n_A). But the condition $Z_A \gg Z_1$, Z_4 is not always satisfied because the thermometer-lead impedance could not be reduced below a few ohms. The correction for this effect was achieved by connecting resistors in parallel with Z_A in turn, which is indicated by the dashed lines in Fig. 5. The "n_A" are plotted against the 400/(resultant resistance) in Fig. 6. Extrapolation of this straight line to the infinite resultant resistance gives the corrected n_A. This means that, since no current flows in this circuit because of its infinite resistance, the voltage drop due to Z_1 does not occur, so the extrapolated n_A corresponds to that which would be obtained if Z_1 is zero. The slope of this straight line increases with increasing $R(T)$ and R_{std}. The magnitude of this correction was less than 3/1000 K at any temperature range studied. The second correction is concerned with the self-heating of the thermometer. Since the Minco thermometer has the higher resistance and smaller volume than the platinum resistor of normal type, the effect of self-heating due to the current flow for measurements could not be neglected. This effect could be eliminated, however, in the following manner. A set of measurements with various bridge carrier voltages was plotted against the power dissipated in the thermometer and the n_A at the zero power dissipation was determined by extrapolation. This n_A value corresponds to that measured at condition where no current flowed in the thermometer. In actual heat capacity measurements, the power dissipation in the thermometer was typically 5 μW. The third correction, *i.e.*, the effect of the inductance of the thermometer element is not quite clear. The inductance of the Minco thermometer (~30 μH) is considerably larger than that of the typical L & N Pt-thermometer (~1.5 μH). Therefore, the DC resistance and the apparent AC resistance of the Minco thermometer can possibly be appreciably different from each other. This possible effect was taken into account by making the calibration of the Minco thermometer at a fixed frequency (390 Hz), while the standard thermometer (L & N Pt-resistor) was measured with DC current. The calibration table is given in the apparent resistance of the Minco thermometer against temperature. In principle, the calibration may have been performed at several frequencies to determine the DC resistance by extrapolation, but it was impracticable because of the instrumental limitation. This caused no inconvenience because the Minco thermometer was always used in conjunction with the ASL AC double bridge at the fixed carrier frequency.

b) Calibration of the Platinum Resistance Thermometer: The Minco platinum resistance thermometer was calibrated against the standard capsule type Leeds & Northrup Pt-thermometer which was recalibrated according to the IPTS-68. Two thermometers were mounted side by side in the well drilled in a copper block and set in the cryostat. The resistance of the standard thermometer was measured with the DC Müller bridge (Leeds & Northrup 8071-B Type G-3), while that of the Minco thermometer by the AC bridge mentioned above. The calibration was carried out at the eight temperatures from 13.81 to 373.15 K. Three measurements were made at each of the internationally defined fix points: *i.e.*, the triple and boiling points of equilibrium H_2, O_2, H_2O, equilibrium H_2 at 25/76 atm and the boiling point of Ne. The accurate values of resistance for the Minco thermometer at these fixed points were determined by interpolation. The temperature determined from the calibration table of the standard thermometer and the resistances of the Minco thermometer were corrected according to the procedure described above.

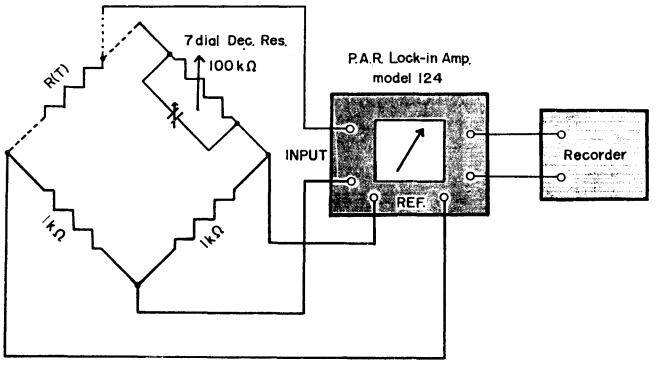

Fig. 7. AC Wheatstone bridge for the thermistor thermometer.

c) Circuit System for the Thermistor Resistance Measurement: Figure 7 shows the AC Wheatstone bridge for the thermistors which was used in the high resolution measurements. A lock-in amplifier (Princeton Applied Research Corp. Model 124) was employed as a high sensitivity detector. The balance of the resistive and the reactive components could be performed easily. The variable air-capacitor connected in parallel with decade resistor was used in balancing a reactive component. The fixed-arm resistors and the seven dial decade resistor box were kept in an air thermostat. Each dial of the decade resistor was calibrated against the 10 kΩ standard resistor by the decade-for-decade method. The leads of the thermistor represented by the dashed lines in Fig. 7 have the same length so as to compensate their impedance effects. Induction noises to the thermometer leads were reduced by twisting the lead wires with each other. All the other lead wires (for the thermocouples and heaters, which were potential noise sources) were also twisted in go-and-return pairs with different pitches.

d) Calibration of the Thermistor: The thermistor was calibrated against the Minco platinum thermometer (IPTS-68) at each measurement. On determining the relation between the temperature scale and the resistance of the thermistor, the equation $T=\sum_{i=1}^{n} A^i(\ln R)^i$ (n=2,3 or 4) was assumed and the expansion coefficients were determined by the least square fit. The deviations of the observed values from this equation were found to be less than 1×10^{-3} K, which was precise enough to determine absolute temperatures by means of this method (Fig. 8).

5) Circuit System for Energy Supply. The power supply and measureing circuit is shown in Fig. 9. A constant voltage circuit was used for the power supply and a digital voltmeter (Takeda Riken Model TR-6515D) for the measurements of

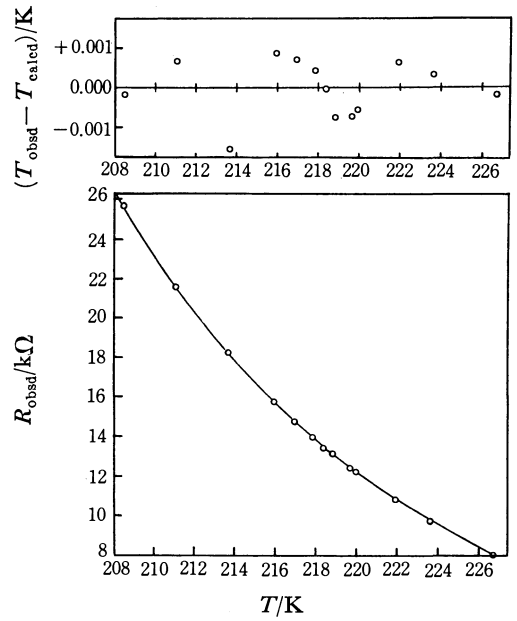

Fig. 8. Relation between the temperature and the net resistance of the five thermistors connected in parallel (lower), and the deviation of the calibration points from this curve (upper).

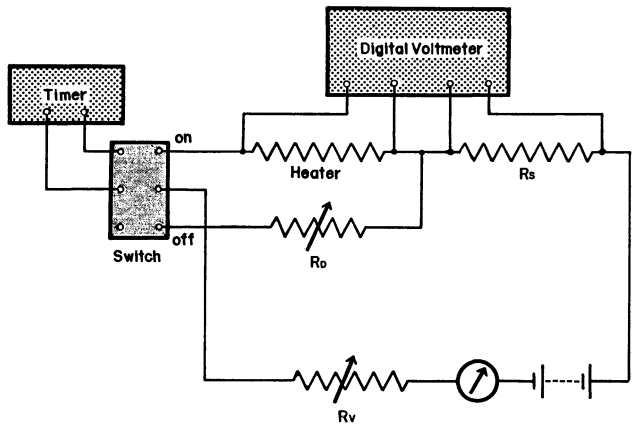

Fig. 9. Power supply and measuring circuit.

the current and voltage. The duration of the heat-on period was measured with a digital multifunction counter (Takeda Riken Model TR-5104). When the switch was put in position "on," the current start to flow through the calorimeter heater and counting of the timer begins. The current through the heater was determined by measuring the potential difference across the standard resistance R_s(100 Ω). A dummy resistor provided a by-pass circuit for the heater current. This device stabilized the out-put of the power supply when the calorimeter heater was switched off.

Results and Discussion

Determination of Heat Capacity of Benzoic Acid. The measurements and calculations of the gross heat capacity were carried out as follows. After the initial temperature T_i; *i.e.* the steady state temperature before heating, was measured, the electrical energy Q was introduced into the calorimeter. When the equilibrium state was confirmed after switching the heater current off, the final temperature T_f was determined. The steady state temperatures T_i and T_f were determined by following the temperature drifts as a function of time. If the natural drifts due to the imperfection of the adiabatic regulation were present, an additional corrections would be required. The electrical energy Q was determined as the product of the average calorimeter heater voltage $\bar{e}$, the current $\bar{i}$, and the time interval t, of the applied power input: *i.e.* $Q=\bar{e}\bar{i}t$. From the knowledge of these quantities, the gross heat capacity was determined by the equation: $Q/(T_f-T_i)$ at the mean temperature $(T_i+T_f)/2$. In the case of the high resolution measurements, the adiabatic regulation was strictly adjusted in order to eliminate the temperature drift for a long time. The precise determination of the heat capacity employing the small temperature increment is more liable to be affected by the heat leak. The thermistor was calibrated over the range of about 30 K including the temperature interval of the high-resolution measurement. The heat capacity is given by the equation, $C=Q/(\mathrm{d}T/\mathrm{d}R)_{T=T_{av}}\Delta R$, where $T_{av}=\{T(R_f)+T(R_i)\}/2$ and $\Delta R=|R_f-R_i|$. This calculation was performed on NEAC 2200 Model 700. In order to ascertain the over-all accuracy of the whole apparatus, the heat capacity measurement was performed on the benzoic acid as standard material which was prepared by the US National Bureau of Standards. The weight of the sample was 12.6106 g. The experimental values of the molar heat capacity are given in Table 1. Fig. 10 shows the deviation plots of our individual data points from the smoothed heat capacity of benzoic acid recommended by the US Calorimetry Conference.[13] The data by Furukawa *et al.*[14] and Cole *et al.*[15] are also plotted. These data were originally based on the IPTS-48, while our measurements were performed on the basis of the new temperature scale (IPTS-68). In order to compare these data with ours, they were converted into IPTS-68.[16]

Deviation of our heat capacity data from the smoothed curve is about 1% of the total heat capacity at 20 K, 0.5% between 25 and 50 K ($\Delta T\approx 1.5$ K) and 0.1%

between 50 and 275 K ($\Delta T \approx 4$ K). It should be noted that the weight of the samples employed by the different authors are considerably different, *i.e.*, 12.6106 g (ours), 100.99 g (Cole *et al.*) and 6.16 g ((Gorbunov *et al.*).[17] Taking into account of the dependence of the precision of the measurement on the amount of the samples, our data are quite satisfying.

Sources of Inaccuracy in the Measurement. Next, we consider two aspects of the errors, namely, the systematic error (contributing to inaccuracy) and the random error (contributing to imprecision). A measure of the former is the deviation of the smoothed curve from the (unknown) "true" heat capacity, while the latter appears as the scattering of the data points about the smoothed curve. Several factors contribute to these errors; *i.e.*, errors in determination of the input energy and temperature and those due to the heat leak. The calorimeter heater voltage and current were determined to within 10 parts per million and the time interval within 1 ppm. Thus the errors due to the energy measurement are not a decisive factors in both the inaccuracy and the imprecision. The deviation of the thermometer calibration from the IPTS-68 was typically 4 mK and varied smoothly with temperature. The inaccuracy of the heat capacity due to the error in the temperature scale was estimated to be 0.3% at the lowest temperature and less than 0.02% at 200 K. The resistance resolution by the ASL bridge was better than 1×10^{-5} Ω which corresponds to 2.3×10^{-4} K at 15 K. At the higher temperatures, the temperature resolution is better than 1×10^{-4} K. Thus, the temperature measurement is not the largest source of the imprecision of the observed heat capacity, provided that the temperature step for one measurement is not too small (1~3 K). The main factor contributing to the imprecision appears to be the heat leak to or from the sample cell. It is caused by transient deviation from the ideal adiabatic condition as well as by any stray emf in the difference-thermocouple circuits. The adiabatic condition in the equilibration period is achieved by eliminating the temperature change of the sample cell. This was done by adjusting the zero shifting emf at the input circuit of the DC microvoltmeter so as to cancel the stray emf in the thermocouple leads, the resultant zero drift rate being taken as the indication of the optimum condition. Once adjusted suitably, the constant zero shifting emf served over a reasonably long series of measurements. If undisturbed, the adiabatic control system can keep the temperature of the sample cell constant within 0.3 mK for 24 hr at the desired temperature. The apparent temperature difference between the cell and the inner jacket was regulated to less than 0.5 mK during heating period. But this temperature difference does not take into account the possible temperature gradient along the surface of the cell and the inner jacket. Error due to this effect is difficult to estimate. But one of the method for its estimation would be to compare the heat capacity data obtained by different heating rates. This has not been done yet with the present calorimeter. At present, the temperature gradient effect and the stray emf, especially its variation with time, seems to be the most important factors limiting the precision of the measurement. In the high resolution measurement, the principle and procedure of the operation are essentially the same as in the ordinary measurement discussed

above, but more ingenuity and experience are required for successful operation because of the small temperature steps (two orders of magnitude smaller than in the ordinary measurements). The temperature was measured by the AC Wheatstone bridge with the imprecision less than 5×10^{-6} K. The heat leak during the equilibration period was minimized by optimizing the zero shifting emf in the difference-thermocouple circuits of the adiabatic jacket as mentioned above. This was done at the beginning of a series of measurements to within a drift rate ±2 μK for at least 30 min. This procedure was facilitated by displaying the out-put signal of the null detector (P.A.R. model 124 lock-in-amplifier) of the bridge. Heat leak during the heating is again difficult to estimate, but it is believed to be less significant than in the ordinary measurement because the lower heater power disturbs the thermal uniformity of the jacket to the lesser extent. The relatively short heating period (60~100 s) is also an advantageous factor in this respect. Figure 11 shows an example of the recorder trace of the

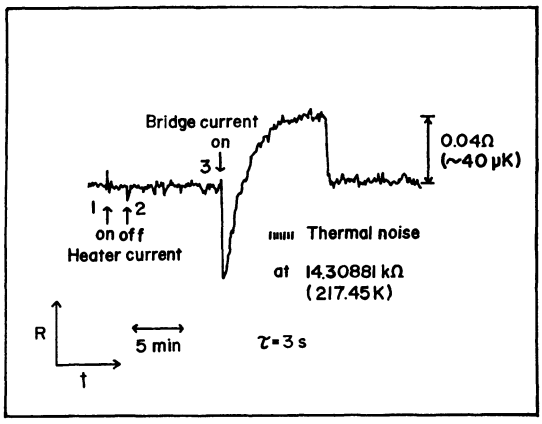

Fig. 11. An example of the high resolution measurement at 217.45 K.
R: the resistance of the thermistors.
t: the time.
τ: the time constant of the lock-in amplifier.

output signal (at 217.45 K) of the bridge null detector. The temperature remains constant within 5 μK after settling in the equilibrium value. It should be noted that the thermal noise from the the thermistor calculated by the Nyquist formula corresponds to about 5 μK. The power dissipated in the thermometer was 0.5 μW.

By use of this calorimeter, we have perfomed high resolution heat capacity measurements in the vicinity of phase transition of $SnCl_2\cdot2H_2O$,[12] $SnCl_2\cdot2D_2O$[18] and Rochelle salt.[19] The imprecision in these measurements was about 0.05%. The accuracy was also found to be satisfactorily high since it was found that the high resolution data agreed closely with those obtained by the ordinary measurement where the latter is available.

Pulse Radiolysis of $Hg(CN)_2$ in Aqueous Solutions

Shin-ichi FUJITA, Hideo HORII, Toshiaki MORI, and Setzuo TANIGUCHI
Radiation Center of Osaka Prefecture, Shinke-cho, Sakai, Osaka 593

(Received June 2, 1975)

The reduction of $Hg(CN)_2$ in deaerated aqueous solutions was studied by the pulse radiolysis technique. $Hg(CN)_2$ reacts with the e_{aq} with $k(e_{aq}+Hg(CN)_2)=(1.3\pm0.1)\times10^{10}$ M^{-1} s^{-1} to yield a transient species of HgCN having an absorption maximum at 285 nm. $Hg(CN)_2$ is also reduced by CO_2^- with $k(CO_2^-+Hg(CN)_2)=(3.4\pm0.2)\times10^9$ M^{-1} s^{-1}. The extinction coefficient of HgCN at 285 nm was determined as $(3.8\pm0.1)\times10^3$ M^{-1} cm^{-1}. HgCN recombines with $2k=(3.4\pm0.5)\times10^9$ M^{-1} s^{-1} to produce another absorption species, assigned as $(HgCN)_2$, in an unstable state. The decay rate of the dimer was accelerated by some additives, such as alcohols and sodium formate. Making use of a proposed mechanism, $(HgCN)_2\rightarrow Hg(aq)+Hg(CN)_2$, the absorption coefficient of atomic mercury in water was evaluated as $(2.8\pm0.1)\times10^3$ M^{-1} cm^{-1}.

The radiolysis of aqueous solutions of some metal ions gives various species in unstable valence states by the action of the reactive primary products coming from water, such as OH radicals, H radicals, and hydrated electrons. The technique of pulse radiolysis, as is well known, is useful in investigating the reaction processes of such short-lived species.[1]

By means of this method the radiolytic reduction of mercuric ions has, recently, been carried out in aqueous solutions.[2-4] The unstable monovalent mercurous ion formed initially behaves differently depending on pH of solutions. In an acidic solution at about pH 4,[3] the stable mercurous ion, Hg_2^{2+}, is formed *via* an additional step after disproportionation of the initial species:

$$Hg^+ + Hg^+ \longrightarrow Hg(0) + Hg(II)$$
$$Hg(0) + Hg(II) \longrightarrow Hg_2^{2+}$$

While in the neutral solution,[4] where the transient mercurous ion exists in the form of HgOH, the dimerization occurs in one step:

$$Hg^+ \longleftrightarrow HgOH$$
$$2HgOH \longrightarrow (HgOH)_2$$

The direct recombination is similar to the case of HgCl formed in the reduction of $HgCl_2$.[5]

Another interesting point on radiolytic reduction of mercuric ion in the neutral solution was the finding of Hg_2O,[4] which had not been proved to exist before.

In comparison with these results, the pulse technique has been applied to aqueous $Hg(CN)_2$ solutions. Another transient mercurous species, HgCN, and its unstable dimer were found optically. The reaction mechanisms are discussed based on some kinetic data.

Experimental

The experimental details of pulse radiolysis measurement have been described previously.[3,4]

Reagent grade $Hg(CN)_2$, HCO_2Na, methanol, ethanol, isopropyl alcohol and *tert*-butyl alcohol (all are supplied from Wako Pure Chemical Industries) were used without further purification.

Triply distilled water was used at natural pH for all the experiments. All the solutions were deaerated by bubbling with argon. When necessary, solutions were saturated with N_2O (special pure grade, $O_2<0.1\%$, Suzuki Shokan Co.)

Product analysis in aqueous $Hg(CN_2)$ solutions containing isopropyl or *tert*-butyl alcohol was carried out on irradiation of 7.9 kCi ^{60}Co source at a dose rate of 1.29×10^5 r/hr. Acetone, being one of the products, was determined on a gas-chromatograph (Hitachi 063) using a column of 1 m Carbowax 20 M at 50 °C.

Results and Discussion

Figure 1 shows typical oscillograms of the changes in optical absorptions at 290 and 210 nm after pulse irradiation in a deaerated aqueous solution of 200 μM $Hg(CN)_2$. The absorption at 285 nm decays approximately according to a second order kinetics. The half life was about 30 μs for a dose of about 2.5 krads per pulse. While, the absorption at 210 nm decays only partly and thereafter remains constant within about 1 ms.

Figure 2 shows the spectra of the absorption immediately and 1 ms after the pulse. The initial spectrum has a peak at 285 nm and rises at wavelengths shorter

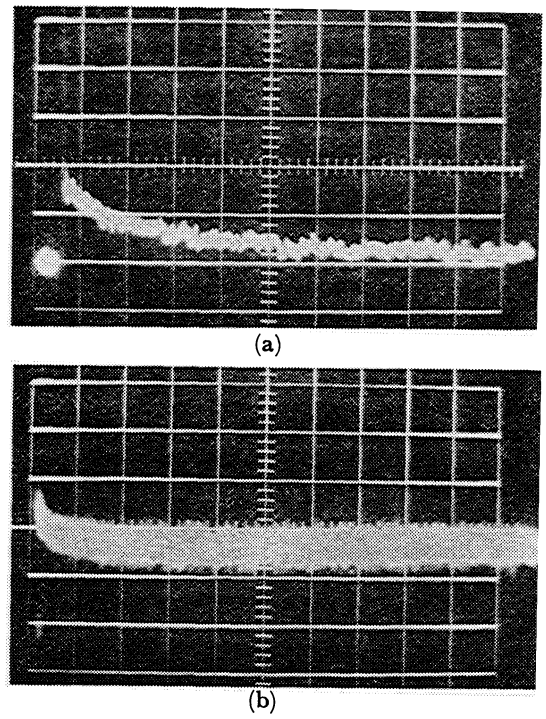

Fig. 1. Oscilloscope traces obtained in a deaerated aqueous solution of 2×10^{-4} M $Hg(CN)_2$: pulse dose, 2.5 krads; ordinates, 4.5 %/large division; (a): at 285 nm, time scale, 20 μs/large division; (b): at 210 nm, time scale, 0.5 ms/large division.

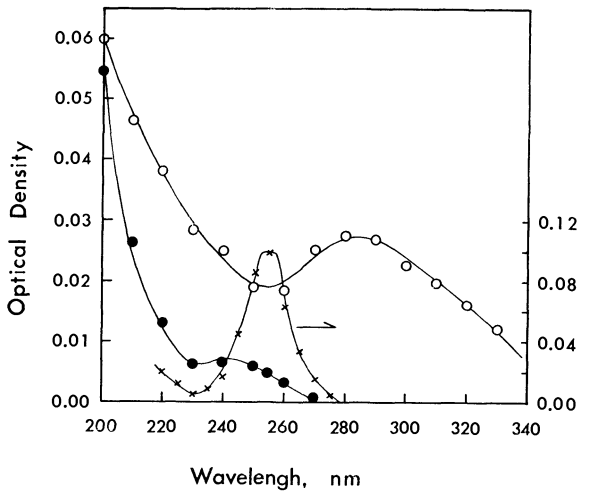

Fig. 2. Absorption spectra in a deaerated aqueous solution of 2×10^{-4} M $Hg(CN)_2$: average dose, 2.0 krads; immediately (○), 2 ms (●) after the pulse; (×), the spectrum about a few minutes after ten repeated pulses.

than 260 nm. The spectrum of the remaining absorption is different from that of the initial one. These absorption did not appear in solutions saturated with N_2O, but were hardly affected by the presence of 10 mM *tert*-butyl alcohol.

Absorption of the electron energy in water liberates the free radicals and molecular products represented by

$$H_2O \longrightarrow e_{aq}^-,\ H,\ OH,\ H_2,\ H_2O_2,\ etc. \qquad (1)$$

It has been well known that N_2O and *tert*-butyl alcohol react rapidly with the e_{aq}^- and the OH radical, respectively:

$$e_{aq}^- + N_2O \longrightarrow N_2 + OH + OH^- \qquad (2)$$

$$OH + t\text{-BuOH} \longrightarrow H_2O + \dot{t}\text{-BuOH} \qquad (3)$$

where $k_2=5\times10^9\ M^{-1}\,s^{-1}$ [6] and $k_3=2.5\times10^8\ M^{-1}\,s^{-1}$.[7] Therefore, the scavenging effects suggest that the optical absorption appearing initially in aqueous solutions of $Hg(CN)_2$ could be due to the mercurous species, the reduced product of $Hg(CN)_2$ by the hydrated electron.

$$e_{aq}^- + Hg(CN)_2 \longrightarrow Hg(I) \qquad (4)$$

The H radical would also function as a reducing agent for $Hg(CN)_2$, by analogy with the cases of other mercuric ions,[3,5,8,9]

$$H + Hg(CN)_2 \longrightarrow Hg(I) \qquad (5)$$

though the contribution to the transient is small due to the low yield ($G_H/G_{aq}^-=0.2$).[10]

Reaction Kinetics of the e_{aq}^- and the CO_2^- Ion with $Hg(CN)_2$. In order to determine the rate constant of Reaction 4, the decay of the hydrated electron after the pulse of about 0.5 μs duration was monitored at 500 nm in the absence and presence of $Hg(CN)_2$. This monitoring wavelength is considerably longer than the absorption band of the transient product of Reaction 4. Under our experimental conditions, where 10 mM *tert*-butyl alcohol was present as a scavenger for the OH radical, the first half-life of the e_{aq}^- was roughly 15 μs. With increasing $Hg(CN)_2$ concentrations from

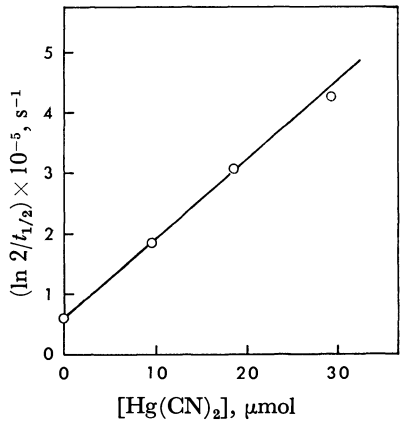

Fig. 3. Dependence of the pseudo-first-order decay rate of the e_{aq}^- on $Hg(CN)_2$ concentration, monitored at 500 nm.

10^{-5} to 3×10^{-5} M the decay of the hydrated electron became first order and the half-life progressively diminished. As seen in Fig. 3, pseudo-first-order rate constants, calculated from these half-lives, were proportional to added substrate concentration over the range investigated. The second-order rate constant, obtained from data in Fig. 3, is $(1.3\pm0.1)\times10^{10}\ M^{-1}\,s^{-1}$. This is about half of the similar reaction to HgO[4] and about one third to $HgCl_2$.[5]

On pulse radiolysis of a 200 μM $Hg(CN)_2$ solution containing 10 mM HCO_2Na and saturated with nitrous oxide, an analogous absorption species was also obtained by about 2 times in the absorption intensity, though the formation rate was slower. As a matter of fact, the spectrum immediately after the pulse was somewhat different from the spectrum in Fig. 2. In a short period of time after the pulse, however, the absorption built-up is observed in the wavelength region longer than 275 nm and shorter than 225 nm, while the absorption around 250 nm starts decaying at the end of the pulse. Within about ten μs the resultant spectrum of the absorption became analogous to the initial one in Fig. 2.

The HCO_2^- ion reacts with the OH or H radical to form a strong reducing species, CO_2^-, that has an optical absorption maximum at 250 nm:[12]

$$OH \text{ or } H + HCO_2^- \longrightarrow CO_2^- + H_2O \text{ or } H_2 \qquad (6)$$

Thus it may be concluded that, similarly to the case of reduction by hydrated electron, the transient mercurous species results also from the reaction of $Hg(CN)_2$ with the CO_2^- radical ion:

$$CO_2^- + Hg(CN)_2 \longrightarrow CO_2 + Hg(I) \qquad (7)$$

On analysis of the formation of the absorption at 285 nm, the plots of $\ln(D_\infty - D_t)$ *vs.* time, where D is the optical density, became linear and the slope was proportional to $Hg(CN)_2$ concentration. An example of the oscilloscope trace and kinetic plots are given in Fig. 4. In solutions of 50 and 100 μM $Hg(CN)_2$ a mean bimolecular rate constant for Reaction 7 was obtained as $(3.4\pm0.2)\times10^9\ M^{-1}\,s^{-1}$ at an average dose of 1.2 krads.

The experiments in the presence of some sorts of alcohols demonstrated that the transient mercurous species was not formed by the action of the radicals,

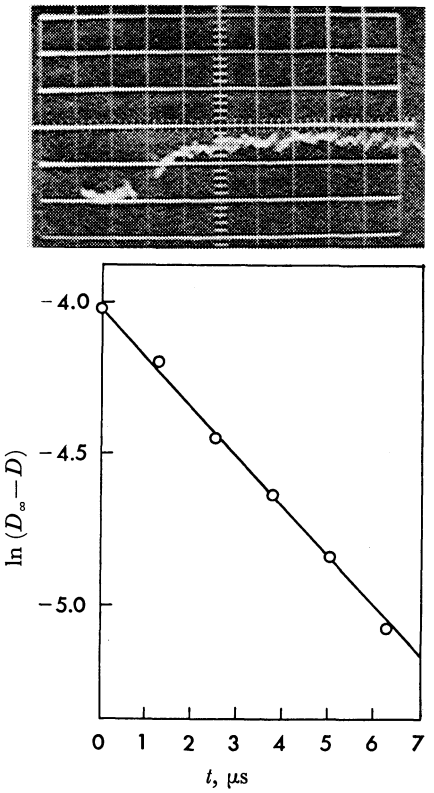

Fig. 4. An oscilloscope trace and first-order plots for the built-in of absorption at 285 nm in a N_2O saturated solution of 50 μM $Hg(CN)_2$ containing 10 mM HCO_2Na; dose, 1.2 krads; ordinates 4.5%/large division; time scale, 5 μs/large division.

such as $\dot{C}H_2OH$, $CH_3\dot{C}HOH$, $(CH_3)_2\dot{C}OH$, and $(CH_3)_2C(OH)\dot{C}H_2$. These radicals were produced by the reactions of the corresponding alcohols with the OH radicals and have been known as reducing agents[13] except the last radical. Such results are different from the case where $HgCl_2$ is the reactant toward the alcoholic radicals. Nazhat and Asmus[5] have reported that $HgCl_2$ is reduced by the isopropyl alcohol radical to form a transient mercurous chloride, HgCl.

Characteristics of the Initial Transient Species. The optical density of the absorption immediately after the pulse at 285 nm was linear against dose up to about 3 krads/pulse in deaerated aqueous solutions of more than a few mM $Hg(CN)_2$ and HCO_2Na. The molar extinction coefficient of the species, ε^{285}, is $(3.8\pm0.1)\times10^3$ M^{-1} cm^{-1}, assuming $G_{Hg(I)}=G_{e^-_{aq}}+G_H+G_{OH}=6.1$[10] in a 10 mM $Hg(CN)_2$ solution containing 5 mM HCO_2Na.

A possibility that might be argued on the assumption concerning the G value of the transient is the addition of H atoms or OH radicals to the -C≡N bond and subsequent oxidation of the ligand. Such reactions possibly take place with rapid rates when H atoms or OH radicals react with HCN or free CN^-.[14] To confirm this possibility, pulse radiolysis of N_2O saturated aqueous solutions containing a concentration of benzene (200 μM) and several concentrations of $Hg(CN)_2$ was carried out. In such solutions most of initial reactive species are OH radicals that react with benzene to produce the hydroxycyclohexadienyl radical with an absorption maximum at 313 nm ($\varepsilon^{313}=4.7\times10^3$ M^{-1} cm^{-1}).[15] No decrease in the absorption due to the radicals was observed with addition of $Hg(CN)_2$ up to 1 mM. Considering the competitive kinetics, the result demonstrates that the OH radical does not react with $Hg(CN)_2$ to a significant extent in these solutions. The nonreactivity of the -C≡N bond seems to be similar to the case for the reaction of the H radical with the $Fe(CN)_6^{4-}$ ion,[16] though there is no data concerning the reactivity against the OH radical in Ref. 16.

Figure 5a shows the test of a second order rate law for the decay of the transient at 285 nm, for different doses, in a 1 mM $Hg(CN)_2$ and 5 mM HCO_2Na solution. In both cases in which the dose per pulse was 2.1 and 4.0 krads, respectively, the plots of $1/D$ *vs.* time are linear. Thus, the kinetics indicate the following reaction:

$$2Hg(I) \longrightarrow \text{product} \qquad (8)$$

and then the slope corresponds to $2k_8/\varepsilon l$, where ε is the extinction coefficient of the absorption and l the optical path length (1.5 cm here). All the slopes obtained for various combinations of $Hg(CN)_2$ concentration (0.2—10 mM) and HCO_2Na (1—100 mM) were in good agreement with a value of $2k_8/\varepsilon^{285}l=(5.9\pm0.4)\times10^5$ s^{-1}. The value was also not affected by the existence of $NaClO_4$ up to 100 mM in a solution containing the substrates in low concentration, as seen in Fig. 5a. Substituting the values of ε^{285} and l, $2k_8$ can be calculated as $(3.4\pm0.5)\times10^9$ M^{-1} s^{-1}.

According to the Debye-Hückel theory of reaction rates in solution, the lack of the effect of ionic strength on the rate suggests that the transient does not carry any charge on it and be assigned most likely to HgCN. It is concluded in addition that the species is not subject to

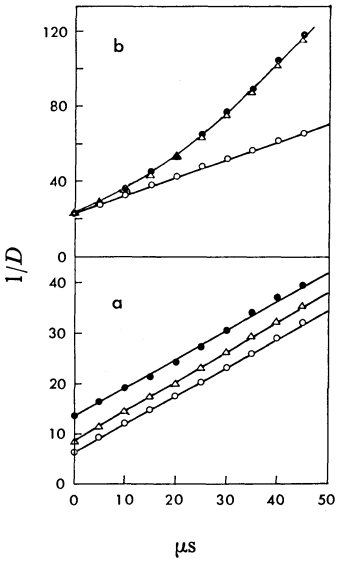

Fig. 5. Second-order plots for the decay of transient absorption at 285 nm, (a): $[Hg(CN)_2]=1.0$ mM, $[HCO_2Na]=5$ mM; ○: dose, 4.0 krads; ●: dose, 2.1 krads; △: 0.1 M $NaClO_4$ further contained, dose, 3.0 krads; (b): $[Hg(CN)_2]=1.0$ mM, dose, 2.6 krads; ○: without additives; ●: 1 mM MeOH; △: 100 mM MeOH.

additional complexing with the HCO_2^- ion, since all the spectral observations and kinetic results were not influenced by addition of the ion. Figure 5b shows similar plots of the transient obtained in a solution containing methanol to scavenge the OH radical. In this case, the decay is no longer of simple second order. The shapes of the decay curves were not influenced at all by methanol concentration in the range from 1 to 100 mM. It might be concluded, therefore, that 1 mM of methanol is enough to scavenge all OH radical to form CH_2OH and that the increase in decay rate with the addition of methanol is due to the onset of the reaction:

$$\dot{C}H_2OH + HgCN \longrightarrow \text{products} \quad (9)$$

If the assumption is right, the rate of decay of HgCN will be given by

$$-d[HgCN]/dt = k_9[\dot{C}H_2OH][HgCN] + 2k_8[HgCN]^2$$

An approximate estimate of k_9 can be obtained from a comparison of the initial decay rate with that in the presence of 5 mM HCO_2Na.[17] Let the initial decay rates of HgCN in the presence of the alcohol and HCO_2-Na be R_1 and R_2, respectively. Then from the data we find $R_1=2.01\ R_2$ and

$$R_1 - R_2 = k_9[\dot{C}H_2OH]_0[HgCN]_0$$

$$1.01 = k_9[\dot{C}H_2OH]_0/2k_8[HgCN]_0.$$

Since the H radical reacts slowly with methanol,[18] it should contribute to the formation of HgCN and the initial yield of $\dot{C}H_2OH$ should be equal to G_{OH}. Then using $[\dot{C}H_2OH]_0/[HgCN]_0=G_{OH}/G_{e^-_{aq}+H}=0.85$, k_9 can be calculated as $4.0\times10^9\ M^{-1}\ s^{-1}$. Similar treatments were also made for solutions of 1 mM $Hg(CN)_2$ containing 5 mM ethanol, isopropyl alcohol, and *tert*-butyl alcohol, wherein respective alcohol radicals must be taken into account. Here, the H radical may also be regarded to contribute to the formation of HgCN.[19] All the results are listed in Table 1, together with k(OH +HgCN) obtained in a solution without any OH scavenger. In Fig. 5b is also shown a result obtained in a 1 mM $Hg(CN)_2$ solution. The plots are found to be rather close to a linear one. It may be explained by the fact that the OH radical is consumed more rapidly by the combination reaction (k(OH+OH)$=8\times10^9$ $M^{-1}s^{-1}$,)[20] than the similar reaction of the alcohol radicals.[21]

Table 1. Reaction rate constants of HgCN with the OH and some alcohol radicals, $[Hg(CN)_2]=1$ mM, $[ROH]=5$ mM

Additive	R_1/R_2	$k(\dot{R}OH+HgCN)$, $M^{-1}s^{-1}$
MeOH	2.01	4.0×10^9
EtOH	1.98	3.9×10^9
2-PrOH	1.59	2.4×10^9
t-BuOH	1.41	1.6×10^9
Nothing	1.77	3.1×10^9 [a]

a) The value will represent the reaction rate constant of the OH radical with HgCN.

It is of interest whether Reaction 9′ gives a stable organomercury compound,

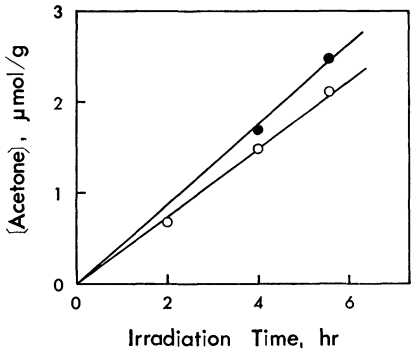

Fig. 6. Dependence of acetone yield on irradiation time in aqueous solutions of 10 mM isopropyl alcohol; ●: with saturated N_2O, ○: with 10 mM $Hg(CN)_2$; the radiation source: 7.9 kCi ^{60}Co, dose rate$=1.3\times10^5$ r/hr.

$$\dot{R}OH + HgCN \longrightarrow \text{products} \quad (9')$$

where $\dot{R}OH$ means an alcohol radical. In order to obtain a few information about it, some experiments were performed in ^{60}CO γ-ray irradiation. Figure 6 shows the dependence of the amount of acetone produced on doses in an aqueous 25 mM isopropyl alcohol solution with 25 mM $Hg(CN)_2$ or with saturated N_2O. In each case the amount increases linearly with doses. From this data the G values of acetone were calculated as 3.0 ± 0.3 and 2.6 ± 0.3 in the solutions with $Hg(CN)_2$ and with N_2O, respectively.

In a N_2O saturated solution, all of the primary reactive species produced by irradiation of water are expected to contribute to hydrogen abstraction from isopropyl alcohol in the form of OH and H radicals,[18] since the e^-_{aq} is converted to the OH radical according to Reaction 2. The resultant radical, $(CH_3)_2\dot{C}OH$, would disproportionate to produce acetone with the G value of $1/2(G_{e^-_{aq}}+G_{OH}+G_H)=3.1$. The experimental result is in good agreement with this expectation. While, in the solution with $Hg(CN_2)$ the e^-_{aq} and the H radical contribute to the formation of HgCN. If Rection 9′ gives rise to a product, such as an organomercury compound that liberates no acetone molecule, the yield of acetone should be smaller than $1/2\cdot G_{OH}=1.4$. From this consideration our result of G(acetone)$=2.6$ in this system demonstrates that most of the isopropyl radical reacts with HgCN to produce Hg(0) and acetone. The small decrease in the yield here may be explained by the contribution of Reaction 8. This conclusion is reasonable in view of the fact that the radical is a strong reducing agent.[13]

On the contrary the opposite conclusion seemed to be reached in the case of the *t*-BuOH radical that has not any reducing properties. Kelm *et al.* have proposed[22] that the radical is rapidly reduced to isobutene by the unstable Ni^+ ion on the radiolysis of an aqueous solution of $NiSO_4$ containing *t*-BuOH. However, no sign of isobutene formation was obtained gas-chromatographically on ^{60}CO γ-ray irradiation of an aqueous solution of $Hg(CN)_2$ with *t*-BuOH. Thus, the experimental result might present indirect evidence for the formation of an organomercury compound, such as $(CH_3)_2$-$C(OH)CH_2HgCN$.

Long-lived Species. In general, attempts to produce $Hg_2(CN)_2$ lead only to $Hg(CN)_2$ and mercury, although it has been suggested that it might be formed in non-aqueous solvents at low temperatures.[23] The unstability of $Hg_2(CN)_2$ has been explained by the reason that the CN^- ion forms a stable complex, $Hg(CN)_2$, with Hg^{2+} through the equilibrium, $Hg_2^{2+} \longleftrightarrow Hg + Hg^{2+}$ ($K = 1.15 \times 10^{-2}$). As seen in the case of Hg_2O,[4] however, a dimer complex of mercurous cyanide is also expected to be found in an unstable state. Thus, the residual absorption species in Fig. 2 may be assigned to a dimerized product, maybe as $(HgCN)_2$. As has been mentioned earlier, the second order reaction kinetics also supports this assignment, thus:

$$2HgCN \longrightarrow (HgCN)_2 \qquad (8')$$

A similar spectrum was obtained also with the doubled yield of absorption in solutions containing the HCO_2^- ion up to 100 mM. The dimerization of the initial species is expected to be fully attained in this solution, where there should be no reactant consuming the initial transient. Considering the stoichiometry in Reaction 8', the absorption coefficient of the dimer was evaluated as $(5.2 \pm 0.2) \times 10^3$ M^{-1} cm^{-1} at 220 nm and $(1.1 \pm 0.05) \times 10^4$ M^{-1} cm^{-1} at 210 nm, from the slope of the yields against pulse doses in a solution of 3 mM $Hg(CN)_2$ and 5 mM HCO_2Na.

In solutions with alcohols, however, the absorption was somewhat larger at shorter wavelengths, which may indicate the contribution from the products arising from Reaction 9 or 9'.

As expected, the long-lived absorption observed at 210 nm was found to decay slowly in the solution without any additives. The decay kinetics did not follow either a first or a second order rate law. The initial half-life is (4 ± 1) s independently of $Hg(CN)_2$ concentration in the range from 0.1 to 10 mM. Since the lifetime was not affected by the presence of 100 mM H_2O_2 added before irradiation, the decay was not due to the reaction with H_2O_2 produced by pulse electron irradiation. In solutions with additives, however, the decay rates become faster. The rates seemed to become constant at more than 5 mM of respective additives, although they were considerably scattered in every solutions. The most plausible half-lives obtained in each solution are listed in Table 2.

Table 2. Most plausible half-lives of $(HgCN)_2$ in 1 mM $Hg(CN)_2$ solutions with some additives

Additive	mM	$[Hg(CN)_2]$ mM	λ_{obsd} nm	$t_{1/2}$ s
no		0.2—1.0	210	4 ± 1
			220	5 ± 1
MeOH	5—100	1.0	220	7×10^{-1}
EtOH	10	1.0	220	1×10^{-1}
2-PrOH	10	1.0	220	8×10^{-2}
t-BuOH	5	1.0	210	2.5×10^{-1}
HCO_2Na	5—10	1.0	220	10×10^{-3}

Figure 2 also shows an absorption spectrum about one minute after ten repeated pulses. The spectrum is very similar to that of atomic mercury dissolved in water.[24] Considering the low solubility of mercury[25] and the short optical path length of the analytical light, however, the absorption in its stable state is expected to be far lower. Thus, it is concluded that mercury dissolved temporarily in excess is produced following the decomposition of $(HgCN)_2$.

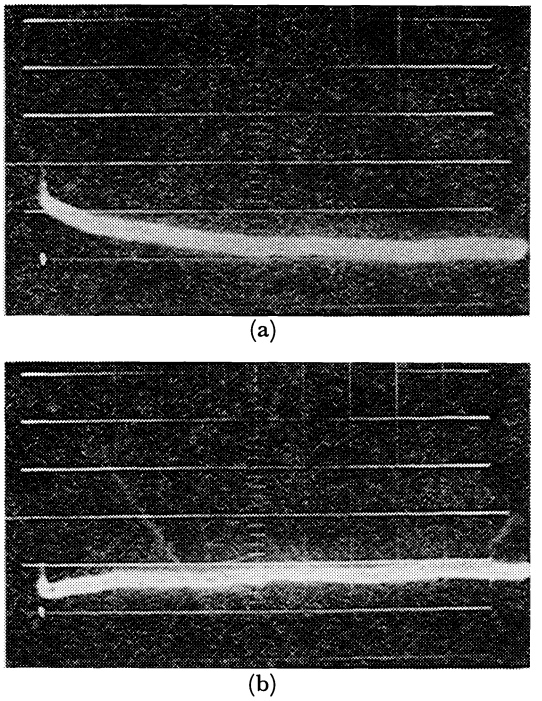

Fig. 7. Decay of the long-lived species at 220 nm (2.6 krads): (a); and increase of absorption at 254 nm (3.2 krads): (b); observed in a 1 mM $Hg(CN)_2$ solution containing 5 mM HCO_2Na; ordinates: 11%/large division, time scale: 5 ms/large division.

$$(HgCN)_2 \longrightarrow Hg(0) + Hg(CN)_2 \qquad (10)$$

A similar behavior has been found in the decomposition of Hg_2O produced by pulse electron irradiation in the neutral solution of mercuric oxide.[4] This conclution is further confirmed by the comparison of absorption changes with time between 254 and 220 nm. Figure 7 shows an example of a couple of oscilloscopic traces at the respective wavelengths obtained in a solution of 1 mM $Hg(CN)_2$ and 5 mM HCO_2Na. Simultaneous changes in absorption are found between the decay of the long-lived species at 220 nm and the formation of the additional absorption at 254 nm. The presence of alcohols as additives also gave similar results. These observations reasonably indicate that the species, the absorption of which increases slowly at 254 nm, has a dimerized mercurous cyanide molecule as its precursor. In solution without any additives, however, such increase in absorption at 254 nm was uncertain, maybe, due to a slow precipitation process of the dissolved mercury.

$$Hg(aq) \longrightarrow Hg(liquid) \qquad (11)$$

Since the decay of the dimer is more rapid in a solution containing HCO_2Na, Process 11 would be negligible at the time when the absorption just become constant in Fig. 7. Thus, if it is assumed that all the absorption

at 254 nm, 50 ms after the pulse, is due to the dissolved mercury arising from Reaction 10, the extinction coefficient can be evaluated. Considering that the concentration of Hg(aq) is equal to that of its precursor, $(HgCN)_2$, ε^{254} of Hg(aq) is calculated as $(2.8\pm0.1)\times 10^3$ M^{-1} cm^{-1} from Fig. 7.

The kinetic behavior of the dimerized species in the presence of these additives seems to be similar to that in a neutral solution of unstable mercurous oxide, $(HgOH)_2$.[4] It is, however, still in question how the decay process is controlled.

Electron Scavenging by Benzene Derivatives in Alcohol Glasses

Akira NAMIKI, Masato NODA, and Takenobu HIGASHIMURA
Research Reactor Institute, Kyoto University, Kumatori-cho, Sennan-gun, Osaka 590-04
(Received June 6, 1975)

Electron scavenging efficiencies by benzene derivatives in alcohol glasses were studied by employing gamma radiolysis at 77 K. Scavenging efficiencies, $1/[S]_{1/2}$, were quasi-linear with the adiabatic electron affinities (*EA*) of the acceptors and they increased as the solvation time of the trapped electron became long. Electron scavenging was explained as a tunneleing of the unsolvated electron; the pre-exponential factor in the tunneling rate was calculated by employing the Morse function developed by Wentworth *et al.* in the gas phase, which gave an *EA* dependence in accordance with the experimental results.

A variety of molecules can capture a low energy electron in the gas phase to form molecular anions or dissociate into fragment radicals and anions. In the condensed matrices, also. the electron capture process has been studied extensively by using polar and non-polar solvents. But few reports have been published which discuss the relation between mechanisms of electron scavenging in the gas and the condensed matrices. This paper is a first step to explain the mechanism of electron scavenging in the glass in terms of reactions in the gas phase.

It has been widely admitted that, in the glass, the trapped or solvated electrons (e_t^- or e_s^-) react withsolutes and their parent positive ions through tunneling. The simple expressions of the tunneling theory were given by Miller[1] and he succeeded in estimating the tunneling distances between e_s^- and solute molecules and also the decay of e_s^- over a very wide range of time.[1,2] However, there are some discrepancies between the estimated values and the experimental results, especially in polar matrices. For example, the experimental tunneling distance of e_s^- in a benzene solution of ethanol was much smaller ($\leq$17 Å) than the estimated value.[1] The observed decay of e_s^- was much slower than the calculated curve for the case of NO_3^- in the alkaline water glass.[2] These discrepancies may result from an oversimplification in his theory, in which the nature of the acceptor molecule is not taken into consideration and in which the tunneling occurs only from the solvated state. The electronic level of the anion of the acceptor molecule must resonate with that of the trapped electron. The transition from the neutral state to the anionic state occurs without changing the nuclear configurations before and after accepting the electron (Franck-Condon principle). In this paper, the Franck-Condon restriction is taken into consideration in the pre-exponential factor of the tunneling rate along with the treatment developed in the gas phase studies.[3,4]

In polar matrices, the electron is stabilized in pre-existing shallow traps.[5] The depth of these potential wells changes with time upon solvation. Miller suggested that the extremely restricted tunneling to benzene in ethanol occurs within 1 μ sec when the traps are shallow.[1] Steen also suggested the importance of tunneling of the pre-solvated electrons.[6] The reactivity of e_t^- in shallow traps in ethanol at 4K was noticably larger than that of e_s^- at 77K, which can be attributed to a more efficient tunneling from shallow traps than from the solvated state.[7]

Halogenated benzene derivatives have been studied as regards the attachment of a low energy electron in the gas phase by both the electron beam experiments[8,9] and the thermal electron attachment experiments.[3,4] Wentworth *et al.*, obtained the formulation for the electron attachment rate using the simple Morse function and succeeded in explaining qualitatively both experimental results.[4] They estimated the adiabatic electron affinities for some halogenated benzenes, which play the most important role in the electron capture process.[4] In this report, Steelhammer and Wentworth's method is extended to the electron attachment through tunneling in condensed media.

Experimental

Reagent grade methanol, ethanol, *n*- and *iso*-propanol were used as solvents without further purification. Reagent grade of benzene derivatives were added aerobically without purification.

The solutions were quenched to glasses by the usual rapid cooling technique in suprasil cells of 0.2 cm thickness. The glasses were irradiated at 77 K by ^{60}Co gamma ray with a dose rate of 1.88×10^{20} eV/g·hr for 3 min in the case of MeOH (5 mol% H_2O) and EtOH glasses and for 5 min in the cases of *n*-PrOH and *iso*-PrOH glasses. The optical density (O.D.) at the peak in the absorption spectrum of e_s^- was measured at 77 K within 1 min after the irradiation.

Dissociative electron attachments to chloro-, bromo-, and iodobenzene do not produce any free radicals, except the solvent radical in the alcohol at 77 K. The anions of benzene, alkylated benzene, and fluorobenzene are protonated, and converted to the hexadienyl type radicals which show an absorption spectrum in the near UV region.[10] Therefore, the O.D. at the peak of e_s^- in the visible region could be obtained accurately for all benzene derivatives.

Results and Discussion

Experimental Results. Figure 1 shows the plots of log O.D. *vs.* the concentrations of the added scavengers in ethanol at 77K. Good linearlity was also obtained for other solvents and solutes. The concentrations, $[S]_{1/2}$, which reduce the e_s^- yield to a half of those in pure solvents, were determined from these semilogarithmic plots and are shown in Table 1.

Experimental tunneling distances, *a*, as defined by Miller,[1] were obtained by the formula:

$$a = \left(\frac{10^3}{8.0\pi}\frac{\ln 2}{[S]_{1/2}}\frac{M}{d}\right)^{1/3} \text{(Å)} \qquad (1)$$

a) τ was assumed to be 10 ns. The same values as in other solvents were inserted for the other parameters.
b) Only this value was estimated from Eq. (7').

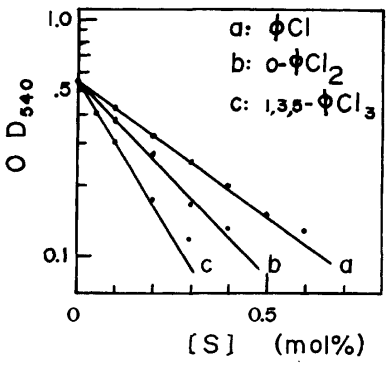

Fig. 1. Semilogarithmic plots of the yields of e_s^- (O.D. at 540 nm) *vs.* scavenger concentrations in ethanol at 77 K.

where M and d are the molecular weight and the density of the solvent and $[S]_{1/2}$ is in mol %. The values of a are tabulated for each solvent in the second column of Table 1.

In Fig. 2 the scavenging efficiencies, the reciprocals of $[S]_{1/2}$, were plotted against the *adiabatic electron affinity*, *EA*,[4] for *o*-$C_6H_4CH_3Cl$, C_6H_5Cl, *o*-$C_6H_4CH_3Br$, C_6H_5-Br, and *o*-$C_6H_4Cl_2$. The scavenging efficiency is nearly linear with the electron affinities of the solutes in all the different alcohols. The deviation from linearity is especially small in ethanol. Because the *EA*'s of C_6H_6, C_6H_5F, and C_6H_5I are unknown, these *EA*'s are estimated by putting their scavenging efficiencies on the best fit line in ethanol. They are −0.75, −0.52, and 0.0 eV, respectively. For these three additional points (a, b, and c in Fig. 2), the linearity is still as good as for other three solvents.

From Fig. 2 and Table 1 we can find two main results.

(1) For various benzene derivatives in each solvent, the scavenging efficiency, $1/[S]_{1/2}$, and the experimental tunneling distance, a, become large as *EA* increases. $1/[S]_{1/2}$ *vs.* *EA* is roughly linear.

(2) $1/[S]_1/_2$ and a are strongly dependent upon the nature of the matrix. The order of increase is MeOH, EtOH, *n*-PrOH, and *iso*-PrOH.

Simple Model for Acceptor. The exponential dependence of the yield of e_s^- on the scavenger concentration in Fig. 1 shows that the scavenging is due to the epithermal electron capture or to the tunneling of the trapped electron. If we take the former process, it is difficult to explain the strong dependence of scavenging efficiency on the matrix because the degradation spectrum of the epithermal electron must not differ so much among these alcohol solvents.

Result (1) of the preceeding section implies clearly that the contribution from *EA* of the acceptor should not be ignored in the tunneling model. Result (2) suggests that tunneling occurs mainly when the potential well of the trapped electron is shallow. The times for the trapped electron to reach the stable spectra at 77K are <3, ~7, ~40, and ~100 μs for MeOH, EtOH, *n*-PrOH,

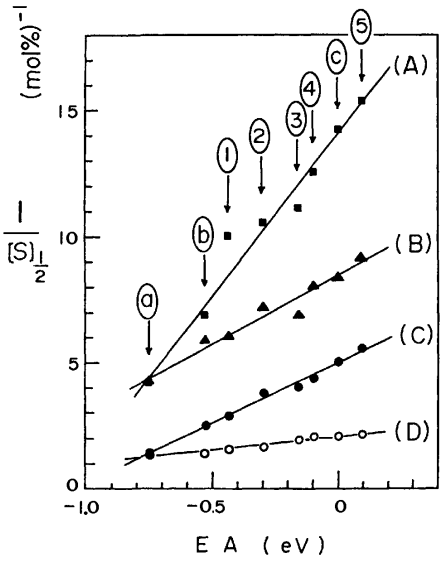

Fig. 2. Plots of $[S]_{1/2}^{-1}$ *vs.* *EA*. The solvents are *iso*-PrOH (A) ■, *n*-PrOH (B) ▲, EtOH (C) ● and MeOH (D) ○.
EA of *o*-$C_6H_4CH_3Cl$ ①, C_6H_5Cl ②, *o*-$C_6H_4CH_3Br$ ③, C_6H_5Br ④, and *o*-$C_6H_4Cl_2$ ⑤ are from Ref. 4, while *EA* of C_6H_6 ⓐ, C_6H_5F ⓑ and C_6H_5I ⓒ were determined from the line (C).

and *iso*-PrOH, respectively.[11] This order is the same as that in result (2).

In order to simplify the ploblem, we make the following assumptions. The secondary electron is stabilized in the pre-solvated state, and it tunnels to the acceptor molecules or it becomes solvated after surviving for a life time of τ. There is only one kind of shallow trap with a depth of V. Once the electron is solvated, it cannot tunnel to the acceptor.

The usual tunneling procedure refers to the final state of the electron in the free continuum. In our case, however, the final state is the electron in a molecular orbital of the anion. Therefore, the expression of the tunneling rate, k_{tun},[12] must be modified by introducing F into the pre-exponential factor as

$$k_{tun} = \nu F \exp\left\{-\frac{2a}{\hbar}\sqrt{2m(V-E)}\right\}, \quad (2)$$

where ν is the impinging frequency of e_t^- in the potential well, a is the tunneling distance or the barrier width, $\hbar$ is Planck's constant divided by 2π, m is the electron mass, V is the depth of the well measured from the bottom of the conduction band, and E is the energy of e_t^- measured from the bottom of the well. F has a meaning close to the Franck-Condon factor and it must be written as a function of the EA of the acceptor. The resonance electron transfer from e_t^- to the acceptor is so fast that the nuclear configuration of the acceptor cannot change during the electron tunneling. Therefore, it can be written as the vertical transition between the two adiabatic potential energy curves of the neutral state and the negative-ion state. For the calculation of F we follow Steelhammer and Wentworth's treatment, which explained successfully the vertical electron attachment process in the gas.[3,4]

When the incident electron has the energy E_v, the vertical transition requires the following energy relation:

$$E_v = -2kD_{AB}^{\circ}e^{-\beta(r-r_o)} + D_{AB}^{\circ}e^{-2\beta(r-r_o)} - EA_{A\text{ or }B} + D_{AB} \quad (3)$$

where the parameters are the same as those in Ref. 4: namely, k is the parameter to determine the potential energy curve of the acceptor anion, D_{AB}° is the bond dissociation energy referenced to the minimum of the function, r_o is the equilibrium internuclear separation for the C–X bond (X=halogen), $\beta=\nu_0(2\pi^2\mu/D_{AB}^{\circ})^{1/2}$, ν_0 is the fundamental vibrational frequency for the C–X stretching mode, μ is the reduced mass, EA_A is the electron affinity of the aromatic radical in the case of the formation of the molecular negative ion and EA_B is that of the halogen atom in the case of a dissociative negative-ion, and D_{AB} is the bond dissociation energy measured from the zero-point energy level.

In condensed media, the energy of e_t^- is $(V-E)$ under the quasi-free electron level. Because the latter is V_o above the vacuum level, the trapped electron state is expressed as $V_o-(V-E)$ referenced to the vacuum level. When the electron is captured by the neutral molecule, the molecular negative ion is stabilized by the medium electronic polarization energy of P_-. Therefore, the electron energy to be given to the acceptor has the following equation:

$$E_v = V_o-(V-E)-P_-. \quad (4)$$

Upon tunneling, the internuclear separation of the neutral molecule, r, must satisfy Eqs. (3) and (4). The probability density, $p(E_v)$, of finding the nuclear configulation at r in the zero vibrational state of the neutral molecule is[4]

$$p(E_v)dE_v = \frac{\sqrt{\alpha/\pi}e^{-\alpha(r-r_o)^2}}{2\beta D_{AB}^{\circ}(e^{-2\beta(r-r_o)}-ke^{-\beta(r-r_o)})}dE_v, \quad (5)$$

where $\alpha=\sqrt{\mu f/\hbar^2}$ and f is the force constant for the C–X bond.

If we assume that the density of the resonance state of the trapped electron is unity within the small range of ΔE_v around E_v and vanishes in the other region, F is expressed as

$$F = p(E_v)\Delta E_v. \quad (6)$$

Under the condition of $\nu F\tau \geqq 10$,[13] the tunneling distance a' is

$$a' \cong 5.0 + \frac{1}{\sqrt{V-E}}\ln(\nu p(E_v)\Delta E_v\tau)\ (\text{Å}), \quad (7)$$

where 5.0 is added as the correction term from the radii of both the trapped electron cavity and the acceptor, and $(V-E)$ is in eV. When $\nu F\tau < 10$,[13] a' is

$$a' \cong 5.0 + \frac{1}{\sqrt{V-E}}(6\nu p(E_v)\Delta E_v\tau)^{1/3}\ (\text{Å}). \quad (7')$$

Miller estimated 10^{15}/s for ν as the case of the one dimensional problem.[1] But if we take into consideration the attenuation from the fractional solid angle into which the electron enters,[14] ν must be reduced by a factor of about 10^2 for the tunneling distances in our results. ΔE_v is the width of the resonant vibrational levels. Though we have no exact knowledge about this width, ΔE_v is assumed to be the order of several spans of the lattice vibration of the matrix around the trapped electrons and less than the vibrational spacings of the acceptor molecule. Tentatively we take $\Delta E_v=10^{-2}$ eV for all solutes and solvents. The absorption band of the pre-solvated electron in ethanol at 4 K shows a threshold at about 0.5 eV. Since the absorption of the pre-solvated electron is a bound-free transition,[15] we take $(V-E)=0.5$ eV. In the case of the other solvents, photo-ionization thresholds of the pre-solvated electron have not been determined, and therefore we assume the same value for the other solvents. There is no direct information for V_o and P_- given by experiment. Fueki *et al.*[16] calculated successfully the energy of the trapped electron in ethanol for the case of $V_o \geq 0$. Allen *et al.*[17] claimed the polarization energy of SF_6^- in the non-polar liquid as about -0.65 eV. Therefore, we have assumed that (V_o-P_-) is roughly 1.0 eV, leading to $E_v=0.5$ eV.

