.5—200 °C on recrystallization from carbon tetrachloride—dichloromethane. The melting points, the analytical data, and the solvent of recrystallization for each compound are summarized in Table 1.

N,N'-*Dipropyl-2,5-dimethoxy-1,4-phenylenediacetamide*(**5**) was prepared by the previously reported method[2] in an 86% yield, mp 197.0—197.5 °C (from carbon tetrachloride—chloroform). IR: 3290(ν_{NH}), 1645(amide I), 1550(amide II), 1220 and 1050(ν_{C-OMe}) cm^{-1}. NMR($CDCl_3$, δ): 0.85 (6H, m), 1.45(4H, m), 3.15(4H, q), 3.51(4H, s), 3.81(6H, s), 5.95(2H, b), 6.82(2H s).

Found: C, 64.30; H, 8.37; N, 8.16%. Calcd for $C_{18}H_{28}N_2O_4$: C, 64.62; H, 8.39; N, 8.33%.

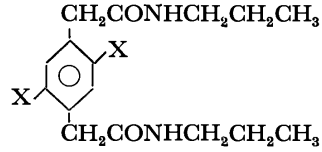
N,N'-*Hexamethylenebis(2,5-dimethylphenylacetamide)*. A stirred mixture of 0.5 g(43 mmol) of hexamethylenediamine, 1.5 g(0.83 mmol) of the 2,5-dimethylphenylacetyl chloride, 3 g of potassium carbonate, and 100 ml of tetrahydrofuran was refluxed for 2 hr. The resulting solid was collected by filtration and washed with water. After recrystallization from carbon tetrachloride—chloroform, it was obtained in an almost quantitative yield, mp 176.5—177.0 °C. IR: 3300(ν_{NH}), 1640(amide I), 1540(amide II) cm^{-1}. NMR ($CDCl_3$, δ): 1.0—1.6(8H, b), 2.22(6H, s), 2.30(6H, s), 3.13 (4H, q), 3.51(4H, s), 5.15—5.60(2H, b), 6.9—7.1(6H, m).

Found: C, 76.26; H, 9.06; N, 6.62%. Calcd for $C_{26}H_{36}N_2O_2$: C, 76.43; H, 8.88; N, 6.86%.

Measurement of the Spectra. The infrared spectra were recorded on either a Hitachi EPI-G2 grating infra-red spectrometer (4000—400 cm^{-1}) with KBr disk or a Perkin-Elmer 112G single beam grating spectrophotometer (3500—3000 cm^{-1}) with dilute chloroform solution. The PMR spectra were measured on a Hitachi R-20B spectrometer operating at 60 MHz at 34 °C. Samples were dissolved in deuteriochloroform, using TMS as an internal reference. Chemical shifts are recorded as ppm down field from TMS. Lanthanide induced shift measurements were performed by the stepwise addition of lanthanide shift reagents (either Eu(fod)$_3$-d_{27} or Eu(dpm)$_3$) to the deuteriochloroform solution of substrate. The molar ratios of the shift reagent to the substrate were from 0 through 0.6. ^{13}C FT NMR spectra were taken with a JEOL PFT-100 spectrometer in the deuteriochloroform-locked mode at 15.358808 MHz. Samples were dissolved in deuteriochloroform and TMS was used an internal reference. The mass spectra were observed on a Hitachi RMU-6L spectrometer.

Results and Discussion

Infrared Spectra. The ν_{NH} absorptions of these compounds are summarized in Table 2 together with those of compounds $\mathbf{1}_n$, $\mathbf{2}_n$, and open-chain models of **5**, **6**, and **7**.



5: X=OCH_3
6: X=H
7: X=CH_3

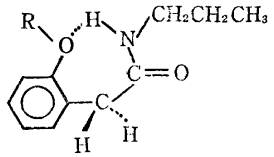
a) The numerical data in parentheses are ε_{max}.

As are seen from Table 2, hetera-*p*-carbophanes which carry alkoxy groups at the benzene ring show two ν_{NH} absorptions in contrast to the presence of only one ν_{NH} absorption in $\mathbf{1}_n$ and $\mathbf{2}_n$. These absorptions occur at *ca.* 3430—3440 cm^{-1} region for compounds $\mathbf{1}_n$ and $\mathbf{2}_n$, whereas $\mathbf{3}_n$ and $\mathbf{4}_{18}$ show absorption at *ca.* 3405 cm^{-1} in addition to an absorption corresponding to those of $\mathbf{1}_n$ and $\mathbf{2}_n$. As a clue to solve the assignment problem, the model compounds (**5**, **6**, and **7**) may be examined. The amide groups in these open-chain compounds may be assumed to take *s-trans* conformation.[2] Interestingly, those which do not possess alkoxy group showed only one absorption due to N—H stretching, whereas **5** showed two ν_{NH} absorptions which correspond to those of $\mathbf{3}_n$ and $\mathbf{4}_{18}$. The absorption at the higher frequency which is common for both types of compounds may be assigned to the *s-trans* amide which is interacting with the π-electrons of the benzene ring.[3] Since the extra band existing in the alkoxy compounds is located at lower frequency than that of N—H···π interacting form, it can not be attributed to a free form. The most probable candidate for the absorption is the N—H···O hydrogen bonded form (**8**), because it is improbable to assume that *s-cis* conformation is possible for compound **5** and the N—H···O bond will lower ν_{NH} frequency to a considerable extent.[6]



8

The same discussion will apply to the assignment of the N—H stretching absorption of $\mathbf{3}_n$ and $\mathbf{4}_{18}$. Thus the ν_{NH} absorption at *ca.* 3405 cm^{-1} is attributed to intramolecular N—H···O bond. However the origin of the absorption at higher frequency is not yet established because none of the possibilities of *s-cis* conformation and N—H···π interaction has yet been ruled out. Thus evidence from other sources is needed for assignment of the IR absorption.

PMR Spectra. PMR spectral data of $\mathbf{3}_n$ and $\mathbf{4}_{18}$ are summarized in Table 3 as well as those of $\mathbf{2}_{11}$ and open-chain compound for comparison. Change in signal shapes of the bridge methylene protons, except the NCH_2 in $\mathbf{3}_n$, according to the bridge length resembles the case of $\mathbf{2}_n$ and reflects rigidity and mobility of the molecules. However the chemical shifts of the bridge methylenes of $\mathbf{3}_n$ with small ring size are located at the higher field, relative to the corresponding methylenes of $\mathbf{2}_n$, by *ca.* 0.1 ppm, suggesting the larger anisotropy effect of the dimethoxybenzene ring. Benzylic protons of $\mathbf{2}_{11}$ and $\mathbf{3}_{11}$—$\mathbf{3}_{16}$ gave signals of the AB type, whereas those of $\mathbf{3}_{18}$, $\mathbf{4}_{18}$, and the open-chain amide (**5**) gave singlet signals. These changes must be interpreted by assuming the fast internal rotation of the benzene ring for the compounds showing the A_2 type signals and the slow rotation for the compounds showing the AB type, because these compounds are expected to give rise to nonequivalent benzylic protons when the internal rotation is frozen on the NMR time scale.

The spectral feature of $\mathbf{3}_{11}$—$\mathbf{3}_{16}$ is that they show two signals at *ca.* 2.8 and *ca.* 3.5 ppm due to NCH_2 protons. In sharp contrast, $\mathbf{2}_n$ was reported to show only one signal for the NCH_2 groups. $\mathbf{3}_{18}$, $\mathbf{4}_{18}$, and **5** also show one signal for the NCH_2. The internal

rotation in compounds $\mathbf{3}_{11}$—$\mathbf{3}_{16}$ is slow, as will be discussed later, whereas that in $\mathbf{3}_{18}$ and $\mathbf{4}_{18}$ is fast. Bifurcation of the NCH_2 signals of $\mathbf{3}_{11}$—$\mathbf{3}_{16}$ may arise from such a steric environment. Namely, because of severe steric conditions in these compounds, one of the amide groups may take *s-cis* conformation, while the other takes *s-trans* conformation. Even in $\mathbf{3}_{18}$ and $\mathbf{4}_{18}$, the amide groups may be *s-cis* and *s-trans*, although they may exchange rapidly at the temperature in question. There is another possibility, however, for the apparent two signals for the NCH_2 group. That is although both amide groups take *s-trans* conformations, the NCH_2 protons are stereoheterotopic due to the slow internal rotation in $\mathbf{3}_{11}$—$\mathbf{3}_{16}$, whereas they become homotopic due to the fast rotation in $\mathbf{3}_{18}$ and $\mathbf{4}_{18}$. In the former case, the NCH_2 protons become nonequivalent and give different chemical shifts, though they both belong to the *s-trans* conformation of amides.

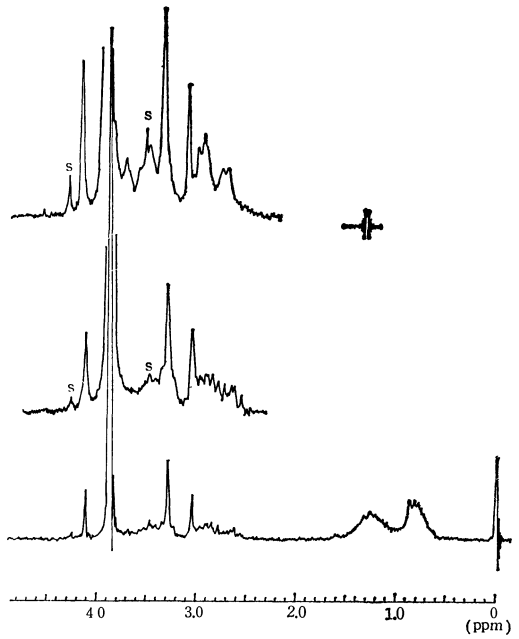

Fig. 1. Normal and decoupled (irradiated at *ca.* 1.3 ppm) PMR spectra of $\mathbf{3}_{12}$.
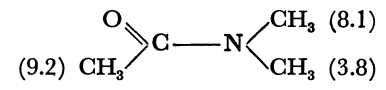
s: side band of OCH_3 at 3.85 ppm.

Double resonance technique would lend help in determining which of the two is the real reason for the bifurcation. Thus β-methylene protons to the nitrogen were irradiated and signals due to α-methylenes were observed. As are seen in Fig. 1, which shows the spectrum of $\mathbf{3}_{12}$ as a typical example, the α-methylenes seem to give a broad AB type signal which is coupled with a proton on nitrogen, although the signals at the lower field are obscured by other strong signals. The broadness of the signals owes to the presence of nitrogen. Thus double resonance experiment is in favor of the postulation that the bifurcation is caused because of the heterotopic nature of the NCH_2 protons. If the bifurcation were to be attributed to the presence of *s-cis* and *s-trans* conformations, the methylene signals would have appeared as a pair of doublets at two magnetic fields. The fact that the mean chemical shift of two signals due to NCH_2's of $\mathbf{3}_{11}$—$\mathbf{3}_{16}$ is very close to the chemical shift of those of diaza[18]paracyclophanes ($\mathbf{3}_{18}$ and $\mathbf{4}_{18}$) in which the dialkoxybenzene ring is rotating rapidly, may be taken as another piece of supporting evidence for the sole presence of *s-trans* conformation.

If the change from heterotopic to homotopic protons *vice versa* could be detected by the temperature dependence study of the PMR spectra, it would be almost a decisive support for the cause that the bifurcation is due to the heterotopy. Thus PMR spectra of $\mathbf{3}_{16}$ in tetrachloroethane were observed at elevated temperatures. The temperature-raise caused coalescence of the two signals in question at 2.9 and 3.5 ppm and a new signal was observed at 3.2 ppm which is very close to the chemical shift of NCH_2's of $\mathbf{3}_{18}$. On the contrary, lowering the temperature of $\mathbf{4}_{18}$ in deuteriochloroform caused the separation of NCH_2 signal at 3.2 ppm into two, at 2.9 and 3.5 ppm. These results suggest that the cause of bifurcation of the NCH_2 signal in these compounds is really the heterotopic nature of the protons of the *s-trans* conformation.

^{13}C NMR Spectra. It was recently reported that the conformation of *N*-monosubstituted amides had a significant effect upon the chemical shifts of carbonyl carbons and those of carbons adjacent to the nitrogen. The difference in chemical shifts due to *s-cis* and *s-trans* conformations amounts to 3.4 ppm in *N*-methylformamide and differences between the two methylene (or methyl) carbons attached to nitrogen in *N,N'*-dimethylformamide, *N,N'*-dibutylformamide, and *N,N'*-dibutylacetamide are found to be 5.1, 5.2, and 3.3 ppm, respectively.[7] Therefore, it is expected that, if the amide groups in diaza[*n*]paracyclophanes in question took *s-cis* and *s-trans* conformation, ^{13}C NMR spectra of these compounds would show a pair of carbonyl carbon signals and pairs of other carbons which are α, β, *etc.* to the nitrogens. Contrary to the expectation, however, ^1H-noise-decoupled ^{13}C FT NMR spectra of $\mathbf{3}_{12}$ and $\mathbf{3}_{13}$ in deuteriochloroform gave rise to nine and ten signals, respectively, as are listed in Table 4 which includes data of $\mathbf{2}_{12}$ and **5** also. The signals are tentatively assigned by use of the single frequency off-resonance ^1H-decoupling technique, known chemical shift rules for various kinds of carbons,[8] and signal intensities. The number of different carbon signals of diaza[*n*]paracyclophanes points out that these should exist as a single conformer which has C_2 symmetry element.

Lanthanide Induced Shift. Lanthanide shift reagent would provide further information about the conformations of amides. In the absence of the steric hindrance, protons in a methyl group *cis* to the carbonyl oxygen in amide moiety are known to experience a larger shift than their counterparts at *trans* position.[9] Thus in *N,N'*-dimethylacetamide, the following data are known.[10]



Since lanthanide shift reagents are known to cause appearence of unexpected peaks and this effect depends

a) The numerical data in parentheses are obtained by using $Eu(dpm)_3$ and the others by using $Eu(fod)_3$-d_{27}. b) NCH_2 signal at the lower magnetic field. c) NCH_2 signal at the higher magnetic field. d) This signal appeared as a quartet. e) *N,N'*-Hexamethylenebis(2,5-dimethylphenylacetamide).

on the nature of the shift reagents used,[11)] careful examination of the spectra will be necessary. However, under the conditions examined, none of the anomalous peaks appeared, the lanthanide shift reagent causing no trouble in obtaining the relative lanthanide induced shift (LIS).

LIS was plotted against [L]/[S] where [L] and [S] are the molar concentrations of a lanthanide shift reagent and a substrate, respectively. These plots yielded good linear relationships and relative slopes of various protons, taking the slope of CH_2CO as a reference, were calculated. The results are listed in Table 5. $Eu(fod)_3$-d_{27} was mainly used but $Eu(dpm)_3$ gave very close values.

The results may be interpreted that the predominant interaction between amides under investigation and the lanthanide reagent is of pseudo-contact nature.[12)] The lower field multiplets for NCH_2' proton suffered a larger induced shift than the NCH_2 proton at a higher magnetic field. The first look of these data would lead to an assignment of the higher and the lower signals to *s-cis* and *s-trans* conformations, respectively, because the signal of NCH_2 protons *trans* to carbonyl is known to appear at the higher magnetic field than that of the *cis*.[13)] Looking carefully at the relative ratios, however, a rather large relative slope for the signals at the lower magnetic field is noticed. The relative slope for the methyl which is *cis* to the acetyl methyl group in *N,N'*-dimethylacetamide is 0.41 (*loc. cit.*) and NCH_2 protons of *N*-methyl-γ-butyrolactam gives the relative slope of 0.41.[14)] Our results on ε-caprolactam indicate that the relative slope for NCH_2 is 0.4, using $Eu(fod)_3$-d_{27}. Although the complexing site of europium may vary from compound to compound to some extent, the relative slope seems to be fairly small in these compounds. On the other hand, the relative ratios of the signals at the lower magnetic field are 0.6—0.8. In addition, average slopes of the two NCH_2 signals are close to the relative slope of NCH_2 in $\mathbf{3}_{18}$ and to those of open-chain amides examined. These results favor that the both amide groups take *s-trans* conformation.

All the above discussions support that the amide groups in $\mathbf{3}_n$ are the *s-trans* form. This necessarily leads to a conclusion that the ν_{NH} absorption of $\mathbf{3}_n$ at *ca.* 3430 cm^{-1} is due to the N—H···π interacting *s-trans* form.

Amide Conformations as Reinvestigated with the Aid of Lathanide Shift Reagent. Since all the evidence presented above indicate that the amide groups in

$\mathbf{3}_n$ take *s-trans* conformation, reinvestigation of the conformations of amides in $\mathbf{1}_n$ and $\mathbf{2}_n$ becomes necessary. Thus $\mathbf{2}_{12}$ and $\mathbf{2}_{13}$ were submitted to the study with the aid of lanthanide shift reagent. The results are shown in Table 5. The PMR spectral data suggest that these compounds take also *s-trans* form only, because the ratios of the chemical shifts of NCH_2 protons referred to that of CH_2CO protons are characteristic of the *s-trans* form. Thus we wish to correct our earlier suggestion that $\mathbf{1}_n$ and $\mathbf{2}_n$ take *s-cis* conformations as regard the amide groups. The ring strain associated with the formation of this kind of cyclophanes does not seem to be large enough to cause preference of the *s-cis* form over the *s-trans*. Thus the ν_{NH} absorption at *ca.* 3430 cm^{-1} of $\mathbf{1}_n$ and $\mathbf{2}_n$ should now be attributed to the N—H$\cdots\pi$ interacting form rather than the *s-cis* conformation.

Internal Rotation of the Dialkoxybenzene Ring. Temperature dependence of the PMR spectra was studied to obtain the free energies of activation for the internal rotation of the aromatic ring. Those of which ansa chain members are 15 or less do not show any temperature dependency on raising the temperature. The barrier to rotation seems very high for these compounds. The AB quartet of $\mathbf{3}_{16}$ in tetrachloroethane gradually broadened on raising the temperature but coalescence was not observed up to 174 °C, though the NCH_2 signals coalesced into a broad singlet at about 160 °C. On changing the solvent to hexadeuteriodimethyl sulfoxide, however, the signals coalesced at 141 °C. On the other hand, the signal of benzylic protons of $\mathbf{4}_{18}$ in deuteriochloroform broadened considerably at low temperatures: the coalescence temperature was found to be −30 °C. Attempts at observing exact chemical shifts and coupling constant of the AB type protons of $\mathbf{4}_{18}$ were unsuccessful because of broadening of signals, and poor solubility in solvents at low temperatures.

The free energies of activation were obtained by putting the NMR parameters into the following equation:[15]

$$\Delta G_c^{\ddagger} = 4.57\, T_c\{9.97+\log_{10}(T_c/\sqrt{\Delta\delta_{AB}^2+6J_{AB}^2})\}$$

The parameters of $\mathbf{3}_{16}$ obtained at 34 °C were used. On the other hand it was not possible to obtain $\Delta\delta_{AB}$ and J_{AB} for $\mathbf{3}_{18}$ and $\mathbf{4}_{18}$. Thus those parameters for compound $\mathbf{3}_{16}$ were used to obtain approximate barriers to rotation of $\mathbf{3}_{18}$ and $\mathbf{4}_{18}$. It will not be too unreasonable to use these parameters because the structures of these compounds are alike. The results are shown in Table 6.

$\mathbf{3}_{16}$ which has two methoxy groups at the aromatic ring shows higher free energy of activation for rotation of the aromatic ring than that of $\mathbf{2}_{16}$ with two methyl groups by about 10 kcal/mol. This large difference in activation energies must be caused by replacement of the methyl groups by the methoxy because the other part of the molecules is the same. Since much difference in energies of the ground states of these molecules is not expected, the results may be attributed to the difference in energies at the transition states. Then the methoxy group must give more steric hindrance at the transition state than the methyl group.

The apparent bulkiness of the methoxy and the methyl groups in these compounds is just the opposite of the generally accepted. Methyl group is known to retard racemization of biphenyls more effectively than methoxy group,[16] even though the latter group contains more atoms than the former. This apparent reversal in giving the steric effect is understood by assuming that, by taking a conformation in which methoxy methyl is far from the site of interaction, oxygen only becomes the part giving steric hindrance. This deduction was supported by essentially the same ultraviolet absorption spectra of 2-*n*-alkylbiphenyls.[17]

In the process of internal rotation of $\mathbf{3}_{16}$, however, the methoxy group must pass through the space provided by the ansa chain. Namely, the methoxy group gives steric effect to the transition state not by the oxygen only but by the group as a whole. The apparent bulkiness of the methoxy group may be reduced by torsion from the coplanarity with the aromatic ring. But this torsion occurs only at the expense of resonance energy.[18] Therefore, the barrier to rotation of the benzene ring is high irrespective to the steric situation of the methoxy group. This, we believe, is the first example that the methoxy group is proven to be bulkier than the methyl.[19]

The ethoxy group seems to be even bulkier than the methoxy group along the lines expected from the above discussion, because it was impossible to observe coalescence temperature for $\mathbf{3}_{18}$ under the similar conditions. Although the ethoxy group may be folded at the transition state to minimize the free energy of activation for rotation, it is still bulkier than the methoxy group. It is expected that other alkoxy groups will affect the barrier to rotation of the aromatic ring in a similar fashion.

The authors wish to express their hearty thanks to Professor T. Shimanouchi and Mr. M. Kakimoto for helpful discussions and technical assistance in using a Perkin-Elmer 112G single beam grating spectrophotometer and to Mr. K. Matsushita of JEOL Ltd. for the measurement of ^{13}C FT NMR spectra.

19) The bulkiness referred to here is defined by the free energy of activation. We believe, however, the methoxy group is bulkier than the methyl in the sense of enthalpy of activation also, because the largest entropy of activation known in the internal rotation of methoxy-substituted biphenyl[20] is not sufficient to reverse the difference of 10 kcal/mol in free energy of activation at ambient temperature.

The Convenient Synthesis of Anhydronucleosides *via* the 2′,3′-*O*-Sulfinate of Pyrimidine Nucleosides as the Active Intermediates

Tsuneo SOWA and Kozo TSUNODA

Research Section, Foodstuffs Plant, Asahi Chemical Ind. Co., Ltd. Nobeoka, Miyazaki 882

(Received June 6, 1974)

The synthesis of 2,2′-*O*-anhydro(1-β-D-arabinofuranosyl) cytosine (**3a**) and 2,2′-*O*-anhydro(1-β-D-arabinofuranosyl) uracil (**3b**) is described. The active intermediates, 2′,3′-*O*-sulfinyl cytidine (**2a**) and 2′,3′-*O*-sulfinyl uridine (**2b**), were prepared from the corresponding nucleosides (**1a** or **1b**) by successive treatment with thionyl chloride in acetonitrile and with water. The 2,2′-*O*-anhydropyrimidine nucleosides were formed quantitatively by heating the intermediates in an acidic aqueous solution or in *N*,*N*-dimethylformamide in the presence of sodium acetate. The treatment of the anhydronucleosides with alkali gave the corresponding arabinonucleosides.

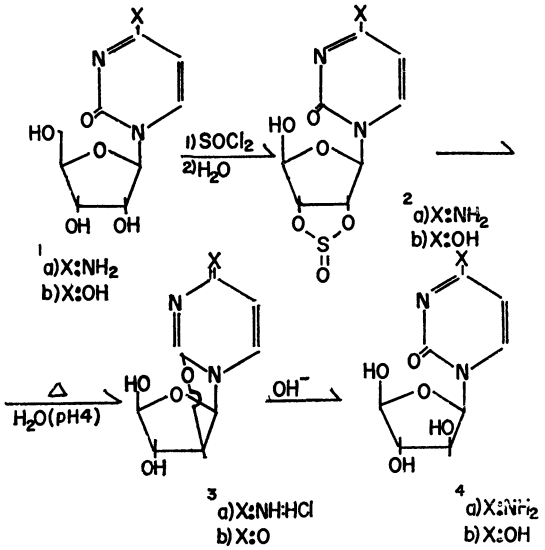
Anhydronucleosides are important modifications of natural nucleosides and have been used as intermediates in the chemical synthesis of arabinonucleosides. 2,2′-*O*-Anhydro-1-β-D-arabinofuranosyl cytosine has been shown to be an useful intermediate[1–3] for the synthesis of a carsinostatic nucleoside, 1-β-D-arabinofuranosyl cytosine,[4] and by itself to be a potent carsinostatic agent.[5] Anhydronucleosides have been synthesized by several procedures from natural nucleosides *via* the corresponding activated intermediates, such as tosyl,[6,7] mesyl,[8,9] carbonyl[10,11] and thiocarbonyl[12] derivatives, but most of those procedure involve tedious steps. Recently, 2,2′-*O*-anhydro(1-β-D-arabinofuranosyl)cytosine was successfully synthesized directly from cytidine with a Vilsmeier-Haack reagent.[13] We wish to describe another simple method for the synthesis of anhydronucleosides.

Results and Discussion

The synthesis of anhydronucleosides is outlined in Scheme 1. The essential step in the scheme is the introduction of a good leaving group at the 2′ and 3′ positions in the ribose moiety of natural nucleosides. In order to establish a convenient method usable on a large scale, a cyclic sulfinyl group was used as the leaving group; it was considered to be more active than either the cyclic carbonyl group[10,11] or the cyclic thiocarbonyl group.[12]

Thionyl chloride, which is readily obtainable on a commercial scale, was reacted with cytidine (**1a**) in dry acetonitrile at room temperature for 2 hr. Paper chromatography showed a single spot with an R_f-value of 0.7, different from that of **1a** (R_f 0.33). The reaction product was isolated in an 80% yield by adding a small amount of water to the reaction mixture. The structure of the acylation product was identified as 2′,3′-*O*-sulfinyl cytidine hydrochloride (**2a**), which was negative to a periodate-benzidine test[14] and which gave an ultraviolet spectrum similar to that of **1a**. The alkali hydrolysis of **2a** eliminated the cyclic sulfinyl group and so yielded **1a**. The **2a** product had three fairly sharp bands due to S=O stretching at 1010, 1021, and 1053 cm^{-1}, and three sharp bands associated with the five-membered cyclic sulfinyl group at 1201, 1205, and 1210 cm^{-1} in the infrared spectrum.[15] The elemental analysis of **2a** agreed with the proposed structure. The structure of **2a** was further confirmed by a subsequent reaction in which it was converted into 1-β-D-arabinofuranosyl cytosine (**4a**) through 2,2′-*O*-anhydro(1-β-D-arabinofuranosyl) cytosine hydrochloride (**3a**).

In the acidic solution, **2a** was stable at room temperature but was transformed into **3a** at an elevated tem-



Scheme 1.

Experimental conditions:
CH_3CN 10 ml, $SOCl_2$ 15 mmol, cytidine 3 mmol at pH 4.0, at the temperature of a) 100 °C, b) 80 °C, c) 60 °C, d) 40 °C.

Table 1. Properties of nucleoside derivatives

Compd.	Mp (dec.)	R_f, P. C.		$[\alpha]_D^{20}$	UV spectrum[a]	
		solv. A	solv. B		λ_{max}	λ_{min}
1a	220—230 °C	0.33	0.53	29.9	280	241
2a	253—254 °C	0.70	—	−50.4	278	240
3a	262 °C		0.81	−22.0	232, 263	243
4a	215 °C	0.33	0.65	158.0	280	241
1b	165 °C	0.51	0.54	4.0	263	230
2b	104—105 °C	0.69	—	—	260	229
3b	234—236 °C	0.48	0.67	11.0	223, 252	236
4b	215—216 °C	0.48	0.58	116.8	263	230

a) at pH 2.0

perature (Fig. 1). When **2a** was refluxed in the acidic aqueous solution at pH 4.0, the reaction went essentially to completion after 1 hr to form a 2,2′-*O*-anhydro-linkage and it could be heated at 80 °C for 2 hr without any deterioration in the reaction yield. By anion-exchange column chromatography, **3a** was isolated in a 74.7% yield and was identified as 2,2′-*O*-anhydro(1-β-D-arabinofuranosyl)cytosine hydrochloride by a comparison of its physical properties with those of an authentic sample.[13] The overall yield of **3a** from **1a** could be increased to 72.8% by omitting the isolation of the intermediate, **2a**.

Uridine (**1b**) was reacted with thionyl chloride under the same conditions as **1a** to give 2′,3′-*O*-sulfinyl uridine (**2b**) as a single product, as was shown by paper chromatography. Its chromatographic behavior and ultraviolet absorption properties are shown in Table 1. By heating **2b** in *N*,*N*-dimethylformamide (DMF) at 80 °C in the presence of sodium acetate, 2,2′-*O*-anhydro-(1-β-D-arabinofuranosyl)uracil (**3b**) was obtained from **1b** in an overall yield of 46.7%. The physical properties of **3b** were in good agreement with those of an authentic material.[11] Compounds **3a** and **3b** were easily converted to 1-β-D-arabinofuranosyl cytosine (**4a**) and 1-β-D-arabinofuranosyl uracil (**4b**) respectively by treating them with alkali. The physical properties of **4a** and **4b** are listed in Table 1; they are identical with those of authentic samples.

The method of synthesizing anhydronucleosides described above is superior to that of Kikugawa[13] or Furukawa[11] in respect to the yield and the simplicity of the procedure.

Experimental

The ultraviolet spectra were recorded on a Hitachi DPS-3T spectrophotometer, and the infrared spectra, on a Hitachi EPI-G2 apparatus. The paper chromatography of the reaction products was carried out by the ascending technique on Toyo-Roshi No. 51 paper (40×40 cm) using the following solvent systems: Solvent A; *n*-butanol–acetic acid–water (4 : 1 : 5); Solvent B; isopropanol–saturated ammonium sulfate–1M-sodium acetate (2 : 79 : 19).

2′,3′-O-Sulfinyl Cytidine Hydrochloride Obtained by the Reaction of Cytidine with Thionyl Chloride. Freshly distilled thionyl chloride (6 g, 50 mmol) was placed in 30 ml of acetonitrile, and the mixture was set aside at room temperature. To the solution was then added cytidine (2.6 g, 10 mmol), and the mixture was stirred at room temperature for 2 hr. A 15-ml portion (0.8 mol) of water was then added to the reaction mixture to destroy the reactant under vigorous stirring. Paper chromatography showed a single spot having an R_f value of 0.7, an aqueous extract of which showed the absorption maximum at 278 nm (pH 1.0). The resulting reaction mixture was kept in the refrigerator overnight, and then the white precipitate thus obtained was collected by filtration, washed with water and then twice with methanol, and dried to yield 2.63 g (81.0%) of 2′,3′-*O*-sulfinyl cytidine hydrochloride; mp 253—254 °C (dec.), $[\alpha]_D^{20}$-50.4 ° (*c*, 0.5, H_2O). The UV and chromatographic properties are shown in Table 1.

Found C; 33.30, H; 3.70, N; 11.30, S; 9.30, Cl; 11.53%. Calcd for $C_9H_{12}N_3O_6SCl$, C; 33.18, H; 3.69, N; 11.90, S; 9.83; Cl; 10.91%.

*2,2′-O-Anhydro(1-β-D-arabinofuranosyl) Cytosine Hydrochloride (**3a**). From 2′-3′-O-Sulfinyl Cytidine Hydrochloride (**2a**):* 2′,3′-*O*-Sulfinyl cytidine hydrochloride (32.5 g, 100 mmol) was dissolved into 1 l of water, and then the solution was adjusted to pH 4.0 with 6M-sodium hydroxide. After refluxing the resulting solution for 4 hr, the reaction mixture was cooled and was then applied to a Diaion W.A.-30 (acetate form) column (2.5×40 cm). The column was washed with 3 l of water, the washings were evaporated *in vacuo* to about 200 ml after the pH of the solution had been adjusted to 4.0 with 6M-hydrochloric acid. A 300-ml portion of ethanol was added to the concentrated solution, and the solid thus precipitated was collected by filtration, washed twice with ethanol, and dried to give 19.5 g (78.4% yield) of 2,2′-*O*-anhydro(1-β-D-arabinofuranosyl) cytosine hydrochloride. Mp 262 °C (dec.), $[\alpha]_D^{22}$ −22 ° (*c*, 0.5, H_2O). The UV and chromatographic properties are shown in Table 1. Found, C; 41.30, H, 4.65, N; 15.85, Cl; 13.60%. Calcd for $C_9H_{11}O_4N_3$ HCl, C; 41.32, H; 4.63; N; 16.07, Cl; 13.61%.

*From Cytidine (**1a**):* Cytidine (2.6 g, 10 mmol) and thionyl chloride (6 g, 50 mmol) were mixed in acetonitrile (30 ml) at room temperature for 2 hr, and then the reaction mixture was poured into ice water (1 l). The aqueous solution was adjusted to pH 4.0 with 6M-sodium hydroxide and then refluxed for 2 hr. The resulting solution was cooled to room temperature and treated essentially by the above method. 1.9 g of 2,2′-*O*-anhydro(1-β-D-arabinofuranosyl) cytosine hydrochloride was obtained as white needles in the yield of 72.8% from material cytidine. mp 262—263 °C (dec.), $[\alpha]_D^{20}$ −22 ° (*c*, 0.5, H_2O). Found, C; 41.28, H; 4.70, N; 16.01, Cl; 13.63%.

*1-β-D-Arabinofuranosyl Cytosine (**4a**).* 2,2′-*O*-Anhydro-(1-β-D-arabinofuranosyl) cytosine hydrochloride (52 g, 200 mmol) was dissolved in 3 l of water, after which the solution was adjusted to pH 10.0 with 2M-sodium hydroxide. The solution was allowed to stand at room temperature for

1 hr and was then applied to an Amberlite 200 (H^+ form) column (5×200 cm). The column was washed with water and eluted with 2 l of 1M-ammonium hydroxide. Fractions having an UV absorption at 260 nm (as checked on an UV spectrophotometer) were collected and concentrated to dryness. The residual crystalline product was recrystallized from ethanol to give 43.7 g of 1-β-D-arabinofuranosyl cytosine; mp 215 °C (dec.), $[\alpha]_D^{20}+158°$ (*c*, 0.5, H_2O). Found, C; 44.49, H; 5.41, N; 17.21%. Calcd for $C_9H_{12}O_5N_3$, C; 44.44, H; 5.39, N; 17.28%.

*2′,3′-O-Sulfinyl Uridine (**2b**).* Into a mixed solution of thionyl chloride (20 g, 160 mmol) and acetonitrile (100 ml) was vigorously stirred uridine (10 g, 40 mmol), and then the reaction mixture was maintained for 4 hr at 5 °C. After water (4.3 g, 240 mmol) had been added to the resulting mixture, the white precipitates were collected, washed with methanol, and then dried to yield 11.1 g (85%) of 2′,3′-*O*-sulfinyl uridine dihydrate. mp 104—105 °C (dec.), Found; C; 33.04, H; 2.98, N; 8.49, S; 9.78%. Calcd for $C_9H_{10}O_2N_7$-$S\cdot 2H_2O$ C; 33.13, H; 3.06, N; 8.58, S; 9.81%.

*2′,3′-O-Anhydro(1-β-D-arabinofuranosyl) Uracil (**3b**)* 2′,3′-*O*-Sulfinyl uridine dihydrate (6.96 g, 21 mmol) and sodium acetate (7.9 g, 96 mmol) were heated in *N,N*-dimethylformamide (400 ml) at 80 °C for 4 hr and then cooled. The solid thus precipitated was filtered off and washed with 50 ml of DMF. The filtrate and washings were combined and concentrated to dryness. The resulting syrup was crystallized from ethanol. The crystalline product (4.7 g) was recrystallized from water to give 2.7 g of 2,2′-*O*-anhydro-(1-β-D-arabinofuranosyl) uracil; mp 234—236 °C (dec.), $[\alpha]_D^{20}-11.0°$ (*c*, 0.5, H_2O). Found, C; 48.15, H; 4.41, N; 12.40%. Calcd for $C_9H_{10}N_2O_5$, C; 48.23, H; 4.45, N; 12.41%.

*1-β-D-Arabinofuranosyl Uracil (**4b**).* 2,2′-*O*-Anhydro(1-β-D-arabinofuranosyl) uracil (1.1 g, 5 mmol) was dissolved in 100 ml of water, and then the solution was adjusted to pH 10.0 with 2M-ammonium hydroxide. The mixture was allowed to stand at room temperature for 1 hr and was then applied to a column containing 20 g of active carbon, granule type. The column was subsequently washed with water and eluted with 50 ml of 0.5 M-ammonium hydroxide. The effluent was evaporated *in vacuo*. The crystallization of the residue from ethanol afforded 1.03 g of 1-β-D-arabinofuranosyl uracil, mp 215—216 °C (dec.), $[\alpha]_D^{20}+114.3°$ (*c*, 0.5, H_2O). Found, C; 44.29, H; 5.01, N; 11.40%. Calcd for $C_9H_{12}N_2O_6$, C; 44.26, H; 4.92, N; 11.48%.

Metalation of 2-Methyl-4*H*-pyran-4-one and its Reactions

Makoto YAMAMOTO and Noboru SUGIYAMA*

Department of Chemistry, Saga University, Saga 840

**Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo 112*

(Received June 24, 1974)

2-Methyl-4H-pyran-4-ones formed metalated products in the presence of sodium amide in liquid ammonia, and the metalated product reacted with alkyl and aralkyl halides or carbonyl compounds to give alkylated or condensed products. Self condensation reactions of 2-methyl-4*H*-pyran-4-ones also occurred in liquid ammonia to give flavone and the γ-pyrone dimer.

Boon[1] reported that 2,6-dimethyl-4*H*-pyran-4-one (**1**) reacts with benzaldehyde in an alkaline aqueous solution to give 2,6-distyryl-4*H*-pyran-4-one. 6-Methyl 1,2-diphenyl-2,3-dihydro-4-pyridone also condensed with benzaldehyde in an alkaline methanol solution to form 6-styryldihydropyridone.[2] These results indicate that the β-methyl hydrogen of an α,β-unsaturated ketone is acidic enough to react with an electrophile in an alkaline media.

This paper describes the metalation of 2-methyl-4*H*-pyran-4-one, and its reaction with some electrophiles.

Results and Discussion

Compound **1** did not give the metalated product **1′** by treating **1** with (a) sodium hydride in refluxing benzene, (b) lithium dimethylamide in ether, or (c) lithium *N*-methylanilide in ether or in tetrahydrofuran at room temperature, and **1** was recovered quantitatively in each case. Compound **1** reacted with *n*-butyl lithium in ether or in tetrahydrofuran at −78 °C under a nitrogen atmosphere to give 2,6-dimethyl-4-*n*-butyl-4*H*-pyran-4-ol (**2**), but at −20 °C or at room temperature **1** merely decomposed.

However treatment of **1** with sodium amide gave the metalated product **1′**. The formation of **1′** was proved that **1** was allowed to react with an equimolar amount of sodium amide in liquid ammonia at −78 °C under a nitrogen atmosphere, and to the resulting red solution was added an equimolar amount of benzyl bromide to give 2-methyl-6-phenethyl-4*H*-pyran-4-one (**3**) in 32% yield, accompanied by 14.5% of a mixture of dialkylated products, 2-methyl-6-(α-benzylphenethyl)-4*H*-pyran-4-one (**4**) and 2,6-diphenethyl-4*H*-pyran-4-one (**5**) (**4** : **5**=73 : 27), and 38% of the starting material **1** was recovered. When the ratio of **1** sodium amide and benzyl bromide was 1 : 2 : 2, the yields of **3** and the dialkylated products (**4**+**5**) were 31.5 and 22.5% (**4** : **5**=1 : 1), and 26% of **1** was recovered.

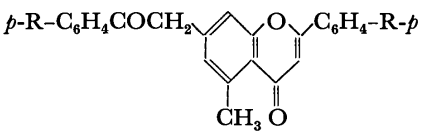
The reaction of **1′** with *n*-butyl bromide gave 2-methyl-6-*n*-pentyl-4*H*-pyran-4-one (**6**) (14.0% yield) and the dialkylated products (**7**+**8**) (6.5%).

2-Methyl-6-phenyl-4*H*-pyran-4-one (**8**) also formed the metalated product **9′** with an equimolar amount of sodium amide in liquid ammonia. An alkylation reaction of **9**, similar to that of **1′**, was carried out with an equimolar amount of benzyl bromide to give 2-phenethyl-6-phenyl-4*H*-pyran-4-one (**10**) in 77.0% yield. When the ratio of **9**, sodium amide and benzyl bromide was 1 : 2 : 2, the products were 2-(α-benzylphenethyl)-6-phenyl-4*H*-pyran-4-one (**11**) (75% yield) and **10** (13% yield).

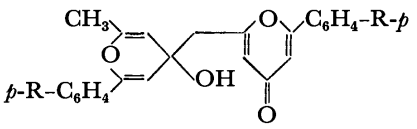
Compound **9′** condensed with benzaldehyde to afford 2-(β-hydroxyphenethyl)-6-phenyl-4*H*-pyran-4-one (**12**) in 65% yield. Chalcone also reacted with **9′** to give only a Michael type addition product, 2-(4-oxo-2,4-diphenylbutyl)-6-phenyl-4*H*-pyran-4-one (**13**) in 81 % yield. The structures of all compounds were determined from their spectra and elemental analyses.

On the other hand, the formation of an aldol type condensation product by the reaction of γ-pyrone with malononitrile[3] suggested that the carbonyl group of γ-pyrone is reactive to a nucleophile. Anticipating a dimerization reaction with one part of **9** behaving as an electrophile and the other part behaving as a nucleophile, **9** was treated with sodium amide in liquid ammonia. When the molar ratio of **9** and sodium amide was 2 : 1, two new compounds **14** and **15** were obtained in 49.0 and 12.1% yields. From spectral data and elemental analyses it was deduced that **14** was 5-methyl-7-phenacylflavone and that **15** was a γ-pyrone dimer. Since the treatment of the dimer **15** with concentrated sulfuric acid or sodium amide in liquid ammonia gave **14**, the dimer **15** was considered to be an intermediate in the formation of flavone **14**. Thus this reaction is a self condensation of **9**.

However when **9** was treated with sodium methoxide



14 : R=H
17 : R=OCH_3



15 : R=H
18 : R=OCH_3

Fig. 2.

in methanol or with sodium in tetrahydrofuran, neither **14** nor **15** was detected. The formation of **14** and **15** was observed only in liquid ammonia.

A similar treatment of 2-(*p*-methoxyphenyl)-6-methyl-4*H*-pyran-4-one (**16**) gave 7-(*p*-methoxyphenacyl)-4'-methoxy-5-methylflavone (**17**)(38.5% yield) and the dimer (**18**) (7.0% yield). Treatment of the dimer **18** with concentrated sulfuric acid also gave the flavone **17**. The structures of **17** and **18** were supported by spectral data and elemental analyses.

The mechanism of the formation of the flavone **14** from γ-pyrone **9** was assumed to be an attack on the carbonyl group of **9** by the monoanion **9'** to give γ-pyrone dimer **15**, followed by elimination of water and isomerization to form the flavone **14**.

Experimental

*2,6-Dimethyl-4H-pyran-4-one (**1**).* Compound **1** was synthesized by reaction of dehydroacetic acid with concentrated hydrochloric acid,[4] mp 130—131 °C (lit,[4] 130 °C).

*2-Methyl-6-phenethyl-4H-pyran-4-one (**3**).* Procedure A: In a 200 ml three-necked flask, about 120 ml of liquid ammonia, containing 11 mmol of sodium amide, were placed. To this solution 1.24 g (10 mmol) of **1** and 20ml of dry ether were added. After stirring for 1 hr at −78 °C, 1.88 g (11 mmol) of benzyl bromide in 10 ml of dry ether was added and the mixture was stirred for an additional 3 hr at −78 °C under a nitrogen atmosphere. After quenching the reaction mixture with excess ammonium chloride, the liquid ammonia was evaporated rapidly on a water bath. Fifty ml of diluted hydrochloric acid and 50 g of crushed ice were added to the resulting residue. The resulting acidic aqueous solution was extracted with chloroform, washed with water, dried over anhydrous sodium sulfate and concentrated giving crude alkylated products. This residue was chromatographed on a silica gel (Merck 7734, 70—230 mesh) column with benzene-ethyl acetate (2 : 1 v/v). The fractions which showed R_f-values of 0.16 and 0.26 on silica gel (Merck 7721) thin layer chromatographs with benzene-ethyl acetate (2 : 1 v/v).

The fractions with R_f=0.16 were collected, concentrated and recrystallized from *n*-hexane-benzene (4 : 1 v/v) to give 694 mg (32.4%) of **3**, mp 75—77 °C (lit,[5] 76.5—77 °C).

IR(KBr): 1660 (νC=O), 1610 (C=C) and 695 cm^{-1} (phenyl).

UV λ_{max}^{EtOH} (ε): 250 (15700) and 261 nm (9060).

NMR(in $CDCl_3$): δ 2.16 (s, 3H), 2.51—3.02 (m, 4H), 5.96 (s, 2H) and 7.00—7.24 (m, 5H).

*The Dialkylated Products (**4**+**5**).* The fractions with R_f=0.26, were collected and concentrated to give 441 mg (14.5%) of the mixture (**4**+**5**), as a light brownish-yellow oil.

IR(liquid film): 1660 (νC=O), 1600 (C=C) and 750, 700 cm^{-1} (phenyl).

The ratio of **4** and **5** was determined from the NMR spectrum as follows: The NMR spectrum of the dialkylated mixture showed a singlet at δ 2.16 (intergration: 36), which corresponded to the 2-methyl protons of compound **4**. The multiplet signal at δ 7.08—7.56 (integration: 165) corresponded to the overlapping of the aromatic protons of the two isomers **4** and **5**. The integration of the ten aromatic protons of the two phenyl groups of **4** was calculated to 120. While the integration 45 was obtained for ten aromatic protons of two phenyl groups of **5**. Thus, 73% of **4** and 27% of **5** were contained in the mixture.

After **4** and **5** had been eluted, the column was again eluted with acetone, and the eluate was concentrated. The residue was crystallized from benzene to give 471 mg (38%, recovered) of the starting material, γ-pyrone (**1**), 128—130 °C.

Five mmol of **1**, 10.5 mmol of sodium amide and 10.5 mmol of benzyl bromide were treated according to procedure A. Three handred and thirtyseven mg of (31.5%) of **3**, 342 mg (22.5%) of the dialkylated products (**4**+**5**) (**4** : **5**=1 : 1) were obtained and 161 mg (26%) of **1** was recovered. Five mmol of **1**, 5.3 mmol of sodium amide and 5.3 mmol of benzyl bromide were treated according to procedure A. When the reaction was quenched after 30 min, 68 mg (11%) of **3** and 197 mg (13%) of the sole dialkylated product **4** were obtained.

NMR spectrum of **4** (in $CDCl_3$): δ 2.16 (s, 3H), 3.00 (broad s, 5H), 5.96 (d, 1H), 6.08 (broad s, 1H) and 7.10—7.56 (m, 10H).

*2-Methyl-6-pentyl-4H-pyran-4-one (**6**).* Using procedure A, from 10 mmol of **1**, 10.5 mmol of potassium amide and 10.5 mmol of *n*-butyl bromide, 252 mg (14.0%) of **6** and 153 mg (6.5%) of the dialkylated products (**7**+**8**) were obtained.

IR spectrum of **6** (liquid film): 1660 (νC=O) and 1610 cm^{-1} (C=C).

NMR spectrum of **6** (in $CDCl_3$): δ 0.90 (t, 3H), 1.12—1.72 (m, 6H), 2.20 (s, 3H), 2.45 (t, 2H) and 5.96 (s, 2H).

*Treatment of **1** with Different Bases*: Compound **1** (5 mmol) was treated with an equimolar amount of sodium hydride (50% in oil) in 50 ml of refluxing benzene, with 5 mmol of lithium dimethylamide in 50 ml of dry ether (distilled from $LiAlH_4$) at —20 °C, at room temperature or under refluxing, with an equimolar amount of lithium *N*-methylanilide in 30 ml of dry ether or in 50 ml of dry THF (distilled from $LiAlH_4$) at room temperature or under refluxing. But in each case, the metalated product **1'** which was tested for by adding benzyl bromide, was not formed, and **1** was recovered quantitatively. This was checked by thin layer chromatography and NMR.

*Treatment of **1** with n-Butyl Lithium*: Compound **1** (5 mmol) was treated with an equimolar amount of *n*-butyl lithium (15% in hexane) in 50 ml of dry THF (distilled from $LiAlH_4$) at −78 °C under a nitrogen atmosphere. After 1 hr an equimolar amount of benzyl bromide in 10 ml of dry THF was added to the resulting red solution, the mixture was then stirred for 2 hr at −78 °C. Thin layer chromatography of the reaction mixture revealed a component with R_f=0.19, which was isolated by silica gel (Merck 7734) column chromatography with benzene-ethyl acetate (2 : 1 v/v). From the spectral data it was speculated that this product was 2,6-dimethyl-4-*n*-butyl-4*H*-pyran-4-ol (**2**).

IR(liquid film): 3200—3450 (broad, νOH) and 1600 cm^{-1}

(C=C).

NMR(in $CDCl_3$): δ 0.90, 1.22—1.82, 2.12 and 6.42.

Compound **1** was also treated with *n*-butyl lithium, as described above, at −20 °C or at room temperature. However after working up as usual, a red oil was obtained. This red oil did not show a clear spot on a thin layer chromatograph, and also **1** could not be detected.

*2-Methyl-6-phenyl-4H-pyran-4-one (**9**)* was synthesized from 1-phenyl-1,3,5-hexanetrione and concentrated sulfuric acid, mp 86—88 °C (lit.[6] 87—88 °C).

*2-Phenethyl-6-phenyl-4H-pyran-4-one (**10**).* Using procedure A, from 10 mmol of **9** and 11 mmol of benzyl bromide, **10** was obtained. Eluting solvent: benzene-ethyl acetate (4 : 1 v/v), yield 2.12 g (77.0%), mp 84—85 °C (lit,[7] 85—86.5 °C).

IR(KBr): 1660 (νC=O) and 1595 cm^{-1} (C=C).

NMR (in $CDCl_3$): δ 3.01 (s, 4H, 6.00 (d, 1H), 6.62 (d, 1H), 7.15 (s, 5H) and 7.50 (m, 5H).

*2-(α-Benzylphenethyl)-6-phenyl-4H-pyran-4-one (**11**).* Following procedure A, 10 mmol of **9**, 20 mmol of sodium amide and 20 mmol of benzyl bromide were reacted. 2.75 g of the dialkylated product **11** was obtained (75%), mp 117—119 °C, accompanied by 380 mg (13%) of **10**. Eluting solvent: Benzene-ethyl acetate (4 : 1 v/v).

IR(KBr): 1640 (νC=O), 1620 (C=C) and 695 cm^{-1} (phenyl).

NMR(in $CDCl_3$): δ 2.98—3.15 (m, 5H), 5.91 (d, 1H), 6.60 (d, 1H), 7.05—7.24 (m, 10H) and 7.44—7.68 (m, 5H).

Found: C, 85.10; H, 6.19%. Calcd for $C_{26}H_{22}O_2$: C, 85.21; H, 6.05%.

*2-(β-Hydroxyphenethyl)-6-phenyl-4H-pyran-4-one (**12**).* Following procedure A, from 5 mmol of **9** and 5 mmol of benzaldehyde, 950 mg (65%) of **12** was obtained. Eluting solvent: Benzene-ethyl acetate (2 : 1 v/v). Crystallized from hot acetone, mp 163—164 °C.

IR(KBr): 3200(νOH), 1645 (C=O) and 700 cm^{-1} (phenyl).

UV λ_{max}^{EtOH} (ε): 228 (12300) and 273 nm (17800).

NMR(in $CDCl_3$): δ 3.00 (d, 2H), 3.60 (s, 1H), 5.14 (t, 1H), 6.22 (d, 1H), 6.59 (d, 1H) and 7.29—7.70 (m, 10H).

Found: C, 77.86; H, 5.40%. Calcd for $C_{19}H_{16}O_3$: C, 78.06; H, 5.52%.

*2-(4-Oxo-2,4-diphenylbutyl)-6-phenyl-4H-pyran-4-one (**13**).* Using procedure A, **13** was synthesized from 10 mmol of **9** and 10 mmol of chalcone. Eluting solvent: Benzene-ethyl acetate (2 : 1 v/v). The fractions which contained **13** were collected, concentrated and crystallized from benzene to give 3.20 g (81%) of **13**, mp 120—122 °C, as white leaflets.

IR(KBr): 1680, 1660 (νC=O), 1625 (C=C) and 695 cm^{-1} (phenyl).

UV λ_{max}^{EtOH} (ε): 248 (19900) and 273 nm (19100).

NMR(in $CDCl_3$): δ 3.01 (m, 2H), 3.38 (d, 2H), 3.80 (m, 1H), 6.01 (d, 1H), 6.56 (d, 1H) and 7.17—7.97 (m, 15H).

Found: C, 82.15; H, 5.62%. Calcd for $C_{27}H_{22}O_3$: C, 82.21; H, 5.62%.

*5-Methyl-7-phenacylflavone (**14**).* Procedure B: In a 300 ml three-nicked flask, 10 mmol of sodium amide, 20 mmol of **9** and 200 ml of liquid ammonia were mixed. The mixture was then refluxed for 3 hr under a nitrogen atmosphere. After quenching with excess ammonium chloride, the reaction mixture was worked up as in procedure A. Thin layer chromatography of the reaction residue with benzene-ethyl acetate (1 : 1 v/v) showed two spots, R_f=0.39 and 0.20, while that of **9** was 0.26. The residue was chromatographed on a silica gel (Merck 7729, 230 mesh) column with benzene-ethyl acetate (1 : 1 v/v). The fractions with R_f=0.39 were collected, concentrated and crystallized from benzene-acetone (4 : 1 v/v) to give 1.70 g (49.0%) of **14**, mp 208—210 °C, as yellow cubic crystals.

IR(KBr): 1640 (νC=O), 1585, 1560 (C=C) and 700, 690 cm^{-1} (phenyl).

UV λ_{max}^{EtOH} (ε): 268 nm (28500).

$\lambda_{max}^{KOH/EtOH}$ (ε): 233 (38200), 268 (33200) and 354 nm (11100).

NMR(in DMSO-d_6): δ 2.31 (s, 3H), 6.12 (d, 1H, J=2.3 Hz), 6.70 (d, 1H, J=2.3 Hz), 6.74 (s, 1H), 6.78 (s, 1H), 7.27 (m, 5H), 7.45 (m, 5H) and 10.01 (broad, disappeared in D_2O).

Mass (*m/e*): 354 (parent peak), 336 (base peak, P–18), 308, 234, 178, 102 and 77.

Found: C, 81.11; H, 5.20%. Calcd for $C_{24}H_{18}O_3$: C, 81.34; H, 5.12%.

*The γ-Pyrone Dimer (**15**).* The fractions with R_f=0.20 were collected, concentrated and crystallized from acetone-ethanol (3 : 1 v/v) to give 450 mg (12.1%) of **15**, mp 188—189 °C.

IR (KBr): 3360 (νOH), 1650 (C=O), 1620 (C=C) and 695 cm^{-1} (phenyl).

UV λ_{max}^{EtOH} (ε): 232 (21100), 273 (19400), 292 (14790) and 307 nm (6000).

NMR(in DMSO-d_6): δ 1.97 (s, 3H), 3.60 (s, 2H), 5.94 (d, 2H), 6.17 (d, 1H), 6.67 (d, 1H) and 7.10—7.47 (m, 10H).

Mass (*m/e*): 372 (parent peak), 354 (P–18), 226, 186, 105 and 77.

Found: C, 77.24; H, 5.45%. Calcd for $C_{24}H_{20}O_4$: C, 77.40; H, 5.41%.

*Conversion of **14** to **15**.* *(a) By Concentrated Sulfuric Acid*: A solution of 5 mg of **15** in 2 ml of concentrated sulfuric acid was allowed to stand at room temperature for 10 min. The reaction mixture was poured into ice-water, and the aqueous layer was extracted with ether. By treating the etheral solution as usual, compound **14** was obtained, which was compared with an authentic sample by thin layer chromatography.

(b) By Sodium Amide in Liquid Ammonia: A mixture of 50 ml of liquid ammonia, 200 mg of **15** and 60 mg of sodium amide was stirred for 3 hr. After evaporation of liquid ammonia and treatment of the residue as usual, the formation of **14** was confirmed by thin layer chromatography using an authentic sample for comparison.

*Treatment of **9** with Bases in Methanol or in Tetrahydrofuran. In Methanol*: 930 mg of **9** was added to a solution of 130 mg of sodium metal in 25 ml of absolute methanol. The mixture was stirred for 4 hr at room temperature. After concentration of the reaction mixture, the residue was added to 10 ml of chloroform and 15 ml of diluted hydrochloric acid, and extracted with chloroform. Thin layer chromatography of the chloroform layer showed neither **14** nor **15** and **9** was recovered.

In Tetrahydrofuran: A mixture of 930 mg of **9** and 130 mg of sodium metal in 80 ml of dry THF was stirred at room temperature for 2 hr. The reaction mixture was treated as described above. Neiter **14** nor **15** was detected.

*2-(p-Methoxyphenyl)-6-methyl-4H-pyran-4-one (**16**).* A solution of 50 mmol (11.7 g) of 1-(*p*-methoxyphenyl)-1,3,5-hexanetrione[6] in 40 ml of concentrated sulfuric acid was cooled to 0 °C and allowed to stand at 0 °C for 2 hr. The reaction mixture was then poured into ice-water and extracted with chloroform. The chloroform layer was washed with water and dried over anhydrous sodium sulfate. After removing chloroform, the resulting residue was crystallized from benzene to give 10.2 g (94%) of **16**, mp 144—146 °C, as colorless needles.

IR(KBr): 1670 (νC=O), 1615 (C=C) and 1510 cm^{-1} (phenyl).

UVλ_{max}^{EtOH} (ε): 224 (17600) and 304 nm (25100).

NMR(in $CDCl_3$): δ 2.33 (s, 3H), 3.84 (s, 3H), 6.11 (d, 1H), 6.57 (d, 1H), 6.95 (d, 2H) and 7.67 (d, 2H).

Found: C, 72.12; H, 5.66%. Calcd for $C_{13}H_{12}O_3$: C, 72.21; H, 5.59%.

*7-(p-Methoxyphenacyl)-4'-methoxy-5-methylflavone (**17**).* Following procedure B, from 4.32 g (20 mmol) of **16** and 10 mmol of sodium amide, **17** was prepared in 38.5% (1.6 g) yield. Compound **17** was isolated from the dimer **18** by silica gel (Merck 7729) column chromatography with benzene-ethyl acetate (2 : 1 v/v). The fractions which contained **17** were collected, concentrated and crystallized from acetone to give light yellow cubic crystals, mp 236—239 °C.

IR(KBr): 1640 (νC=O), 1610 and 1565 cm^{-1} (C=C).

UVλ_{max}^{EtOH} (ε): 225 (33100), 248 (26000), 288 (27000) and 305 nm 24500).

NMR(in DMSO-d_6): δ 2.28 (s, 3H), 3.68 (s, 3H), 3.80 (s, 3H), 6.02 (d, 1H), 6.67 (d, 1H), 6.83 (d, 2H), 6.90 (d, 2H), 6.96 (d, 2H), 7.19 (d, 2H), 7.53 (d, 2H), and 9.90 (broad, 1H).

Found: C, 75.38; H, 5.26%. Calcd for $C_{26}H_{22}O_5$: C, 75.35; H, 5.35%.

*The Dimer **18**.* The dimer eluted after the fraction **17**. Yield 300 mg (7.0%).

NMR(in $CDCl_3$): δ 1.64 (s, 3H), 2.70 (s, 2H), 3.80 (s, 3H), 3.83 (s, 3H), 6.00 (s, 1H), 6.24 (d, 1H), 6.63 (d, 2H), 6.78 (d, 2H), 6.84 (d, 2H), 7.55 (d, 2H) and 7.58 (d, 2H).

*Treatment of the Dimer **18** with Sulfuric Acid.* A mixture of 20 mg of **18** and 3 ml of concentrated sulfuric acid was allowed to stand at room temperature for 10 min. The mixture was added to 10 g of crushed ice and extracted with ether. The flavone **17** was detected by thin layer chromatography of the ether solution using an authentic sample for comparison.

This work was supported by the Scientific Research Fund of Ministry of Education, Japanese Government.

Studies of Reaction Mechanisms with All-valence Electron Semi-empirical SCF MO Theories. IX.[1] The Role of Tetracyclo[4.2.0.0^{2,8}0^{5,7}]oct-3-ene on the Ground State Potential Energy Hypersurfaces of $(CH)_8$ Isomers

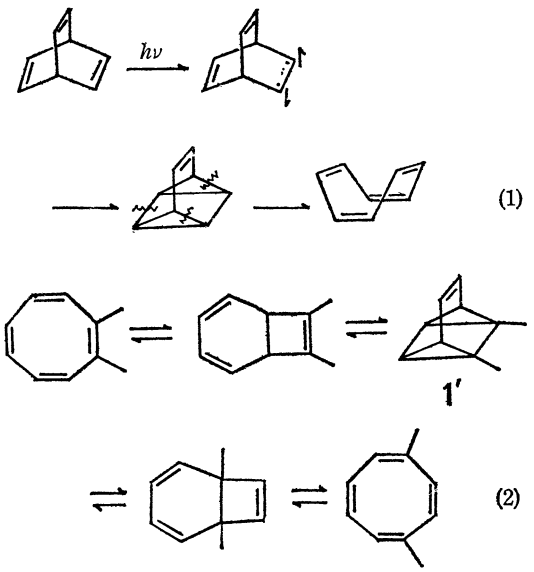
Hiizu IWAMURA and Hiroshi KIHARA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

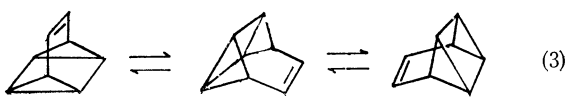
(Received July 2, 1974)

Tetracyclo[4.2.0.0^{2,8}0^{5,7}]oct-3-ene (**1**) is estimated by a MINDO MO calculation to be moderately strained. Interaction between the ethylenic π orbital and the Walsh orbitals of the two cyclopropane rings is extensive in the ground state structure of **1**. The third highest occupied MO is an out-of-phase combination of the ethylenic 2pπ AO's on C_3 and C_4, while the corresponding in-phase combination appears in the lower unoccupied MO's. The interconversion between **1** and bicyclo[4.2.0]octa-2,4,7-triene (**2**) is a typical symmetry-allowed reaction as revealed by a smooth change in bond indices along the reaction coordinates. The isomerization of substituted cyclooctatetraenes *via* **1** and **2** (Eq. (2)) is predicted to be possible at elevated temperatures. The symmetry-allowed degenerate valence isomerization of **1** (Eq. (3)) is energetically less favorable due to skeletal constraint.

While compounds with the tetracyclo[4.2.0.0^{2,8}0^{5,7}]-oct-3-ene structure have never been prepared, the parent hydrocarbon **1** has often been quoted as a possible intermediate in many thermal as well as photochemical interconversions between other $(CH)_8$ isomers. One of the earliest suggestions was that **1** was the intermediate in the singlet excited state reaction of barrelene to give cyclooctatetraene (Eq. (1)).[2] Recently Paquette *et al.* found evidence that **1'** was an intermediate in the thermal isomerization between 1,2- and 1,4-disubstituted cyclooctatetraenes (Eq. (2)).[3]



We have examined the electronic structure of **1** and the ground state potential energy hypersurfaces surrounding the minimum corresponding to structure **1** by MINDO/2 methods.[4] Specifically the reaction coordinates for the intramolecular Diels-Alder reaction of bicyclo[4.2.0]octa-2,4,7-triene (**2**) leading to **1** (see Eq. (2)) have been determined. A degenerate valence isomerization of **1** as represented by Eq. (3) has also been examined.



Method of Calculation

Details of the procedure are nearly the same as reported in the preceding paper.[1] Since no experimental data concerning the structure of the molecules studied here are available, the theoretical geometries of the ground states were sought by minimizing the total energies with respect to changes in all bond lengths and angles. It was only assumed that **1** and **2** have C_{2v} and C_s symmetry, respectively. Although a large number of nuclear configurations have to be considered in order to get information on the reaction paths, it would require tremendous effort to take all conceivable intermediate configurations into account. We have, therefore, made some simplifying assumptions to reduce the computational effort in finding the

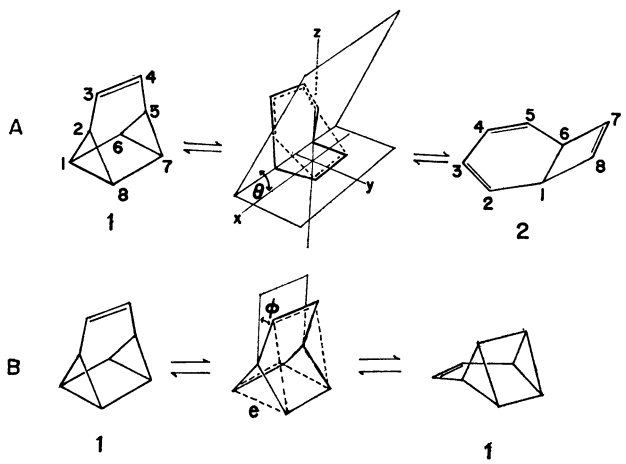


Fig. 1. Parameters used in calculating the reaction paths and numbering of atoms and bonds used in the text and in Table 1.
A: s is a smoothing parameter to describe a profile of **1** (**2**) in passing from **1** (**2**) into **2** (**1**) in the (retro) Diels-Alder reaction. All other geometrical parameters except θ are assumed to vary linearly with s from their values at the end points $s=0.0$ (=**1**) and $s=1.0$ (=**2**), respectively.
B: φ describe the inclination of C_2-C_3-C_4-C_5 plane towards C_7-C_8.

transition state geometries. A few parameters were chosen to describe the most relevant reaction coordinates. These parameters are detailed in Fig. 1. The eigenvalues and eigenfunctions were computed using a set of numerical values of these parameters, and the total energy was minimized by varying these parameters empirically to arrive at the transition state geometries.

An energy partitioning analysis was also made. The total energy (E) of a molecule can be expressed as a sum of one-center terms (E_A) and two-center terms (E_{AB}). The former sum was subdivided into one due to carbon atoms (E_A^C) and one due to hydrogen atoms (E_A^H). The two-center terms were divided into resonance (E_{AB}^R), exchange (E_{AB}^X), and electrostatic (E_{AB}^S) terms. Terms E_{AB} can also be divided into neighboring (E_{AB}^N) and non-neighboring (E_{AB}^{NN}) terms. The definition of each term and standard integrals representations in MINDO/2 formalism were given in the preceding paper.[1] A FORTRAN program was written for a HITAC 8700/8800 system at the Computer Centre of the University of Tokyo.

Results and Discussion

The Optimized Structure, Energy and Bond Parameters. Table 1 shows the equilibrium geometries, two-center energies, Wiberg bond indices, W_{AB},[5] and bond populations defined by taking into account the overlap, P_{AB}^S, defined in Eq. (5).

$$W_{AB} = \sum_{\mu}^{A} \sum_{\nu}^{B} P_{\mu\nu}^2 \tag{4}$$

$$P_{AB}^S = \sum_{\mu}^{A} \sum_{\nu}^{B} P_{\mu\nu} S_{\mu\nu} \tag{5}$$

The numerical values of W_{AB} are close to the conventional bond orders: 2 for double bonds and 1 for single bonds. The calculated geometries are generally in good agreement with those observed for many hydrocarbons possessing three or four-membered rings, except for slightly shorter C–C single bond lengths.

Energies and ionization potentials obtained by using Koopmans' theorem are listed in Table 2.

The absolute values of the heats of formation obtained for **1** and **2** by MINDO/2 might be considerably lower than the actual values, since this method is reputed to underestimate the strain energies of small rings and compounds having a compact skeleton.[4,6] The MINDO/1 method is thought to be more acceptable in calculating the heats of formation.[6] Heats of formation of 12.3 and 54.5 kcal/mol were obtained for **1** and **2** by Franklin's group-equivalent method.[7] The strain energy of **1** was therefore estimated to be 65.6 kcal/mol (the heat of formation from the MINDO/1 method minus that from Franklin's). The strain energy value so obtained is around mid-value among those estimated for all the possible $(CH)_8$ isomers.

Molecular Orbitals of ***1***. **1** may be regarded formally as being constructed of two cyclopropane rings, a cyclobutane ring and an ethylenic double bond. The ability of cyclopropanes to conjugate with an adjacent unsaturated center is well known. Structure **1** has a most desirable configuration for the cyclopropyl and vinyl moieties allowing them to interact adequately (*i.e.* bisected conformation). It is obvious from Table 1 that the C_2–C_3 (and C_4–C_5) bond has double bond character to some extent while the C_1–C_8 (and C_6–C_7) bond is slightly weakened as a result of the cyclopropyl-vinyl-cyclopropyl conjugation. A close inspection of the AO coefficients of the molecular orbitals reveals that the orbital interactions between the Walsh type orbitals of cyclopropane e′ and localized orbitals (π_{CC}, π_{CH_2}, σ_{CC}) of the ethylenic moiety and additional interactions between the orbitals resulting from the interactions described above are evident in the molecular orbital profile of **1**. This qualitative molecular orbital description can be obtained by considering in-phase and out-of-phase combinations between those localized orbitals with the same symmetry. Some higher occupied and lower unoccupied molecular orbitals are illustrated in Fig. 2. It is interesting to note that the third highest occupied

molecular orbital is an out-of-phase combination of the ethylenic $2p\pi$ AO's on C_3 and C_4, while the corresponding in-phase combination appears among the lower unoccupied molecular orbitals.

Potential Energy Surfaces and Reaction Paths for ***1*** *and* ***2***. By calculating a large number of nuclear configurations, the energies of their electronic ground states along the reaction paths was obtained as a function of θ and s. A two dimensional presentation of the energy (in units of the heat of formation) as a function of θ and s is shown in Fig. 3. The most probable reaction path for the interconversion of **1** and **2** is indicated by the dotted line. A clearer picture of this cross section of the potential energy surface is given in Fig. 4 together with the change of bond indices. A smooth change of the bond indices for the bonds, which are formed or broken as the reaction proceeds along the reaction coordinates, is characteristic of symmetry-allowed reactions. Symmetry-forbidden reactions show, in contrast, abrupt changes in bond index.[1] This can be easily understood in

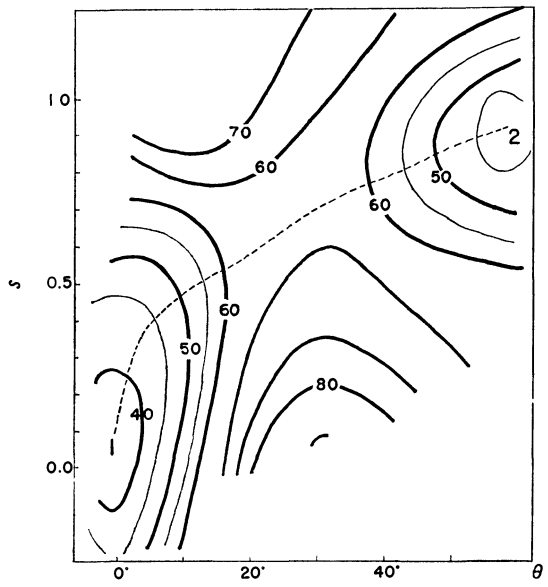

Fig. 3. The potential energy surface for the interconversion of **1** and **2**.

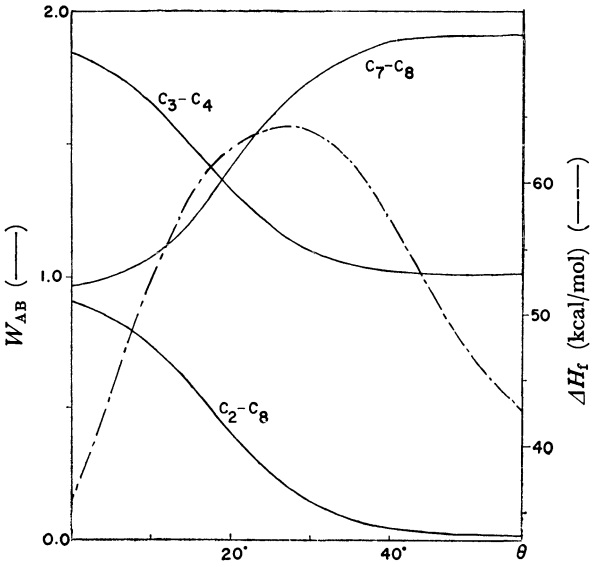

Fig. 4. The energy and the bond indices during the reaction of **1** and **2**.

terms of the well-known orbital correlation diagram.[8] In the case of allowed reactions, no alternation of occupied and unoccupied orbitals occurs anywhere along the reaction paths. In other words, all the occupied orbitals of the reactant can be transformed into the occupied orbitals of the product with continous changes in their shapes. The smooth change of bond indices results from the continuous change of the corresponding AO coefficients of the occupied molecular orbitals. An abrupt change of bond index indicates that alternation of occupied and unoccupied levels takes place somewhere in the reaction path.[9]

Figure 5 shows the calculated geometry and (in parentheses) Wiberg's bond indices for the transition state of the reaction, **2** to **1**. Note that the bond indices are about 1.6 for bonds C_2–C_3 (and C_4–C_5) and C_1–C_8, 1.17 for C_3–C_4, and 0.2 for C_2–C_8 (and C_5–C_7). As shown in Table 3, the two-center energy terms E_{AB} for the transition state geometry are more in pararell with those of **2**. The dihedral angles 83° and 200° of the transition state structure correspond to 57° and 213° in **1** and 104° and 180° in **2**. Thus the configuration of the transition state is electronically similar to **2**, while it is similar to **1** in terms of skeletal displace-

ments. This is in accord with Hammond's postulate[11] and is also reasonable when the geometrical constraints imposed on the molecule in attaining the transition state are considered. It is noted that partial bonds C_2–C_8 (and C_5–C_7) are considerably weaker than those occurring in more facile reactions, *e.g.*, the Cope rearrangements of bridged homotropilidenes.[12] In the latter, the partial bonds in the transition states have a W_{AB} value of 0.4. The smaller W_{AB} value corresponds to the fact that the resonance energy of the aromatic transition state is not large in the present case.

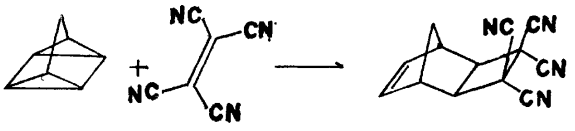
In order to fully characterize the electronic structure of the transition state, the total contribution to the activation energy of the one-center term (ΔE_A) and of the two-center terms (ΔE_{AB}) are given in Table 4. Those were obtained by taking differences between the corresponding values for the ground state and transition state.

The stabilizing contribution to the activation energy comes from changes (ΔE_A) in the one-center terms on passing from the reactants to the transition state. Further inspection reveals that the contribution of hydrogen atoms is very small and that the ΔE_A values are governed by changes in the one-center terms for carbons. The first and third columns of Table 5 show the change (Δq_A) in the electron population of atom A in passing from the reactant to the transition state. A positive Δq_A implies an increase in electron density and also in negative charge. It is seen that the variation of ΔE_A values correlates with those of Δq_A.[13] Note that the terms leading to smaller activation energy are those for the carbon atoms in the "aromatic ring" of the transition state, *e.g.*, atoms 2,3,4,5,7 and 8. In other words, the six carbons involved become effectively more electrogative in going from the reactants to the transition state and the transition state is correspondingly stabilized by a drift of negative charge to those six carbons from the rest of the molecule. On the contrary, the net change in the two-center neighboring terms ΔE_{AB}^N is relatively large with positive sign. Thus the relief of steric strain is not contributing much to the driving force of the reaction.

The activation energy for the valence isomerization of **1** to **2** is estimated at 29 kcal/mol by taking the difference in the energies of **1** and the transition state. Thus the isomerization of substituted cyclooctatetraene *via* **1** and **2** (see Eq. (2)) is predicted theoretically to be possible at elevated temperatures. It is also concluded that **1** is reasonably stable kinetically as well as thermodynamically (see Section A). The height of the potential energy barrier is large enough to give **1** a reasonable life-time at room temperature once prepared by an authentic route.

The reaction of **2** to **1** is favored in terms of orbital interaction owing to the proper geometry in the transition state. It would lead to activation energy of the same order as a typical Diels-Alder reaction of butadienes with ethylenes.[14]

A Degenerate Valence Isomerization of ***1*** *(Eq. (3)).* The reaction represented by Eq. (3) is a symmetry-allowed process. A precedent for the analogous [$_\pi 2_s + {}_\sigma 2_s + {}_\sigma 2_s$] reactions may be found in the bimolecular reaction of quadricyclene with TCNE:[15]



However, the ethylenic pπ orbitals are not suitably disposed for overlap with those of the cyclopropane ring in **1**. Inclination of the etheno bridge by 20° is attained only at the expense of 18 kcal/mol strain. The calculated energy values rise nearly in direct proportion to the increase in the values of φ and e. This is illustrated in Fig. 6. The ethylenic pπ orbitals cannot interact sufficiently with those of the cyclopropane

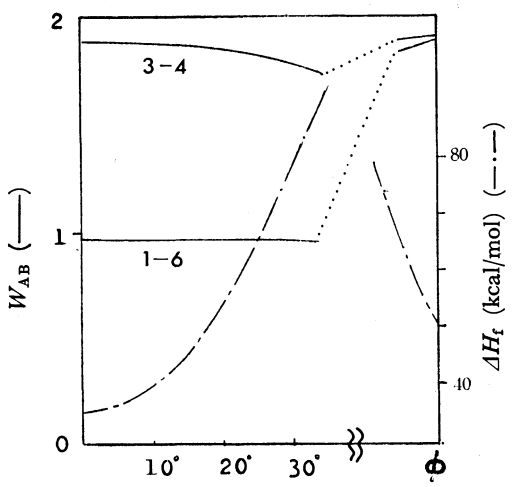


Fig. 6. The energy and the bond indices for the degenerate valence isomerization of **1**.

rings even when a large increase in energy due to strain is imposed. Therefore this formally symmetry-allowed valence isomerization will not take actually place even under severe conditions. Instead, the reaction coordinate represented by the elongation of the bond between C_1 and C_8 (C_6 and C_7), *e*, leads to an unexpected product, barrelene, across a high energy barrier demanded by symmetry considerations.[16]

9) We find it more advantageous to utilize this criterion to predict the allowedness or forbiddenness of concerted reactions of complex systems which have little or no elements of symmetry. While "snap-shot" calculations on a reaction path are often not sufficient to give acceptable activation energy values, they are adequate to show changes in bond index. The conclusion on the allowedness of the reaction under discussion must of necessity agree with the rule obtained more easily by application of the "Conservation of Orbital Symmetry."[8] We prefer the latter rule to be expressed in terms of the concept of the continuity of phase or nodal characteristic of orbitals, since the transition states of concerted reactions are not necessarily symmetric in general.[10]

13) This can be readily understood as follows. When q_A increases (accumulation of electron density on atom A), the one-center core attraction energy increases, while the one-center Coulomb repulsion increases. Since both terms vary with *q* and in opposite directions, they almost cancel one another. The values ΔE_A for the individual carbon atoms pararell quite closely those for the one-center exchange term ΔE_A^x and the latter is correlated with Δq_A. Thus an increase in electron density on carbon A makes E_A^x more negative and consequently E_A more negative.[12b]

16) Lastly, [1,5]sigmatropy in **2** which might be also one of the possible paths taking part in the substituent migration of cyclooctatetraene, has been shown to be a very energetically unfavorable path because of peculiar electronic and steric factors, *i. e.*, additional $p\pi$ orbitals and the length of the migrating carbon chain. Results on energetically unfavorable sigmatropic reactions will appear in a forthcoming paper.

Resonance Energies of Annulenes and Radialenes

Jun-ichi AIHARA
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received July 10, 1974)

Resonance energies of annulenes and radialenes were estimated on the basis of the π-bond energies of infinitely large annulene and radialene, respectively. The widely accepted Hückel's $(4n+2)\pi$ rule was verified for annulenes, whereas radialenes were substantially nonaromatic regardless of the number of π-electrons.

Though the Hückel molecular orbital (HMO) model has shown a great degree of success in the interpretation of gross electronic structures of conjugated systems,[1] the extension of this approach has given rather limited agreement. In particular, it was recently shown that the delocalization energy is not useful in predicting the relative stability of benzenoid and nonbenzenoid hydrocarbons.[2]

In 1965, Dewar and Gleicher, using the semiempirical SCF–MO method, have found that the bond energies of acyclic polyenes are additive.[3] Adopting this principle, Hess and Schaad defined the HMO resonance energy as the difference between the total HMO π-energy and the additive contribution obtained by summing individual π-bond energies.[4] An excellent correlation between the resonance energies calculated in this manner and the observed stability and chemical behavior of many cyclic polyenes was obtained.

We also verified the additivity of π-bond energies of linear polyenes on the basis of the total HMO π-energies of infinitely large annulene and polyene.[5] The most striking advantage of our treatment was that the somewhat arbitrary assignment of values for eight types of π-bond energies made by Hess and Schaad[4] was completely avoided. In order to extend our understanding of aromatic stabilization of cyclic systems within the framework of the HMO theory and without additional assumptions, the same idea was applied to two typical cyclic systems; annulenes and radialenes.

Results and Discussion

It is generally accepted that sufficiently large annulene is considered to suffer from bond alternation, and is almost nonaromatic cyclic polyene.[6,7] It is hence assumed without difficulty that the additive contribution to the total π-energy of any annulene can be estimated from the π-energy of infinitely large annulene. When the classical resonance structure is written for annulene, it is a cyclic chain composed of unit structures, each of which involves the CH=CH bond and the adjacent CH–CH bond. The π-energy of the unit structure (E_U) is then evaluated by dividing the total HMO π-energy of [infinity]-annulene by half the number of carbon atoms. With the use of Hess and Schaad's notation,[2,4] it is expressed as follows:

$$E_U(\text{annulene}) = E_{22} + E_{12} = \frac{8}{\pi}, \quad (1)$$

where E_{22} and E_{12} signify the π-bond energies of the CH=CH and CH–CH bonds, respectively.

The ability to calculate accurately in an additive manner the total π-energy of linear polyene[5] allows us to calculate the additive contribution to the total π-energy of annulene. The additive contribution to the total π-energy of annulene as is defined as the π-energy of the localized structure of annulene is simply expressed as follows:

$$E_A([N]\text{-annulene}) = \frac{N}{2}(E_{22}+E_{12}) = \frac{4N}{\pi}, \quad (2)$$

where N is the number of carbon atoms in annulene.

The resonance energy (E_R) of annulene is hence obtained by substracting E_A from the total HMO π-energy (E_{HMO}), that is,

$$E_R([N]\text{-annulene}) = E_{HMO}([N]\text{-annulene}) - E_A([N]\text{-annulene}). \quad (3)$$

The resonance energies determined by using Eq. (3) as well as E_{HMO} and E_A are all listed in Table 1. REPE denotes resonance energy per π-electron. The geometry of the annulenes investigated is tacitly assumed to be planar with constant resonance integrals over all carbon-carbon bonds.

As is easily seen, the total resonance energy oscillates about zero-axis, approaching zero with increasing N. All [$4n$]-annulenes are correctly predicted to be

antiaromatic with negative resonance energies. The $[4n+2]$-annulenes are predicted to be aromatic up to [infinity]-annulene. Hückel's famous $(4n+2)\pi$ rule which states that $[4n+2]$-annulenes will possess relative electronic stability[8] has been nicely verified in this manner. Above all, it must be noted that, though our present results are in fair agreement with earlier theoretical studies on annulenes,[4,9-12] our simple approach is best grounded on the additivity of π-bond energies of the nonaromatic reference structure.

Dewar and Gleicher predicted that the critical size of annulene at which the bond alternation occurs is between [22]- and [26]-annulene, which was supported by some experimental evidence.[7,13] Though we can not predict the critical size of annulene at which Hückel's $(4n+2)\pi$ rule ceases to hold, their statement seems to be quite consistent with our results as higher annulenes with an REPE less than 0.004 β are considered to be substantially nonaromatic in accordance with the interpretation of the additivity of π-bond energies of acyclic polyenes made by Hess and Schaad.[4] When Hess and Schaad's π-bond energies are employed to calculate the π-energy of the reference structure, the limiting REPE of annulene amounts to $0.0053\,\beta$.[14] This suggests that sufficiently large annulenes are still aromatic with resonance energies of about $0.0053N\beta$, which is in contradiction to the premise that higher annulenes should be nonaromatic. In our case, the resonance energy of $[4n+2]$-annulene diminishes monotonously as n increases.

Similar results can be obtained by taking linear polyene as a reference compound for annulene. According to the procedure given in the previous paper,[5] the additive contribution to the total π-energy of annulene may be rewritten as follows:

$$E_R([N]\text{-annulene}) = E_{HMO}([N]\text{-polyene}) - 2E_{23} + 2E_{22} + E_{12}$$
$$= E_{HMO}([N]\text{-polyene}) + 2 - \frac{4}{\pi} . \quad (4)$$

The list of resonance energies derived from Eq. (4) was omitted here because of their close resemblance to those in Table 1.

On the other hand, the potential utility of the Möbius conformation of annulene in ring-opening reactions has been pointed out by Zimmerman.[15] The Möbius cyclic system is a singly twisted cyclic polyene in which there is only one side of the π-surface.[16] Craig and Paddock also considered the possibility of the Möbius conformation for cyclic phosphonitrilic derivatives.[17]

The resonance energies of the Möbius systems of annulenes were calculated by assuming the same reference structures as those of ordinary annulenes, although the additive principle of π-bond energies may be somewhat obscured for these systems. The change in resonance integrals with twisting was neglected to simplify the calculation. The obtained resonance energies of the Möbius systems are shown in Table 2. They were found to have positive resonance energies when they have $4n$ π-electrons. The resonance energies were negative for the systems with $(4n+2)$ π-electrons. The aromaticity is thus determined by the converse of Hückel's $(4n+2)\pi$ rule in agreement with the conclusion lead by Heilbronner.[16]

As a further application, we may compare the total HMO π-energies and the additive contributions of π-bond energies for radialenes. Radialenes form an apparently very dissimilar series of conjugated polyenes containing a ring of carbon atoms, each doubly bound to a methylene group. In other words, radialenes are all composed of the same unit structures, each involving a CH_2=C bond and an adjacent C–C bond. Therefore, the numbers of the single and double carbon-carbon bonds are the same, and are equated to M. If the π-bonds are localized as in the classical resonance structure, the total π-energy of $[M]$-radialene should be given by (in Hess and Schaad's notation[2,4]):

$$E_A([M]\text{-radialene}) = M(E_{22'} + E_{10}) , \quad (5)$$

where $E_{22'}$ and E_{10} denote the π-bond energies of the CH_2=C and C–C bonds, respectively.

In order to determine the π-energy of the radialene unit structure, we employed the same procedure as used for annulenes. Here, radialenes are assumed to be coplanar with the rings forming regular polygons and free from ring strains. The general HMO solution for radialene was presented by Hess and Schaad.[4] According to them, the m-th orbital energy of $[M]$-radialene is expressed in units of β as follows:

$$\varepsilon_m([M]\text{-radialene}) = \cos\lambda_{Mm} + (\cos^2\lambda_{Mm} + 1)^{1/2} , \quad (6)$$

where

$$\lambda_{Mm} = \frac{2m\pi}{M} \qquad m = 0, 1, 2, \cdots\cdots, (M-1) . \quad (7)$$

As in the case of annulene, if the radialene ring is large enough, it can be considered as a nonaromatic cyclic polyene. The π-energy of the unit structure of radialene is therefore estimated at the nonaromatic limit as

$$E_U(\text{radialene}) = E_{22'} + E_{10}$$
$$= \lim_{M\to\infty} \frac{2}{M} \sum_{m=0}^{M-1} [\cos\lambda_{Mm} + (\cos^2\lambda_{Mm} + 1)^{1/2}]$$
$$= 2\int_0^1 [\cos 2\pi x + (\cos^2 2\pi x + 1)^{1/2}]dx$$
$$= 2.4320134\cdots\cdots . \quad (8)$$

The numerical estimation of the unit energy was made by the double-precision computation. The π-energy of the reference structure of $[M]$-radialene is equated to $2.4320134M\beta$. Table 3 shows the resonance energies of radialenes based on this value, *i.e.*, the differences between the total HMO π-energies and the additive contributions defined by Eq. (5).

50	121.6007	121.6007	0.0

In contrast to annulenes, the agreement between the total π-energies and the additive contributions for radialenes is surprisingly excellent for all M's. All REPE's range between -0.00890β for $M=4$ and 0.00075β for $M=3$. This implies that they are to be considered nonaromatic regardless of the number of the π-electrons, and supports strongly that our way of determining the π-energy of the unit structure is quite reasonable. Radialenes can therefore be well represented in terms of localized single and double bonds in accordance with more elaborate calculations carried out by Dewar and his collaborators.[7,18]

If Table 3 is further examined in detail, it is found that the resonance energies are slightly negative for $M=4$, 8, and 12, and that they are slightly positive for $M=6$ and 10. This behavior of the resonance energies tempts us to present a new version of Hückel's $(4n+2)\pi$ rule for radialenes, in which the number of π-electrons (n) should be replaced by the number of methylene groups (M). However, the applicability of this rule fades very rapidly with increasing M. The additivity of π-bond energies are perfect for radialenes with M-values more than 12, though they are chemically of little importance. These aspects of the resonance energies of radialenes have so far been disregarded because of the tiny deviation of the total HMO π-energies from the additive contributions. The resonance energies of radialenes calculated by Hess and Schaad[4] were all negative as the sum of $E_{22'}$ and E_{10} (2.4358β) was slightly larger than the corresponding value calculated by us.

We have assumed in the present treatment that the geometries of annulenes and radialenes are all planar with constant resonance integrals. This is, however, exactly true only for the six-membered ring systems when they are substantially aromatic with little bond-order fluctuation. In most cases, ring strain and H–H nonbonded repulsions become significant; they would tend to destabilize both small and large rings relative to the six-membered rings. On the other hand, the introduction of bond alternation would often reduce the π-energy of the system. These effects were completely neglected in our simplified approach modeled after Hess and Schaad's.[4] Nevertheless, it must be noted that the resonance energies obtained here still appear to be much improved as an aromaticity index of the compound, and should be utilized, instead of the delocalization energies, to discuss the stability of these cyclic systems.

In conclusion, the well-established additivity of π-bond energies of nonaromatic polyenes allowed us to take infinitely large annulene and radialene as reference compounds in estimating the aromaticity of a given annulene and radialene. Such a procedure removed the difficulty encountered in evaluating the resonance energies of these compounds within the framework of the HMO theory. It is noticeable that the concept of aromaticity thus derived does not violate the simplicity and straightforwardness of the HMO theory, and may be considered as a practical extension of the HMO theory.

We are grateful to the Hokkaido University Computing Center for the use of their FACOM 230-60 on which all the calculations were performed.

The Reaction of Open-chain Unconjugated Dienes with Palladium Acetate. Dependence of the Products on Disposition of the Two Double Bonds

Nobuo ADACHI, Kiyoshi KIKUKAWA, Makoto TAKAGI, and Tsutomu MATSUDA

Department of Organic Synthesis, Faculty of Engineering, Kyushu University; Hakozaki, Higashi-ku, Fukuoka 812

(Received July 16, 1974)

The reaction of open-chain unconjugated dienes with palladium acetate in acetic acid was investigated with particular reference to the behavior of the two double bonds in the course of the acetoxylation. 1,5-Hexadiene produced 3-acetoxymethylenecyclopentane (64%), but 2,6-octadiene bearing two terminal methyl groups gave open-chain acetoxylated products: 3-acetoxy-1,6-octadiene (46%) and 7-acetoxy-2,5-octadiene (47%). The reactions of 1,6-heptadiene and diallyl ether are found to proceed *via* abnormal anti-Markovnikov addition to afford *cis* and *trans* 1-acetoxy-1,6-heptadienes (63%) and γ-acetoxyallyl allyl ethers (84%), respectively. No participation of the second double bond has been observed in the reaction of 1,7-octadiene. The behaviors of these dienes to palladium acetate can be reasonably explained by assuming the formation of π,σ-palladium species possessing a stable pseudo-six membered ring.

Although considerable efforts have been devoted to the reaction of conjugated dienes, especially of 1,3-butadiene, with palladium salts, studies of unconjugated dienes seem to be limited to such compounds as 1,5-cyclooctadiene, dicyclopentadiene, norbornadiene and so on, in which the two double bonds are fixed in cyclic system and favorably located so that they can interact with palladium salt to form a diene-palladium complex of considerable stability. Moreover, the resultant complexes are known to react with several nucleophiles to give π,σ-palladium species.[1]

We previously reported[2] that in the reaction with palladium acetate 1,5-hexadiene underwent cyclization to form a methylenecyclopentyl acetate. This fact strongly suggests that a cyclic intermediate similar to the π,σ-palladium species is involved in the cyclization. This paper deals with the reactions of other open-chain unconjugated dienes and diallyl compounds containing oxygen, nitrogen and sulfur with palladium acetate, and presents a relationship between the structures of the dienes and the oxidation products.

Results

The oxidation of dienes with palladium acetate (1 g) was generally carried out in acetic acid (40 ml) at 50 °C in the presence of ten-fold excess of diene until precipitation of palladium metal was completed (5—7 hr). The principal products obtained from the reactions and their yields based on palladium acetate are tabulated in Table 1. Their analytical data are shown in Table 2. The crude reaction products were usually obtained in yields over 90%, and virtually consisted of monoacetates (or monoketone). The excess dienes were recovered free from isomerization of the double bonds.

The cyclization product obtained from 1,5-hexadiene had previously been assumed to be 2-acetoxymethylenecyclopentane, mainly on the basis of considerably large chemical shift (δ 5.15) of the proton at the carbon carrying an acetoxyl group.[2] However, comparison of its NMR spectrum with that obtained in the reactions of methylenecyclopentane with palladium acetate[5] or mercuric acetate led us to conclude the product to be 3-acetoxy isomer (**1**) (see Table 2, **1** and **1'**). 1,6-Heptadiene yielded a mixture consisting

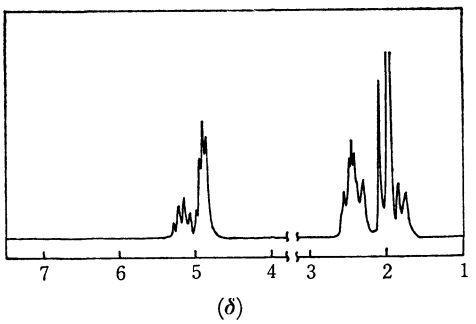

Fig. 1. NMR spectrum of **1**.

of three monoacetoxydienes bearing a terminal vinyl group (δ_{CH} 990—980 and 910 cm^{-1}, and multiplet at δ 4.8—6.2). Two of them were characterized by the presence of higher carbonyl absorption (1765—1770 cm^{-1}) and a doublet absorption at around δ 7 region (Fig. 2b) indicating the presence of CH=CH– group.
OAc

By considering coupling constants of the doublet absorptions, they were assigned to be *cis* (**3**, J=6.5 Hz) and *trans* (**4**, J=12 Hz) isomers of 1-acetoxy-1,6-heptadiene. The structure of the other one was tentatively assigned to 3-acetoxy-1,6-heptadiene (**2**) on the basis of $\nu_{C=C}$ at 1648 cm^{-1} (refer to $\nu_{C=C}$: 1653

cm^{-1} for **5**, but 1670 cm^{-1} for **6** and **9**) and the presence of a methylene group at δ 1.75, although an ambiguity remains in excluding the another isomer, 7-acetoxy-1,5-heptadiene. Two products were obtained from *trans,trans*-2,6-octadiene in nearly equal amount. One of them contained a methyl group (δ 1.68) and a vinyl group, and the other showed the presence of two methyl groups (3H each, δ 1.26 and 1.68). Their NMR and IR spectra were most reasonably explained by assigning their structure to 3-acetoxy-1,6-octadiene (**5**) and 7-acetoxy-2,5-octadiene (**6**), respectively (Figs. 3a and 3b). 1,7-Octadiene afforded a methyl ketone and two acetoxylated dienes (Figs. 4a, 4b, and 4c). Examination of their NMR spectra showed that the structures corresponded to those which were made up by replacing the terminal ethyl group (C7 and C8) with a vinyl group from 2-octanone, 2-acetoxy-1-octene and 1-acetoxy-2-octene, respectively, which were produced in the reaction of 1-octene.[2] Thus, they were concluded to be 1-octen-7-one (**7**), 2-acetoxy-1,7-octadiene (**8**) and 1-acetoxy-2,7-octadiene (**9**), respectively.

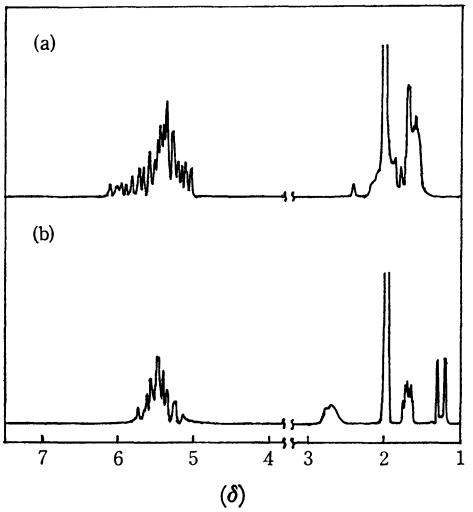

Fig. 3. NMR spectra of **5**(a) and **6**(b).

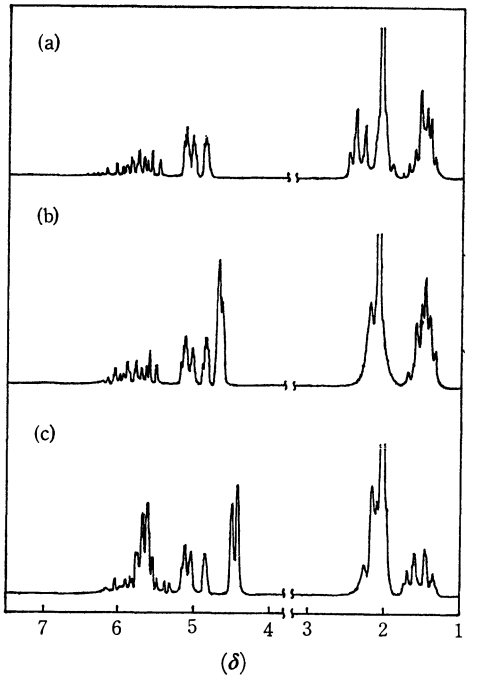

Fig. 4. NMR spectra of **7**(a), **8**(b), and **9**(c).

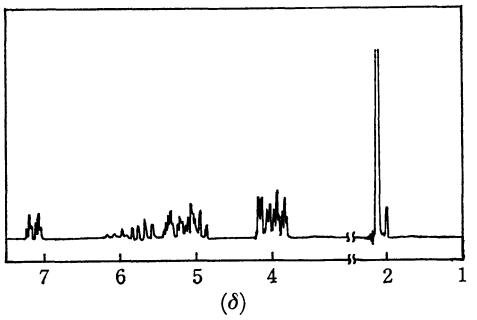

Fig. 5. NMR spectrum of **10**.

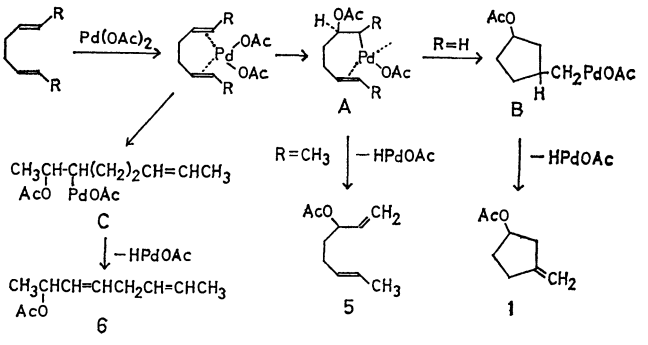
Diallyl ether reacted like other dienes to produce two acetoxylated products. They were assigned to *cis* and *trans* γ-acetoxyallyl allyl ethers (**10** and **11**) by their NMR spectra (Fig. 5) and elementary analyses.

The reactions of diallylamine and diallyl sulfide with palladium acetate proceeded in markedly different manner from the other dienes, and produced little liquid product but a considerable amount of intractable solid materials containing palladium. Since normal acetoxylation attended by precipitation of palladium metal was scarcely observed, the reactions were not examined further.

Discussion

The reaction of 1-octene with palladium acetate in acetic acid yielded 2-acetoxy-1-octene and 1-acetoxy-2-octene in a ratio of 5 : 1 along with 2-octanone and the other minor acetoxylated products.[2] This fact is understood to indicate that in the reaction of palladium acetate with a terminal olefin Markovnikov addition prefers considerably to anti-Markovnikov addition in view of the established route to the palladium acetate oxidation of olefins involving 1,2-addition of PdOAc (acetoxypalladation) and the subsequent *cis* 1,2-elimination of HPdOAc.[3] The formation of **8** and **9** from 1,7-octadiene in a ratio of nearly 5 : 1 as well as of **7** strongly suggests that one of the terminal double bonds reacts like 1-octene without being affected by the presence of the second double bond. However, other dienes utilized in this study afforded characteristic products which reflect the structures of the starting dienes. 1,5-Hexadiene gave the cyclic product **1**, while

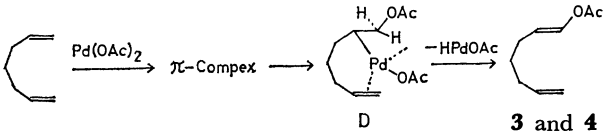


Scheme 1.

2,6-octadiene yielded two open-chain oxidation products **5** and **6**. The marked difference in the products between the two dienes could be reasonably explained in terms of the following scheme.

Addition of one mole of palladium acetate to the dienes would result in the formation of a cyclic π,σ-Pd intermediate since the coordination of the second double bond to palladium can stabilize the initial σ-bonded palladium species. It is noteworthy that in the intermediate (A, R=H) from 1,5-hexadiene β-hydrogen is forced to locate in anti or anti-periplanar position to PdOAc group and cannot enter into the usual *cis* 1,2-elimination of HPdOAc. There are several experimental facts that in the absence of β-hydrogen to be eliminated σ-Pd species enters into another slower processes, such as insertion of a double bond to σ-Pd–C bond[4,5] or formation of π-allylic palladium species.[5,6] Thus, the reaction of 1,5-hexadiene could be depicted that the second double bond in the π,σ-Pd intermediate reacts with σ-Pd–C bond intramolecularly to lead to B, which then undergoes 1,2-elimination to give **1**. On the other hand, in the intermediate (A, R=CH_3) from 2,6-octadiene, a terminal methyl group can act as a β-hydrogen source for the facile 1,2-elimination. Thus, the presence of the methyl group can be regarded as a contributing factor to the formation of **5**, in place of cyclization product. In contrast to the preference for Markovnikov addition of palladium acetate to a terminal double bond, palladium acetate can add to an internal double bond in two alternative ways with much less selectivity.[2] The anti-Markovnikov addition of palladium acetate to 2,6-octadiene is considered to give the intermediate C, which then collapses directly to **6** without forming any cyclic intermediate, since the pseudo-five membered ring species expected by π-donation to palladium must be subjected to considerable steric strain due to a methyl group at C–7 and an α-acetoxyethyl group (–$\underset{\displaystyle CH_3}{\overset{|}{C}}$HOAc) at C–3.

The rationalization of the reaction pathway based on the formation of the stable π,σ-Pd intermediate of pseudo-six membered ring is also applicable to account for the products obtained from 1,6-heptadiene or diallyl ether. Formation of **3** and **4** seems somewhat curious since in the palladium acetate oxidation of simple olefins (except for ethylene) there is no previous example describing the formation of the product bearing 1-acetoxy-1-enyl structure in a considerable yield. If palladium acetate adds to one of the double bonds of 1,6-heptadiene in Markovnikov manner, it would be expected to form either 2-acetoxy-1,6-heptadiene (and/or its isomeric allylic acetates) or a cyclic product through an intermediate of pseudo-seven membered ring. However, it is not the case with the present result except for the formation of a relatively small amount of **2**. On the other hand, a pathway through the pseudo-six membered ring intermediate (D) formed *via* anti-Markovnikov addition is consonant well with the formation of **3** and **4**, because D can not only receive the similar stabilizing effect as was discussed in the reactions of 1,5-hexadiene and 2,6-octadiene, but also possesses β-hydrogen at C–1 available for the facile 1,2-elimination (Scheme 2).



Scheme 2.

Thus, it can be concluded that the formation of a stable π,σ-Pd intermediate of pseudo-six membered ring controls not only the orientation of palladium acetate addition to double bond, but also alters the direction of 1,2-palladium hydride elimination.

The formation of **2** is unusual in view of the normal palladium acetate oxidation involving 1,2-addition and 1,2-elimination, and cannot be explained at present. Although a route involving π-allylic species in place of the σ-Pd bond in D might be an explanation, it is hardly compatible with the formation of **3** and **4**.

Cis and *trans* γ-acetoxyallyl allyl ethers are considered to be produced from diallyl ether in the same route discussed for 1,6-heptadiene, though none of α-acetoxyl isomer was observed. It is to be noted that in the absence of the second double bond the acetoxylation proceeded in a normal manner under the same reaction conditions as evidenced by the formation of β-acetoxyallyl ethyl ether[7] from allyl ethyl ether as a principal product.

It has been reported that allylamines[8] and allyl sulfides[9] gave stable complexes with palladium chloride. The strong dative power of nitrogen and sulfur to palladium could be a principal factor for the present results that diallylamine and diallyl sulfide did not undergo normal acetoxylation with palladium acetate, but afforded intractable solid materials.

Experimentals

Materials. 1,5-Hexadiene[10] and diallylamine[11] were synthesized by the standard methods. 1,7-Octadiene and diallyl sulfide were commercial grade and distilled before use. 1,6-Heptadiene was obtained by the coupling of 4-butenylmagnesium bromide with allyl chloride in the presence of a catalytic amount of ferric chloride,[12] bp 89.0—90.0 °C (lit,[13] bp 91 °C). *Trans,trans*-2,6-octadiene was prepared by the method reported by Webb and Borcherdt[14] consisting of the coupling of crotyl bromide in the presence of nickel carbonyl, bp 123.2—124.0 °C (lit,[14] bp 124.5 °C). Diallyl ether was prepared by the method reported by Skrabal.[15] Palladium acetate was prepared according to the procedure of Wilkinson.[16]

Reaction Procedure. Palladium acetate (1 g, 4.3 mmol) in 40 ml of acetic acid was placed in a 100 ml flask equipped with a reflux condenser and a magnetic stirrer. After the addition of ten-fold excess of diene (43 mmol), the mixture was stirred at 50 °C for 5—7 hr until precipitation of palladium metal was completed. The palladium metal was separated from the reaction mixture by centrifuge, and the supernatant solution was mixed with 300 ml of ether. The ethereal solution was washed successively with water, 30% sodium bicarbonate solution, and saturated sodium chloride solution and dried. Ether and the excess diene were recovered by distillation, and the residue was distilled under reduced pressure to give the following amounts of crude products from the dienes indicated (yields were calculated

as monoacetate and based on the quantity of palladium acetate utilized). 1,5-Hexadiene; 0.58 g (94%), 1,6-heptadiene; 0.68 g (103%), *trans,trans*-2,6-octadiene; 0.72 g (92%), 1,7-octadiene; 0.74 g (100%), and diallyl ether; 0.61 g (100 %).

The crude products were analyzed by glc using one of the 3 mm×2 m columns of Ucon Oil 50HB5100 (10%)-Celite or Reoplex 400 (10%)-Celite. After separation of the main components from the products by glc, their structures were determined by the measurements of IR, NMR and elementary compositions as shown in Table 2.

The Stereochemistry of Autoxidation of Methylcyclohexanes

Shingo MIYAJIMA* and Osamu SIMAMURA**

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received August 30, 1974)

Autoxidation of 1, *c*-3, *c*-5- or 1, *c*-3, *t*-5-trimethylcyclohexane with oxygen in the presence of azobisisobutyronitrile at 60 °C and subsequent reduction with lithium aluminium hydride gave 1, *t*-3, *t*-5- and 1, *c*-3, *c*-5-trimethyl-*r*-1-cyclohexanol in the same ratio of 1/0.85. Such an almost random attack of oxygen on both sides of intermediate methylcyclohexyl radicals was also observed in autoxidation of 1,2-dimethyl-, 1,4-dimethyl-, and 1,1,3,5-tetramethylcyclohexanes. Approximate relative reactivities of tertiary hydrogens in various steric environments in methylcyclohexanes towards abstraction were determined. Steric effects on the attack of oxygen and the abstraction of hydrogen are discussed.

Although the autoxidation of hydrocarbons with formation of hydroperoxides has been extensively studied, the stereochemical features of the reaction seem to deserve more detailed investigation. The present paper deals with the relative reactivity of tertiary hydrogens in various steric environments in methylcyclohexanes towards abstraction and the stereochemistry of the reaction of oxygen with intermediate methylcyclohexyl radicals.

Results and Discussion

Methylcyclohexanes were autoxidized with oxygen in the presence of azobisisobutyronitrile at 60 °C and the stereoisomeric hydroperoxides formed were reduced with lithium aluminium hydride. Since this reagent is expected to reduce stereospecifically the hydroperoxides to the corresponding alcohols,[1] the alcohol compositions reflect the hydroperoxide compositions of the oxidates. The reduced oxidates were analysed by gas-liquid partition chromatography (glpc).

1,3,5-Trimethylcyclohexanes. 1,*c*-3,*c*-5-Trimethylcyclohexane (**1**) gave two products 1,*t*-3,*t*-5- and 1, *c*-3,*c*-5-trimethyl-*r*-1-cyclohexanol (**5** and **6**), while the 1,*c*-3,*t*-5-isomer (**2**) afforded, besides these alcohols, a third one (**7**). Samples of alcohols **5** and **6** were collected and separated by glpc. The analytical and spectral data show that both of them are monohydric tertiary alcohols, which must have been derived from intermediate radical **3** (Fig. 1).

The configurations of alcohols **5** and **6** are assigned on the basis of the IR data. It has been reported that, in a considerable number of secondary and tertiary cyclohexanols, an axial hydroxyl group has a free O–H stretching absorption in the IR spectrum at a higher frequency than that of its equatorial epimer.[2] For example, *c*-4-*t*-butyl-1-methyl- (with an axial hydroxyl) and *t*-4-*t*-butyl-1-methyl-*r*-1-cyclohexanol (with an equatorial hydroxyl) absorb at 3616—7 and 3611—2 cm^{-1}, respectively.[2c,d] According to this correlation, it is concluded that alcohol **5** has an axial hydroxyl group and alcohol **6** an equatorial one, since alcohols **5** and **6** absorb at 3617 and 3611 cm^{-1}, respectively. The assignments are further supported by NMR measurements of the proton resonance due to a hydroxyl group (see Experimental Part).

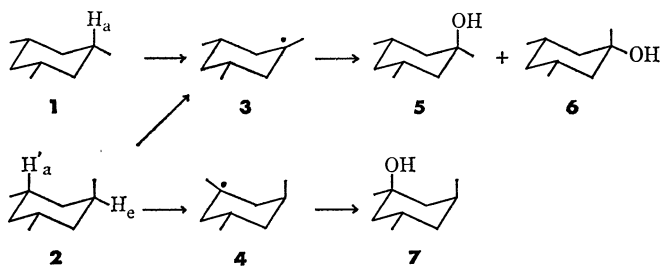

Fig. 1. Autoxidation of 1,3,5-trimethylcyclohexanes.

Isolation of alcohol **7** was not successful. Unquestionably it was derived from intermediate radical **4** generated by abstraction of H_a' in structure **2**, and two forms resulting from axial and equatorial attack of oxygen on radical **4** are of identical configuration and conformationally interconvertible. No other products were detected, indicating that the reaction took place only at tertiary hydrogen atoms.

As shown in Table 1, stereoisomeric 1,3,5-trimethylcyclohexanes **1** and **2** give epimeric alcohols **5** and **6** in the same ratio (1/0.85). Apparently, trimethylcyclohexane **1** or **2**, on abstraction of H_a or H_e, gives radical **3** as a common intermediate. Oxygen attacks this radical from the axial side a little more readily than from the equatorial side. In view of conformational energy, the intermediate peroxy radical corresponding to alcohol **5** should be favoured, at equilibrium, over that corresponding to alcohol **6** by a factor of about 4;[3] consequently, the observed ratio of 1/0.85 indicates an almost random attack of oxygen on both sides of radical **3**. The planar structure of cyclohexyl radicals at the radical centre[5] suggests that oxygen will attack radical **3** with equal probability on both sides of the ring, but the slight preference for axial attack of oxygen may be accounted for by the steric hindrance by the axial hydrogen atoms at positions 2 and 6 to oxygen approaching from the equatorial side. Such steric hindrance has also been suggested to explain the stereochemistry of several reactions including reduction of various cyclohexanones with metal hydrides.[6] It may also be possible that the torsional bond-bond interactions in the transition state suggested by Jensen and coworkers[7] may be a controlling factor in causing this preference.

The relative amounts in which trimethylcyclohexa-

14	6.9	0.024	60.2	48	0.055	1 : 1.16
14[c]			60.2	48		1 : 1.19

a) After reduction with lithium aluminium hydride. b) A mixture of **8** and **9** (75/25). c) Competitive autoxidation with trimethylcyclohexane **1**.

nols **5**, **6**, and **7** are formed reflect approximately the relative reactivities of H_e, H_a, and H_a' towards abstraction. In the accepted scheme of autoxidation[8] involving propagation and termination steps subsequent to initiation:

$$R\cdot + O_2 \rightarrow ROO\cdot \quad \text{(addition)}$$

$$RH + ROO\cdot \rightarrow ROOH + R\cdot \quad \text{(abstraction)}$$

$$2ROO\cdot \rightarrow \text{Inert product} \quad \text{(termination)}$$

the rate constants for abstraction and termination are assumed to be independent of minor difference in structure between the isomeric methylcyclohexylperoxy radicals, and the usual steady-state approximation gives, for the autoxidation of trimethylcyclohexane **1**, the following equation:

$$d([\mathbf{5}^*]+[\mathbf{6}^*])/dt = k_a[H_a](r_i/k_t)^{1/2} \quad (1)$$

where the numerals with an asterisk denote the hydroperoxides corresponding to the alcohols shown in Fig. 1, r_i is the rate of initiation, k_t the rate constant of termination, and k_a that of abstraction of hydrogen atom H_a. Similarly, in the autoxidation of trimethylcyclohexane **2**, we obtain

$$d([\mathbf{5}^*]+[\mathbf{6}^*]+[\mathbf{7}^*])/dt = (k_e[H_e]+k_a'[H_a'])(r_i/k_t)^{1/2} \quad (2)$$

and

$$(d[\mathbf{7}^*]/dt)/\{d([\mathbf{5}^*]+[\mathbf{6}^*])/dt\} = k_a'[H_a']/k_e[H_e] \quad (3)$$

where k_e and k_a' are the rate constants of abstraction of hydrogen atoms H_e and H_a', respectively. Since the autoxidations of hydrocarbons **1** and **2** were carried out under almost the same conditions, we have

$$\frac{d([\mathbf{5}^*]+[\mathbf{6}^*] \text{ from } \mathbf{1})/dt}{d([\mathbf{5}^*]+[\mathbf{6}^*]+[\mathbf{7}^*] \text{ from } \mathbf{2})/dt} = \frac{k_a[H_a]}{k_e[H_e]+k_a'[H_a']} \quad (4)$$

By substituting for the rates of formation of hydroperoxides in Eqs. 3 and 4 the amounts of the corresponding alcohols obtained given in Table 1, since the extent of autoxidation was very limited, the relative rates of hydrogen abstraction are calculated to be $k_e/k_a=2.6$ and $k_a'/k_a=0.22$. Thus, H_e is more reactive than H_a, since it is a less hindered equatorial hydrogen; moreover, the steric strain between the axial methyl group and hydrogens at positions 3 and 5 will be relieved in the transition state of hydrogen abstraction. In contrast, H_a' is less reactive because of the steric hindrance by the axial methyl group at position 3.

1,4- and 1,2-Dimethylcyclohexanes. 1,4- and 1,2-Dimethylcyclohexanes gave corresponding stereoisomeric 1,4-dimethyl- (**11** and **12**) and 1,2-dimethylcyclohexanols (**16** and **17**) (Figs. 2 and 3). These were identified by comparing their glpc retention times with those of authentic samples. The observed ratios **11**/**12** and **16**/**17** are shown in Table 2.

Döring *et al.*[9] reported that *cis*- or *trans*-1,4-dimethylcyclohexane, on autoxidation at 95—110 °C and subsequent reduction with triphenylphosphine or sodium sulphite, afforded alcohols **11** and **12** in a ratio of 1/0.24, which is considerably different from our result (1/0.74), while the ratio of axial to equatorial attack of oxygen on 4-*t*-butyl-1-methylcyclohexyl radical was 1/0.83, in agreement with our data on 1,3,5-trimethylcyclohexanes. The value of 1/0.74 for **11**/**12** is close to that for **5**/**6** from radical **3**, and this is what is

expected, because 1,4-dimethylcyclohexyl radicals are in a rapid conformational equilibrium before reacting with oxygen (**10e** and **10a** in Fig. 2), conformer **10e** predominating over conformer **10a** approximately to the same extent that prevails in the case of methylcyclohexane. The rapid equilibration is supported by Ogawa and Fessenden's conclusion[5b] that the change of linewidth in the ESR spectrum of cyclohexyl radical with temperature (−85—0 °C) corresponds to an activation energy for the ring inversion of 4.9 kcal/mol, which corresponds to a rate of *ca.* $10^9\ s^{-1}$ at 60 °C. Thus, the rate of the inversion will be faster than that of the reaction with oxygen.[10]

With 1,2-dimethylcyclohexanes, the formation of alcohol **17** is slightly favoured over that of alcohol **16**. Conformer **15a** might play a role because of eclipsing of the two methyl groups in conformer **15e** (Fig. 3).

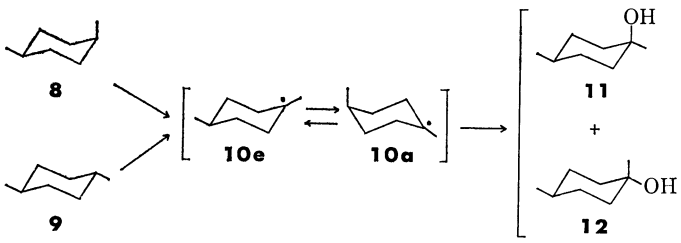

Fig. 2. Autoxidation of 1,4-dimethylcyclohexanes.

The relative reactivity of the axial tertiary hydrogen in *trans*-1,2-dimethylcyclohexane (**14**) towards abstraction was determined by competitive oxidation with trimethylcyclohexane **1**, using the same kind of equation as Eq. 3. The results are shown in Tables 4 and 5. The axial hydrogen in dimethylcyclohexane **14** is less reactive than H_a in trimethylcyclohexane **1**. This retardation is probably due to the steric hindrance by the equatorial methyl group at position 2 to approach of peroxy radicals and/or a crowded transition state with the incipient eclipsing of the two methyl groups.

1,1,3,5-Tetramethylcyclohexanes. Glpc analysis of the reduced oxidate from *cis*- (**18**) or *trans*-1,1,3,5-tetramethylcyclohexane (**19**) revealed two main product peaks. Apparently, these are due to stereoisomeric alcohols **21** and **22** derived from intermediate radical **20** (Fig. 4); the shorter retention time agrees with that of an authentic sample of 1,3,3,*t*-5-tetramethyl-*r*-1-cyclohexanol (**21**) prepared from 3,3,5-trimethylcyclohexanone and methylmagnesium iodide.[13] Although there should be a considerable energy difference (*ca.* 2.0 kcal/mol[14]) between the products from axial and equatorial attack of oxygen on radical **20**, an almost random attack of oxygen was observed also in this case (Table 3). The ratio of axial to equatorial oxygen attack on radical **20** (1/0.96) is slightly smaller than that of oxygen attack on radical **3** (1/0.85), apparently

14	**18**	**19**

because of the steric effect of the axial methyl group at position 3 in radical **20**.

The relative rate of hydrogen abstraction from tetramethylcyclohexane **18** or **19** was determined by competitive autoxidation with 1,3,5-trimethylcyclohexane **1**. The results are shown in Tables 4 and 5. The relative reactivity of H_a'' in hydrocarbon **18** (0.20) agrees reasonably with that of H_a' in trimethylcyclohexane **2** (0.22). It is noteworthy that equatorial hydrogen H_e' in hydrocarbon **19** is much more reactive (relative reactivity, 11).[16] This large value is certainly due to steric acceleration caused by relief of the 1,3-diaxial strain between the two methyl groups at positions 1 and 3 in the transition state for hydrogen abstraction.

Experimental

All melting points and boiling points are uncorrected. Analytical glpc measurements were carried out with a Perkin-Elmer model 154D instrument. Preparative scale glpc was carried out with a Yanagimoto preparative gas chromatograph and an F & M Prep Master 775. NMR data were obtained with a Varian A-60 spectrometer using tetramethylsilane as an internal standard. IR spectra were recorded on a Nihon-Bunko DS-402G or a Perkin-Elmer 112G spectrometer.

1,3,5-Trimethylcyclohexanes. Mesitylene was hydrogenated in acetic acid over platinum oxide at 30—45 °C with an initial pressure of 50 atm of hydrogen to yield a mixture of 1,*c*-3,*c*-5- (**1**) and 1,*c*-3,*t*-5-trimethylcyclohexane (**2**) in a ratio of 83/17. This mixture was separated into each isomer by preparative glpc on a Silicone DC-550 column at 100 °C. Reinjection of the collected materials showed that the *cis* isomer was free of impurities and that the *trans* isomer contained 1.6% of **1**. The IR and NMR spectra were identical with those published.[17,18]

1,2- and 1,4-Dimethylcyclohexanes. Hydrogenation of *o*-xylene by the same procedure as above afforded a mixture of *cis*- (**13**) and *trans*-1,2-dimethylcyclohexane (**14**) in a ratio of 88/12. Dehydration of 1,2-dimethylcyclohexanol, prepared from methylmagnesium iodide and 2-methylcyclohexanone, followed by hydrogenation in methanol with hydrogen at 1 atm on 5% palladium-on-charcoal at room temperature gave a 22/78 mixture of *cis*- and *trans*-1,2-dimethylcyclohexane. From these mixtures each isomer was obtained by preparative glpc using a Silicone DC-550 column at 95 °C: *cis* isomer **13**, n_D^{20} 1.4349 (lit,[19] n_D^{20} 1.43596); *trans* isomer **14**, n_D^{20} 1.4259 (lit,[19] n_D^{20} 1.42695). Reinjection of the collected materials showed that the *cis* isomer contained 1.9% of **14** and that the *trans* isomer was free of impurities.

1,4-Dimethylcyclohexanes were prepared from *p*-xylene in the same manner as with 1,3,5-trimethylcyclohexanes, the *cis*/*trans* ratio being 75/25. This mixture was used without separating it into the isomeric components.

1,1,3,5-Tetramethylcyclohexanes. A procedure similar to that of Allinger and Miller[20] was used. Isophorone was hydrogenated in methanol over palladium-on-charcoal to yield 3,3,5-trimethylcyclohexanone, which was then converted with methylmagnesium iodide into 1,3,3,*t*-5-tetramethyl-*r*-1-cyclohexanol (**21**), mp 80.5—81.5 °C (lit,[13] 80—81.5 °C). Dehydration of this alcohol with formic acid followed by hydrogenation in acetic acid with hydrogen at 1 atm on platinum oxide at room temperature yielded a mixture of *cis*- (**18**) and *trans*-1,1,3,5-tetramethylcyclohexane (**19**) in a ratio of 1.34/1. The components were separated by preparative scale glpc using an SE-30 column at 128 °C: the *cis* isomer, bp 153—153.5 °C (lit,144.5—145 °C,[20] 152.4—152.5 °C[21]), n_D^{20} 1.4300 (lit, n_D^{25} 1.4288,[20] n_D^{20} 1.4319[21]); the *trans* isomer, bp 157.5—158 °C (lit, 148.5—149 °C,[20] 156.4—156.5 °C[21]), n_D^{20} 1.4357 (lit, n_D^{25} 1.4342,[20] n_D^{20} 1.4370[21]). Each of the collected materials showed no impurities on reinjection.

General Procedure of Autoxidation Experiments. Samples (1.0—1.5 ml) of methylcyclohexanes were autoxidized with oxygen at 1 atm in the presence of azobisisobutyronitrile (4—6 mg) in a small glass vessel attached to a gas burette. The reaction temperature was controlled by immersing the vessel in a constant temperature oil bath. The samples were stirred by means of a glass-encased magnetic stirring bar. At a conversion of less than 10% the reaction was stopped, and a portion (0.20—0.50 ml) of the oxidate was withdrawn to determine the hydroperoxide content by the iodometric method of Wagner *et al.*[22]

The rest of the oxidate was transferred into a dropping funnel, using 10 ml of anhydrous ether to rinse the reaction vessel, and was added to a suspension of 0.5 g of lithium aluminium hydride in 10 ml of anhydrous ether with stirring. The mixture was heated under reflux for 2 hr and then allowed to stand overnight at room temperature. Excess of lithium aluminium hydride was destroyed with dilute sulphuric acid, and the aqueous phase extracted with three 10 ml portions of ether. The combined ether solutions were washed with 5% sodium hydrogencarbonate solution and dried over anhydrous sodium sulphate, and then the ether was removed. The resulting solution was analysed for alcohols by glpc.

Product Identification. *1,3,5-Trimethylcyclohexanols*: 1,3,5-Trimethylcyclohexanols **5** and **6** were isolated by preparative glpc using a Carbowax column at 130 °C from reduced oxidate of a mixture of 1,3,5-trimethylcyclohexanes **1** and **2**.

*1,t-3,t-5-Trimethyl-r-1-cyclohexanol (**5**)*: n_D^{20} 1.4498 (Found: C, 75.95; H, 12.71%. Calcd for $C_9H_{18}O$: C, 76.00; H, 12.76%); ν_{max} (0.022 M in CCl_4) 3617 cm^{-1} (OH); δ (0.71 M in CCl_4) 0.85 (d, J 6 Hz, 6H, 3-CH_3 and 5-CH_3), 1.14 (s, 3H, 1-CH_3), 0.2—1.9 (complex, ring protons), 2.32 (s, 1H, OH).[23] The signal of OH proton was shifted to δ 1.02 upon dilution to 0.158 M.

*1,c-3,c-5-Trimethyl-r-1-cyclohexanol (**6**)*: mp 41.5—42.5 °C (Found: C, 76.26; H, 12.86%. Calcd for $C_9H_{18}O$: C, 76.00; H, 12.76%); ν_{max} (0.022 M in CCl_4) 3611 cm^{-1} (OH); δ (0.71 M in CCl_4) 0.91 (d, J 5 Hz, 6H, 3-CH_3 and 5-CH_3), 1.15 (s, 3H, 1-CH_3), 0.3—1.8 (complex, ring protons), 2.90 (s, 1H, OH).[23] The signal of OH proton was shifted to δ 1.38 upon dilution to 0.158 M.

1,4- and 1,2-Dimethylcyclohexanols: The products from 1,4- and 1,2-dimethylcyclohexanes were identified by comparison of their glpc retention times with those of authentic samples

of 1,*c*-4- (**11**) and 1,*t*-4-dimethyl-*r*-1-cyclohexanol (**12**) and those of the components of a mixture of 1,*c*-2- (**16**) and 1,*t*-2-dimethyl-*r*-1-cyclohexanol (**17**). Authentic samples of alcohols **11** and **12** were obtained by reaction of 4-methylcyclohexanone with methylmagnesium iodide, followed by separation of the resulting *cis* and *trans* mixture (**11**/**12**=1/1) by glpc using a Carbowax column at 140 °C: alcohol **11**, mp 66—68 °C (lit,[24] 72.5 °C); alcohol **12**, mp 23—24 °C (lit,[24] 24 °C). A sample of a **16** and **17** mixture was prepared from 2-methylcyclohexanone and methylmagnesium iodide, the **16**/**17** ratio being 3.8/1 in fairly good agreement with the reported value (3/1).[25]

1,3,3,5-Tetramethylcyclohexanols: The preparation of 1,3,3-*t*-5-tetramethyl-*r*-1-cyclohexanol (**21**) has been described above. Glpc analysis of the reduced oxidate from 1,1,3,5-tetramethylcyclohexane **18** or **19** revealed two main product peaks corresponding to alcohol **21** and the epimeric alcohol **22**, the shorter retention time agreeing with that of a sample of alcohol **21**.

Product Analysis. The reduced oxidate from 1,3,5-trimethylcyclohexane **1** or **2** was examined by glpc on a Carbowax column 4 m long at 165 °C; the order of elution was alcohols **5**, **7**, and **6**. Quantitative analysis for alcohol **5** or **6** was carried out using anisole as an internal standard. Since the mole ratio was found to be approximately equal to the peak area ratio with stereoisomers **5** and **6** [mol **5**/mol **6**=0.974× (area **5**/area **6**)], the amount of alcohol **7**, whose authentic specimen was not available, was estimated on the assumption that the mole ratio of **7**/**5** equals the peak area ratio. Stereoisomeric 1,2- or 1,4-dimethylcyclohexanols were analysed using a Carbowax column 2 m long at 150 °C; the order of elution was alcohols **16** and **17** or alcohols **11** and **12**. Analysis of the alcohols from competitive autoxidation of 1,2-dimethylcyclohexane **14** with trimethylcyclohexane **1** was carried out on a Carbowax column (2 m) and a Ucon Oil LB-550-X column (2 m) connected in series at 160 °C; alcohols were eluted in the order **16**, **5**, **17**, and **6**. The products from autoxidation of tetramethylcyclohexane **18** or **19** and competitive autoxidation with trimethylcyclohexane **1** were analysed with the above-mentioned series of columns at 170 °C; the elution of alcohols took place in the order **5**, **21**, **6**, and **22**.

It is apparent that in each pair of the epimeric alcohols examined the one, which has an hydroxyl group predominantly in the axial position, has a shorter retention time than the other, when chromatographed on polyethylene glycol (Carbowax) or polypropylene glycol (Ucon Oil). This observation is in accord with the results by Komer *et al.*,[26] who studied the retention times of the epimeric 2-, 3-, and 4-alkylcyclohexanols using glycerol or erythritol as a stationary phase.

The Stereochemistry of the Reaction of Hydrogen Bromide with Cyclohexene and 1-Methylcyclohexene in the Presence of Oxygen

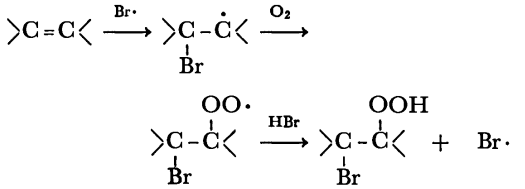
Shingo MIYAJIMA,* Sadao ICHIHARA,** and Osamu SIMAMURA***

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received August 30, 1974)

The reaction of hydrogen bromide with cyclohexene or 1-methylcyclohexene in the presence of oxygen, followed by reduction with lithium aluminium hydride afforded *trans*-2-bromocyclohexanol or *t*-2-bromo-1-methyl-*r*-1-cyclohexanol. These findings show that oxygen attacks intermediate bromocyclohexyl radicals formed by addition of a bromine atom to a double bond exclusively on the side opposite to the bromine substituent. Mechanistic implications are discussed.

The free radical addition of hydrogen bromide to olefins takes place preferentially in *anti* fashion.[1] If oxygen is present, it attacks an intermediate radical generated by addition of a bromine atom to an olefinic bond in competition with hydrogen bromide, giving rise to a bromine-containing hydroperoxide[2] or oxygenated bromine compounds,[3] probably through an intermediate hydroperoxide.

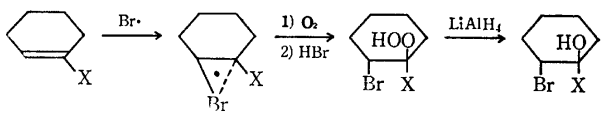


It seemed of interest to examine the stereochemistry of attack of oxygen on the cyclohexyl type of radicals generated by addition of a bromine atom to cyclohexenes, because in the autoxidation of methylcyclohexanes it has been shown that oxygen attacks intermediate radicals with nearly equal probability on both sides of the radical centre.[4] The present report deals with the stereochemistry of reaction of oxygen with the radicals generated by addition of a bromine atom to cyclohexene and 1-methylcyclohexene.

Results and Discussion

Anhydrous hydrogen bromide and oxygen were passed through cyclohexene or 1-methylcyclohexene containing a little benzoyl peroxide at about 60 °C, and reaction mixtures were treated with lithium aluminium hydride to reduce hydroperoxides produced to the corresponding alcohols. Gas-liquid partition chromatographic (glpc) analysis showed that *trans*-2-bromocyclohexanol or *t*-2-bromo-1-methyl-*r*-1-cyclohexanol was formed, but no *cis* isomers were detected. The results are summarized in Table 1.

It is evident that oxygen attacks the intermediate radicals formed by addition of a bromine atom to the cyclohexenes exclusively on the side opposite to the bromine atom, in striking contrast to the case of autoxidation of methylcyclohexanes, in which an almost random attack of oxygen occurs.[4] The completely stereoselective attack of oxygen may be explained in terms of a bromine bridged radical[5] (Fig. 1); thus, oxygen would attack intermediate radical **1** only from the opposite direction of the bromine bridge resulting in *anti* stereochemistry. An alternative explanation for the observed stereochemistry might involve intermediate radical **2**, in which the C-2 bromine occupies an axial position and would prevent an access of oxygen from the *cis* direction (Fig.



1 X=H, CH_3

Fig. 1.

2). This explanation, however, does not seem convincing, because, although the 2-bromocyclohexyl radical will be produced in the form shown in Fig. 2 with the bromine substituent in an axial conformation, it will interconvert in quick equilibrium with the form in which the bromine is equatorial before it reacts with oxygen,[6] undoubtedly resulting in almost random attack of oxygen.

Experimental[7]

Materials. Cyclohexene was prepared by dehydration of cyclohexanol with potassium hydrogensulphate,[8] followed by fractional distillation with a packed column, bp 82—82.5 °C. 1-Methylcyclohexene was prepared according to the method of Bartlett and Rosenwald[9] by the Grignard reaction of cyclohexanone to give 1-methylcyclohexanol, followed by dehydration and fractionation with a concentric column, bp 110.2—110.4 °C. Hydrogen bromide was evolved by the action of bromine on tetralin.[10] The hydrogen bromide was freed from bromine by bubbling through tetralin and dried by passing through a trap cooled at —50 °C and then a tube packed with anhydrous calcium sulphate.

Reactions of Hydrogen Bromide with Cyclohexene and 1-Methylcyclohexene in the Presence of Oxygen. Cyclohexene (0.34 mol) or 1-methylcyclohexene (0.25 mol) containing benzoyl peroxide (1 mmol) was placed in a reaction flask equipped with two bubbler tubes and a reflux condenser protected from moisture by a drying tube filled with anhydrous calcium sulphate. The reaction flask was immersed in a water bath which was kept at about 60 °C. The cyclohexene was stirred by means of a magnetic stirrer, and dry hydrogen bromide and oxygen were passed through simultaneously. The reaction was allowed to proceed for 3—3.5 hr. The reaction mixture was washed with water and dried over anhydrous magnesium sulphate. A portion of this mixture was analysed for peroxides formed by the iodometric method of Wagner *et al.*[11] The remaining portion was dissolved in anhydrous ether and added to a suspension of excess of lithium aluminium hydride in anhydrous ether. After the mixture had been stirred for 1 hr at room temperature, excess of lithium aluminium hydride was destroyed with dilute sulphuric acid. The ether layer was separated, the aqueous layer extracted with ether, and the combined ether solutions were dried over anhydrous sodium sulphate. The ether was removed by distillation and the residue subjected to glpc analysis.

Gas-Liquid Partition Chromatography. A Perkin-Elmer model 154D instrument was utilized. The product mixture from cyclohexene was examined using a Carbowax column 1 m long (steel tube) at 111 °C. The products from 1-methylcyclohexene was analysed using a diisodecyl phthalate column 0.5 m long (glass tube) at 103 °C or a Carbowax column 0.5 m long (glass tube) at 99.5 °C.

Preparation and Characterization of Authentic Samples. cis-*2-Bromocyclohexanol*: To 35 g (0.20 mol) of 2-bromocyclohexanone[12] in 50 ml of methanol was added portionwise 6 g (0.16 mol) of sodium borohydride with stirring. Stirring was continued for an additional 20 min. Dilute aqueous solution of acetic acid was added, the organic layer separated, and the aqueous layer extracted with ether. The combined organic layer and extracts were dried over anhydrous sodium sulphate, and then distilled to give 11 g of colourless liquid, bp 50 °C/1 mmHg, which crystallized in a refrigerator. Glpc analysis showed that it consisted of 90% of *cis*-2-bromocyclohexanol and 10% of the *trans* isomer. Two recrystallizations from petroleum ether gave a pure specimen of the *cis*-isomer in needles, mp 28.5—29.0 °C (lit,[13] mp 29.0—29.5 °C), ν_{max} (liquid film) 3450 cm^{-1} (OH); *p*-toluenesulphonate, mp 77—78 °C (lit,[14] mp 79—80 °C) (Found: C, 47.13; H, 5.35%. Calcd for $C_{13}H_{17}BrO_3S$: C, 46.85; H, 5.14%). The Meerwein-Ponndorff reduction of 2-bromocyclohexanone[13] afforded a mixture of *cis*- and *trans*-2-bromocyclohexanol in a ratio of about 1 : 2.

trans-*2-Bromocyclohexanol*: This compound was obtained according to the procedure of Guss and Rosenthal[15] by the reaction of cyclohexene with *N*-bromosuccinimide in water, bp 87—87.5 °C/10 mmHg, mp 26.5—27 °C (lit, bp 90—91 °C/13 mmHg,[16] mp 27.5 °C[17]), ν_{max} (liquid film) 3400 cm^{-1} (OH); *p*-toluenesulphonate, mp 42—42.5 °C (lit,[14] mp 44—45 °C).

c-*2-Bromo-1-methyl*-r-*1-cyclohexanol*: This compound was prepared according to the method of Bartlett and Rosenwald[9] by the reaction of 2-bromocyclohexanone with methylmagnesium iodide, bp 51—52.5 °C/2 mmHg, n_D^{27} 1.5057 (lit,[9] bp 83 °C/7 mmHg, n_D^{27} 1.5032), ν_{max} (liquid film) 3500 cm^{-1} (OH) (Found: Br, 40.3%. Cald for $C_7H_{13}BrO$: Br, 41.4%). Glpc analysis showed that this material contained trace amount of the *trans* isomer.

t-*2-Bromo-1-methyl*-r-*1-cyclohexanol*: This compound was synthesized according to the directions of Filler *et al.*[18] by the reaction of 1-methylcyclohexene with *N*-bromosuccinimide in water, bp 70.8—72.9 °C/3 mmHg, n_D^{25} 1.5150 (lit,[18] bp 96—98 °C/8.5 mmHg, n_D^{25} 1.5150), ν_{max} (liquid film) 3450 cm^{-1} (OH) (Found: Br, 41.4. Calcd for $C_7H_{13}BrO$: Br, 41.4%).

The Stereochemistry of Autoxidation of 2-Bromo-1-methylcyclohexane

Shingo MIYAJIMA* and Osamu SIMAMURA**

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received August 30, 1974)

Autoxidation of *cis*-2-bromo-1-methylcyclohexane and subsequent reduction of the resulting hydroperoxide with lithium aluminium hydride gave only *t*-2-bromo-1-methyl-*r*-1-cyclohexanol to the exclusion of the *c*-2-bromo-isomer. The reactivity ratio of the C–1 hydrogen in *cis*-2-bromo-1-methylcyclohexane to that in 1, *c*-3, *c*-5-trimethylcyclohexane towards abstraction was estimated to be about 4 by competitive oxidation experiments. An explanation for the acceleration of hydrogen abstraction and the stereospecific oxygen attack on the intermediate radical is given in terms of a bromine bridged radical. Autoxidation of a sample of 2-bromo-1-methylcyclohexane, containing about 90% of the *trans* isomer, took place very slowly as compared with the *cis* isomer.

In previous papers,[1,2] it was shown that oxygen attacks the bromocyclohexyl radicals generated by addition of a bromine atom to cyclohexene and 1-methylcyclohexene exclusively from the *trans* direction to the bromine atom, while an almost random attack of oxygen occurs on both sides of the methylcyclohexyl radicals formed by hydrogen abstraction from a variety of methylcyclohexanes. This paper is concerned with the autoxidation of 2-bromo-1-methylcyclohexane carried out in order to examine the effect of the neighbouring bromine substituent on the reactivity of the hydrogen at position 1 towards abstraction as well as the stereochemical course of oxygen attack on the intermediate radical.

Results and Discussion

cis-2-Bromo-1-methylcyclohexane (**1**) was prepared by radical addition of hydrogen bromide to 1-methylcyclohexene in heptane followed by partial hydrolysis and fractionation for separation from 1-bromo-1-methylcyclohexane, a by-product. The NMR spectrum indicated that the product obtained was free of the *trans* isomer (**2**), as evidenced by the absence of the signal (doublets of a triplet) centered at δ 3.61 due to a Br–C–H proton in the *trans* isomer.[3]

The *cis* bromide (**1**) was autoxidized with oxygen in the presence of azobisisobutyronitrile at 60 °C, and the resulting hydroperoxide was reduced with lithium aluminium hydride to the corresponding alcohol. Gas-liquid partition chromatographic analysis showed that *t*-2-bromo-1-methyl-*r*-1-cyclohexanol (**3**) was the sole detectable alcohol, the retention time agreeing with that of an authentic specimen on each of three different columns (diisodecyl phthalate, polyethylene glycol, and cyanosilicone). The *cis* isomer could not be detected. The results are summarized in Table 1.

In order to estimate the relative rate of abstraction of the C-1 hydrogen in *cis*-2-bromo-1-methylcyclohexane (**1**), competitive oxidation experiments with 1, *c*-3, *c*-5-trimethylcyclohexane (**4**) were performed. The results are shown in Table 2. Treatment of these data with the same method as described previously[1] gave a reactivity ratio of the C-1 hydrogen in bromomethyl-

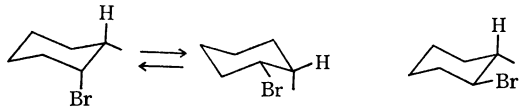
a) Ref. 1.



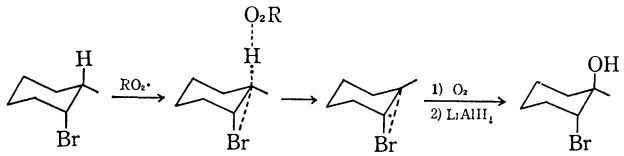
1a **1e** **2**

Fig. 1. Conformation of 2-bromo-1-methylcyclohexanes.

cyclohexane **1** to that in trimethylcyclohexane **4** towards abstraction of about 4 (Table 3), a considerably large value compared with that for an axial hydrogen atom in the ordinary situation.

Although the *cis* bromide (**1**) is not conformationally uniform, conformer **1a** should predominate largely over **1e** (Fig. 1), since the conformational equilibrium constant of **1**, the *gauche* interactions between the methyl and bromine substituent cancelling out for the pair of conformers, is considered to be almost equal to 0.1 for *cis*-4-bromo-1-methylcyclohexane.[4)] The large reactivity of the C-1 hydrogen in the *cis* bromide (**1**) may be in part due to steric acceleration caused by relief, in the transition state, of a *gauche* interaction between the C-1 methyl group and the C-2 bromine in conformer **1a**. However, the contribution of this effect would be of minor importance, since the observed reactivity ratio of 4 corresponds to a difference of 0.9 kcal/mol in free energy of activation, while the *gauche* interaction between a methyl group and a bromine atom is only 0.25 kcal/mol.[5)] The contribution of conformer **1e** would also be insignificant; the equatorial C-1 hydrogen in **1e** would be hindered by the C-2 equatorial bromine substituent, whereas there is no such hindrance suffered by the hydrogen at C-5 in 1, *c*-3,*t*-5-trimethylcyclohexane (**5**). Moreover, the abstraction of the C-1 hydrogen in **1e** would be less favoured than that at C-5 in **5** because of the incipient eclipsing of the methyl and bromine substituent, as the methyl tends to be planar with the other two bonds at carbon atom 1 in the course of abstraction. Even if the relative reactivity of the equatorial hydrogen in **1e** should be equal to 2.6 for compound **5**, the contribution of **1e** to the relative reactivity is only 0.26, since the conformational population of **1e** is estimated to be about 10%.

The relative reactivity of 4 found for *cis*-2-bromo-1-methylcyclohexane (**1**) is thus attributed mainly to the hydrogen in axial position at carbon atom 1, and apparently the value is higher than that expected for a hydrogen in similar steric environments. A special effect causing such an acceleration must be due to the bromine substituent at position 2, although the halogen substituent is known to retard the hydrogen abstraction



1 **3**

Fig. 2. Autoxidation of *cis*-2-bromo-1-methylcyclohexane.

reaction because of electron-attracting inductive effect.[6)] A possible explanation of both the acceleration of hydrogen abstraction and the stereospecific oxygen attack in *cis* bromo-compound **1** may be that the axial bromine substituent anchimerically delocalizes an incipient odd electron in the transition state of hydrogen abstraction and then forms a bridged intermediate radical[7)] (Fig. 2).

Although a mixture of *cis*- and *trans*-2-bromo-1-methylcyclohexane (**1** and **2**) was obtained in a ratio of about 10 : 90 by the Hunsdiecker reaction of silver 2-methylcyclohexanecarboxylate,[3)] attempts to isolate the pure *trans* isomer from this mixture were unsuccessful. Autoxidation of a sample of the mixture took place very slowly, as shown in Table 1. From comparison of the amount of hydroperoxide formed from this mixture with that from the pure *cis* isomer, the approximate reactivity ratio of the C-1 hydrogen in *trans*-2-bromo-1-methylcyclohexane (**2**) to that in trimethylcyclohexane **4** towards abstraction was estimated to be about 0.4. The observed retardation may be ascribed to inductive effect of a bromine substituent and/or a sterically unfavourable transition state with the methyl group and bromine substituent tending to eclipse each other.

Experimental

All melting points and boiling points are uncorrected. Glpc work was carried out with a Perkin-Elmer model 154 D instrument. NMR data were obtained with a Varian A-60 spectrometer using tetramethylsilane as an internal standard. IR spectra were recorded on a Nihon-Bunko DS-402 G spectrometer.

*cis-2-Bromo-1-methylcyclohexane (**1**).* Hydrogen bromide, dried by passing through a trap cooled at −50 °C and a tube packed with anhydrous calcium sulphate, was bubbled through a solution of 80 ml (64.8 g) of 1-methylcyclohexene and 8.2 g of benzoyl peroxide in 600 ml of heptane for 4 hr at 65—75 °C with stirring. After removal of excess of hydrogen bromide with solid sodium hydrogencarbonate, the solution was filtered and the solvent removed from the filtrate under reduced pressure. Distillation of the residual material in vacuum furnished 77 g of a crude addition product, bp 35—38 °C/3 mmHg. To this material was added 500 ml of water and the mixture stirred for 24 hr at room temperature. The organic layer was separated, mixed with 1 l of a 4 : 1 acetone-water mixture, and allowed to stand for 48 hr at room temperature to hydrolyse accompanying 1-bromo-1-methylcyclohexane. Hygrogen bromide liberated amounted to 8.2 mol% based on the starting addition product. After dilution with water, the organic layer was separated and dried over anhydrous magnesium sulphate. A portion (25 g) of this material (66 g) was fractionally distilled through a

spinning band column to yield 19 g of the *cis* bromide (**1**), bp 68 °C/19 mmHg, n_D^{30} 1.4888 (Found: C, 47.53; H, 7.69; Br, 45.17%. Calcd for $C_7H_{13}Br$: C, 47.48; H, 7.40; Br, 45.12%), ν_{max} 656 cm^{-1} (axial C–Br).[8] The NMR spectrum indicated three methyl protons at δ 0.99 (d; J, 5 Hz), a Br–C–H proton at 4.40 (unresolved multiplet), and ring protons at 0.8—2.3 (a complex series of peaks).

A Mixture of cis- *and* trans-*2-Bromo-1-methylcyclohexane.* Methyl *trans*-2-methyl-4-cyclohexene-1-carboxylate[9] (70 g) was hydrogenated with hydrogen at 1 atm on 9 g of 5% palladium-charcoal catalyst in 300 ml of methanol at room temperature. The resulting saturated ester was hydrolysed by boiling with 10% aqueous sodium hydroxide solution, and acidification of the reaction mixture gave 56 g of *trans*-2-methylcyclohexanecarboxylic acid, mp 53—54 °C (lit,[10] mp 51—52 °C). The acid (50 g) was dissolved in a solution of 15.5 g of sodium hydroxide in 160 ml of water. Nitric acid was added dropwise until turbidity appeared; then a solution of 59.7 g of silver nitrate in 96 ml of water was added. The precipitated silver salt was collected on a filter, washed with water and ethanol, air-dried, and then dried over phosphorus pentoxide in a vacuum desiccator. The silver salt (64 g) was treated with bromine (41 g) in carbon tetrachloride (420 ml) according to the directions of Marvel and Sexton.[3] After working up the reaction mixture, fractionation with a spinning band column gave 12.1 g of a middle fraction, bp 62.5 °C/18 mmHg −61.5 °C/15.5 mmHg, ν_{max} 681 cm^{-1} (equatorial C–Br).[8] The NMR spectrum showed an unresolved multiplet at δ 4.40 due to the presence of the *cis* isomer, a sextet (doublets of a triplet; J, 4.5 and 10 Hz) at 3.61 due to the *trans* isomer, a doublet (J, 6 Hz) at 1.11, and a complex series of peaks at 0.8—2.6. The ratio of *cis*-(**1**) to *trans*-2-bromo-1-methylcyclohexane (**2**) was estimated to be 10 : 90 by comparing the areas of the peaks at δ 4.40 and 3.61.

Autoxidation and Reduction of the Oxidates. The experimental procedures for autoxidation have been described previously.[1] After a portion of the oxidate had been titrated iodometrically for hydroperoxide,[11] the rest was dissolved in dry ether and added to a suspension of lithium aluminium hydride (2—3 times the theoretical amount) in dry ether. The mixture was stirred for 30 min at room temperature, and excess of lithium aluminium hydride destroyed with dilute sulphuric acid. The ether layer was separated, washed with water, and dried over anhydrous sodium sulphate. The ether was removed and the residue analysed by glpc.

Product Analysis. The preparations of authentic samples of *c*-2- and *t*-2-bromo-1-methyl-*r*-1-cyclohexanol have been described previously.[2] Qualitative analyses by glpc were carried out using either a diisodecyl phthalate column 0.5 m long at 100 °C, a Carbowax column 1 m long at 111.5 °C, or a cyanosilicone column 1 m long at 112.5 °C. For quantitative analyses a Carbowax column 1 m long was used at 100 °C for 1,3,5-trimethylcyclohexanols and at 112 °C for *t*-2-bromo-1-methyl-*r*-1-cyclohexanol. In gas-liquid partition chromatography of the present bromine containing compounds the use of glass columns was necessary for reliable analyses.

Structural Studies of Tryptophan Metabolites by X-ray Diffraction Method. III. The Crystal and Molecular Structure of 5-Methoxyindole-3-acetic Acid

Toshimasa SAKAKI, Akio WAKAHARA, Takaji FUJIWARA, and Ken-ichi TOMITA
Faculty of Pharmaceutical Sciences, Osaka University, Toneyama, Toyonaka, Osaka 560
(Received September, 7, 1974)

The crystal structure of 5-methoxyindole-3-acetic acid (5-MIAA) has been solved by application of the direct method with symbolic addition procedure. 5-MIAA, colorless transparent prism, is monoclinic, space group C2/c, with lattice parameters: $a=34.461(9)$ Å, $b=6.150(5)$ Å, $c=9.480(5)$ Å, $\beta=96.14(2)$ °, $Z=8$. The molecules are hydrogen-bonded into dimers related by the center of symmetry, which are held together in an infinite double-layered sheet structure perpendicular to the *a*-axis with N–H···O hydrogen bond between indole nitrogen and carboxyl oxygen atoms. The methyl groups of adjacent molecules contact to each other by van der Waals forces. The conformation of the side-chain is quite distinguishable from that of indole-3-acetic acid. The dihedral angle between carboxyl and indole planes is 59.5 ° in this molecule, whereas that is 90.0 ° in indole-3-acetic acid, and the carboxyl group sticks out to be perpendicular to the indole plane.

5-MIAA, one of the final products in a metabolic pathway of tryptophan, is excreted into urine, through 5-hydroxyindole-3-acetaldehyde, *etc.*[1] As a series of structural investigation of tryptophan metabolites,[2–4] the authors describe here the crystal and molecular structure of 5-MIAA in order to obtain the substantial information about the stereospecific conformation of individual metabolites suitable for performing the related enzyme action in living cells.

Experimental

The sample was purchased from the Sigma Co., and preliminary oscillation and Weissenberg photographs using the suitable crystal showed it to be monoclinic with space group as Cc or C2/c from systematic absent spectra, (hkl) with $h+k=2n+1$ and $(h0l)$ with $l=2n+1$. The space group was determined finally as C2/c from the statistical distribution of normalized structure factors (E).[5] The unit cell dimensions were determined with the Rigaku Denki automatic four circle diffractometer at room temperature. The density was measured by the floatation method in a benzene-carbon tetrachloride mixture. The crystallographic data are shown in Table 1. Intensities of 951 independent reflections having the number of counts over three times of standard deviation were measured with the diffractometer using Ni-filtered Cu–$K\alpha$ radiation, by means of $\omega/2\theta$ scan technique (crystal dimension: $0.10\times0.10\times0.35$ mm), and adjusted to the absolute scale by the program for Wilson's statistics. A $\sum_2$ list was then computed using 270 reflections with the normalized structure factors E, greater than 1.2.

22	2	−4	c	3.465

Determination and Refinement of Structure

Phases for the reflections were determined by means of the symbolic addition procedure. To specify the origin for nonprimitive space group C2/c, two reflections with large E-values were chosen to have positive sign.[6] The signs of other reflections having many $\sum_2$ interactions were specified by symbols a, b and c, respectively. This starting set is summarized in Table 2. By hand calculation, the phases of additional 219 reflections were determined in terms of the starting sign and symbols. Of the three-dimensional E maps calculated with possible two combinations (a=b=+, c=− and a=b=−, c=+), the former one revealed reasonable positive peaks which correspond to all non-hydrogen atoms. These positional parameters were refined by successive Fourier syntheses and block-diagonal least-squares method, first with the isotropic thermal parameters for all the non-hydrogen atoms, and then with the anisotropic temperature factors. At this stage, R-value was dropped to 0.120, and the difference Fourier synthesis was computed in order to find the position of eleven hydrogen atoms. (see Fig. 1). The

final refinement by block-diagonal least-squares method was carried out with anisotropic temperature factors for all non-hydrogen atoms and with isotropic temperature factors for all hydrogen atoms to reduce R-value to 0.078. The electron density map is illustrated in Fig. 2. The observed and calculated structure factors obtained by the last cycle of refinement are given in Table 3, and the atomic coordinates and thermal parameters with their estimated standard deviations in Table 4. In the structure factor calculation of 5-MIAA, the atomic scattering factors cited in "*International Tables for X-ray Crystallography*" (1962)[7] were used, and all the numerical calculations were carried out on an NEAC-2200-700 computer of computation center of this University, using the UNICS programs.

Description and Discussion of the Structure

The final bond lengths and angles are shown in Fig. 3, where the average standard deviations for non-hydrogen atoms are about 0.009 to 0.011 Å and 0.6 to 0.7°, respectively. The deviation from a regular trigonal angle of C(2)–C(3)–C(10) is about 11°, which is also observed in serotonin creatinine sulfate (about 6°)[5] and melatonin (about 5°).[2] This may be explained by the fact that the *cis*-orientation of C(3)–C(10) bond with respect to C(1)–C(2) bond around C(2)–C(3) bond causes bond angle C(2)–C(3)–C(10) to be larger by the repulsion between C(10) and C(1). The angle of O(3)–C(6)–C(5) is also about 11° larger than that of O(3)–C(6)–C(7), as well as melatonin (9°)[2] or 5-methoxy-*N*,*N*-dimethyltryptamine HCl (10°).[8] This may be also explainable by similar reason described above, provided the special orientation of methoxy group around C(5)–C(6) bond is effective. The planarity of the two parts of the molecule, indole ring and carboxyl group, was examined by the equation of the least-squares plane.

Equation for indole ring;

$$0.39119X - 0.54044Y + 0.74491Z = 4.74731.$$

Equation for carboxyl group and α-carbon atom;

$$0.31420X + 0.44497Y + 0.83862Z = 6.83928.$$

The deviations of the individual atoms from the best planes are given in Table 5. The H(1) atom lies almost on the plane through four atoms, C(1), O(1), O(2) and α-carbon C(2), whereas C(2) and O(3) are on the plane through indole ring, except C(11) atom which is slightly deviated. It is of interest to compare the molecular conformation of this compound with that of indole-3-acetic acid (IAA).[9] Relevant torsion angles[10] of IAA and 5-MIAA are given in Table 6 in order to elucidate the difference of conformation. The torsion angle C(10)–C(3)–C(2)–C(1) is in the region of anti-clinal in IAA, but syn-periplanar in 5-MIAA. (see Figure 4). The dihedral angle between the two

planes, one through carboxyl group and the other through indole ring, is 59.5° in 5-MIAA, while that is 90.0° in IAA. These facts may reflect that IAA and 5-MIAA are the final products of tryptophan metabolites in different metabolic pathways.[1,11] The molecular arrangements in crystals viewed along b- and c-axes are shown in Figs. 5 and 6. Between the two adjacent molecules related by the center of symmetry, a dimer was formed at carboxyl end with O–H···O hydrogen bond. This dimer was also connected by hydrogen bond N–H(5)··· O(2) around diad axis to make the infinite sheet elongated toward b- and c-axes. The methyl groups have very short contact to each other around the screw diad axis. (3.596 Å) In crystals, the polar part of the molecules is held together by hydrogen bond and the nonpolar part, by van der Waals forces. Therefore, it seems that the molecules are arranged into a double layered sheet structure perpendicular to a-axis with N–H···O hydrogen bonds between indole nitrogen and carboxyl oxygen atoms.

Micellar and Metal Ion Catalysis in the Pyridoxal-Promoted α,β-Elimination of *S*-Phenylcysteine*

Yukito MURAKAMI and Hiroki KONDO

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received September 26, 1974)

The effects of metal ions and detergents on the pyridoxal-catalyzed α,β-elimination reaction of *S*-phenylcysteine have been investigated in 0.01 M borate buffer at 50 °C (the copper ion catalysis at 40 °C in the presence of CTAB micelles). Both copper(II) and nickel(II) ions markedly accelerated the elimination reaction of *S*-phenylcysteine. Since the catalytic efficiency of nickel(II) seems to be obtained due to the poor coordination ability of the leaving group in the present reaction, the previous working hypothesis which was provided for the elucidation of catalytic roles of metal ions in the α,β-elimination of *O*-phosphothreonine has now been approved. Among cationic, anionic, and non-ionic detergents employed in this work as apoenzyme models, only CTAB of cationic nature showed a considerable rate acceleration even in the absence of metal ions. The micellar binding constant was evaluated from the saturation-type correlation between reaction rate and CTAB concentration. The surfactant micelles demonstrated some enzyme-like features of catalysis in the pyridoxal-promoted α,β-elimination reaction, where the reaction is controlled by the entropy term. The CTAB catalysis was greatly inhibited by organic and inorganic anions due to the electrostatic nature of the micellar surface. The catalytic mechanisms for the micellar reactions and their significance as an enzyme model system are discussed.

Although the apoenzyme moieties of pyridoxal-dependent enzymes have not been fully characterized up to the present time, their specific roles may be counted tentatively as follows: (1) they provide the hydrophobic binding site inside the enzymes where pyridoxal phosphate is buried in its vicinity as the coenzyme function, and then (2) catalyze the specified reactions by their various functional groups such as the imidazole group of histidine residue and the ε-amino group of lysine. In our previous work, the catalytic effect of some organic bases of different base-strength was examined in the pyridoxal-catalyzed α,β-elimination reaction of *S*-(*p*-substituted phenyl)cysteines in connection with the catalytic nature of base moieties which are planted in an apoenzyme skeleton.[1] Our special concern has also been placed on the correlation between hydrophobic medium effect and reaction kinetics in these reactions by adopting acetonitrile-water mixed solvent system.[1]

In spite of the substrate and reaction specificity as well as the acceleration effect due to the vitamin B_6 apoenzymes, only a limited information has been obtained on their catalytic and structural nature. Micellar surfactants have often been granted to behave as an enzyme or apoenzyme model as reviewed by several workers.[2,3] In the present study, we have investigated the effects of these detergents as an apoenzyme model for the pyridoxal-catalyzed α,β-elimination reaction of *S*-phenylcysteine. As for the catalytic roles of metal ions in the elimination, *S*-phenylcysteine would render the metal ion effects different from those for *O*-phosphothreonine.[4] A metal ion of strong hexa-coordination tendency has been suggested to bind the leaving phosphate group in the Schiff base derived from pyridoxal and the latter amino acid, thus inactivating the amino acid toward elimination reaction. On the contrary, such a metal ion would not demonstrate any significant coordination ability toward thioether-sulfur in the present amino acid. We have studied from these viewpoints the effects of copper(II) and nickel(II) ions on the pyridoxal-catalyzed α,β-elimination of *S*-phenylcysteine.

* Contribution No. 348 from the Department of Organic Synthesis, Faculty of Engineering, Kyushu University.

Experimental

Materials. *S*-Phenylcysteine was prepared by the reaction of thiophenol with α-acetoamidoacrylic acid and the subsequent acid hydrolysis.[5] Pyridoxal hydrochloride was obtained from Mann Research Laboratories, Inc., New York, U.S.A. Cetyltrimethylammonium bromide (CTAB, Katayama Chemical Co.), sodium lauryl sulfate (NaLS, Eastman Kodak Co.), and polyoxyethylene(23) dodecanol (Brij 35, Nakarai Chemical Co.) were obtained from commercial sources.

Kinetic Measurements. For the micellar catalysis, the reaction was carried out in 0.01 M borate buffer (pH 9.0) at 50.0±0.1 °C without inorganic salt as being a supporting electrolyte. Fifty ml of a reaction mixture containing specified amounts of substrate, detergent, and borate buffer was placed in a jacketed reaction vessel. When the constant temperature was attained, 5 ml of the pyridoxal solution was added. The initial concentrations of *S*-phenylcysteine and pyridoxal were 7.31×10^{-4} and 9.09×10^{-4} M, respectively and the detergent concentration was varied. Aliquot samples were withdrawn from the reaction mixture at appropriate time intervals after the thermal equilibrium was attained (5 min after the pyridoxal solution was added). The reaction rate was determined by measuring the yielded pyruvate as its 2,4-dinitrophenylhydrazone. The analytical procedures were essentially the same as those described previously,[1] but with slight modifications. In the presence of detergents the 2,4-dinitrophenylhydrazone of pyridoxal did not precipitate and the extraction of an excess hydrazine from the resulting filtrate with toluene was not possible due to foam formation. In order to overcome these difficulties 5 ml of acetonitrile was added to the sample solution before treating it with the potassium phosphate—sodium hydroxide buffer to allow the precipitation of pyridoxal hydrazone. Secondly, the extraction of an excess hydrazine with toluene was omitted since this modification did not cause any serious analytical error.

For the metal ion catalysis, the reaction was carried out in borate buffer at either 40 or 50 °C with or without 0.91×10^{-4} M CTAB. The reaction was started by the addition of 5 ml of cupric nitrate or nickel nitrate solution prewarmed to the reaction temperature to 50 ml of a metal-free reaction mixture. The initial concentrations of substrate, pyridoxal, and borate buffer were the same as those for the micellar catalysis, and the initial metal ion concentration was adjusted at either 1.81×10^{-4} or 4.54×10^{-4} M. The reaction rate was measured by the above-mentioned procedures.

Results

Effects of Micellar Surfactants. The kinetic runs for the pyridoxal-catalyzed α,β-elimination reaction were carried out at 50 °C in 0.01 M borate buffer in the presence of three kinds of detergents, cetyltrimethylammonium bromide (CTAB), sodium lauryl sulfate (NaLS), and polyoxyethylene(23) dodecanol (Brij 35). Each reaction rate followed apparent first-order kinetics with respect to the total concentration of unreacted substrate. While the anionic and non-ionic micelles showed little catalytic effect or rather retarding, the cationic micelle promoted the elimination rate (Table 1). The correlation between the apparent first-order rate constant and the CTAB concentration is illustrated in Fig. 1. The rate is markedly accelerated above 1×10^{-3} M CTAB, and tends to level off beyond approximately 3×10^{-3} M of the detergent concentration. The rate acceleration at this saturation level is about 18-fold of the rate without the cationic detergent. On the other hand, CTAB did not show any significant catalytic effect in the absence of pyridoxal under the similar conditions.

The micellar catalysis by CTAB was effectively inhibited by inorganic and organic salts as shown in Table 2. Potassium nitrate is the more effective inhibitor than potassium chloride in a manner as observed for the solvolysis reactions of carboxylic esters,[6] while both of the organic salts, sodium benzoate and sodium benzenesulfonate, demonstrated the larger inhibition effect than the inorganic salts.

Activation parameters for the micellar reaction are listed in Table 3 together with those for the reaction without detergent. The micellar reaction becomes enthalpically unfavorable, and the catalysis is apparently controlled by the entropy term.

0	12.5	−41	25.7

a) Initial concentrations: substrate, 7.31×10^{-4} M; pyridoxal, 9.09×10^{-4} M.

Effects of Metal Ions. When the copper(II) and nickel(II) solutions were added to the reaction mixture containing substrate, pyridoxal, and borate buffer, precipitates were formed. The reduction of metal ion concentration and/or the increase in the acidity of the medium did not improve the situation. Thus, the reaction was carried out in a heterogeneous system.

The reaction followed a fairly good apparent first-order kinetics up to 70% conversion of the substrate in the presence of nickel(II); the initial concentration of the metal ion is 4.54×10^{-4} M. The rate constant of 2.84×10^{-4} s^{-1} corresponds to the 20.6-fold acceleration relative to the non-metallic system. On the other hand, any detectable amount of pyruvate was not liberated in about 30 min of the reaction time upon addition of copper(II); the initial concentration of the metal ion is 4.54×10^{-4} M. This apparently means that copper(II) inhibited the α,β-elimination of S-phenylcysteine completely through the complex formation. The precipitates were recovered for IR measurements (Fig. 2). The precipitates formed in the reaction of these metal ions with the substrate in the absence of pyridoxal were also subjected to IR measurements (Fig. 2). A broad band at 2800 cm^{-1} due to the ammonium group of S-phenylcysteine disappeared in the spectra of these metal complexes. The 1640 cm^{-1} band attributable to the carbonyl stretching mode shifted to the lower frequency region upon coordination. From these evidences the precipitates formed during the reaction can be identified as bis(S-phenylcysteinato)copper(II) and bis(S-phenylcysteinato)nickel(II).

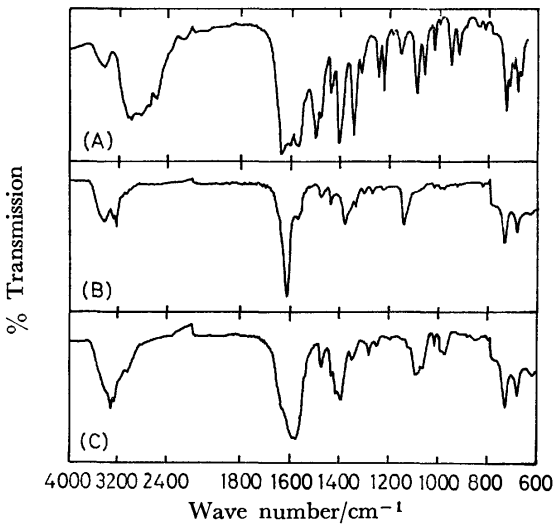

Fig. 2. Infrared spectra (KBr disc method): (A), S-phenylcysteine; (B), the copper(II) complex of S-phenylcysteine; (C), the nickel(II) complex of S-phenylcysteine. S-phenylcysteine underwent reaction with the metal ions in the absence of pyridoxal at the same respective concentrations as employed for the kinetic runs. The precipitates obtained by raising pH up to 9.0 with sodium hydroxide were used for IR measurements. The respective precipitates recovered from the reaction mixtures for kinetic runs gave the completely identical spectra.

The addition of CTAB prevented the precipitation of the metal complexes and consequently the reaction was carried out in a homogeneous system. But the situation is rather complicated in this system (0.91×10^{-3} M CTAB present) as follows. At the outset of the reaction the "burst" of pyruvate formation was detected, followed by the rate deceleration. The overall reaction, therefore, did not follow the first-order kinetics. The rate constants estimated from the initial "burst" part (~2 min period after the addition of metal ions), where the true thermal equilibrium was not still attained, are listed in Table 4. This table also gives the rate data for the reaction period following the "burst" part (a 2—10 min period after the metal addition). The reaction rate was so fast at 50 °C in the presence of copper(II) that the reaction temperature needs to be lowered to 40 °C and the metal concentration to two-fifths of the nickel(II) ion. The rate constants obtained for the "burst" part are greater by one order than those for the following period. Approximately a 60% portion of the substrate has been converted to the products in the "burst" part under these experimental conditions.

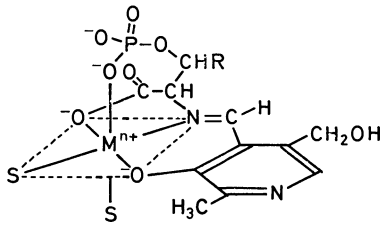
Discussion

Metal Ion Catalysis. In our previous investigations on the pyridoxal-catalyzed α,β-elimination of O-phosphothreonine,[4] the examined six metal ions were classified into two categories from the catalytic aspect: the active group includes copper(II) and vanadyl(IV) while the inactive group consists of nickel(II), iron(III), aluminum(III), and thorium(IV). We pointed out that the differences in catalytic activity of metal ions could not be explained merely in terms of the thermodynamic stability of the metal complexes. But the structural feature of these metal complexes was suggested to be responsible for the catalytic activity. The axial coordination site is available for metal ions of the latter category to bind the leaving phosphate group as shown by **1**. The lack of catalysis by these metal ions was thus attributed to this coordination effect. Taking for example nickel(II) ion of the latter category, this metal ion does not demonstrate any significant coordination ability toward the thioether group as investigated for S-methylcysteine and methionine.[7] The leaving group of S-phenylcysteine, therefore, must be free from coordination with nickel(II) ion. Consequently, nickel ion can be

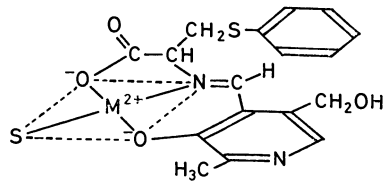
Table 4. Metal ion catalysis in the pyridoxal-promoted α,β-elimination reaction of S-phenylcysteine in the presence of 0.91×10^{-3} M CTAB

Metal ion	concentration, M	Temp. °C	After "burst" part		Initial "burst" part	
			k_{obs}, s^{-1}	k_{rel}[a]	k_{obs}, s^{-1}	k_{rel}[a]
Ni^{2+}	4.54×10^{-4}	50	5.7×10^{-4}	4.1	3×10^{-3}	21
Cu^{2+}	1.82×10^{-4}	40	5.7×10^{-4}	9.5	5×10^{-3}	83

a) Relative to the corresponding rate constant in the absence of metal ions: $k_{obs}(Ni^{2+})$, 1.40×10^{-4} s^{-1}; $k_{obs}(Cu^{2+})$, 6.00×10^{-6} s^{-1}.



1 S : solvent



2 M^{2+} : Cu^{2+}, Ni^{2+}

expected to exert an effective catalytic activity in the present elimination reaction through formation of a metal complex as shown by **2**. In fact, a profound rate acceleration was observed in the presence of nickel(II) under the present experimental conditions, even though a minor part of the substrate and metal ion was out of the reaction mixture due to the complex formation. The apparent complete inertness of copper(II) is undoubtedly attributed to the high thermodynamic stability of bis(*S*-phenylcysteinato)copper(II) which resulted in precipitation in the aqueous system. These behaviors of metal ions are consistent with the reaction sequence given in Scheme 1.

When the reaction was carried out in a homogeneous micellar system, the rate acceleration at the "burst" part reaches nearly a hundred-fold in the copper(II) catalysis (Table 4). In our previous work,[4] the copper(II) catalysis in the α,β-elimination of *O*-phosphothreonine was so enormous that the reaction proceeded smoothly at 45 °C, although the reaction did not occur in the absence of the metal ion even at 80 °C. In conformity with the previous work, both nickel(II) and copper(II) form the corresponding metal complexes at a 1 : 1 ratio of metal to Schiff base ligand of structure **2** in the electrostatic layer of surfactant micelles as the preequilibrium stage. In addition, the metal complexes would be more favorably incorporated into the micellar phase than the metal-free Schiff base since the anionic character of the Schiff base ligand can be neutralized through metal-coordination. The rate-determining α,β-elimination then takes place by the attack of hydroxide ion which has been accumulated in the electrostatic layer due to the micellar effect. It is quite reasonable that copper(II) showed a larger catalytic activity than nickel(II) in homogeneous systems on the basis of the relative stability constants of their Schiff base complexes.[8]

In conclusion, it is interesting to note that copper and nickel did show the catalytic effect on the pyridoxal-catalyzed α,β-elimination reaction of *S*-phenylcysteine, although a part of the catalytic activity was exerted by the micellar effect.

Micellar Catalysis. Only the cationic detergent showed a considerable effect on the pyridoxal-catalyzed α,β-elimination of *S*-phenylcysteine. This micellar catalysis resulted in the 18-fold rate acceleration at the level-off region as shown in Fig. 1. Since the conventional micellar catalysis demonstrates rate enhancement in a 10- to 100-fold range, the present value can be referred to as the indication of moderate catalytic efficiency.[2,3]

One of the prominent features of the CTAB-catalyzed reaction is the saturation behavior of the reaction rate with respect to the detergent concentration as shown in Fig. 1. The rate-saturation is characteristic of the enzymic and related model reactions, and the following formula is consistent with the present scheme.

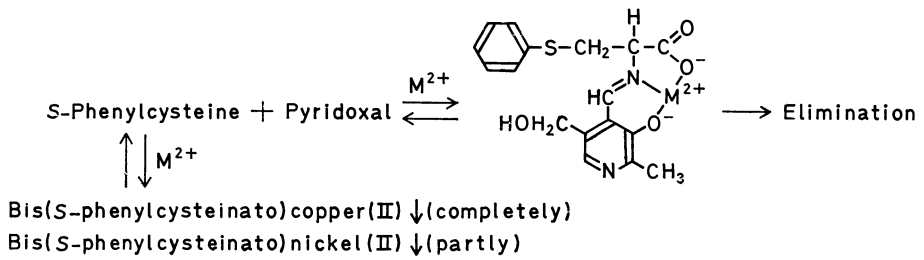
$$\begin{array}{l} S + M \overset{K}{\rightleftharpoons} SM \xrightarrow{k_m} P + M \\ \quad\downarrow k_0 \\ \quad P \end{array}$$

where S, M, and P respectively represent substrate (a Schiff base derived from *S*-phenylcysteine and pyridoxal), micelle, and product, and SM is the substrate-micelle complex. Upon defining C_D, N, and K as detergent concentration, aggregation number (assumed to be 61 in this case), and binding constant, respectively, the above scheme provides the correlation among observed (k_{obs}), spontaneous (k_0), and micellar (k_m) rate constants by Eq. (1).

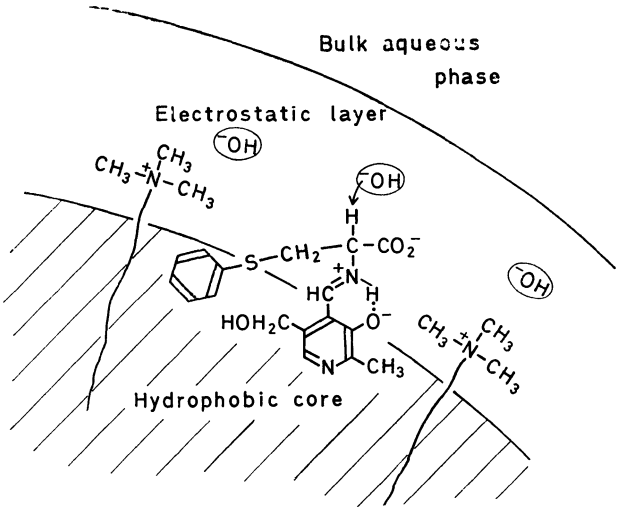
$$\frac{1}{k_{obs}-k_0} = \frac{1}{k_m-k_0} - \left(\frac{1}{k_m-k_0}\right)\left(\frac{N}{K(C_D-CMC)}\right) \quad (1)$$

An analysis of th present data (Fig. 1) gave fairly good linear relationship: $K \simeq 10^5$ and $CMC \simeq 5\times10^{-4}$ M.

A question arises as to the binding and reaction sites in the micellar phase. It has been shown that charged and polar organic compounds are bound to the electrostatic layer of micelle where the charged head groups of surfactant molecules are located, while apolar



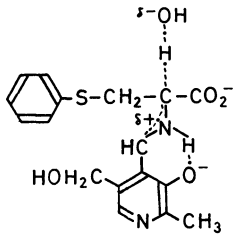
Scheme 1.



Scheme 2.

hydrocarbons are incorporated into the hydrophobic interior of the micelle.[9] Thus, a reactive Schiff base molecule of the present study is most likely incorporated into the micellar phase where the apolar pyridyl ring moiety is inserted into the hydrophobic core and the polar part composed of the Schiff base bond is located on the micellar surface (Stern and electric double layers). This state of affairs is schematically shown in Scheme 2.

Activation parameters obtained at the level of rate saturation for the micellar reaction of *S*-phenylcysteine are listed in Table 2. Although the increase in activation enthalpy has been observed by Bunton and Robinson for the micellar reaction of *p*-nitrophenyldiphenyl phosphate with hydroxide and fluoride ions,[10] it would seem rather unexpected. They ascribed the larger activation enthalpy for the micellar reaction to the high solubility of the neutral substrate in the micellar phase. In the present study, however, another explanation is needed for the high activation enthalpy since the Schiff base formed between *S*-phenylcysteine and pyridoxal possesses a much polar structure relative to the above neutral substrate. In conformity with the reaction scheme given for the non-micellar system,[1] the reaction center of the Schiff base may become less polar in the transition state **3** relative to the initial one. The electrostatic micellar surface in which the reactive center is incorporated destabilizes the transition state



3 (transition state)

and may consequently provide a larger activation enthalpy.

The hydroxide ion is presumably more concentrated on the micellar surface than in the bulk aqueous phase, and the included Schiff base may be readily subject to the attack of hydroxide ion. This state of affairs acts in favor of the activation entropy. As a whole, the CTAB micellar catalysis is exclusively controlled by the entropy term.

When inorganic salts are added to the micellar reaction system, hydroxide ion on the micellar surface is presumably substituted with the chloride or nitrate ion to some extent depending upon the relative concentrations of these salts. Since these inorganic anions are much poorer nucleophiles than the hydroxide ion, the substitution may result in the effective inhibition of the CTAB catalysis. The organic anions may exclude not only the hydroxide ion from the micellar surface but also the Schiff base by occupying the binding site around the charged head groups of surfactant molecules. Thus, these organic salts exerted an inhibition effect much greater than the inorganic salts.

In conclusion, the surfactant micelles demonstrated some enzyme-like features of catalysis in the pyridoxal-promoted α,β-elimination reaction of *S*-phenylcysteine, where the reaction is controlled by the entropy term. This seems to be the first effective organic catalyst ever provided for the pyridoxal-concerned reactions. The catalytic effectiveness is rather small at present relative to the enzyme system, but the modification of the detergent structure by introducing various functional groups into the skeleton will lead to the development of novel and eminent enzyme models of higher activity.

Phosphinidenes and Related Intermediates. III.[1] Reactions of Phosphinylidenes and Phosphinothioylidenes with Conjugated Dienes

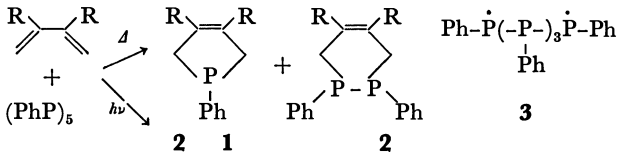
Shigenobu NAKAYAMA, Masaaki YOSHIFUJI, Renji OKAZAKI, and Naoki INAMOTO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received September 28, 1974)

Phenylphosphonic and phenylphosphonothioic dichlorides were dechlorinated with magnesium to generate phenylphosphinylidene and phenylphosphinothioylidene, respectively, in the presence of several 1,3-dienes. Reactions of phenylphosphinothioylidene with 2,3-dimethylbutadiene and 1,3-cyclohexadiene gave Diels-Alder type reaction products, that is, 3,6-dihydro-1,2-thiaphosphorin derivatives (**5** and **6**) and 6-phenyl-5,6-thiaphosphabicyclo[2.2.2]oct-2-ene 6-sulfide (**14**), respectively. Reaction of 2,3-diphenylbutadiene with phenylphosphinothioylidene afforded 1,2,4,5-tetraphenyl-1,2,3,6-tetrahydro-1,2-diphosphorin 1,2-disulfide (**10**), whereas that with phenylphosphinylidene gave 1,3,4-triphenyl-3-phospholene 1-oxide (**12**). The differences of these reactions have been discussed.

Schmidt and Boie[2] reported that thermal decomposition or photolysis of pentaphenylcyclopentaphosphine in the presence of 1,3-dienes gave cyclic compounds such as **1** and **2**, the formation of which can be interpreted by attack of phenylphosphinidene (Ph–P) or a diradical (**3**)[3] upon the 1,3-dienes.

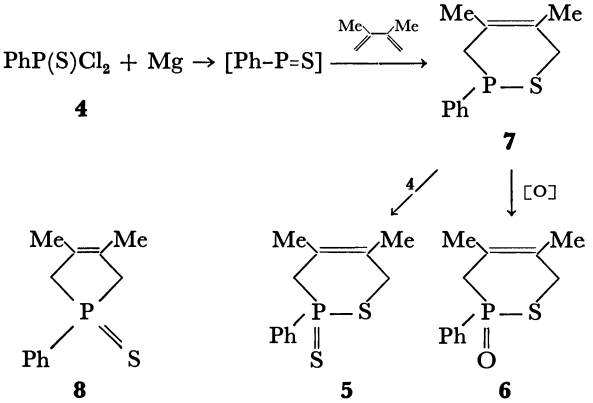


2 **1** **2** **3**

Thus, in the decomposition of the cyclopentaphosphine, phosphinidene is not necessarily the sole reactive intermediate. Furthermore, it is expected that phosphinylidenes (R–P=O) and phosphinothioylidenes (R–P=S) behave not only as analogues of nitrenes and phosphinidenes but also as those of nitroso[4] and thionitroso compounds.[5]

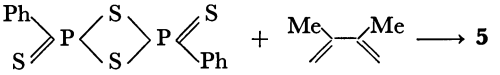
The present paper describes reactions of 1,3-dienes and the related compounds with phosphinylidenes or phosphinothioylidenes[6] generated from magnesium and phosphonic or phosphonothioic dichlorides, respectively.

When phenylphosphonothioic dichloride (**4**) was dechlorinated with magnesium in tetrahydrofuran (THF) in the presence of 2,3-dimethylbutadiene at 50 °C, 4,5-dimethyl-2-phenyl-3,6-dihydro-1,2-thiaphosphorin 2-sulfide (**5**) and the corresponding 2-oxide (**6**) were obtained in 44 and 21% yields, respectively,[7] but another expected product (**8**) could not be isolated.

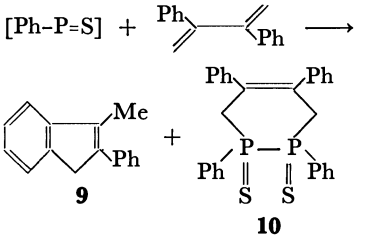


4 **7** **8** **5** **6**

The formation of **5** and **6** is attributable to sulfurization of **7** with **4** and oxidation of **7** during the isolation, respectively. Thus, it is clear that the intermediate (**7**) is formed *via* the Diels-Alder type reaction of the diene with phenylphosphinothioylidene as a 1,2-dipole like thionitroso compounds.[5] The same compound (**5**) has recently been obtained in the following reaction.[8]



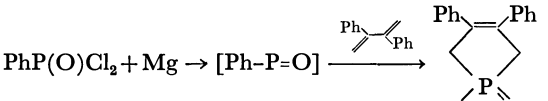
Reaction of **4** with 2,3-diphenylbutadiene and magnesium in THF gave 3-methyl-2-phenylindene (**9**) and 1,2,4,5-tetraphenyl-1,2,3,6-tetrahydro-1,2-diphosphorin 1,2-disulfide (**10**) in 52.5 and 13.5% yields, respectively, after separation by column chromatography.



9 **10**

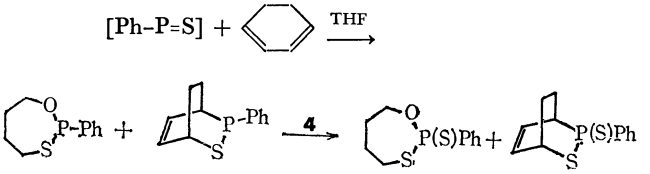
It was proven by a separate experiment that **9** was produced by cyclization of unchanged 2,3-diphenylbutadiene on silica gel (see Experimental).

When phenylphosphonic dichloride (**11**) was used instead of **4**, 1,3,4-triphenyl-3-phospholene 1-oxide (**12**) was obtained in 10% yield.



11 **12**

Dechlorination of **4** with magnesium in the presence of 1,3-cyclohexadiene in THF afforded 2-phenyl-1,3,2-oxathiaphosphepane 2-sulfide (**13**) and 6-phenyl-5,6-thiaphosphabicyclo[2.2.2]oct-2-ene 6-sulfide (**14**) in 6 and 21% yields, respectively.



13 **14**

The compound (**13**) is an insertion product of phenylphosphinothioylidene into the C–O bond of THF. The formation mechanism will be discussed elsewhere.[9] The compound (**14**) is of the same type as **5**.

In the NMR spectrum of **14**, a decoupling experiment showed that two quartets centered at δ 5.98 and 6.58 coupled with two multiplets at δ 2.9—3.4 (–P–CH〈) and 3.8—4.4 (–S–CH〈), respectively, indicating that the two quartets are assignable to olefinic protons adjacent to the C–P and C–S bonds, respectively. From the result, the coupling constants may be evaluated as $J_{H-C=C-H}=J_{HCCH}=J_{PSCCH}=8$ Hz. However, since J_{PSCCH} values are generally very small, it would be more reasonable to consider that the quartet centered at δ 6.58 is due to overlapping of two triplets centered at δ 6.52 and 6.64 assignable to each olefinic proton adjacent to the C–S bond of the two isomers on the phosphorus atom, and that the signals of each olefinic proton adjacent to the C–P bond in the two isomers perhaps coincided with each other by chance. Thus, **14** is suggested to be an equimolar mixture of two isomers.

Detectable reaction products could not be isolated in the reactions of phenylphosphinylidene and cyclohexylphosphinothioylidene with 2,3-dimethylbutadiene, the reactions of cyclohexylphosphinylidene and -phosphinothioylidene with 2,3-diphenylbutadiene, and the reactions of phenylphosphinothioylidene with 1,3-cyclooctadiene, *trans,trans*-1,4-diphenylbutadiene, 1,1′-dicyclohexenyl, thiophene, 2,5-diphenylbenzo[*c*]furan, acetophenone azine, and 1,2-bis(*p*-tolylimino)-1,2-diphenylethane. In some reactions with phenylphosphinothioylidene in THF, **13** was also isolated in 3—11% yields.

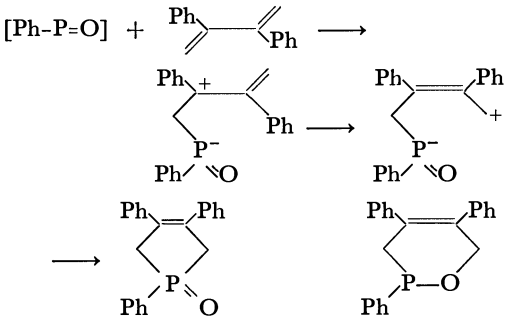
In the reaction of phenylphosphinothioylidene with tetraphenylcyclopentadienone, 2,3,*trans*-4,5-tetraphenylcyclopent-2-en-1-one (**15**) was obtained in 21% yield as the sole product, and may be formed by an analogous mechanism to that reported by Dimroth and Laufenberg[10] or by reduction of tetraphenylcyclopentadienone with magnesium-magnesium(II) chloride system.[1]

Since usually the 1,3-dienes do not react with nucleophiles, participation of Grignard-type intermediate (R–P(X)Cl–MgCl; X=O,S) might be ruled out. Thus, the reactive intermediate is considered to be phosphinylidene and phosphinothioylidene.

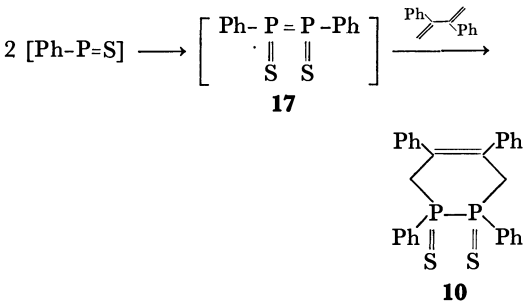
As mentioned above, the types of the products depend on not only the structure of reactive intermediates but also the structure of 1,3-dienes used.

In the reactions of phenylphosphinothioylidene with 1,3-dienes such as 1,3-cyclohexadiene and 2,3-dimethylbutadiene which are fixed in cisoid form or take easily cisoid, phenylphosphinothioylidene behaves as 1,2-dipolar dienophile for 1,3-dienes.

On the contrary, 2,3-diphenylbutadiene takes cisoid form not so easily as 2,3-dimethylbutadiene. Thus the phosphorus atom of phenylphosphinylidene attacks electrophilically on transoid 2,3-diphenylbutadiene and the transoid zwitter ion thus formed converts to the cisoid to form **12**, which is more stable than the isomer (**16**) by a consideration of the bond energies. This difference between the formation of **5**, **6** and **14** and that of **12** may be attributed to the difference in the bond energies of P=O and P=S bonds and to the large nucleophilicity of the sulfur anion.



12 **16**



17

10

In the case of phenylphosphinothioylidene, an analogous transoid zwitter ion is probably less stable because of low electronegativity of the sulfur atom. Then phosphinothioylidene is considered to dimerize competitively to produce a reactive intermediate (**17**) which cyclizes with 2,3-diphenylbutadiene to give **10**.

It is very interesting that phenylphosphinothioylidene shows dual properties in the reactions.

Experimental

All melting and boiling points are uncorrected. IR and mass spectra were measured with Hitachi EPI-G2 and Hitachi RMU-6L spectrometers. ^{1}H-NMR spectra were recorded on Hitachi R-20B, R-24 (60 MHz), R-22 (90 M Hz), and JEOL JNM-4H-100 (100 MHz) spectrometers using TMS as an internal standard. ^{31}P-NMR spectra were taken with a Hitachi R-20B-R-204-PB spectrometer using 85% phosphoric acid as an external standard. All reactions were carried out under nitrogen atmosphere.

Materials. The following compounds were prepared by the method described in the literature: 2,3-dimethyl-[11] (mp 68—71 °C), 2,3-diphenylbutadienes[12] (mp 43—46 °C), 1,3-cyclohexadiene[13] (bp 79—82 °C), tetraphenylcyclopentadienone[14] (mp 218—220 °C), phenylphosphonic[15] (**11**) (bp 143 °C/27 mmHg), and phenylphosphonothioic dichlorides[16] (**4**) (bp 134—138 °C/14 mmHg).

Reaction of 4 and Magnesium with 2,3-Dimethylbutadiene. At room temperature, **4** (2.6 g, 12.4 mmol) was added dropwise to a mixture of 2,3-dimethylbutadiene (12 ml, 107 mmol) and magnesium (0.33 g, 13.9 mg-atom) in THF (10 ml) with stirring. A few drops of methyl iodide were added to start the reaction, and the mixture was stirred at 50 °C overnight. After removal of the solvent, the residue was extracted with chloroform. The chloroform extract was washed with water, dried with anhydrous magnesium sulfate, and chromatographed on silica gel to give **5** (0.69 g, 2.7 mmol,

44%) with benzene and **6** (0.62 g, 2.6 mmol, 21%) with dichloromethane and chloroform.

5: mp 61—62 °C (from ether) (lit,[8] 62 °C); IR (KBr): 1650 cm^{-1} (C=C); NMR (CCl_4, 100 MHz): δ 1.68 (s, 3H, 5-Me), 1.93 (d, J_{PCCCH} 5 Hz, 3H, 4-Me), 2.7—3.9 (m, 4H, $2CH_2$), and 7.2—8.0 (m, J_{PH^o} 15 Hz, 5H, Ph).

Found: C, 56.62; H, 5.86; S, 25.34%. Calcd for $C_{12}H_{15}PS_2$: C, 56.66; H, 5.96; S, 25.21%.

6: mp 85.5—86 °C (from ether); IR (KBr): 1660 (C=C) and 1205 cm^{-1} (P=O); NMR (CCl_4, 100 MHz): δ 1.77 (s, 3H, 5-Me), 1.97 (d, J_{PCCCH} 5 Hz, 3H, 4-Me), 2.4—4.0 (m, 4H, $2CH_2$), and 7.4—8.0 (m, 5H, Ph); MS: *m/e* 238 (M^+).

Found: C, 60.71; H, 6.49%. Calcd for $C_{12}H_{15}OPS$: C, 60.49; H, 6.35%.

Reaction of ***4*** *and Magnesium with 2,3-Diphenylbutadiene.* At room temperature, **4** (5.31 g, 25.2 mmol) in THF (5 ml) was added drop by drop with stirring to a mixture of 2,3-diphenylbutadiene (6.08 g, 29.5 mmol), magnesium (0.66 g, 27.5 mg-atom), and THF (20 ml). A small amount of iodine was added to activate magnesium. The mixture was stirred for 1 hr. Unchanged magnesium and produced magnesium chloride were filtered off, and THF was evaporated from the filtrate *in vacuo*. The residue was treated in a similar way. Elution with carbon tetrachloride and carbon tetrachloride-benzene (2 : 1—1 : 1) afforded unchanged **4** (0.02 g, 0.1 mmol) and **9** (3.19 g, 15.5 mmol, 52.5%), mp 76—77 °C (from *n*-hexane) (lit,[17] 76—77 °C), respectively. Elution with benzene and dichloromethane afforded **10** (0.84 g, 1.7 mmol), mp 233—234 °C (from benzene). The yield was 13.5% based on **4** consumed. IR (KBr): 1110 (P-Ph), 625, and 620 cm^{-1} (P=S); NMR ($CDCl_3$): δ 3.3—4.5 (m, 4H, $2CH_2$), and 7.0—8.2 (m, 20H, 4Ph); MS: *m/e* 486 (M^+, 21%), 346 (M^+-PhPS, 69), 314 (M^+-PhPS_2, 100), 280 (PhP(S)P(S)Ph, 14), and 205 ($CH_2CPhCPhCH_2$, 32).

Found: C, 69.02; H, 4.66%. Calcd for $C_{23}H_{24}P_2S_2$: C, 69.11; H, 4.98%.

Reaction of ***11*** *and Magnesium with 2,3-Diphenylbutadiene.* A solution of **11** (4.29 g, 22.0 mmol) in THF (5 ml) was added dropwise to a stirred suspension of magnesium (0.58 g, 24.0 mg-atom) and 2,3-diphenylbutadiene (4.54 g, 22.0 mmol) in THF (20 ml) under occasional cooling with water. The exothermal reaction ceased in about 1 hr. Then the reaction mixture was refluxed for 3 hr, and treated similarly. Elution with carbon tetrachloride and chloroform afforded unchanged diene (3.23 g, 15.7 mmol) and **12** (0.75 g, 2.3 mmol), respectively. The yield of **12** was 37% based on the diene consumed.

12: mp 162.5—163.5 °C (from carbon tetrachloride); IR (KBr): 1190 cm^{-1} (P=O); ^1H-NMR ($CDCl_3$, 90 MHz): δ 3.0—3.75 (m, 4H, $2CH_2$), 6.9—7.3 (m, 10H, 2Ph), 7.4—7.65 (m, 3H, $2H^m$ and H^p of P-Ph), and 7.65—8.1 (m, 2H, $2H^o$ of P-Ph); ^{31}P-NMR ($CHCl_3$): δ −48 ppm; MS: *m/e* 330 (M^+).

Found: C, 80.10; H, 5.64%. Calcd for $C_{22}H_{19}OP$: C, 77.98; H, 5.80%.

Conversion of 2,3-Diphenylbutadiene into ***9*** *on Silica Gel Column.* 2,3-Diphenylbutadiene (4.95 g, 23.8 mmol) was adsorbed on silica gel for 6 days. Elution with carbon tetrachloride gave 3.72 g (17.9 mmol, 75%) of **9**, mp 76—77 °C.

Reaction of ***4*** *and Magnesium with 1,3-Cyclohexadiene.* A solution of **4** (5.24 g, 24.8 mmol) in THF (7 ml) was added drop by drop to a stirred mixture of 1,3-cyclohexadiene (8.0 g, 100 mmol) and magnesium (0.67 g, 27.9 mg-atom) in THF (10 ml). A small amount of iodine was added to initiate the reaction. Exothermal reaction ended in 1 hr. Then the reaction mixture was refluxed for 3 hr and treated similarly. Elution with benzene afforded 0.20 g (0.8 mmol, 6%) of **13** and 0.66 g (2.6 mmol, 21%) of **14**.

13: mp 62—63.5 °C (from *n*-hexane); IR (KBr): 1115 (P-Ph), 1030 (P-O-C), 650, 645, and 545 cm^{-1} (P(S)-S); NMR ($CDCl_3$, 100 MHz): δ 1.7—2.4 (m, 4H, $2CH_2$), 2.72 (dt, J_{PSCH} 22.5, J_{HCCH} 9 Hz, 2H, SCH_2), 4.0—4.5 and 4.5—5.0 (m, 2H, OCH_2), 7.3—7.6 (m, 3H, $2H^m$ and H^p of P-Ph), and 7.90 (m, J_{PH^o} 15 Hz, 2H, $2H^o$ of P-Ph); MS: *m/e* 244 (M^+).

Found: C, 49.09; H, 5.45; S, 26.44%. Calcd for $C_{10}H_{13}OPS_2$: C, 49.16; H, 5.45; S, 26.25%.

14: mp 92—93.5 °C (from ether); IR (KBr): 1100 (P-Ph), 680, 578, 520, and 488 cm^{-1} (P(S)-S); NMR ($CDCl_3$): δ 1.0—2.9 (m, 4H, $2CH_2$), 2.9—3.4 (m, 1H, P-CH<), 3.8—4.4 (m, 1H, S-CH<), 5.98 (q, $J_{HC=CH}=J_{HCCH}=J_{PCCH}=8$ Hz, 1H, =CH-), 6.52 and 6.64 (2t, $J_{HC=CH}=J_{=CH-CH}=8$ Hz, 1H, =CH-), 7.2—7.6 (m, 3H, $2H^m$ and H^p), and 7.65—8.1 (m, J_{PH^o} 13.5 Hz, 2H, $2H^o$); MS: *m/e* 252 (M^+).

Found: C, 57.28; H, 5.02; S, 25.34%. Calcd for $C_{12}H_{13}PS_2$: C, 57.12; H, 5.19; S, 25.41%.

Reaction of ***4*** *and Magnesium with Tetraphenylcyclopentadienone.* At room temperature, **4** (0.59 g, 2.8 mmol) was added to a stirring suspension of magnesium (0.17 g, 6.9 mg-atom) and tetraphenylcyclopentadienone (1.16 g, 3.0 mmol) in THF (25 ml), and the mixture was heated at 80 °C for 1 day. After similar treatment, elution with dichloromethane gave 0.23 g (0.6 mmol, 21%) of **15**, mp 165—168 °C (from dichloromethane-ethanol) (lit,[10] 161—163 °C); NMR ($CDCl_3$): δ 3.76 (d, J 3 Hz, 1H, CH), 4.56 (d, J 3 Hz, 1H, CH), and 7.0—7.5 (m, 20H, 4Ph).

This work was supported by a grant from the Ministry of Education.

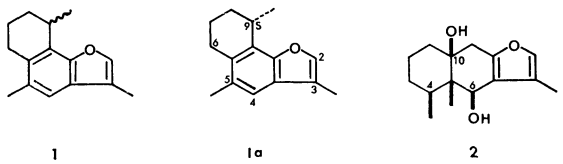
Absolute Stereochemistry of Farfugin A[1]

Masahiro TADA, Yoshihiko MORIYAMA, Yoshiaki TANAHASHI, and Takeyoshi TAKAHASHI
Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113
(Received October 16, 1974)

4,6-Dimethylcoumarin (**3**) was converted to an enantiomer (**1b**) of farfugin A, *via* a levorotatory carboxylic acid (**5b**). This led to the absolute configuration (**1a**) for farfugin A.

The structure of farfugin A, a dextrorotatory benzofuranosesquiterpene isolated from *Farfugium japonicum*, was shown to be **1**.[2] A skeletal rearrangement of furanoeremophilane-6β,10β-diol [(+)-**2**][3] gave farfugin A [(+)-**1**].[4] We wish to report the determination of an absolute configuration of farfugin A (**1a**), which is indispensable for elucidation of the mechanism of this rearrangement.