$p(E_v)$'s of different halobenzene molecules were calculated to explain the line shapes of the electron attachment cross-sections but were given in arbitrary units.[4] In this paper, we recalculated $p(E_v)$ absolutely for various E_v using the same values of parameters in Morse functions as in Ref. 4. Molecular negative-ion potential energy curves were taken for *o*-$C_6H_4CH_3Cl$, C_6H_5Cl, *o*-$C_6H_4CH_3Br$, C_6H_5Br, and *o*-$C_6H_4Cl_2$ and the dissociative negative-ion potential energy curve for C_6H_5I as in the case of Steelhammer and Wentworth.[4] These

Table 2. $p(E_v)$ in $(eV)^{-1}$

	o-$C_6H_4CH_3Cl$	C_6H_5Cl	o-$C_6H_4CH_3Br$	C_6H_5Br	C_6H_5I	o-$C_6H_4Cl_2$
$p(E_v)$	0.157×10^{-3}	0.174	0.524×10^{-1}	0.282	1.04	1.57

imply that the trapped electron tunnels to the π^* orbital for the five Cl or Br substituted benzenes and to the σ^* orbital of the C–X bond for C_6H_5I. The values of $p(E_v)$ at $E_v=0.5$ eV are listed in Table 2.

The halflife of the pre-solvated electron, τ, in ethanol at 77K was measured to be about 2.5 μs at 1260 nm.[18] The τ's in *n*- and *iso*-PrOH at 77K were not obtained, but the absorption spectra of the trapped electron in these matrices and in the EtOH matrix became stable at 40 and 100 μs and at 7 μs after the pulse respectively.[11] The half-lives in *n*- or *iso*-PrOH were then assumed as $2.5/7\times40$ or $2.5/7\times100$ μs respectively by normalizing the above times, which were required for reaching the stable spectra in EtOH. The tunneling distances, a', obtained from Eq. (7) are shown in Table 1. Similar calculations were carried out on MeOH, assuming that τ in this matrix is 10 ns.

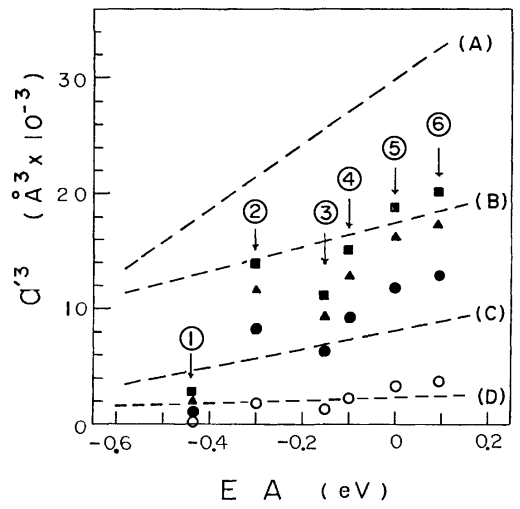

Fig. 3. Plots of a'^3 *vs.* *EA*. The dotted lines are experimental one; (A) *iso*-PrOH, (B) *n*-PrOH, (C) EtOH, and (D) MeOH. Other notations are same as those in Fig. 2 with exceptions of C_6H_5I ⑤ and o-$C_6H_4Cl_2$ ⑥.

Discussion of the Model Calculation. The simulated values of a'^3 are compared to the experimental values of a^3 in Fig. 3. $EA=0.0$ eV for C_6H_5I was tentatively assumed from Fig. 2 for convenience in comparison, though the present model states that the electron tunneling occurs directly to the dissociative state of the orbital for a C–I bond. The simulated values in EtOH and *n*-PrOH are consistent with the experimental ones, not only in the tendency with *EA* but also in their absolute values. In *iso*-PrOH the deviation is serious. This deviation comes partly from the uncertainty of the numerical values in each parameter. Especially τ in *iso*-PrOH may be underestimated, since the absorption spectrum observed by a pulse experiment extended far into the infrared region even at 100 μs after a pulse.[11]

In MeOH, the trapped electron prior to solvation was observed neither by the pulse radiolysis at 77 K[11] nor by the gamma ray radiolysis at 4 K.[5] The spectra obtained in those experiments show that the electron has already been solvated. Therefore, it is reasonable to consider that the solvation time in MeOH is very short. In this paper, a solvation time of 10 ns gives the best fitting in the scavenging curves, as is shown in Fig. 3.

The linear relationship between a'^3 and *EA* can not be proved directly from Eq. (8) *via* Eq. (5). In Eq. (5), k in the case of the molecular negative ion state contains *EA* of the acceptor as

$$k^2=\frac{EA+(D^\circ_{AB}-EA_A)-\frac{1}{2}h\nu_{0AB}+\frac{1}{2}h\nu_{0AB^-}}{D^\circ_{AB}}, \quad (8)$$

where $h\nu_{0AB}$ and $h\nu_{0AB^-}$ are the vibrational energies of the C–X streching mode in the neutral and ionic states.[4] In Fig. 3, o-$C_6H_4CH_3Cl$ and o-$C_6H_4CH_3Br$ deviate seriously. These deviations are partly removed if we take E_v larger than 0.5 eV, though $p(E_v)$ of o-$C_6H_4Cl_2$ decreases in this energy region since the peak in $p(E_v)$ exists at an energy lower than 0.5 eV. But the present simple model cannot explain the linearity of a^3 *vs.* *EA* obtained experimentally.

We checked the possibility of the electron tunneling to the molecular negative-ion state for the case of C_6H_5I. The tentatively assumed value the $EA=0.0$ eV from Fig. 2 is inserted into Eq. (8), neglecting the zero vibrational energy, and gives $k=0.321$. Using this value, we can get $p(E_v)=0.332\times10^{-2}$/eV at $E_v=0.5$ eV. But this value gives a very small tunneling distance for C_6H_5I. This fact suggests that tunneling to the π^* orbital is not involved for C_6H_5I as much as the electron attachment in the gas phase.[3,4] Bond dissociation occurs rather dominantly at C–I rather than C–Br in p-C_6H_4BrI, while both bond dissociations occured at C–Br and C–Cl in p-C_6H_4ClBr.[10] These facts support the contention that the dissociative electron tunneling goes through via a molecular negative-ion state for Cl or Br substituted benzenes, but proceeds by a direct dissociation process for I substituted benzenes.

For an appropriately improved model to explain especially the linear relationship between a'^3 and *EA*, the following features should be taken into consideration. (1) The dynamical process of the solvation by the trapped electrons is more complicated. Though how exactly make the solvation proceed is unclear, it is more realistic to deepen the well continuously rather than discretely. Then, k_{tun} must be a function of time through $(V-E)$. (2) The pre-solvated electrons exist in traps with different potential depths.[15] There may exist more shallowly trapped electrons than 0.5 eV in quicker periods. The distribution of the potential depths must be taken into consideration for k_{tun} in the improved model. This effect may be important especially for small *EA* acceptors.

The condition that $E_v>-EA$, is necessary for the

tunneling of the trapped electron. Since EA is -0.75 or -0.52 eV for C_6H_6 or C_6H_5F as estimated above, this condition is violated for these solutes if E_v is 0.5 eV. But tunneling can occur to C_6H_5F or C_6H_6 experimentally. This difficulty may be partly removed by considering the above situations.

Electron Affinity. There remain remarkable discrepancies among the reported EA values of C_6H_6 and C_6H_5F.[19] EA's in the abscissa in Fig. 2 for the five Cl or Br substituted benzenes were determined through Eq. (8) and, following Eq. (9),[4]

$$k = 1 - \frac{E_v^p + EA_A + \frac{1}{2}h\nu_0}{2D_{AB}^\circ}. \quad (9)$$

This may be also applicable to C_6H_6 or C_6H_5F if we take D_{AB}° of the C–H bond in C_6H_6 and of the C–F bond for C_6H_5F. We tried to test the validity of EA of C_6H_6 or C_6H_5F estimated from Fig. 2 using these relations. The D_{AB}° of the C–H or C–F bond in benzene is 102 or 115 kcal/mol. Neglecting the zero vibrational energy, we obtained $E_v^p=1.5$ eV for C_6H_6 or $E_v^p=1.1$ eV for C_6H_5F by using our estimated values of $EA=-0.75$ or -0.52 eV, respectively. These E_v^p values should be compared to the peak energies in the energy loss resonance, which were interpreted to be a temporary negative ion resonance.[9,20] Compton *et al.*[20] reported that these peak energies were 1.55 eV for C_6H_6 and 1.35 eV for C_6H_5F; here agreement between the estimated E_v^p values and the measured values is good, suggesting that the estimation of the adiabatic electron affinities of benzene derivatives can be determined reasonably well by using the lines in Fig. 2.

Table 3. EA in eV

Formula	EA (eV)
1,3,5-$C_6H_3(CH_3)_3$	-0.78 ± 0.10
1,4-$C_6H_4(CH_3)_2$	-0.72 ± 0.10
$C_6H_5CH_3$	-0.73 ± 0.10
C_6H_6	-0.75 ± 0.10
C_6H_5F	-0.52 ± 0.10
p-$C_6H_4Cl_2$	0.35 ± 0.15
1,3,5-$C_6H_3Cl_3$	0.85 ± 0.20

In Table 3 we tabulated the EA values so determined from the line of EtOH for methylated benzenes and chlorinated or fluorinated benzenes. Large changes in EA are recognized by halogen atom substitution. Addition of one Cl atom to the ring increases EA by about 0.4—0.5 eV, suggesting that additivity in EA is also valid for Cl as well as for F.[21] On the other hand, no large change in EA is seen in C_6H_6 or other methylated benzenes, implying that the effect of the CH_3 group on EA is small compared to the case of a halogen.

The anion of C_6H_6 is known to exist stably in the condensed media,[22] though the EA of C_6H_6 is negative. The condition that the anion can be stable in the condensed medium is

$$V_0 - P_- + EA > 0. \quad (10)$$

Due to the factor of V_0-P_-, stable existence of the benzene anion does not imply necessarily that $EA>0$. In this sense, the recent conclusion that $EA>0$[19a] for C_6H_6 is questionable.

Topochemical Studies. VII. The Crystal and Molecular Structures of Tetrachlorophthalic Acid Hemihydrate and Tetrabromophthalic Anhydride

Kuniaki Ito, Keigo Moriya,* Setsuo Kashino, and Masao Haisa
Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama 700
(Received June 14, 1975)

The crystal structures of tetrachlorophthalic acid hemihydrate (TCPH) and tetrabromophthalic anhydride (TBPA) have been determined from visually estimated Cu$K\alpha$ data. The crystals of TCPH are monoclinic, space group A2/a, $a=19.81(1)$, $b=7.091(5)$, $c=16.22(1)$ Å, $\beta=101.2(2)°$ and $Z=8$. Those of TBPA are monoclinic, space group $P2_1/n$, $a=13.39(3)$, $b=6.19(2)$, $c=12.66(3)$ Å, $\beta=91.1(3)°$ and $Z=4$. The structures of TCPH and TBPA were solved from the sharpened Patterson maps, and refined by the block-diagonal least-squares method to R values of 0.112 and 0.112 for 1287 and 1278 non-zero reflections, respectively. The molecules of TCPH related by a twofold screw axis are linked together by hydrogen bonds between the carboxylic groups to form a chain along the b axis and the chains are held together by hydrogen bonds through water molecules to form a sheet parallel to the (100) plane. The sheets are stacked by van der Waals forces. The dihedral angles of the carboxylic groups with the benzene ring are 68.2 and 48.9°. The crystals of TBPA are isomorphous to those of tetrachlorophthalic anhydride. The benzene ring of TBPA are distorted by the attachment of five membered ring. There is considerable molecular overlap in TCPH, while in TBPA there is no overlap.

The conformation of the benzene ring overcrowded with halogen atoms is of considerable interest. Coulson and Stocker[1] have discussed the planarity of *o*-dihalogenobenzenes on calculations of potentials between halogen atoms, but the problem for more overcrowded benzenes has not always been settled. Strand[2] has shown that the planar molecule of *o*-dibromobenzene belongs to C_{2v} symmetry but the angle between the C–Br bonds is enlarged. Gafner and Herbstein[3] have noted that the intramolecular Br···Br distance of 1,2,4,5-tetrabromobenzene is significantly shorter than the usual van der Waals separation in different molecules. Rudman[4] has determined the structure of tetrachlorophthalic anhydride (TCPA) and pointed out that an anisotropic van der Waals radius plays an important role in the contacts of the halogen atoms. It is of additional interest that some multi-halogenated benzoic acids bear a distinct parallelism between the superdelocalizability for nucleophilic reaction and auxin activity or carcinogenic activity,[5] but the parallelism involves some conflicts to be solved in view of the detailed molecular structures.

Previous work on the topochemical studies has been carried out with 2,5-pyridinedicarboxylic acid–*N*,*N*-dimethylformamide complex monohydrate[6] in order to study the role of π-electron interaction and hydrogen bonding in molecular stacking and overlap on crystal structure formation. The present investigation was undertaken in order to compare the overlappings of the title overcrowded molecules and to study the effects of

overcrowding on the conformation of the benzene rings.

Experimental

Tetrachlorophthalic acid hemihydrate (TCPH) was recrystallized from a hot aqueous solution by cooling as thin plates elongated along the b axis. Crystals of tetrabromophthalic anhydride (TBPA) were obtained from a hot acetone solution by evaporation as prisms elongated along the b axis. Crystallographic data and experimental details are listed in Table 1. The intensity data were collected by the equi-inclination Weissenberg method using Cu$K\alpha$ radiation (λ= 1.5418 Å). Intensities were estimated visually and corrected for Lorentz and polarization factors and for spot shape, but not for absorption. The structure of TCPH was assumed to be centric from the distribution of normalized structure factors and the space group A2/a was confirmed by the analysis.

Structure Determination and Refinement

The structures were solved from three-dimensional sharpened Patterson maps. The hydrogen atoms of TCPH were located by a difference Fourier synthesis. Parameters of all the atoms were refined by the block-diagonal least-squares method. The weighting scheme used was:

$$w = 1.0 \quad \text{for} \quad 0 < |F_o| \leq F_{max}$$

$$\text{and} \quad w = (F_{max}/|F_o|)^2 \quad \text{for} \quad |F_o| > F_{max},$$

where F_{max}=16.0 and 30.0 for TCPH and TBPA, respectively. The final R value of TCPH was 0.112 for 1287 non-zero reflections and that of TBPA 0.112 for 1278. The observed and calculated structure factors are listed in Table 2,** and the final atomic parameters in Table 3.

The atomic scattering factors were taken from International Tables for X-ray Crystallography.[7] The computations were carried out on an NEAC 2200-500 computer at the Okayama University Computer Center. The programs used were HBLS-5 and DAPH.[8]

Table 3. Final atomic parameters and estimated standard deviations ($\times 10^4$)
The anisotropic thermal parameters are defined as: $\exp(-\beta_{11}h^2-\beta_{22}k^2-\beta_{33}l^2-\beta_{12}hk-\beta_{13}hl-\beta_{23}kl)$.

spective planes are listed in Table 4.

Crystal Structures. *(a) TCPH*: The molecules related by the twofold screw axis at $x=1/4$ and $z=1/4$ are linked by the hydrogen bonds between the carboxylic groups to form a chain along the b axis. The chains are held together by the hydrogen bonds through the water molecules on the twofold axis at $x=1/4$ and $z=1/2$ to form a sheet parallel to the (100) plane, which is in accordance with the observed cleavage. The sheets are stacked along the a axis by van der Waals forces.

Geometry of the hydrogen bonds are listed in Table 5. It can be seen that the O–H·····O bonds are nearly linear and the O·····O·····O angles are close to the tetrahedral angle.

As seen from Fig. 2 (a), the perpendicular spacing between the adjacent benzene-ring planes is close to that found in hexachlorobenzene (3.52 Å)[9] and in 1,2,3-trichlorobenzene (3.53 Å).[10]

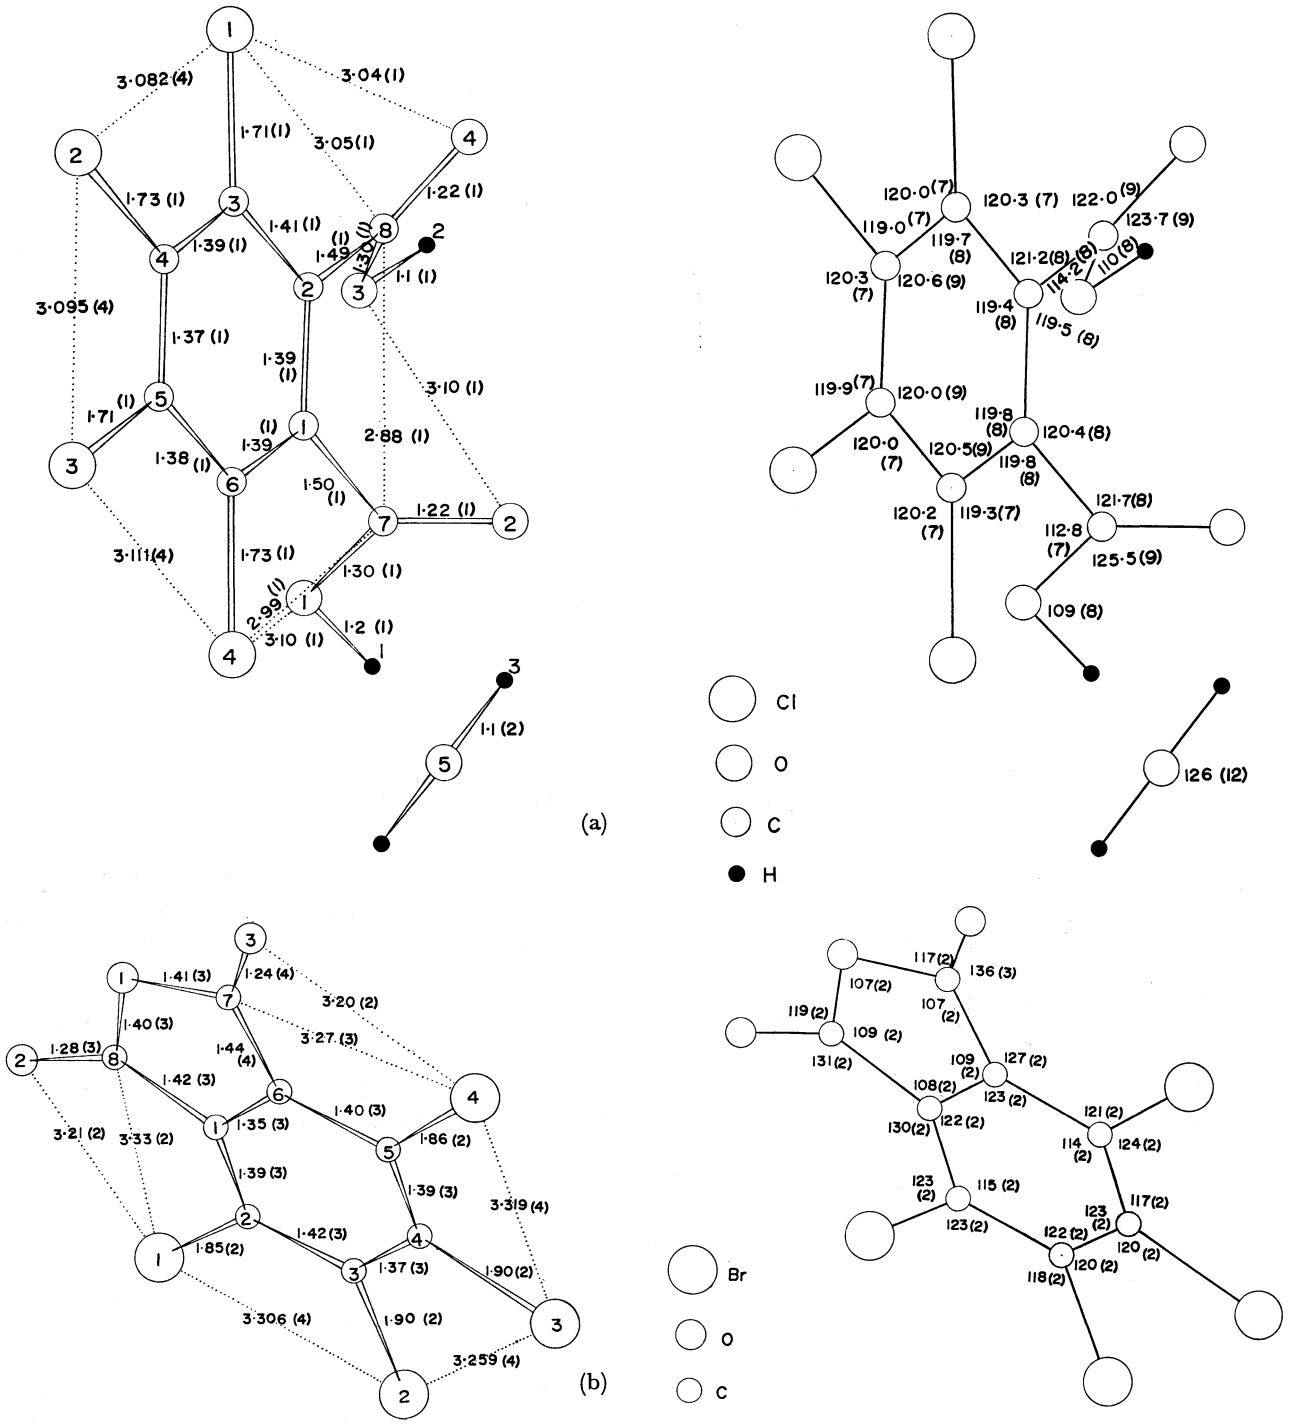

Fig. 3. Bond lengths (Å) and angles (°) of (a) TCPH and (b) TBPA, together with some intramolecular distances (Å). The estimated standard deviations are shown in parentheses.

(b) TBPA: The crystals of TBPA are isostructural with those of TCPA.[4] The molecules related by a center of symmetry, a b translation, and a twofold screw axis pack together by van der Waals forces along the a, b, and c axes, respectively.

The distances Br(1)···Br(1^{v}) and Br(1)···O(2^{v}) are shorter than those expected from the van der Waals radii, and are unexpectedly not longer than the corresponding distances in TCPA, respectively.

As seen from Fig. 2 (b), the perpendicular distance between the planes of the benzene rings of the molecules i and x is close to the distances 3.61 and 3.63 Å found in the 1 : 1 complex of hexabromobenzene with 1,2,4,5-tetrabromobenzene.[11] This distance is determined by the carbon-bromine contacts. On the other hand, the distance between the molecules i and viii is determined by the contacts of the O(3) atom with C(6^{ii}) and C(7^{ii}) atoms. The carbon-oxygen contacts are also found between the molecules i and ix.

Molecular Structures. (a) TCPH: The benzene ring keeps a planar form of regular hexagon within experimental error, but the Cl(1) and Cl(4) atoms are

Table 5. Hydrogen-bond distances (Å) and angles (°) in TCPH

D–H···A	Symmetry	D···A	H···A	Angle
O(1)–H(1)···O(5)	(i, i, i)	2.616(11)	1.44(14)	173(12)
O(3)–H(2)···O(2)	(iii, iii, i)	2.686(9)	1.56(15)	176(13)
O(5)–H(3)···O(4)	(i, i, viii)	2.706(12)	1.62(16)	161(14)

O···O···O	Symmetry	Angle
O(1)···O(5)···O(1)	(i, i, iv)	109.2(4)
O(1)···O(5)···O(4)	(i, i, viii)	97.3(4)
O(1)···O(5)···O(4)	(i, i, v)	124.3(4)
O(4)···O(5)···O(4)	(viii, i, v)	105.9(4)

Symmetry code is given in the legend of Fig. 1.

displaced to both sides of the benzene-ring plane because of the short contacts between the Cl(1) and O(4) atoms, and the Cl(4) and O(1) atoms, respectively. The average C–Cl bond length 1.716 (10) Å is near to the normal value.[4] The distances between the adjacent chlorine atoms are not far from the average value of 3.096 Å. The dihedral angles of both carboxylic groups with respect to the benzene ring are rather large because of cooperative effect of formation of the hydrogen bonds and a repulsive interaction between the O(2) and O(3) atoms.

(b) TBPA: The benzene ring is somewhat distorted from the regular hexagon, the angles C(1)–C(2)–C(3) and C(4)–C(5)–C(6) being significantly smaller than the sp^2 angle. The average C–Br bond length 1.88 (2) Å is close to the normal value.[12] The distance between the Br(2) and Br(3) atoms is shorter than that between the Br(1) and Br(2) atoms, or the Br(3) and Br(4) atoms, as found in TCPA. As seen from Table 4, the molecule is nearly planar but the Br(3) and O(2) atoms deviate from the benzene-ring plane in the same sense as in TCPA.

Comparison of the Mode of Molecular Overlapping. Different modes of overlapping are found for the overcrowded molecules; these is considerable molecular overlap in TCPH, while in TBPA these is no overlap. As noted above, this reflects in the spacings of stacking in both compounds: the spacing in TCPH is rather large and determined by the carbon-chlorine contacts, while in TBPA there are two short spacings determined by the carbon-oxygen contacts in addition to one spacing determined by the carbon-bromine contacts.

Effects of Overcrowding on the Conformation of the Benzene Rings. The observed distances between halogen atoms attached to adjacent carbon atoms on a benzene ring are much less than the sum of the van der Waals radii of the halogen atoms in both TBPA and TCPH. However, the benzene ring in TCPH is not distored. As an explanation for this fact an anisotropic van der Waals radius can be considered as follows. Let the z axis be perpendicular to the benzene ring plane, and the x axis be along the carbon-chlorine bond, then the direction of the $3p_y$ orbital, which is assumed to participate in the van der Waals interaction, deviates outward by 30° from the line between the chlorine atoms. On this model for usual geometry the possible extent of the $3p_y$ orbital is estimated to be 1.80 Å, which is equal to the Pauling's van der Waals radius.

The decrease in the C(1)–C(2)–C(3) and C(4)–C(5)–C(6) bond angles as found in TBPA is commonly observed in the benzene rings attached by five-membered ring as listed in Table 6. Therefore, the decrease is not attributed to the overcrowding of the halogen atoms, but to the attachment of five-membered ring as pointed out recently by Bechtel, *et al.*[16]

Table 6. Decrease in the bond angles of C(1)–C(2)–C(3) and C(4)–C(5)–C(6) in the benzene ring with five-membered ring fused at the C(1) and C(6) atoms

Photochemistry in the Adsorbed Layer. VI. The Type I Selectivity in the Photolysis of Adsorbed 2-Pentanone

Masakazu ANPO and Yutaka KUBOKAWA

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Mozu-Umemachi, Sakai, Osaka 591

(Received June 18, 1975)

A marked high selectivity of the type I reaction in the photolysis of adsorbed 2-pentanone decreases with increasing amount of 2-pentanone adsorbed, approaching the selectivity in the water solution photolysis. In the solution photolysis the type I selectivity decreases in the order water>methanol>*n*-heptane. From these results together with comparison of the blue shifts of the (n,π^*) bands in solution and in the adsorbed layer it has been concluded that such an enhancement of the type I reaction in the adsorbed layer is attributed to a heterogeneity of the surface, *i.e.*, the presence of special active sites, as well as to the surface polarity.

The Norrish type II reactions of alkyl ketones having γ-hydrogen atoms have been investigated by a number of workers.[1-3] On the other hand, there have been few or no studies for the type I reactions of these compounds. We have found that in the adsorbed layer the type I selectivity in the 2-pentanone photolysis is enhanced compared to that in the gas phase.[4] In order to obtain information on the nature of such enhancement, it seems necessary to investigate its photolysis in solution and to compare these results with those in the adsorbed layer. In the present work therefore it has been undertaken to study the solvent effect upon the type I selectivity in the 2-pentanone photolysis and to examine how the type I selectivity in the adsorbed layer photolysis varies with the amount adsorbed in connection with this problem.

Experimental

Materials. All the compounds used in this work were available commercially (Tokyo Kasei Kogyo Co. Ltd., Grade SG) and purified by fractional distillation. Deionized double-distilled water was degassed by alternate freezing and thawing *in vacuo*. Particular care was taken to remove water completely from the solvents and reactants. Porous Vycor glass (Corning, No. 7930) was used as adsorbent.

Apparatus and Procedure. Details of the apparatus and procedure used in the photolysis in the adsorbed layer were described in the previous paper.[4] A conventional vacuum system was used in conjunction with a special quartz cell capable of studying the spectra and photolysis in the adsorbed layer. The specimen of porous Vycor glass which had been heated in oxygen to remove carbonaceous impurities was introduced to the cell and degassed at temperatures ranging from 100 to 800 °C for 7 hr. After a certain amount of 2-pentanone had been adsorbed on the specimen, photolysis was carried out using an ultra high pressure mercury lamp without filter.

Liquid phase photolyses were carried out in a rectangular quartz cell (4.0×1.0 cm) of path length 0.5 cm, having two outlets. One was sealed off after admission and degassing of the sample solution. Another had a breakable seal which made it possible to attach the cell to a conventional analytical system after irradiation. The cell was immersed in a thermostat having a quartz window. The irradiation was carried out using an ultra high pressure mercury lamp without filter. The analytical system consisted of three traps and a modified Ward still. The gaseous products were separated by fractional distillation and analyzed by gas chromatography using a flame-ionization detector.

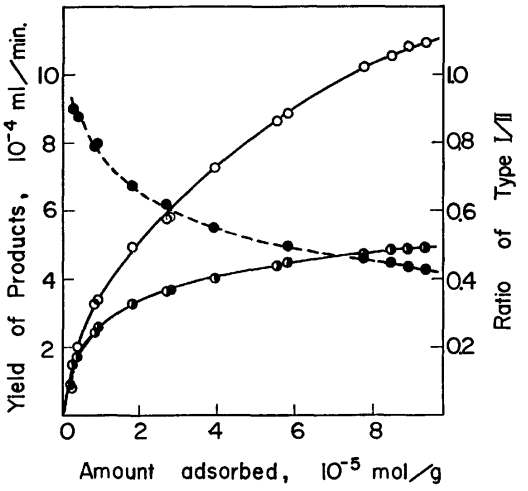

Fig. 1. Effect of amount adsorbed upon the photolysis of 2-pentanone at 25 °C. Irradiation time, 20 minutes. ○, Ethylene; ◑, Propane; ●, Ratio of Type I/II.

Results

In Fig. 1 the rates of propane and ethylene formation are plotted against the amount of 2-pentanone adsorbed. It is seen that the rates of formation increase with increasing amount adsorbed. In the range of the small amounts adsorbed the extent of the increase is large, but decreases with increasing amount adsorbed. Such a trend is more significant for the propane than for the ethylene formation. Accordingly, the ratio of propane (Norrish type I reaction) to ethylene (Norrish type II reaction) decreases with increasing amount adsorbed, finally approaching 0.40.

Results of 2-pentanone photolysis in various solvents are shown in Table 1. The major gaseous products

Table 1. The rates of 2-pentanone photolysis in various solvents[a] (10^{-4} ml/hr)

	Heptane	Methanol	Water
Ethylene	618.0	674.0	755.0
Propane	67.0	167.0	303.0
Ratio of type I/II	0.11	0.25	0.40

a) These values were the corrected rates of formation divided by the relative ε_{max} values (Table 2). The concentration of 2-pentanone was 2.0×10^{-4} mol (0.1 mol%). Photolysis was carried out at 30 °C.

formed are propane and ethylene. The amounts of minor products such as methane, ethane, propylene, and butane did not exceed 10% of the amount of propane, indicating that the rate of the type I reaction is approximately equal to the rate of propane formation. It is seen that the rate of formation increases slightly for ethylene while significantly for propane in the order heptane<methanol<water, *i.e.*, with increasing polarity of the solvents.[5-7] It should be noted that with increasing polarity of the solvent the ratio of propane to ethylene formation increases. The ratio obtained with water solution is essentially the same as the smallest corresponding value in the adsorbed layer photolysis.

TABLE 2. THE (n, π^*) TRANSITION OF 2-PENTANONE IN SOLUTION AND IN ADSORBED LAYER AT 25 °C

	Gas phase	Heptane[a]	Methanol[a]	Water[a]	Vycor glass[b]
Absorption max. (nm)	279	280	275	273	273
Relative ε_{max}	—	1.0	1.1	1.3	—

a) The concentration of 2-pentanone was 2×10^{-4} mol (0.1 mol%). b) Porous Vycor glass was pretreated at 500 °C for 7 hr in vacuum. The amount of 2-pentanone adsorbed was 9×10^{-5} mol/g. The magnitude of the blue shift of the (n, π^*) transition scarcely changed with increasing amount of 2-pentanone adsorbed.

As seen in Table 2, the blue shift of the (n, π^*) transition of 2-pentanone increases in the order *n*-heptane< methanol<water. Similar magnitudes of the blue shift have been obtained by Rao *et al.*[8] As described in the previous paper,[4] we have shown that the blue shift observed for the alkyl ketones adsorbed on porous Vycor glass is attributable to hydrogen bonding between the surface OH groups and C=O groups of the alkyl ketones and can be used as a measure of the polarity of the surface OH groups. This suggests that the surface polarity of Vycor glass may be similar to that for water solution.

Discussion

Wagner *et al.*[2,3] have carried out extensive studies of the solvent effect upon the type II reaction, which show that the rate of the type II reaction increases with increasing polarity of the solvent owing to stabilization of the 1,4-biradical intermediate, *i.e.*, a decreased probability for return of the γ-hydrogen in the biradical (formed by the intramolecular hydrogen abstraction in the excited states) due to hydrogen bonding between the polar solvent and the hydroxyl group of the biradical. The effects of the surface pretreatments upon the yields of the type II reaction of adsorbed 2-pentanone have been interpreted on a similar basis.[9] On the other hand, there have been no studies of the solvent effect upon the type I reaction. The increase in the rate of the type I reaction may be interpreted as follows: As the polarity of the solvent increases, the interaction of the radicals formed in the primary process with the solvent will increase. Such an increase in the interaction would result in the increase in stabilization of the radicals, leading to suppression of the recombination of the alkyl-acyl radical pairs formed in the primary process as well as increased probability of α-cleavage in the excited triplet states, *i.e.*, formation of these radical pairs. Both effects may contribute to enhancement of the yield of the type I reaction.

In the range of the amount adsorbed about 9.00×10^{-5} mol/g the magnitude of the blue shift of the (n, π^*) transition as well as the ratio of the yield for the type I to that for the type II reaction is essentially the same as that observed for water solution. This suggests that at least in this range of the amount adsorbed enhancement of the type I reaction in the adsorbed layer may arise from the surface polarity which is reflected by the magnitude of the blue shift. Such a significant role of the surface polarity in determining the ratio of the yield for the type I to that for the type II reaction is apparent from the effect of surface pretreatments upon the photolysis of adsorbed 2-pentanone described previously.[9] As seen in Fig. 2 this ratio decreases with increasing degassing temperature, *i.e.*, with decreasing surface polarity owing to the decrease in the concentration of surface OH groups.

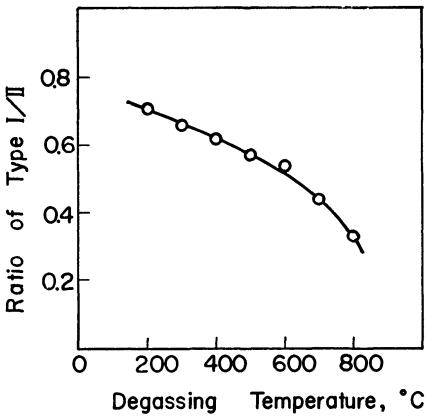

Fig. 2. Effect of degassing temperature upon the photolysis of adsorbed 2-pentanone at 25 °C. Amount of 2-pentanone adsorbed was 2.2×10^{-5} mol/g.

In the range of the amount adsorbed below 4.00×10^{-5} mol/g a marked increase in the type I selectivity as well as the overall yield of the photolysis occurs. Although the true nature of such a marked increase in the type I selectivity is not yet clear, such behavior may be explained by assuming a heterogeneity of the surface, *i.e.*, the presence of special active sites, since the amount adsorbed of 4.5×10^{-5} mol/g corresponds to $\theta=0.05$ using 25 A^2 per one molecule.

It has been reported by Turkevich and Fujita,[10] and by Gesser and his co-workers[11,12] that the radicals produced by the photolysis of methyl iodide adsorbed on porous Vycor glass are trapped much more strongly on a limited number of active sites than other sites. Thus, a significant increase in the radical stabilization would be expected on such special active sites, where suppression of the recombination of the radical pair as well as an increase in the probability of α-cleavage described above would be much more significant than that for other ordinary sites. In addition, it seems necessary to

take into account the following possibility: The type I reaction will be enhanced because of the contribution of hydrogen abstraction from the surface OH groups, which takes place more efficiently in the small amounts adsorbed as described in the previous paper.[13] Furthermore, the presence of special active sites capable of abstracting hydrogen efficiently from 2-pentanone molecules may retard the intramolecular γ-hydrogen abstraction leading to the type II reaction. The presence of such kind of active sites has already been suggested by Low *et al.*[14] for the Vycor glass-acetone system.

We would like to express our thanks to Mr. T. Shimatani for carrying out some parts of the experiments.

The Catalytic Action of TiO_2 for the Isomerization of Butenes

Kunimitsu MORISHIGE, Hideshi HATTORI, and Kozo TANABE
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received June 27, 1975)

The isomerization of 1-butene or *cis*-2-butene and the co-isomerization of *cis*-2-C_4H_8 and *cis*-2-C_4D_8 were carried out at 120 °C over TiO_2 calcined *in air*. It has been found that induction period appeared and the ratio of *cis*-2-butene to *trans*-2-butene in the isomerization of 1-butene was unusually high (5—20). The double bond migration and *cis-trans* isomerization occurred by an intramolecular hydrogen transfer reaction and the kinetic isotope effect (k_H/k_D) was 4—5. The activity was completely or almost lost by poisoning with pyridine or nitric oxide. The isomerization was concluded to proceed by a π-allyl anion mechanism, where the *cis-trans* interconversion is highly restricted and the C–H bond cleavage is involved in the rate-determining step of the double bond migration. Main active sites were suggested to consist of both Lewis acid sites and basic sites (surface oxygen ion, O^{2-}).

TiO_2 has been generally classified as a solid acid on the basis of the experiment on the chemical adsorption of basic Hammett indicators and pyridine.[1] Recently, however, Shannon *et al.* reported that TiO_2 calcined in air showed the similar selectivity as basic catalysts for the isomerization of *n*-butene.[2] From the experiment on co-isomerization of the mixture of C_4H_8 and C_4D_8, they concluded that both the double bond migration and *cis-trans* isomerization were mainly intermolecular and each isomerization proceeded *via* separate mechanisms. However, it seems to be difficult to determine whether the isomerizations are inter- or intra-molecular, since their results showed that considerable isotopic scrambling occurred independently of the isomerizations.

In our previous work, the nature of active sites on TiO_2 was found to depend strongly on the method of preparation and pretreatment of the catalyst.[3] Over TiO_2 prepared by calcining titanic acid *in vacuo* at low temperatures, the ratio of *cis*-2-butene/*trans*-2-butene (abbreviated as *cis*-/*trans*-) from 1-butene was nearly 1, indicating Brönsted acid as active sites. When TiO_2 was prepared by calcining titanic acid *in vacuo* at high temperatures, it gave the high *cis*-/*trans*- ratio. Since the activity of the latter catalyst was decreased by oxygen treatment, the active sites were concluded to be mainly Ti^{3+} ions formed by the reduction of Ti^{4+}. On the other hand, it was reported that the activity of TiO_2 calcined *in air* was not affected by oxygen treatment,[2] though no study was made on the nature of active sites.

The purpose of the present work is to elucidate the reaction mechanism as well as the nature of active sites for the isomerization of *n*-butene over TiO_2 prepared by calcining titanic acid *in air* and to learn about the relation of the acid sites on the catalyst with the basic character giving the high *cis*-/*trans*- ratio.

Experimental

Catalyst and Reagents. TiO_2 was prepared by hydrolyzing $TiCl_4$ with NH_4OH in the solution of $(NH_4)_2SO_4$ and calcining the precipitate in air at 500 °C for 3 hr. X-Ray diffraction of the sample showed a structure of an anatase type. Butenes (Takachiho pure grade) were purified by distilling through a molecular sieves 4A maintained at the temperature of dry ice–ethanol. Perdeuterio-*n*-butenes were prepared by exchange of 1-butene with D_2 over MgO at room temperature, the isomers being separated on a preparative scale chromatographic column.[4] Pyridine (GR of Kanto Chem. Co.) was purified by repeating three times the procedure of a freeze-thaw outgassing cycle after passing over zeolite 13X. NO of more than 95.0% purity supplied by the Gaschro Industry Co. was purified by a vacuum distillation.

Reaction Procedure. The isomerization of *n*-butenes was carried out in a circulating system of *ca.* 330 ml at 120 °C. A small amount (*ca.* 1%) of the reaction products was withdrawn out of the system by expansion at appropriate time intervals and analyzed by gas chromatography using a 7 m column (Cu tubing of 4 mm in diameter) containing 30% propylene carbonate on 30—60 mesh Uniport C. The column was operated at 0 °C. Before use, a catalyst (0.2 g) was treated in a vacuum of 10^{-4} mmHg at 450 °C for 2 hr. Between runs, the catalyst was degassed at 400 °C for 30 min. The same activity and selectivity as those of the first run were maintained by this simple treatment through all the kinetic runs. The surface area of the catalyst was 72 m^2/g.

For co-isomerization experiments, a mixture containing about equal amounts of light *cis*-2-butene (*cis*-C_4H_8) and heavy *cis*-2-butene (*cis*-C_4D_8) was co-isomerized on TiO_2 (18.9 mg) in a static system of 26 ml at 5 cmHg. The isomerized products were condensed into a liquid nitrogen trap, separated by preparative scale gas chromatography and analyzed for the isotopic composition by mass spectrometry. Four runs were carried out and each run was stopped at different conversions. The mixtures of heavy 1-butene (12%) and light *cis*-2-butene (88%) were also co-isomerized at 3.5 cmHg in order to determine the main path in the interconversion from *cis*- to *trans*-2-butene.

Poisoning, IR and ESR Measurements. For poisoning experiment, the prepared catalyst was evacuated at 450 °C, equilibrated with a vapor of pyridine (0.5 cmHg) at room temperature for 30 min, evacuated again overnight at the same temperature and then heated *in vacuo* for 1—2 hr at different temperatures. The activities for the isomerization of 1-butene were examined after the above treatment. The isomerization was also carried out on the catalyst in the presence of NO (2.45 cmHg).

IR spectrum of the catalyst which was evacuated at 200 °C after exposed to pyridine vapor in *in situ* cell was measured at room temperature. ESR spectra of the catalyst with or without pyridine poisoning were measured at −195 °C before and after the introduction of 1-butene (5 cmHg) at 120 °C.

Results

Kinetics of the Isomerizations of n-*Butenes.* The time courses of the isomerizations of 1-butene and *cis*-2-butene are shown in Fig. 1. 1-Butene isomerized pre-

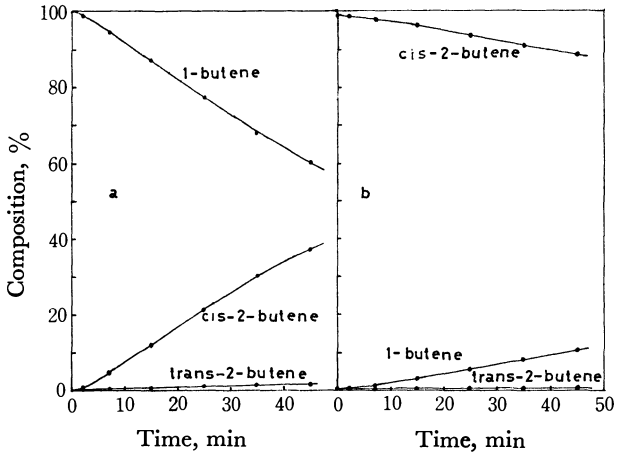

Fig. 1. Isomerization of 1-butene (a) and *cis*-2-butene (b) over TiO_2. Pressure of butenes: 11 cmHg.

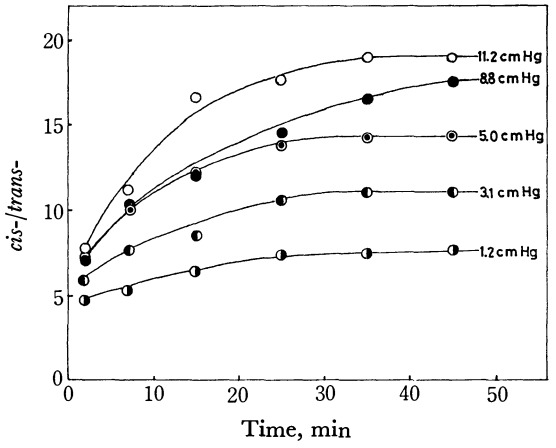

Fig. 2. Ratio of *cis*-2-butene/*trans*-2-butene in isomerization of 1-butene *vs.* reaction time at different pressures.

ferentially to *cis*-2-butene and *cis*-2-butene preferentially to 1-butene, in accord with the results observed by Shannon *et al.*[2] It is interesting that induction periods were observed in our case. Figure 2 shows the time course of the *cis*-/*trans*- ratio when 1-butene was isomerized over the catalyst at different pressures. The figure indicates the two remarkable features which have not been reported before for the isomerization of *n*-butene. The first one is that the *cis*-/*trans*- ratio becomes increasingly far from the equilibrium value as the isomerization progresses. The second one is that the higher the initial pressure, the larger the *cis*-/*trans*- ratio. Similarly, the increase in 1-/*trans*- ratio with reaction time and increasing initial pressure was observed for the isomerization of *cis*-2-butene.

The time courses of the *n*-butene isomerizations obeyed the reversible first order kinetics except the induction period. The initial rate, R_0, was calculated from the first order plots. Assuming that reactant butene is in adsorption equilibrium of Langmuir type and that the surface reaction of the adsorbed molecule is rate-determining, R_0, is given by the equation.

$$R_0 = kKP_0/(1+KP_0), \qquad (1)$$

where P_0 is the initial pressure of the reactant, K the

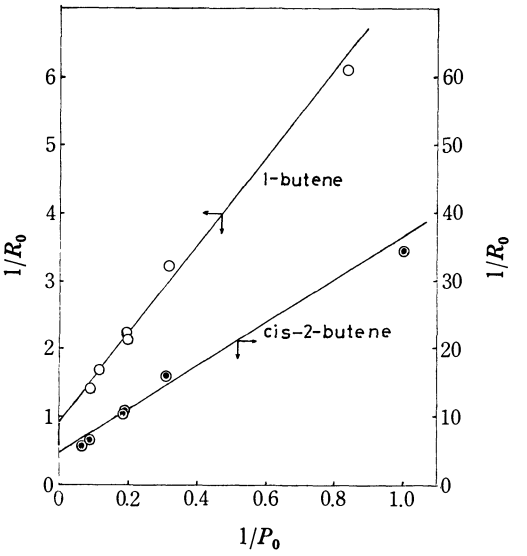

Fig. 3. Plots of reciprocals of initial rates against reciprocals of pressures for isomerizations of 1-butene and *cis*-2-butene.

adsorption constant of the reactant and k the rate constant of the surface reaction. In accord with the above equation, plots of the reciprocals of the initial rates against the reciprocals of reactant pressures were linear as shown in Fig. 3. The intercepts and slopes provided the adsorption constants (K_1 and K_c) of 1-butene and *cis*-2-butene. The adsorption constant of *trans*-2-butene could not be determined by the same way, because the reactivity of *trans* isomer was very low. In order to obtain the adsorption constant, the isomerization of 1-butene was carried out in the presence of different partial pressures of *trans* isomer, where the initial pressure of 1-butene was maintained at 5 cmHg. The initial rate, R_1, was calculated from the first order plots of the disappearance of 1-butene, where the amount of the products from the isomerization of *trans*-2-butene was neglected. The rate data were represented by the competitive reaction equation of Langmuir type.

$$R_{0(1)}/R_1 = K_tP_t/(1+K_1P_1) + 1, \qquad (2)$$

where P_1, P_t, K_1, and K_t are the initial pressures and the adsorption constants of 1-butene and *trans*-2-butene,

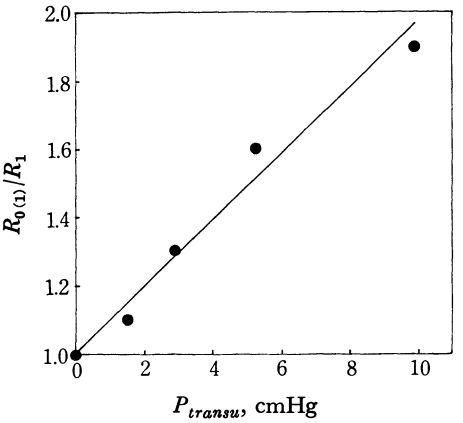

Fig. 4. Effect of partial pressure of *trans*-2-butene on initial rate of isomerization of 1-butene.

respectively. The plots of the Eq. (2) gave a straight line as shown in Fig. 4. K_t was calculated from the slope and K_1. Thus, K_1, K_c, and K_t were obtained to be 0.15 0.17, and 0.18 $cmHg^{-1}$, respectively.

Co-isomerization. From the results of the co-isomerization of a mixture of *cis*-2-C_4H_8 and *cis*-2-C_4D_8, isotope effects and intermolecular hydrogen exchange were determined. The data were analyzed by the method devised by Hightower and Hall.[5] For each isomer, the light fraction is given by the formula.

$$\frac{1}{2}N_4+\sum_{i=0}^{3}N_i \quad (3)$$

where N_i is the mole fraction of each isotopic species containing i deuterium atoms. The heavy fraction is then given by the formula.

$$\frac{1}{2}N_4+\sum_{i=5}^{8}N_i \quad (4)$$

The isotope effects were calculated from the relative activities of the two species; namely, the ratios of light materials to heavy materials in the products divided by the ratio in the starting materials.

Table 1. Product distribution from co-isomerization of *cis*-2-C_4H_8 and *cis*-2-C_4D_8 over TiO_2 at 120 °C

	Composition of products	Isotopic composition, %								
		Light fraction					Heavy fraction			
		d_0	d_1	d_2	d_3	d_4	d_5	d_6	d_7	d_8
1-C_4'	19.2	44.0	3.0	0	0	0	0	0.7	4.2	48.2
trans	8.9	65.5	3.0	0	0	0	0	0	3.6	27.9
cis	71.8	45.8	1.8	0	0	0	0	0	3.7	48.6

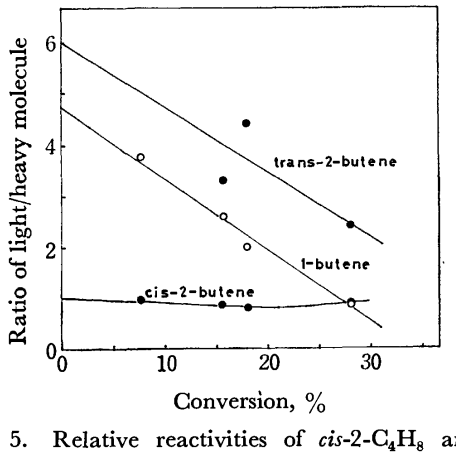

Fig. 5. Relative reactivities of *cis*-2-C_4H_8 and *cis*-2-C_4D_8 over TiO_2 at 120 °C.

Table 1 shows the isotopic distribution and Fig. 5 the ratio of light to heavy material for each isomer at various conversions. The data of Table 1 indicate that double bond migration and *cis-trans* isomerization are much faster than intermolecular H–D exchange. Evidently, both reactions do not involve the intermolecular exchange reaction, *i.e.*, the hydrogen transfers are intramolecular. Since the ratio of light molecule to heavy molecule in products represents kinetic isotope effect, Fig. 5 shows the existence of the large isotope effects, 4—5, in both isomerizations.

Table 2. Poisoning with pyridine and NO

	No poison	pyridine[a]	pyridine[b]	pyridine[c]	NO	NO[e]
Activity	0.451	0	0.049	0.294	0.05[d]	0.294
$(cis/trans)_s$	15		13	16	4	9

Activity: cmHg min^{-1} g^{-1}, $(cis/trans)_s$: selectivity in a stationary state calculated from the plots analogous to Fig. 7.
a) Degassed at 200 °C for 2 hr. b) Degassed at 300 °C for 1 hr. c) Degassed at 400 °C for 1 hr. d) Poisoning occurred increasingly in progress of isomerizartion. e) After adsorption of NO (1.78 cmHg), the catalyst was degassed for 1 hr at 120 °C.

In the co-isomerization of a mixture of 1-C_4D_8 (12%) and *cis*-2-C_4H_8 (88%), the ratio of heavy molecule to light molecule in *trans*-2-butene was 0.093 at the stage of 2% formation of *trans*-2-butene, while the value in *cis*-2-butene was 0.019.

The Results of Poisoning and IR and ESR Spectra. The effects of poisoning with pyridine and NO on the isomerization of 1-butene are shown in Table 2, where the activities are the initial rates evaluated from the reversible first order plots. The catalyst on which pyridine was adsorbed showed no activity even after evacuation at 200 °C. By the poisoning with NO, the activity was decreased to less than one tenth. The selectivities were affected by poisoning with NO, but not with pyridine.

IR spectra of the catalyst poisoned with pyridine exhibited only the pyridine molecules coordinately bonded to the Lewis acid sites, in accord with the literatures.[6-8] ESR spectra of the above sample did not show the existence of dipyridil anion radical which was observed in the cases of the alkaline earth oxides.[9] The intensities of ESR signals[3] indicating Ti^{3+} for both catalysts with and without pyridine poisoning increased about four times on the introduction of 1-butene.

Discussion

Reaction Mechanism. The isomerization of 1-butene or *cis*-2-butene is known to give high ratio of *cis*-2-butene to *trans*-2-butene or 1-butene to *trans*-2-butene over basic catalysts such as MgO, CaO, Na–Al_2O_3 *etc.*[10-13] Since the adsorption constants of each butene isomer were almost the same in the present work, the basic feature of the selectivities, *i.e.*, the very high ratios of *cis*-/*trans*- and 1-/*trans*-, observed for TiO_2 seems not to result from a selective adsorption of *cis*-2-butene or 1-butene in the *cis* configuration on active sites, whose model was once presented for 1-butene isomerization over γ-Al_2O_3 by Gerberich and Hall.[14] In other words, the configurational differences among three isomers do not exert any influence on the adsorption of each isomer. The basic feature of the observed selectivity would result from the difference in the rate of interconversion among each isomer adsorbed on TiO_2.

The data on co-isomerization shown in Table 1 reveal that the hydrogen transfers involved in double bond migration and *cis-trans* isomerization are intramolecular. The large isotope effect observed for *cis-trans* isomeriza-

tion does not reflect the effect for the direct interconversion step, because, in the co-isomerization of 1-C_4D_8 (12%) and *cis*-2-C_4H_8 (88%), the ratio of heavy to light molecule in *trans*-2-butene was larger than that in *cis*-2-butene. Actually, at a reaction temperature (200 °C) at which direct *cis-trans* interconversion becomes predominant, the isotope effect was not observed.[2] Therefore, it is very likely that C–H bond cleavage is involved in the rate-determining step of the double bond migration. These features together with the high *cis/trans* ratio and slow direct *cis-trans* isomerization can be well explained only by a π-allyl anion mechanism,[13] in which the *cis* allyl anion is thermodynamically more stable than the *trans* form and the *cis-trans* conversion is highly restricted.

Active Sites. The activity for the isomerization was completely lost by the adsorption of pyridine. Since pyridine was adsorbed on Lewis acid site to form its coordinately bonded molecule according to IR spectra and not on basic site (surface oxygen ion, O^{2-}) to form the dipyridyl anion[9] according to ESR spectra, Lewis acid sites are considered to participate in active sites for the isomerization. On the other hand, the activity was considerably decreased by poisoning with NO, which is known to react with basic site (O^{2-}) to form nitrato-compound.[15] These facts strongly suggest that the active sites consist of Lewis acid site-basic site pair. The concept that acid-base pair sites are active sites for the isomerization is also proposed for η-Al_2O_3 on the basis of the experiments on the reactivity of substituted olefins.[16]

The active sites on TiO_2 prepared by calcining titanic acid *in vacuo* were previously reported to be Ti^{3+} formed by the reduction of Ti^{4+} on the surface.[3] Since the activity of the present catalyst prepared by calcining titanic acid *in air* and then evacuated was decreased to two thirds of the activity by treating with dry air at 450 °C for 1 hr, the possibility that Ti^{3+} is a part of active sites can not be excluded. However, main active sites on the present catalyst are considered to be Lewis acid (Ti^{4+}) and oxygen ion (O^{2-}) pair. It should be emphasized that the main active sites on TiO_2 for the isomerization are varied by changing preparation condition of the catalyst.

Induction Period and Pressure Dependence of Selectivity.

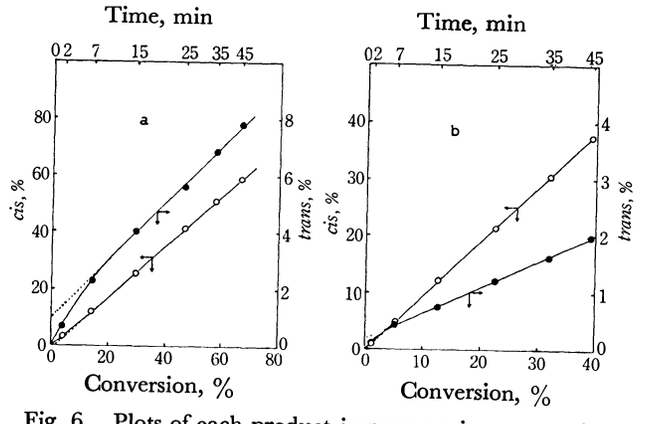

Fig. 6. Plots of each product isomers against conversion % for isomerization of 1-butene. Pressure of 1-butene: a) 1.2 cmHg, b) 11.2 cmHg.

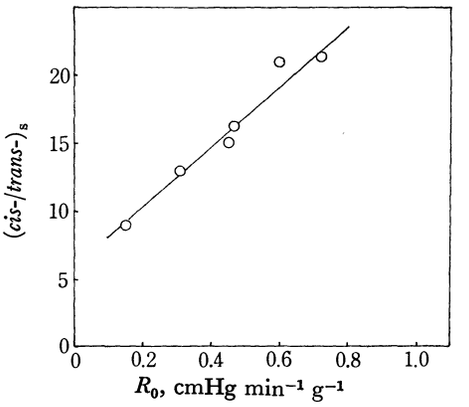

Fig. 7. Correlation between initial rates and selectivities of isomerization of 1-butene in a stationary state.

The remarkable results concerning selectivity and induction period found in the present work were not observed by Shannon *et al.*[2] The difference is presumably due to the difference in the reaction conditions. They carried out the isomerization in a static system at a lower pressure (*ca.* 1.6 cmHg) and at higher temperatures (130—168 °C) than in our case. Only two examples of induction period have been reported for *n*-butene isomerization over solid catalysts. One is for Cu 13X zeolite[17] and another for metal ion exchanged resin.[18] In those cases, the induction period is considered to be caused by the reduction process of Cu^{2+} to Cu^{+} or the complex formation of butene with metal ion, respectively. In our case, a part of Ti^{4+} was reduced to form Ti^{3+} by introducing 1-butene on both catalysts with and without pyridine poisoning. However, the catalyst poisoned with pyridine was completely inactive, though the catalyst without poisoning was active. Hence, the formation process of Ti^{3+} does not seem to cause the induction period.

The plots of % of *cis*- and *trans*-2-butene produced from 1-butene against the % conversion are shown in Fig. 6. The figure clearly indicates that a stationary state in selectivity is reached within 15 min, in accord with time-course curve in Fig. 1. The selectivities in a stationary state are obtained from the ratio of the slope for *cis*-isomer to that for *trans*-isomer in the linear parts. As shown in Fig. 7, the *cis-/trans-* ratio in a stationary state linearly increases with the rate in stationary state. As the initial rate obeyed the rate expression of Langmuir type, it is proportional to the adsorbed amount. Eventually, the larger the adsorbed amount of butenes is, the more the formation of *cis*-2-butene becomes predominant.

Effects of Foreign Gases on Dual Fluorescences of Pyrene Vapor

Kohji CHIHARA and Hiroaki BABA

Division of Chemistry, Research Institute of Applied Electricity, Hokkaido University, Sapporo 060

(Received July 29, 1975)

The characteristics of the dual fluorescences of pyrene vapor at 170 °C and 0.2—0.3 Torr have been investigated in the presence of cyclohexane or oxygen. With increasing cyclohexane pressure, the S_1-fluorescence shows a blue shift and an increase in quantum yield and in lifetime, while the S_2-fluorescence shows only a slight blue shift and a marked decrease in yield and in lifetime. Oxygen efficiently quenches the S_1- and S_2-fluorescence according to the Stern-Volmer relation. The experimental results are well explained by kinetic analyses based on the following assumptions: (1) The internal conversion is reversible and is much faster than other radiative and radiationless processes; (2) cyclohexane causes only vibrational relaxation which can be described in terms of a simple stepladder model; (3) oxygen acts as a quencher on both S_1- and S_2-fluorescence emissions. It is found that one collision with cyclohexane removes on the average a vibrational energy of the order of 1000 cm^{-1} or less from S_1 or S_2 of pyrene, and that one collision with oxygen quenches S_1 or S_2 with a probability close to unity. It is concluded that the S_2-fluorescence consists mainly of a slow component originating from S_2 which is in equilibrium with S_1.

In relation to the theories of radiationless transitions in isolated molecules,[1,2] a number of experimental studies[3,4] have recently been made of the emission properties of organic compounds in the vapor phase at low pressure, where molecules are free from collision during their emission lifetimes. Under such conditions the fluorescence of organic molecules presents peculiar features that cannot be seen in a condensed phase or in a vapor at a high pressure. Thus, in the low-pressure vapor, pyrene and related compounds are known to exhibit distinct fluorescence emission from the second excited singlet state (S_2) in addition to the ordinary fluorescence from the first excited singlet (S_1).[5-9]

In previous papers,[5,6] hereafter referred to as Papers I and II respectively, the following observations were reported on the dual fluorescences of pyrene and its simple derivatives in the vapor phase. (1) As the excitation energy increases, the S_2-fluorescence shifts to the red in much the same way as the S_1-fluorescence, and both S_1- and S_2-fluorescence bands become broad. (2) The quantum yield of the S_2-fluorescence (Φ_{2F}) increases rapidly with excitation into successively higher singlet states, whereas the yield of the S_1-fluorescence (Φ_{1F}) decreases only slowly with increasing excitation energy. The ratio Φ_{2F}/Φ_{1F} is roughly related to ρ_2/ρ_1, where ρ_1 and ρ_2 are the densities of vibrational states in S_1 and S_2 at the energy of excitation. (3) Addition of cyclohexane as an inert foreign gas to the pyrene vapor results in a marked decrease in Φ_{2F}/Φ_{1F}. (4) Most of the S_2-fluorescence emission seems to occur through the mechanism involving reverse internal conversion.

In the presence of cyclohexane, pyrene must undergo vibrational relaxation in its excited state. On the other hand, the excited singlet state of many aromatic compounds including pyrene is known to be quenched by oxygen very efficiently.[10,11] It is to be expected that the changes in emission characteristics caused by addition of such foreign gases are different between the S_1- and S_2-states of pyrene vapor.

The purpose of the present study is to gain a deeper insight into the nature of the dual fluorescences through a detailed examination of the effects of foreign gases, cyclohexane and oxygen, on the S_1- and S_2-emissions of the pyrene molecule in the vapor phase.

Experimental

Pyrene and cyclohexane were purified in the same way as in Paper I. Oxygen obtained from Takachiho Kagaku Kogyo Co. (purity, 99.8%) was used as received. The methods for preparation of the sample vapor, measurement and correction of fluorescence spectra, and for determination of fluorescence quantum yields were the same as described in Paper I, unless otherwise stated. All the experiments were conducted at 170 °C and at pyrene pressures in the range 0.2—0.3 Torr.

Measurements of fluorescence emission of low intensity were made on a high-sensitivity emission spectrophotometer constructed recently in our laboratory. In this spectrophotometer, light from a 150-W xenon lamp was dispersed by a Czerny-Turner double monochromator with an f number of 4.5, consisting of a quartz prism and a grating (1200 lines/mm), to give monochromatic excitation beam. The fluorescence emitted from the sample at right angles to the excitation beam was dispersed by another Czerny-Turner monochromator with an f number of 4.5, consisting of a 1200 lines/mm grating alone. The resulting monochromatic fluorescence emission was detected by the photon counting method, using a Hamamatsu R585 photomultiplier which showed at room temperature a very low dark current corresponding to $\sim$1 count/s. Both excitation and emission wavelengths were scanned discontinuously with the aid of a pulse motor. Fluorescence with a quantum yield as low as 10^{-7} can be measured with this spectrophotometer, provided that an optimum concentration of sample material is used. For fluorescence of higher intensity another emission spectrophotometer was used which was constructed by attaching a photon counting system, similar to the one mentioned above, to the optical system of a Hitachi MPE-2A fluorescence spectrophotometer.

The fluorescence decay was observed using a breakdown spark generated in 2-atm oxygen gas as the exciting light source. The breakdown was induced by a Japan Electron Optics Laboratory JLS-R3A giant pulse ruby laser with a peak output of 150 MW. The oxygen breakdown spark has a high intensity and a duration of about 70 ns, and covers the necessary wavelength range of 210—330 nm. The light beam from the breakdown spark was passed through the following filter systems (a) and (b) for exciting the pyrene molecule into its S_3- and S_4-states, respectively; (a) consists of an interference filter with a transmittance maximum of 17.5% at 264.5 nm and a half bandwidth of 14 nm and a solution filter obtained by dissolving 1.1 mg of 2,7-dimethyl-

3,6-diazacyclohepta-1,6-diene perchlorate in 25 ml water, and (b) is an interference filter with a transmittance maximum of 19% at 234 nm and a half bandwidth of 23 nm. Note that the solution filter in (a) cuts off the stray light falling into the wavelength region of S_2-fluorescence. A monochromator was used for selecting the emission wavelength. For the measurement of S_1-fluorescence decay in the absence of a foreign gas, excitation was made at each of the vibrational peaks belonging to individual electronic absorption bands. In this case, a monochromator was used for selecting the wavelength of the exciting light of the breakdown spark, with the bandwidth being set to 8 nm, and the emission beam was passed through filters of UV-D2 and UV-35 from Toshiba Electric Co., which excluded the scattered exciting light and the S_2-fluorescence emission. All the fluorescence lifetimes were determined by the deconvolution method.[12]

Results

The excited singlet states associated with the four electronic absorption transitions of pyrene appearing in the near ultraviolet region (Paper I) are denoted by S_1,⋯, S_4 in order of increasing energy, and the ground singlet state by S_0. The zero vibrational level of each of the electronic states will be represented by a superscript 0, *e.g.*, S_2^0. The $S_0 \rightarrow S_2$,$\rightarrow S_3$, and $\rightarrow S_4$ transitions show a prominent progression in a totally symmetric carbon stretching vibration of 1400 cm^{-1} frequency (*cf.* Papers I and II). The vibrational levels related to this progression will be expressed as S_2^v *etc.*, where v refers to the quantum number of the vibration concerned (v=0, 1, 2, ⋯).

The effects of cyclohexane added as an inert foreign gas on the S_1- and S_2-fluorescence were examined by exciting the pyrene molecule into various vibronic levels. As an example, changes in fluorescence spectrum caused by addition of different pressures of cyclohexane are shown in Fig. 1 for excitation into S_4^0. Similar spectral

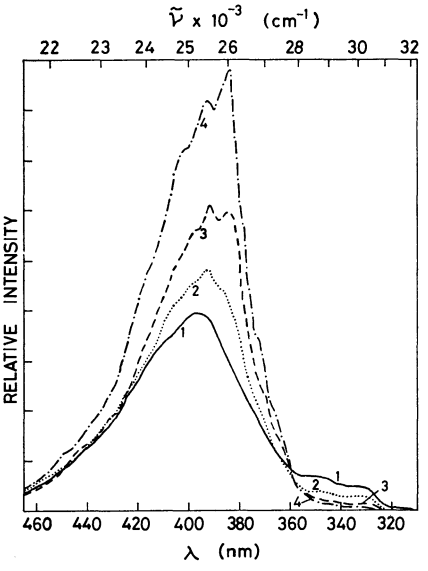

Fig. 1. Fluorescence spectra of pyrene vapor excited at 234 nm (S_4^0) in the presence of cyclohexane of different pressures: (1) 0; (2) 6.3; (3) 23.4; (4) 47.5 Torr. The relative intensity means relative quanta per unit wave-number interval.

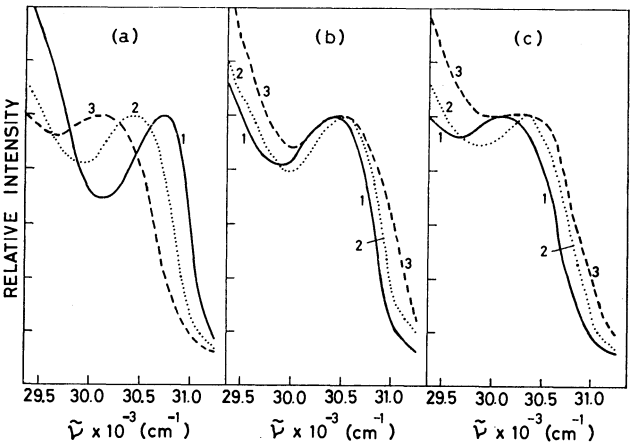

Fig. 2. S_2-fluorescence spectra (normalized) of pyrene vapor. (a) Excited in the absence of cyclohexane at different wavelengths: (1) 298 nm (S_2^2); (2) 266 nm (S_3^0); (3) 234 nm (S_4^0). (b) Excited at 266 nm (S_3^0) in the presence of cyclohexane of different pressures: (1) 0; (2) 12.5; (3) 164 Torr. (c) Excited at 234 nm (S_4^0) in the presence of cyclohexane of different pressures: (1) 0; (2) 23.4; (3) 164 Torr. The relative intensity as in Fig. 1.

changes were observed for excitation into other vibronic levels. As is seen from Fig. 1, cyclohexane has considerable effects on the fluorescence spectra both in position and in intensity. With increasing cyclohexane pressure, the S_1-fluorescence shows a blue shift and an increase in intensity, while the S_2-fluorescence shows only a slight blue shift and a marked decrease in intensity.

The blue shift of the S_1-fluorescence spectrum is clearly seen in Fig. 1. The spectral shifts of the S_2-fluorescence due to the added cyclohexane are illustrated in Fig. 2 for excitation into S_3^0 and S_4^0, together with the frequency shift that occurs on changing the excitation energy in the absence of cyclohexane, *i.e.*, in the pure pyrene vapor. The quantum yields of S_1- and S_2-fluorescence are plotted against the cyclohexane

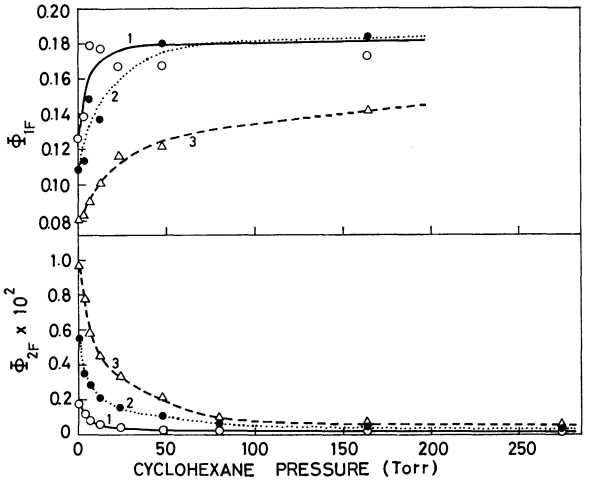

Fig. 3. Plots of Φ_{1F} and Φ_{2F} for pyrene vapor *vs.* the pressure of cyclohexane. Exciting wavelengths: (1) 298 nm (S_2^2); (2) 266 nm (S_3^0); (3) 234 nm (S_4^0).

pressure in Fig. 3 for excitation into different vibronic levels.

The lifetimes of the S_1- and S_2-fluorescence in the absence of cyclohexane, τ_1 and τ_2, are plotted in Fig. 4 against ΔE, which represents the excitation energy in excess of the $S_0^0 \rightarrow S_1^0$ transition energy. Both τ_1 and τ_2 are found to decrease with increasing ΔE. In the presence of cyclohexane, vibrational relaxation must occur in each of the excited electronic states, so that the molecules are distributed among various vibrational levels. The apparent lifetimes obtained in such a condition will be denoted by $\bar{\tau}_1$ and $\bar{\tau}_2$ (instead of τ_1 and τ_2) for S_1- and S_2-fluorescence, respectively. Figure 5 shows $\bar{\tau}_1$ and $\bar{\tau}_2$ as a function of the cyclohexane pressure. It is seen that the lifetime $\bar{\tau}_1$ increases but $\bar{\tau}_2$ decreases with the inert gas pressure, irrespective of excitation energy.

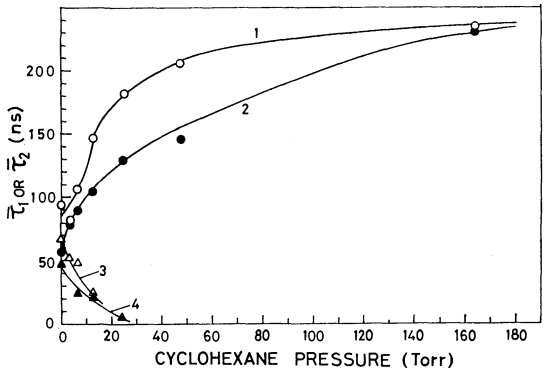

Fig. 5. Plots of $\bar{\tau}_1$ (1, 2) and $\bar{\tau}_2$ (3, 4) for pyrene vapor *vs.* the pressure of cyclohexane. Exciting and monitoring wavelengths: (1) 264.5 nm ($\sim S_3^0$), 400 nm (S_1); (2) 234 nm (S_4^0), 400 nm (S_1); (3) 264.5 nm ($\sim S_3^0$), 330 nm (S_2); (4) 234 nm (S_4^0), 330 nm (S_2).

The effects of added oxygen on the fluorescence properties of pyrene vapor are quite different from the effects of cyclohexane. The spectral changes accompanying the addition of various pressures of oxygen are shown in Figs. 6 and 7, respectively, for S_2^2 and S_4^0 excitation. It is seen that in contrast to the case of cyclohexane oxygen acts as a quencher on both S_1- and

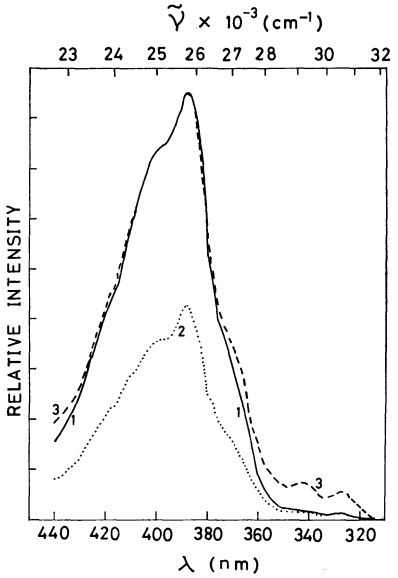

Fig. 6. Fluorescence spectra of pyrene vapor excited at 298 nm (S_2^2) in the presence of oxygen of different pressures: (1) 0; (2) 10.2; (3) 350 Torr. The relative intensity as in Fig. 1. The maximum intensities of spectra 1 and 3 are normalized to a common value (I_{max}); the maximum intensity of spectrum 2 is normalized to $I_{max}/2$.

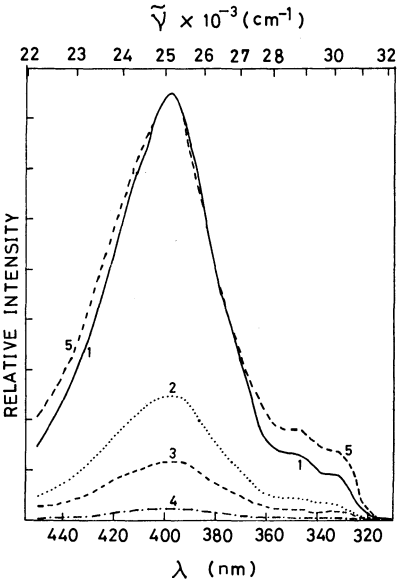

Fig. 7. Fluorescence spectra of pyrene vapor excited at 234 nm (S_4^0) in the presence of oxygen of different pressures: (1) 0; (2) 6; (3) 15; (4) 102; (5) 350 Torr. The relative intensity as in Fig. 1. The intensities of spectra 1—4 are given according to the respective observed emission signals; the maximum intensity of spectrum 5 is normalized to that of spectrum 1.

S_2-fluorescences, and that the quantum yield ratio Φ_{2F}/Φ_{1F} increases, though slightly, with increasing oxygen pressure.

In Fig. 8 Φ_{1F}^0/Φ_{1F} and Φ_{2F}^0/Φ_{2F} are plotted against the oxygen pressure for S_2^2, S_3^0, and S_4^0 excitation; here, the fluorescence quantum yields in the absence and presence of oxygen are denoted by Φ_{1F}^0 (or Φ_{2F}^0) and Φ_{1F} (or Φ_{2F}),

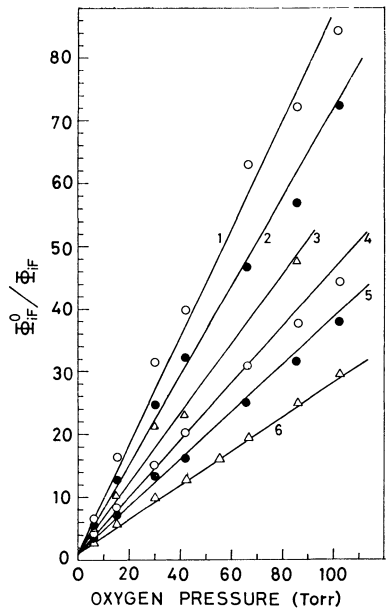

Fig. 8. Stern-Volmer plots for quenching of S_1-fluorescence (1, 2, 5) and S_2-fluorescence (3, 4, 6) of pyrene vapor by oxygen. Exciting wavelengths: (1) 298 nm (S_2^2); (2) 266 nm (S_3^0); (3) 298 nm (S_2^2); (4) 266 nm (S_3^0); (5) 234 nm (S_4^0); (6) 234 nm (S_4^0). For Φ_{iF}^0/Φ_{iF}, $i=1$ or 2.

respectively. The plots are found to be linear over a wide range of the quantum yield ratio, Φ_{1F}^0/Φ_{1F} or Φ_{2F}^0/Φ_{2F}, indicating that the Stern-Volmer equation holds in every case.

Discussion

As has been mentioned, the present experiments were made with the pyrene vapor at 0.2—0.3 Torr and 170 °C. Under these conditions, the mean time between collisions of pyrene molecules (*cf.* Paper I) is somewhat longer than the observed fluorescence lifetimes τ_1 and τ_2 (Fig. 4). It is assumed here, to the first approximation, that the pyrene molecule in the absence of a foreign gas is free from collisions in its excited state S_1 or S_2.

Intramolecular radiative and radiationless processes in polyatomic molecules can be treated both quantum-mechanically and kinetically.[2] In the following, the effects of foreign gases on the dual fluorescences of pyrene vapor will be discussed on the basis of a kinetic scheme involving reverse internal conversion, as in the case of Paper I.

For the pure pyrene vapor, the above scheme predicts that most of the S_2-fluorescence emission should occur through the reverse internal conversion, with its lifetime (τ_2) equal to that of the S_1-fluorescence (τ_1). The S_2-emission of this sort may be called slow S_2-fluorescence, because the lifetime τ_2 is very long compared not only with the lifetime of the direct or prompt S_2-fluorescence but also with the radiative lifetime of S_2 which is to be determined from the integrated absorption intensity. The experiments on the fluorescence quenching by oxygen clearly indicate that the S_2-emission is ascribable almost exclusively to the slow S_2-fluorescence. Also, the lifetime measurements show that τ_2 is comparable, though not strictly equal, to τ_1 in length.

In the absence of a foreign gas, the kinetic analysis given in Paper I is applicable. It is thus assumed that an isolated pyrene molecule is excited directly or indirectly to S_2*, *i.e.* a vibrationally excited level of S_2, and then passes to S_1* whose energy $E(S_1^*)$ is equal to the energy of S_2*, $E(S_2^*)$. It is further assumed that the molecule may return to S_2* from S_1*.

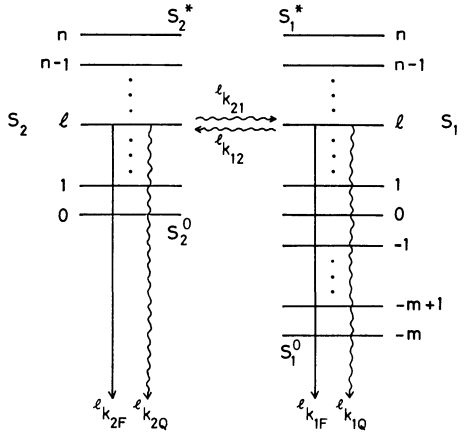

Fig. 9. A schematic diagram showing a stepladder model for vibrational relaxation in S_1- and S_2-states together with various electronic processes involved. Straight-line arrows denote radiative processes, and wiggly-line arrows radiationless processes.

Effects of Cyclohexane. In order to have an understanding of the effects of an inert foreign gas X, *i.e.* cyclohexane in this study, on the emission properties of pyrene vapor, we consider a simple stepladder relaxation model[13] illustrated in Fig. 9. We assume that only a finite series of vibrational levels, represented by $l=n, n-1, \cdots, 0$ for S_2 and by $l=n, \cdots, 0, \cdots, -m$ for S_1, participates in the collision-induced vibrational relaxation, with n, 0, and $-m$ corresponding to S_2* (or S_1*), S_2^0, and S_1^0, respectively. For $n \geqq l \geqq 0$, the vibrational levels $l(S_2)$ and $l(S_1)$ in the stepladder model are isoenergetic with each other, and reversible internal conversion is supposed to occur between them. The difference in energy between any two adjacent levels with $l \geqq 0$ or $l \leqq 0$ is equated to the amount of energy $\triangle\varepsilon$ or $\triangle\varepsilon'$ removed on the average by one collision between a pyrene and an X molecule. Thus we have simple relations $[E(S_2^*)-E(S_2^0)]/\triangle\varepsilon=n$ and $[E(S_2^0)-E(S_1^0)]/\triangle\varepsilon'=m$, where $\triangle\varepsilon'$ may or may not be equal to $\triangle\varepsilon$. Various rate constants for radiative and radiationless processes are defined in Fig. 9.

If the concentration of pyrene in a vibrational level $l(S_i)$ ($i=1$ or 2) in the stepladder model is expressed as $[l]_i$, the following general rate equations are obtained by reference to Fig. 9:

$$\frac{d[l]_2}{dt} = k_C[X][l+1]_2 + {}^{l}k_{12}[l]_1 - {}^{l}\lambda_2[l]_2 \quad (1)$$

$$\frac{d[l]_1}{dt} = k_C[X][l+1]_1 + {}^{l}k_{21}[l]_2 - {}^{l}\lambda_2[l]_1 \quad (2)$$

where

$${}^{l}\lambda_2 = {}^{l}k_{2F} + {}^{l}k_{2Q} + {}^{l}k_{21} + k_C[X] \quad (3)$$

$$ {}^{l}\lambda_1 = {}^{l}k_{1F} + {}^{l}k_{1Q} + {}^{l}k_{12} + k_C[X] \quad (4) $$

k_C is the bimolecular rate constant for the vibrational relaxation by collision and [X] is the concentration of the inert gas X; namely, $k_C[X]$ is the frequency of collision of a pyrene molecule with X molecules. Equations (1) and (3) apply to $n \geqq l \geqq 0$, and (2) and (4) to $n \geqq l \geqq -m$. However, for $l=n$, $[l+1]_i$ in Eqs. (1) and (2) is taken as equal to zero; for $l=0$ and $-m$, the term $k_C[X]$ is removed from Eqs. (3) and (4), respectively; and for $-1 \geqq l \geqq -m$, ${}^{l}k_{21}[l]_2$ in Eq. (2) and ${}^{l}k_{12}$ in Eq. (4) are eliminated. Further, in the case of steady photo-excitation, the rate of excitation (I_0) should be added to the right-hand side of Eq. (1) for $l=n$.

As will be shown later, the following relations exist among the rate constants for the pyrene molecule:

$$ {}^{l}k_{21} \gg {}^{l}k_{2F} + {}^{l}k_{2Q} \quad (5) $$

$$ {}^{l}k_{12} \gg {}^{l}k_{1F} + {}^{l}k_{1Q} \quad (6) $$

$$ {}^{l}k_{21} \gg {}^{l}k_{12} \quad (7) $$

Although the term $k_C[X]$ increases with the inert gas pressure, we have

$$ {}^{l}k_{21} \gg k_C[X] \quad (8) $$

$$ {}^{l}k_{12} \gg k_C[X] \text{ or } {}^{l}k_{12} \gtrsim k_C[X] \quad (9) $$

under the present experimental conditions.

Let us first consider the case of steady excitation. Under photostationary conditions $d[l]_i/dt=0$ in Eqs. (1) and (2). When $l=n$, it follows from Eq. (2) and inequality (6) that

$$ [n]_1/[n]_2 = {}^{n}k_{21}/({}^{n}k_{12}+k_C[X]) \quad (10) $$

Using inequalities (5)—(9), we can verify from Eqs. (1) and (2) that

$$ [l]_1/[l]_2 = {}^{l}k_{21}/{}^{l}k_{12} \quad (n-1 \geqq l \geqq 0) \quad (11) $$

It is useful to define a sort of equilibrium constant ${}^{l}K$ and an effective rate constant ${}^{l}k_{\text{eff}}$ for $n \geqq l \geqq 0$ by

$$ {}^{l}K = {}^{l}k_{21}/{}^{l}k_{12} \quad (12) $$

$$ {}^{l}k_{\text{eff}} = ({}^{l}k_2 + {}^{l}K\,{}^{l}k_1)/(1+{}^{l}K) \quad (13) $$

where

$$ {}^{l}k_i = {}^{l}k_{iF} + {}^{l}k_{iQ} \quad (i=1 \text{ or } 2) \quad (14) $$

Also, for $n \geqq l \geqq 0$, we put

$$ [l]_1 + [l]_2 \equiv [l] \quad (15) $$

We can then derive the following equations:

$$ [n] = I_0/({}^{n}k_{\text{eff}} + k_C[X]) \quad (16) $$

$$ [l-1] = [l]\frac{k_C[X]}{{}^{l-1}k_{\text{eff}} + k_C[X]} \quad (n \geqq l \geqq 1) \quad (17) $$

$$ [l-1]_1 = [l]_1\frac{k_C[X]}{{}^{l-1}k_1 + k_C[X]} \quad (0 \geqq l \geqq -m+2) \quad (18) $$

$$ [-m]_1 = [-m+1]_1 k_C[X]/{}^{-m}k_1 \quad (19) $$

Combining inequalities (7) and (8) with Eqs. (10)—(12), we obtain the relations $[l]_2 \ll [l]_1$ and ${}^{l}K \gg 1$ for $n \geqq l \geqq 0$. Hence

$$ [l]_1 \simeq [l] \quad (n \geqq l \geqq 0) \quad (20) $$

$$ [n]_2 \simeq [n]\frac{1 + k_C[X]/{}^{n}k_{12}}{{}^{n}K} \quad (21) $$

$$ [l]_2 \simeq [l]/{}^{l}K \quad (n-1 \geqq l \geqq 0) \quad (22) $$

If $k_C[X]$ is so large that ${}^{l}k_{\text{eff}} \ll k_C[X]$ for $n \geqq l \geqq 0$ and ${}^{l}k_1 \ll k_C[X]$ for $-1 \geqq l \geqq -m$, it follows from Eqs. (16)—(20) that

$$ I_0/(k_C[X]) \simeq [n] \simeq [n-1] \simeq \cdots \simeq [0] \simeq [-1]_1 \simeq \cdots \simeq [-m+1]_1 \ll [-m]_1 = I_0/{}^{-m}k_1 \quad (23) $$

We are now in a position to discuss fluorescence quantum yields. To the approximation adopted in the present study, it follows from the kinetic analyses given in Paper I that the S_1- and S_2-fluorescence quantum yields obtained on exciting the molecule to the lth level in the absence of the inert gas are

$$ {}^{l}\Phi^0_{1F} = \begin{cases} {}^{l}k_{1F}/{}^{l}k_{\text{eff}} & (n \geqq l \geqq 0) \\ {}^{l}k_{1F}/{}^{l}k_1 & (-1 \geqq l \geqq -m) \end{cases} \quad (24) $$

$$ {}^{l}\Phi^0_{2F} = {}^{l}k_{2F}/({}^{l}K\,{}^{l}k_{\text{eff}}) \quad (n \geqq l \geqq 0) \quad (25) $$

When the molecule is excited to the nth level in the presence of the inert gas, the S_1- and S_2-fluorescence quantum yields, denoted by Φ_{1F} and Φ_{2F} respectively, are given by

$$ \Phi_{1F} = \sum_{l=-m}^{n} {}^{l}k_{1F}[l]_1/I_0 \quad (26) $$

$$ \Phi_{2F} = \sum_{l=0}^{n} \frac{{}^{l}k_{2F}[l]}{{}^{l}K I_0} \quad (27) $$

Here we assume for the sake of simplicity that $k_C[X]$ is negligible in Eq. (10) or (21) compared with ${}^{n}k_{12}$. Strictly speaking, this assumption is not always valid (*cf.* (9)). We can show, however, that even if the above assumption is omitted, the results remain essentially unchanged. Under photostationary conditions the rate of excitation must be equal to the rate of deactivation, so that

$$ I_0 = \sum_{l=0}^{n} {}^{l}k_2[l]_2 + \sum_{l=-m}^{n} {}^{l}k_1[l]_1 $$

Neglecting $k_C[X]$ compared with ${}^{n}k_{12}$ as before, we can rewrite this equation as

$$ I_0 = \sum_{l=0}^{n} {}^{l}k_{\text{eff}}[l] + \sum_{l=-m}^{-1} {}^{l}k_1[l]_1 \quad (28) $$

From Eqs. (24)—(28) and Eq. (20), we obtain

$$ \Phi_{1F} = \frac{\sum_{l=0}^{n} {}^{l}\Phi^0_{1F}\,{}^{l}k_{\text{eff}}[l] + \sum_{l=-m}^{-1} {}^{l}\Phi^0_{1F}\,{}^{l}k_1[l]_1}{\sum_{l=0}^{n} {}^{l}k_{\text{eff}}[l] + \sum_{l=-m}^{-1} {}^{l}k_1[l]_1} \quad (29) $$

$$ \Phi_{2F} = \frac{\sum_{l=0}^{n} {}^{l}\Phi^0_{2F}\,{}^{l}k_{\text{eff}}[l]}{\sum_{l=0}^{n} {}^{l}k_{\text{eff}}[l] + \sum_{l=-m}^{-1} {}^{l}k_1[l]_1} \quad (30) $$

If $k_C[X]$ is large enough for the relation (23) to hold good,[14] we have

$$ \Phi_{1F} \simeq {}^{-m}\Phi^0_{1F} \quad (31) $$

$$ \Phi_{2F} \simeq \sum_{l=0}^{n} {}^{l}\Phi^0_{2F}({}^{l}k_{\text{eff}}/k_C[X]) \quad (32) $$

On the basis of the foregoing kinetic considerations, we examine the spectral data on S_1- and S_2-fluorescence. Referring to Eqs. (29) and (30), we see that Φ_{1F} and Φ_{2F} are closely related to the concentration $[l]$ of the pyrene molecules belonging to the individual levels l. According to Eqs. (16)—(19), as [X] increases, (i) $[l]/[n]$ $(n-1 \geqq l \geqq 0)$ and $[l]_1/[n]$ $(-1 \geqq l \geqq -m)$ increase though $[n]$ itself decreases; and (ii) $[l-1]/[l]$ $(n \geqq l \geqq 1)$,

$[-1]_1/[0]$, and $[l-1]_1/[l]_1$ $(-1 \geqq l \geqq -m+1)$ increase with increasing [X]. The experimental results reported in Paper I indicate that[15]

$$ {}^{n}\Phi_{1F}^{0} < {}^{n-1}\Phi_{1F}^{0} < \cdots < {}^{-m}\Phi_{1F}^{0} \qquad (33a) $$

By combining (ii) with (33a), it can be strictly verified that Φ_{1F} given by Eq. (29) possesses its lowest value ${}^{n}\Phi_{1F}^{0}$ at [X]=0, increases with increasing [X], and finally reaches its highest value ${}^{-m}\Phi_{1F}^{0}$ (see Eq. (31)).

On the other hand, the data in Paper I show that

$$ {}^{n}\Phi_{2F}^{0} > {}^{n-1}\Phi_{2F}^{0} > \cdots > {}^{0}\Phi_{2F}^{0} \qquad (33b) $$

It follows from (ii) and (33b) that, in contrast to Φ_{1F}, the quantum yield Φ_{2F} given by Eq. (30) decreases with increase in [X]. We note that ${}^{l}\Phi_{2F}^{0}$ falls off markedly with a decrease in the number l (Paper I). On increasing [X] from zero, therefore, Φ_{2F} decreases rapidly from its highest value ${}^{n}\Phi_{2F}^{0}$. At sufficiently large [X], Φ_{2F} is expressed in the form of Eq. (32), and hence it is finally reduced to zero.

These considerations are in good agreement, at least qualitatively, with the results of experiments on the intensities (Fig. 1) and quantum yields (Fig. 3) of the S_1- and S_2-fluorescence.

In order to obtain more quantitative information about the dependence of Φ_{2F} on cyclohexane pressure, we made a calculation on the basis of the stepladder model. We treated a case where the initially excited level n corresponds to $S_4{}^0$. The difference between $E(S_4{}^0)=E(S_2{}^*)$ and $E(S_2{}^0)$ is known to be about 12000 cm^{-1} (Paper I). Referring to the literature,[13] we tentatively adopted two values (500 and 1000 cm^{-1}) as $\Delta\varepsilon$. It then follows that $n=24$ and 12, respectively, for $\Delta\varepsilon=$ 500 and 1000 cm^{-1}. According to Eqs. (16), (25), and (27), Φ_{2F} can be expressed in the form

$$ \Phi_{2F} = \sum_{l=0}^{n} {}^{l}\Phi_{2F}^{0} \frac{{}^{l}k_{eff}}{{}^{n}k_{eff}+k_C[X]} \frac{[l]}{[n]} \qquad (34) $$

In Eq. (34), the observed S_2-fluorescence quantum yield as a function of excitation energy (Paper I) was used for ${}^{l}\Phi_{2F}^{0}$. The effective rate constant ${}^{l}k_{eff}$ was assumed to be equal to the reciprocal of the S_1-fluorescence lifetime τ_1 (*vide infra*), which has been measured in the present study as a function of excitation energy (Fig. 4). The rate constant k_C was determined from the standard gas kinetic theory, molecular diameters of 8 and 4 Å being assigned to pyrene and cyclohexane, respectively; the result is $k_C=9.8\times10^6$ $Torr^{-1}$ s^{-1} at 170 °C. The ratio of concentrations, $[l]/[n]$, can be calculated by using Eq. (17) repeatedly. The curves thus obtained theoretically for Φ_{2F} as a function of cyclohexane pressure reproduce fairly well the experimental data, *i.e.*, the lower curve 3 in Fig. 3. The experimental curve lies between the two theoretical ones corresponding to $\Delta\varepsilon=500$ and 1000 cm^{-1}; the latter $\Delta\varepsilon$ value leads to a more favorable result.

The changes in position and shape of the fluorescence spectra on increasing the inert gas pressure must be caused by changes of the extents to which different levels l contribute to the fluorescence transitions concerned.

From Eqs. (16)—(20), (23), and (26) or (29) we may predict that the S_1-fluorescence band will shift toward the position of the emission originating from lower levels, *i.e.* toward the blue, upon increasing the inert gas pressure; and finally, as is seen from Eq. (31), the S_1-fluorescence will originate from the lowest vibrational level of S_1 which gives emission at the shortest wavelengths. The above prediction is in agreement with the behavior of S_1-fluorescence shown in Fig. 1.

The numbers l of the levels responsible for the S_2-fluorescence are such that $n \geqq l \geqq 0$. According to the relations (17) and (23), $[n]>[n-1]>\cdots>[0]$ for any value of [X], and $[n]\simeq[n-1]\simeq\cdots\simeq[0]$ for large [X]. Moreover, as has been mentioned, ${}^{l}\Phi_{2F}^{0}$ decreases rapidly with decreasing l. It then follows from Eq. (27) or (30) that the emissions from the levels with higher l numbers make relatively large contributions to the S_2-fluorescence, irrespective of inert gas pressure. This accounts for the finding that the S_2-fluorescence band shows only small blue shifts even at high inert gas pressures, in contrast to the case where the excitation energy is decreased (Paper II and Fig. 2).

We next proceed to the case of transient processes following the pulse excitation by the breakdown spark. We substitute n for l in both Eqs. (1) and (2), and remove the first terms of the right-hand sides of these equations. In the absence of the inert gas, the fourth terms on the right-hand sides of Eqs. (3) and (4) also are removed. The solution of Eqs. (1) and (2) thus modified is well known.[12] When the relations (5) and (6) hold, $[n]_2$ and $[n]_1$ are expressed in the forms

$$ [n]_2 = [n]_2^0 \left\{ \frac{{}^{n}K}{1+{}^{n}K} \exp(-{}^{n}\tilde{\lambda}_2 t) + \frac{1}{1+{}^{n}K} \exp(-{}^{n}\tilde{\lambda}_1 t) \right\} \qquad (35) $$

$$ [n]_1 = [n]_2^0 \frac{{}^{n}K}{1+{}^{n}K} \{ -\exp(-{}^{n}\tilde{\lambda}_2 t) + \exp(-{}^{n}\tilde{\lambda}_1 t) \} \qquad (36) $$

where

$$ {}^{n}\tilde{\lambda}_2 = {}^{n}k_{21} + {}^{n}k_{12} \qquad (37) $$

$$ {}^{n}\tilde{\lambda}_1 = {}^{n}k_{eff} \equiv 1/{}^{n}\tau_{eff} \qquad (38) $$

$[n]_2$ at $t=0$ is written as $[n]_2^0$, while $[n]_1$ is assumed to be zero at $t=0$.

Since ${}^{n}\tilde{\lambda}_2 \gg {}^{n}\tilde{\lambda}_1$, after a very short time, δt, of the order of $1/({}^{n}k_{21}+{}^{n}k_{12})$, $[n]_2$ and $[n]_1$ will decay with a common rate constant, ${}^{n}k_{eff}$. In the range of time longer than δt, it follows from Eqs. (35) and (36) that $[n]_1/[n]_2={}^{n}K$, that is, a sort of dynamic equilibrium is attained.[12] Note that this equation is obtained also by putting [X] $=0$ in Eq. (10).

Because of the duration (~70 ns) of the flash employed, the present experiments on the time behavior of the dual fluorescences must be concerned with the range of time ($>\delta t$) mentioned above. It is thus expected that the observed lifetimes τ_1 and τ_2 are identical and both are equal to ${}^{n}\tau_{eff}$ defined by Eq. (38). Since ${}^{n}K \gg 1$ in Eq. (13). ${}^{n}\tau_{eff}$ is nearly equal to $1/{}^{n}k_1$, which is estimated to be about 10^2 ns and is much longer than the radiative lifetime ($1/{}^{n}k_{2F}$) of S_2, 6 ns from the integrated absorption intensity (Paper I). The lifetime data given in Fig. 4 indicate that τ_2 is, indeed, considerably longer than the radiative lifetime of S_2. In contrast to the results of kinetic considerations, however, τ_2 is slightly shorter than τ_1. This discrepancy in value between the two lifetimes has been interpreted by Deinum *et al.* as due in part to sequence congestion effects.[8]

Suppose now that the pyrene molecule is excited into the level with $l=n$ by a light pulse in the presence of cyclohexane. As the time proceeds, the lower levels $l=n-1$, $n-2$, $\cdots$ are populated owing to the vibrational relaxation caused by the collision, and the fluorescence is emitted also from these levels. On account of the relations (5)—(9), a dynamic equilibrium will be reached in each of the emitting levels. It is then expected from the relations (33a) and (33b) that an increase in cyclohexane pressure will result in a decrease and an increase in decay rate of the S_1- and S_2-fluorescence, respectively. In other words, the apparent lifetime $\bar{\tau}_1$ will be lengthened but $\bar{\tau}_2$ will be shortened, in agreement with the observations illustrated in Fig. 5.

Effects of Oxygen. When oxygen is added to the pyrene vapor, the S_1- and S_2-fluorescence emissions are quenched, but their spectral shapes and positions are little changed (see Figs. 6 and 7), suggesting that the vibrational relaxation is not induced by collision with oxygen. We are therefore concerned here solely with the vibronic level S_2*, which is initially excited (directly or indirectly), and its isoenergetic partner S_1*. The rate equations and related quantities that have hitherto been used for the vibrational level, $l=n$, can be applied to the case of oxygen quenching by making pertinent modifications. The superscript n will hereafter be eliminated.

The oxygen-quenching rate of the vibronic state S_i* may be expressed in the form $wk_C[Y][S_i^*]$, where [Y] is the concentration of the quencher Y, *i.e.* oxygen, and w is a factor representing the probability that one collision quenches S_i*. In the present study the following relations hold: $k_{21} \gg wk_C[Y]$ and $k_{12} \gg wk_C[Y]$ or $k_{12} \gtrsim wk_C[Y]$ (*cf.* relations (8) and (9)). Thus, under photostationary conditions, it follows from Eqs. (16), (20), and (21) that

$$\Phi_{1F} = k_{1F}/(k_{eff}+wk_C[Y]) \tag{39}$$

$$\Phi_{2F} = \frac{k_{2F}}{k_{eff}+wk_C[Y]} \frac{1+wk_C[Y]/k_{12}}{K} \tag{40}$$

where K and k_{eff} are defined by Eqs. (12) and (13). The quantum yields in the absence and the presence of Y will be denoted, respectively, by Φ_{iF}^0 and Φ_{iF}. Then Eqs. (39) and (40) lead to the following equations of the Stern-Volmer type:

$$\Phi_{1F}^0/\Phi_{1F} = 1 + wk_C\tau_{eff}[Y] \tag{41}$$

$$\frac{\Phi_{2F}^0}{\Phi_{2F}} = \frac{1+wk_C\tau_{eff}[Y]}{1+wk_C[Y]/k_{12}} \tag{42}$$

with $\tau_{eff}=1/k_{eff}$. Unless $wk_C[Y]$ is of comparable magnitude to k_{12}, the denominator on the right-hand side of Eq. (42) may be equated to unity.

The Stern-Volmer plots shown in Fig. 8 are in general agreement with the prediction from Eqs. (41) and (42), except that two straight lines resulting from the plots of the quantum yield ratios Φ_{1F}^0/Φ_{1F} and Φ_{2F}^0/Φ_{2F} which were measured with the same excitation energy have somewhat different slopes. Such a difference between the slopes may be attributed to the fact that the observed lifetimes τ_1 and τ_2, which are both identified as τ_{eff}, are not strictly equal to each other, as has already been mentioned.

Table 1. Kinetic data on quenching of S_1- and S_2-fluorescence by oxygen

Fluorescing state	Exciting wavelength (nm)	Slope of Stern-Volmer plot ($Torr^{-1}$)	Lifetime τ_1 or τ_2 (ns)	$wk_C \times 10^{-11}$ (1 mol^{-1}. s^{-1})	w
S_1	324 (S_2^0)	1.14	157	2.00	0.77
	298 (S_2^2)	0.93	116	2.20	0.85
	266 (S_3^0)	0.71	92	2.14	0.82
	257 (S_3^1)	0.66	81	2.26	0.87
	234 (S_4^0)	0.39	54	1.98	0.75
	226 (S_4^1)	0.36	52	1.93	0.74
S_2	298 (S_2^2)	0.54	—	—	—
	266 (S_3^0)	0.43	65	1.83	0.71
	257 (S_3^1)	0.40	—	—	—
	234 (S_4^0)	0.30	45	1.84	0.71
	226 (S_4^1)	0.24	—	—	—

The values for the quenching rate constant wk_C, obtained at various exciting wavelengths, are listed in Table 1, together with the slopes and lifetimes from which the wk_C values were derived. In contrast to the considerable variation of the lifetimes with exciting wavelength, both S_1- and S_2-fluorescence emissions show comparatively constant wk_C values, ranging from 1.8×10^{11} to 2.3×10^{11} l mol^{-1} s^{-1}, regardless of the excitation energy. Assuming molecular diameters to be 8 and 2 Å for pyrene and oxygen, respectively, we obtain $k_C=2.6\times 10^{11}$ l mol^{-1} s^{-1} (or 9.4×10^6 $Torr^{-1}$ s^{-1}) at 170 °C from the gas kinetic theory. Dividing the experimental wk_C value by the theoretical k_C, we get the probability factor w. The w values thus determined are found to be rather close to unity (Table 1). Although some assumptions are involved in the evaluation of w, it may be concluded that the quenching of the dual fluorescences of pyrene vapor by oxygen is very efficient.

Inspection of the data in Table 1 at exciting wavelengths of 234 and 266 nm reveals that the difference in question between the slopes of the Stern-Volmer plots is due mainly to the difference between τ_1 and τ_2. For a given exciting wavelength, the S_2-fluorescence has a small slope compared with the S_1-fluorescence, so that the intensity of the S_2-fluorescence spectrum relative to that of the S_1-fluorescence increases with the oxygen pressure. As a result, the S_2-fluorescence spectrum becomes more distinct at higher oxygen pressures (see Figs. 6 and 7). In the case of spectral curve 3 in Fig. 6 (S_2^2 excitation at 350-Torr oxygen pressure), the S_2-fluorescence can be observed very clearly, and its intensity relative to the intensity of the S_1-fluorescence is somewhat higher than expected from extrapolation of the linear plots shown in Fig. 8. A conceivable reason for the occurrence of this phenomenon is that in the case concerned the denominator on the right-hand side of Eq. (42) is appreciably larger than unity.

Relations between Rate Constants. In Paper I we attempted to determine the values of the rate constants k_{21} and k_{12}. For that purpose the S_2-fluorescence quantum yield Φ_{2F} was divided into two parts, that is, $\Phi_{2F}=\phi_{2F}+\phi_{12F}$, where ϕ_{2F} and ϕ_{12F} correspond to the quantum yields of the prompt and slow fluorescence

emissions, respectively. The ratio of ϕ_{12F} to ϕ_{2F} was then expressed as

$$\phi_{12F}/\phi_{2F} = \Phi_{1F}(k_{12}/k_{1F}) \quad (43)$$

On the assumption that the residue of S_2-fluorescence at a high pressure of cyclohexane (~70 Torr) ocrresponds to ϕ_{2F}, the ratio ϕ_{12F}/ϕ_{2F} was estimated to be 25 for S_4^0 excitation. As is seen in Fig. 3, Φ_{2F} is still decreasing at a cyclohexane pressure of 70 Torr. Furthermore, the contribution of thermal repopulation to Φ_{2F} (Paper I) cannot be ignored at high cyclohexane pressures. The figure 25 for ϕ_{12F}/ϕ_{2F}, therefore, should be regarded as a tentative one.

As has been mentioned, oxygen quenches the S_1 and S_2 states of pyrene very efficiently, so that practically no vibrational relaxation takes place even at oxygen pressures higher than 100 Torr. Hence, it is not necessary to take account of the thermal repopulation effect when oxygen is used as a foreign gas. So far as the Stern-Volmer plot based on Eq. (42) is linear, the prompt fluorescence yield, ϕ_{2F}, should be negligible compared with ϕ_{12F}. On the basis of these considerations, we inferred from such experimental data as shown in Figs. 6—8 that $\phi_{12F}/\phi_{2F} \gtrsim 10^2$ irrespective of excitation wavelength. It then follows from Eq. (43) that $k_{12} \gtrsim 10^9$ s^{-1}, since k_{1F} is 10^6 s^{-1} (Paper I). On the other hand, according to Paper I,

$$k_{21} \simeq k_{12}\frac{\Phi_{1F}}{\Phi_{2F}}\frac{k_{2F}}{k_{1F}} \quad (44)$$

Φ_{1F}/Φ_{2F} is ~10 for S_4^0 excitation and increases with decreasing excitation energy, and k_{2F} is known to be 1.7×10^8 s^{-1} (Paper I); hence $k_{21} > 10^{12}$ s^{-1}. Thus, it may safely be said that the relations (5)—(7) hold at excitation wavelengths adopted in the present study.

Concluding Remarks. In this paper we hold the view that electronic processes in an isolated pyrene molecule may be treated kinetically on the basis of a scheme in which internal conversion is reversible between S_1* and S_2*, and thereby we can explain, to a good extent, the effects of cyclohexane and oxygen on the dual fluorescences of pyrene vapor. Along this line, it is concluded from the results of the present study that the S_2-fluorescence consists mainly of a slow component originating from S_2* which is in equilibrium with S_1*.

Quantum-mechanically, an intermediate strong coupling[8,16] is expected to occur between S_2* and S_1* because of a small electronic energy gap (3900 cm^{-1}) between the S_2 and S_1 states of the pyrene molecule. The coupling of an S_2* vibronic state with S_1* states that are quasidegenerate with S_2* yields compound states, and results in an anomalously long lifetime of the S_2-fluorescence. Thus, a good correspondence between the kinetic and quantum-mechanical schemes is obtained, as has recently been pointed out by Lahmani *et al.*[2]

Although it is predicted from each of the two schemes that the lifetimes τ_1 and τ_2 for the S_1- and S_2-fluorescence emissions should be equal, there is a slight but systematic difference between the actually obtained values of τ_1 and τ_2. Owing to sequence congestion, the thermal distribution of vibrational energy in the electronic ground state is transferred to the excited state even if a molecular system is excited with light of a given energy. According to Deinum *et al.*[8] the sequence congestion, along with the rapid increase of Φ_{2F}/Φ_{1F} with the excess vibrational energy, may account for about half of the lifetime difference. Further studies must be made to settle this problem.

We wish to express our thanks to Mr. Yoshio Shindo, Mr. Masahisa Fujita, and Mr. Masakatsu Aoi for their help in carrying out the experiments.

Vapor-Phase Photolysis of *cis*- and *trans*-4,5-Dimethylcyclohexenes

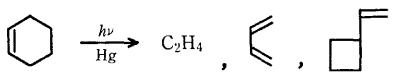
Yoshihisa INOUE,* Setsuo TAKAMUKU, and Hiroshi SAKURAI

The Institute of Scientific and Industrial Research, Osaka University, Yamadakami, Suita, Osaka 565

(Received April 12, 1975)

Direct and sensitized photolyses of 4,5-dimethylcyclohexene vapor were investigated using a stereochemical approach at room temperature over the pressure range from 1 to 9 Torr. In the direct photolysis, decomposition of the retro-Diels-Alder type was the main course of the reaction, leading to the formation of 2-butene and 1,3-butadiene with the retention of the original configuration; 3,4-dimethyl-1-methylenecyclopentane was also formed as a minor product from a pressure-independent process. Mercury sensitization, on the other hand, produced *cis*- and *trans*-2-butenes, butadiene, 2,3-dimethyl-1-vinylcyclobutane, and *cis-trans* isomers of the substrate together with radical-induced products, *i.e.*, hydrogen, 1,2-dimethylcyclohexane, and dimeric products. The intermediacy of a "*hot*," "*triplet*" *biradical* was suggested from the pressure-dependence of the *trans*- to *cis*-2-butene ratio in the mercury sensitization. The differences in the results between the direct and sensitized photolyses are interpreted in terms of spin correlation effects.

Few studies have been reported on the direct photolysis of cycloalkenes, although there is some literature on the mercury-sensitized photolysis of this species.[1] Regarding the cyclohexene derivatives dealt with in the present report, Gunning *et al.* have investigated in detail the kinetics of the mercury-sensitized photolysis of cyclohexene itself.[1a] They proposed a biradical



mechanism for the formation of ethylene, butadiene and vinylcyclobutane, which involves an alkyl-allyl biradical produced by the familiar allylic C–C bond cleavage, and the kinetics seem to support this mechanism. De Maré has reported on the mercury-sensitized photolysis of 3-methylcyclohexene vapor *via* a similar reaction mechanism.[2] However, little evidence has been obtained regarding the nature of the intermediate species and the mechanism involved. We have elucidated the reaction mechanism of the vapor-phase photolysis of cycloalkene using a stereochemical approach.

Recently it has been shown that the spin multiplicity of the intermediate 1,4-biradical drastically affects the stereochemistry of the reaction in Norrish type-II photocleavage,[3] as well as in other systems.[4] A study of the direct and sensitized photolyses of *cis*- and *trans*-4,5-dimethylcyclohexenes (**1c** and **1t**) is of interest since the results are expected to provide insight into both the reaction mechanism and the spin correlation effects.

Experimental

Materials. *cis*- and *trans*-4,5-Dimethylcyclohexenes were prepared according to procedures similar to those described by Peter *et al.*[5] *cis*-4,5-Dihydroxymethylcyclohexene, prepared by the reduction of *cis*-cyclohexene-4,5-dicarboxylic anhydride with $LiAlH_4$ in ether, was converted into ditosylate by a reaction with *p*-toluenesulfonyl chloride in dry pyridine. The *cis*-ditosylate was reduced in turn to *cis*-4,5-dimethylcyclohexene by $LiAlH_4$ in ether. The dimethyl ester of *trans*-cyclohexene-4,5-dicarboxylic acid, prepared by a Diels-Alder reaction of dimethyl fumarate with 1,3-butadiene at 200 °C for 3 hr in an autoclave,[6] was reduced to *trans*-4,5-dimethylcyclohexene by similar successive treatments with $LiAlH_4$, *p*-toluenesulfonyl chloride, and again $LiAlH_4$. All the compounds prepared were identifield by means of infrated and NMR spectrometry. *cis*- and *trans*-Dimethylcyclohexenes thus obtained were purified by preparative gas chromatography (gc) on a 6 m polyethylene glycol-6000 column. Quantitative analysis by gc indicated that the purities of **1c** and **1t** are at least 99.9 and 98.0%, respectively. Samples of **1t** contained a small amount (1%) of **1c** as an impurity. A correction was applied to all of the data for the presence of the impurity. The samples of **1c** and **1t** were admitted to a vacuum line, dried over evaporated sodium, and degassed at liquid nitrogen temperature before use.

The NMR spectra of **1c** and **1t** were in good agreement with those reported by Peter *et al.*[5] Their steric configurations were confirmed by the gc comparison of commercially available *cis*- and *trans*-1,2-dimethylcyclohexanes with the saturated compounds obtained from the hydrogenation of **1c** and **1t** on 5% Pd–charcoal.

Apparatus and Procedure. All the experiments were carried out at room temperature and under static conditions. A cylindrical cell, 5 cm long and 5 cm in diameter, made of Suprasil and a mercury-free vacuum system were available for the vapor-phase direct photolysis. The direct irradiation was run using a 30 W low-pressure mercury lamp fitted with a Suprasil envelope, the light path being flushed with nitrogen gas. The mercury-sensitized photolysis was carried out using a quartz cell of similar size, a conventional vacuum system, and the same mercury lamp fitted with a Toshiba UV-25 filter which removes the 1849-Å resonance line of mercury. The lamp was allowed to warm up for at least 30 min before each run in order to reach stable operating conditions. The quantum yields in mercury-sensitization were determined by ethylene (100 Torr) actinometry.[7] The absorption of the incident radiation was incomplete in the cell and appropriate corrections were made in the determination of the quantum yields.

After each run, materials were trapped in a capillary at liquid nitrogen temperature. The noncondensable products were analyzed and measured by a combination of Toepler pump, gas burette, and Pd-chamber. The condensable material was analyzed by gc on a 6 m column of 20% β,β'-oxydipropionitril (ODPN) on 60/80 Celite 545 at 50—70 °C. The stereoisomers of 2-butene were clearly separated from one another under these conditions, while a trace amount of the stereoisomers of **1** could not be separated from one another enough for quantitative analysis, especially in the higher pressure (>3 Torr) experiments. The analyses of the dimeric products from the mercury-sensitization were conducted by gc on a 3 m column of polyethylene glycol-6000 on Celite at 150 °C and a 1.5 m column of FFAP on Celite at 150 °C. The molecular weights of the dimers were confirmed

using a Hitachi RMS-4 gc-mass spectrometer.

Identification of 2,3-Dimethyl-1-vinylcyclobutane (3). Mercury sensitization of **1c** was carried out on a prepatative scale using the mercury lamp and an apparatus composed of a 5 l Pyrex vessel, two 100 ml quartz cells for irradiation, and a thermosiphon for circulation of the gas. The irradiation of **1c** with 10% nitric oxide in the presence of mercury was run at 1 Torr for 15 hr. The photolyzed sample was trapped at liquid nitrogen temperature and then subjected to preparative gc in order to isolate **3**. The NMR spectrum of **3** was obtained with TMS as an internal standard in CCl_4 and showed three vinyl protons at δ 5.5—6.0(m), 4.9(d), and 4.95(d), six methyl protons at 1.0(d), and five cyclobutyl protons at 1.2—2.2(m). The mass spectrum indicated the following relative intensities: *m/e*, 110(2.1), 95(28.3), 81(40.5), 69(45.5), 68(67.8), 67(70.7), 56(35.1), 55(100), and 54(6.4). These spectral data indicate a 2,3-dimethylvinylcyclobutane structure of **3**, but its steric configuration is not known. The mercury sensitization of **1t** also produced a compound which has the same retention time on the gc and an identical mass spectrum with that of **3**. Consequently, it is considered that the mercury sensitization of both **1c** and **1t** produced dimethylvinylcyclobutane **3** with an identical steric configuration.

Identification of 3,4-Dimethyl-1-methylenecyclopentane (2). Eighty mg of **1c** in a sealed Suprasil tube, 2 mm in diameter, was photolyzed in the liquid phase without a solvent using a 30 W low-pressure mercury lamp. The irradiation was continued for 350 hr resulting in a conversion of *ca.* 10% and the photolyzed sample was subjected to preparative gc to isolate **2c**. The NMR spectrum of **2c** was obtained with TMS in CCl_4, and showed two olefinic protons at δ 3.5(s), six methyl protons at 0.86(d), and six other protons at 1.8—2.4(m). The mass spectrum of **2c** indicated the following relative intensities: *m/e*, 110(26.9), 95(100), 81(32.6), 69(20.0), 68(32.3), 67(60.0), 55(47.7), and 54(26.2). The gc analysis on an ODPN column indicated that the isolated C_8H_{14} isomer has a shorter retention time relative to those of the authentic samples of *cis*-3,4-*trans*-4,5-, *cis*-4,5-, 2,3-, 1,2-dimethylcyclohexenes and 2-methyl-1-methylenecyclohexane, and that the retention time of the saturated compound, prepared by hydrogenation of **2c** on Pd–charcoal, is different from that of *trans*- or *cis*-1,2-dimethylcyclohexane. All the data described above suggest a 3,4-dimethyl-1-methylenecyclopentane structure for **2c**, the steric configuration of which is deduced to be *cis* from that of the starting material(**1c**).

Vapor-phase direct photolysis of **1c** produced the same C_8H_{14} compound (**2c**), the mass spectrometric, gas chromatographic, and chemical (hydrogenation) features of which were identical with those of the **2c** obtained in the liquid-phase photolysis of **1c**. Vapor-phase photolysis of **1t** afforded another C_8H_{14} isomer (**2t**), which has a shorter retention time on ODPN relative to that of **2c**. The mass spectrum of **2t** indicated: *m/e*, 110(33.0), 95(100), 81(41.7), 69(33.0), 68 (46.1), 67(60.0), and 55(54.8). The structure of **2t** was identified to be *trans*-3,4-dimethyl-1-methylenecyclopentane on the basis of resemblance of the mass spectra.

Results

Direct Photolysis. As major decomposition products, 2-butene and 1,3-butadiene were obtained together with a minor isomeric product, 3,4-dimethyl-1-methylenecyclopentane (**2**), in the direct photolysis of **1c** and **1t** at a substrate pressure of 5 Torr, as shown in Table 1. Dimeric products and a vinylcycloalkane derivative, which are usually produced in the mercury-sensitized photolysis of cycloalkenes,[1] were not detected in significant yields. The total yield of 2-butenes was equal to that of butadiene. The photolysis of **1c** and **1t** at 5 Torr gave almost selectively *cis*- and *trans*-2-butenes at *cis-trans* ratios of 16: 1 and 1: 20, respectively. Irradiation of **1** through a UV-25 filter did not result in any products under comparable conditions.

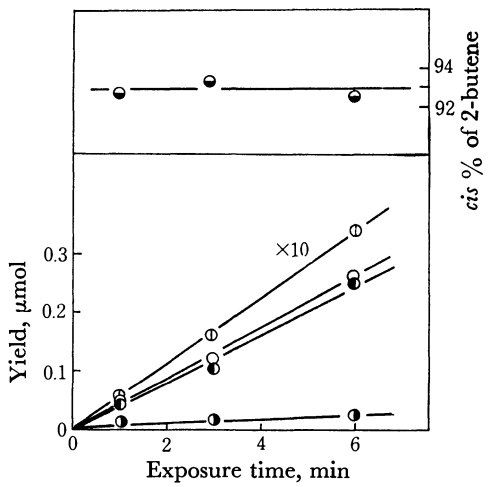

Fig. 1. Product yields as a function of exposure time in direct photolysis of **1c** (8 Torr). ◐, *cis*-2-butene; ◑, *trans*-2-butene; ○, 1,3-butadiene; ⊕, *cis*-3,4-dimethyl-1-methylenecyclopentane (×10); ◒, *cis* % of 2-butene.