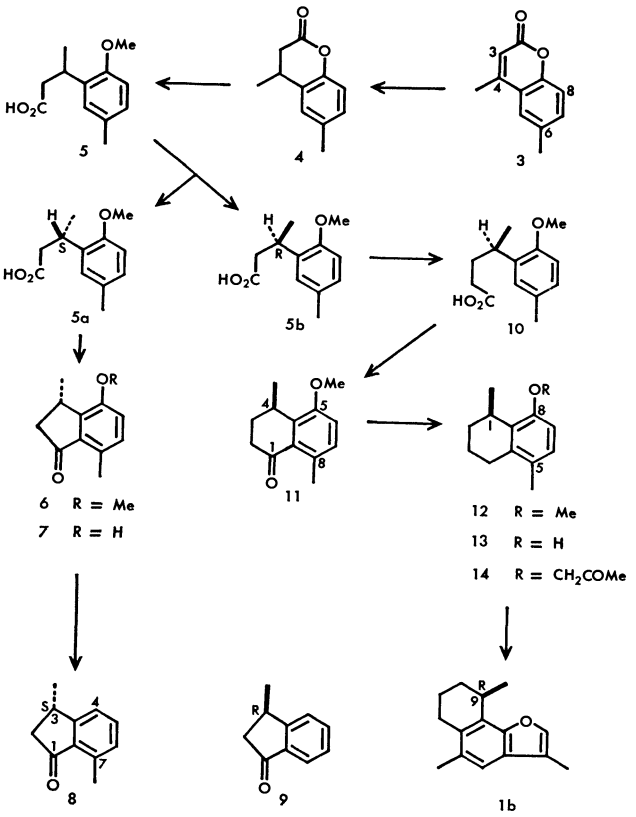


1 1a 2

4,6-Dimethylcoumarin (**3**)[5] was hydrogenated over palladium-charcoal to yield a dihydro derivative (**4**;[6] mp 35—35.5 °C; yield: 90%). Alkaline hydrolysis of **4** followed by methylation with dimethyl sulfate gave 3-(2-methoxy-5-methylphenyl)butanoic acid (**5**; mp 60.5—61.5 °C; yield: 89%). A resolution of the (+)- and (−)-acid [(+)- and (−)-**5**] was carried out *via* their strychnine salts to give a dextrorotatory acid [**5a**; mp 60—60.5 °C, $[\alpha]_D$ +19° (C_6H_6)][7] and a levorotatory acid [**5b**; mp 60 °C, $[\alpha]_D$ −27° (C_6H_6)].[7]

The dextrorotatory acid (**5a**) was converted to (+)-3,7-dimethylindan-1-one (**8**) to determine an absolute configuration of **5a**. When **5a** was treated with polyphosphoric acid, **5a** was cyclized to give (+)-4-methoxy-3,7-dimethylindan-1-one (**6**; an oil; y: 94%), which was demethylated to yield a phenol (**7**;[8] mp 203 °C; yield: 68%). The phenol (**7**) was phosphorylated according to Kenner and Williams,[9] reduced with lithium in liquid ammonia, and then oxidized with Jones' reagent to give (+)-3,7-dimethylindan-1-one (**8**; an oil; y: 50%). These indanone derivatives (**6** and **8**)[10] showed the ORD curves which were almost mirror images to that of known (−)-(3R)-3-methylindan-1-one (**9**).[11] An asymmetric center of the dextrorotatory acid (**5a**) must therefore be in the configuration (S), and that of levorotatory acid (**5b**) in the configuration (R).

The levorotatory acid (**5b**) was subjected to the Arndt-Eistert homologation to give (−)-4-(2-methoxy-5-methylphenyl)-pentanoic acid (**10**; mp 87.5 °C; y: 75%),[12] which was converted *via* **11** and **12** to (+)-8-hydroxy-1,5-dimethyl-1,2,3,4-tetrahydronaphthalene (**13**; mp 91 °C; y: 72%) according to the procedures described in the literatures.[12] By the reaction sequence already reported,[2] **13** was converted to a (−)-8-acetonyloxy-1,5-dimethyl-1,2,3,4-tetrahydronaphthalene (**14**; mp 77 °C; y: 61%), which was then cyclized to give a levorotatory benzofuran [**1b**; mp



78 °C, $[\alpha]_D$−27° (EtOH); y: 55%). This compound (**1b**) was found to be an enantiomer of natural (+)-farfugin A[2] (*cf.* Experimental). Thus, the absolute stereochemistry of natural farfugin A was shown to be **1a** whose configuration at C-9 must be (S).

Experimental

IR spectra were measured using a Hitachi EPI-G2 spectrometer in Nujol mull, unless otherwise stated. UV spectra were determined on a Hitachi EPS-3 spectrophotometer. ORD measurements were carried out on a JASCO ORD/UV-5 spectrometer. Optical rotations were measured on a JASCO DIP-SL polarimeter. Mass spectra were taken on a Hitachi RMU-6-Tokugata mass spectrometer with a direct inlet system operating at 70 eV. PMR spectra were measured using a JEOL PS-100 (100 MHz) or a Hitachi R-20 (60 MHz) spectrometer. Chemical shifts were expressed in δ downfield from TMS as internal standard, and coupling constants in Hz. Thin layer chromatography (tlc) was carried out on Kieselgel PF_{254} (E. Merck, Darmstadt). For column chromatography Wakogel C-200 (Wako Pure Chemical Ind.) was used. All mps were determined on a hot block and reported uncorrected.

4,6-Dimethylcoumarin (3). According to the known procedures,[5] *p*-cresol (76 g) was condensed with ethyl aceto-

acetate (90 g) in polyphosphoric acid [prepared from phosphoric acid (85%; 300 ml) and phosphorus pentoxide (500 g)] at 80 °C for 1 hr to give 4,6-dimethylcoumarin (**3**; 55 g; y: 45%), mp 150—151.5 °C [crystallized from a mixture of light petroleum and benzene (1 : 1)] (lit,[5a] mp 148 °C; lit,[5b] mp 150 °C); IR: 1720, 1627, 1612, 1573, 1491, 1200, 938, 860, and 830 cm^{-1}; PMR ($CDCl_3$): δ 2.41 (6H, s; $C_{(4)}$-CH_3 and $C_{(6)}$-CH_3), 6.22 (1H, m; $C_{(3)}$-H), and 7.2—7.4 (3H, m; $C_{(5)}$-H, $C_{(7)}$-H, and $C_{(8)}$-H); mass spectrum: *m/e* 174 (M^+) and *m/e* 145 (base peak). Found: C, 75.87; H, 6.02%. Calcd for $C_{11}H_{10}O_2$: C, 75.84; H, 5.79%; mol wt 174.2.

*3,4-Dihydro-4,6-dimethylcoumarin (**4**).* 4,6-Dimethylcoumarin (**3**; 45 g) dissolved in a mixture of ethyl acetate (200 ml) and acetic acid (1.8 l) was hydrogenated in the presence of 10% palladium-charcoal (10 g) for 4 hr at 100 °C. The catalyst was removed by filtration and the solvents were evaporated to give a residue, which was extracted with ether. A usual treatment gave an oil which solidified to afford 3,4-dihydro-4,6-dimethylcoumarin (**4**; 41 g; y: 90%), mp 35—35.5 °C (lit,[6] bp 100—105 °C/5 mmHg); IR: 1760, 1620, 1595, 1500, 1260, 1212, 1176, and 832 cm^{-1} (lit,[6] 1770 cm^{-1}); PMR ($CDCl_3$): δ 1.30 (3H, d, J=7 Hz; $C_{(4)}$-CH_3), 2.33 (3H, s; $C_{(6)}$-CH_3), and 6.95 (3H, m; $C_{(5)}$-H, $C_{(7)}$-H, and $C_{(8)}$-H); mass spectrum: *m/e* 176 (M^+) and *m/e* 134 (base peak). Found: C, 75.07; H, 6.75%. Calcd for $C_{11}H_{12}O_2$: C, 74.97; H, 6.86%; mol wt 176.2.

*3-(2-Methoxy-5-methylphenyl)butanoic Acid (**5**).* To a solution of 3,4-dihydro-4,6-dimethylcoumarin (**4**, 90 g) in ethanol (300 ml) was added 2 M sodium hydroxide (1 l), and the mixture was heated under reflux for 2 hr. To the cooled mixture dimethyl sulfate (65 g) was added dropwise with stirring at 0 °C, and the whole was heated under reflux for 8 hr. These procedures were repeated by further addition of dimethyl sulfate (20 g) and 2 M sodium hydroxide (90 ml). The cooled reaction mixture was acidified with 2 M sulfuric acid and heated under reflux for 2 hr. The mixture was cooled, alkalized with 2 M sodium hydroxide, and extracted with chloroform. The organic layer was separated and the solvents (chloroform and ethanol) were removed to give the starting material (**4**: 17 g). The alkaline layer was acidified with 2 M sulfuric acid, and then extracted with chloroform. The chloroform layer was separated, washed with brine, and dried over anhydrous sodium sulfate. The solvent was removed and the residue was distilled at 153 °C under 1 mmHg pressure. The distillate solidified to give 3-(2-methoxy-5-methylphenyl)-butanoic acid (**5**; 95 g; y: 89%), mp 60.5—61.5 °C; IR: *ca.* 3000 (br.), 1710, 1610, 1502, 1250, and 812 cm^{-1}; PMR ($CDCl_3$): δ 1.30 (3H, d, J=7 Hz; *s*-CH_3), 2.27 (3H, s; aromatic CH_3), 3.80 (3H, s; OCH_3), and 6.65—6.95 (3H, m; aromatic protons); mass spectrum: *m/e* 208 (M^+) and *m/e* 149 (base peak). Found: C, 69.36; H, 7.53%. Calcd for $C_{12}H_{16}O_3$: C, 69.21; H, 7.74%; mol wt 208.2.

*Resolution of (+)- and (−)-3-(2-Methoxy-5-methylphenyl)butanoic Acid [**5a** and **5b**].* To a solution of the racemic acid (**5**; 20 g) and strychnine (32 g) in chloroform (25 ml), ethanol (80%; 80 ml) was added. The resulting solution was concentrated to a volume of 20 ml. Water (10 ml) was added, and the solution was kept at room temperature overnight. There appeared the strychnine salt [18 g; $[\alpha]_D$ −68 ° (*c* 2.0, H_2O)], which was separated by filtration and crystallized thrice from ethanol (50%) to give the levorotatory strychnine salt. The rotation values of the salt at different stages of crystallization were: first crystallization, $[\alpha]_D$ −78.7 °; second, $[\alpha]_D$ −81.8 °; third, $[\alpha]_D$ −82.2 ° (*c* 2.0, H_2O).

The third crop (14 g) was added to 1 M sodium hydroxide (80 ml). The resulting mixture was extracted with chloroform, and the organic layer was discarded. The aqueous layer was then acidified with 2 M sulfuric acid and extracted with chloroform. The chloroform layer was washed with brine, dried over anhydrous sodium sulfate, and evaporated to yield an oil which was distilled at 150 °C under 1 mmHg pressure. The distillate solidified to give (−)-3-(2-methoxy-5-methylphenyl)butanoic acid (**5b**; 5 g), mp 60 °C, $[\alpha]_D$ −27 ° (*c* 2.0, C_6H_6).[7]

The mother liquor after separating the levorotatory strychnine salt was concentrated to a volume of *ca.* 20 ml to give the salt of **5b** (1 g); no salt was precipitated on further concentration of the mother liquor. The mother liquor was then alkalized with 1 M sodium hydroxide. The subsequent treatments were followed as before to give an oil which was distilled at 150 °C under 1 mmHg pressure. The distillate solidified to give (+)-3-(2-methoxy-5-methylphenyl)butanoic acid (**5a**; 9 g), mp 60—60.5 °C, $[\alpha]_D$ +19 ° (*c* 2.0, C_6H_6).[7]

*(+)-4-Methoxy-3,7-dimethylindan-1-one (**6**).* The dextrorotatory acid (**5a**; 7 g) was dissolved in polyphosphoric acid [prepared from phosphoric acid (85%; 80 ml) and phosphorus pentoxide (130 g)] at 30 °C, and the resulting solution was then heated at 100 °C for 1 hr. The cooled reaction mixture was poured into a mixture of ice and water and extracted with chloroform. The organic layer was washed with brine, dried, and evaporated to give an oil (6 g; y: 94%). A part of this material was purified by preparative tlc to give (+)-4-methoxy-3,7-dimethylindan-1-one (**6**), an oil; IR (liquid): 1715, 1590, 1500, 1270, 820, and 760 cm^{-1}; UV (cyclohexane): λ_{max} 317 nm (ε 3300), 308 (3500), 252.5 (8600), 246 (8300), and 238 (8000); PMR ($CDCl_3$): δ 1.34 (3H, d, J=7 Hz; $C_{(3)}$-CH_3), 2.20 (1H, dd, J=19 and J=3 Hz; $C_{(2)}$-H), 2.53 (3H, s; $C_{(7)}$-CH_3), 2.85 (1H, dd, J=19 and J=7 Hz; $C_{(2)}$-H), 3.45 (1H, m; $C_{(3)}$-H), 3.82 (3H, s; OCH_3), 6.88 and 7.00 (each 1H, d, J=8 Hz; $C_{(5)}$-H and $C_{(6)}$-H); ORD (*c* 0.18, cyclohexane): $[\Phi]_{589}$ +40 °, $[\Phi]^{peak}_{365}$ +1100 °, $[\Phi]^{trough}_{358}$ +720 °, $[\Phi]^{peak}_{350}$ +1000 °, $[\Phi]^{trough}_{340}$ +220 °, $[\Phi]^{peak}_{335}$ +330 °, $[\Phi]_{325}$ −1200 ° (shoulder), $[\Phi]^{trough}_{313}$ −2200 °, and $[\Phi]_{297}$ 0°; mass spectrum: *m/e* 190 [$M^+(C_{12}H_{14}O_2)$] and *m/e* 175 (base peak).

*(+)-4-Hydroxy-3,7-dimethylindan-1-one (**7**).* To a solution of crude (+)-4-methoxy-3,7-dimethylindan-1-one (**6**; 6 g) in acetic acid (30 ml) was added 5.9 M hydrobromic acid (12 ml), and the mixture was heated under reflux for 8 hr. The solvent was removed under reduced pressure to give a residue. The residue was extracted with ether, washed with 1 M sodium carbonate and then brine, dried over anhydrous sodium sulfate, and evaporated to give a residue, which was crystallized from a mixture of benzene and ether (1 : 1) to yield (+)-4-hydroxy-3,7-dimethylindan-1-one (**7**; 3.8 g; y: 68%), mp 203 °C (lit,[8] racemic **7**, mp 175 °C), $[\alpha]_D$ +25 ° (*c* 0.28, EtOH); IR: *ca.* 3200, 1670, 1590, 1505, 1380, 1305, 1285, and 1250 cm^{-1}; PMR (acetone-d_6): δ 1.36 (3H, d, J=7 Hz; $C_{(3)}$-CH_3), 2.14 (1H, dd, J=19 and J=3 Hz; $C_{(2)}$-H), 2.45 (3H, s; $C_{(7)}$-CH_3), 2.82 (1H, dd, J=19 and J=7 Hz; $C_{(2)}$-H), *ca.* 3.4 (1H, m; $C_{(3)}$-H), and 6.88 (2H, s; $C_{(5)}$-H and $C_{(6)}$-H); mass spectrum: *m/e* 176 (M^+) and *m/e* 161 (base peak). Found: C, 75.29; H, 6.67%. Calcd for $C_{11}H_{12}O_2$: C, 74.97; H, 6.86%; mol wt 176.2.

*(+)-3,7-Dimethylindan-1-one (**8**).* To a solution of (+)-4-hydroxy-3,7-dimethylindan-1-one (**7**; 3.5 g) in a mixture of carbon tetrachloride (30 ml) and ether (10 ml), was added diethyl phosphite (5 ml) and triethylamine (4 ml). The mixture was kept overnight at room temperature, and

then extracted with chloroform. The organic layer was washed successively with 2 M hydrochloric acid, 1 M sodium hydroxide, and brine, dried over anhydrous sodium sulfate, and evaporated to give an oil (6 g). Lithium (4 g) was added to a solution of this oil (6 g) in liquid ammonia (120 ml), and the whole was stirred for 1 hr. Ethanol (20 ml) and then water (40 ml) were added, and the ammonia was allowed to evaporate. The resulting mixture was extracted with ether, washed successively with 1 M sodium hydroxide and brine, dried over anhydrous sodium sulfate, and evaporated to give an oil, which was oxidized with Jones' reagent at 0 °C. The product was taken up in ether and treated as usual to give a residue, which was chromatographed on a column of silica gel (320 g). Elution with a mixture of light petroleum and ether (40 : 3) gave an oil (1.6 g; y: 50%). A part of this material was purified by preparative tlc to afford (+)-3,7-dimethylindan-1-one (**8**) an oil, IR (liquid): 1715, 1600, 1480, and 795 cm^{-1}; UV (cyclohexane): λ_{max} 297.5 nm (ε 2600), 294 (shoulder), 287.5 (2500), 260 (shoulder), and 234 (12000); PMR (CCl_4): δ 1.38 (3H, d, J=7 Hz; $C_{(3)}$-CH_3), 2.26 (1H, dd, J=19 and J=4 Hz; $C_{(2)}$-H), 2.65 (3H, s; $C_{(7)}$-CH_3), 2.90 (1H, dd, J=19 and J=7 Hz; $C_{(2)}$-H), 3.40 (1H, m; $C_{(3)}$-H), and 7.0—7.6 (3H, m; $C_{(4)}$-H, $C_{(5)}$-H, and $C_{(6)}$-H); ORD (c 0.44, cyclohexane): $[\Phi]_{589}$ +8° $[\Phi]_{368}^{peak}$ +600°, $[\Phi]_{359}^{trough}$ +410°, $[\Phi]_{352}^{peak}$ +640°, $[\Phi]_{339}$ +60° (shoulder), $[\Phi]_{324}$ −1200° (shoulder), $[\Phi]_{311}$ −2000° (shoulder), $[\Phi]_{300}^{trough}$ −2700°, and $[\Phi]_{290}$ −2300°; mass spectrum: *m/e* 160 [M^+ ($C_{11}H_{12}O$)] and *m/e* 145 (base peak).

*(−)-4-(2-Methoxy-5-methylphenyl)pentanoic Acid (**10**).* Thionyl chloride (3 ml) was added with stirring to a cooled solution (at 0 °C) of the levorotatory acid (**5b**; 5 g) in a mixture of dry benzene (10 ml) and pyridine (0.5 ml). The mixture was kept at room temperature for 30 min and then warmed at 40 °C for 10 min. The precipitated solid was removed by filtration. To the filtrate was added dropwise at 0 °C with stirring a *ca.* 3% solution of diazomethane in ether (100 ml). After 40 min, the solvents were removed under reduced pressure at room temperature to give a residue. Anhydrous methanol (50 ml) and then silver oxide (0.8 g) were added to this residue. The mixture was warmed at 50 °C for 20 min (an evolution of nitrogen was observed) and then heated under reflux for 20 min. The cooled mixture was filtered, and the filtrate was evaporated to give a residue which was taken up in ether. The ethereal solution was treated with cold 1 M sodium hydroxide to give, after a work-up as usual, (i) a neutral and (ii) an acidic fraction. Ethanol (30 ml), water (20 ml), and potassium hydroxide (2 g) were added to the neutral product (i), and the whole was heated under reflux for 3 hr. The cooled reaction mixture was acidified with 2 M sulfuric acid and extracted with ether to give, after a treatment as usual, (−)-4-(2-methoxy-5-methylphenyl)pentanoic acid (**10**; 4 g; y: 75%), mp 87.5 °C (crystallized from benzene) (racemic **10** prepared by other routes: lit,[12a] mp 94 °C; lit,[12b] mp 93.5—94 °C), $[\alpha]_D$ −14° (c 2.0, EtOH), IR: 1710, 1610, 1500, 1250, 815, 805, and 750 cm^{-1}; PMR ($CDCl_3$): δ 1.20 (3H, d, J=7 Hz; s-CH_3), 2.28 (3H, s; aromatic CH_3), 3.76 (3H, s; OCH_3), and 6.5—7.0 (3H, m; aromatic protons); mass spectrum: *m/e* 222 (M^+) and *m/e* 149 (base peak). Found: C, 70.31; H, 8.31%. Calcd for $C_{13}H_{18}O_3$: C, 70.24; H, 8.16%; mol wt 222.3. The acidic fraction (ii; *ca.* 300 mg) was suggested to be a mixture (*ca.* 1 : 1) of the starting acid (**5b**) and the homoacid (**10**) by examination on tlc.

*(+)-5-Methoxy-4,8-dimethyl-1-oxo-1,2,3,4-tetrahydronaphthalene (**11**).* A cyclization of (−)-4-(2-methoxy-5-methylphenyl)pentanoic acid (**10**) to give **11** was accomplished according to the procedures described for the preparation of racemic **11**.[12b] The homoacid (**10**; 3.8 g) in polyphosphoric acid [prepared from phosphoric acid (85%; 100 ml) and phosphorus pentoxide (160 g)] was heated at 100 °C for 1 hr. After a treatment as usual, the product was purified by chromatography on a column of silica gel (60 g; elution with benzene) to give (+)-5-methoxy-4,8-dimethyl-1-oxo-1,2,3,4-tetrahydronaphthalene (**11**; 3.5 g; y: quantitative), mp 76.5—77 °C (crystallized from light petroleum) (lit, [12b] racemic **11**, mp 50—51 °C; lit, [12a] racemic **11** prepared by other route, bp 150—153 °C/7 mmHg), $[\alpha]_D$ +28° (c 2.0, EtOH); IR: 1675, 1575, 1270, 1045, and 815 cm^{-1}; PMR (CCl_4): δ 1.24 (3H, d, J=7 Hz; $C_{(4)}$-CH_3), 2.48 (3H, s; $C_{(8)}$-CH_3), 3.83 (3H, s; OCH_3), 6.75 and 6.90 (each 1 H, d, J=8 Hz; $C_{(6)}$-H and $C_{(7)}$-H); mass spectrum: *m/e* 204 (M^+) and *m/e* 189 (base peak). Found: C, 76.50; H, 7.60%. Calcd for $C_{13}H_{16}O_2$: C, 76.44; H, 7.90%, mol wt 204.3.

*(−)-8-Methoxy-1,5-dimethyl-1,2,3,4-tetrahydronaphthalene (**12**).* (+)-5-Methoxy-4,8-dimethyl-1-oxo-1,2,3,4-tetrahydronaphthalene (**11**) was converted to **12** according to the procedures described for the preparation of racemic **12**.[12a] A mixture of the tetralone (**11**; 1 g), ethanol (15 ml), and 6.5 M hydrochloric acid (30 ml) was heated under reflux, and then amalgamated zinc (*ca.* 70 g) and 10 M hydrochloric acid (25 ml) were added in portions during 12 hr (under reflux). After a work-up as usual, the product was purified by chromatography on a column of silica gel (20 g; elution with light petroleum) to give (−)-8-methoxy-1,5-dimethyl-1,2,3,4-tetrahydronephthalene (**12**: 930 mg; y: quantitative), an oil (lit,[12a] racemic **12**, bp 120—122 °C/3 mmHg), $[\alpha]_D$ −65.5° (c 0.12, EtOH), IR (liquid): 1590, 1480, 1260, 1245, 1100, and 805 cm^{-1}; PMR ($CDCl_3$): δ 1.17 (3H, d, J=7 Hz; $C_{(1)}$-CH_3), 2.13 (3H, s; $C_{(5)}$-CH_3), 3.78 (3H, s; OCH_3), 6.62 and 6.96 (each 1H, d, J=8 Hz; $C_{(6)}$-H and $C_{(7)}$-H); mass spectrum: *m/e* 190 [M^+ ($C_{13}H_{18}O$)] and *m/e* 175 (base peak).

*(+)-8-Hydroxy-1,5-dimethyl-1,2,3,4-tetrahydronaphthalene (**13**).* (−)-8-Methoxy-1,5-dimethyl-1,2,3,4-tetrahydronaphthalene (**12**) was demethylated according to the procedures described for the preparation of racemic **13**.[12b] The methyl ether (**12**; 900 mg) in acetic acid (10 ml) was demethylated under reflux (for 7 hr) by addition of 5.9 M hydrobromic acid (3.5 ml). After a treatment as usual, the product was chromatographed on a column of silica gel (20 g; elution with benzene) to give the crude tetrahydronaphthol (**13**; 600 mg; y: 72%). A part of this material was purified by preparative tlc to afford (+)-8-hydroxy-1,5-dimethyl-1,2,3,4-tetrahydronaphthalene (**13**), mp 91 °C (crystallized from ethanol) (lit, [12b] racemic **13**, mp 93—94 °C), $[\alpha]_D$ +5° (c 2.1, EtOH); IR (liquid): 3400 (br.), 1590, 1485, 1460, 1270, 1015, and 810 cm^{-1}; PMR ($CDCl_3$): δ 1.23 (3H, d, J=7 Hz; $C_{(1)}$-CH_3), 2.13 (3H, s; $C_{(5)}$-CH_3), 6.53 and 6.85 (each 1H, d, J=8 Hz; $C_{(6)}$-H and $C_{(7)}$-H); mass spectrum: *m/e* 176 [M^+ ($C_{12}H_{16}O$)] and *m/e* 161 (base peak).

*(−)-8-Acetonyloxy-1,5-dimethyl-1,2,3,4-tetrahydronaphthalene (**14**).* (+)-8-Hydroxy-1,5-dimethyl-1,2,3,4-tetrahydronaphthalene (**13**) was acetonylated to give **14** according to the procedures reported for the preparation of racemic **14**.[2] A solution of the crude tetrahydronaphthol (**13**; 400 mg) in dry acetone (20 ml) was refluxed with chloroacetone (0.4 ml), potassium iodide (150 mg), and potassium carbonate (1.5 g). After a work-up as usual, the product was purified by chromatography on a column of silica gel [25 g; elution with a mixture of light petroleum and ether (10 : 1)] to afford (−)-8-acetonyloxy-1,5-dimethyl-1,2,3,4-tetrahydronaphtha-

lene (**14**; 320 mg; y: 61%), mp 77 °C (crystallized from light petroleum) (lit,[2] racemic **14**, mp 50—51 °C), $[\alpha]_D$ −5° (*c* 1.7, EtOH), IR (liquid): 1725, 1590, 1475, and 1105 cm^{-1}; PMR ($CDCl_3$): δ 1.26 (3H, d, J=7 Hz; $C_{(1)}$-CH_3), 2.13 (3H, s; $C_{(5)}$-CH_3), 2.30 (3H, s; -$COCH_3$), 4.48 (2H, s; -OCH_2CO-), 6.46 and 6.92 (each 1H, d, J= 8 Hz; $C_{(6)}$-H and $C_{(7)}$-H); mass spectrum: *m/e* 232 [M^+ ($C_{15}H_{20}O_2$)] and *m/e* 174 (base peak).

(−)-*Farfugin A* (***1b***; *an Enantiomer of Natural Farfugin A*). (−)-8-Acetonyloxy-1,5-dimethyl-1,2,3,4-tetrahydronaphthalene (**14**) was converted to **1b** according to the procedures described for the preparation of racemic farfugin A [(±)-**1**].[2] The ether (**14**; 296 mg) was heated with polyphosphoric acid [prepared from phosphoric acid (85%; 10 g) and phosphorus pentoxide (16 g)] at 100 °C for 20 min. The cooled mixture was poured into a mixture of ice and water and extracted with ether. The organic layer was washed successively with 1% sodium hydroxide and brine, dried over anhydrous magnesium sulfate, and evaporated to give a residue, which was chromatographed on a column of silica gel. Elution with light petroleum gave (−)-farfugin A (**1b**; 150 mg; y: 55%), mp 78 °C (crystallized from ethanol) [lit.,[2] racemic farfugin A [(±)-**1**], mp 73—73.5 °C; lit,[2] natural (+)-farfugin A (**1a**), mp 80.5—82.5 °C], $[\alpha]_D$ −27° (*c* 0.7, EtOH)[7] [lit,[2] natural (+)-farfugin A, $[\alpha]_D$ +39° (*c* 0.34, EtOH)]; IR: 1590, 1540, 1525, 1430, 1325, 1100, 1018, 855, 780, and 765 cm^{-1}; UV (EtOH): λ_{max} 291 nm (ε 2500), 281 (2300), and 252 (10500); PMR ($CDCl_3$): δ 1.38 (3H, d, J=7.5 Hz; $C_{(9)}$-CH_3), 2.18 (3H, d, J=1.2 Hz; $C_{(3)}$-CH_3), 2.28 (3H, s; $C_{(5)}$-CH_3), 7.08 (1H, s; $C_{(4)}$-H), and 7.23 (1H, m; $C_{(2)}$-H); mass spectrum: *m/e* 214 (M^+) and *m/e* 199 (base peak). Found: C, 84.25; H, 8.64%. Calcd for $C_{15}H_{18}O$: C, 84.07; H, 8.47%; mol wt 214.2. The spectral data (IR, UV, PMR, and mass spectrum) of **1b** were identical with those[2] of natural (+)-farfugin A. The compound (**1b**) was thus shown to be an enantiomer of natural (+)-farfugin A.

Conformation and Circular Dichroism of Several *N*-Acyl-L-prolines

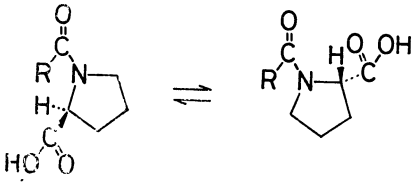
Hisao NISHIHARA, Koji NISHIHARA, Tamio UEFUJI, and Naokazu SAKOTA

Department of Industrial Chemistry, Faculty of Engineering, Ehime University, Bunkyo-cho, Matsuyama 790

(Received Mach 19, 1974)

NMR and CD studies were carried out for acetyl-L-proline, isovaleroyl-L-proline, isobutyroyl-L-proline, pivaloyl-L-proline and benzoyl-L-proline. It was found that *N*-acetyl-L-proline has two rotational isomers about the amide bond, *S-trans* and *S-cis* conformers even at room temperature, and that the population of the former is greater than that of the latter except for pivaloyl-L-proline, which consists only of the *S-trans* conformer. The two isomeric *N*-acyl-L-prolines showed different CD peaks of opposite sign associated with the n→π^* transition of the amide group.

Investigations have been reported for the hindered internal rotation about an amide bond. Phillips[1] reported that two NMR peaks assigned to the methyl groups of *N,N*-dimethyl formamide suggest the coexistence of the two rotational isomers about the amide bond even at room temperature. The alternating photocopolymerization of methacryloyl-L-valine methyl ester with maleic anhydride[2,3] also suggests that the amide compound assumes a planar *S-trans* conformation about the amide bond and the hydrogen bond between the amide proton and the ester carbonyl oxygen. In order to elucidate the participation of the amide proton in this planar conformation, the conformation of methacryloyl-L-proline (MAP)[4] was studied, one of the two rotational isomers about the amide bond, the *S-trans* isomer, being predominant at room temperature.



S-cis *S-trans*

On the other hand, the CD spectrum of MAP shows a negative CD maximum at 227 nm., accompanied by a shoulder at about 245 nm,[4] which would be ascribed to the *S-cis* isomer which was less stable than the other one.

We have synthesized several *N*-acyl-L-prolines, acetyl-L-proline (AP), isovaleroyl-L-proline (IVP), isobutyroyl-L-proline (IBP), pivaloyl-L-proline (PP) and benzoyl-L-proline (BP) in order to investigate their CD and NMR spectra. The NMR signals assigned to the α-methine proton of L-proline moiety are given in Fig. 1. Two quartet resonances appeared except for PP. They would be ascribed to the two rotational isomers about the amide bond as in the case of MAP. PP, however, showed only one resonance peak at 4.17 ppm even at −30 °C. The Stewart model of PP showed that the *S-cis* conformation could not possibly exist and the resonance peak of the methine proton of PP would correspond to that of the *S-trans* conformer. This suggests that a resonance peak at a higher magnetic field (Fig. 1) should be assigned to the methine proton of the *S-trans* conformer, which was the more predominant of the two conformations.

The equilibrium constant ($K=[S\text{-}trans]/[S\text{-}cis]$) (Table 1) was calculated from the area ratio of the corresponding two resonance peaks (Fig. 1), and tends to increase with the bulkiness of the R group.

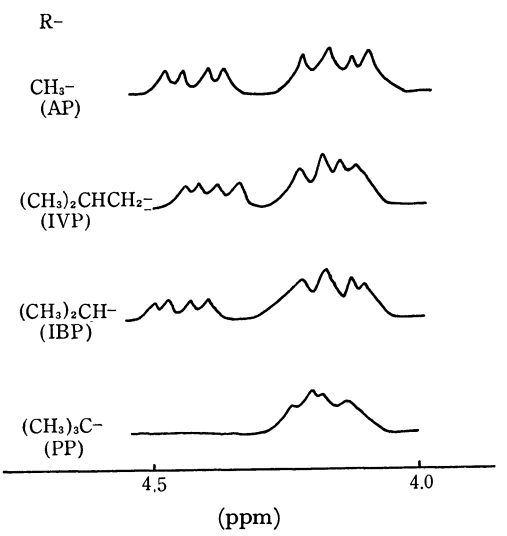


Fig. 1. NMR signal of α-methine proton of *N*-acyl-L-prolines in DMSO-d_6 at 21 °C. Lock; HMDS

TABLE 1. EQUILIBRIUM CONSTANT AND ACTIVATION FREE ENERGY FOR THE TRANSFORMATION BETWEEN *S-cis* AND *S-trans* CONFORMERS (in DMSO-d_6)

Compound	R-	$K\left(=\frac{[S\text{-}trans]}{[S\text{-}cis]}\right)$	$\Delta F^{\neq}_{Tc}$ (kcal/mol)	T_c (K)
AP	CH_3-	2.9	19.0±0.2	365
IVP	$(CH_3)_2CHCH_2$-	3.1	18.6±0.2	361
IBP	$(CH_3)_2CH$-	3.5	18.5±0.2	359
PP	$(CH_3)_3C$-	*a)	—	—

a) *S-trans* only

Temperature dependence of the NMR signals assigned to the α-methine proton of IVP (Fig. 2) shows coalescence between them as well as AP and IBP. The activation free energy for the transformation between the two isomers at the coalescence temperature ($\Delta F^{\neq}_{Tc}$) was caluclated from the NMR data in DMSO-d_6 by

$$\Delta F^{\neq}_{Tc} = 2.303\, RT_c \log \frac{\sqrt{2}\,\kappa k T_c}{\pi \Delta \nu h} \qquad (1)$$

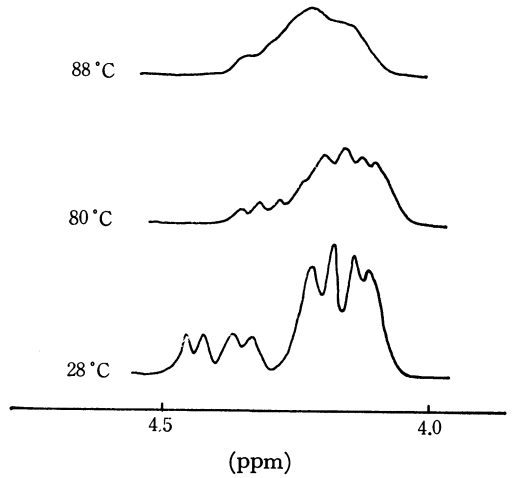

Fig. 2. NMR signal of α-methine proton of IVP in DMSO-d_6. Lock; HMDS

Table 2. Chemical shift of α-methine proton of *N*-acyl-L-prolines from HMDS at 21 °C

Compound	in $CDCl_3$		in DMSO-d_6	
	S-cis	*S-trans*	*S-cis*	*S-trans*
AP	4.37 ppm	4.50 ppm	4.43 ppm	4.15 ppm
IVP	4.42	4.53	4.40	4.17
IBP	4.44	4.51	4.47	4.17
PP	—	4.48	—	4.19
BP	4.22	4.67	4.27	4.37
MAP	4.52	4.53	4.43	4.19

where T_c is the coalescence temperature, $\Delta\nu$ the difference in chemical shift of the α-methine proton of the two isomers, the transmission coefficient κ being assumed to be unity. The $\Delta F^{\neq}_{T_c}$ values suggest that it would not be easy to separate the two isomers from each other.

The chemical shift of α-methine proton of *N*-acyl-L-proline was measured in DMSO-d_6 and $CDCl_3$ at 21 °C. The δ values are shown in Table 2. PP showed only one methine proton signal in both solvents at 21 °C and −30 °C, but the other *N*-acyl-L-prolines showed two methine proton signals in both solvents even at room temperature. The larger of the two methine proton signals was assigned to that of *S-trans* conformer. Thus a methine proton of *S-cis* conformer shows an almost equal δ value in both solvents, but the δ value of methine proton of *S-trans* conformer differed by about 0.35 ppm. It seems that the methine proton of *S-trans* conformer has a larger solvent effect than that of *S-cis* conformer, since the latter would receive a larger steric hindrance by the R group. In the case of BP, however, the methine proton signal of *S-trans* conformer appeared at a lower magnetic field than that of *S-cis* one in both solvents. This might be ascribed to the magnetic anisotropy due to the benzene ring.

The CD spectra of *N*-acyl-L-prolines and L-proline were measured in methanol at 25 °C (Fig. 3). The small CD absorption maximum of L-proline at 220 nm derived from the n–π^* transition of the carboxyl group

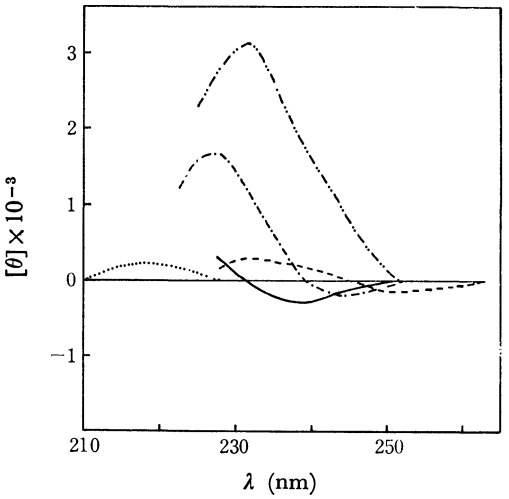

Fig. 3. The CD spectra of AP (——), IVP (----), IBP (—·—), PP (—··—) and L-proline (·····) in methanol at room temperature.

would contribute a negligible effect on the CD curves of *N*-acyl-L-prolines below 225 nm. The CD absorption of the four *N*-acyl-L-prolines over the spectral region from 225 to 255 nm. would be correlated to the n–π^* transition of the amide group. Since the only one conformation of PP was illustrated to be the *S-trans* one by NMR data, the positive CD maximum of PP at 230 nm. would be ascribed to the n–π^* transition of the amide group with *S-trans* conformation. In the case of AP, IVP and IBP which have a *S-cis* conformer together with the *S-trans* conformer, a weak negative absorption maximum appears at 235 to 250 nm. besides a positive absorption maximum around 230 nm. The negative CD maximum, therefore, would be due to the *S-cis* conformer of *N*-acyl-L-proline. The same CD phenomenon as this was found for poly-L-proline.[5,6] The maximum wavelength and sign of the CD maximum of the *trans* isomer was found to differ from those of the *cis* isomer.

The CD spectrum of MAP was measured at 25 °C in methanol.[4] MAP showed a CD curve with a different shape from those of *N*-acyl-L-prolines (Fig. 3).

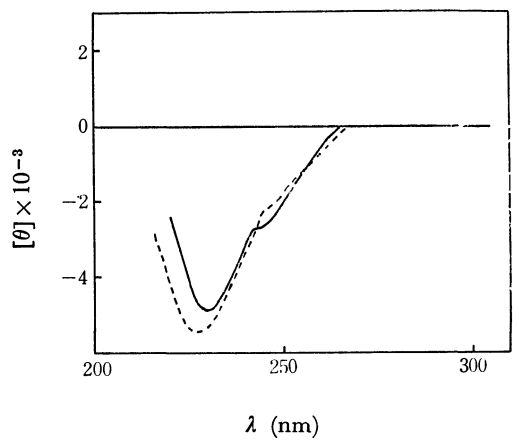

Fig. 4. The CD spectra of BP (——) and MAP (----) in methanol at room temperature.

The former showed a large negative peak centered at 228 nm with a shoulder near 245 nm, while the latter showed a positive peak with a small negative one which appeared at a higher wavelength region. The CD spectrum of BP was similar to that of MAP. Both spectra are shown in Fig. 4. The result will be explained from the fact that both BP and MAP have an α,β-unsaturated carbonyl group.[4,7] They also have two rotational isomers, *S-trans* and *S-cis* conformers as in the case of AP, IVP and IBP, all of which exhibited two CD peaks of opposite sign. Thus, it seems that the sign of the CD maximum of *S-cis* conformer of *N*-acyl-L-proline differs from that of *S-trans* conformer. A shoulder at *ca.* 245 nm appearing in the negative large CD absorption of MAP and BP, would be ascribed to the overlap of a minor positive CD absorption of the *S-cis* conformer on a major negative one of the *S-trans* conformer.

Experimental

N-Acyl-L-prolines were prepared by the reaction of the corresponding acyl chloride with L-proline according to the method of Sakota.[7] Acetyl-L-proline: mp 114.0—115.5 °C, $[\alpha]_D^{24}$ −79.1 ($c=1$, methanol). Isovaleryol-L-proline: mp 70.2—71.9 °C, $[\alpha]_D^{24}$ −81.1 ($c=1$, methanol). Isobutyrol-L-proline: mp 123.0—124.1 °C, $[\alpha]_D^{24}$ −86.7 ($c=1$, methanol). Pivaloyl-L-proline: mp 128.3—129.6 °C $[\alpha]_D^{24}$ −71.9 ($c=1$, methanol). Benzoyl-L-proline: mp 153.9—154.3 °C, $[\alpha]_D^{24}$ −90.9 ($c=1$, methanol).

NMR spectra were recorded with a JEOL Model JNM-4H-100 spectrometer operating at 100 MHz. CD spectra were measured with a JASCO Model ORD/UV5 spectropolarimeter.

Synthesis of Dihydrostreptobiosamine[1]

Sumio UMEZAWA, Hiroshi SANO, and Tsutomu TSUCHIYA

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Kohoku-ku, Yokohama 223

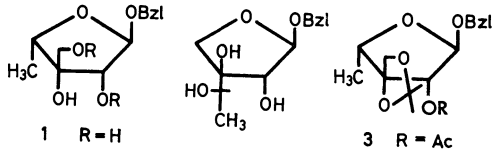
(Received May 28, 1974)

The isopropylidene derivative (**4**) of benzyl dihydrostreptoside and 3,4,6-tri-*O*-acetyl-2-amino-*N*-anisylidene-2-deoxy-α-L-glucopyranosyl bromide (**7**) were prepared, and they were coupled by a modified Koenigs-Knorr condensation. After hydrolysis of the *N*-anisylidene group of the product, *N*-methoxycarbonylation followed by *N*-methylation was accomplished to afford the fully protected derivative (**9**) of dihydrostreptobiosamine, which was, after deblocking, led to benzyl dihydrostreptobiosaminide and dihydrostreptobiosamine.

Dihydrostreptobiosamine is the disaccharide portion of dihydrostreptomycin and obtained[2] by acid hydrolysis of dihydrostreptomycin. In our synthesis of dihydrostreptomycin,[1] the initial objective was the synthesis of dihydrostreptobiosamine, that will be described here in detail.

The syntheses of the individual components of dihydrostreptomycin have been reported by 1965. Dihydrostreptose has been synthesized by Dyer *et al.*[3] and 2-deoxy-2-methylamino-L-glucose, by Folkers and his associates.[4]

Glycosidation of dihydrostreptose[3] or transglycosidation of methyl dihydrostreptosides with benzyl alcohol and hydrogen chloride gave a syrup of benzyl α-dihydrostreptoside (**1**) respectively. Its structure was confirmed by the NMR spectral studies of its diacetyl derivative (**2**), thus excluding a potential rearrangement which may result in the formation of another furanoid compound (**1'**) having the C-3' oxygen atom as a ring oxygen.



The glycosidic linkage between dihydrostreptose and 2-deoxy-2-methylamino-L-glucose is known to be resistant to acid-hydrolysis, however, we found that methanolysis of methyl *N*-methoxycarbonyldihydrostreptobiosaminide, prepared from methyl dihydrostreptobiosaminide[2,5] and methyl chloroformate, was smooth to give methyl α- and β-dihydrostreptoside together with methyl 2-deoxy-2-methoxycarbonylamino-*N*-methyl-L-glucopyranosides.

The glycoside (**1**) was treated with 2,2-dimethoxypropane in *N,N*-dimethylformamide (DMF) in the presence of *p*-toluenesulfonic acid, and the resulting isopropylidene derivative was acetylated with acetic anhydride in pyridine to give the 2-*O*-acetyl-3,3'-*O*-isopropylidene derivative (**3**) in a 50% yield. Isopropylidenation was, therefore, found to occur between hydroxyl groups at C-3 and C-3' in preference to those at C-2 and C-3. The NMR spectrum of **3** revealed the presence of an *O*-acetyl group at C-2. Deacetylation of **3** with sodium methoxide gave **4**. An alternative protection of the hydroxyl groups at C-3 and C-3' with a carbonate group was also found to be successful.[6]

Another key compound for the synthesis of dihydrostreptobiosamine was a fully blocked glycosyl halide of 2-amino-2-deoxy-L-glucose. The 2-amino-2-deoxy-L-glucose has been synthesized from L-arabinose by Kuhn and Kirschenlohr.[7] Incidentally, we have previously reported an improved synthesis[8] of paromamine which is an α-glycoside of 2-amino-2-deoxy-D-glucose. The synthesis of this structurally rather simple antibiotic is characterized by some interesting points such as the formation of α-D-glycosidic linkage and a suitable blocking method for the coupling materials. The Koenigs-Knorr condensation of 3,4,6-tri-*O*-acetyl-2-amino-*N*-anisylidene-2-deoxy-α-D-glucopyranosyl bromide[9] with a protected 2-deoxystreptamine has already been found to give an 85% yield of a mixture of two α-glycosides.

	R_1	R_2
5	H	OH
6	Ac	OAc(β-anomer)
7	Ac	Br (α-anomer)

In analogy to this synthesis, 2-amino-2-deoxy-L-glucose was converted into a Schiff base (**5**) by treatment with anisaldehyde in aqueous ethanol, and, acetylation of the anisylidene derivative with acetic anhydride in pyridine gave the 1,3,4,6-tetra-*O*-acetyl derivative (**6**), which, on treatment with hydrogen bromide–acetic acid in methylene chloride, gave the desired α-glycosyl bromide (**7**). The structure was well defined by the NMR spectrum.

Condensation of **4** with the glycosyl bromide (**7**) in benzene in the presence of mercuric cyanide and Drierite at room temperature was followed by treatment with a mixture of 50% acetic acid and methanol and the crude deanisylidenated product was treated with methyl chloroformate and sodium carbonate in aqueous acetone to give the *N*-methoxycarbonyl disaccharide (**8**) in 42% overall yield from **4**. The NMR spectrum clearly showed that the two components were successfully coupled, and the IR spectrum showed that there occurred no O→N acetyl migration which is sometimes experienced between adjacent amino and acetoxy groups.

Treatment of **8** with methyl iodide and silver oxide in DMF gave the corresponding *N*-methyl derivative (**9**) in a 72% yield. In the NMR spectrum the coupling constant (J 3.3 Hz) indicated an equatorial-axial H-1-H-2 relationship and thus the α-configuration for the 2-amino-2-deoxy-L-glucose moiety.

Deacetylation of **9** with sodium methoxide gave **10**,

and, deisopropylidenation with 2 M hydrochloric acid–methanol (1 : 1) at room temperature gave the benzyl *N*-methoxycarbonyl-α-dihydrostreptobiosaminide (**11**). It was identified with the authentic specimen, which was prepared from benzyl α-dihydrostreptobiosaminide.[10] Treatment of the benzyl α-dihydrostreptobiosaminide with methyl chloroformate readily gave the natural specimen.

Hydrolysis of **11** with aqueous barium hydroxide, followed by neutralization with dilute hydrochloric acid, gave the hydrochloride of benzyl α-dihydrostreptobiosaminide (**12**) in a 48% overall yield from **9**. Finally, hydrogenolysis of the benzyl glycoside (**12**) over palladium black gave dihydrostreptobiosamine (**13**). The IR and NMR spectra of these synthetic benzyl dihydrostreptobiosaminide and dihydrostreptobiosamine were identical with those of the natural specimens,[2,10] respectively, in every respect.

Experimental

Thin layer (tlc) and column chromatography were carried out on silica gel of Silica Rider 5B (Daiichi Pure Chemicals Co., Ltd., Tokyo) and Wakogel C-200 (Wako Pure Chemicals Co., Ltd., Osaka) unless otherwise stated, respectively, and the spots on tlc were visualized with sulfuric acid.

*Benzyl α-Dihydrostreptoside (**1**).* *a) From Dihydrostreptose*: A solution of well dried dihydrostreptose (78 mg) in 2 M hydrogen chloride in benzyl alcohol (4.4 ml) was heated at 50 °C for 40 hr. Basic lead carbonate (1.37 g) was then added and the mixture was stirred for 3 hr. The mixture was filtered and the solid was washed with chloroform. The filtrate and the washings were combined and evaporated to give a yellow oil, which was chromatographed on a column of the silica gel with benzene-ethanol (8 : 1). A colorless syrup (62 mg, 52%) was obtained, $[\alpha]_D^{25}$ −100° (*c* 1, $CHCl_3$).

Found: C, 61.40; H, 7.24%. Calcd for $C_{13}H_{18}O_5$: C, 61.40; H, 7.14%.

NMR (in $CDCl_3$ containing D_2O): τ 8.78 (3H d, *J* 6.6 Hz, CH_3), 6.47 (2H s, CH_2 at C-3′), 5.88 (1H d, 2 Hz, H-2), 5.40 (AB q centered at τ 5.40, *J* 12 Hz, $OCH_2C_6H_5$), 4.98 (1H d, *J* 2 Hz, H-1), 2.68 (5H s).

b) From Methyl α-Didydrostreptoside and Methyl β-Dihydrosteptoside: Methyl α- or β-dihydrostreptoside was treated with benzyl alcohol and hydrogen chloride in a similar manner as described above to give **1** in yields of 50—60%.

Methyl N-Methoxycarbonyldihydrostreptobiosaminide. A solution of methyl dihydrostreptobiosaminide hydrochloride[2,5] (5.20 g) and anhydrous sodium carbonate (1.84 g) in aqueous acetone (1 : 1, 100 ml) was treated with methyl chloroformate (2.65 ml) in a usual manner to give a syrup, 5.15 g (94%), $[\alpha]_D^{24}$ −121° (*c* 1, MeOH).

Found: C, 46.36; H, 7.42; N, 3.17%. Calcd for $C_{16}H_{29}NO_{11}$: C, 46.71; H, 7.11; N, 3.40%.

NMR (in D_2O): τ 8.80 (3H d, CCH_3), 6.98 (3H s, NCH_3), 6.58 (3H s, OCH_3), 6.49 (2H s, CH_2 at C-3′), 6.27 (3H s, CO_2CH_3), 4.95 (2H m, H-1,1′).

Methyl Dihydrostreptosides. A solution of methyl *N*-methoxycarbonyldihydrostreptobiosaminide (44.3 g) in 2 M methanolic hydrogen chloride (720 ml) was refluxed for 64 hr. Basic lead carbonate (223 g) was added and the mixture was stirred for several hours to give pH about 4. Filtration was followed by evaporation under reduced pressure to give an oil, which was chromatographed on a short column of Dowex 50W-X4 (K form) to remove the color impurities accompanied, and then again chromatographed on Dowex 50W-X4 (K form, 6000 ml) with water as eluent to give five fractions. Evaporation of the fractions in turn gave the starting material, methyl α-dihydrostreptoside, methyl 2-deoxy-2-methoxycarbonylamino-*N*-methyl-β-L-glucopyranoside, methyl β-dihydrostreptoside and methyl 2-deoxy-2-methoxycarbonylamino-*N*-methyl-α-L-glucopyranoside, respectively (cited in the order of elution).

Methyl α-Dihydrostreptoside. A syrup, 9.62 g (53%), $[\alpha]_D^{25}$ −111° (*c* 2, $CHCl_3$), R_f 0.39 (tlc with benzene-ethanol 4 : 1); NMR ($CDCl_3$): τ 8.78 (3H d, CCH_3), 6.58 (3H s, OCH_3), 6.44 (2H s, CH_2), 5.10 (1H d, *J* 4.0 Hz, H-1). Found: C, 47.14; H, 7.92%. Calcd for $C_7H_{14}O_5$: C, 47.18; H, 7.92%.

Methyl β-Dihydrostreptoside. A syrup, 1.80 g (10%), $[\alpha]_D^{20}$ +100° (*c* 2, $CHCl_3$), R_f 0.20 (tlc with benzene-ethanol 4 : 1); NMR ($CDCl_3$): τ 8.72 (3H d, CCH_3), 6.53 (3H s, OCH_3), 6.36 (2H s, CH_2), 5.14 (1H d, *J* 4.6 Hz, H-1). Found: C, 46.89; H, 7.84%.

Methyl 2- Deoxy-2- methoxycarbonylamino- N- methyl-α-L-glucopyranoside. A solid, 9.39 g (35%), $[\alpha]_D^{22}$ −143° (*c* 2, MeOH), R_f 0.30 (tlc with benzene-ethanol 4 : 1); NMR (D_2O): τ 7.02 (3H s, NCH_3), 6.58 (3H s, OCH_3), 6.23 (3H s, CO_2CH_3), 5.14 (1H d, *J* 2.1 Hz, H-1). Found: C, 45.18; H, 7.15; N, 5.24%. Calcd for $C_{10}H_{19}NO_7$: C, 45.28; H, 7.22; N, 5.28%.

Methyl 2-Deoxy-2-methoxycarbonylamino-N-methyl-β-L-glucopyranoside. A crystal (from ethanol-ether), 3.59 g (13%), mp 184—185 °C, $[\alpha]_D^{23}$ +19° (*c* 2, MeOH), R_f 0.14 (tlc with benzene-ethanol 4 : 1); NMR (D_2O): τ 7.06 (3H s, NCH_3), 6.43 (3H s, OCH_3), 6.23 (3H s, CO_2CH_3), 5.23 (1H d, *J* 8.0 Hz, H-1). Found: C, 44.90; H, 7.10; N, 5.12%.

Both of the 2-deoxy-2-methylamino-α- and β-L-glucoside derivatives obtained above could be transformed to 2-deoxy-2-methylamino-L-glucose hydrochloride[4] by refluxing them in 6 M hydrochloric acid for 2 hr, respectively, in yield of ~80%, mp 156—161 °C (decomp) (from ethanol).

*Benzyl 2,3′-Di-O-acetyl-α-dihydrostreptoside (**2**).* Compound **1** (178 mg) was treated with acetic anhydride in pyridine in a usual manner to give a syrup, 156 mg (66%), $[\alpha]_D^{21}$ −107° (*c* 2, $CHCl_3$).

Found: C, 60.39; H, 6.33%. Calcd for $C_{17}H_{22}O_7$: C, 60.35; H, 6.55%.

NMR (in $CDCl_3$): τ 8.70 (3H d, CCH_3), 7.92 and 7.87 (each 3H s, Ac), 5.75 (AB q centered at 5.75, *J* 12 Hz, CH_2 at C-3′), 4.87 and 4.78 (each 1H d, H-1 and H-2).

*Benzyl 2-O-Acetyl-3,3′-O-isopropylidene-α-dihydrostreptoside (**3**).* To a solution of **1** (1.26 g) and anhydrous *p*-toluenesulfonic acid (46 mg) in dry DMF (21 ml), 2,2-dimethoxypropane (4.2 ml) was added and the solution was heated at 60 °C for 2.5 hr. The solution was poured into a mixture of saturated sodium hydrogen carbonate solution (100 ml) and benzene (65 ml) under stirring. The aqueous layer was

separated and extracted with benzene (65 ml×2). The combined benzene layer was dried with sodium sulfate, and evaporated to give a syrup (1.4 g). To a solution of the syrup in pyridine (27 ml), acetic anhydride (1.7 ml) was added and the solution was allowed to stand overnight at room temperature. Water (0.3 ml) was added and the solution was poured into water. The mixture was extracted with benzene (70 ml×3). The combined benzene layer was dried over sodium sulfate and evaporated. Chromatography of the resulting syrup on a short column of silica gel with benzene–methyl ethyl ketone (MEK) (30 : 1) gave a syrup, 841 mg (50%), $[\alpha]_D^{25}$ −110° (*c* 2, $CHCl_3$).

Found: C, 64.28; H, 7.22%. Calcd for $C_{18}H_{24}O_6$: C, 64.27; H, 7.19%.

NMR (in $CDCl_3$): τ 8.70 (3H d, CCH_3), 8.64 and 8.59 (each 3H s, isopropylidene), 7.89 (3H s, Ac), 6.13 and 5.69 (each 1H d, J 9.2 Hz, CH_2 at C-3′), 4.93 and 4.82 (each 1H d, J 1.6 Hz, H-1 and H-2).

*Benzyl 3,3′-O-Isopropylidene-α-dihydrostreptoside (**4**).* To a solution of **3** (203 mg), sodium methoxide in methanol was added and the mixture was allowed to stand for 2 hr. After evaporation, the residue was dissolved in benzene (12 ml) and the solution was washed with water, dried over sodium sulfate, and the solvent was removed to give an oil (165 mg, 94%). Tlc with benzene–MEK (20 : 1) gave R_f 0.26, $[\alpha]_D^{18}$ −85° (*c* 1, $CHCl_3$).

Found: C, 65.24; H, 7.28%. Calcd for $C_{16}H_{22}O_5$: C, 65.29; H, 7.53%.

NMR (in $CDCl_3$): τ 8.54 (6H s, isopropylidene), 4.95 (1H d, J∼1 Hz, H-1).

*2-Amino-N-anisylidene-2-deoxy-L-glucose (**5**).* To a solution of 2-amino-2-deoxy-L-glucose hydrochloride (3.21 g) in 1 M sodium hydroxide (15 ml), a solution of anisaldehyde (1.87 ml) in ethanol (3.8 ml) was added and the mixture was stirred at room temperature for 40 min. On seeding, **5** was precipitated as crystals. After storage in a refrigerator overnight, the crystals were filtered and washed with cold water and with a mixture of ethanol–ether (1 : 2), 3.19 g (72%), mp 181—182 °C, $[\alpha]_D^{20}$ −33° (*c* 1, pyridine); IR (KBr): 1610, 1645 cm^{-1}.

Found: C, 56.85; H, 6.43; N, 4.87%. Calcd for $C_{14}H_{19}NO_6$: C, 56.56; H, 6.44; N, 4.71%.

*1,3,4,6-Tetra-O-acetyl-2-amino-N-anisylidene-2-deoxy-β-L-glucopyranose (**6**).* To a suspension of **5** (2.85 g) in ice cold pyridine (14 ml), acetic anhydride (7.46 ml) was added and the mixture was stirred for 1 hr at the temperature. The resulting clear solution was allowed to stand overnight at room temperature and poured into ice-water. Precipitates occurred were filtered and washed with cold water to give a solid of **6**, 3.85 g (86%), mp 187—189 °C, $[\alpha]_D^{24}$ −100° (*c* 1, $CHCl_3$).

Found: C, 56.56; H, 5.77; N, 3.13%. Calcd for $C_{22}H_{27}NO_{10}$: C, 56.77; H, 5.85; N, 3.01%.

NMR (in $CDCl_3$): τ 8.12, 7.98, 7.97, 7.90 (each 3H s, Ac), 6.15 (3H s, OCH_3), 4.02 (1H d, J 8.0 Hz, H-1), 1.81 (1H s, =CH–).

*3,4,6-Tri-O-acetyl-2-amino-N-anisylidene-2-deoxy-α-L-glucopyranosyl Bromide (**7**).* To a suspension of **6** (1.50 g) in dichloromethane (0.7 ml), a saturated solution (2.6 ml) of hydrogen bromide in glacial acetic acid containing 5% acetic anhydride was added and the solution was allowed to stand for 3 hr at room temperature in the dark. A mixture of dry ether (6 ml) and petroleum ether (6 ml) was added to precipitate an oil, which was triturated with the above mixture to give a solid. The solid was dissolved in dichloromethane and washed with an aqueous phosphate buffer (pH 6.8) and then with cold water. After drying over sodium sulfate and then over molecular sieves (3A, Wako Pure Chemicals Co., Ltd., Osaka), the solution was concentrated. Addition of ether deposited some amorphous impurities, which was removed by filtration. Subsequent addition of petroleum ether gave needles, 705 mg (45%), mp 110—111 °C, $[\alpha]_D^{20}$ −194° (*c* 1, $CHCl_3$).

Found: C, 49.35; H, 5.02; N, 2.79, Br, 16.42%. Calcd for $C_{20}H_{24}NO_8Br$: C, 49.40; H, 4.97; N, 2.88, Br, 16.44%.

NMR (in $CDCl_3$): τ 8.12, 7.94, 7.89 (each 3H s, Ac), 3.64 (1H d, J 3.5 Hz, H-1), 1.69 (1H s, =CH–).

*Benzyl 2-O-(3,4,6-Tri-O-acetyl-2-deoxy-2-methoxycarbonylamino-α-L-glucopyranosyl)-3,3′-O-isopropylidene-α-dihydrostreptoside (**8**).* To a solution of well dried **4** (270 mg) in dry benzene (5.1 ml), freshly prepared Drierite (730 mg) was added and the mixture was stirred for 1 hr at room temperature. The glycosyl bromide **7** (723 mg) and well dried mercuric cyanide (705 mg) were added and the mixture was stirred at room temperature for 45 hr. Chloroform (60 ml) was added and the organic layer was filtered and washed with saturated sodium hydrogen carbonate solution and then with water. After drying over sodium sulfate, evaporation of the solvents gave a syrup (826 mg). On tlc with benzene–MEK (7 : 1), the syrup gave a main spot at R_f 0.43.

The syrup was dissolved in a mixture of methanol (34 ml) and 50% acetic acid (14 ml) and the solution was allowed to stand at room temperature for 5 hr. Sodium carbonate (6.3 g) was added and the mixture was concentrated to a small volume (∼15 ml). Addition of acetone (60 ml) gave precipitates, which were filtered off. The filtrate was evaporated to give a syrup. On tlc with benzene–MEK (1 : 1), the syrup gave a main spot at R_f 0.42.

To a solution of the syrup in aqueous 60% acetone (15 ml), sodium carbonate (130 mg×3) and methyl chloroformate (0.16 ml×3) were added at 4 hr intervals with stirring at room temperature. On tlc with benzene–MEK (7 : 1), the mixture gave a main spot at R_f 0.3. The reaction mixture was evaporated, and the resulting syrup was chromatographed on a short column of silica gel with benzene–MEK (7 : 1) to give a syrup of **8**, (248 mg, 42% from **4**); $[\alpha]_D^{24}$ −133° (*c* 0.8, $CHCl_3$); IR (in CH_2Cl_2): 1750, 1725 (shoulder), 1520 cm^{-1}.

Found: C, 56.45; H, 6.21; N, 2.32%. Calcd for $C_{30}H_{41}NO_{14}$: C, 56.32; H, 6.46; N, 2.19%.

NMR (in $CDCl_3$): τ 8.67 (3H d, CCH_3), 8,59 (6H s, isopropylidene), 7.98 and 7.95 (6H s and 3H s, Ac), 6.32 (3H s, CO_2CH_3), 5.36 (AB q, $OC\underline{H}_2C_6H_5$), 2.64 (5H s, C_6H_5).

*Benzyl 2-O-(3,4,6-Tri-O-acetyl-2-deoxy-2-methoxycarbonylamino-N-methyl-α-L-glucopyranosyl)-3,3′-O-isopropylidene-α-dihydrostreptoside (**9**).* To a solution of **8** (168 mg) in dry DMF (2.3 ml), methyl iodide (0.066 ml×4) and silver oxide (80 mg×4) were added at 10 hr intervals and the mixture was stirred at room temperature. Chloroform was added to the reaction mixture and the mixture was filtered. The solution was washed with 5% aqueous sodium cyanide and then with water, and dried over sodium sulfate. Evaporation gave a syrup (167 mg), which was purified by column chromatography on silica gel with benzene–MEK (9 : 1) to give a syrup of **9** (122 mg, 72%), $[\alpha]_D^{20}$ −133° (*c* 1.2, $CHCl_3$); IR (KBr): 1760, 1710 cm^{-1}. The peak at 1520 cm^{-1} in **8** had disappeared.

Found: C, 57.06; H, 6.41; N, 2.33%. Calcd for $C_{31}H_{43}NO_{14}$: C, 56.96; H, 6.63; N, 2.14%.

NMR (in $CDCl_3$): τ 8.73 (3H d, CCH_3), 8.64 (6H s, isopropylidene); 8.01, 7.98, 7.96 (each 3H s, Ac); 7.13 (s, more intense) and 7.09 (s) (3H in total, NCH_3, rotamers;

in pyridine-d_6, the signals collapsed to a singlet at 50 °C), 6.29 (3H s, CO_2CH_3), 4.94 (1H d, J 1 Hz, H-1), 4.86 (1H d, J 3.3 Hz, H-1').

*Benzyl 2-O-(2-Deoxy-2-methoxycarbonylamino-N-methyl-α-L-glucopyranosyl)-3,3'-O-isopropylidene-α-dihydrostreptoside (**10**).* Compound **9** was treated with sodium methoxide in methanol in a similar manner as described for the preparation of **4** to give a syrup in a yield of 99%; $[\alpha]_D^{18}$ −121° (*c* 1.7, $CHCl_3$).

Found: C, 56.84; H, 7.07; N, 2.44%. Calcd for $C_{25}H_{37}NO_{11}$: C, 56.92; H, 7.07; N, 2.65%.

*Benzyl 2-O-(2-Deoxy-2-methoxycarbonylamino-N-methyl-α-L-glucopyranosyl)-α-dihydrostreptoside (**11**).* A solution of **10** (64 mg) in 2 M hydrochloric acid–methanol (1 : 1, 3 ml) was allowed to stand at room temperature for 7.5 hr. After neutralization of the solution with Amberlite IRA-900 (OH form), the solution was evaporated to give a syrup. Recrystallization from methanol-chloroform gave needles (38 mg, 67%), mp 184.5—185 °C, $[\alpha]_D^{18}$ −153° (*c* 2, MeOH); IR (KBr): 1675 cm^{-1}.

Found: C, 53.34; H, 6.81; N, 2.83%. Calcd for $C_{21}H_{33}NO_{11}$: C, 53.05; H, 6.99; N, 2.95%.

NMR (in CD_3OD): τ 8.79 (3H d, CCH_3), 6.92 (3H s, NCH_3), 6.48 (2H s, CCH_2OH), 6.24 (3H s, CO_2CH_3), 4.87 (1H broad s, H-1), 4.78 (1H d, J 3 Hz, H-1').

The melting point of this derivative (**11**) was not depressed by admixture with the specimen derived from natural benzyl dihydrostreptobiosaminide.

*Conversion of Natural Benzyl Dihydrostreptobiosaminide into **11**.* Natural benzyl dihydrostreptobiosaminide hydrochloride[10] was treated with methyl chloroformate and sodium carbonate in a similar manner as described in the preparation of **8** to give **11**; mp 184.5—186 °C, $[\alpha]_D^{22}$ −150° (*c* 1, MeOH).

*Benzyl 2-O-(2-Deoxy-2-methylamino-α-L-glucopyranosyl)-α-dihydrostreptoside Hydrochloride (Benzyl α-Dihydrostreptobiosaminide Hydrochloride) (**12**).* A mixture of **10** (90 mg) and 10% aqueous barium hydroxide (4.5 ml) was heated at 70 °C for 2 hr. Carbon dioxide was introduced and the precipitates were filtered off. The filtrate was evaporated and the residue was dissolved in methanol. After filtration, the solution was again evaporated. The procedure was repeated twice. Neutralization of the final methanol solution with hydrochloric acid followed by evaporation gave a glassy solid (62 mg, 72%), $[\alpha]_D^{20}$ −140° (*c* 1, H_2O) (lit[10], −110°).

Found: C, 51.12; H, 7.02; N, 3.08%. Calcd for $C_{20}H_{31}NO_9 \cdot HCl$: C, 51.56; H, 6.92; N, 3.00%.

NMR (in D_2O): τ 8.70 (3H d, CCH_3), 7.06 (3H s, NCH_3), 4.64 (1H d, J 3 Hz), 4.39 (1H d, J 3.5 Hz), 2.46 (5H s, C_6H_5).

*Dihydrostreptobiosamine (**13**).* To a solution of **12** (67 mg) in water (2 ml), 0.05 ml of acetic acid was added and the solution was hydrogenated with palladium black. The solution was filtered and evaporated to give a solid 41 mg (75%), $[\alpha]_D^{21}$ −104° (*c* 1, H_2O).

Found: C, 44.82; H, 7.32; N, 3.40%. Calcd for $C_{13}H_{25}NO_9 \cdot CH_3CO_2H$: C, 45.11; H, 7.32; N, 3.51%.

NMR (in D_2O): τ 8.78 (d, J 6.7 Hz, more intense than the other) and 8.73 (d, J 6.7 Hz) (3H in total, CCH_3); 8.05 (3H s, Ac), 6.88 (3H, NCH_3), 4.52 (1H d, J 3.7 Hz), 4.34 (1H d, J 3.2 Hz).

Synthesis of Di-*N*-acetyl-di-*N*-benzyloxycarbonyl-*O*-cyclohexylidenestreptidine[1]

Sumio UMEZAWA, Yoshikazu TAKAHASHI, and Tsutomu TSUCHIYA

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Kohoku-ku, Yokohama 223

(Received May 28, 1974)

Reaction of streptidine with excess benzyloxycarbonyl chloride, followed by partial alkaline hydrolysis, gave di-*N*-benzyloxycarbonylstreptidine (**1**), which, by treatment with 3,4-dihydro-2*H*-pyran, gave a tetra-*O*-tetrahydropyranyl derivative (**3**). Acetylation of **3** then gave a di-*N*-acetyl derivative (**4**), which was, after removal of the tetrahydropyranyl groups, allowed to react with 1,1-dimethoxycyclohexane to furnish di-*N*-acetyl-di-*N*-benzyloxycarbonyl-*O*-cyclohexylidenestreptidine (**6**). This is the first preparation of a useful intermediate for the synthesis of streptidine glycosides

Streptidine[2] is the aglycone component of streptomycin and related antibiotics. The gross structure of this strongly basic compound was degradatively established by Carter, Folkers, Wintersteiner, and their coworkers,[3] and, its all-*trans* configuration was confirmed by the total synthesis by Wolfrom *et al.*[4]

For the total synthesis of antibiotics of streptomycin series, glycosidation of streptidine is an inevitable process, however, it has been hindered by the extremely low solubility of streptidine and its ordinary derivatives in organic solvents. Thus, a suitable derivative of streptidine for the Koenigs-Knorr condensation was investigated. In the initial stage of our studies, we prepared *O*-cyclohexylidene-di-*N*-nitro-streptidine* from streptamine by the reaction with *S*-methyl-*N*-nitroisothiourea followed by cyclohexylidenation with 1,1-dimethoxycyclohexane, however, the derivative still showed limited solubility in organic solvents, giving poor yields of glycosides when condensed with some glycosyl halides such as tetra-*O*-benzyl-glucopyranosyl chloride. After some attempts, di-*N*-acetyl-di-*N*-benzyloxycarbonyl-*O*-cyclohexylidenestreptidine (**6**) was found to be useful for the glycosylation. The present paper deals with its synthesis.

Reaction of streptidine sulfate with excess benzyloxycarbonyl chloride and 2 M sodium hydroxide in aqueous dioxane gave a mixture of per-*N*,*O*-benzyloxycarbonylated products, which however gave the di-*N*-benzyloxycarbonylstreptidine (**1**) in a 51% yield on prolonged treatment with a mixture of 2 M sodium hydroxide in dioxane at room temperature. In the formula of **1**, the positions of the benzyloxycarbonyl groups attached to nitrogens remain to be established and thus arbitrarily assigned.

Attempts to prepare tetra-*N*-benzyloxycarbonylstreptidine were unsuccessful because the benzyloxycarbonyl groups further introduced to the guanidino groups were unusually unstable to be hydrolyzed together with *O*-benzyloxycarbonyl groups by weak alkaline treatment. Acetylation of **1** with acetic anhydride and pyridine gave the hexaacetyl derivative (**2**). Its structure was confirmed by the NMR spectrum except for the positions of acetyl and benzyloxycarbonyl groups attached to the nitrogens which had been arbitrarily assigned. All attempts to convert **2** into di-*N*-acetyl-di-*N*-benzyloxycarbonylstreptidine (**5**) by alkaline treatment were unsuccessful.

* Mp 195 °C (decomp.). The details will be published elsewhere.

5	Ac	H

The following route successfully led to **5**. **1** was converted into the tetra-*O*-tetrahydropyranyl derivative (**3**) in a yield of 70% by the treatment with 3,4-dihydro-2*H*-pyran and *p*-toluenesulfonic acid in DMF. Acetylation of **3** with acetic anhydride and pyridine then gave the di-*N*-acetyl derivative (**4**) quantitatively. Removal of the tetrahydropyranyl groups by the treatment with 50% acetic acid at room temperature for 2.5 hr gave **5** in a yield of 56%. This yield was variable according to the reaction conditions and prolonged reaction lowered the yield.

Finally, treatment of the *N*-protected streptidine with 1,1-dimethoxycyclohexane in the presence of *p*-toluenesulfonic acid in DMF furnished the cyclohexylidene derivative (**6**) as a racemate in a yield of 70%.

7	H

An alternative simplified route to **6** from di-*N*-benzyloxycarbonylstreptidine (**1**) involving the reaction sequence of cyclohexylidenation, per-*N*,*O*-acetylation, and selective removal of the *O*-acetyl group was unsuccessful owing to the difficulty of the last selective hydrolysis.

Compound **6** was successfully used for the synthesis of dihydrostreptomycin as described in the successive paper. In this stage we tested for deblocking; on treatment of **6** under weakly alkaline condition, de-*N*-acetylation proceeded smoothly to give **7**, whose benzyloxycarbonyl groups remained intact. Further treatment of **7** with 50% acetic acid followed by hydrogenolysis with palladium black gave streptidine. It should be noted that the first introduced benzyloxycar-

bonyl groups at the guanidino portions are relatively stable to weak alkali, while the next introduced *N*-acetyls are easily removed by weakly alkaline hydrolysis. We were pleased with this demonstration, because, if the *N*-acetyl groups are normally resistant to weak alkali, removal of the benzyloxycarbonyl groups would simultaneously occur and the guanidino groups would be further transformed into ureido groups.

Experimental

Thin layer (TLC) and column chromatography were carried out on silica gel of Silica Rider 5B (Daiichi Pure Chemicals Co., Ltd., Tokyo) and Wakogel C-200 (Wako Pure Chemicals Co., Ltd., Osaka) unless otherwise stated, respectively, and the spots on tlc were visualized with sulfuric acid.

Di-N-*benzyloxycarbonylstreptidine (**1**).* To a suspension of streptidine sulfate (10 g) in aqueous dioxane (2 : 1, 750 ml), 2M sodium hydroxide solution (28 ml) was added under stirring. The mixture was cooled in an ice bath and 2M sodium hydroxide solution (68 ml) and benzyl chloroformate (19 ml) were added all at once under vigorous stirring, and stirring was continued for 10 min under cooling. Another aliquot of 2M sodium hydroxide solution (68 ml) and benzyl chloroformate (19 ml) were added and stirring was continued for 10 min. After neutralization with hydrochloric acid, the reaction mixture was evaporated and the residue was extracted with dimethylformamide (DMF) (100 ml×2). Evaporation of the solvent gave a syrup. On tlc with benzene–methanol (10 : 1), the syrup gave at least seven spots ranging in R_f 0.05—0.9.

To a suspension of the syrup in dioxane (200 ml), 2M sodium hydroxide (17 ml×5) was added at intervals. After 120 hr, the mixture gave, on TLC with benzene–methanol (6 : 1), two spots of R_f 0.05 (**1**) and 0.56 (benzyl-alcohol). The mixture was neutralized with hydrochloric acid and evaporated to give a residue, which was extracted with DMF. The solution was concentrated and, to the concentrate, ether was added to give a yellow solid. The solid was chromatographed on a column of Amberlite CG 50 (NH_4 form) with dioxane–water–1M ammonia (1 : 3 : 0.2) as eluent. The fraction containing **1** was evaporated to give a colorless solid (7.55 g, 51%), mp 216—217 °C (decomp.), R_f 0.46 (tlc with chloroform–ethanol–17% NH_3 (20 : 10 : 1)); IR (KBr): 1530—1680 cm^{-1} (five peaks).

Found: C, 54.00; H, 5.70; N, 15.77%. Calcd for $C_{24}H_{30}N_6O_8$: C, 54.33; H, 5.70; N, 15.84%.

NMR (in DMSO-d_6; the sample was treated three times with D_2O): τ 7—6 (6H, skeleton protons), 4.95 (4H s, $C\underline{H}_2C_6H_5$), 2.6 (10H s, C_6H_5).

Di-N-*acetyl-tetra*-O-*acetyl-di*-N-*benzyloxycarbonylstreptidine (**2**).* To a suspension of **1** (150 mg) in pyridine (1.5 ml), acetic anhydride (0.43 ml) was added and the mixture was stirred at room temperature overnight. Two drops of water were added and the solution was evaporated. Addition of water gave a solid, which was washed throughly with water, 170 mg (77%), mp 210—211 °C; IR(KBr): 1550, 1635 (s), 1710 (w), 1760 cm^{-1}.

Found: C, 55.01; H, 5.45; N, 10.74%. Calcd for $C_{36}H_{42}N_6O_{14}$: C, 55.24; H, 5.41; N, 10.74%.

NMR (in $CDCl_3$): τ 8.07, 8.03, 7.96, 7.81 (3, 6, 3, 6H s respectively, Ac), 5.5—4.9 (2H, C$\underline{H}$NAc (?)), 4.75 (4H s, $C\underline{H}_2C_6H_5$), 4.85—4.45 (4H, C$\underline{H}$OAc (?)), 2.6—2.46 (10H m, C_6H_5).

Di-N-*benzyloxycarbonyl-tetra*-O-*tetrahydropyranylstreptidine (**3**).* A solution of **1** (720 mg), 3,4-dihydro-2*H*-pyran (1.83 ml) and fuse dried *p*-toluenesulfonic acid (600 mg) in DMF (9 ml) was heated at 50 °C overnight. Triethylamine (1.5 ml) was added and the solution was evaporated. A chloroform solution of the residue was washed with sodium hydrogen carbonate solution, and then with water, dried (Na_2SO_4) and concentrated. Petroleum ether was added to give a solid (980 mg), which was chromatographed in a short column of silica gel with chloroform–ethanol–17% ammonia (400 : 32 : 3)), affording a colorless solid, 830 mg (70%), mp 118—119.5 °C, R_f 0.46 (with chloroform–ethanol–17% ammonia (100 : 8 : 1)); IR (KBr): 1540—1660 cm^{-1}.

Found: C, 60.53; H, 7.10; N, 9.31%. Calcd for $C_{44}H_{62}N_6O_{12}$: C, 60.95; H, 7.21; N, 9.69%.

NMR (in $CDCl_3$): τ 8.8—8.1 (24H, $(-CH_2-)_3$ of THP), 6.8—5.8 (14H, $-OCH_2-$ of THP and skeleton protons), 5.4—4.9 (4H, -OCHO- of THP), 4.82 (4H s, $C\underline{H}_2C_6H_5$), 3.5—2.7 (4H, disappeared on deuteration), ~2.6 (10H, C_6H_5).

Di-N-*acetyl-di*-N-*benzyloxycarbonyl-tetra*-O-*tetrahydropyranylstreptidine (**4**).* To a solution of **3** (200 mg) in pyridine (2 ml), acetic anhydride (0.086 ml) was added and the solution was allowed to stand overnight. After addition of a drop of water, the solution was evaporated and the residue was poured into water to give a solid, 214 mg (98%), mp 82—84 °C, R_f 0.41 (tlc with benzene–acetone (8 : 1)); IR (KBr): 1570, 1645 (with fine slight shoulders), 1705(w) cm^{-1}.

Found: C, 60.61; H, 7.04; N, 8.64%. Calcd for $C_{48}H_{66}N_6O_{14}$: C, 60.62; H, 7.00; N, 8.84%.

NMR (in $CDCl_3$): τ 7.80 (6H s, NAc).

Di-N-*acetyl-di*-N-*benzyloxycarbonylstreptidine (**5**).* A solution of **4** (50 mg) in 50% aqueous acetic acid (0.5 ml) was allowed to stand for 2.5 hr. Sodium hydrogen carbonate (360 mg) was added with stirring and water (20 ml) was then added to give colorless solid (27 mg). The solid was chromatographed on a column of silica gel with ethyl acetate–methyl ethyl ketone (4 : 1), affording a solid, 18 mg (56%), mp 114—116 °C, R_f 0.26 (**4** : 0.9) (tlc with chloroform–ethanol (15 : 1)); IR (KBr): 1570, 1640, 1660, 1705(w) cm^{-1}.

Found: C, 55.04; H, 5.68; N, 13.33%. Calcd for $C_{28}H_{34}N_6O_{10}$: C, 54.72; H, 5.58; N, 13.67%.

NMR (in $CDCl_3$): τ 7.84 (6H s, NAc).

Di-N-*acetyl-di*-N-*benzyloxycarbonyl-4,5 (and 5,6)*-O-*cyclohexylidenestreptidine (**6**).* To a solution of **5** (1.50 g) in DMF (30 ml), 1,1-dimethoxycyclohexane (5 ml) and fuse dried *p*-toluenesulfonic acid (230 mg) were added and the solution was heated at 50 °C under reduced pressure (~30 Torr) for 3 hr. Triethylamine (0.5 ml) was added and the solution was evaporated and the residue was dissolved in chloroform. The solution was washed with sodium hydrogen carbonate solution, dried (Na_2SO_4) and evaporated. The residue was chromatographed on a short column of silica gel with benzene–ethyl acetate (2 : 1) and the fraction containing **6** was evaporated and the solid was reprecipitated from chloroform–petroleum ether, 1.18 g (70%), mp 117—118 °C; IR (KBr): 1570, 1640, 1660, 1705 (w) cm^{-1}.

Found: C, 58.41; H, 5.98; N, 11.83%. Calcd for $C_{34}H_{42}N_6O_{10}$: C, 58.78; H, 6.09; N, 12.10%.

NMR (in $CDCl_3$): τ 8.7—8.2 (10H, cyclohexylidene), 7.79 and 7.75 (each 3H s, NAc), 4.84 (4H s, $C\underline{H}_2C_6H_5$), 2.59 (10H s, $CH_2C_6\underline{H}_5$).

Di-N-*benzyloxycarbonyl-4,5 (and 5,6)*-O-*cyclohexylidenestreptidine (**7**).* *(a) From **6**:* To a solution of **6** (45 mg) in acetone (2 ml), 15M aqueous ammonia (1 ml) was added and the solution was allowed to stand for 1 hr. Evaporation of the solution gave a residue, which was dissolved in chloroform. The solution was washed with sodium hydrogen carbonate solution, dried over sodium sulfate and the solvent

was evaporated to give a solid, 31 mg (78%), mp 147—148.5 °C, R_f 0.33 (tlc with benzene–ethanol (10 : 1)).

Found: C, 58.70; H, 6.35; N, 13.55. Calcd for $C_{30}H_{38}N_6O_8$: C, 59.01; H, 6.27; N, 13.76.

NMR (in $CDCl_3$): No peaks assignable to Ac were observed.

(b) From ***1***: Compound **1** was treated similarly as described for the preparation of **6** from **5**. Yield of **7** was 95%.

Recovery of Streptidine from ***7***. A mixture of **7** (35 mg) and 50% acetic acid (1 ml) was heated at 60 °C for 1 hr. The solution was concentrated and ether was added to give a solid, 30 mg, which was dissolved in aqueous dioxane (1 : 1, 3 ml) and, after addition of two drops of acetic acid, the solution was treated with palladium black and hydrogen in a usual manner. The mixture was filtered, concentrated, and an aqueous solution of the residue was passed through a short column of Dowex 1-X2 (Cl form) with water to afford streptidine dihydrochloride (18 mg).

Total Synthesis of Dihydrostreptomycin[1)]

Sumio UMEZAWA, Tetsuro YAMASAKI, Yutaka KUBOTA, and Tsutomu TSUCHIYA

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Kohoku-ku, Yokohama 223

(Received May 28, 1974)

Dihydrostreptomycin has been synthesized from dihydrostreptobiosamine and streptidine. A glycosyl chloride derivative (**10**) of the former was coupled with a protected derivative (**26**) of the latter to give a mixture of four isomeric glycosides, which were separated by chromatography. Deblocking of the desired glycoside led to dihydrostreptomycin. Several other protected derivatives of dihydrostreptobiosamine have also been described.

Streptomycin is the first useful streptomyces antibiotic discovered by Waksman[2)] in 1943. Dihydrostreptomycin[3,4)] is produced by hydrogenation of streptomycin or by fermentation.[5)] Its structure was established by 1948 except for the glycosidic linkage between streptose and streptidine, which was again revised[6,7)] to be α in 1965. We wish here to describe the total synthesis of dihydrostreptomycin in detail as the first synthesis of an antibiotic of streptomycin series.

There appeared to be two possible routes for synthetic approach to dihydrostreptomycin; one of which involves the synthesis of dihydrostreptobiosamine and subsequent coupling of its derivative with protected streptidine, and the other involves the coupling of protected derivatives of dihydrostreptose and streptidine followed by formation of second glycosidic linkage with a protected derivative of 2-deoxy-2-methylamino-L-glucose or 2-amino-2-deoxyl-L-glucose derivative. We chose the former route because the α glycosidic linkage between dihydrostreptose and streptidine is less stable for hydrolytic treatment than that between 2-deoxy-2-methylamino-L-glucose and dihydrostreptose owing to the presence of the methylamino group at C-2 of the latter glycoside moiety. Thus, we have already completed the total synthesis of dihydrostreptobiosamine[1,8)] and the preparation of an appropriate derivative of streptidine.[1,9)]

The next aspect of the synthesis of dihydrostreptomycin was concerned with the preparation of a protected glycosyl halide of dihydrostreptobiosamine. As for a per-*N*,*O*-acylated glycosyl halide of benzyl dihydrostreptobiosaminide,[8)] it was considered to be unfavorable for the deblocking of the condensation product with a streptidine derivative because the guanidino groups are susceptible to alkaline hydrolysis to give urethane. Consequently, the dihydrostreptobiosamine was protected as follows: Treatment of the benzyl α-dihydrostreptobiosaminide (**1**) with 2,2-dimethoxypropane by the usual ketal-exchange procedure[10,11)] gave the diisopropylidene derivative (**2**) in an 81% yield. **2** was further blocked by treatment with *p*-nitrophenyl chloroformate (NPCF) and 1 M sodium hydroxide to give the carbamate (**4**) in a 75% yield, which was alternatively prepared through the intermediate (**3**). We have previously reported[12)] the protecting method of *trans*-vicinal hydroxyl and amino groups. We can confirm the presence of the carbamate ring by an IR absorption band near 1770 cm^{-1}.

In the next step, we faced a problem arising from the isopropylidenated dihydrostreptose moiety, which was labile in the reaction of the anomeric hydroxyl

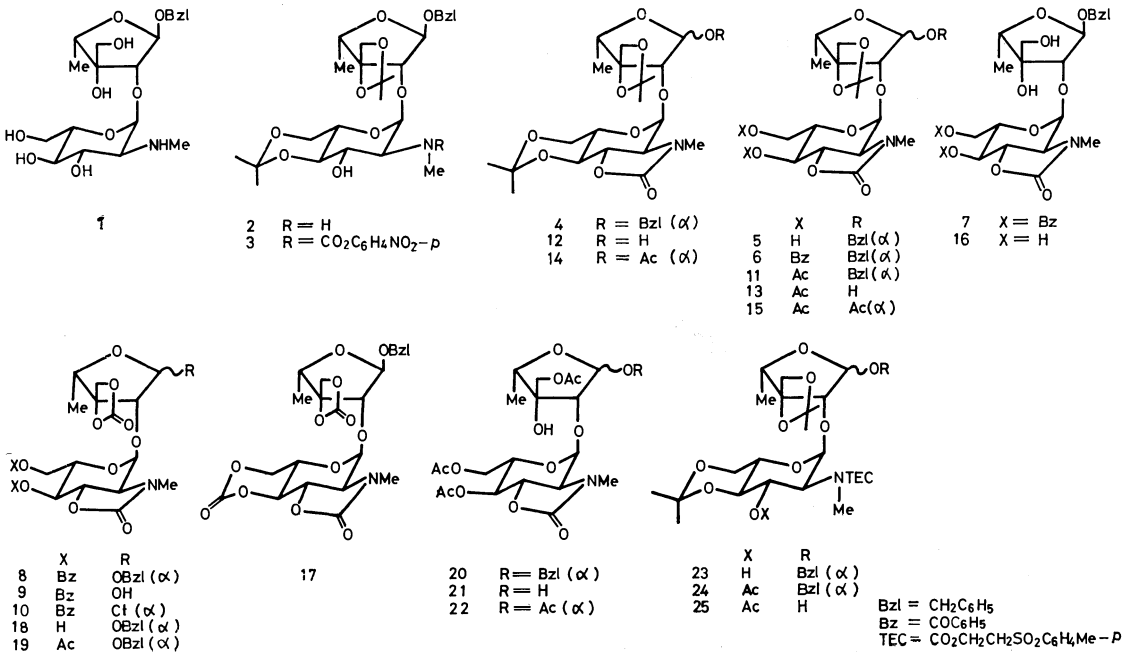

Chart 1.

group with halogenating agents. In a preliminary experiment with a dihydrostreptose derivative, we have observed that transketalization occurred in the chlorination of 2-*O*-acetyl-3,3'-*O*-isopropylidenedihydrostreptose with thionyl chloride. Therefore, we had to take a round-about way as follows: Treatment of **4** with 25% methanolic acetic acid under reflux overnight selectively removed the 4', 6'-*O*-isopropylidene group to give the monoisopropylidene derivative **5** in an 80% yield. This deisopropylidenation was found delicate; when **4** was treated with 50% acetic acid at 70 °C for 4 hr, both of the isopropylidene groups were hydrolyzed to give **16**. The free hydroxyl groups of **5** were then benzoylated to give the dibenzoyl derivative (**6**) in a 90% yield; **6** was found to have larger solubility in benzene. Treatment of **6** with aqueous 75% acetic acid at 70 °C for 6 hr removed the 3,3'-*O*-isopropylidene group to give the diol (**7**) in an 83% yield. When **7** was treated with NPCF in pyridine at room temperatures overnight, the carbonate (**8**) was obtained in a 91% yield. The infrared spectrum of **8** exhibited three distinct carbonyl absorptions for the cyclic carbonate, cyclic carbamate and benzoic esters. Direct treatment of benzyl α-dihydrostreptobiosaminide with NPCF or phosgene followed by benzoylation gave a poor yield of **8.** Hydrogenolysis of the glycosidic linkage of **8** on palladium black in dioxane gave the 1–OH-free disaccharide (**9**) quantitatively. Conversion of **9** into a glycosyl halide was achieved by the thionyl chloride procedure in a usual way. The fully protected glycosyl chloride (**10**) was obtained in a 68% yield. Glycosidation of **10** with benzyl alcohol gave **8** in yield of 59%.

Before proceeding along the main synthetic pathway, we prepared several other derivatives of dihydrostreptobiosamine which were found to be unsatisfactory for the glycoside synthesis.

Acetylation of **5** gave the di-*O*-acetyl derivative (**11**). Hydrogenolysis of **4** and **11** on palladium black gave the free disaccharides **12** and **13**, respectively, and they were respectively acetylated to give the glycosyl acetates, **14** and **15**. However, when the isopropylidene derivatives **14** and **15** were respectively treated with hydrogen bromide in acetic acid, and when **12** and **13** were respectively allowed to react with thionyl chloride, no glycosyl halide was isolated from these reaction products. It is noteworthy that an *N*-anisylidene derivative is useful for C-1 halogenation with hydrogen bromide–acetic acid as described in a preceding paper.[8]

Hydrolysis of **4** or **5** with 50% acetic acid gave the tetrol (**16**), which, on treatment with NPCF, gave the dicarbonate (**17**). When **17** was treated with silica gel in 80% aqueous acetone under reflux, the 4',6'-diol (**18**) was obtained, and this was converted into **8** by benzoylation. Thus, this constitutes an alternative route to **8** which is an intermediate in the main synthetic pathway. Acetylation of **18** gave **19**, which is the diacetyl analog of the above-mentioned useful dibenzoyl derivative (**8**). However, its solubility in organic solvents was still not satisfactory for the further coupling reaction.

Acetylation of **16** gave the triacetate (**20**), which led to the glycosyl acetate (**22**) by way of the free disaccharide (**21**). We have again here experienced that the glycosyl bromide of **21** could not be obtained from **22** by treatment with hydrogen bromide–acetic acid, and that the reaction of **21** with thionyl chloride did not give the glycosyl chloride.

Protection of the methylamino group with (β-*p*-tolylsulfonylethoxy)carbonyl group, which can easily be removed by alkaline hydrolysis,[13] was also studied. Acetylation of the derivative (**23**) gave **24**, which was led to the free disaccharide (**25**) by hydrogenolysis. After reaction with thionyl chloride in pyridine or without pyridine, the glycosyl chloride, which could not be isolated in pure form, was allowed to react with benzyl alcohol in order to test the glycoside formation. However, the benzyl glycoside (**24**) was obtained in a poor yield (13%) only in the presence of pyridine.

Returning to the final stage leading to dihydrostreptomycin, condensation of the glycosyl chloride (**10**) with the protected derivative (**26**)* of streptidine was carried out in anhydrous benzene in the presence of silver carbonate, silver perchlorate, and molecular sieves at 50 °C overnight. Examination of the products by tlc proved the formation of four products, *A*, *B*, *C*, and *D* in their order of mobility. Their separation was accomplished by repeated column chromatography on silica gel. Total yield of the condensation products was 81%. Their IR and NMR spectra respectively supported the structures of these products.

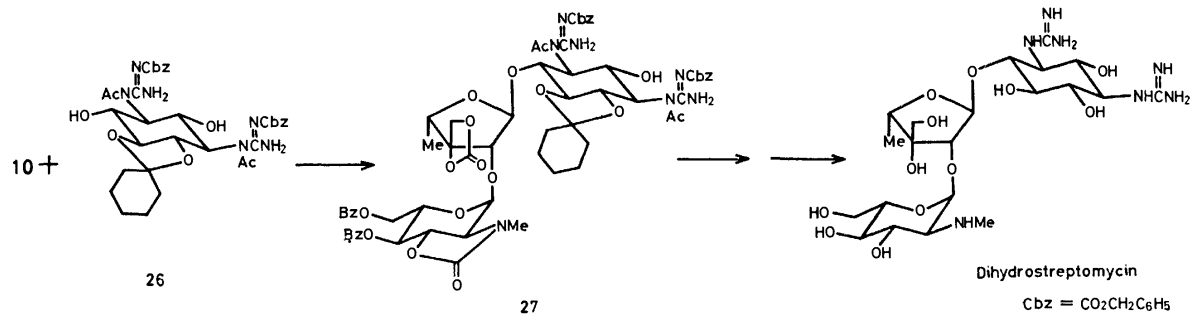

Chart 2.

* The positions of acetyl and benzyloxycarbonyl groups are arbitrarily assigned. See Ref. 9.

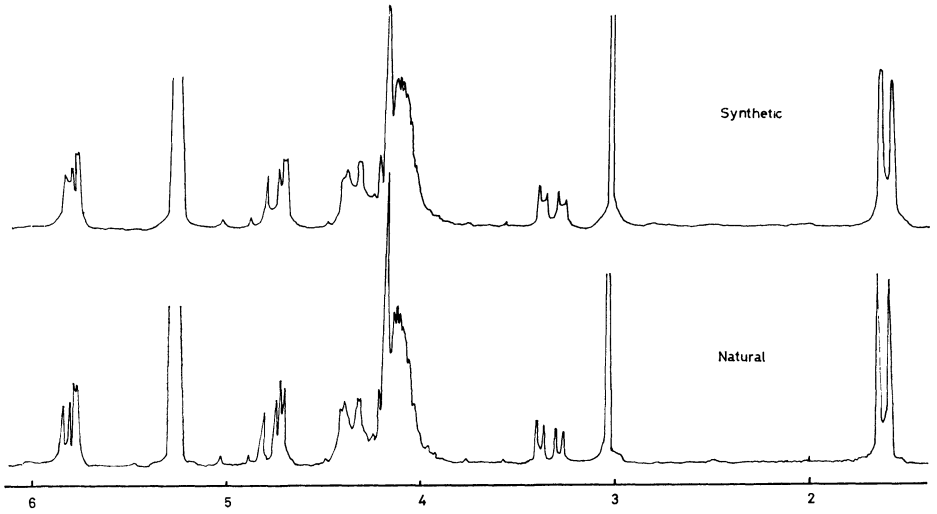

Fig. 1. NMR spectra of natural and synthetic dihydrostreptomycin sesquisulfate (in D_2O at 100 MHz).

Deblocking of the product A (**27**)* led to dihydrostreptomycin. By its treatment with a mixture of 0.025 M barium hydroxide and dioxane at 50 °C, the acetyl, benzoyl, carbonate, and carbamate groups were removed. The remaining cyclohexylidene group was removed by treatment with 50% acetic acid, and the benzyloxycarbonyl groups were removed by hydrogenolysis on palladium black in aqueous dioxane in a usual way to afford dihydrostreptomycin, which was converted into its sesquisulfate. The synthetic dihydrostreptomycin was identical in every respect with natural specimen. The identity was also established by optical rotational shift due to copper complexing ($\Delta[M]_{CuAm}$),[14] specific rotation, IR and NMR spectra (Fig. 1), thin layer and paper chromatographic behavior, paper electrophoresis mobility, and antibacterial spectra (Table 1).

Similar procedures were carried out for deblocking of the other products, *B*, *C*, and *D*, respectively, giving three isomers of dihydrostreptomycin (**29**, **30**, and **31**) which showed no antibacterial activity.

Experimental

General procedure was the same as described in the foregoing paper.

Benzyl 2-O-(2-Deoxy-4,6-O-isopropylidene-2-methylamino-α-L-glucopyranosyl)-3,3'-O-isopropylidenedihydrostreptoside (2). To a solution of the hydrochloride (5.00 g) of **1** in dry DMF, 2,2-dimethoxypropane (8 ml), anhydrous *p*-toluenesulfonic acid (500 mg) and freshly dried Molecular Sieves 5A (30 g, Wako Pure Chem. Ind., Ltd., Osaka) were added, and the mixture was stirred at 60 °C overnight. To the mixture triethylamine (5 ml) was added and the mixture was evaporated. The residue was chromatographed on a short column of silica gel with chloroform–acetone (1 : 1) to give a syrup, 4.90 g (89%), $[\alpha]_D^{18}$ −121° (*c* 0.5, acetone).

Found: C, 61.03; H, 7.60; N, 2.55%. Calcd for $C_{26}H_{39}NO_9$: C, 61.28; H, 7.71; N, 2.75%.

NMR (in $CDCl_3$): δ 1.28 (3H d, $CHCH_3$), 1.42 and 1.50 (9H and 3H s, respectively, isopropylidene), 2.50 (3H s, NCH_3), 5.05 (1H d, J ~1 Hz, H-1), 5.21 (1H d, J 3.5 Hz, H-1').

Benzyl 2-O-[2-Deoxy-4,6-O-isopropylidene-2-(N-methyl-p-nitrophenoxylcarboxamido)-α-L-glucopyranosyl]-3,3'-O-isopropylidenedihydrostreptoside (3). To a solution of **2** (260 mg) in aqueous acetone (1 : 2, 3 ml), triethylamine (60 mg) was added and the solution was cooled to −10 °C. A solution of NPCF (125 mg) in acetone (2 ml) was added and the solution was stirred for 15 min under cooling and at room temperature for additional 2 hr. After addition of triethylamine (70 mg), the solution was evaporated. A solution of the residue in chloroform was washed with saturated sodium hydrogen carbonate solution and with saturated sodium chloride solution, dried over sodium sulfate, and evaporated to give a syrup, 355 mg (98%), $[\alpha]_D^{21}$ −122° (*c* 1, $CHCl_3$); IR (KBr): $\nu_{C=O}$ 1775, 1732 cm^{-1}, ν_{NO_2} 1530, 1350 cm^{-1}.

Found: C, 58.83; H, 6.23; N, 4.11%. Calcd for $C_{33}H_{42}N_2O_{13}$: C, 58.75; H, 6.27; N, 4.15%.

Benzyl 2-O-(2,3-N,O-Carbonyl-2-deoxy-4,6-O-isopropylidene-2-methylamino-α-L-glucopyranosyl)-3,3'-O-isopropylidenedihydrostreptoside (4). To a solution of **2** (1.61 g) in acetone (16 ml) maintained at −10 °C, a cold solution of NPCF (770 mg) in acetone (8 ml) and 1 M aqueous sodium hydroxide (4 ml) were simultaneously added dropwise with stirring. tlc of the reaction mixture with benzene–ether (1 : 1) showed the single spot of **3** at R_f 0.75. An aliquot (4 ml) of the sodium hydroxide solution was added and after standing at −10 °C for 15 min, another aliquot (2 ml) was added and the solution was allowed to stand for further 15 min. On tlc with the above-mentioned solvent system, the spot of R_f 0.75 disappeared and the spot of **4** (R_f 0.55) appeared. After neutralization with 10% acetic acid, the solution was extracted with ether. The ethereal solution was washed with cold 1 M sodium hydroxide until the yellow color of sodium *p*-nitrophenoxide disappeared. The solution was then washed with saturated sodium chloride solution, dried over sodium sulfate, and evaporated. The solid was recrystallized from ether–petroleum ether to give needles, 1.27 g (75%), mp 169—170 °C, $[\alpha]_D^{23}$ −152° (*c* 1, MeOH); IR (KBr): 1770 cm^{-1}.

Found: C, 60.42; H, 6.90; N, 2.60%. Calcd for $C_{27}H_{37}NO_{10}$: C, 60.55; H, 6.96; N, 2.62%.

NMR (in $CDCl_3$): δ 1.28 (3H d), 1.43 and 1.53 (9H and 3H s, respectively, isopropylidene), 2.87 (3H s, NCH_3), 3.37 (1H q, *J* 3 and 11.5 Hz, H-2'), 5.11 (1H d, *J* ~1 Hz, H-1), 5.42 (1H d, *J* 3 Hz, H-1'), 7.32 (5H s, Ph).

Benzyl 2-O-(2,3-N,O-Carbonyl-2-deoxy-2-methylamino-α-L-glycopyranosyl)-3,3'-O-isopropylidenedihydrostreptoside (5). A solution of the diisopropylidene derivative **4** (2.24 g) in 25% acetic acid and methanol (45 ml) was refluxed overnight. The solution was evaporated with toluene to give a solid, which was recrystallized from methanol, 1.75 g (80%), mp 190—190.5 °C, $[\alpha]_D^{23}$ −177° (*c* 1, MeOH); IR (KBr): 1775 cm^{-1}.

Found: C, 58.10; H, 6.78; N, 2.88%. Calcd for $C_{24}H_{33}NO_{10}$: C, 58.17; H, 6.71; N, 2.83%.

NMR (in pyridine-d_5): δ 1.40 (6H s, isopropylidene).

Benzyl 2-O-(4,6-Di-O-benzoyl-2,3-N,O-carbonyl-2-deoxy-2-methylamino-α-L-glucopyranosyl)-3,3'-O-isopropylidenedihydrostreptoside (6). A sample of **5** (1.17 g) was treated with benzoyl chloride and pyridine to give a syrup, which was chromatographed on silica gel (50 g) with chloroform to yield a solid, 1.30 mg, (90%), mp 78—81 °C, $[\alpha]_D^{18}$ −145° (*c* 1, $CHCl_3$); IR (KBr): 1775, 1725 cm^{-1}.

Found: C, 64.59; H, 5.83; N, 1.90%. Calcd for $C_{38}H_{41}NO_{12}$: C, 64.87; H, 5.87; N, 1.99%.

Benzyl 2-O-(4,6-Di-O-benzoyl-2,3-N,O-carbonyl-2-deoxy-2-methylamino-α-L-glucopyranosyl)dihydrostreptoside (7). A sample of **6** (1.20 g) was treated with 75% acetic acid at 70 °C for 6 hr, and the reaction mixture was evaporated. To the resulting syrup was added toluene and the mixture was again evaporated to remove the remaining acetic acid. The residue was chromatographed on a silica gel with benzene–ethyl acetate (1 : 1) to yield a solid, 937 mg (83%), $[\alpha]_D^{18}$ −177° (*c* 1, $CHCl_3$).

Found: C, 63.63; H, 5.67; N, 1.95%. Calcd for $C_{35}H_{37}NO_{12}$: C, 63.14; H, 5.61; N, 2.11%.

Benzyl 2-O-(4,6-Di-O-benzoyl-2,3-N,O-carbonyl-2-deoxy-2-methylamino-α-L-glucopyranosyl-3,3'-O-carbonyldihydrostreptoside (8).

a) From 7. To a solution of **7** (830 mg) in pyridine (20 ml), NPCF (800 mg) was added and the solution was stirred at room temperature overnight. The solution was filtered and, to the filtrate, methanol (1 ml) was added. After standing for 30 min, the solution was evaporated. To the residue was added toluene and the mixture was again evaporated. The residue was chromatographed on a short column of silica gel (40 g) with benzene–ethyl acetate (1 : 2) to give a solid, 798 mg (91%), $[\alpha]_D^{18}$ −145° (*c* 1, $CHCl_3$); IR (KBr): $\nu_{C=O}$ 1815 (carbonate), 1715 (cyclic carbamate), 1725 cm^{-1} (ester).

Found: C, 62.88; H, 5.30; N, 1.91%. Calcd for $C_{36}H_{35}NO_{13}$: C, 62.69; H, 5.12; N, 2.03%.

NMR (in $CDCl_3$): δ 1.40 (3H d, $CHC\underline{H}_3$), 2.91 (3H s, NCH_3), 3.57 (1H q, *J* 3 and 11.5 Hz, H-2'), 5.32 (1H d, *J* ~2 Hz, H-1), 5.33 (1H d, *J* 3 Hz, H-1'), 5.70 (1H t, *J* 10 Hz, H-4').

b) From 18. Treatment of **18** with benzoyl chloride and pyridine in a usual manner gave **8** in yield of 95%.

2-O-(4,6-Di-O-benzoyl-2,3-N,O-carbonyl-2-deoxy-2-methylamino-α-L-glucopyranosyl)-3,3'-O-carbonyldihydrostreptose (9). A solution of **8** (798 mg) in dioxane (20 ml) was hydrogenated (50 psi) with palladium black (prepared from 2 g of palladium chloride), and the product was chromatographed on a 30 g of silica gel with chloroform–acetone (4 : 1) to give a solid, 681 mg, (98%), mp 150 °C, $[\alpha]_D^{18}$ −95° (*c* 1, $CHCl_3$); IR (KBr): 1820, 1775, 1730 cm^{-1}.

Found: C, 58.38; H, 5.07; H, 2.19%. Calcd for $C_{29}H_{29}NO_{13}$: C, 58.10; H, 4.88; N, 23.3%.

2-O-(4,6-Di-O-benzoyl-2,3-N,O-carbonyl-2-deoxy-2-methylamino-α-L-glucopyranosyl)-3,3'-O-carbonyldihydrostreptosyl Chloride (10). A solution of **9** (200 mg) in thionyl chloride (2.0 ml) was allowed to stand at room temperature for 3 hr, and evaporated under reduced pressure (<1 Torr). The residue was dissolved in a mixture of benzene and ethyl acetate (1 : 1, dried over Molecular Sieves 4A). The solution was evaporated to give a syrup, which was chromatographed on 10 g of silica gel (activated at 260 °C *in vacuo* for 5 hr) by elution with dry benzene–ethyl acetate (1 : 1). The product was reprecipitated from dry benzene–*n*-hexane, 141 mg (68%), mp 114—116 °C (decomp), $[\alpha]_D^{20}$ −170° (*c* 1, $CHCl_3$); IR (KBr): 1820, 1770, 1725 cm^{-1}.

Found: C, 55.96; H, 4.59; N, 1.95; Cl, 5.89%. Calcd for $C_{29}H_{28}NO_{12}Cl$: C, 56.36; H, 4.57; N, 2.27; Cl, 5.74%.

NMR (in $CDCl_3$): δ 1.43 (3H d), 2.94 (3H s), 5.32 (1H d, *J* 3 Hz, H-1'), 5.70 (1H t, H-4'), 6.28 (1H d, *J* ~1 Hz, H-1).

Formation of 8 from 10. A mixture of **10** (48 mg), benzyl alcohol (14 mg), and Molecular Sieves 3A (200 mg) in dry benzene (1 ml) was stirred at room temperature for 3 hr. When checked by tlc, hardly any progress of reaction was observed. Freshly prepared and well dried (at 120 °C) silver carbonate (180 mg) and silver perchlorate (20 mg) were added and the mixture was vigorously stirred at room temperature for 2 hr. The reaction mixture was filtered with the aid of benzene and the filtrate was evaporated. The residue was chromatographed on a short column of silica gel with benzene–ethyl acetate (2 : 1) to give a solid, 31 mg (59 %). Its optical rotation and IR and NMR spectra were identical with those of authentic **8**.

Benzyl 2-O-(4,6-Di-O-acetyl-2,3-N,O-carbonyl-2-deoxy-2-methylamino-α-L-glucopyranosyl)-3,3'-O-isopropylidenedihydrostreptoside (11). A sample of **5** was treated with acetic anhydride and pyridine at room temperature overnight and worked up to give a solid in 98% yield, mp 53—56 °C, $[\alpha]_D^{20}$ −176° (*c* 1, MeOH); IR (KBr): 1750, 1780 cm^{-1}.

Found: C, 57.83; H, 6.53; N, 2.39%. Calcd for $C_{28}H_{37}NO_{12}$: C, 58.02; H, 6.43; N, 2.42%.

NMR (in $CDCl_3$): δ 2.05 and 2.10 (each 3H s, Ac).

2-O-(2,3-N,O-Carbonyl-2-deoxy-4,6-O-isopropylidene-2-methylamino-α-L-glucopyranosyl)-3,3'-O-isopropylidenedihydrostreptose (12). A solution of **4** (1.48 g) in dioxan–methanol (1 : 5, 12 ml) was treated with palladium black and hydrogen (50 psi) at

room temperature overnight to yield a syrup, which was reprecipitated from chloroform–*n*-hexane (1 : 3). The solid was chromatographed on silica gel with chloroform–acetone (1 : 1) to give needles, 887 mg (85%), which was recrystallized from chloroform–*n*-hexane, mp 188—190 °C, $[\alpha]_D^{20}$ −113° (*c* 1, $CHCl_3$); IR (KBr): 1765 cm^{-1}.

Found: C, 54.24; H, 6.92; N, 3.22%. Calcd for $C_{20}H_{31}NO_{10}$: C, 53.93; H, 7.02; N, 3.14%.

2-O-(4,6-Di-O-acetyl-2,3-N,O-carbonyl-2-deoxy-2-methylamino-α-L-glucopyranosyl)-3,3′-O-isopropylidenedihydrostreptose (**13**). Compound **11** was hydrogenated by a method similar to that described for the preparation of **12** from **4**. Mp 185—186 °C, $[\alpha]_D^{20}$ −108° (*c* 1, EtOAc); IR (KBr): 1750, 1780 cm^{-1}.

Found: C, 51.66; H, 6.12; N, 2.85%. Calcd for $C_{21}H_{31}NO_{12}$: C, 51.54; H, 6.38; N, 2.87%.

1-O-Acetyl-2-O-(2,3-N,O-carbonyl-2-deoxy-4,6-O-isopropylidene-2-methylamino-α-L-glucopyranosyl)-3,3′-O-isopropylidenedihydrostreptose (**14**). A sample of **12** (887 mg) was treated with acetic anhydride and pyridine and the product was recrystallized from chloroform–*n*-hexane to give crystals, 783 mg (81%), mp 247—250 °C (decomp), $[\alpha]_D^{21}$ −130° (*c* 1, $CHCl_3$).

Found: C, 54.01; H, 6.88; N, 2.80%. Calcd for $C_{22}H_{33}NO_{11}$: C, 54.20; H, 6.82; N, 2.87%.

NMR (in $CDCl_3$): δ 1.30 (3H d, *J* 6.5 Hz, $CHC\underline{H}_3$), 1.43 and 1.52 (9H and 3H s, respectively, isopropylidene), 2.07 (3H s, Ac), 2.84 (3H s, NCH_3), 5.36 (1H d, *J* 3 Hz, H-1′), 6.13 (1H d, *J* 1.5 Hz, H-1).

1-O-Acetyl-2-O-(4,6-di-O-acetyl-2,3-N,O-carbonyl-2-deoxy-2-methylamino-α-L-glucopyranosyl)-3,3′-O-isopropylidenedihydrostreptose (**15**). A sample of **13** was acetylated by a method to that similar described for the preparation of **14** from **12**. Mp 137—138 °C, $[\alpha]_D^{21}$ −142° (*c* 1, $CHCl_3$).

Found: C, 51.73; H, 6.21; N, 2.37%. Calcd for $C_{23}H_{33}NO_{13}$: C, 51.97; H, 6.26; N, 2.64%.

NMR (in $CDCl_3$): δ 2.10 and 2.13 (6H and 3H s, respectively, Ac), 6.14 (1H d, *J* ~1 Hz, H-1).

Benzyl 2-O-(2,3-N,O-carbonyl-2-deoxy-2-methylamino-α-L-glucopyranosyl)dihydrostreptoside (**16**). A solution of **4** (1.00 g) in 50% aqueous acetic acid (20 ml) was heated at 70 °C for 4 hr. Toluene was added and the solution was evaporated. The residue was recrystallized from methanol–ether, 632 mg (74%), mp 199—202 °C, $[\alpha]_D^{20}$ −186° (*c* 1, MeOH); IR (KBr): 1760 cm^{-1}.

Found: C, 55.30; H, 6.34; N, 3.12%. Calcd for $C_{21}H_{29}NO_{10}$: C, 55.38; H, 6.42; N, 3.07%.

Benzyl 3,3′-O-Carbonyl-2-O-(2,3-N,O-carbonyl-4,6-O-carbonyl-2-deoxy-2-methylamino-α-L-glucopyranosyl)dihydrostreptoside (**17**). A sample of **16** was treated with NPCF by a method similar to that described for the preparation of **8** from **7**. On monitoring with tlc with benzene–acetone (2 : 1), the spot of **16** (R_f 0.1) gradually disappeared and two spots of R_f 0.17 and 0.46 (dicabonyl derivatives) appeared. Finally there appeared only one spot of **17** (R_f 0.55). The crude product was recrystallized from acetone–benzene, yielding **17** in 40% yield, mp 269—272 °C (decomp), $[\alpha]_D^{17}$ −120° (*c* 1, acetone); IR (KBr): 1800, 1765 cm^{-1}.

Found: C, 54.39; H, 4.93; N, 2.82%. Calcd for $C_{23}H_{25}NO_{12}$: C, 54.44; H, 4.97; N, 2.76%.

Compound **17** is soluble in acetone, scarcely soluble in methanol, ethyl acetate, and chloroform and insoluble in benzene and ether.

Benzyl 3,3′-O-Carbonyl-2-O-(2,3-N,O-carbonyl-2-deoxy-2-methylamino-α-L-glucopyranosyl)dihydrostreptoside (**18**). To a solution of **17** (100 mg) in 80% aqueous acetone (2 ml), silica gel (1.0 g) was added and the mixture was refluxed for 2 hr. The mixture was filtered and the filtrate was evaporated to give a solid, which was recrystallized from acetone–*n*-hexane, 86 mg (90%), mp 196—197 °C, $[\alpha]_D^{25}$ −160° (*c* 1, MeOH), IR; 1805, 1775 cm^{-1}.

Found: C, 54.61; H, 5.62; N, 2.73%. Calcd for $C_{22}H_{27}NO_{11}$: C, 54.88; H, 5.65; N, 2.90%.

Conversion of **18** *into* **8**. A sample of **18** was treated with benzoyl chloride, pyridine, and triethylamine, and worked up in a usual way. The product was reprecipitated from benzene–*n*-hexane to give **8**, quantitatively, which was identical with the specimen prepared from **7**.

Benzyl 2-O-(4,6-Di-O-acetyl-2,3-N,O-carbonyl-2-deoxy-2-methylamino-α-L-glucopyranosyl)-3,3′-O-carbonyldihydrostreptoside (**19**). A sample of **18** was treated with acetic anhydride and pyridine in a usual manner to yield **19** (80%), $[\alpha]_D^{21}$ −150° (*c* 1, $CHCl_3$); IR (KBr): 1815, 1765, 1740 cm^{-1}.

Found: C, 55.35; H, 5.62; N, 2.42%. Calcd for $C_{26}H_{31}NO_{13}$: C, 55.21; H, 5.53; N, 2.48%.

NMR (in $CDCl_3$): δ 2.05 and 2.11 (each 3H s, Ac).

Benzyl 3′-O-Acetyl-2-O-(4,6-di-O-acetyl-2,3-N,O-carbonyl-2-deoxy-2-methylamino-α-L-glucopyranosyl)dihydrostreptoside (**20**). A sample of **16** was treated with acetic anhydride and pyridine and worked up to give a solid of **20** in 98% yield, which was reprecipitated from ethyl acetate–*n*-hexane, mp 35—36 °C, $[\alpha]_D^{18}$ −149° (*c* 1, MeOH); IR (KBr): 1750, 1775 cm^{-1}.

Found: C, 55.49; H, 6.02; N, 2.40%. Calcd for $C_{27}H_{35}NO_{13}$: C, 55.76; H, 6.07; N, 2.41%.

NMR (in $CDCl_3$): δ 2.03, 2.08, and 2.11 (each 3H s, Ac).

3′-O-Acetyl-2-O-(4,6-di-O-acetyl-2,3-N,O-carbonyl-2-deoxy-2-methylamino-α-L-glucopyranosyl)dihydrostreptose (**21**). A sample of **20** was dissolved in methanol and hydrogenated with palladium black in a usual manner to give **21**, quantitatively, mp 170—172 °C, $[\alpha]_D^{20}$ −103° (*c* 1, MeOH); IR (KBr): 1780, 1745 cm^{-1}.

Found: C, 49.07; H, 5.98; N, 2.75%. Calcd for $C_{20}H_{29}NO_{13}$: C, 48.88; H, 5.95; N, 2.85%.

1,3′-Di-O-acetyl-2-O-(4,6-di-O-acetyl-2,3-N,O-carbonyl-2-deoxy-2-methylamino-α-L-glucopyranosyl)dihydrostreptose (**22**). A sample of **21** was treated with acetic anhydride and pyridine to give **22**, quantitatively, mp 152—153 °C, $[\alpha]_D^{20}$ −128° (*c* 1, $CHCl_3$); IR (KBr): 3600 (sharp), 1780, 1740 cm^{-1}.

Found: C, 49.58; H, 5.77; N, 2.66%. Calcd for $C_{22}H_{31}NO_{14}$: C, 49.53; H, 5.86; N, 2.62%.

Benzyl 2-O-[2-Deoxy-4,6-O-isopropylidene-2-(N-methyl-β-(p-toluenesulfonyl)ethoxycarboxamido)-α-L-glucopyranosyl]-3,3′-O-isopropylidenedihydrostreptoside (**23**). To an ice-cold solution of **2** (2.00 g) in tetrahydrofuran (15 ml), ice-cold sodium hydrogen carbonate solution (600 mg in 15 ml water) and β-(*p*-toluenesulfonyl)ethyl chloroformate[13] (1.4 g) in acetone (15 ml) were added and the mixture was stirred at room temperature for 2 hr. Evaporation of the mixture gave a syrup, which was dissolved in chloroform. The solution was washed with water, dried with anhydrous sodium sulfate and evaporated to give a syrup. The syrup was chromatographed on a short column of silica gel with chloroform–ether (1 : 1) to give a solid, 2.39 g (83%); $[\alpha]_D^{13}$ −91° (*c* 0.4, $CHCl_3$); IR (KBr): 1700 cm^{-1}.

Found: C, 58.73; H, 6.54; N, 1.90%. Calcd for $C_{36}H_{49}NO_{13}S$: C, 58.76; H, 6.71; N, 1.98%.

Benzyl 2-O-[3-O-Acetyl-2-deoxy-4,6-O-isopropylidene-2-(N-methyl-β-(p-toluenesulfonyl)ethoxycarboxamido)-α-L-glucopyranosyl]-3,3′-O-isopropylidenedihydrostreptoside (**24**). A sample of **23** (2.28 g) was treated with acetic anhydride in pyridine at room temperature overnight. The reaction mixture was poured into cold water (5 ml) and then the mixture was evaporated. The residue was stirred with a mixture of water (200 ml) and chloroform (100 ml). The aqueous layer was separated and extracted with chloroform. The chloroform

layers were combined, washed with saturated aqueous solution of potassium hydrogen sulfate, dried over magnesium sulfate and evaporated to give a solid in 90% yield, $[\alpha]_D^{13}$ −74° (*c* 1, $CHCl_3$); IR (KBr): 1753, 1705 cm^{-1}.

Found: C, 58.82; H, 6.51; N, 2.11; S, 4.05%. Calcd for $C_{38}H_{51}NO_{14}S$: C, 58.67; H, 6.61; N, 1.80; S, 4.12%.

NMR (in $CDCl_3$): δ 1.26 (3H d, *J* 6.5 Hz, $CHC\underline{H}_3$), 1.31, 1.35, 1.36, and 1.45 (each 3H s, isopropylidene), 2.03 (3H s, Ac), 2.44 (3H s, $C\underline{H}_3Ph$), 2.75 (~1.8 H s) and 2.94 (~1.2H s) (both NCH_3, rotamers), 5.02 (1H d, *J* ~1 Hz, H-1), 5.09 (1H d, *J* 3.5 Hz, H-1').

*2-O-[3-O-Acetyl-2-deoxy-4,6-O-isopropylidene-2-(N-methyl-β-(p-toluenesulfonyl)ethoxycarboxamido)-α-L-glucopyranosyl]-3,3'-O-isopropylidenedihydrostreptose (**25**).* A sample of **24** (1.70 g), dissolved in dioxane (10 ml), was treated with palladium black and hydrogen in a usual manner. The product was purified by chromatography on a short column of silica gel by elution with chloroform–ether (1 : 1) to yield **25**, 827 mg (55%), $[\alpha]_D^{21}$ −57° (*c* 1, $CHCl_3$); IR (KBr): 1750, 1705 cm^{-1}.

Found: C, 54.03; H, 6.45; N, 1.72; S, 4.89%. Calcd for $C_{31}H_{45}NO_{14}S$: C, 54.13; H, 6.60; N, 2.04; S, 4.66%.

*Formation of **24** from **25**.* A sample of **25** (100 mg) was dissolved in a mixture (0.5 ml) of thionyl chloride, dry benzene, and dry pyridine (0.25 : 10 : 0.31 by volume), Molecular Sieves 3A was added and the mixture was allowed to stand at room temperature for 1 hr. A solution (0.5 ml) of benzyl alcohol in benzene (3 : 100) was added and the mixture was allowed to stand at room temperature overnight. Saturated sodium hydrogen carbonate solution and chloroform were added with stirring and the organic layer was washed with water, dried over sodium sulfate and evaporated to give a syrup, which was chromatographed on a column of silica gel by elution with benzene–MEK (10 : 1) to give **24** (15 mg, 13%). The IR and NMR spectra of the product was quite superimposable on those of authentic **24** prepared from **23**.

*Condensation of **10** with **26**.* To a solution of **26** (1.20 g) in dry benzene (30 ml; dried over $LiAlH_4$ and distilled before use) was added freshly prepared and well dried silver carbonate (3.6 g), well dried silver perchlorate (0.4 g) and Molecular Sieves 3A (dried at 250 °C) and the mixture was stirred at room temperature overnight in the dark. The glycosyl chloride **26** (1.60 g) was added and the mixture was stirred at 50 °C overnight in the dark. The mixture was filtered with the aid of chloroform and the filtrate was evaporated. On tlc with benzene–chloroform–ethanol–concentrated ammonium hydroxide (50 : 50 : 4 : 0.5) (Solvent A), the residue gave four spots other than those of starting materials **10** and **26** and **9** derived from **10**. The condensation products were designated **A**, **B**, **C**, and **D** in their order of mobility. The chromatography of the residue on a column of silica gel (100 g) with Solvent A afforded fractions containing **A**+**B** (434 mg), **C** (669 mg), and **D** (730 mg); total yield 81%. The first fraction was further chromatographed three times on a column of silica gel (20 g) with benzene–90% ethanol (25 : 1) to give **A** and **B**. The second fraction **C** was further purified by chromatography on silica gel (35 g) with Solvent A. The third fraction **D** was also further chromatographed on silica gel (40 g) with chloroform–90% ethanol (10 : 1). Each product, which is chromatographically homogeneous was reprecipitated from benzene–petroleum ether to give **A** (196 mg, 11% based on **26**), **B** (85 mg), **C** (371 mg), and **D** (416 mg; still containing a trace of impurity).

A: $[\alpha]_D^{23}$ −70° (*c* 2, $CHCl_3$); IR (KBr): 1810, 1775, 1725, 1640, 1570 cm^{-1}; NMR (in $CDCl_3$): δ 1.29 (3H d, $CHC\underline{H}_3$), 1.6 (10H broad, cyclohexylidene), 2.07 and 2.20 (each 3H s, Ac), 2.83 (3H s, NCH_3).

Found: C, 59.29; H, 5.58; N, 7.85%. Calcd for $C_{61}H_{69}N_7O_{22}$: C, 59.29; H, 5.45; N, 7.68%.

B: $[\alpha]_D^{22}$ −70° (*c* 2, $CHCl_3$); IR: Almost identical with that of **A**; NMR (in $CDCl_3$): δ 1.24 (3H d), 1.45 (10H), 2.15 (6H s), 2.87 (3H s).

Found: C, 59.13; H, 5.51; N, 7.45%.

C: $[\alpha]_D^{22}$ −8° (*c* 2, $CHCl_3$); IR: Almost identical with that of **A**; NMR (in $CDCl_3$): δ 1.27 (3H d), 1.6 (10H), 2.10 and 2.21 (each 3H s), 2.85 (3H s).

Found: C, 59.21; H, 5.45; N, 7.42%.

D: $[\alpha]_D^{22}$ −10° (*c* 2, $CHCl_3$); IR: Almost identical with that of **A**; NMR (in $CDCl_3$): δ 1.30 (3H d), 1.58 (10H), 2.15 and 2.22 (each 3H s), 2.90 (3H s).

Found: C, 58.88; H, 5.49%.

*Deblocking of the Condensation Products. a) Deblocking of **A**.* To a solution of compound **A** (120 mg) in dioxane (20 ml), 0.025 M barium hydroxide (8 ml×4) was added at 1 hr intervals and the mixture was heated at 50 °C for 3 hr. Carbon dioxide was introduced and the precipitate was filtered off. The filtrate was evaporated and the residue was chromatographed on a column of silica gel with chloroform–ethanol–17% ammonia (20 : 10 : 1) to give a solid (**28**, 38 mg, 44%). In the NMR spectrum of **28**, peaks attributable to the carbobenzoxy and cyclohexylidene groups were observed, and peaks corresponding to acetyl and benzoyl groups disappeared. Additionally, in the IR spectrum of **28**, no trace of the carbonyl absorptions of acetyl, benzoyl, carbonate, and carbamate groups was observed.

Next, a solution of **28** (38 mg) in 50% acetic acid (2 ml) was heated at 60 °C overnight and evaporated. The residue was dissolved in a mixture of water and dioxane (2 : 1) and the solution was hydrogenated (50 psi) with palladium black (about 0.3 ml) at room temperature overnight. The mixture was filtered, and the filtrate was evaporated. The residue was chromatographed on 20 ml of Amberlite CG-50 (NH_4 form) with 5% ammonium carbonate to give a solid (18 mg). An aqueous solution of the solid was passed through a column of Dowex 1×2 (OH form) with water to give the free base of dihydrostreptomycin, which was transformed into its sesquisulfate by neutralizing with sulfuric acid, 14 mg (48%), $[\alpha]_D^{17}$ −85° (*c* 0.1, H_2O); natural specimen: $[\alpha]_D^{17}$ −85° (*c* 0.1, H_2O) [lit,[15] $[\alpha]_D^{25}$ −88.5° (*c* 1, H_2O); $\Delta[M]_{436(CuAm)}^{10}$ −1200°; natural specimen: $\Delta[M]_{436(GuAm)}^{17}$ −1170° [lit,[16] dihydrostreptomycin: $\Delta[M]_{436(CupraB)}$ −1180°].

Found: C, 33.50; H, 6.52; N, 12.37%. Calcd for $C_{21}H_{41}N_7O_{12}\cdot 3/2H_2SO_4\cdot 3/2H_2O$: C, 33.29; H, 6.25; N, 12.94%.

*b) Deblocking of **B**, **C**, and **D**.* Compounds **B**, **C**, and **D** were respectively treated in the same way as described above for **A** to give sesquisulfates **29**, **30**, and **31** respectively.

29: $[\alpha]_D^{17}$ −88° (*c* 0.1, H_2O); $\Delta[M]_{436(CuAm)}^{17}$ +320°.
30: $[\alpha]_D^{17}$ −35° (*c* 0.1, H_2O); $\Delta[M]_{436(CuAm)}^{17}$ +580°.
31: $[\alpha]_D^{17}$ −35° (*c* 0.1, H_2O); $\Delta[M]_{436(CuAm)}^{17}$ −3200°.

The authors are grateful to Professor Hamao Umezawa of The University of Tokyo and of the Institute of Microbial Chemistry for his important ideas and encouragement.

Synthesis of (3*S*, 4*S*)- and (3*S*, 4*R*)-4-Amino-3-hydroxy-6-methylheptanoic Acid, and Their *N*-(Acetyl-L-valyl-L-valyl) Derivatives

Mitsuhiro KINOSHITA, Akito HAGIWARA, and Shinpei ABURAKI

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Kohoku-ku, Yokohama 223

(Received May 30, 1974)

Natural (−)(3*S*,4*S*)-4-amino-3-hydroxy-6-methylheptanoic acid (**10a**) present in pepstatins, specific inhibitors of acid proteases, and its (+)(3*S*,4*R*) diastereomer (**10b**) were synthesized starting from 3-deoxy-1,2-*O*-isopropylidene-α-D-*erythro*-pentodialdo-1,4-furanose (**1**) through highly stereoselective and stereospecific routes. The partial peptide of pepstatin Ac, *N*-(acetyl-L-valyl-L-valyl)-(3*S*,4*S*)-4-amino-3-hydroxy-6-methylheptanoic acid (**15a**) and its (3*S*,4*R*) diastereomer (**15b**) were synthesized *via* azide-coupling of the *t*-butyl esters of **10a** and **10b** with acetyl-L-valyl-L-valine azide, respectively. Compound **15a** inhibited proteolysis by pepsin, however, the diastereomer **15b** showed no inhibition against pepsin.

A new amino acid, (−)4-amino-3-hydroxy-6-methylheptanoic acid[1b](abbreviated (−)AHMHA) which has been isolated from the hydrolyzates of all kinds of pepstatins,[1a–1e] specific inhibitors of acid proteases, was first synthesized together with its (−)diastereomer from L-leucine by Morishima *et al.*[2] Recently, we reported in a communication[3] that the natural (−) AHMHA was identical with (3*S*,4*S*)AHMHA (**10a**), through stereospecific syntheses of all four diastereomers of AHMHA from the appropriate deoxy-sugar derivatives. The synthetically determined absolute configuration 3(*S*), 4(*S*) of natural (−)AHMHA was consistent with the result of the X-ray diffraction study on the natural amino acid which was independently performed by Nakamura *et al.*[4]

The recent studies on pepstatin by Umezawa *et al.*[5,6] have revealed the interesting relationships between the structures of pepstatins and some partial peptides containing natural (−)AHMHA and their inhibition activities against acid proteases. In connection with these studies, it was considered to be important to evaluate the stereochemical effect concerning to the 4(*S*) configuration of natural AHMHA, which may play its role in the enzyme-inhibition activity in the peptide chains of pepstatins or their partial peptides. This paper presents the details of the previously reported synthesis[3] of natural (−) (3*S*,4*S*)AHMHA(**10a**) and its diastereomer (+)(3*S*, 4*R*)AHMHA(**10b**), and the preparation of *N*-(acetyl-L-valyl-L-valyl)-(3*S*,4*S*)AHMHA(**15a**) which is a partial peptide of pepstatin Ac,[1c,1e] and its diastereomer, *N*-(acetyl-L-valyl-L-valyl)-(3*S*,4*R*)AHMHA (**15b**).

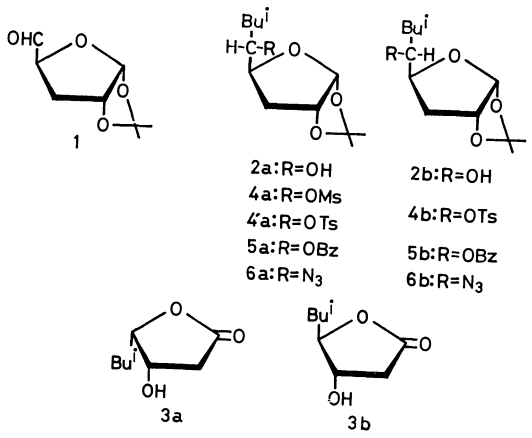

Chart 1.

For the purpose of the stereospecific synthesis of the natural (3*S*,4*S*)AHMHA(**10a**) and its diastereomer (3*S*,4*R*)AHMHA (**10b**), two kinds of diastereomeric deoxy-sugar derivatives, *i.e.*, 3-deoxy-5-*C*-isobutyl-1,2-*O*-isopropylidene-β-L-*lyxo*-pentofuranose(**2a**) and 3-deoxy-5-*C*-isobutyl-1,2-*O*-isopropylidene-α-D-*ribo*-pentofuranose(**2b**) were selected as the starting materials.

The Grignard reaction of 3-deoxy-1,2-*O*-isopropylidene-α-D-*erythro*-pentodialdo-1,4-furanose[7] (**1**) with isobutylmagnesium bromide in ether yielded a crude crystalline addition product (91% yield), which was recrystallized from petroleum ether to afford the pure isomer **2a** in a 67% yield. The 5(*S*) configuration of **2a** was confirmed by the fact that hydrolysis of **2a** followed by oxidation with periodate-hypoiodite[8] gave (3*S*,4*S*)-3,4-dihydroxy-6-methylheptanoic acid-1,4-lactone(**3a**), the 4(*S*) configuration of which was determined by application of Hudson's lactone rule[9] on the rotational change ($\Delta[\alpha]_D^{MeOH}$ (Lactone−potassium salt)=−36 °) of **3a** measured by Witkop's method.[10]

In the following fashion it was ascertained that the Grignard reaction product contained the diastereomer (**2b**) of **2a** as a minor product and that in this case the Grignad reaction was highly stereoselective (about 91%). The minor product **2b** which was concentrated in the mother liquor of the recrystallization of the Grignard reaction product could be isolated in a form of its 5-*O*-benzoyl derivative(**5b**) which was easily separable by silica gel chromatography from the isomeric 5-benzoate(**5a**).

The compound **2a** was converted with methylsulfonyl chloride in pyridine to 5-mesylate (**4a**), which was treated with sodium benzoate in dimethylformamide (DMF) at 140 to 150 °C to afford **5b** in a 52% yield. De-*O*-benzoylation of **5b** with sodium methoxide in methanol gave **2b** in an 81% yield. The 5(*R*) configuration of **2b** was confirmed by the same procedure as that in the case of **2a**; hydrolysis of **2b** followed by oxidation gave (3*S*,4*R*)-3,4-dihydroxy-6-methylheptanoic acid-1,4-lactone(**3b**) which showed a rotational change $\Delta[\alpha]_D^{MeOH}$ +24 °. Compounds **2a** and **2b** could not be separated by tlc in any of the solvent systems examined. The PMR spectra of **2a** and **2b** were apparently distinguishable in the region at δ 3.63 to 4.40, which contains the signals attributed to C–4 and C–5 protons.

Treatment of 5-tosylate (**4b**) prepared from **2b** with sodium azide in DMF at 90 to 97 °C gave 5-azido-3,5-dideoxy-5-*C*-isobutyl-1,2-*O*-isopropylidene-β-L-*lyxo*-pentofuranose (**6a**) as a sole product in an 85% yield. The configuration of C–5 in **6a** was assumed to be "S" because a facile S_N2 displacement of the 5-tosyloxy group by azide ion would proceed under the similar condition to that for the S_N2 reaction of the 5-mesyloxy group in **4a** by benzoate ion. Based on the same principle, the isomeric 5-tosylate **4'a** was treated with sodium azide in DMF at 87 to 95 °C to afford the epimeric (5*R*)-azido compound (**6b**) in an 81% yield.

Hydrolysis of **6a** with 50% aqueous acetic acid, followed by oxidation with sodium periodate gave (3*S*,4*S*)-4-azido-3-formyloxy-6-methylheptanal (**7a**) as a practically pure syrup in a 96% yield. In the same manner the compound **6b** afforded the isomeric aldehyde (**7b**) in a 98% yield.

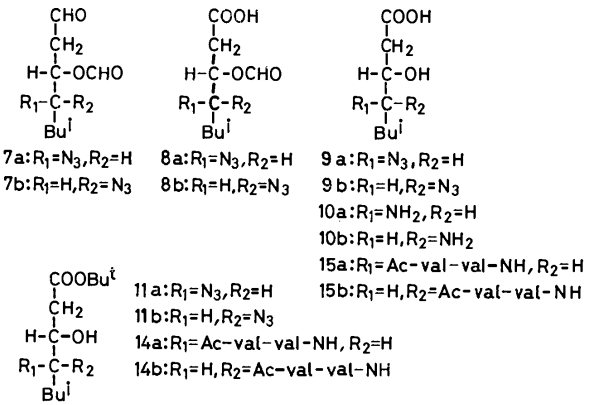

Chart 2.

Oxidations of **7a** and **7b** with a solution of chromium trioxide in acetic acid and pyridine[11] at room temperature afforded (3*S*,4*S*)-4-azido-3-formyloxy-6-methylheptanoic acid (**8a**) and its isomer **8b** as colorless syrup in 76% and 63% yields, respectively. De-*O*-formylations of **8a** and **8b** with dilute hydrogen chloride in aqueous dioxane at room temperature gave the corresponding azido hydroxy acids, **9a**(syrup) and **9b**(crystal) in 72% and 58% overall yields from **7a** and **7b**, respectively. The diastereomeric **9a** and **9b** were stable and their structures were confirmed by elemental analyses, IR, and PMR spectroscopy. By the use of the chromium trioxide solution, instead of the hypoiodite reagent which was previously used[3] the yields of the synthetic steps, **7a**→**9a** and **7b**→**9b** were remarkably improved (about twice).

Hydrogenolysis of **9a** on palladium black in methanol gave (−)(3*S*,4*S*)-4-amino-3-hydroxy-6-methylheptanoic acid (**10a**) in a 93% yield. The synthetic amino acid **10a** was proved to be identical with natural (−)AHMHA by mixture mp, optical rotation, PMR, IR, and high performance liquid chromatography. Hydrogenolysis of **9b** gave the diastereomeric (+)(3*S*,4*R*)AHMHA (**10b**, 81% yield), whose high performance liquid chromatogram showed a single peak having a longer elution time than that of **10a**.

The modified azide coupling according to Rudinger[12] between the free amino acid **10a** and *N*-acetyl-L-valyl-L-valine azide yielded only a small amount of condensation product, *N*-(acetyl-L-valyl-L-valyl)-(3*S*,4*S*)AHMHA (**15a**), probably because of poor solubility of **10a** in DMF. From this result it was decided to use *t*-butyl ester of **10a** for the azide coupling reaction.

t-Butylations of **8a** and **8b** with isobutene and a catalytic amount of sulfuric acid in dichloromethane, followed by de-*O*-formylations with sodium hydroxide in aqueous dioxane afforded the isomeric azidohydroxy acid *t*-butyl esters, **11a** and **11b** in 57% and 58% yields, respectively. Hydrogenolysis of **11a** on palladium black gave *t*-butyl ester of **10a** in quantitative yield, which was immediately coupled with the acid azide prepared from *N*-acetyl-L-valyl-L-valine hydrazide (**13**) by the Rudinger modification to afford *N*-(acetyl-L-valyl-L-valyl)-(3*S*,4*S*)AHMHA *t*-butyl ester (**14a**) in a 74% yield. Treatment of **14a** with trifluoroacetic acid yielded **15a** in a 94% yield. In the same method, the *t*-butyl ester **10b** prepared from **11b** was coupled with the acid azide. Resulting peptide ester (**14b**, 75%) was de-*t*-butylated to give the isomeric peptide (**15b**, 93%).

The synthetic partial peptide **15a**, which contains natural AHMHA, inhibited proteolysis of pepsin at the concentration of 6 μg/ml, in contrast, the diastereomeric peptide **15b** showed no inhibition against pepsin even the high concentration of 250 μg/ml. From this results it is noteworthy that the enzyme-inhibitory activities of pepstatins and their partial peptides may be reflected by the (*S*) configuration of the 4-amino group of AHMHA present in their peptide chains.

Experimental

Melting points were determined on a Mitamura Riken micro hot-stage and uncorrected. IR spectra were taken on a Hitachi IPI-2 spectrometer. PMR spectra were recorded on a Varian A-60D and HA-100D spectrometers using TMS as internal and external standards. Specific rotations were determined with a Zeiss Photoelectric Precision Polarimeter. TLC was performed on WAKOGEL B-5 and silica gel column chromatography on WAKOGEL C-200 which was activated at 110 °C for 1 hr. The following solvent systems were used: A_1 [benzene-ethyl acetate (12 : 1)], A_2[*ibid.* (50 : 1)], A_3[*ibid.* (3 : 1)], A_4[*ibid.* (1 : 1)], B_1[hexane-ethyl acetate (6 : 1)], B_2[*ibid.* (20 : 1)], B_3[*ibid.* (30 : 1)], B_4[*ibid.* (10 : 1)], C[hexane-acetone (6 : 1)], D_1 [hexane-butanone-acetic acid (10 : 1 : 0.17)], D_2[*ibid.* (20 : 2 : 1)], E_1[Chloroform-methanol (30 : 1)] E_2[*ibid.* (20 : 1)], F[chloroform-methanol-acetic acid (80 : 10 : 1)] and G [butanol-ethanol-chloroform-17% aqueous ammonia (7 : 3 : 3 : 3)]. High performance liquid chromatography (HPLC) was carried out on a Waters Associates Liquid Chromatograph ALC 201(RI-Detector) employing an Aminex A-7 (Bio-Rad) column (2.2×600 mm) with 0.1 M pyridine-acetate buffer (pH 5.00) in a flow rate of 0.1 ml/min at 95 °C. In general, all concentrations were carried out under reduced pressure below 40 °C

*1) 3-Deoxy-5-C-isobutyl-1,2-O-isopropylidene-β-L-lyxo-pentofuranose (**2a**).* A solution of 3-deoxy-1,2-*O*-isopropylidene-α-D-*erythro*-pentodialdo-1,4-furanose[7] (**1**) (5.28 g, 31 mmol) in dry ether (240 ml) was added dropwise with stirring over a period of 10 min to an ether solution of iso-

butylmagnesium bromide prepared from magnesium turnings (6.01 g, 247 mmol) and isobutyl bromide (26.6 ml, 247 mmol) in dry ether (100 ml). The mixture which was stirred for 40 min at room temperature, was decomposed with cold water (200 ml), and neutralized with ice-cooled 10% sulfuric acid. The aqueous layer was extracted with ether (200 ml×4). The combined ether layers were washed with saturated aqueous NaCl, dried (Na_2SO_4), and evaporated to afford a crystalline solid (6.40 g, 91%). Recrystallization from petroleum ether gave pure material (**2a**): yield 4.70 g (67%), mp 62.5—63.0 °C, $[\alpha]_D^{19}$ −33° (*c* 1.86, chloroform), δ ($CDCl_3$), 0.93 and 0.95 (each d, $(CH_3)_2CH$, J=6.4 Hz], 1.33 and 1.52 [each s, $(CH_3)C$], 3.63 (dq, H-5, $J_{5,6}$=9.0 Hz, $J_{5,6}$=4.0 Hz), 4.20 (quintet, H-4, $J_{4,5}$=5.2 Hz, $J_{3,4}$=10.2 Hz, $J_{3',4}$=5.2 Hz), 4.82 (dt, H-2, $J_{2,3}$=3.9 Hz, $J_{2,3'}$=~0.5 Hz), and 5.90 (d, H-1, $J_{1,2}$=3.8 Hz).

Found: C, 62.73; H, 9.45%. Calcd for $C_{12}H_{22}O_4$: C, 62.58; H, 9.63%.

*2) 5-O-Benzoyl-3-deoxy-5-C-isobutyl-1,2-O-isopropylidene-β-L-lyxo-pentofuranose (**5a**).* Benzoyl chloride (0.11 ml, 0.94 mmol) was added to a solution of **2a** (108 mg, 0.47 mmol) in pyridine (1 ml), and the mixture was kept at room temperature overnight. It was then diluted with ice-cooled water (6 ml) and extracted with chloroform (3 ml×4). The chloroform extracts were washed successively with saturated aqueous $KHSO_4$ (10 ml), saturated aqueous $NaHCO_3$ (5 ml), and saturated aqueous NaCl (10 ml), dried and evaporated. The syrupy residue (154 mg) immediately crystallized: recrystallization from ether afforded the pure benzoate **5a** (127 mg, 81%); mp 108.5—109 °C, $[\alpha]_D^{13}$ −43° (*c* 2.28, chloroform).

Found: C, 68.56; H, 7.94%. Calcd for $C_{19}H_{26}O_5$: C, 68.24; H, 7.84%.

*3) 3-Deoxy-5-C-isobutyl-1,2-O-isopropylidene-5-O-methanesulfornyl-β-L-lyxo-pentofuranose (**4a**).* To a solution of **2a** (2.64 g, 11.6 mmol) in dry pyridine (26.4 ml) was added methyl-sulfonyl chloride (1.8 ml, 23.2 mmol) and the mixture was set aside overnight at room temperature. Workup in the same manner as described in Exp. 2 afforded a practically pure sample of 5-mesylate **4a** (3.66 g, 100%) as a pale yellow syrup. Silica gel column chromatography of the sample (85 mg) with the solvent A_1 gave an analytical sample of **4a** (72 mg, 85%) as a colorless syrup: $[\alpha]_D^{13}$ −49° (*c* 2.7, chloroform).

Found: C, 50.30; H, 7.70; S, 10.56%. Calcd for $C_{13}H_{24}O_6S$: C, 50.63; H, 7.84; S, 10.40%.

*4) 3-Deoxy-5-C-isobutyl-1,2-O-isopropylidene-5-O-p-toluenesulfonyl-β-L-lyxo-pentofuranose (**4'a**).* Tosylation of **2a** was performed in a usual manner to afford **4'a** as a colorless syrup in a 80% yield: $[\alpha]_D^{13}$ −32° (*c* 2.1 chloroform).

Found: C, 59.51; H, 7.33; S, 8.17%. Calcd for $C_{19}H_{28}O_6S$: C, 59.35; H, 7.34; S; 8.34%.

*5) 5-O-Benzoyl-3-deoxy-5-C-isobutyl-1,2-O-isopropylidene-α-D-ribo-pentofuranose (**5b**).* A solution of **4a** (764 mg, 2.48 mmol) in DMF (55 ml) containing sodium benzoate (1.07 g, 7.43 mmol) was heated at 140—150 °C for 2 hr; tlc (solvent B_1) then revealed the absence of **4a**. The precipitare deposited was filtered off and washed with ethyl acetate. The filtrate and washings were diluted with cold water (100 ml) and was extracted with ethyl acetate (50 ml×3). The combined extracts were washed with saturated aqueous NaCl (30 ml×2), dried and evaporated. The syrupy residue (808 mg) was purified through a silica gel column (120 g, 3×40 cm) with the solvent B_2 to afford a pure sample of **5b** (405 mg, 52%): $[\alpha]_D^{21}$ +13° (*c* 1.31, chloroform).

Found: C, 67.99; H, 7.83%. Calcd for $C_{19}H_{26}O_5$: C, 68.24; H, 7.84%.

*6) 3-Deoxy-5-C-isobutyl-1,2-O-isopropylidene-α-D-ribo-pentofuranose (**2b**).* To a solution of **5b** (900 mg, 2.7 mmol) in dry methanol (4.5 ml) was added 1.32 M methanolic sodium methoxide (4.07 ml, 5.4 mmol) and the mixture was kept for 5 hr at room temperature. An excess of sodium methoxide was neutralized with 20% acetic acid; the solution was evaporated and the residue was extracted with chloroform (20 ml×3). The extracts were washed with saturated aqueous NaCl (20 ml×2), dried and evaporated to give a crystalline mass (620 mg) wihch was recrystallized from petroleum ether: yield of pure **2b** 500 mg (81%), mp 56—57 °C, $[\alpha]_D^{15}$ —4° (*c* 1.38, chloroform), δ ($CDCl_3$), 0.92 and 0.95 [each d, $(CH_3)_2CH$, J=6.3 Hz], 1.33 and 1.52 [each s, $(CH_3)_2C$], 3.8—4.4 (m, H-4 and H-5), 4.80 (dq, H-2, $J_{2,3}$=6.0 Hz, $J_{2,3'}$=0.7 Hz) and 5.89 (d, H-1, $J_{1,2}$=3.8 Hz).

Found: C, 62.27; H, 9.45%. Calcd for $C_{12}H_{22}O_4$: C, 62.58; H, 9.63%.

*7) 3-Deoxy-5-C-isobutyl-1,2-O-isopropylidene-5-O-p-toluenesulfonyl-α-D-ribo-pentofuranose (**4b**).* The tosylation of **2b** was performed in a usual manner to afford **4b** as a colorless syrup: $[\alpha]_D^{15}$ −1° (*c* 1.0, chloroform).

Found: C, 59.47; H, 7.28; S, 8.49%. Calcd for $C_{19}H_{28}O_6S$: C, 59.35; H, 7.34; S, 8.34%.

*8) (3S,4S)-3,4-Dihydroxy-6-methylheptanoic Acid-1,4-lactone (**3a**).* Treatment of **2a** (202 mg) with 20% acetic acid at 120 °C for 20 min gave a syrup of 3-deoxy-5-*C*-isobutyl-L-lyxo-pentose (165 mg). The free sugar was dissolved in acetone (3 ml) and to the solution was added a solution of sodium metaperiodate (645 mg) in water (6.3 ml). After standing at room temperature for 20 min, the precipitate was filtered off and acetone was removed from the filtrate by evaporation. The aqueous layer was extracted with chloroform and the extract was dried and evaporated to afford a syrup (165 mg), which was immediately subjected to the next oxidation reaction. To a solution of the product (163 mg) in dioxane (4 ml) and water (1.6 ml) was added a solution of K_2CO_3 (855 mg) and $KHCO_3$ (618 mg) in water (6 ml) and then a solution of iodine (730 mg) and KI (912 mg) in water (0.8 ml), and the mixture was stirred for 1 hr. The excess of iodine was reduced with solid sodium thiosulfate and then the solution was neutralized with 10% sulfuric acid, extracted with ether (10 ml×3), and the extracts were washed with saturated aqueous NaCl, dried and evaporated. The residual syrup (81 mg) was purified by silica gel chromatography with the solvent C to afford a pure sample of **3a** a colorless liquid: yield 31 mg (23%). Optical rotation in methanol; $[\alpha]_D$ −81°, $[\alpha]_{436}$ −167°, and $[\alpha]_{365}$ −266° (*c* 1.12, 21 °C). Optical rotation in methanol-0.1 M aqueous KOH (1 : 1 vol); $[\alpha]_D$ −45°, $[\alpha]_{436}$ −89°, and $[\alpha]_{365}$ −130° (*c* 0.56, 21 °C). IR: $\nu_{max}^{CCl_4}$ 3480 (OH) and 1775 cm^{-1} (γ-lactone).

Found: C, 60.71; H, 8.79%. Calcd for $C_8H_{14}O_3$: C, 60.74; H, 8.92%.

*9) (3S,4R)-3,4-Dihydroxy-6-methylheptanoic Acid-1,4-lactone (**3b**).* The title compound **3b** was obtained from **2b** (176 mg) in the same procedure as described in Exp. 8; colorless liquid, yield 49 mg (42%). Optical rotation in methanol; $[\alpha]_D$ +41°, $[\alpha]_{436}$ +76°, and $[\alpha]_{365}$ +105° (*c* 1.73, 18 °C). Optical rotation in methanol-0.1 M aqueous KOH (1 : 1 vol); $[\alpha]_D$ +17°, $[\alpha]_{436}$ +34°, and $[\alpha]_{365}$ +57° (*c* 0.87, 18 °C). IR; $\nu_{max}^{CCl_4}$ 3480 (OH) and 1775 cm^{-1} (γ-lactone).

Found: C, 60.57; H, 8.73%. Calcd for $C_8H_{14}O_3$: C, 60.74; H, 8.92%.

10) Isolation of the Minor Product ***2b*** *produced in the Grignard Reaction of* ***1*** *with Isobutylmagnesium Bromide.* A crude product (898 mg) of the Grignard reaction, which was obtained in the same manner as described in Exp. 1, was chromatographed through a silica gel column (100 g, 2.8× 38 cm) with the solvent A_3. The effluent containing the reaction product was collected in the fore-run, the main fraction, and the after-run, which gave crystal I (pure **2a**, 36 mg), crystal II (**2a** contaminated with a small amount of **2b**, 660 mg), and crystal III (a 4 : 3 mixture of **2a** and **2b**, 18 mg), respectively. The ratio of **2a** to **2b** in the mixture was estimated by PMR analysis. The crystals II and III were combined and recrystallized from petroleum ether to afford pure **2a** (485 mg, 72% yield). The mother liquor was evaporated and the residual solid (143 mg, *ca.* 4 : 3 mixture of **2a** and **2b**) was benzoylated with benzoyl chloride (0.15 ml) in pyridine (1.41 ml). The product was chromatographed on a silica gel column (30 g, 2.2×20 cm) with the solvent B_2 to give **5b** (76 mg, syrup) as the faster-moving component, a mixture of **5a**+**5b** (21 mg, syrup), and **5a** (95 mg, mp 107—108.5 °C) as the slower-moving component. From these results, the content of **2b** in the original Grignard reaction product may be estimated as about 9%.

*11) 5-Azido-3,5-dideoxy-5-*C*-isobutyl-1,2-*O*-isopropylidene-β-*L*-lyxo-pentofuranose (****6a****).* A solution of **4b** (1.17 g, 3.05 mmol) in dry DMF (26 ml) was heated at 90—97 °C with sodium azide (646 mg, 9.93 mmol) for 2.5 hr, and then poured into cold water (130 ml). The mixture saturated with NaCl was extracted with chloroform (50 ml×3). The extracts were washed with saturated aqueous NaCl (80 ml), dried and evaporated. The residual syrup (742 mg) was purified through a silica gel column (90 mg, 2.8×38 cm) with the solvent A_2 to afford **6a** as a colorless syrup. Yield 657 mg (85%); $[\alpha]_D^{18}$ −61° (*c* 0.35, chloroform); $\nu_{max}^{CCl_4}$ 2140 cm^{-1} (N_3); δ ($CDCl_3$), 0.94 and 0.96 [each d, $(CH_3)_2CH$ J=6.0 Hz), 1.33 and 1.51 [each s, $(CH_3)_2C$], 3.08—3.40 (m, H-5), 4.28 (quintet, H-4, $J_{4,5}$=5.0 Hz, $J_{3,4}$=5.0 Hz, $J_{3',4}$=10.0 Hz), 4.78 (t, H-2, $J_{2,3}$=5.0 Hz, $J_{2,3'}$=1.0 Hz) and 5.89 (d, H-1, $J_{1,2}$=3.8 Hz).

Found: C, 56.70; H, 8.29; N, 16.71%. Calcd for $C_{12}H_{21}O_3N_3$: C, 56.45; H, 8.29; N, 16.46%.

*12) 5-Azido-3,5-dideoxy-5-*C*-isobutyl-1,2-*O*-isopropylidene-α-*D*-ribo-pentofuranose (****6b****).* The tosylate **4'a** (2.17 g, 5.66 mmol) was treated with sodium azide (1.13 g, 17.4 mmol) in dry DMF (40 ml) at 87—95 °C for 1.7 hr. The S_N2 reaction product (1.63 g) was isolated by the procedure of Exp. 11, and purified by chromatography on silica gel (90 g) with the solvent B_3 to afford **6b** as a colorless syrup. Yield 1.17 g (81%); $[\alpha]_D^{30}$ −31° (*c* 1.88, chloroform); $\nu_{max}^{CCl_4}$ 2140 cm^{-1} (N_3); δ ($CDCl_3$), 0.97 [d, $(CH_3)_2CH$, J=6.0 Hz], 1.35 and 1.52 [each s, $(CH_3)_2C$], 3.60—3.95 (m, H-5), 4.30 (dq, H-4), 4.81 (dq, H-2, $J_{2,3}$=5.5 Hz, $J_{2,3'}$=1.0 Hz), and 5.89 (d, H-1, $J_{1,2}$=3.7 Hz).

Found: C, 56.70; H, 8.26; N, 16.48%. Calcd for $C_{12}H_{21}O_3N_3$: C, 56.45; H, 8.29; N, 16.46%.

*13) (3S,4S)-4-Azido-3-formyloxy-6-methylheptanal (****7a****).* Treatment of **6a** (589 mg) in 50% aqueous acetic acid (10 ml) at 115—125 °C for 20 min, followed by concentration afforded a pale red syrup (497 mg), which was dissolved in acetone (5.6 ml) and treated with a solution of sodium metaperiodate (1.48 g) in water (12.5 ml). After standing at room temperature for 15 min, the reaction mixture was concentrated to an aqueous residue, which was extracted with chloroform (10 ml×3). The extracts were washed with saturated aqueous NaCl, dried and evaporated to give **7a** as a pale yellow syrup; yield 470 mg (96%). This sample appeared as a practically pure material by tlc (solvent A_4) and PMR: $\nu_{max}^{CCl_4}$ 2100 (N_3) and 1730 cm^{-1} (CHO and OCHO); δ ($CDCl_3$), 8.28 (s, OC<u>H</u>O) and 10.07 (dd, $CH_2C\underline{H}O$).

*14) (3S,4R)-4-Azido-3-formyloxy-6-methylheptanal (****7b****).* By the procedure described in Exp. 13, **7b** was obtained from **6b** in a 98% yield: $\nu_{max}^{CCl_4}$ 2100 (N_3) and 1728 cm^{-1} (CHO and OCHO); δ ($CDCl_3$), 8.25 (s, OC<u>H</u>O) and 10.05 (dd, CH_2CHO).

*15) (3S,4S)-4-Azido-3-hydroxy-6-methylheptanoic Acid (****9a****).* A solution of **7a** (470 mg) in a 28.7 ml of chromium trioxide solution[11] (CrO_3 1.1 g in acetic acid 3.3 ml and pyridine 1.1 ml) was allowed to stand at room temperature for 3 hr. The reaction mixture diluted with cold water (160 ml) was extracted with ether (30 ml×4) and the extracts were washed with saturated aqueous NaCl (20 ml×2). The dried ether solution was evaporated to afford a pale green syrup (526 mg). The syrup was chromatographed on a silica gel column (63 g, 2.3×36 cm) with the solvent D_1 to give (3*S*,4*S*)-4-azido-3-formyloxy-6-methylheptanoic acid **8a** (382 mg, 76%) as a colorless syrup; δ ($CDCl_3$), 8.21 (s, OC<u>H</u>O) and 9.60 (COOH). The syrup (382 mg) was dissolved in a mixture of conc. HCl (3.3 ml) and 50% (V/V) aqueous dioxane (56 ml) and the solution was kept at room temperature for 2 hr. The reaction mixture was concentrated and extracted with ether (10 ml×3). The extracts were washed with saturated aqueous NaCl (10 ml), dried and evaporated to afford **9a** (318 mg, 72% based on **7a**). A sample (27 mg) of this product was purified by silica gel chromatography with the solvent D_2 to give the pure sample (21 mg) of **9a** as a syrup: $[\alpha]_D^{21}$ −19° (*c* 0.57, chloroform); $\nu_{max}^{CCl_4}$ 3500 (OH), 2800—2500 (COOH), 2120 (N_3), and 1720 cm^{-1} (COOH); δ ($CDCl_3$), 0.97 and 0.98 (each d, $(CH_3)_2CH$, J=6.2 Hz), 1.13—2.0 (m, H-5, H-5', H-6, and OH), 2.57 (dd, H-2, $J_{2,3}$=4.7 Hz), 2.77 (dd, H-2', $J_{2',3}$=7.9 Hz, $J_{2,2'}$=16.7 Hz), 3.29 (dq, H-4, $J_{4,5}$=8.7 Hz, $J_{4,5'}$=5.0 Hz), 4.08 (dq, H-3, $J_{3,4}$=3.5 Hz), and 6.3 (broad, COOH).

Found: C, 47.85; H, 7.47; N, 21.22%. Calcd for $C_8H_{15}O_3N_3$: C, 47.75; H, 7.51; N, 20.88%.

*16) (3S,4R)-4-Azido-3-hydroxy-6-methylheptanoic Acid (****9b****).* By the procedure described in Exp. 15, **7b** (96 mg) was treated with the chromium trioxide solution to afford (3*S*,4*R*)-4-azido-3-formyloxy-6-methylheptanoic acid (**8b**) (65.2 mg, 63%) as a colorless syrup. A sample (31 mg) of **8b** was then de-*O*-formylated with hydrogen chloride in aqueous dioxane. The product (25.5 mg, 92%, mp 50—55 °C) was purified by silica gel chromatography (solvent D_2) and thereafter was recrystallized from petroleum ether to give a pure sample (16 mg) of **9b**: mp 60.5—61 °C; $[\alpha]_D^{15}$ +1° (*c* 2.82, chloroform); ν_{max}^{KBr} 3380 (OH), 2800—2500 (COOH), 2130 (N_3), and 1725 cm^{-1} (COOH); δ ($CDCl_3$), 0.96 and 0.98 (each d, $(CH_3)_2CH$, J=6.2 Hz), 1.25—1.50 (m, H-5 and H-5'), 1.55—2.0 (m, H-6 and OH), 2.63 (d, H-2 and H-2', $J_{2,3}$=$J_{2',3}$=6.0 Hz), 3.54 (quintet, H-4, $J_{4,5}$=4.5 Hz, $J_{4,5'}$=9.1 Hz), 4.07 (dt, H-3, $J_{3,4}$= 4.5 Hz), and 6.5 (broad, COOH).

Found: C, 47.52; H, 7.37; N, 21.17%. Calcd for $C_8H_{15}O_3N_3$: C, 47.75; H, 7.51; N, 20.88%.

*17) (−)(3S,4S)AHMHA (****10a****).* A solution of **9a** (110 mg) in methanol (10 ml) and water (3 ml) was vigorously stirred for 30 min in a hydrogen atmosphere with palladium black. The crystalline product was washed with dry ether and dry ethanol to afford **10a** (97 mg, 93%) whose HPLC showed a single peak having the same elution time (137 min) as that of natural (−)AHMHA. An analytical sample was obtained by recrystallization from water-ethanol: mp 201—203 °C (decomp.) (lit,[1b] mp 199—

201 °C (decomp.)]; $[\alpha]_D$ −20°, $[\alpha]_{546}$ −28°, $[\alpha]_{436}$ −52°, $[\alpha]_{405}$ −62°, $[\alpha]_{365}$ −75° (*c* 0.64, water, 16 °C) [lit.[1b] $[\alpha]_D^{20}$ −18.9° (*c* 0.424, water), lit,[2] $[\alpha]_{541}$ −20°, $[\alpha]_{436}$ −34°, $[\alpha]_{405}$ −40°, $[\alpha]_{365}$ −49° (*c* 1, water, 21 °C)]. The IR (KBr) and PMR (D_2O) spectra were identical with those of authentic sample* of natural (−)AHMHA.

Found: C, 54.79; H, 9.78; N, 7.93%. Calcd for $C_8H_{17}O_3N$: C, 54.83; H, 9.78; N, 7.99%.

*18) (+) (3S,4R)AHMHA (**10b**).* A solution of **9b** (58 mg) in methanol (6 ml) and water (1.2 ml) was hydrogenolyzed on palladium black. The crystalline product was washed with dry ether and dry ethanol to give **10b** (41 mg, 81%) whose HPLC showed a single peak which has a longer retension time (140 min) than that of **10a**. Recrystallization from water-ethanol afforded an analytical sample: colorless prisms, mp 202.5—203.5 °C (decomp.); $[\alpha]_D$ +20°, $[\alpha]_{546}$ +23°, $[\alpha]_{436}$ +46°, $[\alpha]_{405}$ +53°, $[\alpha]_{365}$ +68° (*c* 0.66, water, 16°C).

Found: C, 54.58; H, 9.54; N, 7.76%. Calcd for $C_8H_{17}O_3N$: C, 54.83; H, 9.78; N, 7.99%.

*19) t-Butyl (3S,4S)-4-Azido-3-hydroxy-6-methylheptanoate (**11a**).* A sample (392 mg) of 4-azido-3-formyloxy-6-methylheptanoic acid (**8a**) (Exp. 15) was dissolved in dichloromethane (3.3 ml) and cooled to −40 °C. To the solution was added isobutene (2.2 ml) and conc. H_2SO_4 (0.033 ml), and the mixture was allowed to warm to room temperature. After standing for 3 hr, the reaction mixture was neutralized with triethylamine and evaporated. The residue was dissolved in ethyl acetate (15 ml) and washed with saturated aqueous NaCl, dried and evaporated to give a syrup (438 mg). To a solution of the syrup (398 mg) in dioxane (7 ml) was added 0.2 M NaOH (7 ml), and the mixture was stirred for 30 min at room temperature, evaporated, the residue was extracted with ethyl acetate (6 ml × 4). The ethyl acetate layers were washed with saturated aqueous NaCl, dried and evaporated. The oily product (358 mg) was chromatographed on silica gel (40 g) with the solvent B_4 to afford a pure sample of **11a**: colorless oil, yield 225 mg (57% based on **7a**); $[\alpha]_D^{15}$ −25° (*c* 2.62, chloroform).

Found: C, 56.09; H, 9.00; N, 16.24%. Calcd for $C_{12}H_{23}O_3N_3$: C, 56.01; H, 9.01; N, 16.33%.

*20) t-Butyl (3S,4R)-4-Azido-3-hydroxy-6-methylheptanoate (**11b**).* By the same procedure as in the preparation of **11a**, a sample (421 mg) of **8b** (Exp. 16) was *t*-butylated and the crude *t*-butyl ester (372 mg) was de-*O*-formylated. The oily product (429 mg) was purified by silica gel column (50 g) with the solvent B_4 to afford a pure sample of **11b**; yield 274 mg (58%), $[\alpha]_D^{26}$ +7° (*c* 1.72, chloroform).

Found: C, 56.19; H, 8.83; N, 16.58%. Calcd for $C_{12}H_{23}O_3N_3$: C, 56.01; H, 9.01; N, 16.33%.

*21) N-Acetyl-L-valyl-L-valine Methyl Ester (**12**).* *N*-Benzyloxycarbonyl-L-valyl-L-valine methyl ester[13] (2.3 g, 6.32 mmol) was hydrogenolyzed on palladium black in methanol (20 ml). The reduction product was acetylated in methanol (20 ml) with triethylamine (0.88 ml, 6.32 mmol) and acetic anhydride (1.18 ml, 12.64 mmol) in a usual manner to afford a crystalline solid (1.71 g). It was recrystallized from ethyl acetate; yield 1.47 g (86%), mp 147—150 °C. This sample was again recrystallized from ethyl acetate to give a pure sample of **12**, mp 155—157 °C, $[\alpha]_D^{33}$ −65° (*c* 1.07, methanol).

Found: C, 57.32; H, 8.90; N, 10 28%. Calcd for $C_{13}H_{24}O_4N_2$: C, 57,33; H, 8.88; N, 10.29%.

*22) N-Acetyl-L-valyl-L-valine Hydrazide (**13**).* A mixture of **12** (1.3 g), methanol (12 ml), and 80% hydrazine hydrate (5.9 ml) was kept overnight at room temperature. The crystalline hydrazide separated was collected by filtration and washed with methanol, chloroform, and water, successively, and dried; yield 1.14 g (88%). Analytical sample was obtained by recrystallization from DMF-water; mp 280 °C (decomp.), $[\alpha]_D^{31}$ −45° (*c* 0.5, dimethylsulfoxide).

Found: C, 53.09; H, 8.70; N, 20.71%. Calcd for $C_{12}H_{24}O_3N_4$: C, 52.92; H, 8.88; N, 20.57%.

*23) N-(Acetyl-L-valyl-L-valyl)-(3S,4S)AHMHA t-Butyl Ester (**14a**).* Isoamyl nitrite (0.056 ml, 0.015 mmol) and 3.93 M HCl in tetrahydrofuran (0.31 ml, 1.21 mmol) was added to a solution of **13** (106 mg, 0.388 mmol) in DMF (0.5 ml) cooled to −20 °C and the mixture was stirred at −20 °C for 30 min to make a clear solution. To this solution containing acetyl-L-valyl-L-valine azide was added triethylamine (0.223 ml, 1.6 mmol) and a solution of (3*S*,4*S*) AHMHA *t*-butyl ester, which was prepared from **11a** (99.6 mg, 0.388 mmol) by catalytic hydrogenolysis on palladium black, in DMF (0.6 ml). After stirring at −20 °C for 4 hr and standing overnight in a refregerator, the solvents were removed. The residue was triturated with water to give a crystalline product which was collected by filtration and washed with water; yield 183 mg (74%). Silica gel chromatography (solvent E_1) of the product (183 mg) gave a practically pure sample of **14a** (98 mg). Recrystallization from methanol-water afforded an analytical sample; mp 219—220 °C, $[\alpha]_D^{16}$ −85° (*c* 0.55, methanol).

Found: C, 60.92; H, 9.43; N, 9.04%. Calcd for $C_{24}H_{45}O_6N_3$: C, 61.12; H, 9.62; N, 8.91%.

*24) N-(Acetyl-L-valyl-L-valyl)-(3S,4R)AHMHA t-Butyl Ester (**14b**).* The *t*-butyl ester of **10b** obtained by hydrogenolysis of **11b** (103 mg) was coupled with acetyl-L-valyl-L-valine azide prepared from **13** (109 mg) by the procedure described in Exp. 23 to afford the product **14b** (141 mg, 75%) which appeared as a homogeneous material on tlc (solvent E_2). A sample (30 mg) of this product was purified by silica gel chromatography (solvent E_2) and by recrystallization from ethanol to give a pure sample (16 mg); mp 215 °C ~ (sublimated), $[\alpha]_D^{17}$ −43° (*c* 0.5, methanol).

Found: C, 61.25; H, 9.49; N, 8.90%. Calcd for $C_{24}H_{45}O_6N_3$: C, 61.12; H, 9.62; N, 8.91%.

*25) N-(Acetyl-L-valyl-L-valyl)-(3S,4S)AHMHA (**15a**).* A solution of **14a** (63 mg) in trifluoroacetic acid (1.5 ml) was allowed to stand for 25 min at room temperature and then evaporated to dryness. The syrupy residue was treated with ether to afford **15a** as a crystalline solid (52 mg, 94%). Silica gel chromatography (solvent F) of the product, followed by recrystallization from methanol-water gave an analytical sample; mp 226—227 °C, $[\alpha]_D^{13}$ −100° (*c* 0.68, methanol).

Found:. C, 57.68; H, 8.97; N, 10.28%. Calcd for $C_{20}H_{37}O_6N_3$: C, 57.81; H, 8.98; N, 10.11%.

*26) N-(Acetyl-L-valyl-L-valyl)-(3S,4R)AHMHA (**15b**).* Treatment of **14b** (144 mg) with trifluoroacetic acid (1.2 ml) for 20 min at room temperature afforded **15b** as a crystalline solid (118 mg, 93%) which appeared to be homogeneous on tlc (solvent F and G). Recrystallization from methanol-water gave a pure sample; mp 215—217 °C, $[\alpha]_D^{15}$ −40° (*c* 0.21, methanol).

Found: C, 57.57; H, 8.77; N, 10.09%. Calcd for $C_{20}H_{37}O_6N_3$: C, 57.81; H, 8.98; N, 10.11%.

The authors wish to express their sincere thanks to Dr. Hamao Umezawa, Institute of Microbial Chemistry, for his helpful advice, and to Prof. Sumio Umezawa,

* The authentic sample of (−)AHMHA was generously supplied by Dr. Tomohisa Takita, Institute of Microbial Chemistry, to whom the authors' thanks are due.

Keio University, for his interest and kind advice. Thanks are also due to Dr. Takaaki Aoyagi and Dr. Takeshi Hara, Institute of Microbial Chemistry, for the enzyme inhibition activity tests and for the measurement of high performance liquid chromatograms.

Stereochemical Aspects of the Photo-Beckmann Rearrangement. Stereochemical Integrity of the Terminus of the Migrating Carbon in the Photo-Beckmann Rearrangements of 5α- and 5β-Cholestan-6-one Oximes[1]

Hiroshi SUGINOME and Hajime TAKAHASHI

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received July 4, 1974)

The Beckmann rearrangement of either *syn*-5β-cholestan-6-one oxime or *anti*-5β-cholestan-6-one oxime with polyphosphoric acid at 90° takes place prior to the *syn-anti* equilibration of these isomers. In the photo-Beckmann rearrangement a pair of lactams, in both of which the original configurations of C_α with respect to the oximino-group of the starting oximes were retained, was produced irrespective of the configuration of the oximino-group of the starting oxime. The difference of the amounts between two isomeric lactams formed in each photolysis is small but the lactams due to the migration of the more substituted carbon are produced always in a slightly larger amount than those due to the migration of the less substituted carbon. Oxygen does not affect the formation of lactams. All these results indicate a concerted reorganization of an excited singlet oxaziridine intermediate, hydrogen-bonded with protic solvent molecule (s), into the corresponding lactams. During these studies, the photochemical epimerization of 5β-steroid-6-one into the 5α-isomer by α-cleavage-recombination sequence was observed.

Since the first report of the photo-Beckmann rearrangement of arylaldoximes by de Mayo[2] further examples with a variety of oximes have been recorded during this decade. The types of oximes investigated include alicyclic ketone oximes,[3a,3c-3f,6,7] naphthalenone oximes,[3b] aliphatic ketone oximes,[3a] styryl ketone oximes,[3g] and α,β,γ,δ-unsaturated aldehyde oxime.[3h]

The mechanistic aspects of this intriguing and potentially useful photochemical rearrangement have been discussed for arylaldoximes,[4] naphthalenone oxime,[3b] styrylketone oximes[3g] and alicyclic ketone oximes.[3c-3e] Common mechanistic features with respect to the formation of amides from all the types of oximes cited above are as follows.

The formation of amides takes place *via* oxaziridine intermediates which are formed rapidly from the excited oximes. This excited state was proved to be a singlet for the arylaldoxime rearrangement[4] and later for the styryl ketone oxime rearrangements.[3g]

Protic solvents, without exception, considerably accerelated the formation of amides from oximes. The photolysis of some steroidal ketone oximes in an aprotic solvent such as benzene does not afford lactams but the parent ketones.[5] In some instances, even alcohol is not sufficient and an acid such as AcOH is needed to cause the rearrangement.[3c]

These observations were taken as evidence that a protonation may be involved at some stage of the rearrangement[3b,3g] or that the oxaziridine formation may proceed *via* a polarized excited state.[3b,3d,3g] Several other features of the mechanism of the amide formation, however, do not conform with hypothesis based on a single mechanism for the all types of oximes and the correct mechanism and the excited species involved for each type of oxime must await further elaboration.

We wish to report here a study of the stereochemical aspects of the over-all rearrangement which had previously been disclosed by us only as a brief communication.[6] Since our publication, similar results were reported by Just and his colleagues.[7] We believe this aspect of the rearrangement is important both from the synthetic and mechanistic point of view.

We have chosen 5α- and 5β-cholestan-6-one oximes as the substrates for this study.

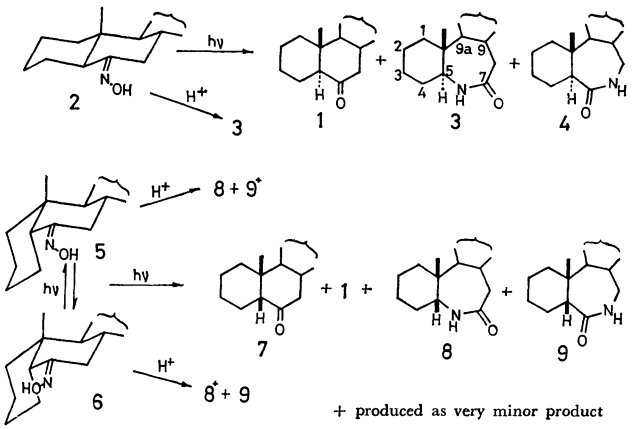
Results

Preparation of Cholestan-6-one Oximes. It was found that the oximation of 5α-cholestan-6-one **1** proceeds at an undetectable rate at room temperature. On the other hand, at reflux temperature, the oximation afforded only a single known oxime **2**.[8-10]

In contrast to the 5α-cholestan-6-one, the oximation of 5β-cholestan-6-one **7** at room temperature proceeded readily and afforded a mixture of two isomeric oximes. These oximes could be separated by preparative tlc to afford the more polar amorphous oxime **5** and the less polar crystalline oxime **6**, mp 144—146 °C, approximately in the ratio of 3 : 1. The methanolic solution of the *syn* isomer or that of the *anti* isomer was set aside for 48 hr at room temperature and examination of the solution by tlc indicated that virtually no *syn* to *anti* nor any *anti* to *syn* isomerization took place under these conditions. However, it has been found that benzene solutions of neither the *syn* isomer nor the *anti* isomer are as stable as methanolic solutions and a significant amount of *syn* isomer is produced from *anti* (and *vice versa*) after 48 hr at room temperature. The observed stability of the configuration of the oximino group in MeOH would probably be associated with the hydrogen bonding between the oximino-group and the protic solvent or with the higher dielectric constant of MeOH.[11]

The Configuration of Cholestan-6-one Oximes: The configuration of the oximino-hydroxyls of the three oximes **2**, **5** and **6** were established both by the Beckmann rearrangement and ^1H NMR spectra.

5α-Cholestan-6-one Oxime 2: In view of the fact that a single oxime is formed it would be reasonable to assume[9b] that the oximino group of **2** will possess the less sterically hindered and more stable *anti* configuration with respect to the C_5–C_6 bond since the interaction between the 4-methylene group and the OH group in both the initial adduct and the oxime in oximation reaction seems considerable.[12] The treat-



Scheme 1.

ment of **2** with PPA[13] afforded a known lactam **3**[9b] as the sole product in 65% yield. This lactam was confirmed as 6-aza-*B*-homo-5α-cholestan-7-one by ^{1}H NMR (Table 2). On this basis it was established that the configuration of the oximino group of **1** was *anti* with respect to the C_5–C_6 bond.

Hydrogens attached to a carbon α to an oximino-group are known to appear downfield,[14] in the ^{1}H NMR spectrum. The NMR spectrum of the oxime **2** exhibited a quartet centered at τ 6.69 (J=13.5 and 3.8 Hz) (Table 1) which may be assignable to a proton α to the oximino-group. This should be the 7β proton on the basis of the examination of the Dreiding model of **2** together with the coupling constants required by the model. The model of the oxime **2** reveals that the dihedral angle between the oximino π bond and the adjacent methylene group is about 74° and a π-bond contribution of approximately 0—1 Hz to the methane geminal coupling constant (12.4 Hz) is expected.[15] This affords the anticipated value of $J_{gem} \simeq 11.4$ Hz for the C-7 protons which is close to the observed geminal coupling constant. Moreover, the dihedral angle between the C_7–βH and the C_8–βH is about 55° and a small splitting of 3.8 Hz is also consistent with the above assignment.

Since the Beckmann rearrangement indicates that the configuration of the oximino-group of **2** is *anti* with respect to the C_5–C_6 bond, it is concluded that a proton H_α, *syn* to the oximino OH of saturated oximes should appear generally downfield from its *anti*-counterpart and this downfield shift of a proton is caused by the oximino OH.

*5β-Cholestan-6-one Oximes (**5** and **6**)*: The configurations of the oximino-groups of the 5β-cholestan-6-one oximes are not able to be differentiated merely from their NMR spectra. Assuming that the preferred conformations of the B-rings of **5** and **6** are chair forms, the 7β–H of the *anti* form should appear as a quartet with $J_{7\alpha,7\beta} \simeq 12$ Hz and $J_{7\beta,8\beta} \simeq 2$—3 Hz and the 5β–H of the *syn* form should also appear as a quartet with $J_{5\beta,4\beta} \simeq 2$ Hz and $J_{5\beta,4\alpha} \simeq 9$—11 Hz.

Table 1. The NMR data of oximes (τ, *J* (Hz), $CDCl_3$, TMS, 100 MHz)

Oxime	18-H	19-H	7β-H	5β-H	
2	9.34	9.25	6.69 (q) (3.8 and 13.5)	—	5	9.36	9.17	6.84 (d) (<1 and 10.5)	—	6	9.36	9.17	—	6.92 (q) (4 and 11)	
Table 2. The NMR data of lactams (τ, *J* (Hz), $CDCl_3$, TMS, 100 MHz)

Lactam	18-H	19-H	8-H	5-H	NH
3	9.35	9.17	—	6.76 (q) (4.0 and 11.0)	4.48 (d) (5.5)
4	9.33	9.11	6.90 ~7.03 (m)	7.44 (q) (5.0 and 11.5)	3.96 (broad)
8	9.34	9.03	—	7.70 (d) (8.0)	3.8 (broad)
9	9.32	8.97	7.02 (b. s) (W_H=11)	—	3.85 (broad)

The NMR spectrum of **5** revealed a one proton doublet at τ 6.84 (J=10.5 Hz, Fig. in Table 1) with a small splitting of less than 1 Hz in each signal and the NMR spectrum of the oxime **6** revealed a one-proton quartet centered at τ 6.92 (J=4 Hz and 11 Hz, Fig. in Table 1). These signals are attributable to a proton α to the oximino-groups but it is not possible to distinguish between the *syn* and *anti*-isomers from the above figures of the coupling constants. Therefore, we carried out Beckmann rearrangements of the two oximes to obtain more reliable evidence for the configurations of the oximino hydroxyls of **5** and **6**.

Treatment of **5** with PPA afforded a single crystalline lactam **8** (IR), mp 95—100 °C, in 80% yield. The NMR spectrum of **8** revealed a broad one-proton doublet at τ 7.70 (J=8.0 Hz) (Table 2). Decoupling the signals at τ 8.35 caused a collapse of the doublet at τ 7.70 into a broad singlet. These data are consistent with those required for the 5β-proton of 6-aza-*B*-homo-5β-cholestan-7-one.

Beckmann rearrangement of **6** using the same proced ure used for **5** afforded an amorphous compound **9**, $C_{27}H_{47}ON$, isomeric with **8** in 90% yield. This was a lactam (IR) and the NMR spectrum of **9** (Table 2) was in agreement with the 7-aza-*B*-homo-5β-cholestan-6-one structure.

It has frequently been pointed out that care must be exercised in relating the stereochemistry of oximes with the lactams derived from the Beckmann rearrangement since *syn anti* isomerization is catalyzed by the reagents used for the Beckmann rearrangement[16,17] and the position of and rate of attaining the *syn* to *anti* equilibrium are temperature dependent.

The distinction among three lactams **3**, **8** and **9** could be readily made with the aid of the different chemical shifts of the 10β-methyl protons in their NMR spectra. Examination of the NMR spectrum of the crude product (see Fig. 1 in Experimental) from the Beckmann rearrangement of **5** indicated the presence of a small amount of **9** (revealed by a pair of weak signals at τ 8.97 and τ 9.32) and the NMR spectrum of the crude product from **6** (see Fig. 2 in Experimental) showed the presence of a small amount of **8** (revealed by a pair of weak signals at τ 9.03 and τ 9.34). The appearance of these signals in the products indicated that the equilibration from *syn* to *anti* or from *anti* to *syn* took place to some extent prior to the Beckmann rearrangement under our experimental conditions. However, it is apparent that the rearrangement of either oxime **5** or **6** is faster than the equilibration of these isomers.

On the basis of these results we concluded that the configurations of the oximino-hydroxyl of the oxime **5** and the oxime **6** are respectively *anti* and *syn* with respect to the C_5–C_6 bond.

Photo-Beckmann Rearrangement of Cholestan-6-one Oximes: The photo-Beckmann rearrangements of all three oximes **2**, **5**, and **6** were carried out in methanolic solution under a N_2 atmosphere at room temperature using a 15-W low pressure Hg arc lamp dipped in the solution. The progress of the photolysis was traced by tlc.

*Photolysis of 5α-Cholestan-6-one Oxime **2***: The photolysis of **2** in dry methanol (3.56×10^{-3} M) for 27 hr resulted in partial transformation of the oxime. Since further irradiation was found to cause secondary photochemical decomposition of the initial products the irradiation was stopped at this stage. Examination of the product by tlc revealed that several products were produced but these were able to be divided into four fractions by preparative tlc (see Experimental). The major part of the least polar fraction was found to be 5α-cholestan-6-one (8% as a ketone) by examination of its spectra. The second least polar fraction (6% as an oxime) was found to be the crude oxime. The third least polar fraction was further separated into two fractions by preparative tlc, using a different solvent system. Of these, the less polar fraction (11% as a lactam) afforded a compound **4** which melted at 110—114 °C after recrystallization from ethanol and the more polar fraction (15% as a lactam) afforded a lactam which was identical with the lactam **3**. Product **4** was also a lactam with the molecular formula $C_{27}H_{47}ON$ but was not identical with either the lactam **8** or the lactam **9** and the NMR spectrum of **4** (Table 2) was consistent with the 7-aza-*B*-homo-5α-cholestan-6-one structure. The 10β-Me protons appeared at τ 9.11 which is 0.06 ppm downfield from those of the isomeric 6-aza-lactam **3**.

*Photolyses of 5β-Cholestan-6-one Oximes **5** and **6***: The *syn*-oxime **6** in dry methanol (5.0×10^{-3} M) was then photolyzed and examination of the progress of the photolysis by tlc indicated that a rapid photostationary state between the *syn* and *anti* forms was established. Tlc examination of the reaction mixture after 3 hr revealed the presence of nearly equal amounts of *syn* and *anti* forms in the solution. The photolysis was stopped after 12 hr irradiation. The reaction mixture was analyzed by preparative tlc as in the case of 5α-cholestan-6-one oxime to afford two gummy ketone fractions, which yielded crystalline 5α-cholestan-6-one (3%) and crystalline 5β-cholestan-6-one (7%), the recovered oxime, and a lactam fraction in order of increasing polarity.

The NMR spectrum of the lactam fraction revealed the presence of sharp peaks at τ 8.97 and τ 9.03. This immediately suggested the presence of 6-aza-*B*-homo-5β-cholestan-7-one and 7-aza-*B*-homo-5β-cholestan-6-one. Preparative tlc of this mixture afforded the lactam **8** (24%) and the lactam **9** (17%). In addition, a fraction considerably less polar than the ketones was also obtained. Judged by the spectra this gum was 5,6-seco-cholestan-6-oic acid methyl ester derived from α-cleavage of the 6-ketone.[18] Nearly the same results were obtained when the photolysis was started with the anti-oxime. The results in this case were as follows; 5α-cholestan-6-one (3%), 5β-cholestan-6-one (5%), 6-aza-*B*-homo-5β-cholestan-7-one (30%) and 7-aza-*B*-homo-cholestan-6-one (12%).

Throughout these photolyses, it was found that the disappearance of the oxime and the appearance of the lactams were faster in the 5β-series than the 5α-series and the yields of lactams were higher in the 5β-series although no quantitative studies were undertaken.

Photo-Beckmann Rearrangement of 5β-Cholestan-6-one Oxime in the Presence of Oxygen: In order to obtain some information on the properties of the excited oxaziridine

from which the observed lactams are formed, the photolysis was carried out in the presence of oxygen. Oxygen is believed to remove triplet state species by both chemical and physical quenching.[19] A mixture of *syn* and *anti* 5β-oximes was chosen as the substrate, since, when compared with the 5α-oxime, the results of the reaction with this substrate were found to contain less by-products.

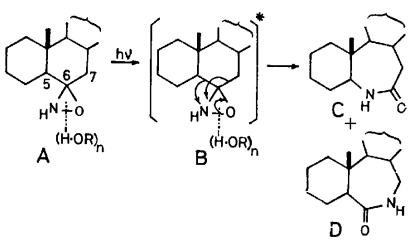
The photolysis of a methanolic solution of 5β-oximes (3.7×10^{-3} M) in the presence of O_2 afforded crystalline 5α-ketone (1%), crystalline 5β-ketone (7%), 6-aza-*B*-homo-5β-cholestan-7-one (16%, amount eluted from tlc) and 7-aza-*B*-homo-5β-cholestan-6-one (14%, amount eluted from tlc) and 4% of the starting oximes were recovered.

Discussion

In the foregoing part we have shown that in the photo-Beckmann rearrangements of 5α- and 5β-cholestan-6-one oximes, when we start off from 5β-oxime, lactams retaining the 5β-configuration are produced but from 5α-epimer only those having the 5α-configuration are formed. Through these experiments, the lactam part of the products was very carefully examined but we were unable to detect any lactams in which the initial configuration at C_a to the oximino-group of the starting oximes was reversed. It should also be noted that in the present results two isomeric lactams due to the migration of the tri-substituted carbon (C_5) and the di-substituted carbon (C_7) were produced in each case and the relative amounts of two lactams were not significantly different in the photolysis of **2** and in the photolysis of **5** or **6**, although in all the photolyses some preference for the migration of tri-substituted carbon over that of disubstituted carbon was shown.

The present results suggest that the reorganization from the oxaziridine intermediate to lactams occurs in a fully concerted manner (*e.g.*, A→B→C and D). At the time of our preliminary publication, we suggested that this mechanistic pathway might operate generally for all aliphatic ketones and aldehydes. However, we subsequently found[20] an exception to that rule. We found that the photolysis of androsterone oxime afforded an epimeric pair of lactams at the 13–Me, although the yields were very poor.

In order to get a general and consistent picture of the mechanistic pathway in regard to the migration step of the saturated oximes, we considered two possibilities for the mode of formation of a lactam from oxaziridine. The first was the migration through the intervention of an ionic or radical intermediate[20] in which bond between oxaziridine ring carbon and the migrating α-carbon (*e.g.*, C_5–C_6 bond or C_6–C_7 bond in A) is cleaved. According to this mechanistic view the present results with cholestan-6-one oxime might be rationalized by considering the involvement of a similar ion pair or radical pair intermediate which is configurationally stable. However, this unifying mechanism for all the saturated ketone oximes fails to interpret the small difference in migratory aptitude between C_5 and C_7 in the present case and in several other cases, *i.e.*, 3α,5-cyclo-5α-cholestan-6-one oxime,[3f] unsymmetrically α-substituted cyclohexanone oxime[7] and norcamphor oxime.[3d] These observation would be better explained if we assumed the formation of lactams *via* a concerted breakdown of the oxaziridines (Scheme 2).



Scheme 2.

This would mean that a dual mechanism is operative in the saturated oximes, depending upon their structural features in the immediate environment of the relevant oximino group. The oxime which can afford a stable ionic or radical species by cleavage would be able to rearrange through an intermediate in which the migrating group becomes free of the migration terminus. The rearrangement of the oximes of androsterone and 13α-androsterone perhaps fall in this category. On the other hand, oximes of cholestan-6-ones, menthone, isomenthone and norcamphor bear the tri-substituted migrating carbon within the framework of the six-membered ring and oxaziridines formed from these oximes would rearrange to afford lactams *via* a concerted breakdown of the oxaziridines.

No meaningful difference between the *syn*-oxime and the *anti*-oxime of 5β-cholestan-6-one was observed with respect to the photolysis products. This shows a fast establishment of photostationary states between *syn* and *anti* prior to substantial progress of the photorearrangement. On the other hand, we could not detect even a trace of the *syn*-form of 5α-cholestan-6-one oxime during the photolysis of *anti* 5α-cholestan-6-one oxime. This difference between 5α-6-one oxime and 5β-6-one oxime is readily understandable since it is inferred that, in the 5α-steroid-6-one oximes, the energy difference between the *syn* form and the *anti* form is large and the thermal relaxation from photogenerated *syn* to *anti* should be very fast. In contrast, in the 5β-steroid-6-one oximes, the energy difference between *syn* and *anti* is not as large and both forms are isolatable species at room temperature.

With regard to the properties of the excited oxaziridine, the result of the photolysis of 5β-cholestan-6-one oxime in the presence of oxygen would imply that a) no radical intermediate would be involved in the present photo-Beckmann rearrangement and b) the formation of lactams from the oxaziridine takes place in its singlet state. The former result is contrasted with the reported case of adamantanone oxime in which the intervention of a radical intermediate at some stage was inferred.[3c] The latter results differ from the case of styrylketone oximes in which a triplet state of protonated oxaziridine rearranges to afford lactams. All the present results of the photolysis are consistent with our original proposal that lactam is formed *via* a concerted breakdown of the oxaziridine.[6]

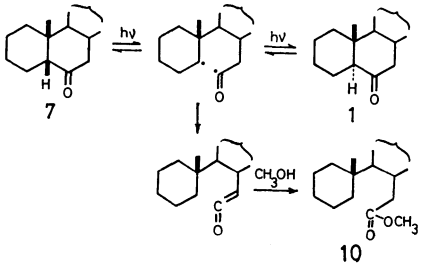
During the photo-isomerization experiments it was observed that the rate of disappearance of the oxime **5** or **6** was considerably faster than that of the oxime **2** and the yields of lactams were much higher than those of the oxime **2**. The faster rates observed in A/B *cis* oxime **5** or **6**, when compared with A/B *trans* oxime **2**, could be mainly attributed to the relief of steric compression due to nonbonded interactions of 2α- and 4α-axial hydrogens with 7α- and 9α-axial hydrogens in going from oxaziridine intermediates formed from the oxime **5** or **6** to the lactam **8** and **9**. With regard to the role of protic solvents in the rearrangement, in all the examples of photo-Beckmann rearrangements described, protic media or organic acids as solvents are reported to be essential.

Mukai and co-workers recently proposed that the excited triplet species of a protonated oxaziridine is involved in the formation of the corresponding lactams from styryl ketone oxime.

In our case the role of methanol would be associated with influencing the rate or efficiency of an electronic energy transfer process, by making hydrogen bonds between the unshared electrons of excited oxaziridines and methanol molecule(s), in the reorganization from excited oxaziridines to lactams. When the protic solvents are absent the excited singlet oxaziridines would lose their singlet energy by various physical deactivation processes prior to their rearrangement to lactams.

The isolation of 5α-cholestan-6-one together with 5β-cholestan-6-one in the photolysis of the 5β-cholestan-6-one oximes would demand an explanation. It was rather difficult to explain the isolation of these isomeric ketones in terms of the initial isomerization of 5β-oximes into 5α-oxime through an α-cleavage-recombination process followed by the decomposition of these oximes into the 5α- and 5β-ketones. The isolation of of both 5α and 5β ketones could be better explained if we assumed an initial formation of 5β-cholestan-6-one either via collision between ground state oxazirdine molecules[3g] or via other routes, including a photochemical one followed by isomerization into the 5α-one via a photochemical α-cleavage-recombination sequence (Scheme 3). This is supported by the results of the separate irradiation of 5β-cholestan-6-one in dry methanol containing dioxane. The solution in a quarz vessel was irradiated for 3 hr with a 15-W low pressure Hg arc lamp. Separation of the product by preparative tlc afforded 5α-ketone (13%), and 5,6-seco-cholestan-6-oic acid methyl ester **10** (14%), together with the original 5β-ketone (44%).

This isomerization is the second case of a photochemical isomerization of a steroidal ketone by an α-cleavage-recombination sequence. The first case of isomerization of steroidal ketone was reported by Butenandt *et al.*,[21] who found that steroidal 17-ketones epimerize at C-13,[22] and later the reversibility of the process was clarified by Schaffner.[23]



Scheme 3.

Experimental

All mps were determined with a Yanagimoto-type hot stage and are uncorrected. Unless stated otherwise, IR spectra were determined in Nujol using a JASCO model IR-E spectrophotometer. The NMR spectrum of oxime **2** was measured on a JEOLCO-JNM-PS-100 high resolution NMR spectrometer in $CDCl_3$ solution using TMS as an internal reference. Other NMR spectra were taken at Japan Electric & Varian Ltd. Wako gel B-5 was used for preparative tlc.

5α-Cholestan-6-one Oxime 2: This was prepared according to the literature procedure. mp 197—201 °C (lit, mp 204—206 °C,[10] mp 195 °C,[8] mp 196—198 °C,[9a] mp 197—198 °C[9b]); IR: 3272 cm^{-1} (OH), 1669 cm^{-1} (C=N), 896, 923, 947 cm^{-1}.

Beckmann Rearrangement of 5α-Cholestan 6-one Oxime 2: 5α-Oxime (94 mg) was added to PPA (Koso Chemical Co., Ltd. Tokyo) (1 g) kept at 100 °C. The reaction mixture was heated at 110—115 °C for 15 min. After being cooled the reaction mixture was neutralized with 10% Na_2CO_3 solution (10 ml) and extracted with ether. The ethereal solution was worked up as usual. Removal of the solvent left a residue which was recrystallized from acetone to yield 61 mg of lactam **3**. mp 173—175 °C (lit,[9b] mp 175—176 °C); IR: 1669 cm^{-1} (lactam C=O), 3230 cm^{-1}, 3090 cm^{-1} (lactam NH); Mass: *m/e* 401 (M^+).

Anti-5β-cholestan-6-one Oxime 5 and syn-5β-Cholestan-6-one Oxime 6: 5β-Cholestan-6-one (320 mg), hydroxylamine hydrochloride (450 mg) and NaOAc (320 mg) in 95% aqueous EtOH (30 ml) were stirred for 2 hr at room temperature. The solvent was removed under reduced pressure and the residue was extracted with ether. Usual work-up of the ethereal solution afforded an amorphous residue (350 mg). Preparative tlc of the residue (305 mg) using benzene as the solvent gave two fractions. The less polar fraction (120 mg) was recrystallized from acetone yielding 63 mg of *syn*-oxime **6**. mp 144—146 °C. (Found: C, 80.82; H, 11.85; N, 3.66%; Calcd for $C_{27}H_{47}ON$: C, 80.73; H, 11.80; N, 3.49%) Mass: *m/e* 401 (M^+); IR: 3276 cm^{-1} (OH), 1656 cm^{-1} (C=N), 925, 942, 954 cm^{-1}. The more polar fraction (249 mg) which was contaminated with a small amount of the less polar fraction was purified twice by preparative tlc ($CHCl_3$/ether—4/1 in vol.) to yield 68 mg of *syn*-oxime **6** and amorphous *anti*-oxime **5**. It was difficult to obtain the *anti*-oxime completely free from the *syn*-form, since during elution with acetone and $CHCl_3$ in the preparative tlc **5** seemed to undergo slight *anti-syn* isomerization. Analysis of *anti-oxime* **5**: (Found: C, 80.82; H, 11.77; N, 3.44%; calcd for $C_{27}H_{47}ON$: C, 80.73; H, 11.80; N, 3.49%).

Beckmann Rearrangement of syn-5β-Cholestan-6-one Oxime 6: Freshly prepared **6** (26 mg) was added to a small amount of PPA kept at 90 °C. The mixture was stirred for 5 min at that temperature and then cooled by ice. The reaction mixture was neutralized with 10% aqueous Na_2CO_3 solution and the solution was extracted twice with ether. Usual work-up of the ethereal solution left amorphous compound **9** (20 mg). The Me proton part of the NMR spectrum of this is shown in Fig. 2. The lactam **8** was removed by preparative tlc. (Found: C, 79.36; H, 11.57; N, 3.22%; Calcd for $C_{27}H_{47}ON$: C, 80.73; H, 11.80; N, 3.49%);

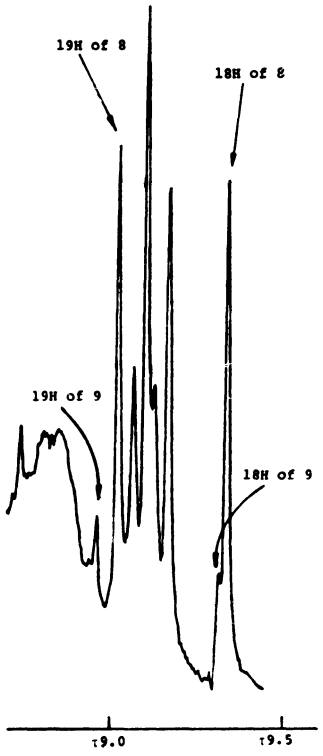


Fig. 1. NMR spectrum of crude **8**.

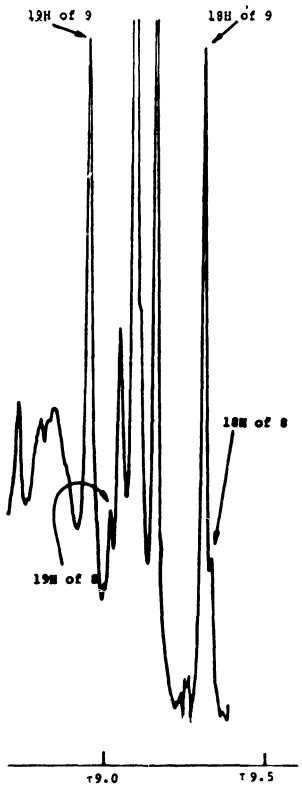

Fig. 2. NMR spectrum of crude **9**.

IR: ($CHCl_3$) 1643 cm^{-1} (lactam C=O), 3210 cm^{-1}, 3410 cm^{-1} (lactam NH).

Beckmann Rearrangement of anti-*5β-Cholestan-6-one Oxime 5*: Compound **5** (20 mg) was added to a few drops of PPA kept at 90 °C. The mixture was stirred for 5 min at that temperature. After being cooled by ice the reaction mixture was neutralized with 10% Na_2CO_3 solution and the solution was extracted twice with ether. Work up of the ethereal solution in the usual manner left 18 mg of an oily residue. The Me proton part of the NMR spectrum of this is shown in Fig. 1. This residue was purified by preparative tlc and then recrystallized from EtOH to yield lactam **8**. mp 76—80 °C.* (Found: C, 80.27; H, 11.94; N, 3.29%; Calcd for $C_{27}H_{47}ON$: C, 80.73; H, 11.80; N, 3.49%); IR: ($CHCl_3$) 1645 cm^{-1} (lactam C=O), 3390 cm^{-1} (lactam NH).