The effects of exposure time on the product yields were examined in the photolysis of **1c** at a pressure of 8 Torr, since the further irradiation of initially formed 2-butene could produce isomeric 2-butene.[8] According to the data appearing in Fig. 1, all the yields increase linearly with exposure time, which indicates that these are the products from the primary process. The percentage of *cis*-2-butene, on the other hand was constant over the range of 1—6 min, and therefore, the isomeric 2-butene cannot result from the further photoisomerization. Direct photolysis of **1c** was performed over the pressure range of 1—8 Torr. The results are shown in Fig. 2. Although the pressure range was limited by the low vapor pressure of the substrate, the suppressing effect of pressure on the formation of butene and butadiene is evident from the data. The percentage of *cis*-2-butene was independent of the pressure, in spite of the decrease in the yields with increasing pressure. The yield of **2c** remained constant over the entire pressure range.

Mercury-sensitized Photolysis. The products of the mercury sensitization were hydrogen, 2-butene,

1,3-butadiene, 2,3-dimethylvinylcyclobutane (**3**), 1,2-dimethylcyclohexanes, and some dimeric products. The gas chromatographic and mass spectrometric analyses of the dimeric products showed that the dimeric fraction is composed of at least five compounds, the molecular weights of which are in the range of 218—222. The mass spectra of the dimers appears to suggest the absence of cyclodimers of **1**. On the basis of these results and observations in other systems,[1] the dimeric products were assumed to have a bicyclohexyl, cyclohexylcyclohexene, or bicyclohexenyl skeleton. The quantum yields of all products except the dimers are shown in Table 2. The distribution of the products from shorter exposure time (1 min) experiments is in good agreement with this result. The total yield of the 2-butenes equals that of butadiene. The 2-butene resulting from the mercury sensitization was predominantly *trans* even when **1c** was used. In addition, the photolysis of both **1c** and **1t** produced dimethylvinylcyclobutane having the same steric configuration as the major product.

A pressure-dependent study was also carried out for the mercury sensitization of **1c** and **1t**. In order to further examine the pressure effects, a higher pressure experiment was also performed above vapor pressure limit of the substrate using **1c** (3 Torr) with xenon added (112 Torr). The results are plotted in Figs. 3 and 4. While the suppressing effect of the pressure on the yields of 2-butene, butadiene, and **3** is evident, the 1,2-dimethylcyclohexane yields show no pressure dependence above *ca.* 5 Torr in the photolysis of both **1c** and **1t**.

An inhibiting experiment was performed with a small amount of nitric oxide added since radical-initiated reactions caused by excited mercury atoms are well-known in the mercury sensitization of hydrocarbons.[9] As can be seen from Table 3, the formation of 1,2-dimethylcyclohexane and the dimeric products were completely suppressed by the addition of nitric oxide which acts as a radical scavenger, while the yields of the other products merely decreased to a small extent.

a) Not detected.

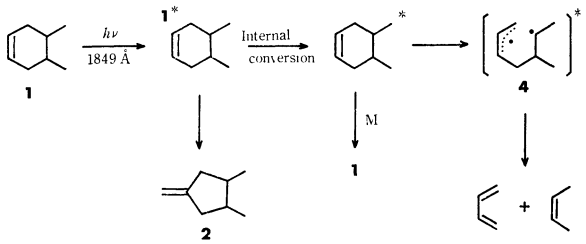
In other experiments, it was observed qualitatively that (i) the sensitized decomposition of **1c** (5 Torr) at 2537 Å in the vapor phase with benzene vapor (5 Torr) as a sensitizer did not produce detectable amounts of any products and (ii) irradiation at 1849 Å of **1c** in the liquid phase with no solvent produced no detectable yields of 2-butene, butadiene, or **3**. The only detectable products were saturated *cis*-1,2-dimethylcyclohexane and isomerized *cis*-3,4-dimethyl-1-methylenecyclopentane (**2c**).

Over the temperature range of 400—700 °C, pyrolyses of **1c** and **1t** were conducted using a Shimadzu PYR-2A pyrolyzer-gas chromatograph. The products of the pyrolysis were merely decomposition products of lower molecular weight, and no 2-butene, butadiene or isomeric product was detected in significant amounts.

Discussion

Decomposition of the retro-Diels-Alder type appears to be the main course of the direct photolysis of **1** in the vapor phase, which results in the stereospecific formation of 2-butene together with an equimolar amount of butadiene. No detectable amounts of 2-butene and butadiene were formed in the direct photolysis of **1** in the liquid phase. Irradiation through a UV-25 filter produced no products in the direct photolysis of **1** in the vapor phase. From these results and the stereospecificity of the reaction, it is inferred that **1** is promoted to an electronically excited singlet state principally by the 1849 Å resonance line of mercury and then decomposes directly or *via* a short-lived biradical produced by an allylic C–C bond cleavage into 2-butene and butadiene with the retention of its original configuration. It is, however, difficult to determine if these are direct products from the electronically-excited states or if significant amounts are formed as a result of decomposition after internal conversion to a vibrationally-excited ground state.

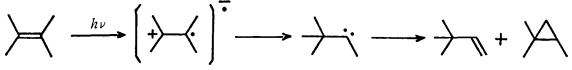
The most significant observation in the direct photolysis of **1c** is the effect of pressure, resulting in a decrease in the yields of the decomposition products with increasing pressure, whereas the yield of *cis*-3,4-dimethyl-1-methylenecyclopentane (**2c**) remains constant. The **2c** observed is, therefore, considered to be formed in a pressure-independent process,* probably from an electronically-excited singlet state which has a lifetime short compared to the effective time between deactivating collisions even at higher pressures. On the other hand, the high pressure dependence of the yields of the other decomposition products suggests that these are the products from a vibrationally-excited ground state, since with molecules of this size, the lifetimes should be long enough to permit collisional deactivation of any energetic ground-state species which might be formed *via* an internal conversion process. This elucidation is also supported by the observation that only **2c** is formed in the liquid-phase photolysis of **1c**, in which vibrational energy is quickly removed. Although 2-butene and butadiene were not detected in the attempted pyrolysis of **1** at 400—700 °C, the vibrationally-excited ground state species as the intermediate in direct photolysis cannot be eliminated from this result since raising the temperature from room temperature to 700 °C is considered to involve very little energy difference relative to the large energy input of the direct photolysis.



Scheme 1.

The detailed mechanism of the photodecomposition of **1** to 2-butene and butadiene is of interest in this work. The fact that several % *trans*-2-butene is formed from **1c** and also *cis*-2-butene from **1t** seems to suggest the biradical mechanism as opposed to the concerted path. However, there may be another possibility that the electronically-excited singlet state of **1** undergoes inter-

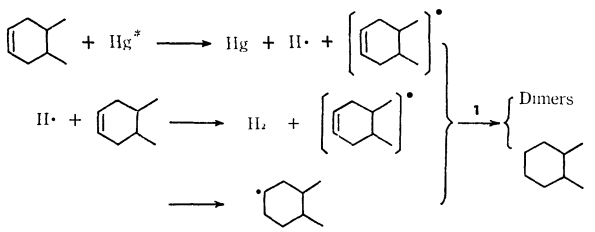
* The formation mechanism of **2** is of interest. Fields and Kropp have reported that only tetrasubstituted alkenes undergo photorearrangement of the alkyl group *via* π,R(3*s*) Rydberg excited states on direct irradiation in a pentane solution; T. R. Fields and P. J. Kropp, *J. Amer. Chem. Soc.*, **96**, 7759 (1974).



In the present system, although the nature of the electronically-excited state involved is uncertain, the disubstituted alkene **1** seems to undergo a similar photorearrangement producing **2** upon direct irradiation in both the liquid and vapor phases. We have also observed photoisomerization of cycloheptene to carbene-derived products, *i.e.*, methylenecyclohexane and norcarane, on direct photolysis in the liquid phase. The detailed mechanism and the nature of the intermediate of these rearrangements are under investigation and will be the subject of a separate report.

system crossing in part to a triplet species, which would give nonstereospecific 2-butene in a manner similar to the sensitized photolysis described below. Although such a process is important in the photolysis of aromatic and carbonyl compounds,[10] it is believed that the large difference in energy causes singlet-triplet intersystem crossing to be very slow in such a monoolefin. The absence of the vinylcyclobutane **3** in the direct photolysis of **1** also indicates the low efficiency of the intersystem crossing since photoisomerization to **3** is characteristic of triplet species as shown in the mercury sensitization of **1**. It is therefore concluded that the photodecomposition of **1** proceeds *via* the short-lived singlet biradical **4**.

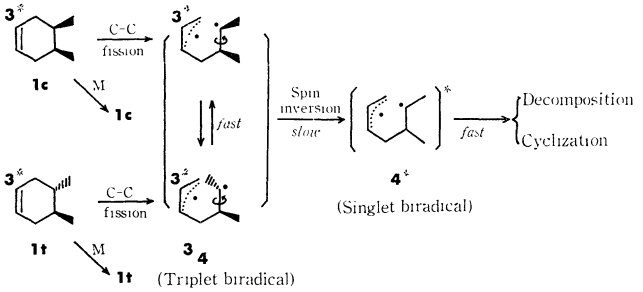
In mercury sensitization, 2,3-dimethyl-1-vinylcyclobutane **3**, the *cis-trans* isomers of **1**, and the radical-induced products were obtained in addition to the decomposition products, as shown in Table 2. Since the formation of 1,2-dimethylcyclohexane and the dimeric products was completely suppressed by the radical scavenger NO, these products, and probably hydrogen, are considered to be formed from the well-known hydrogen abstraction reaction initiated by the excited mercury atom.[1a,9] The mechanism for the formation of hydrogen, 1,2-dimethylcyclohexane and the dimers is deduced to be as follows:



Scheme 2.

In contrast to direct photolysis, the 2-butene resulting from the mercury sensitization of **1** is predominantly *trans* even when **1c** was used. Furthermore, the mercury sensitizations of both **1c** and **1t** produced 2,3-dimethylvinylcyclobutane having the same steric configuration as a major product, and in addition the isomerization of **1c** to **1t** was confirmed at low pressure. On the basis of these results and the generally accepted view of mercury photosensitization of olefins,[1,9,11] it is suggested that the vibrationally-excited triplet state of **1**, produced by energy transfer from the excited mercury atom, undergoes the usual allylic C–C bond fission resulting in an allylic triplet biradical **4**, where rotation about the C–C bond adjacent to the alkyl radical site is possible. Then the biradical ^{3}**4** decomposes into *cis*- and *trans*-2-butenes with an equimolar amount of butadiene, and/or combines to **1** or **3**.

Spin inversion is required in order for the triplet biradical ^{3}**4** to undergo decomposition and/or ring closure. Although the present intermediate is an alkyl-allyl biradical, ring closure of the photolytically derived singlet 1,4-biradical has been shown to be fast relative to the time required for free rotation about the C–C bonds.[12] If the same is true in this system, equilibrium will be established among triplet, not singlet, biradical rotamers. The rate-determining step



Scheme 3.

in the sensitized photolysis may, therefore, be the spin inversion of the triplet biradical.

As for benzene photosensitization in the vapor phase, it has been shown by Schmidt and Lee[13] that energy transfer from the benzene triplet to olefins is fast enough to produce olefin triplets in most cases. It is therefore noted that the triplet state of **1** produced in benzene sensitization resulted in no photoproducts. The difference between the benzene- and mercury-sensitizations can be attributed to the triplet energy of the sensitizers, 84 and 113 kcal/mol, respectively. The triplet state of **1** produced by mercury sensitization is considered to have a larger vibrational energy by *ca.* 30 kcal/mol than that produced by benzene sensitization. Consequently, the excess vibrational energy is suggested to play a singificant role in the triplet reaction.

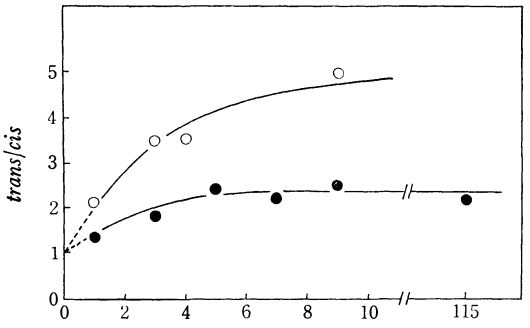


Fig. 5. Pressure dependence of *trans-cis* ratio of 2-butene in mercury-sensitized photolysis of **1c** (●) and **1t** (○). Plot at a pressure of 115 Torr was obtained by adding xenon (112 Torr) to **1c** (3 Torr).

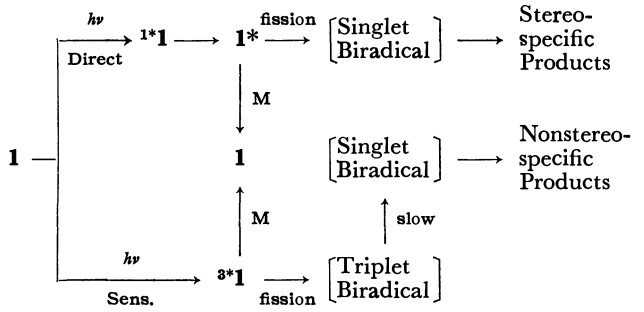
The *trans-cis* ratio of 2-butene in the mercury sensitization of **1** was found to depend on the substrate pressure as shown in Fig. 5. Regardless of which isomer is used, the value of the *trans-cis* ratio seems to approach unity at 0 Torr, while it increases with increasing pressure. The higher pressure experiment with xenon added showed that, although the *trans-cis* ratio decreases considerably at lower pressure (<3 Torr), the ratio is constant from 5 to 115 Torr in the mercury sensitization of **1c**. An explanation of the results may be found in the vibrational energy of the triplet biradical **4**, this alkyl-allyl biradical being a novel instance of a "hot," "triplet" biradical produced in the vapor phase, although a hot, triplet biradical of the alkyl-thiyl type has recently been reported by Dice and Steer.[14] The biradical **4** formed from **1t** is considered to have a

lower vibrational energy than that formed from **1c** by an amount equal to the difference in the stabilities ($\triangle H_f$) of the two isomers, **1t** and **1c**. In the absence of deactivating collisions, the hot, triplet biradical **4** has a large amount of excess vibrational energy, which renders insignificant the slight differences in stabilities, and therefore, the *trans-cis* ratio approaches unity in the sensitized photolysis of both **1c** and **1t**. At higher pressures, the difference between the energies of **4** resulting from **1c** and **1t** has a considerable influence on the value of the *trans-cis* ratio. Because of the lower vibrational energy, the biradical formed from **1t** produces much more *trans*-2-butene than that from **1c** at a comparable pressure. These estimations appear to explain the present results reasonably well, and also suggest that the lifetime of the biradical **4** is not long enough to be deactivated by collisions because the *trans-cis* ratio from **4** is different at higher pressures.



Scheme 4.

The excess energy in the direct photolysis is larger by *ca.* 40 kcal/mol than that in the mercury sensitization, which in itself may account for the different reactivities between the direct and sensitized photolyses, since with increasing excess energy the lifetime of the intermediates should decrease favoring decomposition over rearrangement. If this is the case, it is expected that the stereospecificity of butene-formation in direct photolysis must decrease with increasing pressure, since collisional deactivations diminish the excess energy of the intermediates to give nonstereospecific 2-butene. However, the *trans-cis* ratio of 2-butene in the direct photolysis is not affected by increasing the pressure in spite of the considerable decreases in yield (see Fig. 2). The rate-determining step of the direct photolysis may be the allylic C–C bond cleavage. The different results for the direct and sensitized photolyses are, therefore, attributed to the difference in the spin states of the intermediates.

The Additions of Acetic Acid to Limonene Catalyzed by Sulfuric Acid

Tohr YAMANAKA

Central Research Laboratory of Takasago Perfumery Co., Ltd., Kamata, Ohta-ku, Tokyo 144

(Received May 13, 1975)

The additions of acetic acid (AcOH) to limonene (IV) catalyzed by H_2SO_4 ($(0.367—8.39)\times10^{-2}$ mol/l), without a solvent, were studied. The mole ratio of IV to AcOH was less than 1: 19, and the reaction temperature was 28.5—92.5 °C. The products were α- and β-terpinyl acetates (I and II), and a mixture of *p*-menthadienes (III) as isomers of IV. The selectivity for I and II against III was not affected by the amount of H_2SO_4. The rate constants for I, II, and III were proportional to the amount of H_2SO_4. The apparent activation energy was 10.9 kcal/mol for I and II, and 13.7 kcal/mol for III. Both the proton concentration and the acidity function (h_0) in the reaction medium were regarded as proportional to the H_2SO_4 concentration. It was concluded that the formations of I and II were related to the A-2-type solvolytic mechanism, while that of III was related to the A-1-type specific hydrogen-ion mechanism.

An acid-catalyzed addition of AcOH to an olefin is a convenient method for introducing a hydroxy group into the olefin. However, there have been only a few papers about this reaction.[1] In order to form α-terpinyl acetate (I), some investigators have studied the additions of AcOH or chlorinated acetic acids to limonene (IV) or pinene in the liquid phase, with homogeneous and heterogeneous proton-acid catalysts.[2] Their efforts were concentrated mainly on identifying the products and on improving the yield of I, because the olefinic terpenes are liable to shift double bonds and to resinify in the presence of a strong acid catalyst. So far as the AcOH addition to a terpene is concerned, though, there has been no systematic study of the reaction kinetics and the catalytic mechanism.

We obtained some kinetic data on the additions of AcOH to IV, and the simultaneous isomerizations of IV, under various concentrations of H_2SO_4. The effects of the acid property in the system on catalytic activities and selectivities were discussed. The kinetic study was simplified by using a large excess of AcOH over the stoichiometric requirement, without a solvent; these species are miscible homogeneously within the limited concentration used in this study.

Experimental

Materials. Limonene (IV), a fraction of orange terpenes, was purified by fractional distillation. The fraction used as the starting material consists of IV of 96.7 wt% and two unknown impurities (one: 2.5 wt% and the other: 0.5 wt%), as determined by gas chromatographic (glc) analysis. The AcOH and 98 wt% H_2SO_4 were of a guaranteed reagent grade and were used without further purification.

Procedure. 24.3 g of AcOH and the desired amount of H_2SO_4 were weighed into a 100-ml Erlenmeyer flask equipped with a condenser. An appropriate amount of naphthalene (of a guaranteed reagent grade) was added as an internal standard substance for the glc analysis prior to each reaction run. Then IV was weighed into the flask, and the mixture was promptly stirred with a magnetic stirrer in a water bath with a thermostat. At any reaction time, 2—3 ml of the reaction mixture was sampled, diluted with 70 ml of water saturated with NaCl to stop the reaction, and extracted with hexane. The extract was washed with NaCl-saturated water and, after concentration, used for the glc analysis. Sampling was repeated at arbitrary time intervals. 0.069—0.944 mol/l of IV, 3.67×10^{-3}—8.39×10^{-2} mol/l of H_2SO_4, and 17.5 mol/l (an amount corresponding to a large excess over the stoichiometric requirement) of AcOH were used. The reference volume of the reaction mixture used to express concentrations of species in it was taken at 28 °C.

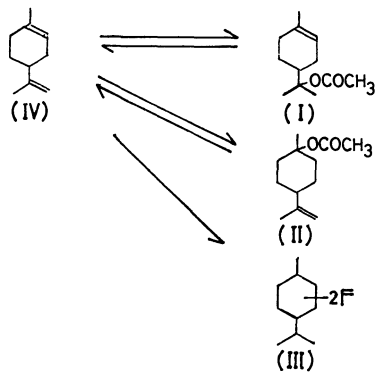
Analysis of the Products. Quantitative analysis was done by means of an internal-standard method, using a Shimadzu GC-3AH apparatus on a 3 m×3 mmϕ column packed with 10 wt% of polyethylene glycol on Diasolin. At a column temperature of 172 °C, the IV, I, and II peaks all appeared in the chromatogram. Under those column conditions, the mixture of all the *p*-menthadienes except IV showed one peak. The difference between the initial content of IV and the sum of the contents of I, II, III, and IV in the reaction mixture was regarded as the resin content.

Identification of the Products. Gas chromatography-mass spectroscopy (Hitachi RMU-6MG) was used for the identifications. The addition products of AcOH to IV were identified as I and II. III was estimated to be a mixture of 1,3-*p*-menthadiene, 1,4-*p*-menthadiene, and 2,8-*p*-menthadiene.

Results

Conversion-Time Curves. Figure 1 shows that the conversions of I and II decrease after each maximum. On the contrary, the formation of isomers (III) shows no maximum in the curve. This suggests that the acetates (I and II) are formed reversibly or as intermediates to cause the irreversible formation of III by the elimination of AcOH. Consequently, the following scheme can be postulated.

In the reaction with 3.68×10^{-3} mol/l of H_2SO_4, 0.54 mol/l of IV, and 15.0 mol/l of AcOH, the maximum con-



Scheme 1.

versions were from 0.198 to 0.08 for I and from 0.05 to 0.02 for II at 35—92 °C.

Order of Reaction. The formation rates of I, II, and III were defined as $dC_i/d\theta$, where θ denotes the reaction time (hr) and where C denotes the concentration of a product, i; i=1, 2, and 3 indicates I, II, and III. Each rate at $\theta=0$ was plotted against the initial concentration of IV (C_0) in Fig. 2. The initial rate for each product is proportional to C_0 when C_0 is less than 0.66 mol/l. Consequently, the rates will be first-order with respect to the concentration of IV; $dC_i/d\theta=k_iC$. C denotes the concentration of IV, and k_i denotes a rate constant. The effect of the concentration of AcOH on the rates was regarded as constant, because the initial mole ratio of AcOH to IV was 28: 1 to 19: 1. The conversion-time curve for each product could be approximated to a straight line when the total conversion of IV was less than 10 mol%.

Effect of H_2SO_4. In Fig. 3, the log k_i values are plotted against log C', where C' is defined by the amount of H_2SO_4 used as a catalyst and not by the amount of the "H_2SO_4 molecule" in the reaction medium. From the linear correlation with a slope of 1.0 in Fig. 3, every k_i is proportional to C'.

TABLE 1. KINETIC DATA

Products	E_i (kcal/mol)	A_i[a] (hr^{-1})
α-terpinyl acetate	10.9	8.90×10^6
β-terpinyl acetate	10.9	6.91×10^5
isomers of limonene	13.7	5.24×10^8

a) The values are at $C'=3.68\times10^{-3}$ mol/l and AcOH: 15.01 mol/l.

Apparent Activation Energies and Pre-exponential Factors. The apparent activation energies (E_i) and the pre-exponential factors (A_i) shown in Table 1 were determined from the Arrhenius plots in Fig. 4. Here, the E_i values for I and II are the same, while the E_3 value for the III isomers is higher than they. This suggests that the mechanism of the formation of III may be different from that of the acetates (I and II), which have the same mechanism and rate-determining step.

The selectivity to form I against II depends entirely on the A_i's; $A_1/A_2\approx13$ from Table 1. This may be interpreted by considering the relative reactivity of the double bonds in the isopropenyl group and in the hexene

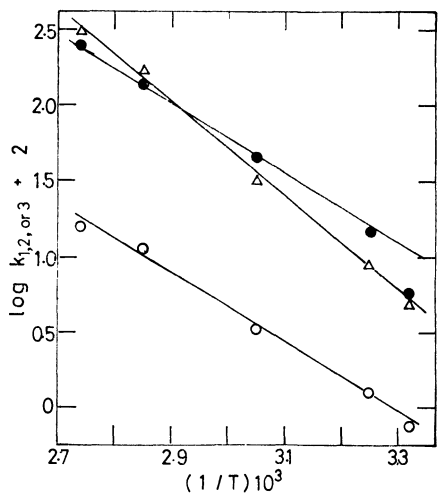

Fig. 4. Arrhenius plots for I (●), II (○), and III (△) with H_2SO_4 3.68×10^{-3} mol/l, limonene 0.540 mol/l and AcOH 15.0 mol/l.

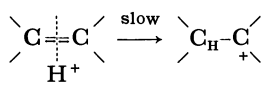
ring of IV. On the other hand, the $A_3/(A_1+A_2)\approx 55$ ratio may be interpreted in terms of the difference between the mechanisms.

Discussion

Isomerization of IV. Bates *et al.* and many other investigators have interpreted the acid-catalyzed isomerizations of *p*-menthadienes in terms of a carbonium-ion mechanism.[4] The isomerization of IV to form III, namely, 1,3-*p*-menthadiene, 2,8-*p*-menthadiene, and 1,4-*p*-menthadiene, will be interpreted to proceed *via* carbonium ions in a similar scheme.

Carbonium ions are also formed by the elimination of the AcO^- anion from the acetates (I and II), as well as by the protonation of IV, which sometimes become isomerized products (III) or resin. The elimination of the AcO^- anion is supported by the decrease in the concentration of I and II after the maxima are reached.

In the isomerization of IV, the rate-determining step is the step of forming carbonium ions from a protonated double bond:[4,5]

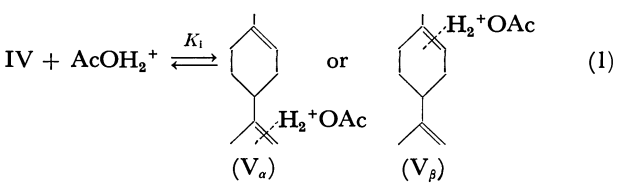


where H_2SO_4 acts as a specific hydrogen-ion catalyst. Therefore, the isomerization rate (also k_3) is proportional[5] to the acidity function, h_0[9], of the medium rather than to $C_{AcOH_2^+}$.

The acidity function, h_0, of H_2SO_4 in a water–AcOH solution has been related to C' by George *et al.*[6] The following relation was obtained from their data, where C' is less than 2.52 mol/l and where the water content is less than 0.99 wt%:[6] $h_0=(C')^{1.1}$. Here, h_0 indicates the ability of proton donation of an acid medium to weak, uncharged, indicator bases. This relation is applicable to estimating the h_0 in the present medium by assuming that h_0, the ability of proton donation to IV, is equal to, or at least proportional to, the h_0 to the indicator bases. Moreover, (1) the effect of IV and naphthalene on h_0 can be neglected, because their concentrations were less than 1 mol/l; (2) the trace of water contained with H_2SO_4 (98 wt%) and the other substances will make an amount not more than 1 wt% in the medium, and (3) C' is $(3.67—8.4)\times 10^{-2}$ mol/l. Consequently, the present h_0 value is nearly proportional to C', and the proportionality of k_3 to C' is observed.

Mechanism of the Acetates Formation. The addition of AcOH will proceed *via* $AcOH_2^+$ in the presence of a strong acid.[8] According to the facts that the formation rates of I and II are proportional to C' and have the same E_i, we propose the following mechanism, like the A-2-type solvolytic reaction defined by Hammett *et al*;[7]

$$HA + AcOH \rightleftharpoons (AcOH_2^+\ A^-) \rightleftharpoons AcOH_2^+ + A^-$$



(1)

$$\left.\begin{aligned} V_\alpha &\rightleftharpoons X_\alpha^* \longrightarrow I \\ V_\beta &\rightleftharpoons X_\beta^* \longrightarrow II \end{aligned}\right\} \text{rate-determining step} \qquad (2)$$

where HA denotes H_2SO_4. This mechanism corresponds to one of the hypothetical mechanisms derived by Corriu *et al.* for the addition of AcOH to cyclohexene.[1] They also supposed the slow formation of a carbonium ion by the elimination of AcOH from a coordination product like V_α and V_β, and the subsequent, rapid addition of AcOH to the carbonium ion; the rate-determining step is the same as the isomerization. The present case cannot be explained by this mechanism, which suggests that $E_1=E_2=E_3$.

The observed activation energies, E_1 and E_2, correspond, respectively, to the sum of the heat of the reaction in Step (1) and the activation energy in the rate-determining step (2). Because E_1 and E_2 are the same in value, the structural changes to the activated complexes, X_α^* and X_β^*, from IV and $AcOH_2^+$ are considered to affect the change of the potential energies in almost the same way. The difference between A_1 and A_2 depends entirely on the difference between the overall changes in entropy from IV and $AcOH_2^+$ to the activated complexes.

In the above scheme, the formation rates of I and II are proportional to the concentration of the solvated proton ($AcOH_2^+$). In such a solvolytic acid-catalyzed reaction of the A-2 types, $C_{AcOH_2^+}$ can be a better measure of the acidity than the acidity function.[9] In fact, the effect of C' on rates other than *via* $C_{AcOH_2^+}$ is not significant considering the small dielectric constant and ionic strength in the AcOH medium,[8] and assuming an analogy between the activated complex (X^*) and $AcOH_2^+$ with respect to the charged part.[7] Consequently, it can be deduced that $C_{AcOH_2^+}$ is proportional to C' in the present medium.

Aspects of the Selectivity of the Acetates. From the above discussion, it must be noted that the similar proportionality shown in Fig. 3 for the AcOH addition and the isomerization is effected *via* two different mechanisms: k_1 and $k_2\propto C_{AcOH_2^+}\approx\gamma C'$, and $k_3\propto h_0\approx\delta C'$. ($\gamma$ and δ are defined as constants in the present medium.) This conclusion suggests that it is impossible to improve the selectivity of the acetates (I and II) against the isomers (III) by changing C', for an increase in C' beyond the present concentration will cause a remarkable increase in δ, while γ probably decreases or, at most, remains constant with an increase in C', as a result of the low dielectric constant of AcOH.[7,8] In fact, we obtained plenty of resin from IV by using the higher C' value than in the present study.

We wish to thank the Takasago Perfumery Co., Ltd., for its permission to publish this article.

The Radiation Synthesis of Hydrogen Cyanide from the Nitrogen-ethylene System. The Effect of Fission-fragment Irradiation

Yasumasa IKEZOE and Shoichi SATO

Japan Atomic Energy Research Institute, Tokai-mura, Ibaraki-ken, 319-11

(Received May 30, 1975)

Upon irradiation by (FF+n+γ), the G(HCN) value from the nitrogen–ethylene system increased with the rise in the pressure, while upon γ and (n+γ) radiations it decreased. This pressure effect was explained in terms of the high concentration of the active species in the FF tracks. At a high pressure, Reaction (5) is considered to take place in the tracks;

$$N_2^+ + e^- \longrightarrow 2N \quad (5)$$

At low pressures, Reaction (6) predominates, as in the γ-ray radiolysis, over Reaction (5) even in the FF tracks,

$$N_2^+ + C_2H_4 \longrightarrow N_2 + C_2H_4^+ \quad (6)$$

and nitrogen molecule cations do not contribute to the formation of hydrogen cyanide.

Hydrogen cyanide is formed from the nitrogen–ethylene system by ionizing irradiation.[1-3] In a previous paper,[2] it was shown that both nitrogen atoms and excited nitrogen molecules were the precursors of hydrogen cyanide in the γ radiolysis.

In the present investigation, the hydrogen-cyanide formation was studied by means of ^{60}Co γ-rays and mixed reactor radiations (n+γ) and by fission-fragment (FF) radiation. The pressure dependence of the G(HCN) value by the FF irradiation differed significantly from that of the G(HCN) value by γ and (n+γ) irradiation. A new mechanism is proposed for the hydrogen-cyanide formation upon the FF irradiation, which is closely related to the structure of the FF tracks.

Experimental

Premixed gas (C_2H_4; 5.25% in N_2, pure gas mixed by Takachiho Chemical) and ethylene (Takachiho research grade, 99.9%) were used as reactant gases without further purification. A stainless steel capsule (inner vol., 43 ml) with a rupture plate at one end was used as the irradiation vessel. The capsule was washed successively with trichloroethylene, ethanol, and hot distilled water, and then vacuum dried. After evacuating the capsule to a vacuum of 5×10^{-3} Torr and purging three times with the reactant gas, a known amount of the gas was charged in the capsule, the pressure being measured by means of a stainless steel Bourdon gauge.

Irradiations were carried out by γ-rays from a 45 kCi ^{60}Co source or by means of reactor mixed radiations with or without an FF source in the Low Temperature Fissiochemical Loop (LTFL).[4] Without the FF source, neutrons and γ-rays, (n+γ), were absorbed by the reactant. With a piece of thin U-Pd alloy foil[5] set at the center of the capsule, the reactant was irradiated by fission fragments, neutrons, and γ-rays, (FF+n+γ). The absorbed dose was determined both by means of a gaseous chemical dosimeter[6] and by calculation using the data of the neutron flux and the average range of an FF in the gas.[7] The resultant dose rates were 0.9 Mrad/h (γ-rays), 5 Mrad/h (n+γ),[8] and 12—40 Mrad/h (FF+n+γ),[9] depending on the amount of the U-Pd alloy foil. The hydrogen cyanide formed was measured by the titration method using a 10^{-4} M mercuric nitrate solution, using copper diethyldithiocarbamate as an indicator.[2] The yields were measured at doses from 5 to 8 Mrad. The G(HCN) value was determined on the basis of the energy absorbed by nitrogen.

Results and Discussion

The Pressure Dependence of G(HCN). In the previous paper,[2] the G(HCN) value upon γ-ray irradiation was found to decrease with the rise in the total pressure from 0.05 to 1.5 atm. In this study, the pressure dependence of the G(HCN) value was examined on three radiations, γ, (n+γ), and (FF+n+γ). The results are shown in Fig. 1.

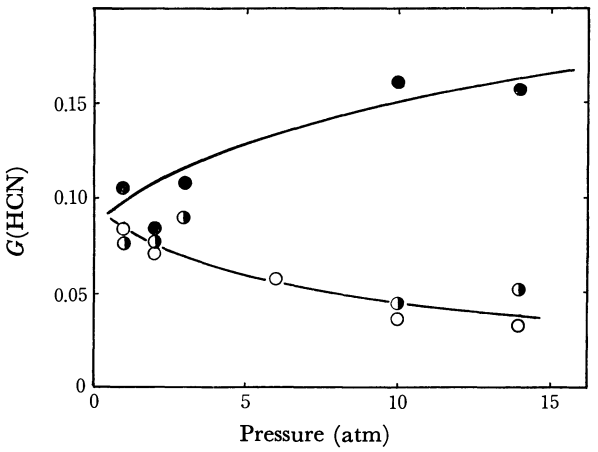

Fig. 1. Pressure effect on $G_{FFn\gamma}$, $G_{n\gamma}$, and G_γ.
N_2; 94.75%, C_2H_4; 5.25%, 43 ml stainless steel capsule, 5—8 Mrad. ●; $G_{FFn\gamma}$, 12—40 Mrad/h. ◑; $G_{n\gamma}$, 5 Mrad/h. ○; G_γ, 0.9 Mrad/h.

The G(HCN) values obtained by γ and by (n+γ) (G_γ and $G_{n\gamma}$, hereafter) decreased from 0.08 to 0.04 with the rise in the total pressure from 1 to 14 atm. This pressure dependence can be explained by the mechanism which was proposed previously[2] for the hydrogen cyanide formation in the γ-ray radiolysis:

$$N_2 \rightsquigarrow N, N_2^+, N_2^*, e^- \quad (1)$$

$$N_2^* \longrightarrow 2N \quad (2)$$

$$N_2^* + M \longrightarrow N_2 + M \quad (3)$$

$$N + C_2H_4 \longrightarrow HCN + CH_3 \quad (4)$$

The formation of nitrogen atoms by Reaction (2) is suppressed by the competitive Reaction (3) with a rise in the total pressure, resulting in a lowering of the

G(HCN) value.

The pressure dependence of the G(HCN) value upon (FF+n+γ) irradiation, $G_{FFn\gamma}$, differed distinctly from those of G_γ and $G_{n\gamma}$. The experimental $G_{FFn\gamma}$ value increased from 0.10 to 0.15 in the same pressure range. However, the ratio of the FF energy to the total energy was not exactly constant.[9] Therefore, for further discussion, the G(HCN) value obtained solely with FF, G_{FF}, was obtained by Eqs. (1) and (2), assuming that the experimental $G_{FFn\gamma}$ value is the mean value of the G_{FF} and $G_{n\gamma}$, weighted with the absorbed energies of the FF and (n+γ):

$$G_{FFn\gamma} = G_{FF}\varepsilon_{FF} + G_{n\gamma}\varepsilon_{n\gamma} \quad (1)$$

$$\varepsilon_{FF} + \varepsilon_{n\gamma} = 1 \quad (2)$$

where ε_{FF} or $\varepsilon_{n\gamma}$ is the ratio of the absorbed dose of FF or (n+γ) to the total dose. The $G_{n\gamma}$ value observed and the G_{FF} value thus calculated are shown in Table 1.

Table 1. Effect of pressure on G_{FF} and $G_{n\gamma}$[a]

Pressure (atm)	1	3	10	14
$G_{n\gamma}$ (observed)	0.08	0.09	0.05	0.05
G_{FF} (calculated)[b]	0.11	0.12	0.22	0.23

a) Absorbed dose; 5—8 Mrad, N_2; 94.75%, C_2H_4; 5.25%, 43 ml stainless steel capsule. b) Calculated by Eq. (1) in the text.

At 1 atm, the G_{FF} value, 0.11, is nearly equal to the $G_{n\gamma}$ value, 0.08, while at 14 atm the G_{FF} value is four times as large as the $G_{n\gamma}$ value. This pressure dependence of the G_{FF} value indicates that a quite different mechanism of the hydrogen-cyanide formation must be considered under the FF irradiation.

FF Tracks. According to Mozumder's model,[10] it is possible to detetmine the core radius and the temperature of the FF tracks in a condensed medium; the core radius is given by the impulse principle of Bohr or by the range of 100 eV electrons. In the gas phase, however, the latter is always longer than the former. By use of the model, the core radius of this system may be regarded as equal to a range of 100 eV electrons.

The concentration of the active species and the temperature in the tracks can be estimated if the core radius is determined. These values at 1 and 10 atm are shown in Table 2.

Table 2. FF tracks[a]

Pressure p (atm)	Core radius r (Å)	Temperature elevation ΔT (°C)	Concentration of active species: $C_{N_2^+=C_e^-}$ (cm^{-3})	$C_{N_2^*}$ (cm^{-3})	C_N (cm^{-3})
1	1.2×10^4	0.2	2.6×10^{13}	4.4×10^{13}	4.4×10^{12}
10	1.2×10^3	15.1	2.6×10^{16}	4.4×10^{16}	4.4×10^{15}

a) Calculated in Appendix.

Chemical Reaction in the Core. The concentrations of active species in the core are several orders of magnitude higher than those of the γ-ray radiolysis (see Appendix). Because of this local high concentration of active species, the recombination of a nitrogen molecule cation[11-13] with an electron may be assumed in the FF track core:

$$N_2^+ + e^- \longrightarrow 2N \quad (5)$$

By Reaction (5), two kinds of nitrogen atoms, N(^{4}S) and N(^{2}D), are formed mainly,[14] and each state of the nitrogen atom is known to react with ethylene to form hydrogen cyanide[15,16], according to Reaction (4).

In the γ-ray radiolysis, the charge on a nitrogen cation is transferred to an ethylene molecule, and no contribution is expected to the hydrogen cyanide formation:

$$N_2^+ + C_2H_4 \longrightarrow N_2 + C_2H_4^+ \quad (6)$$

In the FF radiolysis, Reactions (5) and (6) can compete with each other. The rates of the two reactions in the track core were calculated at 1 and 10 atm, as is shown in Table 3. At 1 atm, Reaction (5) is much slower than Reaction (6) even in the track core, and Reaction (5) can be neglected, as in the γ-ray radiolysis. At 10 atm, however, Reaction (5) predominates over Reaction (6), resulting in the formation of excess nitrogen atoms. The higher the total pressure, the more excess nitrogen atoms are formed in the core by this mechanism. This is in qualitative agreement with the experimental results (Table 1).

Table 3. Reaction rate in the track core

Pressure (atm)	rate of reaction (5);[a] $N_2^+ + e^- \rightarrow 2N$ (cm$^{-3}\cdot$s^{-1})	rate of reaction (6);[b] $N_2^+ + C_2H_4 \rightarrow N_2 + C_2H_4^+$ (cm$^{-3}\cdot$s^{-1})
1	2.0×10^{20}	1.0×10^{22}
10	2.0×10^{26}	1.0×10^{26}

The concentrations of N_2^+ and e^- are given in Table 2. The ethylene concentration is 1.2×10^{18} and 1.2×10^{19} cm^{-3} at 1 and 10 atm (5% C_2H_4 in N_2).
a) Rate constant of reaction (5); $k_5=3\times10^{-7}$ cm$^3\cdot$s^{-1}.[16] b) Rate constant of reaction (6); $k_6=3\times10^{-10}$ cm$^3\cdot$s^{-1}, is estimated from similar reactions.[19]

The Role of Ethylene Molecules. The effect of the ethylene concentration on the $G_{FFn\gamma}$ value was studied in order to clarify the role of ethylene molecules in the formation of hydrogen cyanide upon the FF irradiation. If the mechanism of hydrogen-cyanide formation

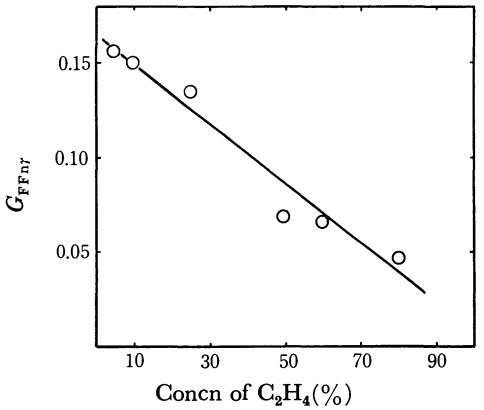

Fig. 2. Effect of ethylene concentration on $G_{FFn\gamma}$.[a] (FF+n+γ); 12 Mrad/h, 6.8 Mrad, ε_{FF}; 0.66, N_2+C_2H_4; 14 atm in 43 ml stainless steel capsule.
a) The G(HCN) value was calculated on the basis of the energy absorbed by nitrogen.

proposed above holds, the G(HCN) value should decrease with the rise in the ethylene concentration because of Reaction (6).

As is shown in Fig. 2, the G(HCN) value actually decreased with the ethylene concentration. Thus, this mechanism is again in agreement with the experimental results.

Local Temperature Effect. Since a small increase in the G_r value has been observed upon reaction-temperature elevation at a low total pressure,[2] the effect of the local temperature rise within the FF track core might be expected on the G_{FF} value also at the high total pressure studied. The measured G_r value was indeed found to increase as the temperature was raised, as is shown in Fig. 3. However, the increase was not large enough to explain the high G_{FF} value obtained. The G_r values were 0.04 and 0.07 at 40 and 400 °C respectively.

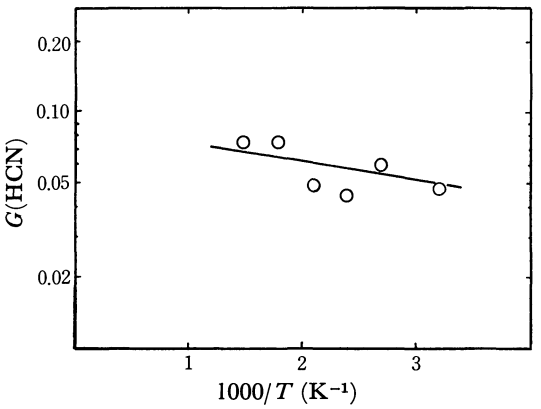

Fig. 3. Arrhenius' plot of G_r.
γ-rays; 0.9 Mrad/h, 4.3 Mrad. N_2; 15.1 g/l, C_2H_4; 5.25% in N_2.

The temperature effect in this system can be neglected because of the small increase in the G_r value with the reaction temperature elevation and because of the low temperature rise in the track cores (Table 2).

Appendix

Radius and Temperature of the Track Cores.[10] The radius of the FF track cores in this system is given by this equation: $r=r_0\rho_0/\rho$, where r_0 is the range of 100 eV electrons in water (15 Å), ρ_0 and ρ, the desities of water and the reactant gas. The temperature rise in the cores is given by this equation: $\Delta T=S/\pi C_v r^2$, where S is the energy loss per unit length (0.4 eV/Å$=0.64\times10^{-11}$ J/cm at 1 atm,[17] and 4 eV/Å$=6.4\times10^{-11}$ J/cm at 10 atm), and C_v, the specific heat at a constant volume (0.75 J/deg·g). Thus, $\Delta T=0.2$ and 15.1 °C at 1 and 10 atm.

Concentrations of Active Species in the Cores. The concentration of an active species, C_A, is given by this equation: $C_A=Sg_A/100\pi r^2$, where g_A is the initial G(A) value. Using appropriate g_A value ($g_{N_2^+}=g_{e^-}=3$, $g_{N_2^*}=5$, and $g_N=0.5$[8]), the concentrations of these active species are found to be as is shown in Table 2. The ratio is $(N)/(N_2)=1.8\times10^{-7}$ at 1 atm. This value is several orders of magnitude greater than the corresponding one in the γ-ray radiolysis (0.9×10^{-13}).[2]

The authors wish to acknowledge the technical assistance in the sample preparation and irradiation provided by Messrs. T. Kobayashi, S. Shimizu, and H. Nakajima of the authors' Institute, and the valuable guidance afforded by Professors K. Oshima and Y. Tabata of the University of Tokyo and Professor A. Danno of Kagoshima University. Discussions with Professor S. Sato of the Tokyo Institute of Technology are also gratefully acknowledged.

11) Because of the fast clustering reaction: $N_2^+ + 2N_2 \rightarrow N_4^+ + N_2$ ($k=6\times10^{-29}$ cm^{-6} s^{-1}), the recombination of both N_2^+ and N_4^+ with electrons may be considered. Also, the formation of N atoms by the recombination of N_4^+ with an electron is energetically possible because of the low binding energy of N_2^+ with N_2 (0.5 eV).[12] However, the equilibrium concentration of N_4^+ is presumably lower than that of N_2^+, as was estimated in the case of O_2^+—O_4^+.[13]

The Synthesis and Ion-exchange Properties of $TiH_2(PO_4)_2 \cdot 1/2H_2O$

Etsuro KOBAYASHI

National Chemical Laboratory for Industry, Hon-machi, Shibuya-ku, Tokyo 151

(Received November 28, 1974)

In order to develop an ion-exchanger for industrial use, a new compound, titanium dihydrogen bis (phosphate) hemihydrate, was prepared by means of a reflux between titanium phosphate and concentrated phosphoric acid; then the conditions of synthesis and the ion-exchange properties of the products were investigated. The amorphous titanium phosphate used as the starting material was formed by the reaction of titanium tetrachloride with phosphoric acid in diluted hydrochloric acid. The phase equilibrium of the TiO_2–P_2O_5–H_2O system has been studied at the refluxing temperatures of the mother liquors. The solid phase in equilibrium with the mother liquor containing 13—64% P_2O_5 had the components of TiO_2 (29—32%), P_2O_5 (53—54%), and H_2O (15—16%); its composition was $TiH_2(PO_4)_2 \cdot H_2O$, which had already been known, but the solid phase in equilibrium with the mother liquor containing more than 64% P_2O_5 had as components TiO_2 (31—32%), P_2O_5 (57—58%), and H_2O (10—11%); therefore, its composition corresponded to $TiH_2(PO_4)_2 \cdot 1/2H_2O$. The X-ray diffraction pattern of this compound was entirely different from that of monohydrate, and some large *d*-values were recognized. From the DTA and TGA, the processes of the dehydration of monohydrate and hemihydrate were also different from each other; however, both compounds were converted to titanium pyrophosphate (TiP_2O_7) at 800 °C. $TiH_2(PO_4)_2 \cdot H_2O$ can adsorb sodium ions, but the ions of a large radius, such as potassium and cecium, are not adsorbed. In contrast to this, $TiH_2(PO_4)_2 \cdot 1/2H_2O$ had an excellent ion-exchange property; its ion-exchange capacities were 4.0 meq/g to K^+ and 2.0 meq/g to Cs^+ at pH 4. These capacities were about eight times those of monohydrate. The solubilities of the phosphate used as an ion-exchanger were remarkably low. Therefore, the titanium dihydrogen bis (phosphate) hemihydrate thus obtained may be utilized as a useful inorganic ion-exchanger for potassium and cesium ions.

The phosphates of poly-valence metals such as chromium,[2] zirconium,[3] and tin,[4] have hitherto been known as inorganic ion-exchangers. In order to develop an inorganic ion-exchanger capable of recovering potassium from sea water, we have previously investigated the ion-exchange characters of magnesium, calcium, aluminium, and iron phosphate,[5] further synthesized iron trihydrogen bis (phosphate), which was fairly stable to phosphoric acid as a regenerant of the exchanger, and examined its ion-exchange character.[6] The phosphates of bivalent and trivalent metals, however, generally do not have enough stability to be good inorganic ion-exchangers.

In the present work, titanium phosphate, which is an economical raw material, has been examined. Titanium phosphates with the composition of $3TiO_2 \cdot P_2O_5 \cdot xH_2O$ ($x=1, 3, 6$) are already known.[7] Also, crystalline titanium hydrogen phosphate with the composition of $TiH_2(PO_4)_2 \cdot H_2O$ was prepared by the reflux of amorphous titanium phosphate with phosphoric acid at the boiling point, and its ion-exchange property was examined.[8] This compound showed a higher resistance to hydrolysis than the amorphous titanium phosphate; it adsorbed Li^+ and Na^+, but not the ions of a large radius, such as K^+ and Cs^+. Therefore, this crystalline titanium hydrogen phosphate is not suitable as an industrial ion-exchanger. Recently, titanium phosphate with the composition of $(TiO)_{0.535}(HPO_4)_{0.639}(OH)_{0.17} \cdot aq.$ was synthesized, and it could recover cesium in radioactive waste materials.[9] The molar ratio of Ti to P in this non-stoichiometric compound is larger than that in the above crystalline titanium phosphate, so it may be supposed that this compound is lacking in chemical resistance to an acidic eluent. Titanium phosphate-silicate for the separation of radioactive materials was also synthesized.[10] In the study of the TiO_2–P_2O_5–H_2O system at 20 °C, $Ti(OH)PO_4 \cdot 2H_2O$ and $TiH_2(PO_4)_2$ existed as solids in the system.[11] However, in the general method of preparing inorganic ion-exchanger by the reflux of amorphous phosphate with phosphoric acid, the data of the above equilibrium system cannot be applied to the preparation because of the difference between the refluxing temperature and room temperature.

When the phase equilibrium of the Fe_2O_3–P_2O_5–H_2O system was examined,[6] the existence of several kinds of iron hydrogen phosphate was known. In the present work, it is supposed that titanium hydrogen phosphate, as the solid phase of the equilibrium to concentrated phosphoric acid, also exists in the TiO_2–P_2O_5–H_2O system. From the results of the phase equilibrium on the reflux of amorphous titanium phosphate with phosphoric acids of various concentrations, it is known that $TiH_2(PO_4)_2 \cdot 1/2H_2O$, which differs in its molar ratio of the water of crystallization, is present. The X-ray diffraction pattern of this compound was entirely different from that of $TiH_2(PO_4)_2 \cdot H_2O$, and large *d*-values were noticed in it. The investigation of its ion-exchange properties showed this salt to have an adsorption capacity to ions of a larger ionic radius, such as K^+ and Cs^+. In this paper, an experimental study of the preparation of titanium dihydrogen bis (phosphate) hemihydrate and its ion-exchange properties will be described.

Experimental

Synthesis. Amorphous titanium phosphate, used as the raw material, was initially prepared in the following way: 800 ml of 2 M HCl placed in a beaker and mixed with 50 g of $TiCl_4$ solution. To this was slowly added 800 ml of 1.45 mol/l H_3PO_4, while simultaneously the mixture in the beaker was vigorously stirred at room temperature. Thus, amorphous titanium phosphate was precipitated. This was allowed to

stand overnight and then separated from the mother liquor by the use of a centrifugal separator. The product was washed with distilled water, centrifugally separated from the wash liquid, and finally vacuum-dried over phosphorus pentoxide for 24 h.

Crystalline titanium phosphate was prepared in the following way: 10 g of amorphous titanium phosphate, prepared previously, was placed in a Kjeldahl flask and mixed with 150—180 ml of phosphoric acid of an appropriate concentration. The mixture was kept at a proper temperature by the evaporation of a little water, and then heated at its boiling point for 12—36 h after the reflux condenser had been connected to the flask. Immediately the resulting precipitate was separated centrifugally from the mother liquor. To the precipitate alcohol or acetone was added, and the mixture was vigorously shaken up; then the precipitate was separated from the wash liquid by using the centrifugal separator. The product thus obtained as the precipitate was washed enough by repeating this procedure several times, and finally it was vacuum-dried over phosphorus pentoxide for 24 h.

Analysis. P_2O_5: A 0.5 g portion of the product was weighed exactly and then refluxed with 50 ml of 1 M NaOH in a stainless steel flask for 60 min. The amorphous precipitate obtained by this treatment was separated from the mother liquor by filtration and washed sufficiently with hot water. The mother liquor and wash liquid were put together, and the volume of the solution was adjusted to 250 ml. The phosphorus content was determined gravimetrically as magnesium pyrophosphate.

TiO_2: A 0.1 g portion of the product was weighed exactly and then refluxed with 10 ml of 18 M H_2SO_4 and 5 g of $(NH_4)_2SO_4$ in a Kjeldahl flask until it had dissolved completely. The volume of the sample solution was then adjusted to 250 ml with distilled water. 10 ml of 9 M H_2SO_4 and 10 ml of 3% H_2O_2 were added to a 25 ml portion of the diluted solution; the meta-titanic acid peroxide thus turned yellow. The titanium content was determined colorimetrically at 420 nm. The content of TiO_2 in titanium phosphate was also derived as follows:

$$100\% - (P_2O_2)\% - (H_2O)\% = (TiO_2)\%$$

H_2O: A 0.2 g portion of the product was weighed exactly and then heated in an electric furnace regulated to 800 °C for about 2 h until it had reached a constant weight. In this case, the weight loss corresponds to the water content of the product. The water content was also given by thermal gravimetric analysis.

The Components in the Liquid Phases: Exactly a 10 ml portion of the mother liquor was taken, and the specific gravity was measured. The volume of the sample solution was adjusted to 250 ml. A 100 ml portion of the diluted solution was neutralized with a sodium hydroxide solution. The white precipitate thus obtained was separated from the mother liquor and washed with hot water. The TiO_2 content was determined gravimetrically by the calcination of the precipitate. On the other hand, the mother liquor and wash liquid were put together, and the volume of the solution was adjusted to 250 ml. The P_2O_5 content was determined gravimetrically as magnesium pyrophosphate by using a portion of the solution.

X-Ray Diffraction Pattern: The X-ray diffraction pattern was obtained by using a Rigaku-Denki model 2001 diffractometer with Ni-filtered Cu$K\alpha$ radiation, with 20 KVP and 15 mA.

DTA and TGA: The differential thermal analysis (DTA) and thermogravimetric measurements (TGA) were performed simultaneously at a heating rate of 5 °C/min with a Rigaku-Denki model DC-C1-S thermal analyzer.

Ion-exchange Titration Curve: A 0.200 g portion of a product was placed in a 50 ml stoppered Erlemeyer flask, and 25 ml of the solution, mixed in the proper ratio of 0.1 M MCl to 0.1 M MOH (M=Na, K, Cs), was added to it. The contents in the flask were shaken up at times, and the pH of the solution was measured after 24 h. Then, the ion-exchange titration curve was drawn from the relations between the pH and the ion-exchange capacity, which was estimated from the mixed ratio of 0.1 M HCl to 0.1 M MOH.

Results and Discussion

Preparation of $TiH_2(PO_4)_2 \cdot H_2O$ and $TiH_2(PO_4)_2 \cdot 1/2H_2O$. The conditions of synthesizing crystalline titanium hydrogen phosphates and the results of the analysis of the products are summarized in Table 1.

Composition by Chemical Analysis: Amorphous titanium phosphate, with the composition of $1.9TiO_2$, P_2O_5, $3.7H_2O$, was used as the raw material. The reaction product No. 1, which was obtained by refluxing amorphous titanium phosphate with a suitable amount of 10%

a) The mixture of amorphous titanium phosphate (raw material, 10) and phosphoric acid (150—160 ml) was refluxed under a certain condition.

phosphoric acid (P_2O_5, 7.3%) for 36 h, was still the non-crystalline powder. It could be expected that when phosphoric acid of a comparatively lower concentration was used, the reaction could not reach the equilibrium state even by means of a reaction at a refluxing temperature for a fairly long time. In the No. 2—7 products, which were equilibrium-solid phases with a 13—62% P_2O_5 content in the mother liquor, their compositions were found to be 29—32% TiO_2, 53—54% P_2O_5, and 15—16% H_2O, and its components corresponded to those of $TiH_2(PO_4)_2 \cdot H_2O$ known already. In the No. 8—10 products, which were equilibrium-solid phases with a P_2O_5 content of more than 64% in the mother liquor and at a refluxing temperature 170—180 °C, the compositions were found to be 31—32% TiO_2, 57—58% P_2O_5, and 15—16% H_2O. From these results, the expected composition was given as $TiH_2(PO_4)_2 \cdot 1/2H_2O$.

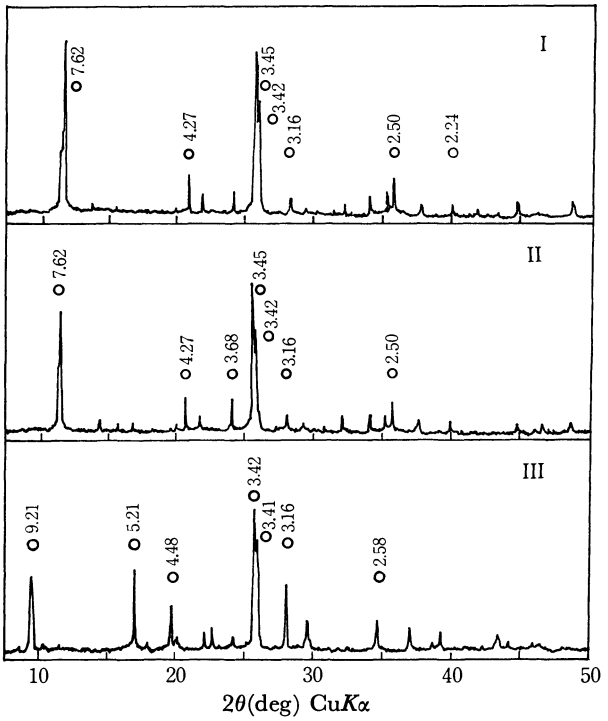

Fig. 1. X-Ray diffraction patterns of titanium hydrogen phosphates.
I: Product obtained by reflux in phosphoric acid of P_2O_5 13.2% at 107 °C for 24 h (No. 2). II: Product obtained by reflux in phosphoric acid of P_2O_5 58.8% at 160 °C for 12 h (No. 6). III: Product obtained by reflux in phosphoric acid of P_2O_5 66.1% at 176 °C for 36 h (No. 9).
Numerals near peaks indicate distance (Å) between planes in crystals.

X-Ray Diffraction Patterns: The X-ray diffraction patterns of the products, which are prepared in different concentrations of phosphoric acid in the mother liquor, are shown in Fig. 1. I and II are the X-ray diffraction patterns for monohydrate, known already. These diffraction data agreed almost entirely with those of the ASTM X-ray data cards and also with those of $TiH_2(PO_4)_2 \cdot H_2O$, prepared by Alberti *et al.*[8] III is the pattern for hemihydrate obtained by the reflux of amorphous titanium phosphate with concentrated phosphoric acid. In this diagram, diffraction lines newly appeared at the positions of 9.21, 5.21, 4.38 Å, *etc.* The X-ray diffraction values of hemihydrate were clearly different from those of monohydrate, as is shown in Table 2. For the formation of two crystalline titanium phosphates having a Ti/P atomic ratio of exactly 1.0, a fairly long time was needed, even at the reflux temperature. The course of the formation of hemihydrate by the reaction between amorphous titanium phosphate and concentrated phosphoric acid is shown in Fig. 2 by the X-ray diffraction patterns changing successively.

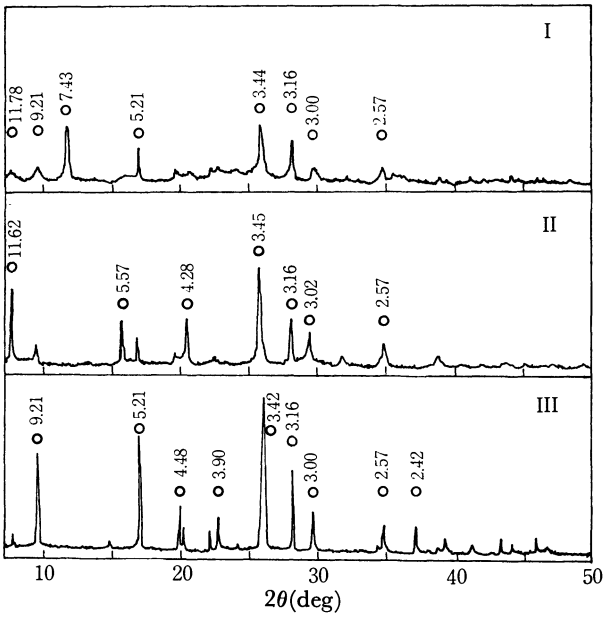

Fig. 2. X-Ray diffraction patterns on course of formation of modification titanium hydrogen phosphate.
I: Product obtained by reflux in phosphoric acid of 63.5% P_2O_5 at 176 °C for 5 h. II: Product obtained by reflux in phosphoric acid of 63.5% P_2O_5 at 176 °C for 12 h. III: Product obtained by reflux in phosphoric acid of 63.5% P_2O_5 at 176 °C for 24 h (No. 8).
Numerals near peaks indicate distance (Å) between planes in crystals.

When the concentration of phosphoric acid in the mother liquor was low, as has been mentioned above, the reaction product did not crystallize easily, so a slight crystallization of the product occurred upon refluxing for several hours, as is shown in I. It was observed from the X-ray patterns that a metastable crystalline product was produced by refluxing for 12 h at 176 °C and also by refluxing for a fairly long time at 170 °C. The X-ray diffraction pattern for this product is shown in II; in the diagram peculier diffraction lines appeared at 11.6 and 5.57 Å. The object, hemihydrate as a stable form, was obtained by refluxing for more than about 20 h at above 170 °C. The X-ray diffraction pattern of hemihydrate is shown in III.

Effect on the Concentration of Phosphoric Acid in the Mother Liquor: From the TiO_2–P_2O_5–H_2O system at the refluxing temperatures of the mother liquors, we ascertained the existences of $TiH_2(PO_4)_2 \cdot H_2O$ and $TiH_2(PO_4)_2 \cdot 1/2H_2O$ as the solid phase in the equilibrium

state to the mother liquor. If pyrophosphoric acid is contained in the liquid phase, it may be supposed, as a matter of course, that another solid phase appears. However, the pure phosphoric acid of P_2O_5 66% theoretically does not contain pyrophosphoric acid.[12] In fact, the existence of condensed phosphoric acids in this liquid phase was not observed by paper or ion-exchange chromatography. The amount of TiO_2 dissolved in the liquid phase was nearly zero when the concentration of phosphoric acid was low; it slightly increased with the increase in the concentration of phosphoric acid.

Change in Titanium Hydrogen Phosphate upon Heating. The DTA and TGA curves for two crystalline titanium phosphates are shown in Fig. 3. The X-ray diffraction values for some titanium phosphates previously registered on ASTM X-ray data cards, the products obtained in this work, and their heated products are summarized in Table 2. In the DTA curve for monohydrate (I), the broad endothermic peak at 70—100 °C seemed to be due to the elimination of water adhering to the crystal powder. It was confirmed from the X-ray diffraction, which characterized pyrophosphate in the heated product at 185 °C, that the endothermic peak at 210 °C was a result of the dehydration of the water of crystallization and the condensation. The endothermic peaks at 260 and 510 °C were also due to the condensation. However, the reason why these condensations take place progressively upon heating is not yet known. The behavior of the DTA and TGA curves for hemihydrate (II) differed from those of I, a dehydration gradually occurred from 100 °C to about 300 °C, and a weight loss corresponding to the weight of the water of crystallization of this salt was observed in this temperature range. Then a large endothermic peak, which was due to the condensation, appeared at 415 °C.

a) According to data on Deutsche Akad. der Wissensch., Berlin, Inst. f. Anorg. Chem. (1968). b) According to Michel and Weiss (1967). c) According to Levi and Peyronel (1935). These data were registered in ASTM X-ray data cards.

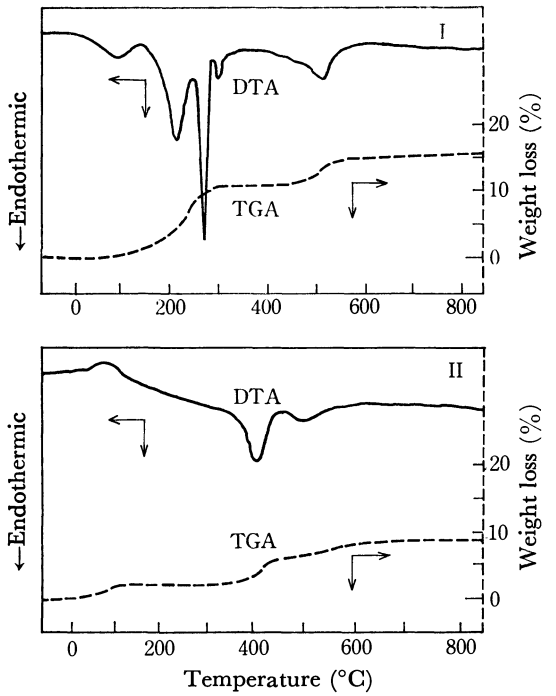

Fig. 3. DTA and TGA curves for titanium hydrogen phosphates.
I: Titanium hydrogen phosphate (No. 3). II: Modification titanium hydrogen phosphate (No. 8).
Sample: 200 mg, heating rate: 5 °C/min.

Hemihydrate and the product obtained by heating it at 185 °C for 2 h gave almost the same X-ray diffraction pattern. Therefore, at this heating temperature, pyrophosphate was not yet formed. However, the X-ray diffraction values of the heated products of monohydrate and hemihydrate at 800 °C were all the same, and these values agreed with the diffraction data of TiP_2O_7 registered on an ASTM X-ray data. It was also confirmed by means of chemical analysis that the two heated products both had the composition of $TiO_2 \cdot P_2O_5$.

Ion-exchange Properties of Titanium Hydrogen Phosphates. It has already been reported that the ion-exchange capacity of $TiH_2(PO_4)_2 \cdot H_2O$ showed values as high as

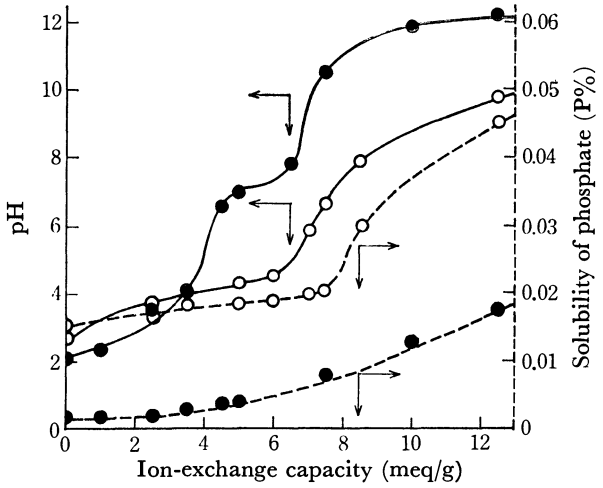

Fig. 4. Na ion-exchange titration curve and solubility of titanium hydrogen phosphates.
○: Titanium hydrogen phosphate, $TiH_2(PO_4)_2 \cdot H_2O$ (No. 3). ●: Modification titanium hydrogen phosphate, $TiH_2(PO_4)_2 \cdot 1/2H_2O$ (No. 8).
Ion-exchanger: 0.200 g, mixed solution of 0.1 mol/l NaOH and 0.1 mol/l NaCl: 25.0 ml.

~7 meq/g for Li^+ and Na^+, but ions with a large radius, such as K^+ and Cs^+, were scarcely adsorbed.[8] The $TiH_2(PO_4)_2 \cdot 1/2H_2O$ prepared in this work gave large *d*-values in the X-ray diffraction data. Therefore, it was supposed that there was a layer structure in the crystal and that, among the layers, various cations could be adsorbed.

Ion-exchange Capacities of Phosphates to Na^+: The sodium ion-exchange titration curves of monohydrate and hemihydrate and their solubilities are shown in Fig. 4. The ion-exchange capacities of monohydrate at pH 4 and 7 were 3.6 and 7.5 meq/g respectively; these capacities were the same as those previously reported.[8] On the other hand, the ion-exchange capacities of hemihydrate at pH 4 and 7 were 3.3 and 5.1 meq/g respectively. In an acid solution the solubility of the ion-exchanger was reduced by about one seventh as compared with that of monohydrate.

Ion-exchanger: 0.200 g, mixed solution of 0.1 mol/l KOH and 0.1 mol/l KCl: 25.0 ml.

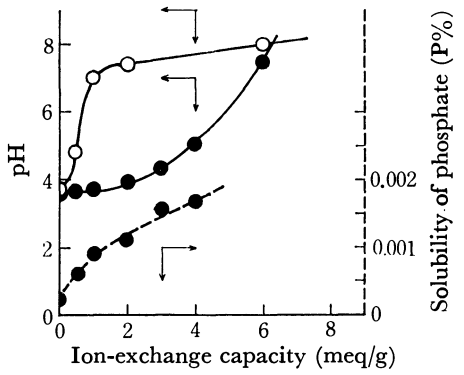

Fig. 6. Cs ion-exchange titration curve and solubility of titanium hydrogen phosphates.
○: Titanium hydrogen phosphate, $TiH_2(PO_4)_2 \cdot H_2O$ (No. 3). ●: Modification titanium hydrogen phosphate, $TiH_2(PO_4)_2 \cdot 1/2H_2O$ (No. 8).
Ion-exchanger: 0.200 g, mixed solution of 0.1 mol/l CsOH and 0.1 mol/l CsCl: 25.0 ml.

Ion-exchange Capacities of Phosphates to K^+: The potassium ion-exchange titration curves of monohydrate and hemihydrate and their solubilities are shown in Fig. 5. The ion-exchange capacities of monohydrate at pH 4 and 7 were 0.5 and 7.5 meq/g respectively. On the other hand, the ion-exchange capacities of hemihydrate at pH 4 and 7 were 4.0 and 4.7 meq/g respectively, and in an acid solution with the same conditions as above the adsorption of the potassium ion was about 8 times that of monohydrate. Besides, the solubility of the ion-exchanger was consideably less than that of monohydrate.

Ion-exchange Capacities of Phosphates to Cs^+: The cesium ion-exchange titration curves of monohydrate and hemihydrate and the solubilities of the latter are shown in Fig. 6. It has previously been reported that the Cs^+ with a large ionic radius was scarcely adsorbed in monohydrate.[8] In the present study, however, a little adsorption was observed, as is shown in the diagram. The ion-exchange capacities of hemihydrate at pH 4 and 7 were 2.0 and 5.5 meq/g respectively, and the solubility of the ion-exchanger was extremely small. The solubility of the monohydrate used as an ion-exchanger could not be estimated, because a colloidal solution was formed by the dissolution of the salt as the pH rose.

As has been mentioned above, the crystalline titanium hydrogen bis(phosphate) hemihydrate could also adsorb such large ions as K^+ and Cs^+; therefore, it may be expected to be an inorganic ion-exchanger.

Preparation and Stereochemistry of the Cobalt(III) Complexes with *N,N'*-Polymethylenedi(salicylideneamine) and Its Related Compounds

Fujio EBINA, Eishin KYUNO, Akira UEHARA, and Ryokichi TSUCHIYA
Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920
(Received February 5, 1975)

Preparation of two series of the cobalt(III) complexes, Na[Co(CN)$_2$(SB)] and [Co(acac)(SB)], was carried out. CN, acac and SB respectively refer to cyanide anion, acetylacetonate anion and the quadridentate Schiff base anion, *N,N'*-polymethylenedi(salicylideneamine), *N,N'*-polymethylenedi(α-methylsalicylideneamine) or *N,N'*-polymethylenedi(2-hydroxy-1-naphthylmethyleneamine). Efforts to obtain Na[Co(CN)$_2$(SB)] only containing the last Schiff base were unsuccessful. It was concluded from their PMR spectra that, for the dicyano complexes, the structure changes from a *trans*-form to a *cis*-one *via* a distorted *trans*-form, whereas for the acetylacetonato complexes, it changes from a distorted *cis*-β-form to an undistorted one with an increase in the length of carbon chain in the bridged polymethylene group of the Schiff bases.

The preparation of the first transition, bivalent metal complexes with salrn as the Schiff base is well-known. Salrn is the abbreviated form of *N,N'*-polymethylenedi(salicylideneamine), $HOC_6H_4CH{=}N(CH_2)_nN{=}CHC_6H_4OH$, which is indicated by salen, saltn and salbn when $n=2$, 3, and 4, respectively. Their structures change from the planar coordination of Schiff base to nonplanar tetrahedral coordination with an increase in the length of carbon chain in the bridged polymethylene group of the Schiff bases from $n=2$ through $n=4$ in Co(II), Ni(II), Cu(II), and Zn(II) complexes.[1-13]

In the tervalent metal complexes, only the cobalt(III) complex containing the above Schiff base as a ligand, where $n=2$, is known.[1,14,15] No other complexes containing bases where n is greater than 3 have been prepared.

Since tervalent metal complexes generally prefer a hexacoordinated octahedral structure, the coordination feature of the Schiff base seems to depend on both the potential denticity of the ligand simultaneously coordinated and the length of carbon chain of the polymethylene bridge.

In the series Na[Co(CN)$_2$(salrn)], when $n=2$, the complex is known to take a *trans*-form structure.[16,17] However, the greater the carbon chain lengthens, the greater the steric strain on the *trans*-form structure.

On the other hand, in the series [Co(acac)(salrn)], when $n=2$, the complex is assumed to take a remarkably distorted *cis*-β-form structure, due to the occupancy of adjacent sites by bidentate acetylacetonate.[18-20] However, as the length of the carbon chain of the polymethylene bridge increases, the above distortion is expected to disappear in contrast to the complexes Na[Co(CN)$_2$(salrn)].

In the present work, the change in the expected steric effect was studied by measuring the PMR spectra of the two series.

In order to confirm the results of PMR spectra of the complexes containing salrn, similar studies were carried out for Na[Co(CN)$_2$(Me-salrn)] and [Co(acac)(Me-salrn)] (Me-salrn is the abbreviated form of *N,N'*-polymethylenedi(α-methylsalicylideneamine) anion, $HOC_6H_4C(CH_3){=}N(CH_2)_nN{=}C(CH_3)C_6H_4OH$, which is indicated by Me-salen, Me-saltn, and Me-salbn when $n=2$, 3, and 4, respectively). Preparation was also made of the cobalt(III) complexes [Co(acac)(Np-salrn)], and their PMR spectra were measured for the sake of stereochemical comparison with the corresponding three types of Schiff base complexes (Np-salrn is the abbreviated form of *N,N'*-polymethylenedi(2-hydroxy-1-naphthylmethyleneamine) anion, $HOC_{10}H_6CH{=}N(CH_2)_nN{=}CHC_{10}H_6OH$, which is indicated by Np-saltn and Np-salbn when $n=3$ and 4, respectively).

Experimental

Preparation. Co(II) Complexes: The Schiff bases and the cobalt(II) complexes containing them were prepared by the procedure given by Hariharan and Urbach[4] and identified by elemental analysis.

Co(III) Complexes. 1) trans-*Sodium Dicyano*-N,N'-*ethylenedi(salicylideneaminato)cobaltate(III)*, trans-*Na[Co(CN)$_2$(salen)] (I)*: Ten milliliters of aqueous solution containing 0.022 mol of sodium cyanide was added to 100 ml of ethanolic solution containing 0.01 mol of Co(II)-Schiff base complex, [Co(salen)] in suspension, and the resulting solution was stirred for 10 min. On being oxidized by blow of air for 2—10 h, yellowish orange powder was precipitated. Needle crystals were separated out by recrystallization from aqueous solution containing a small amount of sodium cyanide. Yield, about 50%. Found: N, 13.90; C, 53.98; H, 3.85%. Calcd for Na[Co(CN)$_2$(salen)]: N, 14.00; C, 54.01; H, 3.53%.

2) trans-*Sodium Dicyano*-N,N'-*trimethylenedi(salicylideneaminato)cobaltate(III) Monohydrate*, trans-*Na[Co(CN)$_2$(saltn)]·H$_2$O (II)*: The procedure of preparation was similar to that for Complex I, [Co(saltn)] being used as Co(II) Schiff base complex of the starting materials, in place of [Co(salen)]. When the resulting solution was oxidized, concentrated to 15 ml at 20 °C, and then allowed to stand overnight in a refrigerator, brown needle crystals were separated out. Recrystallization was achieved by the same procedure as that used for Complex I. Yield, about 40%. Found: N, 12.88; C, 54.81; H, 4.20%. Calcd for Na[Co(CN)$_2$(saltn)]·H$_2$O: N, 12.96; C, 52.78; H, 4.21%.

3) cis-β-*Sodium Dicyano*-N,N'-*tetramethylenedi(salicylideneaminato)cobaltate(III) Trihydrate*, cis-β-*Na[Co(CN)$_2$(salbn)]·3H$_2$O (III)*: This complex was prepared by a procedure similar to that employed for Complex II, [Co(salbn)] being used in place of [Co(saltn)]. Brown cubic crystals were obtained. Recrystallization was carried out from ethanol–ether mixture. Yield, about 30%. Found: N, 11.72; C, 50.92; H, 5.34%. Calcd for Na[Co(CN)$_2$(salbn)]·3H$_2$O: N, 11.62; C, 49.83; H, 5.02%.

4) trans-*Sodium Dicyano*-N,N'-*ethylenedi(α-methylsalicylideneaminato)cobaltate(III) Monohydrate*, trans-*Na[Co(CN)$_2$(Me-salen)]·H$_2$O (IV)*: This complex was prepared and recrystallized by a procedure similar to that employed for Complex I, Me-salen being used in place of salen as a Schiff base. Orange crystals were obtained. Yield, 50%. Found: N, 12.40; C, 54.18; H, 4.44%. Calcd for Na[Co(CN)$_2$(Me-salen)]·H$_2$O: N, 12.56; C, 53.83; H, 4.53%.

5) trans-*Sodium Dicyano*-N,N'-*trimethylenedi(α-methylsalicylideneaminato)cobaltate(III) Dihydrate*, trans-*Na[(CN)$_2$(Me-saltn)]·2H$_2$O (V)*: This complex was also prepared and recrystallized by a procedure similar to that employed for Complex II, Me-saltn being used in place of saltn as a Schiff base. Brown needle crystals were obtained. Yield, about 40%. Found: N, 11.48; C, 54.54; H, 5.38%. Calcd for Na[Co(CN)$_2$(Me-saltn)]·2H$_2$O: N, 11.71; C, 52.72; H, 5.07%.

6) cis-α-*Sodium Dicyano*-N,N'-*tetramethylenedi(α-methylsalicylideneaminato)cobaltate(III) Dihydrate*, cis-α-*Na[Co(CN)$_2$(Me-salbn)]·2H$_2$O (VI)*: This complex was also prepared and recrystallized by a procedure similar to that employed for Complex III, Me-salbn being used in place of salbn as a Schiff base. Yellowish green needle crystals were obtained. Yield, about 20%. Found: N, 11.32; C, 54.97; H, 5.44%. Calcd for Na[Co(CN)$_2$(Me-salbn)]·2H$_2$O: N, 11.38; C, 53.66; H, 5.33%.

Coordination of the cyano group for Complexes I—VI was confirmed from the IR spectra. The charge of these complexes was confirmed by the behavior to an anion exchanger.

7) cis-β-*Acetylacetonato*-N,N'-*ethylenedi(salicylideneaminato)cobalt(III) Quarterhydrate*, cis-β-*[Co(acac)(salen)]·0.25H$_2$O (VII)* This complex was prepared by a modification of the procedure of Fujii *et al.*[17] Ten milliliters of aqueous solution containing 0.006 mol of potassium acetylacetonate was added to 100 ml of methanolic solution suspending 0.005 mol of Co(II)-Schiff base complex, [Co(salen)], and the solution was oxidized by hydrogen peroxide. The resulting solution was refluxed for 1 h and concentrated to *ca.* 20 ml. When the solution was let to stand overnight in a refrigerator, dark green crystals were separated out. They were recrystallized from methanol. Yield, about 70%. Found: N, 6.49; C, 58.60; H, 5.01%. Calcd for [Co(acac)(salen)]·0.25H$_2$O: N, 6.53; C, 58.80; H, 5.06%.

8) cis-β-*Acetylacetonato*-N,N'-*trimethylenedi(salicylideneaminato)cobalt(III) Quarterhydrate*, cis-β-*[Co(acac)(saltn)]·0.25H$_2$O (VIII)*: This complex was prepared and recrystallized by a procedure similar to that employed for Complex VII, saltn being used in place of salen. Dark green crystals were obtained. Yield, about 70%. Found: N, 6.20; C, 59.92; H, 5.44%. Calcd for [Co(acac)(saltn)]·0.25H$_2$O: N, 6.33; C, 59.65; H, 5.36%.

9) cis-β-*Acetylacetonato*-N,N'-*tetramethylenedi(salicylideneaminato)cobalt(III) Hemihydrate*, cis-β-*[Co(acac)(salbn)]·0.5H$_2$O (IX)*: This complex was also prepared and recrystallized by a procedure similar to that employed for Complex VII, salbn being used in place of salen. Bluish green crystals were obtained. Yield, about 60%. Found: N, 5.93; C, 59.75; H, 6.04%. Calcd for [Co(acac)(salbn)]·0.5H$_2$O: N, 6.07; C, 59.86; H, 6.04%.

10) cis-β-*Acetylacetonato*-N,N'-*ethylenedi(α-methylsalicylideneaminato)cobalt(III)*, cis-β-*[Co(acac)(Me-salen)] (X)*: This complex was also prepared and recrystallized by a procedure similar to that employed for Complex VII, Me-salen being used in place of salen. Dark green crystals were obtained. Yield, about 70%. Found: N, 6.18; C, 61.03; H, 15.66%. Calcd for [Co(acac)(Me-salen)]: N, 6.18; C, 61.05; H, 15.58%.

11) cis-β-*Acetylacetonato*-N,N'-*trimethylenedi(α-methylsalicylideneaminato)cobalt(III) Monohydrate*, cis-β-*[Co(acac)(Me-saltn)]·H$_2$O (XI)*: This complex was also prepared and recrystallized by a procedure similar to that employed for Complex VII, Me-saltn being used in place of salen. Dark green crystals were separated out. Yield, about 70%. Found: N, 5.78; C, 59.55; H, 5.96%. Calcd for [Co(acac)(Me-saltn)]·H$_2$O: N, 5.78; C, 59.49; H, 6.05%.

12) cis-β-*Acetylacetonato*-N,N'-*tetramethylenedi(α-methylsalicylideneaminato)cobalt(III)*, cis-β-*[Co(acac)(Me-salbn)] (XII)*: This complex was also prepared and recrystallized by a procedure similar to that employed for Complex VII, Me-salbn being used in place of salen. Bluish green crystals were obtained. Yield, about 60%. Found: N, 5.57; C, 62.26; H, 6.17%. Calcd for [Co(acac)(Me-salbn)]: N, 5.83; C, 62.49; H, 6.10%.

13) cis-β-*Acetylacetonato*-N,N'-*trimethylenedi(2-hydroxy-1-naphthylmethyleneaminato)cobalt(III) Hemihydrate*, cis-β-*[Co(acac)-(Np-saltn)]·0.5H$_2$O (XIII)*: To 0.01 mol of bis-(acetylacetonato)cobalt(II) dihydrate in 150 ml of chloroform was added 0.01 mol of the Schiff base, Np-saltnH$_2$, in 20 ml of chloroform. When the solution was refluxed for 1 hr, the color of the solution turned from pink to dark green. The resulting solution was concentrated to *ca.* 20 ml and let to stand overnight in a refrigerator. Dark green columnar crystals were separated out. They were recrystallized from methanol–chloroform mixture. Yield, about 70%. Found: N, 5.12; C, 65.16; H, 5.36%. Calcd for [Co(acac)(Np-saltn)]·0.5H$_2$O; N, 5.12; C, 65.80; H, 5.17%.

14) cis-β-*Acetylacetonato*-N,N'-*tetramethylenedi(2-hydroxy-1-naphthylmethyleneaminato)cobalt(III) Monohydrate*, cis-β-*[Co(acac)-(Np-salbn)]·H$_2$O (XIV)*: This complex was prepared and recrystallized by a procedure similar to that employed for Complex XIII, Np-salbn being used in place of Np-saltn. Bluish green columnar crystals were obtained. Yield, about 60%. Found: N, 5.23; C, 64.72; H, 5.47%. Calcd for [Co(acac)(Np-salbn)]·H$_2$O: N, 4.91; C, 65.25; H, 5.49%.

Coordination of the acetylacetonate group for Complexes VII—XIV was confirmed from the IR spectra; the characteristic absorption band of coordinated acetylacetonate was observed in the vicinity of 1515 cm^{-1}. Preparation of the cobalt(III) complexes with Np-salen was unsuccessful.

Measurement. The PMR spectra of the complexes were measured with a JEOL JNM-MH-60 spectrometer (60 MHz) at 25 °C using D$_2$O, CD$_3$OD or CDCl$_3$ as a solvent. TMS or NaTMS was used as an internal reference in all the PMR measurements.

The visible and UV absorption spectra were measured with a 323 Hitachi recording spectrophotometer at room temperature using H$_2$O or CHCl$_3$ as a solvent.

Results and Discussion

1) *Dicyano Complexes, Na[Co(CN)$_2$(SB)].* Three geometrical isomers, *trans*, *cis*-α and *cis*-β-form, are possible for a mixed cobalt(III) complex with a quadridentate ligand and two unidentate ligands. Yamada *et al.*[16] reported that [Co(CN)$_2$(salen)]$^-$ ion has a *trans*-form structure. On the other hand, from a consideration of the molecular model it is presumed that it becomes difficult for [Co(CN)$_2$(salrn)]$^-$ ion to have a *trans*-form with an increase in the length of the bridged polymethylene group owing to increasing distortion. The coordination structure of Na[Co(CN)$_2$(salrn)] and Na[Co(CN)$_2$(Me-salrn)] is thus expected to change from *trans*- to *cis*-form depending on the increase in the

length of the bridged polymethylene group.[21]

The PMR spectral data of the dicyano complexes, I through VI, are summarized in Table I. The assignment of each signal in their spectra was given on the basis of the corresponding assignment in the complexes[17] which have similar structures to those of dicyano complexes. In Complexes I and IV, one signal of azomethine proton and one signal of azomethyl proton were observed, respectively. In Complexes II and V, patterns similar to those of Complexes I and IV, respectively, were observed. By referring the patterns to those determined to be *trans*-form,[17] the structures of Complexes I, II, IV, and V can all be assigned to a *trans*-form.

However, the azomethine signal of Complex II is found to shift to higher magnetic field as compared with that of Complex I. From a consideration of the molecular model, such a shift seems to be attributed to the fact that the distortion owing to the steric strain of trimethylene group results in a decreased donation power of the ligand to cobalt(III) ion and, consequently, in an increased electron density of ligand in itself and in an increased shielding effect against the methine proton.

On the other hand, in Complex III, since two signals of azomethine proton were observed, the structure can be assigned to a *cis*-β-form.[17]

Similar features found in Complexes I and II could not be distinctly observed in IV and V. The PMR spectrum of Complex IV was measured in D_2O owing to the small solubility in CD_3OD and, inversely, that of Complex V was measured in CD_3OD owing to the small solubility in D_2O. However, in Complex VI, one signal of azomethyl proton was observed in a higher magnetic field region than in Complex V. The structure of Complex VI seems to be forced into a *cis*-form by the steric strain of the bridged tetramethylene group. From the observation of only one signal concerning azomethyl proton, its structure could be assigned to a *cis*-α-form.

2) *Acetylacetonato Complexes, [Co(acac)(SB)].* For these complexes two geometrical isomers, *cis*-α and *cis*-β-form, are possible since acetylacetonate anion acts as a bidentate ligand. Calligaris *et al.*[18] found by X-ray analysis that the structure of Complex VII takes a distorted *cis*-β-form. This structure is in approximate agreement with that expected by Fujii *et al.*[17] The distortion seems to be due to the shorter length of the bridged ethylene group on salen. It is expected that the greater the length of the bridged group (from salen to salbn), the more weakened the distortion in *cis*-β-form.

The PMR spectral data of the acetylacetonato complexes in chloroform are summarized in Table 2. The assignment of each signal in their spectra was made by referring to that of Complex VII.[17,22] In Complexes VII, VIII, and IX, both the signals of azomethine proton of the coordinated Schiff base and methyl proton of coordinated acetylacetonate were split into two peaks, their four signals being in a relative intensity of 1 : 1 : 3 : 3. In Complexes X, XI, and XII, and Complexes XIII and XIV, similar splittings were observed in relative intensities of 3 : 3 : 3 : 3 and 1 : 1 : 3 : 3, respectively. These patterns correspond to those of *cis*-β-form and, therefore, the structures of all the acetylacetonato complexes can be assigned to a *cis*-β-form.

Some characteristics were found in the spectra: in each of the salrn complexes VII, VIII, and IX, and Mesalrn complexes X, XI, and XII, the apparent separation of two split methyl signals of coordinated acetyl-

Table 2. PMR spectral data of the acetylacetonato complexes in $CDCl_3$

Complex	Peaks of Schiff base (ppm)				Peaks of acac (ppm)

acetonate increases with the increase in the length of the bridged group, where one signal is apparently fixed and the other is shifted to a higher magnetic field. Two methine signals of the coordinated Schiff base for Np-salrn complexes XIII and XIV are shifted to a lower magnetic field than that of salrn complexes VIII and IX. The apparent separation of the corresponding split signals also has a tendency to increase in VIII and IX, and also XIII and XIV, with an increase in the length of the bridged group.

The first tendency may be related to the degree of distortion of the coordination structure in these complexes, but the origin is still obscure. The anisotropic effects of phenyl and naphthyl skeleton of the coordinated Schiff bases seem to play a less important role because of the large distance between methyl groups of acetylacetonate and these skeletons.[23] Other effects, such as solvent effect *etc*, might play an effective role. The origin of the second tendency may be related to the greater deshielding effect of the naphthyl skeleton in Complexes XIII and XIV than that of the phenyl skeleton in Complexes VIII and IV.

The authors wish to express their hearty thanks to Dr. Y. Fujii, Ibaraki University, for his valuable suggestions.

The Thermal Changes in Gels of the SiO_2–Al_2O_3–Sc_2O_3–H_2O System

Mitsuhiro KASAI and Shuichi HAMADA

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received February 7, 1975)

The DTA patterns of synthesized coprecipitated gels, the SiO_2–Al_2O_3–Sc_2O_3–H_2O system, resembled that of allophane as well as those of coprecipitated gels, the SiO_2–Al_2O_3–M_2O_3–H_2O system (M: Fe, Ga, or In). The exothermic reaction around 980 °C in the DTA was confirmed to arise from the formation of mullite. The scandium-rich coprecipitated gels showed a new small exothermic peak at about 1000 °C, based on the formation of thortveitite in the DTA. The apparent activation energy for the mullite formation on the coprecipitated gels decreased with an increase in the scandium content. A large portion of the scandium in the coprecipitated gels was deposited as the thortveitite by heating, while that in the mixed gels was deposited as the scandium oxide. The behavior of such trivalent cations as gallium, iron(III), indium, and scandium in the silicoalumina gels was discussed.

In previous papers,[1–3] the properties of amorphous coprecipitated gels in the systems of SiO_2–Al_2O_3–M_2O_3–H_2O (M: Fe, Ga, and In) were found to resemble those of allophane. Scandium ions are considered to replace aluminum ions in the allophane structure, judging from the similarity in their chemical properties. The thermal properties of the gels, the system of SiO_2–Al_2O_3–Sc_2O_3–H_2O, have not been studied, while Toropov *et al.*[4] reported the phase diagram of the Sc_2O_3–Al_2O_3 system. In this paper, the thermal changes in the scandium-bearing coprecipitated gels were studied.

Experimental

Materials. The coprecipitated samples were prepared in the following manner;[1–3] the coprecipitated gels were obtained by boiling mixed solutions of sodium silicate, aluminum sulfate, and scandium sulfate at pH 5.0—5.7, a pH value obtained by adding hexamethylenetetramine; then they were washed by decantation and air-dried for three weeks. The concentration of the scandium ion in the mixed solutions was varied at the constant ratio of 2.0 as $SiO_2/(Al_2O_3+Sc_2O_3)$. All the coprecipitated samples were identified as amorphous from the X-ray powder diffractograms. The scandium-mixed samples were prepared by mixing a synthesized allophane, free from scandium, and an amorphous hydrated scandium oxide in order to compare the properties of the coprecipitated samples. The amorphous hydrate scandium oxide was prepared at pH 5.5 by using hexamethylenetetramine, because the precipitates obtained with ammonia water were identified as crystalline phases of γ-ScOOH[5] or $Sc(OH)_3$.[6]

Procedure. The amounts of SiO_2, Al_2O_3, and $H_2O(\pm)$[7] in the samples were estimated gravimetrically, while that of Sc_2O_3 was estimated by the chelatometry after it has been separated with a cation-exchange resin (Dowex 50W-X8, H-type).[8]

The differential thermal analysis of the samples was carried out in the temperature range from room temperature to 1100 °C at the heating rate of 10 °C/min with a Rigaku Denki Thermoflex, model 8002, differential thermal analyzer.

The X-ray powder diffraction patterns of the samples were taken with an X-ray diffractometer, model JDX-5P, from the Japan Electron Optics Laboratory Co. The samples were heated at 800, 900, 1000, 1100, and 1200 °C for 5 h in order to examine their thermal changes. The relative amounts of the firing-products were identified and estimated by using the diffraction peaks at (120) and (210) of the mullite, those at (110) and (021) of the thortveitite, and that at (222) of the scandium oxide. The unit-cell dimensions of the mullite, one of the firing-products at 1200 °C, were calculated by using the diffraction peaks at (041), (331), and (002) of the mullite. The diffraction angles were calibrated by using those of silicon.

Results

The chemical compositions of the samples are shown in Table 1.

The Differential Thermal Analysis of the Samples. The results of the differential thermal analysis are shown in Fig. 1. Both the coprecipitated and the mixed samples showed a broad endothermic peak and a sharp exothermic peak in the DTA curves at about 100 and 980 °C respectively. The profile of the DTA curves in these samples was similar to that observed in the allophane. The exothermic-peak temperature in the DTA on the coprecipitated gels was scarcely changed in spite of the variation in the scandium content, unlike as in the case of gallium-coprecipitated samples.[2] A new small exothermic peak was observed at about 1000 °C in the coprecipitated samples with more than 7.23 wt% of Sc_2O_3 (the Sc-7C, -8C, and -9C samples).

a) R_2O_3: $Al_2O_3+Sc_2O_3$ b) The sample is the allophane free from scandium. c) The postscript "C" and "M" denote the scandium-coprecipitated and -mixed samples respectively. d) Calculated.

The causes of the exothermic peaks in the DTA were examined as follows: the samples were preheated in the DTA equipment up to temperatures just below and just above their peak temperatures. The phases of the preheated samples were found by X-ray powder diffractometry to be as shown in Table 2. The exothermic reaction at about 980 °C in the coprecipitated samples was found to arise from the formation of mullite, and that at about 1000 °C, from the formation of thortveitite.

The apparent activation energy for the formation of mullite was estimated by means of the method described by Kissinger.[9] The results for the coprecipitated samples are shown in Table 3.

The Variation in the Firing-products in the Samples during Heat Treatment. The crystalline phases formed in the heat-treated samples at 800, 900, 1000, 1100, and 1200 °C for 5 h were identified as the mullite, the thortveitite,[10] and the scandium oxide[11] by means of X-ray powder diffractometry. The firing-products at each temperatures are shown in Table 4. All the samples formed the mullite above 900 °C, while they were amorphous at 800 °C except for the Sc-12M and -13M samples. The scandium component deposited as the thortveitite in the coprecipitated gels with more than 2.22 wt% of Sc_2O_3, but deposited as the scandium oxide only above 800 °C in the mixed samples. The formation temperature of the thortveitite decreased with an increase in the scandium content. The coprecipitated gel of the SiO_2–Sc_2O_3–H_2O system, with the

SiO_2/Sc_2O_3 molar ratio of 1.79 and free from aluminum, formed the scandium oxide and the thortveitite, while the mixed gels with the same composition formed only the scandium oxide at 1000 °C.

The Unit-cell Dimensions of the Mullite formed in the Heat-treated Samples. The relationships between the unit-cell lengths, a_0, b_0, and c_0, of the mullite formed at 1200 °C for 5 h in the coprecipitated samples and the scadium content in the original samples are shown in Fig. 2. While all the unit-cell lengths increased with an increase in the scandium content up to approximately 4—5 wt%, the increasing tendency in the c_0 was less than those in the a_0 and the b_0. The spacings of the thortveitite formed at 1200 °C were scarcely changed in spite of the variation in the scandium content, while they were slightly smaller than those of a native thortveitite.[10]

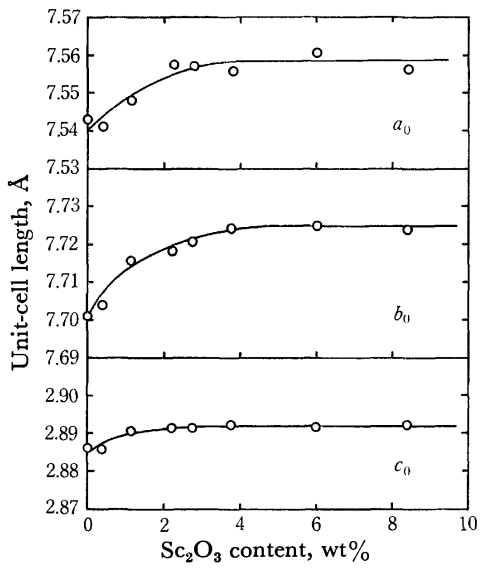

Fig. 2. Relationships between unit-cell length, a_0, b_0, and c_0, of scandium-bearing mullite formed at 1200 °C and Sc_2O_3 content of original gel.

Ďurovič[12] confirmed that the mullite lattice consisted of a AlO_6 octahedron and AlO_4 and (Si, Al)O_4 tetrahedra, that the AlO_6 octahedra were composed of chains, parallel to the [001] direction, by sharing their edges, and that the chains were linked by the AlO_4 and the (Si, Al)O_4 tetrahedra. Judging from the ratio of the ionic radii of Sc^{3+} and O^{2-} (0.73 and 1.32 Å),[13] the scandium ions replace the aluminum ions only in the octahedra of the mullite lattice. Variations in the unit-cell lengths, a_0, b_0, and c_0, of the mullite were found to be nonidentical, as is shown in Fig. 2. Because two octahedra slanting to the [100] and the [010] directions are situated in the <110> directions for each unit-cell of the mullite, though only one octahedron slants in the [001] direction, the replacement of the scandium ions would bring about larger enlargements of the a_0 and the b_0 than that of the c_0. Furthermore, the distortion of the octahedra based on the repulsion between the aluminum ions was considered to decrease slightly by the replacement of the scandium ions, as had also been observed in the octahedra in the α-AlOOH[14] and the α-ScOOH.[15] Therefore, the a_0 and b_0 would be further expanded by this effect.

Discussion

A clear difference between the kinds of firing products obtained from the coprecipitated and the mixed gels has been observed in the SiO_2–Al_2O_3–M_2O_3–H_2O systems (M: Fe, Ga, In, and Sc) in this series of works.[1-3] Judging from these facts, such trivalent cations as iron (III), gallium, indium, and scandium ions were obvious substitutes for the aluminum ions in the allophane structure of the coprecipitated gels. Such trivalent cations were included in the mullite by heating, and they enlarged the lattice; the degree of enlargement is governed by several factors—for example, the amount of the substituting cation, its ionic radius, and the crystallographic geometry, all related to each other.

The order of the amount of trivalent cations includible in the mullite as a solid solution was found to be Ga≫Fe>Sc>In. This result was considered to be reasonable, judging from the ionic radii of the trivalent cations in these systems (Al^{3+}: 0.51, Ga^{3+}: 0.62, Fe^{3+}: 0.64, Sc^{3+}: 0.73, and In^{3+}: 0.81 Å respectively).[13]

Léonard *et al.*[16] have investigated the coordination states of aluminum ions and the structure change in the amorphous hydrated silicoalumina gels by means of X-ray fluorescence spectroscopy and IR spectroscopy. They stated that the aluminum ions were stabilized by forming octahedra sharing corners of the tetrahedra of the SiO_4 and hydroxy-groups in the hydrated silicoalumina gel structure, and that then the sixfold-coordinated aluminum ions were altered to the fourfold-coordinated state as dehydration proceeded upon heating.

The aluminum ion is well known to take both the sixfold- and the fourfold-coordinated states; the gallium ion also can take both the states—for example, in the structure of the β-gallia,[17] though less frequently than the aluminum ion. The iron (III), however, was not found to form the tetrahedra. The clear difference between the gallium and the iron (III) ions in the degree of substitution was considered to be caused by a variability in the coordination state of the gallium ion in spite of the similarity in their ionic radii.

Though the scandium and the indium ions, having large ionic radii, would replace the aluminum ions to some extent by forming the octahedra in the hydrated silicoalumina gels, the stability of the gels would decrease as a result of the great distortion as dehydration proceeded. The apparent activation energies for the formation of mullite or silicoalumina spinel,[1,2] a precursor of the mullite, at the coprecipitated gels decreased with an increase in the content of the substituted cations; this decreasing tendency in the scandium- and the indium-coprecipitated samples was larger than that in the gallium-coprecipitated gels. These facts support the above consideration. Though the scandium ions replaced the aluminum ions in the original allophane structure, a large portion of the scandium is probably excluded by heating from the mullite lattice, because the scandium ion took the sixfold-coordinated state only. The deposition of scandium as disilicate in the

coprecipitated gels would be caused by its lithophilic nature, and the thortveitite, which has only the sixfold-coordinated sites for metal[18] in it, is likely to be stable both thermodynamically and crystallographically.

The Preparation and Absorption Spectra of the Cyanocarbonatotriammine- and Cyanooxalatotriammine-type Complexes of Cobalt(III)

Shoji NAKASHIMA and Muraji SHIBATA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920

(Received March 18, 1975)

The complexes of the $[CoCN(O\text{–}O)(N)_3]$ type (O–O represents CO_3^{2-} or $C_2O_4^{2-}$, and $(N)_3$ represents three NH_3, one NH_3 plus one en, or one dien) have been prepared starting from the $[Co(CO_3)_3]^{3-}$ complex, and their characterization has been achieved on the basis of the absorption and PMR spectra. Among these, each of the *fac*(N) isomers of the carbonato complexes shows a shoulder in the second absorption band and no shoulder in the first absorption band. In contrast, each of the corresponding *fac*(N) isomers of the oxalato complexes shows no such shoulder in the second absorption band, but does show a shoulder in the first absorption band. The same phenomena have been found in the spectra of the *trans*(N)-$[Co(O\text{–}O)(mda)(NH_3)]^-$ complexes (mda stands for the methyliminodiacetate ion).

In our previous studies concerning the preparation of mixed-ligand cobalt(III) complexes containing the cyanide ion as a ligand, we succeeded in obtaining such complexes as $[CoCN(NH_3)_5]^{2+}$,[1] *mer*-$[Co(CN)_3(NH_3)_3]$,[1] *cis*-$[Co(CN)_2(CO_3)_2]^{3-}$,[2] and *cis-cis*-$[Co(CN)_2(CO_3)(NH_3)_2]^-$.[3] The present work was undertaken in connection with those studies and in order to prepare the cyanocarbonatotriammine-type and the cyanooxalatotriammine-type complexes, which are represented by the formula $[CoCN(O\text{–}O)(N)_3]$ ($(N)_3$ represents three NH_3, one NH_3 plus one en, or one dien). These complexes are of interest not only in such preparative work, but also in electronic spectroscopy: Since the three kinds of donor atoms differ greatly in their ligand-field strengths, marked splittings of both the first and second absorption bands were expected for some of these complexes. In practice, the carbonato complexes with a geometrical form with respect to donor atoms showed shoulders in their second absorption bands, whereas the corresponding oxalato complexes showed shoulders in their first absorption bands.

Experimental

Preparation. *1) Cyanocarbonatotriamminecobalt(III), $[CoCN(CO_3)(NH_3)_3]$*: To a cold, green solution of tricarbonatocobaltate(III) (0.1 mol scale)[4] we added potassium cyanide (13 g, 0.2 mol) in portions; the mixture was then stirred vigorously at room temperature for 20 min, whereby a deep red solution was obtained. To this solution we added conc. aqueous ammonia (40 ml, 0.56 mol), after which the mixture was stirred at 50 °C for 40 min. The resulting dark red solution was carefully neutralized with aqueous perchloric acid under an iced condition and then filtered to remove any precipitated material. The filtrate was charged on a column of Dowex 50 WX-8 resin (100—200 mesh, Na-form, 50×400 mm). With careful washing with water, two bands colored yellow-brown and red, descended after the minor band of negatively charged species had been effused. These two bands were collected in fractions labeled A-1 and A-2. Each fraction was concentrated to a small volume, and a small amount of ethanol was added to the concentrate. When the mixture was kept in a refrigerator, fine crystals were deposited. The complexes thus obtained were also named A-1 and A-2. The formation ratio of A-1/A-2 was found to be about 1/5.

2) Cyanocarbonatoammineethylenediaminecobalt(III), $[CoCN(CO_3)(NH_3)(en)]\cdot H_2O$: Concentrated aqueous ammonia (20 ml, 0.28 mol) was added to a deep red solution prepared in the same way (0.1 mol scale) as in 1), and the mixture was stirred at 40 °C for 30 min. The resulting solution was neutralized with aqueous perchloric acid and filtered. To the filtrate ethylenediamine (0.1 mol) was added, after which the mixture was stirred at 40 °C for an hour. The resulting dark red solution was neutralized again with aqueous perchloric acid under an iced condition and filtered to remove any precipitates. The filtrate was chromatographed in the same manner as in 1); two bands, colored yellow-brown and red, were collected in fractions labeled B-1 and B-2. When each concentrate from the fractions was kept in a refrigerator, crystals of the desired complex were deposited. The formation ratio of B-1/B-2 was about 1/10.

3) Cyanocarbonatodiethylenetriaminecobalt(III), $[CoCN(CO_3)(dien)]$: The procedure was the same as that in 1), except for the use of diethylenetriamine (10.3 g, 0.1 mol) instead of conc. ammonia. The chromatographic separation gave three bands, colored yellow-brown, red, and red. These were collected in fractions labeled C-1, C-2, and C-3. Very fine crystals were obtained from C-1 and C-3, whereas no complex was isolated from C-2 because the species was too unstable to be isolated. The formation ratio of C-1/C-3 was found to be about 1/5.

4) Cyanooxalatotriammine-type Complexes, $[CoCN(ox)(N)_3]$: A cyanocarbonato complex, A-1 (10 g, 0.05 mol), which had been obtained in *1)*, was treated with 60% perchloric acid (0.1 mol), and then potassium oxalate (18.4 g, 0.1 mol) was added to the acid-hydrolyzed solution. The resulting solution was stirred at 40 °C for 2 h and then neutralized with an aqueous solution of potassium hydroxide. After the precipitated material had been removed by filtration, the filtrate was chromatographed in the same manner as that in *1)*; two yellow-brown bands, labeled A′-1 and A′-2, were thus obtained. The amount of the second band (A′-2) formed was less than that of the first one (A′-1). One yellow-brown band was obtained when the A-2 complex was used as the starting material, and the complex obtained from this band was the same as A′-2. The other oxalato complexes, labeled B′-1 and B′-2 for the $[CoCN(ox)(NH_3)(en)]$ complex, and C′-1 and C′-3 for the $[CoCN(ox)(dien)]$ complex, were obtained in the same manner as above. The oxalato complexes thus obtained were less soluble in water than the corresponding carbonato complexes. Therefore, the recrystallization of the oxalato complexes was achieved by dissolving them in an aqueous solution of sulfuric acid and by then adding ethanol.

5) Potassium Carbonatomethyliminodiacetatomonoamminecobaltate (III), $K[Co(CO_3)(mda)(NH_3)]\cdot 2.5H_2O$: The ligand, methyliminodiacetic acid (H_2mda), was prepared from methylamine and sodium monochloroacetate according to the method

in the literature.[5] To a solution of $K[Co(CO_5)_2(NH_3)_2]\cdot H_2O$[6] (13.5 g, 0.05 mol) in water, we added an aqueous solution of the ligand (K_2mda, 0.05 mol); the mixture was then stirred for 4 h at 45 °C, whereby a red-blue solution was obtained. It was carefully neutralized with aqueous perchloric acid under an iced condition and then filtered. The filtrate was charged on a column of an anion-exchange resin (Dowex 1X-8, 100—200 mesh, Cl-form, 50×400 mm). When the adsorbed band was eluted with a 0.07 M aqueous KCl solution, one red-violet band was obtained. This fraction was concentrated to a small volume at *ca.* 40 °C. A small amount of methanol was added to remove the KCl used for the elution. When the solution was then kept in a refrigerator, the desired complex was deposited. The recrystallization was performed from water.

6) Potassium Oxalatomethyliminodiacetatomonoamminecobaltate (III), K[Co(ox)(mda)(NH_3)]: This complex was easily obtained by treating an aqueous solution of the carbonato complex obtained in *5)* with a little excess of oxalic acid.

Measurements. The absorption spectra were measured with a Hitachi Model 323 spectrophotometer. The proton magnetic resonance spectra were recorded on a JEOL JNM-PS-100 NMR spectrometer at *ca.* 22 °C, with 20% D_2SO_4 in D_2O as the solvent. The values of the chemical shifts were referred to internal sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) or sodium D_4-trimethylsilylpropionate (TMSP).

Results and Discussion

The possible geometrical isomers of the [CoCN(O–O)$(N)_3$] type complexes are illustrated in Fig. 1, where *mer* and *fac* represent *trans-cis* and *cis-cis* arrangements of the three N atoms, and where the *s-* and *u-* symbols are used to distinguish between the isomer with a plane of symmetry and the one without such a plane.

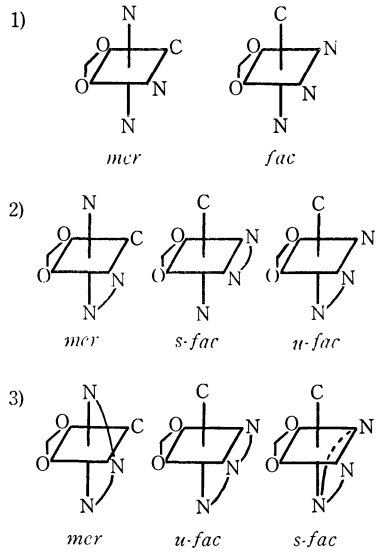

Fig. 1. Possible geometrical isomers of the [CoCN(O–O)$(N)_3$]-type complexes; 1) triammine complex, 2) ammine-ethylenediamine complex, and 3) diethylenetriamine complex.

The results of elemental analysis are given in Table 1 (no elemental analysis of the B′-1 complex was carried out because of the poor yield); these figures are in close agreement with the calculated values. The absorption spectral data are also summarized in Table 1, but that of the A′-1 complex was not measured because of its low solubility. Figure 2 shows the absorption spectra of the cyanocarbonato complexes, A-2, B-2, and C-3. Each spectrum shows a shoulder and a maximum in the second absorption band region. A similar feature of the

a) ( ): calcd. sh: shoulder.

spectrum has been reported for the *mer*(*trans*)-[$Co(CO_3)$-(α-am)$(NH_3)_2$] complexes (*trans* refers to the NH_3 groups, and α-am represents the glycinate, alaninate, or valinate ion),[7,8] and also with the *mer*(N)-[$Co(CO_3)$-(*i*-dtma)] complexes (*i*-dtma stands for *N*,*N*-bis(2-aminoethyl)glycinate ion).[9] The spectrum of the *i*-dtma complex is included in Fig. 2 as an example. Moreover, it has been reported[10] that the absorption spectrum of the *trans*-$[Co(CO_3)_2(py)_2]^-$ complex shows an explicit shoulder in the second absorption band region and that the shoulder is assignable to a split component of the second band on the basis of Yamatera's predictions.[11] Therefore, the band positions for the present $[CoCN(CO_3)(NH_3)_3]$ complex were calculated by means of Yamatera's predictions; the parameters concerning the first and second bands, δ^{I} and δ^{II}, were treated as $\delta^{I}=\delta^{I}_{\sigma}+\delta^{I}_{\pi}$ and $\delta^{II}\approx\delta^{II}_{\sigma}$. The numerical values were estimated from the absorption maxima of the $[Co(NH_3)_6]^{3+}$, $[Co(CO_3)_3]^{3-}$,[4] and *fac*-$[Co(CN)_3(NH_3)_3]$[12] complexes ($\delta^{I}(NH_3-CO_3)=4466$, $\delta^{II}(NH_3-CO_3)=6700$ cm^{-1}; $\delta^{I}(CN-NH_3)=10770$, $\delta^{II}(CN-NH_3)=10130$ cm^{-1}). The predicted positions are given in Table 2.

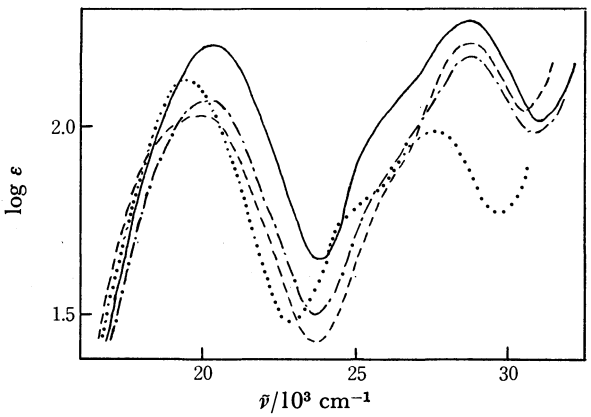

Fig. 2. Absorption spectra of $[CoCN(CO_3)(N)_3]$-type complexes, A-2 (------), B-2 (-·-·-) and C-3 (——), and of *mer*(N)-$[Co(CO_3)$(*i*-dtma)] (·····).

TABLE 2. PREDICTED BAND POSITIONS FOR $[CoCN(CO_3)(NH_3)_3]$

Geometry	I band (in cm^{-1})	II band (in cm^{-1})
fac(N)	18700, 22500, 22500	27500, 27500, 31700
mer(N)	19900, 21400, 22500	27500, 29200, 30000

From the table it may be seen that the separations between the lowest-energy and highest-energy components in both the first and the second band for the *fac*(N) geometry are considerably greater than those for the *mer*(N) geometry. This fact suggests that a splitting of the second absorption band is to be expected for the *fac*(N) complex (namely, A-2). Thus, the remaining complexes, B-2 and C-3, may also be regarded as *fac*(N) isomers from the similarity in the spectrum. It is, however, not possible to differentiate between the *s*- and *u*-configurations for the B-2 and C-3 complexes.

Figure 3 shows the absorption spectra measured with solutions of the *fac*(N)-$[CoCN(CO_3)(N)_3]$ complexes (A-2, B-2, and C-3) acidified with aqueous perchloric

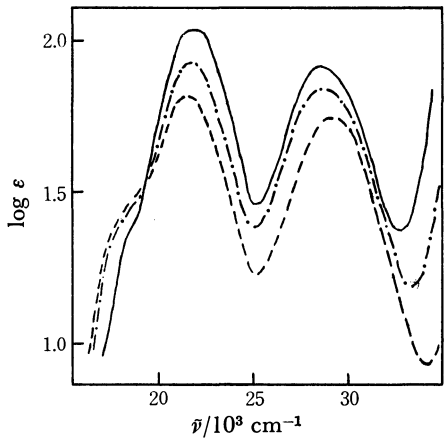

Fig. 3. Absorption spectra of $[CoCN(H_2O)_2(N)_3]$-type complexes derived from A-2 (------), B-2 (-·-·-), and C-3 (——).

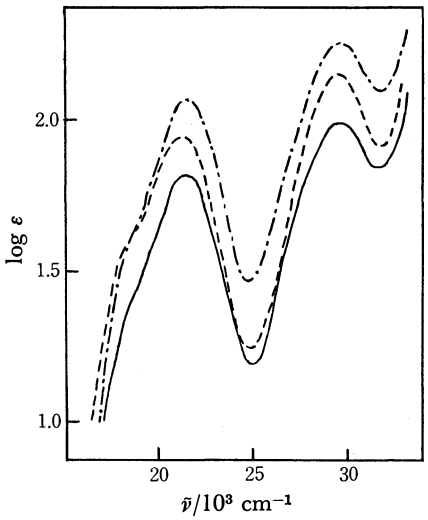

Fig. 4. Absorption spectra of $[CoCN(ox)(N)_3]$-type complexes, A′-2 (------), B′-2 (-·-·-), and C′-3 (——), in *ca.* 20% H_2SO_4.

acid to give acid-hydrolyzed species. Figure 4 shows the spectra of the $[CoCN(ox)(N)_3]$ complexes, A′-2, B′-2, and C′-3. In both figures, each spectrum reveals a shoulder in the first absorption band and no shoulder in the second absorption band. Similar splitting of the first absorption bands have been observed in the spectra of the *mer*(*trans*)-[Co(α-am)$(H_2O)_2(NH_3)_2]^{2+}$ and of the *mer*(*trans*)-[Coox(α-am)$(NH_3)_2$] complexes.[8] On this basis, the A′-2, B′-2, and C′-3 complexes can be identified as the *fac*(N) isomers which correspond, in geometrical configuration, to the above-mentioned *mer*-(*trans*) isomers.

Figure 5 shows the spectrum of the $[CoCN(CO_3)$-(dien)] complex, C-1, and that of the corresponding oxalato complex, C′-1. There are no shoulders in either the first or second absorption band. Similarly shaped spectra have been reported with the *fac*(N)-$[Co(CO_3)$(α-am)$(NH_3)_2]$[8] and also with the *fac*(N)-$[Co(CO_3)$(*i*-dtma)].[9] As for *cis*-$[Co(CO_3)_2(py)_2]^-$, no shoulders have been reported in the first and second absorption bands.[10] Thus, the C-1 and C′-1 complexes can be identified as the *mer*(N) isomers. The same

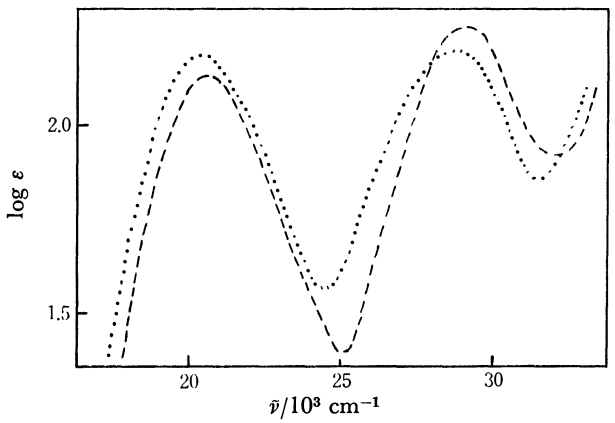

Fig. 5. Absorption spectra of [CoCN(CO_3)(dien)] complex, C-1 (·····) and [CoCN(ox)(dien)] complex, C′-1 (------).

assignment can be made for the remaining complexes (A-1, B-1, A′-1, and B′-1). In addition the elution orders in the chromatographic separations support the foregoing assignments; the earlier eluted species in each run of the chromatographic separations is the *mer*(N) isomer.[7-9]

The PMR spectrum of the *mer*(N)-[CoCN(ox)(dien)] complex, whose structural assignment could be made on the basis of the absorption spectrum, is presented in Fig. 6-a, the spectrum of the corresponding *fac*(N) complex being presented in Fig. 6-b. By a comparison of the two spectra, each peak resonating in a down field (5.7 ppm for the *mer* and 6.9 ppm for the *fac*) is attributed to the NH proton, the two peaks resonating in a middle field (4.8 and 4.4 ppm for the *mer* and 4.3 and 4.1 ppm for the *fac*) being attributed to the NH_2 protons. The integrated ratio of these three peaks is estimated to be 1: 2: 2.

A molecular model for the *mer*(N) isomer indicates that the two protons of each of the two NH_2 groups of the chelated dien are not equivalent with respect to the complexed CN^- ion; one of the protons is located in a position near to the CN^- ion, while the other is far from the CN^- ion. Thus, the observed two peaks for the *mer*(N) complex can be interpreted in terms of such environmentally different situations of the NH_2 protons by assuming the effect of the CN^- ion on the NH_2 resonances. Provided the *fac*(N) complex has the *s-fac*(N) structure, the two peaks due to the NH_2 protons can be interpreted in the same way. If the *u-fac*(N) structure is assumed, its spectrum would have three peaks due to the NH_2 resonances with the integrated ratio of 1: 1: 2. The fact that the CN^- ion affects the NH_2 resonances is clearly recognized in the PMR spectrum of the *cis-cis*-$[Co(CN)_2(H_2O)_2(en)]^+$ complex[13] (Fig. 6-c); there are four peaks corresponding to the four protons of the two NH_2 groups of the chelated en. This fact supports the *s-fac*(N) structure of the C′-3 complex. As to the corresponding carbonato complex, the PMR spectrum was measured in 20% D_2SO_4 (under this condition the complex was converted into [CoCN-$(H_2O)_2$(dien)]$^{2+}$ species). The spectrum exhibited two broad peaks due to the NH_2 resonances, although one peak at a lower field contained a weak peak due to the NH resonance. On the basis of this obervation, the structure of the carbonato complex (C-3) is regarded as of the *s-fac*(N) form.