Photo-Beckmann Rearrangement of 5α-Cholestan-6-one Oxime 2: Oxime **2** (500 mg) in dry MeOH (350 ml) was irradiated for 23 hr. Examination of the reaction products by tlc revealed the presence of four major spots and these were separated by preparative tlc to afford 4 fractions A, B, C, and and D ($CHCl_3$/ether; 10/1 in vol.) in order of increasing polarities. The amount of fraction A was 40 mg and the major part of this was found to be 5α-cholestan-6-one. Recrystallization of fraction B (28 mg) from acetone afforded only 4 mg of the starting oxime. Fraction C (150 mg) was found to be a mixture of two compounds and this fraction gave two spots on a tlc with a mixed solvent of equal volumes of $CHCl_3$ and ether. Preparative tlc of the mixture with this solvent system afforded two compounds. The less polar and amorphous substance (53 mg) afforded 40 mg of crystals of 7-aza-*B*-homo-5α-cholestan-6-one. mp 110—114 °C. (Found: C, 79.12; H, 11.58; N, 3.77%; Calcd for $C_{27}H_{47}ON$: C, 80.73; H, 11.80; N, 3.49%); IR: 1656 cm^{-1} (lactam C=O), 3270 cm^{-1}, 3530 cm^{-1} (lactam NH). The more polar and crystalline compound (75 mg) melted at 174—179 °C and was identical with 6-aza-*B*-homo-5α-cholestan-7-one obtained from a Beckmann rearrangement of oxime **2**. Fraction D (80 mg) did not contain any lactam and was not examined further.

Photo-Beckmann Rearrangement of syn-*5β-Cholestan-6-one Oxime 6*: Oxime **6** (500 mg) in dry MeOH (250 ml) was irradiated for 12 hr. After removal of the solvent under reduced pressure, tlc of the residue revealed the formation of several products. However, there were two major spots. Preparative tlc ($CHCl_3$/ether; 4/1) afforded four fractions A, B, C and D in order of increasing polarity. Fraction A (198 mg) was again submitted to preparative tlc (benzene) and afforded 4 fractions. The NMR spectrum of the least polar fraction showed that this fraction was most probably 5, 6-seco ester. The polarities of the second and the third least polar fractions were close together and the second least polar fraction (30 mg) afforded 15 mg of crystals which were identical with 5α-cholestan-6-one. The third least polar fraction (100 mg) afforded 5β-cholestan-6-one (34 mg).

Fraction B was mainly crude starting material. The amorphous fraction C (229 mg) was again submitted to preparative tlc ($CHCl_3$/ether; 4/1) and afforded 120 mg of lactam **8** and 83 mg of lactam **9**. The most polar fraction D did not contain any lactams and was not examined further.

Photo-Beckmann Rearrangement of anti-*5β-cholestan-6-one Oxime 5*: Freshly prepared anti-5β-cholestan-6-one oxime (500 mg) in dry MeOH (300 ml) was photolyzed in the same manner as the *syn*-isomer. After 11 hr examination of the products by tlc revealed that nearly all the starting oxime had disappeared. After removal of the solvent the residue was extracted with ether. The ethereal solution was washed and dried as usual. The residue was separated by preparative tlc. Using the procedure employed for the *syn*-oxime, pure 5α-cholestan-6-one (13 mg) was obtained from 20 mg of crude fraction. In addition 22 mg of pure 5β-cholestan-6-one was obtained from 30 mg of crude 5β-compound. From the lactam part, 150 mg of lactam **8**

* Recorded previously as mp 95—100 °C.

and 90 mg of crude lactam **9** were obtained and the latter was recrystallized from ethanol to yield 59 mg of pure compound.

*The Photo-Beckmann Rearrangement of 5β-Cholestan-6-one Oxime, **5** and **6**, in the Presence of Oxygen*: A mixture of *syn* and *anti* isomers of 5β-cholestan-6-one oxime (420 mg) in dry methanol (280 ml) was photolyzed for 17.5 hr while dry oxygen was bubbled slowly. After removal of the solvent under reduced pressure the residue was dissolved in $CHCl_3$ and the solution was washed twice with H_2O, dried and evaporated. Another 300 mg of oxime in dry methanol (200 ml) was photolyzed under comparable condition and the solution was treated as above. The residues from these two photolyses were submitted to preparative tlc. The first preparative tlc was carried out with a mixed solvent of $CHCl_3$ and ether (4/1 in vol.). This enabled us to separate the mixture into two major fractions, a less polar fraction A (300 mg) and a more polar fraction B (300 mg). Between these two major bands on the tlc plate, several minor products were observed but these did not contain any lactams and were not examined further.

Fraction A was again submitted to preparative tlc with benzene and afforded four fractions A_1, A_2, A_3 and A_4 in order of increasing polarity. Fraction A_1 (120 mg) was amorphous and it was found to be 5, 6-seco-cholestan-6-oic acid methyl ester on the basis of its IR spectrum. The crystalline fraction A_2 (30 mg) was recrystallized from acetone to yield 5 mg of pure 5α-cholestan-6-one. The crystalline fraction A_3 (70 mg) was recrystallized from acetone to yield 30 mg of pure 5β-cholestan-6-one. The most polar fraction A_4 (30 mg) was found to be a mixture of the starting oximes.

Fraction B was also submitted to further preparative tlc with a mixed solvent of $CHCl_3$ and ether (5/1). Development was carried out twice. This afforded 70 mg of lactam **8** and 60 mg of lactam **9**.

The Photo-isomerization of 5β-Cholestan-6-one: 5β-Cholestan-6-one (80 mg) in dry methanol (25 ml) and dry dioxane (5 ml) was irradiated with a 15-W low pressure Hg arc lamp under an argon atmosphere. After 3 hr irradiation, examination of the solution revealed the formation of a fair amount of 5α-cholestan-6-one, which was less polar than 5β-cholestan-6-one, and a material considerably less polar than these ketones (R_f=0.88, benzene solvent). The solvent was then removed and the residue was submitted to preparative tlc and afforded a gum (16 mg), 5α-cholestan-6-one (10 mg) and 5β-cholestan-6-one (35 mg). The IR spectrum of the gum revealed it to be an ester (ester C=O, 1740 cm^{-1}, $CHCl_3$). The NMR spectrum showed a three-proton singlet at τ 6.34 ($COOCH_3$) two three proton singlets at τ 9.08 (19-H) and τ 9.32 (18-H) and a two-proton triplet at τ 7.44 ($-CH_2$ adjacent to $COOCH_3$). On the basis of these data, the gum should be 5,6-seco-cholestan-6-oic acid methyl ester.

The signals due to the 10β-methyls and the 13β-methyls of the 5α-isomer[24] and the 5β-isomer in the NMR spectra appeared at the following positions:

	19-H (τ)	18-H (τ)
5α-isomer ($CDCl_3$)	9.27	9.34
(CCl_4)	9.30	9.34
5β-isomer ($CDCl_3$)	9.17	9.35

We are grateful to the Ministry of Education of Japan for financial assistance. We thank Dr. T. Nishida of Japan Electric & Varian Ltd., for measuring the 100 MHz NMR spectra and Mrs. T. Okayama for carrying out the spin decoupling experiments.

The Photolysis of 3,4-Bis(hydroxydiphenylmethyl)cyclobut-3-ene-1,2-dione and Related Compounds. The Formation of a New Bislactone, 4,4,8,8-Tetraphenyl-3,7-dioxabicyclo[3.3.0]oct-1(5)-ene-2,6-dione

Fumio TODA and Eishiro TODO

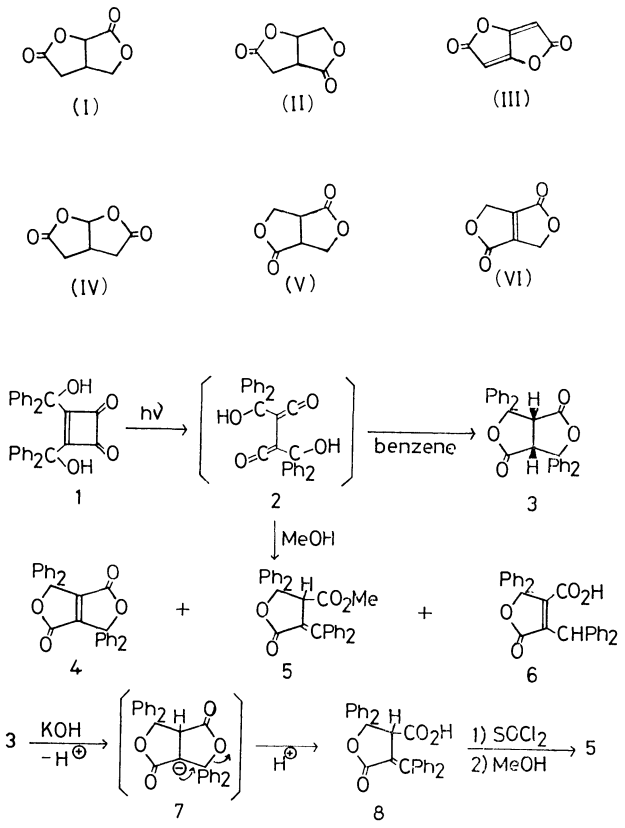
Department of Industrial Chemistry, Faculty of Engineering, Ehime University, Matsuyama 790

(Received July 15, 1974)

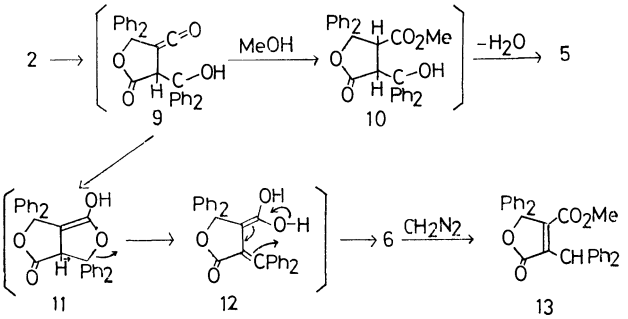
The photolysis of 3,4-bis(hydroxydiphenylmethyl)cyclobut-3-ene-1,2-dione (**1**) in benzene afforded 4,4,8,8-tetraphenyl-3,7-dioxabicyclo[3.3.0]octane-2,6-dione (**3**) in an 80% yield. The photolysis of **1** in MeOH afforded 4,4,8,8-tetraphenyl-3,7-dioxabicyclo[3.3.0]oct-1(5)-ene-2,6-dione (**4**), 4-methoxycarbonyl-3,3-diphenyl-5-diphenylmethylene-2-oxacyclopentan-1-one (**5**), and 4-carboxy-3,3-diphenyl-5-diphenylmethyl-2-oxacyclopent-4-en-1-one (**6**), in 3, 8, and 22% yields respectively. The mechanisms of the formation of the **5** and **6** are discussed. The photolysis of 3-hydroxydiphenylmethyl-4-diphenylmethoxymethylcyclobut-3-ene-1,2-dione (**14**) and 3,4-bis(diphenylmethyl)cyclobut-3-ene-1,2-dione (**18**) was also investigated.

Since the isolation of a novel fungicidal bislactone, *avenaciolide*, which has a 2,7-dioxabicyclo[3.3.0]octane-3,8-dione system (I),[1,2] some bislactones which have 2,7-dioxabicyclo[3.3.0]octane-3,6-dione (II),[3] 4,8-dioxabicyclo[3.3.0]octa-1,5-diene-3,7-dione (III),[4] 2,8-dioxabicyclo[3.3.0]octane-3,7-dione (IV),[5] and 3,7-dioxabicyclo[3.3.0]octane-2,6-dione (V)[6] systems have been reported. This paper will deal with the formation of the title bislactone, which has a hitherto unknown 3,7-dioxabicyclo[3.3.0]oct-1(5)-ene-2,6-dione (VI) system, and a new synthetic route of the bislactone, with the system of V.

The photolysis of 3,4-bis(hydroxydiphenylmethyl)-cyclobut-3-ene-1,2-dione (**1**) in benzene under nitrogen at room temperature afforded 4,4,8,8-tetraphenyl-3,7-dioxabicyclo[3.3.0]octane-2,6-dione (**3**) in an 80% yield. Because the photochemical ring-opening of cyclobutenedione into bisketene has been established,[7] the initial product of the photolysis of **1** should be bisketene (**2**). In order to trap **2**, the photolysis of **1** was carried out in MeOH. The photolysis, however, afforded 4,4,8,8-tetraphenyl-3,7-dioxabicyclo-[3.3.0]oct-1(5)-ene-2,6-dione (**4**), 4-methoxycarbonyl-3,3-diphenyl-5-diphenylmethylene-2-oxacyclopentan-1-one (**5**), and 4-carboxy-3,3-diphenyl-5-diphenylmethyl-2-oxacyclopent-4-en-1-one (**6**) in 3, 8, and 22% yields respectively. Compound **5** was also obtained from **3**. The treatment of **3** with KOH–MeOH afforded 4-carboxy-3,3-diphenyl-5-diphenylmethylene-2-oxacyclopentan-1-one (**8**). The reaction probably proceeds *via* an anion (**7**), which is formed by the deprotonation of **3** (Scheme 1). The treatment of **8** with $SOCl_2$ and then with MeOH afforded **5**.

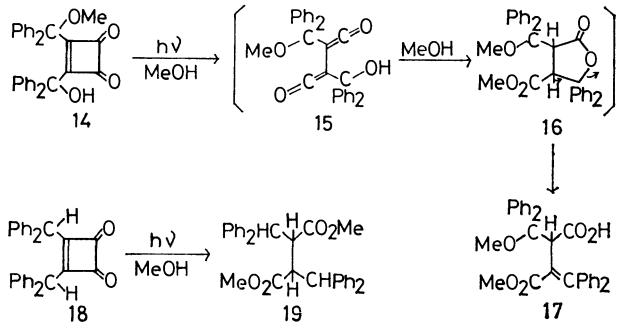


Scheme 1.



Scheme 2.

The formation of **5** and **6** in the photolysis of **1** in MeOH can be interpreted by the reaction sequence shown in Scheme 2. The reaction of **9**, the half-cyclized product of **2**, with MeOH should afford **10**. The dehydration of **10** then finally affords **5**. Because the product ratio of **3**, **4**, and **5** was not varied by a prolonged irradiation of **1** in MeOH, interconversion among the three products during the photolysis can be ruled out. The ring-cleavage of **11**, which is formed by an intramolecular cyclization of **9**, affords **6** *via* the diol (**12**). The reaction of **6** with CH_2N_2 afforded 4-methoxycarbonyl-3,3-diphenyl-5-diphenylmethyl-2-oxacyclopent-4-en-1-one (**13**). Nevertheless, the pathway of the formation of **4** is not clear.



Scheme 3.

The photolysis of 3-hydroxydiphenylmethyl-4-methoxydiphenylmethylcyclobut-3-ene-1,2-dione (**14**) in MeOH afforded 3-methoxycarbonyl-3-diphenylmethylene-2-methoxydiphenylmethylpropionic acid (**17**) in a 65% yield. A possible pathway for the formation of **17** is the ring-cleavage of **16**, which is produced by an intramolecular cyclization of the initially formed bisketene intermediate (**15**) (Scheme 3). The photolysis of 3,4-bis(diphenylmethyl)cyclobut-3-ene-1,2-dione (**18**) in MeOH afforded dimethyl 2,3-bis(diphenylmethyl)succinate (**19**) in a 23% yield. However, both **14** and **18** were inert to the photolysis in benzene.

Experimental

All the melting points are uncorrected. Photolysis was carried out at room temperature under a nitrogen atmosphere, using light from a 100-W high-pressure mercury lamp (Riko Kagaku Sangyo Co.), filtered through Pyrex glass. The IR, UV, and NMR spectra were measured in Nujol mull, EtOH, and $CDCl_3$ respectively, unless otherwise stated. The mass spectra were measured with an ionization energy of 75 eV.

*Photolysis of **1** in Benzene.* A solution of **1**[8] (0.5 g) in benzene (150 ml) was irradiated under stirring for 5.5 hr. The crude crystals left after the evaporation of the solvent were recrystallized from AcOEt to afford **3** as colorless needles; 0.4 g (80%); mp 227—228 °C. IR: 1780 (C=O) and 1210 and 1180 cm^{-1} (lactone); $\lambda_{max}^{CHCl_3}$: 242 (1400), 253 (1000), 259 (1200), 262 (1000), and 269 sh nm (ε, 700); NMR: 2.6—3.2 (m, Ph, 20 H) and 5.85 τ (s, CH, 2H); MS: *m/e* (rel intensity) 446 (M^+, 100), 402 ($M^+ - CO_2$, 7), 358 ($M^+ - 2CO_2$, 15), 264 ($M^+ - Ph_2CO$, 70), and 236 ($M^+ - (Ph_2CO + CO)$, 62).

Found: C, 80.95; H, 4.75%. Calcd for $C_{30}H_{22}O_4$: C, 80.70; H, 4.97%.

*Photolysis of **1** in MeOH.* A solution of **1** (3 g) in MeOH (500 ml) was irradiated under stirring for 6 hr. The crude crystals which separated out after the concentration of the reaction mixture to *ca.* 5 ml were collected by filtration. Recrystallization from MeOH afforded **4** as colorless plates; 0.075 g (3%); mp 280—281 °C. IR: 1765 (C=O) and 1080 and 1010 cm^{-1} (lactone); $\lambda_{max}^{CHCl_3}$: 275 sh nm (ε, 2700); NMR: 2.6—3.2 τ (m, Ph); MS: *m/e* (rel intensity) 444 (M^+, 31), 400 ($M^+ - CO_2$, 23), 356 ($M^+ - 2CO_2$, 38), 278 ($M^+ - Ph_2C$, 100), and 218 ($M^+ - CO_2 - Ph_2CO$, 70).

Found: C, 81.08; H, 4.31%. Calcd for $C_{30}H_{20}O_4$: C, 81.06; H, 4.54%.

The MeOH solution left after the separation of the crude **4** was evaporated to dryness, and the residue was recrystallized from benzene–MeOH to afford **6** as colorless prisms; 0.653 g (22%); mp 204—205 °C. IR: 2800—2500 (OH), 1720 (C=O), and 1635 cm^{-1} (C=C); λ_{max}: 240 sh nm (ε, 8500); NMR: 2.2—3.0 (m, Ph, 20H) and 3.88 τ (s, CH, 1H).

Found: C, 80.84; H, 4.86%. Calcd for $C_{30}H_{22}O_4$: C, 80.70; H, 4.97%.

The benzene–MeOH solution left after the separation of **6** was evaporated to dryness, and the residue was chromatographed on Al_2O_3 with benzene to afford **5** as colorless prisms, after recrystallization from acetone–MeOH; 0.24 g, (8%); mp 189—190 °C. IR: 1775 and 1730 (C=O), 1630 (C=C), 1210 (ester), and 1120 cm^{-1} (lactone); λ_{max}: 287 nm (ε, 11600); NMR: 2.5—3.5 (m, Ph, 20H), 5.6 (s, CH, 1H), and 6.85 τ (s, CH_3, 3H).

Found: C, 80.65; H, 5.35%. Calcd for $C_{31}H_{24}O_4$: C, 80.85; H, 5.25%.

*Methyl Ester of **6**.* A solution of **6** (0.1 g) in THF (10 ml) was combined with a CH_2N_2-ether solution (10 ml), and the mixture was kept at 0 °C overnight. The crude crystals left after the evaporation of the solvent were recrystallized from acetone-MeOH to afford **13** as colorless prisms; 0.09 g (87%); 131—133 °C. IR: 1780 and 1740 (C=O), 1650 (C=C), and 1230 cm^{-1} (ester); λ_{max}: 240 sh nm (ε, 8200); NMR: 2.3—2.8 (m, Ph, 20H), 4.06 (s, CH, 1H), and 6.62 τ (s, CH_3, 3H).

Found: C, 80.63; H, 5.36%. Calcd for $C_{31}H_{24}O_4$: C, 80.85; H, 5.25%.

*Hydrolysis of **3**.* A solution of **3** (0.10 g) in 5% KOH–MeOH (10 ml) was heated under reflux for 1 hr. The crude crystals which were separated out by the acidification of the reaction mixture were recrystallized from CCl_4 to afford **8** as colorless prisms; 0.08 g (80%); mp 206—207 °C. IR: 2800—2500 (OH), 1780 and 1740 (C=O), and 1620 cm^{-1} (C=C); λ_{max}: 286 nm (ε, 10900).

Found: C, 80.54; H, 5.07%. Calcd for $C_{30}H_{22}O_4$: C, 80.70; H, 4.97%.

A mixture of **8** (0.04 g), benzene (15 ml), and $SOCl_2$ (0.05 ml) was heated under reflux for 9 hr. The crude product left after the evaporation of the solvent was dissolved in MeOH (20 ml), and the solution was heated under reflux for 6 hr. The crude crystals left after the evaporation of the solvent were recrystallized from MeOH to afford **5**; 0.02 g (48%).

*Photolysis of **14** in MeOH.* A solution of **14**[8] (0.4 g) in MeOH (150 ml) was irradiated under stirring for 3.5 hr. The crude crystals left after the evaporation of the solvent were recrystallized from AcOEt to afford **17** as colorless needles; 0.277 g (65%); mp 179—180 °C. IR: 2800—2600 (OH), 1710 (C=O), and 1230 cm^{-1} (ester); λ_{max}: 252 (8800), 263 sh (8200), and 270 sh nm (ε, 7200); NMR: 2.3—3.3 (m, Ph, 20 H), 5.31 (s, CH, 1H), 6.68 (s, CH_3,3H), and 6.87 τ (s, CH_3, 3H).

Found: C, 77.84; H, 5.95%. Calcd for $C_{32}H_{28}O_5$: C, 78.03; H, 5.73%.

*Photolysis of **18** in MeOH.* A solution of **18**[8] (0.5 g) in MeOH (150 ml) was irradiated under stirring for 4 hr. The crude crystals left after the evaporation of the solvent were recrystallized from acetone–MeOH to afford **19** as colorless needles; 0.16 g (23%); mp 166—167 °C. IR: 1740 (C=O) and 1220 cm^{-1} (ester); λ_{max}: 260 nm (ε, 1000); NMR: 2.5—3.5 (m, Ph, 20 H), 5.55 (d, J=12 Hz, CH, 2H), 6.52 (s, CH_3, 6H), and 6.60 τ (d, J=12 Hz, CH, 2H).

Found: C, 80.45; H, 6.12%. Calcd for $C_{32}H_{28}O_4$: C, 80.64; 5.92%.

The Michael Reactions of Chloro-substituted-9,9′-bifluorenylidenes with Fluorenes and a Comparison with Analogous Halogen Compounds[1)]

Masahiro MINABE and Kazuo SUZUKI

Department of Industrial Chemistry, Faculty of Technology, Utsunomiya University, Ishii-cho, Utsunomiya 321-31

(Received July 19, 1974)

The Michael reactions of 2-chloro- and 2,7-dichloro-9,9′-bifluorenylidenes with fluorenes were investigated. Structures of these products were confirmed by syntheses through the well-established reactions of 9-lithiofluorenes and 9-bromo-9,9′-bifluorenyls. The formation of some abnormal compounds is explained by intermediary formation of 2,7-dichloro-9,9′-bifluorenylidene from the reaction of 9,9′-bifluorenylidene with 2,7-dichlorofluorene as with the bromo-derivatives. The corresponding fluoro- and iodo-series gave predominantly normal addition products. These differences are explained in terms of the inductive and steric effects of the halogen substituents.

The Michael reactions of chloro-substituted-9,9′-bifluorenylidenes with fluorenes, and the syntheses of some new chloro-derivatives were investigated. 2,7-Dibromo-substituted substrates afforded a large amount of abnormal 2,7,2″,7″-tetrabromo-9,9′ : 9′,9″-terfluorenyl and a small amount of bromine-free 9,9′ : 9′,9″-terfluorenyl (mp 293 °C (dec), **24**).[2)] However, the fluoro-[3)] and iodo-[4)] derivatives underwent predominantly normal additions.

In the present paper, the substituent effect of chlorine atoms in these Michael reaction is examined and compared with the effects of other halogen atoms in the crowded molecule 9,9′ : 9′,9″-terfluorenyl.

The reaction of 9,9′-bifluorenylidene (**7**) with 2,7-dichlorofluorene (**5**) gave the expected 2,7-dichloro-9,9′ : 9′,9″-terfluorenyl (**19**) and abnormal compounds 2,7,2″,7″-tetrachloro-9,9′ : 9′,9″-terfluorenyl(**22**) and **24**. The pathway of the reaction may be similar to that of the bromo-derivatives in which 2,7-dibromo-9,9′-bifluorenylidene is one of the intermediates.

Results and Discussion

Various normal and abnormal chloro-substituted-9,9′ : 9′,9″-terfluorenyls and elimination products were obtained by the reaction of 9,9′-bifluorenylidenes with fluorenes, as shown in Tables 1 and 2.

These reactions of chloro-derivatives afforded exclusively normal products in the presence of sodium carbonate or sodium ethoxide, but the yield of abnormal products in the reactions of **7** with **5** and of 2,7,2′,7′-tetrachloro-9,9′-bifluorenylidene (**10**)[5] with fluorene (**1**) increased with increasing concentration of potassium hydroxide in pyridine.

Scheme 1.

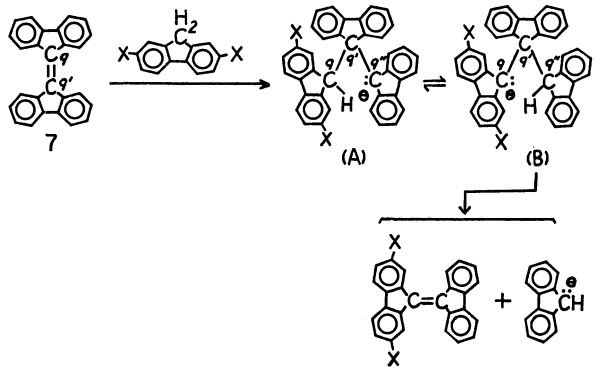
The structures of the new addition compounds were confirmed by syntheses through the interconversion reactions between 9-lithiofluorenes and 9-bromo-9,9′-bifluorenyls.

The Michael reaction of **7** with 2,7-dihalofluorene was carried out in order to examine the effects of different halogen substituents. It is noteworthy that the reaction of **7** with **5** gave significant amounts of abnormal compounds as with the corresponding bromo-derivative: however, 2,7-difluorofluorene gave only the expected compound, and the iodo-derivative afforded chiefly normal product. These irregular results are illustrated in Table 3.

In the primary addition, the overcrowded carbanion (A) (X=Cl) is formed by an attack of 2,7-dichloro-9-fluorenyl ion on the 9-position of the twisting central double bond in **7**. Carbanion (B) may be formed by intramolecular proton-transfer in (A), thus we propose the equilibrium shown in Scheme 2:

The ions (A) and/or (B) are transformed to the normal compound **19** by protonation.

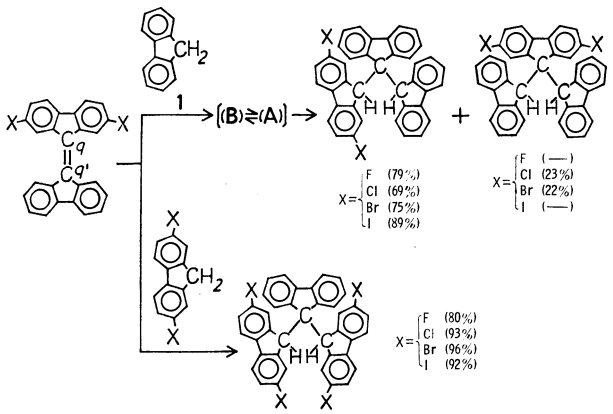
The formation of the abnormal compounds can be explained by a series of reactions: elimination, re-



Scheme 2.

addition, and protonation. Compound 2,7-dichloro-9,9′-bifluorenylidene (**11**) and 9-fluorenyl ion are probably formed by fission of the 9′-9″ carbon-carbon bond in ion (B). Subsequently, the secondary addition product **22** may be obtained by the nucleophilic attack of the 2,7-dichloro-9-fluorenyl ion on the highly-polarized **11**, followed by protonation. The tertiary product **24** could be formed by further reaction of **7** with a fragmentary 9-fluorenyl ion.

The stable abnormal compound **22** was obtained as one of the reaction products of three reactions: **7** with **5**, **10** with **1**, and also **11** with **5**. The reactive **11** which played an important role in the formation of **22** was not isolated in these experiments.[6] In this connection, Scheme 3 shows the reactions of halogen analogues of **11** with fluorenes.



Scheme 3.

From these findings, the 9-carbon atom on **11** is apparently more electronegative than the 9′-carbon due to the inductive effect of the two substituents.[7] The reaction of **11** with **5** gave exclusively **22** instead of 2,7,2′,7′-tetrachloro-9,9′ : 9′,9″-terfluorenyl (**21**). The formation of **22** can be explained by the steric effect in addition to the inductive effect: that is, the mutually repulsive 2,7- and 2″,7″-dichlorofluorenyl groups are placed as far from one another as possible. Therefore, the most stable compound, **22** is formed so as to minimize the steric hindrance.

Isomers **19** and 2′,7′-dichloro-9,9′ : 9′,9″-terfluorenyl (**20**) were obtained by the reaction of **11** with **1**, but no **20** was isolated by the reaction of **10** with **1**. This

can be ascribed to the greater reactivity of **5** compared to **1** and to the low concentration of fragmentary **11** in the latter reaction.

The formation of the expected compound by reaction of **7** with 2,7-difluorofluorene can be explained as follows. The greater inductive effect of the two fluorine atoms will stabilize the ion (B) (X=F) (Scheme 2), and hence prevent the dissociation of the ion (B) into 2,7-difluoro-9,9′-bifluorenylidene and 9-fluorenyl ion. Consequently, protonation of ions (A) and/or (B) may occur readily (see Table 3). Actually, the expected fluoro compound was obtained by the reaction of 2,7-difluoro-9,9′-bifluorenylidene with **1** (Scheme 3).

The influence of the inductive effect of the two iodine atoms in the ion (A) (X=I) is smaller than those of other halogen atoms. Since, in addition to this effect, the 9-carbon atom of ion (A) cannot easily approach the 9″-carbanion on account of the steric repulsion of the bulky two iodine atoms attached to 9-fluorenyl group, intramolecular proton-transfer of (A) to (B) (X=I) is hindered (Scheme 2). Therefore, the normal iodo compound was formed with ease *via* the 9″-carbanion (A) (see Table 3).

The inductive influence of iodine atoms in 2,7-diiodo-9,9′-bifluorenylidene may be smaller than those of other halogen atoms. However, the reaction of 2,7-diiodo-9,9′-bifluorenylidene with **1** afforded predominantly 2,7-diiodo-9,9′ : 9′,9″-terfluorenyl. This indicates that no attack of 9-fluorenyl carbanion on the 9-position of the acceptor occurred due to the steric repulsion between the 9-fluorenyl group and the bulky 2,7-diiodo-9-fluorenylidene.

Consequently, the inductive effects and steric influences of chlorine and bromine atoms in (A) and (B) (X=Cl, Br) are intermediate between those of fluorine and iodine atoms (X=F, I). Thus, in the chloro- and bromo-substituted compounds, both normal and abnormal compounds could be formed in these crowded molecules.

Experimental[8]

*Syntheses of 9,9′-Bifluorenylidenes. 2-Chloro-9,9′-bifluorenylidene (**9**)*: **9** was produced from 2-chloro-9-bromo-9,9′-bifluorenyl or 2-chloro-9′-bromo-9,9′-bifluorenyl by the reaction with potassium hydroxide-methanol in acetone at 2—5 °C, with yields of 60% and 70%, respectively, mp 145—147 °C. Found: C, 85.79; H, 3.83%. Calcd for $C_{26}H_{15}Cl$: C, 86.06; H, 4.17%.

Complexes with 2,4,7-trinitrofluorenone, mp 219—220 °C. Found: C, 62.50; H, 2.32; N, 8.27%. Calcd for $C_{52}H_{25}N_6O_{14}Cl$: C, 62.88; H, 2.54; N, 8.46%.

Dehydration of 2-chloro-9′-hydroxy-9,9′-bifluorenyl by sulfuric acid in acetic acid afforded **9** in 25% yield, accompanied by 2-chloro-9′-acetoxy-9,9′-bifluorenyl (8%), mp 211—211.5 °C. Found: C, 79.37; H, 4.39%. Calcd for $C_{28}H_{19}O_2Cl$: C, 79.52; H, 4.53%. IR (>C=O): 1745 cm^{-1}.

*2,2′-Dichloro-9,9′-bifluorenylidene (**8**)*: 2-Chloro-9-bromofluorene was allowed to react with 1.1 mol equivalent of methanolic sodium hydroxide in acetone at 5—7 °C: red needles of **8** were formed (85%), mp 250 °C (Lit.,[9] mp 258—261 °C). Found: C, 78.64; H, 3.40%. Calcd for $C_{26}H_{14}Cl_2$: C, 78.60; H, 3.55%.

*2,7-Dichloro-9,9′-bifluorenylidene (**11**)*: A mixture of 4.1 g of 2,7-dichloro-9′-hydroxy-9,9′-bifluorenyl, 150 ml of acetic acid, and 2 ml of concentrated sulfuric acid was refluxed for 20 min. Red needles **11** were obtained in 94% yield after recrystallization from acetone, mp 227—228 °C. Found: C, 78.87; H, 3.61%.

*2,7,2′,7′-Tetrachloro-9,9′-bifluorenylidene (**10**)*: **10**, mp 426—428 °C (dec), was synthesized in 84% yield from 2,7-dichloro-9-bromofluorene in a similar manner to **8**. Found: C, 66.69; H, 2.65%. Calcd for $C_{26}H_{12}Cl_4$: C, 66.99; H, 2.59%.

In another method, the reaction mixture obtained as described above was heated for 20 min, and allowed to stand overnight. The resulting mixture was worked up to give **10** in 34% yield, mp 428 °C (dec), 3% of 2,7,2′,7′,2″,7″-hexachloro-9,9′ : 9′,9″-terfluorenyl (**23**), mp 319—320 °C (dec), and 26% of 2,7-dichlorofluorenone (**6**), mp 188—189 °C. Found for **23**: C, 66.92; H, 3.15%. Calcd for $C_{39}H_{20}Cl_6$: C, 66.79; H, 2.87%.

Synthesis of 2,7-Dichloro-9,9′-bifluorenyl. Four milliliters of concentrated hydrochloric acid was added to a boiling mixture of 0.2 g of **11**, 50 ml of acetic acid, and 1.0 g of zinc dust and the mixture was refluxed for 30 min. After filtration of the hot colorless reaction mixture, the dried precipitate was recrystallized from benzene to afford 0.19 g (95%) of colorless needles of 2,7-dichloro-9,9′-bifluorenyl, mp 263—264 °C. Found: C, 78.22; H, 4.01%. Calcd for $C_{26}H_{16}Cl_2$: C, 78.21; H, 4.04%.

*2,2′-Dichloro-9,9′-bifluorenyl (**12**)*:[10] This compound was synthesized from **8** under similar conditions to those for 2,7-dichloro-9,9′-bifluorenyl. Yield 99%, mp 275—276 °C. Found: C, 78.23; H, 3.89%.

2-Chloro-9,9′-bifluorenyl: **9** was reduced by the standard procedure. Yield 90%, mp 237—238 °C. Found: C, 85.82;, H, 4.37%. Calcd for $C_{26}H_{17}Cl$: C, 85.59; H, 4.70%.

*2,7,2′,7′-Tetrachloro-9,9′-bifluorenyl (**13**)*: The compound was obtained from **10**. Yield 90%, mp 300—301 °C. Found: C, 66.36; H, 2.92%. Calcd for $C_{26}H_{14}Cl_4$: C, 66.70; H, 3.01%.

*Syntheses of Bis(4-chloro-2,2′-biphenylylene)-1,3-butadiene (**25**) and Bis(4,4′-dichloro-2,2′-biphenylylene)-1,3-butadiene (**26**).*[11] A mixture of 1.00 g (5 mmol) of 2-chlorofluorene (**3**), 45 ml of ethanol, and 2.5 g of potassium hydroxide in 5 ml of water was refluxed under a gentle stream of air for 20 hr. The precipitate was recrystallized from pyridine to give 0.66 g (62%) of orange needles **25**, mp 386—388 °C (dec). Found: C, 79.75; H, 3.64%. Calcd for $C_{28}H_{16}Cl_2$: C, 79.44; H, 3.81%.

In addition, a small amount of 2-chlorofluorenone (**4**), mp 123—124 °C, was obtained from the ethanol mother solution.

Compound **26** was obtained from **5** in 55% yield, red needles, mp 392—393 °C (dec). Found: C, 68.23; H, 2.59%. Calcd for $C_{28}H_{14}Cl_4$: C, 68.32; H, 2.87%.

Syntheses of 9-Hydroxy-9,9′-bifluorenyls and 9-Bromo-9,9′-bifluorenyls. General procedure: 9-Hydroxy-9,9′-bifluorenyl was prepared under a slow stream of oxygen-free nitrogen in the usual way. To 9-lithiofluorene (obtained by the reaction of 0.035 mol of fluorene with *n*-butyl lithium) in xylene was added 0.03 mol of fluorenone (**2**), and the mixture was refluxed for 30 min. After cooling, the reaction mixture was hydrolyzed with aqueous ammonium chloride, washed with water, dried, and concentrated to dryness *in vacuo*. The precipitate was recrystallized from benzene, cyclohexane, or a mixture of both.

9-Bromo-9,9′-bifluorenyl was synthesized by the reaction of 9-hydroxy-9,9′-bifluorenyl with dry hydrogen bromide in acetic acid below 25 °C

1): 2-Chloro-9-hydroxy-9,9′-bifluorenyl, 97% yield, mp 184—186 °C. IR (–OH): 3540 cm^{-1} (sharp). Found: C, 81.97; H, 4.60%. Calcd for $C_{26}H_{17}OCl$: C, 81.99; H, 4.50%.

2-Chloro-9-bromo-9,9′-bifluorenyl, 86%. mp 180—182 °C (dec). Found: C, 70.57; H, 3.46%. Calcd for $C_{26}H_{16}ClBr$: C, 70.36; H, 3.64%.

2): 2-Chloro-9′-hydroxy-9,9′-bifluorenyl, 95%, mp 177—179 °C. IR (–OH): 3280 cm^{-1}. Found: C, 82.22; H, 4.49%.

2-Chloro-9′-bromo-9,9′-bifluorenyl, 94%, mp 153—155 °C (dec). Found: C, 70.51; H, 3.48%.

3): 2,2′-Dichloro-9-hydroxy-9,9′-bifluorenyl, 81%, mp 182—183 °C. IR (–OH): 3300 cm.$^{-1}$ Found: C, 75.44; H, 3.69%. Calcd for $C_{26}H_{16}OCl_2$: C, 75.19; H, 3.88%.

2,2′-Dichloro-9-bromo-9,9′-bifluorenyl, 83%, mp 184—185 °C (dec). Found: C, 65.67; H, 3.03%. Calcd for $C_{26}H_{15}Cl_2Br$: C, 65.30; H, 3.16%.

4): 2,7-Dichloro-9-hydroxy-9,9′-bifluorenyl, 59%, mp 197—198 °C. IR (–OH): 3265 cm^{-1}. Found: C, 74.85; H, 4.03%.

2,7-Dichloro-9-bromo-9,9′-bifluorenyl, 72%, mp 217—219 °C (dec). Found: C, 65.47; H, 3.32%.

5): 2,7-Dichloro-9′-hydroxy-9,9′-bifluorenyl, 44%, mp 189—191 °C. IR (–OH): 3550 cm^{-1} (sharp). Found: C, 75.39; H, 3.85%.

2,7-Dichloro-9′-bromo-9,9′-bifluorenyl, 83%, mp 201—202 °C (dec). Found: C, 65.76; H, 3.26%.

6): 2,7,2′,7′-Tetrachloro-9-hydroxy-9,9′-bifluorenyl, 51%, mp 227—229 °C. IR (–OH): 3555 cm^{-1} (sharp). Found: C, 64.37; H, 2.80%. Calcd for $C_{26}H_{14}OCl_4$: C, 64.49; H, 2.91%.

2,7,2′,7′-Tetrachloro-9-bromo-9,9′-bifluorenyl, 41%, mp 215—217 °C (dec). Found: C, 57.47; H, 2.35%. Calcd for $C_{26}H_{13}Cl_4Br$: C, 57.08; H, 2.40%.

Formation of 9,9′ : 9′,9″-Terfluorenyls by Lithium-Halogen Interconversion Reaction. General Procedure: To a 9-lithiofluorene solution (prepared from 0.014 g-atom of lithium chips, 7 mmol of *n*-butyl bromide, and 7 mmol of fluorene) was added 4 mmol of 9-bromo-9,9′-bifluorenyl in xylene at 5—10 °C over a period of about 1 hr. After refluxing for 1 hr, the reaction mixture was worked up as usual.

*2-Chloro-9,9′ : 9′,9″-terfluorenyl (**14**)*: This compound was synthesized from **3** and 9-bromo-9,9′-bifluorenyl, mp 255—257 °C (dec) (benzene-ethanol). Found: C, 88.64; H, 4.54%. Calcd for $C_{39}H_{25}Cl$: C, 88.54; H, 4.76%.

*2′-Chloro-9,9′ : 9′,9″-terfluorenyl (**15**)*: From **1** and 2-chloro-9-bromo-9,9′-bifluorenyl, mp 271—272 °C (dec) (ethyl acetate). Found: C, 88.66; H, 4.53%.

*2,2′-Dichloro-9,9′ : 9′,9″-terfluorenyl (**16**)*: From **3** and 2-chloro-9-bromo-9,9′-bifluorenyl, mp 253—254 °C (dec) (benzene-ethanol) Found: C, 83.01; H, 4.36%. Calcd for $C_{39}H_{24}Cl_2$: C, 83.13; H, 4.29%.

*2,2″-Dichloro-9,9′ : 9′,9″-terfluorenyl (**17**)*: From **3** and 2-chloro-9′-bromo-9,9′-bifluorenyl, mp 275—276 °C (dec) (ethyl acetate). Found: C, 83.43; H, 4.15%.

*2,2′,2″-Trichloro-9,9′ : 9′,9″-terfluorenyl (**18**)*: From **3** and 2,2′-dichloro-9-bromo-9,9′-bifluorenyl, mp 279—280 °C (dec) (ethyl acetate). Found: C, 78.02; H, 3.69%. Calcd for $C_{39}H_{23}Cl_3$: C, 78.34; H, 3.88%.

*2,7-Dichloro-9,9′ : 9′,9″-terfluorenyl (**19**)*: From **5** and 9-bromo-9,9′-bifluorenyl, mp 285—287 °C (dec) (ethyl acetate). Found: C, 83.10; H, 4.25%.

*2′,7′-Dichloro-9,9′ : 9′,9″-terfluorenyl (**20**)*: From **1** and 2,7-dichloro-9-bromo-9,9′-bifluorenyl, mp 305—306 °C (dec) (benzene). Found: C, 83.38; H, 4.47%.

*2,7,2′,7′-Tetrachloro-9,9′ : 9′,9″-terfluorenyl (**21**)*: From **5** and 2,7-dichloro-9-bromo-9,9′-bifluorenyl, mp 296—297 °C (dec) (ethyl acetate). Found:,C, 74.26; H, 3.46%. Calcd for $C_{39}H_{22}Cl_4$: C, 74.07; H, 3.51%.

*2,7,2″,7″-Tetrachloro-9,9′ : 9′,9″-terfluorenyl (**22**)*: From **5** and 2,7-dichloro-9′-bromo-9,9′-bifluorenyl, mp 314—315 °C (dec) (pyridine). Found: C, 74.38; H, 3.71%.

*2,7,2′,7′,2″,7″-Hexachloro-9,9′ : 9′,9″-terfluorenyl (**23**)*: From **5** and 2,7,2′,7′-tetrachloro-9-bromo-9,9′-bifluorenyl, mp 320 °C (dec) (benzene). Found: C, 66.91; H, 3.01%. Calcd for $C_{39}H_{20}Cl_6$: C, 66.79; H, 2.87%.

*Michael Reaction of 2,7-Dichloro-9,9′-bifluorenylidene (**11**) with 2,7-Dichlorofluorene (**5**). Typical Procedure*: A mixture of 2.4 g (6 mmol) of **11**, 1.6 g (6.6 mmol) of **5**, 28 ml of pyridine, and 0.3 g (1% for solvent) of potassium hydroxide in 2 ml of water was heated in a sealed tube at 98—100 °C for 15 min. During the heating, the color turned from red to dark green, and colorless crystalline was deposited. Upon cooling, the reaction mixture was added to 400 ml of water, and the deposited material was filtered and sublimed at 160 °C *in vacuo*. The residual part after sublimation was recrystallized from pyridine to afford **22** in 3.56 g (93%), mp 314—315 °C (dec).

The sublimate was chromatographed on alumina with benzene solvent. The elute was concentrated under reduced pressure, and the residue was recrystallized from ethanol to give **5** in 0.08 g yield, mp 123—124 °C: 0.03 g of **6**, mp 186—187 °C (from ethanol), was isolated from the yellow band on the column.

This work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, which is gratefully acknowledged.

The Reactions of β-Amino α,β-Unsaturated Esters with Amines. II. Syntheses of Some New Derivatives of Quinazolines

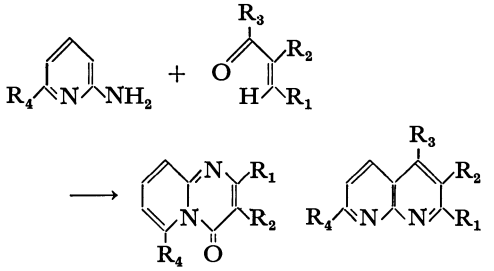
Yasukazu YOKOYAMA, Katsuya SHIBATA, Osamu FUJII, and Eiji IWAMOTO

Research Center of Tekkosha Co., Ltd., 2743-1 Uehara, Hayakawa, Ayase-cho, Koza-gun, Kanagawa 252

(Received July 30, 1974)

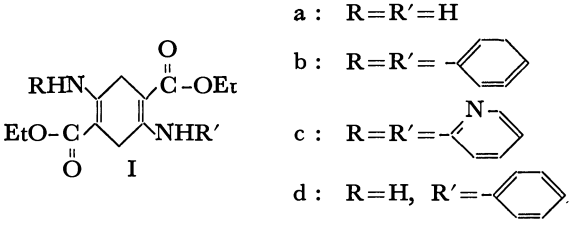
The reaction of 1,4-bis(ethoxycarbonyl)-2,5-diamino-1,4-cyclohexadiene(Ia) with aniline in aprotic solvents gave *N,N'*-diphenylurea, whereas in the presence of a proton acid this reaction gave an amine-exchanged product, 1,4-bis(ethoxycarbonyl)-2,5-dianilino-1,4-cyclohexadiene(Ib). However, when 2-aminopyridine was used in place of aniline for this reaction, 1,4-bis(ethoxycarbonyl)-2,5-bis(2-pyridylamino)-1,4-cyclohexadiene(Ic) was not isolated but its cyclyzed analogue, 6,7,14,15-tetrahydropyrido[2,1-*b*]pyrido[1',2' : 1,2]pyrimido[4,5-*g*]quinazoline-7,15-dione(IIa), was obtained. The reaction of 2-amino-6-methylpyridine with Ia also gave a quinazoline derivative without producing a 1,8-naphthyridine derivative. Since this reaction took place easily in a weak acid, AcOH, this cyclization could proceed by an intramolecular proton-transfer mechanism.

Aminopyridines have two basic nitrogen atoms in the molecule, and their reaction with β-keto esters or β-amino α,β-unsaturated esters is of interest. The condensation of 2-aminopyridine with β-keto ester followed by cyclization in Dowtherm A (a mixture of 23.5% by weight of biphenyl and 76.5% of diphenyl ether) affords the pyridopyrimidines.[1] When the 2-aminopyridine is substituted in the 6-position with an electron-releasing group, the naphthyridine is formed.[2]



Antaki and Petrow have studied the reaction of 2-aminopyridines with ethyl β-aminocrotonate, and obtained pyridopyrimidines and *N,N'*-bis(6-methyl-2-pyridyl)urea.[3] However, this reaction has not been further investigated.

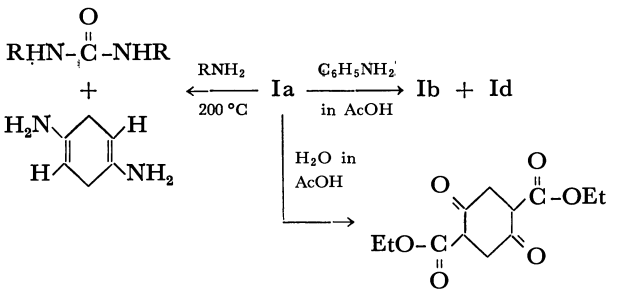
Therefore, in this work, 1,4-bis(ethoxycarbonyl)-2,5-diamino-1,4-cyclohexadiene(Ia) was used as a β-amino α,β-unsaturated ester, and its reaction with 2-aminopyridines was studied. Some new compounds were synthesized and possible reaction mechanisms were investigated by comparing the reactivity to Ia of 2-aminopyridine with that of aniline.



Results and Discussion

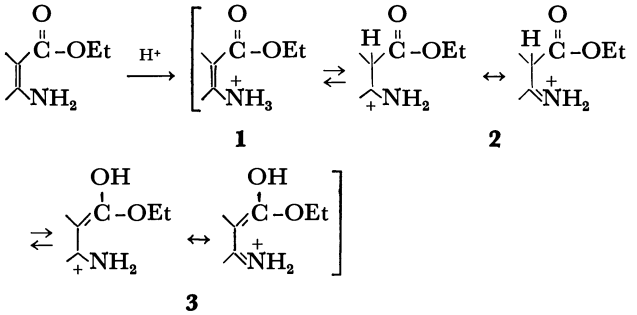
When a mixture of Ia and aniline was heated in *N*-methyl-2-pyrrolidone(NMP) or dimethyl sulfoxide (DMSO) under a nitrogen atmosphere at 200 °C for 2 hr, *N,N'*-diphenylurea was the main product.

However, when a proton acid was used as a catalyst, the amino groups of Ia were replaced by anilino groups, giving Ib and 1,4-bis(ethoxycarbonyl)-2-amino-5-anilino-1,4-cyclohexadiene(Id). When glacial acetic acid was used as the solvent, the yield of Ib was higher. On the other hand, when the reaction was carried out in aqueous acetic acid at elevated temperatures, the amino groups of Ia were replaced by hydroxyl groups, and 1,4-bis(ethoxycarbonyl)-2,5-cyclohexanedione(diethyl succinylsuccinate, DSS) was formed.



DSS

These results indicate that in the absence of a proton acid the nucleophilic attack of an amine takes place upon the carbonyl carbon atom, whereas in the presence of a proton acid this attack takes place upon the β-carbon atom. The former reaction-mechanism has been reported previously.[4] In the latter case, the protonation of β-amino α,β-unsaturated esters could take place on the nitrogen, α-carbon or carbonyl oxygen atom, giving **1**, **2**, or **3**, respectively. The iminium ions **2** and **3** are expected to react with nucleophiles easily.[5] Therefore, an amine-exchange or amine-hydrolysis reaction should proceed readily.

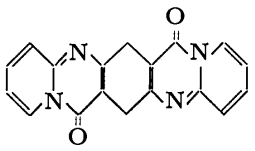


1 **2**

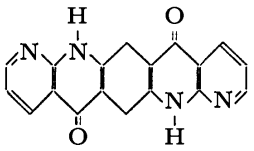
3

The product expected from the reaction between Ia and 2-aminopyridine in glacial acetic acid is Ic. However, its elemental analysis showed the empirical formula $C_9H_6N_2O$. Possible structures are 6,7,14,15-

tetrahydropyrido[2,1-*b*]pyrido[1′,2′ : 1,2]pyrimido[4,5-*g*]quinazoline-7,15-dione(IIa) and 5,6,7,12,13,14-hexahydropyrido[2′,3′ : 2,3]quino[6,7-*b*]-1,8-naphthyridine-7,14-dione (IIb).



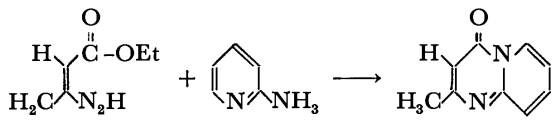
IIa



IIb

The same compound was also obtained when DSS was allowed to react with 2-aminopyridine in glacial acetic acid. This compound was determined to be IIa on the basis of its UV, IR, and NMR spectrum.

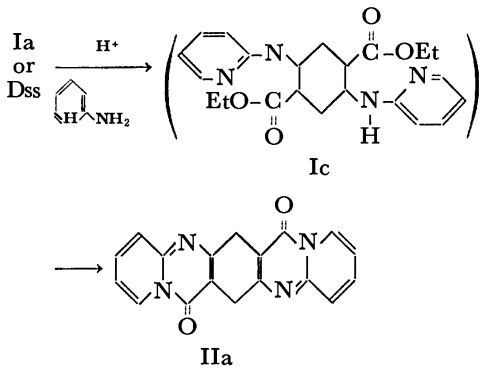
A similar reaction has been studied by Antaki and Petrow. That is, they have reported that 2-methylpyrido[1,2-*a*]pyrimidin-4-one(III) was obtained by heating ethyl β-aminocrotonate with 2-aminopyridine in the absence of a solvent at 160—180 °C for 6—8 hr, and then for a further hour at 200—220 °C.[3] Adams and Pachter confirmed the structure of III by studying its UV spectrum.[1b]



III

However, we easily obtained the same compound by heating ethyl acetoacetate and 2-aminopyridine in glacial acetic acid.

Therefore, it seems that intramolecular cyclization takes place directly in acetic acid, and the reaction between Ia and 2-aminopyridine is postulated to proceed as follows: the amino groups of Ia are replaced



Ic

IIa

by the 2-pyridylamino groups and the Ic formed is converted to IIa by intramolecular cyclization.

Furthermore, 2-amino-3-,4-, and 5-methylpyridine also reacted with Ia or DSS in acetic acid to give 6,7,14,15-tetrahydrodimethylpyrido[2,1-*b*]pyrido[1′,2′ : 1,2]pyr-imido[4,5-*g*]quinazoline-7,15-diones(IIc–e).

On the other hand, Lappin has reported that the condensation of 2-amino-6-methylpyridine with ethyl ethoxymethylenemalonate followed by cyclization affords the 1,8-naphthyridine.[1a] Antaki and Petrow have described the reaction of ethyl β-aminocrotonate with 2-amino-6-methylpyridine and have obtained *N*,*N*′-bis(6-methyl-2-pyridyl)urea.[3] Therefore, 2-amino-6-methylpyridine was treated with Ia or DSS in acetic acid, and 6,7,14,15-tetrahydro-1,9-dimethylpyrido[2,1-*b*]pyrido[1′,2′ : 1,2]pyrimido[4,5-*g*]quinazoline-7,15-dione(IIf) was formed.

These compounds were identified on the basis of elemental analyses, IR, UV, and NMR spectra. Tables 1 and 2 show some pertinent data on II and III.

These results indicate that β-amino α,β-unsaturated esters react with 2-aminopyridine or its methyl-derivatives in acetic acid to give only pyridopyrimidines

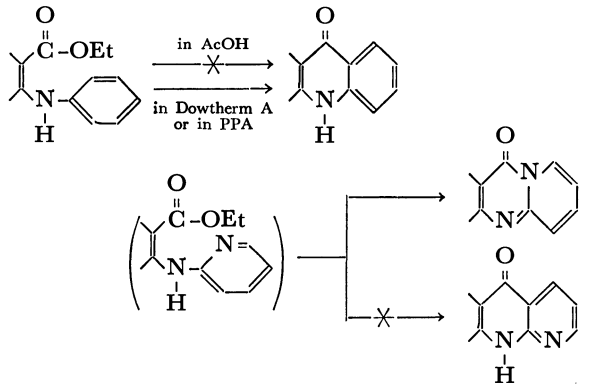
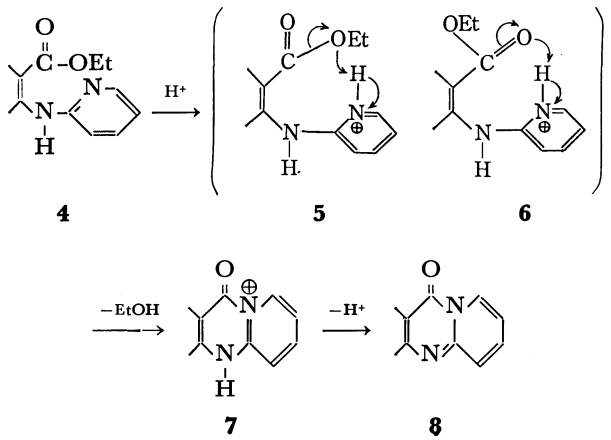
directly without producing a 1,8-naphthyridine derivative.

When Ia or DSS was allowed to react with aniline in glacial acetic acid, only Ib was formed and no further cyclization took place. The cyclization of Ib was achieved by heating in inert solvents at high temperature[6] or in polyphosphoric acid (PPA).[7]

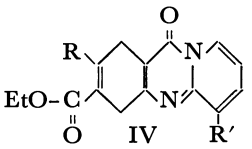


However, the cyclization of Ic occurs more easily than that of Ib in weak acid, acetic acid. This may be explained by assuming the following reaction mechanism. That is, the proton on the nitrogen atom of the



pyridinium ion, **5** and **6**, transfers to the oxygen atom of the ethoxy or the carbonyl group. Then, the carbonium ion formed attacks the nitrogen atom of the pyridine nucleus.

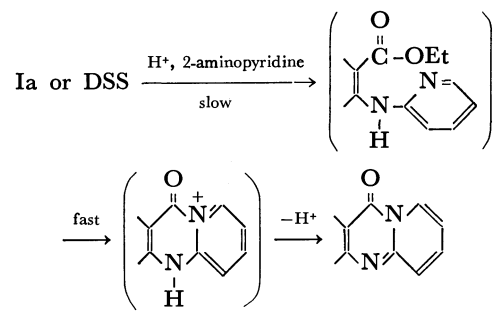
When the reaction of Ia or DSS with 2-aminopyridine in glacial acetic acid was carried out at lower temperatures, the products were 8-amino-7-ethoxycarbonyl-6,9-dihydro-10*H*-pyrido[2,1-*b*]quinazolin-10-one(IVa) or 7-ethoxycarbonyl-6,9-dihydro-8-hydroxy-10*H*-pyrido[2,1-*b*]quinazolin-10-one(IVb), respectively, but Ic was not isolated. The reaction of Ia with 2-aminopyridine in NMP in the presence of *p*-toluenesulfonic acid at 200 °C gave a mixture of IIa and IVa, and that with 2-amino-3-methylpyridine gave a mixture of IIc and 8-amino-7-ethoxycarbonyl-6,9-dihydro-4-methyl-10*H*-pyrido[2,1-*b*]quinazolin-10-one(IVc).



IV

a : $R=NH_2$, $R'=H$
b : $R=OH$, $R'=H$
c : $R=NH_2$, $R'=CH_3$

These observations suggest that the condensation between 2-aminopyridine and Ia or DSS is slow but that the intramolecular cyclization step is very fast.



Compounds II and III are basic compounds and are soluble in acidic solutions such as sulfuric acid or trifluoroacetic acid, and they are reprecipitated upon neutralization or dilution. The UV spectra of III are greatly affected by the change of pH of the solution, as shown in Fig. 1. The absorption of III at 338 nm

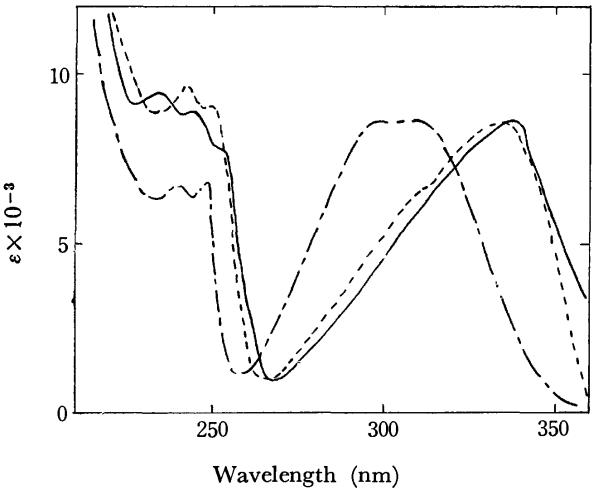


Fig. 1. Electronic absorption spectra of III.
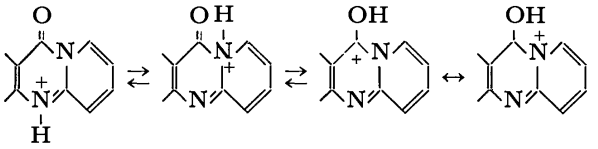
——: in 95% ethanol; ----: in water; ——: in 0.5 M H_2SO_4.

(attributed to the carbonyl group) showed a hypsochromic shift in 0.5 M sulfuric acid solution. The acidic solutions of II showed similar absorptions. These findings suggest that II and III exist in aqueous sulfuric acid solution as tautomers.



Experimental

The IR spectra were determined in KBr disks with a Hitachi EPI-G3 infrared spectrophotometer. The UV spectra were recorded with a Hitachi EPS-3T recording spectrophotometer. The NMR spectra were obtained with a Varian HA-100 high resolution NMR spectrometer, using TMS as an internal standard. For thin layer chromatography (tlc), a plate of Silica-gel HF (E. Merck) was used. Plates were developed with a mixture of benzene and tetrahydrofuran (1 : 1 v/v). Melting points were uncorrected.

Materials. All the reagents except those listed below were obtained from commercial sources and were used without further purification. DMSO and NMP were dried over aluminum oxide and distilled before use. Aniline and 2-amino-3-methylpyridine were dried over synthetic zeolite (Zeolum A-4, Tekkosha) and distilled before use. 2-Aminopyridine, 2-amino-4-, 5-, and 6-methylpyridine were purified by recrystallization. 1,4-Bis(ethoxycarbonyl)-2,5-di(amino- or anilino)-1,4-cyclohexadiene(Ia: mp 117—119 °C, Ib: mp 164—165 °C) were prepared according to the methods described in the literature.[8]

Reactions. *The Reaction of Ia with Aniline*: *a)* A mixture of Ia (9 g), aniline (8 g), and NMP (50 ml) was heated at 197—200 °C for 2 hr while being stirred under a nitrogen atmosphere. The red solution obtained was then cooled and added with stirring to ice-cold 1 M hydrochloric acid (500 ml). The product was extracted with three 200 ml portions of benzene. The combined benzene extracts were washed once with 1 M hydrochloric acid, twice with water, twice with 10% potassium carbonate, once with water, and were finally dried over anhydrous sodium sulfate. The benzene was removed by distillation at reduced pressure, and the residue was washed with methanol, and dried under vacuum. Yield 1.5 g, mp 122—123 °C, Found: C, 56.14; H, 6.13%. IR (cm^{-1}): 1672(C=O), 1640(C=C), 122 and 1070 (ester). The compound was identified as diethyl succinylsuccinate(DSS) by a comparison of its IR spectrum, mp, and tlc R_f value with those of an authentic sample.[9]

White precipitates were formed from the water layer, and were collected by filtration, washed with water, and dried at 60 °C; 2.5 g of white crystals were obtained. The product was determined to be *N,N'*-diphenylurea(DPU) on the basis of a mixed-melting-point determination and a comparison of its IR spectrum and tlc R_f value with those of an authentic sample: mp 242 °C, IR (cm^{-1}): 3325 and 3280(-NH-), 1652, 1557, and 1319 (amide), 755 and 695(phenyl).

b) A mixture of Ia (5 g), aniline (5 g), and DMSO (50 ml) was heated at 186—196 °C for 2 hr with stirring under a nitrogen atmosphere. By the procedure described in *a)*, unreacted Ia was recovered from the benzene layer, and 0.3 g of DPU was isolated from the water layer. Both compounds were confirmed by a mixed-melting-point determination and a comparison of their IR spectra and tlc R_f value with those of authentic samples.

c) A mixture of Ia (5 g), aniline (5 g), and NMP (50 ml) was stirred at room temperature for 2 hr under a nitrogen atmosphere. The orange crystals which appeared were collected by filtration, washed with methanol, and dried in a vacuum to give Ib, which was confirmed by a comparison of its IR spectrum with that of an authentic sample.

d) To a mixture of Ia (5 g), aniline (5 g), and benzene (50 ml), glacial acetic acid (3 ml) was added. The solution was refluxed for 2 hr with stirring under a nitrogen atmosphere. After it was cooled, it was washed with water (120 ml) and concentrated by distillation at reduced pressure. The residue was washed with methanol yielding 2.0 g of Ib as pale orange crystals. The melting point was not depressed when mixed with an authentic sample. The methanol washings were concentrated to give 3.8 g of orange crystals, which were recrystallized from methanol-water: its structure was determined to be 1,4-bis(ethoxycarbonyl)-2-amino-5-anilino-1,4-cyclohexadiene by IR spectroscopy and elemental analysis. Found: C, 65.37; H, 6.61; N, 8.42%. Calcd for $C_{18}H_{22}N_2O_4$: C, 65.44; H, 6.71; N, 8.48%. IR (cm^{-1}): 3460 and 3330 (-NH-), 1650—1670, 1230, and 1100(ester), 750 and 690 (phenyl).

The Hydrolysis of I: A mixture of Ia (5 g), water (5 ml), and glacial acetic acid (50 ml) was refluxed for 2 hr while being stirred under a nitrogen atmosphere. After cooling the solution, pale yellow crystals separated out, yield 70%. This compound was determined to be DSS by a comparison of its IR spectrum, mp, and tlc R_f value.

In a similar manner, the hydrolysis of Ib gave DSS, yield 52%.

The Reaction of Ia or DSS with 2-Aminopyridines: *a)* A mixture of Ia (5.0 g), 2-aminopyridine (5.0 g), and glacial acetic acid (50 ml) was refluxed with stirring under a nitrogen atmosphere for 3 hr. White solids separated, and they were collected on a filter, washed with acetic acid and methanol, and dried at 60 °C. This compound was soluble in strong acid solutions, such as aqueous sulfuric acid or trifluoroacetic acid, and it was reprecipitated upon neutralization or dilution. The UV spectrum was measured in a 0.5 M aqueous sulfuric acid solution, and the NMR spectrum was recorded in trifluoro acetic acid. Its yield and analytical data are listed in Tables 1 and 2. These results proved that the compound was 6,7,14,15-tetrahydropyrido[2,1-*b*]pyrido[1',2' : 1,2]

pyrimido[4,5-*g*]quinazoline-7,15-dione(IIa).

b) Diethyl succinylsuccinate (5.0 g) also reacted with 2-aminopyridine (5.0 g) under the same reaction conditions described above to give 1.5 g of IIa.

c) The reactions of Ia with 2-amino-3-, 4-, 5-, and 6-methylpyridine were carried out in a similar way to that described in *a*). The yields, products, and analytical data of each run are listed in Tables 1 and 2.

The Reaction of Ethyl Acetoacetate with 2-Aminopyridine: An equimolar admixture of ethyl acetoacetate (13.5 ml) and 2-aminopyridine (12 g) was refluxed in glacial acetic acid (50 ml) for 2 hr. After evaporation of the mixture to dryness under reduced pressure, the residue was recrystallized from petroleum benzine as white needles. It was dried at 60 °C, mp 121—122 °C. Its IR, NMR, and UV absorption, and analytical data are summarized in Tables 1 and 2. These results proved that this compound was 2-methylpyrido-[1,2-*a*]pyrimidin-4-one(III).

*8-Amino-7-ethoxycarbonyl-6,9-dihydro-10*H-*pyrido*[*2,1*-b]*quinazolin-10-one(IVa)*: *a)* A mixture of Ia (5.0 g) and 2-aminopyridine (11.0 g) was heated in glacial acetic acid (50 ml) at 100 °C for 30 min under a nitrogen atmosphere. After cooling, the precipitate was collected by filtration, washed with methanol, and dried under vacuum, yielding 5.0 g of white crystals. This compound was soluble in strong acid solutions from which it was reprecipitated on neutralization. The reprecipitated solid was used for analyses, and its structure was determined to be IVa on the basis of its IR spectrum and elemental analysis. Found: C, 63.07; H, 5.21; N, 14.72%. Calcd for $C_{15}H_{15}N_3O_3$: C, 63.16; H, 5.26; N, 14.74%. IR (cm^{-1}): 3425 and 3325 ($-NH_2$), 1680, 1270, and 1060 (ester).

b) A mixture of Ia (5.0 g) and 2-aminopyridine (5.0 g) was refluxed in NMP (50 ml) in the presence of small amounts of *p*-toluenesulfonic acid for 3 hr under a nitrogen atmosphere. After the reaction mixture was cooled, the precipitate was collected by filtration, washed with methanol, and extracted with hot glacial acetic acid. The residue (2.0 g) was determined to be IIa on the basis of its IR spectrum. The extract was diluted with water and neutralized with aqueous ammonia. The white crystals obtained were identified as IVa on the basis of their IR spectra, and the yield was 1.6 g.

*7-Ethoxycarbonyl-6,9-dihydro-8-hydroxy-10*H-*pyrido*[*2,1*-b]*quinazolin-10-one(IVb)*: A mixture of DSS (15 g) and 2-aminopyridine (15 g) was refluxed in glacial acetic acid (100 ml) for an hour while being stirred under a nitrogen atmosphere. The resulting solid (4.5 g) was filtered out at 60 °C, and was determined to be IIa. After cooling the filtrate to room temperature, a white solid separated out. This precipitate was collected and recrystallized from ethanol, yielding 4.7 g of pale yellow crystals. The purified precipitate showed a single spot on tlc and was identified as IVb on the basis of the IR spectrum and elemental analysis. Mp 219—220 °C, IR (cm^{-1}): 1680 (C=O), 1640 (C=C), 1270 and 1060 (ester), Found: C, 62.72; H, 4.95; N, 9.76%. Calcd for $C_{15}H_{14}N_2O_4$: C, 62.94; H, 4.90; N, 9.79%.

*8-Amino-7-ethoxycarbonyl-6,9-dihydro-4-methyl-10*H-*pyrido*[*2,1*-b]*quinazolin-10-one (IVc)*: The reaction of Ia (5.0 g) with 2-amino-3-methylpyridine (5.0 g) gave IIc (1.5 g) and IVc (1.4 g). The structure of IVc was confirmed on the basis of the IR spectrum and elemental analysis. IR (cm^{-1}): 3430 and 3325 ($-NH_2$), 1665—1680 (C=O), 1635 (C=C), 1250 and 1060 (ester), Found: C, 65.18; H, 5.97; N, 14.40 %. Calcd for $C_{16}H_{17}N_3O_3$: C, 64.21; H, 5.69; N, 14.47%.

9) This compound was probably formed by the hydrolysis of Ia with moisture in the NMP or in the atmosphere. It is also possible that the oxygen atom of NMP attacked a β-carbon atom of Ia and the complex obtained was hydrolyzed during the subsequent treatment. No further treatment of the product was undertaken.

Restricted Rotation Involving the Tetrahedral Carbon. XIV. Conformational Equilibria and Attractive Interactions in Substituted 9-Benzyltriptycenes[1]

Fumio Suzuki and Michinori Ōki

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received October 2, 1974)

Several 9-benzyltriptycene derivatives were prepared by addition of benzynes to 9-benzylanthracenes. Rotation about the C_9–C_{benzyl} bond of compounds with a substituent at a *peri*-position to the benzyl group was found to be frozen at low temperatures on the NMR time scale but not at room temperature. In contrast, compounds with two substituents at two *peri*-positions to the benzyl group showed a frozen rotation about the C_9–C_{benzyl} bond at room temperature. Distribution of the conformers, as judged from the PMR intensities, showed preference to the *dl*-isomers in spite of the fact that they are the ones which are highly disfavored by steric effects. Interpretation of the phenomenon was based on the fact that attractive interactions, mainly charge-transfer type, exist between the substituted benzo group in the triptycene skeleton and the benzene ring in the benzyl group.

Many works have been carried out to elucidate the intramolecular interaction in cyclohexanes,[2] heterocyclic systems,[3] and substituted ethanes.[4] They disclosed that the steric interaction and hydrogen bonding are the important factors in determining conformational equilibria. The steric interaction may comprise van der Waals interactions including lone-pair-lone-pair interactions and dipole-dipole interactions. However, we come across examples for which the simple concept of nonbonding interelectronic repulsion does not give correct prediction.[5] In conformational equilibria, anomeric effect[6] and gauche effect[7] are notable examples. Attempts have been made to rationalize these effects on the basis of classical electrostatic interactions or the electron delocalization, but the origin of attractive interaction has remained ambiguous for a long time.

Weak attractive interactions may be present in many cases but they are usually overshadowed by strong repulsive interactions and not detectable. However, if the atoms and groups are held together at the closest proximity and other interactions are surpressed to minimum, there may be a possibility to find such interactions.[8] 9-Substituted triptycenes provide good examples since the substituents at 9- and peri-positions are held within the sum of the respective van der Waals radii.

9-Isopropyltriptycene derivatives exist as conformers of the least repulsion.[9] Thus the isopropyl group is too large to exhibit a weak attractive interaction. A group of the RCH_2 type will give less steric repulsions and there is a possibility that, if group R can possess attractive interaction with a substituent at a peri-position, such a conformation would be favored. Thus it is of interest to study the case of 9-benzyltriptycene derivatives since the phenyl group in the benzyl has relatively low-lying antibonding orbitals which may interact with bonding electrons of high levels of the substituted benzo group in triptycene.

This paper describes the conformational equilibria of 9-benzyltriptycene derivatives, giving evidence for a weak interaction between the phenyl group and the substituted benzene moiety. The phenomena are discussed in terms of orbital interactions. A preliminary report on the conformational equilibria has been published.[10]

Experimental

Syntheses. 9-Benzyltriptycenes were prepared by treating 9-benzylanthracenes with benzynes, as illustrated in the following schema. Some new 9-benzylanthracene derivatives were synthesized by the Grignard reaction of substituted benzylmagnesium chlorides with substituted anthrones, followed by dehydration of the products.

1,4-Dimethyl-9-benzylanthracene. To a solution of benzylmagnesium chloride, prepared from 3.8 g (0.03 mol) of benzyl chloride, 0.7 g (0.03 mol) of magnesium, and 100 ml of ether, was added 2.2 g (0.01 mol) of 1,4-dimethylanthrone[11] in small portions at room temperature. After 30 min, 50 ml of benzene was added and the resulting mixture was refluxed for 1 hr. The mixture was decomposed at 0 °C with dilute hydrochloric acid. The organic layer was separated, dried over sodium sulfate, and evaporated. The residue was taken up in 150 ml of carbon tetrachloride and heated on a steam bath with 30 g of phosphorus pentoxide for 2 hr. The supernatant liquid was decanted, washed with water, and dried over sodium sulfate. After removal of the solvent, the residue was chromatographed on neutral alumina. Elution with hexane gave the desired material, mp 133—134 °C, in 0.9 g (*ca.* 30%) yield. PMR (δ, $CDCl_3$): 2.78 (6H, s), 5.12 (2H, s), 6.90—8.15 (12H, m). Found: C, 93.37; H, 6.91%. Calcd for $C_{23}H_{20}$: C, 93.20; H, 6.80%.

1,2,3,4-Tetrachloro-9-benzylanthracene, mp 174—175 °C, was similarly prepared from 1,2,3,4-tetrachloroanthrone[12] and benzylmagnesium chloride. The yield was *ca.* 15%. PMR (δ, $CDCl_3$): 5.17 (2H, s), 6.80—8.10 (9H, m), 8.85 (1H, s). Found: C, 62.32; H, 2.71; Cl, 35.07%. Calcd for $C_{21}H_{12}Cl_4$: C, 62.10; H, 2.98; Cl, 34.92%.

9-(4-Chlorobenzyl)anthracene, mp 124—125 °C, was prepared from anthrone and 4-chlorobenzylmagnesium chloride[13] in *ca.* 40% yield. PMR (δ, $CDCl_3$): 4.90 (2H, s), 6.80—8.25 (12H, m), 8.38 (1H, s).

1,4-Dimethyl-9-(4-chlorobenzyl)anthracene, mp 170—172 °C, was similarly prepared from 1,4-dimethylanthrone and 4-chlorobenzylmagnesium chloride. The yield was *ca.* 25%. PMR (δ, $CDCl_3$): 2.73 (6H, s), 5.00 (2H, s), 6.80—8.00 (10H, m), 8.42 (1H, s). Found: C, 83.42; H, 5.71; Cl, 10.93%. Calcd for $C_{23}H_{19}Cl$: C, 83.50; H, 5.79; Cl, 10.71%.

9-(4-Methoxybenzyl)anthracene, mp 138—139 °C, was prepared from anthrone and 4-methoxybenzylmagnesium chlo-

ride[14] in 30% yield. PMR (δ, $CDCl_3$): 3.69 (3H, s), 4.93 (2H, s), 6.64—8.45 (13H, m). This compound was directly used for the preparation of a triptycene derivative **7**.

*1,4-Dimethyl-9-benzyltriptycene (**1**).* To a refluxing solution of 0.6 g (0.005 mol) of butyl nitrite and 1.48 g (0.005 mol) of 1,4-dimethyl-9-benzylanthracene in 20 ml of dichloromethane was added 0.68 g (0.005 mol) of anthranilic acid in 20 ml of acetone with stirring. Heating and stirring were discontinued after 0.5 hr and the solvent was evaporated. The residue was taken up in benzene and chromatographed on alumina. Elution with a mixture of hexane and benzene gave 0.61 g (30% yield) of **1**, mp 172—174 °C. The compound was purified by recrystallization from chloroform–ethanol. Found: C, 93.31; H, 6.47%. Calcd for $C_{29}H_{24}$: C, 93.51; H, 6.49%.

*1,4-Dimethyl-9-(4-chlorobenzyl)triptycene (**2**)*, mp 254—256 °C, was similarly prepared by treating a solution of butyl nitrite and 9-(4-chlorobenzyl)anthracene in dichloromethane with anthranilic acid in dry acetone. The yield was 28%. Recrystallization from chloroform-ethanol afforded a pure sample. Found: C, 85.80; H, 5.95; Cl, 8.73%. Calcd for $C_{29}H_{23}Cl$: C, 85.59; H, 5.70; Cl, 8.71%.

*1,2,3,4-Tetrachloro-9-benzyltriptycene (**3**)*, mp 247—248 °C, was prepared by treating butyl nitrite and 9-benzylanthracene with tetrachloroanthranilic acid.[15] The yield was *ca.* 20%. Recrystallization from benzene-hexane afforded a pure sample. Found: C, 67.82; H, 3.08; Cl, 29.31%. Calcd for $C_{27}H_{16}Cl_4$: C, 67.88; H, 3.19; Cl, 29.41%.

*1,2,3,4-Tetrabromo-9-benzyltriptycene (**4**)*, mp 237.5—239.5 °C, was prepared by treating butyl nitrite and 9-benzylanthracene with tetrabromoanthranilic acid.[16] The yield was 20%. The compound gave no satisfactory analytical results probably because of poor combustibility. Purity was checked by PMR spectrum. Mass spectrum showed molecular ion peaks at 656 for ^{79}Br compound and at 664 for ^{81}Br compound.

*1,2,3,4,5,6,7,8-Octachloro-9-benzyltriptycene (**13**)*, mp 258—260 °C, was prepared with the use of tetrachloroanthranilic acid, butyl nitrite, and 1,2,3,4-tetrachloro-9-benzylanthracene. The yield was *ca.* 7%. The compound gave no satisfactory analytical data owing to the poor combustibility. However, no impurities were detected by spectral methods. Mass spectrum showed a molecular ion peak at 616 for a compound with ^{35}Cl.

*1,2,3,4-Tetrachloro-5,8-dimethyl-9-benzyltriptycene (**10**)*, mp 233—235 °C, was prepared from tetrachloroanthranilic acid, butyl nitrite, and 1,4-dimethyl-9-benzylanthracene in 15% yield. Found: C, 68.49; H, 4.22; Cl, 28.09%. Calcd for $C_{29}H_{20}Cl_4$: C, 68.26; H, 3.95; Cl, 27.79%.

*1,2,3,4-Tetrabromo-5,8-dimethyl-9-benzyltriptycene (**12**)*, mp 233—235 °C, was prepared similarly in 15% yield. Found: C, 50.70; H, 3.05%. Calcd for $C_{29}H_{20}Br_4$: C, 50.62; H, 2.93%.

*1,4-Dimethoxy-9-benzyltriptycene (**5**).* A suspension of phenylsodium,[17] prepared from 2.25 g (0.02 mol) of chlorobenzene, 0.92 g (0.04 mol) of sodium and 50 ml of benzene, was added to a stirred solution of 1.72 g (0.01 mol) of 2-chloro-1,4-dimethoxybenzene[18] and 2.14 g (0.008 mol) of 9-benzylanthracene in 20 ml of benzene at room temperature under a nitrogen atmosphere. Stirring was discontinued after 3 hr and the mixture was treated with water. The organic layer was separated, dried over sodium sulfate, and evaporated. The residue was taken up in benzene and chromatographed on alumina. Elution with benzene gave the desired product which was recrystallized from chloroform-ethanol to give a pure sample, mp 256.5—258.5 °C, in 0.97 g (30%) yield. Found: C, 85.81; H, 5.92%. Calcd for $C_{29}H_{24}O_2$: C, 86.11; H, 5.98%.

*1,4-Dimethoxy-5,8-dimethyl-9-benzyltriptycene (**11**)*, mp 239—240 °C, was prepared similarly by treating a mixture of 2-chloro-1,4-dimethoxybenzene and 1,4-dimethyl-9-benzylanthracene with phenylsodium. The yield was 25%. Found: C, 85.96; H, 6.22%. Calcd for $C_{31}H_{28}O_2$: C, 86.08; H, 6.52%.

*1,4-Dimethoxy-9-(4-methoxybenzyl)triptycene (**7**)*, mp 218—219 °C, was prepared from phenylsodium, 2-chloro-1,4-di-

methoxybenzene, and 9-(4-methoxybenzyl)anthracene in 20 % yield. Found: C, 83.14; H, 5.89%. Calcd for $C_{30}H_{26}O_3$: C, 82.92; H, 6.03%.

3,6-Dimethoxyanthranilic acid was prepared according to the method of Banerjee and Chaudhury.[19] Tedious separation of isomers was avoided since products other than the desired one did not form the corresponding benzyne on treatment with nitrite esters. 2,5-Dimethoxybenzoic acid[20] (5 g or 0.027 mol) was added to 20 ml of nitric acid (d=1.38) in small portions at 0—2 °C with stirring. Stirring was discontinued after 3 hr and the mixture was poured into ice-water to precipitate yellow solids in 5.6 g yield. The PMR spectrum of the product indicated that it was a 2 : 1 mixture of 2,5-dimethoxy-6-nitro- and 2,5-dimethoxy-3-nitro-benzoic acids. The mixture in 100 ml of ethanol was hydrogenated over 1 g of 5% Pd-C under atmospheric pressure to give a viscous brown oil which was a 2 : 1 mixture of 3,6-dimethoxyanthranilic acid and 3-amino-2,5-dimethoxybenzoic acid. This mixture was used for subsequent reactions.

*1,4-Dimethoxy-9-(4-chlorobenzyl)triptycene (**6**).* To a refluxing solution of 0.6 g (0.005 mol) of butyl nitrite and 0.60 g (0.002 mol) of 9-(4-chlorobenzyl)anthracene in 20 ml of dichloromethane was added 1.15 g (0.005 mol) of the mixture of aminodimethoxybenzoic acids in 30 ml of dry acetone. Heating and stirring were discontinued after 0.5 hr and the solvent was evaporated. The residue was taken up in benzene and chromatographed on alumina. Elution with hexane–benzene followed by recrystallization of the product from chloroform–ethanol gave the desired product, mp 264—265 °C, in 30% (0.26 g) yield. Found: C, 79.05; H, 5.40; Cl, 7.95%. Calcd for $C_{29}H_{23}Cl$: C, 79.35; H, 5.28; Cl, 8.08%.

*1,4-Demethoxy-9-chloromethyltriptycene (**9**)*, mp 224—225 °C, was similarly prepared from the crude 3,6-dimethoxyanthranilic acid, butyl nitrite, and 9-chloromethylanthracene[21] in 20% yield. Found: C, 76.32; H, 5.17; Cl, 9.41%. Calcd for $C_{23}H_{19}Cl$: C, 76.12; H, 5.25; Cl, 9.77%.

*2,4-Dimethyl-9-benzyltriptycene (**8**).* To a refluxing mixture of 0.36 g (0.015 mol) of magnesium, 2.68 g (0.01 mol) of 9-benzylanthracene and 70 ml of dry tetrahydrofuran was added 2.0 g (0.01 mol) of 3,5-dimethyl-2-fluoro-1-bromobenzene[22] in 20 ml of dry ether with stirring. After 5 hr, the mixture was cooled and treated with water. The organic layer was separated after addition of 100 ml of ether, dried over sodium sulfate, and evaporated. The residue was taken up in benzene and chromatographed on alumina. Elution with hexane–benzene gave pure **8**, mp 145—147 °C, in 0.56 g (*ca.* 15%) yield. Found C, 93.21; H, 6.60%. Calcd for $C_{29}H_{24}$: C, 93.51; H, 6.49%.

The original product was a mixture of **8** and 1,3-dimethyl-9-benzyltriptycene [PMR (δ, $CDCl_3$): 2.10 (3H, s), 2.26 (3H, bs), 4.52 (2H, bs), 5.07 (1H, s), 6.60—8.20 (15H, m)] in 2 : 1 ratio. Assignments of the structure were based on the observation of coalescence at a lower temperature for **8** than the isomer.

Spectral Measurement. PMR spectra were recorded on a Hitachi R-20B spectrometer operating at 60 MHz. The samples were dissolved in appropriate solvents to make up *ca.* 10% (wt/vol) solutions. The temperatures were read by the difference in chemical shifts between methyl and hydroxy protons of methanol and are believed to be accurate within the error of ±1 °C.

The populations of rotational isomers were measured by the direct integration of the signals. The values are given as the averages of 10 integrations. The maximum deviation from the average was not greater than 7%. Logarithms of the equilibrium constants at various temperatures were plotted against $1/T$. Linearity was obtained for every case and ΔH and ΔS were calculated in the usual way.

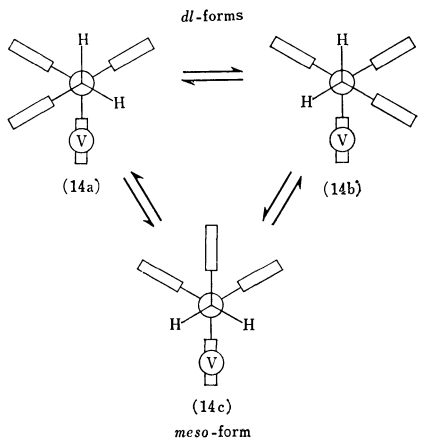
It was not possible to find a single suitable solvent for the measurements of the whole series because of the poor solubility of some compounds at low temperatures (below −55 °C). However, at relatively high temperatures, it was possible to measure the solvent effect on populations: change of the solvent from chloroform-d or carbon disulfide to acetone-d_6 did not affect the conformational equilibria within the experimental errors. The triptycenes with *p*-substituted benzyl groups or those which have two substituents at two *peri*-positions had such poor solubility that the derivation of ΔH and ΔS values was abandoned.

Results and Discussion

Peak Assignment. PMR data of the triptycene (**1**—**8**) in chloroform-*d* at 34 °C are summarized in Table 1. Compounds **1**—**7** give broadened signals for benzyl methylene groups at this temperature, indicating that the rotation about the C_9–C_{benzyl} bond is fairly slow on the NMR time scale. Lowering the temperature generally resulted in the appearance of an AB quartet and a singlet. These signals are best assigned to *dl* and *meso* forms, respectively, since the former should have two benzyl hydrogens in different magnetic environments (**14a** and **14b**) and the latter in the identical ones (**14c**). The down-

Table 1. PMR data of 9-benzyltriptycenes carrying substituents in one benzo group at 34 °C ($CDCl_3$, δ)

Compound	Methyls		Methylene	Bridge head proton	Aromatic protons
1	2.38(3H, bs)	2.48(3H, s)	4.70(2H, bs)	5.64(1H, s)	6.45—7.50(15H, m)
2	2.37(3H, bs)	2.48(3H, s)	4.65(2H, bs)	5.66(1H, s)	6.42—7.60(14H, m)
3			4.91(2H, bs)	6.08(1H, s)	6.85—7.55(13H, m)
4			4.99(2H, bs)	6.18(1H, s)	6.70—7.82(13H, m)
5	3.16(3H, s)	3.81(3H, s)	4.62(2H, bs)	5.91(1H, s)	6.38—7.46(15H, m)
6	3.19(3H, s)	3.81(3H, s)	4.60(2H, bs)	5.94(1H, s)	6.30—7.50(14H, m)
7	3.26(3H, s)	3.75(3H, s) 3.81(3H, s)	4.60(2H, bs)	5.95(1H, s)	6.32—7.62(14H, m)
8	2.11(3H, s)	2.49(3H, s)	4.43(2H, s)	5.62(1H, s)	6.62(1H, bs) 6.80—7.45(14H, m)
9	3.72(3H, s)	3.77(3H, s)	5.45(2H, bs)	5.84(1H, s)	6.47(2H, s) 6.80—7.95(8H, m)

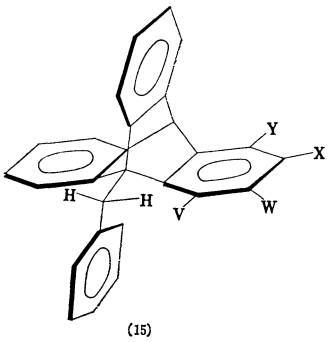


field signal of the AB quartet is reasonably assigned to the proton between the substituent at 1-position and the *peri*-hydrogen at 8-position on the basis that its chemical shift is close to that of the benzyl protons of the *meso* form, the magnetic environment of which is considered to be alike.

At −17 °C, the methyl signal of **1** comprises three signals at δ 2.03, 2.67, and 2.48. The first two are generated by the splitting of the signal at δ 2.38 at 34 °C, the last signal being split into two signals at δ 2.40 and 2.49 on further cooling. A similar phenomenon was also observed for **2** and **11**. The assignment of the signals is self-evident, if the areas of benzyl methylene protons are taken into consideration. Thus the signals at δ 2.03 and 2.49 correspond to methyls of the *dl* form and those at δ 2.40 and 2.67 to those of the *meso* form. Other factors must be taken into consideration for assignment of the signals to methyls at 1- and 4-positions.

The molecular models of these triptycenes show that the phenyl group in the benzyl (benzyl-phenyl hereafter) should take a conformation in which the phenyl group resides in the aperture made by the benzo groups in the triptycene skelton and bisects both the angles of H–C–H (benzyl methylene) and C–C–C (triptycene skelton). This type of conformation is also supported from the coupling constants (−17.4∼−18.0 Hz) of the AB protons in benzyl groups. Theoretically, the π-contribution to the geminal coupling constants is a function of the dihedral angle made by the plane of the π-system and the H–C–C plane,[23] and the π-contribution was estimated to be slightly larger than 4 Hz in a conformation in which the carbon frame of the π-system bisects the angle H–C–H. Since the coupling constant in methane is 13 Hz[24] the coupling constant should be 17 Hz or a little more, if the conformation of the benzyl group is like the one postulated from the molecular model. The observed and the calculated values agree fairly well, conformation **15** thus becoming reasonable.

In such a conformation, substituent (V) at the *peri*-position would be located in a shielding cone of the benzyl-phenyl group. Thus it is reasonable to assume that the methyl at 1-position gives the PMR signal at a higher field than the methyl at 4-position. From the foregoing discussion, the signal at δ 2.03 is assigned



(15)

to the methyl group at 1-position of the *dl*-form and that at δ 2.49 to the methyl at 4-position. The chemical shifts of the methyl groups in the *meso* form are not self-evident, but from the coalescence-splitting behavior with the corresponding signals of the *dl*-forms the signals at δ 2.67 is assigned to the methyl groups at 1-position and that at δ 2.40 to the methyl at 4-position. Assignments along this line are carried out with other compounds and are listed in Table 2.

The situation of the methoxyl groups at *peri*-positions differs slightly from that of the methyl groups. The chemical shift difference between the methoxy-methyls at 1- and 4-positions becomes very small for the *meso* forms. This is reasonable since intervention of the oxygen between the methyl and the benzo groups makes the distance from the phenyl group larger and gives a greater freedom of rotation reducing the chemical shift difference. Nevertheless, since it is possible to assign methoxyl groups in the *dl*-forms, the methoxyl groups in the *meso* form of **6** are assigned from the coalescence-splitting behavior (Table 2).

PMR spectra of compound **9** showed a curious behavior when the temperature was varied. A signal of the chloromethyl group was a little broad at 34 °C, whereas rise and fall in temperature caused sharpening of the signal instead of further broadening or splitting at a low temperature. Sergeyev and co-workers[25] suggested that the barrier to rotation about the C_9–C_{CH_2Cl} bond in 9-chloromethyltriptycene should be higher than 15 kcal/mol. It is thus unlikely that the rotation about the C_9–C_{CH_2Cl} bond in **9** is still too fast on the NMR time scale at −30 °C. It is unrealistic to assume that the chemical shifts of the protons at three sites coincide both for methoxy and methylene protons because of the large magnetic effect of the chlorine substituent.[24,26] Solvent effect did not change the above situations. If the phenomenon is caused neither by the change in solute-solvent interaction nor by the rapid rotation about the bond in question, it is reasonable to interpret the results from the change in population of the rotamers. The internal rotation is slow enough at room temperature to be detected by the NMR technique as a broadening of the signal and the population of the *dl*-isomer is present to the extent that it can be observed. At a lower temperature, however, the less stable *dl*-isomer decreases in population and is not detected, although the rotation in question is sufficiently slow. At a higher temperature, the rotation becomes too fast for the detection of individual species, although the popula-

Table 2. PMR data of 9-benzyltriptycenes carrying substituents in one benzo group at low temperatures (δ)

Compound	Assignment	*meso*	*dl*	J_{gem} (Hz)	Temperature (°C)	Solvent
1	benzyl methylene	4.69	4.19, 4.63	−17.4	−40	$CDCl_3$-CS_2 (2 : 3)

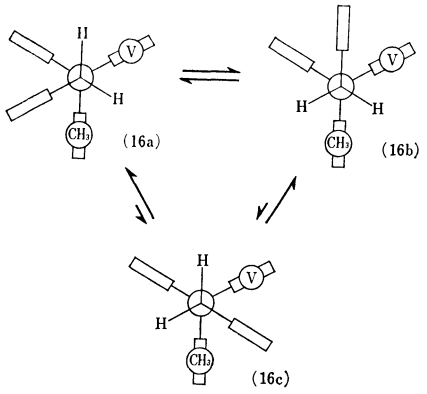
a) Data obtained at 0 °C. b) A single AB quartet is observed to indicate that the chemical shifts of a pair of quartets coincide. c) Assignment of these peaks are reserved because of a small chemical shift difference.

tion of the *dl*-isomers increases. Thus the signal observed at low temperatures should be due to the *meso* form which exists as an overwhelming species among the possible conformations.

1,8-Disubstituted 9-benzyltriptycenes (**10**—**12**) showed PMR signals corresponding to two isomers at room temperature (Table 3). The results suggest that the barrier to rotation is still higher. The absence of an isomer of **16c** type is assumed since the conformation should be of high energy. The assumption is supported by the fact that compound **13** gives only one set of AB quartet, indicating that the compound solely exists as a *dl* form which has the benzyl-phenyl group at the site of the least steric interaction. The conformation **16a** should give a methyl signal at higher magnetic field than **16b**, for the methyl group at 1-position is located within the shielding cone of the benzyl-phenyl group. From the data of compounds **1** and **2**, the methyl group in a similar situation gives the signal at the highest magnetic field among other methyls. Other methyl signals are assigned by considering the signal intensities. The benzyl methylene protons due to conformations **16a** and **16b** can be assigned by taking the intensities into consideration. The downfield signal of each pair of AB protons of the benzyl group is assigned to the proton placed between the substituents at 1- and 8-positions in the Newman projection, since the proton is likely to give a signal at a lower field due to the steric compression and/or the magnetic effects of the substituents. The assignment is in line with the chemical shifts of benzylic protons in **1**—**5** in which a proton neighboring the peri-substituent gives a signal at the lower field.



Rotamer Populations. The quilibrium constants for the equilibria *meso*⇌*dl* of compounds **1**—**8**, the thermodynamic parameters obtained by the measurement of the equilibria at various temperatures, and solvent systems are listed in Table 4. The solvent system had to be varied due to the poor solubility of the compounds. However, those compounds examined in various solvents showed no solvent dependency of the population. Thus, the following discussion seems to be valid.

The data in Table 4 indicate that the *dl*-forms of benzyltriptycenes (**1**—**7**) which carry one substituent at a *peri*-position to the benzyl group are anomalously favored, particularly for compounds **5**—**7**. The equilibrium constant is even larger than 2, which value is expected from mere statistical consideration. The anomaly is striking when we compare the data with that for compound **9** which shows the presence of *dl*-isomers only to a detectable amount at room temperature (*vide supra*), giving a signal corresponding to a *meso* isomer only at lower temperatures. We may thus conclude that the *dl*-forms of the benzyltriptycenes **1**—**7** are anomalously favored.

The relative stability of conformers can be discussed on the assumption that the potential function is approximately divided into three terms: steric repulsion, electrostatic interaction including dipole-dipole interaction and electron delocalization. Such an assumption seems to be supported in simple molecules by theoretical calculations.[27]

The overwhelming relative stability of the *meso* form of compound **9** over the *dl*-form may be explained on a basis that the steric repulsion term outweighs the electrostatic interaction and the electron delocalization. The destabilization factor of dipole-dipole interaction should operate for the *meso* form of compound **9** since the dipole of C–Cl and that of the C–O–C are arranged in the same direction. Electron delocalization by transfer of an electron from the highest occupied molecular orbital (HOMO) of the *p*-dimethoxybenzene to the lowest unoccupied molecular orbital (LUMO) σ^* of the $ClCH_2$ group may occur to a limited extent, but the σ^* orbital seems to be too high to make this contribution significant. On the

Table 4. Equilibrium constants and thermodynamic parameters for 9-benzyltriptycenes **1**—**9**

Compound	Equilibrium constant $K=\frac{dl}{meso}$ (temp. °C)	ΔH (kcal/mol)	ΔS (eu)	Solvent
1	0.85±0.10 (−50)	1.1±0.1	4.9±0.9	$CDCl_3$-CS_2 (2 : 3)
2	0.84±0.10 (−50)			$CDCl_3$-CS_2 (2 : 3)
3	0.68±0.10 (−50)	1.2±0.1	4.3±0.5	CS_2

4	1.0 ±0.1 (−23)			CS_2
5	2.8 ±0.1 (−50)	0.0±0.1	2.1±0.3	$CDCl_3$-CS_2 (3 : 1)
6	3.5 ±0.1 (−50)			$CDCl_3$-CS_2 (3 : 1)
7	2.4 ±0.1 (−50)			$CDCl_3$-CS_2 (3 : 1)
8	1.2 ±0.1 (−83)			CS_2
9	0 (−30)			$CDCl_3$

other hand, steric repulsion is very severe since the atoms in the chloromethyl and *peri*-regions are located within the sum of their van der Waals radii, and weak interactions of electrostatic nature and electron delocalization are not strong enough to overcome it.

The steric conditions of 9-benzyltriptycenes should be more severe than those of compound **9**, since the phenyl group is larger than the chlorine. As in the case of other systems such as cyclohexanes[2] and substituted ethanes,[28] we may expect such overcrowding caused by the benzyl group and the substituent to greatly increase the free energy difference of the two forms. Preference of the *dl*-form therefore cannot be explained by the steric effect. The dipole-dipole interaction also is not favorable for these compounds, since substitution of a chlorine atom by a phenyl group should result in a decrease in bond dipoles. Consequently the preference of the *dl*-form on the electrostatic basis is reduced. Benzene might have a high microscopic dielectric constant along an axis which is perpendicular to the ring. The model is supported by the anomalous behaviors of benzene as a solvent.[29] Application of this idea leads to a conclusion that *dl* isomers are provided stabilization by the electrostatic interactions between the negative benzyl-benzene ring and the oxygen or halogen at 1-position which becomes partly positive due to the electron delocalization. If this were the case, the solvent effect on the conformational equilibria would have been large. It is also difficult to explain the effect of the substituent in the benzyl group on the conformational equilibria. The electron-donating substituent would have given more *dl*-forms contrary to the observed ratio.

Thus the electron delocalization effect becomes a likely cause of the phenomenon. From the data of compounds **5**—**7** we note that the electron-donating substituent disfavors the *dl*-form, whereas the electron-attracting substituent favors it. Since the steric effect in these compounds may be assumed to be the same, the stabilization due to delocalization or through-space interaction will be the major factor, if not the only one. When the through-space interaction[30] between the benzyl-benzene and the *p*-dimethoxybenzene moities in the triptycenes is taken into consideration, the magnitude of stabilization would depend on the difference in energy between the orbitals concerned and the extent to which they overlap, if other factors such as steric repulsion, medium effects and electrostatic interactions are the same. The lower the energy level of LUMO of the benzene ring, the greater the orbital interaction with HOMO of the other moiety, provided that the level of HOMO of the donor is the same, to increase the presence of the *dl*-forms. No such stabilization is possible in the *meso* form since the orbitals lie too far apart from each other. Since the HOMO's of *p*-dimethoxybenzenes in **5**—**7** can be considered to be of the same energy, the lowering in energy of LUMO of the benzyl-benzene should result in the more preferred interaction which leads to the preference of the *dl*-form to a greater extent. The HOMO's and LUMO's of some simple benzene derivatives are given in Table 5. Since the levels of HOMO may be regarded as equal to ionization potentials to a first approximation and we are dealing with the charge transfer type interaction, the ionization potential data have been collected from those given in the literature.[31] The levels of LUMO can be estimated from those of HOMO and the data of electronic absorption spectra.[32]

Table 5. Energy levels of HOMO and LUMO of some benzene derivatives

Compound	HOMO (eV)	LUMO (eV)
Benzene	9.40	4.52
Chlorobenzene	9.31	4.72
Anisole	8.54	3.89
p-Dimethoxybenzene	7.90	3.58
p-Dichlorobenzene	9.17	4.59
p-Xylene	8.71	4.00

The observed trend is in line with what is expected from the HOMO–LUMO interactions. It may be concluded that the preference of the *dl*-forms in compounds **5**—**7** is due to the electron delocalization approximated by donation of electrons from HOMO of *p*-dimethoxybenzene to the antibonding LUMO of the benzyl-benzene. Although the effect of the alkyl substituents on the energy level is neglected here, such approximation may be accepted in a qualitative discussion.

The relative population in these compounds results from a balance between the attractive interaction due to the delocalization and the repulsive interaction due to the steric size. In compounds **5**—**7**, the former factor exceeds the latter. This will be a consequence of the high HOMO level of *p*-dimethoxybenzene moiety. If the HOMO level of the donor is lowered and other steric and electric factors are kept constant, preference for the *dl*-form will be diminished. Comparison of the equilibrium constants of compounds **1** and **5** which possess the same acceptor group indicates that the *dl*-form of **5** is more favored than that of **1**. The result is in line with the available data of HOMO (Table 5).

Stabilization of the *dl*-forms in **1** might be attributed to the interaction between the benzene ring and the electronegative methyl group, as suggested for acetonitrile–benzene system.[33] However, if this were the case, compound **2** should have disfavored the *dl*-form relative to compound **1** because of the lower electron density (or the lower HOMO level) in the chlorophenyl group. Since the equilibrium constants for both compounds are the same within the limit of error, and the phenomenon is understood in terms of orbital interactions, we prefer to attribute the phenomenon to the HOMO–LUMO interaction where the benzene moiety acts as an electron acceptor.

The effectiveness of the overlap of orbitals concerned should be considered, the difference between *meso* and *dl*-forms being a typical example. The more bulky the substituents, the more effective the overlap of orbitals is prevented since the orbitals concerned are more separated from each other. Similarly more accurate estimation for the stabilization by the electron delocalization needs coefficients of atomic orbitals

in most interacting molecular orbitals. In the *dl*-forms of dimethyl compounds **1** and **2**, the interaction may become less favorable because electrons belonging to the methyl group are relatively localized to molecular orbitals of low energy relative to those of the methoxy group in **5**—**7**.

The larger K value for compound **8** than for compound **1** can be attributed to the decrease in steric effect for the former because it has no substituent at peri-positions to interact with the benzyl group. Preference of the *dl*-forms for compound **8** is reduced, as compared with that in 2,4-dimethyl-9-isopropyltriptycene which has been reported to give an equilibrium constant of 2, a statistical factor.[9] The phenomenon can be attributed to the fact that, being an elongated group, the benzyl-phenyl group extends deeply into the aperture of the triptycene skeleton and the repulsive force between the phenyl group and 2-methyl group may become significant in some conformations: the entropy term becomes unfavorable.

In compounds **10**—**13**, the presence of a form of **16c** type is not detected at all. This may arise either by thermodynamic control or kinetic control. Thermal equilibration at 250 °C for 12 hr was attempted. Since a pair of AB quartet signals of these compounds becomes broad at a higher temperature and then collapse into a broad singlet at 120 °C, probably because of the coincidence of the chemical shifts, 250 °C is considered to be high enough to cause a full rotation about the C_9–C_{benzyl} bond and thermal equilibration will ensue to at least some extent, if the energies are feasible. However, it was not possible to detect any of the forms of **16c** by even rapid cooling after the above operation. Although the possibility that the barrier leading to **16c** form is still too high under the conditions applied cannot be ruled out completely, the results strongly suggest that **16c** is thermodynamically unstable. From the standpoint of electron delocalization, the **16c** type conformation should be favored. The steric effect seems to outweigh the electronic effect in these cases.

The data in Table 6 suggest that the conformational preference between **16a** and **16b** can be understood also from the standpoint of HOMO–LUMO interaction. In compound **11**, the conformation of **16b** type will be favored, because the HOMO of the *p*-dimethoxybenzene is higher than that of the *p*-xylene. Compounds **10** and **12** give almost the same equilibrium constants in agreement with the fact that compounds **1**, **3** and **4** give similar equilibrium constants and that the conformational energy of the *meso* forms of these monosubstituted compounds may be assumed the same.

Table 6. Relative populations of rotamers in 9-benzyltriptycenes **10**—**13** at 0 °C ($CDCl_3$)

Compound	Equilibrium constant $K=\frac{\mathbf{16a}}{\mathbf{16b}}$
10	1.2±0.1
11	$\frac{1.0}{3.2}$=0.31±0.02
12	1.1±0.1
13	1.0

In conclusion, the electron delocalization plays a significant role in determining the conformational equilibria in 9-benzyltriptycene derivatives, although the steric effect is also very important. This is an observation rarely made on the charge transfer type interaction in which a benzene ring without any strongly electron-attracting substituent acts as an acceptor in combination with donors of medium to low ability. This kind of orbital interaction is undoubtedly caused by the extreme proximity of the orbitals concerned in the overcrowded molecules.

A New Synthesis of 3,6-Dialkyl-1,4-dimethyl-3,6-epithio- and -3,6-epidithio-2,5-piperazinediones

Juji YOSHIMURA, Hiroshi NAKAMURA, and Kenji MATSUNARI*

Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Meguro-ku, Tokyo 152

(Received October 12, 1974)

A new route for synthesis of 3,6-dialkyl-1,4-dimethyl-3,6-epithio- (**8**) and -3,6-epidithio-2,5-piperazinediones (**9**) *via* the corresponding bromo derivatives was described. Bromination of 3,6-dialkyl-1,4-dimethyl-2,5-piperazinedione with *N*-bromosuccinimide gave 3,3α,6,6α-tetrabromo (**2**) and 3,6-dibromo (**3**) derivatives, depending upon the straight chain (methyl, ethyl, propyl, butyl) or α-branched (isopropyl, *sec*-butyl) alkyl groups, respectively. After tentative substitution of 3,6-bromine atoms of **2** with methanol, 3α,6α-bromine atoms were reduced to give the corresponding 3,6-dialkyl-3,6-dimethoxy derivatives (**5**). Substitution of **3** or **5** with hydrogen sulfide in the absence or presence of zinc chloride, and successive oxidation with potassium triiodide gave **8** and **9** at the same time. Discussions were made on the structure of isomers and on the reaction mechanisms.

3,6-Epidithio-2,5-piperazinedione skeleton is the unique partial structure of a class of antibiotics such as gliotoxin,[1] sporidesmin,[2] and others.[3,4] The simplest compound has been first synthesized through substitution of 3,6-dibromo-1,4-dimethyl-2,5-piperazinedione with sodium thioacetate or sodium tetrasulfide,[5] and the method was successfully applied only for 3,6-diphenyl derivative.[6] A few derivatives were synthesized through condensation of sulfur or sulfur chloride with the corresponding 3,6-dicarbanions obtained by treatment of parent 2,5-piperazinediones with sodium hydride[7] or sodium amide.[8] Recently, Kishi *et al.* synthesized dehydrogliotoxin and sporidesmin A by alkylation of similar carbanions of 3,6-dimercapto-2,5-piperazinediones whose mercapto groups were protected as thioacetal of anisaldehyde.[9] We have tried to extend the first method to 3,6-dialkyl derivatives. However, bromination of 1,3,4,6-tetramethyl-2,5-piperazinedione gave the 3,3α,6,6α-tetrabromo derivative, and substitution of its 3,6-bromine atoms with sulfur-containing nucleophiles gave only 3,6-dimethylene derivative and sulfur, in participation with 3α,6α-bromine atoms.[10] To exclude the participation, reductive removal of the 3α,6α-bromine atoms prior to the introduction of mercapto groups gave successful results. Thus, it was communicated that substitution of 3,6-bromine atoms of the tetrabromide with methanol, reduction of 3α,6α-bromine atoms, substitution of 3,6-methoxy groups with mercapto groups in the presence of zinc chloride,[11] and oxidation gave the corresponding 3,6-epithio and 3,6-epidithio derivatives.[12]

In this paper, this new synthesis is described in detail, together with discussions on the structure of related compounds and on reaction mechanism of the final step.

Results and Discussion

3,6-Dialkyl-1,4-dimethyl-2,5-piperazinediones and their bromination with N-*bromosuccinimide.* *N*-Methylation of 3,6-dialkyl-2,5-piperazinediones obtained by thermal dehydration of α-amino acids[13] with methyl iodide and sodium hydride, instead of silver oxide as a neutralizing reagent,[14] gave a *cis* and *trans* mixture of the corresponding 1,4-dimethyl derivatives (**1**) in over 80% yields. The ratios of isomers were determined by glc, and pure isomers were isolated by fractional crystallization from ether or ether–petroleum ether. As standards, *cis* isomers of **1a**, **1e** and **1f** were synthesized by *N*-methylation of optically active 3,6-dialkyl-2,5-piperazinediones with methyl iodide and silver oxide, and the glc data of the latter one and *cis*-**1g** were supported with that of Manger.[15] For examination of the relationship between the configuration and properties of isomers, physical constants of **1** were summarized in Table 1, in which an isomer having a shorter retention time was arranged at first.

Among the above four examples, **1a** showed an exceptional relationship between the configuration and retention time. However, the chemical shift of 3,6-hydrogens in *trans* isomer showed commonly larger δ value than that of *cis* isomer, as was pointed out for several derivatives in a previous paper.[10] Thus, the common observation was applied for the deduction of the configuration of isomers of **1b–d**. It was shown by X-ray analysis that *cis* and *trans* 3,6-disubstituted-2,5-piperazinedione have a skewed boat and a planar conformation, respectively.[16] If these conformations are maintained to some extent in a solution state, 3,6-hydrogens in *trans* isomer are sterically closer to the plane of vicinal carbonyl groups than those in *cis* isomer, and consequently show a more larger δ value.

The *cis* and *trans* mixture of **1** was used for the next bromination, because the 2,5-piperazinedione ring has a strong tendency to make carbonium cations in substitutions at 3,6-positions. Treatment of **1a** in carbon tetrachloride with four equimolar amount of *N*-bromosuccinimide (NBS) in the presence of 2,2′-azobisisobutyronitrile as an initiator gave the 3,3α,6,6α-tetrabromide (**2a**) in a much better yield (80%) than that with bromine (less than 20%).[10] When two equimolar amount of NBS was used, the corresponding 3,3α-dibromo derivative was produced, which was ascertained as 3-bromomethyl-3-methoxy derivative (**2a′**) by treatment with methanol. This fact indicates that the bromination at 3,6-positions takes place stepwise, and it is followed by elimination of hydrogen bromide addition of bromine produced from hydrogen bromide and NBS to give **2a**. Such successive reactions; *i.e.*,

e: R=*iso*-Pr, R'=H **f**: R=R'=Me **g**: R=Et, R'=Me

Fig. 1. The synthetic routes to **8** and **9**.

bromination, elimination and addition, were also observed in the bromination with bromine.[10]

In a similar way, **1b–d** having linear alkyl groups gave homologous 3,3α,6,6α-tetrabromides, whereas **1f** having α-branched alkyl groups gave the corresponding 3,6-dibromide (**3f**), which was proved by conversion into 3,6-diisopropyl-3,6-dimethoxy-1,4-dimethyl-2,5-piperazinedione (**3f'**) by treatment with methanol. This fact will be attributed to the steric hindrance to be arose in the corresponding elimination product.[17] Although **2b–d** and **3g** were not isolated, the above relation between the structure of 3,6-alkyl groups and the bromination product was confirmed by their conversions to be mentioned in the next item.

Conversion of Bromo Derivatives into 3,6-Epithio- and 3,6-Epidithio-2,5-Piperazinediones. To avoid the participation of 3α,6α-bromine atoms of **2** to the substitution of 3,6-bromine atoms with hydrogen sulfide,[10] the former were removed by hydrogenation after tentative conversion of the latter into methoxy groups, and then the methoxy groups were substituted with mercapto groups. Treatment of **2a** with methanol gave the 3,6-dimethoxy derivative (**4a**) in 86% yield, and hydrogenation of **4a** with tri-*n*-butyltin hydride

a) The first five runs (a—f) indicate yields from **6**, and the last two (f, g) from **1** *via* **3**. b) It is characteristic that the amide absorptions of **8** and **9** appeared broad and sharp, respectively. c) The corresponding **9** could not be obtained.

gave 1,3,4,6-tetramethyl-3,6-dimethoxy-2,5-piperazinedione (**5a**) quantitatively. In the case of **1b–d**, **5b–d** were synthesized by the successive reactions without isolation of **2b–d** and **4b–d**, because they include too many isomers and **2b–d** are unstable. The compound **5e** could not be separated in a pure state by the similar reactions of **1e**. By the same hydrogenation as above, 5a,10a-dimethoxyoctahydro-5*H*,10*H*-dipyrrolo-[1,2-*a* : 1′,2′-*d*]pyrazine-5,10-dione (**6**) was quantitatively obtained from the corresponding 1,6-dibromo-5a,10a-dimethoxy derivative.[10]

The most of **5**, **3f′** and **4a** were separated into two isomers, but, their configurations could not be determined. It seems likely that the configuration of 2,5-piperazinediones having two substituents at both 3,6-positions should be determined by X-ray analysis at the present stage.

For preparation of epidithio derivatives, **6** was treated with hydrogen sulfide in the presence of zinc chloride and then oxidized with potassium triiodide, according to the method of Schmidt *et al.*[11] which was applied to the corresponding 5a, 10a-dihydroxy derivative, to give desired epidithio derivative (**7**) in 78% yield. However, application of the same procedure to **5** gave a mixture of 3,6-epithio (**8**) and 3,6-epidithio-(**9**) derivatives. Moreover, the simple substitution of **3** with hydrogen sulfide and successive oxidation gave again a mixture of **8** and **9**. These mixtures were separated by preparative tlc, and physical constants of pure compounds were summarized in Table 2.

The remarkable difference in the reaction products from **6** and **3** or **5** will be attributed to the rigid planar conformation of **6**, which is caused by fused pyrrolidine rings. The ratios of **8** to **9** were not so much changed by the configuration of **5** (*cis* or *trans*) and also by reaction conditions (temperature and molar ratio of reagents). An attempted reaction of **3f′** with thioacetic acid in the presence of zinc chloride gave directly **8f** as a main product. Similar results were obtained in the conversion of **3f** into **8f** and **9f**. These facts indicate that the both conversions of **3** and **5** into **8** and **9** proceed by the S_N1 mechanism. The first substitution of **3** or **5** with thiol anion and the

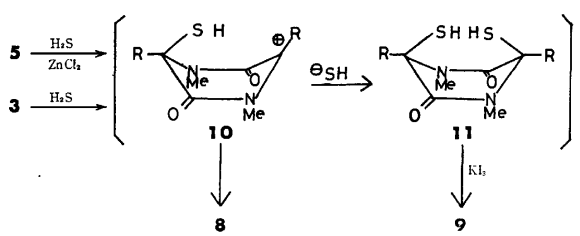

Fig. 2. The mechanism of the formation of **8** and **9**.

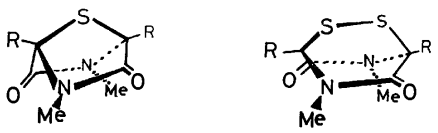

Fig. 3. The conformation of **8** and **9**.

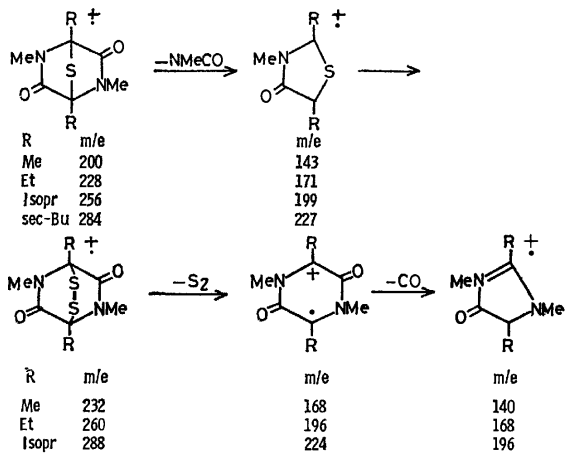

Fig. 4. The characteristic fragmentation of **8** and **9**.

formation of the second carbonium ion will give the key-intermediate (**10**), in which the intramolecular nucleophilic attack of sulfur atom to the carbonium ion affords **8**. While, an intermolecular attack of a thiol anion to **10** gives the corresponding dithiol (**11**), which is oxidized to **9** by potassium triiodide.

On the other hand, NMe proton signal of **8** in NMR spectra appeared generally in higher magnetic field than that of **9**. This fact indicates that the more strained conformation of **8** than **9** draws NMe groups into the diamagnetic field of the carbonyl group in the opposite side of the molecule sterically closer than that of **9**. The characteristic IR absorption of amido groups also clearly distinguishes **8** and **9** (Table 2). Moreover, mass fragmentations of **8** and **9** showed the most intense peaks of *m/e* (M–NMeCO) and *m/e* (M–2S), respectively, as the characteristic peaks.

Experimental

All melting points are uncorrected. The solutions were evaporated under reduced pressure at a bath temperature not exceeding 60 °C. The infrared spectra were measured in KBr discs with a Hitachi EPI-G2 spectrometer. The NMR spectra were obtained at 100 MHz with a JEOL JNM-100H spectrometer in deuteriochloroform, using TMS as an internal reference. Specific rotations were measured in a 0.5-dm tube with a Carl Zeiss LEP-Al polarimeter. The mass spectra were obtained on a JEOL JNS-OLS mass spectrometer, using a direct inlet and an ionization energy of 70 eV. Chemical shifts and coupling constants were recorded in δ and Hz units, and IR frequencies in cm^{-1}.

*3,6-Dialkyl-1,4-dimethyl-2,5-piperazinediones (**1a–g**).* To a suspension of 3,6-dialkyl-2,5-piperazinedione (0.11 mol) in dried DMF (200 ml) was added sodium hydride (10.5 g, 50% in oil, 0.22 mol) portionwise during 30 min under a violent stirring. After the evolution of hydrogen gas subsided, methyl iodide (0.25 mol) was added dropwise to the solution with stirring under ice-cooling, and the reaction mixture was kept at room temperature for 30 min, and then evaporated. The residue in water (200 ml) was extracted with carbon tetrachloride (2×100 ml), and the chloroform layer was dried over sodium sulfate, and evaporated to give **1** quantitatively, which were fractionally recrystallized from ether (**1a-b**) or ether-petroleum ether (**1c–g**) (Table 1).

*Optically Active 3,6-Dialkyl-1,4-dimethyl-2,5-piperazine-diones (**1a, 1e** and **1f**).* Optically active 3,6-dimethyl-, 3,6-diisobutyl- and 3,6-diisopropyl-2,5-piperazinediones were methylated in DMF (*ca* 100 part) with methyl iodide (60 equivalent) and silver oxide (20 part), according to the reported method,[14] to give *N*-methyl derivatives in 2%, 10% and 50% yields, respectively. The low yield of **1a** will be attributed to the insolubility of the starting material, but the reaction does not proceeded in HMPA. These compounds gave correct analytical values, and spectral (IR and NMR) and glc data were consistent with those of *cis* isomers in Table 1.

1a: mp 120 °C, $[\alpha]_D^{22}$ +56.99° (*c* 0.55, $CHCl_3$); **1e**: mp 110 °C, $[\alpha]_D^{22}$ +48.81° (*c* 1.0, $CHCl_3$): **1f**: mp 104—105 °C, $[\alpha]_D^{22}$ −33.31° (*c* 1.0, $CHCl_3$).

*3,6-Dibromo-3,6-bis(bromomethyl)-1,4-dimethyl-2,5-piperazinedione (**2a**).* A solution of **1a** (1 g, 5.9 mmol), NBS (4 g, 24 mmol) and 2,2′-azobisisobutyronitrile (10 mg) in carbon tetrachloride was refluxed until NBS has dissolved, and succinimide deposited was filtered and washed with chloroform (50 ml). The filtrate and washings were evaporated to give white powder, which was triturated with a small amount of ethanol and filtered. Yield, 2.4 g (82%), mp 186—188 °C (lit, [10] 185—188 °C, 18%).

*3-Bromomethyl-3-methoxy-1,4,6-trimethyl-2,5-piperazinedione (**2a′**).* A solution of **1a** (300 mg, 1.765 mmol), NBS (628 mg, 3.53 mmol) and 2,2′-azobisisobutyronitrile (10 mg) in carbon tetrachloride (50 ml) was refluxed for 20 min, and succinimide deposited was filtered and washed with chloroform (20 ml). The filtrate and washings were evaporated, and then a solution of the residue and sodium acetate (1 g, 12.2 mmol) in methanol (50 ml) was refluxed for 2 hr, evaporated, and the residue was extracted with chloroform. The extract was washed with water, dried, and evaporated to give a mixture of **1a**, **2a** and **2a′**, which were separated on a preparative tlc. **2a** and **2a′** were obtained in 24% (165 mg) and 22% (110 mg) yield, respectively. **2a′**: mp 88 °C, IR: 1660 (amide), NMR: 1.59 (CMe; d, J_{vic}=6.5), 2.90 and 3.04 (NMe), 4.01 and 3.53 (CH_2Br; ABq, J_{gem}=10.8).

Found: C, 38.61; H, 5.28; N, 10.01; Br, 28.90%. Calcd for $C_9H_{15}N_2O_3Br$: C, 38.72; H, 5.42; N, 10.03; Br, 28.62%.

*3,6-Diisopropyl-1,4-dimethyl-3,6-dimethoxy-2,5-piperazinedione (**3f′**).* A solution of **1f** (0.5 g, 2.2 mmol), NBS (800 mg, 4.5 mmol) in carbon tetrachloride (30 ml) was treated as above to give a sirupy **3f**, which was then treated with methanol and sodium acetate in a similar manner using benzene as extracting solvent. The sirupy product was crystallized and recrystallized from petroleum ether to give a mixture of isomers (270 mg, 43%) which was separated on a silica gel column using benzene – ethyl acetate (20 : 1) as an eluent.

A: mp 113—115 °C, IR: 1660 (amide), NMR: 0.79 and 1.14 (CMe; d, J_{vic}=7.0), 2.33 (CH; sep), 2.94 (NMe), 3.09 (OMe).

B: mp 193—194 °C, IR: 1660 (amide), NMR: 0.88 and 1.08 (CMe; d, J_{vic}=7.0), 2.27 (CH; sep), 2.87 (NMe), 3.17 (OMe).

Found (A): C, 58.47; H, 9.35; N, 9.67%. (B): C, 58.50; H, 9.31; N, 9.66%. Calcd for $C_{14}H_{26}N_2O_4$: C, 58.72; H, 9.15; N, 9.78%.

*3,6-Bis(bromomethyl)-1,4-dimethyl-3,6-dimethoxy-2,5-piperazinedione (**4a**).* A solution of **2a** (1 g, 2.1 mmol) and sodium acetate (1 g, 12 mmol) in methanol (50 ml) was stirred at room temperature for 10 hr, evaporated, and the residue was extracted with chloroform. The extract was washed with water three times, dried, and evaporated to give crystals (700 mg, 86%) which were recrystallized from chloroform-ligroin. Analytical values of the crystals were consistent with theoreticals, but which were fractionally crystallized into two isomers. A: mp 160 °C (decomp.), IR: 1670 (amide), NMR: 3.01 (OMe), 3.35 (OMe), 3.54 and 4.12 (CH_2Br; ABq, J_{gem}=11.0). B: mp 198—200 °C (sublime), IR: 1670 (amide), NMR: 308 (NMe), 3.28 (OMe), 3.60 and 4.18 (CH_2Br; ABq, J_{gem}=11.3).

Found: C, 31.30; H, 3.91; N, 7.16%. Calcd for $C_{10}H_{16}N_2O_4Br_2$: C, 30.95; H, 4.16; N, 7.22%.

*3,6-Dimethoxy-1,3,4,6-tetramethyl-2,5-piperazinedione (**5a**).* A solution of **4a** (300 mg, 0.77 mmol), tri-*n*-butyltin hydride (465 mg, 1.6 mmol) and 2,2′-azobisisobutyronitrile (5 mg) in toluene (50 ml) was heated at 70 °C for 1 hr under nitrogen atmosphere, and evaporated to give a half-crystalline mass which was triturated with ligroin and filtered. The crystals (180 mg, quantitative) obtained were recrystallized from ether. Analytical values of the crystals were consistent with theoreticals, but which were separated into two isomers by a preparative tlc. A: mp 130 °C (sublime), IR: 1670

(amide), NMR: 1.58 (CMe), 2.98 (NMe), 3.12 (OMe). B: 201—202 °C, IR: 1670 (amide), NMR: 1.69 (CMe), 2.98 (NMe), 3.07 (OMe).

Found: C, 51.70; H, 7.88; N, 12.08%. Calcd for $C_{10}H_{18}N_2O_4$: C, 52.16; H, 7.88; N, 12.17%.

*3,6-Dialkyl-1,4-dimethyl-3,6-dimethoxy-2,5-piperazinedione (**5b–d**).* The compounds **1b–d** (500 mg) were brominated with NBS (4 equivalent) and then methylated, in the same manner as **2a** and **4a**, to give sirupy products (**4b**: 850 mg, **4c**: 830 mg, **4d**: 930 mg, respectively). These sirups were reduced with tri-*n*-butyltin hydride (2.1 equivalent) in the same manner as above to give products (**5b**: 470 mg, 72%, **5c**: 210 mg, 34%, **5d**: 280 mg, 47%, respectively), which were separated into two isomers on a silicagel column using benzene-ethyl acetate (15 : 1) as an eluent.

5b: mp 165—167 °C, IR: 1660 (amide), NMR: 0.83 (CMe; t, J_{vic}=7.2), 1.82 and 2.29 (CH_2; each sex, J_{gem}= 14.5), 2.95 (NMe), 3.16 (OMe).

Found: C, 55.84; H, 8.48; N, 10.97%. Calcd for $C_{12}H_{22}N_2O_4$: C, 55.78; H, 8.58; N, 10.85%.

5c: A: mp 82—83 °C, IR: 1665 (amide), B: mp 110 °C, IR: 1660 (amide). NMR: 0.91 (CMe; t, J_{vic}= 6.5), 0.7—2.45 (CH_2: broad m), 2.94 (NMe), 3.14 (OMe).

Found (A): C, 59.02; H, 8.84; N, 10.01%. (B): C, 59.00; H, 8.90; N, 9.98%. Calcd for $C_{14}H_{26}N_2O_4$: C, 58.72; H, 9.15; N, 9.78%.

5d: A: mp 85—86 °C, IR: 1655 (amide), B: sirup, IR: 1670 (amide). NMR: 0.7–2.5 (CMe and CH_2; broad m), 2.94 (NMe), 3.16 (OMe).

Found (A): C, 60.82; H, 9.46; N, 8.84%. (B): C, 60.65; H, 9.29; H, 8.54%. Calcd for $C_{16}H_{30}N_2O_4$: C, 61.12; H, 9.62; N, 8.91%.

Isomers of **5c** and **5d** could notbe distinguished by NMR spectra.

*5a,10a-Dimethoxyoctahydro-5H,10H-dipyrrolo[1,2-a : 1′,2′-d]pyradine-5,10-dione (**6**).* 1,6-Dibromo-5a,10a-dimethoxyoctahydro-5*H*,10*H*- dipyrrolo[1,2-*a*: 1′2′-*d*]pyridine- 5,10-dione[10] (300 mg, 0.73 mmol) was hydrogenated with tri-*n*-butyltin hydride in the same manner as **5a** to give crystals (185 mg, 99%) which were recrystallized from petroleum ether. Mp 185 °C. IR: 1660 (amide).

Found: C, 56.32; H, 7.11; N, 11.00%. Calcd for $C_{12}H_{18}N_2O_4$: C, 56.68; H, 7.14; N, 11.02%.

*Tetrahydro-6H,10H-5a,10a-epidithio-1H,5H-dipyrrolo[1,2-a : 1′,2′-d]pyradine-5,10-dione (**7**).* To a suspension of **6** (100 mg, 39.3 mmol) in chloroform (30 ml, saturated with hydrogen sulfide) was added zinc chloride (10 mg) and passed dried hydrogen sulfide for 3 hr, and then evaporated. The residue was extracted with chloroform, and the extract was washed with water and shaked with potassium triiodide solution until the chloroform layer colored with iodine. The colored solution was washed successively with sodium thiosulfate and water, dried, and then evaporated to give crystals which were recrystallized from ether. Yield, 78.5 mg (78%), mp 135—136 °C (lit,[11] 135—136 °C), IR: 1680 (amide).

Found: C, 46.55; H, 4.56; N, 10.98%. Calcd for $C_{10}H_{12}N_2O_2S_2$: C, 46.88; H, 4.72; N, 10.93%.

*General Procedure for Preparation of 3,6-Dialkyl-1,4-dimethyl-3,6-epithio- (**8**) and -3,6-epidithio-2,5-piperazinedione (**9**).* i) From 3,6-dialkyl-3,6-dimethoxy derivatives (**8a–d,f** and **9a–d,f**). Compounds **5a–d** and **3f′** were treated in a similar manner as above to give crude products, which were purified and separated into **8** and **9** on a silica gel column (WAKOGEL C–200) using benzene-ethyl acetate (20 : 1) as an eluent.

ii) From **1f,g** *via* the corresponding 3,6-dialkyl-3,6-dibromide (**8f,g** and **9f,g**). Compounds **1f** and **1g** were brominated with NBS (2 equivalent) in the same manner as described in **3f′**. Hydrogen sulfide was passed into a solution of the resulting dibromide in chloroform for 3 hr in the absence of zinc chloride, and the reaction mixture was treated as above to give **8f,g** and **9f,g**.

The yields and their physical constants were summarized in Table 2.

The authors are indebted to the members of the Laboratory of Organic Analysis for microanalyses, to Mr. H. Matsumoto for NMR measurements, and to the members of Analytical center of Kitasato University for mass spectral measurements.

Aminosugars. XXIII. L-Idofuranose Derivatives Containing a Heterocycle at *C*-5,6 Position[1]

Masaharu IWAKAWA and Juji YOSHIMURA

Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Meguro-ku, Tokyo 152

(Received October 12, 1974)

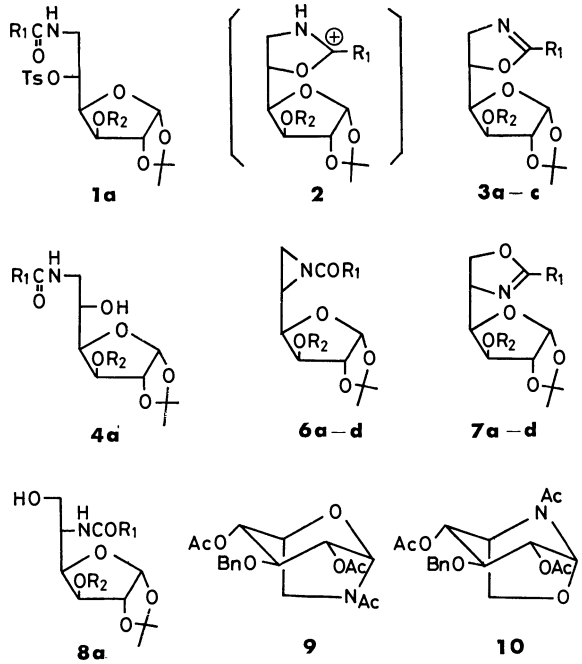
2-Aryl-(5*S*)- and -(4*S*)-(3′-*O*-benzyl- and 3′-*O*-methyl-1′,2′-*O*-isopropylidene-α-D-xylo-tetrofuranos-4′-yl)-2-oxazolines (**3** and **7**) were prepared from 6-aroylamido-6-deoxy-5-*O*-tosyl-D-glucofuranose and 5,6-aroylepimino-5,6-dideoxy-L-idofuranose derivatives, respectively. The corresponding 2-thioxo-(4*R*)- and -(5*S*)-thiazolidine derivatives (**11** and **13**) were also synthesized from 5,6-dideoxy-5,6-epimino-L-idofuranose and 6-azido-6-deoxy 5-*O*-tosyl-D-glucofuranose derivatives, respectively. 2-S-Methylated derivatives of **11** and **13** were reduced with aluminum amalgam to give the corresponding (4*R*)- and (5*S*)-thiazolidine derivatives, respectively. Formation of an intramolecular hemiaminal ring in **11** gave a new type of bicyclic derivatives; (5*S*,6*R*,8*R*)-triacetoxy-(7*S*)-substituted-2-thioxo-(8a*R*)-perhydropyrido[1,2-*c*]thiazole (**16a** and **16b**). The structure of new compounds was examined by NMR spectroscopy.

Although carbohydrate derivatives having fused heterocyclic rings at *C*-1,2 or *C*-2,3 position have been extensively studied,[2] those having a heterocycle at *C*-5,6 position have been scarcely reported, excepting oxazoline,[3,4] isoxazoline,[5] aziridine,[6,7] and triazole derivatives.[8] We have recently communicated syntheses of some isomeric pairs of L-idofuranose derivatives having 2-oxazoline or 2-thioxo-thiazolidine ring at *C*-5,6 position.[9] In this paper, syntheses of these derivatives which can be considered as a kind of reversed *C*-glycoside[5] will be reported in detail.

Results and Discussion

2-Phenyl-(5*S*)-(1′,2′-*O*-isopropylidene-α-D-xylo-tetrofuranos-4′-yl)-2-oxazoline was already synthesized in 50% yield by treatment of 6-benzamido-6-deoxy-5-*O*-tosyl-1,2-*O*-isopropylidene-α-D-glucofuranose with excess sodium acetate in 96% ethanol.[3] Similar treatment of the corresponding 3-*O*-benzyl derivative (**1a**) gave the corresponding oxazoline derivative (**3a**) in 52% yield, together with the corresponding hydrolyzed product; 6-benzamido-3-*O*-benzyl-6-deoxy-1,2-*O*-isopropylidene-β-L-idofuranose (**4a**) in 19% yield. In general, **3** and **4** would be formed by deprotonation or hydrolysis of intermediate carbonium cation (**2**), respectively.[10] To avoid the hydrolysis process the above conversion was tried in an anhydrous condition. When the solution of **1a** and anhydrous sodium acetate in absolute dimethylformamide was refluxed overnight, only **3a** was obtained in 87% yield. In the same manner, the corresponding 2-anisyl derivative (**3b**), and 2-phenyl-(5*S*)-(1′,2′-*O*-isopropylidene-3′-*O*-methyl-α-D-xylo-tetrofuranos-4′-yl)-2-oxazoline (**3c**) were also prepared in good yields from the corresponding 6-aroylamido-6-deoxy derivatives, without isolation of **1b** and **1c**. The compound **1c** was prepared from 1,2-*O*-isopropylidene-3-*O*-methyl-6-*O*-tosyl-α-D-glucofuranose[11] through the corresponding 6-azido, 6-amino, and 6-benzamido derivatives successively.

Moreover, isomeric (4*S*)-2-oxazolines (**7**) were prepared by the isomerization of the corresponding 5,6-aroylepimino derivatives by treatment with sodium iodide in acetone.[12] 3-*O*-Benzyl-5,6-dideoxy-5,6-epimino-1,2-*O*-isopropylidene-β-L-idofuranose (**5**),[7] which was prepared by an improved method, was treated



a: R_1=phenyl, R_2=benzyl
b: R_1=anisyl, R_2=benzyl
c: R_1=phenyl, R_2=methyl
d: R_1=*p*-nitrophenyl, R_2=benzyl

with equimolar amount of aroyl chloride in absolute benzene in the presence of excess triethylamine to give the 5,6-aroylepimino derivatives (**6a**,**b**,**d**) in good yields. The corresponding 3-*O*-methyl derivative (**6c**) was prepared in the same procedure, in which the 5,6-epimino derivative was obtained from the corresponding 6-azido-6-deoxy-5-*O*-tosyl or -5-*O*-mesyl derivative. Refluxing of a solution of **6** and excess amount of sodium iodide in absolute acetone overnight, followed by purification of the product by preparative tlc or by recrystallization gave the corresponding 2-aryl-(4*S*)-(3′-*O*-substituted-1′,2′-*O*-isopropylidene-α-D-xylo-tetrofuranos-4′-yl)-2-oxazolines (**7a**—**d**) in 40—96% yields. Physical constants of **6** and **7** are summarized in Table 1.

Because these oxazoline rings in **3** and **7** are labile to acid, both **3a** and **7a** were easily hydrolyzed to the corresponding benzamido derivatives (**4a** and **8a**) in

Table 1. Physical constants of compounds **6** and **7**

Compound	Mp (°C)	Yield (%)	$[\alpha]_D^{20}$ $CHCl_3$	Molecular formula	Anals. (Calcd) C%	H%	N%	IR[a] (cm^{-1})

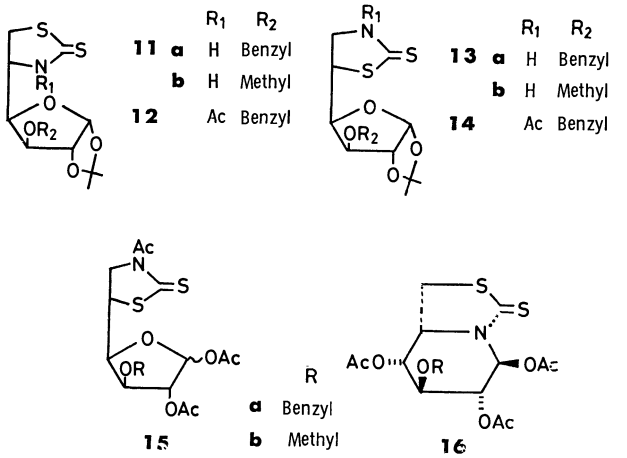
a) The characteristic absorptions of **6** and **7** indicate that of the amide and C=N bond, respectively.

48% and 88% yields, respectively, by treatment with 80% acetic acid for two days at 30—40 °C. Conversion of **4a** into the corresponding bicyclic *N,O*-acetal (**9**)[13] was easily performed by successive de-*N*-benzoylation, de-isopropylidenation, and *N,O*-acetylation. To avoid the conversion into the corresponding pyridine derivatives,[13] *N*-benzoyl group of **8a** was previously converted into *N*-acetyl group, and successive de-isopropylidenation and *O*-acetylation gave successfully the desired *N,O*-acetal (**10**).



On the other hand, aziridines are known to give 2-thioxo-thiazolidines by treatment with carbon disulfide.[14] Thus, **5** was treated with carbon disulfide in a sealed tube at 98 °C for 6 hr to give crystalline 2-thioxo-(4*R*)-(3′-*O*-benzyl-1′,2′-*O*-isopropylidene-α-D-xylo-tetrofuranos-4′-yl)-thiazolidine (**11a**) in 84% yield. Crystalline 3′-*O*-methyl derivative (**11b**) was analogously obtained in 40% yield. Presence of characteristic absorptions at 3260 cm^{-1} (NH) and at 1470 cm^{-1} (NC=S) in IR spectrum supported the formation of 2-thioxo-thiazolidine ring. The structure was also confirmed by the comparison of the NMR spectrum of **11a** with that of *N*-acetylated derivative (**12**). *N*-Acetylation of **11a** caused a remarkable lower shift (1.43 ppm) of H_4 and a higher shift (0.68 ppm) of one of H_5-proton signals (*cf.* Table 2), depending on the acetylation shift[15] and the anisotropic effect of *N*-acetyl group, respectively. For the preparation of isomeric 2-thioxo-(5*S*)-thiazolidine derivatives, the synthetic procedure from a sulfate of β-aminoalcohols and carbon disulfide[16,17] was modified. Refluxing of a solution of 6-amino-3-*O*-benzyl-6-deoxy-5-*O*-tosyl-1,2-*O*-isopropylidene-α-D-glucofuranose,[7] large excess carbon disulfide, and two equimolar potassium hydroxide in ethanol for 2.5 hr gave 2-thioxo-(5*S*)-(3′-*O*-benzyl-1′,2′-*O*-isopropylidene-α-D-xylo-tetrofuranos-4′-yl)-thiazolidine (**13a**) in 98% yield. The corresponding 3′-*O*-methyl derivative (**13b**) was also obtained in 89% yield. Although the acetylation effect could not be clearly observed in the NMR spectrum of the corresponding *N*-acetate (**14**), IR spectrum and elemental analyses supported the structure of **13**. NMR parameters of typical examples of *L*-idofuranose derivatives having a heterocycle at *C*-5,6 position shown in Table 2 indicate that both the heterocyclic ring and the twist furanose ($^3T_2$) ring are generally in the *trans*-conformation with regard to the C_4–C_5 bond axis of the sugar chain, as was deduced in the isoxazoline derivatives.[5]

Hydrolysis of the isopropylidene group of **13** with 70% acetic acid at 90 °C for 5 hr and successive acetylation of the product gave a yellow sirup (**15**). Presence of one *N*-acetyl and two *O*-acetyl groups in NMR spectra, and an amide (1690 cm^{-1}) and an ester (1750 cm^{-1}) absorptions in IR spectra indicated the structure to be 3-*N*-acetyl-2-thioxo-(5*S*)-(1′,2′-di-*O*-acetyl-3′-*O*-benzyl- and -3′-*O*-methyl-α,β-D-xylo-tetrofuranos-4′-yl)-thiazolidine (**15a** and **15b**), respectively. While, analogous conversions of **11a** and **11b** gave crystalline and sirupy products (**16a** and **16b**), respectively, which showed no absorption of an amide. Chemical shifts and coupling constants in NMR spectrum of **16a** (Table 3) indicated that the conformation of the sugar moiety of these compounds is entirely different from those of ordinary D-xylofuranoses (Table 2). Since many long range couplings caused by the W-letter rule[18] were observed, ring protons; H_1, H_2, H_3, and H_4 should be in equatorial position (1*C* conformation of a pyranose ring). The values of $J_{1,4}$, $J_{1,3}$, and $J_{2,4}$ (0.5, 1.5, and 1.0 Hz) were consistent with the values of $J_{1,4}$ and $J_{1,3}$ (0.7 and 1.3 Hz) in the α-gulopyranose pentaacetate system reported by Lemieux.[19] Remarkable lower chemical shift of H_1 will be attributed to the large anisotropic effect of thiocarbonyl group of 2-thioxo-thiazolidine ring.[20] Thus **16a** and **16b** were determined to be a new class of bicyclic sugar derivatives; (5*S*,6*R*,8*R*)-triacetoxy-(7*S*)-benzyloxy- and -(7*S*)-

a) The numbering of hydrogens indicates that of the carbon chain of L-idose.

methoxy-3-thioxo-(8a*R*)-perhydropyrido[1,2-*c*]thiazole, respectively.

Conversion of **11a** and **13a** into the corresponding 2-methylthio-2-thiazoline derivatives (**17** and **18**) was easily performed by successive treatment with equimolar sodium hydride and slight excess methyl iodide under the nitrogen atmosphere. Furthermore, reduction of **17** and **18** with aluminum amalgam[21] gave the corresponding thiazolidine derivatives (**19** and **20**) in good yields.

Because of unexpectedly stable character of heterocycles in **17**—**20**, a few attempts to synthesize *S,N*-analogues of **9** and **10** gave negative results, and it is still under investigation.

Experimental

All melting points were determined with Yanaco micro melting point apparatus and not corrected. The solutions were evaporated under reduced pressure at a bath temperature not exceeding 45 °C. Optical rotations were measured in a 0.5-dm tube with a Carl Zeiss LEP-A1 Polarimeter, using chloroform as a solvent unless otherwise stated. IR spectra were recorded with a Hitachi Model EPI-GS grating spectrometer. NMR spectra were taken with JEOL 4H-100 spectrometer in deuteriochloroform containing tetramethylsilane as an internal reference. Chemical shifts and coupling constants were recorded in δ and Hz units, and IR frequencies in cm^{-1}.

*6-Benzamido-3-O-benzyl-6-deoxy-1,2-O-isopropylidene-5-O-p-toluenesulfonyl-α-D-glucofuranose (**1a**).* Benzoylation of 6-amino-3-*O*-benzyl-6-deoxy-1,2-*O*-isopropylidene-α-D-glucofuranose[7] in methanol with benzoic anhydride gave the corresponding 6-benzamide which was recrystallized from ethanol-*n*-hexane. Yield, 92%, mp 94—95.5 °C, $[\alpha]_D^{22}$ −22.5° (*c* 0.89), IR: 3400 (NH and OH), 1640 and 1520 (amide).

Found: C, 66.38; H, 6.53; N, 3.34%. Calcd for $C_{23}H_{27}NO_6$: C, 66.81; H, 6.58; N, 3.39%.

A solution of 6-benzamide (0.84 g) and *p*-toluenesulfonyl chloride (0.47 g) in pyridine(4 ml) was kept for two days at room temperature, poured into ice-water, and a sirup deposited was extracted with chloroform. Treatment of the extract in a usual manner gave a sirupy product which was purified with a silica gel column, using benzene–ethyl acetate (4 : 1) as an eluent. Yield, 0.96 g (83%), $[\alpha]_D^{22}$ −35.2° (*c* 0.95), IR: 3350 (NH), 1640 and 1520 (amide), 1360 (sulfate).

Found: C, 64.04; H, 5.97; N, 2.23%. Calcd for $C_{30}H_{33}NO_8S$: C, 63.48; H, 5.86; N, 2.47%.

*2-Aroyl-(5S)-(3'-O-benzyl-1',2'-O-isopropylidene-α-D-xylo-tetrofuranos-4'-yl)-2-oxazoline (**3**). i) 2-Phenyl Derivative (**3a**).* (a) A solution of **1a** (220 mg) and anhydrous sodium acetate (200 mg) in 96% ethanol (10 ml) was refluxed for 20 hr, and evaporated. The residue was extracted with

chloroform, after the addition of a small amount of water, and the organic layer was washed with 5% sodium chloride, dried, and evaporated to give a sirup. This sirup showed two components (R_f=0.40 and 0.11) on tlc (benzene : ethyl acetate=4 : 1 in v/v), which were separated on a preparative tlc. The both fractions gave a sirupy **3a** and crystalline **4a** in 52.5% and 19% yields, respectively.

3a: $[\alpha]_D^{22}$ −97.6° (*c* 0.68), IR: 1640 (C=N).

Found: C, 70.03; H, 6.45; N, 3.58%. Calcd for $C_{23}H_{25}NO_5$: C, 69.85; H, 6.37; N, 3.54%.

4a: mp 175 °C, $[\alpha]_D^{22}$ −62.2° (*c* 0.81), IR: 3440 and 3340 (OH and NH), 1630 and 1530 (amide).

Found: C, 66.83; H, 6.58; N, 3.28%. Calcd for $C_{23}H_{27}NO_6$: C, 66.81; H, 6.58; N, 3.39%.

(b) A suspension of **1a** (410 mg) and anhydrous sodium acetate (600 mg) in dry dimethylformamide (20 ml) was treated as above to give **3a** in 87.5% (290 mg) yield, which was identical with the authentic sirup in IR spectrum.

*ii) 2-Anisyl Derivative (**3b**)*: Acylation of 6-amino-3-*O*-benzyl-6-deoxy-1,2-*O*-isopropylidene-α-D-glucofuranose[7] with anisoyl chloride in pyridine in a usual manner gave the corresponding 6-anisamide in 77% yield. Mp 147—147.5 °C, $[\alpha]^{22}$ −24.2° (*c* 1.05), IR: 3460 and 3340 (OH and NH), 1620 and 1530 (amide).

Found: C, 64.92; H, 6.66; N, 3.27%. Calcd for $C_{24}H_{29}NO_7$: C, 65.00; H, 6.59; N, 3.16%.

A solution of the above 6-anisamide (400 mg) and *p*-toluenesulfonyl chloride (250 mg) in pyridine (2 ml) was kept at room temperature overnight, poured into ice-water, and extracted with chloroform. The extract was treated in a usual manner to give a sirupy 5-Otosylate (**1b**, 560 mg). The sirup was dried over phosphorus pentoxide, and treated with anhydrous sodium acetate (770 mg) in DMF in the same procedure as above to give sirupy **3b** in 69% (320 mg) yield. $[\alpha]_D^{22}$ −83.0° (*c* 0.90), IR: 1640 (C=N).

Found: C, 67.70; H, 6.42; N, 3.24%. Calcd for $C_{24}H_{27}NO_6$: C, 67.75; H, 6.40; N, 3.29%.

*2-Phenyl-(5S)-(1′,2′-O-isopropylidene-3′-O-methyl-α-D-xylo-tetrofuranos-4′-yl)-2-oxazoline (**3c**)*. Treatment of 1,2-*O*-isopropylidene-3-*O*-methyl-6-*O*-tosyl-α-D-glucofuranose[11] with sodium azide in a usual manner gave the corresponding azide in 71% yield as a sirup. Reduction of the azide in the presence of Raney-nickel, and acylation of the resulted amine with benzoic anhydride in a usual manner gave the corresponding 6-benzamide as a sirup, which was purified on a silica gel column using benzene–ethyl acetate (4 : 1 in v/v) as an eluent. Yield, 72%; $[\alpha]_D^{22}$ −25.2° (*c* 1.17), IR: 3350 (OH and NH), 1630 and 1530 (amide).

Found: C, 60.72; H, 6.95; N, 4.00%. Calcd for $C_{17}H_{23}NO_6$: C, 60.52; H, 6.87; N, 4.15%.

Tosylation of the above sirup (530 mg) in a usual manner gave 6-benzamido-6-deoxy-1,2-*O*-isopropylidene-3-*O*-methyl-5-*O*-tosyl-α-D-glucofuranose (**1c**, 590 mg) as a sirup. Isomerization of **1c** as before, and fractionation of the product on a silicagel column gave pure **3c** in 28% yield. $[\alpha]_D^{22}$ −75.1° (*c* 0.94). IR: 1640 (C=N).

Found: C, 63.83; H, 6.60; N, 4.26%. Calcd for $C_{17}H_{21}NO_5$: C, 63.93; H, 6.63; N, 4.39%.

*3-O-Benzyl-5,6-dideoxy-5,6-epimino-1,2-O-isopropylidene-β-L-idofuranose (**5**)*. A suspension of 3-*O*-benzyl-5,6-di-*O*-mesyl-1,2-*O*-isopropylidene-α-D-glucofuranose[22] (2.33 g) and sodium azide (1 g) in DMF (50 ml) was heated at 90—100 °C for one hr, poured into cold 5% sodium chloride after cooling, and extracted with ether. The extract was washed with 5% sodium chloride, dried, and evaporated to give a sirupy product (92%). Crystallization and recrystallization of the sirup from ethanol gave 6-azido-3-*O*-benzyl-6-deoxy-1,2-*O*-isopropylidene-5-*O*-mesyl-α-D-glucofuranose as prisms of mp 79.5—80.5 °C. $[\alpha]_D^{22}$ −39.0° (*c* 1.26), IR: 2100 (N_3), 1340 (sulfate), NMR: 1.29 and 1.48 (2x C-CH_3), 3.03 (SO_3CH_3), 3.60 ($H_{6'}$; q, $J_{6,6'}$=13.8, $J_{5,6'}$=10.5), 3.83 (H_6; q, $J_{5,6}$=3.1), 4.09 (H_3; d, $J_{3,4}$=3.7), 4.37 (H_4; q, $J_{4,5}$=7.75), 4.58 (H_2; d, $J_{1,2}$=3.75), 4.60 (CH_2; s), 5.13 (H_5; m), 5.86 (H_1; d), 7.35 (Ph; s).

Found: C, 49.66; H, 5.52; N, 10.08; S, 7.93%. Calcd for $C_{17}H_{23}N_3O_7S$: C, 49.39; H, 5.61; N, 10.17; S, 7.75%.

To an ice-coled solution of the above 6-azido-5-*O*-mesyl derivative (8.39 g) in dry ether (130 ml) was added lithium aluminum hydride (1.67 g) with stirring portionwise, and the mixture was stirred for one hr at room temperature, excess hydride was decomposed by adding a small volume of water, and filtered. The filtrate was evaporated to give a half crystalline mass (5.21 g, 84%), which melts at 93—94 °C (lit,[7] mp 91—94 °C, 69%), after recrystallization from benzene-*n*-hexane.

5,6-Dideoxy-5,5-epimino-1,2-O-isopropylidene-3-O-methyl-β-L-idofuranose. Treatment of 6-azido-6-deoxy-1,2-*O*-isopropylidene-3-*O*-methyl-α-D-glucofuranose, mentioned in the preparation of **3c**, with excess *p*-tosyl chloride or methanesulfonyl chloride in the usual manner gave crystalline 5-*O*-sulfates in 90% and 99% yields, respectively.

5-*O*-Tosylate: mp 134—135 °C, $[\alpha]_D^{23}$ −53.6° (*c* 1.01).

Found: C, 49.54; H, 5.61; N, 9.60%. Calcd for $C_{17}H_{23}N_3O_7S$: C, 49.39; H, 5.60; N, 10.16%.

5-*O*-Mesylate: mp 79—80 °C, $[\alpha]_D^{23}$ −49.8° (*c* 0.98).

Found: C, 39.62; H, 5.72; N, 11.98; S, 9.69%. Calcd for $C_{11}H_{19}N_3O_7S$: C, 39.16; H, 5.68; N, 12.46; S, 9.51%.

Treatment of the above 5-*O*-tosylate or 5-*O*-mesylate in THF with lithium aluminum hydride in the same manner as **5** gave the 5,6-epimino derivative as a sirup in *ca.* 90% yield, which showed no absorption of azide. This sirup was used for preparation of **6c** and **12b** without further identification.

*General procedure for preparation of 5,6-Aroylimino-5,6-dideoxy-1,2-O-isopropylidene-3-O-substituted-β-L-idofuranose (**6a-d**)*. To a solution of **5** or its 3-*O*-methyl derivative and excess triethylamine in dry benzene was added equimolar amount of aroyl chloride, and the precipitate was filtered off, after stirring the reaction mixture for 1—2 hr at room temperature. Evaporation of the filtrate gave the crude product, which was purified by recrystallization or by fractionation with a silica gel column chromatography.

*General procedure for preparation of 2-aroyl-(4S)-(1′,2′-O-isopropylidene-3′-O-substituted-α-D-xyol-tetrofuranos-4′-yl)-2-oxazoline (**7a-d**)*. A solution of **6a-d** (140 mg) and dried sodium iodide (1 g) in dry acetone (5 ml) was refluxed for 15—24 hr, evaporated, and the residue was extracted with chloroform. The extract was washed with 5% sodium chloride, and evaporated to give the product, which was purified by recrystallization, by a preparative tlc, or by a silica gel column chromatography.

*Ring-opening of oxazoline derivatives (**3a** and **7a**)*. A solution of **7a** (700 mg) in 80% acetic acid (40 ml) was heated at 30—36 °C for 2 days, evaporated, and the residue was trituated with ethanol to give crude crystals, which were recrystallized from ethanol to give needles of 5-benzamido-3-*O*-benzyl-5-deoxy-1,2-*O*-isopropylidene-β-L-idofuranose (**8a**) in 48% (350 mg) yield. Mp 161—162 °C, $[\alpha]_D^{22}$ −9.4° (*c* 1.0), IR: 3460 and 3330 (OH and NH), 1620 and 1530 (amide).

Found: C, 66.80; H, 6.57; N, 3.40%. Calcd for $C_{23}H_{27}NO_6$: C, 66.81; H, 6.58; N, 3.39%.

In a similar way, **3a** was converted into **4a** in 88% yield, which was identical with that mentioned before.

*1,6-Acetylimino-3-O-benzyl-6-deoxy-2,4-di-O-acetyl-β-L-idopyranose (**9**).* A suspension of **4a** (130 mg) and potassium hydroxide (800 mg) in 90% ethanol (8 ml) was refluxed for 2 days, poured into ice-water, and extracted with chloroform. The extract was washed with 5% sodium chloride, and evaporated to give de-*N*-benzoylated sirup (80 mg). A solution of the sirup in 2*N*-sulfuric acid (30 ml) was heated at 70—80 °C for 4 hr, neutralized with barium carbonate, and then filtered after the addition of methanol. The filtrate was evaporated, and the residue was dried over phosphorus pentoxide, acetylated with acetic anhydride in a usual manner to give a sirup (30 mg), which was crystallized from ethanol. Yield, 12.5% (15 mg), mp 148—149 °C, $[\alpha]_D^{22}$ −12.9° (*c* 0.52), IR: 1740 (ester), 1640 (amide).

Found: C, 60.30; H, 6.08; N, 3.57%. Calcd for $C_{19}H_{23}NO_7$: C, 60.47; H, 6.14; N, 3.71%.

*N-Acetyl-1,6-anhydro-3-O-benzyl-5-deoxy-2,4-di-O-acetyl-β-L-idopiperidinose (**10**).* A solution of **8a** (250 mg) and potassium hydroxide (2.5 g) in 80% ethanol was refluxed overnight, and then extracted with methylene chloride in a usual manner to give the corresponding 6-amino derivative (70 mg), which was acetylated with acetic anhydride (0.2 g) and triethylamine (0.3 g) in methanol (3 ml) by the procedure reported by Paulson *et al.*[21] to give a sirup. The *N*-acetyl derivative was hydrolyzed with 0.05 M-sulfuric acid (30 ml) at 70 °C for 1 hr, and the dried product obtained by evaporation of the reaction mixture was again acetylated in a usual manner to give a sirup (120 mg) which was purified by a preparative tlc. Yield, 26% (60 mg), $[\alpha]_D^{22}$ +40.8° (*c* 0.85), IR: 1740 (ester), 1660 (amide).

Found: C, 59.85; H, 6.40; N, 3.84%. Calcd for $C_{19}H_{23}NO_7$: C, 60.47; H, 6.14; N, 3.71%.

*2-Thioxo-(4R)-(1',2'-O-isopropylidene-3'-O-substituted-α-D-xylo-tetrofuranos-4'-yl)-thiazolidine (**11**).* *i) 3'-O-Benzyl derivative (**11a**).* A mixture of **5** (1.75 g) and carbon disulfide (5 ml) was sealed in a Pyrex glass at −70 °C, and kept with occasional shaking at room temperature for 1 hr and at 98 °C for 6 hr. The tube was opened at −70 °C, and the content was evaporated to give a sirup which was purified on a silica gel column, using benzene–ethyl acetate (9 : 1) as an eluent, to give crystals in 84% yield. Mp 140—141 °C, $[\alpha]_D^{22}$ −32.1° (*c* 0.87), IR: 3250 (NH), 1469 (NHCS).

Found: C, 55.52; H, 5.76; N, 3.73; S, 17.17%. Calcd for $C_{17}H_{21}NO_4S_2$: C, 55.55; H, 5.76; N, 3.81; S, 17.45%.

*ii) 3'-O-Methyl derivative (**11b**).* 5,6-Dideoxy-5,6-epimino-1,2-*O*-isopropylidene-3-*O*-methyl-β-L-idofuranose (0.52 g) described before was treated with carbon disulfide (2.5 ml) in the same manner as above to give crystals in 40% (280 mg) yield. Mp 195—196 °C, $[\alpha]_D^{22}$ −29.6° (*c* 0.75), IR: 3220 (NH), 1470 (NHCS).

Found: C, 45.44; H, 5.83; N, 4.70; S, 21.91%. Calcd for $C_{11}H_{17}NO_4S_2$: C, 45.34; H, 5.88; N, 4.81; S, 22.01%.

*3-N-Acetyl-2-thioxo-(4R)-(3'-O-benzyl-1',2'-O-isopropylidene-α-D-xylo-tetrofuranos-4'-yl)-thiazolidine (**12**).* A solution of **11a** (100 mg) and acetic anhydride (1 ml) in pyridine (1 ml) was kept at room temperature overnight, poured into ice-water, and the yellow sirup deposited was extracted with chloroform. A usual treatment of the extract gave a sirup (110 mg) which was purified on a silica gel column, using 5% ethyl acetate in benzene as an eluent, to give the pure sirup in 81% (90 mg) yield. $[\alpha]_D^{22}$ −295° (*c* 0.84), IR: 1700 (amide).

Found: C, 55.68; H, 5.73; N, 3.32; S, 15.44%. Calcd for $C_{19}H_{23}NO_5S_2$: C, 55.77; H, 5.67; N, 3.42; S, 15.67%.

When the acylation was performed with *p*-nitrobenzoyl chloride and triethylamine in benzene, the crystalline *N-p*-nitrobenzoate was obtained as yellow needles in 71% yield. Mp 154—155 °C, $[\alpha]_D^{22}$ −148° (*c* 1.18), IR: 1700 (amide).

Found: C, 55.86; H, 4.67; N, 5.49; S, 12.51%. Calcd for $C_{24}H_{24}N_2O_7S_2$: C, 55.81; H, 4.68; N, 5.42; S, 12.41%.

*2-Thioxo-(5S)-(1',2'-O-isopropylidene-3'-O-substituted-α-D-xylo-tetrofuranos-4'-yl)-thiazolidine (**13**).* *i) 3'-O-Benzyl Derivative (**13a**):* A suspension of 6-azido-3-*O*-benzyl-6-deoxy 1,2-*O*-isopropylidene-5-*O*-tosyl-α-D-glucofuranose[7] (3.8 g) in ethanol (150 ml) was reduced in the presence of 10% palladium-charcoal (1.66 g) and acetic acid (0.56 g) for 4 hr, and the catalyst was filtered off. A mixed solution of the filtrate, carbon disulfide (4 ml), and ethanolic potassium hydroxide (1.15 g) was refluxed for 2.5 hr, evaporated, and the residue was washed with water to give crude crystals (2.81 g, 98%) which was recrystallized from ethanol. Mp 120—125 °C, $[\alpha]_D^{22}$ +5.8° (*c* 1.0, acetone), IR: 3250 (NH), 1500 (NHCS).

Found: C, 55.26; H, 5.97; N, 3.66; S, 17.19%. Calcd for $C_{17}H_{21}NO_4S_2$: C, 55.55; H, 5.76; N, 3.81; S, 17.45%.

*ii) 3'-O-Methyl Derivative (**13b**).* 6-Azido-6-deoxy-1,2-*O*-isopropylidene-3-*O*-methyl-5-*O*-tosyl-α-D-glucofuranose mentioned before was treated in the same manner as above to give crystals of mp 148—150 °C in 89% yield. $[\alpha]_D^{22}$ +58.7° (*c* 1.19), IR: 3200 (NH), 1500 (NHCS).

Found: C, 45.59; H, 5.90; N, 4.60; S, 21.77%. Calcd for $C_{11}H_{17}NO_4S_2$: C, 45.34; H, 5.88; N, 4.81; S, 22.01%.

*3-N-Acetyl-2-thioxo-(5S)-(3'-O-benzyl-1',2'-O-isopropylidene-α-xylo-tetrofuranos-4'-yl)-thiazolidine (**14**).* Acetylation of **13a** in the usual manner gave crystals of mp 156—156.5 °C in 90% yield. $[\alpha]_D^{22}$ +34.5° (*c* 1.3), IR: 1690 (amide).

Found: C, 55.43; H, 5.48; N, 3.40; S, 15.72%. Calcd for $C_{19}H_{23}NO_5S_2$: C, 55.73; H, 5.66; N, 3.42; S, 15.66%.

*3-N-Acetyl-2-thioxo-(5S)-(1',2'-di-O-acetyl-3'-O-substituted-α,β-D-xylo-tetrofuranos-4'-yl)-thiazolidine (**15**).* *i) 3'-O-Benzyl Derivative (**15a**).* A solution of **13a** (420 mg) in 70% acetic acid (20 ml) was heated at 90 °C for 5 hr, evaporated, and the residue was dried over phosphorus pentoxide, acetylated in a usual manner to give a sirup which was purified on a silica gel column using 5% ethyl acetate in benzene as an eluent. Yield, 71.5% (345 mg), $[\alpha]_D^{22}$ +96.5 (*c* 1.37), IR: 1750 (ester), 1690 (amide), 1500 (NHCS), NMR: 2.05 and 2.09 (2 x OAc), 2.72 (NAc).

Found: C, 53.01; H, 5.23; N, 3.26; S, 14.32%. Calcd for $C_{20}H_{23}NO_7S_2$: C, 52.97; H, 5.11; N, 3.09; S, 14.14%.

*ii) 3'-O-Methyl Derivative (**15b**).* In the same manner as above **15b** was obtained from **13b** in 56% yield as a sirup. $[\alpha]_D^{22}$ +113.5° (*c* 1.4), IR: 1750 (ester), 1690 (amide), 1500 (NHCS).

Found: C, 45.41; H, 5.24; N, 3.55; S, 16.57%. Calcd for $C_{14}H_{19}NO_7S_2$: C, 44.54; H, 5.07; N, 3.71; S, 16.99%.

*(5S,6R,8R)-Triacetoxy-(7S)-alkoxy-3-thioxo-(8aR)-perhydropyrido[1,2-c]thiazole (**16**).* *i) (7S)-Benzyloxy Derivative (**16a**).* A suspension of **11a** (150 mg) in 70% acetic acid (40 ml) was heated at 90 °C for 4 hr, evaporated, and the residue was dried over phosphorus pentoxide, acetylated in a usual manner to give needles of mp 129—130 °C in 74% (230 mg) yield. $[\alpha]_D^{22}$ −82.0° (*c* 1.1), IR: 1740 (ester), 1380 (NHCS).

Found: C, 53.17; H, 5.10; N, 3.10; S, 13.92%. Calcd for $C_{20}H_{23}NO_7S_2$: C, 52.98; H, 5.11; N, 3.09; S, 14.14%.

*ii) (7S)-Methoxy Derivative (**16b**):* In the same manner as above, **16b** was obtained from **11b** as a sirup in 48% yield. $[\alpha]_D^{22}$ −56.6° (*c* 0.63), IR: 1740 (ester), 1370 (NHCS).

Found: C, 44.35; H, 5.07; N, 3.65; S, 16.51%. Calcd for $C_{14}H_{19}NO_7S_2$: C, 44.56; H, 5.08; N, 3.71; S, 17.00%.

*2-Methylthio-(4R)-(3'-O-benzyl-1',2'-O-isopropylidene-α-D-xylo-tetrofuranos-4'-yl)-2-thiazoline (**17**).* To a suspension

of sodium hydride (170 mg, dispersed in oil *ca.* 50%) in DMSO (4 ml) stirred for 1 hr under nitrogen atmosphere was added dropwise a solution of **11a** (1.2 g) in DMSO (5 ml) and then methyl iodide (2 ml). After keeping the reaction mixture at room temperature for 4 hr, it was poured into ice-water, and extracted with chloroform. The chloroform layer was washed with 5% sodium chloride, dried with magnesium sulfate, and evaporated to give a sirup which was purified on a silica gel column, using 10% ethyl acetate in toluene as an eluent, to give crystals of mp 113—114 °C in 66.5% (0.83 g) yield. $[\alpha]_D^{22}$ −50.0° (*c* 1.0), IR: 1560 (C=N).

Found: C, 56.94; H, 6.06; N, 3.60; S, 16.62%. Calcd for $C_{18}H_{23}NO_4S_2$: C, 56.68; H, 6.08; N, 3.67; S, 16.78%.

The corresponding (5*S*)-2-thiazoline (**18**) was analogously obtained from **13a** in 79% yield as a sirup. $[\alpha]_D^{22}$ −11.8° (*c* 1.22), IR: 1570 (C=N).

Found: C, 57.12; H, 6.06; N, 3.74; S, 16.29%. Calcd for $C_{18}H_{23}NO_4S_2$: C, 56.68; H, 6.08; N, 3.67; S, 16.78%.

*(4R)-(3'-O-Benzyl-1',2'-O-isopropylidene-α-D-xylo-tetrofuranos-4'-yl)thiazolidine (**19**).* To a solution of **17** (0.3 g) in THF (30 ml) was added aluminum amalgam prepared from aluminum turnings (1 g) and then water (5 ml) portionwise under stirring. The reaction mixture was then stirred at 50—60 °C for 24 hr, filtered through filtercell, and the filtrate was evaporated to give crystals almost quantitatively (270 mg). Recrystallization of it from ethanol gave needles of mp 149—151 °C. $[\alpha]_D^{22}$ −95.4° (*c* 0.74), IR: 3200 (NH).

Found: C, 60.58; H, 6.85; N, 4.13; S, 9.55%. Calcd for $C_{17}H_{23}NO_4S$: C, 60.52; H, 6.87; N, 4.15; S, 9.50%.

The corresponding (5*S*)-thiazolidine (**20**) was analogously obtained from **18** in 95% yield as a sirup. $[\alpha]_D^{22}$ −7.9° (*c* 0.63), IR: 3300 (NH).

Found: C, 59.63; H, 6.81; N, 4.09; S, 9.40%. Calcd for $C_{17}H_{23}NO_4S$: C, 60.52; H, 6.87; N, 4.15; S, 9.50%.

The authors are indebted to Mr. H. Matsumoto for NMR measurements, and members of the Laboratory of Organic Analysis for the microanalyses.

Studies of Enamines. VI.[1] The Formation of New Michael Type Adducts and Pyrrolizine Compounds in the Reaction of Enamines with Pyrrole

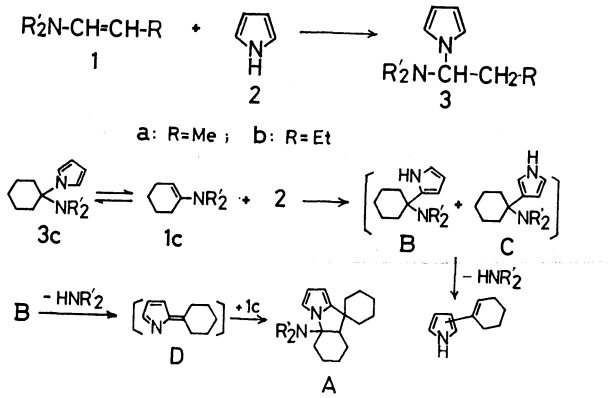
Masashi TASHIRO, Yoko KIRYU, and Otohiko TSUGE*

Research Institute of Industrial Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received October 16, 1974)

While the reaction of 1-(1-pyrrolidinyl)propene (**1a**) and -1-butene (**1b**) with pyrrole (**2**) under mild conditions afforded the Michael type N,N–1 : 1 adducts **3**, under forcing conditions enamines **1** reacted with **2** to give the Michael type C,N– 1 : 1 adducts **4**, accompanied with pyrrolizine compounds **5**. It has been shown that the pyrrolizine **5** was formed *via* the cycloaddition reaction of **1** with an azafulvene intermediate arising from **4** by the elimination of pyrrolidine.

In a previous communication,[2] we have reported that under mild conditions 1-(1-pyrrolidinyl)propene (**1a**), -1-butene (**1b**), and -cyclohexene (**1c**) reacted with pyrrole (**2**) to give the Michael type N,N-1 : 1 adducts **3a**, **3b**, and **3c**, respectively. It has been also found that the adduct **3c** decomposed at elevated temperature to regenerate **1c** and **2**, and that the reaction of **1c** with **2** under forcing conditions afforded the novel pyrrolizine compound **A**, accompanied with cyclohexenylpyrroles. The pathway depicted in Scheme 1 has been tentatively proposed for this novel reaction: under forcing conditions the reaction would proceed *via* an initial formation of Michael type C,N–1 : 1 adducts, **B** and **C**, followed by the elimination of pyrrolidine to yield cyclohexenylpyrroles and azafulvene intermediate **D**. The azafulvene **D** would undergo cycloaddition reaction with **1c** to afford the pyrrolizine **A**.[1]



Scheme 1.

During the course of a further investigation of the reaction of enamines with pyrrole (**2**), it has been found that enamines **1a** and **1b** reacted with **2** to give the new Michael type C,N–1 : 1 adducts whose structures correspond to that of **B**. This paper deals with the reaction of **1a** and **1b** with **2**, and with the discussion of the pathway for the formation of pyrrolizine compounds.

Results and Discussion

The reaction of **1a** with **2** at 110 °C for 12 hr in a stream of nitrogen gave two new compounds **4a**, mp 93—94 °C, and **5a**, bp 124—126 °C/4 mmHg, in 20.6 and 6.1% yields respectively, and Michael type N,N–1 : 1 adduct **3a**, which is a main product in the reaction at 80 °C for 5 min,[2] was not formed.

The molecular formula of **4a** agreed with that of a 1 : 1 adduct of **1a** and **2**, that is, **4a** is an isomer of **3a**, and the IR spectrum showed the band ascribable to NH absorption at 3190 cm^{-1}. The NMR spectrum in carbon tetrachloride (CCl_4) exhibited signals at δ 3.03 (1H, q, $\rightarrow$CH), 5.89 (2H, m, β-protons of pyrrole ring (β-**H**)), and 6.52 ppm (1H, dd, α-proton of pyrrole ring (α-**H**)), besides methylene and methyl protons. On the basis of above spectral data, **4a** was clearly assigned as 1-(1-pyrrolidinyl)-1-(2-pyrrolyl)propane, whose structure corresponds to that of a compound of type **B** assumed as an initial intermediate in Scheme 1.

The minor product **5a**, whose molecular formula corresponded to that of a compound arising from a 2 : 1 adduct of **1a** and **2** by the elimination of one mole of pyrrolidine, was deduced to be 1,2-dihydro-1-ethyl-2-methyl-3-(1-pyrrolidinyl)-3H-pyrrolizine. The IR spectrum showed no NH absorptions, and the NMR spectrum in CCl_4 exhibited signals at δ 4.65 (1H, d, $\rightarrow$C**H**, J=4.5 Hz), 5.60, 5.97 (each 1H, m, β-**H**), and 6.41 ppm (1H, dd, α-**H**), besides methyl, methylene, and methine protons.

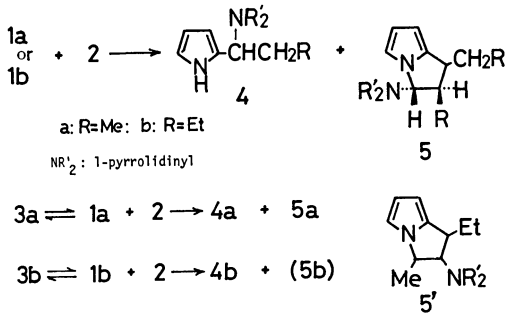
A potential structure, 1-ethyl-3-methyl-2-(1-pyrrolidinyl)pyrrolizine **5'**, might be excluded from the structure for the minor product, because the signal at δ 4.65 ppm in the NMR spectrum might be assignable to the 3-methine proton of **5a**, but not to 2- or 3-methine proton of **5'**. Furthermore, the relative arrangements of substituents of **5a** are similar to those of the pyrrolizine **A** whose structure has been clearly established.[1]

The configuration of **5a** is not clear, because of appearance of 1- and 2-methine protons in a region of methylene protons. In view of the value of coupling constant of 3-methine proton (J=4.5 Hz), however, it may be thought that the 2-methyl and 3-pyrrolidinyl groups are situated *trans*.

Similarly, the reaction of **1b** with **2** at 100 °C for 11 hr afforded the corresponding Michael type C,N–1 : 1 adduct **4b** and pyrrolizine compound **5b** in 44.1 and 7.7% yields, respectively.

When the *N,N*-adduct **3a** was heated at 120 °C for 10 hr, **4a** was obtained in 22.6% yield, along with traces of **5a**. Under similar conditions, however, **3b** gave only **4b**, and no **5b** could be isolated. These facts indicate that **3a** and **3b** as well as **3c** decomposed at elevated temperature to regenerate the correspond-

* To whom inquiries should be addressed.



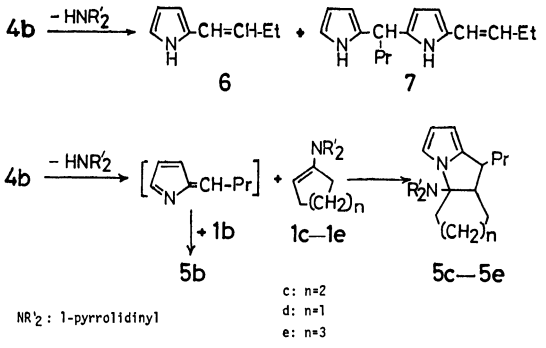
Scheme 2.

ing enamines **1** and **2** (Scheme 2).

In order to know whether the Michael type C,N-1 : 1 adduct is a real intermediate producing alkenylpyrrole and pyrrolizine compound or not, several reactions toward **4b** were investigated.

On heating of **4b** at 150 °C for 5 hr in a stream of nitrogen, the expected 2-(1-butenyl)pyrrole (**6**) and a dimer **7** of **6** were obtained in 34.6 and 39.4% yields, respectively. On the basis of the spectral data, the structure of dimer **7** has been tentatively assigned 1-(2-pyrrolyl)-1-{2-[5-(1-butenyl)]pyrrolyl}butane.

On the other hand, heating of **4b** in the presence of **1b** at 100 °C for 10 hr afforded the expected pyrrolizine compound **5b** in 31.2% yield. Furthermore, **4b** was allowed to react with 1-(1-pyrrolidinyl)cyclohexene (**1c**), -cyclopentene (**1d**), and -cycloheptene (**1e**) under similar conditions, giving the corresponding pyrrolizine compounds **5c**, **5d**, and **5e**, in 65.0, 60.0, and 98.7% yields, respectively (Scheme 3). These facts strongly indicate that an azafulvene intermediate would be initially formed by an alternative elimination mode of pyrrolidine from **4b**, followed by cycloaddition reaction of the azafulvene with enamine **1** to give pyrrolizines **5**.

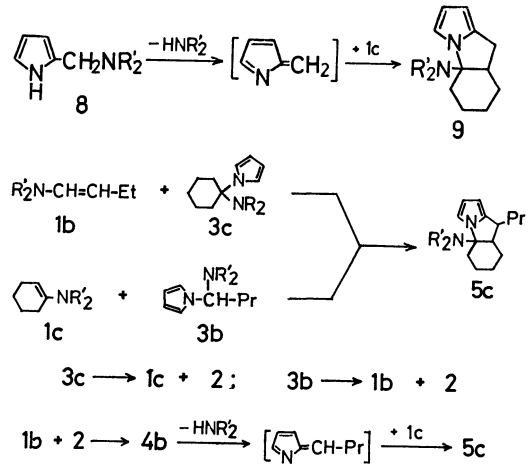


Scheme 3.

Furthermore, the following results seem to provide evidence for the formation of pyrrolizine compound *via* the cycloaddition reaction of an azafulvene with enamine.

2-(1-Pyrrolidinylmethyl)pyrrole (**8**), which would form only an azafulvene by the elimination of pyrrolidine, reacted with enamine **1c** at 120 °C to give the expected pyrrolizine compound **9** in 49.3% yield.

In both reactions of enamine **1b** with the *N,N*-adduct **3c**, and of enamine **1c** with the *N,N*-adduct **3b** at 120 °C, pyrrolizine compound **5c** as a sole isolated product was obtained in 35.3 and 33.7% yields, respectively. These facts indicate the participation of the same intermediate for the formation of **5c** in both reactions. Under the reaction contitions, both *N,N*-adducts **3b** and **3c** decompose to regenerate the respective enamines, **1b** and **1c**, and pyrrole (**2**). This is followed by the reaction of regenerated pyrrole (**2**) with more reactive enamine **1b** than **1c** to form the C,N-adduct **4b**. Then, **4b** is converted to an azafulvene, and the azafulvene undergoes cycloaddition reaction with the remaining enamine **1c** to give **5c** (Scheme 4).



Scheme 4.

In conclusion it is now clear that the reaction of enamine **1** with pyrrole (**2**) proceeds through the pathway illustrated by the reaction of **1c** with **2** in Scheme 1.

Experimental

All melting and boiling points are uncorrected. The mass spectra were obtained on a Hitachi RMS-4 mass spectrometer with a direct inlet and an ionization energy of 70 eV. The NMR spectra were determined at 60 MHz with a Hitachi R-20 NMR spectrometer with TMS as an internal reference.

*Reaction of 1-(1-Pyrrolidinyl)propene (**1a**) with Pyrrole (**2**).* A mixture of 10.0 g (0.09 mol) of **1a** and 4.0 g (0.06 mol) of **2** was stirred at 110 °C for 12 hr in a stream of nitrogen. The reaction mixture was subjected to fractional distillation to give 2.2 g (20.6% based on **2**) of 1-(1-pyrrolidinyl)-1-(2-pyrrolyl)-propane (**4a**), bp 90—93 °C/5 mmHg, as colorless oil which solidified, and 0.8 g (6.1% based on **2**) of 1,2-dihydro-1-ethyl-2-methyl-3-(1-pyrrolidinyl)-3H-pyrrolizine (**5a**), bp 124—126 °C/4 mmHg, as pale yellow oil. Recrystallization from petroleum ether (bp 40—65 °C) afforded pure **4a**, mp 93—94 °C, as colorless prisms.

4a; IR (KBr): 3190 cm^{-1} (ν_{NH}). NMR (CCl_4): δ 0.7 (3H, t, CH_3), 1.5—2.1 (6H, m, CH_2), 2.1—2.9 (4H m, CH_2), 3.03 (1H, q, $>CH$), 5.89 (2H, m, β-**H**), 6.52 (1H, dd, α-**H**), 9.32 (1H, broad **NH**). Mass: *m/e* 178 (M^+). Found: C, 74.30; H, 10.43; N, 15.85%. Calcd for $C_{11}H_{18}N_2$: C, 74.11; H, 10.18; N, 15.71%.

5a; NMR (CCl_4): δ 1.1 (6H, m, CH_3), 1.4—1.95 (6H, m, CH_2), 2.0—3.1 (6H, m, $2\times CH_2+2\times >CH$), 4.65 (1H,

d, >CH, J=4.5 Hz), 5.60, 5.97 (each 1H, m, β-H), 6.41 (1H, dd, α-H). Mass: *m/e* 218 (M^+). Found: C, 76.85; H, 10.19; N, 12.77%. Calcd for $C_{14}H_{22}N_2$: C, 77.01; H, 10.16; N, 12.71%.

*Reaction of 1-(1-Pyrrolidinyl)-1-butene (**1b**) with **2**.* A mixture of 40.0 g (0.32 mol) of **1b** and 43.0 g (0.64 mol) of **2** was stirred at 100 °C for 11 hr in a stream of nitrogen. Excess of **2** was removed by vacuum distillation, and the residue was allowed to stand over night to give colorless crystals. Filtration and recrystallization from petroleum ether (bp 40—65 °C) afforded 26.5 g of 1-(2-pyrrolyl)-1-(1-pyrrolidinyl)butane (**4b**), mp 89 °C, as colorless prisms.

Vacuum distillation of the filtrate afforded 0.6 g of **4b** and 6.06 g (7.7%) of 1,2-dihydro-2-ethyl-1-propyl-3-(1-pyrrolidinyl)-3H-pyrrolizine (**5b**), bp 117—118 °C/2 mmHg, as pale yellow oil.

The total yield of **4b** was 27.1 g (44.1% based on **1b**). IR (KBr): 3180 cm^{-1} (ν_{NH}). NMR (CCl_4): δ 0.7—1.4 (5H, m, CH_3+CH_2), 1.5—2.0 (6H, m, CH_2), 2.1—2.9 (4H, m, CH_2), 3.15 (1H, q, >CH), 5.99 (2H, m, β-H), 6.54 (1H, dd, α-H), 9.37 (1H, broad, NH). Mass: *m/e* 192 (M^+). Found: C, 75.18; H, 10.71; N, 14.66%. Calcd for $C_{12}H_{20}N_2$: C, 74,95; H, 10.48; N, 14.57%.

5b; NMR (CCl_4): δ 1.0 (6H, m, CH_3), 1.2—3.1 (16H, m, $7\times CH_2+2\times$ >CH), 4.8 (1H, d, >CH, J=4.5 Hz), 5.54 (1H, m, β-H), 5.99 (1H, dd, β-H), 6.39 (1H, dd, α-H). Mass: *m/e* 246 (M^+). Found: C, 78.12; H, 10.60; N, 11.44%. Calcd for $C_{16}H_{26}N_2$: C, 77.99; H, 10.64; N, 11.37%.

*Thermal Decomposition of 1-(1-Pyrrolidinyl)-1-(1-pyrrolyl)propane (**3a**).* After 6.45 g of the *N,N*-adduct **3a**[2] was stirred at 120 °C for 10 hr, the reaction mixture was subjected to fractional distillation to give 1.46 g (22.6%) of **4a** and 0.16 g (2.0%) of **5a**.

Under similar conditions heating of 12.0 g of **3b**[2] afforded 2.4 g (20.2%) of **4b**.

*Thermal Decomposition of **4b**.* i) Twenty grams of the *C,N*-adduct **4b** was heated at 150 °C for 5 hr in a stream of nitrogen, and the reaction mixture was then subjected to fractional distillation to afford 4.46 g (34.6%) of 2-(1-butenyl)-pyrrole (**6**), bp 76—78 °C/3 mmHg, as colorless oil, and 4.95 g (39.4%) of 1-(2-pyrrolyl)-1-{2-[5-(1-butenyl)]pyrrolyl}butane (**7**), bp 167—170 °C/3 mmHg, as pale rose viscous oil.

6; IR (neat): 3500 cm^{-1} (ν_{NH}). NMR (CCl_4): δ 1.07 (3H, t, CH_3), 2.18 (2H, m, CH_2), 5.3—5.9 (1H, m, =CH), 6.03 (3H, m, $2\times$β-H+=CH), 6.43 (1H, m, α-H), 7.65 (1H, broad, NH). Mass: *m/e* 121 (M^+). Found: C, 79.18, H, 8.89; N, 11.23%. Calcd for $C_8H_{11}N$: C, 79.29; H, 9.15; N, 11.56%.

7; IR (neat): 3500 cm^{-1} (ν_{NH}). NMR (CCl_4): δ 0.8—1.5 (8H, m, $2\times CH_3+CH_2$), 1.5—2.4 (4H, m, CH_2), 3.7 (1H, t, >CH), 5.3—5.7 (1H, m, =CH), 5.8—6.15 (5H, m, $4\times$β-H+=CH), 6.27 (1H, dd, α-H), 7.29 (2H, broad, NH). Mass: *m/e* 242 (M^+). Found: C, 79.26; H, 9.44; N, 11.62%. Calcd for $C_{16}H_{22}N_2$: C, 79.29; H, 9.15; N, 11.56%.

ii) A mixture of 6.0 g (0.031 mol) of **4b** and 16.0 g (0.128 mol) of **1b** was heated at 100 °C for 10 hr. Fractional distillation of the reaction mixture afforded 2.4 g (31.2% based on **4b**) of **5b**.

*1,2-Dihydro-1-propyl-3-(1-pyrrolidinyl)-2,3-tetramethylene-3H-pyrrolizine (**5c**).* After a mixture of 5.0 g (0.026 mol) of **4b** and 3.9 g (0.026 mol) of 1-(1-pyrrolidinyl)cyclohexene (**1c**) was stirred at 100 °C for 5 hr in a stream of nitrogen, vacuum distillation afforded 4.6 g (65.0%) of **5c**, bp 148—149 °C/2 mmHg, as colorless oil. NMR (CCl_4): δ 1.0 (3H, broad t, CH_3), 1,2—3.2 (22H, m, $10\times CH_2+2\times$ >CH), 5.65 (1H, m, β-H), 5.95 (1H, dd, β-H), 6.38 (1H, dd, α-H). Mass: *m/e* 272 (M^+). Found: C, 79.41; H, 10.57; N, 10.31%. Calcd for $C_{18}H_{28}N_2$: C, 79.36; H, 10.36; N, 10.28%.

Similarly, the reaction of **4b** with 1-(1-pyrrolidinyl)cyclopentene (**1d**) and -cycloheptene (**1e**) afforded 1,2-dihydro-2,3-trimethylene- (**5d**) and -2,3-pentamethylene-3H-pyrrolizine (**5e**) in 60.0 and 98.7% yields, respectively.

5d; bp 163 °C/5 mmHg. NMR (CCl_4): δ 1.0 (3H, m, CH_3), 1.2—3.0 (20H, m, $9\times CH_2+2\times$ >CH), 5.45 (1H,m, β-H), 6.02 (1H, dd, β-H), 6.35 (1H, dd, α-H). Mass: *m/e* 258 (M^+). Found: C, 78.80; H, 10.31; N, 10.74%. Calcd for $C_{17}H_{26}N_2$: C, 79.02; H, 10.14; N, 10.84%.

5e; bp 177—179 °C/3.5 mmHg. NMR (CCl_4): δ 1.0 (3H, m, CH_3), 1.2—3.0 (24H, $11\times CH_2+2\times$ >CH), 5.52, 5.97 (each 1H, dd, β-H), 6.33 (1H, m, α-H). Mass: *m/e* 286 (M^+). Found: C, 79.65; H, 10.58; N, 9.90%. Calcd for $C_{19}H_{30}N_2$: C, 79.66; H, 10.56; N, 9.78%.

*2-(1-Pyrrolidinylmethyl)pyrrole (**8**).* Twenty grams (0.3 mol) of pyrrole (**2**) was added, drop by drop, to a solution prepared from 21.5 g (0.3 mol) of pyrrolidine and 24.5 ml of 37% aqueous formaldehyde with stirring at 0 °C. The reaction mixture was stirred at room temperature for 3 hr and then at 95 °C for 30 min. The mixture was extracted with diethyl ether and the extract was dried over sodium sulfate, and then evaporated *in vacuo* to leave a residue. Several fractional distillations of the residue afforded 18.5 g (41.2%) of **8**, bp 103—104 °C/5 mmHg, which solidified. Recrystallization from petroleum ether (bp 40—65 °C) gave pure **8**, mp 48 °C, as colorless needles. IR (KBr): 3190 cm^{-1} (ν_{NH}). NMR (CCl_4): δ 1.75, 2.52 (each 4H, m, CH_2), 3.56 (2H, s, CH_2), 5.90 (2H, m, β-H), 6.45 (1H, dd, α-H), 10.05 (1H, broad, NH). Mass: *m/e* 150 (M^+). Found: C, 71.68; H, 9.41; N, 18.68%. Calcd for $C_9H_{14}N_2$: C, 71.95; H, 9.39; N, 18.65%.

*1,2-Dihydro-3-(1-pyrrolidinyl)-2,3-tetramethylene-3H-pyrrolizine (**9**).* After a mixture of 4.2 g (0.028 mol) of **1c** and 3.8 g (0.028 mol) of **8** was stirred at 120 °C for 5 hr in a stream of nitrogen, distillation gave 3.0 g (49.3%) of **9**, bp 138—140 °C/3 mmHg, as pale yellow oil. NMR (CCl_4): δ 1.2—3.2 (19H, m, $9\times CH_2+$ >CH), 5.55 (1H, m, β-H), 5.97 (1H, dd, β-H), 6.50 (1H, dd, α-H). Mass: *m/e* 230 (M^+). Found: C, 78.43; H, 9.45; N, 12.05%. Calcd for $C_{15}H_{22}N_2$: C, 78.21; H, 9.63; N, 12.16%.

*Reaction of **1b** with 1-(1-Pyrrolidinyl)-1-(1-pyrrolyl)cyclohexane (**3c**).* A mixture of 2.9 g (0.023 mol) of **1b** and 5.0 g (0.023 mol) of **3c**[2] was stirred at 120 °C for 7 hr in a stream of nitrogen, and then distillation afforded 2.2 g (35.3%) of **5c**.

Similarly, 2.8 g (33.7%) of **5c** was also obtained from the reaction of 4.7 g (0.031 mol) of **1c** with 6.0 g (0.031 mol) of **3b**.

Aromatic Thiocyanation by a Mixture of Antimony(V) Chloride and Lead(II) Thiocyanate

Sakae UEMURA,* Akira ONOE, Hajime OKAZAKI, and Masaya OKANO
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611
(Received November 5, 1974)

Alkyl- and halobenzenes give thiocyano-derivatives when treated with a mixture of $SbCl_5$ and $Pb(SCN)_2$ in CCl_4. The reaction proceeds *via in situ* formation of ClSCN from $SbCl_5$ and $Pb(SCN)_2$ followed by its attack on aromatic compounds catalyzed by $SbCl_5$, the reaction species being $SCN^+SbCl_6^-$.

Nuclear thiocyanation of aryl ethers and amines and polymethylbenzenes has been carried out with thiocyanogen[1] or thiocyanogen chloride.[2] However, thiocyanation of less reactive aromatic compounds requires a Lewis-acid catalyst such as $AlCl_3$.[3] Other methods for the preparation of aromatic thiocyano-derivatives involve the Gattermann and Sandmeyer reaction[1] and the reaction of arylthallium compounds with copper thiocyanates[4] or with KSCN under irradiation of light.[5] We report here another simple method of nuclear thiocyanation of less reactive aromatic compounds such as alkyl- and halobenzenes by a mixture of $SbCl_5$ and $Pb(SCN)_2$.

Results and Discussion

To a heterogeneous mixture of antimony (V) chloride and lead (II) thiocyanate in carbon tetrachloride was added aromatic compound, and the mixture was then heated under reflux for 3 hr to give aryl thiocyanate occasionally together with aryl chloride. Aryl thiocyanate was generally obtained predominantly and in good yield when aromatic compound was added drop by drop at 58—62 °C where the color of the mixture is yellow-orange owing to the formaion of ClSCN, and when the molar ratio of $SbCl_5$ to $Pb(SCN)_2$ is 1—1.67. No isomeric aryl isothiocyanate was found in the reaction products. When more $SbCl_5$ was used, the formation of aryl chloride became predominant as expected.[6] Only in the case of benzene, the best yield of phenyl thiocyanate was obtained when benzene was added at room temperature (20—25 °C) and the mixture was then rapidly heated to reflux. The results are summarized in the Table. Reactions in other solvents such as chloroform and 1,2-dichloroethane did not give the satisfactory results.

The reaction is clearly electrophilic, and no reaction occurred with compounds having strong deactivating substituent, such as nitrobenzene, acetophenone, and ethyl benzoate. The reaction seems to proceed by the following schemes 1 and 2.

$$2SbCl_5 + Pb(SCN)_2 \rightarrow 2SbCl_3 + PbCl_2 + 2ClSCN \quad (1)$$

$$ClSCN + R\text{-}C_6H_5 \xrightarrow{SbCl_5} R\text{-}C_6H_4\text{-}SCN + HCl \quad (2)$$

Namely, thiocyanogen chloride is formed by the interaction of antimony(V) chloride with lead (II) thiocyanate and then it attacks aromatic compound. When cyclohexene instead of aromatic compound was added as substrate in this reaction system ($SbCl_5$/$Pb(SCN)_2$=1−1.67), *trans*-1-chloro-2-thiocyanocyclohexane was formed in 60—80% yield together with *cis*- and *trans*-1,2-dichlorocyclohexanes (10—40%), showing clearly the presence of ClSCN in the reaction mixture. The addition of ClSCN to olefin has already been known.[2a] Here, any trace of 1,2-dithiocyanocyclohexane was not detected in the reaction products. Further, it is clear that $SbCl_5$ activates ClSCN in the succeeding thiocyanation as in the case of the $SbCl_5$-catalyzed halogenation,[7] since only a trace amount and 13% yield of aryl thiocyanate was obtained respectively from the reaction of benzene and toluene with ClSCN formed *in situ* from a mixture of $Pb(SCN)_2$ (10 mmol) and $PhICl_2$ (20 mmol) instead of $SbCl_5$ in CCl_4 (50 ml). The k_T/k_B value of 150—160 and *o*-/*p*- ratio of 0.40—0.46 observed in competitive reaction between toluene and benzene suggest that the attacking species is not molecular ClSCN but slightly activated species. If molecular ClSCN is the reaction species, larger k_T/k_B value should be obtained since the reactivity of ClSCN is known to be nearly the same as ICl[2a] which is less reactive than Br_2. Taking into account the Lewis-acidity of $SbCl_5$, the reaction species seems to be $SCN^+SbCl_6^-$. The above facts mean that $SbCl_5$ acts as both the source of thiocyanogen chloride and a Lewis-acid catalyst for the thiocyanation.

By use of other metal thiocyanates such as AgSCN, CuSCN or $Hg(SCN)_2$ in place of $Pb(SCN)_2$, phenyl thiocyanate was formed from benzene in 41%, 26% or 21% yield respectively under the conditions where 32% yield was obtained by use of the lead salt. Reactions with $Cu(NCS)_2$, $Zn(SCN)_2$, $Cd(SCN)_2$, and KSCN did not give the satisfactory results.

Experimental

The NMR spectra were measured with a Varian A-60 spectrometer in CCl_4, using TMS as an internal standard. The IR spectra were taken with a Perkin-Elmer Model 521 spectrometer. Glc analyses were carried out on Shimadzu 5APTF apparatus, using PEG 6000 (25%)-Chromosorb W (3m) and Apiezon L (30%)-Celite (1 m) columns (N_2 as carrier gas), phenyl isothiocyanate being used as an internal standard for the determination of aryl thiocyanate. Commercial organic materials, $SbCl_5$, and metal thiocyanates were used without purification. The identification of phenyl, tolyl and 3,4-dimethylphenyl thiocyanates[4] and *trans*-1-chloro-2-thiocyanocyclohexane[8] was reported previously. Competitive reaction was carried out by rapid addition of a mixture of benzene (0.2 mol) and toluene (0.1 mol) to a CCl_4 solution of $Pb(SCN)_2$ (10 mmol) and $SbCl_5$ (16.7 mmol)

a) Based on $SbCl_5$ charged. b) Only in this case benzene was added at 25 °C and the mixture was then rapidly heated to reflux. c) Almost *p*-isomer. d) Not determined. e) 2,3- and 3,4-Dimethylphenyl thiocyanates (1 : 9). f) 2,4-Dimethylphenyl thiocyanate. g) 1,4-Dimethylphenyl thiocyanate. h) 2,4,6-Trimethyl phenyl thiocyanate. i) Only *p*-isomer.

at 62 °C and then by stirring at reflux for 1 hr.

Preparation of 2,5-Dimethylphenyl Thiocyanate. The following is a typical procedure for the thiocyanation. *p*-Xylene (10.6 g, 0.1 mol) was added drop by drop (*ca.* in 5 min) at 58—60 °C under vigorous stirring to a yellow-orange heterogeneous solution of $SbCl_5$ (3 g, 10 mmol) and $Pb(SCN)_2$ (3.23 g, 10 mmol) in CCl_4 (50 ml). The mixture was then heated to 79 °C (reflux) and stirred for 3 hr. After being cooled down to room temperature, 300 ml of water was added to the solution and the precipitated white solid of SbOCl (1.6 g, 9.25 mmol) was filtered off. Organic layer of the filtrate was washed with water, dried over Na_2SO_4, and concentrated to *ca.* 25 ml which contained 6.2 mmol (62% yield) of 2,5-dimethylphenyl thiocyanate and a trace amount of chlorinated *p*-xylene. Distillation gave 0.82 g (5 mmol) of 2,5-dimethylphenyl thiocyanate; bp 136—138 °C/20 mmHg. IR 2162 cm^{-1} (ν_{SCN}). NMR δ 2.31 (s. 3H), 2.37 (s. 3H), 7.0—7.1 (m, 2H), 7.34 (s. 1H). Found: C, 65.68; H, 5.67; N, 8.28%. Calcd for C_9H_9NS: C, 66.22; H, 5.56; N, 8.58%.

Characterization of other aryl thiocyanate is as follows. NMR and IR spectra of all compounds were consistent with the structure. IR 2126 cm^{-1} (ν_{SCN}). Reactions of 2,4,6-Tri-*t*-butylnitrosobenzene with Grignard Reagents

Yoshio INAGAKI, Renji OKAZAKI, and Naoki INAMOTO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received November 27, 1974)

Reactions of 2,4,6-tri-*t*-butylnitrosobenzene (**1**) with alkylmagnesium halides afforded 6-alkyl-1-hydroxyimino-2,4,6-tri-*t*-butyl-2,4-cyclohexadienes (**2**), 4-alkyl-1-hydroxyimino-2,4,6-tri-*t*-butyl-2,5-cyclohexadienes (**3**), and *N*-alkyl-2,4,6-tri-*t*-butylanilines (**4**) depending on the Grignard reagents used. The distribution of the reaction products indicated that the oximes were formed *via* an attack of the anionic species on the *ortho*- and the *para*-carbons, respectively, to the nitroso group, but that the *N*-alkylanilines *via* a free radical mechanism involving an electron transfer from the Grignard reagent to **1**. The free radical mechanism was confirmed in the case of *t*-butylmagnesium chloride by trapping the *t*-butyl radicals as 1-*t*-butoxyimino-2,4,4,6-tetra-*t*-butyl-2,5-cyclohexadiene (**8**). Such a mechanistic difference has been explained in terms of the difference in electron affinities of the free radicals derived from Grignard reagents.

As part of studies on the steric effects in the reactions of 2,4,6-tri-*t*-butylaniline (**6**) and 2,4,6-tri-*t*-butylnitrosobenzene (**1**),[1-4] we investigated the reaction of **1** with Grignard reagents.

In the reactions of nitrosobenzenes with Grignard reagents, the formation of *N*,*N*-disubstituted hydroxylamines, secondary amines, and azobenzenes has been demonstrated,[5-9] and the free radical mechanism has been proposed for the formation of the hydroxylamines.[10]

We have preliminarily communicated, in the reactions of **1**, Grignard reagents attack not only the nitrogen atom but also the *ortho*- and *para*-positions of the nitroso group.[11] This paper describes detailed accounts of these reactions and discuss the factors influencing the products distribution and the reaction mechanism.

Results and Discussion

Reaction Products. Reactions of 2,4,6-tri-*t*-butylnitrosobenzene (**1**) with a large excess of Grignard reagents (RMgX) in ether under nitrogen for *ca.* 1 hr at 0 °C, in which an ethereal solution of **1** was added dropwise into a solution of the Grignard reagent, gave 6-alkyl-1-hydroxyimino-2,4,6-tri-*t*-butyl-2,4-cyclohexadienes (**2**), 4-alkyl-1-hydroxyimino-2,4,6-tri-*t*-butyl-2,5-cyclohexadienes (**3**), *N*-alkyl-2,4,6-tri-*t*-butylanilines (**4**), 6-alkyl-2,4-di-*t*-butylanilines (**5**), and 2,4,6-tri-*t*-butylaniline (**6**) depending on the R group. The yields of the products are shown in Table 1.

The structures of the products were confirmed by their analytical and spectral data. Two isomeric oximes (**2** and **3**) were distinguished each other by the UV spectra: isomers with absorption maxima at longer wave length (304—313 nm) were identified as **2**, whereas those with absorption maxima at shorter wave length (243—251 nm) as **3**. There are also some differences between the NMR spectra of the two isomers: a typical spectrum of **2** consists of three singlets due to the three *t*-butyl groups and a pair of doublets due to the two olefinic protons, but a typical spectrum of **3** consists of two singlets with intensity of 2 : 1 due to the *t*-butyl groups and an AB quartet due to the two olefinic protons. However, in the case of **3e** the three *t*-butyl groups appeared as three singlets with equal intensity and the two olefinic protons were equivalent. The abnormality may be ascribed to magnetic anisotropy of the phenyl group.

The oximes **2** and **3** correspond to the 1,4- and 1,6-conjugate addition products of the Grignard reagents to the nitrosobenzene (**1**) respectively, and this is the first example of conjugate addition to the nitrosobenzene system in marked contrast with a great many examples of conjugate addition in carbonyl compounds.[12]

The formation of **4c** and **4d** is noteworthy in view of difficult preparation of the corresponding methyl and ethyl derivatives,[13] the only known *N*-alkylated 2,4,6-tri-*t*-butylanilines; this reaction might provide a synthetic method for 2,4,6-tri-*t*-butylanilines with a bulky alkyl group on the nitrogen.

Mass Spectra of the Reaction Products. The oxime (**2**) was characterized by the four outstanding peaks at *m/e* M−56, M−73, M−87, and M−89, but the oxime (**3**) by the three peaks at *m/e* M−56, M−73, and M−89. The oximes (**2** and **3**) showed very weak molecular ion peaks, which were often obscure

in the oxime (**3**), but the metastable ion peak corresponding to loss of isobutylene (56 mass units) from the molecular ion was observed.

Two outstanding peaks M^+ (23—47%) and $(M-15)^+$ (100%) were characteristic of the anilines **4a**, **4b**, **4c**, **5c**, and **6**. Namely, loss of a methyl radical from the molecular ion was the predominant process, and the corresponding metastable ion peak was observed.

In contrast with those five anilines, the aniline **4d** showed a weak peak at *m/e* 302 (M−15) but outstanding peaks at *m/e* 317 (M^+, 11%), 261 (M−56, 33%), and 246 (M−71, 100%). A metastable ion peak corresponding to loss of 56 mass units from the molecular ion was observed. Therefore the pronounced feature of aniline **4d** is loss of isobutylene (56 mass units) from the molecular ion. Radical cation of **6** thus produced readily loses a methyl radical, as mentioned above, to exhibit the base peak.

Reaction Mechanism. The yields of the products changed systematically depending on the R group. As the bulkiness of the R group increases from methyl to 1-adamantyl (1-Ad), the yield of oxime **2** with a longer conjugate system decreased, while the yield of sterically less hindered oxime **3** increased. The yield ratios of the oximes (**2**/**3**) were alike each other in the reactions of the ethyl and the benzyl Grignard reagents with primary anionic centers, but much different in other cases. Thus the yields of **2** or **3** seem to be dependent mainly on a steric factor.

On the other hand, formation of the secondary amine **4** seems to be independent of the steric factor. Namely, the reaction with *t*-butylmagnesium chloride produced **4d** as a major product along with **3d** only a trace amount. whereas 1-adamantylmagnesium bromide which has also a tertiary anionic center afforded the oxime (**3f**) in a high yield. Moreover, the reactions with methyl, ethyl, and benzyl Grignard reagents did not afford **4**, although they should be sterically much more favorable in the attack onto the nitrogen.

These facts suggest the difference in the formation mechanisms of the oximes (**2** and **3**) and the secondary amine (**4**); the oximes were produced *via* attack of the anionic species on the *ortho*- and *para*-carbons to the nitroso group, while the secondary amine (**4**) *via* the following pathway involving an electron transfer from the Grignard reagent to the nitrosobenzene (**1**)

$$\mathrm{Ar\text{-}N{=}O + RMgX \rightarrow [Ar\text{-}\dot{N}\text{-}O\text{-}MgX + R\cdot]} \quad \mathbf{7}$$
$$\rightarrow \mathrm{ArN(R)OMgX} \xrightarrow{\mathrm{RMgX}} \mathrm{ArN(R)MgX} \xrightarrow{\mathrm{H_2O}} \mathbf{4}$$
(Ar: 2,4,6-(t-Bu)$_3$C$_6$H$_2$)

Such a mechanistic difference can be interpreted as the difference in electron affinitiy of a free radical (R·). The relation between the electron affinities of free radicals and the yields of reaction products is shown in Table 2, in which the order of electron affinities of methyl, ethyl, and isopropyl radicals suggests that the electron affinity of *t*-butyl radical is smaller than that of isopropyl radical. Since 1-adamantyl radical is not so much stabilized as *t*-butyl radical because of its rigid structure,[17] the electron affinity should be much higher than that of *t*-butyl radical. Hence the easiness of the oxidation of the alkyl anion into the corresponding free radical is in the following order:

$$\mathrm{Me} < \mathrm{Et},\ \mathrm{PhCH_2} < i\text{-Pr} < t\text{-Bu} \gg \text{1-Ad}$$

A similar order has recently been reported also for the rates of electron transfer reactions from Grignard reagents to di-*t*-butyl peroxide.[16]

In the case of isopropyl and *t*-butyl Grignard reagents, isopropyl and *t*-butyl anions are so easily oxidized into the corresponding free radicals by **1** that the free radical mechanism which produces **4** is predominant. However, in other cases the anions are not easily oxidized into the corresponding free radicals, so that the anionic mechanism which produces oximes **2** and **3** is predominant. Consequently the Grignard reagents containing an anionic center which is more easily oxidized than isopropyl anion are expected to afford the secondary amine **4** in the reaction with **1**.

If such a free radical mechanism is actually operative, the *t*-butyl radicals derived from the Grignard reagent, in the reaction system composed of *t*-butylmagnesium chloride and an excess of the nitrosobenzene **1**, are expected to attack **1** itself on the oxygen atom, because tertiary alkyl radicals are trapped by **1** on the oxygen atom.[4,18]

This possibility was examined by the following inverse Grignard reaction. To a solution of **1** in ether, an ethereal solution of *t*-butylmagnesium chloride was added dropwise, but the total amount of the Grignard reagent added was a large excess in order to attain a similar final condition. This reaction resulted in the formation of 1-*t*-butoxyimino-2,4,4,6-tetra-*t*-butyl-2,5-cyclohexadiene (**8**) at the expense of **4d**; **8** is the same type of compound as **9** produced by the reaction of **1** with 1-cyano-1-methylethyl radicals.[4]

Thus, this result shows the existence of *t*-butyl radicals in the reaction system, and therefore substantiate the free radical mechanism mentioned above.

The reaction of **1** with *t*-butylmagnesium chloride

gave a considerable amount of **6** in contrast with the reactions with the other five Grignard reagents. Considering the facility of an electron transfer from *t*-butylmagnesium chloride mentioned above, the following pathway appears to be the most probable for the formation of the aniline (**6**): the radical **7** initially formed by an electron transfer from *t*-butylmagnesium chloride as in the formation of **4** is further reduced by the Grignard reagent to give **10**, hydrolysis of which afford **6**.[19]

$$\underset{\mathbf{1}}{Ar\text{-}N{=}O} \xrightarrow{RMgX} \underset{\mathbf{7}}{ArNOMgX} \xrightarrow{2RMgX} \underset{\mathbf{10}}{ArN(MgX)_2} \xrightarrow{H_2O} \underset{\mathbf{6}}{ArNH_2}$$

(Ar: 2,4,6-(*t*-Bu)$_3$C$_6$H$_2$)

The formation mechanism of **5c** is obscure. Since a nucleophilic substitution on the aromatic ring of **1** is improbable, it was presumably formed by reduction of oxime **2c** accompanied by elimination of *t*-butyl group.

Experimental

All melting points were not corrected. The IR and UV spectra were recorded with Hitachi EPI-G2 and Hitachi EPS-3 spectrophotometers respectively. The NMR spectra were measured with a Hitachi R-24 (60 MHz) spectrometer using tetramethylsilane as an internal standard. The mass spectra were recorded with a Hitachi RMU-6L mass spectrometer. All reactions were carried out under nitrogen. Chromatographic separations were performed using dry column chromatography method (Woelm silica gel for dry column chromatography) unless otherwise noted.

Materials. 2,4,6-Tri-*t*-butylnitrosobenzene (**1**),[1] (mp 166.0—166.5 °C; lit, 166—168 °C), 2,4,6-tri-*t*-butylaniline (**6**), (mp 135.5—138.6 °C; lit, 147—148 °C),[13] 2,4,6-tri-*t*-butyl-*N*-methylaniline (**4a**), (mp 109.5—111.0 °C; lit, 111—112 °C),[13] and 2,4,6-tri-*t*-butyl-*N*-ethylaniline (**4b**), (mp 79.5—81.0 °C; lit, 77.78 °C)[13] were prepared by the reported methods.

Reaction of 2,4,6- Tri- t- butylnitrosobenzene (1) with Methylmagnesium Iodide. To an ice-cold ethereal solution (25 ml) of methylmagnesium iodide (31 mmol), 2 g (7.3 mmol) of **1** in 30 ml of ether was added with stirring. After stirring at 0 °C for 3.5 hr, the reaction mixture was poured into cold aqueous ammonium chloride, extracted with ether, washed with water and dried over anhydrous magnesium sulfate. After removal of the solvent *in vacuo*, the residue (1.9 g) was chromatographed on silica gel. Elution with carbon tetrachloride gave 147 mg of white crystals, which were submitted to dry column chromatography with carbon tetrachloride to give 30 mg (2%) of 2,4,6-tri-*t*-butylaniline (**6**), the IR and NMR spectra of which were identical with those of an authentic sample, and 83 mg (4%) of 1-hydroxyimino-2,4,6-tri-*t*-butyl-4-methyl-2,5-cyclohexadiene (**3a**), which was recrystallized three times from aqueous methanol, mp 119.5—120 °C; IR (KBr): 3250 (νOH) and 960 cm^{-1} (νNO); NMR (CCl_4): δ 0.83 (s, 9H), 1.05 (s, 3H), 1.21 (s, 18H), 5.77 (ABq, $\Delta\delta$=0.11, J=2 Hz, 2H), and 7.68 (broad s, 1H); λ_{max} (*n*-hexane): 243 nm (ε 10300); MS: *m/e* 291 (M$^+$, trace), 235 (34%), 218 (43), 202 (46), and 57 (100).

Found: C, 78.29; H, 11.06; N, 5.03%. Calcd for $C_{19}H_{33}NO$: C, 78.28; H, 11.42; N, 4.80%.

Elution with benzene gave 915 mg (46%) of 1-hydroxyimino-2,4,6-tri-*t*-butyl-6-methyl-2,4-cyclohexadiene (**2a**), which was recrystallized three times from *n*-hexane, mp 160.8—161.5 °C; IR (KBr): 3250 (νOH) and 960 cm^{-1} (νNO); NMR ($CDCl_3$): δ 0.96 (s, 9H), 1.08 (s, 9H), 1.32 (s, 12H), 5.42 (d, J=2 Hz, 1H), 6.15 (d, J=2 Hz, 1H), and 9.30 (broad s, 1H); λ_{max} (*n*-hexane): 304 nm (ε 4400); MS: *m/e* 291 (M$^+$, trace), 235 (42%), 218 (60), 204 (46), 202 (41), and 57 (100).

Found: C, 78.29; H, 11.06; N, 5.03%. Calcd for $C_{19}H_{33}NO$: C, 78.28; H, 11.42; N, 4.80%.

Further elution with dichloromethane afforded only tarry mass which could not be identified.

Reaction of 1 with Ethylmagnesium Bromide. To an ice-cold ethereal solution (30 ml) of ethylmagnesium bromide (73 mmol), 2 g (7.3 mmol) of **1** in 25 ml of ether was added dropwise during 15 min with stirring. After additional stirring at 0 °C for 1 hr, the reaction mixture was worked up as usual to give 1.79 g of the residue, which was chromatographed with carbon tetrachloride. The column could be divided into six fractions, each of which was eluted with ether, and the solvent was removed. From the first fraction a trace of **1** was recovered. The second fraction gave white crystals (129 mg), which were tentatively assigned as an isomer of 1-hydroxyimino-2,4,6-tri-*t*-butyl-6-ethyl-2,4-cyclohexadiene (**2b**) from the spectral data, but not purified, IR (KBr): 3300 (νOH) and 970 cm^{-1} (νNO); NMR (CCl_4): δ 0.83 (t, J=7 Hz, 3H), 0.84 (s, 9H), 1.05 (s, 9H), 1.23 (s, 9H), 2.50 (m, 2H), 5.15 (d, J=2 Hz, 1H), and 6.13 (d, J=2 Hz, 1H, and the signal of OH proton was obscure); λ_{max} (*n*-hexane): 311 nm (ε 3400); MS: *m/e* 305 (M$^+$, 2%), 249 (46), 232 (79), 218 (41), 216 (59), and 57 (100).

The third fraction afforded 143 mg (8%) of **6**. The fourth fraction afforded 692 mg (30%) of 1-hydroxyimino-2,4,6-tri-*t*-butyl-4-ethyl-2,5-cyclohexadiene (**3b**), which was recrystallized five times from methanol, mp 120.2—121.1 °C; IR (KBr): 3300 (νOH) and 970 cm^{-1} (νNO); NMR ($CDCl_3$): δ 0.67 (t, J=7 Hz, 3H), 0.85 (s, 9H), 1.27 (s, 18H), 1.65 (q, J=7 Hz, 2H), 5.75 (ABq $\Delta\delta$=0.14, J=2 Hz, 2H), and 8.24 (broad s, 1H): λ_{max} (*n*-hexane): 246 nm (ε 8800); MS: *m/e* 305 (M$^+$, trace), 249 (49%), 232 (63), 216 (58), and 57 (100).

Found: C, 78.56; H, 11.36; N, 4.52%. Calcd for $C_{20}H_{35}NO$: C, 78.63; H, 11.55; N, 4.58%.

The fifth fraction gave 589 mg (26%) of 1-hydroxyimino-2,4,6-tri-*t*-butyl-6-ethyl-2,4-cyclohexadiene (**2b**), which was recrystallized four times from methanol, mp 123.5—124.5 °C; IR (KBr): 3400 (νOH) and 970 cm^{-1} (νNO); NMR ($CDCl_3$): δ 0.75 (t, J=7 Hz, 3H), 0.93 (s, 9H), 1.10 (s, 9H), 1.33 (s, 9H), 1.4—2.3 (m, 2H), 5.33 (d, J=1.5 Hz, 1H), 6.22 (d, J=1.5 Hz, 1H), and 9.75 (broad s, 1H); λ_{max} (*n*-hexane): 308 nm (ε 4400); MS: *m/e* 305 (M$^+$, 0.5%),

249 (37), 232 (62), 218 (37), 216 (43), and 57 (100).

Found: C, 78.69; H, 11.20; N, 4.74%. Calcd for $C_{20}H_{35}NO$: C, 78.63; H , 11.55; N, 4.58%.

Reaction of **1** *with Isopropylmagnesium Bromide.* To an ice-cold ethereal solution (30 ml) of isopropylmagnesium bromide (73 mmol), 2 g (7·3 mmol) of **1** in 23 ml of ether was added dropwise during 15 min with stirring. After additional stirring at 0 °C for 30 min, the reaction mixture was worked up as usual to give 1.95 g of a tarry material, which was chromatographed with carbon tetrachloride. The column could be divided into six fractions. The first fraction gave 129 mg (6%) of 2,4,6-tri-*t*-butyl-*N*-isopropylaniline (**4c**), which was recrystallized three times from methanol, mp 80.5—81.0 °C; IR (KBr): 3440 cm^{-1} (νNH); NMR (CCl_4): δ 0.94 (d, J=7 Hz, 6H), 1.28 (s, 9H), 1.43 (s, 18H), 3.42 (sep, J=7 Hz, 1H), 3.90 (broad s, 1H), and 7.07 (s, 2H); λ_{max} (*n*-hexane): 256.5 (ε 7500) and 292 nm (1400); MS: *m/e* 303 (M^+, 41%) and 288 (100).

Found: C, 83.04; H, 12.27; N, 4.90%. Calcd for $C_{21}H_{37}N$: C, 83.10; H, 12.29; N, 4.61%.

The second fraction afforded 308 mg of a mixture of **2c** and **3c** (by NMR). Further twice dry column chromatography with carbon tetrachloride gave 53 mg (2%) of 1-hydroxyimino-2,4,6-tri-*t*-butyl-6-isopropyl-2,4-cyclohexadiene (**2c**), which was recrystallized three times from methanol, mp 117—120 °C; IR (KBr): 3300 (νOH) and 975 cm^{-1} (νNO); NMR (CCl_4): δ 0.71 (d, J=7 Hz, 6H), 1.07 (s, 9H), 1.13 (s, 9H), 1.24 (s, 9H), 3.72 (sep, J=7 Hz, 1H), 5.62 (d, J=2 Hz, 1H), and 6.12 (d, J=2 Hz, 1H, and the signal of OH proton was obscure); λ_{max} (*n*-hexane): 311 nm (ε 4900); MS: *m/e* 319 (M^+, trace), 263 (19%), 246 (63), 232 (56), 230 (70), and 57 (100).

Found: C, 78.53; H, 11.67; N, 4.20%. Calcd for $C_{21}H_{37}NO$: C, 78.94; H, 11.67; N, 4.38%.

The third fraction gave 1.24 g (54%) of 1-hydroxyimino-2,4,6-tri-*t*-butyl-4-isopropyl-2,5-cyclohexadiene (**3c**) as a tarry material, which crystallized on cooling and was recrystallized five times from cold methanol at −78 °C, mp 73.5—74.5 °C; IR (neat): 3330 (νOH) and 975 cm^{-1} (νNO); NMR ($CDCl_3$): δ 0.96 (d, J=7 Hz, 6H), 0.93 (s, 9H), 1.27 (s, 18H), 1.95 (sep, J=7 Hz, 1H), 5.90 (ABq, $\Delta\delta$=0.16, J= 2 Hz, 2H, and the signal of OH proton was obscure, but in carbon tetrachloride solution observed at 8.60 as a broad singlet); λ_{max} (*n*-hexane): 246.5 nm (ε 8800); MS: *m/e* 319 (M^+, trace), 263 (41%), 246 (54), 230 (61), and 57 (100).

Found: C, 79.04; 11.75; N, 4.56%. Calcd for $C_{21}H_{37}NO$: C, 78.94; H, 11.67; N, 4.38%.

The fourth fraction afforded 50 mg (3%) of 2,4-di-*t*-butyl-6-isopropylaniline (**5c**), which was recrystallized twice from methanol and identical with an authentic sample obtained from the reaction of 2,4,6-tri-*t*-butylnitrobenzene with isopropylmagnesium bromide[22] with respect to the spectral data, mp 84—85 °C; IR (KBr): 3485 and 3405 cm^{-1} (νNH_2); NMR (CCl_4): δ 1.20 (d, J=7 Hz, 6H), 1.26 (s, 9 H), 1.43 (s, 9H), 2.89 (sep, J=7 Hz, 1H), 3.54 (broad s, 2H), and 7.00 (ABq, $\Delta\delta$=0.08, J=2 Hz, 2H); MS: *m/e* 247 (M^+, 23%) and 232 (100).

Reaction of **1** *with t-Butylmagnesium Chloride.* To an ice-cold ethereal solution (40 ml) of *t*-butylmagnesium chloride (73 mmol), 2 g (7.3 mmol) of **1** in 15 ml of ether was added dropwise during 10 min with stirring. After additional stirring at 0 °C for 50 min, the reaction mixture was worked up as usual to give 1.79 g of crystals, which were chromatographed with carbon tetrachloride. The column was divided into four fractions. The first fraction gave 993 mg (43%) of 2,4,6,*N*-tetra-*t*-butylaniline (**4d**), which was recrystallized four times from methanol, mp 63—64.5 °C; IR (KBr): 3045 cm^{-1} (νNH); NMR ($CDCl_3$): δ 0.93 (s, 9H), 1.28 (s, 9H), 1.42 (s, 18H), 3.00 (broad s, 1H), and 7.14 (s, 2H); λ_{max} (*n*-hexane): 223 (ε 1680) and 260 nm (4200); MS: *m/e* 317 (M^+, 11%), 302 (4), 261 (33), and 246 (100).

Found: C, 83.33; H, 12.22; N, 4.21%. Calcd for $C_{22}H_{39}N$: C, 83.21; H, 12.38; N, 4.41%.

The second fraction afforded 714 mg (38%) of **6**. The third fraction gave 84 mg of a colorless tarry substance, which was again chromatographed with carbon tetrachloride. On the basis of the spectral data (IR and NMR) the resulting material was identified as 1-hydroxyimino-2,4,4,6-tetra-*t*-butyl-2,5-cyclohexadiene (**3d**), but failed to be isolated in pure state, IR (neat): 3300 (νOH) and 955 cm^{-1} (νNO); NMR (CCl_4): δ 1.01 (s, 18H), 1.25 (s, 18H), 6.17 (ABq, $\Delta\delta$=0.12, J=2 Hz, 2H, and the signal of OH proton was obscure).

Reaction of **1** *with Benzylmagnesium Chloride.* To an ice-cold ethereal solution (30 ml) of the Grignard reagent (73 mmol), 2 g (7.3 mmol) of **1** in 15 ml of ether was added dropwise during 20 min with stirring. After additional stirring at 0 °C for 30 min, the reaction mixture was worked up as usual to give 4.2 g of partly crystalline substance, which was chromatographed with carbon tetrachloride. The column could be divided into five fractions. The first and the second fractions gave 1.4 g of bibenzyl and 150 mg (6%) of **6** respectively. The third fraction gave 1.16 g (44%) of 1-hydroxyimino-4-benzyl-2,4,6-tri-*t*-butyl-2,5-cyclohexadiene (**3e**), which was recrystallized four times from methanol, mp 169.7—170.8 °C; IR (KBr): 3280 cm^{-1} (νOH); NMR ($CDCl_3$): δ 0.98 (s, 9H), 1.09 (s, 9H), 1.21 (s, 9H), 3.04 (s, 2H), 5.95 (s, 2H), 7.12 (s, 5H), and 7.55 (broad s, 1H); λ_{max} (*n*-hexane): 247 nm (ε 9200); MS: *m/e* 367 (M^+, trace), 311 (34%), 294 (32), 278 (28), 91 (79), and 57 (100).

Found: C, 81.88; H, 10.38; N, 4.01%. Calcd for $C_{25}H_{37}NO$: C, 81.69; H, 10.15; N, 3.81%.

The fourth fraction gave 776 mg (29%) of 1-hydroxyimino-6-benzyl-2,4,6-tri-*t*-butyl-2,4-cyclohexadiene (**2e**), which was recrystallized four times from methanol, mp 158—158.5 °C; IR (KBr): 3280 cm^{-1} (νOH); NMR ($CDCl_3$): δ 0.89 (s, 9H), 0.99 (s, 9H), 1.28 (s, 9H), 2.85 (d, J=15 Hz, 1H), 3.78 (d, J=15 Hz, 1H), 5.47 (d, J=2 Hz, 1H), 6.20 (d, J=2 Hz, 1H), 7.14 (s, 5H), and 8.75 (broad s, 1H); λ_{max} (*n*-hexane): 313 nm (ε 4000); MS: *m/e* 367 (M^+, 1.5%), 311 (32), 294 (100), 276 (15), 278 (26), 91 (43), and 57 (82).

Found: C, 81.91; H, 10.33; N, 3.85%. Calcd for $C_{25}H_{37}NO$: C, 81.74; H, 10.08; N, 3.81%.

Reaction of **1** *with 1-Adamantylmagnesium Bromide.* To an ice-cold ethereal solution (31 ml) of the Grignard reagent (42 mmol), 1.76 g (6.4 mmol) of **1** in 24 ml of ether was added dropwise during 1 hr with stirring. The reaction mixture was worked up as usual to give 7.9 g of light green tar, which was chromatographed with carbon tetrachloride as eluent. The column could be divided into four fractions. The first fraction gave 5 g of a light green crystalline material, which was composed mainly of decomposition product of the Grignard reagent, but contained 300 mg of unchanged **1** according to the signal intensity on the NMR spectra. Yields were calculated on the base of **1** consumed. The second fraction, colorless tarry mass, was a mixture of **6** (36 mg, 3%) and 1-hydroxyimino-4-(1-adamantyl)-2,4,6-tri-*t*-butyl-2,5-cyclohexadiene (**3f**, 1.2 g, 55%) according to the signal intensity on the NMR spectra. By further chromatography with carbon tetrachloride, **3f** was isolated, but **6** could not be isolated in pure state. **3f**: mp 135—136 °C

(five times from methanol); IR (KBr): 3300 (νOH) and 960 cm^{-1} (νNO); NMR (CCl_4): δ 1.05 (s, 9H), 1.28 (s, 18H), 1.60 (broad s, 6H), 1.82 (broad s, 9H), 6.15 (ABq, $\Delta\delta=0.1$, $J=2$ Hz, 2H), and 7.86 (s, 1H); λ_{max} (*n*-hexane): 251 nm (ε 9300); MS: *m/e* 411 (M^+, trace), 355 (2%), 354 (3), 339 (6), 338 (3), 324 (5), 322 (3), 244 (23), 135 (100), and 57 (31).

Found: C, 81.72; H, 10.71; N, 3.36%. Calcd for $C_{28}H_{45}NO$: C, 81.69; H, 11.03; N, 3.40%.

The subsequent fractions afforded about 700 mg of unidentified materials, which could not be isolated in pure state.

Reaction of **1** *with* t-*Butylmagnesium Chloride (Inverse Addition).* To an ice-cold solution of 1.5 g (5.5 mmol) of **1** in 10 ml of ether, an ethereal solution (43 ml) of the Grignard reagent (55 mmol) was added dropwise with stirring during 30 min. After additional stirring at 0 °C for 30 min, the reaction mixture was worked up as usual to give 1.5 g of pale yellow, partly crystalline material, which was chromatographed with *n*-hexane. The column could be divided into three fractions. The first fraction gave 110 mg (5%) of 1-*t*-butoxyimino-2,4,4,6-tetra-*t*-butyl-2,5-cyclohexadiene (**8**) as colorless oil, which was purified by TLC (silica gel, *n*-hexane) and distilled once *in vacuo*, IR (neat): 960 cm^{-1} (νNO); NMR (CCl_4): δ 1.00 (s, 18H), 1.21 (s, 9H), 1.29 (s, 18H), and 6.15 (ABq, $\Delta\delta=0.1$, $J=2$ Hz, 2H); λ_{max} (*n*-hexane): 260 nm (ε 6700); MS: *m/e* 332 (38%), 276 (88), 244 (43).

Found: C, 80.26; H, 11.81; N, 3.89%. Calcd for $C_{26}H_{47}NO$: C, 80.14; H, 12.16; N, 3.59%.

The second fraction gave 477 mg (29%) of **4d**. The third fraction was again chromatographed with a mixture of *n*-hexane and dichloromethane (2 : 1) as eluent. The column could be divided into three fractions. The first fraction gave 421 mg (30%) of **6**. The second fraction afforded 49 mg (3%) of 1-hydroxyimino-2,4,4,6-tetra-*t*-butyl-2,5-cyclohexadiene (**3d**) as white crystals, which were recrystallized three times from aqueous methanol, mp 123—127 °C. Although satisfactory elemental analysis could not be obtained, the following spectral data suggested the structure **3d**; IR (KBr): 3300 (νOH) and 955 cm^{-1} (νNO); NMR (CCl_4): δ 1.02 (s, 18H), 1.26 (s, 18H), 6.17 (ABq, $\Delta\delta=0.12$, $J=2$ Hz, 2H), and 8.0 (broad s, 1H); λ_{max} (*n*-hexane): 249 nm (ε 9700); MS: *m/e* 277 (16%), 276 (14), 260 (28), 246 (30), 244 (43), and 57 (100).

The subsequent fractions gave 82 mg of partly crystalline substance, which could not be purified.

Mass Spectra of Anilines ***4a***, ***4b***, *and* ***6a***. **4a**; *m/e* 275 (M^+, 30%) and 260 (100). **4b**; *m/e* 239 (M^+, 47%) and 224 (100). **6**; *m/e* 261 (M^+, 27%) and 246 (100).

19) The possibility of the reduction of **1** into **6** with magnesium metal, probably in combination with magnesium halides or impurities in the metal, cannot be ruled out completely.[20,21] If **6** is formed in such a way, the yield of **6** should be constant irrespective of the Grignard reagents used, but this is not the case. Therefore the reduction with magnesium metal may not be a predominant pathway leading to **6**.

The Mass-transfer Rate through the Liquid-Liquid Interface. V. Diffusion through an Interface Considering the Variation in the Amount of Adsorption

Teruya SHIMBASHI

Department of Chemical Engineering, Tokyo Institute of Technology, Meguro-ku, Tokyo 152

(Received November 28, 1973)

The diffusion through an interface has been re-formulated considering the variation in the amount of adsorption on the interface in the case of linear diffusion in a finite composite medium.

In the treatment of the diffusion of a substance through interfaces,[1-4] it has generally been assumed that the flux from one phase to the interface is equal to the flux from the interface to the other phase; this implies that the amount of adsorption on the interface is constant during the diffusion process.

Accordingly, if the concentration in a phase immediately next to the interface, which is in an equilibrium relation with the amount of adsorption, actually varies during the diffusion process, the above treatment may give erroneous results.

In this paper, the diffusion through an interface will be theoretically treated by allowing the amount of adsorption on the interface to vary reasonably during the diffusion process in case of linear diffusion in a finite composite medium.[5]

Theory

Fick's diffusion equation is defined by:

$$\partial c_1/\partial t = D_1(\partial^2 c_1/\partial x^2),\ -a<x<0,\ t>0; \tag{1}$$

$$\partial c_2/\partial t = D_2(\partial^2 c_2/\partial x^2),\ 0<x<a,\ t>0, \tag{2}$$

where c_1 and c_2 are the local concentrations of the solute in Phases 1 and 2 respectively, where D_1 and D_2 are the diffusion coefficients, where x is the diffusion coordinate (the direction from Phase 1 to Phase 2 is selected as positive), and where t is the time.

The boundary conditions are represented by:

$$-D_1(\partial c_1/\partial x) + D_2(\partial c_2/\partial x) = \Gamma_\infty(\mathrm{d}\theta/\mathrm{d}t),\ x=0,\ t>0; \tag{3}$$

$$-D_1(\partial c_1/\partial x) = k_{a1}c_1(1-\theta) - k_{d1}\theta,\ x=0,\ t>0; \tag{4}$$

$$D_2(\partial c_2/\partial x) = k_{a2}c_2(1-\theta) - k_{d2}\theta,\ x=0,\ t>0; \tag{5}$$

$$\partial c_1/\partial x = 0,\ x=-a,\ t>0; \tag{6}$$

$$\partial c_2/\partial x = 0,\ x=a,\ t>0, \tag{7}$$

where Γ_∞ is the saturated value of the amount of adsorption per unit of area of the interface, where θ is the fraction of the total interface that is occupied by adsorbed molecules, where k_{a1} and k_{a2} are the rate constants of adsorption to the interface from Phase 1 and Phase 2 respectively, and where k_{d1} and k_{d2} are the rate constants of desorption from the interface to Phase 1 and Phase 2 respectively. Equation (3) relates the variation in the amount of adsorption to the fluxes, while Eqs. (4) and (5) give the relation between the adsorption-desorption mechanism and the fluxes. Equations (6) and (7) give the impermeable wall conditions of the solute.

The initial conditions are assumed to be:

$$c_1 = c_{10},\ -a<x<0,\ t=0; \tag{8}$$

$$c_2 = c_{20},\ 0<x<a,\ t=0; \tag{9}$$

$$\theta = \theta_0,\ x=0,\ t=0, \tag{10}$$

where c_{10}, c_{20}, and θ_0 are constants.

The Laplace transforms of these equations are represented by:

$$\mathrm{d}^2\bar{c}_1/\mathrm{d}x^2 - q_1^2\bar{c}_1 + (c_{10}/D_1) = 0,\ -a<x<0; \tag{1'}$$

$$\mathrm{d}^2\bar{c}_2/\mathrm{d}x^2 - q_2^2\bar{c}_2 + (c_{20}/D_2) = 0,\ 0<x<a; \tag{2'}$$

$$-D_1(\mathrm{d}\bar{c}_1/\mathrm{d}x) + D_2(\mathrm{d}\bar{c}_2/\mathrm{d}x) = \Gamma_\infty(p\bar{\theta}-\theta_0),\ x=0; \tag{3'}$$

$$-D_1(\mathrm{d}\bar{c}_1/\mathrm{d}x) = k_{a1}\bar{c}_1 - \frac{k_{a1}}{2\pi i}\times\int_{x_1-i\infty}^{x_1+i\infty}\bar{c}_1(\sigma)\bar{\theta}(p-\sigma)\mathrm{d}\sigma - k_{d1}\bar{\theta},\ x=0; \tag{4'}$$

$$D_2(\mathrm{d}\bar{c}_2/\mathrm{d}x) = k_{a2}\bar{c}_2 - \frac{k_{a2}}{2\pi i}\times\int_{x_2-i\infty}^{x_2+i\infty}\bar{c}_2(\sigma)\bar{\theta}(p-\sigma)\mathrm{d}\sigma - k_{d2}\bar{\theta},\ x=0; \tag{5'}$$

$$\mathrm{d}\bar{c}_1/\mathrm{d}x = 0,\ x=-a; \tag{6'}$$

$$\mathrm{d}\bar{c}_2/\mathrm{d}x = 0,\ x=a, \tag{7'}$$

where $\bar{c}_1$, $\bar{c}_2$, and $\bar{\theta}$ are the image functions corresponding to c_1, c_2, and θ respectively, where p is the conversion parameter of the Laplace transformation, and where $q_1=(p/D_1)^{1/2}$ and $q_2=(p/D_2)^{1/2}$.

The general solution of Eqs. (1') and (2') may be represented by:

$$\bar{c}_1 = (c_{10}/p) + A_1\sinh(q_1x) + B_1\cosh(q_1x); \tag{11}$$

$$\bar{c}_2 = (c_{20}/p) + A_2\sinh(q_2x) + B_2\cosh(q_2x), \tag{12}$$

where A_1, B_1, A_2, and B_2 are the intergration constants.

These four constants can be solved by virtue of the boundary conditions of Eqs. (4')—(7'). Equation (3') is considered to define the mediate variable, $\bar{\theta}$. If we set the non-linear terms in Eqs. (4') and (5') at zero for the moment, we obtain a solution for the zero perturbation; by then substituting this solution into the non-linear terms, we obtain the solution for the first perturbation, and so on. The solution for the ith perturbation may be represented as:

$$\bar{c}_{1,i}(p) = (c_{10}/p) - A_{1,i}\cosh[q_1(a+x)]; \tag{13}$$

$$\bar{c}_{2,i}(p) = (c_{20}/p) - A_{2,i}\cosh[q_2(a-x)]; \tag{14}$$

$$\bar{\theta}_i(p) = (\theta_0/p) + \Gamma_\infty^{-1}[A_{1,i}q_1^{-1}\sinh(q_1a) + A_{2,i}q_2^{-1}\sinh(q_2a)]; \tag{15}$$

$$A_{1,i} \equiv (pD)^{-1}[\alpha_{1,i}\sinh(q_2a) + \beta_{1,i}\cosh(q_2a)];$$

$$A_{2,i} \equiv (pD)^{-1}[\alpha_{2,i}\sinh(q_1a) + \beta_{2,i}\cosh(q_1a)];\ .$$

$$\alpha_{1,i} \equiv \Gamma_\infty D_1 q_1 [k_{a1}(c_{10} - pI_{1,i}) - k_{d1}\theta_0] + q_1^{-1}[k_{a1}k_{d2}(c_{10} - pI_{1,i}) - k_{a2}k_{d1}(c_{20} - pI_{2,i})];$$

$$\beta_{1,i} \equiv k\Gamma_\infty k_{a2}[k_{a1}(c_{10} - pI_{1,i}) - k_{d1}\theta_0];$$

$$\alpha_{2,i} \equiv k\{\Gamma_\infty D_1 q_1 [k_{a2}(c_{20} - pI_{2,i}) - k_{d2}\theta_0] - q_1^{-1}[k_{a1}k_{d2}(c_{10} - pI_{1,i}) - k_{a2}k_{d1}(c_{20} - pI_{2,i})]\};$$

$$\beta_{2,i} \equiv k\Gamma_\infty k_{a1}[k_{a2}(c_{20} - pI_{2,i}) - k_{d2}\theta_0];$$

$$\boldsymbol{D} \equiv [a_1 \sinh(q_1 a) + a_2 \cosh(q_1 a)] \sinh(q_2 a) + [a_3 \sinh(q_1 a) + a_1 \cosh(q_1 a)] \cosh(q_2 a);$$

$$a_1 \equiv D_1(\Gamma_\infty p + k_{d1} + k_{d2});$$

$$a_2 \equiv k_{a1}(\Gamma_\infty D_1 q_1 + k_{d2} q_1^{-1});$$

$$a_3 \equiv k k_{a2}(\Gamma_\infty D_1 q_1 + k_{d1} q_1^{-1});$$

$$a_4 \equiv k\Gamma_\infty k_{a1} k_{a2};$$

$$k \equiv (D_1/D_2)^{1/2};$$

$$I_{1,i+1} \equiv \frac{1}{2\pi i}\int_{x_1-i\infty}^{x_1+i\infty} [\bar{c}_{1,i}(\sigma)]_{x=0}\bar{\theta}_{,i}(p-\sigma)\mathrm{d}\sigma;$$

$$I_{2,i+1} \equiv \frac{1}{2\pi i}\int_{x_2-i\infty}^{x_2+i\infty} [\bar{c}_{2,i}(\sigma)]_{x=0}\bar{\theta}_{,i}(p-\sigma)\mathrm{d}\sigma,$$

where the subscript i designates the ith perturbation, provided $I_{1,0}=I_{2,0}=0$.

$\bar{c}_{1,i}$, $\bar{c}_{2,i}$, and $\bar{\theta}_{,i}$ are single-valued functions of an arbitrary complex number of p; the inversion to the original functions by the Inversion Theorem, like the integrals of non-linear terms ($I_{1,i}$, $I_{2,i}$), includes only the pole-effects, according to Cauchy's Residue Theorem.

$\bar{c}_{1,i}$, $\bar{c}_{2,i}$, and $\bar{\theta}_{,i}$ have only simple poles at $p=0$ and $p=-D_1\alpha_m^2$, where $\pm\alpha_m$ ($m=1, 2, \cdots$) are the roots (generally complex) of

$$[b_1 \sin(a\alpha) + b_2 \cos(a\alpha)] \sin(ka\alpha) + [b_3 \sin(a\alpha) + b_4 \cos(a\alpha)] \cos(ka\alpha) = 0, \quad (16)$$

where: $b_1 \equiv D_1(\Gamma_\infty D_1\alpha^2 - k_{d1} - k_{d2})$;

$b_2 \equiv -k_{a1}(\Gamma_\infty D_1\alpha - k_{d2}\alpha^{-1})$;

$b_3 \equiv -k k_{a2}(\Gamma_\infty D_1\alpha - k_{d1}\alpha^{-1})$;

$b_4 \equiv k\Gamma_\infty k_{a1}k_{a2}$.

Inversion to the original functions gives:

$$c_{1,i} = k_{a2}k_{d1}A + 2\sum_{n=1}^{\infty}[\boldsymbol{D}']^{-1}[\xi_{1,i}\sin(ka\alpha_n) + \eta_{1,i}\cos(ka\alpha_n)]\cos[(a+x)\alpha_n]\exp(-D_1\alpha_n^2 t); \quad (17)$$

$$c_{2,i} = k_{a1}k_{d2}A + 2\sum_{n=1}^{\infty}[\boldsymbol{D}']^{-1}[\xi_{2,i}\sin(a\alpha_n) + \eta_2\cos(a\alpha_n)]\cos[k(a-x)\alpha_n]\exp(-D_1\alpha_n^2 t); \quad (18)$$

$$\theta_{,i} = k_{a1}k_{a2}A - 2\Gamma_\infty^{-1}\sum_{n=1}^{\infty}[\alpha_n\boldsymbol{D}']^{-1}\{[\xi_{1,i}\sin(ka\alpha_n) + \eta_{1,i}\cos(ka\alpha_n)]\sin(a\alpha_n) + [\xi_2\sin(a\alpha_n) + \eta_{2,}\cos(a\alpha_n)]k^{-1}\sin(ka\alpha_n)\}\exp(-D_1\alpha_n^2 t); \quad (19)$$

$$A \equiv [a(k_{a1}k_{d2} + k_{a2}k_{d1}) + \Gamma_\infty k_{a1}k_{a2}]^{-1}[a(c_{10}+c_{20}) + \Gamma_\infty\theta);$$

$$\boldsymbol{D}' \equiv [\phi_1\sin(a\alpha_n) + \phi_2\cos(a\alpha_n)]\sin(ka\alpha_n) + [\phi_3\sin(a\alpha_n) + \phi_4\cos(a\alpha_n)]\cos(ka\alpha_n);$$

$$\phi_1 \equiv -\Gamma_\infty D_1[2D_1 + a(k_{a1} + k^2{}_{a2})] + a\alpha_n^{-2}(k_{a1}k_{d2} + k^2 k_{a2}k_{d1});$$

$$\phi_2 \equiv -\Gamma_\infty D_1^2 a\alpha_n + \alpha_n^{-1}\{a[k^2\Gamma_\infty k_{a1}k_{a2} + D_1(k_{d1}+k_{d2})] + \Gamma_\infty k_{a1}D_1\} + k_{a1}k_{d2}\alpha_n^{-3};$$

$$\phi_3 \equiv k(-\Gamma_\infty D_1^2 a\alpha_n + \alpha_n^{-1}a[\Gamma_\infty k_{a1}k_{a2} + D_1(k_{d1}+k_{d2})] + \Gamma_\infty k_{a2}D_1\} + k_{a2}k_{d1}\alpha_n^{-3});$$

$$\phi_4 \equiv ka[\Gamma_\infty D_1(k_{a1}+k_{a2}) - \alpha_n^{-2}(k_{a1}k_{d2} + k_{a2}k_{d1})];$$

$$\xi_{1,i} \equiv -\Gamma_\infty D_1\alpha_n^{-1}[k_{a1}(c_{10} + D_1\alpha_n^2 I_{1,i}) - k_{d1}\theta_0 + \alpha_n^{-3}[k_{a1}k_{d2}(c_{10} + D_1\alpha_n^2 I_{1,i}) - k_{a2}k_{d1}(c_{20} + D_1\alpha_n^2 I_{2,i})];$$

$$\eta_{1,i} \equiv k\Gamma_\infty k_{a2}\alpha_n^{-2}[k_{a1}(c_{10} + D_1\alpha_n^2 I_{1,i}) - k_{d1}\theta_0];$$

$$\xi_{2,i} \equiv -k\{\Gamma_\infty D_1\alpha_n^{-1}[k_{a2}(c_{20} + D_1\alpha_n^2 I_{2,i}) - k_{d2}\theta_0] + \alpha_n^{-3}[k_{a1}k_{d2}(c_{10} + D_1\alpha_n^2 I_{1,i}) - k_{a2\,d1}(c_{20} + D_1\alpha_n^2 I_{2,i})]\};$$

$$\eta_{2,i} \equiv k\Gamma_\infty k_{a1}\alpha_n^{-2}[k_{a2}(c_{20} + D_1\alpha_n^2 I_{2,i}) - k_{d2}\theta_0],$$

where $I_{1,i}$ and $I_{2,i}$ are the values[6] at $p=-D_1\alpha_n^2$.

The amounts of the solute in Phase 1 and Phase 2 per unit of area of the interface are represented as:

$$Q_1 = \int_{-a}^{0} c^*{}_1\mathrm{d}x = k_{a2}k_{d1}aA + 2\sum_{n=1}^{\infty}[\boldsymbol{D}']^{-1}[\xi^*{}_1\sin(ka\alpha_n) + \eta^*{}_1\cos(ka\alpha_n)]\alpha_n^{-1} \times \sin(a\alpha_n)\exp(-D_1\alpha_n^2 t); \quad (20)$$

$$Q_2 = \int_0^{a} c^*{}_2\mathrm{d}x = k_{a1}k_{d2}aA + 2\sum_{n=1}^{\infty}[\boldsymbol{D}']^{-1}[\xi^*{}_2\sin(a\alpha_n) + \eta^*{}_2\cos(a\alpha_n)](ka\alpha_n)^{-1} \times \sin(ka\alpha_n)\exp(-D_1\alpha_n^2 t), \quad (21)$$

where the superscript * indicates the convergence value.

Remarks on the Application

Figures 1 and 2 show the time-dependences of the transfer amount of the solute and of the coverage of the interface giving hypothetical values to the parameters in Eqs. (21) and (19). Sample 1 corresponds to the case of less interfacial resistance ($\Delta F^{\ddagger}{}_{di}\sim 4$ kcal/mol), and Samples 2 and 3, to the cases of a distinct interfacial resistance ($\Delta F^{\ddagger}{}_{di}\sim 16$ kcal/mol), where $\Delta F^{\ddagger}{}_{di}$ is the activation free energy of desorption from interface into the ith phase.[7] The dotted curve gives the relation obtained by the usual equation of the semi-infinite composite medium. The equilibrium transfer-amount is computed to be 1.5×10^{-6} mol/cm^2.

The values of the rate constants of adsorption and desorption are given by the following equations:[7]

$$k_{ai} = \lambda_i\frac{\boldsymbol{k}T}{\boldsymbol{h}}\exp(-\Delta F^{\ddagger}{}_{ai}/\boldsymbol{R}T);$$

$$k_{di} = \Gamma_\infty\frac{\boldsymbol{h}T}{\boldsymbol{h}}\exp(-\Delta F^{\ddagger}{}_{di}/\boldsymbol{R}T);$$

$i=1$ and 2, where λ_i ($\sim$10 Å) is the length of the adsorption path from the boundary site of phase i to the interface; $\Delta F^{\ddagger}{}_{ai}$ is the activation free energy of adsorption from phase i to the interface; $\boldsymbol{k}$ is the Boltzmann constant; $\boldsymbol{h}$ is the Planck constant; $\boldsymbol{R}$ is the

gas constant, and T ($\sim$300 K) is the absolute temperature.

The procedure of calculation is as follows.

Assign definite values to k, D_1, Γ_∞, a, k_{a1}, k_{a2}, k_{d1}, and k_{d2} in Eq. (16), and find the positions of the pole on the plane of the complex variable, p. Although the roots of Eq. (16), α_m ($m=1, 2, \cdots$), are generally complex, they are real in our case.

Assign the values to k, D_1, Γ_∞, a, k_{a1}, k_{a2}, k_{d1}, k_{d2}, c_{10}, c_{20}, θ_0, and α_n's ($n\leq 20$ suffices for convergence in our case if $t>1$ s) in Eqs. (21) and (19), and compute the amount of the solute in Phase 2, Q_2, and the coverage, θ, as functions of the time, t. In our case, $\theta\sim 0.005\ll 1$, and the Q_2 and the θ were computed approximately by means of the zero perturbation (see Eqs. (4) and (5)).

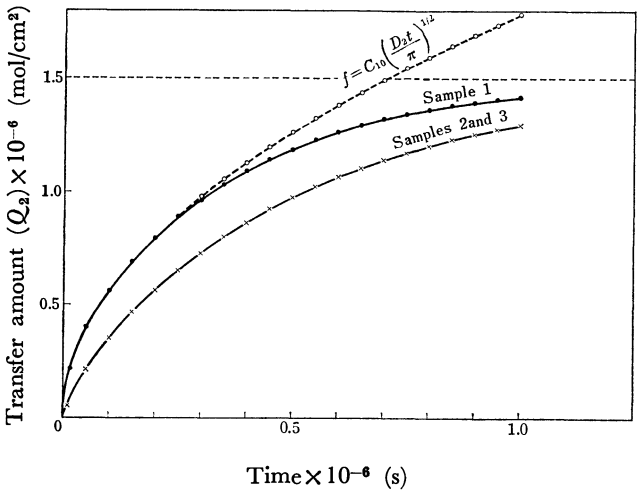

Fig. 1. Time dependences of the transfer amount.

Sample		1	2	3
k	[−]	1	1	1
D_1	[cm²/s]	10^{-5}	10^{-5}	10^{-5}
Γ_∞	[mol/cm²]	7×10^{-10}	7×10^{-10}	7×10^{-10}
a	[cm]	3	3	3
k_{d1}	[mol/(cm²) s]	1	10^{-9}	5×10^{-9}
k_{d2}	[mol/(cm²) s]	1	5×10^{-9}	10^{-9}
k_{a1}	[cm/s]	10^4	10^{-5}	5×10^{-5}
k_{a2}	[cm/s]	10^4	5×10^{-5}	10^{-5}
C_{10}	[mol/cm³]	10^{-6}	10^{-6}	10^{-6}
C_{20}	[mol/cm³]	0	0	0
θ_0	[−]	0	0	0

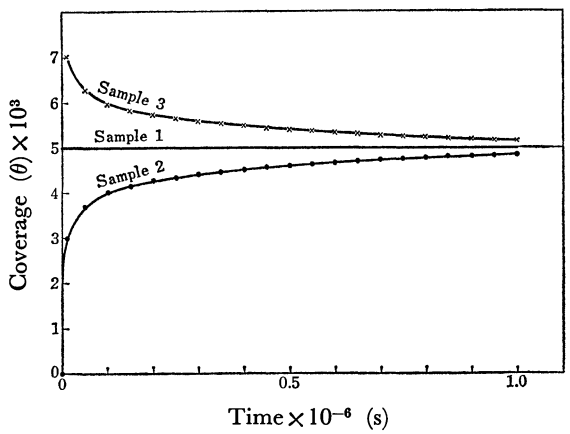

Fig. 2. Time dependences of the coverage of interface.

The curves of Samples 2 and 3 are distinctly below the curve of Sample 1 in Fig. 1, suggesting the possibility of the determination of the interfacial resistances (of this magnitude) by experimental observations of the time-dependence of the transfer amount.

The curves of Samples 2 and 3 are degenerate to a single curve in Fig. 1, indicating the impossibility of the determination of k_{d1} and k_{d2}[8] separately by the same experiment.

On the contrary, the curves of Samples 2 and 3 are greatly separated from each other, and the signs of the tangent differ in a short time in Fig. 2, suggesting the possibility of the determination of the rate-controlling step of desorption by an observation of the interfacial tensions for early stages.

On reflection, the manipulative disturbance on bringing two layers into contact for a transfer experiment may not strictly be avoidable; also, a spontaneous turbulence[9] is likely to occur near the touching time of two layers. These disturbances may generally accelerate the transfer of the solute. We must consider the effect of these disturbances on the analysis of the experimental data.

Suppose that an abnormally swift transfer ceases by $t=\Delta t$, and that the final condition of concentration is approximately given by $c_1=c'_{10}$, $-a<x<0$, $t=\Delta t$; $c_2=c'_{20}$, $0<x<a$, $t=\Delta t$; $\theta=\theta'_0$, $x=0$, $t=\Delta t$, where c'_{10}, c'_{20}, and θ'_0 are constants.

Let the origin of time be transferred to $t=\Delta t$, so that Eq. (21) is applicable.

The rate-controlling step of desorption may be conventionally set up on the side of second phase (for example), by virtue of the exchangeability of the values of k_{d1} and k_{d2}; when k_{d1} is sufficiently greater than k_{d2}, $c'_{10}=c'_{10}(c'_{20})$, and $\theta'_0=\theta'_0(c'_{20})$.

Consequently we may obtain approximate values of k_{di} ($i=1$ or 2), evaluated under the name of k_{d2} in Eq. (21), and c'_{20} by means of experimental determinations of the transfer amount through an interface at each contact time $t(\gg\Delta t)$. The following results of computation show the extent of approximation: $k_{d1}=5\times 10^{-9}$ mol/cm² s, $k_{d2}=0.999\times 10^{-9}$ mol/cm² s, $c'_{20}=1.001\times 10^{-7}$ mol/cm³; $k_{d1}=1$ mol/cm² s, $k_{d2}=0.833\times 10^{-9}$ mol/cm² s, $c'_{20}=1.001\times 10^{-7}$ mol/cm³ ($k=(D_1/D_2)^{1/2}=1$, $D_1=10^{-5}$ cm²/s, $\Gamma_\infty=7\times 10^{-10}$ mol/cm², $a=3$ cm, $K_1=k_{a1}/k_{d1}=10^4$ cm³/mol, $K_2=k_{a2}/k_{d2}=10^4$ cm³/mol, $c_{10}=10^{-6}$ mol/cm³, $c_{20}=\theta_0=0$, $t(1)=5\times 10^5$ s, $t(2)=10^5$ s, $Q_2(1)=1.080\times 10^{-6}$ mol/cm², $Q_2(2)=5.825\times 10^{-7}$ mol/cm²).

The author is indebted to Professors Hikoji Inazumi and Tadao Shiba of this Institute for their helpful discussions concerning this subject.

Surface Tension of Aqueous Solutions of Disodium Monoalkyl Phosphates and Their Mixtures[1)]

Masayuki NAKAGAKI and Tetsurou HANDA

Faculty of Pharmaceutical Sciences, Kyoto University, Sakyo-ku, Kyoto 606

(Received April 9, 1974)

Disodium mono-dodecyl, mono-tetradecyl, and mono-hexadecyl phosphates were synthesized and the surface tension of aqueous solutions of each disodium monoalkyl phosphate (SAP) and of their mixtures were measured. On the basis of the surface tension values thus obtained, the influence of the hydrocarbon chain length of SAP and the effect of the mixing of SAP on the adsorption and the micelle formation were discussed. A modified Szyszkowski equation was derived from the Gibbs adsorption equation and the modified Langmuir adsorption equation by using the activity instead of the concentration. The modified Szyszkowski equation gave calculated values which were in good agreement with the experimental values of the surface tension. It was also found that the energy of adsorption per methylene group, ω, is 682 cal/mol. In mixed solutions, the modified Szyszkowski equation was used to obtain results in good agreement with the measured values of the surface tension, assuming an ideal mixing of SAP in the adsorption layer. Further, the change in the standard free energy was calculated for the micelle formation for each SAP from the hypothetical standard state of the hydrated monomer in solution; it gave the energy of micelle formation per methylene group, ω_m, is 613 cal/mol. The theoretical equation to give the cmc of SAP, was obtained also, assuming the ideal mixing of SAP in the mixed micelle phase; it was proved to be in good agreement with the experimental values of the cmc.

Disodium monoalkyl phosphates (SAP) are interesting materials because they are bi-valent anionic surfactants, in contradistinction to the anionic detergents extensively used, which are mostly uni-valent. This group of surfactants is interesting also as a model compound of phospholipid because it containes a phosphate group, which might have properties different from many other uni-valent polar groups.

Disodium mono-dodecyl and mono-hexadecyl phospates have previously been synthesized in this laboratory, and the degree of hydrolysis of the ester bond measured. As a result, it has been concluded that the aqueous solution of SAP was very stable, at least, at room temperature.[2,3)] The surface tensions of aqueous solutions of these compounds were measured at various concentrations of added salt, and the adsorption amount of SAP at the air-water interface was calculated by applying the Gibbs adsorption equation. It was shown that S-shaped adsorption isotherms were obtained when the adsorption amount was plotted against the concentration, but Langmuir adsorption isotherms of the usual shape were obtained when the same data were plotted against the activity of SAP in the solutions. Furthermore, it was concluded that the activity at the critical micelle concentration was constant, irrespective of the concentration of the added salt.[4,5)]

In the present paper, the influence of the length of the hydrocarbon chain of SAP on the adsorption and the micelle formation will be discussed on the basis of the surface-tension measurements of aqueous solutions of disodium mono-dodecyl, -tetradecyl and -hexadecyl phosphates (SDP, STP and SHP respectively). The adsorption and the micelle formation of mixtures of SAP will also be discussed on the basis of the surface-tension measurements, the latter being performed in 0.01 M sodium hydroxide in order to diminish the binding of H^+ to the long-chain anion in the solutions.[6,7)] By using the experimental values of the surface tension, the modified Szyszkowski equation which is derived from the Gibbs adsorption equation and the modified Langmuir adsorption equation, using the activity instead of the concentration, are tested. A good agreement between the theory and experiments is obtained. As a result, the saturated adsorption amount and the Langmuir coefficients for each SAP are obtained. The theory is then extended to an aqueous solution of mixed SAP.

Experimental

Synthesis of Monoalkyl Phosphoric Acid and Preparation of the Solution of Disodium Salts. Monoalkyl phosphoric acid is synthesized from pyrophosphoric acid and an alcohol of the corresponding chain length, C_{12}, C_{14} or C_{16} in benzene,

$$ROH+H_4P_2O_7=ROPO(OH)_2+H_3PO_4$$

where R is a hydrocarbon chain. Alcohol (0.5 mol) and pyrophosphoric acid (0.7 mol) are dissolved in 200 ml of benzene in an Erlenmeyer flask, after which the mixture is allowed to stand for 4 days at room temperature. The benzene is then evaporated, and the viscous liquid produced dissolved in 300 ml of ether. The ether solution is then added to 500 ml of 1.5 M NaOH solution to extract the product, after which the ethereal layer is separated from the aqueous layer. The pH of the aqueous solution, 12.5, is then changed to 0.5 by the addition of concentrated HCl. The monoalkyl phosphoric acid thus precipitated is extracted with 300 ml of ether. The ether is then evaporated, and the crude product is vacuum-desiccated. Recrystallization from hexane gives a white, crystalline product. Found: C, 54.22; H, 10.13; P, 11.59%. Calcd for $C_{12}H_{26}O_4P$: C, 54.14; H, 10.15; P, 11.70%; mol wt, 265.1. Found: C, 57.24; H, 10.50; P, 10.44%. Calcd for $C_{14}H_{30}O_4P$: C, 57.14; H, 10.54; P, 10.54%; mol wt, 293.1. Found: C, 59.73; H, 10.82; P, 9.50%. Calcd for $C_{16}H_{34}O_4P$: C, 59.62; H, 10.87; P, 9.63%; mol wt. 321.1.

The melting points are 58, 68, and 78 °C respectively in good agreement with the values reported in the litetrature.[8)] An aqueous solution is prepared by dissolving a known amount of monoalkyl phosphoric acid in an adequate amount of NaOH solution. In the final solution, an excess of NaOH (0.01 M) should be remained to prevent the hydrolysis of di-valent phosphate.

Surface-tension Measurements. The surface-tension is measured by the capillary-rise method at 25 °C in 0.01 M NaOH as the solvent. The Willhelmy method was also tested, but it gave values which were different not only from those obtained by the capillary-rise method but also from those reported in the literature. Therefore, the capillary-rise method is adopted in this work, because it gave the surface tension values which are in good agreement with the reported values.[9] The values of the surface-tension γ, can be calculated from the ratio of the heights of the meniscus above the surface for the solution (h) to that for pure water (h_0). According to the Sugden theory,[10]

$$\gamma = \gamma_0 \times \frac{h\rho}{h_0\rho_0} \times \left(\frac{b}{b_0}\right)$$

Here, γ_0 is the surface tension of pure water and is 71.96 dyn/cm at 25 °C. (b/b_0) is the ratio of the principal radii at the bottom of the meniscus of the solution to that of pure water, the value is obtained from Sugden's table.[10] In our experiments, (b/b_0) is 1.0013 for the solution which had the lowest surface tension. (ρ/ρ_0) is the ratio of the density of the solution to that of pure water; its value was, at most, 1.01. The capillary is washed in a chromic acid-sulfuric acid mixture for a day. It can thus be confirmed that solutions wet the wall of the capillary very well. The solution was once raised by an air pump and then lowered freely in the capillary; the equilibrium value of the height was then read within 15 min at most. The error in the readings for the solution of the same concentration was less than 1%.

Results

Surface Tension of SAP Solutions. The surface tensions of aqueous solutions of SAP were measured in the presence of surface-inactive electrolytes. The concentration of SAP is expressed by C (in M). In the case of a mixed solution of two kinds of SAP, C is used for the total concentration, while the concentrations of the individual SAPs are expressed by C_1 and C_2, where $C_1+C_2=C$. The sodium-ion concentration from the surface-inactive electrolytes is expressed by C'(M), so that the total sodium-ion concentration in the solution is $(2C+C')$. When the added electrolyte is NaOH only, C' is equal to its concentration, but when NaOH and Na_2SO_4 are added, C' is equal to $[NaOH]+2[Na_2SO_4]$.

The surface tension measured as a function of the logarithm of the SAP concentration, C, at the added sodium-ion concentration, $C'=0.01$ M, is given in Fig. 1 for a solution of disodium mono-dodecyl, -tetradecyl, or -hexadecyl phosphotes. When comparison is made at a constant concentration, the surface tensions of SDP, STP, and SHP are found to decrease with the increase in chain length. The kink point for each curve is considered to be the critical micelle concentration (cmc); the values of cmc thus obtained are given in Table 1.

The surface tensions measured as functions of the total concentration, C, are also given in Fig. 1. These solutions contain SDP and SHP at various mole fractions of mixing. The concentration of SDP is $C_1=CX_1$, and that of SHP, $C_2=C(1-X_1)$. X_1 is the mole fraction of mixing. When comparsion is made at a constant total concentration, C, the increase in X_1 increases the surface tension. In other words, the total concentration needed to give a constant surface tension in-

Table 1. The values of the Langmuir coefficient, k, and the critical micelle concentration (CMC)

	k	CMC (M)
SDP	4.5×10^5	4.0×10^{-2}
STP	4.8×10^6	1.7×10^{-2}
SHP	3.3×10^7	6.0×10^{-3}
$X_1=0.5$	—	1.0×10^{-2}
$X_1=0.8$	—	1.5×10^{-2}
$X_1=0.9$	—	2.0×10^{-2}
$X_1=0.95$	—	3.0×10^{-2}

creases with X_1. At $X_1=0.5$, the total concentration of a mixture is smaller than the concentration of STP for the same surface tension, as is shown in Fig. 2. The kink points are also considered as cmc.

Figure 3 shows the surface tension of an aqueous solution containing SDP and SHP as a function of the concentration of one of them, while the concentration of the other is kept constant. Moreover, both the total sodium-ion concentration, $(2C+C')$, and the ionic strength, J, are kept constant by using a mixture of NaOH and Na_2SO_4 as the added electrolyte. The

surface tension changes more with the concentration of SHP, C_2 (Curves 1, 2 and 3) than with that of SDP, C_1 (Curves 4 and 5).

Discussion

Effect of the Chain Length on Adsorption. As is well known,[5,11] the Gibbs adsorption equation is a general equation relating adsorption amount, Γ, surface tension, γ, and activity, a.

$$\Gamma = \frac{-1}{RT}\left(\frac{\partial\gamma}{\partial \ln a}\right)_{T,\,P} \tag{1}$$

The activity of SAP in a single solution, a, is defined as:

$$a = \gamma_{\pm}{}^3C(2C+C')^2 \tag{2}$$

where γ is the mean ionic activity coefficient and can be calculated from the Güntelberg approximation of the Deby-Hückel theory:

$$\log\gamma_{\pm} = \frac{-A\sqrt{J}}{1+\sqrt{J}} \tag{3}$$

Here, J is the ionic strength and A is a constant, whose value is 1.022 for SAP at 25 °C.[12] As has already been stated in our previous papers,[4,5] the modified Langmuir adsorption equation using activity instead of concentration is written as:

$$\Gamma = \frac{\Gamma_s ka}{1+ka} \tag{4}$$

where Γ_s is the saturated adsorption amount and where k is the Langmuir coefficient. Equation (1) is integrated with equation (4) to give the modified Szyszkowski equation:

$$F = \gamma_0 - \gamma = \Gamma_s RT\ln(1+ka) \tag{5}$$

F is the surface pressure and γ_0, the surface tension of pure water. A proper numerical value, k, could give a linear relation between F and ln $(1+ka)$.

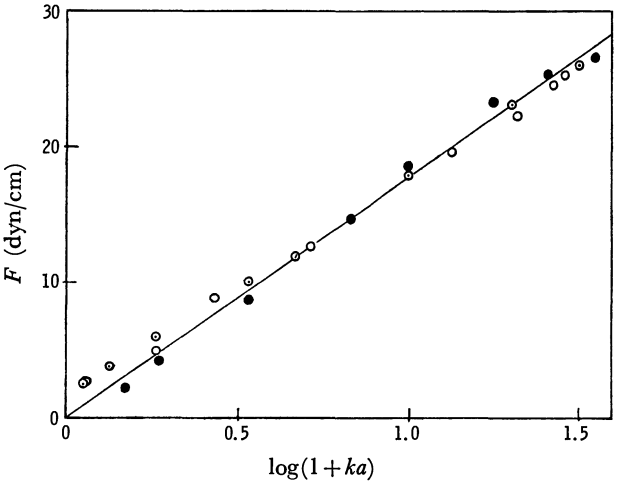

Fig. 4. Surface pressure, F, *vs.* log$(1+ka)$.
○; SDP, ⊙; STP, ●; SHP

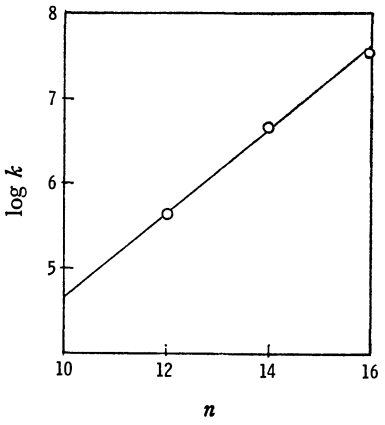

Fig. 5. Logarithm of Langmuir coefficient, log k, *vs.* hydrocarbon length, n.

In Fig. 4, F is plotted against $\ln(1+ka)$. When we used the Langmuir coefficients, the k values of 4.5×10^5, 4.8×10^6, and 3.3×10^7 for SDP, STP, and SHP respectively, the data for these three SAP solutions, plotted in this way, fell on a straight line. The value of Γ_s is 3.1×10^{-10} mol/cm^2, independent of the hydrocarbon-chain length. This corresponds to 53 Å^2 of the area occupied by one molecule. It is shown in Fig. 5 that the logarithm of the Langmuir coefficient, k, changes linearly with the number of carbon atomes in the hydrocarbon-chain, n. This means that the energy of adsorption per methylene group, ω, is constant, because the standard adsorption free energy $\Delta G°$, is given by the following equation:

$$\Delta G° = -RT\ln k \tag{6}$$

The value of ω obtained from the inclination of the straight line in Fig. 5 is 682 cal/mol. This result agrees with Traube's value (ω=650 cal/mol).[13]

Mixed Adsorption of Disodium Monoalkyl Phosphates. Not much works has been reported on the adsorption from aqueous solutions of mixed detergents because of difficulty involved in the calculation of the adsorption amount of each component. It has been shown in our previous paper, moreover that the adsorption

amount calculated directly from the Gibbs adsorption equation and from the modified Szyszkowski equation, which is based on the modified Langmuir adsorption equation, agreed well with each other for an aqueous solution of a single SAP. In this paper, the modified Langmuir adsorption equation is extended to a mixture of the disodium monoalkyl phosphates. Assuming that the mixing of these homologous surfactants in the adsorption layer is ideal, and remembering that Γ_s is independent of the number of carbon atoms, as has been stated in the previous section, the modified Langmuir adsorption equation for a mixed solution may be written as:

$$\Gamma_1 = \frac{\Gamma_s k_1 a_1}{1+k_1a_1+k_2a_2} \tag{7}$$

$$\Gamma_2 = \frac{\Gamma_s k_2 a_2}{1+k_1a_1+k_2a_2} \tag{8}$$

where a_1 and a_2 are the activities of SDP and SHP, where $a_1=\gamma_\pm^3 C_1(2C+C')^2$, and, where $a_2=\gamma_\pm^3 C_2(2C+C')^2$. On the other hand, the Gibbs adsorption equation of a mixed solution is:

$$-d\gamma = \Gamma_1 RT\, d\ln a_1 + \Gamma_2 RT\, d\ln a_2 \tag{9}$$

Equation (9) is integrated with Equation (7) and (8) to give:

$$F = \gamma_0 - \gamma = \Gamma_s RT \ln(1+k_1a_1+k_2a_2) \tag{10}$$

$\ln(1+k_1a_1+k_2a_2)$ is calculated using the values of the Langmuir coefficients, k_1 and k_2, which have previously been obtained for each single solute solution. They are given in Table 1. When F is plotted against $\ln(1+k_1a_1+k_2a_2)$, the linear relation shown in Fig. 6 is obtained. From this slope, the value of $\Gamma_s=3.1\times10^{-10}$ mol/cm^2 is obtained, exactly the same value as was obtained from Fig. 4.

In Fig. 3, the surface tension is measured by holding the activity of one component, $a_2=\gamma_\pm^3 C_2(2C+2[Na_2SO_4]+[NaOH])^2$ or $a_1=\gamma_\pm^3 C_1(2C+2[Na_2SO_4]+[NaOH])^2$, constant; then Equation (9) reduces to either

$$-d\gamma = \Gamma_1 RT\, d\ln a_1 \tag{11}$$

or

$$-d\gamma = \Gamma_2 RT\, d\ln a_2 \tag{12}$$

These equations are integrated using Eq. (7) or (8) respectively; the same equation as Eq. (10) is obtained in both cases. In Fig. 7, the surface pressure, F, is plotted against $\ln(1+k_1a_1+k_2a_2)$. In Figs. 8 and 9, the adsorption amounts, Γ_1 and Γ_2, are calculated from Eqs (11) and (12) respectively by the direct differentiation of the experimental curves and compared with the theoretical values calculated from Eqs (7) and (8). These experimental results agree well with the theoretical ones. Thus, it may be concluded that the modified Langmuir adsorption equation using the activity is valid also in an aqueous solution of mixed SAP, and that the mixing of these homologous surfactants in the adsorption layer is ideal.

Micelle Formation and Chain Length. Herraman treated micelle formation as phase separation and assumed standard states of the hydrated monomer and

of hydrated micelle in an aqueous solution. Then he showed that the thermodynamic quantities calculated on this basis were in good agreement with the experimental values.[14] Applying his theory to SAP, but using the activity instead of the concentration in Herraman's equation, the standard free energy of the micelle formation, ΔG^*, is written as:

$$\Delta G^* = RT \ln a_m \tag{13}$$

where a_m is the activity at the critical micelle concentration. In the case of SAP, the activity, a_m, is given by the following equation:

$$a_m = \gamma_\pm^3 C_m (2C_m + C')^2 \tag{14}$$

where C_m is the critical micelle concentration of SAP and C' is that of the inorganic salt added to the solution. In our previous paper, it was verified that the micelle formation occurred at a constant activity, irrespective of the added amount of inorganic salt. When the logarithm of a_m is plotted against the number of carbon atoms in the hydrocarbon chain, n, for a solution of each SAP, the linear relation shown by the solid line in Fig. 10 is obtained. The energy of micelle

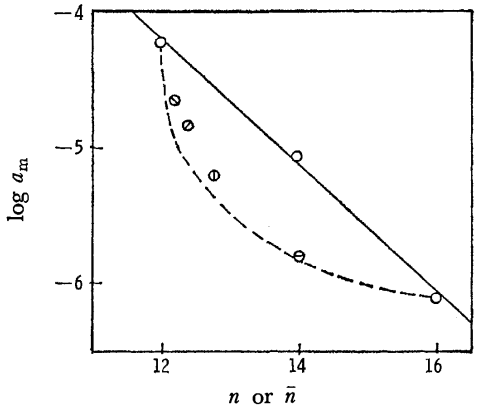

Fig. 10. log a_m *vs.* n or $\bar{n}$.
----; Theory, Eq. (18).

formation per methylene group is therefore, constant and is calculated to be ω =613 cal/mol from the slope of the straight line. On the basis of these results, ΔG^* can be expressed as:

$$\Delta G^* = -n\omega_m + h \tag{15}$$

where h is a constant. As in a previous discussion of the effect of added salt on micelle formation,[4] the critical micelle concentration, C_m, of disodium monoalkyl phosphates can be represented as a function of the counter-ion concentration [Na^+] and the number of carbon atoms in the hydrocarbon chain, n, by the following equation at 25 °C.

$$\log C_m = -31 \log \gamma_\pm - 21 \log[Na^+] - 0.471n + 1.424 \tag{16}$$

Mixed Micelle Formation. Shinoda presented a theory of micelle formation in an aqueous solution of mixed homologous detergents and represented the critical micelle concentration as a function of the hydrocarbon chain length and the mole fraction of mixing.[15] His theory was essentialy based on Hobb's theory[16] and also on the assumption that ideal mixing occurred in a mixed micelle of homologous detergents. In this paper, a theory is derived from a different basis that the activity at the critical micelle concentration is given as a function of the hydrocarbon chain length and the mixing mole fraction of each surfactant.
A mixed micelle is considered to be formed in an aqueous solution of the mixed SAP, and the mixing of the two surfactants in the mixed micelle phase is assumed to be ideal. Then the following equation is obtained:

$$RT \ln a_{m1} = \Delta G^*_1 + RT \ln Y_1 \tag{17}$$

where a_{m1} is the activity of SDP at the critical micelle concentration and where y_1 is its mole fraction in the mixed micelle phase. ΔG_1^* is equal to the ΔG^* of Eq. (15) introduced 12 into n. A similar equation can be written for the 2 component, SHP with n= 16. When y_1 and y_2 are eliminated, the following equation is readily obtained:

$$a_m = e^h (X_1 e^{n_1 \omega_m / RT} + X_2 e^{n_2 \omega_m / RT}) \tag{18}$$

where $a_m = a_{m1} + a_{m2}$, $a_{m1} = X_1 a_m$, and $a_{m2} = X_2 a_m$, because the mean ionic activity coefficients are equal for both components as long as the Güntelberg equation (13) is presumed. Numerical values are introduced into n_1, n_2 and ω_m, and the theoretical value of a_m is calculated. In Fig. 10, the experimental and theoretical values of a_m are compared for various values of the average numbers of carbon atoms:

$$\bar{n} = n_1 X_1 + n_2 X_2 \tag{19}$$

The experimental results plotted are in good agreement with the theoretical values shown by a broken curve. It is, therefore, verified that the theory of ideal mixing is valid for the mixed micelle phase in an aqueous solution of mixed SAP.

ESR Spectra of Monoprotonated Semiquinone Radicals Formed during Photolysis of *p*-Benzoquinone and Its Methyl Derivatives

Tetsuo WARASHINA, Ove EDLUND,* and Hiroshi YOSHIDA*

Research Reactor Institute, Kyoto University, Kumatori-cho, Osaka 590-04

**Faculty of Engineering, Hokkaido University, Kita-ku, Sapporo 060*

(Received May 4, 1974)

Proton hyperfine coupling constants of monoprotonated *p*-benzosemiquinone, durosemiquinone, 2,6-dimethyl-*p*-benzosemiquinone, 2,5-dimethyl-*p*-benzosemiquinone and methyl-*p*-benzosemiquinone radicals were determined from ESR spectra during photolysis of the corresponding quinones under identical conditions, *i.e.*, in ethanol and at about 20 °C. By considering all these constants together, the ESR spectra were assigned and following results obtained: (1) the hydroxyl groups were at the oxygen atom further from the methyl substituents, (2) the coupling constant was generally −1.86—−1.65 G for the hydroxylic protons, (3) the absolute value of the coupling constant for both ring and methyl protons was in the range 0—0.7 G for *ortho*-positions and 4.3—5.2 G for *meta*-positions relative to the hydroxyl group, and (4) the hydroxylic proton of durosemiquinone had an exceptionally small coupling constant because of steric hindrance of the methyl groups. The temperature dependence of the coupling constants in *p*-benzosemiquinone revealed an asymmetry of the meta-ring protons at low temperature due to the hindrance of hydroxyl group rotation. The coupling constants for *p*-benzosemiquinone were calculated with the INDO method. However, the results were not satisfactory because the calculated coupling constant was too large for the ortho-protons and the asymmetry calculated for the conformation with the hydroxylic proton fixed at one of the stationary sites was too small to interpret the observations.

Ultra-violet photolysis of quinones in a hydrogen-donating solvent results in the formation of monoprotonated semiquinone radicals, which have been characterized by flash photolysis studies[1] and by electron spin resonance (ESR) studies during photolysis. ESR spectra of the semiquinone radicals have been observed under various conditions as listed below:

quinone	solvent
p-benzoquinone	alcohols,[2,3,8,9] acetone,[2] tri-*n*-butyl phosphate,[2,3] 1,2-dimethoxyethane,[2,5] tetrahydrofuran,[2,3,4] 1,4-dioxane,[2,8]
duroquinone	alcohols,[3,6,8] acetone,[4,6] tri-*n*-butyl phosphate,[3,6] sulpholane,[6] tetrahydrofuran,[3,4,6] 1,4-dioxane,[6,8] benzene,[6]
2,3-dimethyl-*p*-benzoquinone	1,2-dimethoxyethane,[4]
2,5-dimethyl-*p*-benzoquinone	1,2-dimethoxyethane,[4]
2,6-dimethyl-*p*-benzoquinone	alcohols,[7] acetone,[7] tri-*n*-butyl phosphate,[7] 1,2-dimethoxyethane,[7] tetrahydrofuran,[4,7] 1,4-dioxane,[7]
1,4-naphthoquinone	alcohols,[8,9] 1,4-dioxane,[8]
anthraquinone	2-propanol,[8] 1,4-dioxane.[8]

One of the principal aims of the present investigation is the comparison of the ESR spectra of the *p*-benzosemiquinone radical and its methyl derivatives in a particular solvent, ethanol, because hyperfine coupling constants of semiquinone radicals depend on the nature of solvent[3,6,7] and on the temperature as well.[3,5]

The ESR spectra during photolysis of *p*-benzoquinone and its derivatives in alcohols have been studied:[10,11] it was found that the spectra of both semiquinone radicals and semiquinone anions were recorded simultaneously even in neutral solution. The mechanism of formation of these radicals has also been discussed.[10,11] The present investigation is an extension of our previous ones and concerns only the semiquinone radical spectra observed during steady-state photolysis. The observed hyperfine coupling constants of the *p*-benzosemiquinone[2] and durosemiquinone radicals[6] were compared with those calculated using a valence-bond treatment with variable parameters in an attempt to understand the dependence of the hyperfine coupling constants on the nature of solvent. Later, the spectrum of *p*-benzosemiquinone was reproduced with McLachlan's simple SCF molecular orbital treatment,[5] but the agreement seems to be fortuitous because this treatment included many adjustable parameters and, in addition, it is valid only for alternant hydrocarbon radicals.[12] In the present investigation, the *p*-benzosemiquinone radical spectrum was calculated in the INDO approximation, which has been successful in reproducing ESR spectra of a fairly large number of free radicals.[13] Unfortunately, the INDO treatment did not give satisfactory results for the *p*-benzosemiquinone radical. To demonstrate the failure of the INDO method for this particular radical is another aim of this report.

Experimental

The apparatus used has been described in detail elsewhere.[14] A solution of the quinones in ethanol was first bubbled with helium and then photolyzed with unfiltered light from a super-high pressure mercury arc while flowing at a rate of about 4 ml/min. All chemicals were analytical grade and were used without further purification.

When the intense spectrum of the semiquinone anion interfered the recording of that of the semiquinone radical, the anion was suppressed by adding a small amount of acetic acid to the solution.[10]

Results and Discussion

Assignment of Hyperfine Coupling Constants. The ESR spectrum recorded during the photolysis of durosemiquinone in ethanol with a small amount of acetic acid is shown in Fig. 1A. It clearly shows a hyperfine structure attributable to two sets of six equivalent protons and a proton (as shown by the stick spectrum in the figure), though the outmost hyperfine lines were too weak to be recorded with our conditions. The spectrum is attributed to a monoprotonated durosemiquinone radical and is essentially the same as those previously reported.[3,6] Although the hyperfine coupling constants are temperature dependent, their values at 22 °C are given in Table 1 for comparison with those of other semiquinone radicals.

Figure 1B shows an ESR spectrum (indicated by the sticks) of 2,6-dimethylbenzosemiquinone radical recorded during the photolysis. Some weak lines are observed in the central part, which are thought to be due to 2,6-dimethyl-*p*-benzosemiquinone anion, because they disappeared when a small amount of acetic acid was added to the solution. A large hyper-

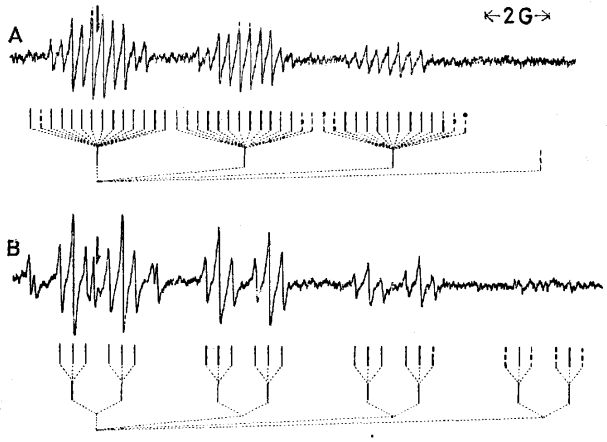

Fig. 1. ESR spectra of monoprotonated (A) durosemiquinone radical observed during photolysis of ethanol solution of duroquinone (5 mM) in the presence of a small amount of acetic acid at 31 °C and (B) 2,6-dimethylbenzosemiquinone radical observed during photolysis of ethanol solution of 2,6-dimethyl-*p*-benzoquinone (5 mM) at 32 °C. A high-field half of the spectra is shown. Arrows indicate the center of the spectra.

Table 1. Observed hyperfine coupling constants of protons in monoprotonated semiquinone radicals formed during photolysis of ethanol solutions

Parent molecule	Temperature	Radicals and hyperfine coupling constants (in G)
p-Benzoquinone	19 °C	 (−5.09) (+0.29) (−1.86)
Duroquinone	22 °C	 (+4.87) (−0.67) (−0.41)
2,6-Dimethyl-*p*-Benzoquinone	23 °C	 (+4.77) (+0.42) (−1.65)
2,5-Dimethyl-*p*-Benzoquinone	18 °C	 (−4.32) (+5.18) (−0.20) (+0.71) (−1.70)
Methyl-*p*-Benzoquinone	24 °C	 (−5.00) (+5.00) (small) (+0.71) (−1.72)

fine splitting of 4.77 G, due to six equivalent protons, indicates that hydrogen addition occurs exclusively on the oxygen atom attached to the carbon at the 4-position, remote from the two methyl groups. The observed hyperfine coupling constants are essentially the same as those reported previously[7] and are listed in Table 1.

In addition to the coupling constants of the two semiquinone radicals, hyperfine coupling constants previously determined[10] at about 20 °C for *p*-benzosemiquinone radical, 2,5-dimethylbenzosemiquinone radical and methyl-*p*-benzosemiquinone radical are shown in Table 1 for comparison. The ESR spectra of 2,5-dimethylbenzosemiquinone radical in alcohols and of methyl-*p*-benzosemiquinone radical have not been assigned before.

Based on a molecular orbital[3,4] and a valence-bond[2,6] treatment, the spin density has a large positive value on carbon atoms at the *meta*-position (relative to the hydroxyl group) and a small negative value on the carbon atom at the *ortho*-position. Therefore, if one considers the induction of a negative spin on the orbital of the ring-hydrogen and a positive spin on the orbital of the methyl-hydrogen, the observed hyperfine coupling constants as well as their sign may be assigned as shown in the third column in Table 1, except for the monoprotonated methyl-*p*-benzosemiquinone radical. The ESR spectrum observed during photolysis of the methyl-*p*-benzoquinone in acidic ethanol had a hyperfine structure due to six protons, four of which are equivalent (see Fig. 6b in Ref. 10). Although one proton is missing, the spectrum is tentatively assigned to methyl-*p*-benzosemiquinone radical as shown in Table 1 by comparing hyperfine coupling constants of other semiquinone radicals and by analogy with photochemical reactions of other quinones. The hyperfine coupling constants of the ring proton and that of the methyl protons at the *meta*-positions are probably accidentally the same, and the hyperfine coupling constant of one of the *ortho*-ring protons was too small relative to the line-width (150 mG) to be observed. The hyperfine coupling constant of the hydroxylic proton was in the range $-1.7\sim-1.9$ G for all semiquinone radicals except for durosemiquinone radical where a large steric hindrance of the methyl groups may exist (see below).

The Temperature Dependence of the Hyperfine Coupling Constants. The absolute value of the hyperfine coupling constant of the ring protons and methyl protons decreases slightly with decreasing temperature, whereas the hyperfine coupling constant of the hydroxylic proton increases rather remarkably, as shown in Fig. 2 for the *p*-benzosemiquinone radical. Although such a tendency has already been reported,[3] it should be stressed that the protons at 2- and 6-positions become inequivalent at low temperature because of hindrance to rapid rotation of the hydroxyl group.

The spectrum of *p*-benzosemiquinone radical consists of three pairs of triplets at high temperature. The third and fourth triplet patterns from the low-field end of the spectrum change of five-line patterns at low temperature. Using the modified Bloch equation,[15] the change of the patterns could be reproduced well from the hyperfine coupling constants and the linewidth estimated from the outer triplets, as shown in Fig. 3. The good agreement between observed and simulated patterns shows unambiguously that the difference in hyperfine coupling constant between protons at 2- and 6-positions is equal to 7.5%. The difference was found to be 6.3% in tetrahydrofuran[4]

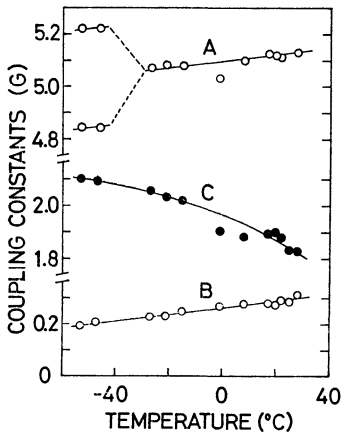

Fig. 2. Temperature dependence of the hyperfine coupling constants of the ring proton at (A) 2- and 6-positions (negative in sign) and (B) 3- and 5-positions and (C) of hydroxylic proton (negative in sign) in monoprotonated *p*-benzosemiquinone radical in ethanol.

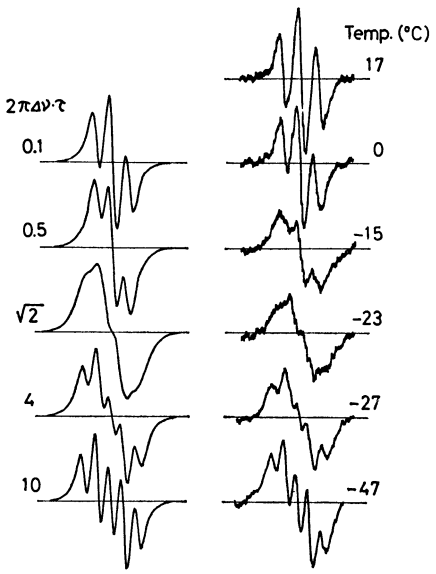

Fig. 3. Change of the ESR spectrum of *p*-benzosemiquinone radical due to the conformational exchange of the hydroxylic proton between two stationary sites in the nodal plane of ring π-system in the intermediate range of exchanging rate. Left spectra: simulated from the modified Bloch equations and the hyperfine coupling constants in Fig. 2 for each value of $2\pi\Delta\nu\cdot\tau$ shown in the figure (see also the text). Right spectra: observed at each temperature shown in the figure. Only the third triplet component (at room temperature) from the low field is shown.

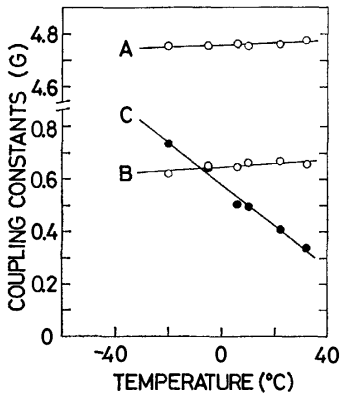

Fig. 4. Temperature dependence of hyperfine coupling constant of methyl protons at (A) 2- and 6-positions (negative in sign) and (B) 3- and 5-positions and (C) of hydroxylic proton (negative in sign) in monoprotonated durosemiquinone radical in ethanol.

and 5.4% in 1,2-dimethoxyethane.[5]

The temperature dependence of the hyperfine coupling constants in durosemiquinone radical is shown in Fig. 4. The absolute value of the hyperfine coupling constant of the hydroxylic proton increases greatly with decreasing temperature, consistent with the previous observation for durosemiquinone radical in 2-propanol, tetrahydrofuran and tri-*n*-butyl phosphate.[3] In addition, it was found in the present study that the hyperfine coupling constants of the methyl protons decrease slightly in absolute value, with decreasing temperature, as do those of the ring protons in the *p*-benzosemiquinone radical. The magnitude and sign of the hyperfine coupling constant of the hydroxylic proton is determined by two opposing contributions: one is a negative contribution from conjugation between the oxygen and the aromatic π-system and the other is a positive contribution from the direct overlap between the aromatic π-system and the proton.[3,16] If the hydroxylic proton is in the nodal plane of the π-system, its hyperfine coupling constant is determined exclusively by the former contribution and therefore has a negative sign. When rotation about the C–O bond brings the proton out of the nodal plane, the coupling constant approaches zero and then increases. The observed magnitude and temperature dependence of the hyperfine coupling constant of the hydroxylic proton indicate that it is negative in ethanol as in 2-propanol and tetrahydrofuran,[3] although the proton is located more out of the nodal plane in the durosemiquinone radical than in the other semiquinone radicals because bulky methyl groups are closer to the hydroxyl group in the durosemiquinone radical. At low temperatures, the position of the hydroxylic proton is closer to the nodal plane, giving a hyperfine coupling with a large negative value.

Molecular Orbital Calculations. Hyperfine coupling constants of semiquinone radicals were first examined theoretically with a valence-bond treatment with parameters adjusted to fit the calculated spin densities to those observed and to account for the dependence of the coupling constants upon the solvent polarity.[2,6] Later, McLachlan's approximate self-consistent treatment was used to reproduce the observed hyperfine coupling constants.[3–5] However, agreement between the observed and calculated coupling constants obtained by this molecular orbital treatment seem to be fortuitous,[5] because the calculation involved many adjustable parameters.

In the present investigation, we tried to calculate the hyperfine coupling constants of the protons in a semiquinone radical using the INDO approximation. However, though this molecular orbital treatment developed by Pople and Beveridge has been shown to be promising in predicting the value of the hyperfine coupling constants for several kinds of free radicals without any parametrization other than the conformation of the free radicals,[12] we could not get satisfactory results.

Table 2. Proton hyperfine coupling constants of monoprotonated *p*-benzosemiquinone radical calculated by the INDO method and those observed in ethanol solution

Hyperfine coupling constants (G)	
Calculated	Observed
Planar	At −53 °C
$a_2 = -6.0218$	−5.22
$a_6 = -6.0041$	−4.84
$a_3 = 3.3539$, $a_5 = 3.4095$	0.20
$a_{OH} = -0.7276$	−2.10
Non-planar	At 19 °C
$a_2 = a_6 = -6.0747$	−5.09
$a_3 = a_5 = 3.4945$	0.29
$a_{OH} = 15.7278$	−1.86

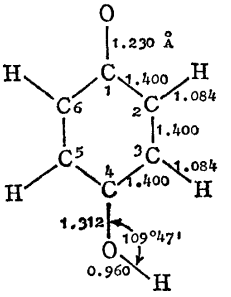

Table 2 shows representative results obtained from the INDO calculations of the proton hyperfine coupling constants in *p*-benzosemiquinone radical for the conformation with normal bond lengths and bond angles also shown in the same table. The isotropic hyperfine coupling for all the protons was derived from the 1s spin density on the corresponding hydrogen atoms obtained from the INDO approximation by using the proportionality constant relating the spin density to the coupling constant, 539.86 G.[13]

The calculated hyperfine coupling constants of the protons do not agree with the observed ones. The hyperfine coupling constants of the hydroxylic proton depend very much on the conformation of the radical, *i.e.*, whether the proton is in the nodal plane or out of it. However, the coupling constants of the ring protons are not affected by the conformation. Both of two extreme conformations (one was planar with the hydroxylic proton in the nodal plane and the other was non-planar with the hydroxylic proton in the symmetry plane perpendicular to the ring) gave hyperfine coupling constants of 3.4~3.5 G for protons at 3- and 5-positions (*ortho*-position relative to the

hydroxyl group) and about −6.0 G for 2- and 6-positions (*meta*-positions relative to the hydroxyl group). Although the values for the *meta*-positions are rather close to the observed ones, the values for the ortho-positions are ten times as large as the observed values. In addition, the calculated difference in hyperfine coupling between the two protons at the *meta*-position is 0.29% for the planar conformation, which is very much smaller than the observed difference of 7.5%.

The agreement between calculation and observation for the hydroxylic proton could be obtained by arbitrarily adjusting the angle of rotation of the hydroxyl group around the C–O bond. However, the disagreement between calculation and observation in the magnitude of the hyperfine coupling constants of the protons at *ortho*-positions and that in the difference in hyperfine coupling of the protons at *meta*-positions indicate that INDO calculations produce very poor results for the monoprotonated *p*-benzosemiquinone radical. The reason for this is not known at this moment and is left to further theoretical investigation. We made several calculations for other bond lengths and bond angles in the acceptable range, but no appreciable improvement could be attained in the calculated results. We also examined unsuccessfully the effect of a hydrogen bond between the hydroxyl group of the radical and solvent ethanol. It may be interesting to note that the INDO method did not give satisfactory results for the hyperfine coupling constants of *p*-benzosemiquinone anion either.[13]

Conclusions

The proton hyperfine coupling constants of shortlived monoprotonated semiquinone radicals (*p*-benzosemiquinone, durosemiquinone, 2,6-dimethylbenzosemiquinone, 2,5-dimethylbenzosemiquinone and methyl-*p*-benzosemiquinone radicals) have been compared with each other under identical conditions, namely, in ethanol solvent and at about 20 °C and assigned. Among them, 2,5-dimethylbenzosemiquinone and methyl-*p*-benzosemiquinone radicals, at least in ethanol, were first assigned in this investigation. The observed hyperfine coupling constants of the hydroxylic proton are all in the range −1.86∼−1.65 G except for the durosemiquinone radical, where the hyperfine coupling constant is as small as −0.41 G, indicating that the hydroxylic proton is far out of the nodal plane of the ring π-system due to the bulky methyl groups located close to the hydroxyl group. The ESR spectrum of methyl-*p*-benzoquinone shows a hyperfine structure due to six protons, but it has been tentatively assigned to methyl-*p*-benzosemiquinone radical by comparing with the coupling constants in other semiquinone radicals.

The proton hyperfine coupling constants for *p*-benzosemiquinone radical were calculated in the INDO approximation. However, the results were unsatisfactory because the calculated hyperfine coupling constant of the protons in the *ortho*-positions relative to the hydroxyl group was much smaller in magnitude than the observed one. Furthermore, the calculated difference in hyperfine coupling between two protons in the *meta*-positions was too small to account for the hyperfine structure of the spectrum observed at low temperature where the hydroxylic proton is thought to be fixed at one of the stationary positions in the nodal plane of the ring π-system.

Physico-chemical Properties of Selenium-Tellurium-Sulfur Crystals

Toshio NAKAGAWA

Department of Chemistry, Faculty of General Education, Hosei University, Fujimi, Chiyoda-ku, Tokyo 102

(Received May 17, 1974)

The temperature dependence of electric conductivity and Vickers hardness of Selenium-Tellurium-Sulfur (Se-Te-S) crystals were studied. The conductivity decreased with an increase in sulfur content, remaining almost constant when the sulfur content was 40—80 atomic % at 20 and 30 atomic % of tellurium content. When tellurium content was 10%, both conductivity and hardness decreased abruptly when sulfur content exceeded 10%. It was found by means of X-ray diffraction that a hexagonal crystal structure with size twice the lattice constant of Se-Te crystals is formed when the sulfur content is 20% at 10% of tellurium content. When sulfur content exceeds 80%, the crystal structure becomes similar to that of pure sulfur (orthorhombic) at 20 and 30% of tellurium.

Hansen[1] reported that the phase diagram of Se-S system is of a complicated peritectic type, that of Se-Te system a basic solid solution type and that of Te-S system a eutectic type with a eutectic point at *ca.* 98—99 atomic % sulfur content. Many reports have appeared on the properties of Se-S, Se-Te, and Te-S systems.[2~5] The phase diagram of the Se-Te-S system has been reported,[6] but not its properties.

In this study, Se-Te-S crystals were prepared by heating amorphous Se-Te-S at 95 °C. The electric conductivity and Vickers hardness were measured. The results were discussed on the basis of X-ray diffraction data.

Experimental

Materials. Selenium (99.999%, Showa. Kagaku Co., Ltd.) and tellurium (99.999% Yokozawa Kagaku Co., Ltd.) were used. Sulfur of special grade was recrystallized twice.

Procedure. Three mixtures of powdered selenium and tellurium (Te, 10, 20 and 30 atomic %) were sealed separately in glass tubes under 10^{-3} Torr and melted at 470 °C. The glass tubes were exposed to the air for quenching. The products were powdered, and various amounts of sulfur were added. The mixtures were sealed separately in glass tubes, melted at 250—300 °C and quenched. The samples were crystallized at 95 °C for 2—24 hr. Specimens for measurement (4×4×7 mm) were cut out and left in the dark for *ca.* 24 hr. Electric conductivity was measured by the voltage drop method under 50 V. Vickers hardness was measured with a micro hardness tester of MVA type (Akashi Co.) under a load of 25~200 g for 1 min. X-ray diffraction was studied by the powder method with a Geigerflex (Rigaku Denki Co.) by means of CuKα line.

Results

Electric Conductivity (σ). The temperature dependence of electric conductivity of three Se-Te-S crystals with tellurium contents (a) 10%, (b) 20% and (c) 30% was studied in the range from room temperature to 95 °C. The relation between log σ and $1/T$ shows a nearly straight line. The relation between electric conductivity and sulfur content at 30 °C is shown in Fig. 1. The conductivity decreases with an increse in sulfur content. In (a), the conductivity decreases abruptly when the sulfur content exceeds 10%. In (b) and (c), the conductivity gradually decreases with an increase in sulfur content up to *ca.* 40%, remains almost constant, and decreases abruptly when

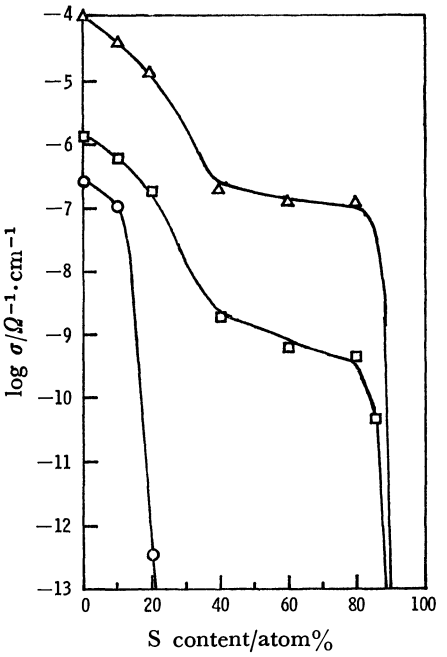

Fig. 1. Electric conductivity of Se-Te-S crystals n 30 °C.
Te content/atom% ○: 10, □: 20, △: 30.

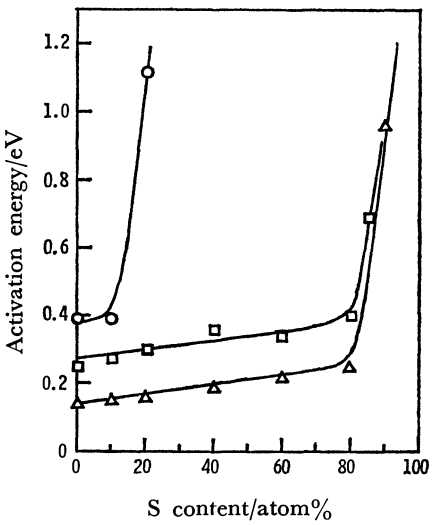

Fig. 2. Activation energy of the electric conductivity of Se-Te-S crystals.
Te content/atom% ○: 10, □: 20, △: 30.

the sulfur content exceeds 80%. The greyish black color of Se-Te crystals turned reddish brown in (a), brown in (b) and (c) at the sulfur concentration at which electric conductivity decreases abruptly.

Figure 2 shows the relation between sulfur content and activation energy. The activation energy was calculated by

$$\sigma = \sigma_0 \exp(-E/kT),$$

where σ and σ_0 are electric conductivities, E activation energy, k the Boltzmann constant, and T absolute temperature. The activation energy remains almost constant in (a) for sulfur content up to 10%, but increases abruptly when it exceeds 10%. The results seem to be the reverse of that for conductivity (Fig. 1). In (b) and (c), the activation energy increases abruptly when sulfur content exceeds *ca.* 80%. Activation energy above 80% sulfur approaches 1.52 eV,[7] the energy of pure sulfur.

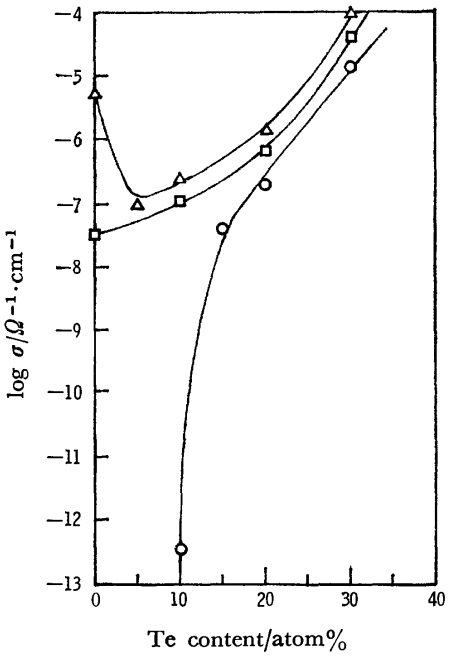

Fig. 3. Electric conductivity of Se-Te-S crystals at 30 °C.
S content/atom% △: 0, □: 10, ○: 20.

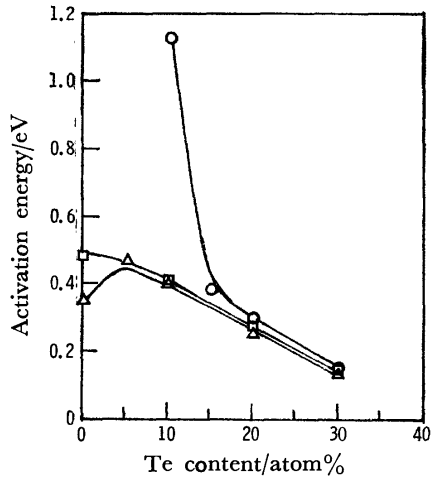

Fig. 4. Activation energy of the electric conductivity of Se-Te-S crystals.
S content/atom% △: 0, □: 10, ○: 20.

The relation between the electric conductivity of Se-Te-S crystals and tellurium content is shown in Fig. 3. When no sulfur is contained, the conductivity decreases with an increase in tellurium content up to ca. 5%, but increases above 5%. When sulfur content is 10%, the conductivity increases with an increase in tellurium content. When sulfur content is 20%, the conductivity abruptly decreases with a decrease in tellurium content below 15%. The relation between activation energy and tellurium content is shown in Fig. 4. The results seem to be the reverse of those for conductivity (Fig. 3).

Hardness. The relation between sulfur content and Vickers hardness of Se-Te-S crystals (a), (b) and (c) is shown in Fig. 5. The hardness decreases abruptly with an increase in sulfur content up to *ca.* 20% in (a) and decreases gradually above 20%. The rapid lowering of hardness corresponds to the decrease in conductivity (Fig. 1). The hardness of selenium crystallized at 95 °C is *ca.* 90 kg/mm², decreasing abruptly with an increase in tellurium content up to *ca.* 20% and decreases gradually above 20%. There is no change in hardness when sulfur content exceeds 80% in (b) and (c).

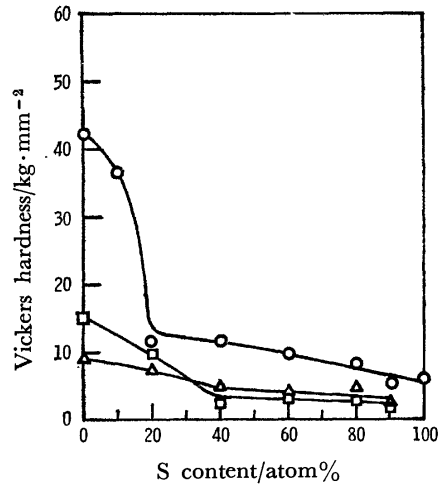

Fig. 5. Vickers hardness of Se-Te-S crystals.
Te content/atom% ○: 10, □: 20, △: 30.

X-Ray Diffraction. The X-ray diffraction patterns for (a), shown in Fig. 6, are nearly the same for the 0 and 10% sulfur contents. When sulfur content is 20%, the diffraction pattern of 0% sulfur disappears, a different pattern appearing. For the samples with sulfur contents 40 and 60%, the diffraction pattern corresponding to 20% sulfur content appears accompanied by a different pattern. The diffraction pattern for 60% sulfur is similar to that of the SeS compound.[8] For 90% sulfur, it is similar to that of pure sulfur. The diffraction patterns for (b) (Fig. 7) are sharper than those for (a). When sulfur content is 10%, the diffraction pattern of 0% sulfur appears, its peaks shifting slightly towards small angles; it partly disappears when sulfur content is 20%, a new pattern appears differing

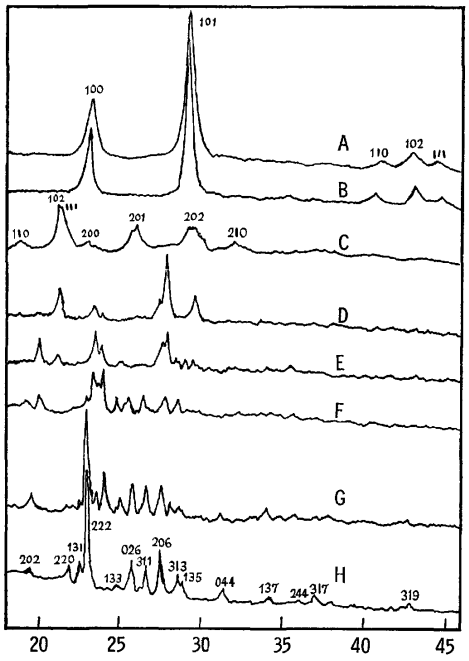

Fig. 6. X-ray diffraction patterns of Se-Te-S crystals containing 10 atom% of tellurium.

from that of (a) with 20% sulfur. The diffraction patterns for 40 and 60% sulfur differ from the pattern for 20% sulfur. The diffraction patterns for 80 and 90% sulfur differ from those for 40 and 60% sulfur, being similar to that of pure sulfur. The diffraction

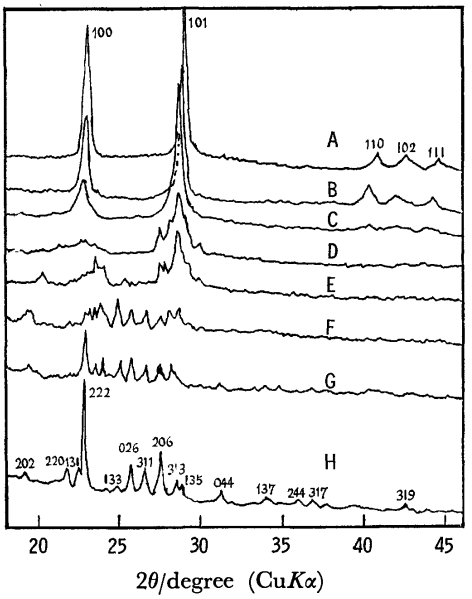

Fig. 8. X-ray diffraction patterns of Se-Te-S crystals containing 30 atom% of tellurium.
S content/atom%
A: 0, B: 10, C: 20, D: 40, E: 60, F: 80, G: 90, H: Pure sulfur (orthorhombic).

patterns for (c) are shown in Fig. 8. When sulfur content is 20%, the diffraction pattern of 0% sulfur partly remains the peaks shifting slightly towards small angles as in (b). The diffraction pattern of 0% sulfur partly remains in those of the Se–Te–S crystals with sulfur contents 40 and 60%. When sulfur content exceeds 80%, the diffraction pattern becomes similar to that of pure sulfur.

Discussion

In (a), the diffraction pattern for 20% sulfur differs entirely from that of the systems with 0 and 10% sulfur. Electric conductivity, activation energy and hardness indicate characteristic behavior when sulfur content exceeds 10%. It can be assumed that the diffraction pattern for 20% sulfur is due to the hexagonal crystal which has a unit cell with size twice Se–Te crystals lattice. Tellurium is substituted into a fixed position of the selenium crystal lattice and sulfur is substituted into a fixed position of the selenium of this lattice. The lattice constant of the new lattice is twice that of Se–Te crystal. It is possible to assign the diffraction pattern (Fig. 6, C). In Se–S crystal, the diffraction pattern differs from that of selenium when sulfur content exceeds *ca.* 7%.[2] In this Se–Te–S crystal (S= 20%), electric conductivity increases abruptly with an increase in tellurium content when tellurium content is below 15% (Fig. 3). For 10% sulfur, no rapid lowering in electric conductivity was observed in the presence of tellurium. No such phenomenon appears when tellurium content exceeds 20% (Figs. 7 and 8). This is due to the fact that sulfur and tellurium form eutectic crystals for large tellurium content. When sulfur content exceeds 80%, the diffraction patterns resemble that of pure sulfur (orthorhombic). It seems

that this causes the electric conductivity to decrease abruptly with an increase in sulfur content when the sulfur content exceeds 80% in (b) and (c).

Emission Spectra of Dimethoxybenzenes by Controlled Electron Impact

Teiichiro OGAWA, Totaro IMASAKA, Minoru TOYODA,
Masaharu TSUJI, and Nobuhiko ISHIBASHI
Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka 812

(Received June 14, 1974)

The emission spectra of *o*-, *m*-, and *p*-dimethoxybenzenes under controlled electron impact excitation (200 eV) were measured in the 220—450 nm region at very low pressures. The photoemissions of the excited parent species and such fragment species as H, CH, CO, and CO^+ were observed and assigned. The relative intensities of the photoemissions of the parent species were compared with those of the fluorescence spectra (photoexcitation) in an *n*-hexane solution. The excited parent species, H, and CH were concluded to be produced in one-electron processes; however, the CO^+ species were assumed to be produced in both one- and two-electron processes, and the relative contributions are evaluated. It was concluded that the rate of the predissociation of *o*-dimethoxybenzene was faster than those of the other two isomers, and the observed characteristics of *o*-dimethoxybenzene had something to do with this faster rate.

Research on molecular excited states has recently been carried out by many investigators, mostly by the photoexcitation method. Among various methods for excitation, the controlled electron impact method has two advantages; (1) the photoemission of excited species can be obtained at very low pressures, where the effect of molecular collision is greatly reduced, and (2) the energy of incident electrons can be controlled externally and continuously from the X-ray energy region (1000 eV) down to the ultraviolet energy region (several eV). Thus, the investigation of emission spectra by this method will be fruitful for the study of the mechanism of the excitation and fragmentation of various molecules.

The emission spectra of various aliphatic[1–3] and aromatic[4–10] molecules produced by this method have been reported, and the mechanism of excitation has been discussed in relation to the intensity measurements. However, no kinetic treatment on the species which may not be produced primarily has ever been carried out. In the present report, the emission spectra of *o*-, *m*-, and *p*-dimethoxybenzenes will be described and the mechanism of their excitation and fragmentation, including species produced secondarily, will be discussed.

Experimental

The electron-impact apparatus is essentially identical with that described in a previous paper.[8] The sample vapor was crossed so as to collide with an electron beam *in vacuo* and the photoemission was observed photoelectrically with a Jarrel-Ash JE 25 monochromator. The slit width used was 100 μ, corresponding to a bandpass of 3.3 Å. The intensity was measured by the peak height of the band at each specified wavelength, where there was negligible overlap with other features.

The dimethoxybenzenes used were obtained from Wako Pure Chemical Ind. They were degassed *in vacuo* a few times just before use.

The relative intensities of the fluorescence were measured with a Hitachi 204 fluorescence spectrophotometer. The solvent, *n*-hexane, was of a non-fluorescent grade (Luminasol) of the Dojindo Co.

Results

Typical emission spectra of *o*-xylene and *o*-dimethoxybenzene in the region of 250—450 nm under electron impact excitation are shown in Fig. 1, where the impact voltage is 300 V and the electron-beam current is 1 mA for *o*-xylene and 200 V and 0.7 mA for *o*-dimethoxybenzene. The characteristic band in the 280—340 nm region of the latter, which overlapped with several sharp bands, was assigned to the electronic transition from the lowest excited singlet state to the ground state of the parent molecule, as in the case of the emission spectra of *o*-xylene,[6] methoxybenzene,[5] and other aromatic molecules,[7–9] since the location of the band was identical to the fluorescence spectra in the n-hexane solution. Many sharp bands in these spectra were assigned to the fragment species. The lines at 434, 410, and 397 nm in both spectra were assigned to the hydrogen Balmer series, and the bands at 431 and 389 nm, to CH ($A^2\Delta$—$X^2\Pi$) and CH ($B^2\Sigma^-$—$X^2\Pi$) respectively. The other bands in the spectrum of *o*-dimethoxybenzene were assigned to the bands of CO and of CO^+, as in the case of methoxybenzene;[5] the bands in the 230—260 nm region, to the first negative system of CO^+ ($B^2\Sigma^+$—$X^2\Sigma^+$), the sharp bands in the 280—330 nm region, to the third positive system of CO ($b^3\Sigma^+$—$a^3\Pi$), and the doublet bands above 336 nm, to the comet-tail

system of CO^+ ($A^2\pi\Pi - X^2\Sigma^+$).

Typical emission spectra of *m*-xylene and *m*-dimethoxybenzene under controlled electron impact excitation are shown in Fig. 2. The band of the A—X transition of *m*-dimethoxybenzene was shifted to wavelengths shorter by several nanometers from that of *o*-dimethoxybenzene, and it is more intense than the latter. Those of *p*-xylene and *p*-dimethoxybenzene are shown in Fig. 3. The band of the A—X transition of *p*-dimethoxybenzene is shifted to wavelengths longer by about 15 nm from that of *o*-dimethoxybenzene, and it is the most intense among the three isomers.

The intensities of the photoemissions of these molecules were determined for various amounts of incident electrons. The dependence of the emission intensities

of the parent molecules of *o*-, *m*-, and *p*-dimethoxybenzenes, and those of H and CH from *m*-dimethoxybenzene, on the electron-beam current are shown in Fig. 4. In all cases, the relative intensity is proportional to the electron-beam current, and an identical relation was obtained for H and CH from the other isomers. The dependence of the emission intensity on the gas pressure was difficult to determine accurately because of the low vapor pressure of dimethoxybenzenes; however, the intensity of the band of *m*-dimethoxybenzene seemed to be proportional to the pressure.

Contrary to these results, the dependence of the emission intensities of the comet-tail bands of CO^+ from dimethoxybenzenes on the electron-beam current failed to show any proportionality. The results are shown in Fig. 5, together with that of CO^+ from CO. A considerable deviation from the linear relationship was observed for CO^+ ($A^2\Pi$) from *m*-dimethoxybenzene, as in the case of CO^+ ($A^2\Pi$) from nitrobenzene;[9] however, the emission of CO^+ ($A^2\Pi$) from CO showed a linear relationship as in the case of CO^+ ($A^2\Pi$) from methanol.[2] Quantitative measurements were difficult for $CO^+(B^2\Sigma^+)$ and for CO

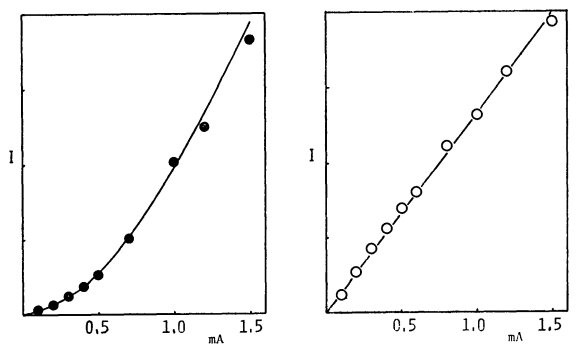

Fig. 5. Dependence of photoemission intensity (*I*, arbitrary units) on the electron-beam current (mA). 200 eV impact.

Right; CO^+ ($A^2\Pi$) from CO (402 nm).

($b^3\Sigma^+$) because of the weak intensity and the band overlap.

Discussion

The three isomers of dimethoxybenzenes give equally the emission spectra of the parent species and of such fragment species as H, CH, CO, and CO^+. While the spectrum of *p*-xylene shows some distinct vibrational structures, no clear structures are observed in the spectra of dimethoxybenzenes. Since the symmetry of the molecule is approximately D_{2h} for *p*-xylene, but lower for *p*-dimethoxybenzene because of the oxygen atoms in the methoxy groups, the spectrum of the latter becomes more diffuse as a result of the increase in the vibrational levels, which interact with the electronic level.

The relative intensities of the A—X transitions of three dimethoxybenzenes to those of the bands of CO^+ differ from each other, as are shown in Figs. 1, 2, and 3; *o*-dimethoxybenzene gives the weakest intensity for the bands of the parent species and the strongest intensity for those of CO^+, while *p*-dimethoxybenzene gives the opposite.

Table 1. Relative emission intensities of the parent species from xylenes and dimethoxybenzenes

isomers			*o*-	*m*-	*p*-
Xylene	photo-excitation	FM[a]	1.3	1.0	1.7
		B[b]	1.1	1.0	2.4
	electron impact[c]		1.2	1.0	2.6
Dimethoxy-benzene	photo-excitation[d]		1.4	1.0	2.8
	electron impact[c]		0.4	1.0	3.2

a) P. M. Froehlich and H. A. Morrison, *J. Phys. Chem.*, **76**, 3566 (1972). b) I. B. Berlman, "Handbook of Fluorescence Spectra of Aromatic Molecules" 2nd Ed. Academic Press. New York (1971). c) Measured at 200 V and 0.1 mA. d) Measured in *n*-hexane solution (7×10^{-6} mol/l).

The relative emission intensities of the parent species from the three isomers of xylenes and of dimethoxybenzenes are shown in Table 1, both for the cases of electron impact excitation (the energy of the electrons was 300 eV; however, the energy which the molecules receive is expected to be around 5—30 eV) and for those of photoexcitation (5.59 eV) in an n-hexane solution. In the case of xylenes, *p*-xylene has a stronger emission band than do *o*- and *m*-xylenes for both methods of excitation. It is noteworthy that there is no notable difference between the results of electron impact excitation and that of photoexcitation, even though the energies in the former method are considerably higher. However, in the case of dimethoxybenzenes, though the relative intensity under photoexcitation is similar to the case of xylenes, the intensity of the photoemission from *o*-dimethoxybenzene by electron impact is remarkably weaker than that of other isomers.

The weak intensity of the band of *o*-dimethoxybenzene under electron impact excitation is probably related to the faster predissociation of the parent molecule from highly excited states. The observation of a more intense photoemission of the fragments from *o*-dimethoxybenzene seems to support this conclusion. Since the sum of the bond-scission energy, the ionization energy (14 eV),[11] and the excitation energy (2.5 eV) of CO^+ ($A^2\Pi$) is larger than the ionization potential of dimethoxybenzenes (7—8 eV),[11] the processes of the production and excitation of CO^+ ($A^2\Pi$) probably involve superexcited species.[12] Identical conclusion can be drawn for H and CH on the basis of similar considerations.[7-9]

The intensities of the photoemission of the parent species, H, and CH were found to be proportional to the electron-beam current, as are shown in Fig. 4. Thus, the mechanism of the production of these excited species was concluded to be one-electron processes for all isomers. However, some secondary process should be involved in the production of CO^+ ($A^2\Pi$) from dimethoxybenzenes, since the linear relation was not established, as is shown in Fig. 5. Ajello did not observe the comet-tail bands of CO^+ in the dissociative excitation of CO_2 by electron impact.[13] In the present study, however, distinct comet-tail bands were observed, and so the mechanism of CO^+ ($A^2\Pi$) production from dimethoxybenzene should be different from that from CO_2.

In the emission spectra by controlled electron impact, the band intensities of photoemission of most of the species have been found to be proportional to the electron-beam current. Two kinds of exceptions have been found; (1) species which have at least two heavy (non-hydrogen) atoms and which are produced through the scission of at least two skeletal bonds (*e.g.*, CN from aniline[9]), (2) species which have to form a new chemical bond on formation (*e.g.*, HCl^+ from chlorobenzene[7]). CO^+ ($A^2\Pi$) from dimethoxybenzene seems to belong to the first group of exceptions; its kinetic behavior was examined in the present study.

Since the emission of CO^+ ($A^2\Pi$) from CO shows a linear relationship (Fig. 5), the non-linear relationship of the photoemission of CO^+ from dimethoxybenzenes is essential to the mechanism of its production from dimethoxybenzenes. This intensity dependence of CO^+ on the electron-beam current can be interpreted by use of the following reaction scheme:

$$M + e \xrightarrow{k_1} CO^{+*} + 2e \quad (1)$$

$$M + e \xrightarrow{k_2} X + e \quad (2)$$

$$X + e \xrightarrow{k_3} CO^{+*} + 2e \quad (3)$$

$$CO^{+*} \xrightarrow{k_4} CO^+ + h\nu \quad (4)$$

where M, e, and X stand for dimethoxybenzene, an electron, and some intermediate species respectively. X may be neutral or ionic; however, X is not such a species as CO_2, as has been mentioned before.

The rate of the appearance of X will be:

$$\frac{d(X)}{dt} = k_2(M)(e) - k_3(X)(e) \quad (5)$$

The second term is assumed to be small and is neglected, since the concentration of X is smaller than that of M

by a few orders of magnitude and since k_3 is not expected to be larger than k_2 by such a magnitude. Then, most of the X produced is removed in the process of evacuation, and the concentration of X is proportional to (M) (e):

$$(X) = k_2'(M)(e) \tag{6}$$

CO^{+*} is produced in Processes (1) and (3) and disappears in the Process (4).

$$\frac{d(CO^{+*})}{dt} = k_1(M)(e) + k_3(X)(e) - k_4(CO^{+*}) \tag{7}$$

The radiative lifetime of CO^{+*} was measured as 2.1—2.9 μs,[14] considerably smaller than the inverval in which the X species remains in the collision region. Thus, the concentration of CO^{+*} can be set as stationary and Equation (7) is equal to 0.
Then,

$$(CO^{+*}) = \frac{k_1(M)(e)}{k_4} + \frac{k_3(X)(e)}{k_4}$$
$$= \frac{k_1(M)(e)}{k_4} + \frac{k_2'k_3(M)(e)^2}{k_4} \tag{8}$$

The intensity (I) of the photoemission of CO^+ ($A^2\Pi$) is proportional to its concentration:

$$I = ak_4(CO^{+*}) \tag{9}$$

where a is a constant. From Eqs. (8) and (9) we obtain:

$$I/e = ak_1(M)(1 + (k_2'k_3/k_1)(e)) \tag{10}$$

The dependence of I/e on e for the bands of CO^+ ($A^2\Pi$) from m-dimethoxybenzene is plotted in Fig. 6. The data reasonably fit a straight line, and so it can be presumed that two-electron dissociative excitation processes, such as (2) and (3), are involved in the production of CO^+ ($A^2\Pi$). From the slopes of the lines, the ratios of CO^+ ($A^2\Pi$) production in the two-electron excitation process to that in the one-electron excitation process, $k_2'k_3/k_1$, are determined to be 1, 5, and 4 for o-, m-, and p-dimethoxybenzenes respectively. Thus, the one-electron process is the most important for o-dimethoxybenzene, which has the weakest parent band and the strongest CO^+ bands.

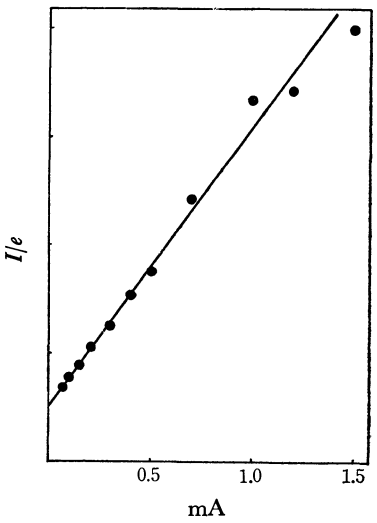

Fig. 6. Dependence of I/e (arbitrary units) on e (mA) for m-dimethoxybenzene at 200 eV.

It may be concluded that the intra-molecular interaction of two adjacent methoxy groups makes the molecule unstable in the highly excited states and that the rate of Process (1) (predissociation) for o-dimethoxybenzene becomes much faster than those of other isomers. This faster rate of Process (1) in o-dimethoxybenzene is concluded to be responsible for the smaller $k_2'k_3/k_1$ ratio; this interaction and the resulting instability of highly excited states probably have something to do with the weaker intensity of the photoemission of the parent species (Table 1). The evaluation of the contribution of the highly excited states on the photoemission by the cascading process in such large molecules has scarcely been studied; a recent investigation of naphthalene has, however, shown the importance of cascading processes.[10]

Although the investigation of CO^+ ($B^2\Sigma^+$) and CO ($b^3\Sigma^+$) as described here will be useful in clarifying the mechanism of the fragmentation of dimethoxybenzene, the research will be left for future study, because of the difficulties involved in the intensity measurements of these species.

The results presented above indicate the usefulness of the controlled electron impact method for the study of the excited states and their reactions.

The Molecular Vibrations and Rotational Isomerism of Chloro(chloromethyl)silane[1]

Keiichi SERA*

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730

(Received June 22, 1974)

The infrared spectra of chloro(chloromethyl)silane, $ClCH_2SiH_2Cl$, and its deuterated species, $ClCH_2SiD_2Cl$, have been measured in the gaseous, liquid, and crystalline states. The Raman spectra have also been measured in the liquid state. The vibrational spectra have shown that two rotational isomers coexist in the gaseous and liquid states, while only one isomer persists in the crystalline state. The fundamental vibrations have been assigned for each isomer. The product rule, the calculation of the skeletal frequencies, and the band contours have indicated that the isomer persisting alone in the crystalline state is the *trans* form and that the other isomer is the *gauche* form. The solvent effects of the spectra have shown that the *gauche* form is more polar than the *trans* form. The normal vibrations have been calculated in a modified Urey-Bradley force field, and the force constants have been adjusted to predict well the observed frequencies for the isomers of both the parent and its deuterated species.

Many studies have been accumulated concerning the rotational isomerism of 1,2-substituted ethanes.[2] We have taken an interest in studying organosilicon compounds of these homologous series, in which the height of the potential barrier around a C–Si bond may be lower than that around a C–C bond.[3] Investigations of such organosilicon compounds as chloroethylsilane,[4] (chloromethyl)methylsilane,[5] and ethylmethylsilane[5] have been reported previously. Chloro(chloromethyl)silane is a molecule in which both the substituents around the C–Si bond are chlorine atoms; it is a homologous molecule of 1,2-dichloroethane, which has previously been investigated in detail.[6]

Therefore, in this paper, we will deal with the molecular vibrations of chloro(chloromethyl)silane in relation to the rotational isomerism in order to compare the results with those of 1,2-dichloroethane and the analogues of alkylsilanes. By methods similar to those used for 1,2-dichloroethane; that is, the product rule and the calculation of the skeletal frequencies, the molecular forms of the isomers will be determined. The normal vibration calculation will also be carried out for each molecular form in a modified Urey-Bradley force field, and the force constants will be adjusted by a least-squares method in order to predict the observed frequencies well.

Experimental

Tetrachlorosilane was treated with diazomethane,[7] and the product ($ClCH_2SiCl_3$) was reduced with $LiAlH_4$ or $LiAlD_4$ in *n*-butyl ether.[8] Chloromethylsilane was then reacted with $HgCl_2$ in a vacuum.[9] The sample of chloro(chloromethyl)silane was purified by distillation in a dry nitrogen atmosphere; bp 75—76 °C/760 mmHg.

The infrared spectra were recorded on a Perkin-Elmer instrument (Model 621) in the 200—4000 cm^{-1} region and on a Hitachi Fis-3 far-infrared spectrophotometer in the 40—300 cm^{-1} region. The spectra in the liquid state were recorded in CsI and polyethylene cells. The spectra in the gaseous state were measured at room temperature with a 10-cm gas cell fitted with CsI windows. In the crystalline state, the vapor of the sample was condensed on a CsI window cooled with liquid nitrogen in a vacuum and was then annealed near the melting point. The solution spectra were measured using a sealed KRS-5 cell (0.2 mm thick), with *n*-hexane and acetonitrile as the solvents. The Raman spectra in the liquid state were measured with a JEOL Raman spectrometer (Model JAS-O2AS), using an argon-ion laser (488.0 nm) for excitation.

Results and Discussion

Rotational Isomerism. It has been determined by microwave studies that such molecules as chloromethylsilane[10] and dimethylsilane[11] have a staggered con-

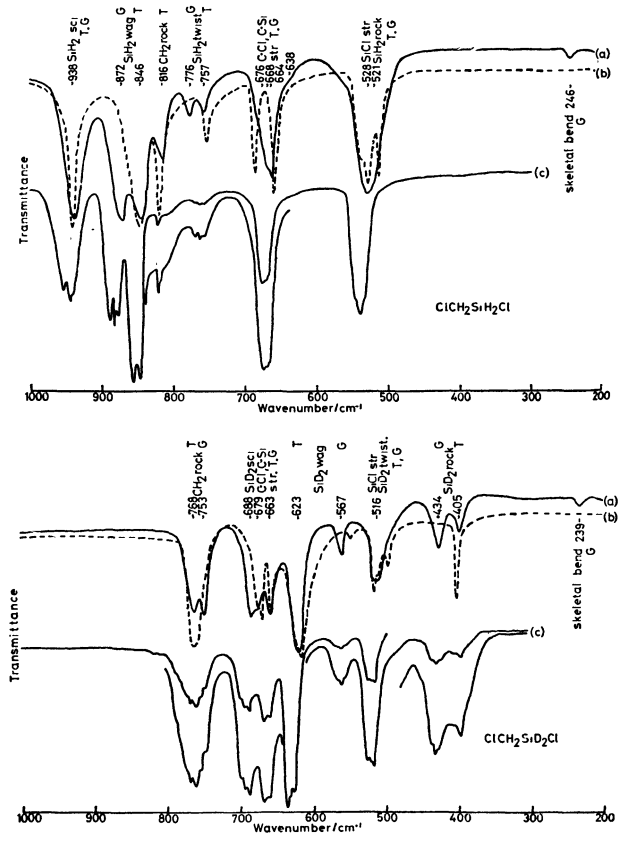

Fig. 1. Infrared spectra of chloro(chloromethyl)silane in the 200—1000 cm^{-1} region; (a): in the liquid state, (b): in the crystalline state, (c): in the gaseous state.

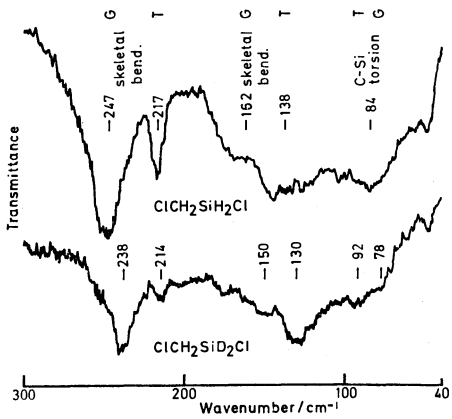

Fig. 2. Far-infrared spectra of chloro(chloromethyl)-silane in the liquid state in the 40—300 cm^{-1} region.

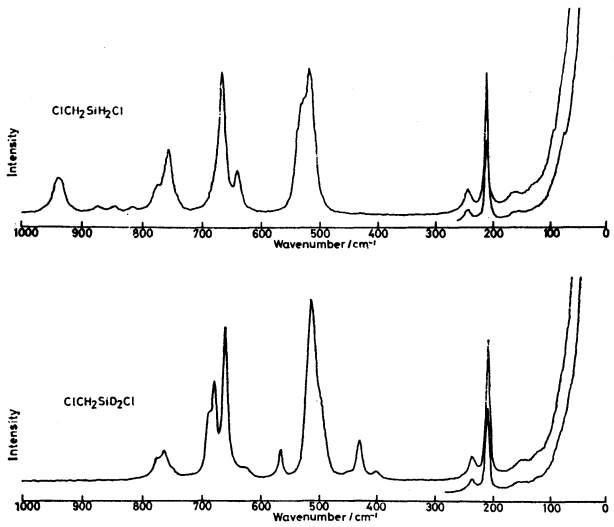

Fig. 3. Raman spectra of chloro(chloromethyl)silane in the liquid state in the region below 1000 cm^{-1}.

figuration around a C–Si bond. Therefore, in this substance, two rotational isomers of the *trans* and *gauche* forms can be expected. If this substance had a unique molecular form, it would show eighteen fundamental frequencies in both the infrared and Raman spectra.

Figures 1—2 and Fig. 3 show the infrared spectra in the 40—1000 cm^{-1} region and the Raman spectra in the region below 1000 cm^{-1} respectively. In the vibrational spectra, too many bands for one isomer are observed in the liquid state, while the absence of some of the bands in the crystalline state shows the existence of the rotational isomers in the liquid state. In the crystalline state, however, the existence of only one isomer is sufficient to account for the number of observed bands.

The vibrational assignments of this substance are made on the basis of the spectra of (chloromethyl)silane[12] and chloromethylsilane,[13] the relative intensities of both the infrared and Raman bands, and the infrared-band contours in the gaseous state. From the assignments of the observed spectra, given in Table 1, the sums of the squares of the fundamental frequencies are found to be:

$$\sum \nu_i^2 = 3.638 \times 10^7 \quad (0.1\% \text{ difference})$$
$$\sum \nu'^2_i = 3.639 \times 10^7$$

for $ClCH_2SiH_2Cl$ and:

$$\sum \nu_i^2 = 3.044 \times 10^7 \quad (0.2\% \text{ difference})$$
$$\sum \nu'^2_i = 3.038 \times 10^7$$

for $ClCH_2SiD_2Cl$, where ν_i and ν'_i indicate the frequencies of the isomers persisting and disappearing in the crystalline state respectively. From the above results, the assignments in Table 1 can be considered as acceptable.

Band Contours. The principal moments of inertia are calculated from the following parameters: C–Cl= 1.788 Å, C–Si=1.889 Å, Si–Cl=2.052 Å, C–H=1.096 Å Si–H=1.477 Å, tetrahedral bond angles, and the internal rotation angles of 180° (*trans*) and 60° (*gauche*). The bond lengths are transferred from those of (chloromethyl)silane[10] and chloromethylsilane[14] determined by microwave studies. Figure 4 shows the *trans* and *gauche* forms of chlorochloromethylsilane in the principal axis system. The *trans* form of this substance may have the C_s symmetry. The 18 normal vibrations are reduced to 11 vibrations of the A′ species and 7 of A″. The a and b internal axes are in the plane of symmetry, while the c axis is perpendicular to it. The A′ vibrations may have either a-, b-, or ab-type infrared-band contours in the case of an asymmetric top. The A″ vibrations, on the other hand, have c-type band contours. The *gauche* form may have no symmetry (point group C_1). All the 18 normal vibrations are of the same symmetry of A.

The principal moments of inertia of I_a, I_b, and I_c calculated are 31.742 (38.838), 424.52 (427.66), and 447.17 (451.55) amu·Å² for the *trans* form of $ClCH_2SiH_2(-D_2)Cl$ and 87.086 (95.978), 275.95 (281.16), and 338.37 (346.60) amu·Å² for the *gauche* form. The Ray asymmetry parameters, κ, are −0.9918 (−0.9895) and −0.8432 (−0.8218) for the *trans* and *gauche* forms of $ClCH_2SiH_2(-D_2)Cl$ respectively; these values show both the forms to be prolate asymmetric top molecules. The expected PR separations are calculated by the use of the method of Seth-Paul and Dijkstra.[15] The

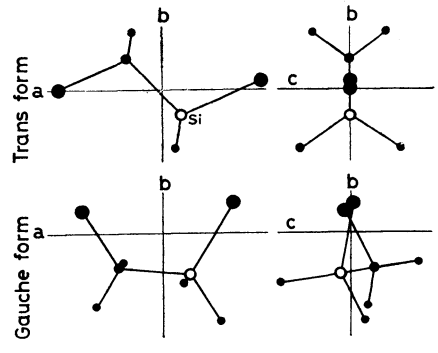

Fig. 4. Possible molecular forms of chloro(chloromethyl)-silane in the principal axis system.

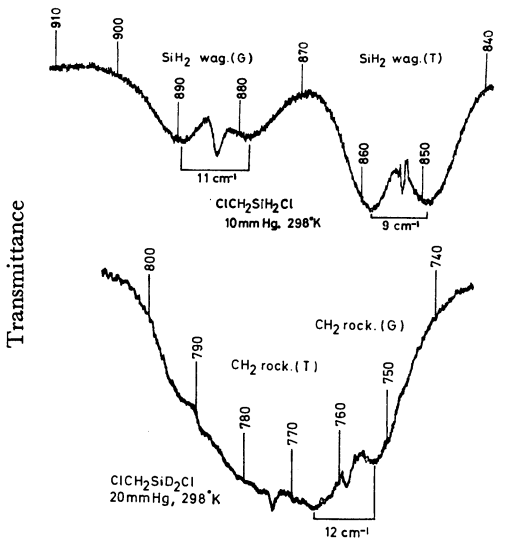

Fig. 5. Infrared band contours of the SiH_2 wagging vibration for $ClCH_2SiH_2Cl$ and the CH_2 rocking vibration for $ClCH_2SiD_2Cl$.

PR separations of the a-, b-, and c-type band contours at the temperature of 298 K are estimated to be 9.6 (9.6), 8.0 (8.0), and 14.4 (14.3) cm^{-1} for the *trans* form of $ClCH_2SiH_2(-D_2)Cl$ and 11.6 (11.6), 9.5 (9.4), and 17.5 (17.4) cm^{-1} for the *gauche* form, where the c-type band contours are expected to produce a PQR structure featuring a sharp Q branch but ill-defined P and R branches.[16]

The PR separations of $ClCH_2SiH_2(-D_2)Cl$ observed are between 8 and 12 cm^{-1}, as is shown in Fig. 5 and Table 1. Especially, for the bands assigned to the SiH_2 wagging vibration, the PR separation of the band at 883 cm^{-1} (11 cm^{-1}) is larger than that of the band at 853 cm^{-1} (9 cm^{-1}), where the former disappears in the crystalline state. The bands assigned to the CH_2 and SiD_2 rocking vibrations and persisting in the crystalline state (the band at 820 cm^{-1} for $ClCH_2SiH_2Cl$ and the bands at 774 and 403 cm^{-1} for $ClCH_2SiD_2Cl$) have c-type band contours, while the corresponding bands disappearing in the crystalline state (the bands at 759 and 436 cm^{-1} for $ClCH_2SiD_2Cl$) feature PQR structures with PR separations of 11—12 cm^{-1}. The results are consistent with the determination of the molecular forms using the product rule and the calculation of the skeletal frequencies to be described below.

Molecular Forms of Isomers. It has been mentioned by Mizushima *et al.*[6] that the product rule and the calculation of the skeletal frequencies are useful for the determination of the molecular forms of the rotational isomers.

The products of the fundamental frequencies are:

$$\pi\nu_i'/\pi\nu_i = 1.146$$

for $ClCH_2SiH_2Cl$ and:

$$\pi\nu_i'/\pi\nu_i = 1.099$$

for $ClCH_2SiD_2Cl$, where ν_i and ν_i' indicate the frequencies of the isomers persisting and disappearing in the crystalline state respectively. When it is assumed that the force field is identical for both the rotational isomers, the relationship between the frequencies of the two isomers is:

$$\pi\nu_i'/\pi\nu_i = (|G(\nu')|/|G(\nu)|)^{1/2}.$$

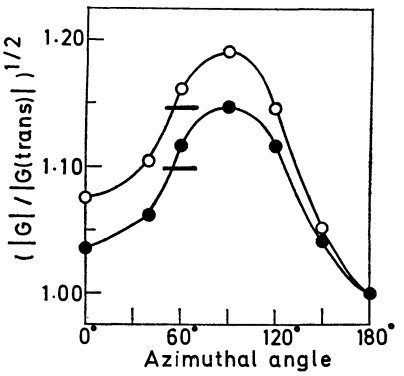

Fig. 6. The calculated values of $(|G'|/|G(trans)|)^{1/2}$ and the observed values of $\pi\nu'/\pi\nu(trans)$;
—○—: $(|G'|/|G(trans)|)^{1/2}$ for $ClCH_2SiH_2Cl$,
—●—: $(|G'|/|G(trans)|)^{1/2}$ for $ClCH_2SiD_2Cl$,
——: observed values.

Figure 6 gives the calculated values of $(|G|/|G(trans)|)^{1/2}$ of a different azimuthal angle, where it is assumed that this substance has a staggered configuration. This shows that the bands persisting in the crystalline state are attributable to the *trans* form and that the bands disappearing in the crystalline state are attributable to the *gauche* form.

In order to confirm the above results, the skeletal frequencies of the parent species are calculated on the basis of the simple Urey-Bradley force field. The force constants used are K(C–Cl)=2.90, K(C–Si)=2.80, K(Si–Cl)=2.59, H(Cl–C–Si)=0.093, H(C–Si–Cl)=0.117, F(Cl·C·Si)=0.21, and F(C·Si·Cl)=0.16 md/Å. The bending and repulsion force constants are transferred from those of (chloromethyl)silane[12] and

a) Int.=intensity; s, m, w=strong, medium, weak; v=very; b=broad; sh=shoulder; T=the *trans* isomer; G=the *gauche* isomer; A′, A″=A′ symmetry species, A″ symmetry species; P.E.D.=potential energy distributions; and ν, s, w, t, r, δ, τ=stretching, scissoring, wagging, twisting, rocking, deformation, torsion. b) Only contributions greater than 20% are included.

chloromethylsilane.[13] Figure 7 shows the dependence of the calculated skeletal frequencies for a different azimuthal angle, where the highest-frequency band observed vanishes in the crystalline state. If this substance had a staggered configuration, the isomer disappearing in the crystalline state would be the *gauche* form, though the calculated frequencies do not satisfactorily reproduce the observed frequencies. Therefore, the previous conclusion of the molecular form determined from the product rule is confirmed.

Solvent Effects of the Spectra. The solvent effects of the infrared spectra are measured using the pair band assigned to the SiD_2 rocking vibrations at 434 and 405 cm^{-1}, where the former disappears in the crystalline state. The band at 434 cm^{-1} increases in its relative intensity when it is mixed with a polar solvent such as acetonitrile, while the band at 405 cm^{-1} increases in its relative intensity in a mixture with a non-polar solvent such as *n*-hexane, as is shown in Fig. 8. Therefore, it can be concluded that the isomer persisting in the crystalline state (the *trans* form) is less polar than the other (the *gauche* form).

On the basis of these results, if the C–Cl bond moment is assumed to have the direction of C^+–Cl^-, the group moment of the $CSiH_2(-D_2)Cl$ group should be mainly in the direction of Si^+–Cl^-, though it has been reported that, for (chloromethyl)methylsilane,[5] the group moment of the C_2SiH_2 group is $+\overset{C}{\underset{C}{>}}Si\overset{H}{\underset{H}{<}}-$ on the bisector of the C–Si–C angle. Therefore, the bond moment of SiCl may be larger than the group moment of C_2SiH_2.

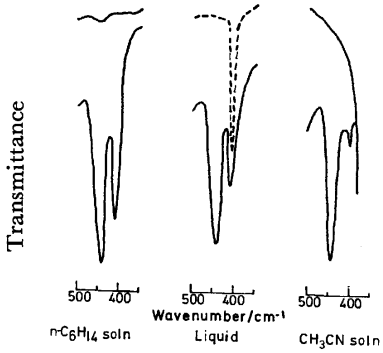

Fig. 8. Solvent effects of the infrared spectra.

Normal Vibration Calculation. The normal vibrations of chloro(chloromethyl)silane were calculated in order to get a reliable set of force constants. The bond lengths and angles used were of the same values used in the calculation of the moments of inertia.

First, we attempted to determine the force constants in the modified Urey-Bradley force field for (chloromethyl)silane[12] and chloromethylsilane[13] and their deuterated species, $ClCH_2SiD_3$ and CH_3SiD_2Cl, in order to get a set of transferable force constants. Second, we tested it for the case of this substance and found that, among the calculated frequencies, the skeletal vibrational frequencies were not in good agreement with the observed frequencies especially. Therefore, the force constants were adjusted by a least-squares method in order to predict well the observed frequencies for both the *trans* and *gauche* forms of the parent and its deuterated species as the assumption that the repulsion force constants were transferable. Modifications of the force field were also made as follows: 1) the bond interaction force constant, p(C–H), was introduced in order to reproduce the observed C–H stretching frequencies and 2) the *trans* coupling constants, $t(CH_2, SiH_2)$, $t(SiCCl, SiH_2)$, and $t(CSiCl, SiCCl)$ were introduced in order to reproduce satisfactorily the observed frequencies of the CH_2 and SiH_2 groups and the skeletal deformation frequencies, where the *gauche* couplings were assumed to be $g=-0.5t$. As a fair agreement was obtained between the observed and calculated frequencies, no further adjustments of the force constants were made.

The calculated frequencies are given in Table 1, together with the predominant internal symmetry coordinates in the potential energy distributions. The force constants obtained are given in Table 2, together

a) The units of the force constants are in md/Å for stretching, K; bending, H; repulsion, and F; bond interaction, p; and in md·Å for intramolecular tension, κ; and *trans* coupling, t. b) Ref. 12. c) Ref. 13. d) The *gauche* coupling constants are assumed to be $g=-0.5\,t$.

with those of (chloromethyl)silane and chloromethylsilane. The values of the adjusted force constants, except for these of the skeleton, are similar to those of such analogues as (chloromethyl)silane and chloromethylsilane; under the repulsion-force constants we fixed the transferred values. However, all the values of the skeletal stretching constants are considerably smaller than those of the analogues. It is interesting to note that the higher-frequency band for the SiH_2 wagging vibration and the lower-frequency band for the SiD_2 wagging vibration vanish in the crystalline state. The potential energy distributions indicate that this is mainly due to the coupling with the CH_2 rocking vibration in the 750—820 cm^{-1} region. The tendency of the $SiH_2(\text{-}D_2)$ wagging and SiD_2 rocking vibrations between the liquid and crystalline states is the same as those of (chloromethyl)methylsilane and ethylmethylsilane.[5]

The author wishes to express his gratitude to Professor Hiromu Murata and Professor Michiro Hayashi of Hiroshima University for their valuable suggestions and kind encouragement. He also wishes to express his thanks to Professor Tatsuo Miyazawa and Dr. Teizo Kitagawa for the use of the far-infrared and Raman spectrophotometers and to Mr. Tsutomu Sato for his help in the syntheses of the samples.

Electronic Spectra and Electric Properties of Poly(1-methyl-4-vinylpyridinium)-TCNQ Salt

Kenji NAKATANI, Tadayoshi SAKATA, and Hiroshi TSUBOMURA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received June 24, 1974)

Electronic spectra and conductivities of poly(1-methyl-4-vinylpyridinium)-TCNQ anion radical salts and complex salts which contain additional neutral TCNQ were studied. By addition of neutral TCNQ, a new electronic absorption band appears at 3500 cm^{-1} and the charge-transfer band between TCNQ anion radicals disappears. It was concluded that this new absorption band is the charge-resonance band between a TCNQ anion radical and neutral TCNQ molecule from the dependence of its absorption intensity on the amount of added neutral TCNQ. The conductivity of the salt changed from 7×10^{-8} to 8×10^{-3} Ω^{-1} cm^{-1} by inclusion of the neutral TCNQ. This change of conductivity was explained in relation with the change of the absorption spectra of these polymer salts.

The salts of tetracyanoquinodimethane(TCNQ) anion radical have high electrical conductivity which depends on the properties of the counter cations and the whole crystal structure.[1,2] There are many kinds of crystals of the type $M^+(TCNQ)_n^-(n>1)$.[3,4] The relation between the crystal structure[5] and anisotropy of the electrical conductivity[6] shows that the conduction arises from the transfer of unpaired electrons through the TCNQ molecules which are stacked face-to-face.[3,4] The optical properties of TCNQ salts were discussed in connection with the motion of unpaired electrons.[7] Iida obtained electronic spectra of various TCNQ salts from diffuse reflectance spectra and found that some salts have intense bands in the infrared region besides the charge-transfer bands.[8,9] Kondow and Sakata found that the infrared absorption spectra show a remarkable temperature dependence and explained it by employing a singlet-triplet model and a band model.[10]

Poly-4-vinylpyridinium TCNQ salt is a film-forming polymer salt,[11,12] suitable for the measurement of electronic spectra. Lupinski *et al.* reported that the conductivity of poly-2-vinylpyridinium TCNQ salt increases remarkably by addition of neutral TCNQ.[11] Recently, Mizoguchi *et al.* proposed the conduction mechanism of TCNQ salts of ionene polymers.[13]

In this paper we report the electronic spectra and electrical conductivity at various temperatures of poly-4-vinyl-pyridinium TCNQ salt ($P4VP^+TCNQ^-$) and complex salts ($P4VP^+TCNQ^-TCNQ_x$) ($0\leqq x<1.5$).

Experimental

Synthesis. Poly(1-methyl)-4-vinylpyridinium TCNQ salt and the complex salts including neutral TCNQ were synthesized according to the method in the literature.[11]

Electronic Spectra. The polymer salt was dissolved in dimethylformamide under nitrogen atmosphere. By evaporation on a quartz plate, a coherent film was deposited. The electronic absorption spectra of films were measured with a Shimadzu: SL-50L spectrometer.

Infrared Absorption Spectra. A coherent film was deposited on a thin aluminum mirror, which was prepared by evaporating aluminum on a glass surface. The infrared absorption spectra were measured with a Hitachi-Perkin Elmer infrared spectrometer, and a reflectrance apparatus we made, shown in Fig. 1.

Electrical Conductivity. The electrical conductivity was measured with a compaction sample prepared by pressing at 50 kg/cm^2, with a Yokogawa-Hewlett Packard Model 4305 A Volt-Ohm meter. The temperature dependence of the electrical resistance was measured *in vacuo* by use of a surface-type cell, consisting of a sample film and vacuum-evaporated Au electrodes.

Results

Electronic Spectra. Both $P4VP^+TCNQ^-$ and $P4VP^+TCNQ^-TCNQ_x$ form homogeneous green films.[11] As Fig. 2 shows, the spectrum of $P4VP^+TCNQ^-$ changes by inclusion of neutral TCNQ so that the charge-transfer band between $TCNQ^-$s at around 9000 cm^{-1} disappears and a new band appears in the near infrared region below 7000 cm^{-1}. As shown

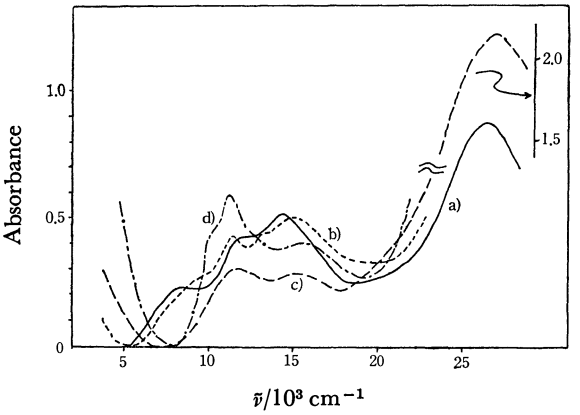

Fig. 2. Absorption spectra of $P4VP^+TCNQ^-TCNQ_x$ polymer films at various mole ratio (x) of added neutral TCNQ:
a) 0, b) 0.5, c) 1.0, d) 1.5.

in Fig. 3, by increasing the amount of neutral TCNQ, the intensity of the new infrared band increases to a mole ratio of about 1.0 and levels constantly. Figure 4 shows the infrared spectrum measured by the mirror reflection method. The new infrared absorption band

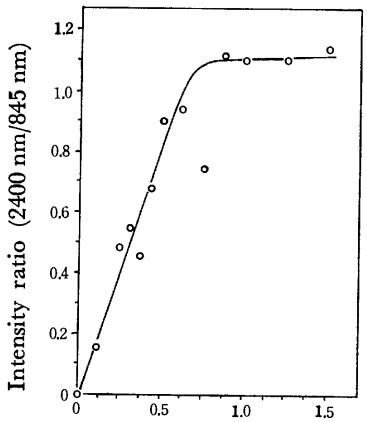

Fig. 3. The dependence of intensity of the new IR band (at 2400 nm) on the neutral TCNQ content.

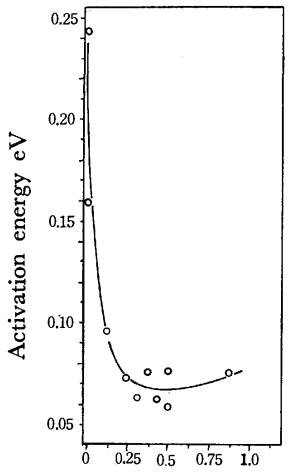

Fig. 7. The dependence of activation energy (E_a) on the neutral TCNQ content.

is seen to have a maximum near 3500 cm^{-1}.

Electrical Properties. The electrical conductivities of powdered samples are shown in Fig. 5 at various mole ratios of neutral TCNQ *vs.* polymer TCNQ salt. With increasing neutral TCNQ, the conductivity changes from 7×10^{-8} to 8×10^{-3} Ω^{-1} cm^{-1} and has a maximum at about a mole ratio of 0.5. The conductivity decreases with the addition of more neutral TCNQ. Log R(electrical resistance) *vs.* T^{-1} (Fig. 6) gives good straight lines for both P4VP+TCNQ- and P4VP+TCNQ-TCNQ$_{1/2}$.

As shown in Fig. 7, the activation energy(E_a) calculated from $R(\Omega)\propto\exp(E_a/KT)$ changed from 0.24 eV for the sample containing no neutral TCNQ to 0.07 eV for the sample containing neutral TCNQ. The variation of activation energy with the TCNQ content has a relationship similar to that of the electrical conductivities (see Figs. 5 and 7) and has a minimum near the mole ratio of 0.5.

Discussion

Absorption Spectra. Poly-4-vinylpyridine is an atactic polymer[11] but the structures of the polymer

TCNQ salts are not known. The absorption spectra of the films are similar to those of other TCNQ salts. It can therefore be presumed that in these polymer salts the TCNQ molecules are packed face-to-face forming somewhat irregular columns as in other TCNQ salts whose crystal structures[5] are known.

The band of P4VP+TCNQ$^-$ at *ca.* 9000 cm^{-1} (Fig. 2) can be assigned to a charge transfer band arising from the charge transfer between the highest half occupied orbitals of TCNQ$^-$ molecules.[8,9] The CT energy has been calculated by use of the SCF-MO method.[14] We measured the absorption spectra of films at various temperatures, from 150 K to room temperature. It was found that the intensity of the CT band increases by lowering the temperature. This suggests that an antiferromagnetic interaction arises between odd electrons of TCNQ$^-$ molecules.[15] The band at *ca.* 11000 cm^{-1} is assigned to the TCNQ$^-$ monomer since the band resembles that of TCNQ$^-$ in EtOH.[16] The band at *ca.* 15000 cm^{-1} (Fig. 2) is attributable to aggregated TCNQ$^-$s since the band resembles that of the TCNQ$^-$ dimer in an aqueous solution[16] and of solid TCNQ$^-$ salts.[8,9]

In the absorption spectra of complex salts with growing amount of neutral TCNQ, the intensity of the CT band at 9000 cm^{-1} decreases and a new absorption band in the IR region below 7000 cm^{-1} arises (Figs. 2 and 3). The intensity of the TCNQ$^-$ monomer band at 11000 cm^{-1} increases relative to that of the TCNQ$^-$ aggregation band at 15000 cm^{-1}. These results can be explained by taking into consideration the fact that added neutral TCNQ is introduced into the TCNQ column as shown by $\langle\cdots A^{\circ}A^{-}A^{\circ}A^{-}A^{\circ}\cdots\rangle$ so that the anion radicals are separated from each other by it. From the two results described above, it seems probable that the new IR absorption band is a charge-resonance band between TCNQ$^-$ and neutral TCNQ. This charge-resonance band is shown to have a peak at 3500 cm^{-1}. Figure 8 illustrates the transitions corresponding to the CT absorption between TCNQ$^-$s and the charge-resonance absorption between TCNQ$^-$ and neutral TCNQ by adopting dimer models.

We have estimated the resonance integral $\langle\phi(A^{-}A^{\circ})|H|\phi(A^{\circ}A^{-})\rangle$ to be *ca.* 0.2 eV from the maximum position of the charge resonance band at ~0.4 eV. This value agrees in the order of magnitude with values obtained by other methods.[7,17] The intensity of this charge-resonance band saturated at about the mole ratio of one neutral TCNQ molecule to one TCNQ$^-$ ion (Fig. 3). This shows that the number of neutral TCNQ molecules which can be inserted into the TCNQ$^-$ column is *ca.* one per one TCNQ$^-$. The CT absorption between TCNQ$^-$ molecules disappeared at a mole ratio of 1.0, suggesting that the neutral TCNQ molecule is evenly distributed and TCNQ$^-$ is isolated (Fig. 2).

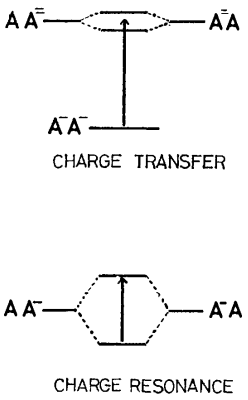

Fig. 8. Schematic illustration of the charge transfer and charge resonance absorptions.

Electrical Properties. According to Onodera's measurements of compressed powder samples, the electrical resistances of both P4VP+TCNQ$^-$ and P4VP+-TCNQ$^-$TCNQ drop rapidly by applying pressure up to *ca.* 100 kbar.[18] This shows that the conduction is due to electron motions[19,20] along the TCNQ column as seen in other TCNQ salts.[21]

The electrical conduction in the solid P4VP+TCNQ$^-$ can be attributed to an electron transfer from a TCNQ$^-$ anion to another, forming TCNQ^0···TCNQ^{2-}.[22] The charge-transfer spectrum, on the other hand, corresponds to an electron transfer from one TCNQ$^-$ to an adjacent TCNQ$^-$. For the usual solid, this corresponds to an excited state, its energy being still much lower than the conduction state. However, in the present case, the two states lie close to each other, because of the lack of coulombic attraction between the hole, TCNQ^0, and electron, TCNQ^{2-}. In the case of the complex salt containing neutral TCNQ, the conduction state corresponds to the charge resonance between TCNQ and TCNQ$^-$, and, hence, corresponds in energy to the charge-resonance band we observed. The absorption spectra of P4VP+TCNQ$^-$ polymer films show that the CT band between TCNQ ions is rather intense and the local excitation bands shift largely as compared with those of monomer ion in solution. This suggests that the interaction between TCNQ$^-$s is not weak in this polymer matrix. The mobility of a carrier is related to the resonance integral expressed as $\beta=\langle\phi_n|H|\phi_{n+1}\rangle$, where ϕ is the lowest vacant molecular orbital of TCNQ, and the suffix n represents the site number.[17] Oohashi and Sakata reported that the resonance integral between the half-occupied orbitals of TCNQ$^-$ is 0.15~0.4 eV, depending on the kind of salt investigated, from the intensity of CT band of reflection spectra.[17] From our preliminary ESR measurement for P4VP+TCNQ$^-$, exchange energy (J) was obtained to be about 0.06 eV and the resonance integral was was calculated as ~0.12 eV by means of the equation $J=4\beta^2/E_{CT}$(E_{CT}=CT energy) which holds for the linear chain radical crystal.[23] This value is slightly smaller than the resonance integral 0.2 eV for the complex salt estimated from the peak position of the charge-resonance band.

Since the difference in resonance integral is small, it can be concluded that the mobility of the simple salt does not differ so much from that of the complex salt.

The variation of conductivity with the mole ratio is parallel to that of activation energy obtained from temperature dependence of resistance (Figs. 5 and 7).

The band gap from the lowest wavelength absorp-

tion edge can be roughly estimated as $\Delta E_1=0.74$ eV for P4VP$^+$TCNQ$^-$ and $\Delta E_2=0.18$ eV for P4VP$^+$TCNQ$^-$-TCNQ, if the CT band and the charge-resonance band are assumed to correspond to transitions from the valence band to the conduction band. The number of carriers per unit cell is assumed to be N for P4VP$^+$-TCNQ$^-$ and 1/2 N for P4VP$^+$TCNQ$^-$TCNQ. Then, the ratio of conductivity σ_c(P4VP$^+$TCNQ$^-$TCNQ)/σ_s(P4VP$^+$TCNQ$^-$) can be represented by the equation

$$\sigma_c/\sigma_s=e\mu 2^{-1}N\exp(-\Delta E_1/2kT)/e\mu N\exp(-\Delta E_2/2kT),$$

which leads to 2.5×10^4 with use of the above values of of ΔE_1 and ΔE_2. This value is in good agreement with the experimental result of the variation of conductivity. Thus, contrary to the explanation given by Mizoguchi *et al.*,[13] the remarkable difference in conductivity might be attributed to the difference in the band gaps. The band gap estimated from the temperature dependence of resistance is about 0.14 eV for P4VP$^+$TCNQ$^-$TCNQ, which is also in good agreement with $\Delta E_2=0.18$ eV obtained from the absorption spectrum. For P4VP$^+$-TCNQ$^-$, the band gap estimated from the activation energy is *ca.* 0.48 eV and smaller than the value, 0.74 eV, obtained from the absorption spectrum, which can be interpreted as giving the lower limit for the band gap. The discrepancy seems to arise from the presence of a trace of neutral TCNQ in P4VP$^+$TCNQ$^-$. Most samples of P4VP$^+$TCNQ$^-$ contain neutral TCNQ. By extracting with benzene, the electrical conductivity of the sample decreases. However, it seems impossible to exclude all the neutral TCNQ which behaves as electron-accepting impurities from the polymer salt.

The intensity of charge-resonance band saturates at over 1.0 mole ratio of neutral TCNQ (Fig. 3). This suggests that the column can include neutral TCNQ molecules as long as the mole ratio becomes 1.0 with TCNQ$^-$ and TCNQ packed one by one, and the TCNQ molecules further added are present at the interstices. The present view also explained the results of conductivities (Fig. 5). The decrease in conductivity at the higher TCNQ content can be attributed to the increasing amount of neutral TCNQ present in the interstices which hinders the electron transfer. The results show that the conductivity shows a maximum at the TCNQ content much lower than unity. This might suggest that, at an increasing TCNQ content, there grows a chance for two TCNQ molecules being packed between two TCNQ$^-$ ions.

In conclusion, the polymer TCNQ salts can be classified into four types according to the neutral TCNQ content.

(1) P4VP$^+$TCNQ$^-$, which does not contain neutral TCNQ and whose conduction state arises from the charge transfer between TCNQ$^-$s.

(2) A salt containing a small amount of neutral TCNQ which acts as an electron-accepting impurity. The situation seems to be analogous to the impurity-doped semiconductor.

(3) P4VP$^+$TCNQ$^-$TCNQ ($0.25<x<1.0$). The conducting state arises from the charge-resonance interaction between TCNQ$^-$ and TCNQ, acquiring quite a different electronic structure from that of P4VP$^+$-TCNQ$^-$. (4) P4VP$^+$TCNQ$^-$TCNQ ($x>1.0$), containing a large amount of neutral TCNQ. The presence of excess neutral TCNQ diminishes the electronic conduction.

(Received July 17, 1974)

Ultrasonic absorption in aqueous solutions of *n*-propyl alcohol was measured in the frequency range of 4.5—220 MHz and in the concentration range of 2.0—13.4 M at 25 °C. Two different relaxation processes were observed; they were attributed to the perturbation of the equilibria expressed by $AB \rightleftarrows A \rightleftarrows 1/3A_3$ where A and B are a single water molecule and an alcohol molecule respectively. The forward and backward rate constants for the two processes were determined from the concentration dependences of the relaxation frequencies. Furthermore, the influence of *n*-propyl alcohol on the water structure was discussed; the addition of *n*-propyl alcohol to liquid water was concluded to promote the water structure.

Because of the predominance of water as the medium in living systems, the hydrogen-bonding properties of water have been of particular interest to chemists and biologists. The effects of electrolyted on the structure of water have attractes considerable attention in recent years, but relatively little work has been published dealing with the solution properties and hydrodynamic behavior of neutral solutes. During the course of an investigation of the properties of aqueous solutions of several amines[1-5] by means of ultrasonic absorption, it became desirable to understand the properties of alcohols in aqueous solutions. The physico-chemical properties of aqueous solutions of alcohols have been studied by many authors[6-9], and the ultrasonic techniques[10-13] have also been applied to the investigation of these solutions. However, though Blandamer and his co-workers[14] have reported on the ultrasonic absorption spectra in an aqueous solution of *n*-propyl alcohol, no quantitative analysis of the excess absorption mechanisms has been done.

The present investigation has aimed at the establishment of the excess absorption mechanisms of ultrasonic waves in an aqueous solution of *n*-propyl alcohol on the basis of the water structure. This type of information is particularly desirable for an understanding of more complex biochemical reactions.

Experimental

The chemicals used were of a guaranteed reagent grade; the purity of the *n*-propyl alcohol, which had been distilled once, was verified to be more than 99.9% by gas chromatography. Water which had been deionized and then distilled was used as the solvent. The sample solutions were made at the required concentrations by weight. The concentration range of all the measurements was 2.00—13.4 M, which corresponded to 0.0402—1.00 mole fractions of *n*-propyl alcohol. The measurements of the ultrasonic absorption were carried out at the odd harmonic frequencies of 0.5, 5, and 20 MHz X-cut transducers by means of the pulse technique.[15] The frequency range of the absorption measurement was 4.5—220 MHz. The sing-around technique operated at a fixed frequency of 1.92 MHz was used to measure the sound velocity. The densities were measured by means of a standard pycnometer, the volume of which was 3.717 cm^3. All the measurements were made at 25 °C. A thermostat was built capable to perform within ±0.03 °C.

Results

The quantity α/f^2, where α is the sound absorption coefficient, and f, the frequency, was found to be frequency dependent for an aqueous solution of *n*-propyl alcohol. The plots of α/f^2 *vs.* the concentration of *n*-propyl alcohol are shown in Fig. 1 at various frequencies. The fact that α/f^2 depends on the frequency leads us to the idea that relaxational phenomena exist in the frequency range measured. In general, the sound absorption caused by the several relaxation processes can be described by the following equation:

$$\alpha/f^2 = \sum_i A_i/[1+(f/f_{ri})^2] + B \qquad (1)$$

where f_{ri} is the relaxation frequency for the i-th process and where A_i and B are constants. Figure 2 shows some representative ultrasonic absorption spectra of aqueous solutions of *n*-propyl alcohol. The spectra in the concentrations lower than 2.75 M show the behavior characteristic of a single relaxation process, which is expressed by $i=1$ in Eq. (1). On the other hand, the experimental results in the concentrations higher than 2.95 M can be expressed by two relaxation processes. The double relaxation spectra were analyzed by a nonlinear least-squares routine, employing a Toshiba 3400 computer. In Table 1, the ultrasonic

absorption parameters and the sound velocities are listed, together with the densities. As may be seen in this table, both the excess absorption, A_4, and the sound velocity, c, exhibit a maximum.

Interpretation of Results

Both water and alcohol molecules have a tendency to form hydrogen bonding, and the latter also has a hydrophobic group. Therefore, the following reaction mechanisms for the relaxation processes will be considered:

$$AB_m \underset{k_{21}}{\overset{k_{12}}{\rightleftharpoons}} mB + A \overset{k_{23}}{\underset{k_{32}}{\rightleftharpoons}} \frac{1}{n}A_n \qquad (2)$$

where A is the molecule of alcohol; B, that of water, and k_{ij}, the rate constant. In this equation, the first equilibrium indicates the interaction between alcohol and water molecules, and the second, the self-association reaction of alcohol. The general approach of the treatment used here is similar to that of Eigen and de Maeyer[16] or that of Hammes and Knoche.[17] If one denotes the molar concentrations of the components, AB_m, B, A, and A_n by C_1, C_2, C_3, and C_4 respectively, the returning rate of the system to equilibrium is governed by the rate law:

$$\frac{dC_1}{dt} = -k_{12}C_1 + k_{21}C_2^m C_3 \qquad (3)$$

$$\frac{dC_4}{dt} = k_{22}C_3^n - k_{32}C_4 \qquad (4)$$

These equations can be linearized in the neighborhood of the equilibrium by the usual procedure:

$$\frac{d\Delta C_1}{dt} = a_{11}\Delta C_1 + a_{21}\Delta C_4 \qquad (3')$$

$$\frac{d\Delta C_4}{dt} = a_{21}\Delta C_1 + a_{22}\Delta C_4 \qquad (4')$$

with $a_{11}=-[k_{12}+k_{21}\ (m^2\bar{C}_2^{m-1}\bar{C}_3+\bar{C}_2^m)]$, $a_{12}=-k_{21}n\bar{C}_2^m$, $a_{21}=-k_{23}n\bar{C}_3^{n-1}$ and $a_{22}=-(k_{23}n^2\bar{C}_3^{n-1}+k_{32})$, where a bar over a symbol indicates the equilibrium value. In the derivation of Eqs. (3') and (4'), the relations of $\Delta C_3=-n\Delta C_4-\Delta C_1$ and $\Delta C_1=-1/m\Delta C_2$ were used. The (3') and (4') rate equations can be written as:

$$\frac{d\boldsymbol{X}}{dt} = \boldsymbol{AX} \qquad (5)$$

where $\boldsymbol{A}$ is the column matrix made up of the a_{ij}'s. Using the normal coordinate transformation, Eq. (5) can be transformed to:

$$\frac{d\boldsymbol{Y}}{dt} = \boldsymbol{BY} \qquad (6)$$

where $\boldsymbol{Y}$ is the column matrix of eigenvectors, and $\boldsymbol{B}$, a diagonal matrix of the negative reciprocal relaxation times. The transformation matrix is as follows[17]:

$$\boldsymbol{M} = \begin{bmatrix} 1 & -[(1/\tau_1+a_{11})/a_{11}] \\ a_{21}/a_{11} & -[(1/\tau_2+a_{11})/a_{11}] \end{bmatrix} \qquad (7)$$

where the relations of $\boldsymbol{Y}=\boldsymbol{MX}$ and $\boldsymbol{B}=\boldsymbol{MAM}^{-1}$ are satisfied. If the first step in Eq. (2) is assumed to

equilibriate rapidly compared to the second, one gets:

$$1/\tau_1 = 2\pi f_{r1} = -a_{11} = k_{21}(m^2\bar{C}_2^{m-1}\bar{C}_3+\bar{C}_2^m) + k_{12} \quad (8)$$

$$1/\tau_2 = 2\pi f_{r2} = \frac{a_{12}a_{21}}{a_{11}} - a_{22}$$

$$= k_{32}+k_{23}n^2\bar{C}_3^{n-1} - \frac{n^2k_{21}k_{23}\bar{C}_2^m\bar{C}_3^{n-1}}{k_{12}+k_{21}(m^2\bar{C}_2^{m-1}\bar{C}_3+\bar{C}_2^m)} \quad (9)$$

$$y_1 = \Delta C_1 + \frac{a_{12}}{a_{11}}\Delta C_4 \quad (10)$$

$$y_2 = -\Delta C_4 \quad (11)$$

For the two relaxation processes, the chemical absorption per wavelength is:

$$\mu_{ch} = 4\mu_{m_1}\pi f\tau_1/[1+(f/f_{r1})^2] + 4\mu_{m_2}\pi f\tau_2/[1+(f/f_{r2})^2] \quad (12)$$

The expression for the maximum excess absorption per wave length, μ_{mi}, for the i-th process is derived as follows:

$$\mu_{mi} = \frac{1}{2}A_i f_{ri} c = (\rho\pi c^2\Gamma_i/RT)\left(\Delta V_i - \frac{\alpha_p^\infty}{\rho C_p^\infty}\Delta H_i\right)^2 \quad (13)$$

where ρ is the density; R, the gas constant; T, the absolute temperature; α_p^∞, the high-frequency limit of the thermal expansion coefficient; C_p^∞, the high-frequency limit of the constant pressure specific heat, and ΔV_i and ΔH_i, the parameters related to the volume and enthalpy changes associated with the reactions. The Γ_i terms is the function of the reactant concentrations and is derived by means of:

$$\Gamma_i = -\frac{RT}{V}\left(\frac{\partial y_i}{\partial A'_i}\right)_{TPy_j} \qquad i \neq j \quad (14)$$

where A_i' is the affinity. In the conditions of a constant temperature and a constant pressure, the maximum excess absorption per wavelength is proportional to $\rho c^2\Gamma_i$ and the other terms are nearly constant. For the reactions expressed by Eq. (2), one can calculate the Γ_i terms using Eq. (14):

$$\Gamma_1 = \frac{1}{V}\left(\frac{1}{\bar{C}_1}+\frac{1}{\bar{C}_3}+\frac{m^2}{\bar{C}_2}-\frac{m^2}{\bar{C}_T}\right)^{-1} \quad (15)$$

$$\Gamma_2 = \frac{1}{V}\left[\frac{n}{\bar{C}_3}\left(n-\frac{a_{12}}{a_{11}}\right)+\frac{n-1}{\bar{C}_T}\left(n-1+\frac{a_{12}}{a_{11}}\right)+\frac{1}{\bar{C}_4}\right]^{-1} \quad (16)$$

where $\bar{C}_T=\bar{C}_1+\bar{C}_2+\bar{C}_3+\bar{C}_4$.

If one denotes the analytical concentration of alcohol by C_a and that of water by C_w, the next equations are set up:

$$C_a = \bar{C}_1 + \bar{C}_3 + n\bar{C}_4 \quad (17)$$

$$C_w = C_w^s + m\bar{C}_1 + \bar{C}_2 \quad (18)$$

where C_w^s is the concentration of the cluster, that is, the concentration of the hydrogen-bonded water molecules. It is well known that the physico-chemical properties of liquid water can be interpreted by a two-state model.[18,19] Therefore, we assume that, in an aqueous solution of alcohol, there exists an equilibrium between hydrogen-bonded and non-hydrogen-bonded water in addition to those equilibria expressed by Eq. (2) and that only non-hydrogen-bonded water molecules participate in the interaction with alcohol molecules. Then, if one denotes the concentration of non-hydrogen-bonded water by C_w^s, the next equations are held:

$$C_w^s/C_w^s = \exp(-\Delta F_w/RT), \quad C_w = C_w^s + C_w^s \quad (19)$$

where ΔF_w is the free energy difference between hydrogen-bonded and non-hydrogen-bonded water molecules.

At this stage, we shall first consider the reaction mechanism associated with the excess absorption observed in the higher frequency range and the case of $m=1$, namely, the case in which a single alcohol molecule interacts with a single water one. We also assume that the concentration of the aggregate of alcohol, $\bar{C}_4$, is very small as compared with those of the other components. Then, one obtains the next equation from Eqs. (8), (17), (18) and (19):

$$1/\tau_1 = 2\pi f_{r_1} = k_{21}\sqrt{(C_a-\beta C_w+K_{12})^2+4\beta C_w K_{12}} \quad (20)$$

where β is the mole fraction of non-hydrogen-bonded water and where K_{12} is defined as $K_{12}=k_{12}/k_{21}=\bar{C}_2\bar{C}_3/\bar{C}_1$. As may be seen in Table 1, the value of the relaxation frequency, f_{r1}, goes through minimum near $C_a=4.5$ M. Therefore, the next condition must be satisfied at $C_a=4.5$ M.

$$\frac{\partial(1/\tau_1)}{\partial C_a} + \frac{\partial(1/\tau_1)}{\partial\beta C_w}\cdot\frac{d\beta C_w}{dC_a} = 0 \quad (21)$$

Thus, the parameters, β and K_{12}, are not independent of each other. A trial-and-error procedure was used to obtain the values of these parameters which provided the best fit to the experimental data using Eq. (20). The best values are $K_{12}=2.6$ M, $\beta=0.15$, and $k_{21}=6.2\times10^7$ M^{-1} s^{-1}. Then, one gets also $k_{12}=1.6\times10^8$ s^{-1} from the definition of K_{12}. The relaxation frequencies calculated by Eq. (20) using the obtained parameters are shown in Fig. 3, along with the experimental values. One can evaluate the concentration dependence of the maximum chemical absorption per wavelength using Eq. (15). Figure 4 shows the calculated values of $\rho c^2\Gamma_1 V$ along with the experimental values of μ_{m1}. As may be seen in this figure, both maxima

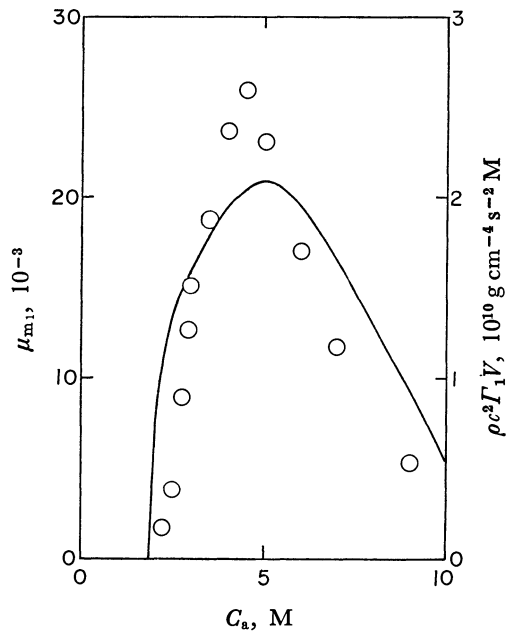

Fig. 4. The variation of μ_{m1} and $\rho c^2\Gamma_1 V$ with the concentration of *n*-propyl alcohol. The solid line represents the calculated values of $\rho c^2\Gamma_1 V$. The circles are the experimental points of μ_{m1}.

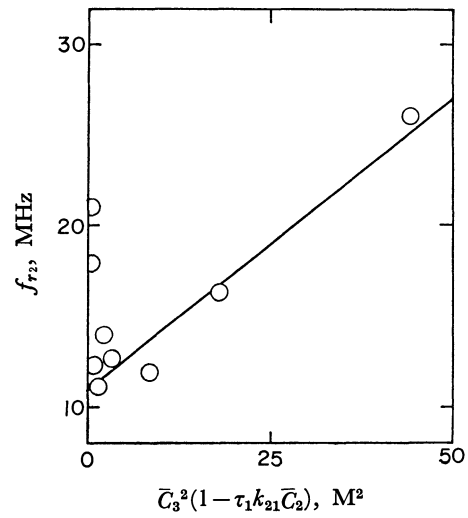

Fig. 5. The plots of f_{r2} *vs.* $\bar{C}_3^2(1-\tau_1 k_{21}\bar{C}_2)$ for the aqueous solution of *n*-propyl alcohol at 25 °C.

appear at almost the same position. This confirms that the excess absorption mechanism in the higher frequency range is due to the perturbation of the first equilibrium expressed in Eq. (2).

Second, let us consider the mechanism of the excess absorption in the lower frequency range. Equation (9) can be transformed as follows.

$$1/\tau_2 = 2\pi f_{r2} = n^2 k_{23}\bar{C}_3^{n-1}(1-\tau_1 k_{21}\bar{C}_2) + k_{32} \qquad (22)$$

Figure 5 shows the plots of f_{r2} *vs.* $\bar{C}_3^2(1-\tau_1 k_{21}\bar{C}_2)$. The parameter, n, which is the aggregation number of *n*-propyl alcohol, was determined so as to give a straight line of the plots of f_{r2} *vs* $\bar{C}_3^{n-1}$ $(1-\tau_1 k_{21}\bar{C}_2)$ and resulted in $n=3$. The rate constants were determined to be $k_{23}=2.2\times10^5$ M^{-2} s^{-1} and $k_{32}=6.9\times10^7$ s^{-1} from the slope and intercept of the straight line respectively. We also calculated the concentration dependence of the maximum chemical absorption per wavelength associated with this aggregation reaction, but the value of $\rho c^2\Gamma_2 V$ increases monotonically with the alcohol concentration.

Discussion

The most interesting and important feature in the ultrasonic absorption study of an aqueous solution of *n*-propyl alcohol is that the excess absorption is observed only in the solutions, not in pure water and pure alcohol, in the frequency range investigated. This means that the causes of the excess absorption mechanisms are closely associated with the peculiar properties of water and *n*-propyl alcohol molecules. The model which is proposed here is a general one which covers all of the equilibria considered in an aqueous solution of neutral solutes, because any molecule which consists of hydrophilic and hydrophobic groups has a tendency to interact with water molecules and to aggregate. The equilibrium between hydrogen-bonded (cluster) and non-hydrogen-bonded water molecules is also taken into accout for the elucidation of the observed excess absorption mechanisms, although the relaxation time for the perturbation of this equilibrium is too short to be observed[18] (It is of the order of 10^{-12} s). At this stage, it is very useful to consider the water structure in an aqueous solution of *n*-propyl alcohol. The parameter, β, is related to the free energy difference between the two states for hydrogen-bonded and non-hydrogen-bonded water molecules, ΔF_w, by the relation; $\beta/(1-\beta)=\exp(-\Delta F_w/RT)$ and one gets $\Delta F_w=1.0$ kcal. In pure liquid water, however, the free energy difference is of an order of less than 1 kcal.[19] The increase in the free energy difference is due to the decrease in the non-hydrogen-bonded water molecule in an aqueous solution of *n*-propyl alcohol. This means that the *n*-propyl alcohol molecule acts as water structure promoter. This conclusion is consistent with the results of other investigations.[8,20] In order to examine the influence

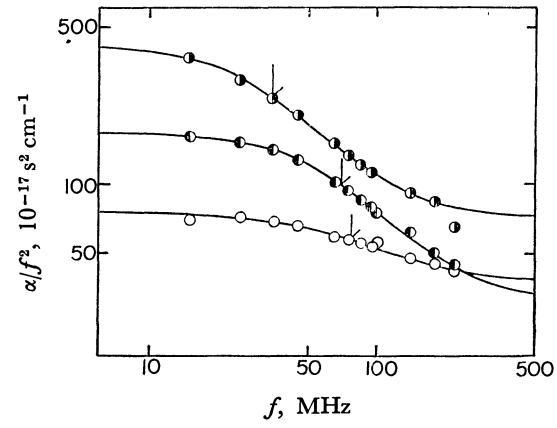

Fig. 6. Ultrasonic absorption spectra of the aqueous solution of 2.60 M *n*-propyl alcohol. The influence of NaCl to the absorption spectra. ○: no added, ◐: 0.507 M NaCl added, ◑: 1.00 M NaCl added.

of the water structure on the water and *n*-propyl alcohol interaction, we also measured the ultrasonic absorption in an aqueous solution of *n*-propyl alcohol to which NaCl was added. The measurements were performed in a solution of 2.60 M of *n*-propyl alcohol, where only a single relaxation process is observed in the higher frequency range. Figure 6 shows the absorption spectra in these solutions; the relaxation frequency decreases with increase of concentration of NaCl. Addition of NaCl to liquid water acts as water structure promoter.[21] According to Eq. (20), the decrease in the non-hydrogen-bonded water molecule must result in the decrease in the relaxation frequencies. As may be seen in Fig. 6, the experimental results are consistent with the above interpretation; this criterion is also taken as sufficient evidence for the correct assignment of the excess absorption mechanism in the higher frequency range observed.

More extensive ultrasonic absorption measurements in aqueous solutions of other alcohols may be desirable to confirm the ultrasonic absorption mechanisms of these solutions. The studies of these solutions are now in progress; the results will be reported in due course.

The authors wish to express their thanks to Dr. Keishiro Shirahama in Saga University for his helpful discussions.

Molecular Structure of Molybdenum Oxide Tetrachloride Studied by Gas Electron Diffraction

Kinya IIJIMA and Shuzo SHIBATA

Department of Chemistry, Faculty of Science, Shizuoka University, Oya, Shizuoka 422

(Received July 27, 1974)

The molecular structure of molybdenum oxide tetrachloride was determined to be a square pyramid by a sector-microphotometer method of gas electron diffraction. The following molecular parameters were obtained by a least-squares method: r_g(Mo–Cl)=2.279±0.003 Å, r_g(Mo–O)=1.658±0.005 Å, and r_g(Cl···Cl(s))=3.142±0.008 Å. The structure of gaseous $MoOCl_4$ is similar to that of gaseous $WOCl_4$. The infrared spectra of $MoOCl_4$ were also measured in solutions.

The molecular structure of MXY_4, where M is a central atom, can be classified into two groups: trigonal bipyramid and square pyramid. The structure of gaseous SOF_4[1,2] was reported to be a trigonal bipyramid, and the structures of $XeOF_4$[3,4] and $WOCl_4$[5,6] in the gas phase were found to be square pyramids, although the OXeF angle (92°) and the OWCl angle (102.4°) differ a great deal from each other. According to infrared spectroscopic study,[7] the $MoOCl_4$ molecule is monomeric and has a square-pyramidal structure in the gas phase as well as in inert solvents. The present study was undertaken in order to determine in more detail the structure of $MoOCl_4$ in the gas phase by the sector-microphotometer method of electron diffraction,[8] in order to see the difference between the configuration of $MoOCl_4$ and those of $WOCl_4$ and $XeOF_4$ and to compare the Mo–O and Mo–Cl bond distances of $MoOCl_4$ with those of other molybdenum compounds such as MoO_2Cl_2,[9] $MoCl_5$,[10] and $MoOCl_3$ (in solid state).[11,12]

The vibrational spectra of $MoOCl_4$ have been measured in the gas phase [7,13] and in solutions.[7,14] We have obtained the infrared spectra of $MoOCl_4$ in inert solvents in a wider range for the purpose of calculating the mean amplitudes of vibration.

Experimental

The sample prepared by refluxing molybdenum trioxide with thionyl chloride[15] was purified by repeated sublimation *in vacuo*. It was then loaded into a high-temperature nozzle in a dry box, vaporized at *ca.* 80 °C. Electron diffraction photographs were taken with an r^3-sector at a camera distance of 144.4 mm. The accelerating voltage was about 40 kV, the exposure times 30∼40 s, and the electron-beam current 0.7 μA. The electron wavelength was determined by means of gold powder patterns. The lattice constant of gold was calibrated by means of X-ray diffraction and checked by an electron diffraction study of CCl_4. Photographs were recorded on Fuji process hard plates. The photographic densities of four plates were measured with a digital microphotometer at intervals of 0.4 mm, and the intensity of each plate was used independently for the structure analysis.

The infrared spectra of $MoOCl_4$ in carbon tetrachloride and cyclohexane solutions were measured in the range 4000∼40 cm^{-1} with a Hitachi EPI-G3 spectrophotometer and a Hitachi FIS-3 far-infrared spectrometer. Carbon tetrachloride and cyclohexane were dried by use of phosphorus pentoxide and sodium metal, respectively, since $MoOCl_4$ readily decomposed with a trace of water in the solvent. Measurement of the Raman spectrum was impracticable because of the intense color of the $MoOCl_4$ solutions.

Structure Analysis

Intensities measured in the range $q=17\sim102$ $Å^{-1}$ were leveled theoretically. The elastic scattering factors of Schäfer *et al.*[16] and the inelastic scattering factors of Cromer and Mann[17,18] were used. The radial distribution is shown in Fig. 1. The N_{ij} functions which fit μ_{ij}[5,19] in a whole range of the scattering angle were as follows:

$$N_{Mo-Cl} = 1.000$$

$$N_{Mo-O} = 1.020 + 0.147\exp(-0.00040\,q^2)$$

$$N_{Cl\cdots Cl} = 1.202 + 0.076\exp(-0.00028\,q^2)$$

$$N_{Cl\cdots O} = 1.245 + 0.395\exp(-0.00060\,q^2)$$

The radial distribution curve, which is very similar to that of $WOCl_4$,[5] suggests that the molecular structure of $MoOCl_4$ is a square pyramid.

Least-squares calculations were carried out in order to refine the molecular parameters. Least-squares analyses of background[20] and molecular intensity[21] values were repeated alternately. An experimental background was approximated using a polynomial of 7th degree, and the weight function given by Konaka and Kimura[22] was assumed.

The molecule was assumed to be a trigonal bipyramid C_{2v}. The OMoCl(equatorial) angles 90°, 100°, 110°, 120°, and 130° with the OMoCl(polar) angle 90° were used as initial values for the least-squares calculations. No convergence was obtained for 90° or 130°. For the other cases, the OMoCl(polar) and OMoCl(equatorial) angles as well as the Mo–Cl(polar) and Mo–Cl(equatorial) distances converge to

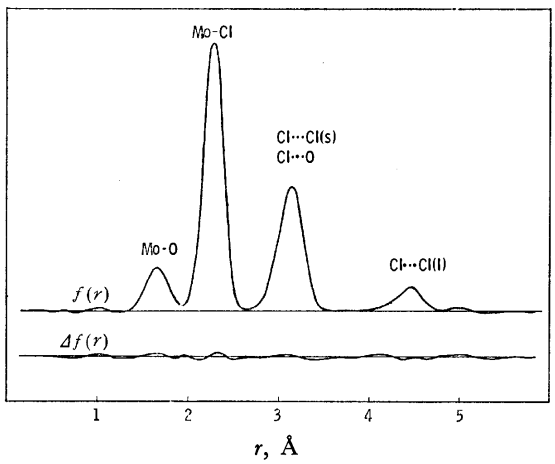

Fig. 1. Experimental radial distribution, $f(r)$, and the difference between the experimental and calculated ones, $\Delta f(r)$. A damping factor, $\exp(-0.0002\,q^2)$, was used.

the same values within the limits of error, indicating that the molecular structure of $MoOCl_4$ is a square pyramid, C_{4v}.

The index of resolution, r(Mo–Cl), r(Mo–O), r(Cl···Cl(s)), and four root-mean-square amplitudes l(Mo–Cl), l(Mo–O), l(Cl···Cl(s)), and l(Cl···Cl(l)) were determined by the least-squares analysis with C_{4v} (Table 1), where l(Cl···O) was fixed because of a large correlation between l(Cl···Cl(s)) and l(Cl···O). The value was obtained by the normal coordinate analysis. Asymmetry parameters for the Mo–Cl and Mo–O were estimated by the diatomic molecule approximation[23] to be 4.0×10^{-6} and 0.6×10^{-6} Å^3, respectively. The parameter in the Morse function, a, was assumed to be 2.0 Å^{-1}, the frequencies of Mo–Cl and Mo–O stretching vibrations 450 and 1015 cm^{-1}, respectively,[7] and the asymmetry parameters for nonbonded distances zero.

The results of the analysis are given in Table 2. r_g parameters were calculated from r_a parameters by means of $r_g=r_a+l^2/r_a$. Random errors were estimated to be 2.5 σ_1 or 2.5 σ_2.[21,24] Systematic errors were estimated from the error in the lattice constant of the reference material (0.06%) and errors in the optical measurement of the diffraction patterns of gold (0.08%) and of the camera distance (0.04%). Correlation matrices[25] are given in Table 3, and the observed and best-fit theoretical intensity curves are shown in Fig. 2.[26] The least-squares computations were carried out by the use of a FACOM 230—60 computer at Nagoya University Computing Center.

The infrared spectra for $MoOCl_4$ were assigned by analogy with the spectra of related molecules such as $WOCl_4$,[27,28] IF_5, BrF_5, ClF_5, and $XeOF_4$.[29] Since the vibrational frequencies of $MoOCl_4$ are similar to those of $WOCl_4$, the frequencies for the B_1 and B_2 modes, which are infrared-inactive, were assumed to be equal to the corresponding values for $WOCl_4$.[28] The fundamental frequencies are given in Table 4. The valence force constants were calculated by the GF matrix method. The mean amplitudes for the bonded and nonbonded distances were calculated by a normal coordinate analysis. The results are given in Table 2.

Discussion

The structure of $MoOCl_4$ in the gas phase is found to be a square pyramid similar to those of $WOCl_4$,[5] $XeOF_4$,[4] and IF_5.[30] The OMoCl angle (102.8±0.7°) is essentially equal to the OWCl angle (102.4±1.3°) in $WOCl_4$ but is much larger than the corresponding angles in $XeOF_4$ (92°) and in IF_5 (81°), where the small angles in the latter molecules can be explained in terms of a nonbonding valence electron pair of central atoms.[31]

The Mo–Cl bond distance in gaseous $MoOCl_4$ (2.279±0.003 Å) is equal to that in $MoCl_5$ (2.27±0.02 Å)[10] and also to that in MoO_2Cl_2 (2.28±0.03 Å).[9] The Mo–O bond distance in MoO_2Cl_2 (1.75±0.10 Å) can not be compared exactly with that in $MoOCl_4$ (1.658±0.005 Å) because of the large experimental errors. The molybdenum atom in $MoOCl_3$

a) Ref. 7. b) Ref. 27.

has a distorted octahedral arrangement due to bridging of chlorine atoms in the crystal state.[12] The terminal Mo–Cl and Mo–O distances in $MoOCl_3$ are 2.26±0.02 Å and 1.63±0.04 Å, respectively. They agree with the corresponding distances in $MoOCl_4$ in the gas phase, although the bridging Mo–Cl is much greater than the terminal one. The OMoCl(terminal) angle in $MoOCl_3$ (103.8±1.4°) is also in good agreement with that in $MoOCl_4$ (102.8±0.7°).

By a normal coordinate analysis the force constants for the Mo–O and Mo–Cl bonds in $MoOCl_4$ were estimated to be 8.29 and 2.68 md/Å, respectively. The Mo–O force constant and the observed Mo–O distance give a good fit to the correlation curve between the distances and the force constants for the Mo–O bond.[32] Although the Mo–O bond in $MoOCl_4$ is formally a double bond, its bond order is estimated to be 3 from the correlation curve between the distance and the bond order.[32] Gray and Hare[33] gave the same bond order in their molecular orbital treatment for the Mo–O bond in the MoO^{3+} group, whose electronic structure consists of Mo^{5+} of [Krypton]$4d^1$ and oxide ion. Since the electronic structure of Mo^{6+} in $MoOCl_4$ is [Krypton]$4d^0$, the properties of the Mo–O bond would differ considerably from that of MoO^{3+}. However, the smallness of the Mo–O distance in $MoOCl_4$ might be mainly due to the double π-bonds formed between the $2p_x$ and $2p_y$ of oxygen and the $4d_{xz}$ and $4d_{yz}$ of molybdenum as in the Mo–O bond in MoO^{3+}.

The elastic scattering factor and the phase angle calculated by means of the Thomas-Fermi-Dirac (TFD) potential[34] were also used for molybdenum atom, a remarkable increment of 0.013 Å being found in the Mo–O mean amplitude but no changes in the bond distances. The case is very similar to the results of tetramethyltin given by Nagashima *et al.*[35] It seems that the phase angle for the molybdenum atom from the TFD potential is too small.

All the mean amplitudes we obtained are significantly larger than those calculated from the normal vibrations, especially with regard to Cl···Cl(1). This is probably due to the lack of accuracy in the frequencies of the B_1 and B_2 modes. A similar discrepancy between the observed mean amplitude of Cl···Cl(1) and the calculated value was reported by McAdam *et al.*[6] in their electron diffraction study of $WOCl_4$ in which they suggested the effect of an anharmonic vibration of the WCl_4 group.

Electron Spin Resonance of Oriented Solid of Isocyanic Acid Irradiated with γ-Rays

Hidefumi HIRAI and Masato FUJIWARA

Department of Industrial Chemistry, Faculty of Engineering, University of Tokyo, Bunkyo-ku, Tokyo 113

(Received July 30, 1974)

Free radicals in the γ-irradiated solid of isocyanic acid at -196 °C have been studied by electron spin resonance (ESR) spectroscopy at -196——-100 °C. An oriented solid of isocyanic acid was prepared by solidification of isocyanic acid around an aluminum rod with cooling for the measurement. The ESR spectra consisted of a pair of triplets and a pair of sextets, when the longitudinal axes of the oriented solid were parallel and perpendicular, respectively, to the dc magnetic field. The absorptions were assigned to an anion radical ($HNCO^-$) by analysis of anisotropy of the spectrum and by deuteration of isocyanic acid. The observed constants were: $g_\perp=2.0025$, $g_{//}=1.9985$; $A_x(N)=21.2$ G, $A_y(N)=24.8$ G, $A_z(N)=21.8$ G. The anion radical was assumed to be preferentially oriented in the oriented solid, taking two orientations whose $g_{//}$ axes were perpendicular both to each other and to the longitudinal axis of the oriented solid.

On the flash photolysis of isocyanic acid vapor, NH, NH_2 and NCO radicals were detected by absorption spectroscopy.[1,2] They were also postulated to account for the result of gas chromatography on the photolysis of vapor.[3] Radicals formed on the γ-irradiation of isocyanic acid solid at low temperatures, however, have not been studied.

In the present work, ESR measurements on isocyanic acid solid irradiated with γ-rays have been carried out. An attempt was made to prepare an oriented solid of isocyanic acid which can be used instead of a single crystal of the acid, since the melting point of the acid, -86 °C,[4] is too low to prepare a single crystal without special apparatus. In addition, deuteration of isocyanic acid was performed for identification of the radicals. Changes in the ESR spectra with light irradiation and with elevation of temperature were also examined.

Experimental

Materials. Isocyanic acid was prepared by the pyrolysis of cyanuric acid vapor in a stream of dry nitrogen at 600 °C according to reported method.[1] Further purification of the resulting isocyanic acid was carried out by distillation under reduced pressure of 5 mmHg. Deuterated isocyanic acid was prepared by the pyrolysis of deuterated cyanuric acid with a 33% yield. The deuterated cyanuric acid was prepared by dissolving cyanuric acid (3.0 g, 0.07 mol) in deuterium oxide (100 g, 5.56 mol) with heating under reflux for 6 hr. The degree of deuteration determined by mass spectrometry was 88%.

Preparation of Oriented Solid of Isocyanic Acid. Oriented solid of isocyanic acid was prepared in the following way. Isocyanic acid was solidified around an aluminum rod (1 mm diameter) in a glass tube (8 mm diameter) by cooling with liquid nitrogen (Fig. 1a), and the resulting oriented solid was sealed in another sample tube (10 mm diameter) in nitrogen atmosphere, as shown in Fig. 1b. After γ-ray irradiation at -196 °C, the solidified isocyanic acid was dislodged from the surface of the aluminum rod. It was then divided radially into several wedge-formed pieces (Fig. 1c), one of which was inserted into a crack in a Teflon tube so as to have the longitudinal axis of the piece, *i.e.* the axis of the mark of aluminum rod, held horizontally (Fig. 1d). The angle between the longitudinal axis of the piece and the direction of the dc magnetic field is referred to as orientation-angle, orientation-angles 0° and 90° indicating the axes parallel and perpendicular, respectively, to the dc magnetic field. The wedge-formed piece was inserted into the Teflon tube crack in order to keep the longitudinal axis parallel to the vertical tube axis and was rotated around its longitudinal axis.

ESR Measurement. The solid of isocyanic acid was irradiated with ^{60}Co γ-rays to a dose of 8×10^5~8×10^6 rad at -196 °C. The ESR measurement was run using a Varian V-4502 X-band spectrometer with a cylindrical cavity in the TE_{110} mode and with 100 kHz field modulation at several different temperatures between -196 °C and -100 °C. The oriented solid could be rotated in the cavity so that ESR spectrum was obtained at any desired orientation-angle. The γ-irradiated solids of isocyanic acid were subsequently exposed to light from an Ushio Denki HB 500/B high pressure mercury lamp (500W; wavelengths>2800 Å) in a transparent quartz Dewar vessel at -196 °C.

Mass Spectrometry. Mass spectra of deuterated isocyanic acid vapor were analyzed with a Hitachi RMU-6 mass spectrometer.

Results

Oriented Solid of Isocyanic Acid. On cooling with liquid nitrogen, solidification of isocyanic acid proceeded from the wall of the glass sample tube to the

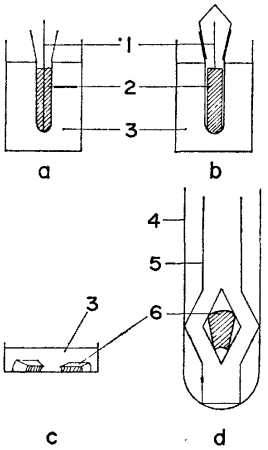

Fig. 1. Preparation of oriented solid of isocyanic acid; aluminum rod (1), isocyanic acid (2), liquid nitrogen (3), ESR sample tube (4), Teflon tube (5) and γ-irradiated isocyanic acid (6).

surface of the aluminum rod. The gradient of temperature of the isocyanic acid turned out to have a cylindrical symmetry around the axis of the aluminum rod. The resulting solid of isocyanic acid was a polycrystal made of needle-like crystallite preferentially oriented with the cylindrical symmetry, since any piece of oriented solid exhibited the same anisotropic spectrum. The narrower wedge-angle of the piece (Fig. 1d) gave a sharper and more symmetric spectrum. It was found that the use of a Teflon rod for solidification of isocyanic acid yielded a broader and less anisotropic spectrum than that obtained with an aluminum rod.