In establishing the structures of the isomers of the *fac*(N)-[CoCN(ox)(NH_3)(en)] complex, the PMR spectral approach did not play a part because similar spectra were expected for both the *s*- and *u*-geometries; the spectrum measured showed two peaks due to the NH_2 groups and one peak due to the NH_3 molecule. Taking into consideration the fact that the *u-fac*(N) isomer of the [CoCN(ox)(dien)] could not be isolated, the present NH_3-en complex may be regarded as a *u-fac*(N) isomer which corresponds to the *s-fac*(N) isomer of the dien complex. From the same point of view, the [CoCN-$(CO_3)(NH_3)$(en)] complex (B-2) may be regarded as a *u-fac*(N) isomer.

When the absorption spectra of the [CoCN$(CO_3)(N)_3$] type complexes are again examined in relation to their established structures, it is found that every complex exhibiting a shoulder in the second absorption band has such a configuration that no chelate ring is formed in a co-plane with the carbonate chelate ring and that the axial positions are occupied by the donor atoms exerting stronger ligand fields than the other donor atoms on the planar positions.

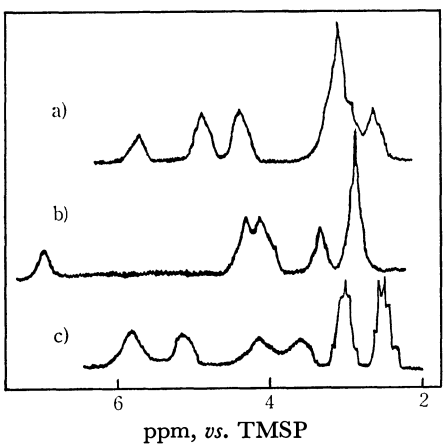

Fig. 6. PMR spectra of;
a) *mer*(N)-[CoCN(ox)(dien)], (b) *s-fac*(N)-[CoCN(ox)-(dien)], c) *cis-cis*-$[Co(CN)_2(H_2O)_2(en)]^+$.

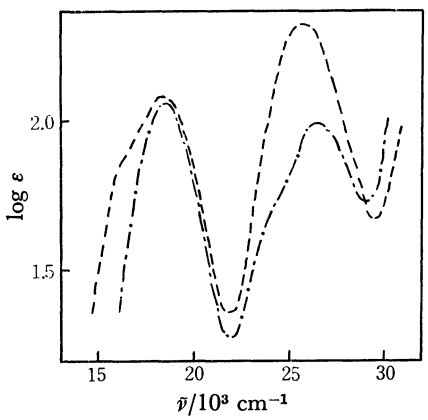

Fig. 7. Absorption spectra of mda complexes of; *trans*(N)-[Co(CO_3)(mda)$(NH_3)]^-$ (-·-·-) and *trans*(N)-[Coox(mda)$(NH_3)]^-$ (------).

In order to confirm such restrictions in configuration, an additional experiment was designed to prepare the $[Co(CO_3)(mda)(NH_3)]^-$ complex; three geometrical isomers, two *cis*(N) and one *trans*(N), can possibly exist, but only one isomer was isolated, as has been mentioned in the Experimental section. The absorption spectrum of the complex is shown in Fig. 7, together with the spectrum of the corresponding oxalato complex. The splitting of the second absorption band is observed for the carbonato complex, whereas that of the first absorption band is observed for the oxalato complex. These facts correspond to those observed for the cyanotriammine complexes and indicate that both the mda complexes are to be their *trans*(N) isomers. This assignment is supported by the PMR spectrum of the oxalato complex (where there is observed an AB pattern due to the two CH_2 groups of the chelated mda).

The Polarography of *trans*-Cobalt(III) Complexes of Tetradentate Schiff Bases and α-Methylbenzylamine in *N,N*-Dimethylformamide and Methanol Solutions

Mutsuo KODAMA

Department of Chemistry, College of General Education, Hirosaki University, Bunkyo, Hirosaki 036

(Received April 21, 1975)

The polarographic behavior of mixed-ligand cobalt(III) complexes of tetradentate Schiff bases and α-methylbenzylamine (pheNH$_2$) of the general formula of [CoZ(pheNH$_2$)$_2$]$^+$ in methanol and *N,N*-dimethylformamide solutions was studied. At the dropping mercury electrode, these metal complexes give well-defined, two-step waves corresponding to the reduction of cobalt(III) to cobalt(II) and that of cobalt(II) to cobalt(I). A careful and systematic study of their polarographic behavior revealed that the reaction mechanism in the presence of uncomplexed pheNH$_2$ can be formulated as:

$$[CoZ(pheNH_2)_2]^+ + e^- \rightleftarrows [CoZ(pheNH_2)_2]^0$$
$$[CoZ(pheNH_2)_2]^0 + e^- \rightleftarrows [CoZ(pheNH_2)_2]^-$$

while, in the absence of pheNH$_2$, the reaction mechanism for the second step of the *N,N'*-ethylenebis(acetylacetoneiminato) and *N,N'*-ethylenebis(benzoylacetoiminate) systems is given by:

$$[CoZ(pheNH_2)_2]^0 + e^- \rightleftarrows [CoZ(pheNH_2)]^- + pheNH_2$$

This can be ascribed to the labile nature of the axial ligand, pheNH$_2$, in these two complexes. The introduction of halogen atoms on the methyl or methylene carbon of *N,N'*-ethylenebis(acetylacetoneiminato) and that of the benzene ring on the framework of the equatorial ligand remarkably shifted the half-wave potential towards more positive potentials. This fact suggests the electron withdrawal from the cobalt atom by these groups. Furthermore, by examining the nature of the half-wave potentials the redox orbitals of *N,N'*-ethylenebis(salicylideneaminato) and *o*-phenylenebis(salicylideneaminato) systems were concluded to be essentially different from those of other Schiff-base systems.

Previously,[1] the present author studied the polarographic behavior of a series of mixed *β-cis* and *trans*-cobalt(III) complexes of tetradentate Schiff-base dianions, baen and salen,[2] in an *N,N*-dimethylformamide (DMF) solution. All these complexes gave two well-defined polarographic steps corresponding to the reduction of cobalt(III) to cobalt(II) and that of cobalt(II) to cobalt(I). A thorough investigation of these led to the conclusion that the planar nature of baen and salen plays an important role in trapping the metal ion in an uncommon oxidation state. In order to get a deeper insight into the nature of the Schiff-base as a equatorial ligand, it seemed that it would be worthwhile to investigate the influence of tetradentate Schiff bases on the polarographic behavior of cobalt(III) complexes. In this paper, the present author will describe a polarographic study of *trans* mixed-ligand cobalt(III) complexes of tetradentate Schiff-base dianions (Z^{2-}) and methylbenzylamine (pheNH$_2$) with the general formula of [CoZ(pheNH$_2$)$_2$]$^+$ [2] in DMF and methanol solutions.

Experimental

Reagents. All the cobalt(III) complexes, [CoZ(pheNH$_2$)$_2$]ClO$_4$, used in this study were obtained from Dr. Y. Fujii (Department of Chemistry, Ibaraki Uiversity, Bunkyo, Mito, Ibaraki). The purification of DMF was described previously.[3] The tetraethylammonium perchlorate (TEAP) was prepared by the method given by Fujinaga *et al.*[4] The methanol used in this study was purified by employing the method given in a previous paper.[5] All the other chemicals used in this study were of a reagent grade and were used without further purification.

Apparatus and Experimental Procedures. The DC polarographic waves were measured by using a manual polarograph similar to Kolthoff and Lingane's or a Yanagimoto pen-recording polarograph, P-8. All the AC polarograms were recorded automatically by employing the above pen-recording polarograph. The DC polarographic data given in this paper were corrected for the residual current and the ohmic drop of the cell circuit (4.2 kΩ). The characteristics of the dropping mercury electrode (DME) used have been given previously.[6] As reference electrodes, a saturated calomel electrode (SCE) and a silver-silver chloride electrode (Ag/AgCl) were used in the DMF and methanol solutions respectively. The Ag/AgCl electrode was prepared by employing the method of Mizuguchi and Ueno.[7] TEAP for the DMF system and LiCl for the methanol system were used as supporting electrolytes. All the other experimental procedures employed were described in a previous paper.[1]

Results and Discussion

As is illustrated by the DC polarogram of [Co(benacen)(pheNH$_2$)$_2$]$^+$ complex in Fig. 1, all the cobalt(III) complexes in DMF and methanol containing an excess of uncomplexed pheNH$_2$ gave two cathodic waves, the limiting currents of which were exactly proportional to their bulk concentration and to the square-root of the effective pressure on the DME. Furthermore, their diffusion-current constants were nearly identical to that of the reduction wave of the tris(acetylacetonate) cobalt(III) complex in the DMF solution, suggesting a one-electron reduction[1] for both steps. The plot of log $(I/(I_d-I))$ against the DC potential, E, invariably gave a straight line with a reciprocal slope falling in the range from −57 mV to −70 mV (20 °C). This indicates that the electrode reactions at both steps proceed reversibly in the polarographic sense. This explanation could be also confirmed AC-polarographically. An AC polarogram with two sharp maximal

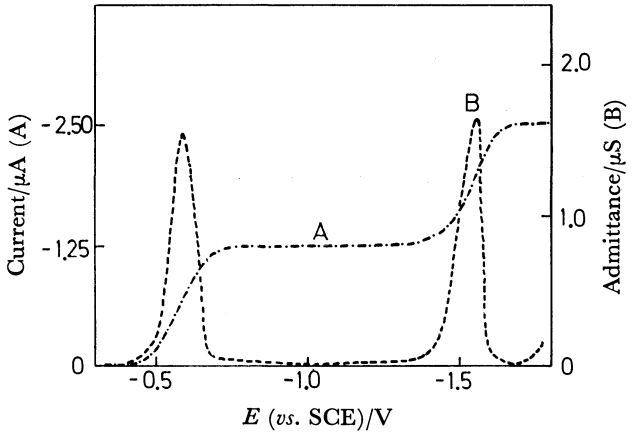

Fig. 1. DC (A) and AC (B) polarograms of 1.20 mM $[Co(benacen)(pheNH_2)_2]^+$ in DMF solution containing an excess of $pheNH_2$.
[TEAP]=0.20 M, $[pheNH_2]$=0.32 M.

currents corresponding to the DC reduction steps was obtained (Fig. 1). The concentration of the excess $pheNH_2$, when higher than 10 mM*, had no effect on the half-wave potential and the wave-height. These findings clearly suggest that the electron-transfer step is not accompanied by the dissociation of $pheNH_2$ from the complex; hence, the reaction mechanisms for the first and second steps can be expressed by Eqs. (1) and (2) respectively:

$$[CoZ(pheNH_2)_2]^+ + e^- \rightleftarrows [CoZ(pheNH_2)_2]^0 \quad (1)$$

$$[CoZ(pheNH_2)_2]^0 + e^- \rightleftarrows [CoZ(pheNH_2)_2]^- \quad (2)$$

The electrode reaction at the second step in the absence of $pheNH_2$ also proceeded reversibly in the polarographic sense. However, the first step became extended, showing an irreversible nature. The plot of $\log(I/(I_d-I))$ against E gave a straight line with a reciprocal slope falling in the range from −75 mV to −85 mV. Furthermore, a prestep appeared at a less negative potential, and its wave-height increased with the time at the expense of the first wave-height (Fig. 2). This prestep can probably be ascribed to the reduction of the $[CoZ(pheNH_2)]^+$ or CoZ^+ formed upon the dissociation of the axial ligand, $pheNH_2$, because the transformation of $[CoZ(pheNH_2)_2]^+$ into $[CoZ(pheNH_2)]^+$ or CoZ^+ lowers the energy level of the redox orbital,[8] which will then accept the electron in the course of the reduction process. The wave-height of the prestep at a given time was almost parallel with the following order of the rate constants for the dissociation of the axial ligand, $pheNH_2$, from the $[CoZ(pheNH_2)_2]^+$, lending strong support to the above explanation:

$$baen > benacen > salen > saloph > tfbaen^{9)}$$

In the light of the above findings, the irreversible nature of the first step in the absence of $pheNH_2$ can probably be ascribed to the slow partial dissociation of the axial ligand in the course of the electron-transfer step. The finding that the second step of the tfbaen complex gave a straight line with a reciprocal slope of −65 mV between $\log(I/(I_d-I))$ and E, while that of the substitution-labile benacen complex gave a linear relationship between $\log(I^2/(I_d-I))$ and E, also supports the above explanation (Fig. 3). The linear relation between $\log(I^2/(I_d-I))$ and E clearly suggests the following reaction mechanism for the second step of the benacen complex:

$$[CoZ(pheNH_2)_2]^0 + e^- \rightleftarrows [CoZ(pheNH_2)]^- + pheNH_2 \quad (3)$$

In the methanol solution, the second step of the baen system merged into the base current. Therefore, no accurate log-plot examination could be achieved under the present experimental conditions. However, in the DMF solution, quite a similar result was obtained by conducting the above log-plot examination. This indicates that the electrode reaction in the second step of the baen system in the absence of $pheNH_2$ can also be given by Eq. (3).

The equatorial ligand will have a profound effect on the physicochemical properties and the reactivity of the ligand at the axial position. With a given axial ligand, the coordination of the equatorial tetradentate ligand,

B) Methanol solution; [LiCl]=0.30 M

which gives the increase in the effective charge on the cobalt atom, will weaken the coordination bond in the axial positions and will shift the half-wave potential towards more negative potentials. Therefore, a close relationship between the half-wave potential and the magnitude of the exchange-rate constant of the axial ligand, pheNH$_2$, can be expected. As is illustrated in Fig. 4, a linear relation was found between the half-wave potential for the first step and the logarithm of the exchange-rate constant, log (k_{ex}/s^{-1}),[9] measured in the methanol solution by employing an NMR method. The half-wave potential determined in the presence of an excess of pheNH$_2$ was compared with log (k_{ex}/s^{-1}), because, only when the electrode process is rigorously reversible and the chemical reactions, including the dissociation of axial ligands which follows the electron transfer can be kept slow enough to be studied separately, the polarographic half-wave potential can give quantitative information concerning the thermodynamic aspects of the interaction of the axial ligand with the rest of the molecule.[10] As is shown by the results in Fig. 4, the replacement of the methyl group of the baen by the phenyl group (benacen) has no appreciable effect on the half-wave potential or the exchange rate of the axial ligand, pheNH$_2$. However, the replacement of the methyl hydrogen atoms of baen by fluorine (tfbaen) and the introduction of the benzene ring onto the framework of the equatorial ligand (salen and saloph) remarkably shifted the half-wave potential towards more positive potentials and reduced the rate of the exchange reaction of pheNH$_2$. The introduction of a chlorine (baen-Cl) or bromine (baen-Br) atom on the 3-position of baen also gave a positive shift of the half-wave potential (Fig. 5). As has been stated above, the half-wave potential gives a relative measure of the electron density on the cobalt atom.[11,12] Therefore, the above findings suggest that the benzene group on the framework of the equatorial tetradentate ligand and the halogen atom on the methyl or methylene carbon of baen can effectively decrease the electron density on the cobalt atom, hence enhancing the strength of the cobalt-pheNH$_2$ bond.

Finally, the present author wants to mention the following fact. As is shown by the results in Fig. 5, a linear relation holds in the DMF solution between the half-wave potentials of the first and second waves for all the tetradentate Schiff-base systems other than the salen and saloph systems. In the methanol solution, a similar linear relation also roughly holds. This probably indicates that the redox orbitals of the salen and saloph systems are essentially different from those of the other Schiff-base systems investigated. In order to describe precisely the nature of the redox orbital, though, further systematic investigation is required.

The author wishes to express his heartfelt thanks to Dr. Yuki Fujii of the Department of Chemistry, Faculty of Sciences, Ibaraki University, for his kind gift of the pure cobalt(III) complexes used in this study.

Electronic Spectra of Tetraphenylporphinatoiron(III) Methoxide

Hiroshi KOBAYASHI, Tadatoshi HIGUCHI, Youkoh KAIZU,
Hisajiro OSADA, and Masaru AOKI

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received April 26, 1975)

Tetraphenylporphinatoiron(III) methoxide in the high-spin state $S=5/2$ gives rise to an absorption spectrum which has been assigned to that of low-spin iron(III) porphyrins. The excited states characteristic of the spectrum of high-spin iron(III) porphyrins are the configuration-interaction admixtures of the lowest triplet and singlet porphyrin (π,π^*) excited states and the low-lying "porphyrin to iron(III)" charge-transfer excited states. The charge-transfer excited states in tetraphenylporphinatoiron(III) methoxide, however, are so high that the charge-transfer excited states are not sufficiently mixed with the lowest triplet (π,π^*) excited states. Thus the high-spin methoxo complex does not exhibit a spectrum characteristic of high-spin iron(III) porphyrins.

Possible spin states of the iron(III) ion embedded in porphyrin ligand are the high-spin state $S=5/2$ and the low-spin state $S=1/2$ depending upon its axial ligand field. The intermediate spin state $S=3/2$ is not obtained for a typical ligand field of porphyrin.[1-3] George, Beetlestone and Griffith separated the high- and low-spin spectral types for the ferrihemoproteins by combining spectroscopic and magnetic data.[4] They could get limiting spectra from the mixture spectra of the two spin states $S=5/2$ and $S=1/2$ in equilibrium. On the other hand, Caughey found that a high-spin iron(III) porphyrin, methoxo iron(III) deuteroporphyrin-IX dimethyl ester, shows an absorption spectrum characteristic of low-spin iron(III) porphyrins.[5,6]

In this paper, an interpretation of the low-spin type of spectrum observed for high-spin porphyrinatoiron(III) methoxides is presented on the basis of experimental observations for tetraphenylporphinatoiron(III) methoxide.

Experimental

Synthesis of the Metal-free Base of Tetraphenylporphin (H_2TPP). H_2TPP was synthesized by the method of Adler *et al.*[7] Chromatographic purification was repeated on activated alumina columns using chloroform as a solvent and also as an eluent. The elute was concentrated, and then excess methanol was added. Purple needle crystals thus obtained were identified by elemental analysis.

Found: C, 86.18; H, 4.61; N, 8.96%. Calcd for $C_{44}H_{30}N_4$: C, 85.97; H, 4.92; N, 9.11%.

Synthesis of Tetraphenylporphinatoiron(III) Chloride (TPPFe(III)Cl). TPPFe(III)Cl was prepared in dimethylformamide (DMF). H_2TPP (0.3 g) and $FeCl_2\cdot 4H_2O$ (1.5 g) were dissolved in DMF (200 ml) and refluxed for 3 h. When the solution was cooled, dilute hydrochloric acid were added in small portions. The dark purple crystals thus precipitated were collected by filtration. The complex was recrystallized twice from a mixture of 1,2-dichloroethane and *n*-hexane.

Found: C, 74.94; H, 3.85; N, 7.92; Fe, 7.97; Cl, 5.10%. Calcd for $C_{44}H_{28}N_4FeCl$: C, 75.07; H, 4.01; N, 7.96; Fe, 7.93; Cl, 5.04%.

Synthesis of Tetraphenylporphinatoiron(III) Methoxide (TPPFe(III)OCH_3). A methanol solution of sodium methoxide prepared by dissolving metal sodium (1 g) in dry methanol (100 ml) was added to a solution of TPPFe(III)Cl (0.7 g) in dry benzene (350 ml). The mixture was refluxed for 3 h and then filtered. The filtrate was concentrated under reduced pressure until crystals appeared and then a small amount of dry methanol was added. The blue crystals thus obtained were collected by filtration, washed with dry methanol, and dried *in vacuo* over silica gel.

Found: C, 77.72; H, 4.64; N, 7.87; Fe, 7.91%. Calcd for $C_{45}H_{31}N_4OFe$: C, 77.26; H, 4.47; N, 8.01; Fe, 7.98%.

Synthesis of Bisimidazoletetraphenylporphinatoiron(III) Perchlorate ([TPPFe(III)$(Im)_2$]ClO_4). TPPFe(III)Cl (35 mg) was dissolved in benzene (5 ml). Silver perchlorate (10 mg) was added to the solution. After being refluxed for 4 h, silver chloride was filtered off and then imidazole (6 mg) was added. Reddish purple crystals precipitated upon the addition of imidazole. When the precipitation was completed, unreacted silver perchlorate and imidazole were dissolved by addition of ethyl ether (5 ml). The precipitate thus obtained was dissolved in 1,2-dichloroethane and then filtered for separation of the contaminating silver chloride. The filtrate was condensed under reduced pressure. Benzene was then added for precipitation. Pure crystals were obtained by recrystallization from a mixture of 1,2-dichloroethane and benzene.

Found: C, 66.18; H, 3.67; N, 12.50; Fe, 6.08%. Calcd for $C_{50}H_{36}N_8FeClO_4$: C, 66.42; H, 4.01; N, 12.39; Fe, 6.18%.

Synthesis of μ-Oxo-bis(tetraphenylporphinatoiron(III)) ([TPPFe(III)]$_2O$). The complex was obtained by shaking a benzene solution of TPPFe(III)Cl with aqueous KOH.[8] The resulting benzene solution was evaporated to dryness. The residue was dissolved in chloroform and then methanol was added. The purple crystals thus precipitated were collected and washed with methanol. The complex was purified by chromatography in a column packed with Sephadex LH-20 using tetrahydrofuran as a solvent and an eluent. The first fraction of the elute was evaporated to dryness. The residue was recrystallized from a mixture of 1,2-dichloroethane and *n*-hexane.

Found: C, 77.74; H, 4.07; N, 8.08%. Calcd for $C_{88}H_{56}N_8OFe_2$: C, 78.11; H, 4.17; N, 8.28%.

Measurements of Absorption and Magnetic Circular Dichroism Spectra. The electronic absorption spectra were recorded on a Shimadzu recording spectrophotometer Model MPS-50. Solvents were benzene, and 1,2-dichloroethane purified by fractional distillation using a 1.5 m Dixson-ring packed column and dried by the usual procedure.[9]

The absorption spectra of the powder samples were measured by the opal glass method.[10] Instead of an opal glass plate, a sheet of tracing paper smeared with the solid sample was placed in front of the window of a head-on type photomultiplier in the Shimadzu spectrophotometer.

The circular dichroism under an external magnetic field (MCD) was measured on a JASCO automatic recording spectropolarimeter Model ORD/UV-5 with its CD attachment and electro-magnet. The magnetic field was set at

10000 Gauss.

Magnetic Susceptibility. The magnetic susceptibilities of the complexes were measured at room temperature by means of the Gouy method. After a calibration of the diamagnetic term by the conventional method, the magnetic moments of the complexes were evaluated.[11]

Infrared Spectra. The infrared spectra of the complexes in KBr disk were taken on a Hitachi infrared spectrometer Model EPI-G3.

ESR Spectra. The ESR spectra were obtained with a Japan Electron Optics Laboratory spectrometer Model JES-ME3X. The static magnetic field was calibrated by means of a proton-resonance gaussmeter.

Results and Discussion

The electronic absorption spectrum of TPPFe(III)Cl is typical of high-spin iron(III) porphyrins. Three other iron(III) porphyins, TPPFe(III)OCH_3, [TPPFe(III)$(Im)_2$]ClO_4 and [TPPFe(III)]$_2O$, exhibit spectra resembling each other, but differing in profile from the spectrum characteristic of high-spin iron(III) porphyrins The absorption and MCD spectra are presented in Figs. 1 and 2.

The absorption spectrum of [TPPFe(III)$(Im)_2$]ClO_4 in 1,2-dichloroethane (Fig. 1) is a typical low-spin spectrum. The low-spin spectrum was also obtained for [TPPFe(III)$(Im)_2$]Cl and [TPPFe(III)$(Im)_2$]ClO_4 in chloroform which consists of ten times or more excess imidazole. La Mar and Walker also observed in their NMR studies that the proton signals of the low-spin species were detected only in the presence of eight times excess imidazole in deuterochloroform.[12] In chloroform, however, a drift of the absorption spectrum was observed for a few hours even in the presence of excess imidazole. This indicates the dissociation of coordinated imidazole in solution. In 1,2-dichloroethane, the absorption spectrum does not change for a few days after the sample is dissolved in the absence of excess imidazole.

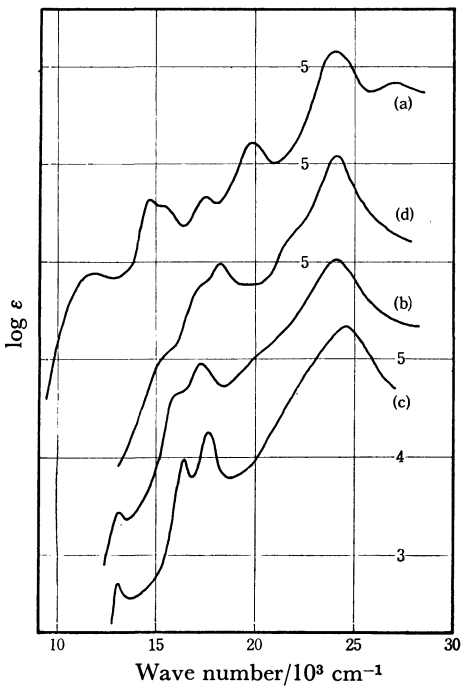

Fig. 1. Absorption spectra of TPPFe(III)Cl(a), TPPFe(III)OCH_3(b) and [TPPFe(III)]$_2O$(c) in benzene, and [TPPFe(III)$(Im)_2$]ClO_4(d) in 1,2-dichloroethane.

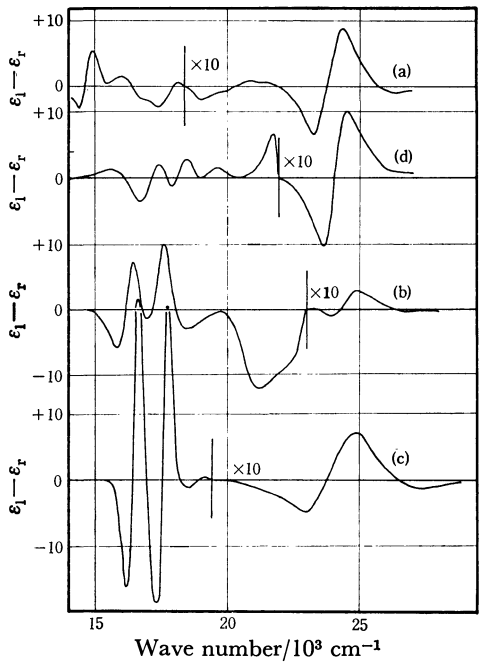

Fig. 2. MCD spectra of TPPFe(III)Cl(a), TPPFe(III)-OCH_3(b) and [TPPFe(III)]$_2O$(c) in benzene, and [TPPFe(III)$(Im)_2$]ClO_4(d) in 1,2-dichloroethane.

The absorption spectrum of TPPFe(III)OCH_3 dissolved in dry benzene (Fig. 1) is very similar to that of [TPPFe(III)$(Im)_2$]ClO_4. Unless the solvent and the

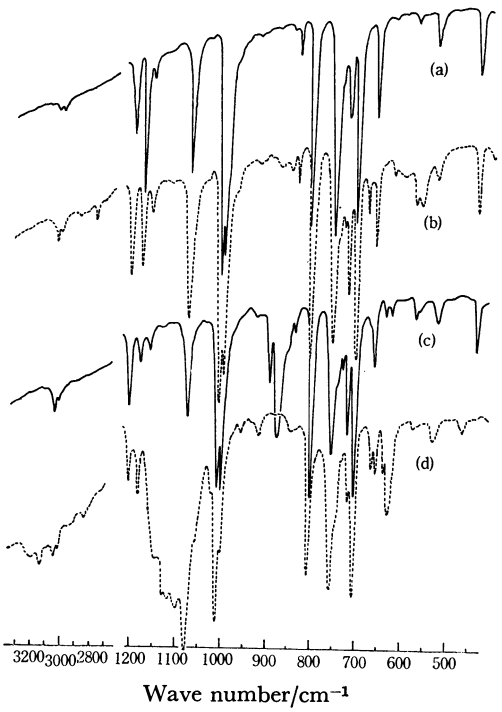

Fig. 3. IR spectra of TPPFe(III)Cl(a), TPPFe(III)-OCH_3(b), [TPPFe(III)]$_2O$(c), and [TPPFe(III)-$(Im)_2$]ClO_4(d) in KBr disk.

apparatus are sufficiently dried, the absorption spectrum gradually changes to that of $[TPPFe(III)]_2O$. The moisture in solution reacts with $TPPFe(III)OCH_3$ forming $[TPPFe(III)]_2O$, a dimer with Fe–O–Fe bridge.[13] $[TPPFe(III)]_2O$ exhibits two strong IR peaks of antisymmetric vibrations of Fe–O–Fe at 875 cm^{-1} and 895 cm^{-1}.[8,13] $TPPFe(III)OCH_3$ lacks such IR peaks in the region but shows a C–H stretching peak of coordinated OCH_3 group at 2800 cm^{-1}. The IR spectra are shown in Fig. 3.

Table 1. Magnetic moments of TPPFe(III)Cl, $TPPFe(III)OCH_3$ and $[TPPFe(III)(Im)_2]ClO_4$

Complex	χ (10^{-6} cgs/mol)	Temperature (K)	μ_{eff} (B.M.)	Spin state
$[TPPFe(III)(Im)_2]ClO_4$	2493	291.7	2.41	$S=1/2$
TPPFe(III)Cl	14733	292.8	5.87	$S=5/2$
$TPPFe(III)OCH_3$	14489	293.3	5.83	$S=5/2$

The magnetic moments which were measured by the Gouy method are given in Table 1. The measurement reveals that the solid sample of $TPPFe(III)OCH_3$ is in the high spin state $S=5/2$, although the absorption spectrum in benzene is of low-spin type. The ESR spectrum of solid $TPPFe(III)OCH_3$ measured at 77 K ($g_\perp=5.30$, $g_{//}=2.00$) is also a spectrum characteristic of high-spin species such as TPPFe(III)Cl ($g_\perp=6.00$, $g_{//}=2.00$).[14] The ESR spectra are shown in Fig. 4. Since an interconversion of the spin state was possible upon dissolution of the sample into a solvent, the absorption spectra of the solid samples were examined by the opal glass method. They were found, however, to coincide qualitatively with the solution spectra (Fig. 5). A spectral change to be attributed to a spin interconversion does not occur on dissolution. The solution spectrum is less dependent upon solvents unless the solvent molecules replace the axial ligands.

The lowest excited states, which are responsible for the absorption spectra of high-spin iron(III) porphyrins and of high-spin manganese(III) porphyrins, are well described as a configuration-interaction admixture of the lowest triplet and singlet (π, π^*) excited states of porphyrin and the "porphyrin to metal" charge-transfer (CT) excited states.[15] Since the ground state of the high-spin iron(III) porphyrin is $^6A_1$ the allowed photo-excited states should be spin-sextet. The energies of the (π, π^*) excited states $^6E_T(\pm 9a)$, $^6E_T(\pm 1a)$, $^6E_Q(\pm 9b)$

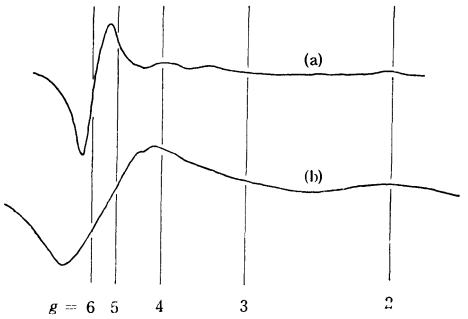

Fig. 4. ESR spectra of TPPFe(III)Cl(a) and TPPFe-(III)OCH_3(b) in the solid state at 77 K.

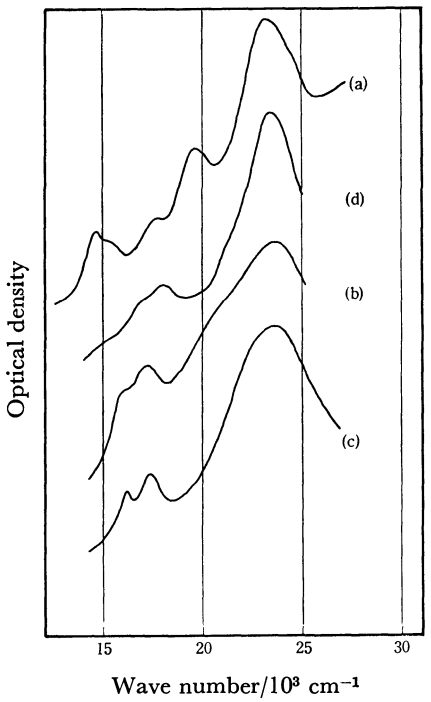

Fig. 5. Absorption spectra of TPPFe(III)Cl(a), TPPFe-(III)OCH_3(b), $[TPPFe(III)]_2O$(c) and $[TPPFe(III)(Im)_2]ClO_4$(d) in the solid state.

and $^6E_B(\pm 1b)$ and the CT excited states $^6E_{CT}(\pm 5)$ and $^6E_{CT}(\mp 3)$ are given in terms of energy parameters E, K_9, K_1, and E_{CT}.[15] The mixing terms of the excited sextets are given in terms of the delocalization parameter β and the off-diagonal corrections ε, ε', and ε'' for the assumption of an accidental degeneracy in the highest filled porphyrin orbitals. The molecular param-

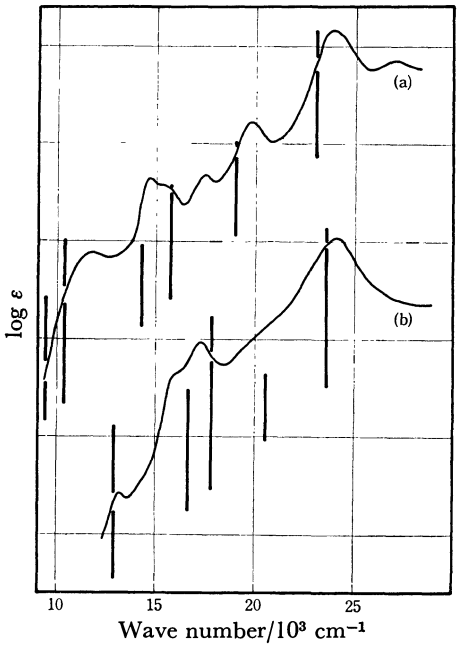

Fig. 6. The calculated lowest excitations of TPPFe(III)-Cl(a)($E_{CT}=12500\,cm^{-1}$) and $TPPFe(III)OCH_3$(b)($E_{CT}=17500\,cm^{-1}$). The assumed parameter values are $E=13070\,cm^{-1}$, $K_1=4600\,cm^{-1}$, $K_9=2730\,cm^{-1}$, $\beta=-3000\,cm^{-1}$, $\varepsilon=1340\,cm^{-1}$, $\varepsilon'=-1340\,cm^{-1}$, and $\varepsilon''=0\,cm^{-1}$.

^6E_Q ($\Lambda_z=\pm9$)	0.0654	−0.1654	0.7077	−0.0268	−0.6223	0.2823
^6E_B ($\Lambda_z=\pm1$)	0.0391	0.1058	−0.1610	0.3829	0.1778	0.8850
Λ_z ($\hbar$)	±4.53	±3.85	±7.52	∓1.27	±6.16	±1.21
Number of the transferred charge	0.135	0.279	0.276	0.678	0.502	0.130

The assumed parameter values are $E=13070$ cm^{-1}, $K_1=4600$ cm^{-1}, $K_9=2730$ cm^{-1}, $\beta=-3000$ cm^{-1}, $\varepsilon=1340$ cm^{-1}, $\varepsilon'=-1340$ cm^{-1}, and $\varepsilon''=0$ cm^{-1}.

eters except E_{CT} were estimated to reproduce the transition energies and the intensity ratio of the Q and B bands of TPPCo(III)Cl in pyridine. The transition energies and intensities for the lowest excited sextets of high-spin iron(III) porphyrins were calculated for a variety of E_{CT}. The calculated lowest excited sextets can well reproduce the observed lowest excited states of TPPFe(III)Cl for $E_{CT}=12500$ cm^{-1}. The electronic absorption spectrum of TPPFe(III)OCH_3 is also reproduced for the same molecular parameters of TPPFe(III)-Cl except a high E_{CT} value of 15000 cm^{-1} or 17500 cm^{-1}. The calculated lowest excited states of TPPFe(III)X are shown with the observed spectra in Fig. 6. In the case of a high-spin iron(III) porphyrin with $E_{CT}=12500$ cm^{-1}, the "porphyrin to iron(III)" charge-transfer excited states crucially mix with the lowest triplet (π, π^*) excited states and give rise to a blue shift of the excited state which is essentially assigned to the Q (π, π^*) state. This results in a typical spectrum of high-spin iron(III) porphyrins. In the case of a high-spin iron(III)porphyrin with $E_{CT}=17500$ cm^{-1}, on the other hand, the charge-transfer excited states do not mix sufficiently with the triplet (π, π^*) excited states, the high-spin iron(III) porphyrin thus exhibiting a spectrum differing from the typical spectrum of high-spin iron(III) porphyrins. Contributions of the composite excited states to each of the lowest excited states are presented in Table 2, together with the calculated values of orbital angular momentum and transferred charge from "porphyrin to iron(III)" in the excited states.

An increase in the charge-transfer energy in high-spin porphyrinatoiron(III) methoxides is attributed to a reduction in the dπ electron affinity of the central iron-(III) ion for a greater charge donation by the coordinated OCH_3. The magnitude of the zero-field splitting of the $^6A_1$ components of ferric ion ($\Delta E_1 \equiv E(^6A_1 \mp 3/2) - E(^6A_1 \pm 1/2)$) has been directly measured by far-infrared spectroscopy on the methoxide and chloride of ferric deuteroporphyrin-IX dimethyl ester (ΔE_1-(OCH_3)$=9.3$ cm^{-1}; ΔE_1(Cl)$=17.9$ cm^{-1}).[16,17] Here, ΔE_1 is given by $2D$ in terms of $D=\zeta^2/5(E_4-E_6)$, where ζ is the spin-orbit coupling constant and E_4-E_6 is the first-order energy difference between $^4A_2(\theta\xi^2+1-1)$ and $^6A_1(\varepsilon\theta\zeta+1-1)$ states.[18] For a strong axial field, an energy difference between ε and θ is reduced and then $^4A_2$ lies higher. This implies that an increase in the axial ligand field results in a reduction in ΔE_1. Thus the observed zero-field splitting supports a greater charge donation by the coordinated OCH_3^-.

The authors wish to express their sincere thanks to Professor W. S. Caughey who brought the low-spin type of spectrum in a high-spin porphyrinatoiron(III) methoxide to their attention during the course of collaboration by one of the authors (H. K.) in Johns Hopkins Medical School. The authors are indebted to Professor J. Higuchi and Dr. T. Ito for the measurements of ESR spectrum.

Complex Formation of Indium(III) with Murexide and the Decomposition of Murexide in the Presence of Indium(III) in Acid Perchlorate Media

Yoichi KAWAI,* Taira IMAMURA, and Masatoshi FUJIMOTO
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received April 28, 1975)

Kinetic and equilibrium data on the complex formation between In(III) and murexide are derived using stopped-flow method and also from the rate of decomposition of the ligand in acid perchlorate media. The rate of complex formation is independent of the acid concentration over the wide range of [H] between 0.001 and 0.5 M. The discrepancies of the stability constants obtained from the direct and the indirect methods are discussed.

Murexide, ammonium purpurate, has long been used as a very useful metallochromic indicator[1] except for acid region, where it decomposes to uramil and alloxan.[2,3] The rate of the decomposition depends on the acid concentration.[2] We are interested in the reaction mechanism of the complex formation between indium(III) and murexide in connection with the possibility of catalytic action of indium(III) on the decomposition of murexide.

The rates of metal complex formations in general are affected by the acid concentration due to the contribution of hydrolyzed forms of the metal ion.[4] The kinetic data on the metal complex formations with murexide in the neutral region were reported in detail by Geier.[5] In the case of indium(III) and murexide, however, we observed no dependence on the hydrogen-ion concentration of the rate of complex formation. In the present report the complex formation between indium(III) and murexide and the decomposition of murexide in the presence of indium(III) ion are studied over a wide range of the hydrogen-ion concentrations 0.001—0.5 M.

Experimental

Materials. Deionized water was distilled. Reagent grade materials were used unless otherwise specified. Indium(III) perchlorate solution was prepared by dissolving indium(III) oxide in a small excess of concentrated perchloric acid. The concentration was titrimetrically determined with EDTA using Xylenol Orange as indicator. Weighed amount of commercial or prepared murexide[6] was dissolved in water immediately before use.

Acidity and ionic strength of the solutions were adjusted with perchloric acid and sodium perchlorate. The stock solution of perchloric acid was standardized by titration with sodium hydroxide. The stock solution of sodium perchlorate was kept for a couple of weeks to precipitate trace amount of metal impurities together with silicates and filtered through a glass filter. An aliquot of the solution was passed through a column of cation-exchange resin (Dowex 50W-X8) in the H-form and titrated with sodium hydroxide.

Measurements. The rates of decomposition and the spectra were measured with a Hitachi EPS-3T spectrophotometer equipped with a recorder. The thermostated reactant solutions were pipetted and mixed with shaking in a thermostated optical cell.

A Yanagimoto SPS-1 stopped-flow apparatus was used to measure the rate of complex formation. The optical cell and the reservoirs were thermostated by circulating the water from a thermostat.

Results

Stability Constant of the Complex Measured by Stopped-flow Method at [H]=0.5 M. Equilibrium data of the complex in the acid range were directly derived from the change in absorbance as measured by stopped-flow technique.

Formation of 1 : 1 complex between indium(III) and murexide (MX) was confirmed by the mole ratio method. The absorption maximum of the complex (InMX) lies at 470 nm with the molar extinction coefficient $\varepsilon_{InMX}=8.82\times10^3$ at [H]=0.5 M and ionic strength 2.0 M ($NaClO_4$). The value ε_{MX} at 470 nm was evaluated to be 4.51×10^3.

Under high acid concentration the rapid complex formation is followed by the slow decomposition of murexide. Stability constant of the complex K_{1a} at 25 °C and [H]=0.5 M was calculated from the change in absorbance at 470 nm memorized on the screen of oscilloscope.

Stability constant K_{1a} is written as follows.

$$K_{1a}=\frac{[InMX]}{\{[In]_0-[InMX]\}\{[MX]_0-[InMX]\}},$$

$$A=\varepsilon_{MX}[MX]_0+(\varepsilon_{InMX}-\varepsilon_{MX})[InMX], \text{ and}$$

$$[InMX]=\frac{A-\varepsilon_{MX}[MX]_0}{\varepsilon_{InMX}-\varepsilon_{MX}},$$

where $[In]_0$ and $[MX]_0$ are the initial concentrations of indium(III) and murexide respectively, and A, ε_{InMX}, and ε_{MX} denote the observed absorbance, the molar extinction coefficients of the complex and the ligand at 470 nm respectively.

The plot of $\{[In]_0-[InMX]\}\{[MX]_0-[InMX]\}$ *versus* [InMX] gave a straight line as shown in Fig. 1 and value of K_{1a} was evaluated from the slope to be 7.2×10^3 M^{-1} at [H]=0.5 M, μ=2.0 M ($NaClO_4$) and at 25 °C.

Rate of Complex Formation and Stability Constants. The rate of complex formation between indium(III) and murexide was measured by following the increase in the absorbance of the complex with time. The rate

* Present address: Sumitomo Chemical Industries, Ltd., Niihama, Ehime.

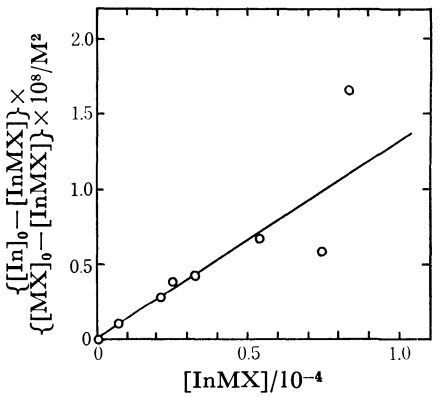

Fig. 1. Plot of $\{[In]_0-[InMX]\}\{[MX]_0-[InMX]\}$ *vs.* [InMX] at 25 °C, μ=2.0 ($NaClO_4$), and [H]=0.5 M.

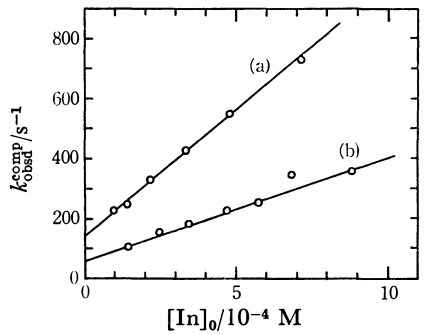

Fig. 2. Plot of k_{obsd}^{comp} *vs.* total concentration of In(III) at [H]=0.5 M and μ=2.0 ($NaClO_4$).
(a) $[MX]_0=4.08\times10^{-5}$ M and at 25 °C; (b) $[MX]_0=1.08\times10^{-5}$ M and at 10 °C.

of complex formation is increased with increasing concentration of indium(III). Figure 2 shows the dependence of the pseudo-first-order rate constant on indium(III) concentration under the conditions of $[In]_0 \gg [MX]_0$, [H]=0.5 M, μ=2.0 M ($NaClO_4$) and at 10 or 25 °C.

The values of $\vec{k}$, $\overleftarrow{k}$ and K_{1b} for the reaction

$$In + MX \underset{\overleftarrow{k}}{\overset{\vec{k}}{\rightleftharpoons}} InMX$$

are evaluated as shown in Table 1.

Table 1. Kinetic and equilibrium data of the indium(III)-murexide complex, measured at [H]=0.5 M and μ=2.0 ($NaClO_4$).

T (°C)	$\vec{k}$ ($M^{-1}\cdot s^{-}$)	$\overleftarrow{k}$ (s^{-1})	$K_{1b}=\vec{k}/\overleftarrow{k}$ (M^{-1})
10	$3.5_4\times10^5$	$57._6$	$6.1_4\times10^3$
25	$8.5_2\times10^5$	130	$6.5_5\times10^3$

Table 2 shows the rate constants k_{obsd}^{comp}, $\vec{k}$ and $\overleftarrow{k}$ for the wide range of acid concentrations at ionic strength 2.0 M ($NaClO_4$) and 10 °C. Since the pseudo-first-order rate constant k_{obsd}^{comp} does not depend on the acid concentration, it would be reasonable to conclude that the both rate constants $\vec{k}$ and $\overleftarrow{k}$ do not depend on the acid concentration.

Effect of $[MX]_0$ *and* $[H]$ *on the Rate of Decomposition of Murexide.* The absorption maximum of murexide

Table 2. [H]-Dependence of the rate of complex formation between indium(III) and murexide at 10 °C and μ =2.0 ($NaClO_4$). ($[In]_0$= 4.77×10^{-4} M, $[MX]_0=5.10\times10^{-5}$ M).

[H] (M)	k_{obsd}^{comp} (s^{-1})	$\vec{k}=(k_{obsd}^{comp}-\overleftarrow{k})/[In]_0$ ($M^{-1}\cdot s^{-1}$)
0.5	230	3.61×10^5
0.4	(162)[b]	$(4.42)^{b}\times10^5$
0.3	(156)[b]	$(4.17)^{b}\times10^5$
0.2	190	2.78×10^5
0.1	230	3.61×10^5
0.05	250	4.03×10^5
0.01	210	3.20×10^5
0.005	220	3.40×10^5
0.001	230	3.61×10^5

a) The value of $\overleftarrow{k}$ was evaluated to be 57.6 s^{-1} (see Table 1). b) The values in parentheses are those from other series of data with $[In]_0=2.36\times10^{-4}$ M and $[MX]_0=2.65\times10^{-5}$ M. Experimental errors for the values of k_{obsd}^{comp} are *ca.* ±8%.

Table 3. $[MX]_0$-Dependence of the rate of the decomposition of murexide at 25 °C, μ=2.0 ($NaClO_4$) and [H]=0.5 M.

$[MX]_0$ (M)	k_{obsd}^{dec} (s^{-1})
2.5×10^{-6}	0.11
5.0×10^{-6}	0.11
2.5×10^{-5}	0.10
1.0×10^{-4}	0.093
1.5×10^{-4}	0.085

lies at 530 nm at [H]=0.5 M and μ=2.0 M ($NaClO_4$) in the concentration range between $[MX]_0=1.0\times10^{-4}$ and 2.5×10^{-6} M. The effect of initial concentration of murexide on the rate of decomposition is shown in Table 3. Though the rate shows some dependence on the concentration of murexide, the observed tendency of decrease was quite small despite of the large concentration change of murexide more than two orders of magnitude. The similar tendency is also reported in Ref. 2.

The decomposition of murexide is accelerated by acid. Figure 3 shows that the reciprocal of the pseudo-first-order rate constant for the decomposition of murexide has a linear relation to $[H]^{-1}$. The proposed reaction scheme is thus as follows.

$$MX + H \underset{}{\overset{K_{2a}}{\rightleftharpoons}} MXH$$

$$MXH \xrightarrow{k_{2a}} Uramil + Alloxan,$$

where MX and MXH denote purpurate anion and purpuric acid respectively.

The rate of decomposition is written as

$$k_{obsd}^{dec\,-1} = \frac{1}{k_{2a}} + \frac{1}{k_{2a}K_{2a}}\cdot\frac{1}{[H]}.$$

According to the above equation the values $k_{2a}K_{2a}$ and k_{2a} are evaluated to be $k_{2a}K_{2a}=0.16$ M^{-1} s^{-1} and $k_{2a}=$ 1.2 s^{-1} from the slope and the intercept respectively. The constant K_{2a} is therefore calculated to be about 0.13 M^{-1}. However, as the intercept passes through

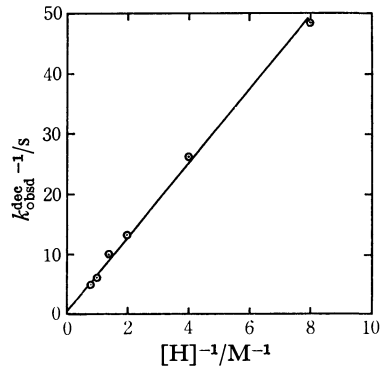

Fig. 3. Plot of $k_{obsd}^{dec\ -1}$ *vs.* inverse of hydrogen-ion concentration.
at 530 nm, 25 °C, μ=2.0 ($NaClO_4$), and $[MX]_0$= 1.02×10^{-4} M.

very near the origin, each value of k_{2a} and K_{2a} has eventually a great inaccuracy of 50%. More accurate value of K_{2a} is given by K_{2b} in the next section from the effect of indium(III) on the decomposition of murexide.

Rate of Decomposition of Murexide in the Presence of Indium(III). The rate of decomposition of murexide was also studied by following the change in absorbance at the absorption peak of the complex at constant acid concentration [H]=0.5 M. The apparent rate of decomposition was decreased with increasing concentration of indium(III). This result is ascribed to the inertness of the indium(III) complex against the decomposition of the ligand murexide.

Now let us write the reaction scheme as follows.

$$In + MX \overset{K_{1c}}{\rightleftarrows} InMX$$

$$MX + H \overset{K_{2b}}{\rightleftarrows} MXH$$

$$MXH \xrightarrow[+H_2O]{k_{2b}} Uramil + Alloxan.$$

The rate of decomposition is written as

$$k_{obsd}^{dec\ -1} = \frac{[H]K_{2b}+1}{[H]k_{2b}K_{2b}} + \frac{K_{1c}}{[H]k_{2b}K_{2b}}\cdot[In]_0.$$

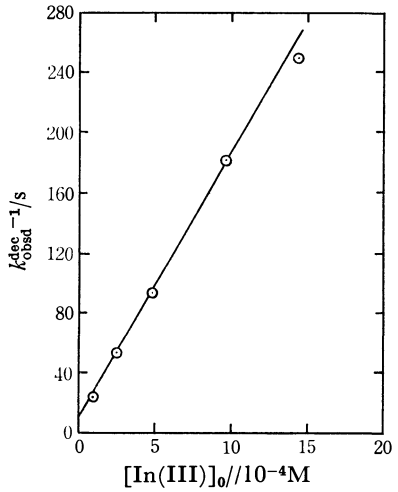

Fig. 4. Plot of $k_{obsd}^{dec\ -1}$ *vs.* total concentration of In(III).
At 470 nm, 25 °C, [H]=0.5, μ=2.0 ($NaClO_4$), and $[MX]_0=1.02\times10^{-4}$ M.

Table 4. Equilibrium data measured at 25 °C, μ=2.0 ($NaClO_4$) and [H]=0.5 M.

$K_{1a}=7.2\times10^3$ M^{-1}	
$K_{1b}=6.5_5\times10^3$ M^{-1}	$K_{2a}=0.13$ M^{-1}
$K_{1c}=14\times10^3$ M^{-1}	$K_{2b}=0.13$ M^{-1}

From the intercept and the slope of the straight line as shown in Fig. 4, the values of K_{2b} and K_{1c} are determined to be 0.13 and 1.4×10^4 M^{-1} at 25 °C, respectively. The data are summarized in Table 4.

Discussion

Stability constant K_{1c} evaluated from the rate of decomposition is about twice as large as the constants K_{1a} and K_{1b} given by the stopped-flow measurements. These results show that the complex formation between indium(III) and murexide plays a role of negative catalysis on the decomposition of murexide under the experimental conditions.

The complex formed between metal ions and the ligand murexide does not show a large molar extinction coefficient until the "nitrogen" atom at the center of the ligand molecule *does* coordinate to the metal ion to form a terdentate structure.[7] The complex followed at 470 nm is thus assigned to the one involving murexide as a terdentate ligand. The terdentate structure of the complex usually stabilizes the ligand molecule against decomposition.[8,9] Therefore the observed larger value of K_{1c} suggests the existence of other type of complexes or some ion pairs that are stable and less active to the acid decomposition of murexide, though not experimentally ascertained.

The result that the rate of the complex formation between indium(III) and murexide does not depend on the acid concentration is very interesting from a point of view that the rate of complex formation of hydroxo metal ion is generally by about 100 times higher than that of the corresponding aquo metal ion.[10-12] The larger value of K_{1c} from the decomposition rate of the ligand as compared with the values of K_{1a} and K_{1b}, and the lack of effect of the hydrogen-ion concentration on the rate of complex formation suggest the contribution of a sort of complex different from the one followed at 470 nm to the reaction system. Then K_{1c} may include the stability constants of the other complexes. Further details of the problem will be discussed elsewhere.

Furthermore it is of practical interest to note that the kinetic results of the acid decomposition suggest the possibility of determining the acid dissociation constant of the organic compounds which are too unstable to determine the constant by static method.

The present work was supported by a grant-in-aid for Scientific Research from the Ministry of Education.

The Crystal Structure of β-$K_4SiW_{12}O_{40}\cdot 9H_2O$, Containing an Isomer of the Keggin Ion

Kazuko Y. MATSUMOTO,* Akiko KOBAYASHI, and Yukiyoshi SASAKI

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received April 30, 1975)

β-$K_4SiW_{12}O_{40}\cdot 9H_2O$ is orthorhombic, with the space group Pnma and $a=20.62(1)$, $b=15.57(1)$, $c=12.95(1)$ Å, $D_m=4.88$ g cm^{-3} and $D_x=5.04$ g cm^{-3} for $Z=4$. The crystal contains a discrete β-$SiW_{12}O_{40}^{4-}$ polyanion, a geometrical isomer of the α-$SiW_{12}O_{40}^{4-}$ with the well known Keggin structure. The idealized Keggin ion has a T_d symmetry, but the β-isomer has only a C_s symmetry. Mutual transformation between the α- and β-structures is possible through a 60° rotation of one of the four W_3O_{13} units, which make a cage around a SiO_4 tetrahedron in both structures. The other possible geometrical isomers of the Keggin structure are discussed.

The 12-tungstosilicic acid and its salts were first synthesized in 1863 by Marignac. Later he reported the existence of two isomers, "*silicotungstic acid*" and "*tungstosilicic acid*" or "*iso-silicotungstic acid*," and found that all the salts also always have two forms, the crystal habit and solubility different from one to another.[1] Similar isomers have also been found in 12-tungstoboric acid, $H_5BW_{12}O_{40}$, and its salts.[2] Though at the begining of this century, Copaux claimed to have confirmed these results,[3,4] the existence of such isomerism was still often regarded as doubtful because of the close resemblance in the chemical properties of each pair of isomers.

Some early workers naturally contrived structural models of the two isomers. Pfeiffer proposed two isomeric structures based upon a Werner-type isomerism of an octahedral coordination around the silicon atom.[5] Pauling thought that one was a dimer of the other.[6] However, no one went beyond speculations. Though, in 1934, Keggin[7] first solved, by the powder X-ray diffraction technique, the structure of $PW_{12}O_{40}^{3-}$, which is isomorphous with $BW_{12}O_{40}^{5-}$ and $SiW_{12}O_{40}^{4-}$, successive similar X-ray investigations of the 12-tungstoborates[8,9] denied the existence of any isomerism in the $BW_{12}O_{40}^{5-}$ polyanion.

Recently, however, these isomers were confirmed by Souchay with the aid of modern physicochemical techniques, together with synthetic works; they were named the α- and β-forms.[10-17] In addition to the 12-tungstosilicate[10] and 12-tungstoborate[11] mentioned above, 12-tungstogermanate,[10] 12-molybdosilicate,[12,13] 12-molybdogermanate,[14] 12-molybdophosphate,[15,16] and 12-molybdoarsenate[15,17] have also been reported to have similar kinds of isomers.

The β-isomers are generally unstable compared to the corresponding α-isomers.[10-17] In 1909 Copaux examined the crystals prepared by Marignac 40 years before and found that the β-tungstosilicic acid samples had been transformed into the α-form in an appreciable amount. When the β-crystals are placed in contact with a saturated aqueous solution in a sealed tube, the transition is completed within one hour at 150 °C.[3] In an aqueous solution, the rate of the transformation depends on the kind of the hetero atom; the stability lies in this order; Si>Ge>P>As.

The 12-heterotungstates are generally more stable than the corresponding 12-heteromolybdates. The transformation from β to α is considerably retarded by the addition of an organic solvent, such as alcohol or dioxane. The present authors have found that the addition of a small amount of a base to an aqueous solution of the β-form accelerates its transformation. The polarographic studies of the α and β isomers show that the β-isomer is more easily reduced than the corresponding α-isomer.[10,11,13,16,17] The features of their polarographic curve are independent of the kind of hetero atom except in the case of β-12-tungstoborate. The polarogram and also the UV absorption spectra suggest that the β-12-tungstoborate anion differs from other β-isomers in its structure.

The crystal-structure determination of β-12-heteropoly acids or their salts has been considered to be indispensable to the elucidation of the structural relation between α and β isomers. With this in mind, β-$K_4SiW_{12}O_{40}\cdot 9H_2O$ has been subjected to X-ray crystal structure analysis, since it appeared suitable for a structural study because of its stability in air and because of the relatively low amount of water of crystallization.

Experimental

Originally β-$K_4SiW_{12}O_{40}\cdot 9H_2O$ was prepared in a very low yield, together with the main product, α-$K_4SiW_{12}O_{40}\cdot 17H_2O$.[1] Recently Souchay, Tézé, and Hervé reported a new synthetic method which gives almost pure β-$SiW_{12}O_{40}^{4-}$.[10] The β-$SiW_{12}O_{40}^{4-}$ was prepared by the acidification of sodium tungstate, followed by the addition of acidified water glass, while the acidification of the mixed solution of sodium tungstate and water glass solutions gave α-$SiW_{12}O_{40}^{4-}$. For purification, β-$SiW_{12}O_{40}^{4-}$ was extracted with hydrochloric acid and ether; then the ether was removed from the extract according to the procedure applied to the α-isomer (see Ref. 18 for the details). The addition of a saturated solution of potassium chloride precipitates β-$K_4SiW_{12}O_{40}\cdot 9H_2O$. The precipitate was recrystallized from water in order to remove a small amount of the α-isomer. The β-isomer is slightly more soluble in water than the α-form.

The crystals of β-$K_4SiW_{12}O_{40}\cdot 9H_2O$ thus prepared are faint yellow, rhombic, and stable in air, while the α-isomer is colorless.

Preliminary oscillation and Weissenberg photographs showed that the crystal is orthorhombic, with the space group Pnma. The crystals quite often gave smeared reflection spots. A specimen was chosen which gave well-shaped reflection spots, its size being $0.1\times 0.12\times 0.07$ mm. The intensities of the reflections were measured on a Rigaku four-circle

* Formerly Kazuko Yamamura in Ref. 21.