ESR Spectrum of Isocyanic Acid. The above procedure for preparing the oriented solid is hereafter referred to as the oriented solid method. The experimental rectangular coordinate system of the oriented solid, X, Y and Z, was defined as shown in Fig. 2. The Z axis corresponds to the longitudinal axis of the aluminum rod and the Y axis coincides with the bisector of the wedge-angle of the wedge-formed piece. The X axis is perpendicular to both the Y axis and Z axis.

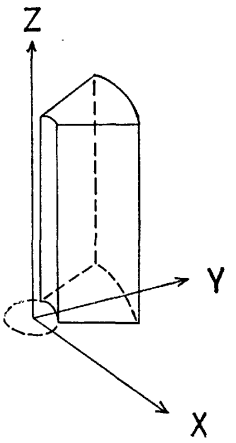

Fig. 2. Experimental rectangular coordinate system of oriented solid.

The γ-irradiated oriented solid prepared by the oriented solid method gave the spectra as shown in Fig. 3 when the solid was rotated around the Y axis keeping the Y axis perpendicular to the dc magnetic field. Remarkable changes in the pattern occurred with change in the orientation-angle from 0° to 90°. The spectrum at 0° consisted of six strong lines with equal intensity, though the lines in higher field became broader (Fig. 3a). At 90° ten lines were observed with relative intensity ratios of about 1 : 1 : 1 : 2 : 1 : 1 : 2 : 1 : 1 : 1 (Fig. 3d). A slight change in pattern can be seen on variation from 0° to 60° (Figs. 3b and 3c).

The six lines can be interpreted by a pair of triplets due to the hyperfine interaction with ^{14}N nucleus (I=1) and with ^{1}H nucleus (Fig. 3a), from a consideration of both line intensities and line spacings. The ten lines can be ascribed to the twelve lines with equal intensity, four of which coalesce forming a pair of lines with relative intensity of two (Fig. 3d). The

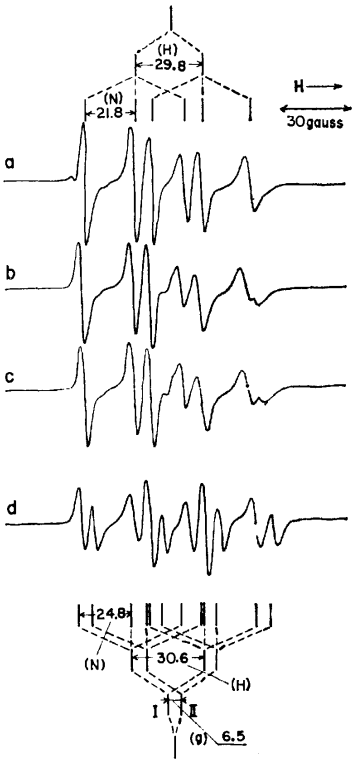

Fig. 3. ESR spectra of oriented solid of isocyanic acid irradiated with γ-rays at −196 °C with orientation-angle 0° (a), 30° (b), 60° (c) and 90° (d).

twelve lines can be divided into two groups, I and II, each of which consists of six lines similar to those observed at orientation-angle 0°. The values of nitrogen splitting change from 21.8 G to 24.8 G, while the change of proton splitting (0.8 G) is small and the proton splitting remains almost constant. The relative intensity ratios of the lines and the hyperfine structure due to N and H of Radical I are equal to those of Radical II. Consequently, Radicals I and II should have the same molecular structure and a different orientations which yield a site splitting of 6.5 G through g-anisotropy at 90°.

The angular dependence of the g-value around the Y axis is shown in Fig. 4, where two kinds of g-value are found, one (Radical I) remains constant throughout the angular change (g=2.0025), while the other (Radical II) takes the minimum value (g=1.9985) at orientation-angle 90°.

The oriented solid gave the spectra as shown in Fig. 5, when the solid was rotated around the Z axis keeping the Z axis perpendicular to the dc magnetic field. Spectrum 5a was obtained when the dc magnetic field was applied in a direction parallel to the Y axis. A rotation of the solid by 90° gave spectrum 5c which is similar both to 5a and 3d. The nitrogen splitting was observed to take a value 21.2 to 24.8 G on the rotation of the oriented solid, while the hydrogen splitting remained almost constant (*ca.* 30 G). The angular dependence of the g-value around the Z axis was also examined. The anisotropies of g-value are shown in Fig. 6. The observed g-values change between 2.0025 and 1.9985, corresponding to the

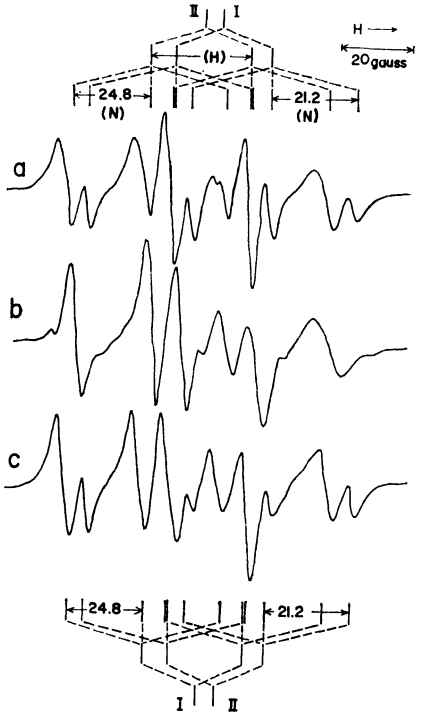

Fig. 5. ESR spectra of oriented solid of isocyanic acid irradiated with γ-rays at −196 °C. The specimen was rotated in the XY plane around the Z axis. Spectrum a was obtained, when the dc magnetic field was parallel to the Y axis. Spectra b and c correspond to a rotation of the sample tube by 45° and 90°, respectively, from the position for Spectrum a around the Z axis.

maximum g-value of Radical I and the minimum value of Radical II, respectively.

When the oriented solid is rotated about the Y axis, one of the triplet patterns (Radical I) remains fixed in position, while the others (Radical II) change (Fig. 3). The oriented solid is considered to be symmetric about the Z axis. Accordingly, the g-tensor of

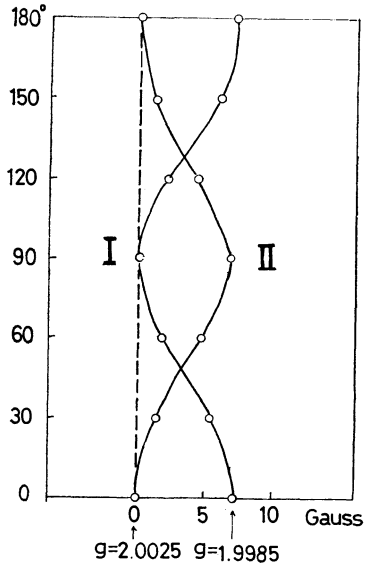

Fig. 6. Plots of the g-value of Radicals I and II for various orientations of the dc magnetic field in the XY plane, with angles measured from the direction of the dc magnetic field in the direction of the Y axis.

the radical produced in γ-irradiated oriented solid is axially symmetric. Both Radicals I and II seem to align to keep the $g_{//}$ axis in the XY plane (Fig. 7). The $g_{//}$ axis of Radical I is parallel to the Y axis, that of Radical II to the X axis. Both the $g_{//}$ axes of Radicals I and II are perpendicular to the Z axis. These orientation states of Radicals I and II can reasonably explain the results shown in Figs. 4 and 6. Both the molecular planes of Radicals I and II are expected to be perpendicular to the Z axis. The observed maximum and minimum values (24.8 and 21.2 G) of nitrogen splitting are considered to be the principal values of nitrogen hyperfine tensor, since the two principal axes of nitrogen hyperfine tensor can be expected to be in the molecular plane (XY plane) of

Structure 1

TABLE 1. PRINCIPAL VALUES OF THE NITROGEN HYPERFINE TENSOR (A) AND THE SPECTROSCOPIC SPLITTING FACTOR (g)

$A_x = 21.2$ G	
	$g_\perp = 2.0025$
$A_y = 24.8$ G	
	$g_{//} = 1.9985$
$A_z = 21.8$ G	

The x, y and z axes are given in Structure 1.

the radicals. The principal values 24.8 and 21.2 G were obtained when the Y axis of the oriented solid was rotated around the Z axis by 0° and 90°, respectively (Fig. 5). Another principal value, 21.8 G, was also obtained when the magnetic field was applied in a direction parallel to the Z axis (Fig. 3a). Structure 1 shows the directions of the g-tensor and the nitrogen hyperfine tensor, and also the radical structure. The experimental g-values and hyperfine splitting constants of nitrogen are given in Table 1.

For the sake of comparison, isocyanic acid in a Spectrosil tube was solidified by cooling with liquid nitrogen without aluminum rod and subsequently γ-irradiated (1×10^6 rad) at -196 °C; this procedure of preparation of specimen for ESR measurement is hereafter referred to as the usual method. The specimen made in this manner exhibits a spectrum as shown in Fig. 8. Almost no changes in the pattern occurred when the Spectrosil tube was rotated about its longitudinal tube axis. The spectrum consisted of six strong lines and additional weak three lines. The six strong lines were centered at $g=2.0025$ and separated by 22 G with equal intensity, though the lines in the higher field also became broader. The absorption lines of hydrogen atom separated by 508 G and two weak lines separated by about 170 G were also recorded.

In order to examine the orientation of the isocyanic acid molecule in the solid prepared by the usual method, the spectra were also measured with the dc magnetic field perpendicular to the longitudinal axis of the Spectrosil tube in the following manner similar to the oriented solid method; the Spectrosil tube containing the γ-irradiated isocyanic acid solid was broken in liquid nitrogen and the resulting wedge-form piece of isocyanic acid solid was inserted in a crack of Teflon tube so as to hold the longitudinal axis of the piece horizontally. The spectra obtained at orientation-angles 0° and 90° are shown in Fig. 9. The dependence of the ESR pattern on the angle was similar to that in the case of the oriented solid method, while the absorption lines in the former case were less anisotropic and broader.

A wider wedge-angle (*ca.* 150°) of the wedge-formed specimen gave a broader absorption lines where the separation of the absorption lines of Radical II from that of Radical I at 90° was not observable (Fig. 10). This suggests that the isocyanic acid molecule in the oriented solid is oriented radially.

The subsequent light irradiation (wavelengths>

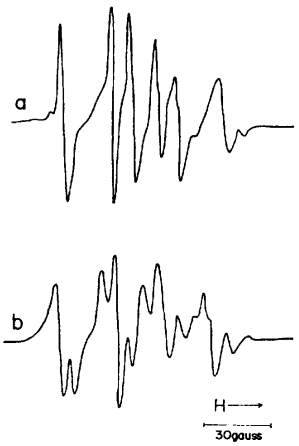

Fig. 9. ESR spectra of isocyanic acid prepared by the usual method with γ-irradiation 1×10^6 rad at -196 °C measured by keeping the longitudinal axis horizontal; orientation-angle 0° (a) and 90° (b).

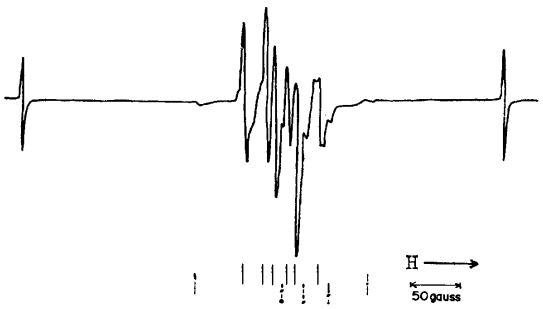

Fig. 8. ESR spectrum of isocyanic acid prepared by the usual method and three kinds of line-spectra shown at the bottom of this figure.

2800 Å) on the specimen caused no change in those spectra obtained in the dark at −196 °C. Raising the temperature of the specimen to about −110 °C gave no change either in intensity or in shape of the spectra. The intensity, however, decreased remarkably at −90 °C with the disappearance of Q-dip on mode check.

ESR Spectrum of Deuterated Isocyanic Acid. Figure 11 shows an ESR spectrum of deuterated isocyanic acid γ-irradiated in a Spectrosil tube at −196 °C according to the usual method. The spectrum consists of nine strong lines with equal intensity due to the hyperfine splitting with ^{14}N nucleus and ^{2}H nucleus. The small line spacing is 4.6 G, corresponding to 1/6.43 of the splitting constant of ^{1}H and ascribed to the deuteron splitting. The large spacing is 22.1 G, corresponding to the coupling of N nucleus. Two weak lines on both ends of he spectrum are due to the coupling of ^{1}H nucleus of undeuterated isocyanic acid. Deuterated isocyanic acid behaves in the same manner as isocyanic acid both on cooling and on γ-irradiation according to the usual method.

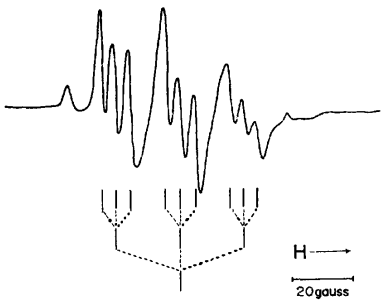

Fig. 11. ESR spectrum of deuterated isocyanic acid irradiated with γ-rays of 1×10^{6} rad at −196 °C.

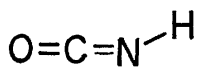
Discussion

Analysis of ESR Spectrum. The structure of isocyanic acid determined by Jones *et al.*[5] using the microwave absorption spectroscopy, is represented by the following structure. The equivalent doublet pattern (Fig. 3) should arise from one β-proton coupling, since the proton splitting almost remains constant throughout the orientation-angle change. The result of deuterated isocyanic acid confirms this conclusion.



Formula 1.

From the experimental values of nitrogen hyperfine tensor, an unpaired electron spin density on nitrogen atom ($=\rho_N$) can be calculated. Isotropic Fermi contact component (A_f) and anisotropic component (A_d) arising from dipole-dipole interaction can be written, respectively, as

$$A_f = \pm 1/3(A_{//}+2A_{\perp}) \quad (1)$$

$$A_d = \pm 1/3(A_{//}-A_{\perp}) \quad (2)$$

where $A_{//}$ and $A_{\perp}$ represent the principal values of the axially symmetric hyperfine tensor. For this case, $A_{\perp}$ is the average value of A_x and A_z, since the value of A_x is nearly equal to that of A_z. In formulas (1) and (2), we can obtain A_f and A_d, using the observed values, $A_{//}=24.8$ and $A_{\perp}=21.5$ G

$$A_f = 22.6 \text{ (G) and } A_d = 1.1 \text{ (G)}$$

Although it could not be determined in this experiment, A_f and A_d may have the same sign. The dipole-dipole term for the 2p electron and Fermi term on a nitrogen atom can be estimated, respectively, by use of the data by Barns and Smith:[6] $A_{2p}=17.1$ G and $A_{2s}=550$ G. Consequently, the spin density of the $2p_z$ orbital and of the 2s orbital can be set, respectively, as

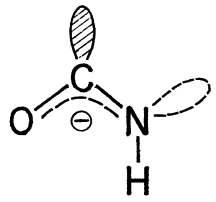
$$\rho_{2p} = A_d/A_{2p} = 0.064$$

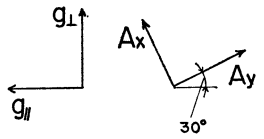
$$\rho_{2s} = A_f/A_{2s} = 0.041$$

Thus, the spin density on nitrogen atom ($\rho_N=\rho_{2p}+\rho_{2s}$) is estimated to be 0.11. The value is similar to that on oxygen atom of CO_2^- anion radical ($\rho_0=0.11$).[7] The results indicate that the unpaired electron occupies an orbital of carbon atom and the unpaired electron spin density is produced upon the sp^2 hybrid orbital of nitrogen atom by the spin delocalization. The radical represented by Structure **1** whose structure is similar to that of CO_2^- anion radical[7] might give a large negative shift of *g*-value through the effect of spin-orbital coupling of the unpaired electron in the sp^2 hybrid orbital of carbon atom with the in-plane 2p orbitals of oxygen atom and nitrogen atom.

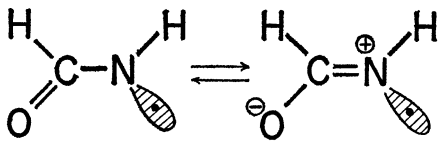
The direction of the largest principal value of nitrogen hyperfine tensor of Structure **1** should be expected to correspond reasonably to the direction of the lobe of the nitrogen sp^2 hybrid orbital occupied by the lone pair electrons, since the unpaired electron spin density is caused upon the sp^2 hybrid orbital by the spin polarization of the lone pair electrons. This is supported by the results for CO_2^- anion radical,[7] $\cdot NO_2$ radical[8] and the radical of γ-irradiated dimethyl glyoxime.[9] The largest principal value (A_y) and the maximum *g*-value of Radical I were obtained when the Y axis of the oriented solid was rotated around the Z axis by 90° from the position where the Y axis became parallel to the dc magnetic field (Figs. 5 and 6). The direction of A_y of Structure **1** might not coincide with that of $g_{\perp}$ axis, since the $g_{\perp}$ axis is not a symmetrical axis of Structure **1**. However, the shift between the two directions can not be distinguished from the experimental results. Therefore, the A_y axis is almost parallel to the $g_{\perp}$ axis.

In Structure **1**, the N–H bond of the radical is in the *cis*-position with respect to the carbon sp^2 hybrid orbital occupied by the unpaired electron. On the other hand, the N–H bond of Structure **1′** is in the *trans*-position. If the N–H bond is in the *trans*-position, the direction of the lobe of the nitrogen sp^2 hybrid orbital occupied by the lone pair electrons might cut the $g_{//}$ axis at an angle 30° (Structure **1′**). This is in line with the result where the A_y axis cuts the $g_{//}$ axis at an angle 90°. The N–H bond of the radical is, therefore, in the *cis*-position with respect to the carbon sp^2 hybrid orbital.

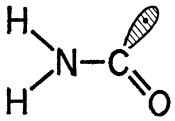




Structure **1**



Structure **2**



Structure **3**

Two possible structures for the radical are given in the following.

They represent the σ-type neutral radicals produced by the addition reactions of a hydrogen atom to isocyanic acid. In each structure, an unpaired electron occupies in sp^2 orbital of nitrogen atom or carbon atom. The large negative shift of g-value can not be explained by Structure **2** which has a similar structure to that of the vinyl radical. Structure **2**, thus, seems to be less acceptable. The resonance pattern arising from Structure **3** might consist of a triplet of triplets, since the unpaired electron couples with two hydrogen nuclei and nitrogen nucleus. The observed pattern, however, consists of a doublet of triplets. Consequently, Structure **3** is discarded and Structure **1** is the most preferable for the assignment of the radical.

The weak absorption separated by 170 G (Fig. 8) may be ascribed to a moiety of decomposed molecule.

Orientation of Isocyanic Acid. From the spectrum 3d, the population of Radical I in the isocyanic acid solid should be equal to that of Radical II. Thus it seems that the N=C=O axis of the isocyanic acid molecule is perpendicular to that of the adjacent acid molecule through a hydrogen bond (Fig. 12). When isocyanic acid molecule (A) traps an electron produced by γ-irradiation, the unpaired electron of the resulting radical (A) occupies the sp^2 hybrid orbital in the *cis*-position to the proton of the molecule (A). This is why the proton is in the *cis*-position of the unpaired electron.

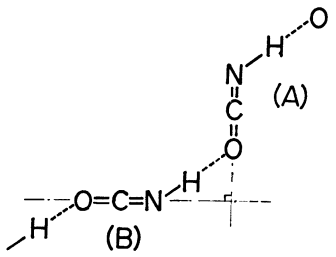


Fig. 12. Alignment of isocyanic acid molecule in the oriented solid.

Radicals which locate on both outer sides of Radicals I and II (Fig. 7), making a wider wedge-angle, should have slightly different orientations of the g-tensors, since they are oriented radically around the aluminum rod. Thus, a wider wedge-angle of the wedge-formed specimen makes the absorption lines broader resulting in a coalescence of the absorption lines of Radical II with those of Radical I (Fig. 10).

The authors wish to thank Dr. Naoyuki Tamura, Japan Atomic Energy Research Institute, for his valuable discussions. They are grateful to Dr. Tosho Sugiura of the same Institute for his kindness in measuring mass spectrum of deuterated isocyanic acid.

^{14}N Nuclear Quadrupole Resonances of Sulfuric Diamide and Its Derivatives

Hisao NEGITA, Tsuneo KUBO, and Kaoru SHIBATA

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730

(Received August 13, 1974)

The study of ^{14}N nuclear quadrupole resonance (NQR) was performed on sulfuric diamide (sulfamide) and its methyl derivatives, such as *N,N*-dimethylsulfamide and tetramethylsulfamide. The ^{14}N NQR parameters for sulfuric diamide and tetramethylsulfamide were ($|e^2Qq|=3905.3$ kHz; $\eta=0.5082$) and ($|e^2Qq|=5325.9$ kHz; $\eta=0.1768$) respectively. In the case of *N,N*-dimethylsulfamide, the parameters were ($|e^2Qq|=4022.9$ kHz; $\eta=0.4799$) for the nitrogen atoms of NH_2 groups and ($|e^2Qq|=5125.0$ kHz; $\eta=0.2024$) for the nitrogen atoms of $N(CH_3)_2$ groups. From the temperature dependence of the resonance lines due to nitrogen atoms in sulfuric diamide, tetramethylsulfamide, and the NH_2 group of *N,N*-dimethylsulfamide, it is considered that the hydrogen bonds in sulfuric diamide are stronger than those in *N,N*-dimethylsulfamide. On the other hand, the electron densities for the N–S bond in sulfuric diamide and its methyl derivatives were derived from the corresponding NQR parameters.

The structural studies of sulfuric diamide have been performed by various spectroscopic means, but not by the nuclear quadrupole resonance (NQR). The NQR method is of especial interest in clarifying the charge distribution on the nitrogen atom. Therefore, we planned to examine ^{14}N NQR in sulfuric diamide and its methyl derivatives such as *N,N*-dimethylsulfamide and tetramethylsulfamide. On the basis of the ^{14}N NQR studies, the hydrogen bond in sulfuric diamide was compared with that in *N,N*-dimethylsulfamide, and the charge distributions on the nitrogen atoms in sulfuric diamide and its derivatives were compared with those in urea and tetramethylurea.

Experimental

The ^{14}N NQR spectra of these compounds were obtained by the use of a frequency-modulated spectrometer described previously.[1] The resonance frequencies were measured by a heterodyne-type frequency meter whose frequency was checked by means of a frequency counter, TR-5578, from the Takeda Riken Co. The Zeeman field was supplied by a Helmholz coil, 40 cm in diameter and 20 cm in gap width. Measurements were carried out at several temperatures between liquid nitrogen and room temperature. The temperatures were measured by the use of a copper-constantan thermocouple.

The sulfuric diamide and tetramethylsulfamide were obtained by the reactions of sulfuryl chloride with liquid ammonia[2] and liquid dimethylamine[3] respectively. The *N,N*-dimethylsulfamide was prepared by the reaction of dimethylsulfamyl chloride with liquid ammonia.[4] These samples were purified by recrystallization from organic solvents, such as acetone, ethyl ether, and ethyl alcohol. In the cases of sulfuric diamide and tetramethylsulfamide, about a 10-g portion of each sample was melted in a tube and used for measurements. In the case of *N,N*-dimethylsulfamide, about a 6-g single crystal was prepared by the Bridgman-Stockbarger method and examined.

Results and Discussion

Generally a pair of ^{14}N NQR frequencies, ν_I and ν_{II}, are observed for a species of nitrogen atoms:

$$\nu_I = |e^2Qq|(3-\eta)/4, \qquad \nu_{II} = |e^2Qq|(3+\eta)/4, \tag{1}$$

where $|e^2Qq|$ and η are the quadrupole coupling constant and the asymmetry parameter respectively. In sulfuric diamide and tetramethylsulfamide, a pair of resonance lines was found. The quandrupole coupling constants and asymmetry parameters derived from these frequencies are listed in Table 1. In *N,N*-dimethylsulfamide, four resonance lines were paired in two groups, depending upon the frequency shifts due to the influence of the Zeeman field. The two pairs of resonance frequencies due to NH_2 and $N(CH_3)_2$ in *N,N*-dimethylsulfamide are not very different from the corresponding pairs of the related compounds, sulfuric diamide and tetramethylsulfamide. The quadrupole coupling constants and asymmetry parameters observed are also listed in Table 1.

Table 1. NQR parameters in sulfuric diamide and its methyl derivatives

Compound	ν_I (kHz)	ν_{II} (kHz)	$\lvert e^2Qq\rvert$ (kHz)	η (%)
$O_2S(NH_2)_2$	2432.8	3425.1	3905.3	50.82
$O_2S(NH_2)N(CH_3)_2$	2534.5	3499.9	4022.9	47.99[a]
	3584.4	4103.1	5125.0	20.24[b]
$O_2S(N(CH_3)_2)_2$	3759.0	4229.8	5325.9	17.68

a) NQR parameters due to NH_2. b) NQR parameters due to $N(CH_3)_2$.

In the case of *N,N*-dimethylsulfamide, the temperature dependence of the ν_I of the NH_2 group was observed only in the temperature range from 148 K to 173 K. The other three resonance lines of the same compound were too weak to be found in this temperature range. Figure 1 shows the temperature dependence of the ν_I frequencies observed in sulfuric diamide, tetramethylsulfamide, and *N,N*-dimethylsulfamide. The absolute temperature coefficient of resonance frequencies in the NH_2 group can be expected to be larger than that in the $N(CH_3)_2$ group, because a hydrogen atom is much lighter than a methyl group. However, this is not the cases in sulfuric diamide and tetramethylsulfamide, as is shown in Fig. 1. This fact can be explained by the intermolecular

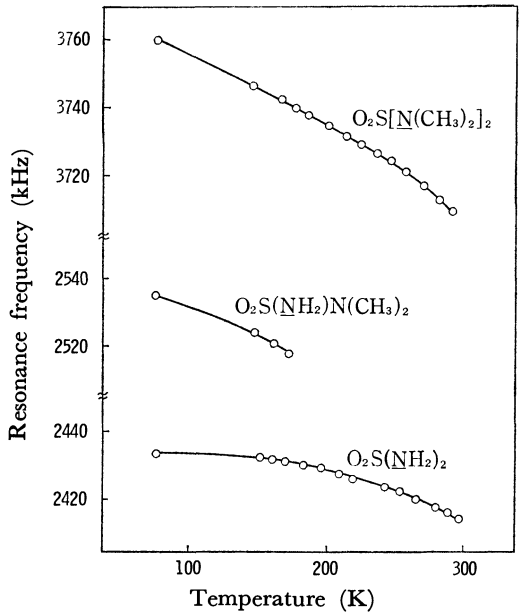

Fig. 1. Temperature dependence of resonance line, ν_I, of the nitrogen atoms (marked by underlines) in sulfuric diamide, tetramethylsulfamide and *N,N*-dimethylsulfamide.

interaction by which the nitrogen atom in sulfuric diamide is fixed by three hydrogen bonds, N–H···O (3.02 Å), N–H···N (3.18 Å) and N···H–N (3.18 Å),[5] while there are no hydrogen bonds in tetramethylsulfamide.[6] That is, the vibration of the nitrogen atom in sulfuric diamide is more suppressed than in tetramethylsulfamide. On the other hand, Fig. 1 shows that the temperature dependence in *N,N*-dimethylsulfamide is nearly equal to that in tetramethylsulfamide. This suggests that the hydrogen bonds in *N,N*-dimethylsulfamide are weaker than in sulfuric diamide.

The ∠HNH bond angle in sulfuric diamide was recently determined by Pedersen to be 110.6°,[7] which is close to the tetrahedral angle (109.5°). However, as the S–N bond length determined by Trueblood and Mayer, 1.60 Å,[5] is appreciably shorter than the single-bond length predicted from the covalent atomic radii, about 1.73 Å, the shape of the NH_2 group may be considered to be nearly planar. Therefore, we assumed sp^2-hybridization for the nitrogen σ-bond orbitals. The crystal structure of tetramethylsulfamide was determined by Jordan *et al.*[6] Despite the ∠CNC bond angle, 112.9°, which is close to the tetrahedral angle, the three bonds around the nitrogen atom in the $N(CH_3)_2$ group lie in a plane. Therefore, we assumed that the nitrogen σ-bond orbitals are sp^2-hybrids. The structure of *N,N*-dimethylsulfamide, however, is not known; therefore, we assumed that both two non-equivalent nitrogen atoms form an sp^2-hybridization and that the ∠HNH and ∠CNC bond angles are 110.6° and 112.9° respectively.

The electron densities on nitrogen atoms in sulfuric diamide and its methyl derivatives were derived from the following equations by Lucken:[8]

TABLE 2. ELECTRON DENSITIES IN SULFURIC DIAMIDE, UREA AND THEIR METHYL DERIVATIVES

Compound	Lone pair	σ_{NC} or σ_{NS}	σ_{NH} or σ_{NCH_3}
$OC(NH_2)_2$	1.68	1.21	1.33
$OC[N(CH_3)_2]_2$	1.76	1.21	1.22
$O_2S(NH_2)_2$	1.74	1.10	1.38
$O_2S(NH_2)N(CH_3)_2$	1.75	1.10	1.37[a]
	1.75	1.08	1.22[b]
$O_2S[N(CH_3)_2]_2$	1.78	1.10	1.22

a) Electron densities due to NH_2. b) Electron densities due to $N(CH_3)_2$.

$$2\eta\cdot|e^2Qq/e^2Qq_p| = 3(c-b)(1-\cot^2\gamma), \quad (2)$$

$$(1-\eta/3)\cdot|e^2Qq/e^2Qq_p| = a-c, \quad (3)$$

where a is the electron density in the lone-pair orbital; b and c, the σ-electron densities in the N–S bond and N–H or N–CH_3 bond respectively; 2γ, the ∠HNH or ∠CNC bond angle, and $|e^2Qq_p|$, the quadrupole coupling constant due to one 2p-electron of a nitrogen atom. In the cases of the $N(CH_3)_2$ groups of tetramethylsulfamide and *N,N*-dimethylsulfamide, it is assumed that $|e^2Qq_p|$ is 9 MHz and that the σ-electron density for the N–CH_3 bond is the same as that for the N–CH_3 bond in tetramethylurea (1.22);[9] therefore, the values of a and b parameters can be evaluated. In the cases of the NH_2 groups of sulfuric diamide and dimethylsulfamide, the σ-electron density in the N–S bond is assumed to be the same as in tetramethylsulfamide; therefore, the values of a and c can be evaluated. Table 2 lists the values obtained in sulfuric diamide, urea, and their methyl derivatives. It may be seen that the σ-electron densities for the N–S bonds in sulfuric diamide and its methyl derivatives are smaller than for the N–C bond in the amido group in urea and tetramethylurea. The ^{35}Cl NQR frequencies in sulfuryl chloride, O_2SCl_2, 37.822 MHz and 37.613 MHz,[10] are higher than those in phosgene, $OCCl_2$, 36.225 MHz and 35.081 MHz.[11] Accordingly, the Cl–S bond in sulfuryl chloride is more covalent than the Cl–C bond in phosgene. From these facts, it may be concluded that the electron-attracting ability of an SO_2 group is stronger than that of a CO group.

Nuclear Quadrupole Resonances of 2,4,6-Trichlorobenzonitrile

Hisao NEGITA, Kaoru SHIBATA, and Tsuneo KUBO

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730

(Received August 13, 1974)

2,4,6-Trichlorobenzonitrile was examined by means of the nuclear quadrupole resonances (NQR) resulting from ^{14}N and ^{35}Cl nuclei. One ^{14}N resonance line (the higher line of the pair) and three ^{35}Cl resonance lines were observed. The Zeeman effect on a single crystal was studied in an attempt to predict the lower ^{14}N line. Thus, $|e^2Qq|=3936.7$ kHz and $\eta=0.1298$ were calculated for the nitrogen atom; the frequency of the lower line was estimated at 2824.8 kHz. On the other hand, ($\eta=0.130$; $|e^2Qq|=71.209$ MHz), (0.128; 72.594), and (0.116; 73.720) were determined for the chlorine atoms in the order of increasing frequencies by studying the Zeeman effect of ^{35}Cl NQR on the single crystal.

Short intermolecular distances between nitrogen and halogen atoms have been known from structural studies of X-ray diffraction in the cyanogen halides and *p*-halobenzonitriles.[1,2] These results have been interpreted as indicating donor-acceptor interaction between adjacent molecules. The crystal structure of 2,4,6-trichlorobenzonitrile was recently determined to be as is shown in Fig. 1,[3] where the intramolecular bonds are represented by the solid lines, while the intermolecular bonds are represented by the broken lines. The shortest distance between the nitrogen and chlorine atoms in this crystal is 3.22 Å, which is shorter by 0.08 Å than the sum of their van der Waals radii.

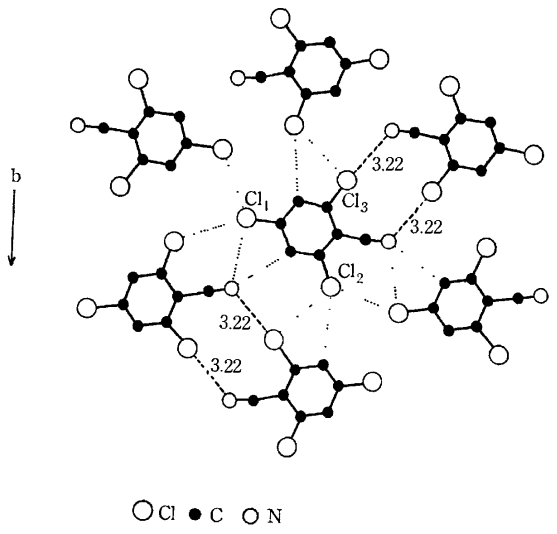

Fig. 1. The projection to the layer of 2,4,6-trichlorobenzonitrile. (Space group $P2_1/c$)

Therefore, there should be a weak interaction between the cyanide groups and *ortho* chlorine atoms, both of which serve to form the dimer. In this respect it seemed that it would be interesting to examine and discuss the chemical bonding in this crystal.

Experimental

The ^{14}N NQR spectrum of 2,4,6-trichlorobenzonitrile was obtained at 77 K by the use of a frequency-modulated spectrometer described previously,[4] whereas the ^{35}Cl NQR spectra of this compound were obtained by the use of a superregenerative spectrometer at 290 K. The resonance frequencies were measured by means of two kinds of heterodyne-type frequency meters, whose frequencies were checked by means of a frequency counter, TR-5578, of the Takeda Riken Co. The Zeeman field was supplied by a Helmholz coil described previously.[5,6]

2,4,6-Trichlorobenzonitrile was prepared from 2,4,6-trichloroaniline *via* 2,4,6-trichloroiodobenzene. This compound was identified by means of its infrared spectrum, its mass spectrum, and its melting point. About a 10-g portion of the sample was used, and a single crystal, 15 mm in diameter and 35 mm in length, was prepared by the Bridgman-Stockbarger method.

Results and Discussion

Our sample of 2,4,6-trichlorobenzonitrile revealed one weak ^{14}N resonance line and three fairly strong ^{35}Cl resonance lines.

^{14}N Resonance Line. Generally a pair of ^{14}N NQR frequencies, ν_I and ν_{II}, are observed as follows:

$$\nu_I = |e^2Qq|(3-\eta)/4, \qquad \nu_{II} = |e^2Qq|(3+\eta)/4, \tag{1}$$

where $|e^2Qq|$ and η are the quadrupole coupling constant and the asymmetry parameter respectively. However, only one resonance line was observed at 3080.2 kHz; it was assigned to the higher line by observing the Zeeman shift. The frequency of the lower line was calculated from the shift of the higher line by applying the Zeeman field, using a single crystal in the same way as before.[6] Figure 2 shows the angular dependence of the Zeeman shift of the higher line when the sample is rotated about a given axis. The Zeeman field was applied along the Y-axis of the laboratory frame, and the resonance frequencies were measured at various rotating angles (Θ) about the X-axis for a constant rotating angle ($\Phi=0°$) about the Z-axis. The maximum frequency or shift was found for $\Theta=335°$. Next, the frequencies were measured at various rotating angles (Φ) about the Z-axis for $\Theta=335°$. The shift was at its maximum at $\Phi=350°$. Therefore, the procedures were repeated until a self-consistent maximum shift was obtained; the maximum frequency was determined to be 3083.4 kHz. Under this condition, the perturbed resonance frequency is at its maximum and expressed as $3083.4=K(3+\eta)+D^2/(2\eta K)$, where K is $|e^2Qq|/4$ and D^2 is 807.8 kHz^2.[6] On the other hand, the higher line in the absence of the Zeeman field is expressed by $3080.2=K(3+\eta)$. Thus, the NQR parameters are calculated as $|e^2Qq|=3936.7\pm7.0$ kHz and $\eta=0.1298\pm0.0057$. Substituting these values into Eq. 1, the frequency of the lower line is obtained as 2824.8±

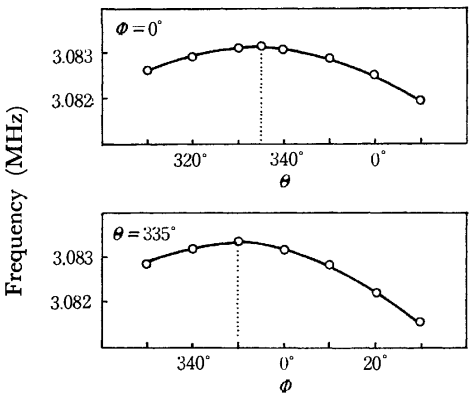

Fig. 2. The angular dependences of the Zeeman shifts.

10.6 kHz. The neighborhood of this frequency was carefully swept again, but, unfortunately, no resonance line was observed.

^{35}Cl Resonance Lines. The ^{35}Cl NQR frequency, ν, is obtained according to the following equation:

$$\nu = |e^2Qq|(1+\eta^2/3)^{1/2}/2. \quad (2)$$

The ^{35}Cl resonance lines of the sample were observed at 35.704, 36.395, and 36.941 MHz, as is shown in Table 1. These lines are labeled as ν_1, ν_2, and ν_3 respectively. Then, referring to the crystal structure of the sample, these lines can be ascribed to the three kinds of chlorine atoms, Cl_1, Cl_2, and Cl_3, in one molecule. One of the zero-splitting patterns of the Zeeman effect on the resonance lines is shown in Fig. 3. For each of the resonance lines, ν_1, ν_2, and ν_3, two loci were obtained. The direction of the principal z-axis of the field gradient on the chlorine atom can be obtained from the zero-splitting pattern; it is assumed to be parallel to the direction of the C–Cl bond. The direction of the b-axis (C_2-axis) of the crystal can be found easily from the symmetrical distributions of the z-axis. The resonance line can be assigned by means of the angle between the b-axis and the z-axis. Thus, it

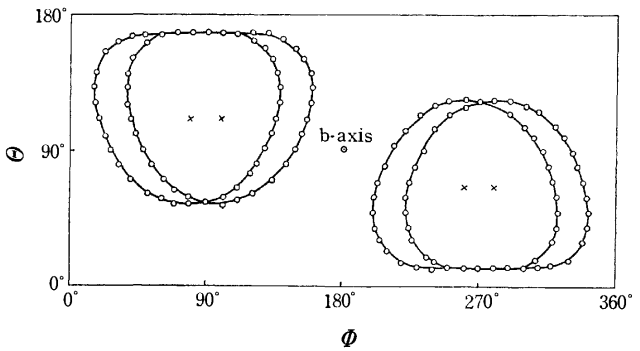

Fig. 3. Zero-splitting patterns of the Zeeman effect on the resonance line, ν_1.

is evident that ν_1, ν_2, and ν_3 originate from the *para-*, *ortho-*, and *ortho-*chlorine atoms respectively. The last interacts weakly with the cyanide group of the adjacent molecule. The condition under which the zero-splitting occurs for the ^{35}Cl nucleus is given[7] by:

$$\sin^2\theta = 2/(3-\eta\cos^2\varphi), \quad (3)$$

where θ and φ are the polar and azimuthal angles for the Zeeman magnetic field with respect to the coordinates of the principal axes of the field gradient at the resonant nucleus. The asymmetry parameters were determined from Eq. (3) by the use of the least-squares method. If the crystal field effects are negligibly small, the quadrupole coupling constant and the double-bond character, f, can be determined from the following equation:[8]

$$f = 2|e^2Qq|\eta/(3|e^2Qq_{\text{atom}}|), \quad (4)$$

where $|e^2Qq_{\text{atom}}|$ is 109.7 MHz.[9] These results are listed in Table 1. The f value of ν_3 is rather smaller. This suggests that the *ortho-*chlorine atom assigned ν_3 interacts with the cyanide group of the adjacent molecule, as is to be expected from the crystal structure of this compound.[3] The ∠CN···Cl angle is 122.4°, although generally the ∠CN···halogen angle is about 180°, as in the acetonitrile–bromine complex.[10] This seems to suggest that the σ-orbital of the nitrogen atom in this molecule has an s-character of less than 50%.

Table 1. NQR parameters in 2,4,6-trichlorobenzonitrile

		ν(MHz)	$\lvert e^2Qq\rvert$(MHz)	η(%)	f(%)
^{14}N		2.8248[a]	3.9367[a]	12.98[a]	—
		3.0802			
^{35}Cl	Cl_1	35.704	71.209	13.0	5.63
	Cl_2	36.395	72.594	12.8	5.65
	Cl_3	36.941	73.720	11.6	5.19

Polarographic Studies of Bis(2,2′,2″-terpyridine) Complexes of Manganese(II), Cobalt(II), Nickel(II) and Europium(III) in Acetonitrile

Makoto AIHARA,* Hirofumi KISHITA, and Seizo MISUMI**

Inorganic Chemistry Laboratory, Faculty of Science, Kyushu University, Fukuoka 812

(Received June 8, 1974)

The reduction mechanism of bis 2,2′,2″-terpyridine complexes of manganese(II), cobalt(II), nickel(II) and europium(III) were investigated in acetonitrile by means of DC and AC polarograph and Kalousek polarograph at DME and cyclic voltammetry at an HDME. It was found that univalent metal complex anions, such as $[M(terpy)_2]^-$ (M=manganese and nickel), were formed at the electrode surface in acetonitrile. For the europium(III) complex, the standard rate constant of the second reduction step was estimated.

It is well-known that ligands such as 2,2′-bipyridine and 1,10-phenanthroline which have available acceptor orbitals for π electrons stabilize low valency states of these metal complexes.[1] Acetonitrile is a more inert solvent than water in the reduction of metal complexes. Formation of univalent tris(2,2′-bipyridine)metal complex anions in acetonitrile has been reported in polarographic studies.[2-4]

In this work, the electrode processes of bis(2,2′,2″-terpyridine)metal(II, III) complexes (metal ions; manganese(II), cobalt(II), nickel(II) and europium(III)) in acetonitrile were investigated by polarography.

Experimental

Materials. Bis(2,2′,2″-terpyridine)metal(II, III) perchlorates were prepared by the methods of Morgan and Burstall,[5] Hogg and Wilkins[6] and Sinha.[7] The compositions were identified by elementary analysis. Acetonitrile (AN) was purified[8] and water content was determined to be 5 mM by Karl Fischer titration. Et_4NClO_4(TEAP) was used as a supporting electrolyte.

Apparatus. The electrolysis cell and reference electrode were the same as previously reported.[9] Cyclic voltammograms were recorded by a Rikendenshi X-Y recorder. Triangular potential signals were obtained from the Yokogawa-Hewlett-Packard 3300 A Function Generator. The DME had the following characteristics: m=0.706 mg/s, t=6.17 s in 0.1 M TEAP–AN medium at −1.4 V *vs.* SCE. The HDME(surface area of HDME; 0.031 cm^2) was used for cyclic voltammetry as a working electrode.

Procedure. A sample solution was prepared by dissolving 0.1—1.0 mM bis (terpyridine) metal(II, III) perchlorate and 0.1 M TEAP in AN. Triton X-100 was used as a maximum suppressor. The dissolved oxygen in the solution was removed by bubbling pure nitrogen presaturated with acetonitrile vapour for 20 min. All the experiments were carried out at 25.0±0.1 °C. Other procedures were the same as previously described.[9]

Results and Discussion

Bis(2,2′,2″-terpyridine)manganese(II) Complex. DC polarograms of 0.5 mM $[Mn(terpy)_2](ClO_4)_2$ complex in acetonitrile are shown in Fig. 1. The complex gave a six-step reduction wave. The maximum (2B) at the second step was not suppressed by the addition of

Triton X-100. The third and fourth waves were close to each other, making it difficult to analyze them. The electrode reactions of the first and second waves were found to be diffusion-controlled. The polarographic data are given in Table 1. The ratio of wave heights for the first four waves was 1.00 : 1.07 : 0.30 : 0.71. The diffusion current constant at the first step was 2.05, which is nearly equal to the value of one-electron reduction of various metal ions[10] and tris(2,2′-bipyridine)manganese(II).[3] From log-plot analysis and Kalousek polarogram, the first and second steps were found to be due to reversible one-electron and quasi-reversible one electron reductions, respectively. The first and second waves were not affected by the addition of free 2,2′,2″-terpyridine, but the third wave was suppressed and the fourth wave showed no distinct diffusion plateau (Fig. 1). AC polarograms of the complex are shown in Fig. 2. The main peak admittance increased with the increase in concentration of the complex, sharp peaks (1B and 2B) being observed at the first and second steps. The 1B peak was suppressed by the addition of triton X-100 but the 2B peak remained unchanged. The electrocapillary curve of manganese(II) complex, shown in Fig. 3, shows a depression in the cathodic potential range. The depression was observed at the potentials whose maximum appeared in AC polarography. This shows that the adsorption of the complex occurs on the electrode surface.

Cyclic voltammograms of manganese(II) complex are shown in Fig. 4. Sharp peaks corresponding to the 1B and 2B peaks appeared at 0.5 mM $[Mn(terpy)_2](ClO_4)_2$ but not at 0.1 mM $[Mn(terpy)_2](ClO_4)_2$. The values of ΔE_{peak} (the difference in peak potentials at the anodic and cathodic sides) are 74 and 51 mV for the first and second waves, respectively. No anodic peak of the third step was observed because of irreversibility of the electrode reaction.

It was found that: 1) the reduction potentials of the third and fourth waves differ from those of 2,2′, 2″-terpyridine; 2) the total diffusion current constant (2.07) of the third and fourth waves is nearly equal to the value of one electron reduction of various metal ions; and 3) the third wave was suppressed by the addition of 2,2′,2″-terpyridine. From these results and those for the first and second waves, the electrode processes are estimated as follows:

$$[Mn(terpy)_2]^{2+}$$

1st wave e ⇓

$$[Mn(terpy)_2]^{+}$$

2nd wave e ⇓

$$[Mn(terpy)_2] \rightleftharpoons [Mn(terpy)] + terpy$$

4th wave e ↓ 3rd wave ↓ e ↓

$$[Mn(terpy)_2]^{-} \rightleftharpoons [Mn(terpy)]^{-} + terpy$$

The 5th and 6th waves correspond to the reduction of terpyridine liberated from the complex.

Thus, the formation of univalent $[Mn(terpy)_2]^{-}$ anion was found at the DME in acetonitrile. The 1B peak is considered to be caused by the weak adsorption

of product, from the fact that the maximum did not interfere with the DC polarogram of the first wave, and the peak at cyclic voltammogram was suppressed by the addition of Triton X-100. On the other hand, the second wave was affected appreciably by the maximum and was not suppressed by the addition of Triton X-100.

Bis(2,2',2"-terpyridine)cobalt(II) Complex. The DC polarogram of 0.5 mM $[Co(terpy)_2](ClO_4)_2$ in acetonitrile is shown in Fig. 5. A four-step reduction wave was observed and the electrode reactions of the first three steps found to be diffusion-controlled (Table 1). The ratio of the first and second wave heights was 1 : 1. The diffusion current constant for the first wave was 1.96, nearly equal to the value of a one-electron reduction of tris(2,2'-bipyridine)cobalt(II) complex.[2] The value of the reciprocal slope for the first and second waves was close to the theoretical value of 0.059 V, while the log-plot of the third wave gave a curve with two linear parts. The AC polarogram of the complex is also shown in Fig. 5. AC peaks corresponding to the first and second steps were observed, but the peak potential of the third did not coincide with that of the ligand.

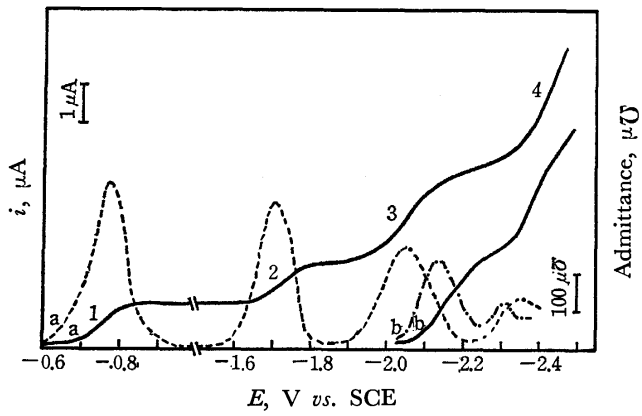

Fig. 5. DC and AC polarograms of 0.5 mM $[Co(terpy)_2](ClO_4)_2$ (curve a) and 0.5 mM 2,2',2"-terpyridine (curve b) in 0.1 M TEAP-AN.

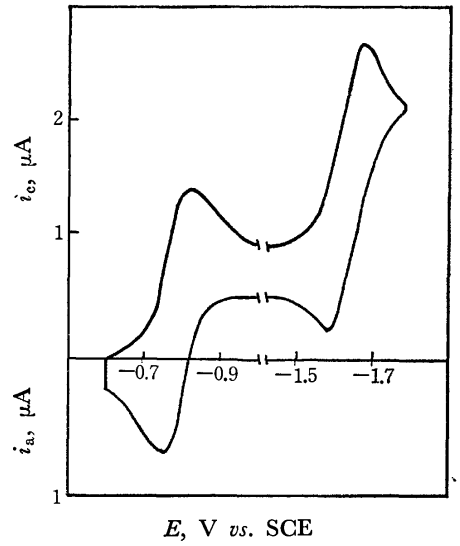

Fig. 6. Cyclic voltammograms of 0.5 mM $[Co(terpy)_2](ClO_4)_2$ in 0.1 M TEAP-AN. Scan rate: 0.03 V/s.

The effect of free 2,2',2"-terpyridine upon the reduction wave was investigated. No effect was observed upon the first and second waves, but the third and fourth waves increased in height with increase in the concentration of 2,2',2"-terpyridine.

Cyclic voltammograms of 0.5 mM cobalt(II) complex are shown in Fig. 6. The values of ΔE_{peak} for the first and second steps are close to the theoretical value of reversible one-electron reduction.

Thus, the electrode reactions are written as,

$$[Co(terpy)_2]^{2+} + e \rightleftarrows [Co(terpy)_2]^{+}$$

$$[Co(terpy)_2]^{+} + e \rightleftarrows [Co(terpy)_2]$$

The formation of $[Co(terpy)_2]^+$ and $[Co(terpy)_2]$ was found in the same way as in the case of bis(2,2',2"-terpyridine) iron(II) complex,[11] but that of $[Co(terpy)_2]^-$ could not be confirmed by DC or AC polarography.

Bis(2,2',2"-terpyridine)nickel(II) Complex. DC and AC polarograms of the nickel(II) complex are shown in Fig. 7. It gave a five-step reduction wave. A small maximum appeared at the positive side of the third wave in DC polarograms. The electrode reactions for the first three waves were found to be diffusion-controlled (Table 1). By the addition of free 2,2',2"-terpyridine to the solution of 0.5 mM complex, the first wave increased and the second wave decreased. The reciprocal slope of the first wave approached the value of a reversible two-electron reduction. The diffusion current constant for the third step is 2.23, which nearly equals the value of one-electron reduction of various metal ions.[10] The total height of the first and second waves was about twice as much as that of the third wave. The 1B peak in AC polarogram was suppressed but the 3B peak remained with the addition of Triton X-100 (Fig. 7). Cyclic voltammetry of the nickel(II) complex was investigated. The sharp peaks corresponding to the 1B and 3B waves also appaered in the cyclic voltammogram. The 1B peak was significantly large at the anodic and cathodic sides. The clear anodic and cathodic peaks of the first and the second steps were observed and the cathodic peak of the third step was observed as a shoulder at −1.9 V *vs.* SCE.

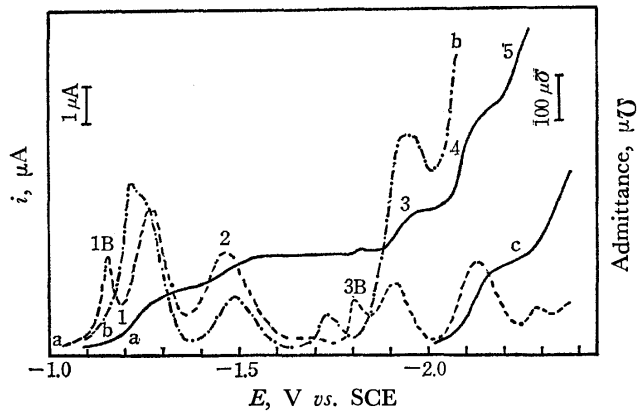

Fig. 7. DC and AC polarograms of $[Ni(terpy)_2](ClO_4)_2$ in 0.1 M TEAP-AN.
a: 0.5 mM $[Ni(terpy)_2](ClO_4)_2$, b: a) +5 mM 2,2',2"-terpyridine, c: 0.5 mM 2,2',2"-terpyridine.

The electrode reactions for the first and third waves are estimated as follows.

$$[Ni(terpy)_2]^{2+} + 2e \rightleftarrows [Ni(terpy)_2]$$

$$[Ni(terpy)_2] + e \rightleftarrows [Ni(terpy)_2]^-$$

The univalent $[Ni(terpy)_2]^-$ anions are formed at the electrode surface. From the fact that the second wave decreased with the addition of 2,2′,2″-terpyridine, the second wave might correspond to the irreversible two electron reduction of dissociated complex species, *e.g.* $[Ni(terpy)]^{2+}$.

Bis(2,2′,2″-terpyridine)europium(III) Complex. DC and AC polarograms of 0.5 mM $Eu(terpy)_2(ClO_4)_3$ are shown in Fig. 8. The europium complex gave a four-step reduction wave, the electrode reactions of the first and second waves being found to be diffusion-controlled (Table 1). The diffusion current constant of the first step was 2.05, which is nearly equal to the value of one-electron reduction. The ratio of the wave heights of the first and second steps is 1 : 1.9. It was concluded that the first and second waves were one- and two-electron reduction waves, respectively. The third and fourth waves are due to the reduction of the ligand.

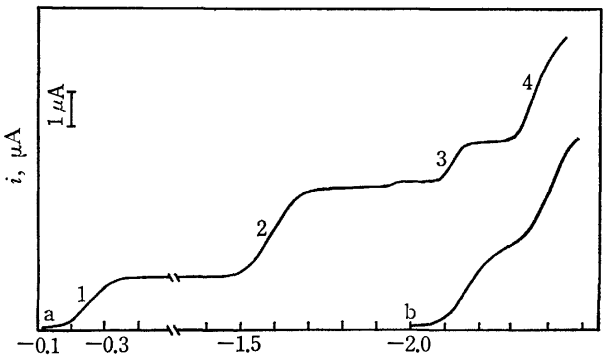

Fig. 8. DC polarograms of 0.5 mM $[Eu(terpy)_2](ClO_4)_3$ (curve a) and 0.5 mM 2,2′,2″-terpyridine (curve b) in 0.1 M TEAP-AN.

With the addition of free 2,2′,2″-terpyridine, the first wave was shifted to a more negative potential and the value of the reciprocal slope became equal to that of a reversible one-electron reduction. The reversibility of the second wave decreased with an increase in concentration of the ligand reagent.

A cyclic voltammogram of the complex is shown in Fig. 9. Peaks of the first and second steps were observed, the peak potential of the second wave shifting to a more negative potential with increasing scan rate. This indicates the irreversibility of the second step, also. The electrode reaction scheme is shown to be as follows.

$$[Eu(terpy)_2]^{3+} + e \rightleftarrows [Eu(terpy)_2]^{2+}$$

$$[Eu(terpy)_2]^{2+} + 2e \rightleftarrows Eu^0 + 2terpy$$

The standard rate constant (k_s) for the second step

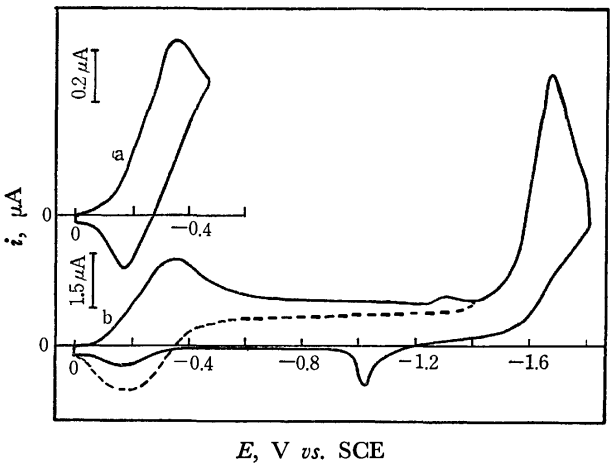

Fig. 9. Cyclic voltammograms of $[Eu(terpy)_2](ClO_4)_3$ in 0.1 M TEAP-AN.
a: 0.5 mM $[Eu(terpy)_2](ClO_4)_3$ at 0.038 V/s, b: 0.7 mM $[Eu(terpy)_2](ClO_4)_3$ at 0.285 V/s.

was determined to be 6.7×10^{-4} cm/s by the single sweep method.

The waves corresponding to the formation of $[M(terpy)_2]^-$ (M=Mn and Ni) were observed in DC polarograms. In the case of the Co(II) complex, the formation of $[Co(terpy)_2]^-$ was not confirmed since the wave overlapped with that of the free 2,2′,2″-terpyridine.

On the other hand, bis(2,2′,2″-terpyridine)europium (III) complex was not reduced to the univalent complex anion but decomposed into metal amalgam and ligands after reduction at the potential of the second wave. This indicates that there is a more stable and stronger tendency of complex formation of d-element than that of f-element in bisterpyridine complexes of metal(0).

The work was carried out with financial support from the Ministry of Education.

Polarography of Europium(III) in Acetonitrile in the Presence of Thiocyanate and Halide Ions

Makoto AIHARA* and Seizo MISUMI**

Inorganic Chemistry Laboratory, Faculty of Science, Kyushu University, Fukuoka 812

(Received August 28, 1974)

Studies were carried out on the polarographic behavior of europium in acetonitrile in the presence of SCN^-, Br^-, I^- and Cl^-. Two reduction waves were found in the Eu(III)–SCN^- system, one corresponding to the reduction of $[Eu(NCS)_6]^{3-}$ and the other to the reduction of $[Eu(NCS)_2]$. In the Eu(III)–Br^- system, the reduction potential of Eu(III)-bromide complex species was more positive than that of the $[HgBr_4]^{2-}$/Hg couple. In the Eu(III)–I^- system, iodide ions were oxidized in acetonitrile by europium(III). The formation constants of Eu(III)–SCN^- system were found to be: $\log \beta_6 = 24.4$ for $[Eu(NCS)_6]^{3-}$ and $\log \beta_2 = 6.0$ for $[Eu(NCS)_2]$. The degree of complexation of europium(III) and mercury(II) with bromide ion was also determined.

Polarographic and potentiometric studies of metal-(II, III)–halide and –thiocyanate complexes in acetonitrile have been reported.[1–3] The polarographic reduction of europium (III) in tetraethylammonium perchlorate in acetonitrile was studied by several authors,[4,5] the reduction process at DME in acetonitrile being Eu(III)→Eu(II) and Eu(II)→Eu(0). In a study on the influence of water on the reduction waves, the addition of small amounts of water was found to give a negative shift of the half-wave potential, which is caused by the rate of the electrode reaction being affected by the presence of water molecules adsorbed on the mercury electrode surface.[5]

The polarographic behavior of europium(III) in the presence of halide ions in non-aqueous solvents has not been studied. The waves of lanthanoids(III) in acetonitrile occur at considerably more negative potentials with tetraethylammonium bromide than with tetraethylammonium perchlorate as a supporting electrolyte.[4] This paper deals with the polarography of europium(III) in the presence of SCN^-, Br^-, I^- and Cl^-. The formation constants for Eu(III)–SCN^- and Eu(III)–Br^- systems were obtained and the electrode process of these systems was also determined.

Experimental

Materials. Commercial acetonitrile was purified by the method of Coetzee *et al.*[6] The water contant was found to be less than 0.01% by Karl Fischer titration. Tetraethylammonium halides and tetraethylammonium thiocyanate were prepared by the procedures reported.[2,3]

Apparatus. The electrolysis cell consists of three electrodes.[1] The reference electrode was an SCE with a salt bridge:

$$\left(\frac{0.5\ \mathrm{M}\ Et_4NClO_4}{AN}\middle|\frac{1\ \mathrm{M}\ NaClO_4}{H_2O}\middle|\frac{1\ \mathrm{M}\ NaCl}{H_2O}\middle|\frac{1\ \mathrm{M}\ KCl}{H_2O}\right)$$

Procedure. Sample solutions were prepared by dissolving 0.5 mM europium(III) perchlorate in acetonitrile with an appropriate amount each of Et_4NX(X^-: SCN^-, Cl^-, Br^- and I^-). Et_4NClO_4 was used to keep the concentration of Et_4N^+ 0.1 M. Other procedures were the same as described previously.[1]

Results and Discussion

Europium(III) Perchlorate in Acetonitrile. Europium(III) gave a two-step reduction wave corresponding to the one- and two-electron reduction. The half-wave potentials were in line with those reported by Cokal and Wise.[5] The electrode reaction of the first and second waves was found to be reversible and diffusion-controlled.

Eu(III)–SCN^- System. Polarograms of 0.5 mM Eu(III) in the presence of thiocyanate ions are shown

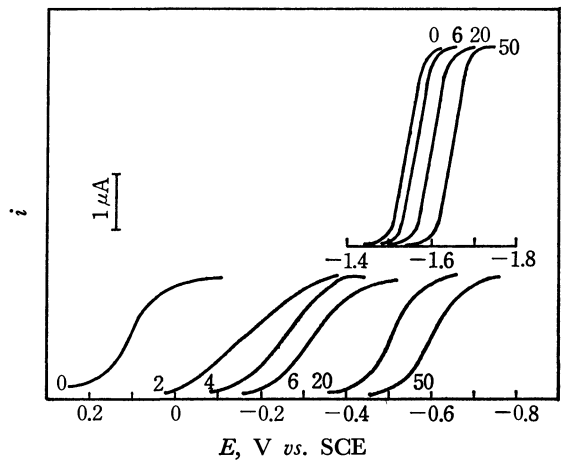

Fig. 1. DC polarograms of europium(III) in the presence of thiocyanate ion. Numbers on curves indicate mole ratio, $[SCN^-]_t/[Eu(III)]_t$.

TABLE 1. POLAROGRAPHIC DATA FOR EUROPIUM(III)–THIOCYANATE SYSTEM

$[Eu(III)] = 0.5$ mM

$[SCN]_t$ / $[Eu(III)]_t$	1st Wave			2nd Wave		
	$E_{1/2}$ V *vs.* SCE	i_d μA	Slope mV	$E_{1/2}$ V *vs.* SCE	i_d μA	Slope mV
0	0.113	1.80	58	−1.624	3.40	28
6	−0.318	1.87	—	−1.650	3.40	30
10	−0.407	1.87	61	−1.660	3.32	30
20	−0.493	1.80	60	−1.687	3.44	31
30	−0.541	1.79	58	−1.696	3.18	34
40	−0.571	1.80	60	−1.714	3.15	35
50	−0.590	1.84	58	−1.725	3.60	34

in Fig. 1. The first wave was shifted towards more negative potentials with increasing concentration of thiocyanate ions. The log-plot was found to be non-linear for $[SCN^-]_t/[Eu(III)]_t<10$. Above this ratio, the electrode reaction of the first wave was found to be a reversible, one electron reduction and diffusion-controlled. The polarographic data are shown in Table 1. The second wave was also shifted towards more negative potentials with increasing concentration of thiocyanate ions. The electrode reaction of the second wave was found to be a reversible, two-electron reduction and diffusion-controlled.

Assuming that Eu^{3+}, EuX_p^{3-p}, Eu^{2+} and EuX_q^{2-q} are reduced reversibly, the electrode reactions are given by

$$Eu^{3+} + e \rightleftharpoons Eu^{2+} \quad (1)$$

$$EuX_p^{3-p} + e \rightleftharpoons EuX_q^{2-q} + (p-q)X^- \quad (2)$$

$$Eu^{2+} + 2e \rightleftharpoons Eu(0) \quad (3)$$

$$EuX_q^{2-q} + 2e \rightleftharpoons Eu(0) + qX^- \quad (4)$$

where X^- is SCN^- or halide ion. The difference of the half-wave potentials for Eqs. (1) and (2), $(E_{1/2})_c-(E_{1/2})_s$, is given by

$$\Delta E = 0.0591 \log (\beta_{EuX_q}/\beta_{EuX_p}) - 0.0591(p-q) \log [X]_0 - 0.0591 \log (I_{EuX_p}\cdot I_{Eu^{2+}}/I_{EuX_q}\cdot I_{Eu^{3+}}) \quad (5)$$

where β is overall formation constant for the complex species, I the diffusion current constant for each species and $[X]_0$ the concentration of the ligand species $[SCN^-]$, at the electrode surface; $[X]_0=(C_x-PC_M/2)/(1+K_A[Et_4N^+])$.[1] The value of $p-q$ can be obtained by

$$p-q = \frac{d(\Delta E)}{d \log[SCN^-]_0}/0.0591 \quad (6)$$

From the plot of ΔE *vs.* $\log[SCN^-]_0$ for the first wave, $(p-q)$ and $\log(\beta_{Eu(NCS)_p}/\beta_{Eu(NCS)_q})$ were obtained to be 4.0 and 18.4, respectively. From the same plot for the second wave, q and $\log \beta_{Eu(NCS)_q}$ were found to be 1.9 and 6.0, respectively. Thus, the electrode reactions are presumed to be as follows.

$$Eu(NCS)_6^{3-} + e \rightleftharpoons Eu(NCS)_2 + 4SCN^- \quad (7)$$

$$Eu(NCS)_2 + 2e \rightleftharpoons Eu(0) + 2SCN^- \quad (8)$$

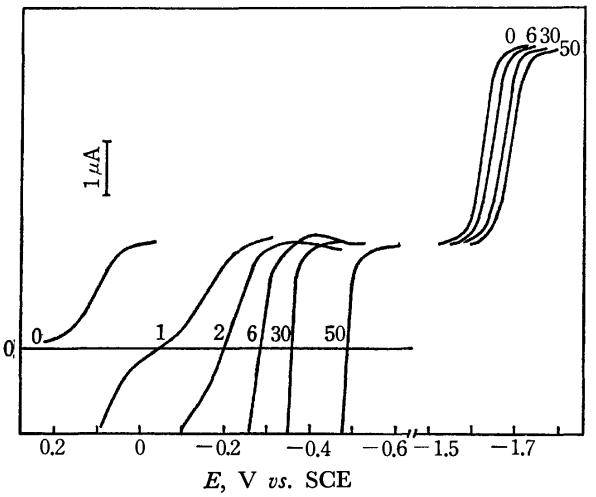

Fig. 2. DC polarograms of europium(III) in the presence of bromide ion. Numbers on curves indicate mole ratio, $[Br^-]_t/[Eu(III)]_t$.

The values of $\log \beta_{Eu(NCS)_6^{3-}}$ and $\log \beta_{Eu(NCS)_2}$ were found to be 24.4 and 6.0, respectively. Formation of $Eu(NCS)_6^{3-}$ in acetonitrile has also been confirmed by Burmeister *et al.*[7]

With increasing concentration of SCN^-, the reciprocal slope of the second wave deviated from the theoretical one. The standard rate constant of reduction ($[SCN_t/[Eu(III)]_t=50$) was determined to be 1.7×10^{-4} cm/s by cyclic voltammetry, indicating that the electrode reaction was quasi-reversible at high concentrations of SCN^-.

Eu(III)-Br^- System. Polarograms of 0.5 mM Eu (III) in the presence of bromide ion are shown in Fig. 2. The solution containing Eu(III) and bromide ions was pale yellow, the coloration disappearing on addition of water. The formation of Eu(III)-bromide complex in acetonitrile was assumed. The first wave may be a composite wave of $EuBr_p^{3-p}\rightleftharpoons EuBr_q^{2-q}$ and $Hg\rightleftharpoons HgBr_x^{2-x}$ couples. Thus, the electrode reactions are given by

$$EuBr_p^{3-p} + e \rightleftharpoons EuBr_q^{2-q} + (p-q)Br^- \quad (9)$$

$$HgBr_x^{2-x} + 2e \rightleftharpoons Hg + XBr^- \quad (10)$$

The half-wave potentials for the reduction of $EuBr_p^{3-p}$ and $HgBr_x^{2-x}$ are as follows.

$$(E_{1/2})_c^{Eu} = (E_{1/2})_s^{Eu} - 0.0591 \log K - 0.0591(p-q) \log [Br^-]_0 \quad (11)$$

$$(E_{1/2})_c^{Hg} = (E_{1/2})_s^{Hg} - 0.0295 \log \beta_{HgBr_x^{2-x}} - 0.0295 \log [Br^-]_0 \quad (12)$$

where $K=\beta_{EuBr_p^{3-p}}/\beta_{EuBr_q^{2-q}}$. In the case of Eu(III)–Br^- system, the half-wave potential of mercury(II) bromide complex is more negative than that of Eu(III) bromide complex; $(E_{1/2})_c^{Hg}<(E_{1/2})_c^{Eu}$. From Eqs. (11) and (12), the following relationship can be obtained at $[Br^-]_0=1$ M.

$$(E_{1/2})_s^{Hg} - 0.0295 \log \beta_{HgBr_x^{2-x}} < (E_{1/2})_s^{Eu} - 0.0591 \log K \quad (13)$$

Since $(E_{1/2})_s^{Hg}=0.557$ and $(E_{1/2})_s^{Eu}=0.113$ V *vs.* SCE in acetonitrile, Eq. (13) is reduced to

$$\log \beta_{HgBr_x^{2-x}} > 2 \log K + 15 \quad (14)$$

The value of $\log \beta_{HgBr_4^{2-}}$ was calculated to be *ca.* 38 by the plot of $\Delta E_{1/2}$ *vs.* $\log [Br^-]_0$. From Eq. (14), we obtain $\log K<$ *ca.* 12. On the other hand, the value of $2 \log K+15$ for Eu(III)–SCE^- system is 52. Thus $2 \log K+15 \gg \log \beta_{Hg(SCN)_4^{2-}}$ ($\approx$38). This indicates that the wave of Eu(III)–SCN^- complex was completely separated from the wave of Hg(II)–SCN^- complex (Fig. 1).

The second wave was found to be a reversible, two-electron reduction and diffusion-controlled. The values of q and $\log \beta_{EuBr_2}$ were calculated to be 1.8 and 5.31, respectively.

Eu (III)–I^- System. Figure 3 shows the polarograms of 0.5 mM Eu (III) in the presence of iodide ions. By addition of iodide ions, the first wave was shifted towards more negative potentials, the height of the second wave becoming smaller. Limiting currents *vs.* $[I]_t/[Eu(III)]_t$ ($=x$) are shown in Fig. 4. The height of the first wave in the presence of iodide ions was nearly equal to that in the absence of iodide ions until $x=2$ and the height of the first wave started

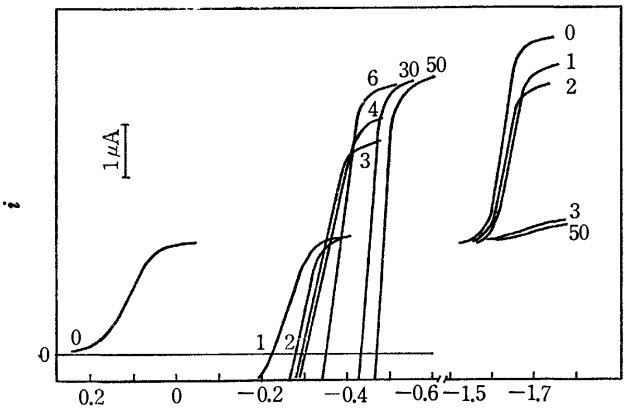

Fig. 3. DC polarograms of acetonitrile solutions containing europium(III) and iodide ion. Number on curves indicates mole ratio, $[I^-]_t/[Eu(III)]_t$.

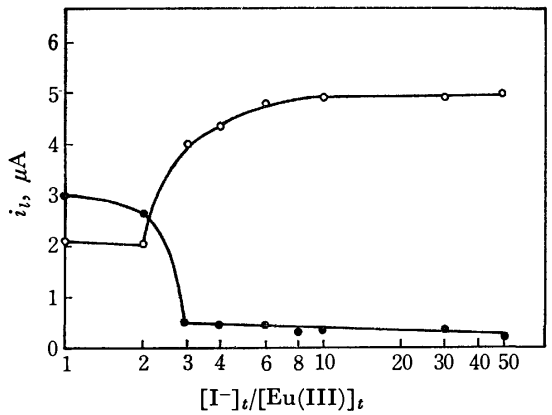

Fig. 4. Limiting currents *vs.* $[I^-]_t/[Eu(III)]_t$ for europium(III)-iodide system.
○: 1st wave, ●: 2nd wave.

to increase at *ca.* $x=2$. The solution containing Eu (III) and iodide ions was yellowish brown, the coloration became stronger with increasing concentration of iodide ions, finally becoming the same as that of iodine in acetonitrile. A polarogram of the solution containing I_2 and Et_4NI was similar to that of the first wave in the presence of excess of iodide ions. This indicates that Et_4NI is oxidized in acetonitrile by europium(III). The reaction product, I_2, is known to form triiodide ion (I_3^-) in the presence of iodide ions.

Since iodine and triiodide ions react rapidly with mercury of the electrode,[8] the mechanisms of chemical and electrochemical processes are given as follows.

chemical processes

$$Eu^{3+} + I^- \longrightarrow Eu^{2+} + \frac{1}{2}I_2 \quad (15)$$

$$I_2 + I^- \rightleftharpoons I_3^- \quad (16)$$

$$I_2 + Hg \rightleftharpoons HgI_2 \quad (17)$$

$$I_3^- + Hg \rightleftharpoons HgI_3^- \quad (18)$$

electrode processes

1st wave

$$Eu^{3+} + e \rightleftharpoons Eu^{2+} \quad (19)$$

$$3HgI_2 + 2e \rightleftharpoons Hg + 2HgI_3^- \quad (20)$$

$$2HgI_3^- + 4e \rightleftharpoons 2Hg + 6I^- \quad (21)$$

2nd wave

$$Eu^{2+} + 2e \rightleftharpoons Eu(0) \quad (22)$$

At $x \leq 2$, the oxidation of iodide ion by europium(III) is not complete.

The first wave might correspond to the reduction of Eqs. (19) and (20).[9] For $x \geq 3$, the reaction of Eq. (21)[9] was predominant, the height of the wave becoming large. The second wave disappeared. This may be caused by the formation of EuI_q^{2-q} which is electroinactive in this potential region.

Eu(III)–Cl⁻ System. For $x<10$, several waves appeared. But a polarogram gave a single reduction wave with a minimum in the diffusion plateau at around −1.0 V *vs.* SCE at $x \geq 10$. The electrocapillary curve of Eu(III)–Cl⁻ system showed a depression in the cathodic range (−0.8——1.0 V *vs.* SCE). The depression was observed at potentials at which a minimum appeared. The hexachloroplatimum(IV) ion[10] produced a minimum similar to that of the complex ion. The minimum may be attributed to the formation of a film of reduction product.

Financial support for this work was given by the Ministry of Education.

Proton Magnetic Resonance Spectra of L- or D-Aspartato (L-2,4-diaminobutyrato)cobalt(III) Complexes

Masatoshi WATABE, Kenji ONUKI,* and Sadao YOSHIKAWA*

General Education Department of Kogakuin University, Hachioji, Tokyo 193

**Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113*

(Received June 17, 1974)

Three diastereomeric isomers of the L-aspartato(L-2,4-diaminobutyrato)cobalt(III) and two of the D-aspartato (L-2,4-diaminobutyrato)cobalt(III), $Co(N)_3(O)_3$ type were prepared and isolated. The isomers were characterized by their electronic absorption and proton magnetic resonance spectra. Their PMR spectra indicate that the carbon proton adjacent to the coordinated N atom resonates at a higher magnetic field when O atom occupies the site *trans* to the N atom than when N atom occupies the same place.

The preparation and characterization of cobalt(III) complexes containing optically active amino acids which are potentially tridentate ligands have been reported for those with L-2,4-diaminobutyrate ion (L-2,4-dba),[1] D- or L-2,3-diaminopropionate ion (D- or L-2,3-dpa),[2] L-aspartate ion (L-asp)[3,4] and L-histidinate ion (L-his).[5]

However, the assignments are tentative except for that for $[Co(L\text{-}2,3\text{-}dpa)_2]^+$, the exact geometries of which have been determined on the basis of an X-ray diffraction study of one of the *cis* O isomers.[6] An alternative proposal has been given for the isomers for $[Co(L\text{-}asp)_2]^-$.[7] The complexes of bis(L-aspartato)-cobaltate(III) and L-aspartato(iminodiacetato)cobaltate(III) belong to the $[Co(N)_2(O)_4]$ type, and the complexes of bis(L-2,4-diaminobutyrato)cobalt(III) and bis(histidinato)cobalt(III) to the $[Co(N)_4(O)_2]$ type. The aim of the present study was to prepare the mixed complexes [Co(L- or D-asp)(L-2,4-dba)] of the $[Co(N)_3(O)_3]$ type.

Experimental

L-2,4-Diaminobutyric acid was prepared from L-glutamic acid by the Schmidt reaction.[8] All the other materials were of reagent grade.

Three Isomers of [Co(L-asp)(L-2,4-dba)]. To a hot solution (*ca.* 70 °C) containing 1.33 g (0.01 mol) of L-aspartic acid and 1.55 g (0.01 mol) of L-2,4-diaminobutyric acid monohydrochloride in 50 ml of water were added 3.6 g (0.01 mol) of freshly prepared $Na_3[Co(CO_3)_3]\cdot 3H_2O$ and 1 g of activated charcoal. The mixture was stirred on a boiling water bath for *ca.* 30 min. The mixture was then filtered and the charcoal was carefully washed with hot water. The washings and filtrate were combined and concentrated to *ca.* 20 ml on a rotary evaporator at about 40 °C and kept in a refrigerator overnight. Violet powder crystals which appeared were filtered off, washed with a small amount of water and air-dried. The filtrate was passed through a column (3.0×30 cm) containing strong acid cation exchange resin in a hydrogen form(Dowex 50 w×8, 25—50 mesh) and successively through a colum (3.0×30 cm) containing strong base anion exchange resin in a hydroxide form (Dowex 21 k, 25—50 mesh). When water was passed through the column a non-charged complex flowed out. The eluate was concentrated to 10—20 ml. Chromatographic separation was then carried through a column (3.0×110 cm) containing strong acid cation exchange resin in a sodium form (Dowex 50w×8, 100—200 mesh). The adsorbed band was eluted with water at a rate of 0.4 ml/min. Three colored bands, violet (L1), redish violet(L2) and red (L3) were eluted in succession. The three eluates were collected separately and evaporated to dryness in a vacuum desiccator. Each crude product was dissolved in water and reprecipitated with ethanol. Since the amount of L3 was very small. The following alternative method was tried. To a solution containing 1.33 g (0.01 mol) of L-aspartic acid, 1.55 g (0.01 mol) of L-2,4-diaminobutyric acid and 1.0 g (0.025 mol) of NaOH in 30 ml of water were added 2.4 g (0.01 mol) of $CoCl_2\cdot 6H_2O$, 5 ml of 10% of hydrogen peroxide and 1 g of activated charcoal. The mixture was stirred on a boiling water bath for 30 min. Treatment of the reaction was the same as above. By this method the L3 isomer was obtained in a relatively higher yield.

Two Isomers of [Co(D-asp)(L-2,4-dba)]. The isomers were obtained by a similar method to that described above. One of the two meridional isomers was not obtaind. Two isomers were separated and are referred to as D1 and D2 by elution order. Found: (L1) C, 29.55; H, 5.14; N, 12.84%. (L3) C, 29.77; H, 5.15; N, 12.99%. Calcd for $CoC_8H_{14}O_6N_3\cdot 1H_2O$: C, 29.54; H, 4.97; N, 12.92%. Found: (L2) C, 30.38; H, 4.63; N, 13.18%. (D1) C, 29.55; H, 5.23; N, 13.22%. Calcd for $CoC_8H_{14}O_6N_3\cdot 0.5H_2O$: C, 30.39; H, 4.02; N, 13.29%. Found: (D2) C, 28.81; H, 5.78; N, 12.21%. Calcd for $CoC_8H_{14}O_6N_3\cdot 1.5H_2O$: C, 28.75; H, 5.13; N, 12.57%.

Measurements. The electronic absorption spectra were measured with a JASCO ORD-UV-5 spectrometer, proton magnetic resonance(PMR) spectra (100 MHz) in D_2O with a JEOL PS 100 spectrometer. Sodium 2,3-dimethyl-2-silapentane-5-sulfonate (DSS) was used as an internal reference.

Results and Discussion

The possible isomers of [Co(L- or D-asp)(L-2,4-dba)] complexes are shown in Fig. 1. They are denoted by L- or D-series with respect to the asp used. Both series of mixed complexes are composed of two meridional and one facial about $[Co(N)_3(O)_3]$. The two L-*mer* isomers are denoted by L-*trans*O_5 *cis*N_5 (oxygen and nitrogen atoms of the five-membered chelate rings are respectively *trans* and *cis* with each other) and L-*cis*O_5 *trans*N_5. The three [Co(L-asp)(L-2,4-dba)] isomers (L-*trans*O_5 *cis*N_5, L-*fac*, L-*cis*O_5 *trans*N_5) seem to be generated at 120° intervals by an imaginary twist of one coordinated ligand relative to the other about an axis passing through the two ligand occupied triangular faces of the cobalt(III) coordination octahedron. The same kind of relationship exists for the three isomers containing D-aspartate ion.

Separation of the two mixed complexes was accomplished by chromatography on a cation exchange

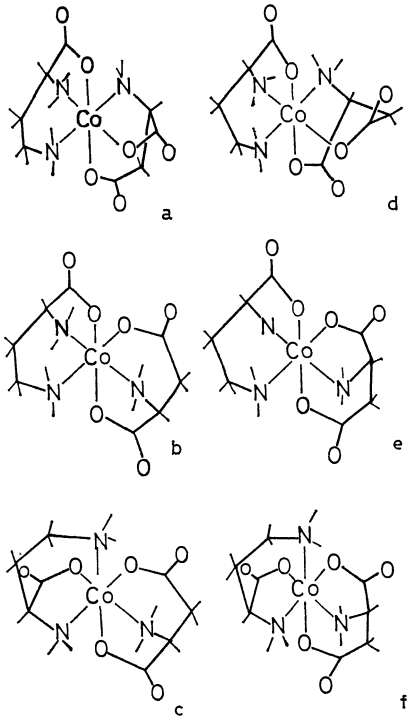

Fig. 1. The six possible geometrical isomers of the [Co(L- or D-asp)(L-2,4-dba)].

resin column. Since the complexes exhibit electronic absorption spectra which agree with the crystal field considerations for *mer* and *fac* isomers (Fig. 2), it is possible to assign the *mer* geometry to L1, L2 and D1, and *fac* geometry to L3 and D2.

Assignment of Isomers. It is of significance to

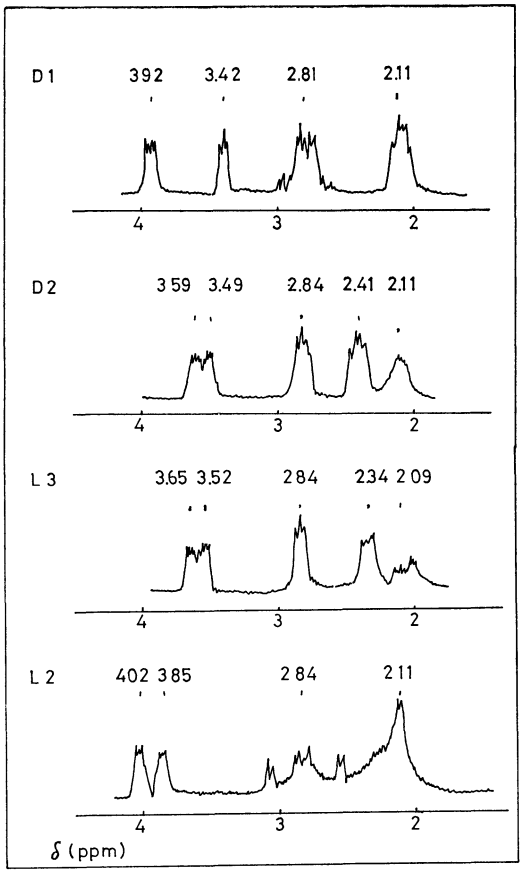

Fig. 3. PMR spectra of the four isomers of the [Co(L- or D-asp)(L-2,4-dba)].

determine the configuration of the *mer* isomers (L1, L2 and D1). Proton magnetic resonance spectra for the four isomers of the [Co(L- or D-asp)(L-2,4-dba)] in D_2O solution are given in Fig. 3. L1 is sparingly soluble in water, and L2, L3, D1 and D2 are soluble in D_2O sufficient for PMR measurements. L1, L3, D1 and D2 are soluble in trifluoroacetic acid, but not L2. Since the PMR specturm of L1 in trifluoroacetic acid resembles that of D1 in the same solvent, the spatial distribution of the ligand atoms (especially N or O atoms) seems to be analogous to that of D1. There is a similarity between the spectra of L3 and D2 in trifluoroacetic acid. The six mixed isomers have C_1 symmetry (Fig. 1). The PMR spectra are thus expected to consist of one ABX pattern due to the CH_2CH moiety of L- or D-asp and one ABMNX pattern due to the CH_2CH_2CH moiety of L-2,4-dba. In order to determine all the resonance lines of these protons, spin decoupling technique was used.

The peak at 2.11 (Fig. 3) can be assigned to the β-methylene protons of L-2,4-dba because of their magnetic shielding and electronegativities. Irradiation of this peak changes the multiplets at *ca.* 3.4—3.5 for D1, D2 and L3 and at *ca.* 3.8 for L2 to a singlet. This indicated that the signals at 3.4—3.5 for D1, D2 and L3 and at *ca.* 3.8 for L2 are attributed to the methine proton of L-2,4-dba moieties. Irradiation of the peak at *ca.* 2.8 makes the lowest field multiplets reduce to a singlet in all the complexes. Thus the lowest field

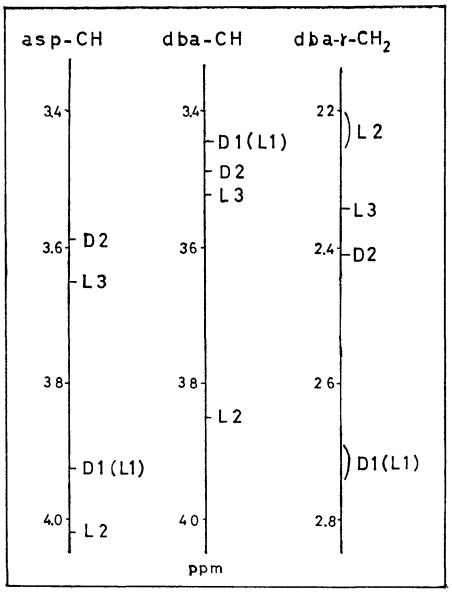

Fig. 4. The distribution of the proton chemical shifts of the [Co(L- or D-asp)(L-2,4-dba)] isomers.

resonance in all of the four spectra should be assigned to the methine proton of aspartic acid and the peak at *ca.* 2.8 to the methylene protons of aspartic acid. Chemical shifts of D1, D2, L2 and L3 are shown in Fig. 4.

The proton resonance peaks of the α-proton of the coordinated asp can be classified into two groups, as can also the chemical shifts of the α-proton and γ-protons of the L-2,4-dba. Although molecular model consideration suggests that the asp and L-2,4-dba coordinated may take several types of conformation, the direction of the C–H bond of α-carbon of both ligands does not seem to change. On the other hand, the difference in conformation of the six-membered chelate ring of L-2,4-dba coordinated seriously affects the orientation of the C–H bonds of γ-carbon, which may give rise to some change in the chemical shifts of γ-carbon protons. As a whole the PMR spectrum of D2 resembles that of L3 (Fig. 3) suggesting that the origin which differentiates the chemical shifts of the α-carbon protons of L-2,4-dba and L- or D-asp into the two magnetic field regions can be ascribed to the effects of the other ligands present, and not to the conformational changes of its own. The bicyclo chelate ring system formed by the coordination of each ligand is common in all six isomers. Because of the identical chelate ring systems, the coupling constant scheme between the eight carbon protons ($OOC-CH_2-\underset{|}{C}HCOO$ and $H_2N\underset{|}{C}H_2-CH_2-CHCOO$) in
NH_2 NH_2
each ligand ring system may be closely resemble each other in the six cases. The geometrical isomers would then reveal themselves mostly in different chemical shifts of the eight carbon-bounded protons in individual cases of the same asp and L-2,4-dba. Different spectra for L2 and L3 and, for D1 and D2 have virtually been observed. For the sake of convenience the three coordination sites occupied by L- or D-asp, situated opposite to the fixed L-2,4-dba, are numbered as indicated

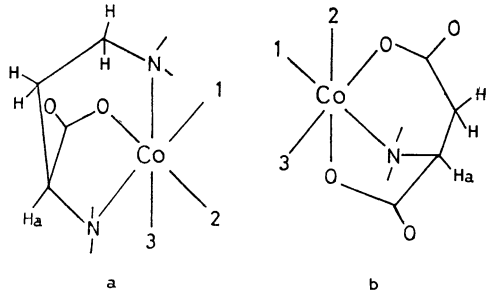

Fig. 5. The relation of the Ha proton chemical shifts and the sites of the other ligand.

in Fig. 5a. For the D2 and L3 isomers the three sites in the order 1,2,3 of the L-2,4-dba are occupied by oxygen, nitrogen and oxygen atoms, respectively (Fig. 5a), while those of the asp are occupied by oxygen, nitrogen and nitrogen atoms, respectively (Fig. 5b). The chemical shift of Ha proton of L-2,4-dba (Fig. 5a) is affected by:[9] 1) the polarity of the amine group due to the polarization of the metal ion induced by the ligand atom of site 1, 2) that of the carboxylate group due to the polarization of the metal ion induced by the ligand atom of site 2, and 3) magnetic anisotropic effects due to site 3. When the chemical shifts of the α-carbon proton of the L-2,4-dba of the complex D2 and L3 are governed by 1), the O atom which occupies site 1 gives rise to a higher field shift of the α-carbon proton of the L-2,4-dba. If this relation holds in the other cases (that is, whenever the O atom occupies site 1 (Fig. 5a), the α-carbon proton adjacent to the N atom *trans* to site 1 resonates at a higher field than when N atom occupies it), the chemical shift of the α-carbon proton of the L-2,4-dba of the D1 isomer which also lies in the higher field suggests that site 1 of D1 is occupied by the O atom. Thus, the isomer is assigned to D-*cis*O_5 *cis*N_5 configuration. The chemical shift of the α-carbon proton of the L-2,4-dba of the L2 isomer which lies in the lower field causes the isomer to be assigned to the L-*cis*O_5 *trans*N_5 configuration, as well. The chemical shift of the α-carbon proton of the L- or D-asp of the L3 and D2 isomer belongs to the higher field group, and site 1 corresponding to these protons should be occupied by the O atom. The chemical shift of the α-carbon proton of the D- or L-asp of the D1 and L2 isomers lies in the lower field, which indicates that site 1 corresponding to these protons is certainly occupied by the N atom. A similar relationship between the chemical shift of the γ-carbon protons of the L-2,4-dba and the atom of the site 1 holds as well (Fig. 4). The relation between PMR chemical shifts of each isomer and the corresponding atom in site 1 is given in Table 1. In the case of sites 2 and 3 no simple explanation for the distinct classification of chemical shifts into two categories of magnetic field region can be given. Thus situation 1) seems to influence the chemical shifts in this case most favorably. The above consideration is in line with the study by Buckingham *et al.*[10] and Clifton and Pratt[11] for pentaammine cobalt(III) complexes $[Co(NH_3)_5X]^{n+}$. The PMR spectra of this series show two NH_3 reso-

nances with a 12 : 3 intensity ratio, the intense band being in the lower field. The 12 equivalent protons belong to the NH_3 groups *cis* to the ligand X and the 3 to the *trans* NH_3 group. Clifton and Pratt[11] suggested that the *cis* protons may have been shifted to a lower field than the *trans*, since the polarity of the *trans* ammine group from the metal ion was reduced by ligand X. Our results are regarded as an extension of the above consideration on the reduced polarity of ammine nitrogen atom to that of the carbon proton adjacent to the ammine group. In order to ascertain whether the method of assignment holds for other complex systems or not, the chemical shifts of the PMR spectra of the $[Co(L\text{-asp})_2]^-$,[4] $[Co(L\text{-asp})(ida)]^-$ [12] and $[Co(L\text{-2,4-dba})_2]^+$ complexes (Fig. 6) were investigated. The PMR spectra of the $[Co(L\text{-2,3-dpa})_2]^+$ complexes were similar to those of the $[Co(L\text{-2,4-dba})_2]^+$ complexes except for the peaks due to the β-carbon protons of the L-2,4-dba. The atom (O or N) in parentheses is the atom occupying site 1 (Fig. 6). Since the chemical shift of the γ-carbon protons of the L-2,4-dba coordinated was not distinct, the whole peaks are shown. The geometry of the F isomer of the $[Co(L\text{-asp})_2]^-$ was *trans* N on the basis of the absorption spectrum. The S and L isomers have *cis* N geometries. The chemical shift of the α-carbon proton of L-asp of the F isomer lies in the lower field, which is in line with the fact that site 1 of this complex is occupied by the N atom. The chemical shift of α-carbon protons of the L-asp of the S and L isomers lies in a higher field in accordance with the fact that their site 1 was occupied by oxygen atom. This agrees with the trend found here. The same situation holds in the case of the $[Co(L\text{-asp})(ida)]^-$ isomers. However the two *cis* N isomres cannot be distinguished from each other. In the $[Co(L\text{-2,4-dba})_2]^+$ complexes, each isomer has been assigned by comparing the PMR spectra of $[Co(L\text{-2,4-dba})_2]^+$ with those of $[Co(L\text{-2,3-dpa})_2]^+$, assignments of which were based on X-ray analysis. The α isomer of the complex $[Co(L\text{-2,4-dba})_2]^+$ has the *trans*O geometry and the β and γ isomers the *cis*O geometries. It has not been possible to assign the two *cis*O isomers so far to the *cis,trans,cis* (the isomers were named by considering the spatial relationship of first the two donor oxygens, then the two α-nitrogens, and finally the two γ nitrogens.) or the *cis,cis,trans* geometries without using the analogies of the PMR spectra of the corresponding complexes $[Co(L\text{-2,3-dpa})_2]^+$. Applying the trend we found to this system, we find that since α-proton of the L-2,4-dba of the γ-isomer resonates in a higher field and that of α and β isomers in a lower field, site 1 of the γ isomer should be occupied by an O atom and that of α and of β by N atoms. The same relationship holds between the γ-protons of L-2,4-dba and the corresponding site 1. We can thus assign the β and γ isomers to the *cis,trans,cis* and *cis,cis,trans* geometries respectively. These assignments agree well with the result by Freeman and Liu.[1] For the $[Co(N)_4(O)_2]$ systems, the two *cis*O isomers can be distinguished by comparing their PMR spectra. For the $[Co(N)_3(O)_3]$ system the two meridional isomers are also distinguishable.

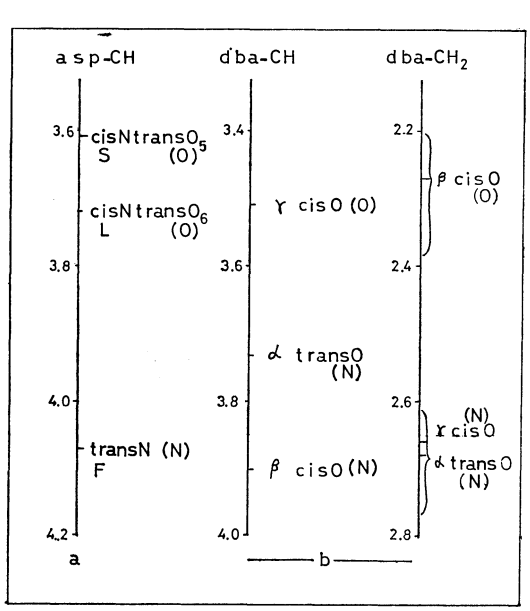

Fig. 6. The distribution of the chemical shifts of the $[Co(L\text{-asp})_2]^-$ isomers (F=first elute, S=second elute, L=last elute) and the $[Co(L\text{-2,4-dba})_2]^+$ (α= first elute, β=second elute, γ=last elute).

The authors wish to thank Drs. M. Saburi and S. Yano for helpful discussions and K. Shimada for measurement of the PMR spectra.

Ionic Equilibria in Mixed Solvents. XI. A Critical Survey of Hydroxo Complexes of Beryllium in Aqueous and Aqueous Mixed Solvents

Hitoshi TSUKUDA, Takayoshi KAWAI, Masunobu MAEDA, and Hitoshi OHTAKI[1)]

Department of Electrochemistry, Tokyo Institute of Technology, O-okayama, Meguro, Tokyo 152

(Received December 4, 1974)

Hydrolytic reactions of beryllium ion were studied in water–methanol, water–ethanol, and water–acetone mixtures, 0.2 mole fraction of an organic component being contained. In all the solutions containing 3M $LiClO_4$ as an ionic medium at 25 °C, we found the Be_2OH^{3+}, $Be_2(OH)_2^{2+}$, $Be_3(OH)_3^{3+}$, and $Be(OH)_2$ complexes. However, in a supplementary work in a 3M $LiClO_4$ aqueous medium in which the solution had been equilibrated with precipitates of beryllium hydroxide and the supernatant was subjected to titration, we found $Be_6(OH)_8^{4+}$ instead of $Be(OH)_2$. From a very slow equilibrium observed in the high pH region, we concluded that the $Be(OH)_2$ complex formed by the addition of an alkaline solution gradually polymerizes to $Be_6(OH)_8^{4+}$ by releasing some OH^- ions. Through these observations a critical survey is described for the species reported by various authors. The solvent effect on the formation constants of hydroxo complexes is also discussed.

According to simple electrostatic theories, an equilibrium constant of a non-isoelectric reaction such as the dissociation of a neutral acid molecule and the hydrolysis of a metal ion might be affected by the dielectric constant of a solvent. However, studies of hydrolytic reactions of beryllium,[2,3)] copper,[4,5)] nickel,[6)] and aluminium[7)] ions in various aqueous dioxane solutions revealed that formation constants of the complexes were very insensitive to the solvent composition over a relatively wide range of the dioxane concentration, 0—85% w/w, in contrast with dissociation constants of carboxylic acids and phenols.[8,9)]

In a reaction in which protons or hydroxide ions are liberated, the acid-base property of a solvent might also contribute to the equilibrium of the reaction beside the dielectric constant and the concentration of water in the solvent. Since studies carried out so far in this series of metal hydrolysis were restricted to aqueous dioxane solutions, we undertake to examine the effect of changing the solvent component on the hydrolysis equilibrium of a metal ion. In the present work we use water–methanol, water–ethanol, and water–acetone mixtures in which 0.2 mole fraction of an organic solvent is contained. The beryllium ion is chosen as an example.

Experimental

Reagents. The methods of preparation and purification of the chemicals used were the same as those described previously.[2,3)] Methanol, ethanol, and acetone (reagent grade) were distilled twice. The solvent mixtures contained 0.2 mole fraction of an organic component, *i.e.*, 30.77% w/w methanol, 38.99% w/w ethanol, and 44.62% w/w acetone, respectively.

Apparatus. Beckman glass electrodes Nos. 40495 and 40498 were used in combination with a silver-silver chloride electrode which was set in an improved type of the "Wilhelm" half-cell (see Fig. 1). An Orion Digital pH Meter 801 was used for emf measurements. A Metrohm *E 211 A* type coulometer was employed as a current source after the current indicator was calibrated with a Yokogawa Decade Resistance Box 2786 as a standard resistance. The method of emf measurements was essentially the same as that in the previous studies.[2,3)]

Results

The plots of Z (average number of hydrogen ions set free per beryllium atom) against $-\log h$ (h denotes the concentration of hydrogen ion at equilibrium) were shown in Figs. 2—4. The concentration of free beryllium ion b was calculated according to the equation[10)]

$$\ln b = \ln B + \int_{\infty}^{\ln h}\left[Z+\left(\frac{\partial Z}{\partial \ln B}\right)_h\right]\mathrm{d}\ln h \qquad (1)$$

where B denotes the total concentration of beryllium ion in solution. The calculation was carried out on the basis of the data in Figs. 2—4 assuming $\int_{\infty}^{-2.0}[2.303Z+(\partial Z/\partial \log B)_h]\,\mathrm{d}\log h=0$.

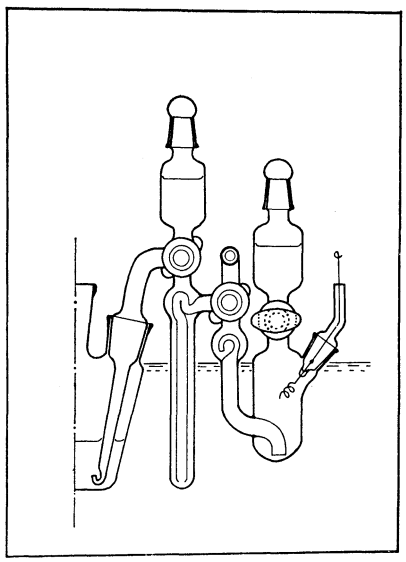

Fig. 1. Cell with silver-silver chloride electrode, salt bridge and titration vessel.

Application of the core-links hypothesis[11)] and calculations of the average numbers of metal and hydroxyl ions in complexes, $\bar{p}$ and $\bar{q}$, respectively, showed that the main product of the reaction was $Be_3(OH)_3^{3+}$. Minor components formed in the lower pH range were estimated by computer calculations.

The plot of $(BZ—3*\beta_{3,3}b^3h^{-3})/2bh^{-2}$ against b in a high pH range gave a straight line independent of the total concentration of beryllium. This shows the formation of the $Be_2(OH)_2^{2+}$ and $Be(OH)_2$ complexes.

Computer calculations also supported the formation

Fig. 5) led to a conclusion of the formation of Be_2OH^{3+}, $Be_3(OH)_3^{3+}$, $Be(OH)_2$, and probably $BeOH^+$. The formation constants obtained are listed in Table 5.

Discussion

In 1967 Mesmer and Baes[13] proposed $Be_5(OH)_7^{3+}$ or $Be_6(OH)_8^{4+}$ instead of $Be(OH)_2$ in 1 *m* NaCl solution at 25 °C. The $Be_6(OH)_8^{4+}$ complex was also found by Lanza and Carpéni.[14] Recently Baes and Mesmer[15] critically reviewed studies on the hydrolysis of beryllium ion and pointed out that the formation constant of $Be(OH)_2$ cannot be so large as reported previously[3,12,16] as long as the solubility data by Gilbert and Garrett[17] and by Schindler and Garrett[18] are accepted. The formation constant of $Be(OH)_2$ determined by means of solvent extraction was $\log {}^*\beta_{2,1} = -13.65$[19], which was consistent with the value expected from the solubility product of $Be(OH)_2$.[17,18] The $Be_2(OH)_2^{2+}$ was not detected by these authors.

Ciavatta and Grimaldi[20] also denied the formation of $Be(OH)_2$ in aqueous solution at an elevated temperature (60 °C) and proposed $Be_3(OH)_4^{2+}$ and $Be_2(OH)_2^{2+}$, together with the main product $Be_3(OH)_3^{3+}$.

In spite of negative conclusions for the formation of $Be(OH)_2$ by some authors, our data could still be well explained in terms of the formation of $Be_2(OH)_2^{2+}$ and $Be(OH)_2$ at a relatively high pH. In order to elucidate the reasons of the diverse conclusions for the minor components at a high pH, we carried out supplementary titrations in a 3 M $LiClO_4$ aqueous medium in which titration procedures were slightly modified.

Test solutions were prepared as follows: pH of a beryllium perchlorate solution (the total concentration of the perchlorate ion was kept constant at 3 M) was increased by reduction of hydrogen ions by electrolysis until beryllium hydroxide precipitated. The solution was left to stand for several days under a nitrogen atmosphere while agitating and the supernatant was subjected to titration by coulometric generation of hydrogen ions. The reverse titration was also performed by alkalifying the solution after the preceding titration over the same pH range. In titrations in which pH decreased (open symbols in Fig. 6) a rapid equilibrium was attained at each point of measurements. On the other hand, a very slow equilibrium was observed at a high pH in the reverse titration (pH of the solution increased), and the emf changed slowly in such a manner that pH increased. It took 10—12 hr until an emf in a reverse titration fell on the titration curve obtained by the preceding titration. The results shown in Fig. 6 were explained in terms of the formation of Be_2OH^{3+}, $Be_3(OH)_3^{3+}$, and $Be_6(OH)_8^{4+}$. Replacement of $Be_6(OH)_8^{4+}$ by any of $Be(OH)_2$, $Be_2(OH)_2^{2+}$, and $Be_3(OH)_4^{2+}$ did not improve values of the error-square sum. Addition of any of these complexes to the set of Be_2OH^{3+}, $Be_3(OH)_3^{3+}$, and $Be_6(OH)_8^{4+}$ did not decrease the error-square sum. The formation of $BeOH^+$ was not conclusive. The final values of the formation constants are tabulated in Table 5, along with values reported by previous authors.

From these observations and the results obtained previously by other workers, we conclude that the $Be(OH)_2$ complex readily formed by the addition of hydroxyl ions is an "over-saturated" species and slowly changes to a polymerized species by releasing some hydroxide ions. The polymerization reaction progresses so slowly that the $Be(OH)_2$ complex is recognized as an equilibrium species in the pH range studied when titrations are carried out with an ordinary speed. Although the equilibrium species at a high pH where $Be(OH)_2$ is detected is expected to be $Be_6(OH)_8^{4+}$ as shown in Table 5, the doubt that the $Be_6(OH)_8^{4+}$ complex could be another intermediate species in the polymerization reaction may hardly be dispelled yet in the present stage of investigation.

Since many hydrolytic reactions proceed very slowly (*e.g.*, as seen in aluminium, iron (III), and even in cadmium[21]), rapid titrations may sometimes cause erroneous conclusions. In order to give a complete scope of hydrolysis equilibria of a metal ion, knowledge of reaction kinetics of slow processes as well as precipitation equilibria and hydrolysis equilibria at low concentrations of the metal ions (where only mononuclear complexes are formed) must be needed.

Although some of the complexes listed in Tables 4 and 5 may not be equilibrium species, the $Be_3(OH)_3^{3+}$ is no doubt the main product and an equilibrium species of the hydrolytic reaction of beryllium ion. The formation constant of the complex practically remained unchanged when an aqueous solvent is replaced with an aqueous organic mixture containing various concentrations of an organic solvent. The change of the organic component in the mixture was also insensitive to the formation constant.

It is widely accepted that the equilibrium constant of an association reaction of a positive and a negative ions increases with an increase in the concentration of an organic solvent in aqueous mixtures. In an isoelectric reaction such as an association reaction of a proton and a neutral molecule, on the other hand, the equilibrium constant is decreased and then steeply increased after passing through a minimum. The

change of the equilibrium constant was accounted for in terms of the medium effect on protons which are distributed in water and organic solvent molecules through the solvation equilibrium.[22] In a non-isoelectric reaction of the hydrolytic reaction of beryllium ion,

$$3Be^{2+} + 3H_2O = Be_3(OH)_3^{3+} + 3H^+$$

as well as those of other metal ions, the free energy change of transfer of three moles of Be^{2+} ion from the aqueous phase to a mixture may not be completely compensated for the sum of the free energy changes of transfer of one mole of $Be_3(OH)_3^{3+}$ and three moles of protons from the mixture to the aqueous phase. The rest of the free energy changes may be further cancelled with the medium effect of protons.

We can rewrite the formation constant of a beryllium hydroxo complex ${}^*\beta_{p,q}$ to $\beta_{p,q}$ as follows:

$$\beta_{p,q} = [Be_q(OH)_p^{(2q-p)+}]/[Be^{2+}]^q[OH^-]^p = {}^*\beta_{p,q}/K_1^p \quad (2)$$

Here K_1 denotes the autoprotolysis constant of a solvent mixture of a constant ionic medium

$$K_1 = [H^+][OH^-] \quad (3)$$

The values of K_1 in the mixed solvents were determined as 14.128 ± 0.003 mol^2 l^{-2} (in 0.2 mole fraction methanol–water mixture) and 14.396 ± 0.008 mol^2 l^{-2} (in 0.2 mole fraction ethanol–water mixture).[23] In the acetone-system K_1 was not determined due to unstable emf's. Acetone may be reduced with hydrogen according to the following equilibrium.[24,25]

$$(CH_3)_2CO + H_2 = (CH_3)_2CH_2O$$

By insertion of the values of K_t into Eq. (2) we see the changes of $\beta_{p,q}$ with the solvent composition. The formation constant $\beta_{p,q}$ markedly increased with the increase in the concentration of an organic solvent from 0 to 0.2 mole fraction. The fact showed that the association reaction

$$qBe^{2+} + pOH^- = Be_q(OH)_p^{(2q-p)+} \quad (4)$$

is subjected to the solvent effect essentially similar to that in the usual ionic association reaction and that the free energy changes due to the distribution of a proton to water and organic solvent molecules must be taken into account as well as the free energy changes of species in the reaction in order to interprete the variation of equilibrium constants with varying solvent compositions.

Isomerization of Heptanes over a Palladium-Zeolite Catalyst

Tomoya SAKAI, Masafumi GOTO, Kei-ichiro HATANO, and Manjiro KATO

Faculty of Pharmaceutical Sciences, Nagoya City University, Tanabe-dori, Mizuho-ku, Nagoya 467

(Received October 1, 1974)

The isomerization of heptane isomers, heptane, 2- and 3-methylhexane, 3-ethylpentane, and 2,3- and 2,4-dimethylpentane, was investigated kinetically over a palladium-zeolite catalyst in the presence of hydrogen at 280—350 °C. First-order rate constants of 11 reaction paths were given with their activation energies and pre-exponential factors. The reaction scheme network including 22 isomerization steps among 9 isomers was constructed through the detailed analysis of primary and secondary reaction products from the individual isomers. Finally, the several proposed isomerization mechanisms were examined on the basis of the present experimental results.

The skeletal isomerization of paraffinic hydrocarbons has been extensively studied over the so-called dual functional catalysts.[1-4] The mechanism has been explained as follows: dehydrogenation of paraffins and hydrogenation of isomerized olefins take place on the metallic site and the formation of carbonium ions from olefins and their rearrangements do on the acidic site. However, the isomerization of butane was discovered by Anderson and Avery[5] to occur on the evaporated film of platinum metal. Boudart and Ptak[6] have reported the isomerization of neopentane to occur on the metal surface of platinum, iridium and gold supported on alumina. Corolleur *et al.*[7] have insisted that the isomerization of hexanes takes place exclusively on the metal site of platinum–alumina, although the intermediate postulated by them differs from that by Anderson and Avery.[5] On the structure of the intermediate, it was proposed recently by Lanewala *et al.*[8,9] that hexane isomerized *via* adsorbed dimeric intermediate on a palladium–zeolite catalyst.

Only a few reports,[10,11] however, have been reported on the isomerization mechanism of heptane isomers. Numbers of isomers may make the system complicated, but the informations therefrom will be plenty. The first aim of the present study is to clarify the detailed reaction paths of heptane isomerization on the palladium–zeolite catalyst through the detailed analysis of the products as well as the kinetic examinations of their formations. The second aim is to select the reasonable mechanism among the several proposed mechanisms on the basis that it should not conflict with the obtained results in the present study.

Experimental

Commercially available *n*-heptane (HP; 99.9 mol%), 2-methylhexane (2MHX; 99.4), 3-ethylpentane (3EP; 99.2), 2,4-dimethylpentane (24 DMP; 99.4), 2,3-dimethylpentane (23DMP; 94.7), and 3-methylhexane (3MHX; 96.5) were used without further purifications. Palladium-zeolite catalyst was prepared from Pd(II) tetraammine chloride and Na–13Y zeolite in the aquatic solution by an ion exchange technique.[12] The amount of palladium metal was 3.0 wt%. The Cl ion free dried catalyst sieved 10 to 20 mesh was calcined in the air at 400 °C for 4 hr, followed by the reduction in the dried and deoxygenated hydrogen stream at 500 °C for 6 hr. Thus the composition of the catalyst is expected to be mostly a metallic palladium on H–Y zeolite, although the X-ray diffraction pattern for metallic palladium was not so clearly obtained.

Experiments were conducted by use of two different reaction apparatus. The one was an usual continuous flow-type apparatus. The reactor was made of a pyrex glass tube (18 mm i.d.) furnished with a co-axial thermowell (8 mm o.d.), in which 2.5 g (apparent volume, 5 ml) of the unreduced catalyst was packed. After the reduction of the catalyst, the temperature was settled to begin the isomerization reaction by passing the hydrogen stream through a reactant container which was dipped in an ice–water bath. The concentration of the reactant was maintained at 1.0 mol%. Variations on the concentration were attained by controlling the streaming ratio of hydrogen through the reactant container. The hydrogen pressure was maintained at 770 mmHg. The space velocities* were between 0.2 and 5.0 s^{-1}. The reaction products were analyzed by glc equipped with a flame ionization detector and a capillary column coated with squalane.

The other apparatus was of a conventional micro pulse reactor which was linked directly to a glc equipped with a thermal conductivity detector and a packed column containing dioctylphthalate on celite-545. A small amount (0.25 g) of the unreduced catalyst was placed at the bottom of a U-shaped pyrex tube of 5 mm i.d., then it was reduced. Hydrogen pressure was maintained at 1400 mmHg. Mostly 2.0 μl of the reactant were injected in each run by a microsyringe into the preheated hydrogen stream.

Results

Isomerization of HP and 3MHX with the Continuous Flow-type Apparatus. The experimental results were listed in Table 1. The isomerization of HP was effectively catalyzed on the palladium–zeolite catalyst above 280 °C. The predominant products were 2MHX and 3MHX. The hydrogenolysis products were very small in their amounts. The selectivity for isomerization was found to exceed 97% even at the most severe condition. Among minor isomerized products, 3EP and 23DMP were formed in distinct amounts from the early stage of the reaction.

In the case of 3MHX feed, the predominant products were 2MHX, 3EP, 23DMP, and HP.

Table 2 shows the resulted conversions in the case of HP isomerization at 305 °C by varying the reactant concentration between 0.6 and 2.0 mol%. The invariance of conversion confirms the first-order rate

* The space velocity was defined as the ratio of the volumetric rate of inlet gas at the reaction temperature and pressure to the apparent packed volume of unreduced catalyst. The reciprocal of which was defined as the contact time.

Table 1. Experimental results with the continuous flow-type apparatus

equation in respect to HP under the condition of excess hydrogen. Moreover, the first-order rate plots were confirmed to hold for HP isomerization at 280, 300, 320 and 340 °C, and also for 3MHX isomerization at 290 °C, by use of the data in Table 1.

Isomerization of Six Heptane Isomers with the Micro Pulse Apparatus. HP, 3MHX, 2MHX, 3EP, 24-DMP, and 23DMP were subjected to isomerization by use of the micro pulse apparatus. Injection of 2.0 μl of reactants in a hydrogen stream resulted in a constant contact time of 0.2 s. The first-order rate equation was confirmed for all reactants by varying the injection amount and obtaining the same conversions and product distributions. The intrinsic deviations existed for the rate constants of HP and 3MHX isomerizations between the results of the two different apparatus. i.e., average 40.0% lower by the micro pulse reactor than by the continuous flow type one. As the reactant to H_2 molar ratio was sufficiently low, the small deviations could be attributed to the difference of temperature distribution through the catalyst layer. So that the coefficient, 1.40, was introduced for the interconversion between the results obtained with the two apparatus.

The experiments were performed in the range of temperature where the conversions resulted between 2 and 30% of reactant isomers. The followings are the reactants, the temperature necessary to achieve the conversion of 10%, obtained products and their percentages in the total products.

HP	346 °C	3MHX(43.5%), 2MHX(34.2%), 23DMP(4.3%), 3EP(3.7%), 24DMP(1.6%), 22DMP(1.5%)
3MHX	308 °C	2MHX(59.0%), 3EP(30.6%), HP(6.2%), 24DMP(1.0%), 22DMP(1.0%), 33DMP(0.7%)
2MHX	312 °C	3MHX(86.1%), 3EP(4.0%), HP(3.9%), 24DMP(2.3%), 22DMP(2.1%), 33DMP(1.2%)

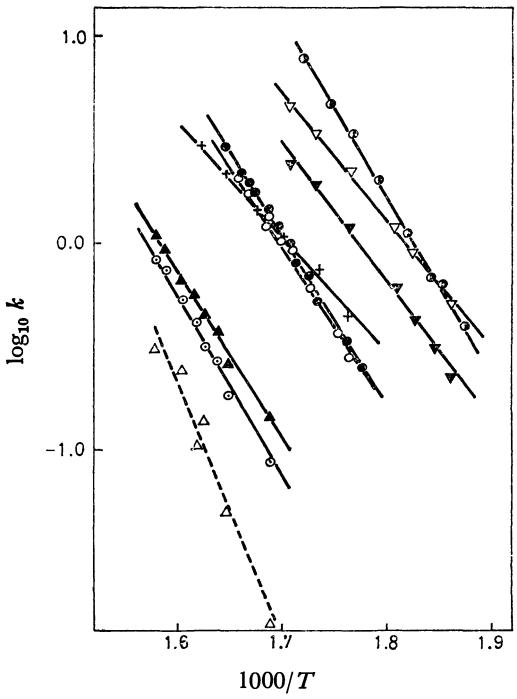

Fig. 1. Arrhenius plots of isomerization of heptane isomers.
⊙, HP → 2MHX; ▲, HP → 3MHX; ●, 2MHX → 3MHX; ○, 3MHX → 2MHX; ◑, 3EP → 3MHX; +, 24DMP → 23DMP; ▼, 23DMP → 33DMP; ▽, 23DMP → 24DMP+22DMP; △, HP → *n*-Hexane.

Arrhenius plots of the 9 main primary reactions including hydrogenolysis of HP were shown in Fig. 1. Activation energies and pre-exponential factors of the reactions above were tabulated in Table 3 along with the rate constants normalized at 320 °C. Obtained data for the two relatively minor reactions, 3MHX→ HP and 2MHX→HP, were also tabulated.

Discussion

The Reaction Scheme. Based on the primary product distributions obtained in the preceding section, the net-work of the reaction path was constructed as shown in Fig. 2. This reaction scheme is composed of 22 isomerization steps among 9 isomers of heptane, neglecting hydrocracking reactions. The characteristic features of the present scheme are that 3EP is generated exclusively from 3MHX and that 23DMP mediates between methylhexanes and other dimethylpentanes. The first proposal is based on the fact that the primary product of 3EP isomerization was solely 3MHX, and that 30.6% of product was 3EP in the reverse reaction of 3MHX. The second proposal is based on the fact that 23DMP is generated prior to other dimethylpentanes in the isomerization of HP and of 3MHX as is seen in Table 1. Besides, the reaction of 23DMP proceeded rapidly to 24DMP, 22DMP, and 33DMP. Although 24DMP and 22DMP were not separated as two distinct gas chromatographic peaks in this case, the amount of them could duly be estimated as one to one from the peak. In the reactions of HP, 3MHX, and 2MHX, the production ratio of 24- to 22-DMP

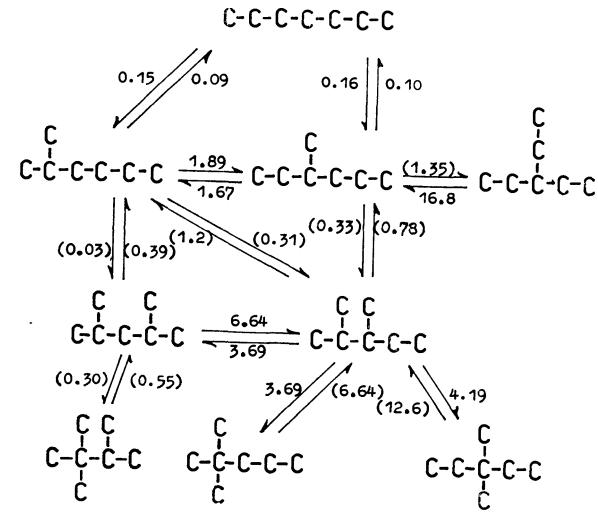

Fig. 2. The proposed isomerization scheme of heptane isomers. Rate constants obtained and (evaluated) at 320 °C.

were almost one to one. In this connection, however, the minor but direct reaction path from 2MHX to 24DMP should exist, because the molar production ratio of 24DMP to 33DMP in the reaction of 2MHX is larger (*ca.* 2.0) than that in the reaction of 3MHX (*ca.* 1.4).

The values of rate constants normalized at 320 °C were prepsented in Figure 2. Those values with parentheses mean the poor reliability of data because of the very small amounts of reaction products and the lack of reverse reactions in the present experiments. They were evaluated not to conflict with the experimental results and the reported equilibrium distribution among 9 isomers.[13] By use of the above values, the numerical integrations of the first-order rate equations were performed by the RUNGE-KUTTA method to examine the validity of the postulated reaction scheme. The results of calculation for the isomerization of HP at 280, 300, 320, and 340 °C, and of 3MHX at 290 °C agreed satisfactorily with the experimental plots of Table 1. Figures 3(a), (b), and (c) show the product distribution *vs.* conversion curves calculated for the reaction of HP at 320 °C together with the experimental results. Figures 4(a) and (b) show the result of examination for the reaction of 3MHX at 290 °C. In this case, product yield *vs.* reciplocal SV curves were adopted.

Examination of Several Proposed Reaction Mechanisms. There have been proposed several mechanisms for the skeletal isomerization of alkanes over acidic and metallic catalysts. Isomerization on the acidic catalysts has been postulated to occur as the carbonium ion mechanism through the 1,2-shift of alkyl anion.[14] Recently, through the examination of the reaction in superacid, the nonclassical protonated cyclopropane was proposed to be an intermediate.[15]

Corolleur *et al.*,[7] and Barron *et al.*[16] adopted the cyclopentane type intermediate on the metal surface. The former used isotope-labeled hexanes on the platinum–alumina catalyst. Anderson and Avery[5] proposed an entity of the 1,3-triadsorbed intermediate by which the skeletal rearrangement was accomplished

Table 3. Kinetic data for the isomerization of heptanes

Reaction	Temperature range (°C)	Activation energy (kcal/mol)	log A	k at 320 °C (V/V/s)
HP ⟶ 3MHX	320—360	38.3	13.3	0.158
HP ⟶ 2MHX	320—360	41.3	14.2	0.153
3MHX ⟶ HP	290—340	32.3	11.1	0.101

23DMP ⟶ 24DMP+22DMP	260—320	28.2	11.3	7.38
23DMP ⟶ 33DMP	260—320	30.9	12.0	4.19
HP ⟶ n-hexane	320—380	49.0	16.0	0.0093

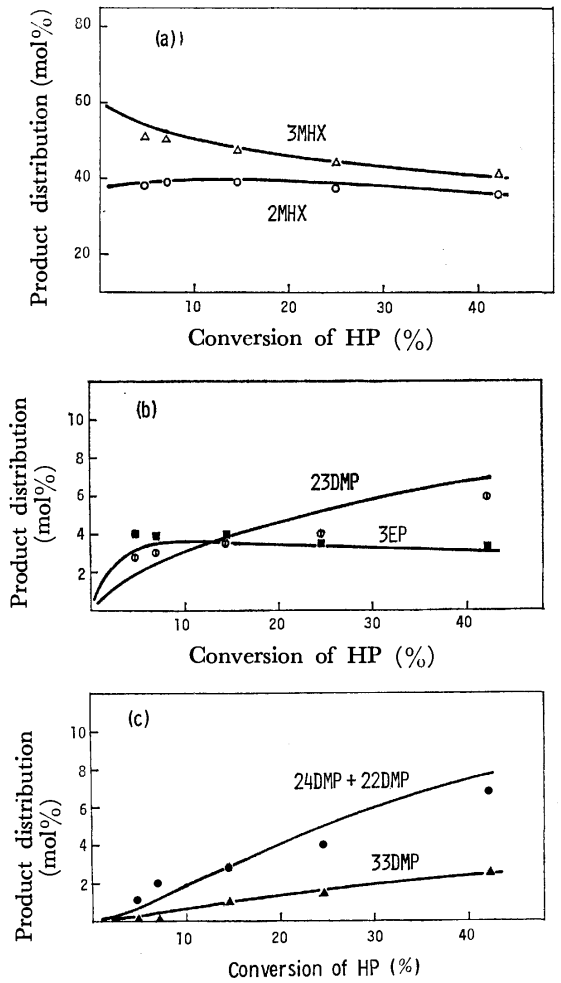

Fig. 3. Calculated (solid lines) and obtained (points) product distribution in the isomerization of HP at 320 °C.

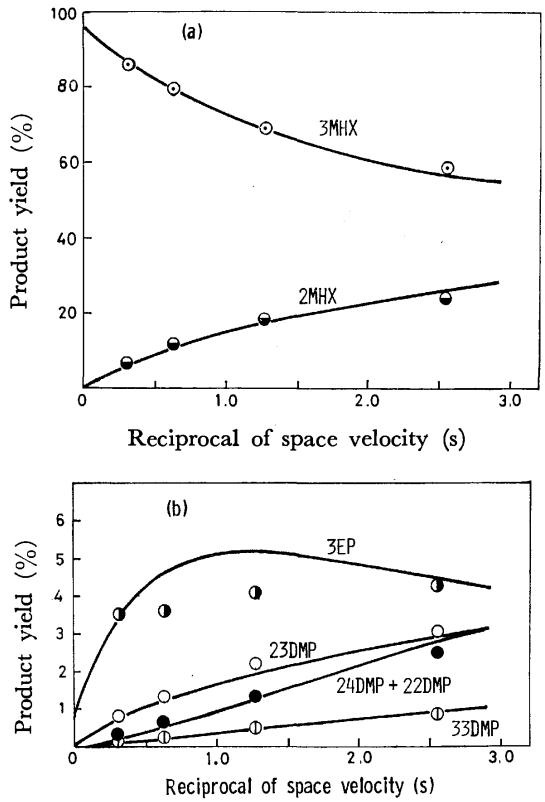

Fig. 4. Calculated (solid lines) and obtained (points) product yield in the isomerization of 3MHX at 290 °C.

via a bridged transition state. The intermediate was considered to be stabilized by transferring a fractional electron from the adsorbed hydrocarbon to the surface metal. This mechanism was supported by themselves through a calculation of the Hückel molecular orbitals.[17] Boudart and Ptak[6] discovered that platinum, iridium and gold, excluding palladium, catalyzed isomerization of neopentane and proposed that metals of sufficient electro-negativity were capable to catalyze the reaction. The intermediate, postulated by them, is a 1,3-triadsorbed species which has some character of the carbonium ion.

Lanewala *et al.*[8,9] conducted the isomerization of hexanes on a palladium–zeolite catalyst. They have proposed a bimolecular mechanism on the surface metal on the basis of their detailed product analyses.

There exists some ambiguity for the supported metal catalysts whether their active sites are metallic or acidic. In the present discussion, the several mechanisms described above will be examined from the point

of proposed intermediates referring to the obtained reaction paths in Fig. 2. Three reaction steps are worth while to consult in the evaluation of the above mechanisms, *i.e.*, (i) simultaneous formations of 2MHX and 3MHX from HP, (ii) reversible isomerization between 3EP and 3MHX, and (iii) reversible reaction between 23DMP and 24DMP.

Formally, the present results are well explained by the carbonium ion mechanism for acidic catalysts if the methyl and ethyl groups shift to the adjacent carbon atom in the reactions (i) and (iii), and in the reaction (ii), respectively. But this mechanism is criticized not to occur on a metal surface.[5]

It seems reasonable that reaction (ii) proceeds *via* the cyclopentane type intermediate.[7,16] However, the reaction (i) and (iii) could not be interpreted by the same intermediate. They require participations of six- and four-membered cyclic intermediates, respectively. The proposal by Lanewala *et al.*[8,9] does not hold in the present results because no trace of octane isomers was detected and no evidence of direct formation of 23DMP from HP was found.

The remaining two mechanisms, those involve 1,3-triadosorbed intermediate[5,6] and the protonated cyclopropane,[15] cannot be distinguished by the present results, because both mechanisms lead to the same conclusion in regard to the cleavage and the formation of C–C bonds. All the reactions in the scheme are interpreted in terms of either of these mechanisms.

Activation energies obtained in the present work for the reactions of six heptane isomers were 30—40 kcal/mol. These values are larger than those found on the acidic catalysts (15—25 kcal/mol)[18–20] and smaller than those on the metallic catalysts (40—50 kcal/mol).[21] Namely, the palladium–zeolite catalyst in the present work exhibits a metallic character in regard to the activation energy and, at the same time, an acidic character in regard to its activity for the isomerization, because the pure palladium metal has been reported not to catalyze the isomerization of hydrocarbons.[6]

Negative Photoconduction in Solution of Aromatic Amine and Benzoquinone by Flash Excitation

Jun-ichi NAKATA, Takeshi IMURA, and Kazuo KAWABE

Electrophysics Laboratory, Department of Electrical Engineering, Faculty of Engineering, Osaka University, Suita, Osaka 565

(Received October 11, 1973)

Synopsis. The conductivity of a solution of benzoquinone and TMPD decreased after being subjected to flash excitation. This is attributed to the decrease of free ions due to the equilibrium shift produced by photo-induced disappearence of the ion pair.

When the absorption of light causes a decrease in the electrical conductivity of a material, the phenomenon is called negative photoconduction. It occurs occasionally in some inorganic solids.[1)]

A new type of negative photoconduction (on continuous excitation) was observed[2)] in organic solution containing both *N,N,N',N'*-tetramethyl-*p*-phenylenediamine (TMPD) and *p*-benzoquinones under the following conditions: (I) In the wavelength range of exciting light 400—500 nm, where *p*-benzoquinone or its chloro-derivatives and small amounts of their semiquinone anion radicals have characteristic absorption bands, the anion radicals are slightly present in the solution due to equilibrated ionic dissociation. (II) For solvents, the negative photoconduction was observed only in appropriately polar ethers such as THF and 1,2-dimethoxyethane, but not in dioxane, a non-polar ether, nor in other moderately polar solvents such as acetone, benzotrifluoride and 1,2-dichloroethane.

We have studied the transient change in the conductivity of a solution after being subjected to flash irradiation for a few μs and the origin of the phenomenon.

Materials,[2)] the apparatus and procedure[3)] are the same as described. The input energy of discharge to obtain a light pulse was 180 J. Two glass filters (Toshiba VY-42 and VB-46) were used. Current signal was read through 10 kΩ resistor; the time constant of the circuit is estimated to be about 1 μs. High purity nitrogen (more than 99.999%) was substituted for dissolved oxygen in the solution. All the experiment were carried out at room temperature.

The conductivity of a THF solution containing both TMPD and chloro-*p*-benzoquinone of the same concentration 1.0×10^{-2} M momentarily increased for *ca.* 15 μs, before the subsequent negative photoconduction was slowly initiated (Fig. 1(a)). Conductivity reached the minimum value at 1.5—2.0 ms, and then recovered exponentially to the original value in the dark within a few seconds. At minimum the decrease in conductivity was a few percent of the original conductivity ($2.3\times10^{-8}\Omega^{-1}$ cm^{-1}).[2)]

The following equilibrium was reached in the solution:

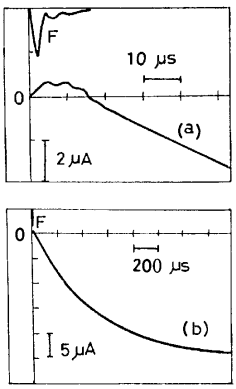

Fig. 1. Photocurrent of THF solution containing both TMPD and chloro-*p*-benzoquinone with the same concentrations of 1.0×10^{-2} M.
Negative photoconduction is shown to begin slowly after the light pulse(F) is over (a), and the minimum value is reached at about 1.5—2.0 ms (b).

$$A + D \rightleftharpoons A\cdot D \rightleftharpoons A^-\cdot D^+ \rightleftharpoons A^- + D^+. \qquad (a)$$

Concentration of the ion pair was estimated to be more than 10^{-6} M from the absorption spectra assuming the molar extinction coefficient of D^+ (mainly in the ion pair) to be 10^4 M^{-1} cm^{-1}; the concentration of free A^- was evaluated to be 10^{-7} M.[2)]

By optical excitation of $A^-\cdot D^+$, an electron will be ejected and subsequently trapped by $A\cdot D^+$:

$$A^-\cdot D^+ + h\nu \rightarrow e_s^- + A\cdot D^+ \rightarrow A\cdot D \text{ or } A + D. \qquad (b)$$

This brings about reduction in the concentration of the ion pair $A^-\cdot D^+$ with subsequent recovery of equilibrium:

$$A^- + D^+ \xrightarrow{k_c} A^-\cdot D^+ \longleftarrow A\cdot D. \qquad (c)$$

According to the left-hand side of (c), the conductivity of the solution decreases. This was verified from the second-order plot of Fig. 1(b). The rate constant k_c was estimated to be of the same order as diffusion limited.

The positive conductivity change appearing within *ca.* 15 μs at the first portion of the responce (Fig. 1(a)) is attributed to the formation of charge carriers according to the left-hand side of (b).

Free anion is also photo-ionized and ejects an electron:

$$A^- + h\nu \rightarrow e_s^- + A. \qquad (d)$$

This is a minor reaction as compared with (b). The electron in (d) will be scavenged by A in a moment. Thus, (d) takes no part in negative photoconduction. We proposed[2] that the origin of the negative photoconduction is attributed to (d) and the subsequent trapping of electron by D^+:

$$e_s^- + D^+ \rightarrow D. \qquad (e)$$

However, the solvated electron is to be scavenged by A in competition with (e):

$$e_s^- + A \rightarrow A^-. \qquad (f)$$

These reactions yields no conductivity change.

Slow recovery from the negative photoconduction was expressed by first order kinetics, and corresponds to ionic dissociation of A·D *via* $A^-\cdot D^+$. The right hand side of (c) might be slow. Slow ionization of quinones by interaction with aliphatic amines was reported[4] by the rapid scan spectrophotometric method.

No solvated electron could be detected spectroscopically with our flash apparatus. The concentration of solvated electron should be 10^{-6} M or less since all A^- is not photo-ionized. Optical path-length of about 100 cm is required if the molar extinction coefficient of solvated electron in THF is about 10^4 M^{-1} cm^{-1}.

Estimation of Structures and Electronic States of Radicals Using INDO-SCFMO Method. II. Alkylperoxyl Radicals

Katsutoshi OHKUBO and Futoshi KITAGAWA

Department of Synthetic Chemistry, Faculty of Engineering, Kumamoto University, Kurokami, Kumamoto 860

(Received November 16, 1973)

Synopsis. The energetically most stable CH_3OO and CH_3CH_2OO radicals have been found to have the following geometric values: $r(O_\alpha\text{-}O_\beta)=1.12$ Å, $r(O_\alpha\text{-}C)=1.38$ Å for the former and 1.39 Å for the latter, $\angle CO_\alpha O_\beta=112°$ for the former and 115° for the latter, and $r(C\text{-}C)=1.47$ Å for the latter.

Alkylperoxyl radicals (referred to as ROO·) have been postulated as reactive intermediates participating in the oxidation and polymerization reactions. The said radicals are recently believed to play an important role in the air-pollution cycle:

Hydrocarbons such as olefin $+{}^1O_2 \rightarrow$ Hydroperoxide $\xrightarrow{\text{dec.}}$ Radicals such as RO·

$$RO\cdot + {}^3O_2 \rightarrow (RO_3\cdot) \xrightarrow{NO_2} ROO\cdot + NO_2$$

$$ROO\cdot + NO \rightarrow RO\cdot + NO_2$$

The molecular structures and electronic states of ROO·, however, are yet open to question, although aspects of HOO· have been investigated by INDO[1] and *ab initio* SCF[2] methods. There are, therefore, good reasons for embarking on an MO-study of ROO· with a view of estimating how their structures and electronic properties. We wish now to report our results on ROO· (R=CH_3 and CH_3CH_2).

Method of Calculation

The following two systems were investigated in this work: (a) the methylperoxyl radical, CH_3OO· and (b) the ethylperoxyl radical, CH_3CH_2OO·. The geometric parameters of the above species are shown in Fig. 1. All the valence-bond angles except those denoted by θ were uniformly taken to be 109°28′ for the sake of simplicity.

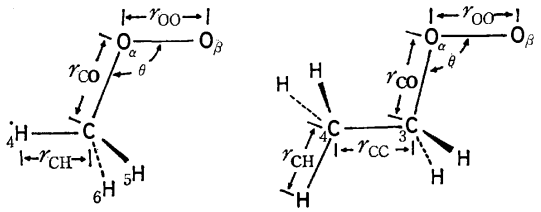

Fig. 1. Geometries used for calculations. ($r(O_\alpha\text{-}O_\beta)$, $r(O_\alpha\text{-}C)$, $r(C\text{-}C)$, $r(C\text{-}H)$, and θ denote geometric parameters.)

The method of calculation is a semiempirical INDO, using the integrals and parametrization in Ref. 3.

Results and Discussion

Methylperoxyl Radical. The INDO calculations were first performed on CH_3OO· with three variables of the bond distances ($r(O_\alpha\text{-}O_\beta)$, $r(O_\alpha\text{-}C)$, and $r(C\text{-}H)$) and one variable of the valence bond angle (θ) by changing $r(O_\alpha\text{-}O_\beta)$, θ, $r(O_\alpha\text{-}C)$, and $r(C\text{-}H)$ in turn.[4] As can be seen from Table 1, the set of $r(O_\alpha\text{-}O_\beta)=1.20$ Å, $r(O_\alpha\text{-}C)=1.38$ Å, $r(C\text{-}H)=1.12$ Å, and $\theta=112°$ gives the lowest SCF total energy (E_{SCF}) for CH_3OO·.[5] The estimated bond length of $O_\alpha\text{-}O_\beta$ (1.20 Å) is very close to that of O_2 (exptl.=1.207 Å[7]), but appreciably shorter than that of HOO·[8] (exptl.=1.30 Å[9]), while the O_α–C length (1.38 Å) is fairly short as compared with the single C–O bonds (1.43 Å). The C–H bond

$r(O_\alpha\text{-}O_\beta)$/Å	θ	$r(O_\alpha\text{-}C)$/Å	$r(C\text{-}H)$/Å	E_{SCF}/a.u.	Q_A		Odd-electron density	μ/D
					O_α	O_β		
1.19	112°	1.44	1.09	−44.3438	−0.036	−0.125	1.218	2.18
1.20	112°	1.44	1.09	−44.3439	−0.043	−0.120	1.207	2.16
1.21	112°	1.44	1.09	−44.3430	−0.048	−0.116	1.200	2.16
1.20	111°	1.44	1.09	−44.3438	−0.042	−0.121	1.208	2.15
1.20	112°	1.44	1.09	−44.3439	−0.043	−0.120	1.207	2.16
1.20	113°	1.44	1.09	−44.3438	−0·043	−0.120	1.208	2.18
1.20	112°	1.37	1.09	−44·3498	−0.039	−0.120	1.205	2.04
1.20	112°	1.38	1.09	−44.350295	−0.040	−0.120	1.206	2.06
1.20	112°	1.39	1.09	−44.350290	−0.040	−0.120	1.207	2.09
1.20	112°	1.38	1.11	−44.3539	−0.039	−0.119	1.205	2.03
1.20	112°	1.38	1.12	−44.3543	−0.038	−0.119	1.208	2.03
1.20	112°	1.38	1.13	−44.3540	−0.038	−0.118	1.205	2.01

(1.12 Å) is also estimated to be longer than the normal C–H distance (1.09 Å). The angle of θ (112 °) also differs by 4° from that of HOO· (exptl.=180°[9]). Moreover, the estimated dipole moment (2.03 D) of $CH_3OO\cdot$, which possesses the slightly negative formal charges (Q_A) of two oxygen atoms, may be close to those of CH_3OH (exptl.=1.69 D[10]; calcd. by INDO=1.94 D[3]) and H_2O (exptl.=1.846 D[11]; calcd. by INDO=2.10 D[3]).

With regard to the g value of the CH_3OO radical, it was evaluated to be 2.003 by means of the Stone equation.[12] The g value is found to be in good agreement with the experimental value of 2.015.[13]

The odd-electron (its density=1.208) is predominantly localized in the following half-occupied MO (−0.5005 a.u.), ϕ_{odd}^{occ}:

$$\phi_{occ}^{odd} = 0.592Z_{O\alpha} - 0.729Z_{O\beta} + 0.150Z_C + 0.223S_{5H} - 0.223S_{6H},$$

while the lowest unoccupied MO (0.1608 a.u), ϕ_{unocc}^{odd}, comes mainly from the following AOs:

$$\phi_{unocc}^{odd} = 0.873Z_{O\beta} - 0.416Z_{O\alpha} - 0.147Z_C + 0.148S_{5H} - 0.148S_{6H}$$

where $Z_{O\alpha}$, Z_C, S_{5H}, *etc.* stand for the p_z of O_α, the p_z of C, the s of 5H, *etc.* respectively.

It is observed that the O_β p_z-orbital contributes distinctly to the formation of both MOs.

Ethylperoxyl Radical. As Fig. 1 indicates, the ethylperoxyl radical, $CH_3CH_2OO\cdot$, has four geometric parameters ($r(O_\alpha$–$O_\beta)$, $r(O_\alpha$–C), r(C–C), and θ) in the present INDO calculations. The calculated results with respect to the most energetically stable $CH_3CH_2OO\cdot$ are summarized in Table 2. The angle of θ (115°) is larger than that of $CH_3OO\cdot$, though the O_α–O_β and O_α–C lengths are just (or nearly) the same as those of $CH_3OO\cdot$. The r(C–C) of 1.47 Å is shorter than the usual single C–C bond (1.54 Å). The INDO calculations, however, sometimes estimate the C–C bond length of hydrocarbons too short; for example, the C–C bond lengths of C_2H_6 (1.46 Å) and C_2F_6 (1.49 Å) are reasonably shorter than those of the experiments (1.536 and 1.51 Å respectively). Moreover, the two oxygen atoms of $CH_3CH_2OO\cdot$ were found to be more positively charged than those of $CH_3OO\cdot$, although the magnitude of the odd-electron density (1.204) is small in comparison with $CH_3OO\cdot$.

Finally, it is worthy of emphasis that, in the INDO calculations, a π-conjugation consisting of the lone-pair p_z-orbital of O_α and the half-occupied p_z-orbital of O_β was recognized in both the radicals (for instance, see the bond-orders of the O_α–O_β bond of $CH_3CH_2OO\cdot$ in Table 2).

The calculations were carried out on a FACOM 230-60 computer at the Data Processing Center of Kyushu University.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 48(2), 705—706 (1975)

A Method for Determining the Degree of Dissociation of Symmetrical Associated Electrolytes from the Conductivity and Activity Data

Reita TAMAMUSHI

The Institute of Physical and Chemical Research, 2-1 Hirosawa, Wako, Saitama 351

(Received May 13, 1974)

Synopsis. A method is presented for determining the degree of dissociation of symmetrical associated electrolytes from a set of conductivity and activity data. The method was applied to the determination of the dissociation constants of several metal sulfates in aqueous solutions.

In a previous paper,[1] individual ionic activity coefficients were estimated on the basis of the conductivity data by using the correlation between the activity and conductivity equations, in which the effect of the Debye-Hückel interaction is assumed to be represented by a common parameter, χ, on both the activity and the conductivity. A similar consideration provides a new method for determining the degree of dissociation of symmetrical associated electrolytes from a set of conductivity and activity coefficient data. This method does not require an *a priori* assumption of the ion-size parameter.

Let us consider the following dissociation equilibrium of a symmetrical electrolyte, MA, in solution;

$$\mathrm{MA} \rightleftarrows \mathrm{M} + \mathrm{A} \tag{1}$$

with

$$K_c = \frac{\alpha^2 c}{1-\alpha} = K(\gamma_M \gamma_A)^{-1} \tag{2}$$

where α is the degree of dissociation; c, the stoichiometric concentration of MA; γ, the individual ionic activity coefficient; K_c, the conditional dissociation constant, and K, the thermodynamic dissociation constant; the charge of each ionic species is omitted for the sake of simplicity. In Eq. (2) the activity coefficient of the associated electrolyte is assumed to be unity.

The stoichiometric mean activity coefficient, $\gamma_\pm$, of the electrolyte, which can be determined directly from measurements, is given by,[2]

$$\log \gamma_\pm = \log \gamma_\pm^{\mathrm{DH}} + \log \alpha \tag{3}$$

where $\gamma_\pm^{\mathrm{DH}}$ is the activity coefficient due to the Debye-Hückel ionic interaction. In dilute solutions, $\gamma_\pm^{\mathrm{DH}}$ can be represented by the Debye-Hückel equation:

$$\log \gamma_\pm^{\mathrm{DH}} = -A\chi^{-1} \tag{4}$$

where A is the Debye-Hückel limiting slope and where χ is the length which is related to the thickness of the ionic atmosphere (see Eq. (8)). By rearranging the relation obtained by introducing Eq. (4) into Eq. (3), we obtain χ as a function of α and $\gamma_\pm$;

$$\chi^{-1} = (\log \alpha - \log \gamma_\pm)/A \tag{5}$$

On the other hand, the Onsager-Robinson-Stokes

a) The conductivity data were taken from Ref. 4, and the activity data from Ref. 5. b) The conductivity data were taken from Ref. 6, and the activity data from Ref. 7. c) The conductivity data were taken from Ref. 8 and 9, and the activity data from Ref. 7.

theory[3] gives the conductivity equation for a symmetrical associated electrolyte;

$$\Lambda = \alpha(\Lambda^{\infty} - S\chi^{-1}) \quad (6)$$

where Λ is the equivalent conductivity; Λ^{∞}, the Λ-value at an infinite dilution, and S, the Onsager limiting slope.

By introducing Eq. (5) into Eq. (6), the relationship among Λ, α, and $\gamma_{\pm}$ is derived;

$$\frac{\Lambda}{\Lambda^{\infty}} = \alpha\left[\left(1+\frac{S}{A\Lambda^{\infty}}\log\gamma_{\pm}\right) - \frac{S}{A\Lambda^{\infty}}\log\alpha\right] \quad (7)$$

This relationship can be used for the determination of α from the conductivity and activity data. It must be noted that, in the derivation of Eq. (7), it is not necessary to know the exact expression of the χ parameter.

Only a small number of experimental data are available in the literature[4-9] for use in estimating the applicability of the present method. Table 1 shows the results obtained with several sulfate salts of divalent metal ions in aqueous solutions.

The thermodynamic dissociation constants, which were determined by the extrapolation of the plot of $\log K_c$ as a function of the square root of the ionic strength, I, as is shown in Fig. 1, are compared in Table 2 with the values reported in the literature.

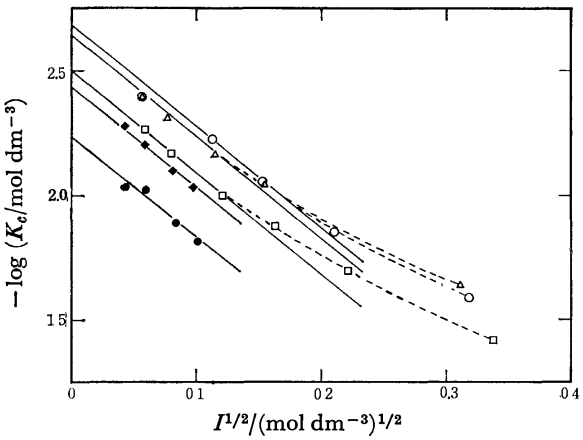

Fig. 1. Plot of $-\log K_c$ as a function of $I^{1/2}$ ($I=4\alpha c$): ● $MgSO_4$ (0 °C), ■ $NiSO_4$ (0 °C), ○ $CuSO_4$ (25 °C), □ $ZnSO_4$ (25 °C), △ $CdSO_4$ (25 °C). The solid lines represent the theoretical slope by the Debye-Hückel limiting equation.

Table 2. Thermodynamic dissociation constants of several metal sulfates in aqueous solutions, as computed by different methods

Metal sulfate	$-\log(K/\text{mol dm}^{-3})$

$CuSO_4$ (25 °C)	2.6_7	—	—	2.10—2.46
$ZnSO_4$ (25 °C)	2.5_0	—	—	2.27—2.38
$CdSO_4$ (25 °C)	2.6_5	—	—	2.29

a) Ion-size parameter $a=5.59$Å. b) Ion-size parameter $a=5.86$Å. c) Depending on the ion-size parameter ($a=3$—4 Å).

In Table 2, the third column gives the log K-values[4] determined by the analysis of the conductivity data according to the Fuoss-Onsager equation, in which a set of log K and the ion-size parameter, a, is obtained in such a way that the theoretical equation gives the best fit to the experimental conductivity data. The fourth column of Table 2 gives the log K-values[5] calculated from the activity data by assuming different values of the ion-size parameter. The present method seems to result in slightly larger values of pK than the values reported in the literature.

It is the advantage of the present method that an *a priori* assumption of ion-size parameter is not required in the determination of the dissociation constant. However, if we assume the Debye-Hückel expression for χ;

$$\chi = a + \kappa^{-1} \quad (8)$$

where κ^{-1} is the Debye-Hückel length of the ionic atmosphere, we can calculate the ion-size parameter, a, by means of Eqs. (5) and (8). The a-values derived in this way at each concentration are shown in Table 1. The present method gives concentration-dependent values for the ion-size parameter; the a-values at lower concentrations are larger than those commonly accepted, and in some cases they exceed Bjerrum's parameter (14 Å for 2 : 2 electrolytes in aqueous solutions). The relatively large pK values obtained by the present method may be correlated with the large ion-size parameters, as has been mentioned above.

Further discussions on the validity of the present method will become possible only when more accurate experimental data have been obtained with various electrolytes.

Molecular Vibrations and Force Fields of Alkyl Sulfides. XI. C-S Stretching Vibrations of Some Simple Aliphatic Sulfides

Masaru OHSAKU

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received June 11, 1974)

Synopsis. Infrared spectra of alkyl sulfides were measured. Some correlations of the C–S stretching frequencies to the molecular conformations were proposed.

For alkyl chlorides[1] and alkyl disulfides,[2] the correlations between the C–Cl or C–S stretching frequencies and the molecular conformations have been extensively discussed. In the case of alkyl sulfides, such a relation can also be expected. In the present note, therefore, the observed C–S stretching frequencies of the sulfides will be studied in relation to their molecular conformations.

The infrared spectra of the sulfides were measured in the liquid and solid states by means of a Perkin-Elmer Model 621 spectrophotometer. Table 1 shows the frequencies of the infrared bands, which may be due to the stable form in the solid state. The notations in this table, P_H, P_C, and S_{HH}, are the same as those used in the previous papers.[1,2] From this table we can find the frequency dependence upon the molecular conformations, similar to the C–Cl stretching frequencies of alkyl chlorides[1] and to the C–S stretching frequencies of alkyl disulfides.[2]

A characteristic CH_3–S stretching vibration is observed in the 690—750 cm^{-1} region. The C–S stretching vibrations due to the P_H and P_C conformations appear in the regions of 640—700 cm^{-1} and 710—750 cm^{-1} respectively. In the case of the secondary sulfides, the C–S stretching vibration due to the S_{HH} conformation lies in the 630—660 cm^{-1} region. Our observed frequencies on the alkyl sulfides, therefore, in general correspond very well to the C–Cl stretching frequencies of alkyl chlorides[1] and the C–S stretching frequencies of alkyl disulfides,[2] although we cannot make a straightforward comparison of them with each other, since we could not take into consideration the bands due to the rotational isomers. The CH_3–S stretching frequencies of the fulfides fit the CH_3–Cl stretching frequency of methyl chloride better than the CH_3–S stretching frequencies of alkyl disulfides. Detailed vibrational treatments including the rotational isomers of these sulfides are now in progress; the results will be reported elsewhwere in the near future.

Thanks are due to Professor Hiromu Murata and Associate Professor Yuji Shiro for their valuable comments.

The Effect of Partial Deuteration on the Phosphorescence Lifetime of *N,N,N',N'*-Tetramethyl-*p*-phenylenediamine

Nobutoshi YOSHIDA and Nozomu EBARA

Department of Chemistry, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153

(Received June 24, 1974)

Synopsis. A position-dependent deuterium effect on the phosphorescence lifetime of *N,N,N',N'*-tetramethyl-*p*-phenylenediamine was found. Aromatic ring protons and methyl protons were shown to contribute to the radiationless transition independently and differently. Important terms in the decay constant are briefly discussed.

Phosphorescence lifetimes have been measured for *N,N,N',N'*-tetramethyl-*p*-phenylenediamine (TMPD) and its deuterium derivatives;
(I) $(CH_3)_2N$–C_6H_4–$N(CH_3)_2$, (II) $(CH_3)_2N$–$C_6H_2D_2$–$N(CH_3)_2$, (III) $(CH_3)_2N$–C_6D_4–$N(CH_3)_2$ (91%), (IV) $(CD_3)_2N$–C_6H_4–$N(CD_3)_2$ (94%), and (V) $(CD_3)_2N$–C_6D_4–$N(CD_3)_2$ (85%).
II—V were prepared by ammonolysis of *p*-dibromobenzenes in an autoclave under a nitrogen pressure of 25 kbar followed by methylation with dimethyl sulfate in H_2O or D_2O.[1,2] Values in parentheses are the isotopic purities measured by low-voltage mass spectroscopy. II was a mixture of compounds in which deuterium was distributed statistically on the aromatic ring and NMR spectra showed its deuterium content to be ~50%. All samples were dissolved in 3-methylpentane(3MP) or in EPA, degassed with 6—7 freeze-thaw cycles. Phosphorescence lifetimes were measured at 77 K by a standard technique and the triplet decay was displayed on a Riken Denshi High Speed SP-J-5V recorder. The observed decays were exponential over 3—4 lifetimes. The results are listed in Table 1. k_{II} contains a considerable error, as II was a mixture of compounds with different rate constants. It was not discarded because the main part of k_{II} seems to come from the doubly substituted compound.

Following Watts and Strickler,[3] the triplet decay constant was expressed as

$$k = \tau^{-1} = k_d + N_{me}k_{me} + N_{ar}k_{ar},$$

where k_d is the decay constant in the perdeuterated TMPD (V), N_{me} and N_{ar} are the numbers of methyl and aromatic ring protons, and k_{me} and k_{ar} represent changes in the radiationless rate constants when a proton is replaced by a deuteron at the methyl or aromatic ring position, respectively. Our data fitted well to this equation with the least squares values of k_d=0.185, k_{me}=0.0046, and k_{ar}=0.030 s^{-1} in 3MP, and k_d=0.168, k_{me}=0.0038, and k_{ar}=0.029 s^{-1} in EPA. The coincidence is striking as can be seen from the last colume of Table 1. It shows that not only protons at different positions of an aromatic ring, but protons of different groups conform well to Watts' equation. An aromatic ring substitution was 6—8 times more effective in decreasing the decay rate than a methyl substitution. In contrast to toluene in which the methyl protons have a negligible effect,[4] those of TMPD showed a small but difinite effect. Generally lifetimes were longer in EPA than in 3MP.

TABLE 1. TRIPLET DECAY TIMES AND RATE CONSTANTS OF PARTIALLY DEUTERATED TMPD

Solvent	Compound	τ (s)	$k_{obs.}$ (s^{-1})	$k_{calc.}$ (s^{-1})	Δk (%)
3MP	I	2.7	0.37	0.36	−2.7
	II	3.4	0.29	0.30	+3.4
	III	4.2	0.24	0.24	0
	IV	3.3	0.30	0.31	+3.3
	V	5.3	0.19	0.19	0
EPA	I	2.9	0.34	0.33	−2.9
	II	4.0	0.25	0.27	+8.0
	III	4.5	0.22	0.21	−4.5
	IV	3.6	0.28	0.28	0
	V	5.9	0.17	0.17	0

The radiationless rate constant is represented by

$$k = \frac{2\pi}{\hbar}\rho \sum_l \left| \langle f|H_{so}|i\rangle \prod_m \langle \chi^f_{m,l}|\chi^i_m\rangle - \sum_n \frac{\hbar^2}{\mu_n}\left[\sum_j \frac{\langle f|H_{so}|j\rangle\left\langle j\left|\frac{\partial}{\partial Q_n}\right|i\right\rangle}{E_j - E_f} + \sum_k \frac{\left\langle f\left|\frac{\partial}{\partial Q_n}\right|k\right\rangle\langle k|H_{so}|i\rangle}{E_k - E_i}\right] \times \left\langle \chi^f_{n,l}\left|\frac{\partial}{\partial Q_n}\right|\chi^i_n\right\rangle \prod_{m\neq n}\langle \chi^f_{m,l}|\chi^i_m\rangle \right|^2,$$

where i and f denote initial and final pure spin electronic states and j and k are virtual pure spin states. χ^i_i and $\chi^f_{i,l}$ are the vibrational wave-functions coresponding to the normal coordinate Q_s and belonging to the mixed spin initial and final Born-Oppenheimer states, which we were to observe. Here, n refers to the promoting mode and m to the accepting mode. Suffix l runs over the final Born-Oppenheimer manifold Ψ^f_l, isoenergetic with each other and with the initial state, and belonging to a single mixed spin electronic state.

Assuming that a single accepting mode is excited in each of Ψ^f_l and ignoring the contribution of $\chi^f_{n,l}$ to the energy of Ψ^f_l, the sum over l can be replaced by the sum over m, so that the leading term in k becomes

$$k = [\langle S\rangle + \sum_n \langle P_n\rangle] \sum_m \langle A_m\rangle$$

with

$$\langle S\rangle = \frac{2\pi}{\hbar}\rho|\langle f|H_{so}|i\rangle|^2$$

$$\langle P_n\rangle = \frac{\pi\hbar^3}{\mu_n^2}\rho\left|\left[\sum_j \frac{\langle f|H_{so}|j\rangle\left\langle j\left|\frac{\partial}{\partial Q_n}\right|i\right\rangle}{E_j-E_f}\right.\right.$$
$$\left.\left. + \sum_k \frac{\left\langle f\left|\frac{\partial}{\partial Q_n}\right|k\right\rangle\langle k|H_{so}|i\rangle}{E_k-E_i}\right]\left\langle \chi_n^f\left|\frac{\partial}{\partial Q_n}\right|\chi_n^i\right\rangle\right|^2$$

and

$$\langle A_m\rangle = |\langle \chi_m^f|\chi_m^i\rangle|^2$$

where $\chi_{n,i}^f$ has been replaced by χ_n^f in accordance with the selection rule. In TMPD, the first term, $\langle S\rangle$, vanishes by symmetry.[5] For the promoting mode, n, Burland and Robinson[6] claimed that non-totally symmetric in-plane skeletal modes (b_{2u} in benzene) cause radiationless transition by contributing to the π-π Herzberg-Teller matrix elements, whereas Henry and Siebrand[7] stressed the importance of C–H out-of-plane modes which are responsible for σ-π vibronic terms due to breakdown of the Born-Oppenheimer approximation. The latter mechanism was used to account for the position dependent deuterium effect in benzene, naphthalene[7] and anthracene.[8] However, the relative importance of these two mechanisms has not yet been established. From our data we shall make a rough estimate of the relative contribution of two mechanisms. For simplicity, we take only three terms for the promoting modes; skeletal modes, ring C–H out-of-plane modes and ring C–D out-of-plane modes. Notations ⟨CC⟩, ⟨CH⟩ and ⟨CD⟩ stand for the terms $\langle P_n\rangle$ containing these modes. For the accepting mode m, there seems to be little doubt that the C–H stretching modes are most important: we retain only these modes in the present approximation. As the C–H bonds of the ring and those of the methyl group contribute different amounts, we denote their Franck-Condon integrals with ⟨R⟩ and ⟨M⟩, respectively. There are as many terms as there are normal modes, and these symbols represent sums of like terms. The rate of a radiationless transition is expressed by a sum of product terms; ⟨CC⟩⟨R⟩, ⟨CH⟩⟨R⟩, ⟨CD⟩⟨R⟩, ⟨CC⟩⟨M⟩, ⟨CH⟩⟨M⟩, and ⟨CD⟩⟨M⟩. For example $k_I = k_0 + \langle CC\rangle\langle R\rangle + \langle CH\rangle\langle R\rangle + \langle CC\rangle\langle M\rangle + \langle CH\rangle\langle M\rangle$, $k_{III} = k_0 + \langle CC\rangle\langle M\rangle + \langle CD\rangle\langle M\rangle$ and $k_{IV} = k_0 + \langle CC\rangle\langle R\rangle + \langle CH\rangle\langle R\rangle$, where k_0 represents the radiative rate constant. Then $k_I - k_{IV} = 0.070$ (3MP) corresponds to $\{\langle CC\rangle + \langle CH\rangle\}\langle M\rangle$ and $k_{III} - k_V = 0.050$ to $\{\langle CC\rangle + \langle CD\rangle\}\langle M\rangle$. Taking the ratio of these two expressions, we obtain

$$\frac{\langle CC\rangle + \langle CD\rangle}{\langle CC\rangle + \langle CH\rangle} = 0.71\,,$$

According to Siebrand,[7] ⟨CD⟩/⟨CH⟩ is roughly equal to $\omega_D\mu_H/\omega_H\mu_D$, where ω_H and ω_D are the frequencies and μ_H and μ_D are the reduced masses of the corresponding normal modes. Our measurement shows that

$$\frac{\omega_D\mu_H}{\omega_H\mu_D} = \frac{720}{812}\times\frac{7}{13} = 0.48\,,$$

which leads to

$$\frac{\langle CH\rangle}{\langle CC\rangle} = 1.3 \quad \text{(3MP)}\,.$$

A similar calculation gives 0.5 for EPA. The difference may be attributed to the rough approximation employed and to errors in the measured values. We can only infer that neither mechanism can be ignored. To account for the large difference in k_{ar} and k_{me}, we compare $k_I - k_{IV}$ with $k_{IV} - k_V$,

$$\frac{k_I - k_{IV}}{k_{IV} - k_V} = \frac{\langle CC\rangle\langle M\rangle + \langle CH\rangle\langle M\rangle}{\langle CC\rangle\langle R\rangle + \langle CH\rangle\langle R\rangle} = \frac{\langle M\rangle}{\langle R\rangle}.$$

This ratio is 0.6 in 3MP and 0.5 in EPA. Note that there are four terms in ⟨R⟩ and twelve terms in ⟨M⟩. The large difference between k_{ar} and k_{me} may therefore be attributed to the difference in Franck-Condon factors. As the ring protons are attached directly to the carbon atoms which carry π-electrons, it is quite natural that the electronic excitation causes a change in the ring C–H stretching normal modes to give a large k_{ar} value. The absence of contributions to the radiationless rate constant from alkyl groups in alkylbenzenes can be understood as they are separated from the π-electron center. In TMPD, however, the charge density at the nitrogen atom, which carries π-electrons, changes considerably when the molecule is excited, and this may have an inductive effect on methyl C–H bonds giving rise to a moderate deuterium effect.

Photolysis of Ethylene at 1470 Å

Hiroshi HARA, Kenji KODAMA, and Ikuzo TANAKA

Department of Chemistry, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo 152

(Received on July 1, 1974)

Synopsis. Relative quantum yields of the primary processes in the photolysis of ethylene at 1470 Å were determined. No energized vinyl radical was found. Photolysis in the presence of nitric oxide suggests that about 20% of 1-butene is produced through the direct addition reaction of excited ethylene to ground state ethylene, $C_2H_4^* + C_2H_4 \rightarrow 1\text{-}C_4H_8$.

The primary process of the photolysis of ethylene has been reported to be as follows.[1-4]

$$C_2H_4 + h\nu \longrightarrow C_2H_2 + H_2 \qquad \phi_1 \qquad (1)$$

$$\longrightarrow C_2H_2 + 2H \qquad \phi_2 \qquad (2)$$

$$\longrightarrow C_2H_3 + H \qquad \phi_3 \qquad (3)$$

The energized vinyl radical formation was found at 1634 Å.[5]

$$C_2H_4 + h\nu \longrightarrow H + C_2H_3^{**} \xrightarrow{k_d} C_2H_2 + H + H$$

$$C_2H_3^{**} \xrightarrow{k_s[M]} C_2H_3^*$$

$$H + C_2H_3^* \longrightarrow C_2H_3 + H$$

In this investigation, ethylene was photolyzed at 1470 Å in order to examine the existence of the energized vinyl radical and to determine the relative quantum yields of the primary processes.

Experimental

Experimental procedures were almost the same as described previously.[4] The light source of 1470 Å was an electrodeless discharge xenon lamp. The reaction cell was equipped with a LiF window.

Results and Discussion

The products of photolysis at 1470 Å were hydrogen, acetylene, ethane, *n*-butane, and 1-butene, and were the same as those at 1634 Å. No C_4 compounds other than *n*-butane and 1-butene were observed.

If the energized vinyl radical is formed at this wavelength, the ratio of 1-butene to *n*-butane should follow a straight line with a definite slope against ethylene pressure.[5] The ratios plotted as a function of ethylene pressure in Fig. 1 show no pressure dependence. Thus, existence of the energized vinyl radical in the photolysis at 1470 Å can be excluded. This is reasonable for the following reason. If the energized vinyl radical were formed at 1470 Å, the maximum available energy of the vinyl radical would be 89 kcal mol^{-1}, and that at 1634 Å 70 kcal mol^{-1}. At 1470 Å, therefore, the energized vinyl radical would decompose into acetylene and a hydrogen atom before being stabilized by collision.

Relative quantum yields of the primary processes were obtained assuming the same secondary processes as in the photolysis at 1634 Å[4]. The values are given in Table 1 together with other reported ones. Both values are seen to agree. The quantum yields at 1470 Å are shown in Table 2 together with those at 1634 and 1849 Å.[4] The relative quantum yields are wavelength dependent, *viz.*, ϕ_2 decreases and ϕ_3 increases with increasing wavelength, but not ϕ_1.

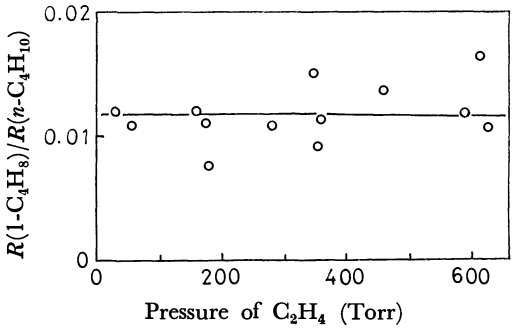

Fig. 1. $R(1\text{-}C_4H_8)/R(n\text{-}C_4H_{10})$ *vs.* pressure of ethylene (Torr).

Table 1. Relative quantum yields at 1470 Å

ϕ_1	ϕ_2	ϕ_3	Ref.
45%	54%	1%	This work
40	59	1	(3)
46	54	—	(6)

Table 2. Quantum yields at 1470, 1634, and 1849 Å

Wavelength	ϕ_1	ϕ_2	ϕ_3
1470 Å	45%	54%	1%
1634	47	48	5
1849	53	33	14

Relative yields of 1-butene and *n*-butane to acetylene were measured at various nitric oxide pressure with a fixed ethylene pressure (350 Torr) as shown in Table 2. On addition of nitric oxide, the yield of 1-butene decreased rapidly by about a factor of 5 and then became constant. On the other hand, the formation of *n*-butane was completely suppressed even at 0.46% nitric oxide. 1-Butene and *n*-butane removed by nitric oxide are formed through the recombination reactions of vinyl and ethyl radicals, and two ethyl radicals, respectively, since nitric oxide scavenges both ethyl[7] and vinyl radicals.[8] However, about 20% of 1-butene can be formed through a nonradical reaction, which is probably the direct addition of excited ethylene to a ground state one:

$$C_2H_4^* + C_2H_4 \longrightarrow 1\text{-}C_4H_8 \qquad (4)$$

The relative quantum yield ϕ_4 of this process, can be roughly estimated as follows.

Table 3. Relative yields of 1-C_4H_8 and n-C_4H_{10} to C_2H_2 in the presence of NO (C_2H_2=350 Torr)

(NO/C_2H_4)%	0	0.46	1.1	1.3	2.7	5.0	9.3
1-C_4H_8	0.0061	0.0011	0.0013	0.0010	0.0016	0.0013	0.0014
n-C_4H_{10}	0.52	0	0	0	0	0	0

$$\phi_4 = \phi(1\text{-}C_4H_8)/5$$
$$= \frac{k_7}{k_5+k_6+k_7} \cdot \frac{\phi_3}{5}$$
$$= 0.08\%$$

where the k's are the rate constants of the reactions.

$$C_2H_3 + C_2H_5 \longrightarrow 2C_2H_4 \quad (5)$$
$$\longrightarrow C_2H_2 + C_2H_6 \quad (6)$$
$$\longrightarrow 1\text{-}C_4H_8 \quad (7)$$

The quantum yield is very small compared with the others. At present, our results do not permit us to speculate on the nature of C_2H_4*.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 48(2), 713—714 (1975)

Densities and Molar Volumes of Molten Binary $PrCl_3$–KCl, $PrCl_3$–NaCl, $PrCl_3$–$CaCl_2$, $NdCl_3$–KCl, $NdCl_3$–NaCl, $NdCl_3$–$CaCl_2$ Systems

Junichi Mochinaga and Kazuo Igarashi

Department of Synthetic Chemistry, Faculty of Engineering, Chiba University, Yayoi-cho, Chiba 280

(Received October 3, 1974)

Synopsis. The densities of $PrCl_3$, $NdCl_3$, $PrCl_3$–KCl, $PrCl_3$–NaCl, $PrCl_3$–$CaCl_2$, $NdCl_3$–KCl, $NdCl_3$–NaCl, and $NdCl_3$–$CaCl_2$ melts measured dilatometrically were represented by the empirical equations as functions of temperature. The molar volumes of the melts were calculated from the density data.

Densities and molar volumes of molten salts are the important properties in thermodynamic considerations, and are necessary to calculate the molar quantities. The ideal solution has the additivities of extensive properties except for entropy. Therefore, very few is known to have ideal behavior among the real mixture melts, but there are several molten mixture systems that have approximately the additive behavior for some of the extensive properties. In the previous paper, we reported on the densities and molar volume isotherms of molten YCl_3–KCl, YCl_3–NaCl, YCl_3–KCl–NaCl systems.[1] In the present experiment, the densities of 6 binary mixture systems ($PrCl_3$–KCl, –NaCl, –$CaCl_2$, and $NdCl_3$–KCl, –NaCl, –$CaCl_2$) in the molten state were measured, and the molar volume isotherm equations of these melts at 800 and 1000 °C were calculated.

Experimental

Materials. $PrCl_3$ and $NdCl_3$ were prepared by heating the respective rare-earth oxide with NH_4Cl at 350 and 370 °C, respectively, for 1.5 hr in evacuating with a rotary pump. The mixing ratio of NH_4Cl for each oxide was 2.5 times the theoretical amount. The chlorides were then purified by heating at about 850 °C *in vacuo* to remove the excess amount of NH_4Cl by sublimation. The analysis of impurities in the purified chlorides are shown in Table 1. The ratios of rare-earth and chlorine elements were 1 : 2.96 for both chlorides.

KCl, NaCl, and $CaCl_2$ were dried by heating *in vacuo* for 5 hr or more at the temperature lower by about 50 °C than the melting points of the salts.

Density Measurement. The dilatometric method was used. A dilatometer was made of transparent silica, and the volume of a dilatometer was determined by use of distilled water at room temperature because the thermal expansion coefficient of quartz is very smaller than that of molten salts. In the measurement the meniscus of melt in a dilatometer was read with a cathetometer.

Table 1. Impurities in $PrCl_3$ and $NdCl_3$[a]

$PrCl_3$		$NdCl_3$	
Element	Content (ppm)	Element	Content (ppm)
La	<50	Ce	160
Ce	<30	Pr	<30
Nd	<20	Sm	27
Sm	<20	Eu	<30

a) Fluorescent X-ray analysis.

Results and Discussion

Densities of Molten $PrCl_3$ and $NdCl_3$. Since the change in density of molten salt with increasing temperature is linear, the densities of molten $PrCl_3$ and $NdCl_3$ were represented by the following empirical equations as functions of temperature by use of the method of least squares for the density data observed.

$PrCl_3$; $d=4.139-1.030\times10^{-3}\,t$ $(850\leq t\leq1000)$

$\sigma=0.017$

$NdCl_3$; $d=3.992-0.8047\times10^{-3}\,t$ $(802\leq t\leq1009)$

$\sigma=0.011$

where d is the density of $PrCl_3$ or $NdCl_3$ melt in g/cm^3, t the temperature in °C. σ is the standard error of estimate in density equations in g/cm^3. The results were in fairly good agreement with the densities reported by Cho *et al.*[2]

Densities of Six Binary Systems. The density equations of molten mixtures in various compositions of six binary systems are shown in Table 2.

Molar Volumes of Binary Systems. Molar volume of mixture melt is calculated by the equation, $V_{mix}=\Sigma(X_i\cdot M_i)/d_{mix}$, where V_{mix} is the molar volume of the mixture melt, X_i the mole fraction of i-th component, M_i the molecular weight, and d_{mix} the density of the melt. The molar volume isotherm of $PrCl_3$–KCl system at 800 and 1000 °C are shown in Fig. 1. For six binary systems the molar volume isotherm equations are shown in Table 3.

The phase diagrams of binary $PrCl_3$–NaCl[3], $PrCl_3$–$CaCl_2$, $NdCl_3$–NaCl,[4] and $NdCl_3$–$CaCl_2$[4] systems

indicate the simple eutectic melts, and have no intermediate compounds. The linear molar volume isotherms of these systems at 800 and 1000 °C are the reasonable results, which may suggest the random mixing of ions in molten state. But the phase diagrams of $PrCl_3$–KCl[3,5] and $NdCl_3$–KCl[5] systems show the formation of intermediate compounds, and though the existance of complex ions in these mixture melts might be expected, the molar volume isotherms at 800 and 1000 °C have the linear behaviors.

The authors with to thank Mr. Matsuji Sato for assistance in the analysis of materials, and wish to thank Mr. Osamu Ugazin for his capable assistance in this work.

The Separation and Determination of Chromium(VI) by Reducing Elution Using Anion Exchange Resin and Sodium Sulfite

Takashi YAMASHIGE, Hirofumi IZAWA, and Yasumasa SHIGETOMI*

Miyoshi Health Center, Miyoshi-shi 728

** Department of Chemistry, Okayama College of Science, Okayama-shi 700*

(Received March 14, 1974)

Synopsis. The reducing elution of chromium(VI) by anion exchange using sodium sulfite has been investigated. Chromium(VI) is reduced to chromium(III), which is eluted quickly and easily separated from interfering substances by colorimetry using diphenylcarbazide.

The contamination of an environment by heavy metals has become of interest in recent years. The standards of the content of total and hexavalent chromium for industrial waste water have been established by the Government.

Generally, chromium is determined by atomic absorption spectrophotometry[1] after extraction with MIBK. A simple determination as of JIS can be carried out by spectrophotometry using diphenylcarbazide, but this method necessitates the separation of chromium (VI) to prevent the interference of some metals and that of reducing substances.

Already, several separation methods of chromium such as precipitation by oxidation in basic media[2] and solvent extraction[3] using diethyldithiocarbamate, have been reported. However, it is imposible to determine only chromium (VI) using diphenylcarbazide after separating chromium by these methods. Also, the separation by cation exchange using acetate as the eluent[4] and that by anion exchange using mixed salts of thiocyanate and chloride as the eluent[5] are known.

However, these separation methods are not suitable for spectrophotometry using diphenylcarbazide.

The present authors examined the method of the separation of chromium (VI) by ion exchange, which is suitable for spectrophotometry using diphenylcarbazide. As a consequence of their experiments, the method of ion exchange using mixed solution of sulfuric acid and sodium sulfite as the eluent was found to be suitable for this purpose.

Experimental

A column 0.8 cm in diameter and 10 cm in length was loaded with 5.0 ml of 100—200 mesh Dowex 1X8(hydroxide form).

A Hitachi model 101 spectrophotometer was used for the determination of chromium(VI).

A reagent of a special grade was used without purification.

The elution curves were made of the metal content per 10 ml fraction of the eluate, after demasking by boiling, oxidizing to chromium(VI) and coloring.

Results and Discussion

Concentration of Sulfuric Acid and Sodium Sulfite. The following experiments were performed. Chromium(VI) absorbed on the column of anion-exchange resin is eluted with the mixed solution of sulfuric acid and sodium sulfite. The excess of sulfite in the effluent is decomposed by boiling it for 20 min. The process of adding 2 or 3 drops of 0.3% potassium permanganate solution to the solution and of then boiling it for 5 min is rereated until the color of permanganate is only. After subsequent cooling, 10-ml portion of 20% urea solution is added to 100 ml of the sample solution. Then a 10% sodium nitrate solution is added to the sample solution until the color of the permanganate disappears. Finally, diphenylcarbazide is added to the solution for colorimetry.

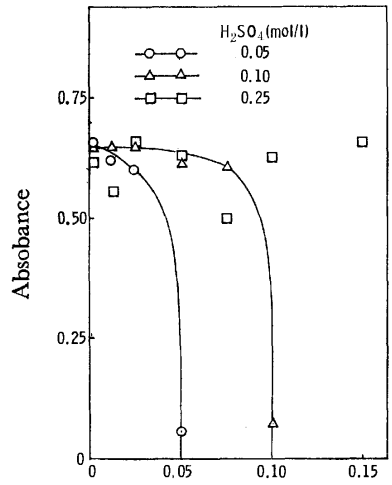

Fig. 1. Effects of concentration of H_2SO_4 and Na_2SO_3 on coloring.

In the above-mentioned experiments, we examined how the concentrations of sulfuric acid and sodium sulfite affected the absorbance. The results are shown in Fig. 1. For instance, when a mixed solution of 0.05 M sulfuric acid and 0.005 M sodium sulfite is used, the absorbance per ppm of chromium (VI) was 0.65, while in the case of 0.05 M sulfuric acid and 0.025 M sodium sulfite, the absorbance of the solution containing one ppm of chromium (VI) was 0.61. This means that, when more than 0.025 M sodium sulfite and 0.05 M sulfuric acid are used, sulfite remains after 20 minutes' boiling and so excess of permanganate has to be added in order to decompose the sulfite. As a result of this, the acidity in the sample solution falls and the absorbance lowered.

The tendency for the absorbance to be lowered is observed when more than 0.075 M sodium sulfite and 0.1 M sulfuric acid are used. Also, when more than

0.25 M sulfuric acid is used, the absorbance varies irregularly. Therefore it was concluded that the concentration of sulfuric acid should be 0.1 M while that of sodium sulfite in an eluent should be between 0.02 M and 0.005 M.

Elution of Chromium (VI) by the Mixed Solution of Sulfuric Acid and Sodium Sulfite. It was found that the direct addition of a mixed eluent leads to uncertain the elution curves, caused by foam generated by the neutralization heat which is brought about by the reaction of hydroxide in resin with sulfuric acid. Therefore, before the elution of chromium, hydroxide in resin was neutralized by introducing 0.1 M sulfuric acid, and then the chromium (VI) was eluted with a mixed solution of sulfuric acid and sulfite.

The metal content in a 10-ml fraction was determined by spectrophotometry using diphenylcarbazide after oxidation by the above-mentioned treatments. The results are shown in Fig. 2. In the first 50-ml effluent eluted by 0.1 M sulfuric acid alone, a slight amount of chromium was contained, but most of the chromium was contained in the next 200-ml fraction, obtained, using the eluent in which more than 0.01 M

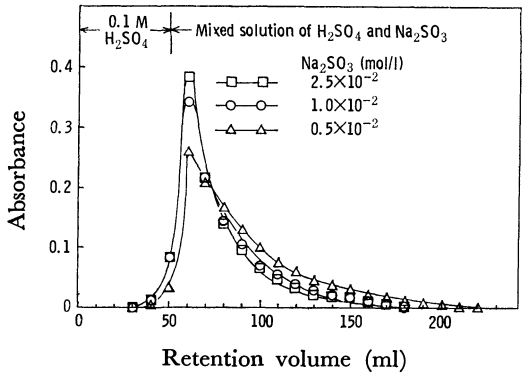

Fig. 2. Elution curves of Cr(VI), using mixed solution of H_2SO_4 and Na_2SO_3.

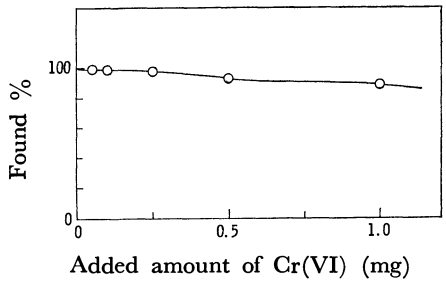

Fig. 3. Relation between found% and added amount.

Table 1. Determination of chromium(VI)[a]

Diverse subs.	ppm of diverse subs.	Cr(VI) ppm, found[b]	Cr(VI) ppm, found[c]
Fe^{+++}	0.5	0.48	0.45
Fe^{+++}	5.0	0.45	0.39
Zn^{++}	0.5	0.50	0.55
Pb^{++}	0.5	0.49	0.50
Cu^{++}	0.5	0.48	0.49
Cd^{++}	0.5	0.49	0.55
HCHO	1%	0.49	0.33
waste water	BOD 50 ppm	0.49	not detected

a) 0.5 ppm Cr(VI), added. b) After the separation. c) By JIS.

of sodium sulfite and more than 0.1 M of sulfuric acid were present.

When various quantities of chromium were added to the column and eluted by the same procedure, the found %, that is, the quantity of chromium in the effluent to that of the added chromium is as shown in Fig. 3. If less than 0.1 mg of chromium is used, most of the chromium is found in the first 250-ml effluent.

Effects of Diverse Substances. A 100-ml fraction of a solution containing 0.5 ppm chromium and various metals or reducing substances was introduced into the column. The chromium, separated by the above-mentioned treatment using 50 ml of sulfuric acid and 200 ml of the solution of 0.1 M sulfuric acid and 0.01 M sodium sulfite, was determined by spectrophotometry using diphenylcarbazide. The results are shown in Table 1 along with those obtained by determination by JIS. The reaction is interfered with by iron, zinc, and cadmium, and much by reducing substances. Especially, in BOD 50 ppm of industrial waste water, no chromium was detected, while chromium could be precisely analysed when this separation method was used.

Substitution Reaction of Ethylenediaminetetraacetatoaluminate(III) with Indium(III) in Aqueous Solutions

Michiko TSUCHIMOTO

Department of Industrial Chemistry, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184

(Received April 25, 1974)

Synopsis. The kinetics of substitution reaction between the aluminium(III) EDTA complex and the indium-(III) ion has been studied in aqueous solutions of pH 2—10; the aluminium(III) complex is more labile than the gallium(III)[1] and the indium(III)[2] complex.

Previous kinetic studies on the isotopic exchange of ethylenediaminetetraacetatogallium(III),[1] indium-(III)[2] and thallium(III)[3] could not be extended to the corresponding aluminium(III) complex because of lack of suitable radioisotope. Indium(III) complex of EDTA (H_4Y) has a much greater stability constant than that of the aluminium complex $[AlY]^-$ and the following equilibrium shifts towards the right.

$$[AlY]^- + In^{3+} \rightleftarrows [InY]^- + Al^{3+} \quad (1)$$

EDTA complexes of tervalent cations have one mole of coordinated water. The formula would be more complicated than that written in terms of MY^- as done for the sake of simplicity. Determination of the rate of decrease in $[AlY]^-$ concentration is best. For measuring the rate of reaction (1) towards the right. However, $[AlY]^-$ cannot be determined quickly without separation, which takes too long as compared with the progress of the substitution reaction. Thus the concentration of free indium ions was determined by titration with EDTA. Since the liberated aluminium and excessive indium ions give a precipitate in the neutral or basic region, tartrate ions had to be added.

Reaction (1) is very fast below pH 2. The rate was determined in the pH regions 2—4, and 4—9.5 in the absence and the presence of tartrate ion, respectively. When the concentration of the indium ion ($\simeq 10^{-3}$ M) exceeds that of $[AlY]^-$ ($\simeq 10^{-4}$ M), a pseudo first-order kinetic law holds in the initial stages. The apparent first-order rate constant k_1 is a measure for the rate.

$$k_1 = (1/t) \ln (a/a-x) \quad (2)$$

The concentration of $[AlY]^-$ at time t is obtained from $(a-x)$, where x is the decrease in concentration of free indium(III) and a the initial concentration of $[AlY]^-$. The overall dependence of k_1 upon pH is shown in Fig. 1.

Titration of the indium ion took *ca.* 1 min., and had to be carried out at 3—10 min time intervals. The difference $(a-x)$ is relatively small as compared with a and x, and the overall error for k_1 values seems to be *ca.* ±10%. Hence only qualitative discussion was made for the initial stage of the reaction.

In Acid Region. The k_1 values increase almost linearly with increase in indium(III) ion concentration, being independent of the complex concentration at pH 2.8 (Table 1). The apparent Arrhenius activation energy is 13 kcal/mol at pH 2.8. The increase in k_1 below pH 2.5 seems to be due to acid catalysis. Dependence on indium(III) ion concentration can indicate either an electrophilic attack of indium(III) or the retardation of recombination of free acetate branch of partly dissociated $[AlY]^-$. Differentiation of the two mechanisms is difficult. However, the E_A values in acid do not differ from those in neutral or basic region. Hence the rate-determining step seems to lie in the dissociation of $[AlY]^-$, and the dependence on indium ion concentration can be reckoned as Lewis acid catalysis. Indium(III) may give an ion pair or a segment with the complex, retarding the recombination of the free end, $-CH_2COO^-$.

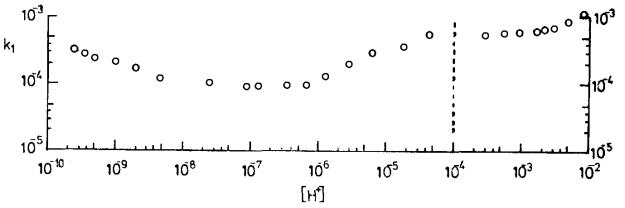

Fig. 1. pH Dependence of the rate constant k_1 in the whole pH region.
20 °C, I=0.2(KNO_3), In^{3+} 4.0×10^{-3} M, Al-EDTA 4.0×10^{-4} M; over pH 4, potassium tartrate 0.02 M, sodium barbiturate 0.002 M.

4.0	4.8			6.8×10^{-4}
4.0	6.0	1.2×10^{-4}	7.9×10^{-5}	8.4×10^{-4}
4.0	8.0	1.2×10^{-4}	8.2×10^{-5}	

20 °C, I=0.2(KNO_3); at pH 7.0 and 8.7, potassium tartrate 0.02 M, sodium barbiturate 0.002 M.

In Neutral and Basic Region. Tartrate ion does not affect titration. k_1 is independent of the free indium(III) ion concentration, but increases linearly

Table 2. Influence of ionic strength(KNO_3) and potassium tartrate upon the rate constant k_1

KNO_3 (M)	Potassium tartrate (M)	k_1 (s^{-1}) pH 8.7	pH 7.0	pH 2.8
0.05	0.02	1.3×10^{-4}	7.5×10^{-5}	6.1×10^{-4}
0.4	0.02	1.4×10^{-4}	8.1×10^{-5}	5.5×10^{-4}
0.2	0.01	1.2×10^{-4}	7.0×10^{-5}	
0.2	0.016	1.4×10^{-4}	8.2×10^{-5}	
0.2	0.03	1.8×10^{-4}	1.5×10^{-4}	
0.2	0.04	2.2×10^{-4}	2.0×10^{-4}	

20 °C, In^{3+} 4.0×10^{-3} M, Al-EDTA 4.0×10^{-4} M; at pH 7.0 and 8.7, sodium barbiturate 0.002 M.

with increase in tartrate ion concentration (Table 2). E_A depends on the tartrate ion concentration; 16 and 13 kcal per mole in the presence of 0.02 M tartrate ion for 4.0×10^{-4} M complex, at pH 7.0 and 8.7, respectively. The buffering agent, barbiturate, does not affect the rate; neither does the ionic strength. k_1 decreases slightly with increase in the complex concentration.

The complex has a coordinated water which dissociates with a $pK\simeq10^{-6}$ and can be replaced by other ligands including tartrate.[4] Substitution of tartrate for the ligand water seems to facilitate the bond break of $[AlY]^-$. With increase in complex concentration, coordinated tartrate may act as a bridging ligand to give a binuclear complex such as $[YAl\cdot tart\cdot AlY]^{4-}$, which may dissociate with slightly greater difficulty than the uninuclear species.

Comparison with Related Reactions. It is remarkable that the dissociation reaction of $[AlY]^-$ is faster than that of the corresponding gallium(III) and indium(III) complex (*e.g.* R/a values are 1.7×10^{-5}, 4.3×10^{-5}, 3.7×10^{-5} and 4.0×10^{-5} s^{-1} for $[GaY]^-$ at pH 1.0 and 8.6 and $[InY]^-$ at pH 1.36 and 10.98, respectively.[1,2]). The lability of $[AlY]^-$ seems to be reflected in the smaller E_A values given above. (The E_A values for the isotopic exchange between MY^- and M^{3+} (M=Ga, In) are 15 to 18, and 25 kcal/mol, M in acid and basic regions respectively.[1,2]) Aluminium(III) is generally understood to be more inert than gallium(III) and indium(III) towards substitution reactions, on the basis of kinetic studies of solvent exchange in water and dimethylformamide,[5] intermolecular ligand isotopic exchange[6] and intramolecular site-exchange of β-diketonato complexes involving one bond break.[7] The present study does not allow more precise discussion because of experimental difficulty. The results, however, suggest remarkable influence of the ligand on the lability, especially of the coordinating atoms in such a multidentate ligand. Figure 1 shows a similar pattern to that of the isotopic exchange of $[GaY]^-$ and $[InY]^-$, although the details are different. Such must be the common pattern for substitution reactions of EDTA complexes of tervalent typical metal ions.

Experimental

Procedure. Aqueous solution (10^{-3} M, 50 ml) of indium(III) nitrate of a given pH containing potassium nitrate (and tartrate whenever necessary) was mixed with the complex[4] solution (10^{-4} M, 50 ml) of the same pH. Ten milliliter portions were withdrawn at appropriate time intervals, diluted with 20 ml of water (and 1 ml of 0.02 M potassium tartrate solution, when the reaction mixture does not contain tartrate ion), and titrated with 0.01 N disodium salt of EDTA with 0.1% xylenol orange solution (1 or 2 drops) as indicator, the pH being adjusted to 4—5 with an acetate buffer. The acid concentration below pH 4 was adjusted with nitric acid.

The free aluminium(III) ion liberated by reaction (1) did not interfere with the titration of free indium(III) in the presence of tartrate ion. Reaction (1) proceeds very slowly at pH 4—5 under the given conditions.

The author wishes to thank Professor Kazuo Saito, Tohoku University, for valuable discussions and suggestions, and Dr. Kazuko Ogino, Tohoku University, for numerical calculations.

The Solubility Parameter of Tetrasulfur Tetranitride

Shuichi HAMADA, Yoshiyuki KUDO, and Masako KAWANO

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received June 3, 1974)

Synopsis. The solubilities of tetrasulfur tetranitride in thirteen organic solvents were measured. The solubility parameter of tetrasulfur tetranitride was estimated from the solubilities and its deduced activity to be 13.$_7$ at 25 °C; we assumed it to be regular.

Only a few solubilities of tetrasulfur tetranitride, S_4N_4, have been reported — for example, those for carbon disulfide, ethanol, dioxane, and benzene.[1] Consequently, the solubility parameter of this compound has not been reported. In this work, the solubilities and the solubility parameter of tetrasulfur tetranitride were estimated.

Experimental

Materials. The tetrasulfur tetranitride was prepared by the method described by Jolly and Goehring[2] and was recrystallized repeatedly from the benzene solution. Thirteen solvents were used to estimate the solubilities, as is shown in Table 1. All the solvents were purified in the usual ways.

Procedure. Suitable amounts of the tetrasulfur tetranitride and an organic solvent were put into a three-necked flask and were then stirred continuously for 2 hr at the temperature range from 20 to 40 °C (from 10 to 30 °C for the dichloromethane) with a precision of ±0.03 °C. An aliquot of the solution was withdrawn through a fine Teflon tube with a glass filter by applying an excessive pressure in the flask. The concentration of the solution was estimated from its optical absorbance at 400 nm, after it has been diluted to a suitable concentration, by using the working curves for the respective solvents previously determined with a double-beam spectrophotometer, model UV-200, from Shimadzu Seisakusho. The solubility was estimated repeatedly, at least three times, under the same conditions; its deviation from an average value was less than ±1.5%.

Results and Discussion

The X-ray powder diffractogram of the sample showed patterns attributable to tetrasulfur tetranitride only.[3] The melting point of the sample was determined microscopically to be 178—179 °C. This value agreed with that of the purified tetrasulfur tetranitride.[4,5]

The solubilities, X_2 (molar fraction), and the heats of solution, ΔH^d, of the tetrasulfur tetranitride in various solvents are shown in Table 1.

The absorption peak in the UV spectra of the tetrasulfur tetranitride was observed at approximately 250 nm in all the solvents except for those with themselves a strong absorption band near 250 nm. In the methanol and the ethanol solutions, a new absorption peak was observed at 420 nm, and the absorbance at 420 and 250 nm decreased with the lapse of time. When the alcoholic solutions were concentrated by heating, the tetrasulfur tetranitride decomposed into sulfate. Though the solubilities in the pyridine and the carbon disulfide at 25 °C (after 2 hr) were estimated to be 1.0×10^{-2} and 4.3×10^{-3} respectively, a black fine precipitate was deposited from the solutions on heating. Consequently, their data are not presented in Table 1.

Table 1. Solubilities, heats of solution, and solubility parameters of tetrasulfur tetranitride at 25 °C

Solvent	X_2 ($\times10^3$)	ΔH^d kcal/mol	δ_1[a]	δ_2
Methanol	0.23	9.9		
Ethanol	0.28	7.6		
Dichloromethane	5.3	4.8	9.7	14.$_0$
1,2-Dichloroethane	5.5	5.5	9.8	14.$_0$
1,1,2,2-Tetrachloroethane	11	4.9	9.7	13.$_3$
n-Hexane	0.32	7.7	7.30	13.$_4$
Cyclohexane	0.64	7.9	8.20	13.$_9$
Cyclooctane	1.2	7.6	8.55	13.$_9$
Benzene	4.9	5.5	9.15	13.$_5$
Chlorobenzene	5.7	5.8	9.5	13.$_7$
Dioxane	8.8	4.9	10.0	13.$_8$
Chloroform	5.7	5.2	9.3	13.$_5$
Carbon tetrachloride	1.7	6.5	8.6	13.$_7$

a) The solubility parameters of the solvents, δ_1, were those at 25 °C.[6]

It is assumed that these solutions are regular solutions,[7] the following equation can be obtained:[8]

$$RT\ln a_2 = RT\ln X_2 + V_2\phi_1^2(\delta_1-\delta_2)^2 \quad (1)$$

where a_2 is the activity of the solute based on its supercooled liquid state at a given temperature; V_2, the molar volume of the solute in the liquid state; ϕ_1, the volume fraction of the solvent; δ_1 and δ_2, the solubility parameters of the solvent and the solute, and R, the gas constant. The activity of the solute can be calculated by means of the following equation:[7]

$$\ln a_2 = -\frac{\Delta H^f}{R}\left(\frac{T_f-T}{T_fT}\right) \quad (2)$$

where ΔH^f is the molar heat of fusion, and T_f, the melting point of the solute.

The molar heat of the fusion of the tetrasulfur tetranitride was deduced approximately as the difference between the molar heat of sublimation, ΔH^s, and that of vaporization, ΔH^v; it could not be estimated because the tetrasulfur tetranitride decomposed with fusion. Sato[9] pointed out that the molar entropy of vaporization of the normal liquids related to their vapor pressures, p (mmHg), at given temperatures as follows:

$$\frac{\Delta H^v}{T} = 23.61\left(\frac{p}{T}\right)^{-0.119} \quad (3)$$

The calculated values agreed with the actual values with a precision of 5%. This relation was derived from the Hildebrand general rule.[10]

The vapor pressure of the tetrasulfur tetranitride at its melting point (178 °C) was calculated to be 10.8 mmHg from the vapor pressure at 90 °C and the molar heat of sublimation (3.51×10^{-2} mmHg and 21.2 kcal/mol),[5] while the temperature change in the molar heat of sublimation was neglected. Assuming that the relation of Eq. (3) is possible on an imaginary liquid tetrasulfur tetranitride, its molar heat of vaporization, ΔH^v, at the melting point was calculated to be 16.6 kcal/mol. From the difference in the ΔH^s and the ΔH^v, the molar heat of fusion of the tetrasulfur tetranitride was obtained to be approximately 4.6 kcal/mol. The activity of the tetrasulfur tetranitride at 25 °C was calculated from Eq. (2) to be approximately 7.2×10^{-2}.

By using the values of the a_2, the X_2, the V_2, the ϕ_1, and the δ_1,[6] the solubility parameter, δ_2, of the tetrasulfur tetranitride at 25°C was calculated from Eq. (1); the results are shown in Table 1. The molar volume, V_2, of the tetrasulfur tetranitride in the supercooled liquid state was deduced from the partial molar volume (86 cm^3/mol), which was itself estimated from the benzene solutions at 25 °C with a precision of ±0.01 °C by using a modified Lipkin-Davison-type pycnometer. The solubility parameter of the tetrasulfur tetranitride at 25 °C was estimated to be 13.$_7$ as an average value.

Composition of Single Crystal of Iron Sulfide Grown by Normal Freezing

Kohei AMETANI and Tatsuo TAKAHASHI

RCA Research Laboratories, Inc., Zushi-machi, Machida-shi, Tokyo 194-02

(Received July 6, 1974)

Synopsis. The composition of a single crystal of iron sulfide was determined as a function of position along the growth axis using atomic absorption spectrophotometry. The observed composition was consistent with the phase diagram for the iron-iron sulfide pseudo binary system and the results of physical measurements.

Single-crystal ingots of iron sulfide, FeS, are grown from iron-rich nonstoichiometric melts by normal freezing.[1] The maximum size of crystals obtained is 10 mm in diameter and 30 mm in length. To investigate the physical properties of this material, the composition must be determined as a function of position along the growth axis of the crystal. In this paper, a method using 25 mg of samples in each analysis is described. The sample is dissolved in nitric acid containing bromine and sulfur is precipitated as barium sulfate by adding a known amount of barium chloride. After filtration, iron is determined directly by its atomic absorption, and sulfur, indirectly by the atomic absorption of an excess barium content in the filtrate.[2]

Experimental

Reagents. The standard barium solution was prepared by dissolving barium chloride dihydrate in deionized water and standardized by chelatometry using EDTA (5 mg Ba/ml). The standard iron solution was prepared by dissolving iron metals (99.9% up) in hydrochloric acid and stocked as 0.1 M hydrochloric acid solution (1 mg Fe/ml). Reagents used were of analytical reagent grade.

Atomic Absorption Measurements of Iron and Barium. Atomic absorption measurements were made at 372.0 nm for iron and 553.6 nm for barium in a nitrous oxide-acetylene flame using a Hitachi model 208 atomic absorption spectrophotometer and hollow cathode lamps HLA-3. The nitrous oxide-acetylene flame is recommended over an air-acetylene flame for reducing or eliminating the chemical interference by coexisting elements.[3] However, barium has a relatively low ionization potential (5.21 eV) and is readily ionized in the nitrous oxide-acetylene flame, unless a large amount of an easily ionized element is added to suppress the barium ionization.[4] In this work, lanthanum chloride was used as the suppressor. We already described the usefulness of this reagent in the measurements of several rare earths[5] which have ionization potentials (5.67—6.8 eV) similar to barium. As shown in Fig. 1, the barium absorption was increased with an increase of the lanthanum chloride concentration. For example, in the presence of 5000 ppm of lanthanum chloride, the barium absorption is about 2.3 times greater than without this reagent. The iron absorption was not generally affected by the presence of lanthanum chloride. In this lanthanum chloride matrix, iron did not affect the barium absorption and *vice versa*.

Analysis of Single Crystals. Samples, 1.0—2.0 mm thick, were sliced from the single-crystal ingot of iron sulfide perpendicular to the growth axis for each analysis. Twenty-five mg of crystals were dissolved in 2 ml of concentrated nitric acid containing bromine. After the removal of nitric acid by evaporation with hydrochloric acid, the sample solution was diluted to about 40 ml and warmed to about 80 °C. The ferric ions were reduced to ferrous ions by adding ascorbic acid. The solution was adjusted to 0.05 M hydrochloric acid and sulfur was precipitated as barium sulfate by adding 9 ml of the standard barium solution (5 mg Ba/ml). The precipitate was allowed to settle for 1 hr on a hot water bath. After aging for more than 40 hr at room temperature, the precipitate was filtered and washed with six 5-ml portions of boiling water. The filtrate was adjusted to 0.1 M hydrochloric acid and 5000 ppm

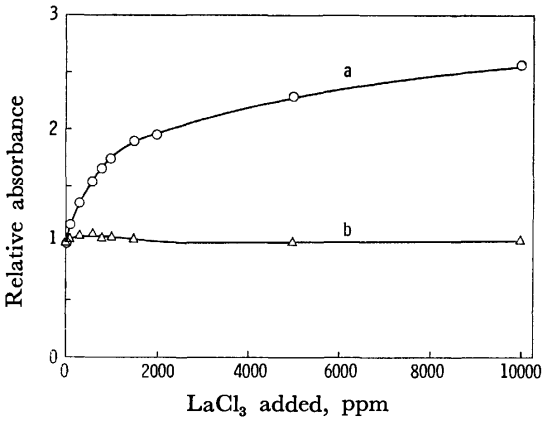

Fig. 1. Effects of lanthanum chloride on atomic absorptions of barium and iron in 0.1 M hydrochloric acid.
a: Ba 50 ppm, b: Fe 20 ppm.

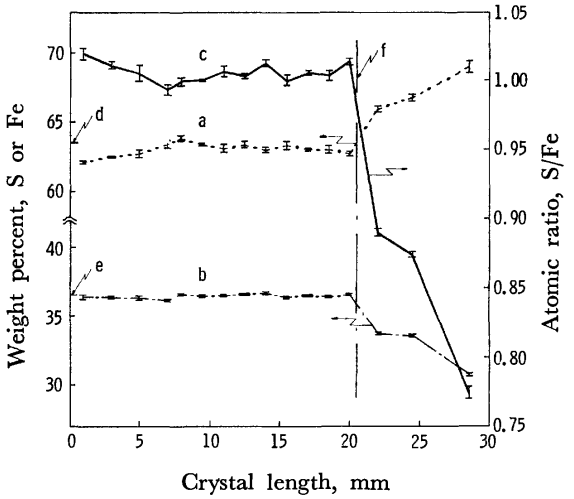

Fig. 2. Composition of the crystal as a function of position along the growth axis.
a: Fe wt%, b: S wt%, c: Atomic ratio S/Fe, d: Fe wt% expected for the composition FeS, e: S wt% expected for the composition FeS, f: Interphase boundary in crystal.

of lanthanum chloride. A similar adjustment was made for the iron and barium standards. Iron was determined directly by atomic absorption, and sulfur, indirectly by the atomic absorption of an excess of barium in the filtrate.

The results are shown in Fig. 2, where the observed wt% values of iron and sulfur are plotted as a function of position along the length of the crystal growth axis. The distance is measured from the bottom of the long single crystal. From the observed wt% values the calculated atomic ratio S/Fe is also plotted. The variation of the observed values for each analysis was usually ± 0.3 wt% for iron and ± 0.1 wt% for sulfur, so that the atomic ratio can be determined within ± 0.004. The sum of the wt% values for iron and sulfur ranged from 98.5 to 100.3 in all analyses. As can be seen in Fig. 2, the chemical composition at the bottom is slightly sulfur rich ($\sim FeS_{1.02}$), but is almost stoichiometric ($FeS_{1.00} \sim FeS_{1.01}$) starting from approximately 7 mm and up to the interphase boundary which appears at a height of 20.5 mm. Above the interphase boundary the composition becomes abruptly iron-rich. This compositional variation is consistent with the solidus curve in the phase diagram for the iron-iron sulfide system,[1,6] and also with the results of physical measurements, such as the transition temperature from hexagonal NiAs structure to distorted NiAs structure and metallographic observations.[1]

The Reactions of Cyclic Sulfilimines with Cyanide Ion and Phosphine: Evidence for Substitution on Trivalent Sulfur

Tetsuo AIDA, Masashi NAKAJIMA, and Teruhiko INOUE

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

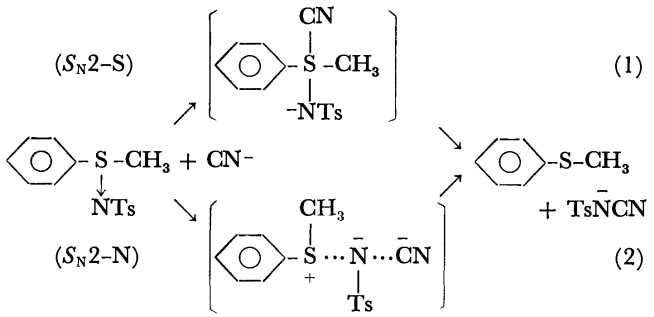
Naomichi FURUKAWA, and Shigeru OAE

Department of Chemistry, University of Tsukuba, Sakura-mura, Niihari-gun, Ibaraki 300-31

(Received January 18, 1974)

Synopsis. The effect of ring size on the reaction of *N*-*p*-tosylsulfilimine with such nucleophiles as CN^- and *n*-Bu_3P was investigated kinetically and compared with the effect on the reaction of the corresponding cyclic sulfonium salt. The results indicated that the S_N2–S process is more probable than the S_N2–N route.

Recently, we found that the reaction of alkyl aryl *N*-*p*-tosylsulfilimines with such nucleophiles as CN^- and *n*-Bu_3P[1,2] afforded the corresponding sulfides in high yields. We postulated two pathways for the mechanism of this reaction the one involving an initial nucleophilic attack on the trivalent sulfur atom by CN^- or *n*-Bu_3P(S_N2–S), the other proceeding *via* a rate-determining nucleophilic attack on the imine-nitrogen atom(S_N2–N). These two mechanisms are shown in Scheme 1. Although the kinetic and steric observations



Scheme 1.

seem to support an S_N2 attack on the sulfur atom[3] (S_N2–S), mechanism(2) cannot be ruled out. One way to make choice between these two mechanisms is to compare the effect of ring size on the rate of the nucleophilic substitution reaction of cyclic sulfilimines with that on the analogous reaction of the corresponding cyclic sulfonium salt. Since the following sulfonium salts are known to react with nucleophiles to afford the cyclic sulfides *via* an S_N2 attack on the methyl carbon, the small effect of ring size on reaction(3) should also be found in reaction path(2).

$$(CH_2)_n S^+\text{-}CH_3 + Nu \rightarrow (CH_2)_n S + CH_3\text{-}Nu \quad (3)$$
$$(n=5,6,7;\ Nu=CN^-,\ n\text{-}Bu_3P)$$

In contrast, the effect of ring size would be substantial when the reaction proceeds *via* pathway(1) (S_N2–S), as in S_N2 attacks on sp^3 carbon atom[4] or in S_N2-like reactions of the trivalent sulfur atom.[5,6,7] In the reduction of cyclic sulfoxides by hydroiodic acid[8] which proceeds *via* the S_N2–S path, the reactivities fall in the following order: 5>7>6-membered rings, in keeping with the correlation between the reactivities and the steric effect for the transition complex (I). Johnson and his co-workers[9] also found a similar trend in the reaction of cyclic sulfoxides with sodium hydrogen sulfite, and postulated a transition state or an energetically contiguous intermediate (II) as shown below.

(I) (II)

Thus, we have carried out the reaction of cyclic *N*-*p*-tosylsulfilimines and cyclic sulfonium salts with CN^- or *n*-Bu_3P in DMF (Table 1) and compared the effects of ring size (5, 6, and 7-membered rings) in these systems by means of competition reactions (Table 2).

Inspection of these data indicates that the effect of ring size is a quite different in the two reactions. The effect of ring size on the reaction of sulfilimines with CN^- or *n*-Bu_3P is found to fall in the following order: 5>7>6-membered rings, whereas, for the sul-

TABLE 1. REACTION OF CYCLIC SULFILIMINE OR SULFONIUM SALT WITH NUCLEOPHILES[a]

Nucleophile	Yield of cyclic sulfide (%)					
	$(CH_2)_n S\rightarrow NTs$			$(CH_2)_n S^+\text{-}CH_3\ ClO_4^-$		
	$n=4$	5	6	4	5	6
CN^-	quant	quant	78	quant	quant	quant
n-Bu_3P	quant	quant	81	quant	quant	quant

a) These reactions were carried out in DMF solution.

TABLE 2. RELATIVE REACTIVITIES OF CYCLIC SULFILIMINE AND SULFONIUM SALT[a]

Nucleophile	Molar ratio of sulfide					
	$(CH_2)_n S\rightarrow NTs$			$(CH_2)_n S^+\text{-}CH_3\ ClO_4^-$		
	$n=4$	5	6	4	5	6
CN^-	15.0	1.0	13.0	0.7	1.0	1.5
n-Bu_3P	25.0	1.0	10.0	0.9	1.0	1.7

a) These reaction were carried out in DMF solution.

fonium salts only small differences of the reactivities were found. Therefore, we conclude that the reactions of sulfilimines with CN^- and n-Bu_3P proceed *via* route 1 and not *via* the S_N2–N route.

Experimental

Materials. *Cyclic* N-p-*Tosylsulfilimines*: All the cyclic *N-p*-tosylsulfilimines were prepared by the modified Mann-Pope reaction[10] from the corresponding sulfides and chloramine-T. For the five membered cyclic sulfide a commercial product was used without purification, while the six and seven membered ones were prepared by known methods.[9] All the cyclic *N-p*-tosylsulfilimines were identified by comparing their mp, IR and NMR spectra with those reported earlier.[10]

Cyclic Sulfonium Perchlorates: All the cyclic sulfonium perchlorates were prepared by treating the corresponding sulfides with methyl iodide and silver perchlorate in methanol solution.

Competitive Reaction of Cyclic N-p-*Tosylsulfilimine with Nucleophile*: A typical run was as follows. A mixture of each of the cyclic *N-p*-tosylsulfilimines(5, 6, and 7-membered cyclic sulfilimines, each 0.1 mmol) and NaCN (0.2 mmol) was dissolved in 4 ml of DMF and the whole solution was placed in a sealed tube. It was heated in a constant temperature oil bath at 100°C for 5 hr. The tube contents were then poured into ice-water and the sulfide formed was extracted with petroleum ether. The distribution of the sulfides was determined by gas chromatography; the molar ratio of 5 : 6 : 7-membered cyclic sulfides was 15.0 : 1.0 : 13.0.

Competitive Reaction of Cyclic Sulfonium Perchlorate with Nucleophile: A typical run was as follows. One ml of DMF solution containing all the cyclic sulfonium salts (5, 6, and 7-membered cyclic derivatives, each 0.1 mmol) and 1 ml of DMF solution of tri-*n*-butyl phosphine (0.2 mmol) were prepared. Both solutions were kept at constant temperature (100 °C) in an oil bath before mixing. The reaction was started by mixing the two solutions and continued for 3 hr. The reaction mixture was then poured into 5 ml of water and the sulfides formed were extracted with 1 ml of petroleum ether. The distribution of the sulfides formed in the reaction was determined by gas chromatography: The molar ratio of 5 : 6 : 7-membered cyclic sulfides was 0.9 : 1.0 : 1.7. The reaction of cyclic sulfonium perchlorates with NaCN was carried out at 100 °C for 1 hr and the distribution of sulfides formed in the reaction was determined as described above.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 48(2), 725—726 (1975)

The Syntheses of Several Pyrimido[4,5-*e*][1,2,4]triazines

Takashi SUGIMOTO and Sadao MATSUURA

Department of General Education, Nagoya University, Nagoya 464

(Received July 1, 1974)

Synopsis. A new synthetic method for some derivatives of pyrimido[4,5-*e*][1,2,4]triazine, using 5-nitrosopyrimidines as the starting materials, was studied. That is, the condensation of 5-nitrosopyrimidin-2,4,6-trione and its methyl derivative with amino- or alkylamino-guanidine gave several 3-aminopyrimidotriazin-6,8-diones.

The discovery and identification of three naturally-occuring antibiotics, Toxoflavin,[1,2] Fervenulin,[3,4] and MSD-92,[5,6] derivatives of pyrimido[5,4-*e*][1,2,4]triazine, have aroused considerable interest in the syntheses and chemistry of these antibiotics and related compounds.[7-10] The isomeric pyrimido[4,5-*e*][1,2,4]-triazine series is also of increasing interest recently[11-14] because certain derivatives of this series have been found to have antiviral activities.[15,16] In this paper we wish to report a convenient method for the synthesis of several derivatives of the latter series, using readily-available 5-nitrosopyrimidines as the starting material.

Heating 1,3-dimethyl-5-nitrosopyrimidin-2,4,6-trione (**2**) with 2-amino-1-ethylguanidine in dimethylformamide(DMF) under reflux gave 3-ethylamino-5,7-dimethylpyrimido[4,5-*e*][1,2,4]triazin-6,8-dione(**7**) in a single step. A similar procedure afforded its 3-methylamino analogue(**6**), but failed to give their 5,7-demethyl homologues (**9**, **10**); when 5-nitrosopyrimidin-2,4,6-trione(**1**) was boiled in DMF with 2-amino-1-ethyl(or methyl)guanidine, only dark-colored materials were obtained. However, the treatment of **1** in boiling dil. hydrochloric acid with aminoguanidine afforded alloxane guanylhydrazone(**3**) in a good yield; this cyclized to 3-aminopyrimidotriazin-6,8-dione(**8**)[17] in boiling ammonia. Similarly, its 3-methylamino[17] and 3-ethylamino[18] analogues(**9**, **10**) were made from **1** and 2-amino-1-methylguanidine or the ethyl homologue respectively *via* the corresponding guanylhydrazones(**4**, **5**).

11, X=NH_2, Y=OH
12, X=OH, Y=NH_2
13, X=OH, Y=$NHCH_3$

Attempts to make the 6-amino analogue of **8** from 2-amino-5-nitrosopyrimidin-4,6-dione(**11**) and aminoguanidine in a similar manner resulted only in the formation of **8**; the starting aminopyrimidine inevitably suffered hydrolysis at the initial condensation step under the conditions employed and gave **3**. Similarly, the reaction of 4-amino-5-nitrosopyrimidin-2,6-dione (**12**) or its 4-methylamino analogue(**13**) with aminoguanidine again gave only the same guanylhydrazone (**3**).

Experimental

The analyses were done by the Analytical Section, Meijo University, Nagoya; the UV spectra were measured with a JASCO model ORD/UV-5 spectrophotometer.

*3-Ethylamino-5,7-dimethylpyrimido[4,5-*e*][1,2,4]triazin-6,8-dione (**7**) and its 3-Methylamino Analogue (**6**).* A solution of **2** (3.5 g) and 2-amino-1-ethylguanidine·2HCl (3.5 g) in DMF (40 ml) was boiled under reflux for 1 hr. The subsequent removal of the solvent under reduced pressure and the trituration of the residue with water (10 ml) gave colorless needles (1.3 g) of **7**; mp 267—267.5 °C (from methanol) (Found: C, 45.8; H, 5.0; N, 35.7%. Calcd for $C_9H_{12}N_6O_2$: C, 45.8; H, 5.1; N, 35.6%); λ_{max}^{MeOH} nm (log ε): 338 (3.90), 257 (4.19), and 224 (4.46).

The use of 2-amino-1-methylguanidine·HBr in place of its ethyl homologue in the foregoing condensation gave **6** (36%), mp 290—291 °C (from water) (Found: C, 43.5; H, 4.4; N, 38.0%. Calcd for $C_8N_{10}N_6O_2$: C, 43.2; H, 4.5; N, 37.8%); λ_{max}^{MeOH} nm (log ε); 337 (3.92), 255 (4.19), and 223 (4.49).

*3-Aminopyrimido[4,5-*e*][1,2,4]triazin-6,8-dione (**8**).* A solution of **1** (1.6 g) and aminoguanidine bicarbonate (1.5 g) in 1M–HCl (100 ml) was boiled under reflux for 1 hr. The subsequent concentration under reduced pressure to *ca.* 30 ml and chilling gave **3** as hydrochloride (1.7 g); mp >300 °C (Found: C, 25.6; H, 2.9; N, 36.1%. Calcd for $C_5H_6N_6O_3$·HCl: C, 25.6; H, 3.0; N, 35.8%). The same compound was also obtained from **11** (52% yield), **12** (58% yield), and **13** (55% yield) when these aminopyrimidines were treated with aminoguanidine as above; the structure of the product was confirmed by satisfactory elemental analyses.

A suspension of **3** (hydrochloride, 2.0 g) in 1% ammonia (100 ml) was boiled under reflux for 2 hr. The subsequent acidification with formic acid gave an ivory powder (1.5 g, 93%) of **8**; mp 300 °C (lit,[17] mp>350 °C) (Found: C, 33.1; H, 1.45; N, 46.8%. Calcd for $C_5H_4N_6O_2$: C, 33.1; H, 2.2; N, 46.7%); pK_a 7.08±0.03; λ_{max} nm (log ε) at pH 4.0: 327(3.85) and 244(4.11); at pH 9.3: 335(3.93), 255(sh., 3.93), and 229(4.56).

*3-Methylaminopyrimido[4,5-*e*][1,2,4]triazin-6,8-dione (**9**).* A solution of **1** (3.5 g) and 2-amino-1-methylguanidine·HBr (5.0 g) in 1M–HCl (100 ml) was boiled for 5 hr, and then the solution was treated as above to give **4** as hydrochloride (4.0 g); mp ~300 °C (Found: C, 28.9; H, 3.4;

N, 33.7%. Calcd for $C_6H_8N_6O_3 \cdot HCl$: C, 29.0; H, 3.65; N, 33.8%). Similar treatments of **11**, **12**, and **13** with 2-amino-1-methylguanidine gave the same product (**4**) in 77, 79, and 73% yields respectively.

A suspension of **4** (hydrochloride, 2.5 g) in 1% ammonia (100 ml) was refluxed for 2.5 hr. The resulting solution was acidified with formic acid and chilled to give a colorless powder (1.2 g, 63%) of **9**; mp>300 °C (lit,[17] mp>350 °C) (Found: C, 36.7; H, 3.0; N, 43.5%. Calcd for $C_6H_6N_6O_2$: C, 37.1; H, 3.1; N, 43.3%); pK_a 7.24±0.04; λ_{max} nm (log ε) at pH 4.0: 360(sh., 3.74), 335(3.83), and 254(4.20); at pH 9.6: 360(sh., 3.89), 341(3.96), 265(sh., 3.91), and 235(4.57).

*3-Ethylaminopyrimido[4,5-e][1,2,4]triazin-6,8-dione (**10**).* A solution of **11** (4.0 g) and 2-amino-1-ethylguanidine·HBr (7.0 g) in 1M-HCl (100 ml) was boiled for 5 hr. The subsequent chilling of the solution gave yellow leaflets (2.0 g) of **5** as hydrochloride; mp>300 °C (Found: C, 31.8; H, 4.1; N, 32.3%. Calcd for $C_7H_{10}N_6O_3HCl$: C, 32.0; H, 4.2; N, 32.0%). The heating of **5** with 1% ammonia as above gave **10** (75% yield); mp>300 °C (lit,[18] mp >350 °C) (Found: C, 40.9; H, 3.7; N, 41.2%. Calcd for $C_7H_8N_6O_2$: C, 40.4; H, 3.9; N, 40.4%).

The Synthesis of 24-Norfriedel-4-en-3-one

Hiroshi KAKISAWA, Tsuneyuki HORIE, and Takenori KUSUMI

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Bunkyo, Tokyo, 112

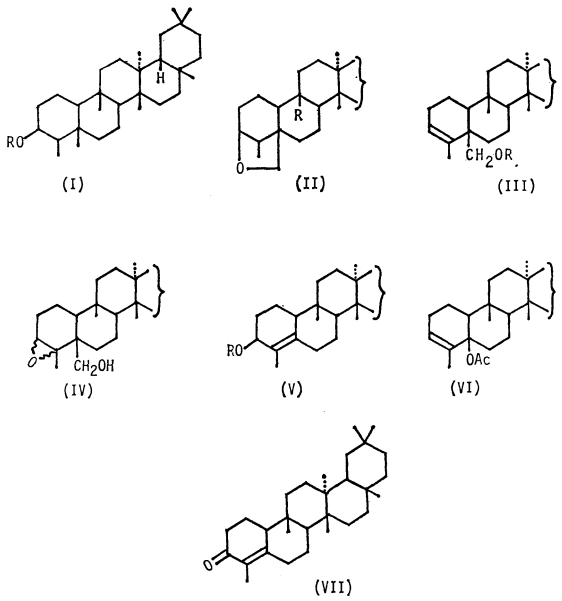
(Received July 1, 1974)

Synopsis. The lead tetraacetate oxidation of 24-hydroxyfriedel-3-ene, prepared from friedelin, afforded a 3-acetoxy-24-norfriedel-4-ene, which was then convered into the title compound.

Pristimerin and celastrol have been shown to have the carbon skeleton of 24-norfriedelane.[1] In connection with the structural investigation of these compounds, we studied the removal of the 24-methyl group from friedelin.

The functionalization of the 24-methyl group in friedelin was studied by Fukuda *et al*;[2] they prepared 3β-hydroxyfriedelan-24-oic acid lactone from 3β-friedelanol (I R=H) by lead tetraacetate–iodine oxidation, followed by chromic oxidation, or by the photolysis of a nitrile (I R=NO), followed by the oxidation of the resulting oxime. Although photoirradiation on 3β-friedelanol (I R=H) in the presence of iodine and mercuric oxide had been reported to form 3β,24-oxidofriedelane (II R=CH_3),[3] Wenkert and Mylari pointed out that the same reaction in the presence of lead tetraacetate instead of mercuric oxide affords 25-iodo-3β,24-oxidofriedelane (II R=CH_2I) besides 3β,24-oxide (II R=CH_3).[4] The formation of the iodo ether seems to be due to an excess of the oxidizing reagent in the photolysis. The photolysis of 3β-friedelanyl hypobromite (I R=Br), which had been prepared from friedelanol, bromine, and mercuric oxide in a dark place, is found to afford 3β,24-oxidofriedelane (II R=CH_3) in a modest yield.

Upon treatment with boron trifluoride-etherate and acetic anhydride, the ether linkage of 3β,24-oxide (II R=CH_3) was cleaved to afford a homoallyl acetate (III R=Ac),[3] which was then further converted into the corresponding alcohol (III R=H) by alkaline hydrolysis. Attempts to remove the hydroxymethyl group of (III R=H) *via* an epoxy derivative (IV) were unsuccessful. However, it was found that the reaction of (III R–H) with lead tetraacetate caused the elimination of the methylol group, affording a norcompound with the composition of $C_{31}H_{50}O_2$. This product showed an acetoxyl absorption band in the IR spectrum at 1730 cm^{-1} and gave a postive test with tetranitromethane. The NMR spectrum indicated a singlet at δ 2.05 due to the methyl group bonded to an olefin group and a multiplet at δ 5.06 assignable to either a carbinyl proton of allyl acetate or a vinyl proton. The product, therefore, appeared to be an unsaturated noracetate, most probably either 3-acetoxy-24-norfriedel-4-ene (V R=Ac) or 5-acetoxy-24-norfriedel-3-ene (VI). The base hydrolysis of the acetate afforded a corresponding allyl alcohol, the NMR spectrum of which showed a new signal at δ 3.86 instead of the signal at δ 5.06 in the original acetate. This change indicates that the signal at δ 5.06 is due to a carbinyl proton of allyl acetate, and



so the structure (V) is assigned to the lead tetraacetate oxidation product. The allyl alcohol (V R=H) was finally converted by oxidation with manganese dioxide into the α,β-unsaturated ketone (VII), which has the desired 24-norfriedelane carbon skeleton.

Experimental

3β-Friedelanol (I R=H). Sodium borohydride (4 g) was added portion by portion to a solution of friedeline (3 g) in diglyme (800 ml), and then the mixture was allowed to stand for 15 hr. After the addition of water (1000 ml), the separated precipitate was collected, washed with water, and dried. The material was recrystallized from chloroform to give 2.2 g of 3β-friedelanol (mp 270—273°C), which was identical with the sample prepared by the authentic method.[1]

3β,24-Oxidofriedelane (II R=CH_3). To a solution of 3β-friedelanol (500 mg) in carbon tetrachloride (1000 ml) containing yellow mercury oxide (900 mg), was added drop by drop a solution of bromine (0.08 ml) in carbon tetrachloride (3 ml) at 0 °C over 1-hr period in a place protected from light. After it had been stirred for 3 hr at 0°C, the mixture was filtered and the filtrate was irradiated with a tungsten lamp (300 W; 15 cm from the liquid level) at 0 °C under a nitrogen atmosphere for 1 hr, after which period the orange color of the solution had faded. The solution was washed with an aqueous sodium chloride solution, dried, and evaporated to give a white solid. The crude product was dissolved in benzene. The solution was purified through a column of alumina (15 g). Elution with benzene yielded 240 mg of pure oxide, which was then recrystallized from chloroform; mp 210—212 °C, ν (KBr) 2980—2850, 1450, 1380 cm^{-1}, $\delta(CDCl_3)$ 3.40(1H,d,J=8 Hz), 3.86(1H,m), 4.24(1H), 4.24(1H,d,J=8 Hz).

24-Hydroxyfriedel-3-ene (III R=H) was prepared from the oxide (II R=CH_3) by the method developed by Courtney and Stern.[3]

3-Acetoxy-24-norfriedel-4-ene (V R=Ac). To a stirred solution of the hydroxyfriedelene (III R=H) (150 mg) in 30 ml of benzene containing 0.07 ml of pyridine, was added 300 mg of lead tetraacetate. The mixture was stirred for 30 min. After subsequent treatment with water, the mixture was extracted with ether. The ether extract was washed successively with aqueous cupric sulfate and an aqueous sodium chloride solution, and dried. The ether was then removed, and the residue was fractionated by the column chromatography of alumina to give white crystals of the allyl acetate (159 mg); mp 172—175 °C, ν(KBr) 1730, 1240 cm^{-1}, $\delta(CDCl_3)$ 2.05(3H,s), 1.68(3H,s), 5.06(1H,m). Found: $(M-HOAc)^+$, 394.36102. Calcd for $C_{29}H_{46}$: 394.35990.

3-Hydroxy-24-norfriedel-4-ene (V R=H). The allyl acetate (V R=Ac, 140 mg) dissolved in ethanol (100 ml) was hydrolysed by means of a reaction with potassium hydroxide (4 g) under an atmosphere of nitrogen to give the allyl alcohol (V R=H, 125 mg); mp 209 °C, ν(KBr) 3430 cm^{-1}, $\delta(CDCl_3)$ 1.78(3H,s), 3.86(1H,bs). Found: $(M-H_2O)^+$, 394.36001. Calcd for $C_{29}H_{46}$: 394.35990.

24-Norfriedel-4-en-3-one (VII). A mixture of the allyl alcohol (V R=H, 45 mg), active manganese dioxide (450 mg), and methylene chloride (5 ml) was stirred for 4 hr. The inorganic substance was removed by filtration, and the filtrate was evaporated *in vacuo* to give a crude α,β-unsaturated ketone (45 mg). A pure compound was obtained by recrystallization from chloroform–methanol; mp 201 °C, ν(KBr) 1675, 1610 cm^{-1}, $\delta(CDCl_3)$ 1,78(3H,s). λ_{max} 252 nm (ε 14900). Found: 410.3566. Calcd for $C_{29}H_{46}O$: 410.3548.

Cationic Arylation. VIII. Reactions of Benzenediazonium Tetrafluoroborate with Some Sulfur Compounds

Michio KOBAYASHI, Hiroshi MINATO, Junko FUKUI, and Nobumasa KAMIGATA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya, Tokyo 158

(Received July 2, 1974)

Synopsis. Reactions of benzenediazonium tetrafluoroborate (I) with thioanisole in acetonitrile yielded dimethylphenylsulfonium tetrafluoroborate, diphenyl sulfide, methylthiobiphenyls and acetanilide. Reaction of I with cyclohexene yielded 1-cyclohexylcyclohexene and cyclohexyl phenyl ether. Reactions of I with dimethyl sulfide yielded trimethylsulfonium tetrafluoroborate and thioanisole. Mechanisms of these reactions were discussed in terms of the attack of phenyl cation toward the lone electron pair of sulfur atoms and the benzene electrons.

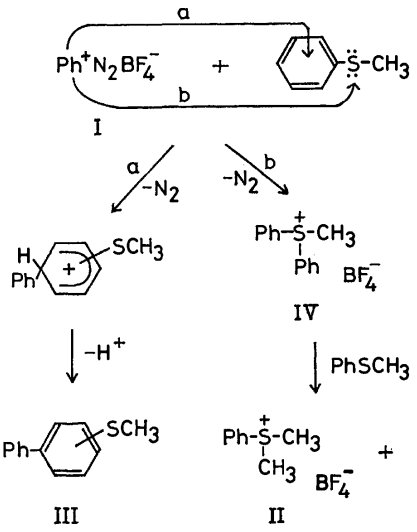
Many papers have described the arylation of aromatic compounds with aryldiazonium tetrafluoroborate (I)[1-3] or some other aryl cation sources.[4-7] However, very few papers have been published on the reaction of aryl cation with compounds other than arenes. Nesmeyanov and his coworkers found that the reaction of I with diaryl sulfides gave triarylsulfonium salts in low yield, but no other products were described.[8]

In order to determine the reactivity of phenyl cation toward compounds other than arenes, the reactions of I with some sulfides, disulfides and cyclohexene have been investigated. The results are described in this paper.

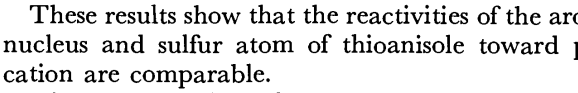
Results and Discussion

I is insoluble in aromatic solvents, but soluble in such aprotic polar solvents as acetonitrile and nitromethane. Therefore, the reaction of I with thioanisole was carried out in acetonitrile. The reaction products were dimethylphenylsulfonium tetrafluoroborate (II), diphenyl sulfide, isomeric methylthiobiphenyls (III), and acetanilide. Methyldiphenylsulfonium tetrafluoroborate (IV) which is the most-likely product from the reaction of phenyl cation with thioanisole was not isolated. The formation of acetanilide in the reaction of phenyl cation with acetonitrile is known.[3,8] Isomer distributions of methylthiobiphenyls formed by the phenylation of the thioanisole nucleus with I were *o*-57%, *m*-14%, *p*-29%; they are similar to those in cationic phenylation of anisole (*o*-64%, *m*-8%, *p*-28%) reported previously.[3]

The formation of products described above can be explained by assuming the following mechanism. Phenyl cation attacks the aromatic nucleus and the sulfur lone pair of the thioanisole competitively, yielding III and IV; the latter further reacted with another molecule of the unchanged thioanisole to give II and diphenyl sulfide. Since IV was not isolated in the reaction mixture, the reaction of IV with thioanisole must be very rapid. In a separate experiment, methyldiphenylsulfonium perchlorate (V) was prepared and treated with thioanisole in acetonitrile. About equal amounts of dimethylphenylsulfonium perchlorate (VI) (33%) and diphenyl sulfide (38%) were found as expected.[9]



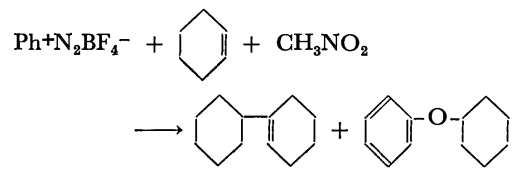
I III II IV



V VI

These results show that the reactivities of the aromatic nucleus and sulfur atom of thioanisole toward phenyl cation are comparable.

Then the reaction of I with cyclohexene was investigated in nitromethane. The products found were 1-cyclohexylcyclohexene and cyclohexyl phenyl ether.



Cyclohexyl phenyl ether was probably formed *via* *O*-phenylation of nitromethane followed by the reaction with cyclohexene. 1-Cyclohexylcyclohexene was probably formed by protonation of cyclohexene, the addition of cyclohexyl cation to cyclohexene, and subsequent deprotonation.

When I was let to react with dimethyl sulfide in acetonitrile, the products found were II, trimethylsulfonium tetrafluoroborate (VII) and thioanisole.

Since II was found in the reaction mixture, the reaction of II with dimethyl sulfide is not so rapid as that of IV with thioanisole.

When I was let to react with dimethyl disulfide in acetonitrile, the only product which was identified was

$$Ph^+N_2BF_4^- + CH_3SCH_3 \xrightarrow{-N_2} Ph\text{-}\overset{+}{S}(CH_3)\text{-}CH_3 \; BF_4^-$$

II

$$\xrightarrow{CH_3SCH_3} CH_3\text{-}\overset{+}{S}(CH_3)\text{-}CH_3 \; BF_4^- + PhSCH_3$$

VII

$$Ph^+N_2BF_4^- + CH_3SSCH_3 \xrightarrow{-N_2} CH_3\text{-}S\text{-}\overset{+}{S}(Ph)CH_3 \; BF_4^-$$

VIII

$$\longrightarrow PhSCH_3 + \overset{+}{(SCH_3)}$$

thioanisole. The reaction probably involved the formation of methylmethylthiophenylsulfonium ion (VIII), which was attacked by some nucleophiles, yielding thioanisole. However, no products other than thioanisole were characterizable.

Experimental

Materials. I,[9] V,[10] and cyclohexene[11] were prepared according to the procedures described in the literature. Thioanisole was prepared by methylation of thiophenol with dimethyl sulfate; bp 75 °/15 mmHg. Dimethyl sulfide and dimethyl disulfide of Tokyo Kasei Co., Ltd. were used without further purification. Acetonitrile was refluxed over phosphorus pentoxide, and then distilled at 81 °C. Nitromethane was dried with calcium chloride and then distilled at 101 °C.

Reaction of I with Thioanisole. A solution of I (4.82 g, 25 mmol) and thioanisole (6.20 g, 50 mmol) in acetonitrile (12.2 g) was stirred at 40°C for 5 hr. After removal of acetonitrile, the ether-insoluble part of the residue was dissolved in aqueous acetone, and eluted through an ion exchange resin column (Amberlite I.R.A.-400) containing perchlorate anions; crystals of dimethylphenylsulfonium perchlorate were obtained (0.56 g, 2.34 mmol). The ether-soluble part was analyzed by glc (Apiezon L, 1 m, 200 °C): diphenyl sulfide (0.33 mmol) and III (isomeric mixture, 0.99 mmol) were found. A very small amount of acetanilide was isolated by the elution chromatography (Florisil) of the ether-soluble part (23 mg, 0.13 mmol).

Reaction of V with Thioanisole. A solution of V (0.60 g, 2.0 mmol) and thioanisole (1.20 g, 11 mmol) in acetonitrile (0.7 g) was stirred at 40 °C for 5 hr. After acetonitrile was evaporated, ether was added to the residue, and the ether-soluble part was analyzed by glc (Apiezon L, 1 m, 190 °C) and the amount of diphenyl sulfide formed was determined (0.76 mmol, 38%). The ether-insoluble part was submitted to NMR analyses, and the amounts of VI formed (0.66 mmol, 38%) and unchanged V (1.34 mmol, 67%) were determined.

Reaction of I with Cyclohexene in Nitromethane. A solution of I (1.01 g, 5.2 mmol) and cyclohexene (5.2 g, 63 mmol) in nitromethane (10 ml) was stirred at 40 °C for 5 hr. After nitromethane was evaporated, the residue was submitted to elution chromatography (Florisil) and the following products were identified by NMR and mass spectroscopy; 1-cyclohexylcyclohexene (82 mg, 0.52 mmol), cyclohexyl phenyl ether (44 mg, 0.25 mmol). Neither phenylcyclohexene nor phenylcyclohexanol was detected.

Reaction of I with Methyl Sulfide. A solution of I (0.96 g, 5 mmol) and methyl sulfide (1.55 g, 25 mmol) in acetonitrile (3.5 g) was stirred at 40 °C for 5 hr. Acetonitrile and methyl sulfide were evaporated, then the reaction products were determined quantitatively by NMR (internal standard: $CHCl_2CHCl_2$). The following products were identified; thioanisole (1.9 mmol, 38%), II (0.48 mmol, 9.6%), and VII (1.63 mmol, 33%).

Reaction of I with Dimethyl Disulfide. A solution of I (1.92 g, 10 mmol) and dimethyl disulfide (1.50 g, 16 mmol) in acetonitrile (8.9 g) was stirred at 40 °C for 5 hr. After acetonitrile was evaporated, the reaction mixture was submitted to elution chromatography (Florisil); thioanisole (196 mg, 1.58 mmol) and acetanilide (177 mg, 1 mmol) were isolated.

9) The incomplete conversion of V can be ascribed to the smaller ratio of PhSMe/V (=5.5) in comparison with that in the reaction of I with thioanisole (PhSMe/V=50/2.34=21.4). It cannot be ascribed to the difference in the counter anion, since the rates of reaction between diethyl sulfide and dibenzylethylsulfonium ion are uninfluenced by the kind of counter anion, ClO_4^- or BF_4^- (D. Van Ooteghem, R. Deveux and E. J. Goethals, *Int. J. Sulfur Chem*, **8**, 33 (1973)).

Photoreaction of Bicyclo[5.3.0]dec-1(7)-en-2-one with Cyclopentene and Cyclohexene

Atsutaka KUNAI, Takeshi OMORI, Koji KIMURA, and Yoshinobu ODAIRA

Department of Petroleum Chemistry, Faculty of Engineering, Osaka University, Suita-shi, Osaka 565

(Received July 2, 1974)

Synopsis. The photoreaction of the enone (I) with cyclopentene gave the radical coupling products, (VII) and (VIII), along with the hydrogen abstraction product (VI), but not [2π+2π] photocycloadduct. On the other hand, the photoreaction of I with cyclohexene proceeded in somewhat different manner to give the [2π+2π] photocycloadduct (V) other than the hydrogen abstraction product (VI) and the radical coupling product (IX).

In the chemistry of α,β-unsaturated carbonyl compounds, much attention has been shown about the photochemistry of cyclic enones. Especially, the [2π+2π] photocycloaddition of some cyclic enones, such as cyclopentenones and cyclohexenones, has been extensively studied[1] and utilized for preparation of a wide variety of poly fused alicyclic compounds.[1,2] On the contrary, cycloheptenone, being a next higher cyclic enone, has been of no consequence. This is because it cannot undergo the crossed photocycloaddition with olefins owing to the facile isomerization to its *trans* isomer.[3] More recently, we reported our preliminary finding concerning the crossed photocycloaddition of a certain cycloheptenone derivative, bicyclo[5.3.0]dec-1(7)-en-2-one (I), having a rigid bicyclic system, with some seven- and eight-membered ring olefins, such as cycloheptene, cyclooctene, and 1,5-cyclooctadiene.[4] In the case of I, the ethylene linkage of cycloheptenone is fixed tightly with five membered ring and, therefore, an unfavorable *cis-trans* isomerization may be entirely inhibited. This situation resulted in the predominant formation of two stereo isomers of the respective cycloadducts IIa, IIb—IVa, IVb.[4] In the present paper, emphasis has been placed on the effect of smaller ring sized olefins, such as cyclopentene or cyclohexene, on the photochemical reaction of I.

Experimental

Generals. The enone (I) was prepared according to the procedure of Dev[5] and Cope and Holzman[6] and purified by fractionation using Taika Kogyo SM-NB spinning band column before use. Irradiation was carried out using a Eikosha Halos 500-W water cooled high pressure mercury lamp. Products were isolated using a Varian Aerograph 90-P gas chromatograph and analyzed by a Hitachi 063 gas chromatograph (column: PEG-20M, SE-30, or FFAP). Yields were based on the enone I reacted. The deuterium exchange reaction was carried out according to the procedure of Pfeffer[7] and Osman and the products were analyzed by mass spectra using a Hitachi RMU-6E mass spectrometer.

Photoreaction of I with Cyclopentene. A mixture of I (2.97 mmol) and cyclopentene (29 mmol) placed in a sealed Pyrex tube (1×10 cm) was irradiated with an external mercury lamp at a distance of 2 cm at room temperature for 7 hr. After removal of remaining cyclopentene, residue was distilled *in vacuo* (10^{-3} mmHg) to afford 0.373 g of oil, which consisted of three products (glpc) mainly. Each product was isolated by preparative glpc; yields: VI 22%; VIII 12%; VIII 14%. VII: ν_{max} 1680 cm^{-1} (CO); δ(CCl_4) 1.10—2.15(m,18H), 2.20—2.40(m,2H), 5.55—5.80(m,2H); *m/e* 218(M^+), 152($M-C_5H_6$); 2,4-dinitrophenylhydrazone, mp 171—172 °C; Found: C, 62.98; H, 6.58; N, 13.93%. Calcd for $C_{21}H_{26}O_4N_4$: C, 63.30; H, 6.58; N, 14.06%. VIII: ν_{max} 1675 cm^{-1} (CO); δ(CCl_4) 1.30—2.20(m, 19H), 2.25—2.60(m, 2H), 5.60—5.85(m, 1H); *m/e* 218(M^+), 152($M-C_5H_6$); 2,4-dinitrophenylhydrazone, mp 172—173 °C; Found: C,63.23; H, 6.75; N, 14.26%. Calcd for $C_{21}H_{26}O_4N_4$: C, 63.30; H,6.58; N,14.06%. On treating with the solution of D_2O-dioxane-NaOD twice,[7] both VII and VIII were changed into the deuterated compounds X; *m/e* 220(M^+, $C_{15}H_{20}OD_2$) and XI; *m/e* 220(M^+, $C_{15}H_{20}OD_2$), respectively.

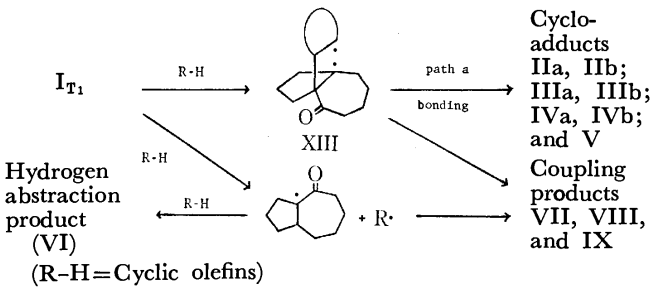
Photoreaction of I with Cyclohexene. A mixture of I (2.76 mmol) and cyclohexene (30 mmol) was irradiated for 3 hr, in a similar manner as described above. After removal of remaining cyclohexene, residue was distilled *in vacuo* (10^{-3} mmHg) to afford 0.444 g of oil, which consisted of three products (glpc) mainly. Each product was isolated by preparative glpc; yields: V 21%; VI 19%; IX 5%. V: ν_{max} 1680 cm^{-1} (CO); δ(CCl_4) 1.20—2.10 (m,22H), 2.20—2.70(m,2H); *m/e* 232(M^+), 151($M-C_6H_9$); Found: C, 82.41; H, 10.61%. Calcd for $C_{16}H_{24}O$: C, 82.70; H, 10.41%; 2,4-dinitrophenylhydrazone, mp 147—148 °C. IX: ν_{max} 1675 cm^{-1} (CO); δ(CCl_4) 1.20—2.40(m, 20H), 2.45—2.90(m, 2H), 5.30—5.85(m, 2H); *m/e* 232(M^+), 152($M-C_6H_8$); 2,4-dinitrophenylhydrazone, mp 163—165 °C; Found: C,63.92; H, 6.61; N, 13.88%. Calcd for $C_{22}H_{28}O_4N_4$: C, 64.06; H, 6.84; N, 13,58%. On treating with the solution of D_2O-dioxane-NaOD twice,[7] IX was changed into the deuterated compound XII; *m/e* 234(M^+, $C_{16}H_{22}OD_2$).

Results and Discussion

As reported previously,[4] the photoreaction of I with some seven- and eight-membered ring olefins, such as cycloheptene, cyclooctene, and 1,5-cyclooctadiene, always afforded two stereo isomers of respective cycloadducts.

Concerning the stereochemistry of above cycloadducts, we assume, presently, that two *trans*-fused isomers of four possible ones are more probable candidates.[8] Interestingly, the photoreaction of I with cyclopentene proceeded in a quite different manner as compared to the reaction with the larger ring sized olefins described above. Namely, the formation of cycloadduct of I with cyclopentene was not observed at all. Instead, two radical coupling products, VII and VIII, and one hydrogen abstraction product VI were obtained in 12%, 14%, and 22% yields. Structural determination of VII and VIII was made on the basis of elemental analyses and spectrometric data in addition to the results of the deuterium exchange reaction. Especially, from the fact that only two hydrogens were always exchanged for deuteriums in each compound, the coupling position of the cyclopentenyl groups was determined to be α-bridgehead to the carbonyl group. On the other hand, the photoreaction of I with cyclohexene proceeded in somewhat different manner to give the cycloadduct V together with the hydrogen abstraction product VI and the radical coupling product IX.

One of the most significant results in these reactions is the finding that the variation in the ring sizes of cyclic olefins has definitive influence on the reaction paths. To account for these results, we would like to make some proposals. It appears that the photo-excited state of I would not be different in a series of the above cyclic olefins, though the excited state of I is uncertain as yet. Moreover, in the case of cyclohexene, three types of products were obtained simultaneously in moderate yields. Taking these points, into consideration it may be reasonable to assume that the photochemical reaction proceeds stepwisely in radical manner through an intermediary 1,4-biradical (XIII), formed between the triplet state of I and cyclic olefins, as shown in Scheme 1. When cyclic olefins are larger ring sized olefins, such as cycloheptene and cyclooctene, the cycloaddition from XIII, according to the path a, smoothly could occur to form the cycloadduct, possessing large strained energy. On the other hand, in the case of smaller ring sized cyclic olefin, such as cyclopentene, the formation of cycloadduct from XIII may be entirely suppressed because of instability of cycloadduct, being highly strained structure.[8] Consequently, two other types of reactions accelerate to give the radical coupling products VII and VIII, and the hydrogen abstraction product VI. Concerning the occurrence of the latter two reactions, it may be also considered that cyclopentene is the substrate having the great hydrogen-donating ability. In the case of cyclohexene, circumstance lies between and the formation of cycloadduct V has barely become feasible. As a result, three types of products are given at the same time.



Scheme 1.

Further research for the photoreaction of I in the presence of strained olefins are in progress and will be reported shortly.

8) The structure of cycloadducts, IVa and IVb, is now under study by means of X-ray analysis. At the time, we suppose that, as a plausible structure, the cycloadducts have *trans*-fused structure. In the photocycloaddition of some bicyclic enones with cyclic olefins, the formation of *trans*-fused cycloadducts occasionally dominates. For example, the reaction of bicyclo[4.3.0]non-1(6)-en-7-one with cyclic olefins, such as cyclohexene and cyclooctene, afforded only *trans*-fused cycloadducts which were confirmed by means of X-ray analysis (A. Kunai, H. Omura, K. Kimura, and Y. Odaira, unpublished result, and to be published). On the other hand, the formation of *cis*-fused cycloadduct is observed only when the cycloadduct is substantially free from the repulsion of *syn* overlap. For example, cyclopentenone adds to cyclopentene to afford the corresponding *cis*-fused *anti*-adduct in good yield (P. E. Eaton, *J. Amer. Chem. Soc.*, **84**, 2454 (1962)).

On the Mechanism of the Diels-Alder Reaction between 1,3-Cyclopentadiene and 1,3-Cyclohexadiene

Terunobu MAEDA, Sawako HAMANAKA, and Masaya OGAWA

Department of Applied Chemistry, Faculty of Engineering, Kansai University, Suita-shi, Osaka 564

(Received July 8, 1974)

Synopsis. The reaction of 1,3-cyclopentadiene with 1,3-cyclohexadiene, when carried out at 94—118 °C for 5—7 hr, gave tricyclo[4.4.0.$1^{2,5}$]undeca-3,7-diene rather than tricyclo[5.2.2.$0^{2,6}$]undeca-3,8-diene.

In the study of the Diels-Alder reaction, many investigations[1-5] have been carried out in an attempt to elucidate the bonding sequence of two new σ-bonds formed during the reaction. Recently, Salem[3] suggested a new transition structure with secondary attractive force (s.a.f.) like that of the Cope rearrangement and supported a two-stage mechanism postulated by Woodward and Katz.[4] On the other hand, Herndon[5] showed that the prefered *endo*-addition pathway can be interpreted principally in teams of a geometrical relationship rather than s.a.f. and then suggested a one-step mechanism in which the planes of the two reactants are assumed to intersect at an angle of 60°. In our previous work[6] concerning the reaction of 1,3-cyclopentadiene(CP) with 1,3-butadiene, we also imagined a one-step mechanism by considering that the transition state of this reaction is different from that of the Cope rearrangement of one product (*endo*-5-vinyl-2-norbornene) to another (*cis*-3a,4,7,7a-tetrahydroindene). The present work will presents some evidence for the one-step mechanism of the reaction between two different *s*-cisoid dienes, such as CP and 1,3-cyclohexadiene(CH).

The reaction of CP with CH was carried out under N_2 in a sealed tube at a fixed temperature. The reaction products were separated by fractionation into the following fractions; monomers(79—83 °C/760 mmHg), dimers(83—105 °C/66mmHg), trimers(105 °C/5mmHg), and higher polymers(residue). The dimer fraction was analyzed by glc. Two codimers, *A* and *B* (Fig. 1), were isolated from the dimer fraction by preparative glc. The structural assignment of *A* and *B* is based on the following data: *A* —NMR (60 MHz, CCl_4, δ), 1.41 (2H, k, m), 0.95—2.70(4H, a b, m), 2.45(2H, l e, m), 2.80(2H, f i, m), 5.56(2H, c d, m), 5.92(2H, g h, t); (NaCl), 1569 and 1676 cm^{-1}: *B* —NMR(60 HMz, CCl_4, δ), 1.32, 1.44(4H, j k, m), 1.02—2.35(3H, ai, m), 2.48(2H, e h, m), 3.01(1H, d, m), 5.43(2H, b c, t), 6.07(2H, f g, $J_{fg}=4.8$ Hz, $J_{ef}=J_{hg}=3.0$ Hz); IR (NaCl) 1610 and 1645 cm^{-1}.[7] The results of the reaction of CP with CH are shown in Table 1.

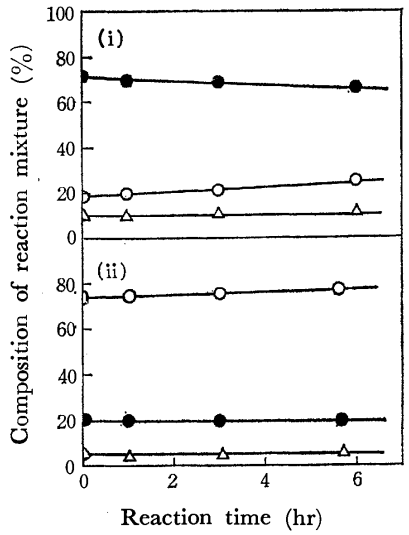

Fig. 2. Rearrangement of codimer.
—●— *A*, —○— *B*, —△— unknown
i) The reaction of *A*-rich fraction
ii) The reaction of *B*-rich fraction

A *n*-hexane solution(10 vol%) of an *A*- or *B*-rich fraction prepared from the reaction products was caused to react by heating at 139.0 °C. The results are shown in Fig. 2. Furthermore, in the reaction of the *A*-rich fraction with acryronitrile at 139.0 °C for 6 hr, no addition product with CH or CP was obtained. Consequently, the decomposition of *A* to CH and CP did not occur at this temperature.

The transition state of the reaction to produce an *A* or *B* codimer is considered to be I* for a one-step me-

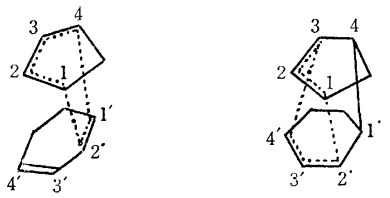

Fig. 3. Hypothetical transition stats.

chanism and *II** for a two-stage mechanism (Fig. 3). In the one-step mechanism, CP probably acts as a diene since the bond distance at C_1—C_4 is shorter than that at the C_1'—C_4' of CH. Therefore, the *A* product can be obtained through *I**. On the other hand, *II** has σ-bond at C_4–C_1' and two weak bonds at C_1—C_2 and C_3—C_4'. As the latter two weak bonds are similar in their reactivity, *II** may give both products, *A* and *B*. According to the additivity rule of strain, the relative stabilities of both *A* and *B* were calculated on the basis of the data estimated by Turner[8] and Alder;[9] *B* was found to be more stable than *A* by 11.4 kcal/mol. Consequently, when the reaction proceeds through the two-stage mechanism, *B* may be predominantly obtained in the products.

As was seen in Table 1 and Fig. 3, the results obviously show that *A* was initially produced and was then converted to *B*. Therefore, the reaction proceeds mainly along the following reaction course;

$$CP+CH \rightarrow I^* \rightarrow A \rightarrow II^* \rightarrow B$$

On the other hand, some portion of *B* may also be formed by the direct reaction of CP with CH, especially at higher temperatures.

Experimental

In glc, the columns used were R-90(0.25 mmϕ) for analysis and PEG-20(25%, 8mmϕ×3 m) for preparation. The measurements of the NMR and IR spectra were performed with JEOL-JNM-3H-60 and Shimadzu-IR-27G apparatuses respectively. All the reactions were carried out in sealed tubes maintained within ±0.1 °C.

Oxidation by Iron(III) Complexes. IX.[1] The Preparation of α-Diketones by the Oxidation of Enolizable Ketones with the Iron(III) Chloride-Pyridine Complex under Oxygen

Hiroo INOUE, Hiroyuki HATA, and Eiji IMOTO

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai, Osaka 591

(Received August 10, 1974)

Synopsis. The oxidation of deoxybenzoin and *p*-substituted deoxybenzoins with an iron(III) chloride–pyridine complex under air or oxygen was investigated. The reaction afforded the corresponding α-diketones in a satisfactory yield.

We have recently reported that enolizable deoxybenzoin (Ia) is oxidized with iron(III) chloride dispersed in benzene to undergo direct arylation with benzene at the α-position of the carbonyl group.[2] In the course of our studies, we found that the reaction pathway alters in the direction of the formation of an α-diketone, benzil(IIIa), upon the addition of pyridine to the reaction system, and that the reaction proceeds *via* the formation of an intermediate, α-chlorodeoxybenzoin(IIa), followed by the oxidation of IIa with oxygen in the presence of iron(II) chloride and pyridine. We wish to report here a novel method for the preparation of α-diketones from I.

$$\underset{\text{I}}{p\text{-XC}_6\text{H}_4\text{CH}_2\text{COC}_6\text{H}_5} \xrightarrow{\text{FeCl}_3/\text{C}_5\text{H}_5\text{N}} \underset{\text{II}}{p\text{-XC}_6\text{H}_4\overset{\text{Cl}}{\overset{|}{\text{C}}}\text{HCOC}_6\text{H}_5}$$

a; X=H
b; X=Cl
c; X=CH_3

$$\xrightarrow[\text{O}_2]{\text{FeCl}_2/\text{C}_5\text{H}_5\text{N}} \underset{\text{III}}{p\text{-XC}_6\text{H}_4\text{COCOC}_6\text{H}_5}$$

Results and Discussion

The Formation of α-Diketone. When pyridine was added to dry benzene containing the dispersed anhydrous iron(III) chloride (in the pyridine/iron(III) chloride molar ratio of 1:1), the iron(III) chloride solid changed to a black-brown paste which adhered to the wall of the reaction vessel. Ia was then added to the reaction system, and the solution was heated at 80 °C under an atmosphere of air. As the reaction time proceeded, the paste changed to a black-brown solid containing an iron(III) ion and pyridine as the major components. Ia was converted to IIIa, along with the by-products of benzaldehyde, benzoic acid, and 2,2-diphenylacetophenone(IV), as is shown in Table 1. The other products were a high-melting material and a tarry matter, although the structures of the products are still uncertain. In the absence of the iron(III) chloride and/or pyridine, IIIa was not obtained at all. When the reaction was carried out under oxygen, the yield of IIIa became higher than that in the case of air (Table 1). The substituted deoxybenzoins (Ib and Ic) were also converted to the corresponding α-diketones (IIIb and IIIc). In the case of propiophenone, however, the α-diketone was not obtained under similar conditions, although α-chloropropiophenone was produced in a good yield.[2] Thus, the existence of the phenyl group at the α-position of the carbonyl group is required for the formation of the α-diketone.

TABLE 1. THE REACTION OF I WITH AN IRON(III) CHLORIDE-PYRIDINE (1 : 1) COMPLEX UNDER AIR OR OXYGEN[a]

Ketone	Atmosphere	Yield, %	
		III	*p*-XPhCHO
Ia[b]	Air	56	11
Ia	O_2	73	2
Ib	O_2	78	7
Ic	O_2	67	8

a) The reaction time: 24 hr. The remaining I was not detected after 24 hr. b) IV was obtained in 8% yield. In a large scale reaction benzoic acid was isolated in 4% yield.

Catalytic Behavior. The oxidation of Ia with the iron(III) chloride–pyridine complex under air was carried out in the molar ratio of Ia, iron(III) chloride, and pyridine of 10 : 1 : 1. After a reaction of 118 hr, IIIa was produced in a 56% yield (based on Ia). This means that the iron(III) complex acts as a catalyst for the formation of IIIa.

Reaction Pathway. In the initial period of the reaction, IIa was detected by means of glc, although the amount produced was very small. After a long reaction, however, IIa could not be detected at all. This fact suggests that IIa is produced as an intermediate in the formation of IIIa. The reaction of Ia with the iron(III) chloride–pyridine (1: 1) complex under nitrogen at 80 °C for 24 hr afforded only IIa in a 56% yield, with a 35% recovery of Ia. In this reaction, the iron(III) ion was reduced to the iron(II) ion in a 55% yield. In addition, IIa was oxidized with oxygen in the presence of the hydrated iron(II) chloride and pyridine to afford IIIa in a good yield (Table 2), along with an iron(III) complex. In the absence of iron(II) chloride and pyridine, IIIa was not obtained at all. These facts led to the conclusion that IIIa is produced *via* the formation of IIa, followed by the oxidation of IIa with oxygen in the presence of the iron(II) complex produced.

On the other hand, the yields of benzaldehyde and benzoic acid became higher in a homogeneous reaction

Table 2. The reaction of Ia or IIa with the Fe(II) or Fe(III) complex[a)]

Ketone	Fe(II) or Fe(III) complex	Atmosphere	Time hr	Yield, %		Recovery, % Ketone
				IIIa	PhCHO	
Ia[b)]	$FeCl_3/CH_3CN$	Air	24	15	38	10
Ia[c)]	$[Fe(DMF)_3Cl_2][FeCl_4]$	Air	96	26	58	9
IIa[c,d)]	$FeCl_2/C_5H_5N$	O_2	24	83	0	0

a) The molar ratio of Ia or IIa to Fe(II) or Fe(III) ion: 1 : 2. b) IIa and benzoic acid were isolated in 14 and 20% yields, respectively. c) The solvent: benzene. The temperature: 80 °C. d) The Fe(II) ion was oxidized to the Fe(III) ion in 90% yield. The $FeCl_2/C_5H_5N$ molar ratio: 1.

of Ia with iron(III) chloride in acetonitrile under an atmosphere of air. A similar phenomenon was observed in the reaction of Ia with $[Fe(DMF)_3Cl_2][FeCl_4]$[3)] dispersed in benzene (Table 2). Thus, the yields of IIIa and benzaldehyde can be altered by changing the structure of the iron(III) complex. Benzaldehyde and benzoic acid are produced by the carbon-carbon cleavage of the $-CH_2-CO-$ bond, although the mechanism is ambiguous.

Experimental

Materials. The anhydrous iron(III) chloride was prepared by the method described in a previous paper.[1)] The hydrated iron(II) chloride, $FeCl_2 \cdot 5H_2O$, was prepared by the recrystallization of commercial iron(II) chloride from water. The Ia, Ib, Ic, IIa, IIIb, and IIIc were prepared by the methods described in the literature.[4)]

Oxidation. By Iron(III) Chloride-Pyridine Complex: Similar procedures were used for all the reactions. Pyridine (1 mmol) was added to dry benzene (5 ml) containing the dispersed iron(III) chloride (1 mmol). Ia (0.5 mmol) was then added to the solution. The resulting solution was heated at 80 °C under an atmosphere of air, oxygen, or nitrogen for the desired time. In the case of a nitrogen atmosphere, the reaction tube was degassed by the freeze-thaw method and then sealed. After the reaction, 2 ml of water was added to the resulting mixture, and then an internal standard, biphenyl, was added. The benzene layer was analyzed by glc. The products were identified by a comparison of their retention times in glc with those of authentic specimens, and their amounts were determined by means of glc. The products were isolated out by the following method. To dry benzene (40 ml) containing the dispersed iron(III) chloride (1.36 g), we added pyridine (0.64 g) and then Ia (0.85 g), after which the solution was heated at 80 °C under air. After a 24-hr reaction, a black-brown solid (2.08 g) was collected from the brown solution by filtration and washed with benzene. Found: C, 28.08; H, 2.58; N, 5.40; Cl, 38,45; Fe(II), 2.4; Fe(III), 15.27%. The combined benzene solution was extracted with a 10% sodium bicarbonate solution and then subjected to chromatography on alumina. Elution with benzene gave 0.025 g (3%) of the unreacted Ia and 0.1 g (8%) of IV. The formation of benzaldehyde was confirmed by means of glc. Elution with methanol gave 0.47 g (52%) of IIIa (mp 94—95 °C). Elution with methanol-water gave 0.26 g of a white, amorphous product (mp>280 °C), which did not become crystalline, along with a tarry matter. The white product exhibited an IR spectrum with broad peaks at 3050, 1660, 1600, 1550, 1410, 1210, 1180, 1070, 880, 840, 800, 703, and 680 cm^{-1}. The sodium bicarbonate solution was acidified with dilute aqueous hydrochloric acid and extracted several times with benzene. The benzene extracts were then combined and the solvent removed to yield 0.021 g (4%) of benzoic acid. IIIb (mp 71—72 °C) and IIIc (mp 30—31 °C) were isolated and identified by a method similar to that used in the case of IIIa.

By $[Fe(DMF)_3Cl_2][FeCl_4]$: A solution of Ia (0.53 mmol) in benzene (5 ml) containing the iron(III) complex (1.1 mmol) was heated at 80 °C for 96 hr. The amounts of IIIa and benzaldehyde were then determined by means of glc.

By Iron(III) Chloride in Acetonitrile: An acetonitrile solution (30 ml) of a mixture of Ia (3.2 mmol) and iron(III) chloride (6.3 mmol) was refluxed under air for 24 hr. After the subsequent removal of the acetonitrile, the residue was added to benzene. The amounts of the products were determined by means of glc.

Analyses. The iron(II) or iron(III) complex isolated was analyzed by the methods described in a previous paper.[5)] Analytical determinations of the products were carried out using a Hitachi K-53 gas chromatograph fitted with a 3 mm × 1 m stainless steel column packed with 30% high-vacuum silicon grease on Celite 545.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 48(2), 737—738 (1975)

The Synthesis and Polymerization of 2-(*p*-Vinylphenyl)-4,6-diamino-*s*-triazine[1]

Eizo OIKAWA and Kazuya HORIGUCHI

Faculty of Engineering, Niigata University, Nagaoka, Niigata 940

(Received August 23, 1974)

Synopsis. A new olefinic *s*-triazine, that cited in the title, was prepared by the reaction of *p*-cyanostyrene with dicyandiamide. Methyl *p*-vinylbenzoate could provide the triazine in an improved yield. The triazine readily underwent radical polymerization in an aprotic solvent to give a soluble and thermally stable polymer.

The reaction of nitriles with dicyandiamide (DCDA) has long been utilized for the preparation of many guanamines. This method has not, however, been successful in the preparation of olefinic guanamines, which contain an unsaturated group attached directly to the ring. However, the use of this method seems possible if one uses an unsaturated nitrile containing another group or atoms between the unsaturated and cyano group, but very few attempts to do so have thus far been reported.[2] We used *p*-cyanostyrene (*p*-CNSt) as such a nitrile in an attempt to prepare polymerizable *s*-triazine compounds; we could thus prepare the new title compound (VPAT), as is summarized in Table 1. In the actual performance of the reaction, a lower reaction temperature is desirable in order to minimize the polymerization of *p*-CNSt, but the precipitation of the white product did not take place for 2 hr, not until the temperature attained 115 °C. Although the reaction was continued for 2 hr, 1 hr appears to be enough from a comparison of SGH-1 with SGH-4. The amount of potassium hydroxide had an influence on the yield. The optimum molar ratio of the catalyst to *p*-CNSt was about 0.25. A higher amount might give rise to unidentified side reactions to a greater degree.

While *p*-CNSt brought a yield of 20% at best, methyl *p*-vinylbenzoate (MVB) increased the yield of VPAT more than double. A basic catalyst, sodium methoxide, did not markedly affect the reaction.

VPAT readily underwent radical polymerization in a good conversion, as will be described in the Experimental section. Comparable intrinsic viscosities were obtained for heterogeneous polymerization in DMF, but a higher viscosity was obtained for a homogeneous polymerization in DMSO.

Poly(VPAT) has a *s*-triazine ring as a side group in every repeating unit. It is possible to introduce the same side group to a polymer possessing cyano groups, but the complete reaction is generally difficult.[3] In our work, at best about 93% of the cyano group of poly(*p*-CNSt) reacted in DMSO at 100°C for 3 hr. In this respect, poly(VPAT) can be regarded as 100% converted poly(*p*-CNSt).

These polymers were soluble only in DMSO and concentrated sulfuric acid, and were insoluble in other common organic solvents. They showed a relatively good thermal stability in air; the weight losses for PVBG-2 were 10% at 350 °C and 15% at 396 °C; for PVBG-4, they were 10% at 375 °C and 15% at 400 °C.

Experimental

2-(p-Vinylphenyl)-4,6-diamino-s-triazine (VPAT) from p-CNST. *p*-CNSt was prepared from bromobenzene.[4] The reaction was conducted in a 100-ml, three-necked flask fitted with a mechanical stirrer, a condenser, and a thermometer under the conditions listed in Table 1. Thirty or forty min after the reaction started, white solids were precipitated. After the required period, the reaction mixture was cooled to room temperature. The precipitate was filtered and washed with warm water, methanol, and then nitromethane to remove any unreacted materials and the polymer. When the filtrate was poured into water, a white precipitate was obtained. It was treated similarly. Both solids could be purified by either recrystallization from nitromethane or sublimation under reduced pressure, and were found to be the same product from their melting points and the IR spectra; mp 222—223 °C (in a sealed capillary). Found: C, 61.35; H, 5.25; N, 33.75%; Calcd for $C_{11}H_{11}N_5$: C, 61.96; H, 5.20; N, 32.84%. IR (KBr): NH_2 (3520 w, 3320 m, 3130 s, 1680s, 1640s), *s*-triazine ring (1530—50s, 820m), vinyl (900m, 980w, 995w), NMR (DMSO-d_6): *p*-substituted benzene ring (7.91 δ, q, $J=8$, 4H), NH_2 (6.77 δ, s, 4H), vinyl (6.95—5.30 δ, m, 3H).

TABLE 1. REACTION OF *p*-CNSt WITH DCDA[a]

No.	SGH-2	SGH-4[b]	SGH-1	SGH-3
p-CNSt mmol	31.0	31.1	38.8	31.2
DCDA mmol	48.0	48.6	65.0	43.0
KOH mmol	3.7	7.3	10.4	14.8
(mol/l)	(0.46)	(0.91)	(1.04)	(1.85)
[KOH]/[*p*-CNSt]	0.119	0.233	0.268	0.475
Yield %	10.0	19.6	16.0	15.2

a) *p-t*-Butylcatechol: 0.1 g (0.6 mmol); Methyl cellosolve: 8—10 ml, 115 °C, 2 hr. b) 115 °C, 1 hr.

VPAT from MVB. MVB was prepared from β-bromoethylbenzoic acid.[4-6] The reaction was carried out according to the procedure of Ref. 7. The yield in the case of no catalyst was 41.7% (No. SG-1); mp 225—6 °C (in a sealed capillary). Found: C, 62.04; H, 4.95; N, 32.47%. The addition of sodium to methanol or sodium methoxide (16 mol% based on MVB) afforded the same product in a better yield (48.0%, No. SG-2).

Polymerization of VPAT. The polymerization was carried out in a sealed tube with azobisisobutyronitrile (1.05 mol% based on VPAT) at 80 °C for 5 hr. The DMF solution became turbid in a few minutes, and the polymer started to precipitate. The polymer was purified by reprecipitation from DMSO-methanol. One gram of SGH-2 in 5 ml of DMF gave a yield of 73.3% and an intrinsic viscosity of 0.263 at 25 °C in DMSO (No. PVBG-2), and 0.694 g of

SG-2 in 3.5 ml of DMF gave 91.0% and 0.271 (No. PVBG-3). In 1.8 ml of DMSO, 0.365 g of SGH-4 gave 82.5% and 0.325 (No. PVBC-4).

The weight loss was measured with a solenoid-type thermobalance, Model SE-52, of Tokyo Koki Seizosho.

Syntheses and Ring Opening Reactions of 2-Alkyl-3,3-dichlorospiro-[cyclopropane-1,9′-fluorene] Derivatives

Eiji WADA*, Shizuo FUJISAKI, Akiko NAGASHIMA, and Shoji KAJIGAESHI

Department of Industrial Chemistry, Faculty of Engineering, Yamaguchi University, Tokiwadai, Ube 755

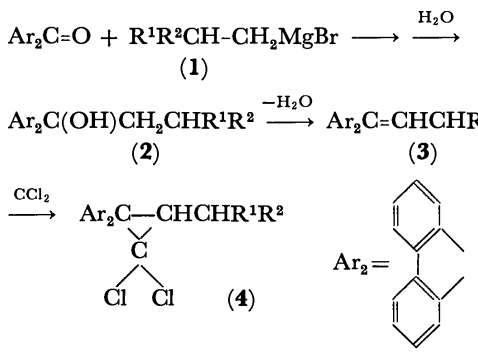
(Received September 12, 1974)

Synopsis. 2-Alkyl-3,3-dichlorospiro[cyclopropane-1,9′-fluorene] derivatives (**4**) were obtained by the addition of CCl_2 to 9-alkylidenefluorenes. Ring opening reactions of **4** with bases gave enynes, butadienes, or butatrienes.

Most spiro[cyclopropane-1,9′-fluorene] derivatives have been synthesized from the reactions of 9-diazofluorene with olefins by heating or by irradiation with UV light.[1] In the present paper, we wish to present a convenient method for the syntheses of similar spiro compounds, in which 2-alkyl-3,3-dichlorospiro[cyclopropane-1,9′-fluorene] derivatives (**4**) are prepared in good yields by the reactions of 9-alkylidenefluorenes (**3**) with dichlorocarbene. Furthermore, we wish to report the ring opening reactions of **4** with some bases.

The olefins **3** were obtained by dehydration of the corresponding 9-alkyl-9-fluorenols (**2**) which were prepared from the reaction of fluorenone with alkylmagnesium bromides (**1**). The dichlorocarbene was generated from the reaction of chloroform with aqueous sodium hydroxide solution (50%) in the presence of catalytic amounts of benzyltriethylammonium chloride (method A[2]), or from the reaction of ethyl trichloroacetate with sodium methoxide (method B[3]).

Syntheses of 4. A group $-CH_2-CHR^1R^2$ was chosen as the alkyl group in Grignard reagents **1**, and the syntheses of **2**, **3**, and **4** are shown in Scheme 1. The melting points and yields of the products are summarized in Table 1. All the products had satisfactory



Scheme 1.

elemental analyses (C and H), and the structures of the products were confirmed by their IR and NMR spectra. Compound **4e** was a mixture which was separated into two isomers **4e–1** and **4e–2** by fractional crystallization. The structures of **4e–1** (mp 125—127 °C) and **4e–2** (mp 155—157 °C) were confirmed as *threo* and *erythro* isomers, respectively, from their NMR spectra.[7]

a) CC_2 was generated by the method A.[2] b) CCl_2 was generated by the method B.[3]

Ring Opening Reactions of 4 with Bases. The ring opening reactions of **4a**, **4b**, and **4c** with sodium alkoxides in alcohols or with pyridine gave unidentified polymeric powders or tars in each case. However, the products of the reactions of **4d**, **4e**, and **4f** with bases were derivatives of enynes, butadienes, and butatrienes conjugated with the fluorene moiety. The structures of these derivatives were confirmed by elemental analysis and spectral data. The experimental results are summarized in Table 2.

When pyridine was used as a base, compounds of type **5** were isolated. The reaction of **5f** with sodium

methoxide in MeOH led to **6f**,[8] which was easily converted into **7f** by sodium methoxide in DMSO. Therefore, the following mechanism would account for the formation of products **5**, **6**, and **7** from **4** in the presence of bases.

Experimental

*Syntheses of **4** by Method A.*[2] A typical procedure was as follows. Compound **2a** (5.3 g, 0.028 mol) in $CHCl_3$ (12 ml) was added to a mixture of 50% aq. NaOH (20 ml) and $PhCH_2N(C_2H_5)_3 \cdot Cl$ (0.4 g). The mixture was stirred for 4 hr at 40 °C, and then poured into water (100 ml). The organic layer was separated and the aqueous phase was extracted with ether. The combined organic extracts were washed with water and dried over $MgSO_4$. The dry ether solution was concentrated in a rotary evaporator. Recrystallization of the residue from ethyl alcohol gave **4a**: 5.0 g (72%); mp 110—112 °C.

*Ring Opening of **4** by Bases.*[3] A typical procedure was as follows. Compound **4d** (0.5 g, 0.0014 mol) was reacted with commercial sodium methoxide (0.17 g, 0.003 mol) in DMSO (70 ml) for 4 hr at room temperature. The resulting mixture was poured into water and then extracted with ether. The ether solution was washed with water and dried over $MgSO_4$. Concentration of the dry ether solution gave **8d**: 0.11 g (35%); mp 88—90 °C (from petroleum benzine–benzene (1 : 1 v/v)).

5) N. Campbell and K. W. Delahunt, *J. Chem. Soc., C*, **1966**, 1910.

6) R. Kuhn, H. Fischer, F. A. Neugebauer, and H. Fischer, *Ann. Chem.*, **654**, 64 (1962).

7) The NMR data of **4e** are as follows: **4e-1**; δ ($CDCl_3$) 1.65 (d, J=8 Hz, 3, CH_3), 2.76 (d, J=11 Hz, 1, -CH-), 3.55 (two q, J=11 Hz, and J=8 Hz, 1, -CH-CH_3), 6.82 (s, 5, -Ph), 7.0—7.7 (m, 8, fluorene nucleus), **4e-2**; δ ($CDCl_3$) 1.0 (d, J=6.5 Hz, 3, CH_3), 2.76 (d, J=11 Hz, 1, -CH-), 3.55 (two q, J=11 Hz, and J=6.5 Hz, 1, -CH-CH_3), 7.0—7.82 (m, 13, aromatic ring protons). It appeared that both the phenyl protons in the stable conformation of the *threo* form and the methyl protons in the stable conformation of the *erythro* form are located above the fluorene ring. Therefore, these protons above the fluorene ring should be shifted to higher field. From the above NMR data, it may be seen that **4e-1** is the *threo* isomer and **4e-2** is the *erythro* isomer.

Reaction of Benzylic Chlorides with Hexamethylphosphoric Triamide

Seiji ARIMATSU, Ryohei YAMAGUCHI, and Mituyosi KAWANISI

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606

(Received April 18, 1974)

Synopsis. Benzyl chloride was converted into benzyldimethylamine (**1**), dibenzylmethylamine (**2**), and benzylpentamethylphosphoric triamide (**3**), when it was heated in hexamethylphosphoric triamide (HMPT). Diphenylmethane (**4**), benzhydrylmethylamine (**5**), and benzophenone methylamine (**6**) were obtained when benzhydryl chloride was used in place of benzyl chloride. Triphenylmethyl chloride afforded triphenylmethane (**7**) as the sole isolable product.

Monson reported that primary and secondary alcohols possessing β-hydrogen atom are readily transformed into the unrearranged olefins in hexamethylphosphoric triamide (HMPT) at 230—240 °C *via* the corresponding alkyl tetramethylphosphorodiamidates,[1] and that primary alkyl halides having β-hydrogen atom afford in HMPT unrearranged 1-alkenes in good yields.[2] In the case of alcohols having no β-hydrogen atom, we found that the reaction proceeds in different ways to give reduction products, substituted products and phosphorodiamidated products.[3] In the reaction of benzyl alcohol with HMPT, we isolated benzyl tetramethylphosphorodiamidate which Monson suggested as an intermediates, and showed that bis(*N*,*N*-dimethylamino) phosphoryl group could behave as a leaving group to give the substituted compounds.

Benzyl chloride has no β-hydrogen atom, but has a chlorine atom which is thought to be a better leaving group than bis(*N*,*N*-dimethylamino)phosphoryl group. We wish to report results (see Table) obtained by the thermal treatment of benzylic chlorides with HMPT.

The results are similar to those of the reaction of benzylic alcohols with HMPT except for two points: i) An additional product was produced—benzylpentamethylphosphoric triamide (**3**) in the case of benzyl chloride, and benzophenone methylimine (**6**) in the case of benzhydryl chloride. ii) The yields of the products were higher than in the case of benzylic alcohols. Triphenylmethyl chloride and triphenylmethanol gave triphenyl methane (**7**) in 83% and 44% yields,[3] respectively. This might be ascribed to the nature of chlorine atom as a better leaving group than that of the bis(*N*,*N*-dimethylamino)phosphoryl group.[5]

TABLE 1. REACTION OF BENZYLIC CHLORIDES WITH HMPT

Substrate	Isolated products (%)
$PhCH_2Cl$	$PhCH_2NMe_2$ (39), $(PhCH_2)_2NMe$ (27), (**1**) (**2**)
	$PhCH_2NMeP(O)(NMe_2)_2$ (23) (**3**)
Ph_2CHCl	Ph_2CH_2 (13), Ph_2CHNMe_2 (40), (**4**) (**5**)
	$Ph_2C{=}NMe$ (6) (**6**)
Ph_3CCl	Ph_3CH (83) (**7**)

Experimental

All the temperatures are uncorrected. The IR and MS spectra were obtained on a Shimadzu IR-27 spectrometer and Hitachi RMS-4 mass spectrometer, respectively. The NMR spectra were obtained on a Varian EM-360 spectrometer, TMS being chosen as an internal standard.

Hexamethylphosphoric Triamide (HMPT). Commercial HMPT was refluxed for 5 hr under N_2 with calcium hydride, and then distilled, bp 110 °C/15 mmHg.

Starting Materials. Commercial benzyl chloride was distilled before use. Benzhydryl chloride and triphenylmethyl chloride were prepared according to the published methods.[6,7]

General Procedure for the Reaction with HMPT. The substrate (0.01 mol) was dissolved in HMPT and heated at 230—240 °C under N_2 for 1 hr. After HMPT had been removed by distillation under diminished pressure, the residue was separated by a combination of vacuum distillation, column chromatography and preparative glc. Each reaction product was identified by comparison with the authentic specimen.[3b,8]

Molecular Vibrations and Force Fields of Alkyl Sulfides. X. Skeletal Bending Vibrations of Several Simple Aliphatic Sulfides

Masaru OHSAKU

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received April 30, 1974)

Synopsis. The skeletal bending vibrations of several normal alkyl sulfides were analysed. It is found that a heterogeneous system as this case can also be explained in the same manner as a homogeneous system.

In recent years, the relations existing between molecular chain lengths and frequencies for the skeletal bending vibrations have been extensively examined on homogeneous oligomer-type molecules, *e.g.*, *n*-paraffines,[1] $CH_3(CH_2)_nCONH_2$[2] and $CH_3(CH_2)_n$-$COND_2$,[2] and $CH_3O(CH_2CH_2O)_nCH_3$.[3] On the other hand, Miyazawa *et al.*[4] treated the relation between the skeletal bending and the phase-difference on such heterogeneous systems as normal alkyl ethers of the same length. The relationships between the frequency and the phase-difference may show a particular behavior, since alkyl sulfides contain a sulfur atom with a fairly large atomic mass in molecules.

In this experiment, we have tried to analyse the skeletal bending vibration by using the frequency-phase difference relation for such heterogeneous system as alkyl sulfides with different lengths.

Results and Discussion

We have recorded the infrared spectra in the liquid and solid states for methyl propyl (MeSPr), methyl butyl (MeSBu), ethyl propyl (EtSPr), ethyl butyl (EtSBu), and dipropyl (PrSPr) sulfides. The observed frequencies of dimethyl (MeSMe),[5] methyl ethyl (MeSEt),[6] diethyl (EtSEt)[6] sulfides, MeSPr, MeSBu, EtSPr, EtSBu, and PrSPr used are those which may be due to the stable form in the solid state, judging on the basis of the normal coordinate treatment. All of the skeletal bending vibrations are infrared-active. Figure 1 shows the observed $\delta_{nk}=k\pi/(n+1)$ plots. The assignments of the k values are shown on the right-hand side, where $n=1$ corresponds to MeSMe, $n=2$ to MeSEt, $n=3$ to MeSPr or EtSEt, $n=4$ to MeSBu or EtSPr, and $n=5$ to EtSBu or PrSPr. The theoretical studies[7] of polyethylene have revealed that the dispersion curve has a ν_{max} of *ca.* 550 cm^{-1} near the phase-difference of $\pi/3$. The plots of the sulfides shifted to a frequency lower region by *ca.* 100 cm^{-1} from that of polyethylene. However, the position of ν_{max} near $\pi/3$ and the shape of the dispersion of the sulfides correspond very well to those of the polyethylene curve. This suggests that the skeltal form in the solid state of the sulfides is the same as that of polyethylene. For the oxygen analogs,[4] the bending vibrations observed are explained well by the theoretical curve of polyethylene. It is, therefore, likely that the effects of the sulfur atom and the methylene group on the vibrational spectra are very different from those of the oxygen atom and the methylene group on the vibrational spectra, since sulfur has a fairly large atomic mass.

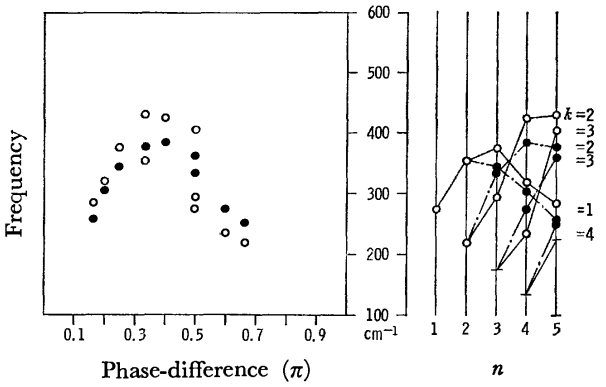

Fig. 1. Frequency-phase difference curve and assignments of k values for the skeletal bending vibrations.
○: MeSMe, MeSEt, MeSPr, MeSBu, EtSBu.
●: EtSEt, EtSPr, PrSPr. —: Calculated.

The skeletal bending vibrations mainly consist of three vibrational modes,—CCC, SCC, and CSC binding, strongly coupled with each other. The bands appearing from the pair of sulfides of the same length are fairly different in frequency, although the regularity is nearly the same in both filled and open circles. These differences arise from the effects of the heavy sulfur atom. Consequently, in the present case it is not simple to explain the relation existing between the chain lengths and the frequencies, but in general it is possible to analyse the band progression in nearly the same manner as in the case of the homogeneous system; rather disperse plots are obtained, though.

The author wishes to thank Professor Hiromu Murata and Associate Professor Yuji Shiro for their helpful advice.

Preparation of Tetramethylphthalimide

Koji CHIBA, Eiji ENDO, and Kyoji YAMAKA

Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa, Yamagata 992

(Received June 17, 1974)

Synopsis. Treatment of tetramethylphthalic anhydride (I) with 28% aqueous ammonia at room temperature afforded ammonium tetramethylphthalimide (IV) and and 2-cyano-3,4,5,6-tetramethylbenzoate (V). The amount of IV increased by heating at 100 °C, tetramethylphthalimide (VI) being precipitated. A plausible reaction path is proposed.

Of the phthalocyanine group, copper phthalocyanine is the most easily synthesized, but there is difficulty in bringing crude products into acceptable pigments, as well as in preventing a reduction of strength resulting from dispersion in vehicles.

We obtained tetramethylphthalic anhydride (I) by the hydrolysis of bis(nitromethyl)prehnitene.[1] Copper polymethylphthalocyanine synthesized from I might be expected to form more stable dispersion with vehicles, since methyl groups appear to have an affinity to them. However, when a mixture of I, urea and copper salt was heated, no copper phthalocyanine was obtained. It was obtained when tetramethylphthalimide (VI) was used instead of I.

The present study deals with the preparation of VI. We have studied the reaction of I with aqueous ammonia and found a useful procedure.

Phthalimide is formed by heating ammonium phthalate or phthalic anhydride and gaseous ammonia up to 300 °C.[2] Ammonium phthalamidate is formed by heating phthalic anhydride with aqueous ammonia, the dry salt being converted into phthalimide at about 200 °C.[3,4]

By treating I with 28% aqueous ammonia at room temperature for 5 min (Expt. No. 1), ammonium tetramethylphthalimide (IV) and 2-cyano-3,4,5,6-tetramethylbenzoate (V) were obtained in good yields, but neither tetramethylphthalate (VII) nor tetramethylphthalamidate (II) was detected. By warming, IV increased whereas V decreased (Table 1). On continued warming (Expt. No. 4), VI was obtained as a white precipitate, which may have been formed by releasing of ammonia from IV.

VI precipitated when finely powdered VI was dissolved in 28% aqueous ammonia at room temperature and the resulting clear solution was then heated at 100 °C at atmospheric pressure.

Table 1. Experimental results

Expt. No.	Conditions		Products (mol %)			
	Temp.	Time	IV	V	VI[a]	VII

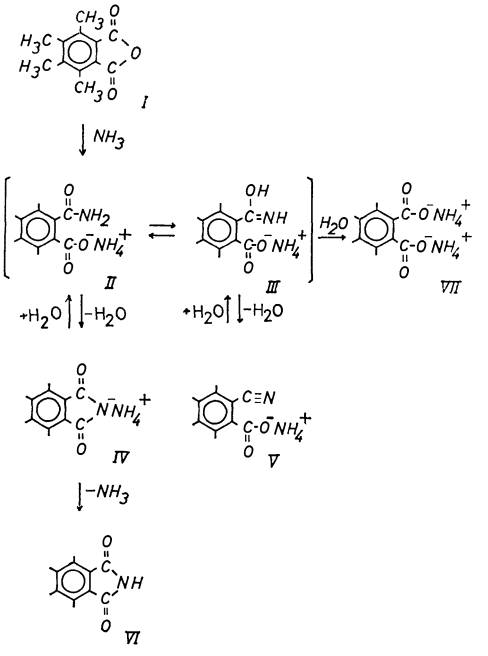
2	100(°C)	1	62.3	31.1	0.0	0.0
3	100	90	56.0	9.5	10.0	14.9
4	100	180	33.8	8.4	40.0	15.3
5	100	240	—	—	70.3	—

a) Obtained as a white precipitate.

IV does not seem to be formed from ammonium tetramethylphthalate (VII) by the removal of water and ammonia, but from intermediary II. Since the repulsion of the four methyl groups on II facilitates cyclization between the amide group and the carboxyl group, IV might be formed as the cyclized product even under mild conditions, and thus II cannot be detected. VII seems to be formed by the hydrolysis of III as a minor product.

A plausible reaction path is shown in the following (Scheme 1).



Scheme 1.

Experimental

I was obtained by the hydrolysis of bis(nitromethyl)prehnitene, prepared by the nitration of hexamethylbenzene.[1]

Procedure. I (1.0 g) was added to 250 ml of 28% aqueous ammonia, and the mixture was stirred for a certain time at room temperature or 100 °C. Ammonia gas was allowed to escape through a reflux condenser. The color of the reaction mixture turned from opaque to clear after about 3 min even at room temperature.

Isolation of IV, V, and VII. Excess silver nitrate (100 g/H_2O 70 ml) was added to the above solution (30 ml). The resulting precipitate was filtered off, dried, and refluxed with excess methyl iodide in benzene for 3 hr. After filtration of insoluble material, the filtrate was chromatographed on alumina, and the products were eluted with petroleum and benzene. Each fraction was evaporated and the residue was

recrystallized from chloroform to give three products. The first fraction afforded *N*-methyltetramethylphthalimide (*N*-methylated VI); colorless needles, mp 180—181 °C. Found: C, 71.67; H, 7.05; N, 6.55%. Calcd for $C_{13}H_{15}NO_2$: C, 71.86; H, 6.96; N, 6.45%. IR(KBr, cm^{-1}): 1754, 1697 (C=O), 1440, 1384 (CH_3), 1253, 1105, 1003(C–N) and 757. NMR($CDCl_3$, δ ppm): 2.25 (s, $-CH_3$, 6H), 2.63 (s, $-CH_3$, 6H) and 3.08 (s, $N-CH_3$, 3H).

N-Methylated VI was also obtained by treatment VI with diazomethane in ether. The second fraction afforded methyl 2-cyano-3,4,5,6-tetramethylbenzoate (methylated V); colorless needles, mp 75—76 °C. Found: C, 71.73; H, 7.08; N, 6.51%. Calcd for $C_{13}H_{15}NO_2$: C, 71.86; H, 6.96; N, 6.45%. IR(KBr, cm^{-1}): 2220 (C≡N), 1732 (C=O), 1207 and 1180 (C–O–C). NMR(CCl_4, δ ppm): 2.24(s, $-CH_3$, 6H), 2.30 (s, $-CH_3$, 3H), 2.49(s, $-CH_3$, 3H) and 3.95 (s, $-OCH_3$, 3H). Colorless needles (mp 127.5—128.5 °C) were obtained from the final fraction, and identified as dimethyl tetramethylphthalate (methylated VII) by comparing the retention time in glc and IR spectrum with that of an authentic sample.[1)]

These reaction products were determined by glc (column; 10% Silicone DC 550/Cellite 80—100 mesh, 4 mm×2 m, temp; 215 °C, N_2; 40 ml/min).

Isolation of VI. 1.0 g of I was added to 250 ml of 28% aqueous ammonia, and the mixture was heated at 100 °C. The reaction mixture turned instantly from opaque to clear. On continued heating, a white precipitate was formed. After heating for 3 hr, the mixture was cooled to room temperature and the precipitate was filtered off; yield 0.4 g (40 mol% as VI). Recrystallization from methanol gave colorless needles; mp 289—290 °C. Found: C, 70.74; H, 6.32; N, 7.07%; mol wt (Rast), 206. Calcd for $C_{12}H_{13}NO_2$: C, 70.91; H, 6.45; N, 6.89%; mol wt, 203. IR(KBr, cm^{-1}): 3190 (N–H), 1752, 1696 (C=O), 1127 and 1038 (C–N). NMR (DMF-d_7, δ ppm): 2.24 (s, $-CH_3$, 6H), 2.56 (s, $-CH_3$, 6H) and *ca.* 10.7 (s, NH, 1H).

Rate of the Dushman Reaction in Iodic Acid at Low Iodide Concentration. Complexity of Iodic Acid

Ryusaburo FURUICHI* and Herman A. LIEBHAFSKY

Department of Chemistry, Texas A&M University, College Station, Texas 77843, U.S.A.

(Received March 20, 1974)

Three rate laws have been postulated for the Dushman reaction, $6H^+ + 5I^- + IO_3^- = 3H_2O + 3I_2$, with total reaction orders of four, five and six, at iodide ion concentrations below 10^{-8} M. New direct measurements of the rate and an examination of thermodynamic data for iodic acid solutions have eliminated some of the confusion. The complexity of iodic acid solutions, with and without added salt, makes it impossible to establish a single reaction order from the radioactive iodine exchange measurements. The new results are best expressed by a quasiempirical rate equation, $-d[IO_3^-]/dt = 8.59 \times 10^4 [H^+]^2(I^-)[IO_3^-]$ mol l^{-1} min^{-1}, which is closely approximated by $-d[IO_3^-]/dt = \gamma_{\pm p}^4 (H^+)^2(I^-)(IO_3^-)\{k' + k''(HIO_3)\}$ mol l^{-1} min^{-1}, with $k' = 2.83 \times 10^5$ mol^{-3} l^3 min^{-1} and $k'' = 6.60 \times 10^6$ mol^{-4} l^4 min^{-1} for 25 °C. The second rate law is interpreted in terms of a reasonable mechanism that takes into account the thermodynamically established polymerization in iodic acid solutions.

A series of preliminary investigations[1-4] into the oscillatory decomposition of hydrogen peroxide by iodine species has shown that the decomposition is accompanied by oscillatory changes in iodine concentration and that the Dushman reaction,

$$6H^+ + 5I^- + IO_3^- = 3I_2 + 3H_2O \qquad (1)$$

participates in the oscillations. For Reaction (1), three rate laws[5-7] have been reported in which the total reaction order is four, five and six, respectively. The first rate law is based on direct rate measurements of iodine formation and an assumption that iodic acid is a strong electrolyte. This rate law gave smaller calculated rate values than those obtained in our experiments. The last two rate laws[6,7] are based on the measurements of rates of radioactive iodine exchange ($I^{131}I + IO_3^- = I_2 + {}^{131}IO_3^-$), which is an indirect method since the measurements are carried out at chemical equilibrium of Reaction (1). These rate laws were derived by using the stoichiometric activity coefficient of iodic acid measured by Abel, Redlich and Hersch[8] which shows unusual change of degree of dissociation with change in concentration of the acid (Fig. 2).

On the other hand, the results of direct rate measurements[9] gave a quasiempirical rate law, satisfactory up to 50 °C.

$$-\frac{d[IO_3^-]}{dt} = k_2'[H^+]^2(I^-)[IO_3^-] \qquad (2)$$

in which concentrations in M actually existing, or calculated to exist are donoted by ( ) and terms for M added to make the reaction mixture are denoted by [ ]. Equation (2) gave calculated rates in sharp conflict with those from the two rate laws established by the radioactive iodine exchange study. However, Eq. (2) does not establish the mechanism of Reaction (1).

The present investigation was undertaken in the hope of explaining some of this disquieting confusion about the Dushman reaction and its mechanism. Emphasis is placed on the thermodynamic complexity of iodic acid solutions, the radioactive exchange data has been re-examined, and new direct rate measurements are made under the simplest possible conditions; *i. e.*, for the most part, in reaction mixtures consisting of iodic acid (0.137—0.833 M) in equilibrium with solid silver iodide and solid silver iodate to maintain the iodide ion concentration constant below 10^{-9} M.

Experimental

Measurements were carried out by a method similar to that already described[9] and are summarized here. Thirty grams of solid AgI, 10 ml of 10^{-2} M-$AgNO_3$ solution and 80 ml of deionized water were mixed in the reaction vessel[10] and stirred at a rate of 1600 rpm in a thermostated water bath. Ten milliliter of HIO_3 solution was then added to start the reaction. The reaction time was measured after 5 ml of the acid has been added. All the reagents were of analytical grade (J. T. Baker Chem. Co.).

Ten seconds prior to each sampling, stirring was stopped and

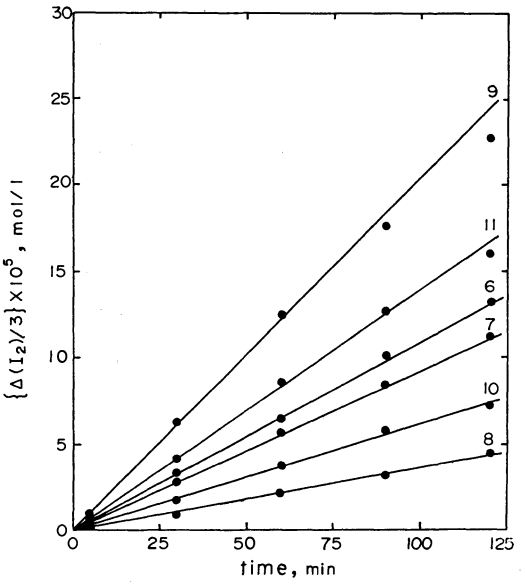

Fig. 1. Rate of the Dushman reaction measured in iodic acid solutions at 25 °C.
Concentrations of iodic acid solutions used are shown in Table 1 for experiments numbered 6—11.
Amount of silver iodide: 30 g/100 ml-solution, Initial silver nitrate concentration: 10^{-3} M, Stirring speed: 1600 rpm.

* Present address: Department of Applied Chemistry, Faculty of Engineering, Hokkaido University, Sapporo 060 Japan.

solid AgI was allowed to settle, which halted the reaction. The solution, 3 ml, was then withdrawn with a syringe and discharged into a small separatory funnel containing 4 ml of CCl_4. The iodine was extracted by shaking for 3 min, and the CCl_4 was transferred to a cuvette and centrifuged for 1.5 min to separate residual solid AgI. The content of I_2 in CCl_4 was spectrophotometrically determined from the absorbance at 500 nm (Hitachi-Perkin-Elmer Double-Beam Type Spectrophotometer).

The iodide ion concentration of the reaction mixture was maintained at constant values below 10^{-9} M by the establishment of the solubility equilibria of AgI[11] and $AgIO_3$[12]. The concentration of H^+ and IO_3^- were also practically constant, since the amount of I_2 formed by the reaction was sufficiently small. The rate of reaction was estimated from the linear relation between the amount of formed I_2 and the time (Fig. 1.). In order to test the salt effect on the rate, five measurements were carried out at 5 °C in solutions containing 1.035 M-$LiClO_4$. In no experiment was formation of solid I_2 observed.

Results and Discussion

Estimation of Rate for 25 °C. The results of the measurements are summarized in Table 1. Rate constant k_2' for Eq. (2) was calculated[13] from the measured rates at 5, 25, 30, and 50 °C.

The reaction order and rate constant should be evaluated from the results of measurements over a sufficiently wide range of iodic acid concentration. However, since the reaction is of high order, an adequate concentration range could not be covered satisfactorily at one temperature. Consequently, the results of measurements carried out at suitably different concentrations over the temperature range 5—50 °C were converted into those at 25 °C for a final test of the different rate laws by the following method.

For each temperature (Table 1), mean values of the k_2' values lie very near the line defined by

$$\log k_2' = \frac{-1.612\times10^3}{T} + 10.339 \qquad (3)$$

The numerical values compare favorably with 1.628×10^3 and 10.504, which appear in the corresponding equation[9] for reaction mixtures prepared by using sodium iodate and perchloric acid instead of iodic acid. Over the temperature range, the two equations obtained by these two sets of values give almost identical values of k_2' since the numerical differences between the equations tend to compensate. There can be no doubt that the conversion of the newly measured k_2' values into those at 25 °C is reliable. Except at high concentrations, constancy of the $k_{2(25°)}'$ values is reasonably good. The mean value of the $k_{2(25°C)}'$ values is 8.59×10^4 mol^{-3} l^3 min^{-1}, to be compared with 11.80×10^4 mol^{-3} l^3 min^{-1}, the corresponding results from the (sodium iodate+perchloric acid) system.[9]

acid is an intermediate electrolyte, neither weak nor strong, and the complexity of its aqueous solutions is further increased by the formation of various polymers of pentavalent iodine, *e. g.*, the dimers $H_2I_2O_6$ and $HI_2O_6^-$. The complexity is of thermodynamic and kinetic importance. Results of thermodynamic examination are given in Fig. 2.

Pethybridge and Prue[14] gave a precise thermodynamic treatment of the dissociation equilibrium of iodic acid ($HIO_3 \rightleftarrows H^+ + IO_3^-$) and the formation of polymer ($HIO_3 + IO_3^- \rightleftarrows HI_2O_6^-$), below 0.1 M at 25 °C on the basis of the Debye-Hückel equation and of Eqs. (4)—(6),

$$K = \frac{(\gamma_\pm)^2(H^+)(IO_3^-)}{(HIO_3)} = \frac{\alpha(\alpha-\beta)(\gamma_\pm)^2[HIO_3]}{(1-\alpha-\beta)} = 0.157 \text{ mol l}^{-1} \quad (4)$$

$$K_1 = \frac{(HI_2O_6^-)}{(HIO_3)(IO_3^-)} \quad (5)$$

$$= \frac{\beta}{(\alpha-\beta)(1-\alpha-\beta)[HIO_3]} = 4.1 \text{ mol}^{-1} \quad (6)$$

where K is the acidity constant, K_1 the stability constant of $HI_2O_6^-$, $[HIO_3]$ the formal concentration of iodic acid added to make the solution, α is the degree of dissociation ($(H^+)/[HIO_3]$), β ($(HI_2O_6^-)/[HIO_3]$, and $\gamma_\pm$ the activity coefficient. The values of α and β measured by Pethybridge and Prue are shown in Fig. 2, Curves $1(\alpha)$ and $1(\beta)$.[14]

Three other results for iodic acid solution are expressed by defining the degree of dissociation α' by

$$K = \frac{(\gamma_s)^2[HIO_3]}{(1-\alpha')}, \text{ Cryoscopy}^{8)} \quad (7)$$

where γ_s is the stoichiometric activity coefficient and equal to $\gamma_\pm\alpha'$,

$$\gamma_s = \gamma_\pm\alpha' \quad (8)$$

$$K_c = \frac{(H^+)(IO_3^-)}{(HIO_3)} = \frac{(\alpha')^2[HIO_3]}{(1-\alpha')}, \text{ Conductivity}^{8)} \quad (9)$$

$$(IO_3^-) = \alpha'[HIO_3], \text{ Raman-spectrum}^{16)} \quad (10)$$

The calculated values of α' on the basis of data in Refs. 8 and 16, and of Eqs. (7)—(10) are shown in Fig. 2, Curves $2(\alpha')$, $3(\alpha')$ and $4(\alpha')$.

The minimum of Curve $2(\alpha')$ (Fig. 2) and the high values of α' would be due to polymerization in iodic acid solutions. In the treatment of Pethybridge and Prue,[14] only the dimer $HI_2O_6^-$ was considered giving

$$(\gamma_s)^2 = (\gamma_\pm)^2\alpha(\alpha-\beta). \quad (8a)$$

This equation was used to correct Curve $2(\alpha')$; β is the vertical distance between this curve and Curve $2(\alpha')_{corr}$. Figure 2 shows that the correction is not adequate.

The thermodynamic data for iodic acid solutions above 0.1 M are still uncertain and the solutions are highly complex. Curves $5(\alpha'')$ and $6(\alpha'')$ in Fig. 2 show a degree of dissociation for 0 and 25 °C which was calculated by trial-and-error method by the equation,

$$K = \frac{(\gamma_{\pm p})^2(\alpha'')^2[HIO_3]}{(1-\alpha'')} \quad (11)$$

where $\gamma_{\pm p}$ is the mean activity coefficient of perchloric acid[15] and K the dissociation constant of iodic acid from Ref. 9, Eq. (17). This newly defined α'' is quasi-empirical, but it seems to give reasonable values and a reasonable change with the concentration up to 1 M. Accordingly, for calculating (H^+), (IO_3^-) and (HIO_3), Curves $1(\alpha)$ and $6(\alpha'')$ are used in concentration ranges below and above 0.1 M, respectively. The values of concentrations thus calculated are given in Table 2.

Comparison of Rate Laws. New rate measurements were carried out in order to obtain results that could remove confusion concerning the rate law of the Dushman reaction at iodide ion concentrations below 10^{-8} M. The thermodynamic complexity of iodic acid solutions (Fig. 2) and the lack of thermodynamic data for such solutions containing added salt make the assignment complicated. A comparison of rates calculated for 25 °C from various rate laws is given in Table 3, at each iodic acid concentrations shown in Table 2. In the calculation of rates, it is assumed that $\gamma_{\pm(HIO_3)} = \gamma_{\pm(HI)} = \gamma_{\pm p}$ for a comparison of the different rate laws.

New rates, calculated according to Eq. (2) by use of the $k_2'_{(25°C)}$ values (Table 1) are given in Table 3.

They were calculated from

18	0.55	0.75	2.34	0.27	0.56

a) Calculated from $k'_{2(25°C)}$ in given Table 1, by use of Eq. (2). For iodic acid solutions, the right-hand side of Eq. (2) equals to $k_2'[HIO_3]^3(I^-)$. This simple form is not quite applicable here. See Table 1, footnote a).

$$-\frac{d[IO_3^-]}{dt} = 11.18\times10^4[IO_3^-](I^-)[H^+]^2 \text{ mol l}^{-1}\text{ min}^{-1} \quad (12)$$

which represents the results of our direct rate measurements[9] on reaction mixtures made from perchloric acid and sodium iodate. The agreement between the two sets of rate is good except at higher concentrations of the acid where thermodynamic complexities are to be expected.

Rates for Eqs. (13) and (14) are based on the results of measurements of the rate of exchange of radioactive iodine at chemical equilibrium (an indirect method); those for Eq. (13) were calculated from

$$-\frac{d(IO_3^-)}{dt} = (\gamma_{\pm p})^6(IO_3^-)(I^-)(H^+)^3\{4.42\times10^8(IO_3^-) + 6.60\times10^6(ClO_4^-)\} \text{ mol l}^{-1}\text{ min}^{-1} \quad (13)$$

which is given by Myers and Kennedy[7] and those for Eq. (14) were calculated from

$$-\frac{d(IO_3^-)}{dt} = 1.1\times10^6(IO_3^-)(I^-)(H^+)^3 \text{ mol l}^{-1}\text{ min}^{-1} \quad (14)$$

which is given by Connick and Hugus.[6]

The rates calculated by Eq. (14) are only a small fraction of those by Eq. (13), which means that the two investigations using radioactive iodine do not agree with each other. The rates obtained from the direct rate measurements all fall between the corresponding data based on the radioactive exchange measurements. In part, the divergences result from different ways of dealing with salt effects. Connick and Hugus[6] assumed that these effects would not vary at constant, high ionic strength; the assumption has not been confirmed. Myers and Kennedy[7] followed Randall and Allen[17] in defining the activity coefficient of iodic acid, and used $\gamma_\pm$ obtained from freezing-point data.[8] The procedure ignores polymerization and relies on the unreasonable α' values of Curve 2(α'). The rate of radioactive iodine exchange in the present system is given by

$$R = k_a(I_2)^{0.6}(IO_3^-)^n(H^+)^p(\gamma_\pm)^{n+p} = k_a(I_2)^{0.6}[HIO_3]^{n+p}(\alpha)^{n+p}(\gamma_\pm)^{n+p} \quad (15)$$

where R is the exchange rate, n and p are the reaction orders. The other symbols were defined previously. This is the starting point for Eq. (13), and the rate

$$R = k_c(I_2)^{0.6}(IO_3^-)^n(H^+)^p = k_c(I_2)^{0.6}[HIO_3]^{n+p}(\alpha)^{n+p} \quad (16)$$

may serve similarly as a starting point for Eq. (14). Since the Dushman reaction (Eq. (1)), with the following equilibrium constant at 25 °C[18]

$$\frac{(I_2)^3}{(\gamma_\pm)^{12}(H^+)^6(I^-)^5(IO_3^-)} = 10^{47.2} \quad (17)$$

was assumed to be in equilibrium during course of the radioactive exchange reaction, the term $(I_2)^{0.6}$ can be eliminated from Eqs. (15) and (16), as follows;

$$(I_2)^{0.6} = 10^{47.2/5}(\gamma_\pm)^{12/5}(IO_3^-)^{1/5}(H^+)^{6/5}(I^-) = 10^{9.44}(\gamma_\pm)^{2.4}(\alpha)^{1.4}[HIO_3]^{1.4}(I^-) \quad (18)$$

Under the simplest conditions, the total order of a reaction is independent of concentration and temperature. Calculations we re carried out to see whether this would hold in the present case when the total order was established according to Myers and Kennedy.[7] Figure 3 shows the logarithm of the exchange rate R as a function of log $\gamma_{\pm p}\alpha''[HIO_3]$ at 0, 25, and 50 °C, the α'' being calculated from Eq. (11) for each temperature.[9] From Eqs. (15) and (18), the total reaction order is given by $(n+p+2.4)$; thus the slopes of the lines in Fig. 3 indicate a change

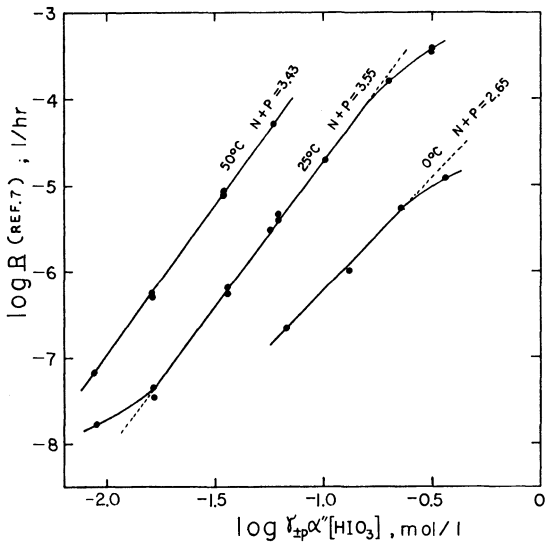

Fig. 3. Re-evaluation of radioactive iodine exchange rate data from Ref. 7.

in total order from 5.05 to 5.95. A similar plot for the rates obtained in direct rate measurements gave a similar result: the total order[19] varied systematically; *i.e.*, 4.7 at 5 °C, 5.04 at 25 °C, 5.14 at 30 °C, and 5.22 at 50 °C.

The most precise way of determining the total order from R values is to use the thermodynamic data of Pethybridge and Prue,[14] which are definitive in the concentration range below $[HIO_3]=0.1$ M, and of R values measured by Myers and Kennedy[7] for solutions of 0.05 and 0.1 M. The thirteen applicable R values were corrected to these iodic acid concentrations and to $(I_2)=10^{-3}$ M. It was found that, at $[HIO_3]=0.1$ M, the mean R value of 4.167×10^{-6} hr^{-1} was obtained for nine data ranging from 3.970×10^{-6} to 4.297×10^{-6} hr^{-1}; at $[HIO_3]=0.05$ M, the mean R value of 0.5916×10^{-6} hr^{-1} was obtained for four data ranging from 0.5510×10^{-6} to 0.6542×10^{-6} hr^{-1}. These means are close to the values of 3.93×10^{-6} and 0.616×10^{-6} hr^{-1}, which were calculated by the equation for R at 25 °C,[7] $R=7.40(\gamma_{\pm p})^{3.6}(I_2)^{0.6}(IO_3^-)^{1.8}(H^+)^{1.8}$ hr^{-1}, in which $n=p=1.8$ was used. Re-evaluation of total order can be made by using these mean R values and Eqs. (15) and (16) with $(\alpha-\beta)^n$ replacing $(\alpha)^n$ to allow for the formation of $HI_2O_6^-$, which was assumed to be inert toward iodide ion. The total order may then be obtained from the ratio between mean R values at $[HIO_3]=0.1$ and 0.05 M, provided that an order with respect to iodate ion concentration is assumed. The results of the calculations are summarized in Table 4, which show total reaction orders not far from six in iodic acid solutions below 0.1 M.

Table 4. Total reaction order ($n+p+2.4$) of radioactive exchange rate estimated from data[14] at $[HIO_3]=0.05$ and 0.1 M.

Assumption[7]	$n=0.8$	$n=p$
Concentration calculation (Eq. (16))	5.87[a]	5.94
Activity Calculation (Eq. (15))	6.24	6.36[b]

a) Corresponding value from Ref. 6 is 5; *i.e.* $(H^+)^3(IO_3^-)(I^-)$. b) Corresponding value from Ref. 7 is 6; *i.e.* $(H^+)^3(IO_3^-)^2(I^-)$.

The radiochemical-exchange results do not give a single, constant total order applicable to the Dushman reaction over a wide range of conditions. The complexity of iodic acid solutions is mainly responsible.

Effect of Added Perchlorate. In order to test the dependence of perchlorate ion concentration required by Eq. (13), five experiments at 5 °C were repeated with reaction mixtures containing 1.035 M of lithium perchlorate (Table 1, Nos. 19—23). The addition of this salt always gave reduced rates: the ratios of rates in the solution containing lithium perchlorate to the corresponding rates obtained from Nos. 1—5 were found to be 0.86, 0.89, 0.91, 0.77, and 0.90, respectively. Furthermore, in the radioactive exchange experiments given in Ref. 7, Table 3, R values of 20.2, 20.4, 20.1, and 14.8×10^{-6} hr^{-1} were obtained for $[HIO_3]=0.2$ M at $[NaClO_4]$ values of 0, 0, 0.053, and 2.000 M, respectively. Both sets of results indicate a 10—25% reduction in rates; this proves that Eq. (13) does not hold. The measured salt effect in this system is small for an ionic reaction of high order.

New Rate Law and Reaction Mechanism. No single, satisfactory reaction order can be found for the Dushman reaction at iodide ion concentration below 10^{-8} M. The quasiempirical rate law, Eq. (2), is the most satisfactory from the results given in Tables 1—3.

The existence of polymeric pentavalent iodine species is indicated by Fig. 2. The work of Pethybridge and Prue[14] supports the existence of a dimeric species, $HI_2O_6^-$, in dilute iodic acid solutions. It is natural to assume that all such species can react with iodide ion. Such reactions would increase the order of the reaction with respect to iodic acid or iodate ion. If only a dimeric species is assumed to react, the expected rate law would have the form

$$-\frac{d[IO_3^-]}{dt}=(\gamma_{\pm p})^4(H^+)^2(IO_3^-)(I^-)\{k'+k''(HIO_3)\} \quad (19)$$

In order to test this equation, the 25 °C rates given for Eq. (2) in Table 3 were divided by $(\gamma_{\pm p})^4(H^+)^2(IO_3^-)(I^-)$, calculated by use of the values in Table 2, and plotted as a function of (HIO_3) at 25 °C. The results (Fig. 4) show a line that gives $k'=2.83\times10^5$ mol^{-3} l^3 min^{-1} and $k''=6.60\times10^6$ mol^{-4} l^4 min^{-1}. The data scatter to some extent at (HIO_3) values above 0.12 M. The rates calculated by use of Eq. (19) with the numerical values of k' and k'' are listed in Table 3. They agree fairly well with those obtained from Eq. (2).

We believe that Eq. (19) gives an improvement on the rate law for the Dushman reaction at low iodide ion concentrations, and that it can replace the other rate laws to establish the reaction mechanism. It should be noted that (HIO_3) can always be replaced by $K(\gamma_\pm)^2(H^+)(IO_3^-)$ because the dissociation of iodic acid is rapid and reversible. It is thus not possible to confirm whether only iodic acid molecule, or only its ions, react; or whether both reaction paths exist. For the sake of simplicity, iodic acid molecule is assumed to be the reacting species, a similar assumption being made for $H_2I_2O_6$. The following

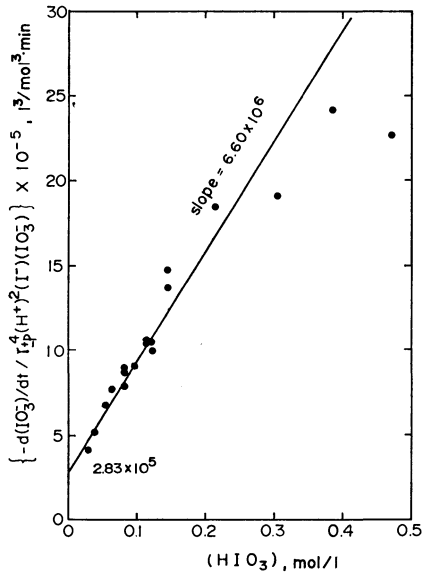

Fig. 4. Plots of Eq. (19) and estimation of the rate constants for 25 °C.
The values of rate, $\gamma_{\pm p}$ and concentrations necessary for the calculations are shown in Table 2, and Table 3, Column 2.

parallel kinetic paths are then postulated to explain Eq. (19);

Monomeric-pentavalent-iodine path (k'; intercept in Fig. 4):

Rapid reversible reaction:

$$H^+ + I^- + HIO_3 \rightleftharpoons H_2I_2O_3 \quad (20)$$

Rate-determining step:

$$H_2I_2O_3 \longrightarrow HIO + HIO_2 \quad (21)$$

Dimeric-pentavalent-iodine path (k''; slope in Fig. 4)
Dimerization equilibrium:

$$2HIO_3 \rightleftharpoons H_2I_2O_6 \rightleftharpoons H^+ + HI_2O_6^- \quad (22)$$

Rate-determining step:

$$H^+ + I^- + H_2I_2O_6 \longrightarrow 3HIO_2 \quad (23)$$

The mechanism should includes the dissociation equilibria of iodic acid. It is completed by the rapid reactions of hydrogen ion and iodide ion with hypoiodous acid and iodous acid to form iodine. The reactive intermediate species $H_2I_2O_3$ has been proved to be useful.[3,10,20–24] The work of Pethybridge and Prue[14] makes $H_2I_2O_6$ (or $HI_2O_6^-$) more logical for the dimeric-pentavalent-iodine path than $IO_2^+IO_3^-$ (closely related to I_2O_5), postulated by Myers and Kennedy.[7] Our mechanism for this path is simpler than that of Edwards,[25] in which iodate ion is assumed to react with I_2O_2 (dehydrated $H_2I_2O_3$) in the rate-determining step.

The present investigation has shown that the confusion concerning the Dushman reaction mainly arises from the complexity of iodic acid solutions, which leads to proposed rate laws that can not be verified by direct measurements of the rate. However, the usefulness of radioactive-exchange measurements in simpler systems is recognized.

We thank Professor J. K. Gladden for helpful discussions and the Robert A. Welch Foundation for supporting the work.

Molecular Structure of 7-Oxanorbornane as Studied by Gas Electron Diffraction

Kazuko OYANAGI, Tsutomu FUKUYAMA, Kozo KUCHITSU,
Robert K. BOHN,* and Shu-tung LI*

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113
**Department of Chemistry and Institute of Materials Science, University of Connecticut, Storrs, Connecticut 06268, U.S.A.*

(Received September 24, 1974)

The structure of 7-oxabicyclo[2.2.1]heptane (7-oxanorbornane) in the gas phase has been investigated by making joint use of the electron diffraction intensities measured in the present study and the rotational constants reported by Creswell. The thermal average bond lengths are: $r_g(C_1-C_2)=1.533\pm0.014$ Å, $r_g(C_2-C_3)=1.571\pm0.015$ Å, $r_g(C-O)=1.442\pm0.010$ Å, and $r_g(C-H)=1.117\pm0.008$ Å. The bond angles in the zero-point average structure (r_{av}) are: $\angle C-O-C=94.5\pm2.2°$, θ (the dihedral angle between the $C_1-C_2-C_3-C_4$ and $C_4-C_5-C_6-C_1$ planes)$=113.5\pm0.8°$ and $\angle H-C-H=105\pm5°$. The uncertainties represent the estimated limits of experimental error. The C_2-C_3 bond is longer than the C_1-C_2 bond, and the latter distance is nearly equal to that of a normal C–C single bond. The C–O bond is about 0.02 Å longer, and the C–O–C bond angle is about 17° smaller than the corresponding parameters in dimethyl ether. These trends are analogous to those observed for norbornane and 7-thianorbornane.

As part of our systematic studies of the structures of polycyclic molecules,[1–7] norbornane (bicyclo[2.2.1]-heptane)[4] and 7-thianorbornane[5] have recently been studied by gas electron diffraction. The effect of intramolecular strain is clearly demonstrated in the valence angles of skeletal atoms. In particular, the $C_1-C_7-C_4$ and C_1-S-C_4 angles are both smaller than the corresponding angles in propane and dimethyl sulfide, respectively, by about 19°. Furthermore, the weighted averages of their C–C bond lengths are significantly longer than a normal C–C single bond. A further analysis of the norbornane structure suggested that the C_1-C_7 and C_2-C_3 bonds were appreciably longer than the C_1-C_2 bond, which seemed to be nearly normal. However, it was difficult to precisely determine the individual C–C bond lengths since the rotational constants were not available. Similar circumstances were also encountered in the analyses of thianorbornane,[5] quadricyclene,[6] and nortricyclene[7] using electron diffraction data only. On the other hand, a set of rotational constants for 7-oxanorbornane (Fig. 1) for the normal isotopic species in the ground vibrational state has now become available, and hence, a joint analysis[9–12] of electron diffraction intensities and the rotational constants should be sufficient to uniquely determine the skeletal structure. There is no previous structure work on this molecule except in two theses.[8,13] Thus it is the purpose of the present study to apply this method to a cyclic system for the first time to examine whether there is any significant difference between the C_1-C_2 and C_2-C_3 bond lengths and whether the oxygen valence angle follows the same trend as that observed in the carbon and sulfur valence angles in norbornane and thianorbornane.

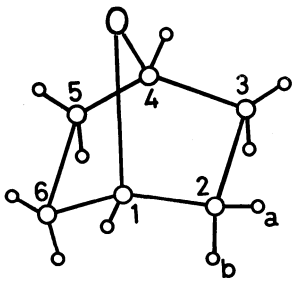

Fig. 1. 7-Oxanorbornane.

Experimental

A commercial sample (Aldrich), kindly supplied by Professor Dewitt Coffey, Jr. of California State University, San Diego, was used after distillation (bp 115 °C). A gas chromatographic analysis indicated that the sample was at least 99.9% pure.

Diffraction photographs were taken at camera lengths of 107.8 and 243.2 mm with an apparatus equipped with an r^3-sector.[14] The accelerating voltage was about 40 kV. During the exposure the sample was maintained in thermal equilibrium with its liquid phase at room temperature. The vapor pressure was about 10 Torr. The scale factors of the diffraction patterns were calibrated to within 0.10% with reference to the r_a(C=O) distance of carbon dioxide (1.1646 Å) measured under nearly the same experimental conditions. Other experimental details are described elsewhere.[14,15]

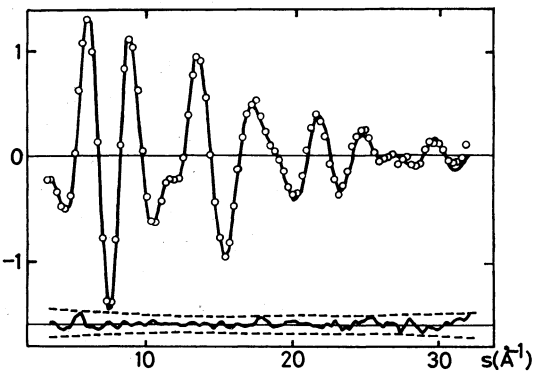

Fig. 2. Molecular intensities for 7-oxanorbornane. Observed values are shown as open circles, and the solid curve represents the best-fit theoretical intensity. The lower solid and broken curves represent the residuals and the error limits, respectively, in the $sM(s)$ to a fractional error of 1×10^{-3} in the original photocurrent.

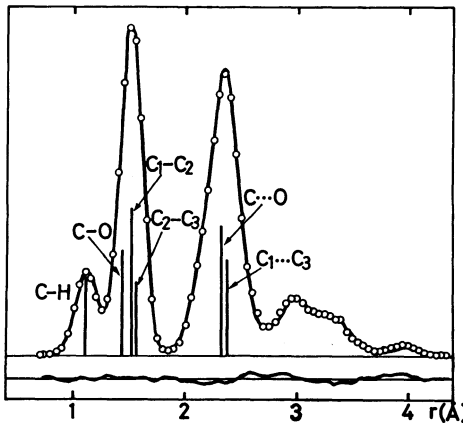

Fig. 3. Experimental (open circles) and the theoretical radial distribution curves for 7-oxanorbornane. Vertical bars represent principal atom pairs. A damping factor, $\exp(-0.0022s^2)$, was used. The residuals are shown below in the same scale.

Two photographic plates taken at the long camera length and three at the short camera length were selected for intensity measurements. Molecular intensities in the ranges $s=3.1$—18.8 and 7.9—32.0 Å^{-1} were obtained from the long and short distance data, respectively, by use of hand-drawn backgrounds. Since they agreed with each other in the overlapping region within experimental error, they were joined at $s=12.6$ Å^{-1}. The elastic and inelastic scattering factors and the phase shifts were taken from the tables prepared by Schäfer *et al.*[16] A typical molecular intensity curve is shown in Fig. 2,** and the corresponding radial distribution curve is shown in Fig. 3. Most of the calculations were carried out on a HITAC 8800/8700 in the Computer Center of the University of Tokyo.

Analysis

Preliminary Analysis of Electron Diffraction Data. The molecular intensities were analyzed by a least-squares method with the following initial assumptions:

1) The molecule had C_{2v} symmetry.
2) The H–C_2–H plane was perpendicular to the C_1–C_2–C_3 plane and bisected the C_1–C_2–C_3 angle, and *vice versa.*
3) The C–C–H angles and the O–C–H angle at the bridgehead were equal to one another, *i.e.*, $\angle C_2$–C_1–H=$\angle C_6$–C_1–H=$\angle$O–C_1–H.
4) All the C–H bond lengths were equal.
5) The C_1–C_2 and C_2–C_3 bond lengths were equal.
6) The H–C–H bond angles were equal to 110°.

With these approximations, the structure was defined by five parameters: the weighted average C–C bond length, the C–O bond length, the weighted average C–H bond length, the C_1–O–C_4 angle and the dihedral angle between the C_1–C_2–C_3–C_4 and C_4–C_5–C_6–C_1 planes (denoted as θ). Assumptions 1—4 were maintained throughout, but constraints 5 and 6 were released in a later stage of the joint analysis of diffraction and spectroscopic data.

** Numerical experimental data of the leveled total intensity and the background have been deposited with the Chemical Society of Japan (Document No. 7503).

Table 1. Estimated force constants for 7-oxanorbornane[a]

K(C–C)	2.3	H(C–C–O)	0.28	F(C–C–O)	0.6
K(C–O)	2.8	H(C–C–C)	0.32	F(C–C–C)	0.2
K(C–H)	4.3	H(C–O–C)	0.53	F(C–O–C)	0.47
Y(C–C)$_g$	0.17[b]	H(H–C–O)	0.26	F(H–C–O)	0.74
Y(C–C)$_c$	0.11[b]	H(H–C–C)	0.2	F(H–C–C)	0.48
Y(C–O)	0.15	H(H–C–H)	0.42	F(H–C–H)	0.07

a) Estimated force constants taken from cyclohexane[18] and ethyl ether.[19] The torsional force constants (Y) are in md·Å, and the others are in md/Å units. b) Symbols g and c represent the C–C axes which have *gauche* and *cis* C···C atom pairs, respectively.

Table 2. Mean amplitudes (l_{ij}) and shrinkage corrections (r_a-r_α) for 7-oxanorbornane[a]

	l_{ij}	r_a-r_α		l_{ij}	r_a-r_α
C_1–C_2	523	10	$C_1\cdots H_{3a}$	1131	22

a) Calculated at 20°C (in 10^{-4}Å).

The mean amplitudes and the vibrational corrections for shrinkage effects (r_a-r_α)[17,18] for all the internuclear distances were calculated on the basis of an estimated force model using the Urey-Bradley force field listed in Table 1: the force constants were transferred from cyclohexane[19] and ethyl ether.[20] The numerical results listed in Table 2 were used as fixed constants in the analysis. The asymmetry parameter κ for the C–H bond was estimated to be 1×10^{-5} Å^3 by a diatomic approximation.[21] The κ parameters for other atom pairs were ignored.

The r_α structure[18] was determined with a conventional diagonal matrix[22] by a least-squares analysis of molecular intensities. The r_α and r_g structures with estimated limits of error are listed in Table 3.

The estimated error limits contain contributions from several sources:[9,23] 1) random errors estimated from the standard deviations of the least-squares analysis

and the discrepancies observed in each refined parameter among different plates, 2) experimental systematic errors originating mainly from the uncertainties in the scale factors (0.07%) and sector imperfections (0.05%), 3) the uncertainty in the C–H bond length caused by the assumed value for κ(C–H) (0.002 Å), (The uncertainties in the other κ parameters ignored cause negligible errors.) 4) the effect of the uncertainties in the fixed mean amplitudes, 5) uncertainties originating from assumption 5 on the C–C bond lengths, and 6) those from assumption 6 on the H–C–H bond angle.

In order to estimate the errors due to source 4, the following method[24] was employed. The uncertainties in the calculated mean amplitudes are essentially caused by those in the assumed force constants; they were tentatively assumed to be 10% for bonded atom pairs and 20% for nonbonded atom pairs.[3] Least-squares refinements were carried out by separately varying each of the fixed mean amplitudes systematically to the limit of the estimated uncertainty. This procedure was applied to all the fixed mean amplitudes except for the H···H pairs, which had only a negligible effect. The uncertainties due to sources 5 and 6 were similarly estimated: the maximum difference between the C_1–C_2 and C_2–C_3 bond lengths was estimated to be $\pm$0.03 Å, and the H–C–H bond angle was assumed to be $110\pm5°$. Uncertainties arising from the fixed mean amplitudes are appreciable for all parameters, those from equal C–C bond lengths are appreciable only for the angles, and uncertainties from the assumed H–C–H bond angle are almost negligible.

Joint Analysis of Electron Diffraction Intensities and Rotational Constants. The rotational constants for the ground vibrational state, A_0, B_0, and C_0, determined by Creswell[8] from microwave spectroscopy, were transformed into A_z, B_z, and C_z by making vibrational corrections.[17,24] The uncertainties in A_z, B_z, and C_z (listed in Table 4) mainly originating from the uncertainties in these corrections[12] were tentatively estimated to be 20% of the total vibrational corrections.

The r_a structure determined in the foregoing analysis was extrapolated to zero Kelvin[17,18] by use of a diatomic approximation for bond stretching anharmonicity and the quadratic force constants for the perpendicular amplitudes, and the corresponding rotational constants, A_a^0, B_a^0, and C_a^0, were calculated from the r_a^0 structure. They agree with the corresponding rotational constants derived from microwave spectroscopy within their uncertainties, as shown in Table 4. Therefore, the latter constants were merged into a joint least-squares analysis.[9–12]

C	0.0949851(9)	0.094954(6)	0.096 (2)	0.094953(5)

a) Uncertainties attached to the last significant digits are given in parentheses. b) Observed rotational constants for the ground vibrational state. Ref. 8. c) Average rotational constants calculated from A_0, B_0 and C_0 with corrections for vibrational effects. The limits of error are estimated from the uncertainties in the quadratic force constants used for calculating the corrections. d) Rotational constants calculated from the r_a^0 structure given in Table 3. e) Best-fit rotational constants corresponding to the r_{av} structure, listed in Table 5, derived from the combined analysis of diffraction and microwave data. Uncertainties represent 2.5 times the estimated standard deviations.

The weights for the rotational constants were adjusted so that the 2.5 times the standard deviations for the rotational constants were approximately equal to their uncertainties. They were 5×10^9, 7×10^9, and 5×10^9 for A_z, B_z, and C_z, respectively, in comparison with unit weights assigned to the molecular intensities from s=6.3 to 26.7 $Å^{-1}$ taken at $\pi/10$ intervals.

It was now possible to release the constraint on the C–C bond lengths, since the rotational constants A_z and B_z were sensitive to the C_2–C_3 and C_1–C_2 bond lengths, respectively. Furthermore, three mean amplitudes, l(C–C), l(C_2···O), and l(C–H) were also varied: the two C–C amplitudes, l(C_1–C_2) and l(C_2–C_3), were

a) X_1=C_1–C_2, X_2=C_2–C_3, X_3=C–O, X_4=C–H, X_5=∠C–O–C, X_6=θ, X_7=∠H–C–H, l_1=(C–C), l_2=(C–H), l_3=(C_2···O), k_1, k_2=indices of resolution for the long and short distance data (0.92 ± 0.03 and 1.02 ± 0.07), respectively. Units ($\times10^{-4}$) for the distances and mean amplitudes are Å, those for the angles are rad, and those for the indices are dimensionless.

assumed to be equal to each other. The mean amplitudes l(C–O) and l($C_1 \cdots C_3$) were not varied, however, since they were correlated strongly with the other refined parameters. Therefore, ten independent parameters were now refined. The corresponding error matrix is given in Table 5.

Chiang *et al.*[25] suggested that the methylene group in norbornane could have a structure distorted from local C_{2v} symmetry. However, it was not necessary to release assumption 2) and introduce an additional parameter representing the distortion in any of our analyses of norbornane,[4] thianorbornane[5] and oxanorbornane (the present study) to fit the experimental electron diffraction intensities to within the estimated experimental error.

The error limits were estimated by the method described in the preceding section. Since it was possible to release the constraints 5) and 6) and to vary a part of the mean amplitudes, the systematic uncertainties due to these constraints were eliminated in the present joint analysis. The final structure and mean amplitudes with estimated error limits are listed in Tables 6 and 7.

Discussion

The r_g-r_{av} structure of 7-oxanorbornane determined in the present study is consistent with the rotational constants determined by Creswell.[8] This structure is compared in Table 8 with those of norbornane[4] and 7-thianorbornane.[5] The following points may be noted:

1) Weighted averages of the C_1–C_2 and C_2–C_3 bond lengths in these molecules are essentially equal to one another and about 0.01 Å longer than the normal single C–C bond length.

2) The C_2–C_3 bond in oxanorbornane is longer than the C_1–C_2 bond, which is similar to a normal single bond. The C_2–C_3 bonds of norbornane and bicyclo[2.2.2]octane[1] are also longer than the C_1–C_2 bonds, but in oxanorbornane, the difference appears to be larger (*ca.* 0.04 Å). The C_2–C_3 bond length of 1,4-diazabicyclo[2.2.2]octane[2] is also about 0.02 Å longer than that of cyclohexane.[26]

3) The dihedral angle θ in oxanorbornane is nearly equal to that in norbornane and about 2° less than that in thianorbornane.

	32)	33)	4)
C–C	1.532 (3)	1.546 (1)	1.56_0 (2_4)
$\angle$CCC	112.4 (12)α	102—106[d]	93.1 (17)α

a) r_g distances in Å and r_a (a), r_α (α), and r_{av} (av) angles in degree with the uncertainties quoted in the literature attached to the last significant digits. b) The present study. c) Estimated from the r_a distances reported in the literature by addition of l^2/r_a. d) Pseudorotation.

4) Oxanorbornane has the smallest C_1–C_2–C_3 angle among the three, this angle being about 9° less than the tetrahedral angle.

The structure of oxanorbornane is compared in Table 9 with those of tetrahydrofuran[27,28] (a monocyclic ether), and dimethyl ether[29] (an acyclic ether). The C–O–C bond angle in oxanorbornane is about 17° smaller than that in dimethyl ether and in tetrahydrofuran (nearly free pseudorotation). Also the C–O bond in oxanorbornane is longer than those in tetrahydrofuran and dimethyl ether by about 0.01 and 0.02 Å, respectively.

These trends conform to those observed in the corresponding hydrocarbons and sulfides[30–33] (except that the C–S bond in tetrahydrothiophene seems to be slightly longer than or nearly equal to that in thianorbornane), and present a quantitative basis for semiempirical or empirical calculations[34] of the effect of intramolecular strain in bicyclic compounds.

The authors wish to thank Professor I. M. Mills, the University of Reading, for sending to us information on the rotational constants for 7-oxanorbornane measured by Dr. R. A. Creswell prior to publication. They are also indebted to Dr. Ken-ichi Karakida for his helpful comments on the manuscript.

After the present article was submitted for publication, Dr. Robert A. Creswell of Michigan State University has kindly sent us a preprint of his paper on the microwave spectrum of this molecule (*J. Mol. Spectrosc.*, in press). He determined the $r_s(C_1$–$C_2)$ and $r_s(C_2$–$C_3)$ distances by use of the normal and two singly substituted ^{13}C species. His $r_s(C_2$–$C_3)$ is slightly different from the $r_g(C_2$–$C_3)$ determined in the present study, but the difference is probably due to a systematic difference in the definitions. As discussed in Ref. 18, the r_g-r_{av} parameters determined in the present study have clear physical significance (very likely more clear than the r_s parameters) to within the quoted limits of error.

Kinetic Studies of Oxygen Chemisorption on the Rutile Single-crystal Surface by Means of Electrical Conductivity

Masayoshi KOMURO*

Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received October 30, 1974)

The reaction of oxygen with the surface of a rutile single crystal was studied in the temperature range from 212 to 362 °C and in the pressure range from 10^{-1} to 10^{2} Torr. The process of the surface oxidation was examined by monitoring the electrical conductance change due to oxygen chemisorption. Two types of chemisorption kinetics were found for the rutile which had been reduced to different extents *in vacuo* before the introduction of oxygen. For the low-reduced rutile, the kinetics obeyed the parabolic rate law; this was interpreted by the diffusion-controlled reaction theory. On the other hand, it was found for the high-reduced rutile that the kinetics obeyed the Elovich equation; this could be explained by the boundary layer theory. The apparent activation energy for the former was 14.2 kcal/mol. For the latter, it was 4 kcal/mol and increased with an increase in the chemisorbed surface-charge density. In addition, the rate of oxygen chemisorption in the latter case was proportional to the pressure at a constant density of the chemisorbed surface charge.

It is well known that the electrical properties of semiconductor surfaces are influenced by the change in the ambient atmosphere. The adsorbed active molecules can drastically change the density of charge carriers in the solid and the work function. Since oxygen generally acts as an acceptor-type adsorbate, it is expected that the electrical conductivity of an n-type or p-type semiconductor will decrease or increase, respectively, when oxygen gas is introduced. These phenomena have been extensively studied for many kinds of semiconductor materials by means of the conductivity method.[1-9] It has been reported that the kinetics of oxygen chemisorption on the surfaces of Ge,[10] CdSe,[2,7] CdS,[3] SnO_2,[5] and ZnO[11] follows the Elovich equation and can be explained according to the "boundary layer" theory.[3,12] However, no detailed examinations of the pressure dependence of the chemisorption and the activation energy have been made, and little is known about the oxidation kinetics on the surface of titanium dioxide.[13]

When titanium dioxide is evacuated at a high temperature or treated in a reducing gas, such as hydrogen or carbon monoxide, oxygen atoms tend to be removed from the surface and also from the bulk through the surface region.[14] A reduced rutile exhibits the characteristics of an n-type semiconductor, for the crystal lattice develops defects which act as donors with a low ionization energy.[15] For a reduced rutile, the electrical,[16,17] photoelectric,[18] and dielectric properties[19] have been investigated in order to clarify the electronic structure. On the other hand, the photovoltaic effect has been found for a once-reduced and then reoxidized rutile[20] which has a barrier layer of the Schottky-Mott type in the surface region.[21] It is of interest to examine the surface oxidation, which has much influence on the electrical properties of a reduced rutile. Further, the oxidation process may be expected to be affected by the degree of reduction.

In this paper, the kinetics of oxygen chemisorption was investigated for a single crystal surface of rutile by measuring the electrical conductivity in the temperature range from 212 to 362 °C and in the oxygen pressure range from 10^{-1} to 10^{2} Torr. As a result, it was revealed that the reaction of oxygen with the rutile became remarkable above 200 °C, depending on the temperature and the oxygen pressure, and that the rate of chemisorption followed two types of rate equations because of a difference in the degree of reduction of the rutile.

Experimental

Material. A rutile single crystal grown by the Nakazumi Crystal Co. by means of the Verneuil method was used in this study. A spectroscopic analysis indicated that its purity was above 99.99% and that the main impurity was sodium, the amount of which was less than 0.005%.[22] The crystal was cut into a rectangular wafer $10\times10\times0.18$ mm^3 so as to make large the ratio of the surface to the bulk; the largest face, the (110) plane, was polished mechanically. The sample was then treated with a chromic acid mixture, washed thoroughly with distilled water, and dried at 100 °C. Evaporated gold was used for the electrodes. The distance between the electrodes was 6 mm. The electric contact between the rutile and gold was probably ohmic.[17]

The sample connected with electrodes was mounted on a sample holder, using an insulating spacer of mica so as to facilitate the contact between both (110) planes and the introduced oxygen gas.

Treatment. A rutile single crystal mounted on the sample holder was placed in the apparatus, as is shown in Fig. 1. The measurements of the chemisorption were carried out for the rutile which had been treated by the following two different procedures:

(1) The sample was heated in an atmosphere of oxygen at 450 °C for 10 hr and then evacuated at the same temperature for 5 hr.

(2) The sample was evacuated at 450 °C for 20 hr.

After the measurement of the oxygen chemisorption, the oxidized surface was returned to the initial state by evacuating at 450 °C for 5—8 hr, the residual pressure being about 10^{-6} Torr. The two electrodes were grounded except when the conductivity was checked during the thermal treatment. It was very difficult, however, to get a constant conductivity after the treatment. As a result, the rutile sample had a conductivity varying between 10^{-5} and 10^{-4} mho·cm^{-1} at temperatures between 212 and 362 °C. In order to prevent

any effect of organic contaminants and mercury vapor, liquid-nitrogen traps, an O-ring joint, and a greaseless stop-cock were used, as is illustrated in Fig. 1.

Measurements. The kinetics of the oxygen chemisorption was examined at temperatures between 212 and 362 °C for the rutile treated as has been described above. The sample, an equilibrium state *in vacuo*, was brought into contact with dry oxygen by breaking the glass seal which separated the sample from the oxygen reservoir. Subsequent chemisorption was followed by monitoring the change in the electrical conductivity of the rutile. Electrical conductance measurements were made in the dark by detecting the current between two electrodes, to which a voltage of about 1.2 V was applied by means of a dry battery. The current was measured by means of a Takeda Riken-TR-8651 electrometer connected with a recorder (with a response less than 0.5 s). The pressure of oxygen was measured by means of a mercury manometer at high pressures and a Pirani gauge at low pressures.

Results and Discussion

Oxygen Chemisorption on Low Reduced Rutile. The oxygen-chemisorption measurements were carried out for a sample which had been treated by Procedure (1) and which had a free electron density of about $10^{15}/cm^3$ at the measurement temperature. The conductivity decreased when oxygen gas was introduced at temperatures ranging from 212 to 362 °C. Figure 2 shows some representative results of conductance changes with the time. There was a difference in the initial conductance prior to the introduction of oxygen gas; this was a result of a difference in the temperature or the treatment. However, these results revealed that the conductance change increased with a rise in the temperature of the sample. It was found that the current change was proportional to n powers of time. This current change may be ascribed to a change in the number of free electrons, because the electrons are captured by the oxygen adsorbed on the surface. Therefore, the density of trapped electrons on the

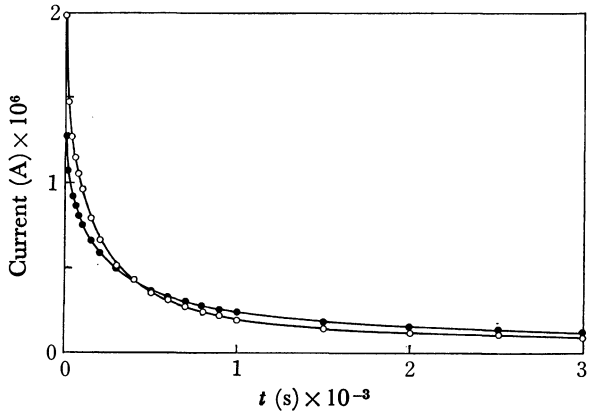

Fig. 2. Conductance change of low reduced rutile with time after the introduction of oxygen at 40 Torr and 212 ° (●) and 262 °C (○).

surface, that is, the chemisorbed surface-charge density, $N_c(t)$, can be estimated from the following equation:[4]

$$N_c(t) = (V/S)n_0(\Delta I/I) \quad (1)$$

where V is the volume of the sample; S, its area in contact with oxygen; n_0, the initial free electron density; I, the initial current at $t=0$, and ΔI, the current change at $t=t$. This equation is obtained by assuming that the electron mobility remains unchanged throughout the run. Since the mobility of the electron in rutile was found to be proportional to $T^{-5/2}$ at temperatures between −196 and 27 °C,[17] the mobility in this study was estimated by extrapolating the relationship in the low-temperature range to 362 °C. By the use of the mobility value thus obtained, the free electron density, n_0, was determined to be about $10^{15}/cm^3$, as has been described above.

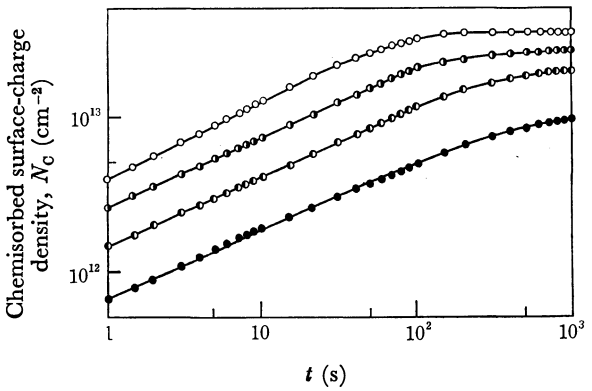

Fig. 3. Surface charge density of low reduced rutile as a function of time on log-log scale after the introduction of oxygen at 40 Torr and 362° (○), 316° (◑), 262° (◐), and 212 °C (●).

The chemisorbed surface-charge density was plotted as a function of the time on the log-log scale, as is shown in Fig. 3. These plots gave approximately straight lines, indicating that the following relationship holds:

$$N_c(t) = Bt^n \quad (2)$$

where B is a constant at a given temperature; n, a constant independent of the temperature and nearly

equal to 1/2, and t, the time after the admission of oxygen. This parabolic rate law has been explained in terms of the diffusion-controlled reaction;[23] the reaction occurs at the gas-solid boundary, forming oxygen ions, and the rate is controlled by the rate of migration of the oxygen ion on the surface. Such phenomena are conceivable, since the surface region of the sample is reduced rather than the bulk. It was estimated from the results of conductivity measurements that more than 95% of the free electrons were trapped by chemisorbed oxygen after 10^3 s. From the ESR studies of oxygen adsorbed on the TiO_2 surface, it has been considered that the chemisorbed oxygen exists in the form of the O^- ion in the temperature range of 140—450 °C.[24] It may be considered, therefore, that the oxygen ion diffuses into the surface region in the form of the O^- ion, resulting in the formation of the O^{2-} ion in the final state.

Activation Energy. It is evident from Fig. 3 that the chemisorption of oxygen requires an activation energy. Murty *et al.* have discussed the estimation of the activation energy, E_a, for a type of kinetic equation such as Eq. (2).[25] Often the B constant in Eq. (2) has an exponential temperature dependence as follows:

$$B = B_0 \exp(-Q/RT) \tag{3}$$

where B_0 is the constant; Q, the term in connection with the activation energy; R, the gas constant, and T, the absolute temperature. From Eq. (2), the rate equation is given by:

$$dN_c/dt = nBt^{n-1} = nN_c/t \tag{4}$$

From Eqs. (2) and (4),

$$nBt^{n-1} = nB^{1/n}N_c^{1-1/n} \tag{5}$$

Thus,

$$\ln(dN_c/dt) = \ln n + 1/n \ln B_0 - Q/nRT + (1-1/n)\ln N_c \tag{6}$$

On the other hand, the Arrhenius equation can be rewritten as:

$$\ln(\text{rate}) = \ln A - E_a/RT \tag{7}$$

By a comparison of Eq. (6) with Eq. (7), we obtain:

$$E_a = Q/n \tag{8}$$

Therefore, the activation energy can be obtained from the plots of ln(rate) *vs.* $1/T$ for a given N_c. From Eqs. (4) and (5), we obtain:

$$N_c/t = B^{1/n}N_c^{1-1/n} \tag{9}$$

The plots of $\ln(N_c/t)$ *vs.* $\ln N_c$ yield a family of parallel lines with the intercepts of $1/n \ln B$ for various temperatures, while the slope of the $1/n \ln B$ *vs.* $1/T$ plots gives the apparent activation energy. Thus, the apparent activation energy was determined to be 14.2 kcal/mol.

Oxygen Chemisorption on High Reduced Rutile. The sample which was treated by Procedure (2) had a free electron density of about $10^{16}/cm^3$ at the measurement temperatures, as estimated in the manner described previously. The changes in the currents after the introduction of oxygen gas are shown in Fig. 4. The kinetics of oxygen chemisorption exhibited the temperature and pressure dependences. However, there

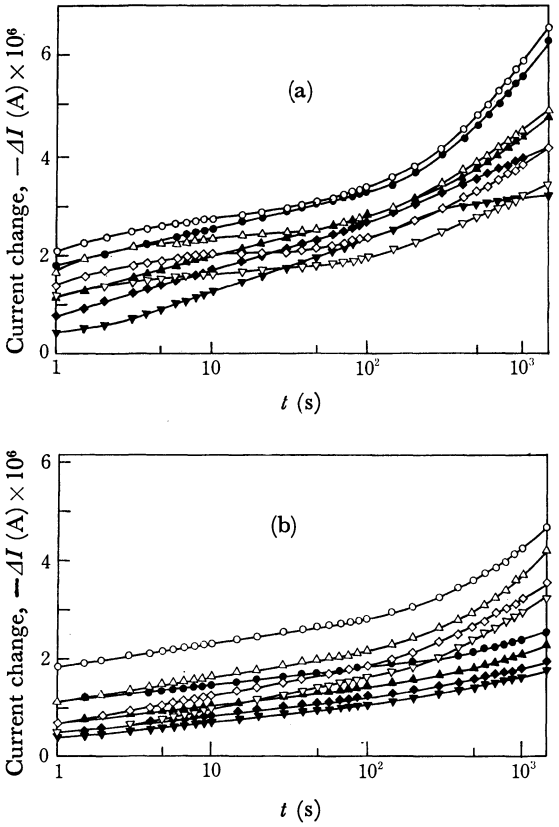

Fig. 4. Current change of high reduced rutile with time after the introduction of oxygen;
(a), at 362 °C and 140 Torr (○), 18.5 Torr (△), 1.6 Torr (◇), and 0.25 Torr (▽) and at 316 °C and 133 Torr (●), 16.0 Torr (▲), 2.0 Torr (◆), and 0.34 Torr (▼).
(b), at 262 °C and 134 Torr (○), 16.5 Torr (△), 2.4 Torr (◇), and 0.52 Torr (▽) and at 212 °C and 148 Torr (●), 17.5 Torr (▲), 2.0 Torr (◆), and 0.44 Torr (▼).

was a difference in the kinetics between the low reduced rutile and the high reduced one; the kinetics for the latter did not obey the parabolic rate law. The plots of ΔI *vs.* $\log t$ gave a family of straight lines until about 200 s, except for the results of chemisorption at 362 °C; these lines for various pressures at a given temperature were nearly parallel to one another. Consequently, these semi-logarithmic plots are in accordance with the Elovich equation:

$$-\Delta I = b \log t + c \tag{10}$$

where b and c are the constants at a given temperature and pressure. This expression can be derived from the boundary layer theory,[12] as will be described below.

Oxygen molecules once physisorbed on the surface are then chemisorbed by combining with free electrons and become negative ions. The charges in the negative ions are compensated for by the positive space-charge region caused by ionized donors near the surface. Thus, the potential-energy barrier, the so-called Schottky barrier, appears in the space-charge region. The chemisorption rate is limited by the arrival rate of electrons to the surface across the barrier, the height of which increases with an increase in the quantity of

negative ions on the surface. Therefore, the rate of increase in the surface-charge density due to the chemisorbed ions is given by:[3,12]

$$dN_c/dt = N_p Cvn \exp(-eV_s/kT) \quad (11)$$

where N_p is the density of the physisorbed oxygen molecules; C, the capture cross section of the physisorbed oxygen molecule for an electron; v, the thermal velocity of the electron; n, the density of the conduction electrons; e, the electronic charge; V_s, the Schottky barrier height, and k, the Boltzmann constant. The height of the Schottky barrier can be expressed as:[12]

$$V_s = (eN_c^2)/(2\varepsilon N_d^+) \quad (12)$$

where ε is the dielectric constant, and N_d^+, the density of the immobile, ionized donors. Assuming that the density of the physisorbed molecules is proportional to $1/m$ power of the pressure with a form such as the Freundlich isotherm,[12] the rate equation is given by:

$$dN_c/dt = P_{O_2}^{1/m} K \exp(-\alpha N_c^2) \quad (13)$$

where P_{O_2} is the oxygen pressure; m, the constant that depends on T, $K=Cvn$, and $\alpha=e^2/(2\varepsilon N_d^+)$. This equation cannot be integrated directly. It should be noted that the current decreases abruptly, followed by a gradual decrease when oxygen is introduced, as is shown in Fig. 4. Thus, the surface density of the trapped electrons increases suddenly to a certain value, N_c°, resulting in a build-up of the potential barrier, V_s, in the surface region. Therefore, the surface-charge density, N, must be increased gradually by the transfer of electrons from the bulk to the chemisorbed surface layer over the potential barrier. Since $N_c^\circ \gg N$, Eq. (13) can be integrated in the region from $N_c=N_c^\circ$ at time $t=t_0$ to $N_c=N_c^\circ+N$ at time $t=t$:

$$P_{O_2}^{1/m} K \Delta t = \exp\{\alpha(N_c^\circ)^2\} \times \{\exp(2\alpha N N_c^\circ) - 1\}/(2\alpha N_c^\circ) \quad (14)$$

After rearrangement, this expression becomes:

$$N_c = \{1/(2\alpha N_c^\circ)\} \ln[2\alpha N_c^\circ P_{O_2}^{1/m} K \Delta t \times \exp\{-\alpha(N_c^\circ)^2\} + 1] \quad (15)$$

When $2\alpha N_c^\circ P_{O_2}^{1/m} K \Delta t \exp\{-\alpha(N_c^\circ)^2\} \gg 1$,

$$N_c = b \ln \Delta t + d + b/m \ln P_{O_2} \quad (16)$$

where $b=1/(2\alpha N_c^\circ)$ and $d=\ln(2\alpha K N_c^\circ)[\exp\{-\alpha \times (N_c^\circ)^2\}]/(2\alpha N_c^\circ)$. If P_{O_2} is constant, this equation can be expressed as Eq. (10).

The deviations from the Elovich equation at 362 °C and above about 200 s may be explained as follows. When oxygen is introduced at 362 °C, the oxygen reacts abruptly with the surface of the rutile, trapping a great number of the free electrons near the surface. As a result, a high potential barrier is formed in the surface region. Any subsequent reaction may be much limited by the barrier. On the other hand, when the reaction time is long, the assumption that $N_c^\circ \gg N$ can not hold, or oxygen ions on the surface may diffuse into the surface region or the bulk in the form of O^{2-} ions.

Activation Energy. The chemisorbed surface-charge density obtained exhibited the temperature dependence shown in Fig. 5. All the terms in Eq. (11) depend on the temperature. By combining Eq. (13) with the

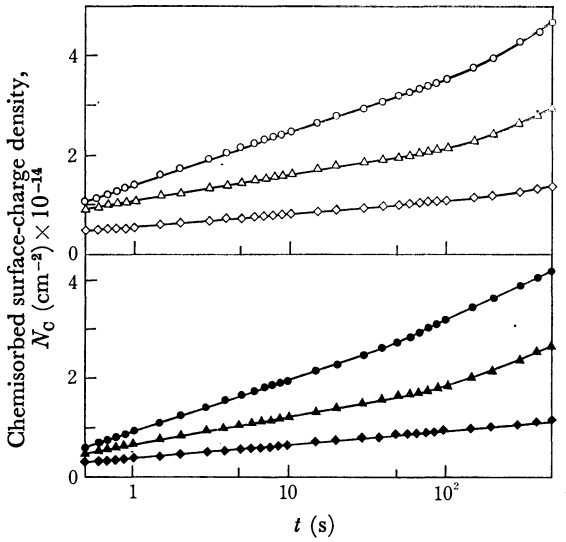

Fig. 5. Surface-charge density of high reduced rutile as a function of time after the introduction of oxygen at 17 Torr and 316 ° (○), 262 ° (△), and 212 °C (◇) and at 2 Torr and 316 ° (●), 262 ° (▲), and 212 °C (◆).

Arrhenius equation, the apparent activation energy, E_a, can be determined at a given chemisorbed surface-charge density and pressure. Instead of Eq. (13), however, the equation obtained by differentiating Eq. (16) by t can be used when the chemisorption kinetics obeys the Elovich equation.[26] The expression for the rate, r, at time t is given by:

$$r = dN_c/dt = b/t \quad (17)$$

where the value of b is determined from the slope of the N_c *vs.* $\ln t$ plots in Fig. 5. Thus the following relationship is obtained:

$$b/t = A \exp(-E_a/RT) \quad (18)$$

The slope of the $\ln b/t$ *vs.* $1/T$ plots for a constant value of N_c is equal to E_a/R, which makes possible the evaluation of the activation energy.

The apparent activation energy in the temperature range of 212—316 °C was obtained in the above manner at various values of the chemisorbed surface-charge density and at the pressures of about 2 Torr and about 17 Torr. Figure 6 shows the apparent activation energy as a function of N_c. It seems that the difference in

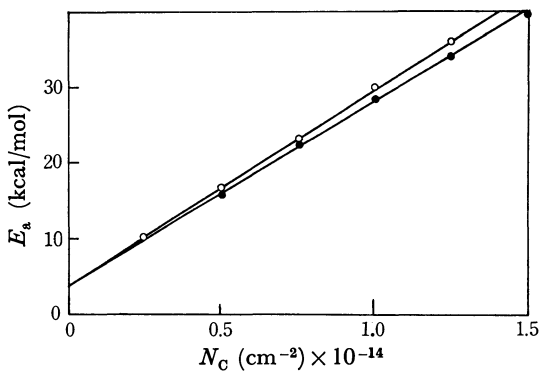

Fig. 6. Apparent activation energy for high reduced rutile as a function of N_c at 2 Torr (○) and 17 Torr (●).

oxygen pressure has scarcely any influence on the activation energy. In this chemisorption, the activation energy can be expressed by:

$$E_a = (25\pm1)\times10^{-14}N_c + 4\,\text{kcal/mol} \quad (19)$$

Pressure Dependence. The straight lines of the N_c *vs.* ln t plots for various pressures at a given temperature were nearly parallel to one another, as can be seen in Fig. 5. By dividing both sides of Eq. (16) by b, the following equation is obtained:

$$N_c/b = \ln t + d/b + 1/m \ln P_{O_2} \quad (20)$$

Plots of N_c/b *vs.* ln P_{O_2} at a given temperature and time give a straight line whose slope is equal to $1/m$. Plots of this type at $t=10$ s for three temperatures are shown in Fig. 7. From these slopes, the value of m was determined to be approximately unity, regardless of the temperature. This suggests that some of the oxygen molecules which strike the surface are physically adsorbed in the manner represented by the Henry law. From Eq. (13), therefore, the rate of oxygen chemisorption is proportional to the pressure at a constant density of the chemisorbed surface charge.

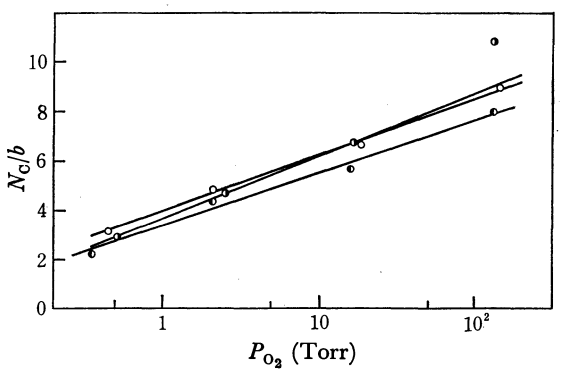

Fig. 7. Plots of N_c/b as a function of the pressure of oxygen at 212 ° (○), 262 ° (◑), and 316 °C (◐).

Conclusions. Two types of chemisorption kinetics were found for reduced rutile. This may be explained as follows: When a well-oxidized rutile is treated at a high temperature *in vacuo* for a relatively short time, only the surface region is reduced by the removal of the oxygen atoms, leaving electrons in the oxygen vacancies or at titanium ions in the neighborhood of the oxygen vacancies. These electrons are not restricted to the surface defects, but are raised to the conduction band at a moderate temperature. As a result, the surface is positively charged and the energy band for the electron bends downwards; the accumulation layer then appears in the surface region. In this case, the free electron density in the bulk is low because the bulk is almost unreduced. When the surface is exposed to oxygen gas in such a state, the oxygen takes free electrons from the accumulation layer and adsorbs chemically on the surface, thus compensating for the positive charge on it. Further, the oxygen ion thus produced tends to migrate toward the oxygen vacancy in the surface region. As a result, the chemical constitution and physical properties of the surface region approach those of the bulk. When most of the surface charges are neutralized by chemisorbed oxygen ions, scarcely any free electrons exist in this solid. Therefore, no potential-energy barrier appears in the surface region, or its height may be low even if one does exist. In such a case, the oxygen chemisorption belongs to the diffusion-controlled reaction and its kinetics obeys the parabolic rate law.

On the other hand, when a rutile is evacuated at a high temperature for a long time, not only the surface region but also the bulk is reduced, and the free electron density is fairly high, even in the bulk. The accumulation layer may also exist. In this case, the chemisorption of oxygen can continue even after the potential barrier appears in the surface region because of the large free electron density in the bulk. However, the reaction is limited by the height of the barrier. The chemisorption kinetics of such a type follows the Elovich equation.

The apparent activation energies were obtained as 14.2 kcal/mol and $(25\pm1)\times10^{-14}$ N_c+4 kcal/mol for the former type and the latter type respectively.

In addition, it was found that, in the latter type, the reaction rate of oxygen with the rutile surface was proportional to the pressure at a constant density of the chemisorbed surface charge.

The author wishes to express his cordial gratitude to Professor Masaji Miura for his continuous guidance and encouragement throughout this work. Thanks are also due to Dr. Toru Iwaki for his stimulating and informative discussions.

Theoretical Study of Proton Chemical Shifts Induced by the Paramagnetic Anisotropy of Cobaltic Ion

Yoshiaki NAKASHIMA, Ushio SAKAGUCHI,* and Hayami YONEDA*

Department of Physics, Faculty of Education, Wakayama University, Wakayama 640

(Received November 25, 1974)

A new theoretical relation between proton and cobalt-59 chemical shifts in cobalt(III) compounds has been established on the assumption that the proton shift comes primarily from the anisotropy of the second-order paramagnetism of the central cobalt(III) ion. The additivity observed for cobalt-59 chemical shifts in solution is explained and applied to the problem of proton shifts. The relation between ^{1}H and ^{59}Co chemical shifts, coupled with this additivity, allows one to calculate the chemical shift of a proton under the influence of the paramagnetic anisotropy of a cobalt ion.

In previous papers,[1,2] we have reported the chemical shifts of ammine protons of a series of pentaammine cobalt(III) complexes. The shifts have been interpreted as arising primarily from the paramagnetic anisotropy of the central cobalt ions.

In this paper a more rigorous and convenient method of calculating the PMR shifts for cobalt(III) ammines is given. This new result can explain quantitatively the ammine proton chemical shifts. It has already been applied to α-aminocarboxylato cobalt(III) compounds.[3]

The core of the present theory is the use of cobalt-59 chemical shift data. First we establish a relation between the proton chemical shift and the paramagnetic susceptibility tensor of a cobaltic ion using the formulation of Ramsey[4] and McConnell.[5] Next the paramagnetic susceptibility of the central cobalt ion will be shown to be directly proportional to the chemical shift of the cobalt-59 nucleus. Thus, PMR shifts can be obtained from data on cobalt-59 chemical shifts which have been documented for the vast majority of cobaltic complexes. Finally, an additivity of cobalt-59 shifts will be used to show that proton shifts can be calculated very easily.

Theory

Chemical Shift Induced by Paramagnetic Anisotropy. We start with Ramsey's expression for the chemical shift[4]

$$\sigma(^{1}H) = (e^2/2mc^2)\langle 0|\sum_j\{1(r_j^0)^2-r_j^0r_j^0\}/(r_j^0)^3|0\rangle - 2\sum_n(E_n-E_0)^{-1}[\langle 0|\sum_j m_j^0/(r_j^0)^3|n\rangle \times\langle n|\sum_j m_j^0|0\rangle+\text{c.c.}] \quad (1)$$

All notations have their usual significance[1,2] and c.c. denotes the complex conjugate. The origin of the coordinate system is at the proton under consideration. Equation (1) has been simplified by McConnell,[5] using the point dipole approximation, to the form

$$\sigma(^{1}H) = \left(\frac{1}{R^3}-\frac{3\boldsymbol{R}\cdot\boldsymbol{R}}{R^5}\right)\chi \quad (2)$$

Here, the vector $\boldsymbol{R}$ is from the atom exerting the dipole field, in the present case the central cobalt(III) ion, to the proton in question. The magnetic susceptibility tensor of the cobalt(III) ion may be written:

$$\chi = -(1/2)(e^2/2mc^2)\langle 0|\sum_i\{1(r_i)^2-r_ir_i\}|0\rangle + \sum_n(E_n-E_0)^{-1}[\langle 0|\sum_i m_i|n\rangle\langle n|\sum_i m_i|0\rangle+\text{c.c.}] \quad (3)$$

Note that quantities with the superscript 0 refer to the proton and those without 0 to the metal center. We assume that the first term of the right-hand side of Eq. (3) is nearly isotropic and constant over a wide variety of cobaltic complexes and consider only the second term which we denote by $\chi^{p}(^{59}Co)$. The validity of this assumption has been discussed extensively[2,6] and has been well established for many cobalt compounds.[6] With this assumption, we need to treat only the paramagnetic term in proton chemical shift. Thus, we obtain

$$\sigma^{p}(^{1}H) = \left(\frac{1}{R^3}-\frac{3\boldsymbol{R}\cdot\boldsymbol{R}}{R^5}\right)\chi^{p}(^{59}Co) \quad (4)$$

Relation to ^{59}Co Chemical Shifts. The chemical shift of a cobalt-59 nucleus can be calculated from

$$\sigma(^{59}Co) = \sigma^{d}(^{59}Co) + \sigma^{p}(^{59}Co) \quad (5)$$

where

$$\sigma^{p}(^{59}Co) = -2\sum_n(E_n-E_0)^{-1}[\langle 0|\sum_j m_j/r_j^3|n\rangle \times\langle n|\sum_j m_j|0\rangle+\text{c.c.}] \quad (6)$$

For the reasons mentioned above, we need to consider only the term $\sigma^{p}(^{59}Co)$. We use a simple molecular orbital theory, which takes into account the covalency and the anisotropy in chemical shift. The wavefunctions used here are assumed to be well approximated by those appropriate in a crystal field of O_h symmetry, irrespective of the real symmetry of the complex in question. Thus, the theory is similar, in some respects, to that which Yamatera[7] used to explain the absorption spectra of diamagnetic cobalt compounds. This we call the O_h approximation.

The excited state that contributes most to $\sigma_p(^{59}Co)$ is the $^{1}T_{1g}$ state, which corresponds to the first absorption band in cobaltic complexes. In the O_h approximation, it will suffice to investigate the zz component as an example. It is a straightforward matter to show that Eq. (6) can be reduced to

$$\sigma_{zz}^{p}(^{59}Co) = -4(E_E-E_0)^{-1}[\langle\Psi_{t2g(z)}|m_z/r^3|\Psi_{eg(z)}\rangle \times\langle\Psi_{eg(z)}|m_z|\Psi_{t2g(z)}\rangle+\text{c.c.}] \quad (7)$$

for a cobalt(III) ion in a crystal field of O_h symmetry. Here, E_E and E_0 are the energies of the excited state

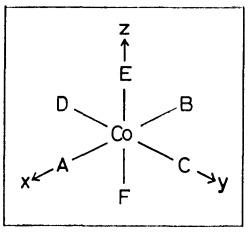

Fig. 1. The coordinate system for a complex [Co(ABCDEF)]. A, B, ···, F stand for ligand molecules.

$^1T_{1g}$ and the ground state $^1A_{1g}$, respectively. Covalency effects can be taken into account by using the molecular orbitals of the form

$$\Psi_{eg(z)} = c_{M1}3d_{x^2-y^2} + c_{L1}\Phi_{L1} \quad (8)$$

$$\Psi_{t2g(z)} = c_{M2}3d_{xy} + c_{L2}\Phi_{L2} \quad (9)$$

Here, the ligand molecular orbitals are defined by linear combinations of atomic orbitals:

$$\Phi_{L1} = (\sigma_A+\sigma_B-\sigma_C-\sigma_D)/2 \quad (10)$$

$$\Phi_{L2} = (\pi_A+\pi_B-\pi_C-\pi_D)/2 \quad (11)$$

The subscripts A, B, C, and D stand for ligand molecules or ions, see Fig. 1. In cases where ligand π^* orbitals are important, molecular orbitals (11) should be replaced by

$$\Psi_{t2g(z)} = c_{M3}3d_{xy}+c_{L3}\Phi_{L3} \quad (12)$$

$$\Phi_{L3} = (\pi_A^*+\pi_B^*-\pi_C^*-\pi_D^*)/2 \quad (13)$$

Substitution of Eqs. (8) and (9) into Eq. (7) yields

$$\sigma_{zz}^p(^{59}Co) = -32\beta^2\langle r^{-3}\rangle(E_E-E_0)^{-1} \times(c_{M1}c_{M2}+c_{M2}c_{L1}S_\sigma+c_{M1}c_{L2}S_\pi)^2 \quad (14)$$

where we have used the relations

$$\Phi_{L1} = S_\sigma 3d_{x^2-y^2} + S_\sigma' 4d_{x^2-y^2} + \cdots \quad (15)$$

$$\Phi_{L2} = S_\pi 3d_{xy} + S_\pi' 4d_{xy} + \cdots \quad (16)$$

in which

$$S_\sigma = \langle 3d_{x^2-y^2}|\Phi_{L1}\rangle \quad (17)$$

$$S_\pi = \langle 3d_{xy}|\Phi_{L2}\rangle \quad (18)$$

We have neglected small terms in S_σ^2 and S_π^2, which do not affect the final result (see below). $\langle r^{-3}\rangle$ is an average of r^{-3} over a metal 3d orbital.

Almost the same calculation leads us to an expression for $\chi_{zz}^p(^{59}Co)$.

$$\chi_{zz}^p(^{59}Co) = 16\beta^2(E_E-E_0)^{-1} \times(c_{M1}c_{M2}+c_{M2}c_{L1}S_\sigma+c_{M1}c_{L2}S_\pi)^2 \quad (19)$$

Thus, we obtain

$$\chi_{zz}^p(^{59}Co) = -\sigma_{zz}^p(^{59}Co)/2\langle r^{-3}\rangle \quad (20)$$

and hence

$$\chi^p(^{59}Co) = -\sigma^p(^{59}Co)/2\langle r^{-3}\rangle \quad (21)$$

This result is quite general and does not depend on the symmetry of the complex in question. In the previous paper,[2] we verified the above relation using molecular orbitals appropriate to C_{4v} symmetry and applied it to the calculation of the proton chemical shift of $[CoX(NH_3)_5]$. From Eqs. (4) and (21), we obtain

$$\sigma^p(^1H) = -\left(\frac{1}{R^3}-\frac{3\boldsymbol{R}\cdot\boldsymbol{R}}{R^5}\right)\sigma^p(^{59}Co)/2\langle r^{-3}\rangle \quad (22)$$

which establishes the relation between the proton and cobalt-59 chemical shifts.

Additivity of ^{59}Co Chemical Shifts. Since the pioneering work of Proctor and Yu,[8] the chemical shift of the cobalt-59 nucleus has been the subject of many investigations.[4,6,9-17] Freeman, Murray, and Richards[14] and Griffith and Orgel[15] have noted that the shift is inversely proportional to the energy of the first absorption band in cobalt(III) complexes. Betteridge and Golding[16] and Fujiwara and coworkers[6] have pointed out that the covalency between the metal and ligand orbitals should be considered. Recently, it has been reported by Fujiwara *et al.*[17] that an additivity holds for shift values of a wide variety of cobaltic compounds, namely, the observed shift value in solution can roughly be given by the sum of contributions from each ligand. To this additivity rule we present an interpretation and an extension, which we believe explains all the above observations. The details are given in the Appendix. The results may be summarized as follows: this rule comes from the additivity valid for each (xx, yy, and zz) component of the shielding tensor.

$$\sigma_{xx}^p(^{59}Co) = \sigma(C) + \sigma(D) + \sigma(E) + \sigma(F) \quad (23)$$

$$\sigma_{yy}^p(^{59}Co) = \sigma(A) + \sigma(B) + \sigma(E) + \sigma(F) \quad (24)$$

$$\sigma_{zz}^p(^{59}Co) = \sigma(A) + \sigma(B) + \sigma(C) + \sigma(D) \quad (25)$$

where $\sigma(X)$ is the contribution from a ligand X to the paramagnetic term of the cobalt-59 shielding. The $\sigma(X)$ values of typical ligands are given in Table 1.

Table 1. $\sigma(X)$ values for some ligands. Data are taken from refs. (10) to (12) and (17).
ox=$C_2O_4^{2-}$, en=ethylenediamine, phen=phenanthroline.

X	σ (X)	Calcd from	
NH_3	−4860 ppm	−19440 ppm of	$[Co(NH_3)_6]$
en	−9205	−18410	$[Co(en)_3]$
Cl	−5910	−20140	$[Co(NH_3)_5Cl]$
Br	−5865	−20110	$[Co(NH_3)_5Br]$
NO_2	−4073	−18915	$[Co(NH_3)_5NO_2]$
CN	−2760	−18040	$[Co(NH_3)_5CN]$
N_3	−5655	−19970	$[Co(NH_3)_5N_3]$
OH	−6345	−20430	$[Co(NH_3)_5OH]$
H_2O	−6255	−20370	$[Co(NH_3)_5H_2O]$
CO_3	−12090	−21020	$[Co(NH_3)_4CO_3]$
ox	−11440	−19900	$[Co(en)_2ox]$
phen	−9135	−18270	$[Co(phen)_3]$

The method for obtaining these values is expounded in the Appendix. Thus, the cobalt-59 chemical shift for a complex [CoABCDEF] in solution is given by

$$\sigma_{iso}^p(^{59}Co) = \sum_i \sigma_{ii}^p(^{59}Co)/3 \quad (26)$$

$$= (2/3)\sum_X \sigma(X) \quad (27)$$

Substituting Eqs. (23) to (25) into Eq. (22), we obtain

$$\sigma_{xx}^p(^1H) = -(1-3\sin^2\theta\cos^2\phi) \times(\sigma(C)+\sigma(D)+\sigma(E)+\sigma(F))/2R^3\langle r^{-3}\rangle \quad (28)$$

$$\sigma_{yy}^p(^1H) = -(1-3\sin^2\theta\sin^2\phi) \times(\sigma(A)+\sigma(B)+\sigma(E)+\sigma(F))/2R^3\langle r^{-3}\rangle \quad (29)$$

$$\sigma_{zz}^p(^1H) = -(1-3\cos^2\theta) \times(\sigma(A)+\sigma(B)+\sigma(C)+\sigma(D))/2R^3\langle r^{-3}\rangle \quad (30)$$

The proton chemical shift in solution is given by

$$\sigma^{p}_{iso}(^1H) = \sum_i \sigma^{p}_{ii}(^1H)/3 \quad (31)$$

Discussion

Hendrickson and Jolly[18] have pointed out, in their interpretation of the PMR spectra of cobalt(III) pentaammines, the importance of the second-order paramagnetism of the central metal ion. However, their explanation for the shifts is only qualitative. They qualitatively explained a gradual change in chemical shifts when the sixth ligand is varied along the spectrochemical series. Buckingham and Stephens[19] were the first to try to treat quantitatively the chemical shift of a proton under the influence of the magnetic anisotropy of metal ions. They considered transition metal hydrides and made an almost *ab initio* calculation. Their calculation was, however, hampered by the paucity of experimental data necessary for the estimation of several parameters, resulting in a qualitative explanation.

We formulated the theory of proton chemical shifts in such a way as to use cobalt-59 chemical shifts. This is because a vast amount of data has been accumulated for many cobaltic compounds. The results obtained here afford a quantitative explanation of proton chemical shifts in cobalt(III) ammines. This we will show in subsequent publications.

Appendix

It seems worthwhile to determine the origin and the implication of the empirical additivity rule for cobalt-59 chemical shifts. As in previous discussions, we use the O_h approximation. The energy levels pertinent to the present discussion are the ground level $^1A_{1g}$ and the excited level $^1T_{1g}$.

Now, the excited state $^1T_{1g}$ is obtained by a one-electron excitation from the t_{2g} to the e_g state. The energy of the $^1T_{1g}$ state may be considered to contain the following terms;[7] $5\times\varepsilon(t_{2g})$, $\varepsilon(e_g)$, the electron repulsion energies, and the configuration interaction energies, where $\varepsilon(t_{2g})$ is the one-electron energy of the t_{2g} state and $\varepsilon(e_g)$ the corresponding energy of the e_g state.

$$E_E = 5\varepsilon(t_{2g}) + \varepsilon(e_g) + \cdots \quad (A1)$$

Similarly, the energy of the ground state $^1A_{1g}$ is given by

$$E_0 = 6\varepsilon(t_{2g}) + \cdots \quad (A2)$$

Contributions from kinetic and potential energies of valence electrons in the field of metal core have been included in $\varepsilon(t_{2g})$ and $\varepsilon(e_g)$. We assume that of these terms only $\varepsilon(t_{2g})$ and $\varepsilon(e_g)$ vary from ligand to ligand and the others remain almost unaltered. This assumption is equivalent to that of Yamatera,[7] who has been successful in explaining the shifts and splittings of the absorption spectra of diamagnetic cobalt complexes. The justification for this assumption can be found in his paper. The change in the denominator of Eq. (14), (E_E-E_0), on going from one complex to another is therefore set equal to the change in $(\varepsilon(t_{2g})-\varepsilon(e_g))$.

In a simple molecular orbital scheme,[20] the energies $\varepsilon(t_{2g})$ and $\varepsilon(e_g)$ are given by

$$\varepsilon(t_{2g}) = H_{MM}(t_{2g}) + S_\pi^2 H_{MM}(t_{2g}) H_\pi (H_{MM}(t_{2g}) - H_\pi)^{-1} \quad (A3)$$

$$\varepsilon(e_g) = H_{MM}(e_g) + S_\sigma^2 H_{MM}(e_g) H_\sigma (H_{MM}(e_g) - H_\sigma)^{-1} \quad (A4)$$

where we define

$$H_{MM}(t_{2g}) = \langle 3d_{xy}|H|3d_{xy}\rangle \quad (A5)$$

$$H_{MM}(e_g) = \langle 3d_{x^2-y^2}|H|3d_{x^2-y^2}\rangle \quad (A6)$$

$$H_\sigma = \langle \Phi_{L1}|H|\Phi_{L1}\rangle \quad (A7)$$

$$H_\pi = \langle \Phi_{L2}|H|\Phi_{L2}\rangle \quad (A8)$$

and

$$H = H_{core} + U \quad (A9)$$

H_{core} is the energy of an electron in the field of the metal core and U the potential energy of an electron in the field of the ligands. In Eqs. (A3) and (A4), the following relations have been used.[20]

$$\langle 3d_{x^2-y^2}|H|\Phi_{L1}\rangle \simeq S_\sigma (H_{MM}(e_g) H_\sigma)^{1/2} \quad (A10)$$

$$\langle 3d_{xy}|H|\Phi_{L2}\rangle \simeq S_\pi (H_{MM}(t_{2g}) H_\pi)^{1/2} \quad (A11)$$

Further, the coefficients c_{M1} and c_{L1} should obey the normalization condition,

$$c_{M1}^2 + 2c_{M1}c_{L1}S_\sigma + c_{L1}^2 = 1 \quad (A12)$$

$$c_{M2}^2 + 2c_{M2}c_{L2}S_\pi + c_{L2}^2 = 1 \quad (A13)$$

If we assume that the value of $H_{MM}(e_g)$ is little influenced by ligand substitution,[7] Eqs. (A3) and (A12) indicate that $\varepsilon(e_g)$, c_{M1}, and c_{L1} are functions of two independent variables, S_σ and H_σ. Likewise, $\varepsilon(t_{2g})$, c_{M2}, and c_{L2} can be considered to be functions of S_π and H_π. Thus, under these conditions $\sigma^{p}_{zz}(^{59}Co)$ is a function of four variables: S_σ, S_π, H_σ, and H_π, the values of which vary of course from ligand to ligand. However, the changes in these values upon going from one complex to another may be assumed to be much smaller than the corresponding values in the parent complex.[7] Therefore, we might as well develop $\sigma^{p}_{zz}(^{59}Co)$ into a power series in these increments. For convenience, we denote the zz component of the shielding tensor for a complex [Co-ABCDEF] as σ^{p}_{zz}(ABCDEF) (see Fig. 1).

$$\begin{aligned}\sigma^{p}_{zz}(ABCDEF) = {} & \sigma^{p}_{zz}(000000) \\ & + \frac{\partial\sigma^{p}_{zz}}{\partial S_\sigma}\sum_X (s_X^\sigma - s_0^\sigma) + \frac{\partial\sigma^{p}_{zz}}{\partial H_\sigma}\sum_X (\varepsilon_X^\sigma - \varepsilon_0^\sigma) \\ & + \frac{\partial\sigma^{p}_{zz}}{\partial S_\pi}\sum_X (s_X^\pi - s_0^\pi) + \frac{\partial\sigma^{p}_{zz}}{\partial H_\pi}\sum_X (\varepsilon_X^\pi - \varepsilon_0^\pi) \\ & + (\text{second-order terms}) \end{aligned} \quad (A14)$$

Note that the summation runs from A to D. We have employed the relation

$$S_\sigma = \sum s_X^\sigma, \quad s_X^\sigma = \langle 3d_{x^2-y^2}|\pm\sigma_X\rangle/2 \quad (A15)$$

$$S_\pi = \sum s_X^\pi, \quad s_X^\pi = \langle 3d_{xy}|\pm\pi_X\rangle/2 \quad (A16)$$

$$H_\sigma = \sum \varepsilon_X^\sigma, \quad \varepsilon_X^\sigma = \langle \sigma_X|H|\sigma_X\rangle/4 \quad (A17)$$

$$H_\pi = \sum \varepsilon_X^\pi, \quad \varepsilon_X^\pi = \langle \pi_X|H|\pi_X\rangle/4 \quad (A18)$$

where X=A, B, C, and D and the subscript o represents some "reference" ligand, *e.g.* NH_3 or ethylenediamine. Equation (A14) can be recast into

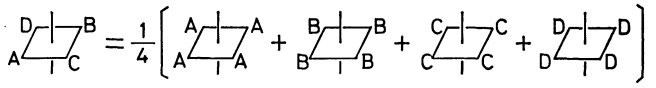
$$\sigma^{p}_{zz}(ABCDEF) = \sigma(A) + \sigma(B) + \sigma(C) + \sigma(D) \quad (A19)$$

Here

$$\begin{aligned}\sigma(X) = {} & \tfrac{1}{4}[\sigma^{p}_{zz}(000000) \\ & + \frac{\partial\sigma^{p}_{zz}}{\partial S_\sigma}4(s_X^\sigma - s_0^\sigma) + \frac{\partial\sigma^{p}_{zz}}{\partial H_\sigma}4(\varepsilon_X^\sigma - \varepsilon_0^\sigma) \\ & + \frac{\partial\sigma^{p}_{zz}}{\partial S_\pi}4(s_X^\pi - s_0^\pi) + \frac{\partial\sigma^{p}_{zz}}{\partial H_\pi}4(\varepsilon_X^\pi - \varepsilon_0^\pi)] \\ = {} & \sigma^{p}_{zz}(XXXX00)/4 \end{aligned} \quad (A20)$$

is just one fourth of the zz component of the shielding tensor for a complex [Co(XXXX00)], which is in turn equal, in

the O_h approximation, to that for [Co(XXXXXX)]. Thus, the situation may be visualized simply as



In the O_h approximation, the xx and yy components can be obtained by interchanging the symbols in parentheses.

$$\sigma^p_{xx}(ABCDEF) = \sigma(C) + \sigma(D) + \sigma(E) + \sigma(F) \quad (A21)$$

$$\sigma^p_{yy}(ABCDEF) = \sigma(A) + \sigma(B) + \sigma(E) + \sigma(F) \quad (A22)$$

The cobalt-59 chemical shift for a complex [Co(ABCDEF)] in solution is given by Eqs. (26) and (27) in the text.

Fujiwara *et al.*[6] reported $\sigma^p_{iso}(^{59}Co) = -19440$ ppm for $[Co(NH_3)_6]^{3+}$. This value can be used, along with

$$\sigma^p_{iso}(^{59}Co) = (2/3)6\sigma(NH_3) = 4\sigma(NH_3) \quad (A23)$$

to obtain $\sigma(NH_3) = -4860$ ppm, which is in turn used to evaluate $\sigma(X)$ from data on $[CoX(NH_3)_5]$ ($X = Cl^-$, Br^-, CN^-, OH^-, NO_2^-, N_3^-, and H_2O). These values are summarized in Table 1.

The results obtained here permit us to estimate the chemical shift anisotropy of a cobalt-59 nucleus. It is clear from the procedure that the method used here can be applied to those physical quantities that are closely connected to the optical transitions of six-coordinated metal complexes. In fact, if the physical quantity under consideration is the energy of the electronic transition itself, we can obtain results which are in complete agreement with those reported by Yamatera.[7]

The authors thank Prof. S. Fujiwara and Dr. A. Yamasaki, Tokyo University, for informing them of the cobalt-59 chemical shift data prior to publication and for stimulating discussions.

Proton Magnetic Resonance Spectra of Metal Ammine Complexes. III.* Interpretation of the Chemical Shifts in Cobalt(III) Pentaammines

Yoshiaki NAKASHIMA

Department of Physics, Faculty of Education, Wakayama University, Wakayama 640

(Received November 25, 1974)

The ammine proton chemical shifts of a series of compounds $[CoX(NH_3)_5]^{n+}$ have been explained quantitatively. The shifts are ascribed to the paramagnetic anisotropy of central cobalt(III) ions. The discrepancies between the calculated and the observed shift values, though small, noted for the *trans* ammine protons of complexes with $X=CN^-$ and NO_2^- may be caused by large inductive effects of these ligands.

In the preceding paper,[1] a theory of proton chemical shifts induced by the paramagnetic anisotropy of a central cobalt(III) ion was expounded. This paper is to show how well the above theory can explain the observed shift values of pentaammine cobalt(III) complexes. A qualitative explanation has already been reported.[2]

A pentaammine cobalt(III) ion contains two types of ammonia molecules, *cis* and *trans*. To take the NH_3-rotation into account, we shall slightly modify Eqs. (28)—(30) of Ref. (1). If we take the z-axis as the symmetry axis of $[CoX(NH_3)_5]$, we obtain

$$\sigma_{xx}^{p}(^1H) = -(1-3\sin^2\theta\cos^2\phi) \times (3\sigma(NH_3)+\sigma(X))/2R^3\langle r^{-3}\rangle \quad (1)$$

$$\sigma_{yy}^{p}(^1H) = -(1-3\sin^2\theta\sin^2\phi) \times (3\sigma(NH_3)+\sigma(X))/2R^3\langle r^{-3}\rangle \quad (2)$$

$$\sigma_{zz}^{p}(^1H) = -(1-3\cos^2\theta)(4\sigma(NH_3))/2R^3\langle r^{-3}\rangle \quad (3)$$

For *cis* ammine protons, we take the x-axis as the new z-axis and y- and z-axes as the new x- and y-axes. Thus, the following expressions apply to *cis* protons.

$$\sigma_{xx}^{p}(^1H) = -(1-3\sin^2\theta'\cos^2\phi') \times (3\sigma(NH_3)+\sigma(X))/2R^3\langle r^{-3}\rangle \quad (4)$$

$$\sigma_{yy}^{p}(^1H) = -(1-3\sin^2\theta'\sin^2\phi') \times (4\sigma(NH_3))/2R^3\langle r^{-3}\rangle \quad (5)$$

$$\sigma_{zz}^{p}(^1H) = -(1-3\cos^2\theta') \times (3\sigma(NH_3)+\sigma(X))/2R^3\langle r^{-3}\rangle \quad (6)$$

The definitions of θ, ϕ, θ', and ϕ' are in Fig. 1. After averaging over ϕ and ϕ' for *trans* and *cis* ammonias, respectively, the proton chemical shift in solution may be shown to be

$$\sigma_t^p = (3\cos^2\theta-1)(\sigma(NH_3)-\sigma(X))/6R^3\langle r^{-3}\rangle \quad (7)$$

$$\sigma_c^p = -(3\cos^2\theta'-1)(\sigma(NH_3)-\sigma(X))/12R^3\langle r^{-3}\rangle \quad (8)$$

where the subscripts t and c refer to *trans* and *cis* protons. Note that these equations give shift values relative to the shift of $[Co(NH_3)_6]^{3+}$. It is seen that the shift of *trans* protons with respect to $[Co(NH_3)_6]^{3+}$ is in the opposite direction to and twice that of *cis* protons.

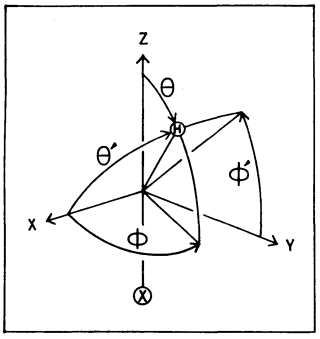

Fig. 1. Definition of the coordinate system.

Method of Calculation

The geometrical factors necessary for the calculation of Eqs. (7) and (8) can be estimated as follows. By taking the Co–N distance as 2.0 Å (3.78 a.u.) and the N–H distance as 1.0 Å (1.89 a.u.),[4] we obtain $R=$ 4.77 a.u. (2.52 Å). If we further assume a tetrahedral configuration for coordinated ammonia molecules, we obtain $\theta=22.0°$ and $\theta'=22.0°$. The value of $\langle r^{-3}\rangle$ is estimated from Eq. (14) of Ref. (1) using the data for $[Co(NH_3)_6]^{3+}$. It is reported that $(E_E-E_0)=(E_{T_{1g}}-E_{A_{1g}})=2.10\times10^4$ cm^{-1},[5] $\sigma_{zz}^{p}(^{59}Co)=-1.91\times10^{-2}$,[3] and $c_{M1}=0.924$, $c_{L1}=-0.61$, $S_\sigma=0.2$, $c_{M2}=1.0$, $S_\pi=0.5$.[5] Substitution of these values into Eq. (14) of Ref. 1 gives 5.77 a.u. for $\langle r^{-3}\rangle$. I asumed the same values of R, θ, θ', and $\langle r^{-3}\rangle$ for all the complexes examined here. As seen from Eq. (14) of Ref. 1, $\sigma_{zz}^{p}(^{59}Co)$ can be considered to be constant over a series of pentaammines.[3] The contribution $\sigma(X)$ from a ligand X to cobalt-59 chemical shifts is summarized in Table 1 of Ref. 1. The relevant quantities in the present study are $\sigma(NH_3)=-4860$, $\sigma(CN)=-2760$, $\sigma(NO_2)=-4073$, $\sigma(H_2O)=-6255$, $\sigma(OH)=-6345$, $\sigma(Cl)=-5910$, and $\sigma(Br)=-5865$ ppm.

Results and Discussion

Clifton and Pratt[6] were probably the first to observe proton resonance spectra of cobalt(III) pentaammines. They found two NH_3 resonances with an intensity ratio of 4 to 1, the intense absorption being at lower field. They suggested that the *cis* protons may be shifted to lower field than the *trans* by (i) intramolecular hydrogen bonding between the *cis* ammine groups and the sixth ligand X, (ii) the effects of magnetic anisotropy of X, and (iii) the reduced polarity of the *trans* ammine group due to polarization of the metal ion by the sixth ligand. As discussed by Lehman and Fung[7] and Hawkins,[8] the magnetic anisotropy effects cannot explain even the

* Part II: Y. Nakashima, U. Sakaguchi, and H. Yoneda, *Chem. Lett.*, **1974**, 503.

sign of chemical shifts. Thus, Lehman and Fung concluded that the point dipole approximation for the magnetic anisotropy of the sixth ligand is too great a simplification to account for the proton shifts. Hawkins argued that since the chemical shift differences were observed for a variety of substituents with widely differing hydrogen bonding capabilities, the intramolecular hydrogen bonding is of minor importance. The polarization effects were suggested as the dominant contributor. Hendrickson and Jolly[9] compared the proton resonance spectra of some pentaammine complexes of cobalt(III) with those of rhodium(III) and iridium(III). Since the latter compounds showed only a single peak, the low-lying paramagnetic states of Co(III) ion were suggested as responsible for the two peaks in cobalt complexes. They qualitatively explained the gradual change in chemical shifts when the sixth ligand was varied along the spectrochemical series.

I consider that the anisotropy in the second-order paramagnetism of the central cobalt ion has the dominant contribution. The calculated proton chemical shifts are illustrated in Fig. 2, together with the observed shift values.[2] The agreement between the calculated and the observed values is remarkably good for complexes with X=H_2O, OH^-, Cl^-, and Br^-. For X=CN^- and NO_2^-, the agreement is also good except for *trans* ammine protons. In view of the extreme approximations used, this agreement may be fortuitous but it is satisfying that correct orders of magnitude could be obtained for the chemical shifts. Therefore, it can be concluded that the proton chemical shifts in pentaammine cobalt(III) complexes can be attributed to the anisotropy in the second-order paramagnetism of the central cobaltic ion. Note that for a weak field ligand X ammine protons *trans* to X appear at higher field than *cis* ammines. If X lies higher in the spectrochemical series than NH_3, the shift pattern is reversed. This behavior is similar to the observation by Watabe *et al.*[10] that in α-aminocarboxylato cobalt(III) complexes the α (to NH_2) C–H proton appear at higher field when it is *trans* to an oxygen atom while it moves to lower field when *trans* to a nitrogen atom.

In a previous communication,[11] the proton shifts in $[CoX(NH_3)_5]$ were treated in the following way. After taking the NH_3-rotation into account, the proton shift in solution may be written

$$\sigma_t^p = [\sigma_{zz}^p(^{59}Co) - \sigma_{xx}^p(^{59}Co)](3\cos^2\theta - 1)/6R^3\langle r^{-3}\rangle \quad (9)$$

$$\sigma_c^p = -[\sigma_{zz}^p(^{59}Co) - \sigma_{xx}^p(^{59}Co)](3\cos^2\theta' - 1)/12R^3\langle r^{-3}\rangle \quad (10)$$

These results are easily obtained from Eq. (22) of Ref. (1). The following equation applies to complexes of C_{4v} symmetry.

$$\sigma_{iso}^p(^1H) = [2\sigma_{xx}^p(^{59}Co) + \sigma_{zz}^p(^{59}Co)]/3 \quad (11)$$

Thus, Eqs. (9) and (10) are reduced to

$$\sigma_t^p = [\sigma_{zz}^p(^{59}Co) - \sigma_{iso}^p(^{59}Co)](3\cos^2\theta - 1)/4R^3\langle r^{-3}\rangle \quad (12)$$

$$\sigma_c^p = -[\sigma_{zz}^p(^{59}Co) - \sigma_{iso}^p(^{59}Co)](3\cos^2\theta' - 1)/8R^3\langle r^{-3}\rangle \quad (13)$$

As stated earlier, $\sigma_{zz}^p(^{59}Co)$ can be considered to be constant for pentaammines. This result indicates that the proton chemical shifts should be directly proportional to the cobalt-59 chemical shifts. Since the details have been reported,[11] it suffices to say that Eqs. (12) and (13) can give almost the same results for pentaammines as those in Fig. 2. However, the above procedure does not allow us to treat complexes of low symmetries.

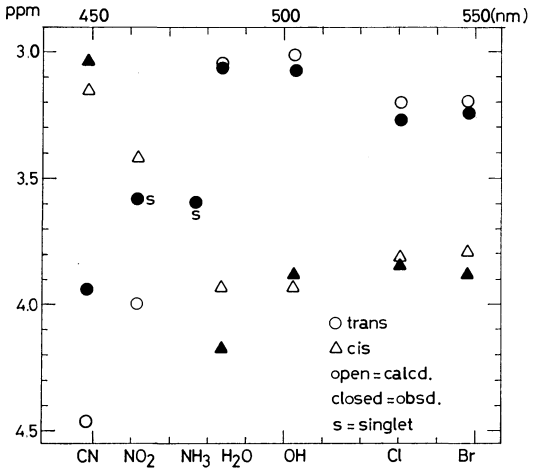

Fig. 2. Comparison of the calculated shift values with the observed values. Shifts are from DSS internal standard and the abscissa is the reciprocal of the excitation energy of the first absorption band ($E_E - E_{A1}$).

Discrepancies between the calculated and the observed shift values, though small, may be noted for *trans* ammines of compounds with X=CN^- and NO_2^-. The cause of these discrepancies may be in the approximations used: disregard of the possible variation of Co–N distances, neglect of several overlap integrals, neglect of the probable change in $\langle r^{-3}\rangle$, or the point dipole approximation itself. Solvent effects may have some contribution.[9] It is also probable that the additivity of cobalt-59 chemical shifts is not sufficiently exact to predict the anisotropy of the shifts. To eliminate several of these possibilities, we are measuring the rate of isotopic deuterium exchange in these complexes. The observed upfield shifts for *trans* ammines of X=CN^- and NO_2^- point to an increase of electron densities on these ammine protons. Thus, it is expected that the *trans* protons are exchanged much more slowly than the *cis* protons. Preliminary results of HD exchange confirmed this expectation. The details will be published in subsequent papers.

I wish to thank Prof. H. Yoneda and Dr. U. Sakaguchi, Hiroshima University, for helpful discussions.

The Reaction of Hydrogen Atoms with Acetylene

Toshio IBUKI and Yoshimasa TAKEZAKI
Institute for Chemical Research, Kyoto University, Gokanosho, Uji, Kyoto 611
(Received December 10, 1973)

The addition of hydrogen atoms to acetylene has been investigated at room temperature. The relative rate constant for

$$H + C_2H_4 \longrightarrow C_2H_5, \quad (1)$$
$$H + C_2H_2 \longrightarrow C_2H_3, \quad (2)$$

was found to be $k_1/k_2=9.99\pm0.16$. The ratios of the rate constant of disproportionation to that of the combination for the same radicals and for different radicals were determined to be as follows:

$$C_2H_5 + C_2H_3 \longrightarrow 1\text{-}C_4H_8, \quad (4)$$
$$\longrightarrow C_2H_6 + C_2H_2, \quad (4a)$$
$$\longrightarrow 2C_2H_4, \quad (4b)$$
$$k_{4a}/k_4 = 0.369,$$
$$k_{4b}/k_4 = 0.68,$$
$$C_2H_3 + C_2H_3 \longrightarrow 1,3\text{-}C_4H_6, \quad (5)$$
$$\longrightarrow C_2H_4 + C_2H_2, \quad (5a)$$
$$k_{5a}/k_5 = 0.087.$$

Although a large amount of quantitative data is now available on the addition of atomic hydrogen to simple olefins,[1-3] comparatively little is known about the reactions of unsaturated radicals, probably because of the difficulty of obtaining clean sources of these radicals, and also because of the problems in analysis, *i.e.*, the polymerization of an unsaturated radical.[4]

Recently, however, Hoyermann, *et al.*[5] have produced a vinyl radical by the addition of a hydrogen atom to acetylene and proposed a rate constant of: 2.3×10^{12} exp(−2500 cal mol$^{-1}/RT$) for the addition reaction. Cowfer, *et al*[6]. have obtained the ratios of the rate constants for H atom-olefin reactions to that for the H atom–acetylene system. In spite of quantitative studies[7-11] which have been published concerning the reactions of vinyl radicals, the data for the ratio of the disproportionation to the combination of the radicals show large discrepancies (see the last column of Table 2), and it remains difficult to say which value should be preferred.

In the present work, we have employed the competitive technique developed for determining the relative rate constants of the reactions of hydrogen atoms with olefins;[3] we have thus determined the relative rate constant of the addition of H atoms to acetylene and the ratio of the disproportionation to the recombination of vinyl radicals. Similar ratios of reactions between vinyl and ethyl radicals have also been obtained.

Experimental

Hydrogen atoms were generated by the Hg6($^3P_1$) sensitized decomposition of H_2. The 2537 Å radiation was obtained from a low-pressure mercury lamp with a Vycor glass filter. A conventional vacuum apparatus was used.

The acetylene and ethylene were purchased from the Takachiho Co.; both gases contained methane and ethane as impurities. The acetylene and ethylene were purified by a gas chromatograph provided with a 1.75 m activated charcoal column at 200 °C, and with a 0.7 m Molecular Sieves 13X column at 200 °C, respectively. The purified gases contained no impurity within the limits of sensitivity of a gas chromatograph with a flame ionization detector; therefore, both gases had a minimum purity of 99.999%. Takachiho research-grade hydrogen (99.999 vol%. O_2 content less than 0.1 ppm) was used without further purification.

The experiments were carried out at 22.7±1.0 °C, and the reactant-product mixture was analyzed by means of a gas chromatograph using a 4 m column of phenylisocyanate on Poracil C (Waters Associates, Inc.,) at 30 °C, and a flame ionization detector. The benzene was measured using a 2 m column of dioctylphthalate, followed by a 2 m column of polyethyleneglycol-4000 on Celite 545 at 80 °C.

In order to compare the rate constant for the H+C_2H_2 reaction with that for the H+C_2H_4 reaction in the photolysis of the H_2–C_2H_2–C_2H_4 system, it is necessary to determine the rate of the formation of the *n*-butane which would be formed if acetylene was absent in the system (denoted by r_B*). Thus, the rate of butane formation was monitored by using two reaction cells, a "mixture" cell (203 ml) and a "reference" cell (204 ml), under identical photolytic conditions. At first, the same pressures of ethylene (3.4—32.5 Torr) and hydrogen (~630 Torr) were admitted simultaneously to both cells, each containing a few drops of mercury, and then the cells were illuminated by an identical light source. Thus, the ratio of the rates of the formation of *n*-butane: $R_{n\text{-}C_4H_{10}}$ (Mixture cell)/$R_{n\text{-}C_4H_{10}}$ (Reference cell), was obtained in the H_2–C_2H_4 system; we define it as the "reference ratio."

Next, in the main run, the same pressures of ethylene (15—30 Torr) and hydrogen (~630 Torr) were put into both cells, while various pressures of acetylene were added to the "mixture cell." Then photolysis was performed in the same way as in the preliminary run. Thus, the value of r_B* was calculated by means of the following relation:

r_B^* = (reference ratio)
× (the rate of *n*-butane formation in the reference cell in the main run).

The reference ratio was checked both before and after the photolysis of the H_2–C_2H_2–C_2H_4 system; if the two values differed, the mean value was used in the calculation.

Table 1. Data for Hg-photosensitized reaction of C_2H_2–C_2H_4–H_2 mixtures

Reactants(Torr at 22.7 °C)			Photolysis time (min)	C_4H_{10} yield (μM)		Reference[a] ratio	Products (n-C_4H_{10}=1.000)

a) Reference ratio=$R_{C_4H_{10}}$(Mixture)/$R_{C_4H_{10}}$ (Reference). See text. b) Incident light was reduced to about one tenth. c) 2.0 Torr of NO was added. d) Mean value of 15 experiments. Pressure of ethylene was varied from 3.4 to 32.5 Torr.

Results and Discussion

In a series of experiments designed to ascertain the rate measurements, the H_2 pressure was kept higher than 600 Torr and constant. The total olefin pressure was very much smaller than the hydrogen pressure and was also kept approximately constant (~30 Torr). The products were ethane, n-butane, 1-butene, 1,3-butadiene, benzene, and negligible amounts of propane and propylene. The relative rate of the formation of each product is given in Table 1.