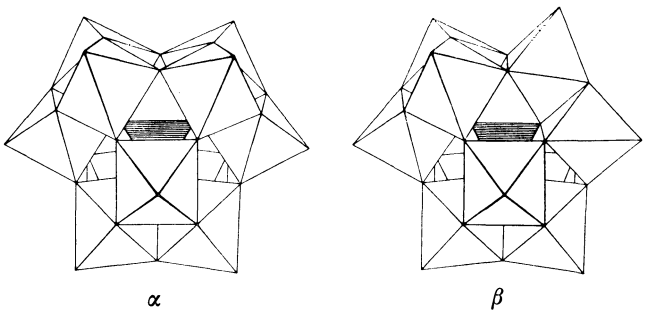
diffractometer with Mo$K\alpha$ radiation ($\lambda=0.71069$ Å). The ω-2θ scan technique was employed; 2007 independent reflections, for which $|F_o|\geqq 110$ (F_o: absolute scale) up to $2\theta=60°$, were obtained. The data were corrected for Lorentz and polarization factors. Though the crystals have a large μ value, no absorption correction could be made bacause of the irregular shape of the sample and because of its brittleness, which made polishing of the specimen practically impossible. The unit-cell dimensions and their standard deviations are $a=20.62(1)$, $b=15.57(1)$, $c=12.95(1)$ A; $V=4157$ Å^3 at 23 °C, $D_m=4.88$, $D_x=5.04$ g cm^{-3} for $Z=4$, F.W. 3157.3, μ(Mo$K\alpha$)$=376.2$ cm^{-1}.

Solution and Refinement of the Structure

The structure was solved by the heavy atom method. All the coordinates of the atoms of the polyanion were obtained by several Fourier syntheses. Refinements were carried out with anisotropic temperature factors for the tungsten and potassium atoms and with isotropic ones for all the oxygen and silicon atoms to the final R value of 0.138. A weighting scheme, $w=0.2$ if $|F_o|<150$ and $w=1$ otherwise, was employed. The atomic scattering factors were taken from Ref. 19, and corrections for anomalous dispersion were made for the tungsten, potassium, and silicon atoms.[20] The atomic parameters and their estimated standard deviations are listed in Table 1. The F_c—F_o table is kept at the office of this Bulletin as Document No. 7523. A preliminary report of this work has already been published elsewhere.[21] All the calculations were performed on a HITAC 8700/8800 Computer at the Computer Centre of the University of Tokyo, using a local version of UNICS.[22]

Description of the Structure and Discussion

A recent investigation of α-$Ba_2SiW_{12}O_{40}\cdot 16H_2O$[23] and α-$K_4SiW_{12}O_{40}\cdot 17H_2O$[24] proved that the α-$SiW_{12}O_{40}^{4-}$ anion has the well-known Keggin structure[7]



α β

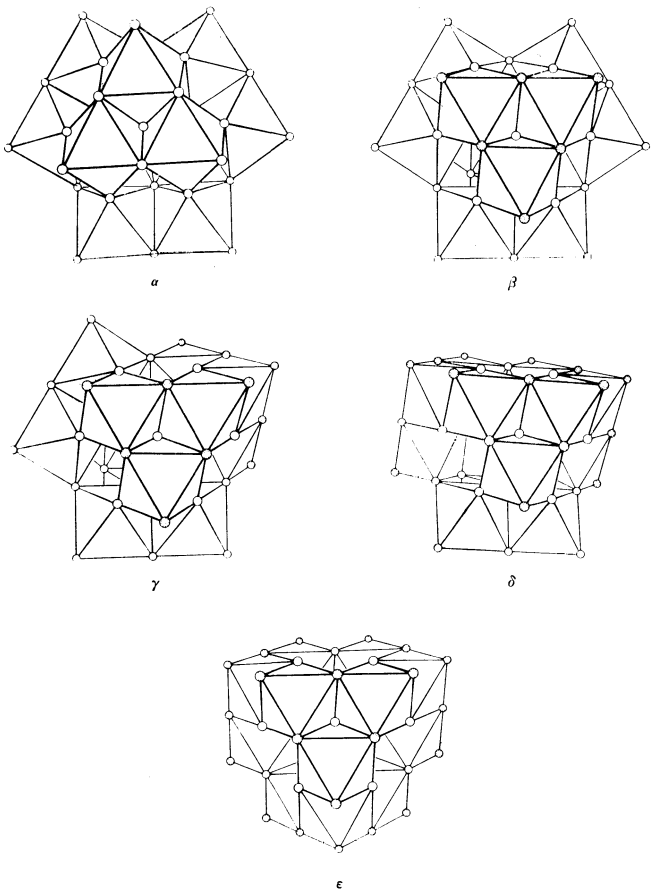

Fig. 2. Five possible isomeric structures of the Keggin structure. The models $A^tB_{12}O_{40}$ are constructed by idealized regular tetrahedra A^tO_4 and BO_6 octahedra. White and dotted balls represent oxygen atoms. The β, γ, δ, and ε (Jahr structure) models are made by rotating one, two, three, and all the four W_3O_{13} moieties of the α (Keggin structure) by 60°. The W_3O_{13} units with dotted balls are rotated parts.

(*cf.* Fig. 1α and 2α). The present work has revealed that the β-$SiW_{12}O_{40}^{4-}$ anion has the structure shown in Figs. 1β and 2β. Note that the β-isomer results from a 60° rotation about the threefold axis of one of the trigonal edge-sharing W_3O_{13} units of the α-isomer and from reattachment again *via* corner sharing. The possibility of such geometrical isomers has been predicted by Baker and Figgis[24] on the basis of stoichiometric and structural speculations.

Table 2 lists the interatomic distances within the anion, along with their standard deviations.

The central SiO_4 tetrahedron is largely distorted, the Si–O distances ranging from 1.37 to 1.83 Å. Each WO_6 octahedron is also greatly distorted. The oxygen atoms are classified into four groups, which will be called O_a, O_b, O_c, and O_d. The positions of these types of oxygen atoms are indicated in Fig. 3, which represents one of the W_3O_{13} units and the central SiO_4 tetrahedron. The O_a oxygen atoms are shared between three WO_6 octahedra and one SiO_4 tetrahedron. The O_b oxygen atoms are shared between adjacent W_3O_{13} units. The O_c oxygen atoms are shared between $2WO_6$ octahedra in a W_3O_{13} unit. The O_d oxygen atoms are unshared with other

polyhedra. The O_a–O_c edges are shared between two WO_6 octahedra. The W–O distances are W–O_a 2.24—2.53, W–O_b 1.74—2.10, W–O_c 1.75—2.10, and W–O_d 1.59—1.80 Å. These values show that the tungsten atoms are off-centered in the respective WO_6 octahedron and that all the tungsten atoms are displaced toward the outside of the anion. Similar displacements have been observed for the tungsten atoms in $PW_{12}O_{40}^{3-}$,[7] $CoW_{12}O_{40}^{5-}$,[26] and α-$SiW_{12}O_{40}^{4-}$,[23,24] and also for the molybdenum atoms in $TeMo_6O_{24}^{6-}$,[26] $As_4Mo_{12}O_{50}^{8-}$,[28] and $CeMo_{12}O_{42}^{8-}$,[29] such displacement is considered to be a characteristic feature of not only Keggin-type structures but also of other types of heteropolymolybdates and heteropolytungstates.

The crystal structure projected along the b and c axes are presented in Figs. 4 and 5 respectively. Two anions lie on the crystallographic mirror plane at $y=1/4$, and other two, on the mirror plane at $y=3/4$. The rotated W_3O_{13} unit is dipicted as W6–W7–W7^{I}. An attempt to locate the water molecules was not successful, since many

electron density peaks, which were lower than those of the anion oxygens, were smeared out in the cavities between the polyanions. In order to investigate the crystal water, thermal analysis was carried out on β-$K_4SiW_{12}O_{40}\cdot 9H_2O$. The results confirm the presence of a total of nine water molecules per formula unit (weight loss at 230 °C: calcd 5.1%, obsd 4.9%). The crystals begin to lose the water at a temperature as low as 70 °C, which, together with the X-ray diffraction study, suggest that the present crystals possibly contain mobile zeolitic water. It has been established that heteropoly compounds very often contain zeolitic water in the crystals.[11,29] Interanionic and interanion-cation distances less than 3.5 Å are listed in Table 3. Some parts of adjacent anions seem to come in contact with one another directly. All the potassium ions are partly coordinated by anion oxygens, the remaining coordination numbers being presumably completed by the addition of the water oxygens, which were not located in the present work.

The structural relationship between the α- and β-isomers has been clarified for the first time by this investigation, though with large standard deviations of the positions of the light elements, as is shown in Tables 1 and 2.

On the Other Possible Geometrical Isomer of the Keggin Structure

Figure 2 shows all five possible isomers of $SiW_{12}O_{40}^{4-}$ or the Keggin ion in general. The models are constructed of idealized octahedra (WO_6) and tetrahedra (SiO_4). In the β-model, one W_3O_{13} of the Keggin ion (α) is rotated by 60°; such a reorientation of two, three, and all four W_3O_{13} moieties leads to γ, δ, and ε isomers successively. The ε model was once proposed for 12-heteropolyanions by Jahr[31] and later found by Johansson in the $Al^tO_4Al_{12}(OH)_{24}(H_2O)_{12}^{7+}$ ion,[32,33] where Al^tO_4 denotes AlO_4 tetrahedron and where the other 12 aluminum atoms are surrounded by an octahedral array of 6 oxygen atoms.

None of the five isomers can be optically active, and a close-packing of the oxygen atoms is realized only in δ and ε. If we use A, B, and C to label the layers of oxygen atoms, as is common in discussions of the close-packing (ABAB for a hexagonal close-packing and ABCABC for a cubic one), the arrangements of the oxygen atom layers in δ and ε are ABCB and ABCA. In both anions, the A and B layers both contain 12 atoms and C, 10, while the last B layer in δ and the last A in ε contain 6 oxygen atoms each. One isomer of $BW_{12}O_{40}^{4-}$, which gives

unique polarographic waves among all the 12-heteropoly acids, might have a γ, δ, or ε structure; an X-ray diffraction study of the crystals containing this anion is highly desirable.

The present work was partly supported by a Grant in aid for Cooperated Research of the Ministry of Education. The authors are also indebted to the late Professor P. Souchay, Dr. A. Tézé, and Dr. G. Hervé of the University of Paris for their advice about the procedure of preparing the β-isomers. Thanks are also due to Dr. H. Iwasaki of the Institute of Physical and Chemical Research for reading through the manuscript and for his advice.

The Structure of Polyvanadotungstates. II. The Crystal Structure of $K_7V_5W_8O_{40}\cdot 12H_2O$

Keiko NISHIKAWA,* Akiko KOBAYASHI, and Yukiyoshi SASAKI

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received May 7, 1975)

Crystals of $K_7V_5W_8O_{40}\cdot 12H_2O$ are cubic, with the space group of $P\bar{4}3m$ and with the cell dimension of $a=10.62(1)$ Å. The structure was determined by the single-crystal X-ray diffraction technique. All the non-hydrogen atoms were located, and the final R value was 0.057. The $V_5W_8O_{40}^{7-}$ anion has the Keggin structure, with a central VO_4 tetrahedron. The twelve outer metal positions are randomly occupied by four vanadium and eight tungsten atoms. A detailed discussion of the configuration isomers is impossible because of the orientational disorder. The present work, and the former X-ray structure determination of $V_2W_4O_{19}^{4-}$ show that polyvanadotungstates can be regarded as substituted homologues of isopolytungstates: $V_nW_{6-n}O_{19}^{(n+2)-}$ ($n=1, 2$) has a hexaniobate-type structure, and $V^tV_nW_{n-12}O_{40}^{(n+3)-}$ ($n=2, 3, 4$), the Keggin structure, where V^t represents the central vanadium atom.

When a solution of orthotungstate (WO_4^{2-}) and metavanadate (VO_3^-) salts is acidified, polyvanadotungstate crystals are precipitated.[1] Several species of polyvanadotungstates have been reported as salts, their composition varies with the pH, the constitution, and the concentration.[1-4] Recently, Pope and Flynn proposed, in their preparative studies,[5-7] that these polyvanadotungstate anions can be divided into two groups: $V_nW_{6-n}O_{19}^{(n+2)-}$($n=1,2$) and $V^tV_nW_{12-n}O_{40}^{(n+3)-}$(where V^t is the vanadium in the center of the tetrahedron, $n=2,3,4$). For the former series, we have determined the crystal structure of α-$(CN_3H_6)_4V_2W_4O_{19}$ and showed[8] that, as Pope proposed, it has the "*hexaniobate structure*"[9] shown in Fig. 1. This paper will report the structure of $K_7V_5W_8O_{40}\cdot 12H_2O$, which belongs to the latter series.

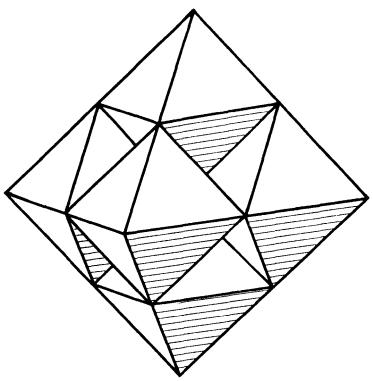

Fig. 1. The coordination polyhedra model of $V_2W_4O_{19}^{4-}$ anion. All the octahedra are idealized.

Experimental

Crystals of $K_7V_5W_8O_{40}\cdot 12H_2O$ were prepared by Pope's method.[7] Potassium tungstate, K_2WO_4 was added to an aqueous solution of potassium metavanadate, KVO_3; the mixture was acidified with formic acid to pH=3 and then heated until just before boiling. From the red-brown crystals obtained after cooling, a single crystal $0.2\times0.2\times0.15$ mm in size was chosen for the X-ray diffraction experiments. The reflection data were collected on a Rigaku four-circle diffractometer with Mo$K\alpha$ radiation monochromatized by a graphite crystal ($\lambda=0.7107$ Å). The $\omega-2\theta$ scan technique was employed, and 256 independent reflections with intensities larger than 3σ were obtained to $2\theta=60°$. The intensities were corrected for the Lorentz and polarization factors, but not for absorption. The crystal data are as follows:

$K_7V_5W_8O_{40}\cdot 12H_2O$

cubic

$a = 10.62(1)$ Å

$V = 1199$ Å^3

space group $P\bar{4}3m$

$Z = 1$ ($D_m=4.0$ g cm^{-3}, $D_x=3.97$ g cm^{-3})

(Mo$K\alpha$) = 233.3 cm^{-1}

The conventional heavy atom method was used to solve the structure.** The positional parameters and anisotoropic thermal parameters for all the non-hydrogen atoms were refined by the block-diagonal, least-squares method to $R=0.057$. No significant peak was found on the residual electron density map. The F_o—F_c table is kept by the Chemical Society of Japan as Document No. 7525. A weighting scheme of $w=0.5$ for $|F_o|<104.4$ and $w=1$ otherwise was employed. The atomic scattering factors were taken from the "International Tables for X-Ray Crystallography," but those for W and V were corrected for the anomalous dispersion.[10] The calculations were performed on a HITAC 8700/8800 computer at the Computer Centre of the University of Tokyo using a local version of UNICS.[11]

Results and Discussion

The Structure of the Polyanion. As is shown in Fig. 2, one unit cell contains one Keggin-type polyanion, $V^tM_{12}O_{40}^{7-}$, where V^t represents the central vanadium atom of the VO_4 tetrahedron and where M_{12} means 4V

* Present address: Department of Chemistry, Faculty of Science, Gakushuin University, Mejiro, Toshima-ku, Tokyo 171.

** The possible space groups observed in connection with the systematic extinctions are $P\bar{4}3m$, $Pm3m$, and $P432$. Considering the composition of the polyanion, the Patterson map was solved only by assuming the positional disorder of metal atoms. A trial structure obtained on the assumption of the $P\bar{4}3m$ space group gave an R value of 0.27; however, $Pm3m$ and $P432$ gave 0.8—0.9.

a) The estimated standard deviations in parantheses here and elsewhere are in units of the last significant digit.
b) $M=\frac{4V+8W}{12}$, see text. c) The Evans classification of oxygen atoms in the Keggin structure (see text).[12]

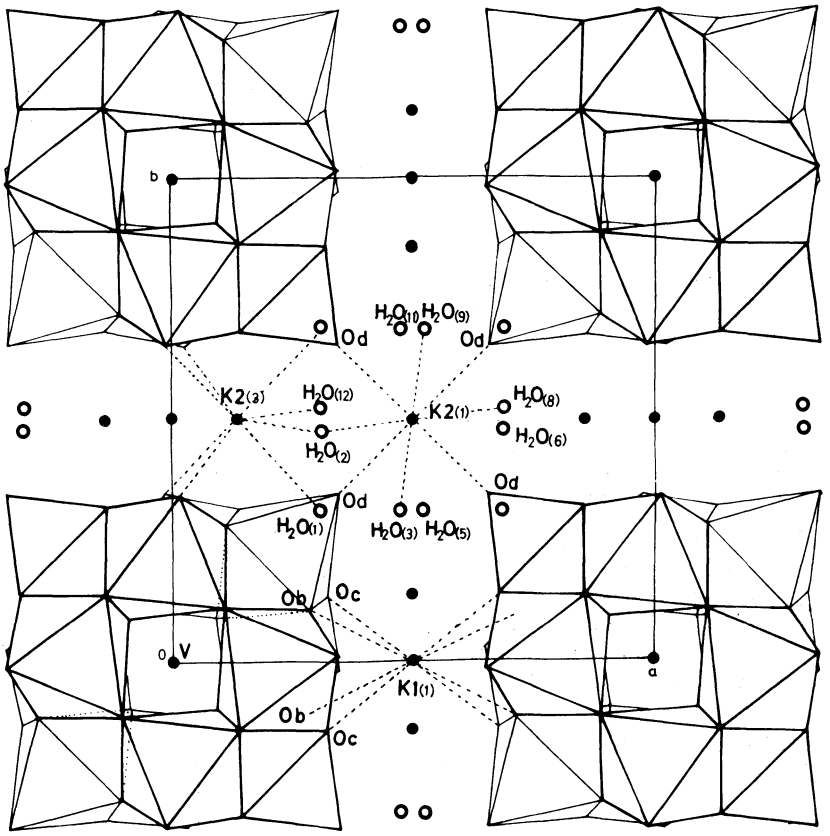

Fig. 2. A view of the structure as projected down the c axis. The $V_5W_8O_{40}^{7-}$ anion has three two fold axes parallel to the crystal axes. The coordination bonds around K^+ are designated by dotted lines.

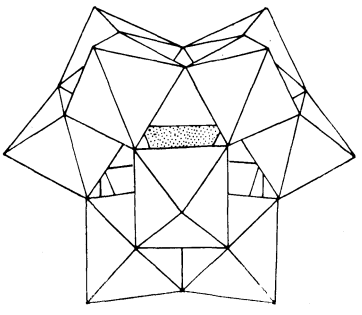

Fig. 3. The coordination polyhedral model of Keggin structure.

and 8W atoms randomly mixed. In Fig. 3 the polyanion is shown as a coordination polyhedral model. Three MO_6 octahedra link together by sharing edges to form a M_3O_{13} unit with a trigonal symmetry (Fig. 4). Four such M_3O_{13} units link in a T_d symmetry with a central hetero-atom by sharing corners to build the structure known as the Keggin ion.[13]

The twelve metal positions are occupied by four vanadium and eight tungsten atoms with a 4: 8 probability. The space-group symmetry requires that twelve metal positions are crystallographically equivalent; it is impossible to discriminate the 38 possible isomers with a different distribution of four vanadium and eight tung-

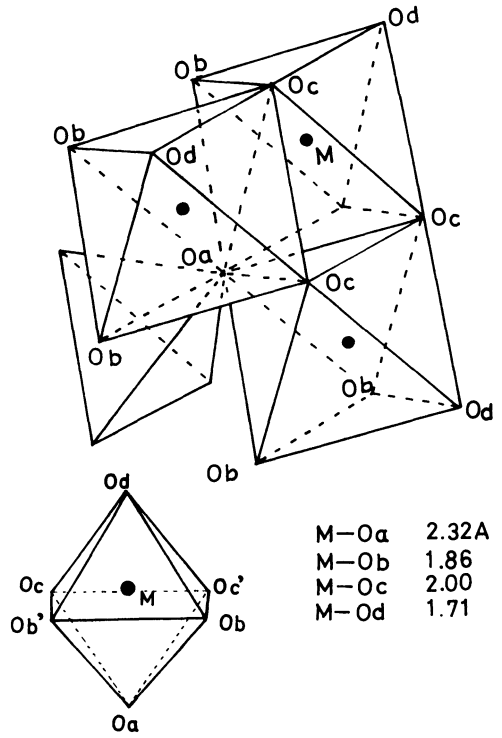

Fig. 4. The coordination polyhedral model of M_3O_{13} unit and central VO_4 tetrahedron and MO_6 octahedron. The classification of the oxygen atoms conform to those given by Evans.[12]

sten atoms on the twelve metal positions in a $V^tM_{12}O_{40}^{7-}$ anion. The assumption that the sample is a mixed crystal of many configurational isomers cannot be definitely ruled out on the basis of the present diffraction data. There is no evidence for the tungsten atoms being randomly mixed in the central vanadium position.

Oxygen atoms in the polyanion are classified into four groups—Oa, Ob, Oc, and Od, as is shown in Fig. 4. Oa is the oxygen atom bound to one central vanadium atom and to three metal atoms, while Ob is shared by two metal atoms of different M_3O_{13} units. Oc is bound to two metal atoms in the same M_3O_{13} unit. Od is the terminal oxygen atom combined with only one metal.

TABLE 2. INTERATOMIC DISTANCES (d/Å) AND ESTIMATED STANDARD DEVIATIONS WITHIN THE ANION $V_5W_8O_{40}^{7-}$

(1) The metal–metal interatomic distances	
M–M (in M_3O_{10} unit)	3.486 (9)
M–M (nearest M–M in different M_3O_{13} units)	3.578(11)
M–V^t	3.532 (9)
(2) The distances between metal and oxygen atoms	
M–Oa	2.32(12)
M–Ob	1.86 (5)
M–Oc	2.00 (5)
M–Od	1.71 (4)
V^t–Oa	1.75(12)
(3) The distances between oxygen atoms	
Oa–Ob	2.94(13)
Oa–Oc	2.51(13)
Ob–Oc	2.74 (8)
Oc–Od	2.78 (8)

The M–O distances in Table 2 (2) are the weighted average of the W–O and V–O distances, since the M in each position is occupied by randomly distributed V and W atoms. All the MO_6 octahedra are deformed. The M atom is not at the center of the octahedra, but near Od; it is displaced 0.35 Å outside the plane made by two Ob and two Oc atoms. Three Oc atoms form a triangle 0.43 Å inside the plane which three Od atoms make. On the other hand, one Oa and six Ob atoms form an almost perfect plane.

The $V^tV_4W_{12}O_{40}^{7-}$ is the sole example of the Keggin structure containing a vanadium (V) atom in the center as V^t. From the standpoint of vanadium structure chemistry, it is interesting to see whether or not the V^t-$(Oa)_4$ tetrahedron is deformed, because, in general, VO_4 has a remarkable tendency to deviate from the tetrahedral symmetry. For instance, Evans reported that, in VO_4 (tetrahedron),[14] VO_5 (trigonal bipyramid), or VO_6 (octahedron),[15] two V–O bonds are always shorter, suggesting the existence of bent O–V–O bondings stronger than other V–O bonds. Banks, Greenblatt, and Post, in their structure study of K_3VO_4, found that the deformation of VO_4^{3-} is more remarkable than that of AsO_4^{3-}.[16] In the present case, however, the polyanion apparently has the T_d symmetry. As a result, such a deformation of the $V(Oa)_4$ tetrahedron, if it occurred at all, must have been smeared out by the orientational disorder. Though the large observed standard deviations in the positional and thermal parameters of the Oa atoms, and consequently the large errors in the V–Oa distances, are consistent with this model of the random orientation of the deformed polyanion, there is no difinite proof of it.

Potassium Ions and Water of Crystallization. One unit cell contains seven potassium ions, of which three, K(1), the 3d sites, are at (1/2, 0, 0; 0, 1/2, 0; 0, 0, 1/2). Other four ions, K(2), are distributed among the sixfold positions, 6g ($\pm x$, 1/2, 1/2; 1/2, $\pm x$, 1/2; 1/2, 1/2, $\pm x$) with equal probability. This assumption explains the peak heights on Fourier maps [K(1): K(2): O (oxygen atom of H_2O)=4: 2: 1] and gives reasonable temperature factors and the lowest R value. Both K(1) and K(2) are coordinated by eight oxygen atoms, as is shown in Fig. 2. The K(1) is surrounded by four Oc and four Ob atoms, and K(2), by four water molecules and four terminal Od atoms of the polyanions. Table 4 shows the K–O distances. The coordination numbers of potassium ions by oxygen atoms are known to be 6, 7, 8, 9, 10, and 12,[17] and for the 8 coordination, the K–O

H_2O-H_2O	3.13(10)
Oc-H_2O	3.38 (8)

distance has been reported to be in the range from 2.66 to 3.10 Å.[17] The present data of bond lengths seem to be typical.

Water of Crystallization. Water molecules are used only as ligands to potassium cations. There is no hydrogen bonding between the oxygen of the polyanion and water molecules (the shortest distance, H_2O–Oc, is 3.38 Å).

Comparison with Isopolyvanadates and Isopolytungstate. Isopolytungstates in the solid phase have always been found in the solid phase as discrete polyanions, such as $W_6O_{19}^{2-}$,[18] $W_{10}O_{32}^{4-}$,[19] $H_2W_{12}O_{42}^{10-}$ (paratungstate),[20] and $H_2W_{12}O_{40}^{4-}$ (metatungstate)[21]. No infinite polymer has been reported; these polyanions seem all to exist in aqueous solutions. On the other hand, all the isopolyvanadate crystals so far studied, with the sole exception of $K_2Zn_2V_{10}O_{28}\cdot 16H_2O$ crystals containing discrete $V_{10}O_{28}^{6-}$ [15] anions, have infinite polymeric structures.

The CsV_3O_8 crystals contain a plane sheet consisting of VO_6 octahedra-sharing edges,[22] $K_3V_5O_{14}$ consists of VO_5 square pyramids, and VO_4 of tetrahedra bound by sharing corners.[23] The equilibria of isopolyvanadates in an aqueous solution are fairly complicated. The following species have been reported:[24] VO_2^+, $H_2V_{10}O_{28}^{4-}$, $HV_{10}O_{28}^{5-}$, $HV_6O_{17}^{3-}$, $HV_2O_7^{3-}$, $V_2O_7^{4-}$, HVO_3, VO_3^-, H_3VO_4, $H_2VO_4^-$, HVO_4^{2-}, and VO_4^{3-}. However, the existence of any infinite polymer in the aqueous phase has never been proved.

We have already determined the structures of the five polyvanadotungstates, $(CN_3H_6)_4V_2W_4O_{19}$,[8] $K_7V_5W_8O_4\cdot 12H_2O$, $Ag_4V_2W_4O_{19}$,[25] and $(CN_3H_6)_5HV_2^{IV}W_4O_{19}$,[26] but no isopolyvanadate-like infinite polymer has been found; the structures are always similar to those of the isopolytungstates.

These results support Pope's proposal[5–7] that all the polyvanadotungstates form two homologous series, $V_nW_{6-n}O_{19}^{(n+2)-}$ (n=1,2) and $V^tV_nW_{12-n}O_{40}^{(n+3)-}$ (n=2,3,4). According to him, the two series are derived from the hexatungstate $W_6O_{19}^{2-}$ with the hexaniobate structure and from the hypothetical heteropolytungstate, $V^tW_{12}O_{40}^{3-}$, which is a Keggin ion as a result of the partial replacement of W(VI) by V(V). The Keggin ions are stable in acidic solutions, and the niobate-type anion, $V_2W_4O_{19}^{4-}$, is reversibly converted to a Keggin ion, $V_4W_9O_{40}^{6-}$, on acidification.

In the both series, a lower pH stabilizes polyanions containing fewer vanadium atoms. This may be correlated with the facts that the basicity of V(V) is stronger than that of W(VI) and that the VO_2^+ cation is stable in acidic media.

Chemical Vapor Growth of Titanium Diboride Whisker

Seiji MOTOJIMA, Fumio SUGIMORI, Yasutaka TAKAHASHI, and Kohzo SUGIYAMA
Department of Synthetic Chemistry, Faculty of Engineering, Gifu University, Gifu 504
(Received May 14, 1975)

Titanium diboride whisker was grown by chemical vapor deposition from a gaseous mixture of $TiCl_4$, BCl_3, H_2, and Ar. The relations between the growth conditions and the crystal morphologies were investigated. The predominant factors for whisker growth were found to be the substrate temperature and the kind of impurities painted on the substrate. The optimum temperature was determined as 1050—1070 °C where whiskers grew up to 250 μm in length and 0.1 to 1 μm in diameter for 30 min. Au, Pt, and Pd were found to be promissing impurities for whisker growth. From an observation of the droplet on whisker tip, the growth mechanism for the whiskers was supposed to be VLS mechanism. The form of whisker grown was tetragonal and hexagonal pillar, and the growth direction was determined as [100]direction.

A few investigations have been reported on the single crystal growth of titanium diboride by Verneuil's process,[1,2] and from fused metal solutions.[3,4] However, few papers have been published on the single crystal growth by chemical vapor deposition (CVD) except for polycrystalline coatings.[5-7] In this paper, chemical vapor growth conditions of titanium diboride whisker were studied in relation to the effects of impurities to the whisker morphology and growth mehcanism.

Experimental

Figure 1 shows the apparatus for whisker growth. A gaseous mixture of hydrogen and argon passed through a $TiCl_4$ saturator which consisted of an evaporator and a condenser, the top temperature of which was regarded as saturating temperature. Another gas stream of chlorine was flowed into a boron trichloride generator filled with boron carbide regulated at 800 °C. Two gas streams were mixed to flow into reaction tube of quartz glass (27 mm i.d.). Substrate and atmosphere were heated doubly by four rods of outer and a rod of inner carborundum resistants. A quartz glass tube (8 mm i.d.) was used as substrate for whisker growth, and the inner carborundum rod was inserted to the substrate tube. Surface temperature of the substrate was measured by an optical pyrometer and was corrected by a calibration curve. As an impurity, various salts of metals were painted on the substrate scratched by abrasives in the form of the aqueous solutions, and decomposed or reduced to the respective metal, in hydrogen atmosphere at 1000 °C.

The term of whisker length in this paper means the average length of ten samples selected in the order from the longest in the field of microscope magnified by 150.

Results and Discussion

The Effects of Impurities. In preliminary experiments, the optimum conditions were roughly determined as follows; substrate temperature of 1070 °C, gas phase temperature of 870 °C, total gas flow rate of 2.3 cc/s (NTP), and the concentration of boron trichloride, titanium tetrachloride, hydrogen, and argon of 9, 17, 44, and 30 vol%, respectively. Under these conditions, the impurities of In, Cr, Cu, Co, Ni, Fe, Mn, and V

Reaction temperature: 1070 °C; $BCl_3/TiCl_4/H_2/Ar$= 8.8/17.5/43.4/30.2 (vol%). a) (—): Non or negative effect; (+): Weak positive effect (up to 200—300 μm); (++): Positive effect (longer than 300 μm). b) Atomic percent of titanium and boron metal in corresponding binally alloy systems, are shown in the parenthesis, respectively.

compounds resulted in no or even negative effects for whisker growth. In these cases, titanium diboride deposition took place in a form of homogeneous coatings or fine crystallites, and the thickness of the coatings or deposits on impurity painted zone was the same as or rather thinner than those on upainted zone. On the contrary, the compounds of Au, Ag, Pt, Pd, and Rh resulted in positive effects to titanium diboride deposition. Whisker grew on the half part of substrate near to outlet, while coatings or fine crystallites on the other half part near to inlet. Of the positive effect elements, Au was the most effective one, and Pt and Pd were found to be considerably effective. Rh exhibited weak effect and Ag also gave an effect only at somewhat lower temperature range than that of Au. These impurity effects for titanium diboride whisker growth are summarized in Table 1 together with those for the boron whisker growth[8] and the eutectic temperature of relevant binary systems. It is interesting that the excellent impurities for boron whisker growth such as Co, Ni, Cu metals are in effective in titanium diboride whisker growth.

Figure 2 shows the appearance of whiskers commonly grown with Au impurity at 1050 °C (a) and hexagonal pillar crystals grown with Pd impurity at 1120 °C (b and c). Hereafter the results were taken under painting of 2% chloroauric acid unless otherwise described.

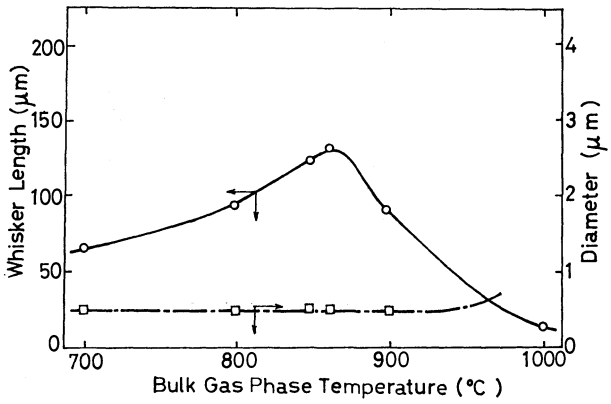

Fig. 3. Effect of temperature of bulk gas phase. Substrate temperature: 1100 °C; reaction time: 30 min.

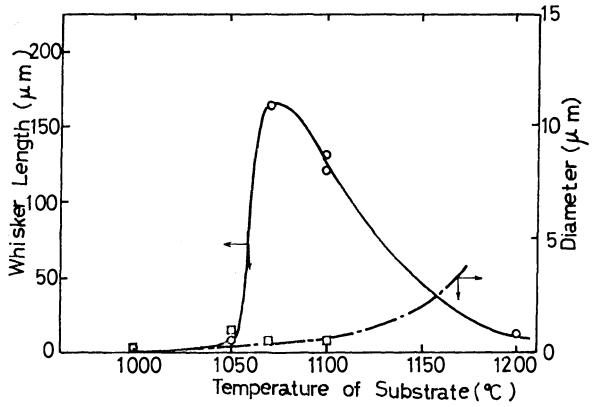

Fig. 4. Effect of substrate temperature. Bulk gas phase temperature: 870 °C; reaction time: 30 min; total flow rate: 2.3 cc/s; $TiCl_4/BCl_3/H_2/Ar$= 8.8/17.5/43.5/30.2 (vol %).

The Effect of Temperature. When the substrate temperature was kept at 1100 °C, whisker length and its diameter after 30 min are moderately varied with the gas phase temperature as shown in Fig. 3. The whisker length became the shorter above 870 °C. Therefore, the gas phase temperature of 870 °C was selected hereafter. On the other hand, the substrate temperature exhibited a sharp effect for whisker growth (Fig. 4). The longest whisker grew at 1060—1080 °C, above which decrease of length and increase of diameter took place gradually, and at the temperature higher than 1100 °C, pillar crystals and thick polycrystalline coatings deposited (Fig. 5). On the contrary, at the substrate temperature lower than 1050 °C whiskers did not grow to observable length.

Time Dependence of Whisker Growth. Average whisker length increased with time up to 30 min, then decreased apparently as shown in Fig. 6. This results may be explained by rapid linear growth, followed by gradual thickning to touch each other especially at the foot part of the whiskers.

In Fig. 7, whisker length and diameter are plotted

Substrate temperature: 1100 °C.

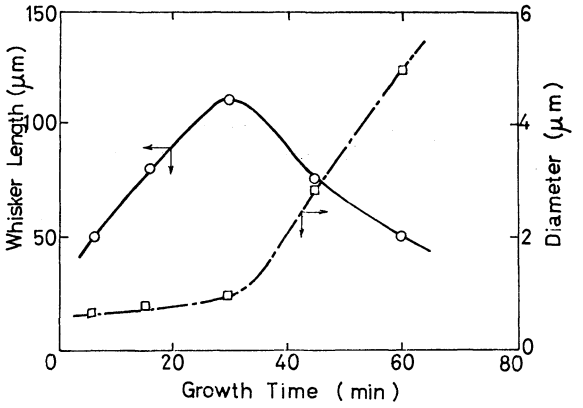

Fig. 6. Effect of reaction time.
Bulk gas phase temperature: 870 °C; substrate temperature: 1070 °C; total flow rate: 2.3 cc/s; $TiCl_4/BCl_3/H_2/Ar=13.1/13.1/45.6/28.2$ (vol %).

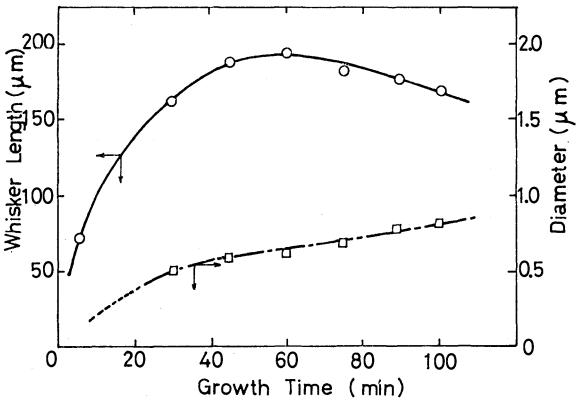

Fig. 7. Effect of growth time with repeptive painting of gold.

against the reaction time during which repetitive gold paintings of about 0.05 mg/cm² of substrate area were carried out. It is found that the repetitive paintings resulted in only a slight effect and the average whisker length increased to 200 μm (maximum length of 350 μm) up to 60 min of growth time, and average diameters also increased up to 0.9 μm for 100 min.

Effect of the Gas Flow Rate and its Composition. In Fig. 8, total flow rate for obtaining the longest whisker is found at 2.0—3.0 ml/s. The average whisker diameters retain 0.9—1.0 μm above the flow rate of 2.5 ml/s. In Fig. 9, the concentration of titanium tetrachloride is

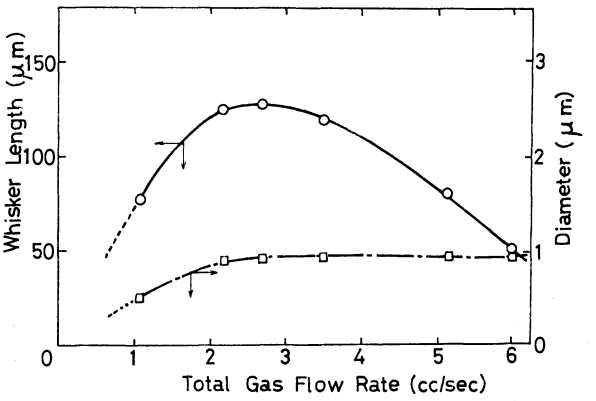

Fig. 8. Effect of total gas flow rate.
Bulk gas phase temperature: 870 °C; substrate temperature: 1070 °C; reaction time: 30 min; $TiCl_4/BCl_3/H_2/Ar=10/20/50/20$ (vol %).

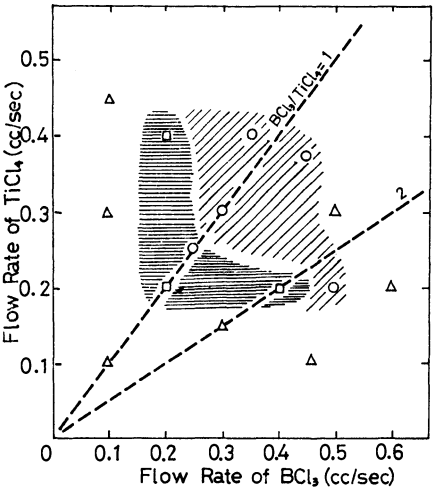

Fig. 9. Effects of the gas flow rate and its composition
Bulk gas phase temperature: 870 °C; substrate temperature: 1070 °C; reaction time: 30 min; total flow rate: 2.3 cc/s, (△): below 100 μm; (○): 100—150 μm; (□): above 150 μm.

plotted against that of boron trichloride in relation to whisker length under a total flow rate of 2.3 ml/s, and the optimum growth conditions are in the hatched range. The longest whiskers were not obtained at the concentration ratio of $BCl_3/TiCl_4=2$, which corresponds to the stoichiometric ratio of the reaction of

$$2BCl_3 + TiCl_4 + 5H_2 = 10HCl + TiB_2,$$

but at a ratio of $BCl_3/TiCl_4 \approx 1$. At the concentration range of boron trichloride higher than the range shown in Fig. 9 the formation of boron whisker was detected, however, which could not be identified by X-ray diffraction for its low diffraction ability, but was discriminated against the titanium diboride whisker by thin curled appearance and by easy dissolution in nitric acid.

Morphologies and Growth Mechanism of TiB_2 Crystals. Some interesting morphologies are shown in Fig. 10. The whisker growth along the hexagonal edges (10a), and from a center of a hexagonal to the six corners of it (10b) are seen when Ag was painted as impurity. When substrate was scratched by pure gold plate, the gold are

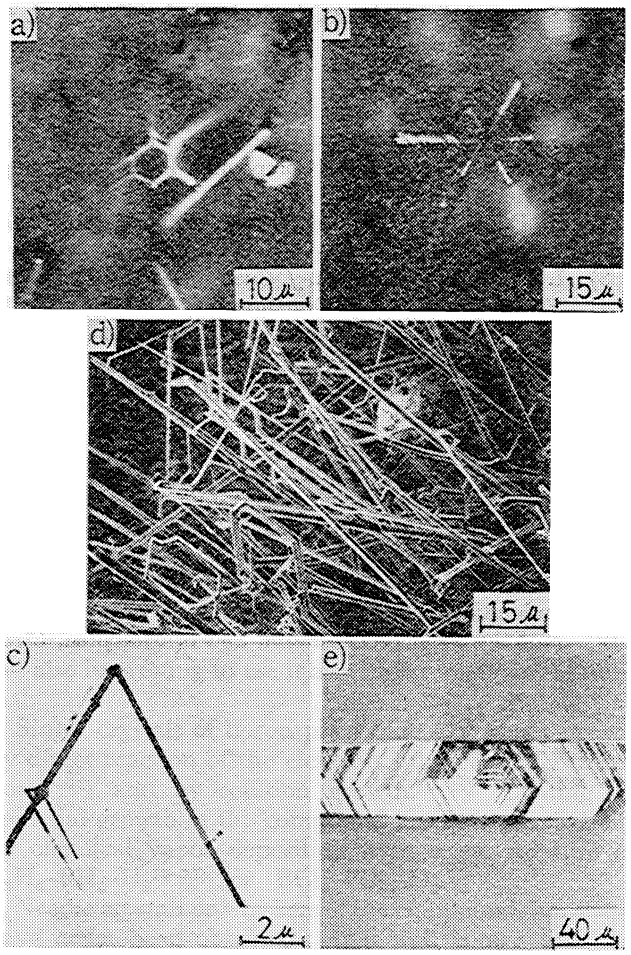

Fig. 10. Some interesting morphologies of TiB_2 whiskers.
a) Whisker grown along a hexagonal edges, b) whiskers grown from the center of hexagonal, c) and d) kinked whiskers, e) growth steps on the side of pillar crystal.

regarded as one of the heaviest dopings. On the zone scratched by gold, whiskers are apt to grow with two kinds of kink angles of 60° (Fig. 10c) and 120° (Figs. 10c and 10d). On the sides of tetragonal pillar crystals (Fig. 10e), multiple growth steps of hexagonal patterns are found, and six fold symmetry axis perpendicular to the side plane was confirmed by Laue photograph. Also additional information for growth direction was obtained from X-ray diffraction diagrams as shown in Fig. 11. The whiskers as grown gave a diagram (Fig. 11b) having peak intensities like those of powder diffraction (Fig. 11a). On the contrary, when about one milligram of whiskers was thoroughly disintegrated in a few drops of water, poured on a holder glass, and dried, the X-ray diffraction diagram is deficient of (10$\bar{1}$1) peak (Fig. 11d) which is the strongest one in powder diffraction peaks (Fig. 11a). From above results, the whisker shape is considered to be tetragonal pile, and the growth direction to be ⟨100⟩axis. Then the kink angles of 60° and 120° are reasonable for equivalent ⟨100⟩directions.

It may be seen in Fig. 5 that pillar whiskers grow only on the part of Au impurity painted zone (A-part), furthermore, on the tip of whisker a droplet can be seen as in Fig. 12a. The existence of a cap on the whisker tip leads to the VLS mechanism for whisker growth. There

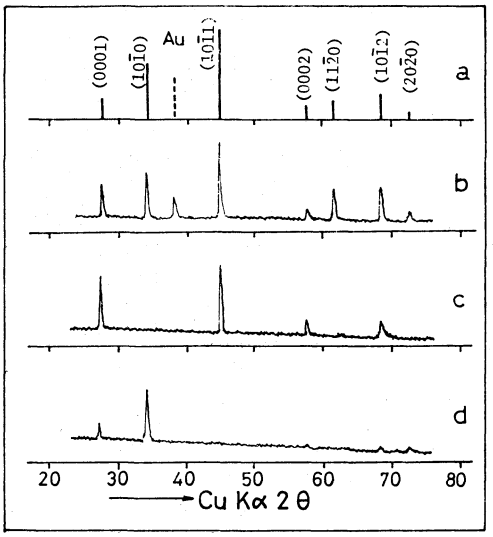

Fig. 11. X-ray diffraction profiles.
a) ASTM data for pulverized TiB_2, b) whiskers as grown, c) hexagonal piles as grown, d) whiskers dispersed on glass.

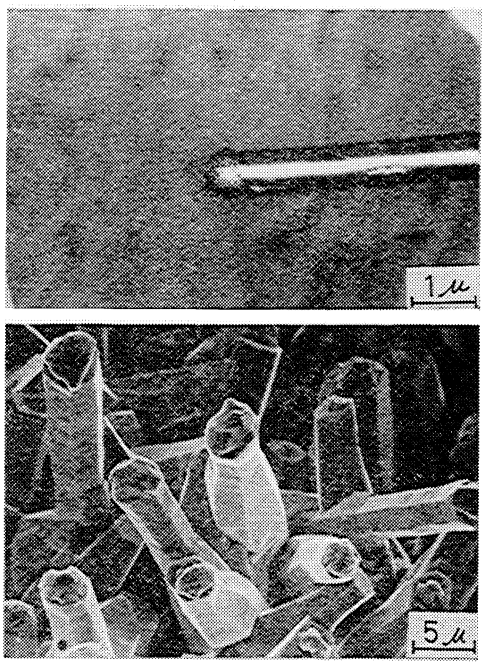

Fig. 12. The tips of the whiskers and pillar crystals.
a) Impurity: Au, substrate temperature: 1050 °C.
b) Impurity: Pd, substrate temperature: 1120 °C.

is, however, a problem to support the mechanism, that is, no liquid phase is found in the binary systems Ti–Au,[9] Ti–B,[9] and Au–B, below 1063 °C which is the melting point of Au. Whiskers grew above 1050 °C. Then the liquid phase may be formed by contamination with silicon from the substrate as reported on the titanium nitride whisker growth[10] or by lowering of liquidus in ternary system Ti–Au–B compared with any of relevant binary systems.

On the other hand, the growth process of hexagonal piles are supposed from their appearance (Figs. 2b and 2c) that the piles grew to [001] direction under the influence of impurity at first, followed by the growth to the direction perpendicular to c-axis.

In Fig. 12b, which is the sample grown on the Pd painted zone near inlet, droplets are also found on the tips, but have different figure from that of Fig. 12a. These hexagonal piles are grown from a BCl_3 rich atmosphere relative to that for the whisker which was grown on the half part substrate near outlet. By the deposition of polycrystalline TiB_2 on the half part of substrate near inlet, the ratio of $BCl_3/TiCl_4$ in gas stream may steeply decrease from unity at inlet to nearly zero outlet. Then, hexagonal piles grown on the zone painted of Pd near inlet are considered to grow under a condition of VS (Vapor-Solid) growth, that is, high concentrations of reactants and high temperature (1120 °C). It is supposed that VS growth rate to [001] direction is low as seen from the hexagonal steps in Fig. 10e. The stacking of the atomic planes to the direction of [001] of titanium diboride consisted of alternative planes of boron and titanium, whereas the stacking to the direction of [100] is that of self-consistent plane of titanium diboride. If one of the reasons for the low growth rate to [001] direction is assumed to be the nucleation of boron, the role of palladium impurity is recognized by easier nucleation of boron plane from a liquid phase of Pd–B alloy, and VS growth from the nuclear along the (0001) plane develops the figure shown in Fig. 12b.

Metallic Impurity-Activated Crystal Growth of Boron Phosphide by Chemical Vapor Deposition and Its Physical Properties

Seiji MOTOJIMA, Yasuo MIURA, Kohzo SUGIYAMA, and Yasutaka TAKAHASHI
Department of Synthetic Chemistry, Faculty of Engineering, Gifu University, Gifu 504
(Received May 26, 1975)

Needle single crystals of boron monophosphide as large as 5—100 μm in diameter and 4 mm in length were obtained by chemical vapor deposition on an impurity painted zone of quartz substrate at 1060—1120 °C. The impurities such as Mn, Ni, Pt, Ag or Au were painted on the substrate in a form of aqueous solution of their salts and decomposed or reduced to the respective metal in hydrogen atmosphere at 1000 °C. Needle crystals with the homo p-n junction were also prepared using Ni impurity. The colors of grown crystals varied with the change of gas composition. Differences of electrical resistivity and thermoelectric power were found between the crystals of different colors.

Cubic boron monophosphide (BP, boron phosphide hereafter) has been extensively investigated during the past decade for its eminent properties as semiconductor.[1-3] Other properties of the compound, such as high melting point (about 3000 °C), high hardness (4000 kg/mm^2),[4] high oxidation resistance in air,[5] and high corrosion resistance in various chemicals,[6-8] moreover, are also interesting to use it as a high temperature material.

Single crystals of boron phosphide have been grown by direct reaction of the elements,[9] by chemical transport[10-12] and by solution growth.[13-14] Coating or epitaxial growth of the compound has been carried out by chemical vapor deposition from a gas mixture of B_2H_6–PH_3–H_2[15-17] or BCl_3–PCl_3–H_2.[18]

Needle crystals or whiskers of the compound, however, have never been obtained. It is well known that the existence of some kind of impurities accelerates the growth of whisker or needle crystals. In the present work, the growth conditions of the single crystal of boron phosphide in use of metal impurities by chemical vapor deposition from a gas mixture of boron trichloride, phosphorus trichloride, hydrogen and argon were investigated together with some physical properties of the grown crystals.

Experimental

Materials. Commercial G. R. grade phosphorus trichloride, boron carbide, and liquefied chlorine were used without further purification. Boron trichloride was prepared from boron carbide *in situ* (*vide infra*).

Preparation of Boron Phosphide. Apparatus is shown in Fig. 1. A quartz tube (7 mm o.d. and 50 mm in length), in which SiC heater was inserted, was placed at a center of reaction tube (quartz of 23 mm i.d.) as a substrate for the crystal growth. The substrate was heated at 900—1200 °C dually from outside and inside. A chlorine stream was flowed into a boron carbide bed kept at 800 °C to form boron trichloride, and the other stream of argon was bubbled through a phosphorus trichloride saturator maintained at 0 °C. The two streams were mixed at the growth zone. The surface temperature of the substrate was measured by an optical pyrometer through a window (corrected with emmision factor) and the bulk gas phase temperature by a C–A thermocouple.

Aqueous solutions of eleven compounds such as nickel acetate, hexachloroplatinic acid, tetrachloroauric acid, silver nitrate, *etc.* were painted as impurities on the substrate scratched by abrasives and decomposed or reduced to fine particles or islands of the respective metals in hydrogen atmosphere at 1000 °C.

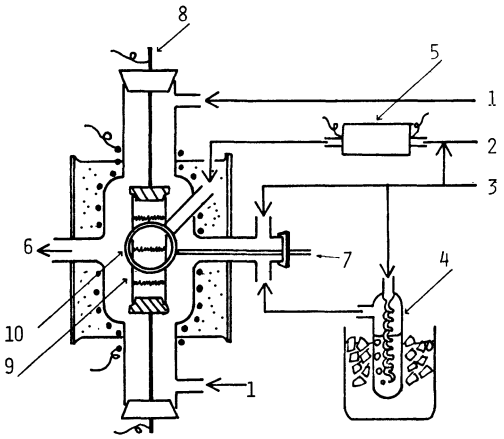

Fig. 1. The apparatus for BP growth.
(1) H_2, (2) Cl_2, (3) Ar, (4) PCl_3 saturator, (5) B_4C, (6) outlet, (7) C–A thermocouple, (8) electrode, (9) quartz substrate, (10) window.

In this paper, length of needle crystals is shown by the average length of about twenty samples selected in the order from the longest in the field of microscopy magnified by 150. Reaction time was fixed at 30 min, unless otherwise described.

Electrical Resistivity Resistivity measurements of needle crystals were performed under argon atmosphere at the temperature range of 20—120 °C using a DC wheatstone bridge (Ando Elec. Co., Model LCR-4) by conventional two probe method using a silver paste (Fujikura Chemicals, Dotite D-550) to contact the leads.

Thermoelectric Power. Crystal was bridged and attached between two copper plates (3×5 mm) separated 1 mm each other, one of which was heated by nichrome heater, where temperature difference of two edges of the crystals was measured by an iron-constantan thermocouple, and controlled in the range of 1—1.5 °C. Thermoelectric power was measured by a potentiometer.

I—V Measurements. The relationship between the current and the applied voltage (DC) was taken by a current interruptor (Hokuto Denki Co., CL-2515).

Results and Discussion

Identification of Products and Impurity Effect. In the preliminary experiment, it was found that the forms of

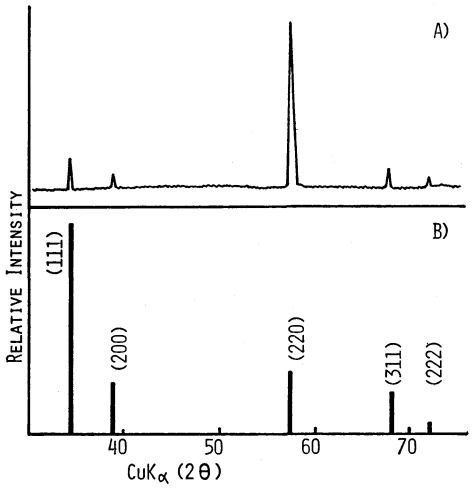

Fig. 2. X-Ray diffraction profiles.

Reactions: conditions: Temperature; 1090 °C; reaction time, 30 min; $BCl_3/PCl_3/H_2/Ar=0.12/0.03/0.8/1.5$ (cc/s). a) (−): no or negative effects, (+): weak positive effects (below 1 mm long), (++): strong positive effects (longer than 1 mm).

data of the boron phosphide[19] (Fig. 2B), from the anomalous intensity of (110) in Fig. 2A and from the hexagonal shape (Fig. 12), it is supposed that the growth direction is ⟨111⟩, thus the side planes (110). The different growth conditions and impurities resulted in the needle or pillar crystals of different colors such as black, dark-red, and orange or yellow, while the structures and the growth directions were determined as the same as the pillar crystals grown at 1070 °C with nickel impurity described above.

When nickel impurity is painted on the substrate, pillar crystals grow only on the impurity painted zone as shown in Fig. 3A, indicating the impurity indispensable for pillar crystal growth. In Table 1, impurity effects of various metals on the pillar crystal growth at 1090 °C are summarized together with the eutectic temperatures of the relevant binary alloys.[20-22] Of the examined impurities, chromium, cobalt, iron, palladium, and copper resulted in no or negative effect on pillar crystal growth at 1090 °C, where deposition took place in a form of coatings or polygonals. On the contrary, manganese, nickel, platinum, silver, and gold indicated a positive effect at the same temperature as above, affording a straight and well-formed pillar crystal as large as 2 mm for 30 min and up to 4 mm for 90 min.

Of cource, the impurity effect varies with growth temperature. In Fig. 4, the temperature ranges of substrate for respective impurities where pillar crystal growth is possible are shown by vertical lines at the eutectic temperatures of the systems, boron–impurities. It is found that cobalt, rhodium, and iron indicate the positive effect at the higher temperature. It may be seen that

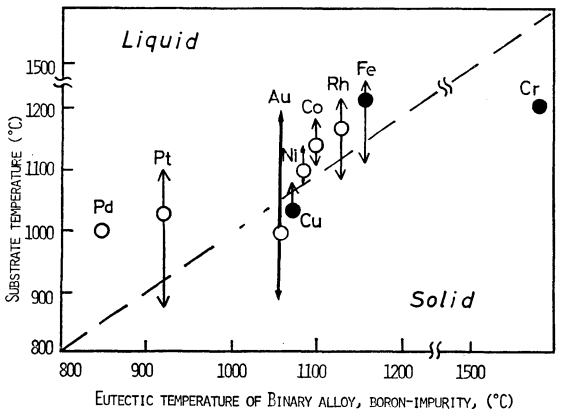

Fig. 4. Relationship between the substrate temperature and the eutectic temperature of binary alloys, boron and impurities, in BP pillar crystal growth.
(○): up to 1 mm long, (●): below 1 mm, In the case of Au impurity, the mp of Au metal it self are shown because boron is not dissolved in it.

the higher the eutectic temperature of the system of boron-impurity, the higher temperature is required for pillar crystal growth.

Hereafter nickel or platinum was used as an impurity, unless otherwise noted. The surface concentration of the impurity was fixed at *ca.* 50 μg/substrate area (cm^2) without reasons.

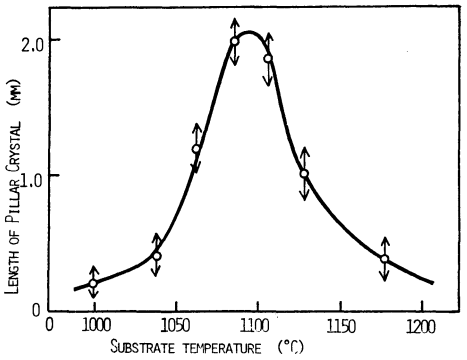

Fig. 5. Effect of substrate temperature on the length of pillar crystal.
Impurity: Pt; reaction time: 30 min; $BCl_3/PCl_3/H_2/Ar=0.05/0.023/1.3/1.25$ (cc/s).

The Effect of Substrate Temperature. The predominant factor to control the maximum length of pillar crystal is the substrate temperature. One of the results is shown in Fig. 5, where platinum was used as the impurity. An average length of 1.8—2.0 mm and the thickness of 10—50 μm was attained at 1070—1100 °C, above or below which the maximum length steeply decreased below 500 μm.

Effects of Gas Composition and Flow Rate on Pillar Crystal Growth. In the Case of Platinum Impurity: The effect of the concentration of BCl_3 and PCl_3 on the pillar crystal length is shown in Fig. 6, where total flow rate was fixed at 2.6 cc/s. According to the reaction:

$$BCl_3 + PCl_3 + 3H_2 = BP + 6HCl$$

stoichiometric ratio of $BCl_3/(BCl_3+PCl_3)$ equals to 0.5. However, the longest pillar crystal of black and hexa-

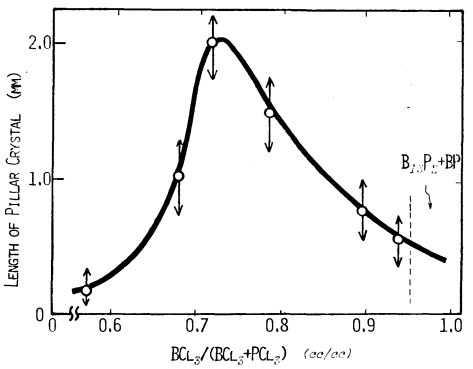

Fig. 6. Effect of the flow ratio $BCl_3/(BCl_3+PCl_3)$ on pillar crystals growth.
Impurity: Pt; reaction temperature: 1080 °C; reaction time: 30 min; H_2: 1.3 cc/s, total flow rate: 2.6 cc/s.

gonal or trigonal shape was obtained between the ratios of 0.7—0.8. Woolly and faint yellow whiskers were grown at the ratio of higher than 0.95, and were determined as the mixture of boron phosphide and tridecaboron diphosphide.

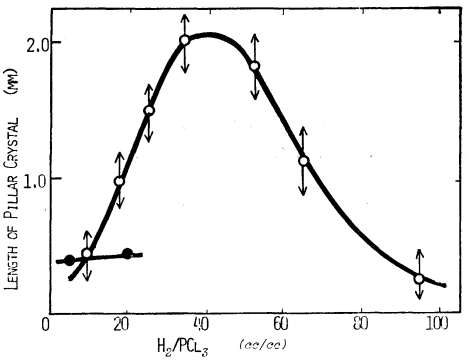

Fig. 7. Effect of the flow ratio H_2/PCl_3 on pillar crystal growth.
Impurity: Pt; reaction temperature: 1090 °C; reaction time: 30 min; $BCl_3/PCl_3=4$ (cc/cc); total flow rate: 2.4 cc/s. (○): black crystal, (●): red-orange crystal.