Now, if ethylene or acetylene quenches Hg6($^3P_1$) atoms and undergoes chemical reactions, acetylene and benzene should be formed from excited ethylene[12] and acetylene[13] respectively. On the other hand, in the experiments with the mixtures of ethylene (3.4—32.5 Torr) and hydrogen (~630 Torr), no acetylene was detected. Table 1 also shows that benzene formation is suppressed in the H_2–C_2H_2–C_2H_4 system by the addition of a small amount NO, which is known to suppress radical reactions. These observations imply that the excited olefin molecules formed by quenching are efficiently deactivated in collisions with other molecules present, without undergoing a chemical reaction.

The C_2H_6/n-C_4H_{10} ratio in the H_2–C_2H_4 system is very close to the normal ratio of the disproportionation to the combination of ethyl radicals, 0.13—0.14.[14] This shows that the H atom-radical reaction is negligible:

$$H + C_2H_5 \longrightarrow C_2H_6.$$

The formation of products may be explained by the following competitive reactions:[3]

$$Hg6(^1S_0) + h\nu(2537\,Å) \longrightarrow Hg6(^3P_1), \quad (a)$$
$$H_2 + Hg6(^3P_1) \longrightarrow 2H + Hg6(^1S_0), \quad (b)$$
$$H + C_2H_4 \longrightarrow C_2H_5, \quad (1)$$
$$H + C_2H_2 \longrightarrow C_2H_3, \quad (2)$$
$$C_2H_5 + C_2H_5 \longrightarrow n\text{-}C_4H_{10}, \quad (3)$$
$$\longrightarrow C_2H_6 + C_2H_4, \quad (3a)$$
$$C_2H_5 + C_2H_3 \longrightarrow 1\text{-}C_4H_8, \quad (4)$$
$$\longrightarrow C_2H_6 + C_2H_2, \quad (4a)$$
$$\longrightarrow 2C_2H_4, \quad (4b)$$
$$C_2H_3 + C_2H_3 \longrightarrow 1,3\text{-}C_4H_6 \quad (5)$$
$$\longrightarrow C_2H_4 + C_2H_2, \quad (5a)$$
$$C_2H_3 + C_2H_2 \longrightarrow C_4H_5, \quad (6)$$
$$C_4H_5 + C_2H_2 \longrightarrow C_6H_7, \quad (7)$$
$$C_6H_7 \longrightarrow C_6H_6 + H, \quad (8)$$
$$C_4H_5 + nC_2H_2 \longrightarrow \text{polymer}, \quad (9)$$

where Reactions 6—9 have been proposed by Tsunashima and Sato.[13]

In the competitive reaction technique, the basic premise is that the rates of the mutual interaction of the radicals formed are determined statistically:[3]

$$k_5 + k_{5a} = f(k_3 + k_{3a}).$$

If f happens to be unity, and if the simple collision theory of chemical kinetics can be applied to Reactions 3—5a, the activation energies of which are considered to be small,[15] one can get the following equation:

$$k_4 + k_{4a} + k_{4b} = 2(k_3 + k_{3a}) = 2(k_5 + k_{5a}) = 2k. \quad (A)$$

It will be shown below that Eq. (A) is a good approximation.

Table 1 shows that the benzene formation is less than 3% of the products measured at the reduced intensities of the incident light which is favorable for polymerization. Therefore, Reactions 6—9 are neglected in the following kinetic considerations at relatively high intensities.

A steady-state treatment gives the following equation:

$$\frac{[C_2H_2]_{initial}}{[C_2H_4]_{initial}} = \frac{k_1}{k_2}[(r_B^*/r_B)^{1/2} - 1], \quad (1)$$

where r_B^* is the rate of the formation of n-butane in Reaction 3 when ethylene is alone, and where r_B is that when acetylene is added to it.

Cvetanović and Doyle[3] have discussed the case when f is not unity. They have assumed the rate constant of the cross interaction of two radicals to be twice the arithmetic mean of the rates of the self-interaction of the radicals, *i.e.*:

$$k_4 + k_{4a} + k_{4b} = (k_3+k_{3a}) + (k_5+k_{5a}) = (1+f)k. \quad \text{(B)}$$

This seems to be logical.

Under such conditions, the steady-state treatment gives the following expression for k_2/k_1:

$$\left(\frac{k_2}{k_1}\right)^* = \frac{[C_2H_4]}{[C_2H_2]}\left\{\left[\delta\left(\frac{r_B}{r_B^*}\right)^{1/2}\left(1+\frac{(\delta^2-1)r_B}{r_B^*}\right)^{1/2} - \frac{(\delta^2-1)r_B}{r_B^*}\right]^{-1} - 1\right\}, \quad \text{(1a)}$$

where $\delta=(1+f)/2f^{1/2}$.

From Eqs. (1) and (1a), it may be seen that:

$$\rho = \frac{(k_2/k_1)^*}{k_2/k_1} = \left\{\left[\delta\left(\frac{r_B}{r_B^*}\right)^{1/2}\left(1+\frac{(\delta^2-1)r_B}{r_B^*}\right)^{1/2} - \frac{(\delta^2-1)r_B}{r_B^*}\right]^{-1} - 1\right\}\left[\left(\frac{r_B^*}{r_B}\right)^{1/2} - 1\right]^{-1}.$$

They have computed ρ for a wide range of f and r_B^*/r_B values and have shown that even when $f=0.6$, ρ differs from unity by less than 2% in the range of $(r_B^*/r_B)\leq 7$.

In the present case, the rates of the self-interaction of ethyl and vinyl radicals may be almost equal to the collision numbers, so that:

$$f = \frac{k_5+k_{5a}}{k_3+k_{3a}} = \frac{\sigma^2(C_2H_3)}{\sigma^2(C_2H_5)}\left[\frac{M(C_2H_5)}{M(C_2H_3)}\right]^{1/2},$$

where σ and M are the collision cross section and the molecular weight of each radical respectively. The collision diameters are $\sigma(C_2H_3)=4.23$ Å and $\sigma(C_2H_5)=4.33$ Å,[16] which give 0.989 as the value of f. Therefore, we have used Eq. (1) instead of (1a) to obtain k_1/k_2.

The steady-state treatment for the reaction mechanism described above leads to:

$$\frac{R(C_2H_6)}{R(n\text{-}C_4H_{10})} = \frac{k_{4a}}{k_4}\cdot\frac{R(1\text{-}C_4H_8)}{R(n\text{-}C_4H_{10})} + \frac{k_{3a}}{k_3}, \quad (2)$$

$$\frac{R(C_2H_6)}{R(n\text{-}C_4H_{10})} - \frac{k_{3a}}{k_3} = \frac{k_{4a}}{k_3}[(r_B^*/r_B)^{1/2}-1], \quad (3)$$

and

$$\frac{R(1,3\text{-}C_4H_6)}{R(n\text{-}C_4H_{10})} = \frac{k_5}{k_3}[(r_B^*/r_B)^{1/2}-1]^2. \quad (4)$$

Taking the data from Table 1, one can plot Eqs. (1)—(4) as is shown in Figs. 1—4. Good linear plots are obtained, as required by the equations. The slope of each figure gives the relative rate constant.

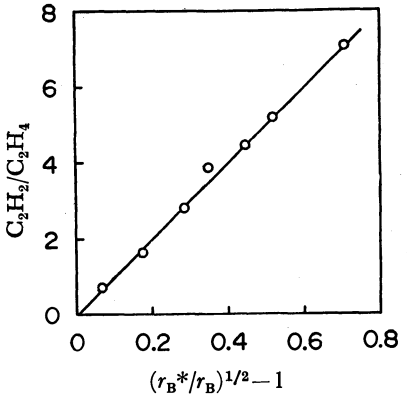

Fig. 1. Experimental plot of Eq. (1).

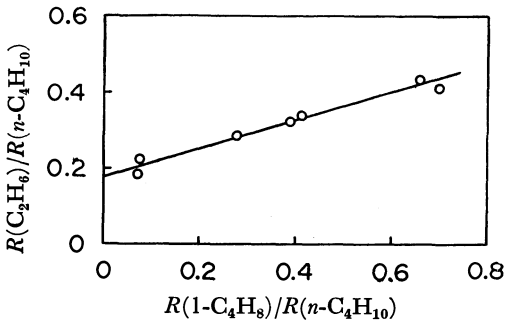

Fig. 2. Experimental plot of Eq. (2).

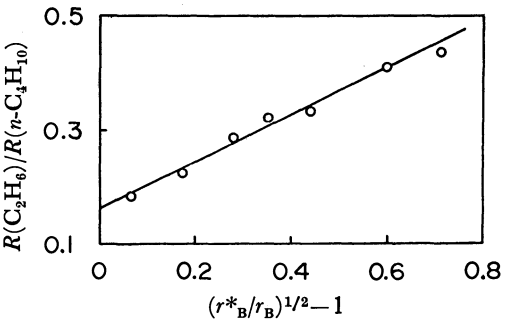

Fig. 3. Experimental plot of Eq. (3).

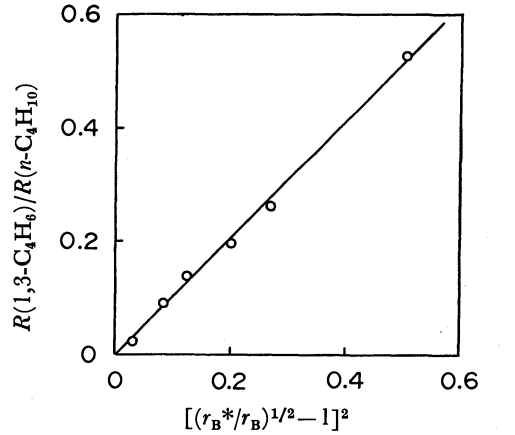

Fig. 4. Experimental plot of Eq. (4).

Using these relative rate constants and Eq. (A), the rate constants of Reactions 3a—5a relative to that of Reaction 3 are calculated to be as is shown in Column 2 of Table 2; they have not been measured hitherto. Column 3 shows the recalculated values expressed in a way similar to the literature values given in the last column.

It can be seen that a good agreement exists between the value of k_1/k_2 obtained in the present work and that of Cowfer, *et al.*[5] though their value has been obtained at total pressures of 10—15 Torr. However, there are some complications involved in obtaining the absolute value of k_2 from the new relative value for acetylene. The main one is that the rate constant for H-atom addition to ethylene is complicated by the redissociation of the vibrationally excited ethyl radical. Therefore, in the region of low pressures the absolute value of k_1 shows a tendency to increase with an increase in the total pressures.[17] Recetnly, Eyre *et al.*,[17j] have obtained the value of k_1

Table 2. Summary of the relative rates of reactions of C_2H_3 and C_2H_5 radicals

Reactions	Relative rate constants: Present results (22.7°C)		Relative rate constants: Literature values	Ref.
1	2	3	4	
$H+C_2H_4 \rightarrow C_2H_5$	9.99±0.16		8.6±1.3	6
$H+C_2H_2 \rightarrow C_2H_3$	1.00		1.00	
$C_2H_5+C_2H_5 \rightarrow n\text{-}C_4H_{10}$	1.00			
$\rightarrow C_2H_6+C_2H_4$	0.157±0.002			
$C_2H_5+C_2H_3 \rightarrow 1\text{-}C_4H_8$	1.13±0.20	1.00	1.00	
$\rightarrow C_2H_6+C_2H_2$	0.417±0.016	0.369	0.115(161—175 °C)	7
$\rightarrow 2C_2H_4$	0.77±0.20	0.68	0.034(161—175 °C)	7
$C_2H_3+C_2H_3 \rightarrow 1,3\text{-}C_4H_6$	1.03±0.04	1.00	1.00

a) Ref. 18. b) J. R. Dingle and D. J. Le Roy, *J. Chem. Phys.*, **18**, 1632 (1950). c) Ref. 19. d) Ref. 6. e) Ref. 5. f) E. L. Tollefson and D. J. Le Roy, *J. Chem. Phys.*, **16**, 1057 (1948). g) This work.

$=(5.5\pm0.5)\times10^{11}$ cm^3 mol^{-1} s^{-1}, independent of H_2 pressures of 750—1750 Torr at 298 K; the pressure region and the temperature are close to those used in the present work. If this absolute value is adopted, the relative rate constant obtained in this work leads to $(5.5\pm0.5)\times10^{10}$ cm^3 mol^{-1} s^{-1} as the rate constant for the addition of the H atom to acetylene; it is tabulated in Table 3. Recent studies[5,6,18-20] have indicated that the value of k_2 shows a pressure dependence when determined in the low-pressure region (1 to 50 Torr). This pressure dependence seems to be the reason for the discrepancies in the absolute values given in Table 3. In order to obtain a more reliable value, it may be necessary to study the decomposition of the vibrationally excited vinyl radicals over a wide range of pressures.

The agreements are not good between the literature values and those obtained in the present work for the ratio of the rate constants for the disproportionation to the combination of vinyl and ethyl radicals. There is uncertainty in the analysis of the data to obtain the ratio, as has been mentioned by authors themselves in their papers;[9,11] moreover, the available data are few in number. However, it can be seen at least that the value obtained for the vinyl radical reaction agrees in the order of magnitude with that proposed by Sherwood and Gunning.[7] Though a detailed discussion is impossible at present, it seems safe to conclude that the rate constant of the disproportionation of the vinyl radical does not exceed that of the recombination by one-tenth at room temperature.

An MO-theoretical Approach to the Aquation Mechanism of Carboxylatopentaammineruthenium(III) Complexes in Acid Solutions

Kastutoshi Ohkubo, Futoshi Kitagawa, Hiroyuki Sakamoto, and Akira Ohyoshi
Faculty of Engineering, Kumamoto University, Kurokami, Kumamoto 860

(Received March 1, 1974)

The aquation mechanism of carboxylatopentaammineruthenium(III) complexes, $(NH_3)_5RuO_2CR^{2+}$, where R=H, CH_3, C_2H_5, $(CH_3)_2CH$, and CH_2OH, has been investigated with the Wolfsberg-Helmholz-LCAO-MO extended Hückel method augmented by metal d-orbitals. The very weak Ru–O coordination linkage (bond population=0.085—0.092) formed mainly by the antibonding $d_{z^2}p_z$-σ and p_zp_z-σ orbitals facilitates the heterolytic bond-breaking of the Ru–O (dissociation energy=4.61—9.22 kcal/mol), and the order of the bond populations of the Ru–O is well reflected in that of the overall aquation rates. The preferable structure of the protonated complex is $(NH_3)_5RuOHC(=O)R^{2+}$, produced by the interaction between the H^+ catalyst and the non-bonding lonepair orbital of the neighboring oxygen atom attached to the metal. The H_2O solvent was found to play an important role in the bond dissociation of the metal-oxygen linkage from a linear dependence between the reactivity index $(1/2N_{z^2}^{LU})$ of the protonated complex to such nucleophiles as H_2O and the activation energy for the S_N2 aquation reaction. The proposed tetragonal pyramidal intermediate of $(NH_3)_5Ru^{3+}$ combines easily the Ru–O through the lowest unoccupied d_{z^2} Ru-orbital, forming an aquo-complex with the binding energy of with H_2O linkage, 30.25 kcal/mol.

The aquation of carboxylatopentaammineruthenium-(III) complexes (referred to as $(NH_3)_5RuO_2CR^{2+}$, where R=H, CH_3, C_2H_5, $(CH_3)_2CH$, and CH_2OH) has proved to be accelerated by an acid catalyst (H^+), in accordance with:[1]

$$(NH_3)_5RuO_2CR^{2+} + H_2O \underset{E_a=18.58-25.43\ \text{kcal/mol}}{\overset{H^+}{\rightleftharpoons}} (NH_3)_5RuH_2O^{3+} + RCO_2^- \quad (1)$$

where E_a denotes the activation energy. A simulation analysis of the above aquation reaction has led to the proposing of the following reaction sequences of an S_N1 mechanism combined with an S_N2 one:[2]

$$(NH_3)_5RuO_2CR^{2+} \xrightarrow[E_a=18.12-22.22\ \text{kcal/mol}]{H^+} (NH_3)_5Ru^{3+} + RCO_2^- \quad (2a)$$

$$(NH_3)_5RuO_2CR^{2+} \xrightarrow[E_a=21.82-30.29\ \text{kcal/mol}]{} (NH_3)_5Ru^{3+} + RCO_2^- \quad (2b)$$

$$(NH_3)_5Ru^{3+} + H_2O \underset{E_a=6.869\ \text{kcal/mol}}{\overset{E_a=2.094\ \text{kcal/mol}}{\rightleftharpoons}} (NH_3)_5RuH_2O^{3+} \quad (2c)$$

where $(NH_3)_5Ru^{3+}$ stands for a momentarily living five-coordinated intermediate (tetragonal pyramidal structure). The five-coordinated intermediate has also proved to be plausible in an anation study[3] of aquopentaammineruthenium(III) complexes.

In the aquation mechanism of carboxylatopentaammine complexes of Co(III),[4–6] Rh(III),[6] or Ir-(III),[6] however, there remain some obscurities in terms of the structure of the protonated complex, $(NH_3)_5MO_2CR^{n+}$—H^+ (M=central metal), the position of the bond-breaking of the complex (metal-oxygen or acyl-oxygen bond), and the reaction sequences (S_N1, S_N2, *etc.*).

Since the aquation mechanism is still open to question on a molecular level, it seems of interest and significant to reinvestigate the mechanism in connection with the electronic properties of the reactant, the intermediate, and the product in Reactions (2a—c).

Some extended-Hückel-MO-base SCF methods[7] have been used to investigate the electronic structures of metal complexes. However, the reliability of such self-consistent charge and configuration-MO calculation depends directly on the parameters for the diagonal and off-diagonal Hamiltonian matrix elements. In this respect, the EHMO (without SCF) method seems to be useful so long as the parameters are suitably selected to explain such experimental results as d-orbital splittings, electron-excitation energies, *etc.* In our previous EHMO treatment of the pentacyanocobaltate(II) complex,[8] it was found that the EHMO-method produced sufficient calculation results for the electronic property of the metal complex to be discussed qualitatively or quantitatively.

In this paper, we attempted to apply the Wolfsberg-Helmholz-LCAO-EHMO method[9] to explain the electronic structures of ruthenium complexes, in connection with their aquation reactions.

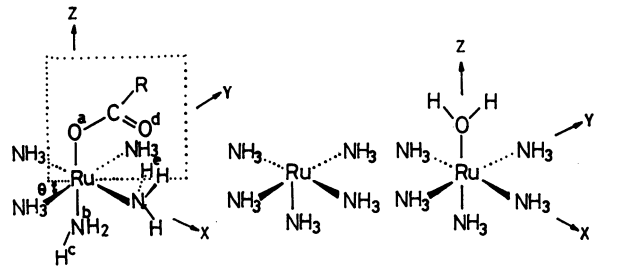
Method of Calculation

The following four systems were investigated in this work: (a) carboxylatopentaammineruthenium(III) complexes, $(NH_3)_5RuO_2CR^{2+}$ (R=H, CH_3, C_2H_5, $(CH_3)_2CH$, and CH_2OH), (b) an interacting system of $(NH_3)_5RuO_2CH^{2+}$ and the acid catalyst (H^+), (c) an intermediate, $(NH_3)_5Ru^{3+}$, and (d) an aquo-complex, $(NH_3)_5RuH_2O^{3+}$.

The diagonal terms for the central ruthenium metal orbitals, H_{ii}, are estimated from the negative of the valence-state ionization energies (VSIE) of Fe, Co, Rh, Ir, *etc.*; That is the VSIE values for the d, s, and p orbitals of Ru were, respectively, taken to be 12.0,[10] 9.0,[10] and 7.0 eV.[10] The off-diagonal terms, H_{ij}, were evaluated by the Wolfsberg-Helmholz approximation:[11]

$$H_{ij} = K(H_{ii}+H_{ij})S_{ij}/2$$

where K is a constant of 1.75 and where S_{ij} is the overlap integral between the i-th AO and the j-th AO. The orbital exponents were taken from Clementi,[12]



Ru–O=2.5 Å; Ru–N=2.23 Å; N–H=1.031 Å

$(NH_3)_5$-RuO_2CR^{2+} (R)	C–C/Å	C–O/Å	C–O/Å	∠OCO	∠OCC or ∠OCH	∠COH
H	—	1.36	1.23	122.4°	118.8°

Fig. 1. Geometries used for the calculation.

while the VSIE values for H, C, N, and O atoms were supplied by Hinze and Jaffe.[13]

The geometries used for the calculation are illustrated in Fig. 1; for simplicity of computation, the interatomic distances of Ru–O and Ru–N were uniformly taken to be the purely covalent bond lengths of 2.5 and 2.23 Å respectively, and the valence angle of Ru–O–C in the bond between the metal-carboxylato ligand was assumed to be 105° a value which corresponds to that of H–O–C of usual carboxylic acids (RC(=O)OH).

Calculated Results and Discussion

Electronic Property of $(NH_3)_5RuO_2CR^{2+}$. Mention should first be made of the molecular structure of $(NH_3)_5RuO_2CR^{2+}$. In the energetically stable state of $(NH_3)_5RuO_2CR^{2+}$, the RCO_2 ligand has a rotation angle of $\pi/4$ ($\theta=\pi/4$ in Fig. 1) in the direction of d_{xz} Ru-orbital expansion; $(NH_3)_5RuO_2CCH_3^{2+}$ in the case of $\theta=\pi/4$ is, for example, energetically more stable by 18.34 kcal/mol than that in the case of $\theta=0$. In such a situation, an intramolecular hydrogen bonding can be expected between the carbonyl oxygen of the RCO_2 ligand and the hydrogen atom of the ammine group (see Table 1). This hydrogen bond may stabilize the complex molecule.

Now, let us examine the d-orbital splittings and electron-excitation energies of $(NH_3)_5RuO_2CR^{2+}$ in order to check the reliability of the calculation results. The d-orbital separation of $(NH_3)_5RuO_2CR^{2+}$ is very similar to that of usual octahedral metal complexes such as $M(NH_3)_6^{3+}$, and $M(NH_3)_5H_2O^{3+}$; that is, the separation is shown by triply-degenerate d_{xy}, d_{yz}, and d_{xz} (at about −11.95 eV) and by doubly-degenerate d_{z^2} and $d_{x^2-y^2}$ (at about −11.1 eV[14]).

The 10 Dq value for $(NH_3)_5RuO_2CR^{2+}$ is, then, estimated to be 5.36—5.45 kK from the energy difference between the t_{2g} and e_g orbitals.

The 10 Dq value for such octahedral ruthenium complexes as $Ru(NH_3)_5H_2O^{3+}$ and $Ru(NH_3)_6^{3+}$ has been reported to be 1.14 Dq[15] on the basis of the crystal-field theory. Taking into consideration the fact that the Dq for the second transition series is some 50% greater than the first series (Dq=2.10 kK[16]), the value of 1.14 Dq corresponds almost exactly to 3.59 kK, which is approximately in agreement with the above 10 Dq value for $(NH_3)_5RuO_2CR^{2+}$.

In regard to the electron-excitation energies for the CT transition from the central Ru metal to the carboxylato ligand, the CT transition of $(NH_3)_5RuO_2CR^{2+}$ was found from the UV absorption spectra of $[(NH_3)_5$-$RuO_2CR](ClO_4)_2$ in water to occur in the range of 24.9—34.1 kK. The electron-excitation energy calculated from the d_{xz} (or d_{yz}) orbital to the oxygen p_x (or p_y) orbital falls in the range of 27.5—36.0 kK, which is in good accordance with the above experimental results. The present calculation results, thus, seem to be useful for a qualitative or quantitative discussion of electronic property of the ruthenium(III) complex.

Next, let us discuss the charges (of $(NH_3)_5RuO_2CR^{2+}$) calculated by means of Mulliken's electron population analysis.[17]

According to the electronic charge (Q_A) in Table 1, the electron distribution in the complex seems to be somewhat characteristic; the central trivalent ruthenium is negatively charged, as are the neighboring O and N atoms attached to the metal, while the charges of the H atoms in the NH_3 ligands are markedly positive (+0.365). The negativeness of the Ru(III)-charge may be due to the electron-inflowing from the NH_3 ligand through the σ-bond, because the electron-inflowing of the ligand electrons from the NH_3 to the Ru metal cannot be expected through the d-π delocalization. Concerning the Ru–O coordination linkage, the negative charges localized on the neighboring O and N atoms may make the Ru–O bond very weak; in this respect, the weakness of the Ru–O bond is reflected in the very small bond population (M_{AB}) of the Ru–O bond and the small heterolytic bond dissociation energies of 4.61—9.22 kcal/mol.[18] It is of interest here that the order of the M_{Ru-O} values except for that of the glycolato-complex is in satisfactory accordance with that of the E_a values for Reaction (1) (and also with that of the overall aquation rates: formato>acetato>propionate>isobutylato>glycolato) This may suggest qualitatively that the aquation of $(NH_3)_5RuO_2CR^{2+}$ proceeds *via* the S_N1 mechanism in which the bond breaking of the Ru–O linkage is more important than the bond making between the Ru metal and H_2O. It is also noticeable in respect to the Ru–O linkage that the antibonding $d_{z^2}p_z$-σ and p_zp_z-σ orbitals predominantly favor the formation of the Ru–O coordination bond. This implies the nucleophilic attack of such a third body as an electron-releasing solvent or base catalyst on the above antibonding nature of the Ru–O linkage so as to break the bond. In this respect, the order of the AO bond population (N_{Ru-O}) is also in harmony with that of the aquation rates mentioned above.

As to the superscripts of a—e, see Fig. 1.
a) The Q_A values for Ru were evaluated on the basis of the trivalent state of Ru (outer-shell electrons=5).

We will now, then, examine whether the above-mentioned antibonding dp-σ or pp-σ orbital plays an important role in the Ru–O bond-breaking in Reaction (2b). In view of the fact that the lowest unoccupied MO (LUMO) of the complexes is predominantly localized by the d_{z^2} Ru-orbital, the net orbital population of the d_{z^2}-orbital at the LUMO (abbreviated by $1/2N_{z^2}^{LU}$) can be taken as the reactivity index to such nucleophiles as H_2O, which is a stronger base than CH_3CO_2H. If H_2O takes part in the bond breaking of the Ru–O through its nucleophilic attack on the LU d_{z^2} Ru-orbital, there should exist a correlation between the $1/2N_{z^2}^{LU}$ values and such kinetic parameters as the E_a values for Reaction (2b). However, there was no parallelism between them. Therefore, the bond-breaking of the Ru–O linkage in Reaction (2b) may easily occur without the direct effect of H_2O on the bond dissociation of the Ru–O linkage, in view of the fairly small heterolytic dissociation energy of the metal-oxygen bond (the E_a values for Reaction (2b) are also small).

Role of the Acid Catalyst in the Dissociation of Metal-Oxygen Bond in $(NH_3)_5RuO_2CR^{2+}$. Up to now, the H^+ catalyst has been considered to participate in the protonated complex formation[19] as follows:

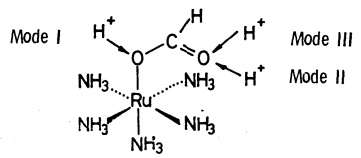
$$(NH_3)_5MO_2CR^{n+} + H^+ \rightleftharpoons \begin{matrix}(NH_3)_5MOC(-OH)R^{(n+1)+} \\ \text{or} \\ (NH_3)_5MOC(=O)R^{(n+1)+} \\ \quad H\end{matrix} \quad (3a)$$

$$\begin{matrix}(NH_3)_5MO(-OH)R^{(n+1)+} \\ \text{or} \\ (NH_3)_5MO(=O)R^{(n+1)+} \\ \quad H\end{matrix} + H_2O \longrightarrow (NH_3)_5MH_2O^{(n+1)+} + RCO_2^- + H^+ \quad (3b)$$

where M means such central metals as Co(III), Rh(III), and Ir(III); the protonated complexes of $(NH_3)_5MOC(-OH)R^{(n+1)+}$ and $(NH_3)_5MOHC(=O)R^{(n+1)+}$ have been supported by Kuroda[5] (and/or Saito *et al.*[20,21]) and Basolo *et al.*[6] respectively.

Let us now discuss the structure and reactivity of the protonated complex. In regard to the interacting system between the complex and the H^+ catalyst, there exist three representative modes of interaction (Modes I, II, and III in Table 2). As may be seen from Table 2, the positive stabilization energy (ΔE_s) favors the formation of the protonated complex, in particular that *via* Mode I. In view of the weakening

Table. 2. Electronic property of the protonated complex.



Mode	ΔM_{Ru-O}	HO	LU	$\frac{1}{2}N^{HO}$	$\frac{1}{2}N^{LU}$	ΔE_s/eV[a]	LUMO energy/eV
I	0.012	d_{xy}	d_{z^2}	0.986	0.848	4.46	−11.28
II	0.000	d_{yz} (d_{xz})	d_{xy}	0.827	0.959	2.34	−11.28
III	−0.003	d_{xy}	d_{z^2}	0.985	0.849	3.00	−11.28

a) Stabilization energy was estimated from $E_{EH}((NH_3)_5RuO_2CR^{2+}) + E_{EH}(H^+) - E_{EH}((NH_3)_5RuO_2CR^{2+}-H^+)$ where R=H.

of the Ru–O linkage by the protonation (reflected by the decrease in the M_{Ru-O}, ΔM_{Ru-O}), the protonation probably occurs through Mode I, in which the H^+ reacts with the nonbonding lone-pair oxygen 2p-orbital of the oxygen atom attached to the metal. It is worthy to emphasize that the bond-weakening of the acyl-oxygen linkage by the protonation cannot be expected through Modes I, II, and III. This means that the dissociation of the acyl-oxygen bond would not be promoted by the acid catalyst. It is also of interest to consider the effect of the H_2O solvent on the dissociation of the Ru metal-oxygen bond. In connection with the plausibility of Mode I, there is a noticeable correlation between the reactivity of the protonated complex formed by Mode I and the E_a value for Reaction (2a), in which the direct effect of H_2O on the Ru–O bond dissociation is not emphasized. The reactivity of $(NH_3)_5RuOHC(=O)R^{3+}$ toward such nucleophiles as H_2O can be mainly discussed by taking notice of the interaction between the LU d_{z^2} Ru-orbital of the former and the lone-pair orbitals of the latter.

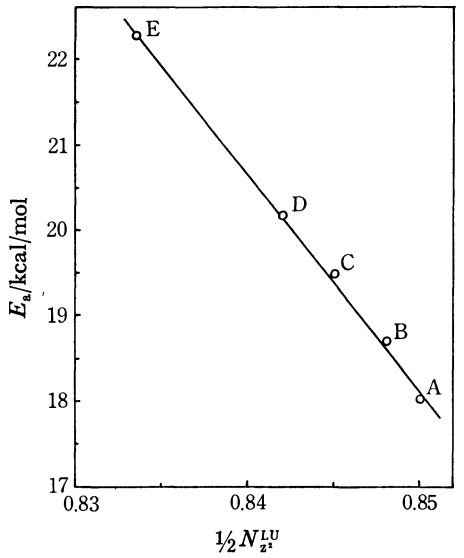


Fig. 2. Plots of E_a values for Reaction (2a) *vs.* $\frac{1}{2}N_{z^2}^{LU}$ values for $(NH_3)_5RuOHC(=O)R^{3+}$.
R: A=H, B=CH_3, C=C_2H_5, D=$(CH_3)_2CH$, E=CH_2OH

Figure 2 shows that there is a linear dependence between the $1/2N_{z^2}^{LU}$ values of $(NH_3)_5RuOHC(=O)R^{3+}$ and the E_a values. It may be deduced, therefore, that the H_2O solvent may promote the bond-dissociation of the Ru–O linkage and that Reaction (2a) can be divided into following steps:

$$(NH_3)_5RuO_2CR^{2+} + H^+ \overset{\text{fast}}{\rightleftharpoons} (NH_3)_5RuOHC(=O)R^{3+} \xrightarrow{H_2O} (NH_3)_5Ru^{3+} + RCO_2^- + H^+ \quad (4)$$

Reaction (4) would then be followed by:

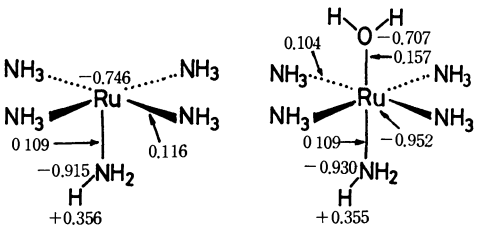
$$(NH_3)_5Ru^{3+} + H_2O \longrightarrow (NH_3)_5RuH_2O^{3+} \quad (5)$$

Reaction (4) proceeds more easily than Reaction (2b), with a lower activation barrier. However, there is, even now, an ambiguity with regard to the presence of $(NH_3)_5Ru^{3+}$, although we can cast doubt on the acyl-oxygen bond-breaking mechanism[22] from the MO-theoretical point of view; that is, there is a possibility of the direct formation of the aquo-complex through the proposed S_N2 mechnism:[4-6,20,21]

$$(NH_3)_5RuO_2CR^{2+} + H^+ \overset{\text{fast}}{\rightleftharpoons} (NH_3)_5RuOC(=O)R^{3+} \xrightarrow{H_2O} (NH_3)_5RuH_2O^{3+} \quad (6)$$

Bearing in mind that, in the aquation of Co(III) complexes in an acid solution, the complexes possessing the NH_3 (or NO_2^-) ligand at the *cis* or *trans* position toward the releasing ligand (in the present case, the RCO_2 ligand) react with a retention of configuration,[23] the five-coordinated tetragonal pyramidal intermediate is selectively formed so long as the bond breaking of the metal-releasing ligand occurs first. Moreover, the seven-coordinated octahedral wedge-type intermediate cannot be excepted so long as the aquation proceeds through the d_{z^2} metal-orbital. Therefore, the nonbonding lone-pair 2p O-orbital of H_2O would start to make a tight bond with the d_{z^2} Ru-orbital of $(NH_3)_5Ru^{3+}$ (LUMO=d_{z^2}) after the releasing of the RCO_2 ligand from the metal, because there is a large steric hindrance to the reaction of H_2O with $(NH_3)_5RuOC(=O)R^{3+}$ before the releasing of the RCO_2 ligand (the orbital overlapping between the above-mentioned orbitals is also small). Taking account of the above discussion, the five-coordination of $(NH_3)_5Ru^{3+}$ seems to be present and seems to be the plausible intermediate, mainly made from Reaction (4) in the aquation mechanism; in the experimental analysis, the concentration of the intermediate was very low (by a factor of approximately $1/10^3$), as compared with that of $(NH_3)_5RuH_2O^{3+}$ under the conditions shown in Refs. 1 and 2.

Electronic Property of $(NH_3)_5Ru^{3+}$ and $(NH_3)_5RuH_2O^{3+}$. From the electronic structure of $(NH_3)_5Ru^{3+}$ shown briefly in Fig. 3, it may be seen that the intermediate does not differ extremely from the parent carboxylato-complexes in terms of the Q_A and M_{AB} values and the frontier orbitals. This is in harmony with the fact that the coordination of RCO_2^- to $(NH_3)_5Ru^{3+}$ with a small binding energy (4.61—9.22 kcal/mol) has no



Frontier orbitals	LUMO	d_{z^2}	$d_{x^2-y^2}$
	HOMO	d_{xy}	d_{xy} or d_{xy}
Electron densities	d_{xz}	2.000	1.509
	d_{yz}	1.004	1.524
	d_{xy}	1.010	2.000
	$d_{x^2-y^2}$	0.356	0.356
	d_{z^2}	0.225	0.415

Fig. 3. Electronic structures of $(NH_3)_5Ru^{3+}$ and $(NH_3)_5RuH_2O^{3+}$.

marked effect on the d Ru-orbital separation of $(NH_3)_5RuO_2CR^{2+}$ (only the d_{z^2}-orbital energy was elevated slightly).

The intermediate of $(NH_3)_5Ru^{3+}$ once formed can easily be reconciled with the nucleophilic attack of the H_2O solvent on its d_{z^2}-orbital so as to form the aquo-complex. The coordination of H_2O to the Ru metal is relatively strong as compared with that of RCO_2^- to the metal, in view of the relatively large binding energy of 32.25 kcal/mol. This is reflected in such an electronic structure of $(NH_3)_5RuH_2O^{3+}$ as its Ru–O bond population (0.157).

The calculations were carried out on a FACOM 230-60 computer at the Data Processing Center of Kyushu University.

Theoretical Considerations of Lower Excited States of *trans*-Polyenecarbaldehydes. II. Radiative and Nonradiative Properties

Kozo Inuzuka

Department of Applied Science, Tokyo Electrical Engineering College, Kanda, Chiyoda-ku, Tokyo 101

(Received March 8, 1974)

The spin-orbit coupling energies between the lowest $^1(n,\pi^*)$ and $^3(\pi,\pi^*)$ states, and between the lowest $^1(\pi,\pi^*)$ and $^3(n,\pi^*)$ states, for the four polyenecarbaldehydes were calculated using the results calculated within the framework of the conventional P–P–P SCF–MO–CI method. In the present paper, the general properties of the emission spectra of polyenecarbaldehyde are theoretically considered using the calculated results for the spin-orbit coupling energy and their lower electronic structure.

In a previous paper,[1] the electronic structures of the lower n,π^* and π,π^* states of planar *trans*-polyenecarbaldehydes (acrolein, 2,4-pentadienal, 2,4,6-heptatrienal, and 2,4,6,8-nonatetraenal) and their oscillator strengths for the π-π^* transition were studied within the framework of the conventional P–P–P SCF–MO–CI method and then discussed. We can not even tentatively discuss the overall features of the emission property of polyenecarbaldehydes, however, because experimental data on the emission spectra of polyenecarbaldehyde are relatively rare except for acrolein[2] and for retinal,[3] which corresponds to 2,4,6,8,10-dodecapentaenal in the skeletal structure of the π electron system. In this investigation, the general features of their radiative and nonradiative properties will be discussed theoretically, using the previous results.[1]

Method of Calculation

When a single-electron operator is used for the spin-orbit Hamiltonian, the coupling of the n,π^* and π,π^* states is as follows:

$$\beta\langle n\pi^*|\pi\pi^*\rangle = \pm(\hbar e^2/4m^2c^2)\langle\pi|H_o|n\rangle \quad (1)$$

where H_o is the orbital part of the spin-orbit coupling operator for molecular systems.[4]

$$H_o = (e^2/2m^2c^2)\sum_{\lambda}\sum_{i} Z_\lambda^* l_i/r_{i\lambda}^3 \quad (2)$$

where Z_λ^* is the Slater effective charge of the nucleus, λ; $r_{i\lambda}$, the distance of the electron, i, from the nucleus, λ and l_i, the orbital moment of the i electron. $<\pi|$ and $<n|$ are the wavefunctions of the π- and n-electrons respectively for the ground state. $<\pi|$ has already been obtained by means of the P–P–P SCF–MO–CI method, and $<n|$ has been assumed in the previous paper[1] to be 2p-type atomic orbital localized on the oxygen atom of the carbonyl group. If we neglect all the two-center integrals, the spin-orbit coupling energy between the n,π^* and the π,π^* states is represented by Eq. (3):

$$\beta\langle n\pi^*|\pi\pi^*\rangle = \pm i(\hbar^2e^2/4m^2c^2)(Z_o^{*4}c_o/3n_o^{*3}a_H^3) \quad (3)$$

where Z_o^* corresponds to the effective nuclear charge of the 2p atomic orbital of the oxygen atom and c_o, to the coefficient of the 2pπ-AO of the oxygen atom of the π-MO; n_o^* is the effective principal quantum number of the n electron, and a_H is the Bohr radius (0.529 Å). In the present calculation the numerical values of $Z_o^*=4.55$ and $n_o^*=2$ were used. When $\alpha=\pm i(\hbar^2e^2Z^{*4}/12m^2c^2n_o^{*3}a_H^3)$ is substituted into Eq. (3), the absolute value of the square of Eq. (3) may be represented as follows:

$$|\beta\langle n\pi^*|\pi\pi^*\rangle|^2 = |\alpha|^2c_o^2 \quad (4)$$

The absolute value of α for the oxygen atom is equal to 52.2 cm^{-1}. The calculation of the spin-orbit interaction matrix element between $^1(\pi,\pi^*)$ and $^3(\pi,\pi^*)$ states or $^1(n,\pi^*)$ and $^3(n,\pi^*)$ states is not as easy as the calculation of the spin-orbit interaction matrix element between the different configurations. However, it is known that this quantity is much smaller than the corresponding one with a different configuration because of the lack of the contribution from the one-center term in the spin-orbit interaction matrix element. Here, this quantity is assumed to be of the order of 1 cm^{-1}.[5] Thus, the spin-orbit coupling between the two states with different configurations is more important than that between those with the same configuration; the former energy may be several orders of magnitude greater than the latter one. Therefore, the efficiency[6] of the intersystem crossing process, $^1(\pi,\pi^*)\rightsquigarrow{}^3(n,\pi^*)$ or $^1(n,\pi^*)\rightsquigarrow{}^3(\pi,\pi^*)$, is larger than that for the $^1(\pi,\pi^*)\rightsquigarrow{}^3(\pi,\pi^*)$ or $^1(n,\pi^*)\rightsquigarrow{}^3(n,\pi^*)$ process.

On the other hand, the energy separation between the lowest π,π^* singlet state, S_1, and the n,π^* triplet state, T_{n,π^*}, decreases, whereas the corresponding one between the n,π^* singlet state, S_{n,π^*}, and the lowest π,π^* triplet state, T_1, increases[1] as the molecular size increases. Therefore, the $S_{n,\pi^*}\rightsquigarrow T_1$ process plays a more important role in the radiationless deactivation of acrolein than does the $S_1\rightsquigarrow T_{n,\pi^*}$ process, but the situation is reversed as the molecular size increases. In order to ascertain the relation between the spin-orbit interaction energy and the energy separation of the two states concerning the radiationless process, the conversion time for the radiationless process was estimated using the Robinson-Frosch equations, (5) and (6):[7]

$$k = 0.71\times10^{12}\times\beta_{ij}^2\times S_{ij} \quad (5)$$

$$S_{ij} = \exp(-0.25\times E_{ij}^{0.4}) \quad (6)$$

where β_{ij} is the matrix element of [the interaction operator between i and j states, and where S_{ij} corresponds to the over-all vibrational factor in their paper.[7] The conversion time can, then, be represented by Eq. (7):

$$\tau_{1/2} = \ln 2/k \quad (7)$$

As Eqs. (5) and (6) were developed for aromatic compounds,[7] the application of these equations to polyenecarbaldehydes might not be justified. The critical comparison of the numerical values might be impossible, but the order-of-magnitude consideration may be useful for the discussion of the intersystem crossing process.

Results and Discussion

The absolute value of the square of the operator matrix elements for the spin-orbit coupling between S_{n,π^*} and T_1, and for that between S_1 and T_{n,π^*}, of the present four molecules and the conversion time were calculated by means of Eqs. (4) and (7), respectively. The calculated results are presented in Table 1. The square of the spin-orbit interaction between S_{n,π^*} and T_1, and/or S_1 and T_{n,π^*}, decreases rapidly with an increase in the number of atoms in the conjugated system. The calculated energy values[1] for the singlet and triplet states are plotted in Fig. 1.

In order to discuss the radiative and nonradiative processes of the excited states of polyenecarbaldehyde, we classified the electronic structures of their lower excited states into the following four groups (see also Fig. 2 for a schematical diagram). Acrolein, whose lowest excited singlet and triplet states are of an n,π^* character, was assigned to *Group* (1), and the remaining three polyenecarbaldehydes, to *Group* (2), for which the lowest excited singlet state is of an n,π^* character, while the lowest excited triplet state is of a π,π^* character. Although the assignment of nonatetraenal to *Group* (2) may be controversial in that its lowest singlet π,π^* state was calculated to be a little lower than the lowest n,π^* singlet state, the lowest π,π^* singlet state of nonatetraenal is estimated to be higher than its n,π^* singlet state on the basis of the experimental results for retinals,[3] as has been discussed in the previous paper.[1] Some polyenecarbaldehydes with longer skeletal chains than nonatetraenal, *e.g.*, dodecapentaenal, were assigned to *Group* (3), for which both the lowest singlet and triplet states of the molecule are of a π,π^* character; other, longer polyenecarbaldehydes whose lowest n,π^* triplet states are higher in energy than their lowest singlet π,π^* states were assigned to *Group* (4).

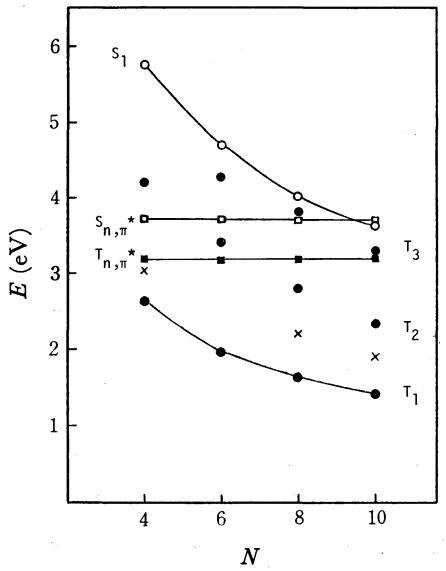

Fig. 1. Calculated lowest n,π^* and π,π^* state energies of *trans*-polyenecarbaldehydes.
N corresponds to the number of atom in the conjugated system of polyenecarbaldehyde. × corresponds to the observed value for the lowest π,π^* triplet state energy (see Ref. 1).

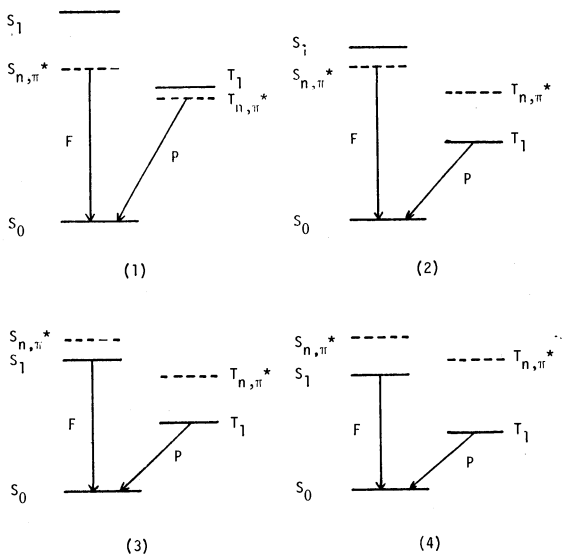

Fig. 2. Schematic energy level diagrams of polyenecarbaldehydes: (1), (2), (3), and (4) correspond to group (1), group (2), group (3), and group (4) (see text).

The general features of radiative and nonradiative properties for each case may be described as follows:

(i) *Group* (1). The observed electronic structure of the lower-lying excited states of acrolein is different in the order of T_{n,π^*} and T_1 states from the calculated

TABLE 1. CALCULATED VALUES FOR THE ABSOLUTE SQUARE OF SPIN-ORBIT COUPLING ENERGY AND CONVERSION TIME[a] BETWEEN S_{n,π^*} AND T_1, OR BETWEEN S_1 AND T_{n,π^*} OF *trans*-POLYENECARBALDEHYDES (in cm^{-2} and s)

	Acrolein	2,4-Pentadienal	2,4,6-Heptatrienal	2,4,6,8-Nonatetraenal
$\lvert\langle S_{n,\pi^*}\rvert H_{SO}\rvert T_1\rangle\rvert^2$	650	280	150	90
$\lvert\langle S_1\rvert H_{SO}\rvert T_{n,\pi^*}\rangle\rvert^2$	430	210	130	80
$\tau(S_{n,\pi^*} \rightsquigarrow T_1)$	3.4×10^{-12}	3.1×10^{-10}	1.4×10^{-9}	3.7×10^{-9}
$\tau(S_1 \rightsquigarrow T_{n,\pi^*})$	3.0×10^{-9}	2.1×10^{-10}	4.0×10^{-11}	0.7×10^{-11}

a) The conversion time was obtained by Eq. (7) in text.

results shown in Fig. 1. The lowest triplet is T_{n,π^*}, lying at 3.01 eV,[8,9] while the next triplet state is of a π,π^* character, lying at 3.05 eV.[10] As the separation between the two states is very small, the lowest n,π^* state may be mixed with the lowest triplet π,π^* state by the vibronic coupling. Excitation to the lowest S_{n,π^*} state may result in fluorescence, internal conversion to S_0, and/or intersystem crossing to the T_1 state. The experimental results[2] for acrolein showed that the fluorescence is very weak ($\Phi_F(77\text{ K})=0.007$) and of an n,π^* character; the phosphorescence is also very weak ($\Phi_P(77\text{ K})=4\times10^{-5}$).

On the other hand, it will be useful to refer to the spectra of testosterone and its derivatives, which contain conjugated systems similar to that of acrolein in their skeletal structures. Their lowest triplet states have been assigned as the π,π^* type, primarily on the basis of the lifetime of the phosphorescence and the separation of the onset of phosphorescence from the observed S_0—T_{n,π^*} excitation spectrum.[11,12] These quantum yields ranged from 0.2—0.3, but no fluorescence was reported. The fluorescences for these compounds are expected to be very weak due to the effective intersystem crossing from S_{n,π^*} to T_1 and the weak intensity of the n-π^* transition. The relationship[13] between the absorption intensity and the fluorescence lifetime of the molecule suggests that the radiative lifetime for the fluorescence with an n,π^* character may be much longer than the nonradiative lifetime for the intersystem crossing process from S_{n,π^*} to T_1 states.

The lowest triplet state of acrolein may be populated mainly *via* the $S_{n,\pi^*}\rightsquigarrow T_1\rightsquigarrow T_{n,\pi^*}$ and $S_1\rightsquigarrow T_{n,\pi^*}$, while the corresponding state of the above-mentioned keto steroid is populated *via* the $S_1\rightsquigarrow T_{n,\pi^*}\rightsquigarrow T_1$ and $S_{n,\pi^*}\rightsquigarrow T_1$ processes. With respect to the efficiency of the lowest triplet population of the two compounds, the keto steroid may have an advantage, because the radiationless lifetime for the $S_{n,\pi^*}\rightsquigarrow T_1$ process is much shorter than that for the $S_1\rightsquigarrow T_{n,\pi^*}$ process, as is shown in Table 1. The reason for the difference in the intensity of phosphorescence of the two compounds may be explained to some extent by the assumption that the following equation holds for the phosphorescence state of the two compounds:

$$[k(T_{n,\pi^*}\rightsquigarrow S_0)/k(T_{n,\pi^*}\rightarrow S_0)] \gg [k(T_1\rightsquigarrow S_0)/k(T_1\rightarrow S_0)] \quad (8)$$

Where the $k(T_i\rightsquigarrow S_0)$ and $k(T_i\longrightarrow S_0)$ notations correspond to the rate constants for the nonradiative and radiative processes respectively from the lowest triplet to the ground state.

However, the above discussion is not enough to explain the difference in the Φ_P values for the two compounds. The difference in the Φ_P may be attributed to the twisting of the carbon-carbon double bond of acrolein[2] in the π,π^* triplet state and to the stability of the cyclic structure of testosterone. Although a restricted twisting is possible in testosterone and its derivatives, the twisting will not give rise to the *cis-trans* isomerization. Also, the intersystem crossing to the ground state is expected to be less than for acrolein because of the restricted twisting. Therefore, the quantum yield of phosphorescence may be considerably larger than for acrolein.

(ii) *Group* (2). There are some higher-lying π,π^* triplet states between the S_{n,π^*} and T_1 states. Accordingly, the radiationless deactivation processes from S_{n,π^*} by spin-orbit coupling include not only $S_{n,\pi^*}\rightsquigarrow T_1$, but also the $S_{n,\pi^*}\rightsquigarrow T_i$ (i-th π,π^* triplet state)$\rightsquigarrow T_1$ process. These processes may compete with the radiative process from S_{n,π^*}. The increase in the fluorescence for *Group* (2) may not be expected. In Table 1, the spin-orbit interaction matrix elements between S_{n,π^*} and T_1 or S_1 and T_{n,π^*} decrease with an increase in the molecular size, but the energy separation between S_1 and T_{n,π^*} decreases rapidly.

The calculated lifetime for the radiationless process, $\tau(S_1\rightsquigarrow T_{n,\pi^*})$, becomes shorter and its process becomes important for the population of the lowest triplet state, T_1. The lowest triplet state for *Group* (2) is populated through the same processes for the keto steroid and the other two processes, $S_{n,\pi^*}\rightsquigarrow T_i\rightsquigarrow T_1$ and $S_1\rightsquigarrow T_{n,\pi^*}\rightsquigarrow T_i\rightsquigarrow T_1$, but the latter two processes may be less efficient than the $S_{n,\pi^*}\rightsquigarrow T_1$ process. The present discussion shows that the efficiency of the population for the lowest triplet state of *Group* (2) may be worse than that of acrolein and the keto steroid. The phosphorescence for *Group* (2) may be expected to be very weak or not emissive if we take into account the twisting effect.

(iii) *Group* (3). The fluorescence has been observed for *trans*-retinal,[3] a model compound of *Group* (3), but no phosphorescence spectrum was observed at 77 K. The calculated value for the radiationless lifetime, $\tau(S_1\rightsquigarrow T_{n,\pi^*})$, for nonatetraenal shows that the radiationless deactivation of the S_1 state becomes dominant. This result suggests that the excitation to the lowest singlet state, S_1, of *trans*-retinal may result in a rapid intersystem crossing to the T_{n,π^*} state before it fluoresces, as long as the lowest singlet state is of a π,π^* character. In a previous paper,[3] the fluorescence quantum yield of retinal was reported to be 0.71 (exciting at 440 nm at 77 K), but the value seems to be too large[14] in view of the above considerations and the comparison with the corresponding value of acrolein ($\Phi_F(77\text{ K})=0.007$). The previous calculation[3] showed that the *cis-trans* isomerization occurs in the lowest π,π^* singlet and triplet states. Its isomerization is one kind of radiationless deactivation process in the excited states. The experimental results for *trans*-retinal[3] suggest that such isomerization plays an important role in the emissibility of polyenecarbaldehyde. Therefore, the phosphorescence of *Group* (3) may be expected to be very weak or not emissive when we take the isomerization in the lowest triplet state into account.

(iv) *Group* (4). The fluorescence of *Group* (4) may become stronger than that of the other groups because of the decrease in the efficiency of the spin-orbit coupling for the $S_1\rightsquigarrow T_1$ radiationless process resulting from the same configuration, although the internal conversion, $S_1\rightsquigarrow S_0$, may increase. As the energy separation between S_1 and T_1 states decreases with an increase in the molecular size, the population of the T_1 state *via* the S_1 state may become relatively better in efficiency

as the molecular length becomes larger.

As the lowest singlet and triplet states of *Group* (4) are all of a π,π^* character, β-carotene[15] and retinyl polyenes[16] may be model compounds for *Group* (4) in lower π electronic structures. These experimental results suggest that the fluorescence of *Group* (4) is much stronger than that of the other groups. In the case of β-carotene,[15] the phosphorescence was observed at 77 K, although it was weak. The conjugated system of the β-carotene is much longer than that of *trans*-retinal. Its energy separation between the S_1 and T_1 states was about 1000—1500 cm^{-1},[15] while the corresponding theoretical value of the model compound for *trans*-retinal was about 1600 cm^{-1}.[3] The delayed emission of β-carotene has been tentatively assigned to the S–T phosphorescence due to the thermal excitation.[15] This type of emission requires a small S–T energy separation. Therefore, such emission can not be expected for the small polyenecarbaldehyde in *Group* (4). As an increase in the conjugated system makes for a small S–T energy separation, there is a possibility that the phosphorescence may be detected for the longer polyenecarbaldehyde. However, the most important factor for the observation of the emission spectra is the twisting effect in the conjugated system of polyenecarbaldehyde through all the groups.

This work was supported by a grant from the Tokyo Electrical Engineering College Research Fund. The author wishes to thank Professor R. S. Becker of the University of Houston for his kind communication regarding retinals.

Apparent Molal Volumes and Adiabatic Compressibilities of *n*-Alkanols and *α,ω*-Alkane Diols in Dilute Aqueous Solutions at 5, 25, and 45°C. I. Apparent Molal Volumes

Toshio NAKAJIMA, Tsuyoshi KOMATSU, and Tsurutaro NAKAGAWA

Department of Polymer Science, Faculty of Science, Hokkaido University, Sapporo 060

(Received March 15, 1974)

Density measurements have been carried out on a series of dilute aqueous solutions of *n*-alkanols and *α,ω*-alkane diols. The apparent molal volumes, ϕ_V, have been derived, and the ϕ°_V values (V°_2) at an infinite dilution have been estimated. The $\bar{V}^\circ_2$, the $\partial^2\bar{V}^\circ_2/\partial T$, and the $\partial^2\bar{V}^\circ_2/\partial T^2$ of the CH_2, the CH_3, and the CH_2OH groups were obtained from the dependence of the $\bar{V}^\circ_2$ and its temperature behavior upon the alkyl-chain length. It was found that the $\partial^2\bar{V}^\circ_2/\partial T^2$ value well reflects the structural effect.

Much attention has been devoted to the effect of the structural change in water caused by a solute on the thermodynamic properties.[1-4] On the basis of the data of the partial specific volumes, φ_v, of 15 nonelectrolytes in dilute aqueous solutions, Neal and Goring found that the $\partial^2\varphi_v^\circ/\partial T^2$ value of the hydrophobic compounds is positive, while that of the hydrophilic compounds is negative.[5] A similar discussion has been made by Hepler in relation to the pressure dependence of the partial molal heat capacity.[6] Further, Neal and Goring found that the specific expansibility, $\partial\varphi_v^\circ/\partial T$, and the concentration dependence of φ_v is closely related to the hydrophobic-hydrophilic balance in a solute.[5] This difference in the volumetric behavior between the hydrophobic and the hydrophilic compounds is considered to be related to the structural change in water caused by a solute. The purpose of the present paper is to obtain further information about the structural effect on the basis of the effect of the successive addition of the CH_2 group in the series of *n*-alkanols and *α,ω*-alkane diols on the partial molal volume and its temperature and concentration behavior.

Experimental

Materials. The *n*-alkanols from methanol to pentanol and the *α,ω*-alkane diols from 1,2-ethanediol to 1,6-hexanediol were used for the experiments. The best grade available from commercial sources (mostly guaranteed reagents) was dried over calcium sulfate and then fractionally distilled. The 1,6-hexanediol was distilled without such pretreatment. The water used was obtained by the distillation of deionized water by a quartz still and was degassed immediately before use.

Density Measurements. The densities were obtained by a float method analogous to that used by Desnoyers and Arel.[7] The float was suspended to the pan of the balance (Mettler: H20T) by a nylon thread 110 micron in diameter and was immersed in the solution in a thermostated cell. The water circulating in the cell was taken from a well-insulated bath kept at a constant temperature (±0.002 °C). The difference between the density of the solution, d, and that of the water, d_0, is obtained from weights, W and W_0, of the float in the solution and in water by means of this relation: $d-d_0=(W-W_0)/V$, where V is the volume of the float. The volume of the float is about 200 ml. The accuracy of the density measurement is within $\pm 10^{-6}$ g/ml. The density of pure water was taken from Kell's data.[8]

The solution was prepared by adding weighed amounts of a sample into a cell containing a known amount of pure water.

The apparent molal volume, ϕ_v, was obtained from the relation:

$$\phi_v = \frac{1000(d_0-d)}{mdd_0} + \frac{M}{d} \quad (1)$$

where m is the molality and M, the molecular weight of the solute.

Results

Some typical examples of the plot of ϕ_v *vs.* concentration (m) are shown in Fig. 1. The ϕ_v (m) is linearly related to m in the concentration range studied (0.01—0.2 mol/kg). The limiting partial molal volume, $\bar{V}^\circ_2$ ($=\phi^\circ_v$), is obtained from the linear extrapolation of the ϕ_v (m) to an infinite dilution. The experimental error estimated in the $\bar{V}^\circ_2$ is within 0.1 ml/mol. The values of V°_2 of *n*-butanol at 5 and 25 °C are in agreement with the values reported by Franks and Smith[9] within 0.03 ml/mol. The values of $\bar{V}^\circ_2$ and the slope of ϕ_v (m) are summarized in Table 1.

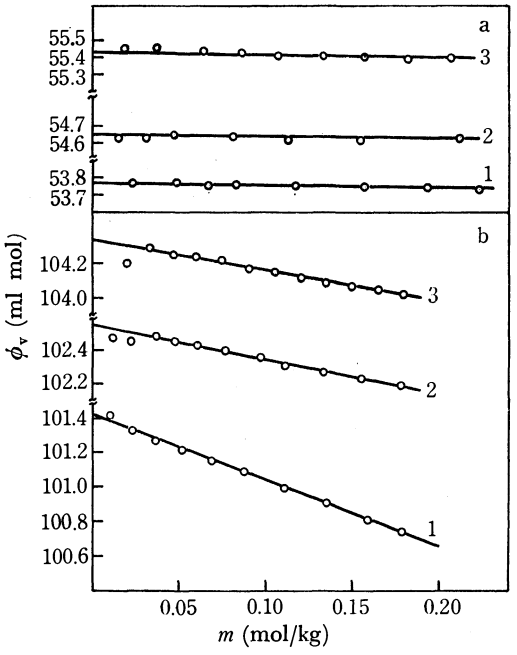

Fig. 1. Apparent molal volumes of 1,2-ethanediol (a) and *n*-pentanol (b) in water at 5 (1), 25 (2), and 45 °C (3).

Discussion

Partial Molal Volumes of CH_2 and CH_3 Groups. The limiting partial molal volume is expressed by the following expression:

$$\bar{V}_2^\circ = \bar{V}_{2,o}^\circ + \Delta\bar{V}_i^\circ + \Delta\bar{V}_h^\circ \qquad (2)$$

where $\Delta\bar{V}^\circ_i$ and $\Delta\bar{V}^\circ_h$ are the volume change, resulting from the iceberg formation around the hydrophobic group and the hydration by the hydrophilic group respectively, and where $\bar{V}^\circ_{2,0}$ is the partial molal volume when the iceberg formation and the hydration do not occur.

The $\bar{V}^\circ_2$ increment per CH_2 group is illustrated in Fig. 2 as a function of the chain length. The increments in the two homologs are different in their dependence upon the chain length, but they approach a common value as the chain length increases. The increment seems to become constant at $n=3$—4 in n-alkanol and at $n=5$—6 in α,ω-alkane diol. The deviation in the $\bar{V}^\circ_2$ increment per CH_2 group in a homologous series is frequently discussed in connection with the range of influence of the polar group on the structure of water.[7,10] This deviation in the V°_2 increment, however, is also observed in the case of the homologous series of n-alkanol in several nonaqueous solvents without the hydrogen-bonded structure, and the dependence of the $\bar{V}^\circ_2$ increment on the chain length partly resembles that in water.[11] In view of this fact, it is difficult to interpret this deviation only in terms of the effect of the polar group on the water structure.

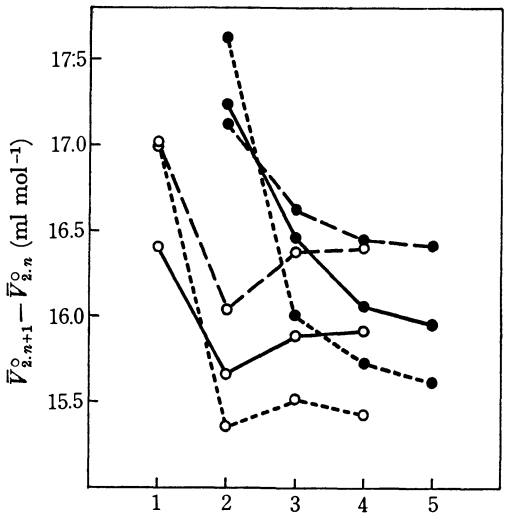

Fig. 2. The $\bar{V}^\circ_2$ increments per CH_2 group as a function of a chain length at 5 (-----), 25 (——), and 45 °C (----). ○: $H(CH_2)_n$-OH, ●: $(CH_2)_n$-$(OH)_2$.

The increment in the case of a longer chain length corresponds to the partial molal volume of the CH_2 group free from the influence of the OH groups. The values are shown in Table 2. The value of $\bar{V}^\circ_2(CH_2)$ is in good agreement with the corresponding value obtained from the homologous organic salts.[7,10]

Since, as may be seen from Fig. 2, the range of influence of the OH group is at most up to the γ-CH_2 group, the $\bar{V}^\circ_2$ values of the $(CH_2)_3OH$ group in n-butanol and in 1,6-hexanediol should be similar. Therefore, the difference between the $\bar{V}^\circ_2$ of n-butanol and a half of that of 1,6-hexanediol corresponds to the $V^\circ_2(CH_3)$ value outside the region of influence of the OH group. The $\bar{V}^\circ_2$ of the CH_2OH group in the long-chain alcohols was estimated by assuming that the $\bar{V}^\circ_2$ values of both the β- and the γ-CH_2 groups are similar to the $\bar{V}^\circ_2(CH_2)$ value free from the influence of the OH groups. The results are shown in Table 2. The $\bar{V}^\circ_2(CH_3)$ value calculated from the data[10] of $CH_3(CH_2)_3COONa$ and $(CH_2)_6(COONa)_2$ at 25 °C is 26.3 ml/mol, in good agreement with our result.

The $\bar{V}^\circ_2$ values of CH_3CH_3 and $CH_3CH_2CH_3$ calculated from the $\bar{V}^\circ_2$ values of the CH_2 and the CH_3 groups are in agreement with the experimental values of 53.3[12] and 51.2[13] for ethane and of 67.0[13] for propane at 25 °C.

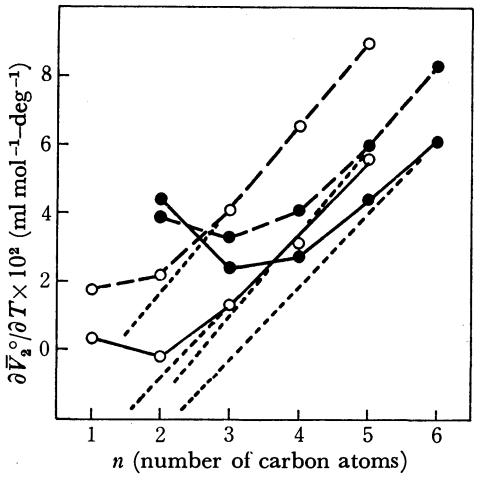

Fig. 3. Plot of the $\partial\bar{V}^{\circ}_2/\partial T$ against a chain length at 15 (——) and 35 °C (– – –), symbols as for Fig. 2.

$/\Delta T$) at 15 and 35 °C as a function of the chain length. The $\partial\bar{V}^{\circ}_2/\partial T$ values seem to fall on straight lines, with a similar slope, as the chain length increases. The $\partial\bar{V}^{\circ}_2/\partial T$ values seem to fall on straight lines when the chain length, n, is 3 for n-alkanol and 5—6 for α,ω-alkane diol. The region of the influence of the OH group on the $\partial\bar{V}^{\circ}_2/\partial T$ increment per CH_2 group seems to be up to the β- or the γ-CH_2 groups. This finding is similar to that observed in the $\bar{V}^{\circ}_2$ increment. The $\partial V^{\circ}_2/\partial T$ value of the CH_2 group free from the influence of the OH group is obtained from the slope of the straight line. By the same procedure as was used in the preceding section, the $\partial\bar{V}^{\circ}_2/\partial T$ values of the CH_3 and the CH_2OH groups were estimated. The values are shown in Table 2.

Neal and Goring found that the temperature dependence of the limiting partial specific volume, $\partial\bar{v}^{\circ}_2/\partial T$-($=\partial\bar{V}^{\circ}_2/\partial T/M$), of hydrophobic compounds is lower than that of hydrophilic compounds at low temperatures, and proposed that the $\partial\bar{v}^{\circ}_2/\partial T$ value is a useful measure of the effect of a nonelectrolyte on the water structure.[5] Figure 4 shows the plot of the $\partial\bar{v}^{\circ}_2/\partial T$ value against the chain length. It is evident from the figure that, contrary to the proposal by Neal and Goring, the $\partial\bar{v}^{\circ}_2/\partial T$ value obviously increases with the increase in the hydrophobic part of a solute. As may be seen from Column 5 in Table 2, the expansibility of the CH_2 group is markedly larger than those of the CH_3 and the CH_2OH groups. The increase in the $\partial\bar{v}^{\circ}_2/\partial T$ value with the increase in the chain length results from the large expansibility of the CH_2 group.

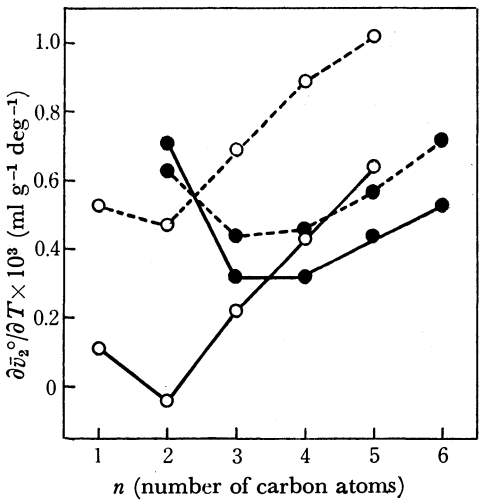

Fig. 4. Plot of the limiting specific expansibility, $\partial\bar{v}_2{}^{\circ}/\partial T^2$ against a chain length at 15 (——) and 35 °C (– – –), symbols as for Fig. 2.

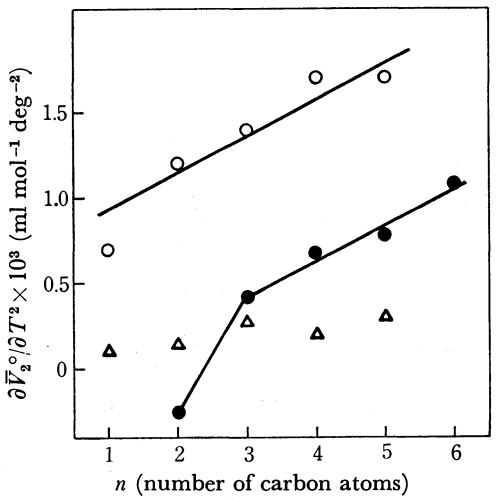

Fig. 5. Plot of the $\partial^2\bar{V}^{\circ}_2/\partial T^2$ against a chain length at 25 °C, symbols as for Fig. 2. △ corresponds to the $\partial^2\bar{V}_2/\partial T^2$ of pure alcohols calculated from the data in Ref. 14.

Figure 5 shows the plot of the $\partial^2\bar{V}^{\circ}_2/\partial T^2$ in solution and the $\partial^2\bar{V}^{\circ}_2/\partial T^2$ of pure alcohols at 25 °C against the chain length. It is noteworthy that the $\partial^2\bar{V}^{\circ}_2/\partial T^2$ of n-alkanol is remarkably high when compared with $\partial^2\bar{V}_2/\partial T^2$. From Eq. (2), $\partial^2\bar{V}^{\circ}_2/\partial T^2$ is given as:

$$\partial^2\bar{V}^{\circ}_2/\partial T^2 = \partial^2\bar{V}^{\circ}_{2,0}/\partial T^2 + \partial^2\Delta\bar{V}^{\circ}_1/\partial T^2 + \partial^2\Delta\bar{V}^{\circ}_h/\partial T^2 \quad (3)$$

Since $\partial^2\bar{V}^{\circ}_{2,0}/\partial T^2$ in Eq. (3) is free from the structural effect caused by a solute, $\bar{V}^{\circ}_{2,0}$ may be expected to be almost linearly related to the temperature; that is, $\partial^2\bar{V}^{\circ}_{2,0}/\partial T^2$ may be expected to be negligible. If this is accepted, the observed $\partial^2\bar{V}^{\circ}_2/\partial T^2$ values of hydrophobic compounds and those of hydrophilic compounds should correspond to the positive $\partial^2\Delta\bar{V}^{\circ}_2/\partial T^2$ and the

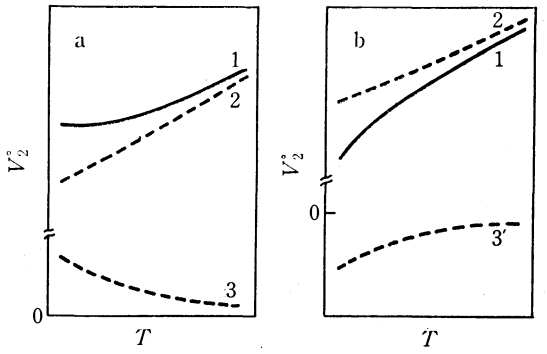

Fig. 6. Schematical figures of the temperature dependence of $\bar{V}^{\circ}_2$, $\bar{V}^{\circ}_{2,0}$, and $\Delta\bar{V}^{\circ}_1$ for hydrophobic compounds (a) and $\bar{V}^{\circ}_2$, $\bar{V}^{\circ}_{2,0}$, and $\Delta\bar{V}^{\circ}_h$ for hydrophilic compounds (b). (1): $\bar{V}^{\circ}_2$, (2): $\bar{V}^{\circ}_{2,0}$ (3): $\bar{V}^{\circ}_1$, and (3′): $\bar{V}^{\circ}_n$.

negative $\partial^2 \Delta \bar{V}^\circ_h/\partial T^2$ respectively.[5] By assuming the linear change of $\bar{V}^\circ_{2,0}$ with the temperature and the monotonous decrease in the structural effect with an increase in the temperature, the temperature dependences of $\bar{V}^\circ_2$, $\bar{V}^\circ_{2,0}$, and $\Delta \bar{V}^\circ_i$ for hydrophobic compounds and of $\bar{V}^\circ_2$, $\bar{V}^\circ_{2,0}$, and $\Delta \bar{V}^\circ_h$ for hydrophilic compounds are schematically shown in Figs. 6a and 6b respectively. It may be seen from the figure that $\Delta \bar{V}^\circ_i$ is positive and that $\Delta \bar{V}^\circ_h$ is negative.

The $\partial^2 \bar{V}^\circ_2/\partial T^2$ values lie on straight lines with the same slope except for 1,2-ethanediol. We note that the distance to the OH group does not significantly affect the $\partial^2 \bar{V}^\circ_2/\partial T^2$ increment per CH_2 group. The present results, therefore, seem to indicate that the water structure[15] around the CH_2 group is only slightly affected by the OH group. A similar result is obtained from the linear dependence of the limiting partial molal heat capacity on the chain length for the different solute series.[16]

The $\partial^2 V^\circ_2/\partial T^2$ value of the CH_2 group is obtained from the slope of the straight lines in Fig. 5. On the basis of the additivity of the $\partial^2 V^\circ_2/\partial T^2$ value for each group, the $\partial^2 V^\circ_2/\partial T^2$ values of the CH_3 and the CH_2OH groups except for 1,2-ethanediol were estimated. These values are given in Column 7 of Table 2. The positive $\partial^2 \bar{V}^\circ_2/\partial T^2$ values of the CH_2 and CH_3 groups reflect the effect of the iceberg formation around these groups.

As is shown in Fig. 5, only the $\partial^2 \bar{V}^\circ_2/\partial T^2$ value of 1,2-ethanediol deviates from the straight line and is negative. Further, Table 2 shows that the $\bar{V}^\circ_2$ and the $\partial \bar{V}^\circ_2/\partial T$ values of the CH_2OH group in 1,2-ethanediol apparently differ from those of the CH_2OH group in long-chain alcohols. These findings suggest that the effect of the adjacent OH groups in 1,2-ethanediol on the water structure differs from that of the OH groups existing relatively apart in higher diols and from those in monovalent alcohols. The negative $\partial^2 \bar{V}^\circ_2/\partial T^2$ values observed in glycerol,[5] glucose,[5] and sucrose[17] may also be attributed to the effect of the adjacent OH groups.

Excess Partial Molal Volume. The excess partial molal volume in an infinite dilution, $\bar{V}^{\circ E}_2$, is defined as:

$$\bar{V}^\circ_2 = V_2 + \bar{V}^{\circ E}_2 \tag{4}$$

where V_2 is the molal volume of a pure solute. It is known that the $V^{\circ E}_2$ value of the hydrophobic compounds is negative and that the absolute value of V°_2 increases as the hydrophobicity increases (*cf.* Fig. 7).[14,18] These facts can be interpreted by the idea that the structural change of water caused by the hydrophobic group results in a volume contraction.[14,18] However, there appear to be some questions in considering the $V^{\circ E}_2$ as a measure of the structural effect, as will be described below.[19] From the view point that the negative $V^{\circ 2}_E$ value is attributable to the iceberg formation, Franks and Smith proposed that the increase in $|V^{\circ E}_2|$ with an increase in the temperature proves the structure promotion by the hydrophobic group.[9] However, this proposal seems to be questionable in view of the conventional concept that the structural effect decreases as the temperature increases. From Eqs. (2) and (4), the $V^{\circ E}_2$ value is given by:

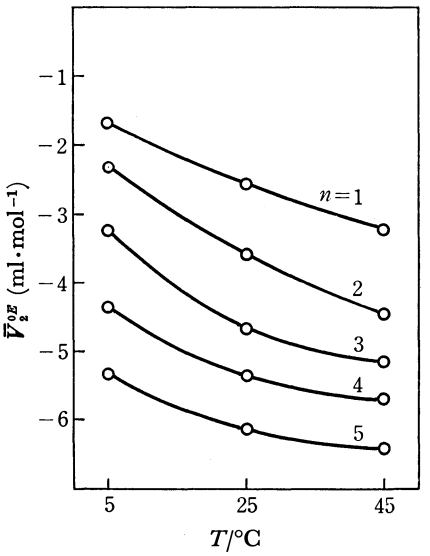

Fig. 7. Plot of the $\bar{V}^{\circ E}_2 (= \bar{V}_2 - V_2)$ of *n*-alkanols, $H(CH_2)_n$–OH, against temperature. The V_2 values were obtained from the data in Ref. 14 and 21.

$$\bar{V}^{\circ E}_2 = (\bar{V}^\circ_{2,0} - V_2) + \Delta V^\circ_i + \bar{V}^\circ_h \tag{5}$$

The $\bar{V}^{\circ E}_2$ does not directly reflect the structural effect unless the $(\bar{V}^\circ_{2,0} - V_2)$ value is negligible. In the previous section we concluded that the ΔV°_i is positive (*cf.* Fig. 6a). Therefore, the $(V^\circ_{2,0} - V_2)$ must be negative in order for $V^{\circ E}_2$ to be negative. Judging from the fact that the V°_2 decreases as the cohesive energy densities of solvents increase,[13,20] the $\bar{V}^\circ_{2,0}$ value can be expected to be small in water, a highly cohesive liquid; therefore, the $(\bar{V}^\circ_{2,0} - V_2)$ is negative. If the negative $(\bar{V}^\circ_{2,0} - V_2)$ value is accepted, the increase in $|V^{\circ E}_2|$ with an increase in the temperature (Fig. 7) can be interpreted in terms of the monotonous decrease in the positive $\Delta \bar{V}^\circ_i$.

Concentration Dependence of the ϕ_V. The slopes of $\phi_V(m)$, $\partial \phi_V/\partial m$, are shown in Table 1. The $\partial \phi_V/\partial m$ value is negative and increases numerically with an increase in the chain length and with a decrease in the temperature. Although the factor determining the slope is of a complicated nature, the above finding appears to indicate that the slope is mainly related to the effect of the hydrophobic groups on the water structure. This tendency of the slope can be interpreted in terms of the overlapping of the icebergs.[22] The contribution of the icebergs to the ϕ_V value, ΔV_i, is positive, as has been shown in the previous section. The decrease in the contribution of the $\Delta \bar{V}_i$ with the increase in the concentration due to the overlapping of the icebergs results in the decrease in the ϕ_V value.

Apparent Molal Volumes and Adiabatic Compressibilities of *n*-Alkanols and *α,ω*-Alkane Diols in Dilute Aqueous Solutions at 5, 25, and 45°C. II. Apparent Molal Adiabatic Compressibilities

Toshio NAKAJIMA, Tsuyoshi KOMATSU, and Tsurutaro NAKAGAWA
Department of Polymer Science, Faculty of Science, Hokkaido University, Sapporo 060
(Received March 15, 1974)

Ultrasonic velocity measurements have been made on a series of dilute aqueous solutions of *n*-alkanols and *α,ω*-alkane diols by means of the sing-around method. The apparent molal adiabatic compressibilities, ϕ_K, have been derived, and the ϕ°_K at an infinite dilution has been estimated. The ϕ°_K values per CH_2 and CH_3 groups were estimated from the additivity of the ϕ°_K value for each group. The values are negative at low temperatures and markedly decrease with a decrease in the temperature. This fact suggests that the iceberg formation makes a negative contribution to the ϕ°_K.

Shigehara,[1] Conway and Verrall,[2] and Laliberte and Conway[3] have discussed the effect of the iceberg formation[4] (the hydrophobic hydration) around CH_2 groups on the adiabatic compressibility in terms of its dependence on the alkyl chain length of organic salts. In view of the fact that the structural effect is sensitive to the temperature, the study of the temperature dependence of the compressibility is of use in order to obtain further information concerning the structural effect. In the present paper we wish to report our findings regarding the apparent molal adiabatic compressibilities, ϕ_K, of a series of *n*-alkanols and *α,ω*-alkane diols in dilute aqueous solutions and their temperature dependence. The ϕ°_K data will be discussed in relation to the ϕ°_V data presented in the previous paper (Part I).[5]

Experimental

Materials. The same samples as were used in Part I, $H(CH_2)_nOH$ (n=1—5) and $(CH_2)_n(OH)_2$ (n=2—6), were used for the experiments.

Ultrasonic Velocity Measurements. The ultrasonic velocity measurements in solutions were made with the sing-around velocimeter developed by Greenspan and Tschieg.[6] Two quartz transducers were mounted at the ends of a glass tube. A pulse from the first transducer travels through the liquid in the time L/u, where u is the sound velocity and L is the effective path length. The pulse received by the second transducer is used to retrigger the first transducer to send another pulse, thus repeating the process. The pulse repetition frequency, f, is determined by the pulse transit time in the liquid, L/u, and the total electronic delay time, t_e, as follows:

$$\frac{1}{f} = \frac{L}{u} + t_e \qquad (1)$$

The f value was measured by using a 6-figure digital electronic counter. The constants, L and t_e, were determined from the best fittings on the sound vilocity of water[7] at various temperatures from 5 to 45 °C. The accuracy of the ultrasonic velocity measurements was within ±1 cm/s.

The solutions were prepared by adding weighed amounts of a sample into a cell containing a known amount of pure water.

The coefficient of the adiabatic compressibility, κ, was calculated from the $\kappa = 1/du^2$ relation, where d is the density and is obtained from the data in Part I. The apparent molal adiabatic compressibility of the solute, ϕ_K, is defined by the $\phi_K = -(\partial\phi_V/\partial T)_s$ relation;[8] it is calculated by means of the following formula:

$$\phi_K = \frac{1000(\kappa-\kappa_0)}{md_0} + \phi_V\kappa \qquad (2)$$

where ϕ_V is the apparent molal volume and is obtained from the data in Part I.

Results

Figure 1 shows the experimental $\phi_K(m)$ results for *n*-butanol and 1,2-ethanediol at 5, 25, and 45 °C. The $\phi_K(m)$ is linearly related to the concentration, as was observed in the case of $\phi_V(m)$ in Part I. The limiting partial molal compressibility, $\bar{K}^\circ_2(=\phi^\circ_K)$, was obtained from the linear extrapolation of the $\phi_K(m)$ to an infinite dilution. The $\bar{K}^\circ_2$ values and slopes of the $\phi_K(m)$ are summarized in Table 1.

Discussion

Partial Molal Adiabatic Compressibilities of CH_2 and CH_3 Groups. The limiting partial molal adiabatic compressibility is expressed as follows:

$$\bar{K}^\circ_2 = \bar{K}^\circ_{2,0} + \Delta\bar{K}^\circ_i + \Delta\bar{K}^\circ_h \quad (3)$$

where $\Delta\bar{K}^\circ_i$ and $\Delta\bar{K}^\circ_h$ are the compressibility change resulting from the iceberg formation around the hydrophobic group and the hydration by the hydrophilic group respectively, and where $\bar{K}^\circ_{2,0}$ is the partial molal compressibility under the conditions when the iceberg formation and the hydration would not occur.

The $\bar{K}^\circ_2$ increment per CH_2 group is illustrated in Fig. 2 as a function of the chain length. The pattern of the behavior of the $\bar{K}^\circ_2$ increment resembles that of the $\bar{V}^\circ_2$ increment (*cf.* Fig. 2 in Part I). The $\bar{K}^\circ_2$ increments in the two series approach a similar value with the increase in the chain length. This value corresponds to the $\bar{K}^\circ_2$ value of the CH_2 group free from the influence of the OH groups. The $\bar{K}^\circ_2$ values of the CH_3 and CH_2OH groups in long-chain alcohols were estimated by the same procedure as was described in Part I. These results are shown in Table 2. The $\bar{K}^\circ_2(CH_2)$ calculated from the $\bar{K}^\circ_2$ data[2] of n-Pr_4N^+ and n-Bu_4N^+ is -2.6×10^{-4} ml/mol bar at 25 °C. This value is somewhat smaller than our result. The $\bar{K}^\circ_2(CH_2)$ obtained from the compressibility data[1] for a series of surface-active substances is -0.6×10^{-4} ml/mol bar at 30 °C. This value is in agreement with the value estimated from our results at 25 and 45 °C.

It should be noted that the $\bar{K}^\circ_2(CH_2)$ and the $\bar{K}^\circ_2(CH_3)$ values are negative at low temperatures and markedly decrease with a decrease in the temperature. As it is clear that the $\bar{K}^\circ_{2,0}$ value is always positive, the negative value of $\bar{K}^\circ_2$ can be attributed to the negative $\Delta\bar{K}^\circ_i$ value. This suggests that the iceberg is less compressible than bulk water.[2]

Temperature Dependence of the $\bar{K}^\circ_2$. Figure 3 shows the plot of the $\partial\bar{K}^\circ_2/\partial T(\approx\Delta\bar{K}^\circ_2/\Delta T)$ values at 15 and 35 °C against a chain length. The $\partial\bar{K}^\circ_2/\partial T$ values in both series approach straight lines with the same slope with an increase in the chain length. The pattern of the deviation from the straight lines resembles that of

$1/2(CH_2OH)_2$[b]	−1.9	2.4	4.7	2.13	1.16	−4.6

a) CH_2OH group in long chain alcohols. b) CH_2OH group in 1,2-ethanediol.

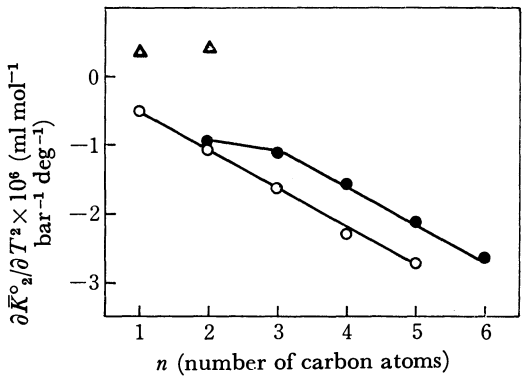

Fig. 4. Plot of the $\partial^2\bar{K}^\circ_2/\partial T^2$ against a chain length at 25 °C, symbols as for Fig. 2. △ corresponds to the $\partial^2 K_2/\partial T^2$ of pure alcohols calculated from the data in Ref. 9, where K_2 is $-(\partial V_2/\partial P)_s$.

$\partial\bar{V}^\circ_2/\partial T$ in Part I. The slope of the straight lines corresponds to the $\partial\bar{K}^\circ_2/\partial T$ value of the CH_2 group outside the region of influence of the OH group. The $\partial\bar{K}^\circ_2/\partial T$ values of the CH_3 and CH_2OH groups in long-chain alcohols were estimated as before. These results are given in Table 2.

Figure 4 shows the $\partial^2\bar{K}^\circ_2/\partial T^2$ value and the $\partial^2 K_2/\partial T^2$ value at 25 °C, where K_2 is $-(\partial V_2/\partial P)_s$, as a function of the chain length. It is noteworthy that the $\partial^2\bar{K}^\circ_2/\partial T^2$ has a large negative value in contrast with the slightly positive value of the $\partial^2\bar{K}_2/\partial T^2$ of pure alcohols From Eq. (3), $\partial^2\bar{K}^\circ_2/\partial T^2$ is given as:

$$\partial^2\bar{K}^\circ_2/\partial T^2 = \partial\bar{K}^\circ_{2,0}/\partial T^2 + \partial^2\Delta K^\circ_i/\partial T^2 + \partial^2\Delta\bar{K}^\circ_h/\partial T^2 \quad (4)$$

Since $\partial^2\bar{K}^\circ_{2,0}/\partial T^2$ in Eq. (4) is free from the structural effect, it can be expected that the $\bar{K}^\circ_{2,0}$ almost linearly relates with the temperature; that is, $\partial^2\bar{K}^\circ_{2,0}/\partial T^2$ is negligible. Therefore, the negative values of $\partial^2\bar{K}^\circ_2/\partial T^2$ shown in Fig. 4 result from the negative values of $\partial^2\Delta\bar{K}^\circ_i/\partial T^2$ and $\partial^2\Delta\bar{K}^\circ_h/\partial T^2$. By assuming a monotonous decrease in the structural effect with an increase in the temperature, the temperature dependences of ΔK°_i and ΔK°_h are schematically shown in Fig. 5. As may be seen from the figure, the negative values of the K°_2 at low temperatures are related to the large negative values of $\partial^2\Delta\bar{K}^\circ_i/\partial T^2$ and $\partial^2\Delta\bar{K}^\circ_h/\partial T^2$.

The $\partial^2\bar{K}^\circ_2/\partial T^2$ values in both series lie on the straight lines with the same slope except for 1,2-ethanediol

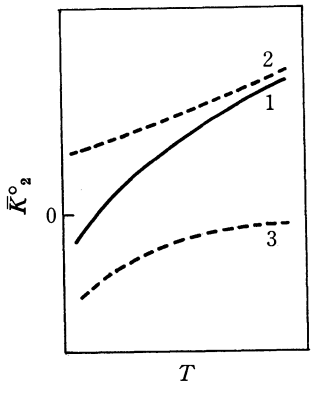

Fig. 5. Schematical figure of the relation between the temperature dependence of K°_2 and $\Delta\bar{K}^\circ_i$(or $\Delta\bar{K}^\circ_h$). (1): $\bar{K}^\circ_2$, (2): $\bar{K}^\circ_{2,0}$, (3): $\Delta\bar{K}^\circ_i$ or $\Delta\bar{K}^\circ_h$.

(Fig. 4). The $\partial^2\bar{K}^\circ_2/\partial T^2$ of the CH_2 group is evaluated from the slope of the straight lines. The $\partial^2\bar{K}^\circ_2/\partial T^2$ values of the CH_3 and the CH_2OH groups except for 1,2-ethanediol are estimated on the basis of the additivity of the $\partial^2\bar{K}^\circ_2/\partial T^2$ value for each group. The values are given in Table 2.

Only 1,2-ethanediol deviates from the straight line, as is shown in Fig. 4; the $\bar{K}^\circ_2$ and the $\partial\bar{K}^\circ_2/\partial T$ of the CH_2OH group in 1,2-ethanediol apparently differ from those of the CH_2OH group in long-chain alcohols, as has been shown in the cases of the $\bar{V}^\circ_2$ and the $\partial\bar{V}^\circ_2/\partial T$ (*cf.* Table 2 in Part I). These results suggest that the effect of the adjacent OH groups in 1,2-ethanediol on the water structure differs from that of the OH groups existing relatively apart in higher diols and those in monovalent alcohols.

Concentration Dependence of the ϕ_K. The slopes of $\phi_K(m)$, $\partial\phi_K/\partial m$, are shown in Table 1. The dependences of the slope upon the temperature and the chain length are not as clear as those for $\phi_v(m)$ presented in Part I, but it appears that the slopes are positive and increase with an increase in the chain length and with a decrease in the temperature, in contrast to the case of the slope of the $\phi_v(m)$. This tendency, as in the explanation of the slope of the $\phi_v(m)$ proposed in Part I, can be interpreted in terms of the overlapping of the icebergs.[10] The value of ΔK°_i resulting from the iceberg formation is negative, as was shown in the previous section. The contribution of the $\Delta\bar{K}^\circ_i$ to the ϕ_K becomes less negative with an increase in the concentration due to the overlapping of the icebergs; this results in the increase in the ϕ_K value.

The authors wish to thank professor Kiyoshi Arakawa, Dr. Nobuo Takenaka, and Dr. Masao Sakurai for their helpful advice. The present work has been supported in part by a Grant for Scientific Research from the Ministry of Education.

Magnetic Susceptibility of the Solid Oxygen-Fluorine Mixture

Akira SAKAKIBARA,* Yoshihiro MORI,** and Hiroo INOKUCHI
The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106
(Received June 13, 1974)

The magnetic susceptibility of an oxygen–fluorine solid mixture with a 20—75% oxygen content was measured from 12 K to each melting point. The small susceptibility found below 45 K with a 20—60% oxygen content is interpreted in terms of direct- and super-exchange interaction. The supercooling of the cubic phase is suggested in the case of a 75% oxygen content.

Oxygen and fluorine are neighbouring elements of the second row of the Periodic Table, and their molecular sizes and shapes resemble one another: at the 0.002 a.u. contour of the total molecular-charge density, which includes over 95% of the molecular charge, the O_2 molecule is 4.18 Å long and 3.18 Å wide, while the F_2 molecule is 4.18 Å long and 2.86 Å wide.[1] Besides, the packings of the molecules in the solid phase resemble one another: solid oxygen occurs in three phases, α, β, and γ,*** of which the crystal structures are monoclinic (C2/m),[2] rhombohedral ($R\bar{3}m$)[3] and cubic (Pm3n)[4] respectively. On the other hand, the crystal structures of α- and β-fluorine**** are monoclinic (C2/m)[5] and cubic (Pm3n),[6] strikingly similar to those of the α- and γ-solid oxygen. Because of these similarities, we can expect that oxygen and fluorine molecules mix well to form solid solution.

Concerning the physical properties of these solid phases, previous workers[7] have established that antiferromagnetic spin ordering exists in the α-phase, while in the β- and γ-phases the ordering is limited to a short range. As for the magnetic properties of the O_2–Ar solid solution system, Blocker *et al.* have investigated lower concentrations of oxygen molecules in an attempt to determine the exchange interaction between oxygen molecules:[8] argon molecules serve to dilute the oxygen concentration and intercept the magnetic interaction among the oxygen molecules. When there is a higher concentration of O_2 in the O_2–Ar system, however, we have found from our magnetic susceptibility measurements that argon molecules directly affect the antiferromagnetism and also the crystal transformation of the solid oxygen.[9] Therefore, it seemed that it would be interesting to study the magnetic properties of solid solution of oxygen and another molecule such as fluorine, which more strongly interacts with oxygen.

In this paper, the results of the magnetic susceptibilities of oxygen–fluorine mixtures will be presented and discussed in terms of the exchange interaction.

Experimental

The magnetic susceptibility measurements were carried out from 12 K to each melting point of the oxygen–fluorine mixture by the Faraday method, as has previously been described.[10] The magnetic field was set at about 9×10^3 Oe throughout the measurements. The $H(\partial H/\partial x)$ value was calibrated by measuring the susceptibility of sucrose, the mass susceptibility of which was taken to be -0.566×10^{-6} emu/g.

A gaseous mixture of oxygen and fluorine in various ratios, but containing 2—8 mg of oxygen, was thoroughly condensed into a small quartz tube cooled at the temperature of liquid helium, after which the tube was quickly sealed off with an oxyhydrogen flame.

Because of the reactivity of fluorine, especially with even a trace of water, the preparation process was carried out carefully as follows. Each of the oxygen and fluorine gases (commercially obtained) was passed through a liquid-nitrogen trap. Quartz tubes were at first baked for 3 hr at 1050 °C and then treated for a further 12 hr at 500 °C in a vacuum before introducing the sample into the tubes. The tubes and valves for the preparation system, composed of monel metal were also baked at 200 °C. The quartz tube was joined to the monel metal with coval metal, not with a seal using O rings, with attention paid to the resistivity to the heat treatment. The quartz-tube ampoules containing the O_2–F_2 mixture were placed in liquid nitrogen. In spite of the use of such a careful method for preparation and storage, however, the inner wall of the quartz ampoule containing the mixture was partially corroded; therefore, the final molar ratio of oxygen and fluorine is estimated to be larger by at least a few percent.

This quartz ampoule (5 mm in diameter and about 100 mm in length) was suspended by a Pyrex glass string from the arm of a vacuum balance, a Sartorius Electrono Microbalance, and cooled down to about 50 K; warming and cooling were then repeated around the melting point. After this, it was cooled down to 12 K in less than ten minutes. The temperature was measured with an Au: Co–Cu thermocouple placed below the ampoule and calibrated by the phase-transition points of pure oxygen and also by measuring the susceptibilities of the paramagnetic Tutton's salts, $(Fe(NH_4)_2(SO_4)_2\cdot6H_2O)$ and $(Mn(NH_4)_2(SO_4)_2\cdot6H_2O)$. Measurements of the temperature dependence of the magnetic susceptibility were started about three hours later, at a time when the temperature of the sample rose naturally after the evaporation of the liquid helium. The susceptibility was corrected for the diamagnetism of the quartz ampoule, but not for that of the sample itself, which would be negligible in this case.

Results and Discussion

Figures 1—3 show the temperature dependence of the magnetic susceptibilities of the oxygen–fluorine mixture (O_2–F_2). In case of a mixing O_2–F_2 ratio of

*** α: below 23.88 K, β: 23.88—43.76 K, and γ: 43.76—54.39 K.
**** α: below 45.6 K and β: 45.6—53.5 K.

50: 50 or 60: 40 in Fig. 1, there exists only one phase transition, at 45 K; no transition was found around 24 K, corresponding to the α-β phase transition temperature in pure solid oxygen and also in the 95% O_2–5% Ar mixture.[9] This finding indicates that the solid phases of oxygen and fluorine are not segregated from each other, but that solid solutions are preferably formed below 45 K.

The rapid increase in the susceptibility toward the low-temperature region is due to the free spins of the oxygen molecules isolated in the fluorine matrices. The ratio of the oxygen molecules contributing to this paramagnetism is at most a small percentage at those contents.

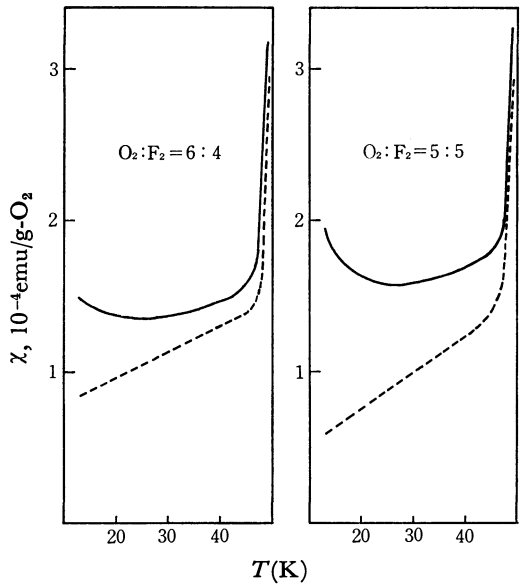

Fig. 1. Magnetic susceptibility for O_2: F_2=60: 40 and 50: 50 mixture as a function of temperature.
——: Measured susceptibility
----: Susceptibility removed of Curie's paramagnetism.

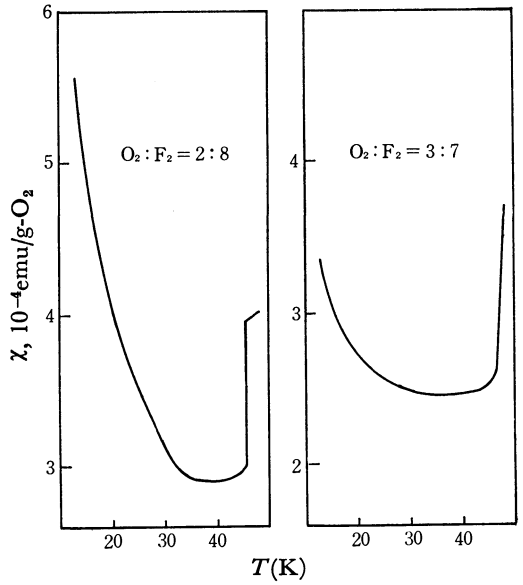

Fig. 2. Magnetic susceptibility for O_2: F_2=20: 80 and 30: 70 mixture as a function of temperature.
——: Measured susceptibility.

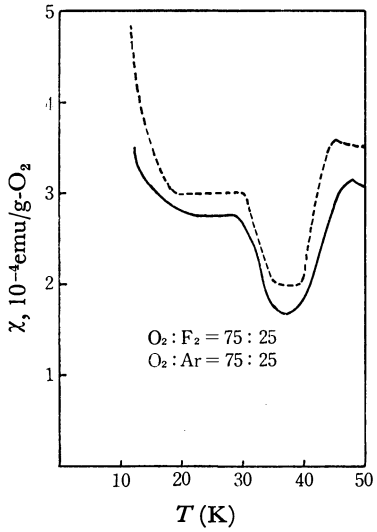

Fig. 3. Magnetic susceptibility for O_2: F_2=75: 25 compared with O_2: Ar=75: 25 mixture as a function of temperature.
——: O_2–F_2, ----: O_2–Ar

The dotted lines in Fig. 1 show the susceptibilities, with their paramagnetism removed by 4% for the 50: 50 mixture and 2% for the 60: 40 mixture according to Curie's law. The exact contribution of this paramagnetic oxygen could not be determined. There appears, then, a monotonously decreasing susceptibility below 45 K (dotted lines in Fig. 1). This temperature dependence of the magnetic susceptibility suggests that there exists a strong antiferromagnetic interaction in these solids, as in the α-phase of pure oxygen. A possible model for this antiferromagnetism of the O_2: F_2=50: 50 solid solution is presented below.

No experimental data for the crystal structure of the O_2–F_2 mixture in the solid phase have been reported. However, considering that the lowest-temperature phases, monoclinic, of both oxygen and fluorine and the molecules resemble each other in shape and size, as has been mentioned above, the crystal structure of the O_2–F_2 solid solution below 45 K can be expected

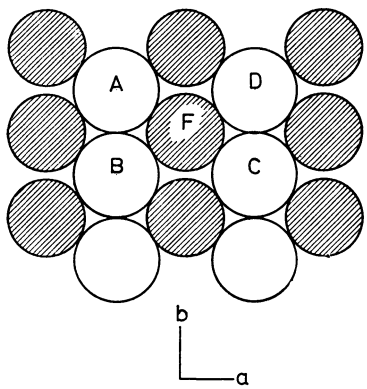

Fig. 4. A possible model for the molecular packing of O_2 and F_2. The contour is at the 0.002 a.u. of the total molecular charge density, which includes over 95% of the total charge. The lattice parameter, a or b, in the model is taken to be an average of that for α-oxygen and α-fluorine. Shadowed are fluorine molecules and non-shadowed are oxygen.

to be monoclinic. In Fig. 4, one of the possible models for the arrangement of oxygen and fluorine molecules in the ab plane is presented. The molecular packing of this arrangement can be predicted to be a nearly closed-packed one judging from that of the α-phase of oxygen and fluorine, and also from the molecular size. Because the fluorine molecule is narrower in width than the oxygen molecule, the distance between A and B may decrease in comparison with that of the same pairs in pure oxygen, 3.43 Å. Then the orbital overlap between them will so increase that the spin of the A oxygen strongly interacts with that of B antiferromagnetically. This direct antiferromagnetic exchange interaction is the most important factor.

The direct-exchange interaction between A and C or A and D can be neglected because of the long distance between them. However, the spin of the A oxygen may indirectly interact with that of the C oxygen through the F fluorine, as there may be a large overlap between the orbitals of A and F and between those of C and F, as is to be expected from their molecular packing shown in Fig. 4. This indirect interaction can be understood in terms of the super-exchange interaction, which has proceeded in some antiferromagnetic ionic compounds. That is, the electron of the $1\pi_g$ orbital of the A oxygen molecule interacts with that of the $1\pi_g$ of the C oxygen molecule, including the electron transfer from fluorine to oxygen. Then the spins of A and C are ordered in antiparallel fashion. The same interaction through F also occurs between A and D. In this case, the spin of A may be ordered parallel to that of D, because the two $1\pi_g$ orbitals of the F fluorine which interact with A and D are orthogonal.

In the ($\bar{2}01$) plane of the monoclinic lattice also, the molecular packing may be nearly closed, as in α-oxygen, in which case exchange interaction will occur directly or indirectly *via* a fluorine molecule.

As a matter of fact, it is still questionable whether or not an ordered distribution of O_2 and F_2 occurs, but in any case, including a randomly distributed model, the antiferromagnetic ordering in this solid solution would be realized by the direct- and also the super-exchange mechanism described above.

The magnetic susceptibilities of the O_2: F_2=20: 80 and 30: 70 mixtures at low temperatures are rather large in comparison with that of the 50: 50 mixture, but the decrease in the susceptibility around 45 K, though a little smaller, was also observed in these mixtures with lower oxygen contents. On the other hand, the susceptibilities of O_2–Ar mixtures of the same ratio do not decrease around 45 K and show a Curie-Weiss paramagnetism in this temperature region.[8] Therefore, in this case of O_2–F_2, oxygen molecules may not be distributed more thinly in one region and may be more concentrated in the other region.

For the case of O_2: F_2=75: 25, the temperature dependence of the susceptibility is very similar to that for O_2–Ar of the same ratio, O_2: Ar=75: 25. The large susceptibility at lower temperature, and the transition at about 27 K are characteristic. For the case of O_2–Ar, there appears a novel phase below 27 K, the crystal structure of which is cubic and very similar to that of the γ-phase.[11] This novel phase can be observed even at a composition and temperature where the monoclinic phase is stable when a rapid cooling quenches the structure of a higher temperature.[9,11] For the case of O_2–F_2 also, supercooling occurs from around 50 K and the cubic lattice is quenched to the lowest temperature.

The authors are much indebted to Drs. G. Fujisawa, M. Iwasaki, and S. Tsujimura of the Tokai Research Establishment, Japan Atomic Energy Research Institute, for preparing the sample and to T. Takeda for his skillful glass work. We are also grateful to Dr. H. Kawamura for helping us to prepare the apparatus.

Ion-Molecule Reactions in Carbonyl Sulfide-Hydrocarbon Mixtures

Akira MATSUMOTO, Satoshi OKADA,* Toshiyuki MISAKI,

(Received July 15, 1974)

Thermal energy ion-molecule reactions in carbonyl sulfide–hydrocarbon (methane, acetylene and propylene) mixtures were studied using a mass spectrometer equipped with a pulsed ion source. The rate constants for sulfur atom transfer, sulfur ion transfer and sulfur ion addition reactions were measured.

Several papers have been published on ion-molecule reactions in mixtures of hydrocarbons and sulfur-containing compounds.[1-4] However, reactions leading to RHS^+ (RH represents saturated or unsaturated hydrocarbons) have not yet been reported with the exception of ethane studied by Dzidic *et al.*[2] They reported that RHS^+ is produced in a mixture of ethane and carbonyl sulfide exclusively *via* S^+ transfer from COS^+ to ethane, but is not produced in a mixture of methane or ethylene and carbonyl sulfide.

In the present work, further study of the reactions leading to RHS^+ and RS^+ in mixtures of hydrocarbons such as methane, acetylene and propylene and carbonyl sulfide has been carried out using a mass spectrometer equipped with a pulsed ion source. The rate constants of the reactions have been determined.

Experimental

The operating characteristics of a pulsed ion source used in conjunction with a magnetic deflection instrument have been described previously;[5,6] only a brief description need be given here. Primary reactant ions were produced by an electron pulse of 0.2 μs duration and 10—16.3 V amplitude. Ions were extracted for mass analysis by applying a positive pulse of 1 μs duration and 10 V amplitude to the repeller plates. Primary and secondary ion currents were recorded as a function of the delay time between the ionizing pulse and the ion removal pulse. A repetition rate of 100 kHz was used.

In order to avoid the production of the excited ion $S^+(^2D^0)$, measurements were carried out at the electron energies below 16.7 eV (the appearance potential of $S^+(^2D^0)$ from COS).[7]

COS purchased from Matheson was purified by distillation under reduced pressure: analysis showed it to be more than 99.0% pure. H_2S and CS_2 were detected as minor impurities. All other gases were Takachiho high purity grade (99.9%) and were used without further purification.

The rate constants of ion-molecule reactions studied were calibrated with reference to the reported rate constant, $k=1.22\times10^{-9}$ cm^3 mol^{-1} s^{-1}, for the hydrogen transfer reaction $CH_4^+ + CH_4 \longrightarrow CH_5^+ + CH_3$.[8]

Results and Discussion

CH_4–COS System. The ion-molecule reactions for the formation of CH_4S^+ and CH_3S^+ ions in a CH_4–COS mixture were studied at total pressures up to 10^{-4} Torr in the ion source. At electron energies between 10 and 15 eV, the significant primary ions were COS^+, CH_4^+, CH_3^+, and S^+ in the ground state ($^4S^0$).

The ion-molecule reactions forming CH_4S^+ and CH_3S^+ can be discribed by the scheme

$$CH_4 + COS^+ \longrightarrow CH_4S^+ + CO \quad (1)$$
$$CH_4^+ + COS \longrightarrow CH_4S^+ + CO \quad (2)$$
$$CH_4 + S^+ \longrightarrow CH_4S^+ \quad (3)$$
$$CH_4 + COS^+ \longrightarrow CH_3S^+ + HCO \quad (4)$$
$$CH_4^+ + COS \longrightarrow CH_3S^+ + HCO \quad (5)$$
$$CH_3^+ + COS \longrightarrow CH_3S^+ + CO \quad (6)$$
$$CH_4 + S^+ \longrightarrow CH_3S^+ + H \quad (7)$$

The ion intensities of secondary ion CH_4S^+ (m/e=48) and CH_3S^+ (m/e=47) may be written:

$$I_{48} = (k_1 I_{60}[CH_4] + k_2 I_{16}[COS] + k_3 I_{32}[CH_4])t + C_1 \quad (I)$$

$$I_{47} = (k_4 I_{60}[CH_4] + k_5 I_{16}[COS] + k_6 I_{15}[COS] + k_7 I_{32}[CH_4])t + C_2 \quad (II)$$

where I_M is the intensity of ion (m/e=M), k_i the rate constant of the i-th reaction, t the reaction time, and C_1 and C_2 are constants.

In the formation of CH_4S^+, Reactions 1, 2, and 3 may be selected by choosing an appropriate electron energy. However, at lower electron energies (<15.1 eV) where only COS^+ and CH_4^+ are formed as significant primary ions, the amount of the secondary ion, CH_4S^+, formed was too small to determine the rate

TABLE 1. TOTAL RATE CONSTANTS UNDER VARIOUS CONDITIONS IN THE CH_4–COS SYSTEM

Run	Electron energy (eV)	Pressure in reservoir (Torr)		I_{16}/I_{32}	I_{60}/I_{32}	Total rate constant*
		CH_4	COS			
1	15.8	83.08	53.05	4.22	15.1	7.53×10^{-11}
2	16.0	83.08	53.05	4.33	13.7	6.08×10^{-11}
3	14.4	74.55	55.03	10.55	67.1	11.89×10^{-11}
4	15.1	74.55	55.03	6.23	27.1	8.41×10^{-11}
5	14.7	76.66	51.25	10.56	66.4	12.64×10^{-11}
6	15.4	76.66	51.25	7.93	34.5	7.25×10^{-11}
7	15.1	81.57	49.63	8.90	38.6	9.43×10^{-11}
8	15.8	81.57	49.63	5.89	19.9	8.16×10^{-11}
9	15.8	85.76	64.88	4.16	19.4	8.08×10^{-11}
10	16.0	85.76	64.88	4.41	18.1	7.06×10^{-11}
11	14.7	86.50	68.29	7.78	62.5	10.52×10^{-11}
12	15.4	86.50	68.29	6.26	32.2	7.57×10^{-11}

*Total rate constants are expressed by $(k_1 I_{60}/I_{32} + k_2 I_{16}[COS]/I_{32}[CH_4] + k_3)$ in cm^3 mol^{-1}s^{-1}.

constants k_1 and k_2 with sufficient accuracy. Therefore, the experiments were performed in the higher energy region (<16.7 eV) where Reactions 1, 2, and 3 occur simultaneously. From the results of Table 1 obtained under various conditions using least-squares means, the rate constants for Reactions 1, 2, and 3 were calculated to be $(3.8\pm0.1)\times10^{-13}$, $(6.0\pm0.1)\times10^{-12}$, and $(4.42\pm0.02)\times10^{-11}$ cm^3 mol^{-1} s^{-1}, respectively. The rate constant for S atom transfer from COS, k_2, is about 15 times that for S^+ ion transfer from COS^+, k_1. The rate constant for S^+ ion addition reaction, k_3, is about 7 times as large as k_2. It should be pointed that the formation of CH_4S^+, which was not observed by Dzidic *et al.*, has been confirmed. Furthermore, in the formation of RHS^+, S transfer from COS to RH^+ is faster process than S^+ transfer from COS^+ to RH in the CH_4–COS mixture. On the other hand, Dzidic *et al.* concluded that S^+ transfer from COS^+ to RH occurs exclusively in C_2H_6–COS mixture.

In the lower electron energy region (<14.25 eV, A.P. of CH_3^+ from CH_4), CH_3S^+ is produced by Reactions 4 and 5. Using Eq. (II), the rate constants k_4 and k_5 were determined to be $k_4=3.0\times10^{-12}$ and $k_5=1.6\times10^{-11}$ cm^3 mol^{-1} s^{-1}, respectively. However, in the high electron energy region (14.25<E<16.7 eV), Reactions 6 and 7 as well as 4 and 5 take place. The rate constants k_6 and k_7 were determined by substituting in Eq. (II) the above values for k_4 and k_5. Figure 1 shows a plot of $k_6+k_7I_{15}[COS]/I_{32}[CH_4]$ *vs.* $I_{15}[COS]/I_{32}[CH_4]$: the intercept and the slope correspond to $k_6=5.9\times10^{-10}$ and $k_7=9.5\times10^{-10}$ cm^3 mol^{-1} s^{-1}. The rate constant k_6 obtained here is in good agreement with the 5.0×10^{-10} cm^3 mol^{-1} s^{-1} reported by Dzidic and co-workers.[2]

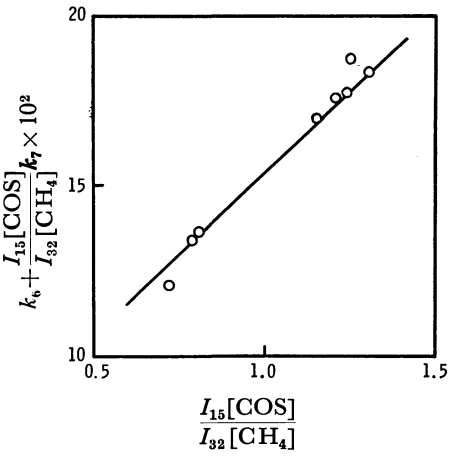

Fig. 1. Plots of $k_6+\frac{I_{15}[COS]}{I_{32}[CH_4]}k_7$ *vs.* $\frac{I_{15}[COS]}{I_{32}[CH_4]}$ in CH_4–COS system.

C_2H_2–COS System. In C_2H_2–COS mixtures, the ion $C_2H_2S^+$ is formed by the reactions such as

$$C_2H_2 + COS^+ \longrightarrow C_2H_2S^+ + CO \quad (8)$$

$$C_2H_2^+ + COS \longrightarrow C_2H_2S^+ + CO \quad (9)$$

$$C_2H_2 + S^+ \longrightarrow C_2H_2S^+ \quad (10)$$

Figure 2 shows the results obtained at lower electron energy where only $C_2H_2^+$ and COS^+ ions are formed as primary ions: the rate constants for Reactions 8 and 9 were determined to be 8.0×10^{-11} and 1.3×10^{-9} cm^3 mol^{-1} s^{-1}, respectively. At higher electron energy, Reaction 10 also yields $C_2H_2S^+$. In Fig. 3 $k_9+k_{10}I_{32}[C_2H_2]/I_{26}[COS]$ is plotted *vs.* $I_{32}[C_2H_2]/I_{26}[COS]$—the value of 8.0×10^{-11} cm^3 mol^{-1} s^{-1} obtained above is used for k_8. From the intercept and the slope $k_9=1.5\times10^{-9}$ and $k_{10}=8.0\times10^{-10}$ cm^3 mol^{-1} s^{-1} were obtained. k_9 determined from Fig. 3 is in good agreement with k_9 obtained at lower electron energy.

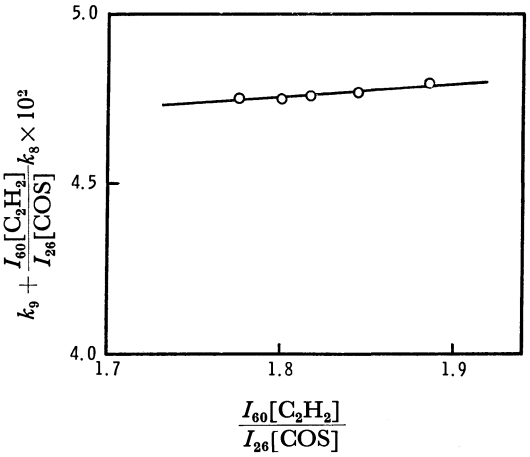

Fig. 2. Plots of $k_9+\frac{I_{60}[C_2H_2]}{I_{26}[COS]}k_8$ *vs.* $\frac{I_{60}[C_2H_2]}{I_{26}[COS]}$ in C_2H_2–COS system.

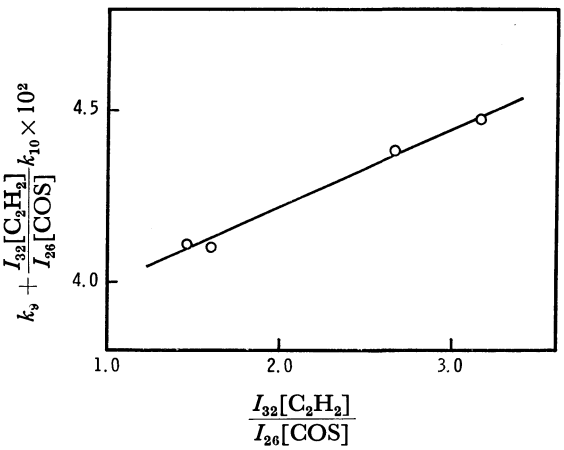

Fig. 3. Plots of $k_9+\frac{I_{32}[C_2H_2]}{I_{26}[COS]}k_{10}$ *vs.* $\frac{I_{32}[C_2H_2]}{I_{26}[COS]}$ in C_2H_2–COS system.

As in the CH_4–COS system, the rate constant k_9 for S atom transfer from COS is about 17.5 times as large as k_8 for S^+ ion transfer from COS^+. On the other hand, the rate constant k_{10} for the S^+ ion addition reaction is smaller than k_9 for S atom transfer reaction. The rate constant of 1.4×10^{-9} cm^3 mol^{-1} s^{-1} for Reaction 9 is surprisingly large compared with the value[2] of 4.7×10^{-11} cm^3 mol^{-1} s^{-1}, reported for the same reaction of the fragment ion $C_2H_2^+$ from C_2H_4. The implication of this difference still remains to be determined.

The possible reactions to account for the formation

of C_2HS^+ are

$$C_2H_2 + COS^+ \longrightarrow C_2HS^+ + CO + H \quad (11)$$

$$C_2H_2^+ + COS \longrightarrow C_2HS^+ + CO + H \quad (12)$$

$$C_2H^+ + COS \longrightarrow C_2HS^+ + CO \quad (13)$$

$$C_2H_2 + S^+ \longrightarrow C_2HS^+ + H \quad (14)$$

Thermochemical data shows that Reactions 11 and 12 are endothermic. Therefore, these processes are expected to occur only slightly. The secondary ion, C_2HS^+ was not detected in the low electron energy region where only COS^+ and $C_2H_2^+$ are observed as primary ions. After all, the formation of C_2HS^+ is attributed to Reactions 13 and 14. Rate constants of 1.1×10^{-10} and 1.5×10^{-9} cm^3 mol^{-1} s^{-1} for Reactions 13 and 14 were obtained from the results shown in Fig. 4.

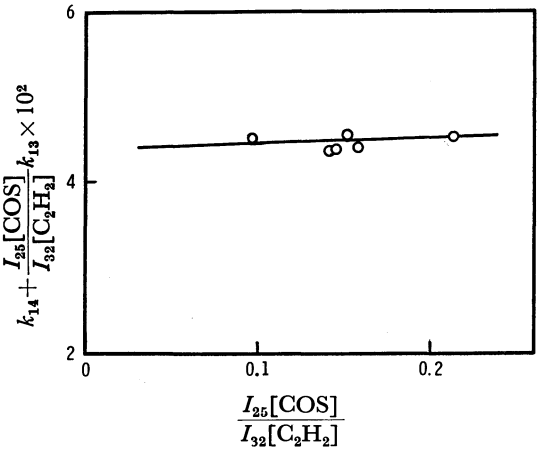

Fig. 4. Plots of $k_{14}+\frac{I_{25}[COS]}{I_{32}[C_2H_2]}k_{13}$ *vs.* $\frac{I_{25}[COS]}{I_{32}[C_2H_2]}$ in C_2H_2–COS system.

C_3H_6–COS System. In C_3H_6–COS mixtures, the following processes yielding $C_3H_6S^+$ were considered:

$$C_3H_6 + COS^+ \longrightarrow C_3H_6S^+ + CO \quad (15)$$

$$C_3H_6^+ + COS \longrightarrow C_3H_6S^+ + CO \quad (16)$$

$$C_3H_6 + S^+ \longrightarrow C_3H_6S^+ \quad (17)$$

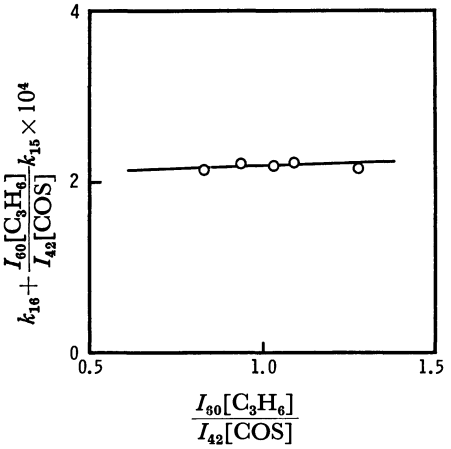

Fig. 5. Plots of $k_{16}+\frac{I_{60}[C_3H_6]}{I_{42}[COS]}k_{15}$ *vs.* $\frac{I_{60}[C_3H_6]}{I_{42}[COS]}$ in C_3H_6–COS system.

From the results shown in Fig. 5, obtained at lower electron energy where $C_3H_6^+$ and COS^+ are the only significant primary ions, the rate constants for Reactions 15 and 16 were determined to be $k_{15}=8.0\times10^{-14}$ and $k_{16}=9.3\times10^{-12}$ cm^3 mol^{-1} s^{-1}. At higher electron energies, the Reaction 17 also occurs. k_{17} was evaluated to be 4.6×10^{-11} cm^3 mol^{-1} s^{-1}, in a manner similar to the case of C_2H_2–COS system.

The following processes involved in the $C_3H_5S^+$ formation are

$$C_3H_6 + COS^+ \longrightarrow C_3H_5S^+ + HCO \quad (18)$$

$$C_3H_6^+ + COS \longrightarrow C_3H_5S^+ + HCO \quad (19)$$

$$C_3H_5^+ + COS \longrightarrow C_3H_5S^+ + CO \quad (20)$$

$$C_3H_6 + S^+ \longrightarrow C_3H_5S^+ + H \quad (21)$$

Since Reactions 18 and 19 are endothermic, $C_3H_5S^+$ formation in C_3H_6–COS systems is attributed to Reactions 20 and 21. From the intercept and the slope of the plot of $k_{20}+k_{21}I_{32}[C_3H_6]/I_{41}[COS]$ *vs.* $I_{32}[C_3H_6]/$

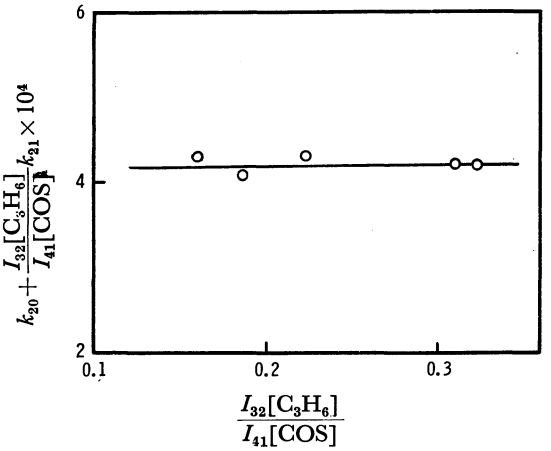

Fig. 6. Plots of $k_{20}+\frac{I_{32}[C_3H_6]}{I_{41}[COS]}k_{21}$ *vs.* $\frac{I_{32}[C_3H_6]}{I_{41}[COS]}$ in C_3H_6–COS system.

TABLE 2. RATE CONSTANTS IN COS-HYDROCARBON SYSTEMS

Reaction	Rate constant cm^{3}mol^{-1}s^{-1}
CH_4–COS system	
$CH_4+COS^+ \rightarrow CH_4S^+ + CO$	$3.8\pm0.1\times10^{-13}$
$CH_4^+ + COS \rightarrow CH_4S^+ + CO$	$6.0\pm0.1\times10^{-12}$
$CH_4+S^+ \rightarrow CH_4S^+$	$4.42\pm0.02\times10^{-11}$
$CH_4+COS^+ \rightarrow CH_3S^+ + HCO$	3.0×10^{-12}
$CH_4^+ + COS \rightarrow CH_3S^+ + HCO$	1.6×10^{-11}
$CH_3^+ + COS \rightarrow CH_3S^+ + CO$	5.9×10^{-10}
$CH_4+S^+ \rightarrow CH_3S^+ + H$	9.5×10^{-10}
C_2H_2–COS system	
$C_2H_2+COS^+ \rightarrow C_2H_2S^+ + CO$	8.0×10^{-11}
$C_2H_2^+ + COS \rightarrow C_2H_2S^+ + CO$	1.4×10^{-9}
$C_2H_2+S^+ \rightarrow C_2H_2S^+$	8.0×10^{-10}
$C_2H^+ + COS \rightarrow C_2HS^+ + CO$	1.1×10^{-10}
$C_2H_2+S^+ \rightarrow C_2HS^+ + H$	1.5×10^{-9}
C_3H_6–COS system	
$C_3H_6+COS^+ \rightarrow C_3H_6S^+ + CO$	8.0×10^{-14}
$C_3H_6^+ + COS \rightarrow C_3H_6S^+ + CO$	9.3×10^{-12}
$C_3H_6+S^+ \rightarrow C_3H_6S^+$	4.6×10^{-11}
$C_3H_5^+ + COS \rightarrow C_3H_5S^+ + CO$	1.8×10^{-11}

I_{41}[COS] shown in Fig. 6, the rate constants for Reactions 20 and 21 were determined to be $k_{20}=1.8\times10^{-11}$ $cm^3\ mol^{-1}\ s^{-1}$ and $k_{21}\leq10^{-13}$ $cm^3\ mol^{-1}\ s^{-1}$, respectively. The small value of k_{21} estimated for the highly exothermic reaction 21 suggests that the product ion, $C_3H_5S^+$ may be followed by fragmentation.

In the low electron energy region, the ion-molecule reactions yielding CH_4S^+, $C_2H_2S^+$, and $C_3H_6S^+$, in methane–COS, acetylene–COS and propylene–COS systems may be classified into three groups; S^+ ion transfer, S atom transfer and S^+ ion addition. As seen in Table 2, the rate constants for S atom transfer are very large compared with those for S^+ ion transfer in methane–COS and propylene–COS mixtures although not in acetylene–COS mixtures. In acetylene–COS mixtures, all the reactions are very fast compared with those in methane–COS and propylene–COS mixtures. This seems to be attributable to the triple bond of acetylene.

Photochromism of 2-Hydroxytriphenylmethanol and Its Derivatives

Sanyo HAMAI and Hiroshi KOKUBUN

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received July 19, 1974)

2-Hydroxytriphenylmethanol (HM) shows photochromism in air-saturated acetonitrile and other solvents and also in the crystalline state. The colored form has been deduced to be *o*-fuchsone, produced by photochemical dehydration of HM. The photochromism mechanism is entirely different from that of other triarylmethane derivatives. The colored form is the same species as in thermochromism. The reactive state of HM was found to be the excited singlet state from the results of quenching experiments. The quantum yield of the photochemical reaction was determined to be 0.62 in acetonitrile by a method based on the equilibrium between the photochemical and thermal bleaching reactions. Photochromism occurs also at 77 K. At this temperature, HM radical is produced beside the colored form. The ratio of the concentration of HM radical to the colored form increases with irradiation time. Several HM derivatives show photochromism similar to HM.

Photochromism of many triarylmethane derivatives, especially triphenylmethane derivatives, has been studied extensively.[1] In the photochromism of triarylmethane dye leuco derivatives, such as leuco malachite green and leuco crystal violet, the colored forms are the respective cations.[2,3] In the photochromism of *o*-nitrotoluene derivatives, for example 2,4,2′,4′,2″, 4″-hexanitrotriphenylmethane, the colored form is an aci-nitro acid or an anion.[4,5] It has been reported that 2-hydroxytriphenylmethanol[6,7] (HM) and (3-hydroxy-2-naphthyl)-diphenylmethanol[7] show thermochromism. Gomberg and Nishida[6] attributed the thermochromism of HM to the formation of the quinoidal colored form(I), but, Bowden and Beynon[7] suggested the same phenomenon was due to the broadening of the near ultraviolet absorption band. However, both these views do not seem to be fully supported by experimental evidence.

We have found photochromism of HM and its derivatives. The photochromism was studied in various solvents at room temperature as well as at liquid nitrogen temperature. For comparison thermochromism was also studied.

Experimental

Materials. HM was synthesized from methyl salicylate or phenyl salicylate and phenylmagnesium bromide by the Grignard reaction[8] and, after treatment with activated charcoal, recrystallized several times from an ethyl ether–*n*-hexane mixture. 2-Hydroxy-4-methoxytriphenylmethanol (HMM) was also synthesized from 2-hydroxy-4-methoxybenzophenone by the Grignard reaction and, after treatment with activated charcoal, recrystallized several times from ethyl ether–*n*-hexane and methanol–water mixtures. 5-Chloro-2-hydroxytriphenylmethanol and (3-hydroxy-2-naphthyl)-diphenylmethanol were synthesized from 5-chloro-2-hydroxybenzophenone and methyl 3-hydroxy-2-naphthoate by the Grignard reaction and purified by the method used for HM. *o*-Naphthofuchsone was obtained by refluxing dichlorodiphenylmethane, *β*-naphthol and aluminum chloride in carbon disulfide, decomposing the products by ice, steam distilling, and recrystallizing from acetic acid.[9]

Acetonitrile was distilled over phosphorus pentoxide. Ethyl ether was distilled over sodium wire after being stood overnight with calcium chloride and used immediately. Wako G.R. grade acetic acid, methanol and ethanol were used as received.

Piperylene was distilled over sodium wire. Biacetyl was used immediately after distillating three times.

Apparatus. A 6W germicidal lamp was used as a 253.7 nm light source. A Toshiba SHL-100 UV high pressure mercury lamp combined with a Toshiba UV-D2 filter was used for the 365 nm source. An Ushio USH-100 superhigh pressure mercury lamp combined with a photographic plate as a filter was used for the experiment at 77 K. A combination of an Ushio UXL-150 xenon lamp and a Hitachi G-3 grating monochromator was used to obtain 280 nm light for the piperylene quenching experiments.

The absorption spectrum and thermal decay were recorded on a Hitachi EPS-3T spectrophotometer at room temperature. The absorption spectrum at 77 K was measured with a Hitachi 356 Dual-Wavelength spectrophotometer. A JEOL Type P-10 ESR spectrometer was used for measurement of the ESR spectrum.

Results and Discussion

Irradiation of the air-saturated solution of HM in acetonitrile by 253.7 nm light at room temperature turned the colorless solution to a yellowish brown. Photochromism occurs in ethyl ether, 1,2-dichloro-

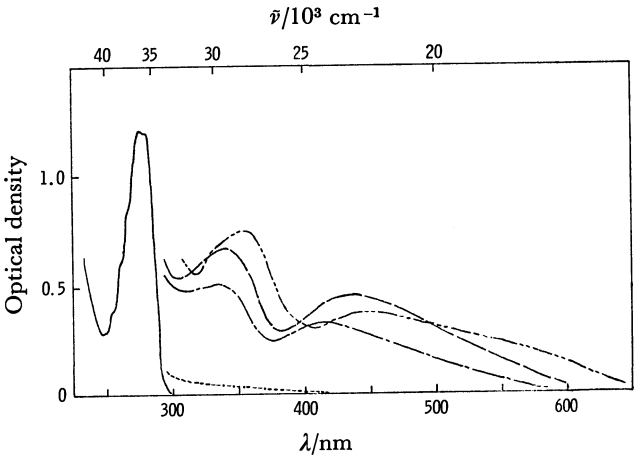

Fig. 1. Absorption spectra of (——) HM in acetonitrile (5.30×10^{-4}M), (----) the colored form in photochromism of HM in acetonitrile, (——) the colored form in photochromism in ethyl ether, and (·····) *ca.* 24 hours aged after the irradiation in acetonitrile ceased. Absorption spectrum of (——) the colored form for thermochromism in acetic acid.

ethane, and benzene and also in the crystalline state. The color bleaches gradually and finally disappears on keeping the solution in the dark. The bleaching, however, is not complete. The absorption spectrum after prolonged storage in the dark indicates the presence of a small amount of the irreversible photoproduct as shown in Fig. 1. The absorption spectra of HM in acetonitrile and its colored form in acetonitrile and ethyl ether are also given in Fig. 1. The absorption maxima of the colored form at 340 (A band) and 440 nm (B band) in acetonitrile shift to 334 and 416 nm respectively in the less polar ethyl ether.

The thermochromic colored form in acetic acid has absorption maxima at 354 and 450 nm. The spectrum closely resembles that of the photochromic colored form as shown in Fig. 1.

The photochromic behavior of HMM in polar solvents is similar to that of HM. In contrast to HM, HMM is photochromic at room temperature in saturated hydrocarbons (*n*-hexane, cyclohexane, methylcyclohexane) in which HM merely decomposes photochemically. Furthermore, thermochromism of HMM was observed in *n*-hexane. Hence, comparison of the absorption spectra of the photochromic and thermochromic forms in the same solvent became possible. As seen from Fig. 2, complete agreement was found between the absorption spectra of the photochromic and thermochromic forms. Consequently, it may safely be concluded that the photochromic form is the same species as the thermochromic one.

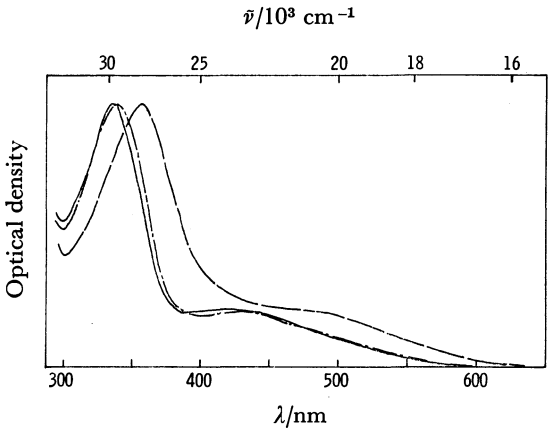

Fig. 2. Absorption spectra (maximum peaks at shorter wavelengths are normalized) of (——) the colorled form in photochromism and thermochromism of HMM in *n*-hexane, (– – –) the colored form in photochromism of HMM in acetonitrile, and (– · –) the colored form in thermochromism of HMM in acetic acid.

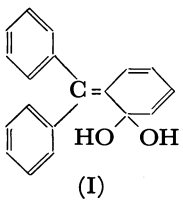
The rate of bleaching measured for the A band agreed well with that for the B band. The ratio of the optical density of the A band to that of the B band is little affected by solvent and temperature. These observations strongly support the view that both A and B bands originate from the same species and the colored form in photochromism as well as in thermochromism consists of a single species.

The absorption spectra of the colored form of HMM are shown in Fig. 2. The absorption maxima shifted to longer wavelengths when the solvent was changed from ethyl ether to acetonitrile. In acetic acid, the absorption maxima were located at considerably longer wavelengths than in acetonitrile in spite of the smaller dielectric constant of acetic acid. This implies the existence of a specific interaction between solute and solvent. The most plausible one is hydrogen bond formation.

2-Hydroxytriphenylmethyl cation is not the colored form, since its absorption spectrum has maxima at 410 and 438 nm. The radical, which is produced frequently in the photochemistry of triphenylmethane derivatives, may also be excluded because the colored form in acetic acid does not give an ESR signal.

Compound (I) may be considered as a possible structure of the colored form. However, 2-methoxytriphenylmethanol shows neither photochrmism nor thermochromism indicating that the 2-hydroxy group plays an important role. Therefore, (I) may be excluded.



(I)

The thermal bleaching reaction of the colored form of HM obeys first-order kinetics. In acetonitrile the bleaching rate constant is proportional to the concentration of water added, whereas the rate constant is little affected by the addition of *n*-hexane. Similar effects of water and *n*-hexane were observed in ethyl ether solution. The result in acetonitrile is shown in Fig. 3. Thus the first-order kinetics observed in acetonitrile and ethyl ether must be pseudo-first order due to the presence of water as an impurity. In dimethoxyethane, which was so carefully dried over sodium-potassium alloy that the solvent became blue in color due to solvated electrons, the order of the bleaching reaction was found to be close to two. Also, it has been reported that HM dehydrates and then forms 9-phenylxanthene at elevated temperatures.[6] Thus it

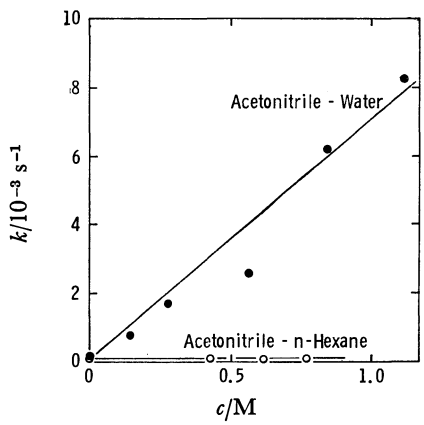


Fig. 3. Effect of added water (●) and *n*-hexane (○) on the first-order bleaching rate constant in acetonitrile.

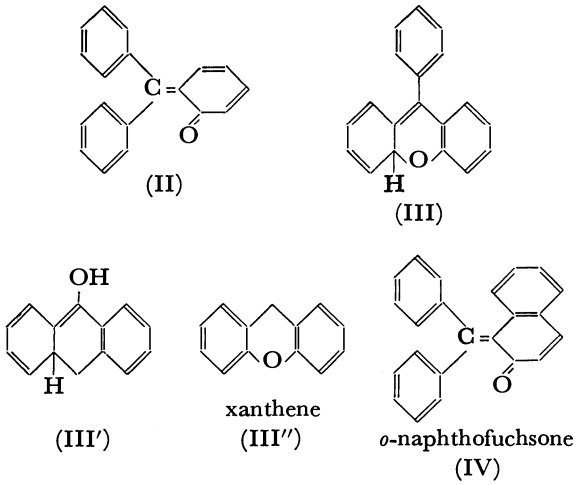
is evident that the colored form is a dehydrated form of HM.

Compounds (II) and (III) are the possible dehydrated forms of HM. In 2-propanol the absorption spectrum of (III') which has some similarities to (III) in its structure has a maximum at 383 nm,[10] considerably to the blue of the peak for the colored form. The large red shift of the absorption spectrum in acetic acid is not expected for (III). A related compound to (III), xanthene (III'') has absorption maxima at 283 nm and shoulders at 287 and 291 nm in both acetonitrile and acetic acid.



If the colored form is (II), *o*-fuchsone, the observed large red shift in acetic acid can be explained by hydrogen bond formation between (II) and acetic acid. *o*-Naphthofuchsone (IV) is a condensed homologue of *o*-fuchsone, and is stable to be isolated. The absorption spectra of (IV) in two solvents are presented in Fig. 4. The absorption maximum at 360 nm in acetonitrile shifts to 370 nm in acetic acid reflecting the hydrogen bonding with the acetic acid.

Although the colored form can not be isolated for structural determination, spectral and kinetic behavior strongly supports reaction scheme (1) for photochromism as well as thermochromism.

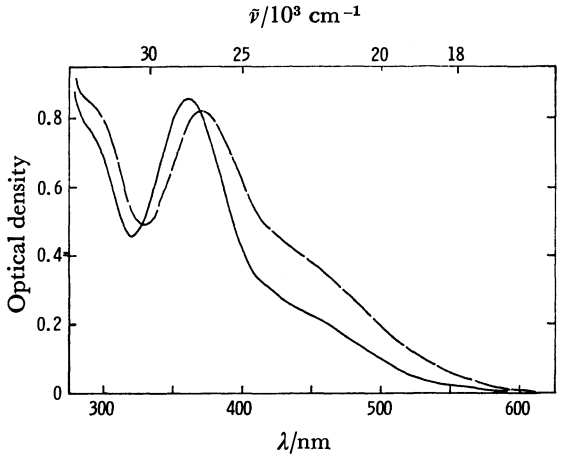


Fig. 4. Absorption spectra of *o*-naphthofuchsone (——) in acetonitrile (1.0×10^{-4}M) and (----) in acetic acid (1.04×10^{-4}M).

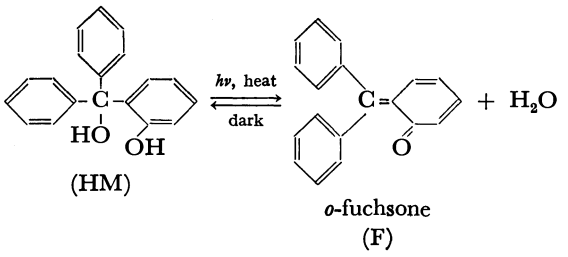

Scheme 1.

This is a new reaction mechanism for photochromism and thermochromism of triarylmethane derivatives.

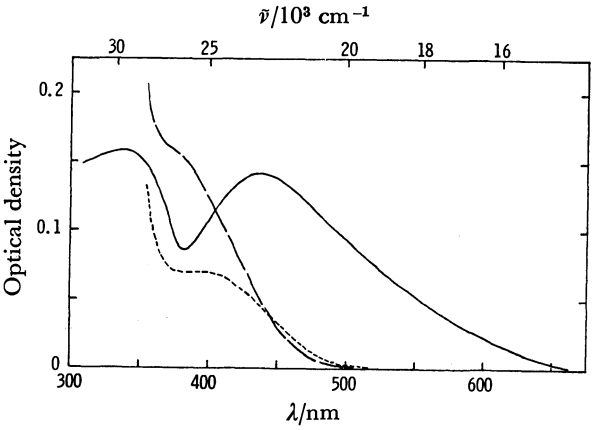

Fig. 5. Absorption spectra of (——) the colored form of ClHM in acetonitrile, (----) after irradiation of HNM, and (·····) *ca.* 24 hours aged after the irradiation in acetonitrile for HNM ceased.

5-Chloro-2-hydroxytriphenylmethanol (ClHM) and (3-hydroxy-2-naphthyl)-diphenylmethanol (HNM) showed the same type of photochromism as HM and HMM. In the case of HNM, however, an irreversible reaction became important. Figure 5 shows absorption spectra of the colored forms of ClHM and HNM.

Photochemical Reaction, Photo and Thermal Bleaching at Room Temperature. Tables 1 and 2 show the effect of the concentration and light intensity on the quantum

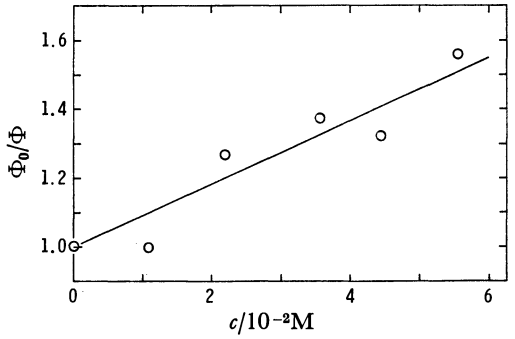

Fig. 6. Quenching by biacetyl in acetonitrile.

yield of the photochemical reaction, HM to F, in acetonitrile. Both concentration and light intensity do not affect the quantum yield, so that the reaction is a one-photon process. The result of the quenching of the photochemical reaction by biacetyl is given in Fig. 6. Quenching by piperylene is very small, if any occurs at all, whereas biacetyl quenches the photochemical reaction significantly. Since piperylene can quench only the triplet state of HM, whereas biacetyl quenches both singlet and triplet states, the state quenched by biacetyl must be the singlet state. The lifetime of the excited singlet state was estimated to be 0.54 ns from the slope of Φ_0/Φ *vs.* concentration of biacetyl in Fig. 6 with the assumption that quenching occurs at the diffusion-controlled rate.

A reactive singlet state with a short lifetime is consistent with the observation that the photochemical reaction occurs even in air-saturated solutions and that no transient intermediate was observed by conventional flash photolysis. Since triphenylmethyl radical is produced from the triplet state,[11,12] HM radical is not a reaction intermediate. Other species, such as phenoxy radical and phenoxy anion derivatives, are not intermediates, since in triphenylmethane derivatives C–H bond cleavage at the central carbon atom generally occurs,[1] and no transient was observed by flash photolysis. Therefore, the photoreaction of HM occurs by a one-step process.

Irradiation by 365 nm light which is absorbed solely by the colored form F accelerates the bleaching of F. This photobleaching occurs not only in air-saturated solutions but also in nitrogen-saturated solutions. The rate constant for thermal bleaching is the same in air and nitrogen-saturated solutions, and also the same before and after the 365 nm irradiation. During the irradiation photo and thermal bleaching occur simultaneously and independently. The rate of bleaching of F is given by

$$-\frac{dC_F}{dt} = \phi'' I_0'(1-10^{-OD})\frac{\varepsilon_F C_F}{OD}\times 10^3 + kC_F \qquad (1)$$

where ε_F is the molar extinction coefficient, OD is the optical density, I_0' is the light intensity at 365 nm, ϕ'' is the quantum yield of photobleaching, k is the thermal bleaching rate constant, and C_F is the concentration of F. Integration of Eq. (1) leads to

$$\ln\frac{OD_F^0}{OD_F} - kt = \phi'' I_0'\varepsilon_F\times 10^3\int(1-10^{-OD})\frac{dt}{OD} \qquad (2)$$

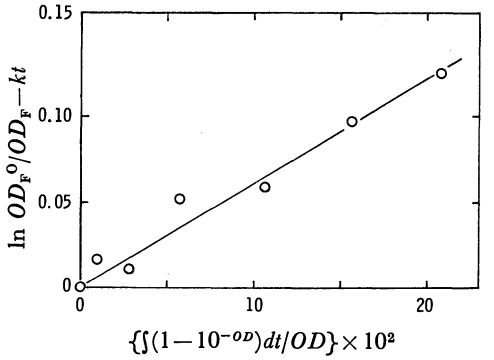

Fig. 7. Plot of $\ln OD_F^0/OD_F - kt$ *vs.* $\{\int(1-10^{-OD})\,dt/OD\}\times 10^2$ in acetonitrile. Suffix, F, stands for the colored form. The exciting wavelength is 365 nm.

where OD_F^0 is the initial optical density. Evaluation of the integral part of Eq. (2) was performed graphically. Plots of $(\ln OD_F^0/OD_F - kt)$ *vs.* $\int(1-10^{-OD})dt/OD$ are presented in Fig. 7. Using ε_F determined by a method described later, ϕ's were estimated to be 0.0079 for air-saturated and 0.12 for nitrogen-saturated solutions. The large discrepancy in the quantum yields means that the reaction of the triplet state of F is the major process in the photobleaching.

When the photochemical reaction of HM is in equilibrium with the photo and thermal bleaching reactions, Eq. (3) holds.

$$I_0(1-10^{-OD})\frac{\varepsilon C}{OD}\times 10^3 = \phi' I_0(1-10^{-OD})\frac{\varepsilon_F' C_F}{OD}\times 10^3 + kC_F \qquad (3)$$

where ε and ε'_F are the molar extinction coefficients of HM and F at 253.7 nm, C is the concentration of HM, ϕ and ϕ' are the quantum yields of photochemical reaction of HM and photobleaching of F, OD is the optical density at 253.7 nm, and I_0, the light intensity at 253.7 nm. Since the irreversible portion of the photochemical reaction of HM is quite small, $C_0 = C + C_F$ holds approximately, where C_0 stands for the initial concentration of HM. Then Eq. (3) is reduced to:

$$\frac{C_0}{OD_F^\lambda} = \frac{1}{\varepsilon_F^\lambda}\left(1+\frac{\phi'\varepsilon_F}{\phi\varepsilon}\right) + \frac{kOD}{\varepsilon_F^\lambda\varepsilon\phi I_0(1-10^{-OD})\times 10^3} \qquad (4)$$

where the superscript λ represents a value at a wavelength λ. Since, it is probable that ϕ' is not so different from the ϕ'' determined already, $\phi'\varepsilon_F/\phi\varepsilon$ may be very small compared to 1. Thus, Eq. (4) may be simplified to

$$\frac{C_0}{OD_F^\lambda} = \frac{1}{\varepsilon_F^\lambda} + \frac{kOD}{\varepsilon_F^\lambda\varepsilon\phi I_0(1-10^{-OD})\times 10^3} \qquad (5)$$

An analysis at 340 nm is given in Fig. 8. ε_F^{340} was determined to be 4.76×10^3. ϕ was found to be 0.62. The same value of ϕ was obtained at 440 nm. The fairly high value of the photochemical quantum yield in aerated solution provides further evidence that the reactive state is predominantly the excited singlet state.

Photochemical Reaction at 77 K. The absorption spectra of the photoproducts from HM in methanol-

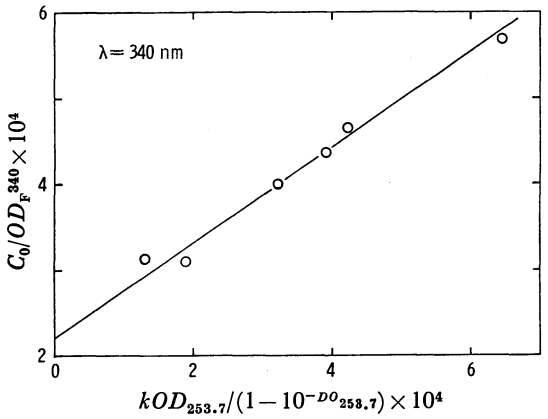

Fig. 8. Plot of $C_0/OD_F^{340}\times10^4$ *vs.* $kOD_{235.7}/(1-10^{-OD_{253.7}})\times10^4$ in acetonitrile. C_0, k, OD^{340} and $OD_{253.7}$ are the initial concentration of HM, the bleaching rate constant, the optical density of the colored form at 340 nm and the optical density at 253.7 nm.

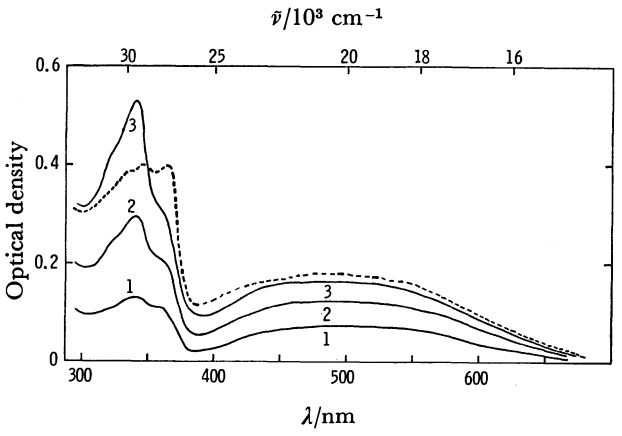

Fig. 9. Absorption spectra of the irradiated HM in methanol–ethanol (1:1) at 77 K; 1— after 10 minute irradiation, 2—35 minutes, 3—115 minutes; ---- cooled to 77 K immediately after melting the solution.

ethanol mixture (1: 1 in volume) at 77 K are shown in Fig. 9 for different irradiation times. The increase in optical density at 340 nm is larger than that at 480 nm indicating that the product is not a single species, since HM has no absorption in this wavelength region. The irradiated glassy solution was allowed to melt and cooled to 77 K again immediately. The resulting absorption spectrum is the dotted curve in Fig. 9. The decrease in optical density around 340 nm is appreciable. 2-Methoxytriphenylmethyl radical obtained by irradiation of 2-methoxytriphenylmethanol under the same conditions as for HM has an absorption maximum at 338 nm. Hence, the absorption around 340 nm belongs to 2-hydroxytriphenylmethyl radical (HM radical) generated photochemically. This conclusion is also supported by the ESR spectra. The irradiated HM solution shows ESR signals which can be assigned to methanol, ethanol, formyl, and HM radicals. All these signals disappear upon melting of the solution, and do not reappear on freezing the solution again.

The solution initially irradiated by 253.7 nm was further irradiated by the light from a superhigh pressure mercury lamp filtered by either a Toshiba VY-43 (transmits longer than —430 nm) or a photographic plate (longer than —300 nm). No change in the absorption spectrum was observed, so that the mechanism by which HM radical is produced by hydrogen atom abstraction of excited F from the surrounding solvent molecules may be almost excluded. It might be possible, however, that F excited by 253.7 nm abstracts hydrogen and that another kind of biphotonic process occurs on 253.7 nm irradiation.

The formation of F is a one-photon process as it is at room temperature, since the yield of F at the early stage of the reaction is proportional to the light intensity.

We are indebted to Prof. N. Suzuki and Mr. H. Watarai, M.S. at Tohoku University for the use of a Hitachi 356 Dual-Wavelength Spectrophotometer.

The Mechanism of the Selective Hydrogenation of 1,3-Butadiene on Copper Surfaces

Eiji NISHIMURA, Yasunobu INOUE, and Iwao YASUMORI

Department of Chemistry, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152

(Received August 3, 1974)

The hydrogenation of 1,3-butadiene on copper surfaces was studied in detail. A highly selective formation of 1-butene was observed in the range of temperatures from 27 to 76 °C; the initial rate of the formation was well expressed in terms of the partial pressures of hydrogen, p_h, and butadiene, p_b, as $v=kp_h/(1+Kp_b)^2$ in the pressure range of 5—100 Torr. The reaction with D_2 gave butene-d_0 and -d_1 as the main products, and the butadiene was partly exchanged with D_2 during the hydrogenation. The microwave spectroscopic analysis revealed that the 1-butene produced consisted of $CH_2=CHCH_2CH_2D$, $CH_2=CHCHDCH_3$, and $CHD=CHCH_2CH_3$, without even a trace of $CH_2=CDCH_2CH_3$. Therefore, it was concluded that the reaction proceeds *via* the isobutenyl surface intermediate and that the dissociative adsorption of hydrogen is rate-determining. The structural analysis of the surface suggested that the stable lattice planes, such as (111), (100), and (110), are responsible for the reaction. The origin of the high 1-butene selectivity was discussed on the basis of the surface geometry and the proposed mechanism.

The hydrogenation of 1,3-butadiene has frequently been investigated from the viewpoint of selective catalysis, but it has been studied mainly on such d-metals as Ni,[1] Pd, and Pt.[2,3] Though the reaction on these metals produces 1-butene, *trans*-2-butene, *cis*-2-butene, and a smaller amount of *n*-butane from the initial stage of reaction, the isomer distributions of the produced butenes are considerably different from each other. In order to explain this variation, reaction mechanisms including such surface intermediates as π-allylic or σ-π-bonded species have been proposed. The identification of these adsorbed species, however, has not always been successful because of the complication of the simultaneous formation of butene isomers. On the other hand, it has been found that copper, a typical s-metal, is highly selective in the formation of 1-butene. However, only a few works of the hydrogenation on this metal have been reported,[1] and the features of the reaction are not known in detail. The aim of the present study is to ascertain the mechanism of the reaction and to reveal the origin of the high selectivity on the basis of the structure of the copper surface and the mechanism.

In order to ascertain the detailed mechanism of the reaction, the deuterium distribution in the products and the reactants on the reaction with deuterium were examined mass-spectroscopically; further, the deuterated positions of the produced 1-butene-d_1 and their relative abundances were determined by applying microwave spectroscopic analysis. The adsorbed states of hydrogen and butadiene were analyzed by using the thermal-desorption technique.

In the study of butadiene hydrogenation on Ni, it was found that a drastic change in activity and selectivity occurred when Ni was annealed in the temperature range of 350—400 °C.[4] A similar change in the activity was observed in the acetylene hydrogenation on Pd when the catalyst was annealed at temperatures between 250 and 300 °C. These results show that fine structures such as surface vacancies play an important role in the reactions.[5] In the present study, the effect of annealing on these catalytic properties was examined over a wide range of annealing temperatures, from 180 to 500 °C; the corresponding change in surface structure was followed by means of X-ray and electron diffractions.

Experimental

The kinetic measurements were carried out by using conventional closed systems of 360 or 670 ml incorporating a circulation pump. The reaction was examined in the range of temperature from 27 to 76 °C and in the range of total pressure between 5 and 100 Torr. The pressure change during the course of reaction was followed by means of a glass Bourdon gauge, while the composition of the products was determined by the use of a gas chromatograph connected to the reaction system. A 16 m DMS column was used at room temperature for the separation of butadiene, butenes, and butane.

The copper powder catalyst was prepared in a way similar to the method reported by Hirota *et al.*[6] Copper nitrate, $Cu(NO_3)_2\cdot 3H_2O$ of a guaranteed-reagent grade, was dissolved into distilled water at 80 °C, and then a 20% solution of NaOH was added steadily. The copper oxide thus precipitated was washed several times, calcinated in air at 110 °C for 1 hr, and then evacuated for 1 hr. Prior to the reaction, the oxide was reduced *in situ* with hydrogen of 100 Torr at 180 °C for 3 days and then evacuated for 2 hr at the same temperature. Though a step-by-step decrease in the activity occurred in a repeated run, contact with H_2 at 180 °C prior to each kinetic run could recover the initial activity within a 10% decrease. The catalytic activity was also examined on copper catalysts annealed at 300, 400, and 500 °C *in vacuo* for 1 hr. The surface area was evaluated by means of the BET method, using Kr at 77 K, while the change in surface structure was investigated by means of the X-ray and electron diffractions.

In the reaction of butadiene with D_2, the products were separated gas chromatographically, and the deuterium distributions in respective components were determined by using a mass spectrometer, Hitachi RMU-5B. The relative abundance of 1-butene-d_1 and -d_2 with different deuterium positions was determined by means of microwave spectroscopy.[7] Hydrogen, hydrogen deuteride and deuterium were analyzed gas chromatographically.[8]

The thermal desorption spectra were obtained by using an apparatus which could be pumped out at a constant rate

during the desorption of surface species from the heated catalyst. Copper (1.06 g) was exposed to hydrogen or butadiene of 10 Torr at room temperature for 10 min; then it was cooled and evacuated at −78 °C for several minutes. The temperature of the cell containing copper was raised at a constant rate of 0.14 °C/s by means of an electric furnace. The pressure of the desorbed gases was monitored by means of a Pirani gauge, and the composition of the desorbed gas was determined by using a quadrupole mass spectrometer.

Butadiene (99.6% purity), hydrogen (99.9%), and deuterium (containing 0.3% HD) were obtained from the Takachiho Co., Ltd., and were used without further purification.

Results

A typical time-course of the hydrogenation, when the copper catalyst was reduced at 180 °C, is shown in Fig. 1. The only products at the initial stage were butenes; the absence of butane was evident. The butenes consisted of 1-butene (92%), *t*-2-butene (3%), and *c*-2-butene (5%); this composition was almost unchanged until more than 95% of the butadiene had been consumed. This finding predicts that, in the initial stage of the reaction, each butene is formed directly by the hydrogenation of adsorbed butadiene and that the butenes, once desorbed into the gas phase, hardly participate in the further process of the reaction. After the butadiene in the gas phase had disappeared, however, the isomerization of 1-butene and the slow hydrogenation of butenes took place concurrently, producing 2-butenes and *n*-butane respectively. This selective formation of 1-butene was observed also on the Cu annealed at 500 °C under similar conditions. In the absence of hydrogen, neither the isomerization nor hydrogenation occurred, not even at 76 °C, the highest reaction temperature in the present study.

Kinetics of Hydrogenation. The kinetic measurements were carried out in the temperature range of 27—76 °C, using Cu annealed at 180 and 500 °C. By changing the partial pressure of hydrogen from 13 to 97 Torr, and that of butadiene from 7 to 36 Torr, the initial rate of 1-butene formation, v, was measured. It was found that the rate was proportional to the hydrogen pressure, p_h, and that a linear relationship held between the square root of the reciprocal of v and the butadiene pressure, p_b, as is shown in Fig. 2. Accordingly, the rate was well expressed in this form;

$$v = kp_h/(1+Kp_b)^2 \quad (1)$$

where k and K are constants. From the temperature dependence of the rate, the apparent energy of activation was estimated; it is listed in Table 1, together with that for the reaction with D_2.

Annealing temperature	Reaction	Activation energy (kcal/mol)
180 °C	$C_4H_6+H_2$	13.5±0.2
180 °C	$C_4H_6+D_2$	13.8±0.1
500 °C	$C_4H_6+H_2$	13.4±0.2

Deuterium Distributions. The distributions of deuterium in butenes and butadiene were investigated on the reaction with deuterium at 50 °C. Figure 3 shows the changes in the fractions of 1-butene-d_0~-d_3 with the degree of conversion. In the stage of low conversion, the main products were 1-butene-d_0 and -d_1. The decrease in 1-butene-d_0 with an increase in the conversion was counterbalanced by the formation of d_1~d_3 compounds. It should be noted that a considerable amount of butadiene-d_1 appeared as the reaction proceeded; at 40% conversion, the d_1 fraction

reached 35% of all the butadienes, as is shown in Fig. 4. It is apparent that the formation of 1-butene-d_2 and -d_3 in the region of high conversion is due to the hydrogenation of deuterobutadiene. On the other hand, a negligibly small amount of HD was found in the gas phase. In the reaction of butadiene with an equi-molar mixture of H_2 and D_2, the amount of HD produced was also negligibly small. These results clearly indicate that the recombination of surface hydrogen into the molecule is very slow.

The microwave spectroscopic analysis was applied to the products at conversions of 15.5 and 48%. The results for butene-d_1 are summarized in Table 2. The deuterium positions of products other than 1-butene-d_1 could not be determined because of their small yields (below the limits of analysis). As may be seen from Table 2, about 54% of the CH_2=$CHCH_2CH_2D$ (4-d_1) and 31% of the CH_2=$CHCHDCH_3$ (3-d_1) were formed at the stage of low conversion. A small fraction, 15%, of CHD=$CHCH_2CH_3$ (1-d_1) was also produced, but CH_2=$CDCH_2CH_3$ (2-d_1) was not detected. The increase in the fraction of the 1-d_1 component was compensated for the decrease in that of the 3-d_1 compound.

b) Values in parentheses represent deuterium fraction per hydrogen atom.

The rate of the reaction with H_2 was approximately five times as fast as that of the reaction with D_2 at 50 °C. This isotope effect is mainly attributable to the mass ratio, $(m_D/m_H)^{5/2}$, in the frequency factors of the hydrogen and deuterium adsorption rates, though the difference in activation energy contributes to some extent.

Adsorbed States of Hydrogen and Butadiene. By the use of copper annealed at 180 °C, the adsorption measurement of butadiene was carried out at 50 °C under pressures up to 30 Torr. The adsorption was saturated at equilibrium pressures higher than 7 Torr, and the surface was occupied by 1.9×10^{14} molecules/cm^2, corresponding to about 20% of all the surface Cu atoms. After the evacuation at 50 °C, a considerable amount of the butadiene, 1.3×10^{14} molecules/cm^2, still remained on the surface. The reaction with hydrogen at the same temperature decreased this strongly bound butadiene to 0.47×10^{14} molecules/cm^2, with a slower rate compared to the stationary rate of the hydrogenation.

The thermal desorption spectra of butadiene showed a broad peak which spread over −40~100 °C, with a maximum at 53 °C, indicating that even the most strongly adsorbed butadiene is almost desorbed at temperatures higher than 100 °C. On the other hand, the desorption spectra of hydrogen showed a sharp peak with a maximum at 58 °C; this peak has the characteristic shape of the second-order desorption, indicating a drastic fall on the high-temperature side. This result suggests that the hydrogen is adsorbed dissociatively and exists in a single state on the surface.

Carbon monoxide was added to the reactant up to 22 Torr, but no decay in the activity was observed. However, a preliminary study of ethylene hydrogenation at 50 °C using an equi-molar mixture of ethylene and hydrogen (24 Torr in total pressure) showed that the activity of the copper catalyst decreased proportionally with the pressure of the introduced CO up to about 3 Torr. These results provide evidence of the stronger bond between butadiene and the copper surface than that between ethylene and Cu.

Effect of Annealing on the Activity and the Surface Structure. The effect of annealing on the catalytic activity and the surface area is shown in Fig. 5. It is evident that the decreases in the activity and the surface area are parallel with each other, keeping the specific

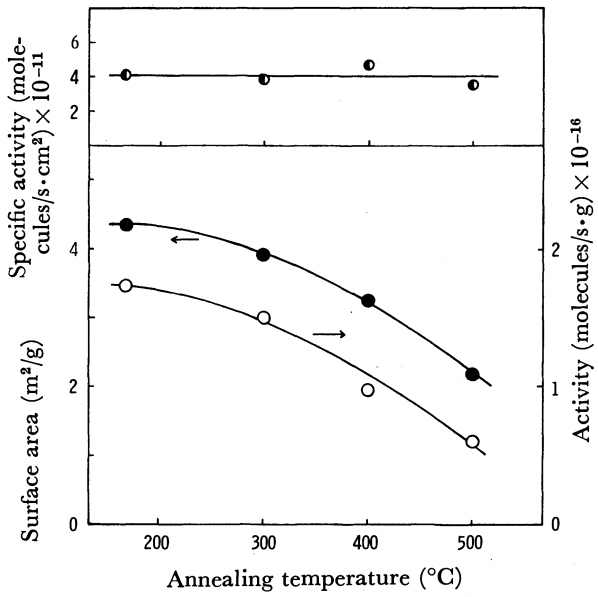

Fig. 5. The changes in activity and surface area with annealing temperature.

activity, the rate per unit area, constant. In the case of the 500 °C-annealed Cu, the selectivity of 1-butene formation was higher than 90% and the activation energy was estimated as 13.4 kcal/mol, as is shown in Table 1. These values coincide with those in the case of the 180 °C-annealed Cu.

X-Ray and electron diffractions of the 180 °C-annealed Cu showed the characteristic patterns due to the (111), (220), and (200) planes. When the copper was annealed at 500 °C, the pattern remained almost unchanged, except that the intensity of the (200) plane became slightly weaker. These findings were in close agreement with those observed by Yamaguchi[9] and by Young *et al.*[10] and showed that the exposed surface was mainly composed of the stable (111), (100), and (110).

Discussion

In the present study using the Cu metal, the high selectivity of 1-butene formation was observed under all the conditions used. The kinetics of the reaction on Cu is not markedly different from those on Pd, Pt, and Ni metals of lower selectivities. However, there were some differences in the activation energy; the value for Cu is considerably higher than those for the other metals. The dissociative adsorption of hydrogen on Cu was also confirmed from a study of the H_2–D_2 equilibration reaction.[11] The adsorption and the thermal-desorption measurements showed that the Cu surface was covered, to a large extent, with butadiene, which is in the reversibly adsorbed and the strongly bound states. The mass analyses showed a considerable formation of butadiene-d_1 and -d_2 during the hydrogenation with deuterium. However, it is clear that the dissociatively adsorbed butadiene scarcely contributes at all to the hydrogenation, since 1-butene-2-d_1 was completely absent in the products, whereas 1-butene-3-d_1 were present in large amounts. Hence, the reversibly adsorbed butadiene and butenyl radicals can be suggested as the intermediates. The following reaction scheme is proposed:

$$C_4H_6 \underset{\overleftarrow{Ia}}{\overset{\overrightarrow{Ia}}{\rightleftharpoons}} C_4H_6(a) \qquad (Ia)$$

$$H_2 \underset{\overleftarrow{Ib}}{\overset{\overrightarrow{Ib}}{\rightleftharpoons}} 2H(a) \qquad (Ib)$$

$$H(a) + C_4H_6(a) \underset{\overleftarrow{II}}{\overset{\overrightarrow{II}}{\rightleftharpoons}} C_4H_7(a) \qquad (II)$$

$$H(a) + C_4H_7(a) \xrightarrow{\overrightarrow{III}} C_4H_8 \qquad (III)$$

where the symbol (a) denotes the adsorbed state which participates in the reaction. The first-order dependence of the rate with respect to the hydrogen pressure leads to the conclusion that either step, $\overrightarrow{Ib}$ or $\overrightarrow{III}$, is rate-determining. In both reactions, with D_2 and with an equimolar mixture of H_2 and D_2, the amount of HD formed was found to be negligibly small. This suggests that the adsorption of hydrogen is irreversible during the hydrogenation. Accordingly, the $\overrightarrow{Ib}$ step is considered to be rate-determining and the rate of hydrogenation is given by:

$$v = k_1 p_h (1-\theta_b)^2 \qquad (2)$$

where θ_b is the fraction of surface coverage of the reversibly adsorbed butadiene and where k_1 is the rate constant of the $\overrightarrow{Ib}$ step. When the pseudo-equilibrium between gaseous and adsorbed butadiene is established, θ_b is expressed as:

$$\theta_b = Kp_b/(1+Kp_b) \qquad (3)$$

where K is the adsorption constant. Then, by substituting Eq. (3) to Eq. (2), the final expression:

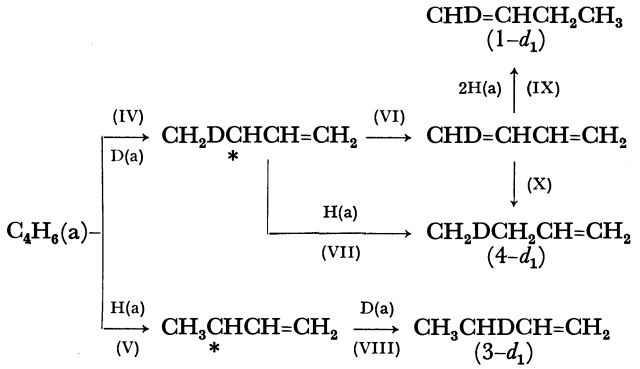
$$v = k_1 p_h/(1+Kp_b)^2 \qquad (4)$$

is obtained. The pressure dependence shown by this equation is in accord with the empirical one given by Eq. (1). It should be noted that the same rate-determining step was concluded in the hydrogenation of ethylene on evaporated copper film at low temperatures.[12] No other mechanism which includes the disproportionation between two adsorbed butenyls as the rate-determining step can interpret the observed dependence of the rate on the butadiene pressure.

The remarkable formation of butene-d_0 at the early stage of reaction was quite similar to the formation of ethane-d_0 in the C_2H_4–D_2 reaction on the Ni surface.[13] The present situation of the reaction predicts the following order of the rates of elementary processes: $v(\overrightarrow{Ib}) < v(\overrightarrow{III}) < v(\overrightarrow{Ia}) \simeq v(\overleftarrow{Ia}) \simeq v(\overrightarrow{II}) \simeq v(\overleftarrow{II})$. Thus, it can be understood why the concentration of surface hydrogen becomes reasonably high, because the adsorbed deuterium is quickly consumed through the Ia and II steps by exchanging with hydrogen atoms in the hydrocarbon species. The observed isotope effect on the hydrogenation can be related to the straightforward isotope effect, as is seen in the adsorption of hydrogen and deuterium on copper.[11]

Transition metals of Group VIII, such as Ni,[1] Pd, and Pt,[2,3] provide a considerable amount of *trans*-2-

and *cis*-2-butenes in the products of the hydrogenation. These results can be explained by assuming π-allylic or σ-π bonded intermediates formed by the simultaneous interaction of two double bonds in butadiene with the surface atoms. In the case of copper, however, the absence of 2-butenes predicts that only one double bond of the molecule associates with the surface. The formation of 1-butene-1-d_1, 3-d_1 and 4-d_1 can be well expressed by making use of this adsorbed state:



where the asterisk indicates the active site. The attack of the terminal and second carbon atoms of the adsorbed butadiene with D and then H atoms produces butene-4-d_1 (IV and VII). The formation of 3-d_1 is attributed to the hydrogen addition in the reversed order (V and VIII). In the case of 1-d_1 formation, however, deuteriobutadiene-1-d_1 is hydrogenated with two hydrogen atoms (VI and IX). It is clear that no *n*-butenyl such as $\overset{*}{C}H_2CH_2CH=CH_2$ is produced on the surface, since such a formation would result in the formation of butadiene-d_1, $CH_2=CDCH=CH_2$, the subsequent hydrogenation of which would produce both butene-2-d_1 and -3-d_1 in similar amounts. Therefore, it may safely be concluded that the reaction intermediate is isobutenyl, $CH_3\overset{*}{C}HCH=CH_2$. At a high conversion of 48%, the fraction of deuterium at the 1t and 1c positions increases and that of 3-d_1 decreases. As the partial pressure of mono-deuteriobutadiene became higher with an increase in the conversion, the chance of a reaction proceeding *via* Steps (IX) and (X) increases as compared to the chance *via* Step (VIII).

The importance of surface defects in catalysis has been pointed out; Uhara *et al.*[14] reported that the activity of Cu on the decomposition of benzene diazonium chloride was markedly depressed by heat treatment around 350 °C and correlated this depression with the disappearance of dislocations. However, in the present study the decrease in the catalytic activity due to annealing was parallel to that of the surface area. This suggests that the activity of the hydrogenation is not due to the characteristic surface structure of defects, but depends only on the number of exposed metal atoms.[15] The fact that annealing at 500 and 180 °C makes no difference in the activation energy provides other evidence for this conclusion. The present result also supports the previous conclusion that the structural defects in the s-metals are less important in catalysis.[11]

X-Ray and electron diffraction studies indicated that the surfaces of Cu annealed at 180 and 500 °C were mainly composed of low index planes, such as (111), (100), and (110). The valence state of copper is characterized by a half-filled s-band which makes no directed bond. Therefore, the atomic distance in the lattice plane becomes a dominant factor in the interaction with adsorbed molecules. These lattice planes have the closest atomic distance of 2.56 Å; this configuration is not suited to the simultaneous use of two double bonds of butadiene upon adsorption, because the carbon-to-carbon bond length, 1.48 Å, is too short to make a bridge between two copper atoms. As for the isobutenyl radical on the surface, the length of the carbon chain containing a double bond is 1.54 Å. The intermediate can hardly find the copper atom located at a suitable position where the remaining double bond may interact so as to give adsorbed 2-butenes. Accordingly, it seems reasonable that this surface geometry is responsible for the high selectivity of 1-butene formation.

The authors wish to thank Dr. Shuji Saito of the Sagami Chemical Research Center for making the microwave spectroscopic measurements.

Positron Lifetimes in γ-Irradiated Eicosane and Polyethylene

Yasuo Ito and Yoneho Tabata*

National Universities' Laboratory for the Common Use of JAERI Facilities, Japan Atomic Energy Research Institute, Tokai-mura, Ibaraki 319-11

**Nuclear Engineering Research Laboratory, Faculty of Engineering, University of Tokyo, Tokai-mura, Ibaraki 319-11*

(Received August 15, 1974)

The positron lifetimes in a γ-irradiated single crystal of *n*-eicosane and amorphous polyethylene have been measured at -78 °C in a vacuum. The lifetime, τ_2, of the long-lived component decreases upon irradiation in both systems, and the increase in the annihilation rate, λ_2, is proportional to the concentration of free radicals. Assuming that the decrease in τ_2 is entirely due to the reaction of orthopositronium (*o*-Ps) with free radicals, the diffusion constant of *o*-Ps has been estimated to be $D=0.58$—1.75×10^{-5} cm^2 s^{-1}. The intensity, I_2, of the long-lived component decreases markedly in *n*-eicosane, levelling off at about 20%. I_2 in polyethylene does not decrease upon irradiation. Some possible explanations are given.

It is a well-known fact that the lifetime spectra of positrons in solids are influenced both by the chemical properties and by the physical structure.[1] A fraction of the positrons can capture an electron from the surrounding medium and form a bound state called "positronium". The positronium with a total spin number of $S=0$ is called the "parapositronium" (*p*-Ps). The lifetime of *p*-Ps is small ($\tau_p=0.125$ ns), and usually we cannot distinguish, with our conventional time-analyzer, this lifetime component from that of free positrons.

The positronium with a total spin number of $S=1$ is called the "orthopositronium" (*o*-Ps). The lifetime of *o*-Ps is 140 ns in a vacuum, but it is much shortened as a result of the following processes: 1) pick-off quenching, 2) conversion quenching, and 3) chemical quenching.

In a condensed medium, a positron in *o*-Ps has an opportunity to sample an electron in the medium and be annihilated into two gamma quanta. This is called "pick-off quenching." In general, the lifetime of *o*-Ps becomes shorter in a smaller free volume, because, in a smaller free volume, the positron in *o*-Ps has a larger opportunity to sample electrons in the medium. This phenomenon is called the "free volume effect" on *o*-Ps lifetimes.

If the medium contains paramagnetic species, *o*-Ps may be converted to *p*-Ps upon collision with them. The lifetime of *o*-Ps is also reduced by this process. This is called "conversion quenching."

If there are molecules which are reactive toward *o*-Ps to form a positronium compound, the lifetime of *o*-Ps is also reduced, because in a positronium compound the positron has a large opportunity to be annihilated with electrons in the compound. This is called "chemical quenching."

The formation probability of positronium, on the other hand, ranges from 0 to about 50%, depending on the substance. The so-called "Ore model" provides a simple method to estimate the formation probability. This model states that positronium formation is predominant in the region of positron energies from E (the energy of excitation of the first electron level of molecules) to $V-6.8$ eV (V is the ionization potential of molecules, and 6.8 eV is the dissociation energy of positronium). This model, however, must be modified in a condensed phase because of the affinity of the medium to electrons, positrons, and positronium. However, even without these complicating factors, there are cases where the formation of positronium is inhibited due to: 1) the process of the inelastic slowing down of positrons, as a result of which positrons quickly go below the Ore gap and 2) the process of the capture of positrons in the energy region of the Ore gap. Furthermore, in certain circumstances it is possible that positronium is chemically quenched, while it is not thermalized; in this case, the apparent formation probability of positronium may be decreased.

All of the above processes can be affected by radiation-induced changes in solid materials. It has indeed been reported by the present authors[2] and by others[3] that the positron lifetime spectra in various organic solids are altered in various ways by γ-irradiation.

In this paper we wish to report the results of our positron lifetime measurements in γ-irradiated *n*-eicosane (*n*-$C_{20}H_{42}$) and polyethylene. The former has been obtained in the form of single crystals, while the latter is known to contain many amorphous regions and defects. Positron annihilation studies in irradiated polyethylene have been reported by Chandra *et al.*[3a] and J. H. Green *et al.*;[3c] however, since their studies were carried out with samples in air at room temperature, many complex radiation chemical changes should have been taking place and it is difficult to interpret the changes in the lifetime spectra. In order to avoid such complexity, it is advantageous to carry out γ-irradiation and lifetime measurements at a lower temperature *in vacuo*.

Experimental

Sample Preparation. About 15 μCi of ^{22}NaCl was deposited on two single crystals of *n*-eicosane. They were positioned face to face on the deposited side and then placed in a glass ampoule which was subsequently sealed off in a vacuum.

Polyethylene, which had been supplied and named "Takathene" by the Takasaki Radiation Chemistry Research Establishment, JAERI, is the product of the high-pressure radiation-induced polymerization of gaseous ethylene; therefore, it is expected to contain no impurities. This polymer

was pressed in the form of two tablets ($10\phi \times 3$ mm), which were then prepared as a sample for lifetime measurement in the same manner as in the case of *n*-eicosane.

Irradiation and Measurements. Both lifetime measurements and γ-irradiations were carried out at -78 °C, except for those in which the samples were irradiated and measured at room temperature for the sake of comparison.

The lifetime measurements were carried out with a conventional time-analyzer using delayed coincidence technique as has been reported previously.[2] The resolution of the, time-analyzer was 0.34 ns at full width at half maximum of the Co-60 prompt peak for the Na-22 energy selection. It took a run of about 2 days to obtain a single spectrum with a total of approximately 5×10^5 counts. The peak-to-background ratio was greater than 10^4. The lifetime spectra were analyzed by the method of least squares to determine the intensity, I_2, and the lifetime, τ_2, of the long-lived component. The intensity was calculated as the ratio of the area of the long-lived component to that of the total area under the distribution curve.

The concentration of free radicals was measured with an ESR spectrometer (JEOL PE-3X) using a calibrated amount of DPPH in a benzene solution frozen at -78 °C as a standard.

Results and Discussion

Positron Lifetimes in Non-irradiated Samples. The lifetime spectra in *n*-eicosane and polyethylene could be resolved into two components. The mean lifetimes and intensities for non-irradiated samples are given in Table 1. Each datum is the average of at least three measurements carried out under different instrumental conditions—*i.e.*, with different window widths of the wide-channel energy selection and with different time widths per channel (0.05—0.10 ns/channel).

Table 1. Positron annihilation data for *n*-eicosane and takathene before irradiation

	τ_1 (ns)	τ_2 (ns)	I_2 (%)
n-Eicosane (-78 °C)	0.124±0.02	1.15±0.05	52.7±1.5
n-Eicosane (0 °C)	0.28 ±0.03	1.32±0.02	30.4±0.8
Takathene (-78 °C)	0.19 ±0.02	1.71±0.05	29.3±1.0
Takathene (0 °C)	0.36 ±0.04	2.62±0.05	19.2±3

It has often been reported that there are two *o*-Ps components in most polymeric systems, the longer component being attributed to *o*-Ps annihilation in amorphous regions and the shorter one to that in crystalline regions.[4] We could, however, observe only one *o*-Ps component in Takathene. This is natural in view of the special features of this polymer: it has been postulated from the X-ray diffraction and NMR studies of Takathene that the crystal size is small (130—160 Å) and that, moreover, many defects are included in the crystalline regions.[5] In such a structure, *o*-Ps, even if produced in the crystalline regions, may quickly diffuse out to non-crystalline regions or be trapped in crystal defects, since most *o*-Ps has, at the time of its production, a considerable energy above thermal and, therefore, can move a substantial distance. This situation is analogous to the escape of *o*-Ps from inside crystal particles of metal oxides to their surfaces.[6] We will, therefore, assign the long-lived component in Takathene to the annihilation of the *o*-Ps which is thermalized in the non-crystalline regions.

τ_2 in Takathene is larger than that in *n*-eicosane. This is natural in view of the free volume effect, because the density of *n*-eicosane is larger than that of amorphous polyethylene.

I_2 in *n*-eicosane and Takathene is larger at -78 °C than at 0 °C. Since we have not measured the positron lifetimes at temperatures between -78 and 0 °C, it is not clear whether this is connected with the "phase transition effect" on positron lifetimes which has often been reported for various materials.[7]

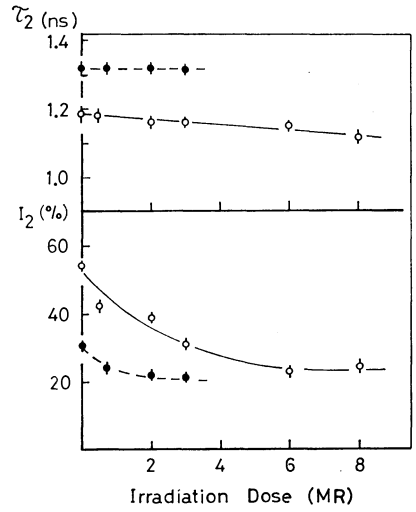

Fig. 1. I_2 and τ_2 in *n*-eicosane at -78 °C (○) and at a room temperature (●) as a function of the dose of γ-irradiation. The vertical bar at each point shows the statistical error of the coincidence counting rate.

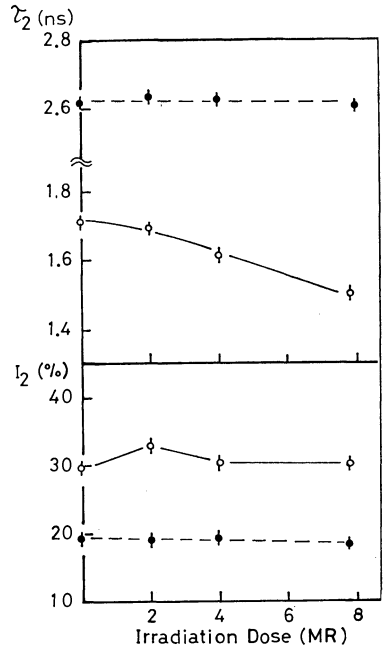

Fig. 2. I_2 and τ_2 in amorphous polyethylene at -78 °C (○) and at a room temperature (●) as a function of the dose of γ-irradiation.

Effect of γ-Irradiation on τ_2. The variations in τ_2 and I_2 are shown in Figs. 1 and 2 as a function of the γ-ray dose. τ_2 decreases upon γ-irradiation in both systems, although the decrease seems smaller in *n*-eicosane than in polyethylene. This may, however, be only apparent, because the radiation yield of free radicals (mainly alkyl radicals $-CH_2\dot{C}HCH_2-$) in *n*-eicosane is approximately one-third that in polyethylene under the present conditions. Moreover, if we plot $\Delta\lambda_2=\lambda_2-\lambda_2^0=1/\tau_2-1/\tau_2^0$ (where λ_2^0 and τ_2^0 are the annihilation rate and the lifetime in a non-irradiated sample respectively) against the spin concentration, it is expressed by a linear relation, as is shown in Fig. 3. From this result, we may assume that the decrease in τ_2 is the result of *o*-Ps reaction with free radicals:

$$o\text{-Ps} + R \xrightarrow{k[R]} PsR \longrightarrow 2\gamma \qquad (1)$$

The fact that τ_2 does not vary when the sample is irradiated at room temperature also supports this assumption, because the spin concentration in samples irradiated at room temperature is far smaller than in those irradiated at −78 °C.

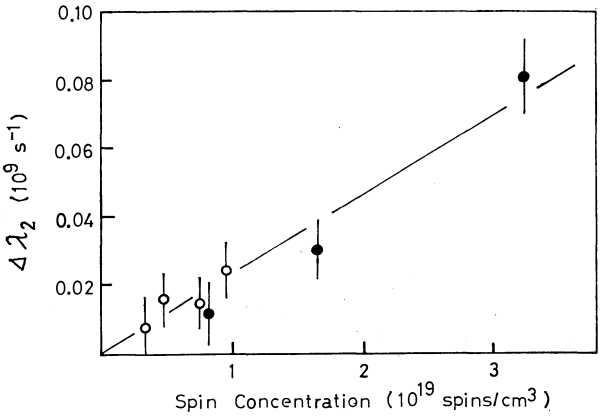

Fig. 3. The increase in the annihilation rate of *o*-Ps ($\Delta\lambda_2=\lambda_2-\lambda_2^0$) in *n*-eicosane (○) and amorphous polyethylene (●) as a function of the concentration of free radicals.

If the observed decrease in τ_2 is entirely due to the reaction of *o*-Ps with free radicals, the rate of Reaction 1 can be calculated to be;

$$k = 0.22\times10^{-11} \quad cm^3\cdot s^{-1}\cdot spin^{-1}$$

This is more than a factor of ten smaller than those for *o*-Ps reactions with various acceptors in organic liquids ($0.1—10\times10^{-10}$ cm^3 s^{-1} $molecule^{-1}$), in which the reaction is believed to be controlled by the diffusion of *o*-Ps.[8] Assuming that the mobility of *o*-Ps in the present substances can also be described in terms of diffusion, the following Smolkovskii formula is given:

$$k = \omega 4\pi(r_{Ps}+r_R)(D_{Ps}+D_R) \qquad (2)$$

where r is the radius, D is the diffusion constant, and ω is the probability factor for the reaction. In applying Eq. (2) we take $r_{Ps}=1$ Å, $r_R=1—2$ Å, $\omega=1$, and $D_R \ll D_{Ps}$. The latter assumption is based on the fact that free radicals can be regarded as immobile in the time scale of the lifetime of *o*-Ps. We thus obtain:

$$D_{Ps} = 0.58-1.75\times10^{-5} \quad cm\cdot s^{-1}$$

This value is as large as that obtained from the reaction of *o*-Ps with DPPH in solid pyridine at −78 °C.[9] It is more than one-third smaller than those previously reported for metal oxides ($\gtrsim 6\times10^{-5}$ cm^2 s^{-1}).[6] However, since the diffusion constants in metal oxides were calculated from the intensity of *o*-Ps or *p*-Ps which has diffused from inside crystal particles to their surfaces, they have been averaged over all the energy spectrum of Ps and therefore, must be larger than those for the thermalized Ps. The fact that our diffusion constant is smaller than those in organic liquids, but is close to those in other solids, supports our assumption that thermalized *o*-Ps can react with free radicals. It must be noted, however, that we have taken $\omega=1$ in Eq. (2), assuming that every encounter of *o*-Ps with free radicals leads to compound formation or conversion quenching. Our diffusion constant is, therefore, a lower limit to the real one. We may conclude either that the mobility of *o*-Ps is small ($\omega=1$) or that the reactivity of *o*-Ps with alkyl radicals is small ($\omega\ll1$).

It must be noted that our diffusion constant is far smaller than those given by Gol'danskii *et al.*,[10] who also applied the Smolkovskii formula for the reaction rate of *o*-Ps with O_2 in solid cyclohexane ($D=1.2\times10^{-3}$ cm^2 s^{-1}) and solid benzene ($D=0.7\times10^{-3}$ cm^2 s^{-1}) at −196 °C, assuming that $\omega=1$. One possible explanation for this discrepancy is that, in solidified cyclohexane and benzene, thermalized *o*-Ps exists in vacancies at the grain boundaries of the polycrystals. Since O_2 molecules may also be selectively concentrated in the grain boundaries, *o*-Ps feels in reality a much larger concentration of O_2 than that averaged over all the volume of the substance. The diffusion constants calculated using the averaged O_2 concentration should be larger than the real ones. Detailed investigations will be required to confirm this, but it may be of great importance to consider in what domain of substances thermalized *o*-Ps exists and how it migrates in it.

Effect of γ-Irradiation and Thermal Annealing on I_2. I_2 decreases upon irradiation in *n*-eicosane and levels off at a value of about 20% (Fig. 1). It is interesting to note that the room temperature value of I_2 also decreases and levels off at 20%. It is expected that

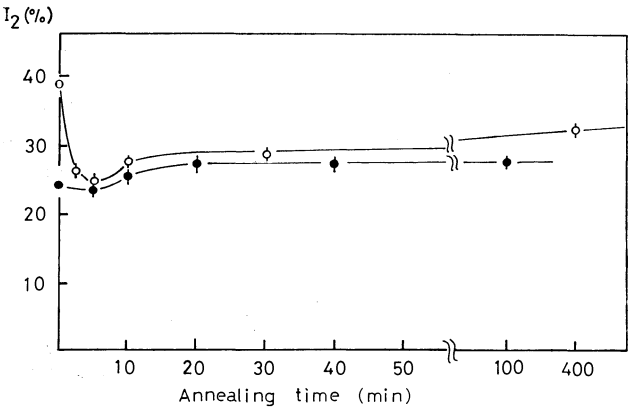

Fig. 4. Effect of thermal annealing at 30 °C on the intensity I_2 in *n*-eicosane irradiated to 2 MR (○) and 8 MR (●).

there is some threshold in the mechanism of the inhibition of thermalized *o*-Ps formation.

I_2 in irradiated *n*-eicosane varies upon thermal annealing, as is shown in Fig. 4. When *n*-eicosane, irradiated to 2 MR, is thermally annealed at 30 °C, I_2 decreases conspicuously to about 20% at first and then increases only slightly. However, in *n*-eicosane irradiated to 8 MR—*i.e.*, to a dose at which the decrease in I_2 levels off at −78 °C, the change due to thermal treatment is small, although it shows a similar tendency. This means that some structural and/or chemical changes which occur after the heat treatment are responsible for the initial decrease in I_2. It may be that, at the dose of 8 MR, such changes have already taken place to a degree sufficient to reduce I_2 to its lowest value and that further heat treatment does not induce any further change in I_2. There are several possibilities to be noted as such changes; the redistribution of free radicals, the conversion of the alkyl radical to the allyl radical (–CH=CH–$\dot{C}$H–CH_2–), *etc.* It remains to be studied which of these possibilities holds true.

Table 2. Effect of thermal annealing on τ_2 and I_2 in amorphous polyethylene

Conditions	τ_2(ns)	I_2 (%)
After irradiation of 8 MR at −78 °C	1.50±0.02	29.3±1.0
Annealed at 0 °C for 1 hr	1.41±0.02	28.8±1.1
Further annealed at 28 °C for 2.5 hr	1.53±0.04	32.3±0.8
Further annealed at 50 °C for 2.5 hr	1.51±0.03	34.5±1.5
Further annealed at RT for 800 hr	1.50±0.02	33.2±1.5

Contrary to the case of *n*-eicosane, I_2 in polyethylene does not decrease upon irradiation at −78 °C, and when thermally treated, it increases only slightly (Fig. 2 and Table 2). This is to be expected because the polyethylene used in the present experiment is quite amorphous, and the structure change due to irradiation or thermal treatment does not affect the positronium formation process as much as in crystalline *n*-eicosane.

Several explanations are possible for the observed decease of I_2 in *n*-eicosane both during γ-irradiation at −78 °C and during thermal treatment. Whatever the explanation may be, however, it must explain (1) the existence of a limit in I_2 reduction, (2) the significant I_2 reduction in annealed *n*-eicosane, and (3) the fact that γ-irradiation is ineffective in reducing I_2 in amorphous polyethylene. One possible explanation is the reaction of energetic *o*-Ps. It is expected that energetic *o*-Ps is rapidly thermalized in amorphous polyethylene by giving its energy to the vibration of molecular chains. Thus, in polyethylene energetic *o*-Ps migrates only a short distance before it is thermalized and has little chance to undergo reaction with acceptors such as free radicals. In crystals of *n*-eicosane, energetic *o*-Ps may migrate a significant distance before thermalization and thus may be able to undergo reaction. It is interesting to recollect in this connection the work by O. Mogensen *et al.*,[11] who showed that positronium moves in a fine crystal of ice as a Bloch wave and that it is rapidly localized in defect sites if such exist in the crystal. They suggested that a higher degree of order in the solid phase will enhance the Ps transport and lead to a stronger interaction. In *n*-eicosane, *o*-Ps may similarly be rapidly transported and localized in defect sites upon collision with them, and since the defect sites are paramagnetic in this case, energetic *o*-Ps may be quenched by the latter, resulting in the reduction of I_2.

If the above explanation is correct, it follows that there is essentially no difference between the mechanism by which τ_2 in *n*-eicosane and polyethylene is shortened and the mechanism by which I_2 in *n*-eicosane is reduced by the irradiation; the reaction of energetic *o*-Ps with free radicals reduces I_2, while the reaction of thermalized *o*-Ps shortens τ_2.

The limits in I_2 reduction might be attributed either to a "cage effect," which confines Ps with an energy below a certain thereshold in a limited region of the substance, or to the presence of some resonance in the mechanism by which *o*-Ps is transported in the crystal of *n*-eicosane.

We cannot, of course, exclude other explanations for the I_2 reduction. The existence of the paramagnetic sites might enhance the direct annihilation of positrons either by narrowing the effective Ore gap or by rapidly moderating the positron energies below the gap. Paramagnetic sites might also capture positrons and form positron compounds, thus inhibiting positronium formation. It seems difficult, however, to explain in terms of these processes why I_2 is not decreased in amorphous polyethylene by the irradiation, while it is decreased in *n*-eicosane.

Our present study involves many problems, and most of them are scarecely understood at present. Further extensive study is needed, but the problems raised in this work will be of importance in understanding the fundamental processes of positronium chemistry in organic solids.

We are grateful to Professor Joseph Silverman and Dr. Naoyuki Tamura, who provided us with single crystal of *n*-eicosane and with Takathene respectively. We are also indebted to Mr. Kiyofumi Sugimoto for helpful assistance.

Semi-empirical SCF-MO Studies of Platinum Hydrides and the Insertion Reaction of Ethylene into the Pt(II)-H Bond

Shigeyoshi SAKAKI, Hiroshi KATO,* Hiroyoshi KANAI, and Kimio TARAMA

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606
**Department of General Education, Nagoya University, Chikusa-ku, Nagoya 464*

(Received August 19, 1974)

Semi-empirical SCF-MO calculations were carried out on *trans*-$PtHX(PH_3)_2$ (X=halogen and CN^-). The absolute value of E_{pt-H} decreases in the following order: F>Cl>Br>I>CN; this agrees with the order of the bond strength of the Pt-H bond. The electron density on the H ligand is remarkably large in all the complexes (*ca.* 1.25 e) and decreases in this order: F>Cl>Br>I>CN. An insertion reaction of ethylene into the Pt-H bond was investigated by the use of the MO method. The intermediate five-coordinate π-olefinic hydride complex has a trigonal bipyramid structure in which Cl and H ligands are positioned *trans* to each other. Three reaction paths of the insertion were investigated, and the following reaction path seems the best: The H ligand starts first to approach ethylene and then the Cl ligand starts to move to the *trans*-position of the H ligand. The reactivities of *trans*-$PtHX(PH_3)_2$ increase in this order: F<Cl<Br<I<CN. MO calculations also reveal that the catalytic ability of *trans*-$PtHX(PH_3)_2$ increases as follows in the hydrogen-deuterium exchange reaction of ethylene: F<Cl<Br<I.

The role of transition metal complexes in homogeneous catalytic reactions is currently a topic of great interest in the fields of both the pure and applied chemistry. In these catalytic reactions, isomerization and hydrogenation of olefins and acetylenes have been particularly studied, as has been reviewed recently.[1,2] It has been accepted in many catalytic isomerizations and hydrogenations that the formation of the metal-hydride (M-H) bond and its reaction with unsaturated compounds are key steps in the overall reaction.[2,3] Many transition metal hydrides have been found and several insertion reactions of olefins into M-H bonds have been reported.[4]

Stable hydride complexes of platinum(II), *trans*-$PtHX(PH_3)_2$ (X=halogen *etc.*), were prepared by Chatt and Shaw.[5] Structural studies have been carried out on *trans*-$PtHX(PEt_3)_2$ (X=Cl and Br),[6,7] and spectroscopic studies such as NMR and IR have been reported.[5,8-11] However, little theoretical study has been done, even though it is necessary in order to investigate the bonding character of the Pt(II)-H bond.

It is wellknown that ethylene reacts with *trans*-$PtHCl(PEt_3)_2$ under vigorous conditions (95°C/80 atm) to give an ethylplatinum(II) complex:[5,12]

$$\textit{trans}\text{-}PtHCl(PEt_3)_2 + C_2H_4 \rightleftarrows \textit{trans}\text{-}Pt(C_2H_5)Cl(PEt_3)_2 \quad (1)$$

Several investigations have been carried out on the insertion reaction of ethylene in order to elucidate the reaction mechanism.[12-17] The suggestion has been accepted that both forward and reverse reactions proceed *via* five-coordinate π-olefinic hydride complexes.[12-13,17]

In this work, we have carried out semi-empirical SCF-MO calculations of hydride complexes of platinum(II) in order to investigate their electronic structures. Studies have also been done of the ethylene insertion reaction into the Pt(II)-H bond. We will discuss the electronic structure of the intermediate five-coordinate π-olefinic hydride complex, $PtHCl(PH_3)_2(C_2H_4)$. The ligand effects and the role of the Pt(II) ion in the ethylene insertion reaction will also be discussed. We have tried to anticipate the ligand effect on the catalytic abilities of *trans*-$PtHX(P_3R)_2$ in the hydrogen-deuterium (H-D) exchange reaction of ethylene.

MO Calculations and Geometries of Complexes

MO Calculations. The MO calculations were performed by the use of the CNDO-type MO method. This method gave reasonable results on tetrachloroplatinate, Zeise's salt, the Pt(0)-ethylene complex, the Pt(0)-acetylene complex, *etc.*[18] The approximations used in this MO method have been reported in detail elsewhere.[18] Here, let us describe important features. (1) The Fock-matrix elements are obtained by the CNDO-type approximations.[19] (2) The resonance integrals are evaluated by the Wolfsberg-Helmholz approximation,[20] where the parameter "K" is taken as 0.90 for AO pairs including a d-orbital and as 0.80 for AO pairs including only s- and p-orbitals.[18] (3) The one-center Coulomb repulsion integrals of the Pt atom are estimated by multiplying a correction factor by nonempirical values calculated by means of single Slater-type orbitals. (4) The two-center Coulomb repulsion integrals are evaluated by the use of a modified Ohno's approximation[18] for AO pairs including only one outer 6s- or 6p-orbital of the Pt atom and by the use of Ohno's original approximation[21] for the other AO pairs.

The quantity of E_{AB}[22,23] is used as the bond index in this work; it is defined as the energy contribution of the AB bond to the total energy. Under the approximations used here, E_{AB} is written as follows;[19]

$$E_{AB} = E_{AB}^{(1)} + E_{AB}^{(2)} + E_{AB}^{(3)} \quad (2)$$

$$E_{AB}^{(1)} = 2.0\sum_r^A\sum_t^B P_{rt}H_{rt} \quad (3)$$

$$E_{AB}^{(2)} = -0.5\sum_r^A\sum_t^B P_{rt}^2\gamma_{rt} \quad (4)$$

$$E_{AB}^{(3)} = \sum_r^A\sum_t^B (P_{rr}-N_r)(P_{tt}-N_t)\gamma_{rt} \quad (5)$$

where $E_{AB}^{(1)} + E_{AB}^{(2)}$ and $E_{AB}^{(3)}$ represent approximately

a covalent bonding interaction and an electrostatic one respectively. The negative value of E_{AB} indicates the bonding interaction. The larger the absolute value of E_{AB}, the greater the interaction between A and B atoms becomes.

Geometries of Complexes. trans-*PtHX*$(PR_3)_2$: The bond lengths of the Pt–Cl and Pt–Br were taken from X-ray studies,[6,7] while those of the other Pt–X bonds were estimated from the covalent bond radii of X's. The bond lengths of the Pt–P and Pt–H bonds were fixed as 2.268 and 1.62 Å respectively for all the complexes. While the ∠PPtCl and ∠PPtBr angles were slightly larger than 90° as a result of the steric effects of Cl and Br ligands,[6,7] ∠PPtX was assumed to be 90° in all the complexes, for the value of this angle had not been known in the other complexes. The PR_3 group (R=phenyl or alkyl group) was replaced by the PH_3 group for the sake of simplicity; its structure was assumed to be the same as that of the uncomplexed one.[24] In spite of these simplifications, MO calculations on these models gave reasonable and sufficient results to enable us to discuss the ligand effect of X, as will be described in the following section.

trans-*PtX*$(C_2H_5)(PH_3)_2$: Since no X-ray study had been carried out on this complex, the bond lengths of the Pt–C and Pt–Cl bonds were taken from the structure of $[Pt(CH_3)_3Cl]_4$,[24] and the Pt–P bond length was fixed in all the complexes. The bond lengths of the other Pt–X bonds were estimated in the same way as those in *trans*-$PtHX(PH_3)_2$. The Pt–P bond length and the structure of the PH_3 group were assumed to be the same as the corresponding ones in *trans*-$PtHX(PH_3)_2$. In these complexes, the structure of the ethyl group was taken from Ref. 24, while only the β-hydrogen atom of the ethyl group was brought slightly close to the Pt atom (β-H–Pt=2.22 Å [25] and β-H–C=1.09 Å) when the abstraction of the β-hydrogen atom was investigated.

Five-coordinate π-Olefinic Hydride Complexes and an Insertion Reaction of Ethylene into the Pt(II)–H Bond. Two types of five-coordinate intermediate complexes were investigated in the insertion reaction of ethylene into the Pt(II)–H bond; they are shown in Fig. 1. In both structures, the structure of the ethylene part was assumed to be the same as the uncomplexed one. The coordination bond of ethylene was also assumed to intercept the double bond of ethylene perpendicularly at its center, and the coordination bond distance was fixed as 2.0 Å by reference to that of Zeise's salt.[26] The A structure can be expected from the substitution reaction of *trans*-$Pt(NO_3)H(PEt_3)_2$ with ethylene which was reported by Deening *et al.*[15] The B structure has been proposed by Uguagliati *et al.*;[14] also, a similar intermediate complex has been isolated by Clark *et al.* in the insertion reaction of tetracyanoethylene with *trans*-$Pt(CH_3)(CN)(PEt_3)_2$.[16]

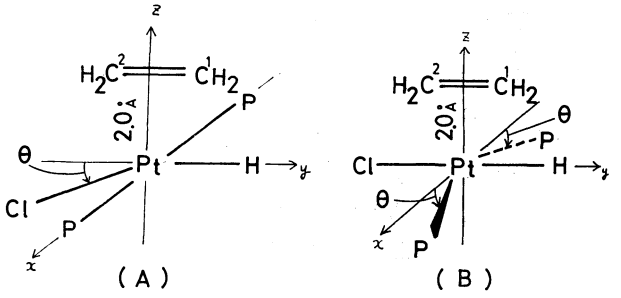

Fig. 1. Five-coordinate π-olefinic hydrido-complexes. P; PH_3. The bond distances of the Pt–P, Pt–H and Pt–Cl and the structure of the PH_3 group are the same as those in the *trans*-$PtHCl(PH_3)_2$.

Since the B structure was more stable than that of A, as will be described below, the insertion reaction was considered to proceed from the B structure (θ=45°); the three reaction paths shown in Fig. 2 were investigated. In the C reaction path, ethylene approaches the hydride ligand parallel with the Pt–H bond. Also, in the D reaction path, ethylene approaches the hydride ligand. In this attack, the δ angle between the coordination bond of ethylene and the z-axis increases, the other part does not vary. In the E reaction path, the hydride ligand attacks ethylene, where the δ angle between the Pt–H bond and the y-axis increases, while the other part does not vary. The states in which hydrogen atoms were displaced out of the original ethylene plane opposite to the Pt atom (10°) were investigated in two reaction paths, D and E; only the $C(1)H_2$ group was bending in the IV state, and both $C(1)H_2$ and $C(2)H_2$ groups were bending in the V state.

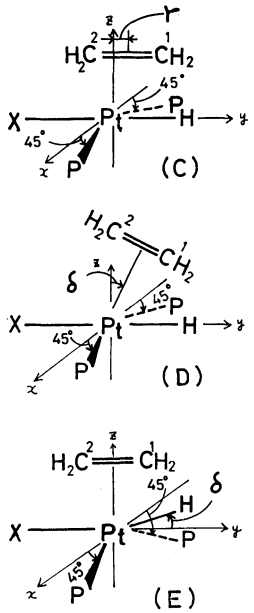

Fig. 2. Insertion reaction paths of ethylene into the Pt(II)–H bond.
P; PH_3. In the reaction paths C and D, the $PtHCl(PH_3)_2$ is the same as the state V of the five-coordinate intermediate B (Fig. 1). In the reaction path E, the H ligand transfers to ethylene and the other part is the same as the state V of the intermediate B.

Results and Discussion

Electronic Structures of trans-*PtHX*$(PH_3)_2$. The results are given in Table 1. The electron density on the Pt atom increases with the decrease in the elec-

tronegativity of the X ligand; *i.e.*, F<Cl<Br<I<CN. The H ligand has a remarkably large negative charge, suggesting its hydride character. The electron density on the H ligand decreases with an increase in the electron density on the Pt atom and with a decrease in the electron density on the halogen. This result seems to be similar to the alternative inductive effect;

$$\overset{\delta-}{X}\!\!-\!\!\overset{\delta+}{Pt}\!\!-\!\!\overset{\delta-}{H}$$

Scheme I.

However, this result cannot be explained by hyperconjugation, since the Pt–H bond is not contributed to by hyperconjugation. Because the energy levels of the Pt's valence orbitals decrease as the X ligand goes from F^- to CN^-,[27] the electron transfer increases in this order; F<Cl<Br<I<CN, and the electron density on the H ligand decreases in this order; F>Cl>Br>I>CN.

The absolute value of E_{Pt-H} decreases in this order; F>Cl>Br>I>CN, suggesting that the strength of the Pt–H bond also decreases in this order. From the frequencies of the stretching vibration, ν_{Pt-H}, it is expected that the strength of the Pt–H bond decreases in this order; Cl>Br>I>CN,[9,11] since ν_{Pt-H} gives a measure of the strength of the Pt–H bond. Thus, our finding on the strength of the Pt–H bond agrees qualitatively with the experimental findings. The value of E_{Pt-H} is mainly contributed to by the $E_{Pt-H}{}^{(1)}$ and $E_{Pt-H}{}^{(2)}$, as is shown in Table 1; this suggests the covalent bonding character of the Pt–H bond.

Five-coordinate π-Olefinic Hydride Complexes. The various conformations of the A and B structures (see Fig. 1) were investigated, as is shown in Fig. 3 and Table 2. The increase in θ does not bring about the stabilization of the A structure, but that of the B structure, which is the most stable at $\theta=45°$. In the B structure, the steric repulsion between PH_3 and ethylene decreases greatly. However, it does not change in the A structure, while the streic repulsion between Cl and ethylene decreases. Therefore, the B structure is more favorable than the A structure for the intermediate five-coordinate complex. We will hereafter consider the insertion reaction of ethylene into the Pt(II)–H bond in the B structure.

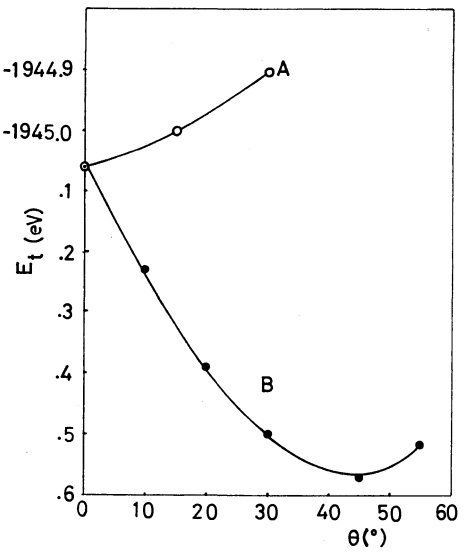

Fig. 3. Total energies of five-coordinate π-olefinic hydrido-complexes, $PtHCl(PH_3)_2(C_2H_4)$.
○: The structure A. ●: The structure B (see Fig. 1.)

An increase in θ brings about an increase in the bonding interaction between the Pt atom and ethylene in both structures, A and B; the absolute value of $E_{Pt-C(1)}+E_{Pt-C(2)}$ also increases with an increase in θ, as is shown in Table 2. In the A structure ($\theta\neq0$), the $5d_{z^2}$ and $5d_{yz}$ orbitals of the Pt atom are bonding

orbitals, while these are very weak bonding orbitals in the square pyramidal complex. Ethylene donates its electrons to the $5d_{z^2}$ orbital and accepts d-electrons from the $5d_{yz}$ orbital into its π^*-MO, while it scarcely interacts with these d-orbitals in the square pyramidal complex. Of course, ethylene donates its π-electrons to the $6p_z$ orbital of the Pt atom in both the square pyramidal and trigonal bipyramidal complexes. Thus, the interaction between the Pt atom and ethylene is larger in the trigonal bipyramidal complex (A) than in the square pyramidal one; this results in the larger absolute value of $E_{Pt-C(1)}+E_{Pt-C(2)}$ in the former than in the latter. Decreases in the π-bond order of ethylene, P_π, and the quantity of transferred electrons from ethylene, Δq, suggest a greater increase in the π-acceptor bond than in the σ-donor bond, as is shown in Table 2. In the B structure, the $5d_{z^2}$ and $5d_{xz}$ orbitals of the Pt atom also become bonding orbitals. The $5d_{xz}$ orbital can not interact with ethylene, as is shown in Fig. 1. Ethylene donates its π-electrons to the $5d_{z^2}$ orbital of the Pt atom through the σ-donor bond, while it scarcely donates its π-electrons to the $5d_{z^2}$ orbital in the square pyramidal complex. The formation of this interaction brings about increases in the Δq and the $E_{Pt-C(1)}+E_{Pt-C(2)}$ and the decrease in the P_π.

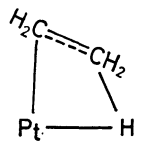
E_{AB}; eV unit. a) H=the hydride ligand coordinating to Pt(II). b) The quantity of transferred electrons from the system $C_2H_4+H^-$ to $PtX(PH_3)_2^+$ part.

Inserion Reaction of Ethylene. The results on the reaction paths and those on the ligand effect in this reaction are shown in Tables 3 and 4 respectively.

In the C reaction path, the total energy increases slightly. The absolute values of E_{C-H}, E_{C-C}, and $E_{Pt-C(2)}$ increase as the reaction proceeds from the I state to the III state, while those of $E_{Pt-C(1)}$ and E_{Pt-H} decrease. (In this paper, the H's of the Pt–H and C–H represent the hydride coordinated to the Pt atom.) These results show the increase in the C–H interaction. However, the increase in the absolute value of E_{C-C} suggests an increase in the strength of C–C bond. This rules out the C reaction path, because the C=C double bond must become a C–C single bond after an insertion reaction.

In the D reaction path, the total energy decreases as the reaction proceeds from the I state to the III state.[31] The absolute values of E_{C-H} and $E_{Pt-C(2)}$ increase in this reaction course, while those of E_{Pt-H}, E_{C-C}, and $E_{Pt-C(1)}$ decrease. These results reveal that the C–H and Pt–C(2) interactions become stronger and that the Pt–H, Pt–C(1), and C–C interactions become weaker. This situation agrees with that in the four-center-type reaction;[28]



Scheme II.

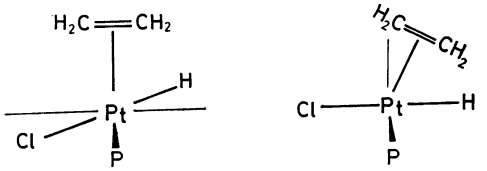
Therefore, the D reaction path is reasonable for the ethylene insertion reaction.

In the E reaction path, the total energy decreases as the reaction proceeds from the I state to the III state.[31] The bonding interactions of the C–H and Pt–C(2) bonds become stronger and those of the C–C, Pt–C(1), and Pt–H bonds become weaker, similarly to those of

the D reaction path, as the reaction proceeds. The E reaction path also seems reasonable.

In two reaction paths, D and E, the bending of the CH_2 group, in which hydrogen atoms are displaced out of the original ethylene plane opposite to the Pt atom, brings about increases in the absolute values of E_{C-H} and $E_{Pt-C(2)}$, and decreases in those of $E_{Pt-C(1)}$ and E_{C-C}, while it scarcely changes the total energy (see the IV and V states in Table 2). These results suggest the bending of the CH_2 groups is brought about in this reaction course; this corresponds to the C(1) and C(2) atoms becoming sp^3 character from their original sp^2 character.

It is worthwhile to investigate which ligand, ethylene or hydride, transfers in the ethylene insertion reaction. As is shown in Table 3, the II state in the E reaction path has a lower total energy, a larger absolute value of E_{C-H}, and smaller absolute value of E_{Pt-H} and E_{C-C} than that in the D reaction path; that is, the former state has a stronger C–H bonding interaction and weaker Pt–H and C–C bonding interactions than the latter one. From these results, the H ligand can be expected to transfer more easily than ethylene in the initial stage of the reaction. The following states, III—V, in the D reaction path have a larger absolute value of E_{C-H} and smaller ones of E_{Pt-H} and E_{C-C} than those in the E reaction path, while the reaction states in both reaction paths have almost the same total energies. These results suggest, at first glance, that ethylene transfers to the H ligand more favorably than the latter does to the former in the more advanced reaction states. In the E reaction path, however, the Cl ligand should also transfer, as is shown in Scheme III, as the reaction advances, since the final product is the square planar *trans*-$Pt(C_2H_5)Cl(PH_3)_2$.



The more advanced reaction state in the reaction path E

The reaction path D

Scheme III.

The transfer of the Cl ligand in the E reaction path results in almost the same intermediate state as that in the D reaction path, while the position of PH_3 is slightly different. The III—V states in the D reaction path can reasonably be considered to be more advanced reaction states in the E reaction path. Thus, our results suggest that the H ligand starts first to attack ethylene and that then the Cl ligand starts to move to the *trans*-position of the H ligand. Of course, this problem should be studied in more detail experimentally and theoretically.

In order to investigate the role of the Pt(II) ion in the insertion reaction, a hypothetical state is studied; it is obtained by removing the $PtCl(PH_3)_2^+$ part from the III state in the D reaction path. This hypothetical state is considered to be a limiting state of the C_2H_4+

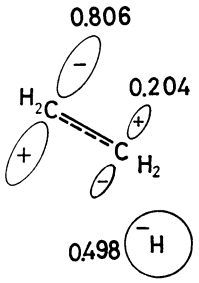


Fig. 4. AO coefficients of the HOMO of the hypothetical state, $C_2H_4+H^-$.

LiH reaction system in which the bond distance of Li–H is infinitely lengthened. This hypothetical state has the following characteristics: (1) The electron density on the C(2) atom is remarkably large (4.64 e); this is a result of the large electron density on its p_π orbital (1.84 e). (2) The highest occupied (HO) MO has a remarkably high orbital energy (−0.345 eV). (3) As is shown in Fig. 4, its HOMO has a non-bonding character; electrons are localized in the $2p_\pi$ orbital of the C(2) atom and the 1s orbital of the H atom. Where the Pt part exists, the MO of this type is obtained at about −10 eV and the $2p_\pi$ orbital of the C(2) atom interacts with the $5d_{z^2}$, 6s, and $6p_\pi$ orbitals of the Pt atom in the D reaction path, as is shown in Fig. 5.

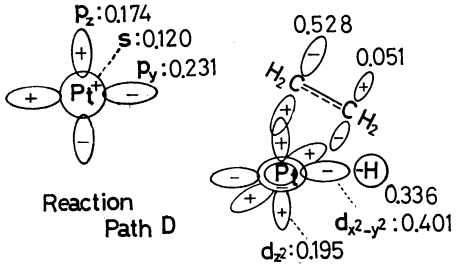

Fig. 5. AO coefficients of an important MO in the interaction between the C(2) and Pt atoms.

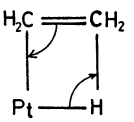
As a consequence of these interactions, the electron density on the $2p_\pi$ orbital of the C(2) atom, $P_{\pi C(2)}$, is remarkably reduced in $PtHX(PH_3)_2(C_2H_4)$ relative to the hypothetical state, as is shown in Table 4. Thus, it is the important role of the Pt atom to accept the excess π-electrons on the C(2) atom and to stabilize the HOMO of the hypothetical system. In other words, the insertion reaction mechanism may be represented as follows:



Scheme IV.

The ligand effects on the insertion reaction were studied in the III state of the D reaction path, as is shown in Table 4. In all the reaction systems, the electron density on the C(2) atom and the absolute value of $E_{Pt-C(2)}$ are larger than that on the C(1) atom and that of $E_{Pt-C(1)}$ respectively. The negative values of E_{C-H} in all the systems reveal the C–H bonding

interaction. Its absolute value increases in this order; F<Cl<Br<I<CN, while the absolute values of E_{Pt-H} and E_{C-C} decrease in the same order. Also, the values of ΔQ, which is defined as the quantity of transferred electrons from the $C_2H_4+H^-$ part to the $PtX(PH_3)_2^+$ part, increase, and the values of $P_{\pi C(2)}$ decrease, in this order. From these results, the reactivity of *trans*-$PtHX(PH_3)_2$ in the insertion reaction can be effected to increase in the same order. This order of increase agrees with the order of increase of the *trans*-effect of the X ligand; this is consistent with the experimental results.[29]

The decreasing order of ΔQ of F>Cl>Br>I>CN is the same order as in the electron transfer from the H ligand to the Pt part in *trans*-$PtHX(PH_3)_2$. The results for ΔQ in the former case may also be due to the same reason.[27]

Hydrogen-Deuterium Exchange Reaction. *trans*-$PtHCl(PEt_3)_2$ catalyzes the H–D exchange reaction of ethylene.[30] The H–D exchange reaction is composed of two steps: the ethylene insertion into the Pt(II)–H bond, and the β-hydrogen abstraction in the Pt(II)-ethyl complexes. The transition state in the β-hydrogen abstraction is considered to be the same as that in the ethylene insertion reaction. Therefore, it is only necessary to investigate the interaction between the Pt atom and the β-hydrogen of the ethyl group in the Pt(II)-ethyl complexes. The results are given in Table 5.

TABLE 5. THE INTERACTION BETWEEN Pt AND β-H ATOMS IN *trans*-$PtX(C_2H_5)(PH_3)_2$

		F	Cl	Br	I	CN
Electron density	Pt	9.98	9.96	9.98	10.01	10.03
	β-H[a]	0.82	0.82	0.82	0.82	0.82
E_{C-H}[a]		−0.60	−0.73	−0.75	−0.81	−0.80

E_{AB}; eV unit. a) H=β-H atom of ethyl group.

The absolute values of E_{Pt-H} increase in this order: F<Cl<Br<CN<I, as is shown in Table 5. The β-hydrogen atom is abstracted easily as follows: F<Cl<Br<CN<I. As has been described previously, the ligand effect on the reactivity in the ethylene insertion increases in this order: F<Cl<Br<I<CN. Therefore, the catalytic ability of *trans*-$PtHX(PR_3)_2$ in the H–D exchange reaction increases: F<Cl<Br<I; it is difficult to determine which is more active, the iodo- or the cyano-complex.

These calculations were carried out with Facom 230-75 Computer of the Data Processing Center in Kyoto University.

The authors are grateful to Professor Akio Yamamoto for his creative suggestion. They also wish to thank Dr. Hideyuki Konishi for his help with calculations.

27) Under the approximations used here, a diagonal Fock matrix element is written as follows:
$F_{rr} = -I_r + \gamma_{rr} + (0.5 p_{rr} - N_r)\gamma_{rr} + \sum_{s \neq r} (p_{ss} - N_s)\gamma_{rs}$
Going from F to CN$^-$, the values of P_{rr} of the Pt atom increase and those of F_{ss} and γ_{rs} decrease, where r and s represent the valence orbitals of the Pt atom and those of the X ligand respectively. The increase in P_{rr} raises the value of F_{rr} through the third term on the right-hand side. However, the decreases in P_{ss} and γ_{rs} reduce the F_{rr} through the fourth term, since the $P_{rr}-N_{rr}$ is negative in these cases. The change in the value of the third term is less than that of the fourth one, mainly because of the change in the values of γ_{rs}. Thus, the values of F_{rr} decrease as a result of the fourth term as follows: F>Cl>Br>I>CN. This result is not because of our approximations but because of the fundamental nature of the X ligand; the atom which has contracted valence orbitals raises the energy of an electron of the other atom through the electronic repulsion integrals, relative to the atom whose orbitals expand largely.

31) It has not been ascertained that the MO method used here can give a correct energy difference between the initial state (*trans*-$PtHCl(PH_3)_2+C_2H_4$) and the interacting state ($PtHCl(PH_3)_2(C_2H_4)$). While Table 3 gives us a negative activation enthalpy, it should be studied in more detail.

The Magnetic Properties of Verdazyl Free Radicals. VIII. The Crystal Structure of 1,3,5-Tri-*p*-tolylverdazyl Radical

Nagao AZUMA, Yasuo DEGUCHI, Fumiyuki MARUMO,* and Yoshihiko SAITO**

Department of Chemistry, Faculty of Science, Kyoto University, Kitashirakawa, Sakyo-ku, Kyoto 606
***The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106*

(Received September 2, 1974)

The crystal structure of 1,3,5-tri-*p*-tolylverdazyl has been determined by X-ray diffraction. The crystals are monoclinic, with the space group of $P2_1/m$ and with $a=8.173(3)$, $b=20.23(1)$, $c=6.075(2)$ Å, $\beta=105.4(1)°$, and $Z=2$. The structure was deduced from the sharpened Patterson synthesis and refined by the block-diagonal least-squares method to the final R value of 0.048 for the 1212 non-zero reflections collected by the counter-method. The *sym*-tetrazinyl ring has an asymmetrical boat form. The molecules are arranged approximately parallel to the $(20\bar{1})$ plane. The maximum intermolecular overlap is observed between the *sym*-tetrazinyl and *C*-tolyl groups, suggesting a weak exchange interaction between unpaired electrons.

For studying the magnetic properties of radical solids with an unpaired electron delocalized over the whole molecular frame-work, precise knowledge about both the spin-density distribution and the crystal structure is of great importance. Based on such knowledge, the magnetic properties of 1,3,5-triphenylverdazyl and galvinoxyl radicals were discussed in a previous paper.[1] However, there has thus far been little systematic study in this area. Thereupon, crystal structure analyses were carried out on verdazyls, which exhibit magnetic properties different from one to another in spite of their similar spin-density distributions. Figure 1 shows a generalized canonical formula of the verdazyls of our interest. Their spin distributions have been published elsewhere.[2]

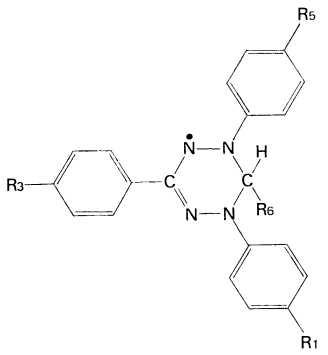

Fig. 1. Constitutional formula of verdazyl radicals. R_1, R_3, and R_5 stand for H, CH_3, and so on. R_6 is H or CH_3.

This and the following papers describe the crystal structures of 1,3,5-tri-*p*-tolylverdazyl (TTV), and 1,3,5-triphenyl-6-methylverdazyl (MeTPV)[3] respectively, whose magnetic susceptibilities indicate, respectively, a weak exchange interaction and a fairly strong isotropic exchange interaction between the unpaired electrons. The details of the magnetic properties of them and of other radicals will be presented in a separate paper.

Experimental

The TTV was prepared from *p*-tolualdehyde, *p*-toluidine, and formaldehyde by a method analogous to that described by Kuhn and Trischmann[4] (Found: C, 78.07; H, 6.65; N, 15.54%; Calcd for $C_{23}H_{23}N_4$: C, 77.72; H, 6.52; N, 15.76%). The crystals used for the structure analysis were obtained by standing a solution of TTV in a mixture of acetone and methanol at room temperature.

Table 1. Crystal data

Molecular formula	$C_{23}H_{23}N_4$
Molecular weight	355.5
Melting point	137—138 °C
Specimen used for the data collection	*ca.* (0.25 mm)^3
Crystal system	Monoclinic
Cell dimensions;	
a	8.173±0.003Å
b	20.23±0.01
c	6.075±0.002
β	105.4±0.1°
V	968.2Å^3
Z	2
Density (calculated)	1.222 g/cm^3
Density (observed by flotation)	1.214
$F(000)$	378
Linear absorption coefficient	0.9 cm^{-1} (Mo$K\alpha$)
Systematic absence	$0k0$: $k=2n+1$
Space group	$P2_1/m$ or $P2_1$

The unit-cell dimensions obtained from Weissenberg photographs were refined by the least-squares method by employing higher-order reflections measured on an automated four-circle diffractometer with Mo$K\alpha$ radiation ($\lambda=0.7107$ Å) monochromated by a graphite crystal. The crystal data are given in Table 1. The intensities of 2321 independent reflections up to $2\theta=55°$ were measured on the same diffractometer using Mo$K\alpha$ radiation. An ω–2θ scan technique was employed. The reflections with $|F_o|$ values of less than $(10/3)\sigma(F_o)$ were measured up to four times. The intensities were corrected for Lorentz and polarization effects. Neither absorption nor extinction corrections were made. A total of 1212 reflections with $|F_o|$ values not less than $2.5\sigma(F_o)$ were regarded as non-zero reflections and were used for the structure analysis.

Structure Determination and Refinement

Wilson's statistics indicated the presence of a center of symmetry. A three-dimensional Patterson map showed 98 resolved peaks in an asymmetric unit. Of

* Present address: Research Laboratory of Engineering Materials, Tokyo Institute of Technology, Ookayama Meguro-ku, Tokyo 152.

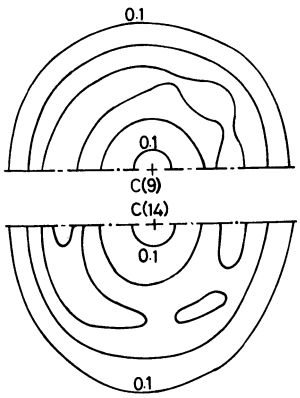

Fig. 2. Difference Fourier maps of the methyl hydrogen atoms. The sections correspond to the planes defined by the methyl hydrogen atoms. The contours are at intervals of 0.1 e/Å^3. The numbering system is referred to Fig. 3.

these, seven prominent peaks were arranged on a line $(0, v, 0)$; this suggested the presence of a plane of symmetry. Accordingly, the space group of $P2_1/m$ was adopted. The starting model was deduced from the Patterson map with the aid of the molecular geometry of 1,3,5-triphenylverdazyl (TPV).[5] This model gave an R value of 0.27.

The block-diagonal least-squares refinement was then undertaken; the R value decreased to 0.12 after four cycles of refinement with individual isotropic thermal parameters. Three further cycles of refinement with anisotropic thermal parameters reduced the R value to 0.095. At this stage, a difference Fourier map was synthesized, from which the positions of the eight ring-hydrogen atoms were located. With anisotropic thermal parameters for the non-hydrogen atoms and isotropic ones for the hydrogen atoms, four cycles of refinement reduced the R value to 0.071. A new difference Fourier map was then computed. As is shown in Fig. 2, there were annular distributions of the residual electron densities near the methyl carbon atoms. The following approximation was then introduced tentatively in order to execute further refinement. The methyl groups ($-CH_3$) were replaced by $-CH_6$, in which the atomic weights for the hydrogen atoms were one half of those for the corresponding ordinary methyl hydrogen atoms. Of course, the $-CH_6$ groups satisfied the symmetry required. The C–H bond length was obtained by inspecting the residual electron-density map. The refinement was continued until all the positional shifts for the non-hydrogen atoms became less than 0.25 σ. The final R value was 0.048 for the 1212 reflections.

Unit weight was given to all the reflections. The atomic scattering factors used were taken from "International Tables for X-Ray Crystallography."[6] The final atomic coordinates and anisotropic thermal parameters of the non-hydrogen atoms are listed in Tables 2 and 3 respectively. The final parameters for the hydrogen atoms are shown in Table 4. The observed and calculated structure factors are compared in Table 5.

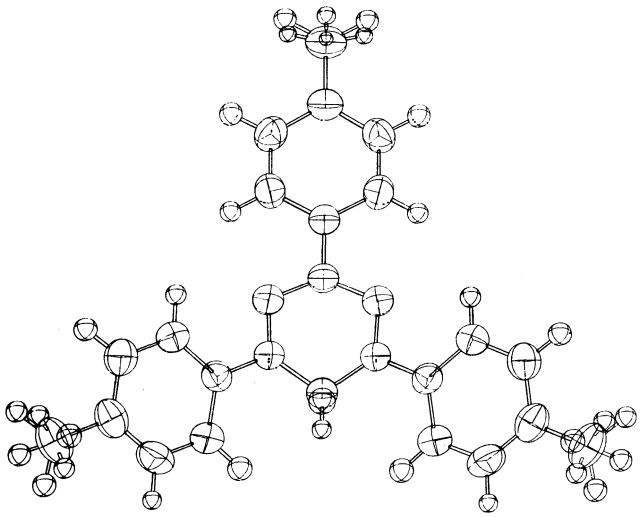

Fig. 4. Molecular structure and thermal ellipsoids.[14] An approximation made on the methyl groups is referred to the text. The thermal ellipsoids enclosing a probability of 50%, except for hydrogen atoms, were viewed approximately along the normal of the nitrogen plane.

Table 6. Bond lengths, pertinent intramolecular contacts, and their estimated standard deviations in parentheses (Å)

Bond	Length	Bond	Length
C(1)–N(1)	1.447(4)	C(7)–C(8)	1.378(4)

N(2)---H(C8)	2.42(3)	H(C4)---H(C4′)	3.50(7)
N(2)---H(C11)	2.43(3)	H(C8)---H(C11)	3.29(4)

the configuration of the two *N*-tolyl groups is antipropellor. However, H(C4) and H(C4′) are still staggered betwen H(Cl-1) and H(Cl-2). In comparison with the no-twist case, the configuration mentioned above enlarges the distance between H(C4) and H(C4′) and simultaneously decreases the repulsion between the *N*-tolyl groups and the methylene group. A parallel description holds in the cases of TPV and MeTPV as well.

The equation of the least-squares plane through five atoms, C(1), C(2), C(3), N(1), and N(2), is given by:

Table 7. Bond angles and their estimated standard deviations (in degree)

a) TTV; 1,3,5-tri-*p*-tolylverdazyl, TPV; 1,3,5-triphenyl-verdazyl, MeTPV; 1,3,5-triphenyl-6-methyl-verdazyl, TEAZN; *sym*-tetrazine, DPAZN; 3,6-diphenyl-*sym*-tetrazine.

$$0.8868X - 0.3856Y - 0.2521Z + 2.3566 = 0 \text{ (Å)}, \quad (1)$$

where the Cartesian reference axes are taken as follows: $X=ax+cz\cos\beta$, $Y=by$, and $Z=cz\sin\beta$. The atomic deviations from this plane are C(1)=−0.001, C(2)=0.117, C(3)=0.035, N(1)=0.026, and N(2)=−0.161 Å. The dihedral angle between this and the *N*-tolyl planes is close to that of the twist about the N(1)–C(3) bond. Accordingly, it seems reasonable to divide the TTV molecule into three planes. Two of them are the plane defined by Eq. (1) and its mirror image. The last one covers the *C*-tolyl group and the C(2) atom, at which the three planes intersect. On the other hand, N(2)–C(2)–N(2′) angle is close to that of the ideal trigonal bond. Therefore, the molecular structure of TTV seems to be favorable for the delocalization of an unpaired π-electron. The above consideration holds in both TPV and MeTPV. Actually, the dimensions of the *sym*-tetrazinyl ring of verdazyls are similar to those of TEAZN and DPAZN, both of which are

planar molecules with conjugated double bonds.[8,9]

To summarize, the mutually distinguishable magnetic properties of TTV, MeTPV, and TPV can probably be attributed to the variety of the molecular packing patterns of the respective radicals, taking account of the similarity in molecular structure as well as in this spin-density distribution.[2]

Residual Electron Densities. None of the methyl hydrogen atoms could be located unequivocally, as is shown in Fig. 2. Such annular distributions of the electron densities suggest the rotation of the methyl groups about the C–C bond.

The final difference Fourier map was then calculated. The residual electron densities on this map varied from −0.16 to 0.16 e/Å^3. A composite electron-density map is shown in Fig. 5. The standard deviation of the electron density, $\sigma(\rho)$, was estimated to be 0.02 e/Å^3 following the method of Cruickshank.[10] The residual electron densities at the middle point of every bond exceed $2\sigma(\rho)$; this is probably to be attributed to the aspherical distribution of electrons as a result of the bond formation.

Molecular Packing. The mutual arrangement of the TTV molecules is shown in Fig. 6. The pertinent intermolecular contacts and their estimated standard deviations are listed in Table 9.

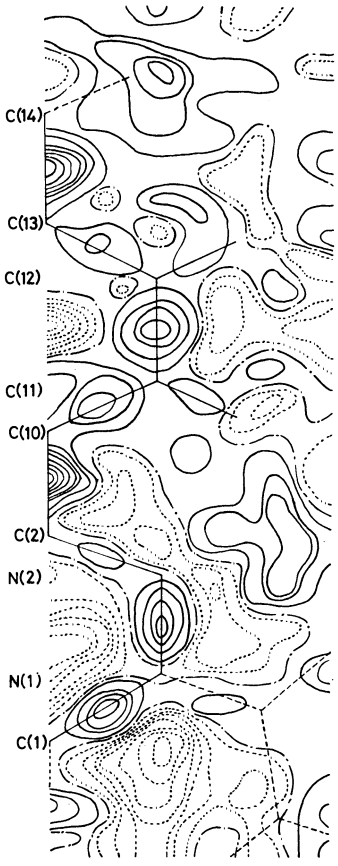

Fig. 5. The final composite residual electron-density sections through the pair of bonds between non-hydrogen atoms and between their counterparts on the opposite side beyond the mirror plane. The contours are at intervals of 0.02 e/Å^3. The solid, dashed, and broken contours indicate positive, zero, and negative values, respectively. The solid and broken straight lines represent the bonds on and out of the section, respectively.

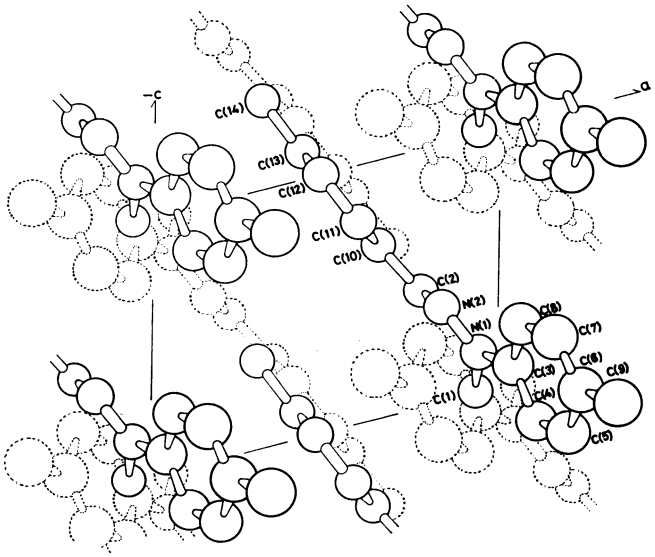

Fig. 6. Mutual arrangement of the molecules viewed along the b-axis. The hydrogen atoms were not drawn.

Table 9. Pertinent intermolecular contacts and their estimated standard deviations

Atom (1) at (x, y, z)	Atom (2)	Distance (Å)	Symmetry operation applied to the second atom
N(1)	C(14)	3.647(6)	$1+x,\ y,\ 1+z$
C(1)	C(10)	3.516(7)	$x,\ y,\ 1+z$

C(12)	C(9′)	3.746(5)	$-x,\ 1/2+y,\ -1-z$
C(9)	C(7)	4.053(5)	$1-x,\ 1/2+y,\ -z$
C(9)	C(5′)	4.943(6)	$1-x,\ 1/2+y,\ -z$
C(9)	C(9′)	3.960(9)	$1-x,\ 1/2+y,\ -z$

The shortest C···C, C···N, C···H, and N···H intermolecular distances are 3.516 Å along [001], 3.647 Å along [101], 2.16 Å along [001], and 2.89 Å along [101] respectively. The fairly planar molecules are arranged in sheets approximately parallel to the (20$\bar{1}$) plane. A complete overlap of the molecular plane is observed between the *sym*-tetrazinyl and *C*-tolyl groups, while the other interplanar overlaps are incomplete. The interplanar distance of the complete overlap is roughly 4.2 Å. This maximum overlap leads to a column along the c-axis.

It is worth noting that the TTV crystal contains only two molecules in the unit cell with the center of symmetry. Fortunately, for the purpose of magnetic resonance studies, this means that the so-called similar-dissimilar relation can be disregarded. In general, the resonance spectra consist of contributions from both the single molecules and the whole crystal. However,

it is quite difficult to resolve the spectrum into the component contributions, particularly when dissimilar paramagnetic molecules or different magnetic sites are present. Therefore, we presume that the TTV crystal will give more knowledge peculiar to the verdazyl single molecule in the solid phase than any other verdazyl crystal will give.

Spin Densities and Exchange Interaction. Following the method of Fischer, who has treated the lone pairs on N(1) and N(1′) as π-electrons,[11] the McLachlan spin densities of TTV were calculated. The results are shown in Fig. 3. Those values can explain the qualitative ENDOR (electron nuclear double resonance) spectra of TTV. A considerable amount of spin density can be observed on every atom in the π-electron framework.[2]

On the other hand, the magnitude of the exchange interaction between the π-electron spins may be conjectured on the basis of the spin densities and the molecular packing. For the sake of simplicity, we focus our attention on the column along the c-axis. The exchange interaction of conjugated π-spin radicals being considered, the following two-spin Hamiltonian proposed by McConnell[12] is certainly useful:[1]

$$H^{AB} = -\boldsymbol{S}^{A}\cdot\boldsymbol{S}^{B}\sum_{ij}J_{ij}^{AB}\rho_{i}^{A}\rho_{j}^{B}, \qquad (2)$$

where $\boldsymbol{S}^{A}$ and $\boldsymbol{S}^{B}$ are the total spins on the A and B molecules and where ρ_{i}^{A} and ρ_{j}^{B} are the π-spin densities on the i and j atoms of A and B molecules. The exchange integral, J_{ij}^{AB}, depends on the overlap integral between the $2p_{z}\pi$-orbitals of the i and j atoms, and is certainly negative for all the interatomic contacts in the present case,[1] though we cannot estimate its precise magnitude at present. Using the spin densities in Fig. 3, we consider that the contribution due to the overlap integrals between the *sym*-tetrazinyl and the *C*-tolyl groups is ferromagnetic: that is, the sum in Eq. (2) is positive, while the other contributions are antiferromagnetic. This implies that the effective exchange integral, $|J|$, is small when the summation is carried out over all the atoms in the adjacent molecules. In fact, the magnetic susceptibility of TTV follows the Curie-Weiss law with a negative Weiss constant of *ca.* -1 K down to the lowest temperature reached, 1.8 K. Therefore, we presume that the weak exchange interaction inferred from the susceptibility can be attributed mainly to such competitive contributions.

Computer Programs. All the calculations were carried out on a FACOM 270-30 computer at the Institute for Solid State Physics, the University of Tokyo, with a local version of the Universal Crystallographic Computation Program System, UNICS.[13] The thermal ellipsoids were drawn on a HITAC 5020E computer at the Computer Center, the University of Tokyo.[14]

The authors wish to express their deep thanks to Mr. Kohji Watanabe of the Institute for Chemical Research, Kyoto University, for his kind performance of the molecular orbital calculation, and also to the other colleagues with whom they have done this series of investigations. The present work was supported in part by a Scientific Research Grant of the Ministry of Education, to which the authors' thanks are due.

(Received September 2, 1974)

The crystal structure of 1,3,5-triphenyl-6-methylverdazyl has been determined by X-ray diffraction. The crystals are orthorhombic, with the space group of Pnma and with $a=18.25(1)$, $b=16.65(1)$, $c=5.776(2)$ Å, and $Z=4$. The structure was deduced from the sharpened Patterson synthesis and was refined by the block-diagonal least-squares method to the final R value of 0.055 for 960 non-zero reflections collected on an automated four-circle diffractometer. The *sym*-tetrazinyl ring has an asymmetrical boat form, as has been observed in both 1,3,5-triphenylverdazyl and 1,3,5-tri-*p*-tolylverdazyl. The complete intermolecular overlap was observed in a tilted face-to-face array along the c-axis; this accounts for a fairly strong antiferromagnetic exchange interaction between the unpaired electrons.

In the last paper,[1] the present authors have reported the crystal structure of 1,3,5-tri-*p*-tolylverdazyl (TTV), whose electron-spin exchange interaction energy, $|J/k|$, is 1 K at most.[2] The qualitative explanation for the weak exchange interaction has been made on the basis of the crystal structure and π-electron spin densities.[1] On the other hand, the magnetic susceptibility *vs.* temperature curve of 1,3,5-triphenyl-6-methylverdazyl (MeTPV) has a broad maximum in the vicinity of 12 K. This susceptibility can be well described by the linear antiferromagnetic Heisenberg model,[3] and the estimated exchange integral, $|J/k|$, is about 10 K.[2] However, ESR and ENDOR measurements have indicated that the spin-density distribution of MeTPV is almost the same as that of TTV.[4] These facts have made us select MeTPV for the crystal-structure analysis.

Experimental

The crystals of MeTPV prepared by the method of Kuhn and Trischmann[5] were obtained by the recrystallization from an acetone–methanol solution. The results of the elementary analysis showed reasonable values; Found: C, 77.10; H, 5.97; N, 17.03%. The ESR spectrum measured in degassed 2-methyltetrahydrofuran exhibited nine lines, with the nitrogen hyperfine coupling constant of 5.6 gauss. This value was in agreement with the constant of 5.8 gauss (observed in benzene) presented in the literature.[5] However, the melting point of the present sample was higher by ten degrees than the value in the literature;[5] Obs., 193.5—194.5 °C; Lit., 183—184 °C.

The crystal data are shown in Table 1. The lattice constants and intensity data were obtained by using an automatic four-circle diffractometer with Mo$K\alpha$ radiation ($\lambda=0.7101$ Å) monochromated by a graphite crystal. A total 2089 independent reflections were measured up to $2\theta=55°$ by employing the ω-scan technique. Out of these, 960 reflections with $|F_o|$ values not less than $2.5\sigma(F_o)$ were regarded as non-zero reflections and were adopted for the structure determination. The Lorentz and polarization corrections were made as usual, but the correction for absorption was not made in view of the small size of the specimen and the low absorption coefficient.

Structure Determination and Refinement

Wilson's statistics indicated the presence of the center of symmetry; therefore, the Pnma space group was adopted. The crystal structure was solved by the Patterson method. The starting model gave an R value of 0.23. Thereupon, the block-diagonal least-squares refinement was undertaken. Several cycles of the refinement with anisotropic thermal parameters reduced the R value to 0.096. At this stage of the refinement, all the positions of hydrogen atoms were located from a difference Fourier map. With anisotropic thermal parameters for non-hydrogen atoms and isotropic ones for hydrogen atoms, the final R value was 0.055 for 960 non-zero reflections.

Unit weight was adopted for all 960 reflections. The atomic scattering factors used were taken from the International Tables for X-Ray Crystallography.[6] The final parameters for the non-hydrogen atoms are shown in Tables 2 and 3. The positional parameters for the hydrogen atoms are listed in Table 4. The mean

isotropic thermal parameter for the hydrogen atoms was 3.2 Å². The observed and calculated structure factors are compared in Table 5.

Results and Discussion

The molecular structure of MeTPV and the numbering system used in this text are illustrated in Fig. 1. The bond lengths and bond angles are shown in Tables 6 and 7 respectively. The MeTPV molecule has a plane of symmetry and has the molecular structure similar to those of TTV[1)] and TPV.[7)]

C(1) and C(2) are below th N(1)N(2)N(2')N(1') plane (referred to as the N-plane) by 0.622 and 0.105 Å respectively. The corresponding dihedral angles at both ends of the N-plane are 44.1° and 10.1° respectively. Therefore, the conformation of the *sym*-tetrazinyl ring of MeTPV is an asymmetrical boat form, as has been observed in TTV and TPV. The *N*-phenyl ring is above the N-plane by 18.8°, which is the angle between the N-plane and the N(1)–C(4) bond, while the dihedral angle between the plane of the *C*-phenyl ring and the N-plane is 2.6°. The distance of N(1) from the plane through C(1), N(2), and C(4) is 0.055 Å. Accordingly, we can use the following definition for the twist angle about the N(1)–C(4) bond: the twist angle is the dihedral angle between the *N*-phenyl plane and the C(1)N(2)C(4) plane. This twist angle is 21.2°, which is close to the maximum value observed in TPV. The configuration of the *N*-phenyl groups is antipropellor. The two twists of the *N*-phenyls are in opposite directions, since the MeTPV molecule has a plane of symmetry.

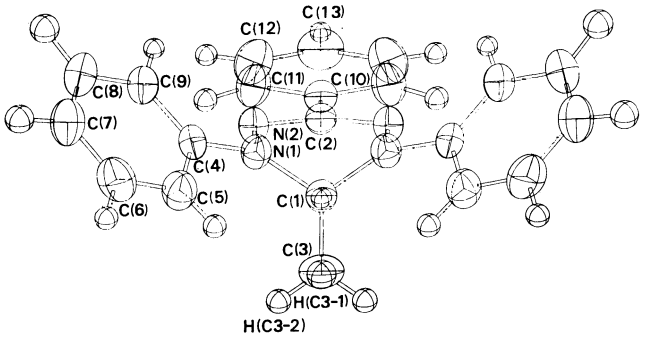

Fig. 1. The molecular structure of MeTPV viewed down the a-axis, along with the numbering system. The thermal ellipsoids enclose a probability of 50%, except for hydrogen atoms. The reflected atom will be represented in terms of its counterpart's symbol followed by a prime, *e.g.* N(1'). The ring hydrogen atom will be labelled by, for example, H(C5) where C5 stands for the ring carbon atom attached by it.

The methyl group attached to the tetrahedral carbon atom, C(1), occupies the *axial* position of the boat. The *ortho* hydrogen atoms, H(C5) and H(C5'), remain *staggered* between H(C1) and C(3).

A less significant molecular structural difference has been observed among three symmetrically substituted verdazyls, TPV, TTV, and MeTPV. On the other hand, the effect of the methyl groups, introduced in the TTV and MeTPV molecules, upon the spin-density distribution in a molecule has been examined by the ENDOR technique. As was expected, little effect has been revealed by the aid of a comparison of their proton hyperfine coupling constants with those of TPV.[4] Accordingly, these radical solids are optimal for our purpose to correlate the magnetic properties of a neutral radical with a delocalized unpaired electron spin with its molecular packing.

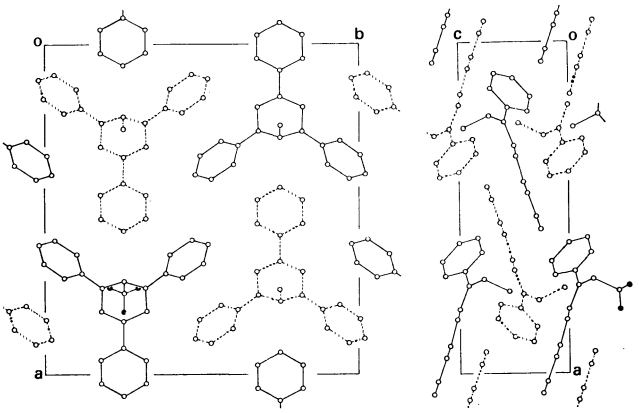

Fig. 2. The mutual arrangement of the MeTPV molecules. The left and the right were viewed along the c- and b-axis, respectively. The doubled circles in the reference molecule stand for the methyl hydrogen atoms, while the other hydrogen atoms were not drawn.

Figure 2 shows the mutual arrangement of the MeTPV molecules. The pertinent intermolecular distances are listed in Table 8. The molecules with a plane of symmetry pack in a tilted face-to-face array along the c-axis. Within the array, the shortest intermolecular distance is 2.94 Å for the N(2)···H(C3-2) contact, and the corresponding N···C distance is 3.489 Å. The intermolecular distance between C(2) and C(3) is 3.397 Å, while the intramolecular distances of the N(1)---C(3) and N(2)---C(3) contacts are 2.468 and 3.054 Å respectively. This intermolecular distance may suggest the deformation of the methyl group from the ordinary tetrahedral conformation.

The melting point of MeTPV is higher than those of its homologues by about 50 °C. This can be mainly attributed to the complete overlap of the adjacent molecules in the array along the c-axis. Such molecular packing will certainly enhance the exchange interaction between the π-electron spins. The magnetic susceptibility of the MeTPV solid is well described by the Heisenberg linear chain model[3] down to the lowest temperature examined so far, 2 K. This fact indicates a less significant coupling of the magnetic chains. The exchange integral estimated from the susceptibility of the MeTPV solid is about -10 K, which corresponds to one of the strongest exchange interactions among those observed in verdazyl free radical solids. The present authors and their colleagues have already interpreted the magnetic properties of TPV, galvinoxyl, and TTV radical solids in terms of both the overlap of $2p_z\pi$-orbitals inferred from the molecular packing and the spin densities.[8,1] From the same point of view, the fairly strong exchange interaction in the MeTPV solid may be attributed to the complete overlap of the molecular planes in the tilted face-to-face array. The excellent magnetic linear chain is also attributable to the uniform intermolecular spacing in the array. The sufficient magnetic insulation between the magnetic chains can be explained by considering the isolation of the chemical chains or the arrays along the c-axis. Speaking in more detail, the interchain contacts occur around the hydrogen atoms or between the atoms whose $2p_z\pi$-orbitals cause a so-called π-overlap and which have small spin densities at that; this will give rise to less significant interchain exchange interactions. The magnetic properties of MeTPV will be discussed quantitatively in a separate paper, together with those of other verdazyls.

The calculations were carried out on a FACOM 270-30 computer at the Institute for Solid State Physics, the University of Tokyo, with a local version of UNICS.[9] The thermal ellipsoids were drawn on a HITAC 5020E computer at the Computer Center, the University of Tokyo.[10] This work was supported in part by a Scientific Research Grant of the Ministry of Education. Thanks are due to authors' colleagues with whom the present authors have done this series of investigations.

Interfacial Capacity between a Silver Bromide Solid Electrolyte and a Blocking Electrode

Noriyoshi KIMURA, Takahisa ŌSAKI, and Shinobu TOSHIMA

Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Aramaki-Aoba, Sendai 980

(Received September 3, 1974)

The interfacial capacity between a silver bromide single crystal and graphite and platinum blocking electrodes was measured using an AC bridge in the potential range 0.05—0.55 V *vs.* Ag/AgBr at 200—400 °C. The observed capacity-potential curves were compared with the calculated values from the space charge layer capacity. In the case of the graphite electrode, the capacity had a minimum value at 0.15—0.20 V *vs.* Ag/AgBr, whereas for the platinum electrode, the capacity was considerably larger and the differential capacity-potential curves were complicated. It is concluded that the space charge layer capacity predominates for the graphite electrode, but for the platinum electrode, its interaction with silver ion must be taken into account.

The structure and polarization capacity of the interface between an electrode and an ionic crystal have been discussed by many researchers.[1-3] In particular, the interfaces of ionic crystals containing excess electrons or positive holes as charge carriers, namely semiconductors, have been extensively investigated both theoretically and experimentally.[4,5] As is well known, in the neighborhood of a semiconductor surface, a space charge layer exists owing to charge excess or depletion, which is analogous to the Gouy-Chapman layer in an ionic aqueous solution.

In the case of an ionic conductive crystal, so called solid electrolyte, lattice defects act as charge carriers, and a space charge layer may be formed at the interface. Such a space charge layer model has been treated theoretically by Grimley and Mott,[6,7] and more recently by Kliewer.[8,9] The real crystal-electrode interface has been discussed many times and although considerable attention has been focussed on the measurements of the interfacial characteristics, we note that the measured values differ appreciably among researchers. This is probably mainly due to the uncertainty of the contact between crystal and solid electrode and partly due to the difficulty in preparing a clean and ordered surface of the crystals. These factors are particularly significant when polycrystalline samples are used.

In the present investigation, single crystals of silver bromide were used. A slight elasticity of the crystal enabled a good contact between the crystal and the electrode to be made. Since silver bromide has a simple crystal structure (NaCl type) and has Frenkel type lattice defects,[10] the interstitial silver ions and silver ion vacancies act as charge carriers in the crystal. Weiss[11] measured polarization current when the electrode potential was changed, and then considered the space charge layer on the basis of the excess electron distribution in the silver bromide. Raleigh treated the interfacial capacity mainly by galvanostatic and potentiostatic charging method.[12-14] We measured the variations of the interfacial capacity with the electrode potential for both graphite and platinum as the blocking electrode in order to consider the interfacial characteristics.

Experimental

Sample Preparation. Silver bromide was prepared by adding hydrobromic acid to silver nitrate solution. All chemicals were of reagent grade and hydrobromic acid was distilled before use. The precipitate was dried under vacuum and melted in a quartz tube. After pinholing, the melted salt was treated in a bromine atmosphere and finally a pure sample was obtained by vacuum distillation. Single crystals were grown by the Bridgeman method. For the sample containing cadmium ion, a given amount of cadmium bromide was added to the silver bromide before vacuum drying. Then it was treated as described above except for the vacuum distillation. The crystal was machined into a disk 15 mm in diameter and 5 mm thick, and then polished. It was etched in 40% sodium thiosulfate and 0.2% potassium cyanide solution, and then washed well in redistillated water followed by heating in vacuum at about 200 °C. The sample preparation and cell assembly were carried out in the dark.

Cell Assembly. The working electrode was either a

wire of platinum or a rod of graphite, 1 mm in diameter. These electrodes were polished with γ-alumina (particle size 2 mμ), and were washed in acetone. The counter electrode was prepared by vacuum evaporation of silver on one plane of the cylindrical crystal pellet, and the silver foil was placed on it. For a reference electrode, silver wire was wound around the cylindrical pellet. The cell consisted of a silver bromide crystal pellet spring-loaded between the working and the counter electrodes as shown in Fig. 1. The cell was annealed in a nitrogen atmosphere at 400 °C for half a day before measurement.

An AC bridge shown in Fig. 2 was used for impedance measurements. A potentiometer was included for applying a given potential to the working electrode. The input voltage to the bridge was regulated to be less than 5 mV p-p in the frequency range 0.2 to 10 kHz.

Results

Typical potential sweep curves were shown in Fig. 3. No appreciable rises in current were observed between 0.05 and 0.60 V. The current below 0.05 V is assumed to be due to deposition of silver and that beyond 0.60 V to be due to decomposition of silver bromide. So the differential capacity was measured in the range from 0.05 to 0.60 V. The observed capacity increases to some extent at low frequency, but it becomes almost constant at high frequency at higher temperatures. However, at temperatures below 250 °C, the observed capacity decreases with increasing frequency above 1 kHz. In fact, the resistance of the crystal becomes

considerable at this temperature, which suggests that the influence of the geometric capacity[15] seems to increase. Therefore, the capacity-potential curves were measured at a frequency of 1 kHz throughout this work.

The capacity-potential curves with graphite electrode are presented in Figs. 5—7 for silver bromide crystals which contained various amounts of cadmium bromide,

in order to change the amount of silver ion vacancies in them. The corresponding curves with a platinum electrode are shown in Figs. 8—10.

Discussion

Space Charge Layer. Kliewer[9] treated the space charge layer of silver chloride as a typical ionic crystal with Frenkel type defects. The same treatment may be applied to the silver bromide crystal. In a crystal slab of thickness $2L$, the potential φ will obey Poisson's equation with the boundary condition, $\varphi=\varphi_0$ at $x=0$, $x=2L$ (crystal surface) and $d\varphi/dx=0$, $\varphi=\varphi_b$ (in the bulk of crystal),

$$d^2\varphi/dx^2 = -4\pi\rho/\varepsilon, \quad (1)$$

where ε is the static dielectric constant, ρ is the charge density in the crystal. In the silver bromide crystal, the densities of silver ion vacancy (effective charge: $-e$), n_v, and interstitial silver ion (effective charge: $+e$), n_i, are given by

$$n_v = N\exp[\{-F_v+e(\varphi-\varphi_0)\}/kT], \quad (2)$$

$$n_i = N_i\exp[\{-F_i-e(\varphi-\varphi_0)\}/kT]. \quad (3)$$

assuming $n_v \ll N$, the density of silver ion lattice sites, and $n_i \ll N_i$, the density of interstitial sites, and the condition $2N=N_i$ is valid in the silver bromide crystal.

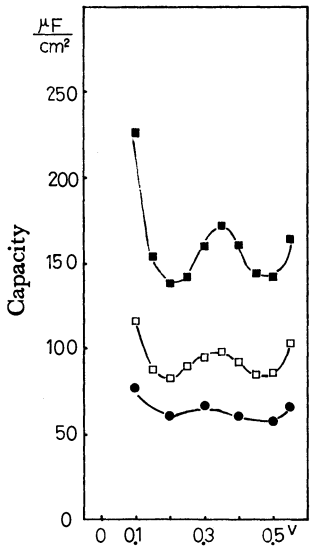

Fig. 10. Observed potential-capacity curves for platinum/AgBr–$CdBr_2$ (0.5 mol%).
■: 399 °C □: 350 °C ●: 303 °C

F_v and F_i are the formation free energy of the vacancy and the interstitial ion. If a divalent cation is introduced into the silver bromide, such a cation has an effective charge $+e$ when it does not associate with the vacancy. The density of unassociated divalent cations may be expressed as

$$n_f = N\exp[\{-\alpha-e(\varphi-\varphi_0)\}/kT], \quad (4)$$

where α is a Lagrange multiplier. Thus, the charge density is given by

$$\rho = e(n_i-n_v+n_f). \quad (5)$$

Within the bulk of the crystal, the condition of electrical neutrality will be satisfied. The condition may be obeyed well when $\kappa L \gg 1$, where $1/\kappa=(\varepsilon kT/8\pi e^2N)^{1/2} \times\exp\{-(eU-F_v)/2kT\}$, substituting $U=\varphi_b-\varphi_0$. This value is about 1×10^{-7} cm, for the silver bromide crystal at 300 °C. For a pure crystal, the equation

$$U = (F_v-F_i+kT\ln 2)/2e \quad (6)$$

may be derived from the condition of electrical neutrality. Substituting Eqs. (2), (3), (4), and (5) into (1), and then integrating it, the electric field is found to be

$$d\varphi/dx = (32\pi kTN/\varepsilon)^{1/2}\exp\{(eU-F_v)/2kT\} \times\sinh\{e(\varphi-\varphi_b)/2kT\}. \quad (7)$$

The surface charge density is given by $\sigma_0=(\varepsilon/4\pi) \times(d\varphi/dx)_{x=0}$. The space charge layer capacity is found to be $C_s=d\sigma_0/d\varphi_0$. In the bulk of the pure crystal, $n_{ib}=n_{vb}=n$ and $n=N\exp\{(eU-F_v)/kT\}$ are derived from the condition of electrical neutrality, so the capacity may be written

$$C_s = (\varepsilon e^2n/2\pi kT)^{1/2}\cosh(eU/2kT). \quad (8)$$

Using Eq. (8), the capacity of the space charge layer for the silver bromide crystal was calculated and the result is shown in Fig. 4. This equation is similar to the space charge layer capacity for an intrinsic semiconductor.

Graphite Electrode. The differential capacity curves measured with the graphite electrode shown in Fig. 5 have a minimum value at a potential 0.15—0.20 V. With increasing temperature, the minimum point appears more sharply and the value of capacity increases, which is similar to the behavior shown in Fig. 4. The observed values of the capacity at minimum points agree fairly well with the calculated values of the space charge layer capacity. The crystals containing cadmium ion show similar characteristics to the pure crystal as shown in Figs. 6 and 7. This seems to be due to the fact that at high temperature intrinsic defects are predominant in the crystal lattice. A structure sensitive region for these crystals appeared in our conductivity-temperature measurements below 250 and 125 °C with crystals containing 0.5 and 0.1 mol% cadmium bromide, respectively. The observed capacity at these temperature varied little with potential in the neighborhood of the capacity minimum point, so that the potential of the capacity minimum was not remarkable.

The potential of zero charge on the silver bromide surface can be considered in connection with the potential of minimum capacity. If the formation energy of defects F_v and F_i were known, the potential of zero charge of the pure crystal can be calculated from the Eq. (6). Trautweiler[16] reported that the surface potential of the silver bromide was −0.14 V in reference to the crystal bulk. The potential of Ag/AgBr was reported to be 1.4 V by Mott and Grimley[6] and recently to be less than 0.6 V by Weiss.[11] Then, the potential of zero charge on the silver bromide may be considered to be less than several hundred millivolts with reference to the potential of Ag/AgBr. In order to obtain a precise value of the zero charge potential in the solid-solid system, it may be difficult to employ the method of Karpachev,[17,18] who studied some fused metal electrodes on stabilized zirconia by potential-surface tension measurements. We would rather regard the observed potential of minimum capacity as the potential of zero charge in the case of the graphite electrode. Therefore, the differential capacity of the graphite in the measured potential range can be considered to be mainly due to the space charge layer capacity, caused by the distribution of the interstitial silver ions and silver ion vacancies.

Platinum Electrode. The observed capacity of the platinum electrode is considerably larger than that of the graphite electrode and the dependence on potential is complicated. The capacity curve had two minimum points at 0.20 and 0.45 V, and a small peak was observed between them. The shape of the differential capacity curve was not changed by addition of cadmium ion, therefore this characteristic was apparently not due to impurities. The same characteristic was observed by Raleigh[12] near the melting point. We consider it difficult to explain this capacity-potential relation by a simple space charge layer model, in which a charge carrier is regarded as an ideal point charge and its interaction with the electrode is not taken into account. In addition, the charge carriers in the real crystal have finite volume, therefore the closest distance of the ion

to the electrode and its interaction must inevitably be considered. This concept is similar to Stern's theory for ionic solutions, except for the solvent action. If an assumption is introduced that the ions interact with the electrode only in the layer adjacent to the surface (first layer), but the ions in the second and the following layer have a distribution determined by the space charge layer model, the electrode potential may be described as

$$\varphi_0 - \varphi_b = (\varphi_0 - \varphi_1) + (\varphi_1 - \varphi_2) + (\varphi_2 - \varphi_b), \quad (9)$$

where φ_1, φ_2, and φ_b represent the potential in the first and second layers and the bulk of the crystal. The surface charge density is given by

$$\sigma_0 = \sigma_1 + \sigma_s, \quad (10)$$

where σ_1 and σ_s denote the charge density in the first layer and the space charge layer. Then the capacity may be written as

$$1/C = \partial(\varphi_0 - \varphi_b)/\partial\sigma_0 = 1/C_{0-1} + (1/C_{1-2} + 1/C_s)(1 - \partial\sigma_1/\partial\sigma_0), \quad (11)$$

where $C_{0-1} = \partial\sigma_0/\partial(\varphi_0 - \varphi_1)$, $C_{1-2} = \partial\sigma_s/\partial(\varphi_1 - \varphi_2)$, and $C_s = \partial\sigma_s/\partial(\varphi_2 - \varphi_b)$. C_s can be determined from Eq. (8), but if any interaction between ion and electrode is present, the observed capacity is not given by the simple space charge layer model. Thus, the platinum electrode is considered to show significant interaction with the silver ion. When there is no interaction, $\partial\sigma_1/\partial\sigma_0 = 0$, and therefore $1/C = 1/C_i + 1/C_s$ is valid, where C_i is the capacity which arises from the finite size of ions. The graphite electrode is considered to have little interaction with the silver ion. When $C_i \gg C_s$, the observed capacity is predominantly due to C_s.

This research was partly supported by the Science Research Fund of the Ministry of Education.

A Configuration Analysis of the Electronic States of Aniline

Satoshi SUZUKI and Tsuneo FUJII

Department of Industrial Chemistry, Faculty of Engineering, Shinshu University, Wakasato, Nagano 380

(Received September 11, 1974)

The method of configuration analysis has been applied to the interpretation of the ground and the excited electronic states of aniline. The results of full analysis, including all the singly and the doubly excited configurations, is presented. The electronic wave functions analyzed were obtained by a procedure of the Pariser-Parr-Pople type. The first excited singlet state of aniline is assigned to the ^1L_b. The second, the third, and the fourth excited singlet state are assigned to the mixed state of the ^1L_a and $^1CTS1$ states, the ^1CTA, ^1B_b, and ^1L_b states, and the ^1B_a and ^1L_a states respectively. The lowest triplet state of aniline is assigned to the ^3L_a state. The total weights of all the singly excited configurations range from 88% to 95%, except for the ground state. The inclusion of all the doubly excited configurations improves the weights up to 99.6% or more.

The effects of substitution on electronic spectra have been extensively investigated for benzene derivatives.[1-5] Aniline, which is a typical derivative of benzene with an electron-donating group, has received much attention; numerous papers on its semi-empirical calculations have been published.[6-22] From a chemical point of view, the excited states of substituted compounds have been interpreted in terms of locally excited states and charge-transfer states. In accordance with this standpoint, Murrell,[8] Kimura *et al.*,[15] and Godfrey and Murrell[16] determined the assignment of the excited states of aniline by using the localized-orbital or the composite-molecule description. Using the two-step transformation of the wave functions obtained by the Pariser-Parr-Pople method through natural spin orbitals, Fischer-Hjalmars[11] described the excited states of aniline in terms of locally excited and charge-transfer states. There has also been some discussion of the assignment of the second absorption band of aniline. Kimura *et al.*[15] as well as Murrell[8] assigned the band to a charge-transfer transition, whereas Baba[10] and Fischer-Hjalmars[11] assigned it to a locally excited transition.

The present paper will interpret the excited electronic states of aniline in terms of the locally excited states and the charge-transfer states by the application of configuration analysis.[23,24] A full analysis including all the doubly excited configurations will also be given, and contributions from the doubly excited configurations will be discussed.

Method of Calculation

The Pariser-Parr-Pople method with limited configuration interaction was used for the calculation of the π-electronic states of benzene and aniline. The Coulomb repulsion integrals were obtained by means of the following formula:[24,25]

$$\gamma_{pq} = 14.40/[a \exp(-0.3r^2) + r] \text{ eV}$$

where r is the distance in Å units between a pair of atoms, p and q. The parameter, a, is determined by the following formula:

$$a = 14.40 \Big/ \left\{ \frac{1}{2}[(I_p - A_p) + (I_q - A_q)] \right\} \text{ eV}$$

where I_p and A_p are the ionization potential and the electron affinity of an atom, p, respectively.

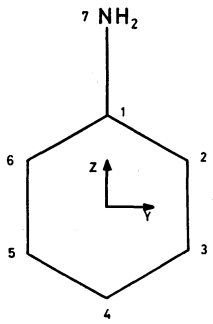

Fig. 1.

The aniline molecule is regarded as being planar and belonging to the C_{2v} symmetry group. The numbering of the atoms and the coordinate axes are shown in Fig. 1. It is assumed that the benzene ring consists of a regular hexagon, with every C–C bond length equal to 1.40 Å, and that the C–N bond length is 1.41 Å. The valence-state ionization potential and the electron affinity for a carbon atom are taken as follows:

$$I_C = 11.16 \text{ eV}, \quad A_C = 0.03 \text{ eV}$$

The resonance integral, β_{CC}, is adjusted to fit the benzene spectrum.

$$\beta_{CC} = -2.48 \text{ eV}$$

In order to discuss the effect of substitution on the electronic spectra, it is reasonable to compare the observed shifts caused by the introduction of a substituent with the calculated shifts, instead of making a direct comparison between the observed and the calculated state energies. From this point of view, the ionization potential, the electron affinity, and the resonance integral related to a nitrogen atom are varied until a satisfactory agreement between the calculated and the observed shifts caused by the introduction of an amino group into benzene is achieved. The best fitted values are as follows:

$$I_N = 26.7 \text{ eV}, \quad A_N = 9.7 \text{ eV}, \quad \beta_{CN} = -1.9 \text{ eV}$$

The SCF MO's are numbered from 1 to 6 for benzene and from 1 to 7 for aniline, in the order of increasing energy. The excited configurations included in the CI calculations are the following one-electron transitions: 2→4, 2→5, 3→4, and 3→5 for benzene and 4→5, 4→6, 3→5, 3→6, 2→5, and 2→6 for aniline.

The ground and the excited state functions of aniline thus obtained are submitted to configuration analysis. The procedure for configuration analysis was presented previously.[23,24] The symbols used in the present paper have the same meanings as in Ref. 24, unless otherwise noted. In the present paper, the reference SCF MO's consist of ϕ°_1, ϕ°_2, $\cdots$, ϕ°_6, which are the SCF MO's of benzene, and ϕ°_N, which represents the π-AO of the substituent of aniline.

Results

Table 1 summarizes the observed and the calculated state energies for benzene and aniline, including the f values. The singlet excited state wave functions are denoted by $^1\Psi_I$, $^1\Psi_{II}$, $\cdots$ in the order of increasing energy, while the ground state function is written as $^1\Psi_G$. The triplet excited wave functions are denoted by $^3\Psi_I$, *etc.*

The results of the configuration analysis for the ground and the excited singlet states of aniline are given in Table 2. The results for the triplet states are given in Table 3. In these and the following tables, the reference-state wavefunctions are indicated by a superscript °. The locally excited states are classified by the group theoretical notation and the Platt notation. The charge-transfer configurations arising from the one-electron excitation from $\phi^\circ_N \rightarrow \phi^\circ_4$, $\phi^\circ_N \rightarrow \phi^\circ_5$, and $\phi^\circ_N \rightarrow \phi^\circ_6$ are denoted by Ψ°_{CTS1}, Ψ°_{CTA}, and Ψ°_{CTS2} respectively. The higher excited configurations, which are not included in the CI calculations of benzene, are written as Ψ°_{15}, which means a one-electron excitation configuration from ϕ°_1 to ϕ°_5, *etc.*

column of band assignment. If there is no reference state the weight of which singly exceeds 50%, the state notations for the reference states of the most important contribution are indicated in parentheses.

Configuration analysis including all the doubly excited configurations has been performed for both the singlet and the triplet states. All the doubly excited configurations which have a contribution higher than 0.0001 are given in Table 4 for the singlet states and in Table 5 for the triplet states. The notations concerning the doubly excited configurations are the same as in Ref. 24. The total weight means the sum of the weights of all the singly and doubly excited configurations.

Discussion

The calculated shifts in transition energies caused by the introduction of an amino group are compared with the observed shifts in Table 6. The calculated and the observed shifts agree well. Therefore, the electronic wave functions which were subjected to configuration analysis in the present study are appropriate to a discussion of the effect of substitution on the electronic spectra.

The ground state of aniline may safely be assigned to the ground reference state. The charge-transfer reference states have a weight of 11.84% in the ground state. In the first excited state of aniline, the reference state which has the highest contribution to this state is the ^1L_b, the wight of which is 59.55%. The first excited state of aniline may, therefore, be assigned to the locally excited reference state, ^1L_b. The weight of the charge-transfer contributions to this state is 28.47%. The contribution of the ^1B_b to the first excited state is only 2.53%, but the origin of the absorption intensity of the first absorption band in aniline may be explained by the mixing with the ^1B_b.

In the second excited state of aniline, there is no reference state which alone has a weight of contribution higher than 50%. The reference state of the highest contribution to this excited states is the ^1L_a; however, the weight of the ^{1}CTS1 state is comparable to, and a little lower than, that of the ^1L_a state. It is reasonable that the second excited state of aniline is assigned to the mixed state of the ^1L_a and the ^{1}CTS1 reference state. The ^1B_a reference state has a weight of 3.90%; the intensity of the second absorption band may be derived from the ^1B_a state. The weight of the ground reference state is 5.87%.

In the third excited state of aniline, the reference state with a maximum wight is the ^{1}CTA state. However, there are two other reference states which have weights comparable to that of the ^{1}CTA, namely, the ^1B_b and ^1L_b states. The third excited state of aniline is, therefore, assigned to the mixed state of the ^{1}CTA, ^1B_b, and ^1L_b states. The ^1B_a reference state makes the highest contribution to the fourth excited state of aniline. The ^1L_a reference state also makes a considerable contribution to this excited state. It is found that the higher excited states of aniline are difficult to explain in terms of a single locally excited state or a single charge-transfer state.

Table 6. Comparison of the band shifts caused by the introduction of an amino group into benzene

Band	Band shift (eV)			
	Obsd	This work	Fischer-Hjalmars	Kimura *et al.*
I	−0.49	−0.475	−0.198	−0.17
II	−0.78	−0.742	−0.619	−0.75
III	−0.58	−0.645	−0.501	−0.56
VI	−0.10	−0.287	−0.336	−0.12

In the first excited triplet state, the ^3L_a state alone has a weight higher than 50%; therefore, the first triplet state of aniline may be assigned to the ^3L_a reference state. The ^{3}CTS1 state and the ^3B_a state have weights of 27.35 and 7.70% respectively. The assignments of the higher triplet states of aniline are given in Table 3. It is of interest that the weights of the charge-transfer reference states in the $^3\Psi_V$ and $^3\Psi_{VI}$ states have values higher than 50%, whereas the charge-transfer reference states make little contribution to the $^3\Psi_{III}$ and $^3\Psi_{IV}$ states. In general, it is found that the reference states in the triplet states are mixed together to a lesser extent than those in the singlet states.

All the contributions from the doubly excited configurations were calculated for both the singlet and the triplet states of aniline. The $^1V^\circ_{25.N4(2)}$ reference configuration has a weight of 7.58% relative to the $^1\Psi_{IV}$ state. The reference configurations which have weights higher than 2% are as follows: $^1V^\circ_{35.N4(2)}$ ($^1\Psi_I$); $^1V^\circ_{N4.N4}$ and $^1V^\circ_{34.N4}$ ($^1\Psi_{II}$); $^1V^\circ_{24.N4}$ ($^1\Psi_{III}$); $^1V^\circ_{25.N4(2)}$ and $^1V^\circ_{25.N6(2)}$ ($^1\Psi_{IV}$); $^1V^\circ_{35.N4(2)}$ ($^1\Psi_V$); $^1V^\circ_{N4.N4}$ and $^1V^\circ_{24.N4}$ ($^1\Psi_{VI}$). All the other reference configurations have weights less than 2% relative to the individual singlet states. The contributions of individual doubly-excited configurations are not important, however, the sum weights from all the doubly excited configurations have values ranging between 7.39 and 11.66%, except for the ground state. The sum weight of all the singly excited states or configurations for the ground state has a value of 99.58%, but the sum weights for the excited singlet states have values of about 90% (from 88.00 to 92.54%). The inclusion of all the doubly excited configurations improves the sum weights of the excited states up to 99.66% or more. It may be said that the "accuracy" of the description of the lower excited electronic states of aniline in terms of the locally excited states and the charge-transfer states within the singly excited configurations is approximately 90%. The inclusion of the doubly excited configurations improves the "accuracy" of the description, but the brevity of the description is lost. When the sum weights of all the singly excited configurations are far from 100%, the selection of reference states or configurations should be reconsidered. If a proper selection of reference states is impossible, one should abandon the description of the excited states in terms of locally excited states and charge-transfer states.

The reference states included in the calculation by Kimura *et al.*[15] are the ground state, $^1\Psi^\circ_G$, the four locally excited states, $^1\Psi^\circ_{Lb}$, $^1\Psi^\circ_{La}$, $^1\Psi^\circ_{Bb}$, and $^1\Psi^\circ_{Ba}$, and the two charge-transfer states, $^1\Psi^\circ_{CTS1}$ and $^1\Psi^\circ_{CTA}$. The sum weights of these seven reference states in the present configuration analysis are as follows: 90.55% ($^1\Psi_I$), 88.24% ($^1\Psi_{II}$), 89.59% ($^1\Psi_{III}$), 87.07% ($^1\Psi_{IV}$), 83.50% ($^1\Psi_V$), and 83.89% ($^1\Psi_{VI}$). This implies that a portion of the electronic interactions is neglected in the localized-orbital description compared with the Pariser-Parr-Pople method (10—16% in the case of aniline). In other words, the wave functions of locally excited states or charge-transfer states cannot be regarded as the basis functions of rapid convergence in the expansion of excited states of aniline.

Murrell,[8] Kimura *et al.*,[15] and Godfrey and Murrell[16] obtained the electronic wave functions of aniline as the linear combinations of locally excited and charge-transfer state functions by using the localized-orbital method. On the other hand, Fischer-Hjalmars[11] transformed the excited wave functions obtained by the Pariser-Parr-Pople method into locally excited or charge-transfer state functions through natural spin orbitals. In Table 7, the results of the present configuration analysis are compared with those of the other investigations.

Table 7. Comparison of the results

$^1A_1$

Reference state	$^1\Psi_{II}$ CA[a]	$^1\Psi_{II}$ Fischer-Hjalmars	$^1\Psi_{II}$ Kimura *et al.*	$^1\Psi_{IV}$ CA[a]	$^1\Psi_{IV}$ Fischer-Hjalmars	$^1\Psi_{IV}$ Kimura *et al.*
$^1\Psi^\circ_G$	6.7		3.7	1.3		0.4
$^1\Psi^\circ_{La}$	46.7	57.5	34.9	36.3	26.1	53.1
$^1\Psi^\circ_{Ba}$	4.4	4.2	11.4	49.8	55.4	37.5
$^1\Psi^\circ_{CTS1}$	42.2	38.3	50.0	12.6	18.7	9.0

$^1B_2$

Reference state	$^1\Psi_I$ CA[a]	$^1\Psi_I$ Fischer-Hjalmars	$^1\Psi_I$ Kimura *et al.*	$^1\Psi_{III}$ CA[a]	$^1\Psi_{III}$ Fischer-Hjalmars	$^1\Psi_{III}$ Kimura *et al.*
$^1\Psi^\circ_{Lb}$	65.8	89.5	74.6	29.8	5.7	21.4
$^1\Psi^\circ_{Bb}$	2.8	0.7	2.7	32.2	60.5	39.9

a) The results of the present work. Weights are normalized to 100% within the states listed in the table.

In the assignment of the first excited state of aniline, a qualitative agreement is found among these results. Kimura *et al.* as well as Murrell assigned the second excited state of aniline to the charge-transfer state, ^{1}CTS1. On the contrary, Baba[10] and Fischer-Hjalmars assigned the band to the locally excited state, ^1L_a. The present study supports the latter assignment rather than the former one, but the weight of the ^1L_a state does not exceed 50%. The third excited singlet state shows a remarkable mixing among the ^1L_b, ^1B_b, and ^{1}CTA states in the present study and in the work of Kimura *et al.*, but it was assigned to the ^1B_b reference state in the work of Fischer-Hjalmars. In the fourth excited state, the result of the present analysis resembles that of Fischer-Hjalmars rather than that of Kimura *et al.* The result obtained by Murrell showed a qualitative resemblance to that obtained by Kimura *et al.*, but the result obtained by Godfrey and Murrell resembled that obtained by Fischer-Hjalmars.

Kimura and Tsubomura[26] calculated the wave functions of the triplet states of substituted benzenes by using the localized-orbital method. They assigned the lowest triplet state of aniline to the ^3L_a, in accordance with the results of the present analysis.

The calculated band shifts caused by the introduction of an amino group into benzene are compared with the

observed shifts as well as the calculated shifts obtained by the other studies in Table 6. Band I of aniline, which was assigned to the locally excited transition of benzene, ^1L_b, shows a considerable red shift compared with Band I of benzene. In the calculation of state energies by the localized-orbital method adopted by Murrell, by Kimura *et al.*, and by Godfrey and Murrell, the observed transition energies of benzene are used as the state energies of the locally excited configurations. Nevertheless, the localized-orbital method can not correctly reproduce the red shift of Band I. The result obtained by Fischer-Hjalmars does not give the red shift of Band I correctly, either. Furthermore, the mixing of the ground state with the excited reference states has been neglected in the work of Fischer-Hjalmars.

Theoretical Calculation of ^{13}C Chemical Shielding Anisotropy in Some Organic Compounds. II.

Isao ANDO and Atsuo NISHIOKA

Department of Polymer Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received September 18, 1974)

The ^{13}C chemical shielding anisotropies of acetic acid and its related compounds were calculated theoretically by the LCGI-MO theory, using the MINDO/2 method; the results were found to agree with the experimental data measured by Pines *et al.* As for acetic acid, a dimer structure was suggested to be preferable to the monomer structure on the basis of the calculated and experimental results.

In our previous paper[1] we calculated theoretically the ^{13}C chemical shielding anisotropies of benzene and its derivatives, and of acetone with a linear combination of the gauge invariant atomic orbitals-molecular orbital (LCGI-MO) theory of Pople,[2] using the MINDO/2 method;[3] we thus obtained good agreement with the experimental data measured by Pines *et al.*[4] In the same way, we will now calculate the ^{13}C chemical shielding anisotropies of acetic acid, taking into account the monomer and dimer structures, and compare our results with Pines' results in order to obtain information on its molecular structure. Further, we will discuss the ^{13}C shielding parameters of its related compounds containing the carbonyl group, acetic anhydride, methyl formate, and acetaldehyde.

Calculation

The ^{13}C chemical shielding is dominated by the paramagnetic terms, σ_{xx}, σ_{yy}, σ_{zz}, which are estimated by the use of the LCGI-MO theory using 2p orbitals, as follows (*e.g.*, σ^p_{xx}):

TABLE 1. THE CALCULATED AND EXPERIMENTAL[4] ^{13}C CHEMICAL SHIELDING PARAMETERS IN ACETIC ACID, ACETIC ANHYDRIDE, METHYL FORMATE, AND ACETALDEHYDE

Compound	Calculated (ppm)				Experimental (ppm)			
	σ^p_{xx}	σ^p_{yy}	σ^p_{zz}	$\Delta\sigma_{calc}$ [a]	σ_{11}	σ_{22}	σ_{33}	$\Delta\sigma_{obs}$ [a]
Acetic acid								
Case I  CO	−445.8	−278.5	−223.2	138.9				
Case II  CO	−439.9	−262.8	−238.2	113.2	CO	−140±6	−55±6	19±6	116.5±6
Case III  CO	−413.8	−285.2	−229.4	120.1				
Acetic anhydride  CO	−367.9	−196.2	−215.9	95.7		−152±6	13±6	13±6	82.5±6
Methyl formate  CO	−443.0	−276.5	−228.9	130.8		−124±6	−7±7	22±7	87.5±7
Acetaldehyde  CO	−447.1	−381.8	−221.6	192.8		−147±7	−105±6	42±6	168±6

a) $\Delta\sigma_{calc}$ and $\Delta\sigma_{obs}$ are the calculated and observed shielding anisotropies, respectively.

$$\sigma^{p}_{xx} = -(2e^2\hbar^2/m^2c^2)\langle r^{-3}\rangle_{2p}\sum_{i}^{occ}\sum_{k(\neq i)}^{unocc}\Delta E^{-1}_{k-i} \times (C_{i_{y_A}}C_{k_{z_A}} - C_{i_{z_A}}C_{k_{y_A}})\sum_{B}(C_{i_{y_B}}C_{k_{z_B}} - C_{i_{z_B}}C_{k_{y_B}}) \quad (1)$$

where $C_{i_{x_A}}$ is the coefficient of the $2p_x$ atomic orbital on the A atom of the i-th molecular orbital in the LCAO MO theory, where $\sum_{i}^{occ}$ and $\sum_{k(\neq i)}^{unocc}$ are the summations over occupied and unoccupied orbitals respectively, where $\sum_{B}$ runs over all atomic orbitals in the molecule, and where ΔE_{k-i} is the singlet-singlet excitation energy between the i-th occupied and the k-th unoccupied orbitals. $\langle r^{-3}\rangle_{2p}$ represents the atomic 2p orbital dimension given by:[5]

$$\langle r^{-3}\rangle_{2p} = 34.33a_0^{-3}(1.0-0.323q_A')/24 \quad (2)$$

where a_0 is the Bohr radius and where $-q_Ae$ is the net charge. The MINDO/2 method was used as the molecular orbital method, because the excitation energy for the molecule with π-electrons is said to be interpreted well by this method without taking the configuration interaction into account.

The bond lengths and bond angles used were set at standard values.[6] In the dimer of acetic acid, the distance between the oxygen atoms in the hydrogen bond (C–O–H···O=C) used was 2.76 Å.[7]

The calculations were carried out by means of the HITAC-8800/8700 computer of the Computer Center of the University of Tokyo.

Results and Discussion

First, let us examine the acetic acid molecule. Generally, carboxylic acids are well-known to form hydrogen bonding in the liquid and solid states.[8] Thus, as the molecular structure of acetic acid, we consider the cyclic dimer structure, together with the two monomer structures, as is shown in Table 1. In calculating each component of the chemical shielding, it is necessary to know the direction of the principal axis of the molecule. We assume that the principal axis is along the C=O bond. This seems appropriate approximately for the carbonyl carbon. The principal values, σ^{p}_{xx}, σ^{p}_{yy}, and σ^{p}_{zz}, calculated for the carbonyl carbons are shown in Table 1, together with the experimental values, σ_{11}, σ_{22}, and σ_{33}, measured by Pines *et al.*; the latter are the components of the shielding tensor. The experimental chemical shielding anisotropy is defined as $\Delta\sigma_{obs}=\sigma_{33}-(\sigma_{11}+\sigma_{22})/2$, in which σ_{33} is the most shielded component ($\sigma_{11}<\sigma_{22}<\sigma_{33}$); on the other hand, the calculated anisotropy, $\Delta\sigma_{calc}$, is estimated by taking the most shielded component as the component corresponding to σ_{33} in the experimental results (here, in acetic acid σ^{p}_{yy} is taken as its component). As for the carbonyl carbon, the $\Delta\sigma_{cal}$ values of Cases II and III are found to agree with the experimental ones better than that of Case I. For a more detailed comparison between these, the stick spectra of each shielding tensor are shown in Fig. 1. From this figure the results of Case III are found to agree well with the observed values and also with the results obtained by another method.[8]

Next, let us discuss the $\Delta\sigma$ value of the carbonyl carbon in acetic anhydride. The calculated $\Delta\sigma_{calc}$ value is 95.7 ppm. If the values of σ^{p}_{yy} and σ^{p}_{zz} are averaged with each other by taking into account the observed fact that $\sigma_{22}=\sigma_{33}$, the calculated $\Delta\sigma_{calc}$ value is obtained as 80.9 ppm. This agrees well with the observed value, 82.5 ppm. The stick spectra are shown in Fig. 1. In acetic anhydride, the most shielded component is σ^{p}_{yy}, which is slightly more shielded than σ^{p}_{zz}. This is different from the case of acetic acid, in

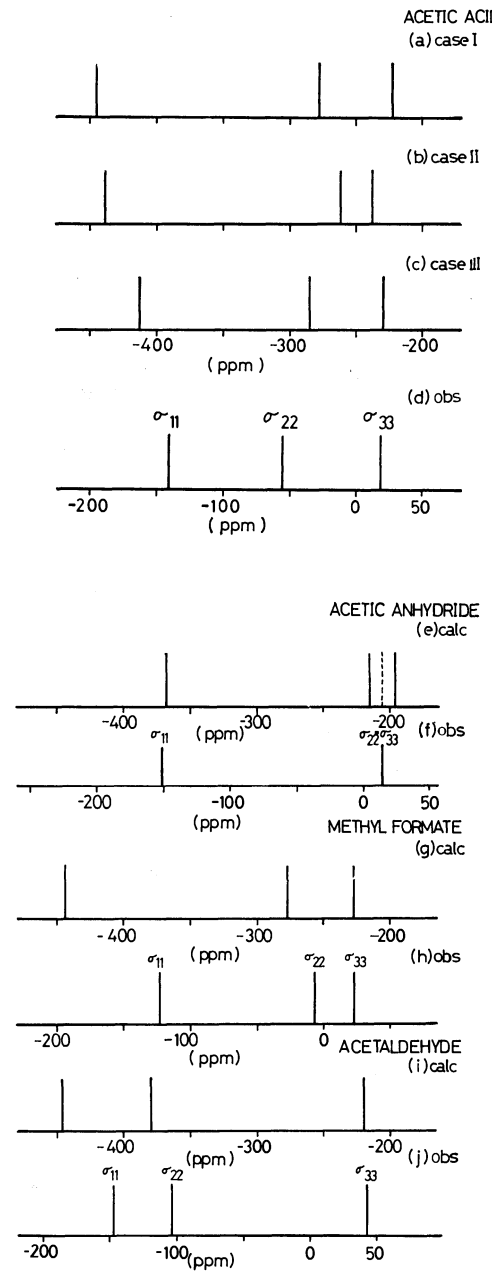

Fig. 1. The calculated and observed[4] stick spectra of acetic acid, acetic anhydride, methyl formate, and acetaldehyde.
acetic acid: calculated, (a)—(c), observed, (d), acetic anhydride: calc, (e). The dash-line is one averaged over σ^{p}_{yy} and σ^{p}_{zz}. observed, (f).
methyl formate: calculated, (g), observed, (h).
acetaldehyde: calculated, (i), observed, (j).

which the most shielded component is σ^{p}_{zz}.

The calculated $\Delta\sigma_{calc}$ values of the carbonyl carbons of methyl formate and acetaldehyde molecules are also shown in Table 1. The calculated results are somewhat larger than the observed ones, but the tendency of the shielding tensors of these carbons is plausible, as is shown in Fig. 1.

If the calculated $\Delta\sigma_{calc}$ values of the carbonyl carbons in all of the molecules are seen as a whole, the order of their magnitutes is found to be; acetaldehyde> methyl formate>acetic acid>acetic anhydride. This order agrees with the observed one. Moreover, we notice the tendency of each shielding tensor through all the compounds. The σ^{p}_{yy} value is found to be especially sensitive to the substituent in the calculated results. This sensitivity is also displayed by the observed results.

Only the most shielded component in acetic anhydride is σ^{p}_{yy}; the other compounds are σ^{p}_{zz}. This may be because the π-electrons of the carbonyl group in acetic anhydride are more delocalized than in the others; therefore, the shielding of the yy component increases in comparison with the other compounds. In acetic anhydride the magnitudes of σ^{p}_{yy} and σ^{p}_{zz} are near to each other, but in other compounds they are not. This would also be qualitatively interpreted by the above reason.

Our theoretical approach to the ^{13}C chemical shielding anisotropy will contribute to obtaining valuable information on the molecular structure in the solid state and to determining the principal axis of the molecule concerned.

The Role of Anion in the Demethylation Reaction of Methylcobalamin with Mercuric Salts

Haruhiko YAMAMOTO, Takashi YOKOYAMA, Ju-Ling CHEN, and Takao KWAN
Faculty of Pharmaceutical Sciences, University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113
(Received August 5, 1974)

The demethylation of methylcobalamin with mercuric salts containing ClO_4^-, AcO^-, Cl^-, Br^-, SCN^-, or CN^- was kinetically investigated by a conventional spectroscopic technique. The rates of reaction for mercuric chloride were proportional to $[CH_3\text{–Co}]$ and $[HgCl_2]$ while those for acetate depended little on $[Hg(AcO)_2]$, but increased in proportion with $[AcO^-]$. The rates of reaction varied depending on the concentration and species of anion, and the following sequence was obtained: $AcO^- \gg Cl^- \geq SCN^- \geq Br^- \gg CN^-$. The sequence was reversely correlated with the stability constant of the equilibrium reaction, $HgL_{n-1}+L \rightleftarrows HgL_n$ ($n=1$ or 2), so that it was considered that HgL^+ is an attacking electrophile in the cleavage of cobalt-carbon bond by the mercuric salts. The activity of $HgCl_4^{2-}$ for the reaction was somewhat lower than that of $HgCl_2$ while that of HgClCN was lower to a greater extent.

Mercuric salts are known to be active for the cleavage of cobalt-carbon bond. Halpern and Maher[1] reported, as the first demonstration of this kind of reaction, the formation of methylchloromercury from the reaction of mercuric chloride with methylpentacyanocobaltate(III). Since then, the demethylation reaction of alkylcobalamins and their model compounds with mercuric salts has been investigated by a number of groups,[2–10] especially in connection with organo mercury poisoning.

So far, however, the authors have been primarily concerned with the identification of reaction products, the relationship between the reaction rates and the size of alkyl groups, and/or the influence of the sixth ligand of the alkyl cobalt complexes with respect to the demethylation reaction. Only a little work has been carried out on the effect of mercuric salt species on the reaction by Bertilsson and Neujahr,[9] who described the efficiency of some organo mercuric salts ($HgCl_2$, CH_3HgCl, C_6H_5HgCl, $CH_3COCH_2CH_2HgBr$, C_6H_5-HgOH, CH_3Hg dicyandiamide) for the reaction.

We have therefore studied the effect of anion in mercuric salts on the demethylation reaction. In this paper we describe the reaction features on using ClO_4^-, AcO^-, Cl^-, Br^-, SCN^-, or CN^- as ligands for the mercuric ion, the relationship between the reaction rates and the stability constants of mercuric complexes, and a possible reaction mechanism.

Experimental

Materials. Cyanocobalamin (*Daiichi Pure Chemical*) was used to synthesize methylcobalamin according to the accepted procedure.[11] The methylcobalamin sample was further purified on Amberlite XAD-2 resin. Its purity was checked by paper chromatography on Toyo Filter Paper No. 51 with 1-butanol–2-propanol–acetic acid–water (100-70-1-100, *v/v*) as a solvent.[12]

The concentration of methylcobalamin thus prepared was estimated from spectral data of the Müllers.[13] The sample of methylcalbalamin solution was transferred little by little into a micro tube and preserved in a frozen state. The sample tube was defrosted just before use.

Mercuric chloride and acetate (Koso Chemical GR) were used without further purification. Mercuric perchlorate was prepared from mercuric chloride and silver perchlorate (Kojima Chemical, GR). All the other chemicals used were commercial (GR).

Procedures. Fresh solutions of methylcobalamin and of mercuric salts were made up for a few experiments at a time. The reaction was started by adding a suitable amount of mercuric salt solution to 3 ml of methylcobalamin solution with a micro syringe (Jintan Thermo) and by stirring with a Teflon bar. The spectrum change in the range 340—600 nm was then traced with a Hitachi Recording Spectrophotometer EPS-3T. Finally, the spectrum of completely demethylated sample was obtained by 3 min irradiation of the reaction system with a 100 W projecter lamp.

Demethylation reactions were performed usually with excess mercuric salts over methylcobalamin in the cell of spectrophotometer around room temperature. The concentration range was $40—50\times10^{-6}$ M for methylcobalamin and $400—1600\times10^{-6}$ M for mercuric salts.

Results and Discussion

Mercuric Chloride. Since mercuric chloride reveals no spectral absorption in the region 340—600 nm, it was possible to observe the rates of demethylation of methylcobalamin by measuring the optical absorbance, A, of methylcobalamin at 350 nm. The spectral changes due to the demethylation reaction, $CH_3\text{–Co}\rightarrow H_2O\text{–Co}$, appeared to progress with isosbestic points.

When the natural logarithms of the absorbance change $\ln\{(A-A_\infty)/(A_0-A_\infty)\}$ were plotted against time, a straight line was obtained, A_0 and A being the absorbance at time zero and infinity (or irradiated), respectively. The slope of the straight line, denoted as k_1, will be used as a rate parameter. The dependence of k_1 on the concentration of mercuric chloride was then investigated. It was found that k_1 increases in proportion to the concentration of mercuric chloride. The results are shown in Figs. 1 and 2. Thus, the demethylation rate, r, for mercuric chloride satisfies the following rate law:

$$r = k[CH_3\text{–Co}][HgCl_2] \quad (1)$$

Methylcobalamin is known to conform to different molecular forms depending on the pH.[14] It exists as a "base-on" form in which benzimidazole is axially coordinated while a "base-off" exists at low pH and hence protonated. The corresponding pK_a was re-

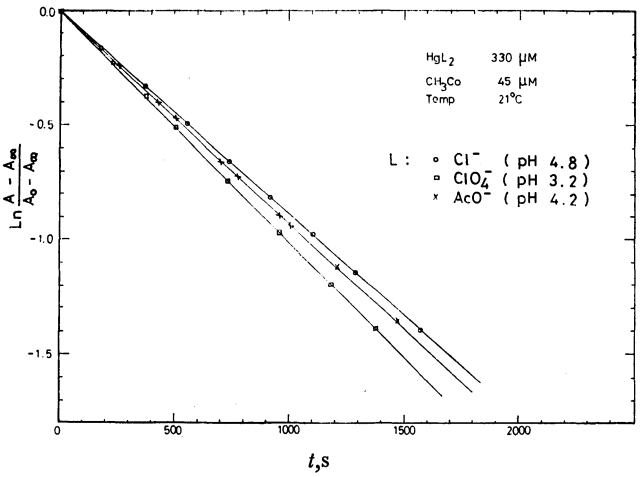

Fig. 1. Representative first-order plots for the demethylation of methylcobalamin with HgL_2.

○: L=Cl^-, pH=4.8
[HgL_2]=330 μM, [CH_3–Co]=45 μM, Reaction temperature 21 °C. A: measured at 350 nm

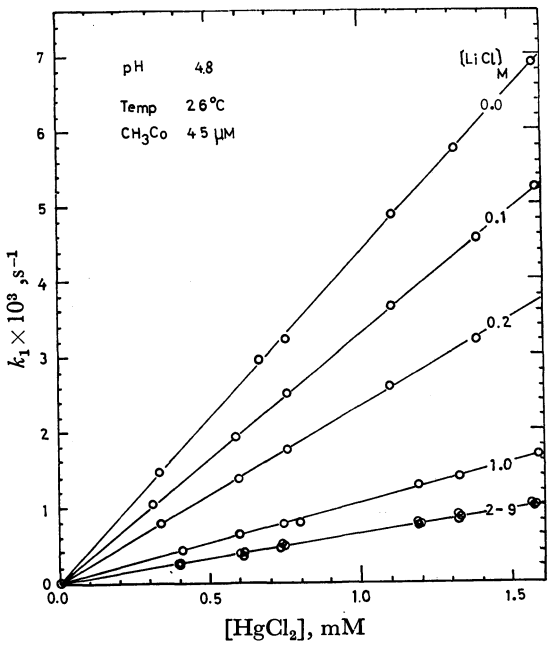

Fig. 2. Dependence of k_1 on the concentration of mercuric chloride and lithium chloride.
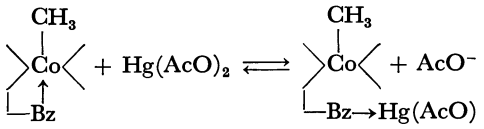
[CH_3–Co]=45 μM, pH=4.8. Reaction temperature 26 °C.

ported to be 2.72[14] so that the predominant species should be "base-on" forms above pH 3.5. Thus, the pH dependence of k_1 was investigated in the pH range 1—5 by adding perchloric acid, phosphoric acid or hydrochloric acid to the reaction system.

The spectra of methylcobalamin at the initial stage were explained by the reported pK_a value if pure "base-on" (λ_{max}=520 nm) and "base-off" forms (λ_{max}=460 nm) were respectively present at pH 5.0 and 1.0. Addition of hydrochloric acid to the reaction system usually caused a monotonous decrease of k_1; k_1 was about 25 times larger at pH 4 than at pH 1. A similar tendency was also observed with perchloric acid and phosphoric acid although the decreasing behavior was somewhat peculiar, being associated with the inexplicable action of oxo-acid anions.

The salt effect was investigated under a constant pH. No significant difference in k_1 was observed in 0.1—1 M acetate buffer (pH=4.2), while the effect of lithium chloride was remarkable; k_1 appeared to decrease gradually with increasing [LiCl], falling down to one-seventh of the initial k_1 (Fig. 2). The depression of k_1 at higher [LiCl] (2—9 M) approached a constant value. It might be associated with the formation of $(HgCl_4)^{2-}$.

Mercuric Acetate. The demethylation of methylcobalamin in the presence of mercuric acetate took place similarly as in the case of chloride; the spectral change due to the demethylation progressed with isosbestic points. It was found, however, that the "base-off" type of methylcobalamin is present during the reaction even at pH=4.2. From the results obtained by Desimore *et al.*[10] and by us, an equilibrium between base-off and base-on methylcobalamin upon addition of mercuric acetate can be written as follows:



(i)

The demethylation rates, as expressed by $\ln\{(A-A_\infty)/(A_0-A_\infty)\}$ *versus* time, gave a straight line similar to the case of mercuric chloride. However, unlike the chloride case, k_1 was little dependent on the concentration of mercuric acetate (0.2 power), increasing nearly in proportion to the concentration of acetate ion in the acetate buffer (Fig. 3). Thus, 1 mM mercuric acetate is far more active than 1 mM mercuric chloride for the cleavage of cobalt-carbon bond provided that acetate ions were present sufficiently in the solution. The rate of demethylation for mercuric acetate, r', is given by

$$r' \fallingdotseq k'[CH_3\text{–Co}][AcO^-] \quad (2)$$

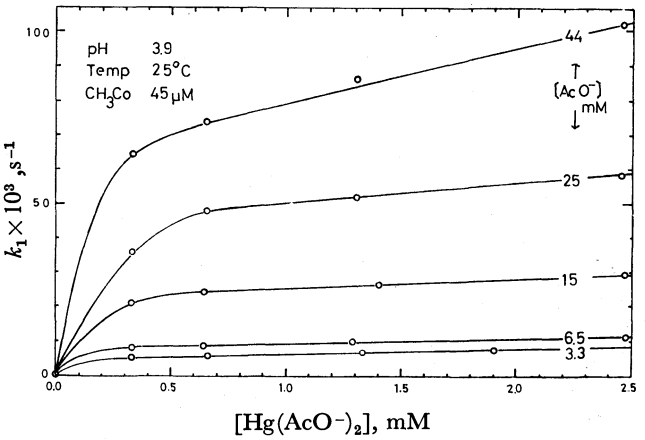


Fig. 3. Dependence of k_1 on the concentration of mercuric acetate and sodium acetate.
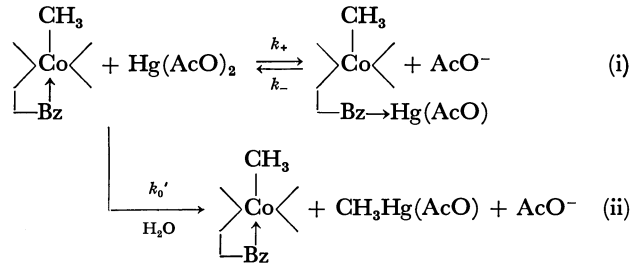
[CH_3–Co]=45 μM, pH=3.9, Reaction temperature 25 °C.

The effect of foreign anions was examined. When 3-fold excess of lithium chloride was present over 0.5 mM mercuric acetate in 44 mM acetate buffer, the reactivity of mercuric acetate was found to decrease remarkably, falling down nearly to that of mercuric chloride. Such a phenomenon can be interpreted if the anions of mercuric salt are replaced according to the stability constant of mercury complex (Table 1).

Desimore *et al.*[10] have so far investigated the mechanism of demethylation with mercuric acetate, based on the finding that methylcobiamide (a model compound of base-off methylcobalamin) is far less reactive than base-on methylcobalamin. In the light of their studies and our observations, the following reaction scheme is proposed.



If the equilibration (i) is fast as compared with (ii) and tends to the right-hand side, the rate of demethylation, r', can be approximately given by

$$r' = \frac{k_0'}{K}[CH_3\text{–}Co][AcO^-] \qquad (3)$$

where $K=k_+/k_-$ and $[CH_3\text{–}Co]$ is the total amount of methylcobalamin. The derived expression 3 is essentially the same as the observed one 2.

It is of interest to compare the intrinsic reactivity of mercuric acetate with that of mercuric chloride. For this the ratio k_0'/k was taken into consideration. It follows from Eqs. (1) and (3) that

$$\frac{k_0'}{k} = \frac{r'[CH_3\text{–}Co][HgCl_2]K}{r[CH_3\text{–}Co][AcO^-]} \qquad (4)$$

This can be transformed into an experimentally accessible one by introducing the rate parameter k_1 (k_1' is used for mercuric acetate):

$$\frac{k_0'}{k} = \frac{k_1'}{k_1}\cdot\frac{[HgCl_2]}{[Hg(AcO)_2]}\cdot\frac{K[Hg(AcO)_2]}{[AcO^-]} \qquad (5)$$

The right side of Eq. (5) consists of three factors. The first factor, k_1'/k_1, can be obtained from the observed data in Figs. 2 and 3, and the third one might correspond to the ratio of "base-off" to "base-on" methylcobalamin which can be estimated from the optical absorption.

When the second factor is unity or $[HgCl_2]=[Hg(AcO)_2]=1$ mM at $[AcO^-]=44$ mM, the first factor can be estimated to be *ca.* 20. The major part of methylcobalamin in the case of mercuric acetate was "base-off" so that equilibrium (i) shifted fairly to the right. From an inspection of the optical absorption we see that the third factor, $K[Hg(AcO_2]/[AcO^-]$ is *ca.* 10. Thus, we have

$$\frac{k_0'}{k} \geq 10^2$$

The result shows that mercuric acetate is about 100 times more reactive than mercuric chloride.

Mercuric Perchlorate. Addition of mercuric perchlorate to a methylcobalamin solution caused instantaneous formation of base-off form even at pH 4.5, followed by demethylation reactions. A good first-order plot was obtained in the lower concentration range (below 0.5 mM) as shown in Fig. 1 together with ones for mercuric chloride and acetate. However, at higher concentrations (above 0.5 mM) the plot was found to deviate from linearity, the rate decreasing. The reactivity of mercuric perchlorate was not studied further because of the complicated nature of the reaction.

Mercuric Cyanide, Bromide, and Thiocyanate. Since mercuric salts are less soluble in water, attempts were made to investigate their reactivities indirectly, *viz.* to investigate the effect of potassium cyanide, bromide and thiocyanate added to the reaction system of methylcobalamin and mercuric perchlorate. It was anticipated that mercuric salts in interest would be immediately formed.

30 μl of 0.1 M mercuric perchlorate was added to a 3 ml aqueous or acetate-buffered methylcobalamin solution containing 16 mM potassium salt, namely, CN^-, Br^-, or SCN^-. The role of Cl^- and AcO^- was also investigated in a similar manner. The rate parameter k_1 was obtained for each case (Table 1).

Table 1. Kinetic data for the demethylation of methylcobalamin with mercuric complexes and their stability constants

L	k_1 10^4 s^{-1} a) in H_2O	k_1 10^4 s^{-1} a) in 0.2 M AcO^-	Stability constants M^{-1} b) K_1	K_2	K_3	K_4	
AcO^-	260	$\geq 10^4$	10^5	10^4	—	—	15,16)
Cl^-	32	28	10^7	10^6	10	10	17)
Br^-	7.6	3.5	10^9	10^8	10^2	10^2	18)
SCN^-	8.9	5.4	10^9	10^7	10^3	10^2	15,19)
CN^-	<0.01	<0.01	10^{18}	10^{17}	10^4	10^3	15)

a) $CH_3\text{–}Co=40$ μM, $[L]=16$ mM, $[Hg(ClO_4)_2]=1$ mM, Reaction at 27 °C. b) $HgL_{n-1}+L \rightleftarrows HgL_n$, $K_n = \frac{[HgL_n]}{[HgL_{n-1}][L]}$

In the unbuffered reaction system, k_1 of acetate ion was in good agreement with that derived from mercuric acetate (Fig. 3) while k_1 of chloride ion was slightly less than that of mercuric chloride. It seems that the added anion rapidly combines with mercuric ion.

The k_1 value of Br^- and SCN^- did not differ much from that of mercuric chloride obtainable at high lithium chloride concentrations (≥ 2 M). Addition of CN^- (16 mM) inhibited the demethylation to a considerable extent.

In the 0.2 M acetate buffered solution without the addition of anions, demethylation took place too fast to be followed by a spectroscopic technique in accordance with the finding described. Rate parameter k_1 was also estimated like the unbuffered one for 16 mM Cl^-, Br^-, SCN^-, and CN^-. In these reactions methylcobalamin was of base-on form.

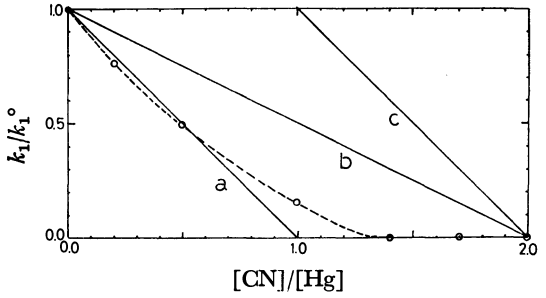


Fig. 4. Inhibition effect by cyanide ion.
···o···: observed values, a, b and c: see text.
$k_1°$: rate parameter for $HgCl_2$
k_1: rate parameter for $HgCl_2$–KCN
$[CH_3\text{–}Co]=45\ \mu M$, $[HgCl_2]=1$ mM, pH=5.0.
Reaction temperature 26 °C.

The inhibition of CN^- was further investigated in the concentration range 0—2 equivalent of KCN for the added $HgCl_2$ (1 mM). The result is shown by the open circles in Fig. 4, and compared with the solid lines a, b, and c which were drawn under the following assumptions (a), (b), and (c) and the anion replacement reactions iii, iv, and v.

$$HgCl_2 + CN^- \longrightarrow HgClCN + Cl^- \quad \text{(iii)}$$

$$HgClCN + CN^- \longrightarrow Hg(CN)_2 + Cl^- \quad \text{(iv)}$$

$$HgCl_2 + 2CN^- \longrightarrow Hg(CN)_2 + 2Cl^- \quad \text{(v)}$$

(a): Reaction iv occurs after the completion of Reaction iii. Reactivities of HgClCN and $Hg(CN)_2$ are negligibly small as compared with that of $HgCl_2$.

(b): Ligation of CN^- occurs according to Reaction v. $HgCl_2$ is much more reactive than $Hg(CN)_2$.

(c): Ligation of CN^- occurs according to (a). Both $HgCl_2$ and HgClCN have the same reactivity, $Hg(CN)_2$ being inactive.

As shown in Fig. 4, assumption (a) is closest to the observed one. It seems that HgClCN and $Hg(CN)_2$ are inactive for the cleavage of cobalt-carbon bond as compared with $HgCl_2$.

Reactivity and Stability Constant of Mercuric Complex. The stability constants of various mercury complexes in the literature[15–19] are shown in Table 1. From these values we can infer the main mercury species in the solution as well as the concentration of anions (shown in parentheses).

$Hg(ClO_4)_2$[15]	Hg^{2+}	ClO_4^- (<1M)
$Hg(AcO)_2$	$Hg(AcO)_2$	AcO^- (1—100 mM)
$HgCl_2$	$HgCl_2$	Cl^- (<100 mM)
$HgCl_2$	$(HgCl_4)^{2-}$	Cl^- (>1 M)
HgBr, $Hg(SCN)_2$, $Hg(CN)_2$	$(HgL_3)^-$ and/or $(HgL_4)^{2-}$	L^- (≥10 mM)

The transformation of $HgCl_2$ into $(HgCl_4)^{2-}$ was inferred when the concentration of Cl^- was increased from 100 mM to 2 M. This is in line with the fact that rate parameter k_1 for mercuric chloride decreased with increasing concentration of lithium chloride as shown in Fig. 2. Addition of mercuric perchlorate or mercuric acetate gave rise to base-off methylcobalamin even at pH 4 while the addition of mercuric chloride retained base-on methylcobalamin. It indicates that the axial benzimidazole can displace the anion in the mercuric complex to yield base-off form when the stability constant K_2 is less than $10^4\ M^{-1}$.

It has been pointed out that the reaction scheme and the type of mercuric complex really depend on the anion species present in the solution. In the light of these observations and in particular from the data shown in Table 1, the reactivities of HgL_2 for the cleavage of cobalt-carbon bond are estimated to be in the following sequence.

$$Hg(AcO)_2 \gg HgCl_2 \geq Hg(SCN)_2 \geq HgBr_2 \gg Hg(CN)_2$$

It is apparent that the above sequence is reverse to the stability constant K_2. It seems to indicate that the elimination of L from HgL_2 is required prior to the cleavage of cobalt-carbon bond. In this connection, it is noteworthy that an equivalent mixture of $HgCl_2$ and KCN is a less active reagent for the cleavage than $HgCl_2$. The cyanide in the mixed ligand complex, HgClCN, might strengthen the Hg–Cl bond.

Complexes between Nucleotide Base and Amino Acid. I. Crystal Structure of Cytosine: *N*-Formylglycine

Minoru Ohki, Akio Takenaka, Hirotaka Shimanouchi, and Yoshio Sasada

Laboratory of Chemistry for Natural Products, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received September 25, 1974)

Cytosine: *N*-formylglycine complex crystallizes in the space group $Pna2_1$, with cell dimensions of $a=8.444(2)$, $b=21.169(5)$, and $c=5.120(1)$ Å. The structure was solved by the trial-and-error method on the basis of a Patterson map. A full-matrix least-squares refinement led to an R value of 0.035. The difference map revealed the protonation of cytosine by the carboxyl group of *N*-acylamino acid and the involvement of ionic interaction in complex formation. This mode is the same as proposed for cytosine: *N*-benzoylglycine complex in spite of different molecular environment. Such arrangement of cytosine and ionized carboxyl group of amino acid may suggest a mutual recognition scheme between nucleic acid and protein.

Interactions between nucleic acids and proteins take an important part in several processes of protein synthesis, its regulation, the repair of nucleic acids, and so on. In nucleic acid-protein interactions, several kinds of weak bonds must be formed between individual nucleotide and amino acid residues. It is, therefore, interesting to find if there are some specific binding patterns between components of nucleic acids and proteins. They should provide a stereochemical basis for the molecular mechanism of mutual recognition.

Complex formation between nucleotide base and amino acid has been investigated extensively.[1] Tamura, Hata, Sato, and Sakurai[2] showed by an X-ray analysis of cytosine: *N*-benzoylglycine monohydrate (abbreviated hereafter as CBG complex) that the complex is formed by the two hydrogen bonds between the carboxyl group of amino acid and the two nitrogen atoms (amino group and N(3) atom) of cytosine. Recently, we have found a different type of complex formation between cytosine and undissociated acidic side group of glutamic acid.[3] In the former complex, however, the proton migration was deduced from the examination of bond lengths and angles without the direct proof by a difference map. It is well known that cytosine is easily protonated at N(3) by strong acids[4] and the high proton affinity has been justified by the theoretical calculation of π-electron distribution.[5] In view of the nucleic acid-protein interactions, it is important to confirm the protonation of cytosine by amino acid. We have done this by an accurate analysis of the crystal structure of the title complex which is an analogue of the CBG complex.

Experimental

Square-prism crystals were obtained from an aqueous solution containing equimolar cytosine and *N*-formylglycine. The complex formation was confirmed by an elementary analysis and IR spectrum of the crystals. Found: C, 39.1; H, 4.7; N, 25.5%. Calcd for $C_4H_5N_3O \cdot C_3H_5NO_3$: C, 39.3; H, 4.7; N, 26.2%. Laue symmetry and systematic absences of reflexions indicated the space group to be $Pna2_1$ or Pnam. The unti-cell dimensions were determined by least-squares calculation from the spacings of 64 reflexions, $0kl$ and $hk0$, on Weissenberg photographs, calibration being made with superposed silicon lines ($a=5.43075$ Å). The density was measured by flotation in a chloroform-carbon tetrachloride mixture. Crystal data are given in Table 1.

Table 1. Crystal data for cytosine: *N*-formylglycine complex

Crystal system: orthorhombic		
Systematic absences: $0kl$ with $k+l=2n+1$ and $h0l$ with $h=2n+1$.		
Space group: $Pna2_1$.		
$a=8.444(2)$ Å	$b=21.169(5)$ Å	$c=5.120(1)$ Å
$U=915.1(3)$ Å^3	$Z=4$	
$D_x=1.554$ g cm^{-3}	$D_m=1.55_7$ g cm^{-3}	
μ(CuKα)$=11.4$ cm^{-1}		

Intensity data were collected on integrated, equi-inclination Weissenberg photographs ($hk0$-$hk4$ and $0kl$-$6kl$) using Ni-filtered CuKα radiation and the intensities were measured by a TV densitometer.[6] The sizes of crystals used for the a- and c-axis rotations were $0.10\times0.15\times0.40$ mm and $0.15\times0.20\times0.60$ mm, respectively. Corrections were made for Lorentz and polarization factors, but not for absorption. Intensities of both of extended and contracted reflexions on upper layer photographs were corrected by a method proposed by Takenaka and Sasada,[7] and were averaged; a discrepancy index, $R'=\sum||F_{ext}|-|F_{cont}||/\sum|F_{mean}|$, was 0.040, where subscripts ext and cont stand for the extended and contracted spots, respectively. Two sets of intensity data thus obtained were cross-correlated and then placed on an absolute scale by the Wilson's method. A total of 1090 independent reflexions was obtained, of which zero-reflexions numbered 103.

Structure Determination and Refinement

Although $N(z)$ test[8] was not effective, a three-dimensional Patterson map indicated that the space group is $Pna2_1$. The Patterson map also gave the approximate position of the cytosine moiety. The remaining non-hydrogen atoms were found by successive Fourier syntheses. Atomic coordinates and temperature factors, first isotropic and then anisotropic, were refined by the block-diagonal least-squares method; the minimized function was $\sum w\Delta F^2$, where $\Delta F=|F_o|-|F_c|$. After the conventional R factor reached to 0.074, a difference synthesis revealed all the hydrogen atoms. Further refinement including these hydrogen atoms reduced the R factor to 0.037. In the final stage, the full-matrix least-squares method was applied, where the following weight function was used:

$w=\exp(-as^2-bt^2-cst-ds-et-f)$ for $|F_o|\neq 0$, where $s=|F_o|$ and $t=\sin\theta/\lambda$; $w=1/\langle\Delta F^2\rangle$ for $|F_o|=0$. The coefficients, a, b, c, d, e, and f, were evaluated by least-squares at each cycle of the structure refinement so that $\langle w\Delta F^2\rangle=1$; at the final stage, they were 0.001778, 41.00, 0.4658, −0.1752, −42.77, and 8.107, respectively. The refinement was terminated when the largest shift of parameters was less than 0.3σ. The final values of R and R_w, where $R_w=(\sum w\Delta F^2/\sum w|F_o|^2)^{1/2}$, were 0.035 and 0.043, respectively. There were no residual peaks greater than 0.2 e Å^{-3} in the final difference map.

Atomic scattering factors used were taken from "International Tables for X-ray Crystallography".[9]

The computations were done on a HITAC 8800 computer at the University of Tokyo and on a HITAC 8700 computer at Tokyo Institute of Technology. The programs, TLSU for the determination of cell dimensions, TDRW for the data reduction, TFLS for the full-matrix least-squares refinement, and DCMS for the stereo-pair drawing of the crystal and molecular structure, all written by two of the authors (A.T. and Y.S.), and DAPH in the Universal Crystallographic Computation Program System,[10] were used.

The final positional and thermal parameters are given in Table 2. Observed and calculated structure factors are listed in Table 3. Numbering of atoms and thermal ellipsoids are shown in Fig. 1, the crystal structure in Fig. 2, and the bond lengths and angles in Fig. 3. The standard deviations for bond lengths and angles involving C, N, and O are 0.004 Å and 0.4°, respectively, and those involving hydrogen are about ten times of the above values. The hydrogen bonds are listed in Table 4. The least-squares planes of six-membered ring of cytosine, the carboxyl group and the amide group of amino acid are given in Table 5, together with the displacements of atoms from the planes.

Discussion

As shown in Fig. 1, the complex is formed by the two hydrogen bonds between the ionized carboxyl group of amino acid and the two nitrogen atoms, N(4) and the protonated N(3), of cytosine. The present study has proved definitely the protonation of N(3) and the involvement of ionic interaction in complex formation. In this "double hydrogen-bonded system", the two N···O distances are not equal to each other (Fig. 2), contrary to those in CBG complex. The N(4)H···O(3) distance is comparable to the normal distance of NH···O type hydrogen bond,[11] while the

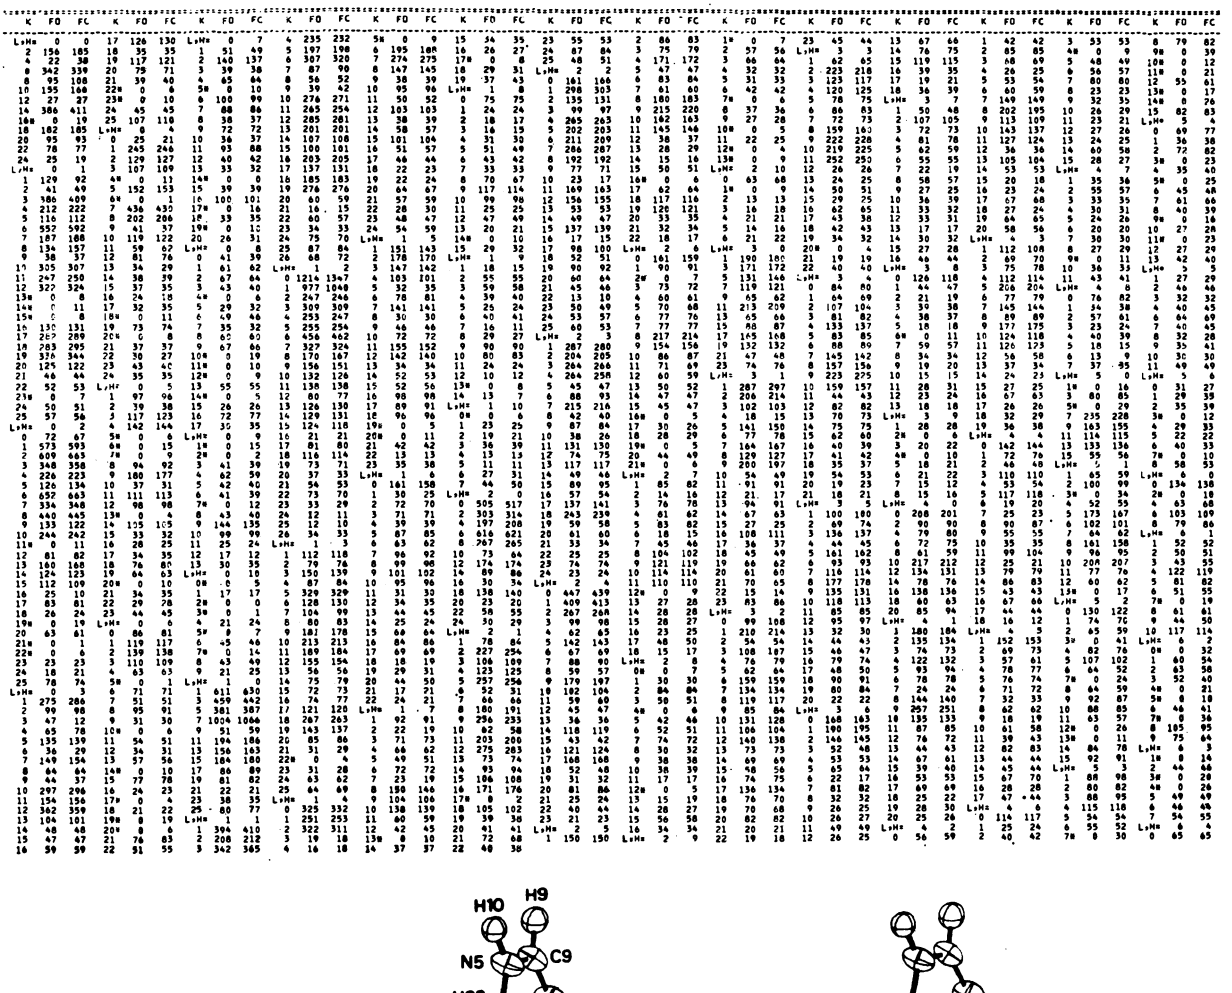
TABLE 3. OBSERVED AND CALCULATED STRUCTURE FACTORS ($\times 10$)



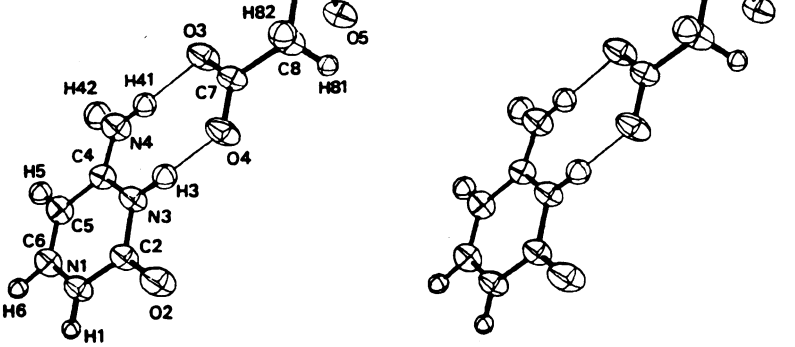


Fig. 1. A stereoscopic view of cytosine: *N*-formylglycine complex. Thermal ellipsoids are drawn at the 50% probability level.

N(3)H···O(4) distance is very close to that between carboxylate oxygen and protonated imidazole nitrogen atoms found in *N*-acetyl-L-histidine monohydrate.[12] This implies that the positive and negative charges are mostly located at N(3) and O(4) atoms, respectively. The differences between the C(7)–O(3) and C(7)–O(4) bond lengths and between the C(8)–C(7)–O(3) and C(8)–C(7)–O(4) angles (Fig. 3) also support this. Other hydrogen bonds are found between the carbonyl O(5) atom of amino acid and the N(1) atom of cytosine, between the N(4) and O(2) atoms of cytosines, and between the O(3) and N(5) atoms of the amino acids. These hydrogen bonds, except for the last one, are schematically the same as those in the CBG complex. The approach of the two amino acids in the CBG complex is impeded by the bulky phenyl groups and they are connected through the hydrogen bonds with the water molecule between them. In the present complex, however, they are linked directly by the N(5)H···O(3) hydrogen bond. The charge distribution in the "double hydrogen-bonded system" seems to be affected by such a different environment.

The closest nonbonding intermolecular contacts are between O(4) of amino acid and C(5) of cytosine at $1/2+x$, $1/2-y$, $1+z$ and between C(9) of amino acid and O(2) of cytosine at $1/2-x$, $1/2+y$, $-1/2+z$.

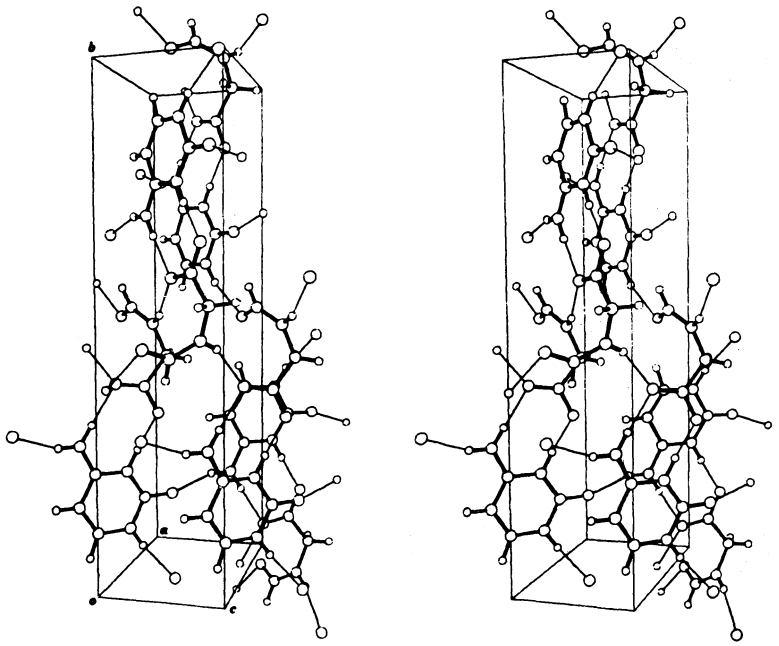

Fig. 2. A stereoscopic view of the crystal structure.

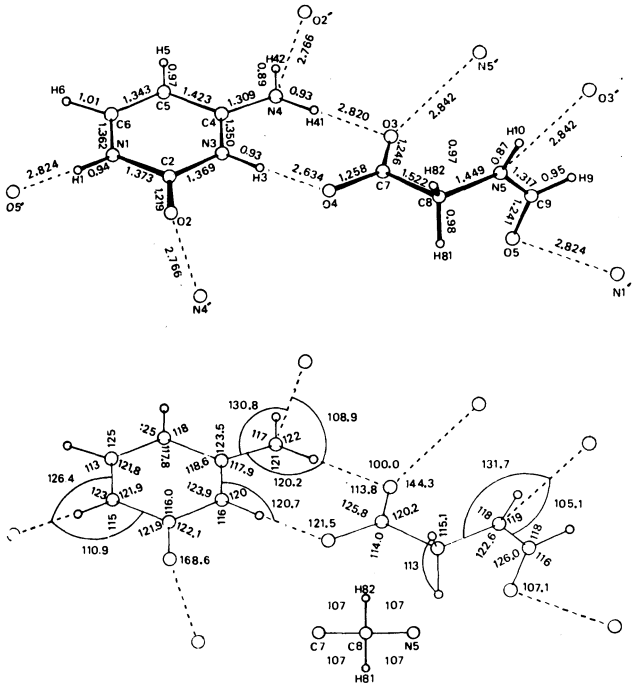

Fig. 3. Distances and angles.
The standard deviations for bond distances and angles are 0.004 Å and 0.4 °, respectively, while those involving hydrogen are about ten times larger.

These distances, 3.274 and 3.164 Å, respectively, are slightly larger than the minimum van der Waals contacts.[13] If the hydrogen atoms are taken into account, however, the H···O distances are somewhat shorter than the sum of these van der Waals radii;[13] H(5)···O(4) 2.32 Å and H(9)···O(2) 2.40 Å. Relevant angle is 170° for C(5)–H(5)–O(4) and 137° for C(9)–H(9)–O(2). It seems that there are some C–H···O interactions, at least in the former.

The bond lengths and angles of amino acid are in good agreement with those found in other amino acids and oligopeptides. The torsion angles of C(7)–C(8)–N(5)–C(9) and of O(3)–C(7)–C(8)–N(5) are −81.1 and 4.2°, respectively, which are close to those found in many dipeptides.[14] The O(5) and C(8) atoms are *cis* around the C(9)–N(5) bond.

Table 4. Distances and angles of the hydrogen bonds

N	H	O	Distance (l/Å) N···O	Distance (l/Å) H···O	Angle (ϕ/°) N–H···O
N(3)	H(3)	O(4) (a)	2.634	1.71	176
N(4)	H(41)	O(3) (a)	2.820	1.89	176
N(4)	H(42)	O(2) (b)	2.766	1.91	160
N(1)	H(1)	O(5) (c)	2.824	1.90	167
N(5)	H(10)	O(3) (d)	2.842	2.03	157
	(a) at		x,	y,	z
	(b) at		$-1/2+x$,	$1/2-y$,	$-1+z$
	(c) at		$1/2-x$,	$-1/2+y$,	$1/2+z$
	(d) at		$-x$,	$1-y$,	$1/2+z$

The protonation to cytosine results in the lengthening of the C(2)–N(3) and N(3)–C(4) bonds, the shortening of the C(2)–O(2) and C(4)–N(4) bonds, and the widening of the C(2)–N(3)–C(4) angle, these features being similar to those in other protonated cytosines as shown in Fig. 4 where the average bond distances and angles are given for the neutral and protonated species.[15–19] The slightly different dimensions between the present and other protonated cytosines are caused by the effects of alkylation at N(1)[20] and hydrogen bond with O(2),[15] since the O(2) atoms of other protonated species are not hydrogen bonded.

The N(3) atom deviates by 0.011 Å from the mean plane of the six-membered ring. The exocyclic atoms, O(2) and N(4), displace in the direction opposite to N(3) by 0.040 and 0.015 Å, respectively. Such a tendency is the same as found in 1-(β-D-arabinofuranosyl)cytosine hydrochloride,[19] but is different from

that in other protonated species.[16–18] The dihedral angle between pyrimidine and carboxyl planes, 3.9°, is close to 3.0° found in CBG complex.

In the present and CBG complexes, a common feature of the "double hydrogen-bonded system" is observed, in spite of different molecular arrangements in their crystals. So, this seems to be a specific arrangement between cytosine and ionized carboxyl group of amino acid. The "double hydrogen-bonded system" could be a model for mutual recognition between nucleic acid and protein, such as binding mode between the unpaired cytosine in CCA terminus of *t*RNAs and the *C*-terminal carboxyl group in amino-acyl-*t*RNA synthetase or CCA pyrophosphorylase.

Lanthanide-Induced Nuclear Magnetic Resonance Shifts and Molecular Structure of L-Azetidine-2-Carboxylic Acid. I. Evaluation of the Shifts Intrinsic to the Lanthanide-Substrate 1:1 Complex

Fuyuhiko INAGAKI, Seizo TAKAHASHI, Mitsuo TASUMI, and Tatsuo MIYAZAWA

Department of Biophysics and Biochemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received November 5, 1974)

The lanthanide-induced PMR shifts (LIS) were observed in D_2O solution of L-azetidine-2-carboxylic acid using europium nitrate as shift reagent. Two series of measurements were carried out with the successive dilution and the incremental dilution methods. The analysis of observed data shows that the formation of 1:2 complex between the lanthanide ion and the substrate molecule should be taken into account in addition to 1:1 complex. The LIS's intrinsic to 1:1 and 1:2 complexes were evaluated. An experimental method appropriate for obtaining the ratio of the LIS's intrinsic to 1:1 complex is proposed.

One of the most important features of the lanthanide-induced nuclear magnetic resonance shift (LIS) lies in its potentiality of giving quantitative information on the structure of molecules in solution. As is well known, however, there are several points to be checked before the observed shift data are utilized for the determination of molecular structures.[1-3] In the first place, it is necessary to evaluate the LIS intrinsic to 1:1 complex formed between a lanthanide ion (or, more generally, a lanthanide shift reagent) and a substrate molecule. This is not a simple task, since the contributions of 1:2 and other complexes to the observed LIS are expected to vary case by case. In this paper we treat the equilibrium between the europium ion and L-azetidine-2-carboxylic acid in aqueous solution and propose a method for evaluating the intrinsic LIS's and the shift ratios for 1:1 complex. This method may be applicable to other systems as well. The results obtained here will be used in a subsequent paper for determining the molecular conformation of L-azetidine-2-carboxylic acid in aqueous solution.

Experimental

L-Azetidine-2-carboxylic acid was kindly provided by Mr. H. Sugano of Tanabe Pharmaceutical Company. Commercially available nitrate of Eu(III) (99.9%) was used without further treatments.

PMR spectra were recorded on a Hitachi R-22 (90 MHz) spectrometer in the frequency-sweep mode. The LIS measurements were performed for D_2O solution at a probe temperature of 37 °C using DSS as an internal standard. The shifts were determined by a frequency counter with the accuracy of ± 0.1 Hz. All the resonance lines shifted to high field in the presence of europium nitrate. The pH value of each sample solution was adjusted to be in the range between 4.6 and 5.0, so that the zwitter ion is the predominant species of the sample molecule.

The computation and curve plotting were carried out at the Computer Centre of the University of Tokyo using HITAC-8800/8700 computers and a Calcomp 563 curve plotter. The programs used for the spectral analysis were NMRTRY, NMRFIT, and NMRPLOT. The curve fitting for the LIS data was carried out with the program SHIFT. All these programs were prepared in our laboratory.

Results and Discussion

PMR Spectrum of L-Azetidine-2-Carboxylic Acid in D_2O Solution. The observed PMR spectrum of L-azetidine-2-carboxylic acid in D_2O solution is shown in Fig. 1, together with the simulated. The absorptions indicated as A, B, C, D, and E in this figure may be assigned to five protons, *viz.*, A and B to the β, C and D to the γ, and E to the α protons (see Fig. 2). The least-square adjustments gave the chemical shifts and spin-spin coupling constants listed in Table 1, which

are essentially in agreement with the values obtained by Thomas and Williams.[4)]

Analysis of the Lanthanide-Induced Shifts. (a) Coordination Site: The measurements of LIS were made in the pH range between 4.6 and 5.0, where L-azetidine-2-carboxylic acid exists as a zwitterion. As LIS was found negligible below $pK_a(=1.7)$ of the carboxylate group, the coordination site for the lanthanide ion must be the carboxylate group of L-azetidine-2-carboxylic acid.

(b) Stoichiometry of the Lanthanide-Substrate Complex and the Evaluation of the LIS Intrinsic to 1:1 Complex: Much work has been done on the stoichiometry of the lanthanide-substrate complex and now the formation of not only 1:1 complex but also 1:2 complex has been established.[2,3)] The equilibria between the lanthanide ion (L) and the substrate molecule (S) may be described by the following schemes (two-step mechanism) under the assumption that the formation of the complex between one lanthanide ion and three (or more) substrate molecules can be neglected.

$$L + S \overset{K_1}{\rightleftharpoons} LS \quad (1)$$

$$LS + S \overset{K_2}{\rightleftharpoons} LS_2 \quad (2)$$

where K_1 and K_2 are the association constants given as

$$K_1 = [LS]/[L][S] \quad (3)$$

$$K_2 = [LS_2]/[LS][S] \quad (4)$$

If the LIS (with respect to the i-th nucleus) intrinsic to LS and LS_2 complexes are expressed as Δ^i_1 and Δ^i_2, respectively, the observed shift ($\Delta\delta^i_{obs}$) may be given as

$$\Delta\delta^i_{obs} = \frac{[LS]}{[S_0]}\Delta_1{}^i + 2\frac{[LS_2]}{[S_0]}\Delta_2{}^i \quad (5)$$

where $[S_0]$ refers to the total concentration of the substrate. Equations (3)—(5) are used to analyse the observed data described below to obtain Δ_1, Δ_2, K_1, and K_2. The following two series of measurements have been made.

(1) Successive Dilution Method:[5)] The changes of chemical shifts are observed with changing $[L_0]$ (total concentration of the lanthanide ion) and $[S_0]$ by successive addition of the solvent (D_2O) to the original solution which contains both the lanthanide ion and the substrate. Accordingly, the mole ratio $\rho(\equiv[L_0]/[S_0])$ is kept constant throughout the measurements. The shifts observed by this method for the five protons of L-azetidine-2-carboxylic acid are shown in Figs. 3 and 5, where ρ was set equal to 1.01.

(2) Incremental Dilution Method:[2)] The changes of chemical shifts are observed with changing $[L_0]$ and ρ by successive addition of the substrate solution to the original solution. The concentration of the substrate solution is made equal to that of the substrate in the original solution, so that no change in $[S_0]$ occurs

The dotted curve indicates the dependence of the ratio [LS_2]/[LS] upon [S_0].

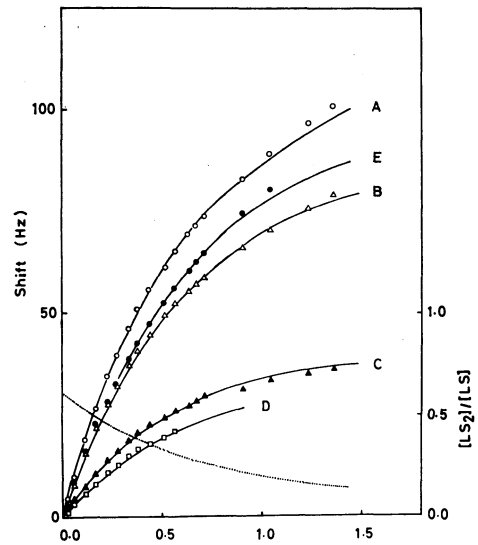

Fig. 6. Eu(III)-induced shifts ($\Delta\delta_{obs}$) of L-azetidine-2-carboxylic acid observed by the incremental dilution method *vs.* the mole ratio (ρ). D_2O solution, 37 °C, [S_0]=0.991 M. ○, A; △, B; ▲, C; □, D; ●, E. The full curves were obtained by theoretical fitting based on the two-step mechanism. The dotted curve indicates the dependence of the ratio [LS_2]/[LS] upon ρ.

throughout the measurements. The shifts observed by this method are shown in Figs. 4 and 6, where [S_0] was chosen to be 0.991 M.

At first the shift data obtained above were analyzed by assuming that only the LS complex was present (one-step mechanism). In this case, $\Delta\delta'_{obs}$ is simply given by the first term in the righthand side of Eq. (5). The best-fit curves obtained by the least-squares adjustments are shown in Figs. 3 and 4. The parameters obtained (Δ_1's and K_1) are given in Table 2. It is noted that in Fig. 3 the calculated curve tends to deviate from the observed data in the high [S_0] region, whereas in Fig. 4 the deviation is found both in the high and low ρ regions. These results indicate the inadequacy of the assumption of one-step mechanism. Then, the analysis in terms of the two-step mechanism has been carried out and the best-fit curves obtained are shown in Figs. 5 and 6. The agreement between the calculated curves and the observed data is now much better, giving a strong support for the LS_2 formation. The parameters obtained (Δ_1's, Δ_2's, K_1, and K_2) are listed in Table 2. The dotted curves in Figs. 5 and 6 indicate the calculated mole ratio [LS_2]/[LS]. The contribution of LS_2 is smaller for the successive dilution method under the present experimental conditions. The contribution of LS_2 decreases with decreasing [S_0] in the successive dilution method (Fig. 5), whereas it increases with decreasing ρ in the incremental dilution method (Fig. 6). These ratios [LS_2]/[LS] explain very well the origin of deviation between the calculated curves and the observed data in Figs. 3 and 4.

Table 2. Lanthanide-induced shifts[a] intrinsic to the LS copmlex (Δ_1) and LS_2 complex (Δ_2) and the association constants[b] for the step L+S⇄LS (K_1) and LS+S⇄LS_2 (K_2)

Proton	One-step mechanism[c]	Two-step mechanism[d]

a) Shifts for the probe frequency of 90 MHz. b) In the unit of M^{-1}. c) Mechanism involving only L+S⇄LS. d) Mechanism involving L+S⇄LS and LS+S⇄LS_2.

The procedures described above gives the LIS intrinsic to the LS complex quite straightforwardly. The simultaneous use of two series of experimental data, *viz.*, those obtained by the successive dilution and the incremental dilution methods, enhances the reliability of the calculated parameters. However, this method requires much experimental work followed by computer analysis of the data. So it seems desirable to introduce a method convenient for evaluating the LIS intrinsic to the LS complex by an experimental procedure. Taking into account that the shift ratio is a quantity more useful than the absolute shift in treating the structural problem, we show here that the shift ratio for the LS complex can be obtained by extrapolating the ratio of successive dilution data to [S_0]=0. The ratio of the LIS of the i-th nucleus and that of the

s-th nucleus may be expressed from Eqs. (3)—(5) as

$$\frac{\Delta\delta^i_{obs}}{\Delta\delta^s_{obs}} = \frac{\Delta_1{}^i + 2K_2[S_0]\Delta_2{}^i + 2K_2(\Delta_1{}^i - \Delta_2{}^i)[LS]}{\Delta_1{}^s + 2K_2[S_0]\Delta_2{}^s + 2K_2(\Delta_1{}^s - \Delta_2{}^s)[LS]} \quad (6)$$

Then, extrapolating the ratio of successive dilution data to zero substrate concentration, we get

$$\lim_{[S_0]\to 0} (\Delta\delta^i_{obs}/\Delta\delta^s_{obs}) = \Delta_1{}^i/\Delta_1{}^s \quad (7)$$

The ratios of LIS's obtained by the successive dilution method are shown in Fig. 7, where the LIS of the proton A is taken as reference. In Table 3 the observed shift ratios are compared with the values calculated using the parameters for the two-step mechanism listed in Table 2. Satisfactory agreement between the observed and calculated values provides evidence for the consistency between the curve fitting analysis and the shift-ratio extrapolation method. The method of extrapolating the shift ratio obtained by successive dilution to zero substrate concentration would be useful also in other systems for evaluating the ratio of LIS's intrinsic to 1 : 1 complex, particularly in the case with a rather small association constant (K_1). This point will be treated in a separate paper by comparing the two cases with small and large association constants.

Profiles of the Distribution of Atoms in the Nitrous Oxide-acetylene Flame

Kitao FUJIWARA, Hiroki HARAGUCHI, and Keiichiro FUWA

Department of Agricultural Chemistry, Faculty of Agriculture The University of Tokyo, Tokyo 113

(Received January 7, 1974)

The distributions of neutral atoms in the nitrous oxide–acetylene flame have been measured by nebulizing aquo ions of the following sixteen elements into the flame; cadmium, nickel, zinc, copper, lead, cobalt, manganese, iron, chromium, molybdenum, calcium, tin, gallium, indium, titanium, and boron. The distributions have been figured on the response surfaces on which the changes in distribution are expressed as functions of the flame height and the acetylene flow rate. The response surfaces for the temperature and the OH radical were also investigated. The response surfaces for the atomic absorptions of the elements can be related to the thermodynamic properties of the oxides of the elements. The results have then been used for the discussion of the atomization processes of the elements in the flame. In addition, the sensitivities of absorption spectrometry in the nitrous oxide–acetylene flame have been compared to those in the air–acetylene flame.

In atomic absorption spectrometry, it is important to know the atomization processes of analytical elements, which are reflected in the distribution of atoms in the flame. The distribution of atoms depends on the condition of the flame, particularly on the composition of the flame, which is usually expressed by the ratio of the fuel to the supporting gas.[1–6] However, the relation between the atomic distribution and the properties of the flame has not been well established. Hence, in a previous work a detailed investigation of the atomic distributions of fourteen elements in the air-acetylene flame has been carried out.[7]

In the present study, the absorbances of atoms in the nitrous oxide–acetylene flame are measured as the function of two variables, the acetylene flow rate and the height above the burner, while keeping the flow rate of nitrous oxide constant. The results are shown as a map of the distribution of the atoms, where the abscissa indicates the flow rate of acetylene, and the ordinate the height above the burner. This map of distribution will be refered to as "the response surface" hereafter. The present authors have investigated the response surfaces for atoms of sixteen elements, the OH radical and the temperature, and have discussed the mechanism of atomization in the nitrous oxide-acetylene flame.

Experimental

Reagents. All the reagents used were of an analytical grade and were purchased from the Wako Pure Chemical Ind. Ltd. Sample solutions of metal ions were prepared by dissolving the nitrates of Mn^{2+}, Fe^{3+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, Ca^{2+}, Cr^{3+}, In^{3+}, Ga^{3+}, Cd^{2+}, and Pb^{2+} into distilled water containing 0.2% nitric acid. The solutions of ammonium molybdate and boric acid were prepared by dissolving the respective salts into water. The titanyl sulfate was dissolved into a 0.2 N sulfuric acid solution, while the stannic chloride was dissolved into a 0.2% nitric acid solution. The analytical concentrations of the elements are listed in Table 1.

Apparatus. The Hitachi 207 Atomic Absorption Spectrophotometer was used after somewhat modifying the focussing of the light beam so that a single light path with a beam 2—3 mm in diameter was produced at the measuring position in the flame. The details of this modification have already been reported elsewhere.[4]

Most of the hollow cathode lamps which were used in the experiments were produced by Hitachi Ltd.; one for gallium was produced by Westinghouse, and one for tin by Varian Tectron Pty., Ltd., Australia. As the continuous light source, a 200 W deuterium discharge tube, Model HS 200 DS from Dr. Körn Gmbh and Co. was used. For the temperature measurements, a 250 W tungsten lamp, Halogen-bellaphot 64653, of the Osram Co. Ltd., was used as the incandescent light source; a mechanical chopper made by the K. K. Ewig Co. and an optical pyrometer, Model 201 N_1, of the Hokushin Electric Works were also used.

Table 1. Sample solutions and analytical lines

Reagent	Concentration of metal ions (μg/ml)	Analytical line (nm)
$Cd(NO_3)_2 \cdot 8H_2O$	2	228.8
$Ni(NO_3)_2 \cdot 6H_2O$	20	352.4
$Zn(NO_3)_2 \cdot 6H_2O$	1	213.8
$Cu(NO_3)_2 \cdot 3H_2O$	5	327.4
$Pb(NO_3)_2$	20	283.3
$Co(NO_3)_2 \cdot 6H_2O$	20	243.2
$Mn(NO_3)_2 \cdot 4H_2O$	20	403.0
$Fe(NO_3)_3 \cdot 7H_2O$	20	271.9
$Cr(NO_3)_3 \cdot 9H_2O$	20	427.4
$SnCl_4 \cdot 5H_2O$	500	286.3
$Ga(NO_3)_3$	20	287.4
$In(NO_3)_3$	20	303.9
$Ca(NO_3)_2 \cdot 4H_2O$	5	422.6
$(NH_4)_2MoO_4$	20	313.2
$TiOSO_4$	200	364.2
H_3BO_3	1000	249.8

A water-cooled burner with a 50 mm slot was used for the nitrous oxide–acetylene flame.

Procedure. A sample solution was nebulized into the burner at a rate of about 3 ml/min. The light beam was passed through the center of the flame just above the slot of the burner. The absorbances were measured at the positions in the flame, with intervals of 2.5 mm; the positions were adjusted by moving the burner vertically. The conditions of the flame were changed by varying the acetylene flow rate by 0.5 l/min., while the flow rate of nitrous oxide was kept constant at 6 l/min.

The atomic absorption lines for the elements are listed in Table 1.

Temperature Measurement: Temperature of the flame was measured by the sodium 5889 Å line-reversal method.[8,9] Two pin holes were set along the light path, one for obtaining a narrow light beam from the incandescent light source, and the other, behind the flame, for excluding the extra emission

of the flame. The current of the incandescent lamp was controlled by an auto-transformer, while the temperature of the tungsten filament in the lamp was measured by means of the optical pyrometer at the reversal point of absorption and emission. In this measurement, an aqueous solution of 1000 μg Na/ml was nebulized into the flame. The reproducibility of the measurements was within 10 °C.

OH Radical Measurement: The concentration of the OH radical was measured by the molecular absorption method as follows. The luminous intensity of the deuterium discharge was almost constant in the range from 305.0 to 306.7 nm while the flame was not ignited. The absorption spectra of the flame were, therefore, measured by scanning the wavelengths in the above range continuously, and the relative concentrations of OH radicals were evaluated in terms of 305.8 and 306.4 nm. In this measurement, distilled water was nebulized into the flame.

Results

The experimental data for the flame temperature, the concentrations of the OH radical, and the atomic absorptions of Cd, Ni, Zn, Cu, Pb, Co, Mn, Fe, Mo, Ca, Cr, Sn, Ga, In, Ti, and B, which were observed as functions of two variables, such as the acetylene flow rate and the height above the burner, have been indicated in the response surface.

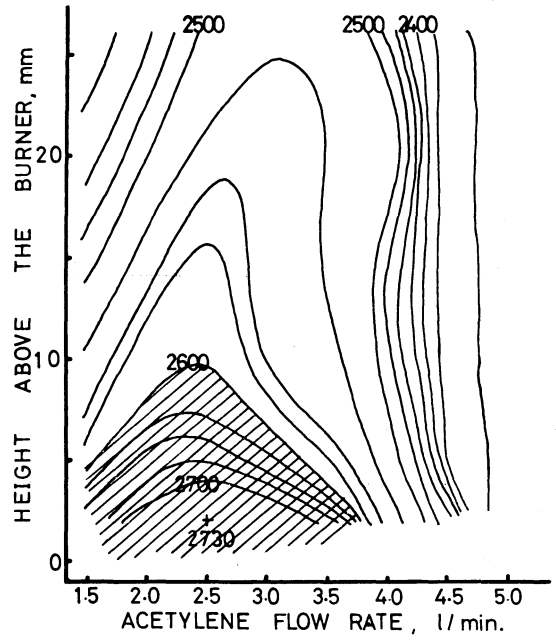

Fig. 1. Response surface of temperature.
Temperature in the hatched region is higher than 2600 °C.

In Fig. 1, the response surface for the flame temperature is shown. The temperatures were measured at 48 positions in the nitrous oxide-acetylene flame; the observed values are plotted in the response surface map. Thus, the isothermal contour lines are obtained with an interval of 25 degrees. In Fig. 1, the areas with a temperature range from 2300 to 2730 °C are shown. The maximal temperature is found at a height of 2 mm and with an acetylene flow rate of 2.5 l/min. The hatched area refers to when the flame temperature is higher than 2600 °C.

In Fig. 2, the response surface for the OH radical is shown. In this case, the absorbances of the molecular absorption of OH at 80 positions in the flame are plotted in the figure; the iso-absorbances are shown as contour lines with an interval of 0.012. The maximal absrobance of OH, 0.036, is found at the position with an acetylene flow rate of 1.5 l/min and a height of 5—20 mm. The absorbance in the hatched region is larger than 0.032.

In Figs. 3—7, the response surfaces for 16 elements are shown in the same way. The absorbances for those elements were measured at 40—72 positions of the

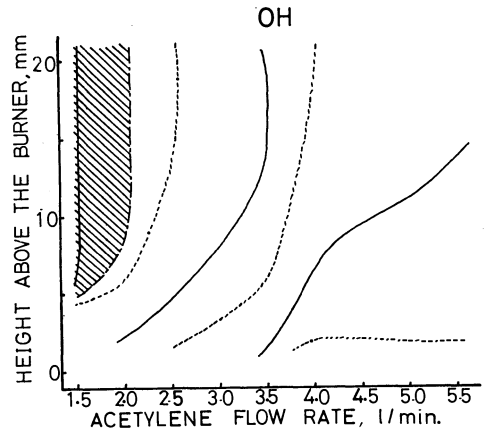

Fig. 2. Response surface of OH radical absorbance.
The absorbance in the hatched region is higher than 0.032.

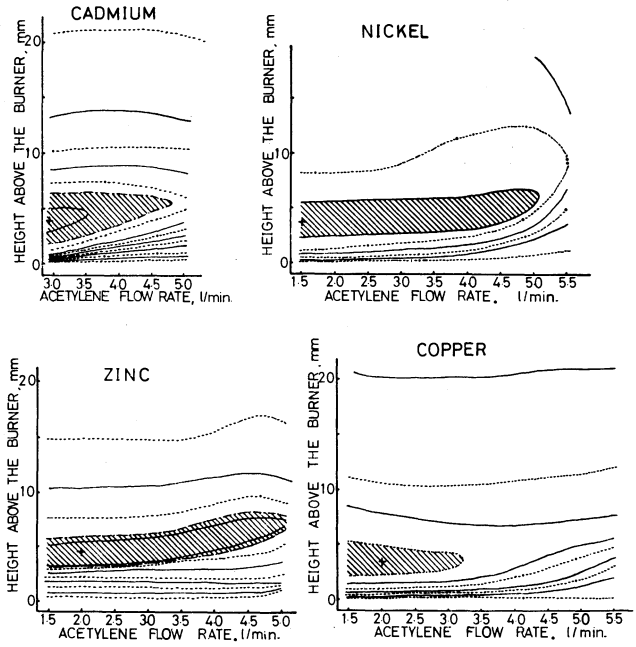

Fig. 3. Response surfaces of absorbances of cadmium, nickel, zinc, and copper.
The absorbances in the hatched regions are higher than 0.056, 0.036, 0.040, and 0.042 for cadmium, nickel, zinc and copper, respectively. The cross point indicates the position that gives the maximal absorbance.

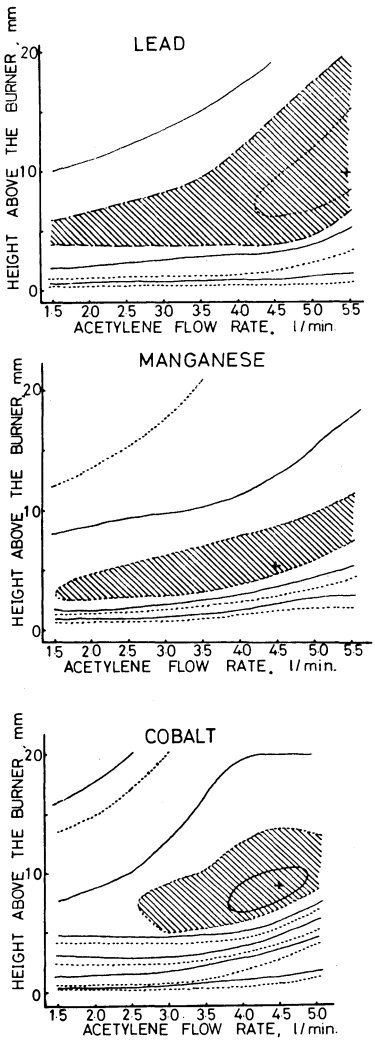

Fig. 4. Response surfaces of absorbances of lead, cobalt and manganese.
The absorbances in the hatched regions are higher than 0.028, 0.054, and 0.030 for lead, cobalt and manganese, respectively. The cross point indicates the position that gives the maximal absorbance.

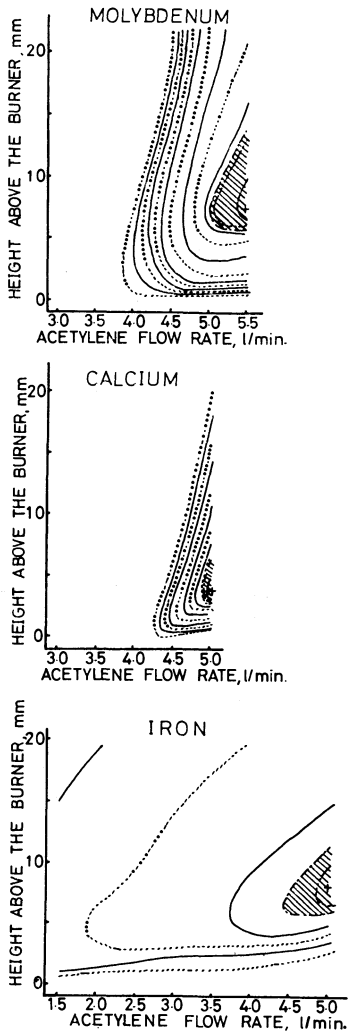

Fig. 5. Response surfaces of absorbances of calcium, molybdenum and iron.
The absorbances in the hatched regions are higher than 0.055, 0.065, and 0.028 for calcium, molybdenum and iron, respectively. The cross point indicates the position that gives the maximal absorbance.

flame. The response surfaces are classified into 5 groups. The basis of this classification will be described later. The maximal absorbances obtained in the nitrous oxide–acetylene flame are summarized in Table 2. The hatched regions in Figs. 3—7 refer to those giving an absorbance larger than nine-tenth of the maximal one. The contour lines giving the highest absorbance in the response surfaces of each element are summarized in Fig. 8.

Discussion

In the normal conditions of the flame in the present experiment system, the acetylene flow rate has been set at 4.0 l/min. This actually corresponds to the ratio of acetylene to nitrous oxide of 2 to 3 in volume. The region where the acetylene flow rate is larger than the normal condition of the flame is conventionally referred to as an acetylene-rich flame, and the smaller one, as an acetylene-lean flame.

Temperature in the Nitrous Oxide–acetylene Flame. The nitrous oxide–acetylene flame has been known as a high temperature flame. In fact, the temperature of this flame, as measured by the method reported previously, is about 300 degrees higher than that in the air–acetylene flame, the range of which is from 1900 to 2300 °C.[7] It should be noted that the highest temperature in the nitrous oxide–acetylene flame, 2730 °C, is observed in the lower part of the acetylene-lean region, and that the flame temperature decreases towards the upper part and the acetylene-rich region.

No distinct correlation in distribution between atoms and temperature in the response surfaces is observed. The sensitive regions of Cu, Ni, Cd, Zn, Co, Pb, and Mn spread from the region with the lowest temperature to that with the highest temperature. In the other elements, the sensitive regions are apart from the highest-temperature region.

OH Radical Distribution. The OH radical is produced by the oxidation of the fuel; it oxidizes the reductive component of the flame and also the metal

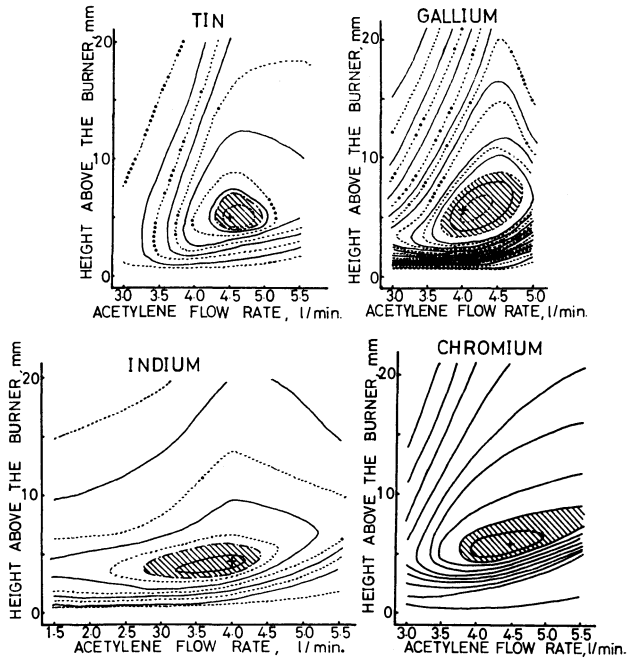

Fig. 6. Response surfaces of absorbances of tin, gallium, indium and chromium.
The absorbances in the hatched regions are higher than 0.050, 0.114, 0.044, and 0.108 for tin, gallium, indium and chromium, respectively. The cross point indicates the position that gives the maximal absorbance.

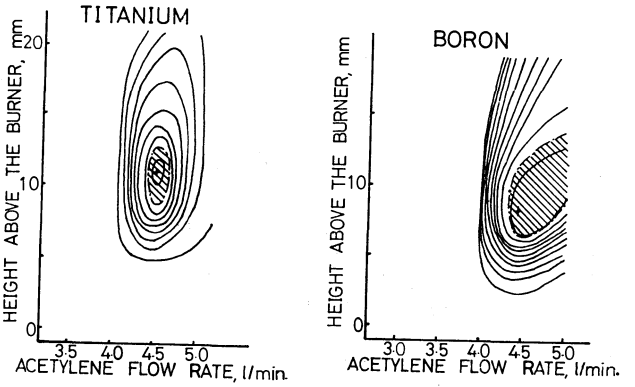

Fig. 7. Response surfaces of absorbances of titanium and boron.
The absorbances in the hatched regions are higher than 0.091 and 0.112 for titanium and boron, respectively. The cross point indicates the position that gives the maximal absorbance.

atoms.[10] Hence, the relative concentration of the OH radical (shown in Fig. 2) has been used as an index of the oxidation potential of the flame. Its concentration becomes higher in the upper part of the acetylene-lean region. On the other hand, the atomic concentrations of all the elements become lower in this region. This suggests that the oxidative reactions are predominant in this region and that the atomization of the analyzed element is prevented by the formation of oxide.

On the other hand, as may be seen in Fig. 8, the absorption maxima of many elements can be observed in the region of the OH radical minimum. This

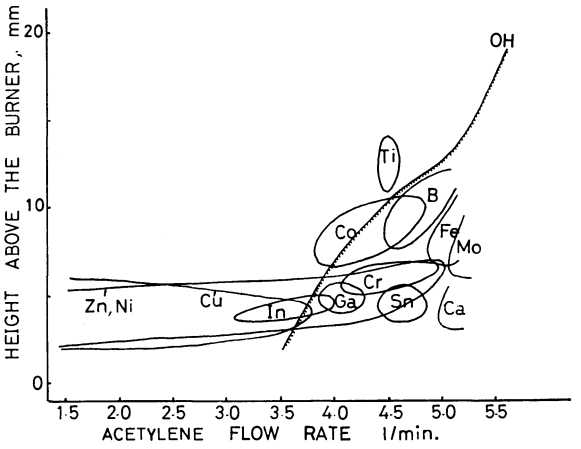

Fig. 8. Locations of higher sensitive regions of elements investigated.
The cited areas refer to those of higher sensitivities. The hatched line, ||||||||, denotes the OH concentration, *i.e.*, the area which is right-hand side of the line refers to that of low concentration, absorbance of OH is lower than 0.012.

region is actually reductive; this suggests that the reductive condition is favorable for the atomization of many elements in the nitrous oxide–acetylene flame.

Sensitivities of the Nitrous Oxide–acetylene Flame and the Air–acetylene Flame. In Table 2 the sensitivities for the analyzed elements in the nitrous oxide–acetylene flame and in the air–acetylene flame are compared; the sensitivity is expressed in terms of the ratio of maximal absorbance. The values in Table 2 refer to those obtained after the normalization with respect to

Table 2.

Element	Heat of formation of M_xO_y (Ref. 15) (eV)		Dissociation energy of MO (Ref. 12, 13, 14, 16) (eV)	Maximum absorbance	Ratio of max. absorbance in N_2O–C_2H_2 flame to that in air–C_2H_2 flame
Cd	CdO	2.6	3.8	0.063	0.61
Ni	NiO	2.5	3.9	0.041	0.34
Zn	ZnO	3.6	2.8	0.052	0.64
Cu	CuO	1.6	3.3—4.1	0.047	0.48
Pb	PbO	2.3	3.9	0.031	0.32

B	B_2O_3	13.1	8.0—8.3	0.130	a)

a) Absorbance is not obtained in the air–acetylene flame.

the length of the burner. Those of Ga, Sn, Cr, and B show the ratios larger than one. This indicates the higher sensitivity in the nitrous oxide–acetylene flame. All these elements, except Sn, form stable oxides whose heats of formation are larger than about 10 eV. The results obtained here suggest that the formations and the thermal decompositions of these oxides are essentially important processes for the atomization, which will be discussed later. Sn may form type of oxide other than SnO_2.[11]

Classification of the Elements in Terms of the Response Surface Patterns. The profiles of the response surfaces for 16 elements are shown in Figs. 3—7. Some of the elements are similar to each other. The elements may be classified into the following five groups according to the similarity;
Group A: Cd, Cu, Zn, Ni (Fig. 3); Group B: Pb, Co, Mn (Fig. 4); Group C: Fe, Mo, Ca (Fig. 5); Group D: In, Ga, Cr, Sn (Fig. 6); Group E: Ti, B (Fig. 7).

The characteristics of each group can be summarized as follows.

Group A: The contour lines for the iso-absorbance are almost horizontal and parallel with each other. This indicates that the absorbances of these elements are almost independent of the composition of the flame, although they are slightly more sensitive in the very acetylene-lean region than in the acetylene-rich one.

Group B: The contour lines run from the lower-left to the upper-right, and sensitive regions, expressed by the hatched area, spread towards the acetylene-rich region.

Group C: The contour lines in the response surfaces form half-rounded loop, which open mouth towards the acetylene-rich part. Moreover, the hatched region is very narrow and is located in the most acetylene-rich region. It should be noted that the absorbances of these elements can be hardly detected in the acetylene-lean region. This suggests that the increase in the reductive components of the flame rather than a high temperature is necessary for the atomizations of these elements.

Group D: The hatched regions are in a small circle of the contour line at the lower part of the flame height in the rather acetylene-rich region. The sensitivities of the elements in this group decrease in the relatively-lower-temperature part. This is characteristic of the elements whose oxides have large heats of formation as listed in Table 2.

Group E: The hatched regions are observed in longitudinally elongated loops of the contour lines in the acetylene-rich region. They are located at a upper position of flame height comparing to the other elements. The absorbances of these elements can be observed only in the extreme neighbourhood of the absorption maxima.

Atomization Processes. The thermodynamic properties, the heats of formation of the oxide, M_xO_y, and the dissociation energies of monoxides, MO, with respect to the elements are summarized in Table 2. They are concerned with the atomization processes of elements.

The patterns of the response surfaces obtained show that two different patterns of the atomization process exist. One is independent of the change in the nature of the flame. The response surface of *Group A* is typical of this pattern. The other is directly susceptible to the nature of the flame; *i.e.*, the atomization is promoted by an increase in the fuel flow rate. A typical pattern is *Group C*. *Group B* is intermediate between the former and the latter. For an explanation of this difference, the dissociation energy of the monoxide should be considered. The elements in *Group A* have small dissociation energies of monoxides, lower than 3.9 eV. Therefore, the monoxides of *Group A* elements are easily decomposed, and the monoxide formation does not actually interfere with the atomization of the element. In the case of *Group C*, whose monoxides have dissociation energies larger than 4.5 eV, the reduction of monoxide by the reduction components of the flame is an important process in the atomization. The energies of the monoxides of elements in *Group B* are between those of *Group A* and *C*, 3.9—4.2 eV; this explains why the response surface pattern of *Group B* is intermediate between those of *A* and *C*.

On the other hand, the locations of the sensitive region for the elements in *Group D* and *E* can not be interpreted only in terms of the dissociation energies of their monoxides. The hatched regions of Ga and In are located near the normal flame region, while the dissociation energies of their monoxides are very small. The hatched region of Sn is located in a less fuel-rich region than those of Fe and Mo, while the dissociation energy of SnO is larger than those of FeO and MoO. Those of Ti and B, whose monoxides have the largest dissociation energies among the elements investigated, do not appear in the most acetylene-rich region. It is noted that the sensitive regions of *Groups D* and *E* appear in a temperature region higher than those to be expected from the magnitudes of the dissociation energies of their monoxides. The fact mentioned above seems to be due to the formation of stable oxides, M_xO_y, of these elements in the flame. According to the description given in the previous section, the higher sensitivities are obtained in the higher-temperature flame for the elements whose oxides have heats of formation of more than about 10 eV. This fact suggests that the decomposition of the stable oxide proceeds under high-temperature conditions.

In the case of *Group E* elements, the oxides, TiO_2 and B_2O_3, and monoxides, TiO and BO, are all extremely stable compared to those of other elements. For the atomizations of these elements, a high temperature and a reductive atomosphere are indispensable. The atomic absorption spectrometry of these elements is difficult in the air–acetylene flame. This may be due to the facts that the temperature of the flame is as low as below 2100 °C in the fuel-rich region,[7] and that their oxides are not decomposed. The atomic absorption spectrometry of these elements is also difficult in the hydrogen–oxygen flame even though the temperature of this flame is almost equal to that of the nitrous oxide–acetylene flame.[5] We assume that the carbon components play an important role in the decomposition of the stable monoxide.

In summary, on the basis of the above discussions, the following atomization processes of the elements can be considered in the nitrous oxide–acetylene flame:

$$M(OH_2)_n^{m+} \longrightarrow M_xO_y \quad (1)$$

$$M_xO_y \xrightarrow{\Delta} MO \quad (2)$$

$$MO + C \longrightarrow M + CO \quad (3)$$

where Δ represents the pyrolysis reaction; M, the atom of the analyzed element, and C, the carbon component in the flame. Reaction (2) expresses the pyrolysis of the oxides; it is important for the elements in *Group D* and *E*. Reaction (3) expresses the reduction of monoxide by means of the flame components. This must play a significant role in the atomizations of the elements in the *Group C* and *E*.

Studies on Mass Spectrometry of Metal Chelates. III. Mass Spectrometry of 2-, 4-, 5-, 7-Methyl-, and 5-Chloro-oxine Metal Chelates

Shinobu NAGA, Yoshinori KIDANI, and Hisashi KOIKE*

Faculty of Pharmaceutical Sciences, Nagoya City University, Tanabe-dori, Mizuho-ku, Nagoya 467
**School of Medical Technology and Nursing, Fujita Gakuen University, Toyoake, Aichi 470-11*

(Received April 15, 1974)

For application of mass spectrometry to metal chelate chemistry, a group of divalent metal chelates (Co, Ni, Cu, Zn, and Pd) of 2-Me-oxine, 4-Me-oxine, 5-Me-oxine, 7-Me-oxine, and 5-Cl-oxine has been investigated. 2-Methyl-oxine and 4-Me-oxine of these ligands give similar spectra and are considered to have similar fragmentation patterns. The same was found for 5-Me-oxine and 7-Me-oxine. However, the spectra of 2-Me-oxine and 4-Me-oxine metal chelates differ from each other, as do also the spectra of 5-Me-oxine and 7-Me-oxine. Thus fragmentation patterns may vary with the metal chelate formation of the ligands even when they have the same fragmentation patterns. Each metal chelate gave two peaks corresponding to metal-containing ions, a molecular ion (I) of a 2:1 (ligand: metal) chelate, and a fragment ion (II) of a 1:1 chelate due to the loss of a ligand radical from ion I. In the case of Co, Ni, Zn, and Pd chelates of 2-Me-oxine, a peak corresponding to the loss of a methyl radical from I was observed, apparently caused by steric effect. In the metal chelates of 5-Me-oxine, a peak corresponding to the loss of a hydrogen radical from I was also observed. However, the fragmentation pathway of formation of II from I is commonly observed in all metal chelates. Since this pathway is comparable with the second successive formation reaction (k_2) in solution, the peak intensity ratio of the ion of I to that of II was calculated. From the results it was found that the stability of the chelates decreases in the order Zn>Ni>Pd~Co>Cu and that it depends on the charge-radius ratio (e/r) of the central metal ion, or the stability constant (log k_2) observed in solution.

We have studied the divalent metal chelates of 8-quinolinol (oxine)[1] and 8-quinolinethiol (thiooxine)[2] and estimated the stability of these metal chelates under electron impact from the intensity ratio of the peaks. It was found that the stability of these oxine and thiooxine metal chelates is in the order Zn>Ni>Pd~Co>Mn>Cu>Pb and that it depends on the charge-radius ratio (e/r) of the central metal ion.

The results of mass spectral analysis of divalent metal chelates of 2-methyl-8-quinolinol (2-Me-oxine), 4-methyl-8-quinolinol (4-Me-oxine), 5-methyl-8-quinolinol (5-Me-oxine), 7-methyl-8-quinolinol (7-Me-oxine), and 5-chloro-8-quinolinol (5-Cl-oxine) are reported.

Results and Discussion

Mass Spectra of Ligands and Their Fragmentation Patterns. The mass spectra of 2-Me-oxine, 4-Me-oxine, 5-Me-oxine, 7-Me-oxine, and 5-Cl-oxine are shown in Fig. 1.

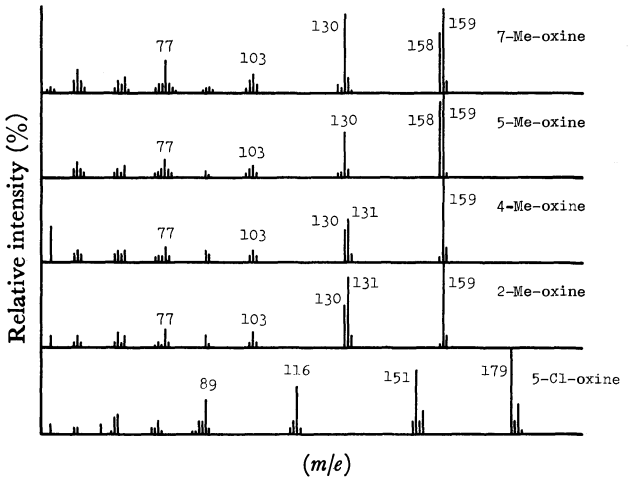

Fig. 1. Mass spectra of oxine derivatives.

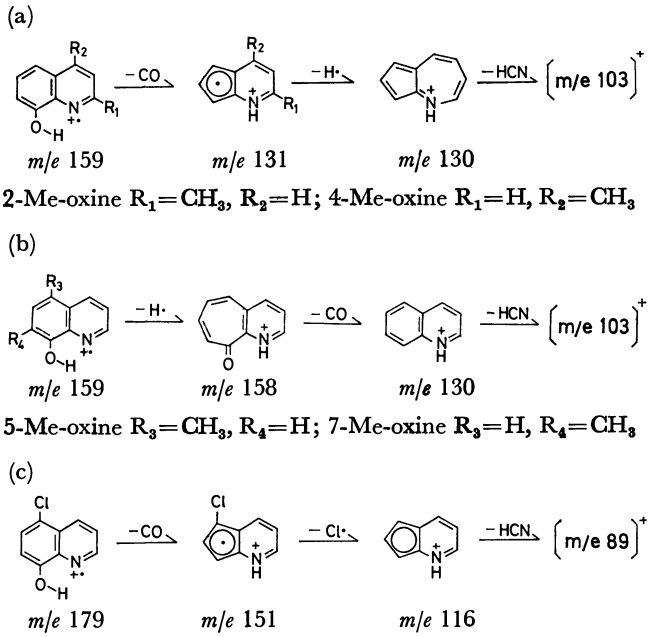
Each spectrum gives a strong molecular ion peak (2-, 4-, 5-, and 7-Me-oxine: *m/e* 159; 5-Cl-oxine: *m/e* 179).

The spectrum of 2-Me-oxine is similar to that of 4-Me-oxine, both ligands having fragment ion peaks at *m/e* 131, 130, and 103. The fragmentation patterns of 2-Me-oxine and 4-Me-oxine were reported by Stevenson *et al.*[3] (Scheme 1-a). The molecular ion loses CO to give an ion of *m/e* 131, and then this ion loses H· to produce an azatropylium type ion of *m/e* 130, which in turn loses HCN to produce an ion of *m/e* 103.

Similar spectra are also observed for 5-Me-oxine and 7-Me-oxine, both having the strongest peak, except the molecular ion peak, at *m/e* 158 ($M^{+}-1$); main fragment ion peaks can be observed at *m/e* 130 and 103. The peak at *m/e* 158 is the one corresponding to the loss of H· from the molecular ion, and is due to a tropylium type ion (Scheme 1-b). The peak at *m/e* 130 is due to the ion produced by the loss of CO from the ion of *m/e* 158. The ion of *m/e* 130 might lose HCN to produce an ion of *m/e* 103.

5-Chlorooxine shows main fragment ion peaks at *m/e* 151, 116, and 89. The difference between the molecular ion peak and the peak at *m/e* 151 is 28, corresponding to the loss of CO from the molecular ion. It appears that the peak at *m/e* 116 is due to the ion produced by the loss of Cl· from the ion of *m/e* 151. The peak at *m/e* 89 seems to be due to the ion produced by the loss of HCN from the ion at *m/e* 116. The fragmentation patterns of these oxine derivatives are summarized in Scheme 1-a, b, and c.

In the case of oxine derivatives with a methyl group on its pyridine ring, the molecular ion initially loses CO and then H· to produce an azatropylium type ion. On the other hand, in the case of oxine derivatives with a methyl group on its benzene ring, the molecular ion initially loses H· to produce a tropylium type ion, which then loses CO in succession. A distinct dif-



Scheme 1. Fragmentation of oxine derivatives.

ference in fragmentation patterns was found between the two cases. However, it was difficult to find a difference between 2-Me-oxine and 4-Me-oxine and between 5-Me-oxine and 7-Me-oxine from their mass spectra.

The values calculated and found for the metastable ion peaks observed in each fragmentation pathway (Scheme 1) are summarized in Table 1.

TABLE 1. METASTABLE ION PEAKS IN THE MASS SPECTRA OF OXINE DERIVATIVES

Compound	Transition	m* Calcd.	m* Found	Expelled fragment
5-Cl-oxine	179→151+28	127.38	127.1	CO
	151→116+35	89.11	—	Cl·
	116→ 89+27	68.28	68.3	HCN
2-Me-oxine	159→131+28	107.93	108.0	CO
	131→130+ 1	129.01	129.0	H·
	130→103+27	81.61	81.5	HCN
4-Me-oxine	159→131+28	107.93	108.0	CO
	131→130+ 1	129.01	129.0	H·
	130→103+27	81.61	81.5	HCN
5-Me-oxine	159→158+ 1	157.01	157.0	H·
	158→130+28	106.96	107.0	CO
	130→103+27	81.61	81.5	HCN
7-Me-oxine	159→158+ 1	157.01	157.0	H·
	158→130+28	106.96	107.0	CO
	130→103+27	81.61	81.5	HCN

Mass Spectra of Divalent Metal Chelates and Their Fragmentation Patterns. 2-Me-oxine Metal Chelates: Figure 2 shows the spestra of Ni, Co, Cu, Zn, and Pd chelates with 2-Me-oxine. Molecular ion peaks of chelates were observed in the highest mass region of all the spectra, showing that the ligand and metal are combined in a 2: 1 molar ratio. Except for Cu chelate, a fragment ion peak due to the loss of CH_3· from the molecular ion is observed. On the other hand, all spectra have a peak corresponding to the loss of 158

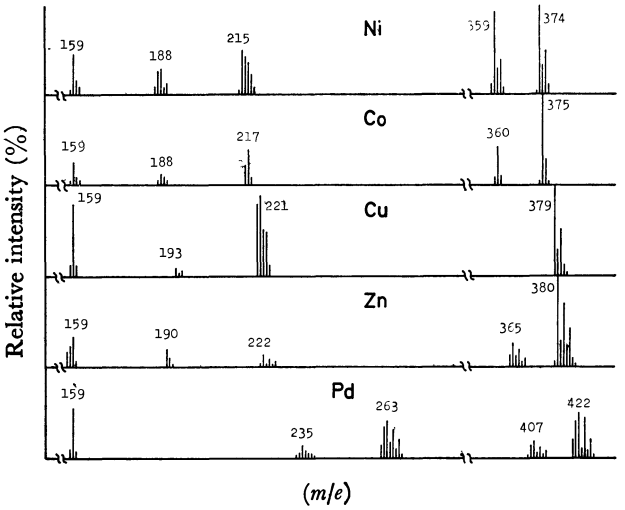


Fig. 2. Mass spectra of 2-Me-oxine metal chelates.

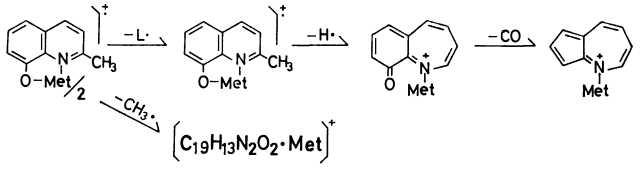
amu (one molecule of 2-Me-oxine) from the molecular ion, the peak due to the ion having a 1: 1 ligand to metal ratio. Another peak due to the loss of H· from this ion, which appears to be azatropylium type ion, is observed. The loss of CO from this ion takes place except for Zn chelate. The fragmentation pattern of 2-Me-oxine metal chelates is shown in Scheme 2.



Met=divalent metals

Scheme 2. Fragmentation of 2-Me-oxine metal chelates.

4-Me-oxine Metal Chelates: Figure 3 and Scheme 3 show the spectra of Ni, Co, Cu, Zn, and Pd chelates with 4-Me-oxine and their fragmentation patterns. The molecular ion peak of each chelate corresponding to a 2: 1 ligand to metal ratio was observed in the highest mass region of all the spectra, followed by a fragment ion peak due to the loss of one molecule of 4-Me-oxine

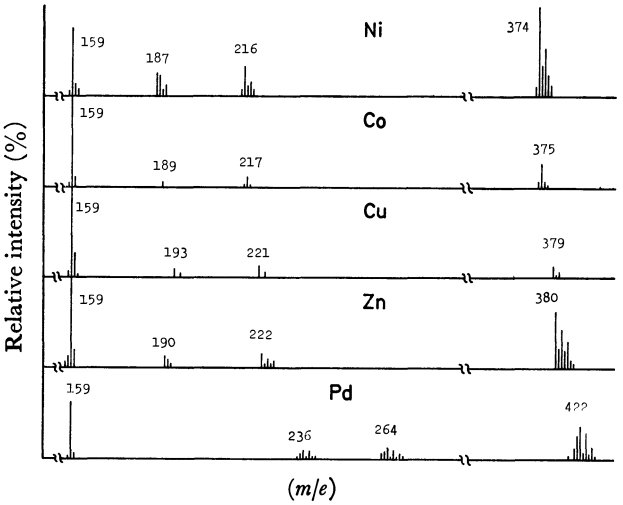


Fig. 3. Mass spectra of 4-Me-oxine metal chelates.

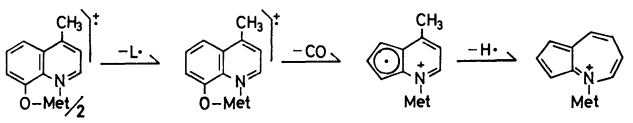

Met=divalent metals

Scheme 3. Fragmentation of 4-Me-oxine metal chelates.

(158 amu), and with a 1:1 ligand to metal ratio. Except for the Zn chelate the peak was followed by another peak corresponding to the loss of CO from the 1:1 chelate ion.

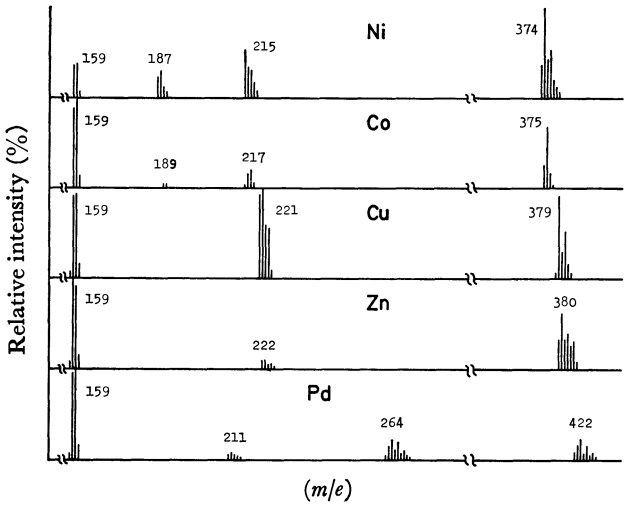

Fig. 4. Mass spectra of 5-Me-oxine metal chelates.

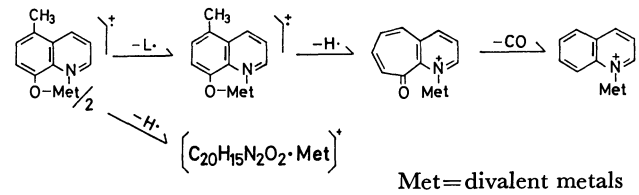
5-Me-oxine Metal Chelates: Figure 4 shows the spectra of Ni, Co, Cu, Zn, and Pd chelates with 5-Me-oxine. The molecular ion peak of each chelate corresponding to a 2:1 ligand to metal ratio was observed in the highest mass region of all the spectra, followed by a peak corresponding to the loss of one amu (corresponding to $H^{\cdot}$). The ion M^{+}–1 would have a mixed ligand complex structure since either of the two ligands can lose a hydrogen to form tropylium type structure. On the other hand, a fragment ion peak corresponding to the loss of 158 amu from the molecular ion also appears with a 1:1 ligand to metal ratio. The peak is followed by another peak, which seems to be a tropylium type ion by the loss of H· from that ion. This is followed by a fragment ion peak corresponding to the loss of CO from tropylium type ion except for Zn chelate, the fragment ion peak being weak (Scheme 4).



Met=divalent metals

Scheme 4. Fragmentation of 5-Me-oxine metal chelates.

7-Me-oxine Metal Chelates: Figure 5 shows the spectra of Ni, Co, Cu, Zn, and Pd chelates with 7-Me-oxine. The loss of 158 amu, one molecule of 7-Me-oxine, from

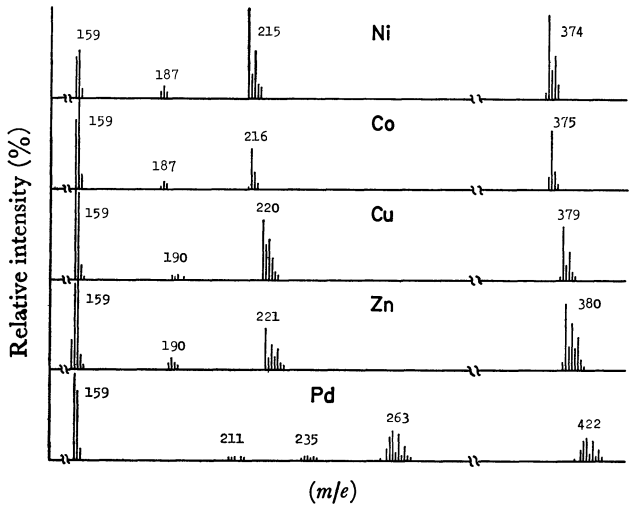


Fig. 5. Mass spectra of 7-Me-oxine metal chelates.

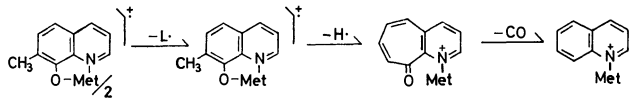
the molecular 2:1 chelate ion appears to give a fragment ion peak corresponding to a 1:1 lignad to metal ratio. This is followed by a peak with high intensity, corresponding to the loss of H· from the 1:1 chelate ion. The peak with low intensity resulting from the loss of 28 amu corresponding to CO is observed in the spectra except for Zn chelate (Scheme 5).



Met=divalent metals

Scheme 5. Fragmentation of 7-Me-oxine metal chelates.

5-Cl-oxine Metal Chelates: Figure 6 shows the spectra of Ni, Co, Cu, Zn, and Pd chelates with 5-Cl-oxine. The molecular ion peak of each chelate was observed in the highest mass region of all spectra corresponding to a 2:1 ligand to metal ratio. A fragment ion peak due to the ion produced by the loss of 178 amu from the molecular ion was also observed. Since 178 amu corresponds to one molecule of 5-Cl-oxine, the ion produced has a 1:1 ligand to metal molar ratio. Except

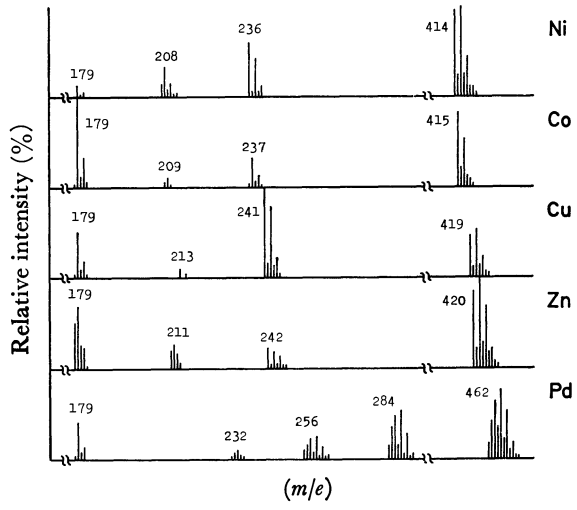


Fig. 6. Mass spectra of 5-Cl-oxine metal chelates.

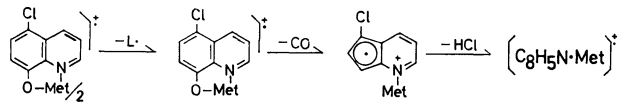

Met=divalent metals

Scheme 6. Fragmentation of 5-Cl-oxine metal chelates.

for Zn chelate, the loss of 28 amu corresponding to CO from the 1:1 chelate ion is observed. The peak is followed by a fragment ion peak which lost HCl. The fragmentation pattern is shown in Scheme 6.

The fragmentation patterns of 2-Me-oxine and 4-Me-oxine and those of 5-Me-oxine and 7-Me-oxine are similar to each other, but the metal chelates of these methyloxine derivatives show fairly different fragmentation patterns. In the case of 2-Me-oxine, a fragment ion peak due to the loss of $CH_3\cdot$ from the molecular ion can be observed, but in that of 4-Me-oxine metal chelates no corresponding fragmentation occurred. A peak corresponding to the loss of H· from the molecular ion was observed in the case of 5-Me-oxine, but not in that of 7-Me-oxine.

In each spectrum the loss of either H· or CO from the 1:1 fragment ion was observed. The fragment ions produced are expected to contain a metal atom combined with the nitrogen atom. Thus, in the 1:1 fragment ion, the metal atom seems to be bound more strongly with the nitrogen atom than with the oxygen atom. However, each Zn chelate shows no loss of CO from the 1:1 fragment ion or from the fragment ion produced by the loss of H· from the 1:1 ion. This may be related to the valence change of the metal in the fragmentation process for acetylacetone metal chelates.[4] According to the classification of metals by Budzikiewicz *et al.*,[5] the valence change in Zn seems to be difficult, and the oxygen-zinc bond might be stronger than the other oxygen-metal bond, resulting in the difficult loss of CO.

The loss of $CH_3\cdot$ from the molecular ion occurs in Co, Ni, Zn, and Pd chelates of 2-Me-oxine only. The fragmentation pathway is not observed for the other methyloxine metal chelates. This may be partly caused by a steric influence of the methyl group at 2-position on the quinoline ring. Thus, in gaseous state the molecular ions of Co, Ni, Zn, and Pd chelates with 2-Me-oxine might take such a sterically hindered structure, which favors the loss of the methyl group.

Each spectrum of the metal chelates includes the peaks due to the ligand itself. It seems that prior to vaporization the chelate is thermally decomposed and the peak due to the ligand itself may be observed together.[1]

Stability under Electron Impact. Various metal chelates of mono-methyl-oxine derivatives show different fragmentation patterns depending on the position of the methyl group. However, a fragmentation pathway common to all the metal chelates can be observed, *i.e.*, the pathway in which a ligand radical is lost initially from a 2:1 molecular ion (I) to transform into a 1:1 fragment ion (II). This fragmentation pathway can be compared with the second successive formation reaction of metal chelates in solution. Thus,

Table 2. Intensity ratios of the molecular ion, I, to the fragment ion, II.

Ligand	Metal				
	Zn	Ni	Pd	Co	Cu
oxine[1]	67	63	61	61	48
thiooxine[2]	52	48	45	45	30
2-Me-oxine	87	77	75	74	55
4-Me-oxine	86	75	75	74	56
5-Me-oxine	75	69	67	65	50
7-Me-oxine	85	77	74	75	57
5-Cl-oxine	65	62	58	57	43

in order to examine the stability of ion I under electron impact, the peak intensity of I was calculated as the intensity ratio of I to the sum of I and II (Table 2). The peak intensity of I for each ligand is in the order: Zn>Ni>Pd~Co>Cu. This suggests that the peak intensity is related to the characteristics of the central metal ions and not to those of the ligands in the chelates. The values in Table 2 are plotted against the charge-radius ratio (e/r) of the central metal ions,[6] *viz.*, charge density, which is known to affect the stability of metal chelate in solution (Fig. 7).[7] We see that the peak intensity of I is proportional to the charge density; even under electron impact the molecular ion of a metal chelate having a central metal ion of high charge density is more stable than that of another chelate having a metal ion of low charge density.

Based on the assumption that the fragmentation pathway from I to II is correlated to the formation process of a 1:1 chelate from a 2:1 chelate in solution, which is expressed in terms of the stability constant,

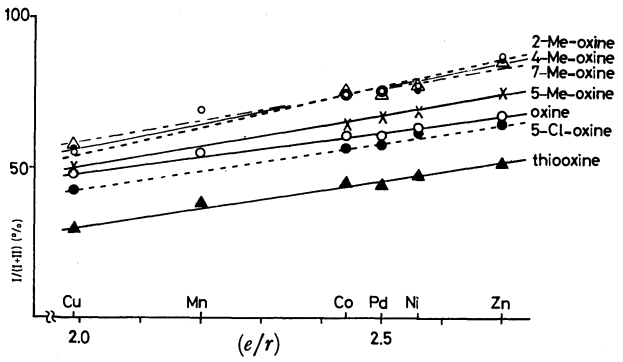

Fig. 7. Correlation between the intensity ratios and the charge-radius ratios of metals.

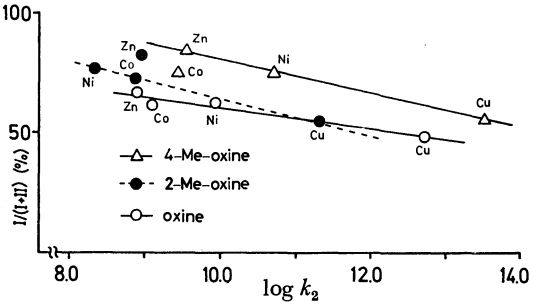

Fig. 8. Correlation between the intensity ratios and stability constants, log k_2.

log k_2, a close relation between the stability of I under electron impact and log k_2, is expected. The values in Table 2 are plotted against log k_2 (Fig. 8).[8] A linear relation holds between the stability of I under electron impact and log k_2 in the metal chelates of 4-Me-oxine, 2-Me-oxine, and oxine. 5-Methyloxine, 7-Me-oxine, and 5-Cl-oxine are not included, since the values of log k_2 are not known.

We can thus distinguish the metal chelates of similar methyl-oxine derivatives, and the molar ratio of ligand to metal in a chelate can be simply determined with a minute quantity of sample. It is possible to identify the metal contained from the isotope ratio in the molecular ion peak. By further detailed examinations of the spectra, the stability of the metal chelates under electron impact can also be studied. All these results indicate that mass spectrometry can be applied effectively to investigations of the metal chelates with methyl-oxine derivatives.

Experimental

Apparatus: Mass spectra were measured with a Hitachi RMU-7 mass spectrometer by means of a direct inlet system, at 70 eV ionization voltage.

Reagents: 2-Methyl-oxine and 5-Cl-oxine (reagent grade, Tokyo Kasei Kogyo Co., Ltd.) were used without further purification. 4-Methyl-oxine,[9] 5-Me-oxine,[10] and 7-Me-oxine[10] were synthesized according to the reported methods.

Syntheses of Metal Chelates: Alcohol solutions of metal chlorides were added to alcohol solutions of the ligands. The mixtures were warmed on a water bath and the resulting precipitates were separated by filtration. After washing with hot alcohol and water several times, the precipitates were dried at *ca.* 110 °C under reduced pressure. The composition of each metal chelate was confirmed by elemental analysis.

The authors' thanks are due to Professor Akira Tatematsu, Faculty of Pharmacy, Meijo University, for use of the apparatus.

Thermal Dehydration and Decomposition of Dioxalato Complexes of Be(II), Mn(II), Co(II), Ni(II), Cu(II) and Zn(II) in Solid State

Kenzo NAGASE, Katsuya SATO,* and Nobuyuki TANAKA*

College of General Education, Tohoku University, Kawauchi, Sendai 980

(Received July 10, 1974)

The structures of anhydrous dioxalato complexes $K_2[M(C_2O_4)_2]$ (M: Mn(II), Co(II), Ni(II), Cu(II), and Zn(II)) prepared by heating their hydrates, were examined by means of infrared absorption and visible reflectance spectroscopy. It was found that the anhydrous complexes of Mn(II), Co(II), and Zn(II) exist in a polynuclear octahedral form with a bridging oxalate group, and those of Ni(II) and Cu(II), in a monomer form. On further heating, the complexes of Be(II), Mn(II), and Zn(II) decomposed into the corresponding metal oxides and potassium oxalate, and those of Co(II), Ni(II), and Cu(II) into the corresponding metals and potassium oxalate. Except for the beryllium(II) complex, the complexes decomposed at lower temperatures with an increase in $1/r$, where r is the radius of metal ion.

The thermal properties of bivalent metal oxalates-(monooxalato-type complex) and trioxalato-type complexes of tervalent metals have been extensively studied. However, only fragmentary information is available on the thermal decomposition reactions of dioxalato-type complexes of bivalent metals. The TG, DTA, and EG curves for $K_2[Cu(C_2O_4)_2]\cdot 2H_2O$, $K_2[Zn(C_2O_4)_2]\cdot 2H_2O$, $K_2[Pd(C_2O_4)_2]\cdot 3H_2O$, and $K_2[Pt(C_2O_4)_2]\cdot 2H_2O$ were presented and the reaction stoichiometries discussed.[1,2]

Most bivalent metal oxalates(monoxalato-type complexes) exist in a polynuclear form with bridging oxalate groups, the water molecules contained being coordinated directly to the metal ions.[3] Thus, the dehydration temperatures are considerably high (>100 °C). The nature of the metal ions is well reflected not only on the dehydration reactions but also on the decomposition reactions of the anhydrous salts. Trioxalato-type complexes of tervalent metals exist in the mononuclear octahedral form. The coordination number of tervalent metals is usually six, and thus in these complexes, all coordination positions are occupied by the oxygen atoms of three bidentate oxalate groups. All the water molecules contained are crystalline water and dehydration takes place below 100 °C. Interest in the thermal reactions of these complexes has been limited to the decomposition reactions of the anhydrous salts. Dioxalato complexes seem to be of particular interest, since they exist in either a mononuclear or a polynuclear form. The metal ions with coordination number 4 will be mononuclear, whereas those with the number 6 can form both the mononuclear (two of the six positions are occupied by two water molecules) and polynuclear (the bridging oxalate groups act as quadridentate ligand) form complexes. In the case of anhydrous dioxalato complexes, the complexes of the metals with the number 6 should exist in the polynuclear form.

We have examined the structures of the anhydrous dioxalato complexes of Mn(II), Co(II), Ni(II), Cu(II), and Zn(II) prepared by heating their hydrates in solid state by means of infrared absorption and visible reflectance spectroscopies. The thermal properties, as determined by the techniques of TG, DTA, DSC, and EG, are given for $K_2[Be(C_2O_4)_2]$, $K_2[Zn(C_2O_4)_2]\cdot 5H_2O$, $K_2[Mn(C_2O_4)_2]\cdot 2H_2O$, $K_2[Co(C_2O_4)_2]\cdot 6H_2O$, $K_2[Ni(C_2O_4)_2]\cdot 6H_2O$, and $K_2[Cu(C_2O_4)_2]\cdot 2H_2O$.

Experimental

Materials. The dioxalato complexes were prepared as follows: Beryllium(II) complex was obtained by adding $K_2C_2O_4$ to an aqueous solution of $BeSO_4\cdot 4H_2O$. For the other complexes, the corresponding metal oxalates were dissolved in an aqueous solution containing a stoichiometric amount of $K_2C_2O_4$. After filtration, the desired samples were crystallized from the filtrates by addition of methanol. The results of elemental analyses for C and H agreed with the calculated values within $\pm 0.3\%$ for all the complexes.

Measurements. Thermogravimetric (TG) and differential thermal analytic (DTA) curves were obtained in the range from room temperature to 1000 °C with a Shinku Riko TGD-3000, at a heating rate of 5 °C/min in a nitrogen atmosphere with a 50 ml/min flow rate. 20 mg of powdered sample was placed in a platinum crucible and used in each measurement. Heats of dehydration and decomposition were determined with a Rigaku Denki 8002 CS differential scanning calorimeter (DSC) at a 5 °C/min heating rate in a nitrogen atmosphere with a 30 ml/min flow rate. 20 mg of powdered sample was placed in an aluminum crucible, a lid of the same material being then placed inside the crucible. The instrument was calibrated against the heat of transition of KNO_3 which appears at 128 °C with ΔH of 12.28 kcal/mol.