Phosphorus trichloride is readily reduced by hydrogen to phosphorus element. Thus the ratio of H_2/PCl_3 is expected to affect the boron phosphide crystal growth. In Fig. 7, the relationship between the length of pillar crystal and the ratio of H_2/PCl_3 in the feed stream is shown where the ratio of $BCl_3/(BCl_3+PCl_3)$ was fixed at 0.8. In spite of the dilution of phosphorus trichloride and boron trichloride by hydrogen, the length of the pillar crystal increases with the ratio up to 40, which corresponds to the phosphorus trichloride concentration of 2.5% and to the total chloride concentration of 10%. At the dilution (H_2/PCl_3) lower than twenty the color of grown crystals varied to red-orange. When the concentrations of boron trichloride, phosphorus trichloride, hydrogen, and argon calculated from the feed rates are kept at 2.0, 1.0, 50, and 47 vol %, respectively, the total flow rate to grow the longest whisker was between 2.3—3.0 cc/s which corresponds to the linear velocity of about 3 cm/s at the growth temperature of 1090 °C.

In the Case of Nickel Impurity. It was found that

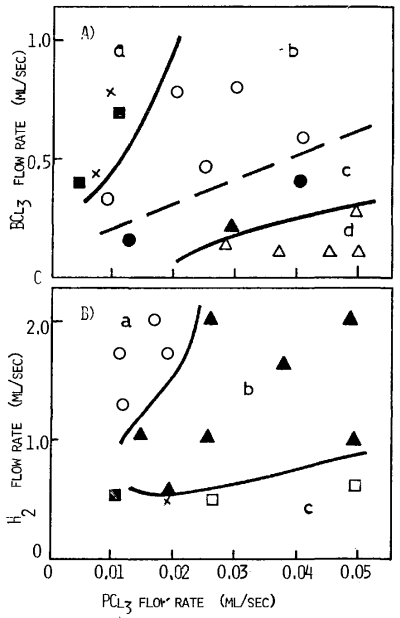

Fig. 8. Effect of relevant gas flow rates on the crystal colors and the compositions.
Impurity: Ni; (○): black pillar crystal; (●): black and orange pillar crystal; (△): orange or yellow pillar crystal; (▲): red-orange and black pillar crystal; (×): black coatings of boron and boron phosphide; (□): black coatings or brown woolly crystals of BP and $B_{13}P_2$; (■): blown and white woolly crystals of boron and boron phosphide.
A) H_2 flow rate: 1.0 cc/s, B) $BCl_3/PCl_3=0.7$ (cc/cc).

the kind of impurity affects not only morphologies of grown crystal, but also the colors of it. In Fig. 8, the distributions of the colors and the compounds of grown crystals are shown in relation with the flow rates of boron trichloride, hydrogen, and phosphorus trichloride using nickel impurity. It is found that the colors of the pillar crystals of boron phosphide vary from black of b-region to orange or faint yellow of d-region in Fig. 8A, and also from black of a-region to orange of b-region in Fig. 8B. The preferable concentration ratio of BCl_3/PCl_3 to grow the black pillar crystal of boron phosphide is about twenty, which is far rich in boron trichloride compared with the result in the case of platinum impurity, where the ratio was about three as seen from Fig. 6.

Preparation of the Crystal with Homo p-n Junction.
During the CVD experiment of boron phosphide, it was found that the pillar crystal with the homo junction between the p-type black and n-type orange boron phosphide grew spontaneously by a local fluctuation of gas composition. The growth condition of the experiment was substrate temperature of 1090 °C, the gas concentration of $BCl_3/PCl_3/H_2/Ar$ of (3.7—7.4)/(1.1—1.5)/(37—38)/(55—58) vol%, and total flow rate of 2.6—2.8 cc/s in use of nickel as an impurity. The black and the orange pillar crystals are apt to grow in mixture at the part near inlets of boron trichloride and phosphorus trichloride only when nickel was used as an impurity. It was supposed that the variation of colors of pillar crystals arised from unexpected change of the ratio BCl_3/PCl_3. Thus, during the growth the inlets of boron trichloride and phosphorus trichloride was exchanged

Impurity: Ni; reaction temperature: 1090 °C; reaction time: 30 min; $BCl_3/PCl_3/H_2/Ar=0.2/0.04/1.0/1.6$ (cc/s).

each other after the growth time of 30 min from the heavy lines in Fig. 9 to the dashed line, and the growth was continued for 15—30 min. The color of the pillar crystal changed from orange at the first step to black partly near tip at the second step. In Fig. 10, one of the grown crystals is shown. The black part consists of the

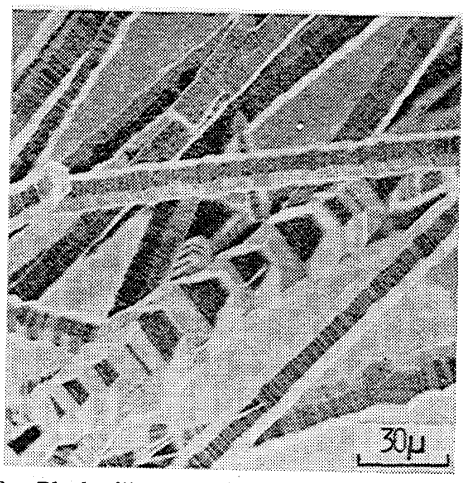

Fig. 12. Black pillar crystals with multiple growth steps on the side.
Impurity: Pt; reaction temperature: 1090 °C; reaction time: 30 min; $BCl_3/PCl_3/H_2/Ar=0.1/0.025/1.5/1.3$ (cc/s).

outer black layer and the orange core. The I–V property of the crystal will be shown later.

Crystal Morphologies and Growth Mechanism of Pillar Crystals. In contrast with the well formed red-orange crystals grown in use of nickel impurity (Fig. 11), multiple growth steps were seen frequently on the side of black pillar crystals in use of platinum impurity as shown in Fig. 12. The cross section of these crystals was commonly hexagonal- or trigonal-shaped irrespective of their colors.

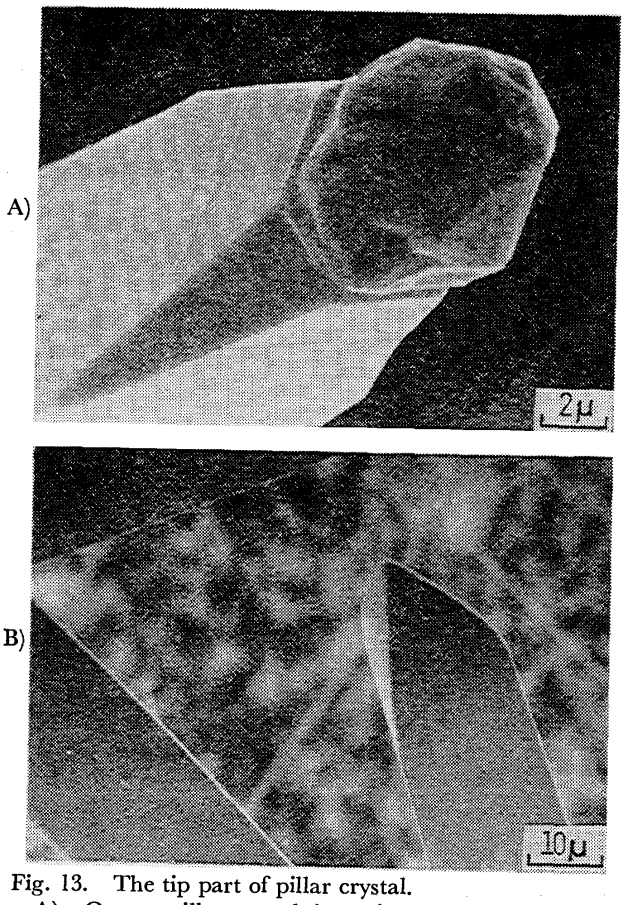

Fig. 13. The tip part of pillar crystal.
A) Orange pillar crystal, impurity: Ni.
B) Black pillar crystal, impurity: Pt.

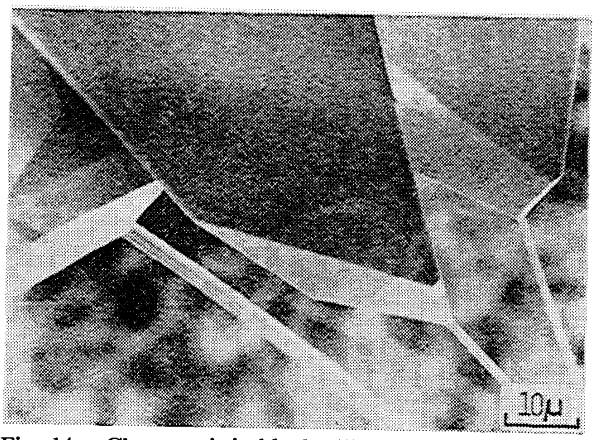

Fig. 14. Characteristic black pillar crystal grown on an orange whisker.
Impurity: Ni; reaction temperature: 1090 °C; reaction time: 30 min; $BCl_3/PCl_3/H_2/Ar=0.7/0.02/1.0/1.2$ (cc/s).

The impurities, intended to be a liquid forming agent, are indispensable for the growth of pillar crystals as described above. When nickel was used as an impurity, on the tip of the orange pillar crystal there can be seen commonly globules which may be considered to be impurity drops (Fig. 13A). On the contrary, no globules were seen on the tip of black pillar crystals irrespective of the kind of impurities (Fig. 13B). In Fig. 14, the foot part of black crystals is shown. The whole of them has yellow thin leg, from which the growth mechanism is supposed to be fast linear growth of yellow crystal by "VLS" mechanism followed by growth of black crystal by slow "VS" mechanism to the direction perpendicular to the growth axis. Unfortunately, such a double structure can be seen only when nickel was used. Thus the

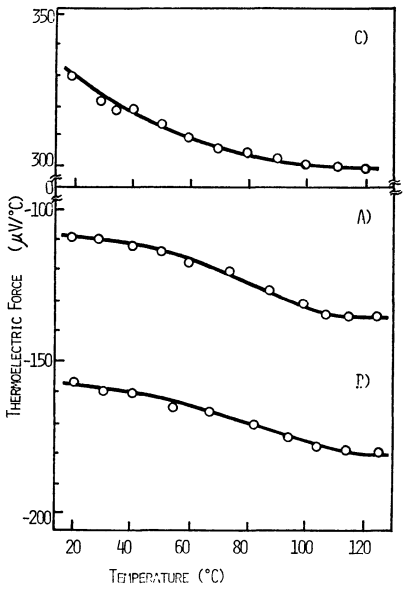

Fig. 16. Temperature dependence of thermoelectric force.

growth mechanism for other impurities than nickel remains open to further investigations.

Properties of Boron Phosphide Crystals. Electrical Resistivity: The resistivities of well-formed black, dark-red and orange or yellow crystals of hexagonal or trigonal pillars are shown in Fig. 15. These crystals were obtained in use of Pt, Ni, and Ni metal as an impurity, respectively. Although the measurements were carried out on three crystals of respective colors, the results were characteristic of respective colors within the experimental errors. Figure 15 shows that the resistivity decreases with increasing temperature, showing a characteristic semiconductor behavior. Crystal of black, dark-red, and orange have the resistivities of 3.1, 2.2, and 0.4 Ω·cm at room temperature, respectively. Chu *et al.*[12] and Nishinaga *et al.*[15] reported that the resistivities of boron phosphide were 0.5 Ω·cm (for single crystal of p-type) and 5×10^{-3} Ω·cm (for undoped layers of n-type), respectively. The resistivity of orange crystals is in good accordance with that of the former.

Thermoelectric Power. Thermoelectric powers of boron phosphide crystals of three colors, black, dark-red, and orange, are shown in Fig. 16, indicating the thermoelectric powers of −110, −160, +330 μV/°C at room temperature, respectively, and decrease with temperature. These values obtained roughly agree with the value of 240 μV/°C reported by Grinberg *et al.*[23]

Conduction types were determined as p, p, and n for crystal of black, dark-red, and orange, respectively.

Schono *et al.*[17] reported that boron phosphide of p-type and n-type was grown epitaxially on a silicon substrate at low and high flow rates of phosphine, in the reaction of phosphine, boran, and hydrogen at 950—1100 °C, respectively. Takenaka *et al.*[24] obtained a thin red-brown layer of n-type boron phosphide. From the results obtained by Schono *et al.*[17] and in present work, it is supposed that the conduction types of boron phosphide are determined by excess boron or phosphorus as p or n, respectively. Thus the transition of the growth mechanism from "VLS" (orange whisker) to "VS" (black pillar) may be resulted from the solubility change of boron in impurity liquid with the whisker length because of the temperature decrease from hot surface of substrate to warm wall of reaction tube.

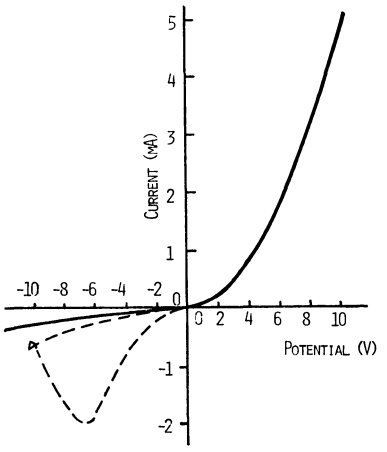

Fig. 17. I—V curve of the pillar crystal with homo p–n junction.

I—V Curve. The relationship of the applied voltage and the current of the crystal with homo p–n junction indicates a considerable rectification (Fig. 17).

An NMR and Mössbauer Spectroscopic Study of Mixed-valence Iron Fluoride Heptahydrate and Related Compounds

Takuhiko SAKAI and Takeshi TOMINAGA*

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received May 17, 1975)

The powder X-ray patterns of $Fe^{III}Fe^{II}F_5 \cdot 7H_2O$, $AlFe^{II}F_5 \cdot 7H_2O$, $Fe^{III}ZnF_5 \cdot 7H_2O$ and $AlZnF_5 \cdot 7H_2O$ indicate that they are all isomorphous. When the Mössbauer spectra of the fluorides containing iron were measured, Fe^{II} and/or Fe^{III} oxidation states were recognized distinctly. The ^{19}F NMR spectra reveal that all the fluorine atoms are bonded to the trivalent metal ion (Al or Fe^{III}) in these compounds. On the basis of these results, a possible structure is proposed for $Fe^{III}Fe^{II}F_5 \cdot 7H_2O$.

Although a few works have been reported on the Mössbauer spectrum[1,2] and the X-ray powder pattern[3] of the mixed-valence iron fluoride heptahydrate, $Fe^{III}Fe^{II}F_5 \cdot 7H_2O$, no previous study has elucidated the bonding of ligands to iron in this compound. While Mössbauer spectroscopy can be used to recognize different oxidation states of central iron atoms in such mixed-valence systems, the ^{19}F and proton NMR spectra may provide us with important information concerning the bonding of ligands to central atoms. Hence, we have recently investigated $Fe^{III}Fe^{II}F_5 \cdot 7H_2O$ and several related compounds, such as $Fe^{III}ZnF_5 \cdot 7H_2O$, $AlFe^{II}F_5 \cdot 7H_2O$ and $AlZnF_5 \cdot 7H_2O$ (containing paramagnetic and/or non-magnetic metal ions), by means of Mössbauer and/or NMR spectroscopy, and have concluded that all the fluoride ions are bonded to the ferric iron.[4] The object of this article is to report the results of our recent work in further detail.

Experimental

Materials. *$Fe^{III}Fe^{II}F_5 \cdot 7H_2O$*: This compound was prepared as has been reported previously.[2] Found: Fe(III), 16.8; Fe(II), 16.8; F, 28.3%. Calcd for $Fe^{III}Fe^{II}F_5 \cdot 7H_2O$: Fe(III), 16.8; Fe(II), 16.8; F, 28.6%.

$AlFe^{II}F_5 \cdot 7H_2O$: A hot 20% HF solution containing iron powder was heated for several hours on a water bath under a reducing atmosphere. The resulting Fe^{2+}–HF solution was filtered, and more iron powder was added to the filtrate so as to ensure the complete reduction of Fe^{3+} to Fe^{2+} in the solution. The solution was then filtered and poured over iron wire, immediately mixed with an equivalent amount of $Al(OH)_3$, and heated for one hour on a water bath. After the solution had stood for several hours, pale green crystals of $AlFe^{II}F_5 \cdot 7H_2O$ were filtered, washed with water and dried in air. Found: Al, 9.1; Fe(II), 18.3; F, 31.7%. Calcd for $AlFe^{II}F_5 \cdot 7H_2O$: Al, 8.9; Fe(II), 18.4; F, 31.3%.

$Fe^{III}ZnF_5 \cdot 7H_2O$: This was prepared by modifying Weinland's method[5] as follows: $Fe(OH)_3$ was dissolved in a hot 20% HF solution, to which an equivalent amount of $ZnCO_3$ was then added. After the solution had been condensed by heating on a water bath, it was kept standing overnight at room temperature. Then, white crystals of $Fe^{III}ZnF_5 \cdot 7H_2O$ were filtered out, washed with water and dried in air. Found: Fe(III), 16.3; Zn, 19.1; F, 28.2%. Calcd for $Fe^{III}ZnF_5 \cdot 7H_2O$: Fe(III), 16.3; Zn, 19.1; F, 27.8%.

$AlZnF_5 \cdot 7H_2O$: The procedure of preparation was similar to that used for $Fe^{III}ZnF_5 \cdot 7H_2O$, except that $Al(OH)_3$ was used as the starting material instead of $Fe(OH)_3$. Found: F, 30.6%. Calcd for $AlZnF_5 \cdot 7H_2O$: F, 30.3%. The determination of the metal contents was interfered with by the presence of fluoride ions.

$Fe^{III}CoF_5 \cdot 7H_2O$ and $Fe^{III}NiF_5 \cdot 7H_2O$: They were prepared by procedures similar to that used for $Fe^{III}ZnF_5 \cdot 7H_2O$, except that basic cobalt carbonate or basic nickel carbonate was used instead of $ZnCO_3$.

Measurements. The powder X-ray patterns of $Fe^{III}Fe^{II}F_5 \cdot 7H_2O$, $Fe^{III}ZnF_5 \cdot 7H_2O$, $AlFe^{II}F_5 \cdot 7H_2O$ and $AlZnF_5 \cdot 7H_2O$ were obtained at room temperature by using Cu$K\alpha$ radiation. The observed data were calibrated by referring to the spectrum of the quartz added as an internal standard.

The Mössbauer spectra of $Fe^{III}Fe^{II}F_5 \cdot 7H_2O$, $Fe^{III}ZnF_5 \cdot 7H_2O$, and $AlFe^{II}F_5 \cdot 7H_2O$ at 80, 195, and 293 K, as well as those of $Fe^{III}CoF_5 \cdot 7H_2O$ and $Fe^{III}NiF_5 \cdot 7H_2O$ at 80 and 293 K, were measured by means of a Shimadzu MEG-2 Mössbauer Spectrometer with a ^{57}Co source diffused into copper foil.

The NMR measurements of the powder samples of these compounds were made at 298 and 113 K by a Varian VF-16 broad-line NMR Spectrometer operating at 7.994 MHz or at about 16 MHz.

Results and Discussion

Powder X-Ray Patterns. The powder X-ray patterns of the four fluorides shown in Fig. 1 appear to be generally alike except for an unimportant difference observed in the vicinity of the diffraction angle, $2\theta \sim 20°$. The lattice constants of these compounds were calculated for the tetragonal symmetry from the data calibrated by referring to the spectrum of the quartz used as the internal standard. The lattice constants obtained in the

$Fe^{III}NiF_5\cdot 7H_2O$	0.42		0.53	0.52		0.53

a) With respect to the centroid of the spectrum of iron foil at 293 K.

Mössbauer Spectra. Some typical Mössbauer spectra of $Fe^{III}Fe^{II}F_5\cdot 7H_2O$, $AlFe^{II}F_5\cdot 7H_2O$, and $Fe^{III}ZnF_5\cdot 7H_2O$ obtained at 293 K are shown in Fig. 2. In Table 1 are summarized the Mössbauer parameters of these compounds at 80, 195, and 293 K, together with those of $Fe^{III}CoF_5\cdot 7H_2O$ and $Fe^{III}NiF_5\cdot 7H_2O$ at 80 and 293 K. The Mössbauer spectrum of $Fe^{III}Fe^{II}F_5\cdot 7H_2O$ appears to consist of two sets of doublets of nearly equal intensities. The outer doublet corresponds to Fe(II), while the inner doublet is ascribed to Fe(III). At 80, 195, and 293 K, the Mössbauer parameters of the Fe(II) doublet in $Fe^{III}Fe^{II}F_5\cdot 7H_2O$ are in good agreement with those of the doublet in $AlFe^{II}F_5\cdot 7H_2O$. The spectrum of $Fe^{III}Fe^{II}F_5\cdot 7H_2O$ can be resolved to reveal the Fe(III) peaks distinctly by subtracting the superposed Fe(II) doublet (the broken lines in Fig. 2a). The shape of the Fe(III) peaks thus obtained is similar to the spectra of $Fe^{III}ZnF_5\cdot 7H_2O$, $Fe^{III}CoF_5\cdot 7H_2O$, and $Fe^{III}NiF_5\cdot 7H_2O$. Accordingly, the Mössbauer results are compatible with the conclusion based on the X-ray data, indicating that these compounds are all isomorphous. Furthermore, it is worth mentioning that the shape of the Fe(III) peaks in either $Fe^{III}Fe^{II}F_5\cdot 7H_2O$ or $Fe^{III}ZnF_5\cdot 7H_2O$ (Fig. 2) appears to be a composite of at least two sets of unresolved doublets. Accordingly, the spectra of $Fe^{III}Fe^{II}F_5\cdot 7H_2O$ and $Fe^{III}ZnF_5\cdot 7H_2O$ were analyzed by means of a computer fitting based on the assumption that the Fe(III) peaks were composed of two sets of doublets. The best-fit curves obtained imply the presence of at least two different Fe(III) sites (Fig. 3).

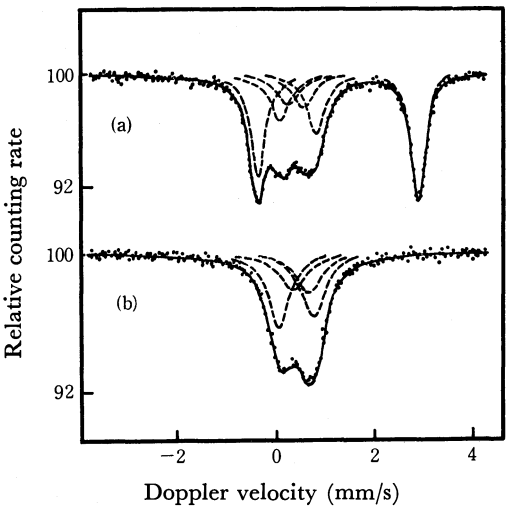

Fig. 3. Computer-fitting analysis of Mössbauer spectra (293 K) of (a) $Fe^{III}Fe^{II}F_5\cdot 7H_2O$, and (b) $Fe^{III}ZnF_5\cdot 7H_2O$.

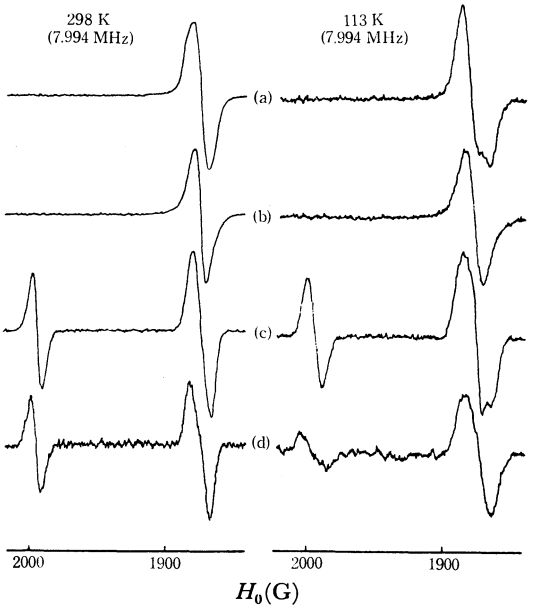

Fig. 4. NMR spectra at 298 K (left) and 113 K (right) of (a) $Fe^{III}Fe^{II}F_5\cdot 7H_2O$, (b) $Fe^{III}ZnF_5\cdot 7H_2O$, (c) $AlFe^{II}F_5\cdot 7H_2O$, and (d) $AlZnF_5\cdot 7H_2O$.

^{19}F NMR Spectra. Figure 4 represents the nuclear magnetic resonances of ^{19}F and protons in these fluorides observed at 113 and 298 K. The signals at about 2000 G and 1880 G indicate the NMR lines of ^{19}F and the protons respectively. As is shown in Fig. 4, the ^{19}F nuclear magnetic resonances are observed only in $AlFe^{II}F_5\cdot 7H_2O$ and $AlZnF_5\cdot 7H_2O$, not in $Fe^{III}ZnF_5\cdot 7H_2O$ and $Fe^{III}Fe^{II}F_5\cdot 7H_2O$. Since the comparison of

the area under the ^{19}F and proton signals in the NMR spectra of $AlFe^{II}F_5 \cdot 7H_2O$ and $AlZnF_5 \cdot 7H_2O$ indicates the $^{19}F/^{1}H$ ratio of 5/14, it may be presumed that all the ^{19}F and ^{1}H nuclear spins are detected in these compounds.

While the ^{19}F resonance signals in paramagnetic compounds would, in general, be unobservable because of the large internal dipole or hyperfine field arising from the electronic spins,[6] the resonance signals of the ^{19}F atoms bonded to such diamagnetic ions as Al^{3+} and Zn^{2+} should be observable because of the weak influence on ^{19}F of the magnetic field due to the diamagnetic ions. The absence of the ^{19}F resonance signals in $Fe^{III}ZnF_5 \cdot 7H_2O$ reveals that all the ^{19}F atoms are bonded to Fe^{3+}, but not to Zn^{2+}, and that these ^{19}F atoms are possibly influenced by the very strong internal magnetic field due to the paramagnetic spins of the Fe^{3+} ions. The ^{19}F NMR spectra thus indicate that all the fluorine atoms are bonded to M^{III} (Al^{3+} or Fe^{3+}) in these fluorides. Since the X-ray and Mössbauer data have shown that they all isomorphous, the structures of the four fluorides, $M^{III}M'^{II}F_5 \cdot 7H_2O$ ($M^{III}=Fe^{III}$ or Al, and $M'^{II}=Fe^{II}$ or Zn), may be generally represented as $[M^{III}F_5OH_2] \cdot [M'^{II}(OH_2)_6]$, and we may presume the structure of $Fe^{III}Fe^{II}F_5 \cdot 7H_2O$ to be $[Fe^{III}F_5OH_2] \cdot [Fe^{II}(OH_2)_6]$.

Proton NMR Spectra. In the proton NMR spectra at 7.994 MHz, the proton signals of $Fe^{III}Fe^{II}F_5 \cdot 7H_2O$ and $AlFe^{II}F_5 \cdot 7H_2O$ at 113 K appear to be asymmetric (Fig. 4). In order to make a more detailed analysis convenient, the proton NMR spectra of these fluorides, together with those of $Fe^{III}CoF_5 \cdot 7H_2O$ and $Fe^{III}NiF_5 \cdot 7H_2O$ were also measured during operation at 16 MHz; asymmetric signals were obtained at 113 K in all the compounds except $Fe^{III}ZnF_5 \cdot 7H_2O$ (Fig. 5). In accordance with the proposed structures, these results may be generally explained as follows. The asymmetric proton NMR signals reflect the influence of the magnetic anisotropy of the paramagnetic ion with a short spin-relaxation time (*i.e.*, Fe(II), Co(II), or Ni (II)), to which the water molecules are bonded. If a water molecule is bonded to a ferric ion with a long spin-relaxation time, however, the local magnetic field changes slowly and the proton experiences various magnetic fields. Hence, the proton NMR line-width is so broadened that the resonance can hardly be detected. Since all proton signals can be observed in $AlFe^{II}F_5 \cdot 7H_2O$, its spectrum is composed of asymmetric signals reflecting the magnetic anisotropy of Fe(II) and the superimposed, unperturbed signals from protons of the water bonded to Al. In $Fe^{III}ZnF_5 \cdot 7H_2O$ we observed only the symmetrical signals of protons of water bonded to Zn(II), which are not perturbed magnetically.

The proton NMR spectra of these compounds observed at 298 K are all symmetrical (Figs. 4 and 5). This may be attributable to the disappearance of the magnetic anisotropy because of the accelerated motion of protons around the oxygen atom at elevated temperatures.

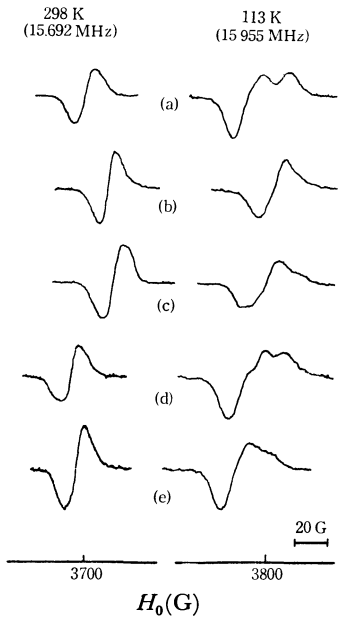

Fig. 5. Proton NMR spectra at 298 K (left) and 113 K (right) of (a) $Fe^{III}Fe^{II}F_5 \cdot 7H_2O$, (b) $Fe^{III}ZnF_5 \cdot 7H_2O$, (c) $AlFe^{II}F_5 \cdot 7H_2O$, (d) $Fe^{III}CoF_5 \cdot 7H_2O$, and (e) $Fe^{III}NiF_5 \cdot 7H_2O$.

The authors wish to thank Professor Nobufusa Saito for his encouragement and support and to Drs. Yoji Arata and Akira Yamasaki for many helpful discussions. They are also greatly indebted to Dr. Keikichi Nakamura of the National Research Institute of Metals for the NMR measurements. Their thanks are also due to Dr. Takamitsu Yamanaka of the Department of Mineralogy, the University of Tokyo, where the X-ray powder patterns were made and the computer analysis done, and to Dr. Fumitoshi Ambe of the Institute of Physical and Chemical Research, where the computer analysis of the Mössbauer data was done.

Metal Complexes of Amino Acids. VIII.[1] Carbon-13 Nuclear Magnetic Resonances of Cobalt(III) Complexes Containing L-Aspartic and L-glutamic Acids

Takaji YASUI and Tomoharu AMA

Faculty of Arts and Sciences, Kochi University, Asakura, Kochi 780

(Received June 5, 1975)

The ^{13}C NMR spectra of cobalt(III) complexes containing L-aspartic acid or L-glutamic acid as unidentate, bidentate, or bridged ligand were measured, and the relationship between the coordination types and the changes in chemical shift of carboxyl carbons in these amino acid complexes was discussed. Two structural isomers were newly separated for the *trans*(O)-[Co en_2(L-aspH_2 or L-gluH_2)$_2$]X_3 complex by a column chromatographic method. The structures of the earlier eluted isomers for the *trans*(O)-[Co en_2(L-aspH_2)$_2$]X_3 and -[Co en_2(L-gluH_2)$_2$]X_3 complexes were assigned to *trans*(O_0, O_γ) and *trans*(O_0, O_δ) (O_0, O_γ and O_δ indicate the coordinated oxygen atoms of C_0OO, $C_\gamma OO$, and $C_\delta OO$), respectively, and the structures of the later eluted isomers for the both complexes to *trans*(O_0, O_0), on the basis of the shift patterns of carboxyl carbons.

It is well known that the ^{13}C NMR technique gives many useful informations about structural analyses of organic compounds.[2,3] Recently this technique has been applied to the metal complexes.[4–7] In the previous paper[8] we studied the ^{13}C NMR of cobalt(III) complexes containing various amino acids.

In the present paper, the relationship between the coordination types and the changes in chemical shift of carboxylate groups in amino acid-cobalt(III) complexes containing L-aspartic and L-glutamic acids as unidentate, bidentate and bridged ligands will be discussed on the basis of their ^{13}C NMR spectra. Furthermore the structural assignments for the newly obtained structural isomers of the *trans*(O)-[Co en_2(L-aspH_2)$_2$]X_3 and [Co en_2(L-gluH_2)$_2$]X_3 complexes will be made.

Experimental

Preparation of Complexes. Trans(O_0,O_γ)- and trans(O_0, O_0)-[Co en_2(L-aspH_2)$_2$]$Br_3\cdot H_2O$: To an aqueous solution containing 5.2 g (0.01 mol) of [Co$(OH_2)_2en_2$]$(ClO_4)_3$ in 50 ml of water was added 3.2 g (0.024 mol) of L-aspartic acid, and the mixture was gradually evaporated to dryness on a steam-bath. The residue was dissolved in 20 ml of water, and the solution was evaporated again. This procedure was repeated three or four times more. The final residue was dissolved in about 300 ml of water, and the solution was poured into a SP-Sephadex cation-exchange column (C-25, K-form, $\phi 4.5\times 50$ cm). After two days two purplish-red bands were separated from the upper adsorbed band by sweeping with 0.03 M aqueous solution of KBr which was slightly acidified with hydrobromic acid. Each split band was taken out and transfered into a short column. The purplish-red solution obtained from each column by elution with concentrated KBr solution was concentrated by using a vacuum evaporator at 30—35 °C. The deposited KBr was removed by filtration and the filtrate was evaporated almost to dryness. The purplish-red complex was extracted from the residue with methanol and the solution was filtered. The crude complex was obtained by evaporation of the methanolic solution. Purification of the complex was carried out by adding acetone to a concentrated aqueous solution. The purplish-red powder (*trans*(O_0,O_γ) isomer) and crystals (*trans*(O_0,O_0) isomer) were obtained from the earlier and later eluted fractions, respectively, and yields were 0.20 g and 0.75 g.

Found: C, 20.85; H, 4.79; N, 11.88% for *trans*(O_0,O_γ) isomer and C, 20.76; H, 4.83; N, 12.02% for *trans*(O_0,O_0) isomer. Calcd for $C_{12}H_{32}N_6O_9Br_3Co$: C, 20.50; H, 4.60; N, 11.95%.

Trans(O_0,O_δ)- and trans(O_0,O_0)-[Co en_2(L-gluH_2)$_2$]Br_3. These isomers were obtained by a similar procedure to that for the L-aspartic acid complex except for use of 3.5 g of L-glutamic acid. In the case of L-glutamic acid, however, at the first stage three purplish-red bands were separated from the adsorbed band. All of the complexes eluted from these bands showed the absorption spectra pattern corresponding to the type *trans*(O)-[CoN_4O_2] complex,[9] but unfortunately no analytically pure complex was isolated from the first eluting band. The purplish-red powder (*trans*(O_0,O_δ) isomer) and crystals (*trans*(O_0,O_0) isomer) were obtained from the second and third eluted fractions by the same way as used for the L-aspartic complex, respectively, and yields were 0.15 g and 0.50 g.

Found: C, 23.82; H, 4.80; N, 12.10% for *trans*(O_0,O_δ) isomer, and C, 23.36; H, 4.59; N, 11.50% for *trans*(O_0,O_0) isomer. Calcd for $C_{14}H_{34}N_6O_8Br_3Co$: C, 23.57; H, 4.81; N, 11.79%.

[Co(NH_3)$_5$(L-glnH)]$Br_3\cdot H_2O$. This complex was prepared by modification of the method described in previous paper.[9,10] To an aqueous solution containing 4.8 g (0.01 mol) of [Co$(NH_3)_5(OH_2)$]$(ClO_4)_3\cdot H_2O$ in 50 ml of water was added 2.0 g (excess) of L-glutamine, and the mixture was gradually evaporated to 10 ml on a water-bath at 55—60 °C. The resulting solution was filtered and the filtrate was diluted to 100 ml with water and poured into a short column ($\phi 7\times 5$ cm) containing SP-Sephadex cation-exchanger (C-25, Na-form). The orange eluting solution obtained by elution with 0.03—1.0 M aqueous solution of KBr was evaporated by using a vacuum evaporator. The deposited KBr was removed by filtration and the filtrate was evaporated again. The crude complex obtained was recrystallized from an aqueous solution by adding methanol. The orange complex deposited as plate crystals was filtered and washed with 90% methanol, 99% methanol and then ether, and dried in air.

Found: C, 10.86; H, 5.17; N, 18.22%. Calcd for $C_5H_{27}N_7O_4Br_3Co$: C, 10.95; H, 4.98; N, 17.89%.

[Co(NH_3)$_5$(L-asnH)](ClO$_4$)$_3$.[11] This complex was obtained as orange needle crystals by the same method as for the L-glutamine complex.

(+)$_D$-[Co(L-asp)en_2]$ClO_4\cdot 2H_2O$, (+)$_D$-[en_2Co(L-asp)Co(NH_3)$_5$](ClO$_4$)$_4\cdot H_2O$, (+)$_D$-[en_2Co{(L-asp)Co en_2}$_2$](ClO$_4$)$_5\cdot 5H_2O$, (+)$_D$-[Co(L-glu)en_2]ClO_4, (+)$_D$-[en_2Co(L-glu)Co(OH_2)en_2](ClO$_4$)$_4\cdot 2H_2O$, and (+)$_D$-[en_2Co{(L-glu)Co en_2}$_2$](ClO$_4$)$_5\cdot 4H_2O$. Preparations of these complexes are described in

the previous study.[12]

Measurements. The absorption spectra were obtained by using a Hitachi Model EPS-3T spectrophotometer. The ^{13}C NMR spectra were recorded on a JEOL-MFT-100 spectrometer with JEC-6 spectrum computer in pulse Fourier transform/proton noise decoupled mode at 25.15 MHz and at room temperature. An internal D_2O rocking form was used for the measurements. Peak positions were measured relative to external benzene, and D_2O is used as solvent of the samples. Chemical shifts are reported relative to TMS using the relation $\delta_{TMS}=\delta_{benzene}-128.5$ ppm.[3] Experimental errors were ± 0.1 ppm. Some samples were converted to the chloride to obtain higher solubility in D_2O.

Results and Discussion

Structural Isomers of trans*(O)-[Co en$_2$(L-aspH$_2$ or L-gluH$_2$)$_2$]X$_3$ Complex.* L-Aspartic and L-glutamic acids have three functional groups, two carboxylates and one amino. Therefore, these amino acids will provide the complexes of three coordination types containing them as unidentate, bidentate,[13–17] and terdentate[18,19] ligands It is well known that a large number of amino acids form easily unidentate complexes in which the amino acids coordinate to cobalt(III) with only carboxylates.[9–11] However, the unidentate complexes containing L-aspartic and L-glutamic acids have not been isolated so far. In this study we attempted to prepare the type *trans*(O)-[Co en$_2$(L-aaH$_2$)$_2$]X$_3$ complex containing L-aspartic acid or L-glutamic acid as unidentate ligand. There are three structural isomers possible in this type complex, that is, *trans*(O$_\gamma$,O$_\gamma$), *trans*(O$_0$,O$_\gamma$) and *trans*-(O$_0$,O$_0$) isomers for L-aspartic acid complex, and *trans*-(O$_\delta$,O$_\delta$), *trans*(O$_0$,O$_\delta$) and *trans*(O$_0$,O$_0$) isomers for L-glutamic acid complex, as shown in Fig. 1. Indeed the existence of three structural isomers for the L-glutamic acid complex was confirmed on a column chromatogram. These isomers showed the absorption spectra corresponding to the typical *trans*(O)-[Co N_4O_2] complex[9] as shown in Fig. 2, but unfortunately it was unsuccessful to isolate the analytically pure complex from the earliest eluted fraction (perhaps *trans*(O$_\delta$,O$_\delta$) isomer) of three split bands because of its unstability in aqueous solution. On the other hand in the L-aspartic acid complex the bands corresponding to two structural isomers, *trans*(O$_0$,O$_\gamma$) and *trans*(O$_0$, O$_0$), were confirmed on a column chromatogram, but another one (*trans*(O$_\gamma$, O$_\gamma$) was not detected on it.

The structural assignment of each isomer will be mentioned in section of ^{13}C NMR spectra. The notations of all carbon atoms in L-aspartic and L-glutamic acids are shown below.

^{13}C NMR Spectra. The observed ^{13}C NMR shifts of L-aspartic and L-glutamic acids and of their cobalt(III) complexes are listed in Table 1, and their shift patterns are shown in Figs. 3 and 4. The resonance of carboxyl carbons, α-carbons and methylene carbons (C_β and C_γ) of the free and coordinated L-aspartic and L-glutamic acids, and ethylene carbons of ethylenediamine were observed in the ranges of 171.9—187.4, 49.8—58.1, 24.5—39.7, and 42.8—45.9 ppm, respectively.

As described in the previous paper[8] the carboxyl carbon resonances of various α-amino acids show upfield shifts in the range of 2.5—3.0 ppm in acidic solution, compared with those in neutral solution. Quite similar behaviors in ^{13}C chemical shift are also observed for two carboxyl carbons in L-aspartic and L-glutamic acids of the present study, as shown in Figs. 3 and 4. The changes in chemical shifts of these carboxyl groups can be related to the changes of their chemical environments. Horsley[20] and Quirt[21] have demonstrated from the pH titration studies for various amino acids that the carboxyl carbon resonance exhibits large shift with pH

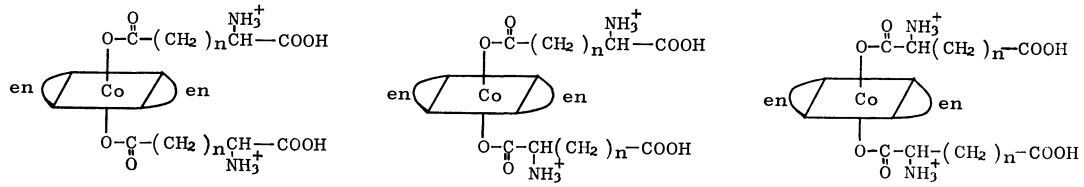

Fig. 1. The structures of three possible isomers in *trans*(O)-[Co en$_2$(L-aspH$_2$ or L-gluH$_2$)$_2$]X$_3$ complex.

change. Generally the protonation (acidic solution) and deprotonation (alkaline solution) of the amino acid provide upfield and downfield shift changes for the carboxyl carbon resonance, respectively. Such upfield shift changes also appear on protonations of uncoordinated carboxyl groups ($C_\gamma OO$ and $C_\delta OO$) in IV and XIV complexes. On the other hand the α-carboxyl carbons in chelated complexes (IV, V, XIV, and XV)

show downfield shifts, relative to those in unidentate complexes and free amino acids,[8] and their chemical shifts are almost constant within the range of 186.3—187.4 ppm. This constant shift can be applied to assignments of the chelated α-carboxyl carbons in the μ-L-aspartato (VI and VII) and μ-L-glutamato (XVI and XVII) complexes.

The structural assignments of two newly obtained isomers for the type *trans*(O)-[Co en_2(L-aaH_2)$_2$]X_3 complex can be easily made from the shift patterns of the carboxyl carbons. These isomers show considerably different shifts patterns from each other, that is, the earlier eluted isomers (IX and XIX) exhibit double peaks for each of two carboxyl carbons (C_0 and C_γ for L-aspartic acid complex, and C_0 and C_δ for L-glutamic acid complex), α-methine, β- and γ-methylene carbons, while the later eluted isomers (X and XX) do single peak. On the other hand for four carbons of two chelated ethylenediamines in these isomers only one resonance peak was observed. This means that four carbons are equivalent in chemical environment, and suggests that two isomers are structural ones taking *trans*(O) structure.

The peaks at 178.7 ppm of IX and X correspond well to the peak at 179.1 ppm of the coordinated carboxyl C_0 in VIII where L-asparagine coordinates with α-carboxyl group as a unidentate ligand, while the peaks at 175.1 ppm of IX and X do to the peak at 174.9 ppm of carboxyl C_γ in the protonated L-aspartic acid (I). Therefore the former peak of 178.7 ppm can be assigned to the coordinated carboxyl carbon (C_0) and the latter one (175.1 ppm) to the uncoordinated and protonated carbon (C_γ). The peaks at 172.8 and 182.4 ppm of IX correspond to the peaks of the protonated α-carboxyl C_0 in I (171.9 ppm) and of the coordinated carboxyl C_γ in VI and VII (183.8 and 184.4 ppm), respectively. From these results it is concluded that one of two L-aspartic acids contained in IX coordinates to cobalt(III) with C_0OO group and the other with $C_\gamma OO$ group as a unidentate ligand, while those in X coordinate with C_0OO groups only.

The same discussion can be made about two structural isomers (XIX and XX) of the L-glutamic acid complex. The peak at 179.5 ppm of XIX and that at 179.7 ppm of XX may correspond to that at 179.5 ppm of the coordinated α-carboxyl C_0 in XVIII where L-glutamine coordinates to cobalt(III) as a unidentate ligand. The peak at 177.9 ppm of XIX and that at 178.0 ppm of XX correspond to the peak at 178.4 ppm of the protonated carboxyl C_δ in XI, and the peaks at 172.9 and 186.4 ppm of XIX to that at 172.5 ppm of the protonated α-carboxyl C_0 in XI and to those at 185.8 and 187.4 ppm of the coordinated carboxyl C_δ in XVI and XVII, respectively. Therefore, for two structural isomers (XIX and XX) of L-glutamic acid complex the structures of (B) and (C) shown in Fig. 1 can be assigned.

Preparation of the Co(III) Complexes with a Tridentate Hexaniobato and a Bi- or Tri-dentate Amino Carboxylato Ligand

Yutaka HOSOKAWA, Jinsai HIDAKA,* and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received June 7, 1975)

Twelve new Co(III) complexes containing a hexaniobate ion $Nb_6O_{19}^{8-}$ as a tridentate ligand were synthesized. The hexaniobato ligand coordinates facially, and the remaining three coordination sites are occupied by a tridentate amino carboxylato ligand or by a bidentate amino carboxylato ligand and NH_3 or H_2O. Two glycinato complexes, $[Co(Nb_6O_{19})(gly)(X)]^{6-}$ ($X=NH_3$ or H_2O), were optically resolved, and a L-valinato complex $[Co(Nb_6O_{19})(L\text{-val})(NH_3)]^{6-}$ was separated into two diastereomers. The structures of these complexes were determined from their visible and ultraviolet absorption, circular dichroism, and proton magnetic resonance spectra.

Several papers have appeared for the heteropoly-condenced compounds containing Co(III) ion, but only a few concerned to a hybrid type between ordinary metal complex and heteropoly oxoanion, such as $K_5[SiCoW_{11}O_{39}(NH_3)]\cdot 14H_2O$,[1] $(+)_{589}$-$Na_4[Co_4I_3O_{18}(OH_2)_4(L\text{-ala})]\cdot 8H_2O$,[2] and $Na_5[CoNb_6O_{19}(OH_2)(en)]\cdot 17H_2O$.[3] The last named compound was prepared by Flynn and Stucky in a reaction of *trans*-$[CoCl_2(en)_2]Cl$ with $Na_7HNb_6O_{19}\cdot 15H_2O$. They assumed that the hexaniobate ion $Nb_6O_{19}^{8-}$ coordinates to the central Co(III) ion through three niobium-bridging oxygen atoms and the remaining three coordination sites of Co(III) octahedron are occupied by ethylenediamine (en) and H_2O. This means that the hexaniobate ion is functioning as a bulky tridentate ligand. This kind of coordination was confirmed from an X-ray study on the crystal of $Na_{12}[Mn(Nb_6O_{19})_2]\cdot 15H_2O$.[4] The free ligand $Nb_6O_{19}^{8-}$ consists of six NbO_6 octahedra condenced by edge-sharing and has a m3m(O_h) point group symmetry as in Fig. 1.[5] The

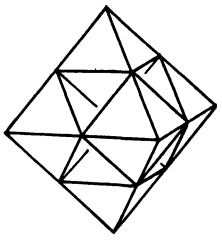

Fig. 1, Structure of $Nb_6O_{19}^{8-}$

present study is concerned with the preparation of new hexaniobato Co(III) complexes with some kinds of tridentate or bidentate ligands and with subsequent electronic absorption and circular dichroism (CD) investigations of the complexes. The tridentate ligands used are iminodiacetate(ida), L-aspartate(L-asp), L-methioninate(L-methio), and diethylenetriamine(dien), and the bidentate ligands glycinate (gly), L-valinate (L-val), and L-alaninate(L-ala).

Experimental

Preparation. *(1)* *$Na_5[Co(Nb_6O_{19})(dien)]$*: This complex was prepared by the similar method to that of $Na_5[Co(Nb_6O_{19})(OH_2)(en)]\cdot 17H_2O$.[3] Sodium hydrogenhexaniobate $Na_7HNb_6O_{19}\cdot 15H_2O$ (1.3 g; 1 mmol) and *mer*-$[CoCl_3(dien)]$ (0.27 g; 1 mmol) were dissolved in 40 cm³ of boiling water. After a 10 cm³ portion of 1 M NaOH had been added to the resulting violet-red solution, it was concentrated to about two-thirds of its original volume on a water bath. The concentrated solution was boiled for 1 hr. The solution was cooled to room temperature, filtered, and an appropriate amount of methanol was gradually added to the filtrate. After the filtrate had been kept in a refrigerator overnight, the purple product deposited was separated by a centrifuge, recrystallized from water by adding methanol and dried in a desiccator over $CaCl_2$. Found: C, 4.22; H, 1.90; N, 3.63%. Calcd for $Na_5[Co(Nb_6O_{19})(dien)]$: C, 4.22; H, 1.26; N, 3.69%.

(2) *$Li_7[Co(Nb_6O_{19})(L\text{-}asp)]\cdot 13H_2O$*, *$Li_7[Co(Nb_6O_{19})(L\text{-}asp)(OH_2)]\cdot 16H_2O$*, *$Li_7[Co(Nb_6O_{19})(L\text{-}asp)(NH_3)]\cdot 13H_2O$*: A solution of 2.7 g (10 mmol) of $K[Co(CO_3)_2(NH_3)_2]$ in 80 cm³ of water was added to a solution of 13.7 g (10 mmol) of $K_7HNb_6O_{19}\cdot 13H_2O$ in 200 cm³ of water, and to this mixture was added 0.6 g (10 mmol) of KOH. The color of solution changed from violet to blue green and then dark green. The pH was about 10.6. The solution was evaporated to about 50 cm³ and a small amount of light green precipitate resulted, which seemed to be a salt of unreacted $Nb_6O_{19}^{8-}$, was filtered off. After a little amount of methanol had been added to the filtrate, it was kept in a refrigerator overnight. The viscous dark green product deposited was dried on a vacuum desiccator, after the supernatant had been decanted. The crude product was crystallized from water by addition of ethanol. This complex, which seems to be $K_7[Co(Nb_6O_{19})(CO_3)(NH_3)]$, is very useful as a starting material for the syntheses of amino carboxylato complexes (2)—(5).

To a solution of 1.2 g of $K_7[Co(Nb_6O_{19})(CO_3)(NH_3)]$ in 80 cm³ of water was added a mixed solution of 0.12g (0.9 mmol) of L-aspartic acid and 0.1 g of KOH in 40 cm³ of water. The mixture was gradually evaporated almost to dryness on a water bath at about 70 °C. The resulting material was dissolved in a little amount of water and the solution was poured into a column (3 cm×60 cm) of strong base anion-exchanger (QAE Sephadex A-25, chloride form). The adsorbed band was eluted with 0.35 M LiCl solution at a rate of about 0.5 cm³/min. Three colored bands, blue one, blue green one and green one, were eluted in this order. The three eluates were separately concentrated to about 20 cm³ at 30 °C in a rotatory evaporator, and a large volume of ethanol was added to each of the concentrated solutions. After the solution had been kept in a refrigerator overnight, the product deposited was collected by a centrifuge and washed several times with ethanol and then acetone–water mixture. Each of the complexes was recrystallized from water by adding

* Present address: Department of Chemistry, The University of Tsukuba, Ibaraki 300-31

ethanol and washed repeatedly with ethanol and ether. Found for the blue complex: C, 3.69; H, 2.13; N, 2.21%. Calcd for $Li_7[Co(Nb_6O_{19})(L\text{-asp})(NH_3)]\cdot 13H_2O$: C, 3.76; H, 2.13; N, 2.19%. Found for the blue green complex: C, 3.53; H, 2.46; N, 1.19%. Calcd for $Li_7[Co(Nb_6O_{19})(L\text{-asp})]\cdot 13H_2O$: C, 3.60; H, 2.35; N, 1.05%. Found for the green complex: C, 3.35; H, 2.73; N, 1.07%. Calcd for $Li_7[Co(Nb_6O_{19})(L\text{-asp})(OH_2)]\cdot 16H_2O$: C, 3.41; H, 2.80; N, 0.99%.

(3) $Li_7[Co(Nb_6O_{19})(ida)]\cdot 14H_2O$: The same procedure to that of the L-aspartato complex (2) was adopted using iminodiacetic acid instead of L-aspartic acid. In this case, however, the reaction was carried out at 65 °C. The column chromatography showed only one green band. Found: C, 4.28; H, 2.39; N, 0.99%. Calcd for $Li_7[Co(Nb_6O_{19})(ida)]\cdot 14H_2O\cdot 1/2C_2H_5OH$: C, 4.29; H, 2.60; N, 0.99%.

(4) $Li_6[Co(Nb_6O_{19})(S.C\text{-}methio)]\cdot 8H_2O$: This complex was prepared by a similar method to (2). The column chromatography showed only a bluish-green band. Found: C, 4.75; H, 2.80; N, 1.20%. Calcd for $Li_6[Co(Nb_6O_{19})(L\text{-methio})]\text{-}8H_2O$: C, 4.72; H, 2.16; N, 1.10%.

(5) $Li_6[Co(Nb_6O_{19})(am)(OH_2)]\cdot nH_2O$ *and* $Li_6[Co(Nb_6O_{19})(am)(NH_3)]\cdot nH_2O$ *(am=amino carboxylate)*: The complex with glycinate, L-valinate or L-alaninate was prepared by the same method as that of L-aspartato complex described in (2). The reaction temperature was 65 °C. Each of the products separated on the column gradually into two colored bands, blue one and green one, when eluted with 0.30 M LiCl solution. In the case of L-valinato complex, however, the blue band further separated gradually into two bands F_1 and F_2 (denoted by the elution order), with the formation ratio $F_1/F_2=2$. Each of the complexes isolated was purified by the same method as that of the L-aspartato complex. Found for the blue glycinato complex: C, 2.13; H, 2.87; N, 2.18%. Calcd for $Li_6[Co(Nb_6O_{19})(gly)(NH_3)]\cdot 12H_2O\cdot 1/8C_2H_5OH$: C, 2.12; H, 2.53; N, 2.19%. Found for the green glycinato complex: C, 1.95; H, 2.18; N, 1.29%. Calcd for $Li_6[Co(Nb_6O_{19})(gly)(OH_2)]\cdot 10H_2O$: C, 1.95; H, 2.18; N, 1.13%. Found for the blue L-valinato complex (F_1): C, 4.69; H, 3.15; N, 2.05%. Calcd for $Li_6[Co(Nb_6O_{19})(L\text{-val})(NH_3)]\cdot 13H_2O$: C, 4.58; H, 2.98; N, 2.11%. Found: for the blue L-valinato complex (F_2): C, 7.31; H, 3.67; N, 1.82%. Calcd for $Li_6[Co(Nb_6O_{19})(L\text{-val})(NH_3)]\cdot 19H_2O\cdot 9/4C_2H_5OH$: C, 7.42; H, 3.84; N, 1.82%. Found for the green L-valinato complex: C, 4.51; H, 2.93; N, 1.09%. Calcd for $Li_6[Co(Nb_6O_{19})(L\text{-val})(OH_2)]\cdot 13H_2O$: C, 4.51; H, 2.89; N, 1.09%. Found for the blue L-alaninato complex: C, 2.74; H, 2.53; N, 2.24%. Calcd for $Li_6[Co(Nb_6O_{19})(L\text{-ala})(NH_3)]\cdot 11H_2O$: C, 2.84; H, 2.21; N, 2.47%. Found for the green L-alaninato complex: C, 2.83; H, 2.58; N, 1.16%. Calcd for $Li_6[Co(Nb_6O_{19})(L\text{-ala})(OH_2)]\cdot 10H_2O$: C, 2.88; H, 2.27; N, 1.16%.

(6) Resolution of $[Co(Nb_6O_{19})(gly)(X)]^{6-}$ *(X=*NH_3 *or* H_2O*)*: A solution of 0.12 g of $(+)_{589}$-$[Co(en)_3]Br_3$ in 500 cm^3 of water was gradually added with mechanical stirring to a solution of 0.35 g of $Li_6[Co(Nb_6O_{19})(gly)(NH_3)]\cdot 12H_2O$ in 1 dm^3 of water. The mixed solution was evaporated to about 300 cm^3 in air stream. The dark yellow-green diastereomer deposited was isolated by filtration and washed with water and then methanol several times. This sparingly soluble diastereomer was stirred mechanically in an aqueous solution containing cation-exchange resin (Dowex 50 W×8, Na^+ form). When the color of solution changed to blue, the solution was filtered to remove the resin, and the filtrate was concentrated to obtain the blue sodium salt, $\Delta\varepsilon_{546}=+0.61$, $\Delta\varepsilon_{589}=-0.028$.

The resolution of $[Co(Nb_6O_{19})(gly)(OH_2)]^{6-}$ was made by the same method; $(+)^{CD}_{546}$-$[Co(Nb_6O_{19})(gly)(OH_2)]^{6-}$ which was derived from the less soluble diastereomer has $\Delta\varepsilon_{546}=+0.061$ and $\Delta\varepsilon_{589}=-0.012$.

Measurements. Electronic absorption spectra of the complexes in the visible and near ultraviolet regions were measured by a Shimadzu UV-200 spectrophotometer in aqueous solutions. Circular dichroism spectra were recorded on a Jasco Model J-20 spectropolarimeter with a CD attachment. A Yanagimoto spectropolarimeter was used to check the optical rotations. The proton magnetic resonance spectra were measured in deuterium oxide with a Varian XL-100-15 NMR spectrophotometer, using *tert*-butyl alcohol (TBA) as an internal reference. The infrared spectra were obtained with a Hitachi EPI-001 infrared photometer with NaCl prisms using KBr disks. All measurements were made at room temperature.

Results and Discussion

The hexaniobato Co(III) complexes obtained are summarized in Table 1 with their d–d absorption data and the representative absorption curves are shown in Figs. 3 and 4. It is expected stereochemically that only one complex is possible for each of $[Co(Nb_6O_{19})(dien)]^{5-}$, $[Co(Nb_6O_{19})(ida)]^{7-}$, $[Co(Nb_6O_{19})(L\text{-asp})]^{7-}$, and $[Co(Nb_6O_{19})(L\text{-methio})]^{6-}$, and this was chromatographically confirmed. Two diastereomers (Fig. 2) are

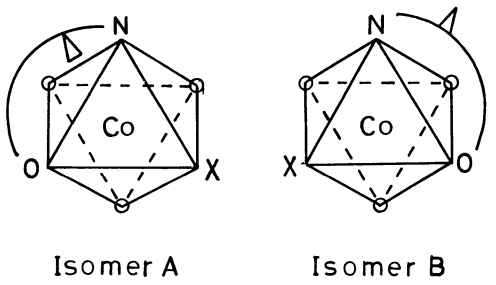

Fig. 2. Diastereomers of $[Co(Nb_6O_{19})(L\text{-am})X]^{6-}$: X= OH_2 or NH_3; N–O=L-ala or L-val. The circled three apices are occupied by $Nb_6O_{19}^{8-}$.

possible for $[Co(Nb_6O_{19})(L\text{-val})(NH_3)]^{6-}$ and this was also confirmed by the chromatographic separation of F_1(earlier eluted) and F_2 (later eluted) isomers. In addition, the corresponding glycinato complexes, $[Co(Nb_6O_{19})(gly)(NH_3)]^{6-}$ and $[Co(Nb_6O_{19})(gly)(OH_2)]^{6-}$, were resolved into their optical isomers. These facts support the Flynn and Stucky's inference for the structure of ethylenediamine complex $[Co(Nb_6O_{19})(OH_2)(en)]^{5-}$. Diastereomers are also expected for the other complexes with L-aminocarboxylate as a bidentate ligand, but the present chromatographic separation procedure was uneffective for the separation of the isomers. As is seen in Fig. 3 and Table 1, the first and second absorption bands of the complexes shift to shorter wave lengths reasonably in the order of complex type CoO_5N→*cis*-CoO_4N_2→*fac*-CoO_3N_3. The first absorption band of CoO_5N type complex shows a vague shoulder at lower energy of the absorption maximum and that of *cis*-CoO_4N_2 type at higher energy. These are in accordance with the facts that $(+)^{CD}_{546}$-$[Co(Nb_6O_{19})(gly)(OH_2)]^{6-}$ shows three CD components in the first absorption band region, and $(+)^{CD}_{546}$-$[Co(Nb_6O_{19})(gly)(NH_3)]^{6-}$ two CD components (Table 2 and Fig. 5). The *fac*-CoO_3N_3 type complex shows a sharp first

Table 1. Absorption data of the complexes

Type	Complex	σ_{max}[a] (log ε) I band	II band

fac-CoO_3N_3	$[Co(Nb_6O_{19})(dien)]^{5-}$	18.2 (1.80)	25.6 (1.80)
CoO_4NS	$[Co(Nb_6O_{19})(L\text{-methio})]^{6-}$	17.1 (2.06)	*ca.* 24 (shoulder)

a) In the unit of 10^3 cm^{-1}.

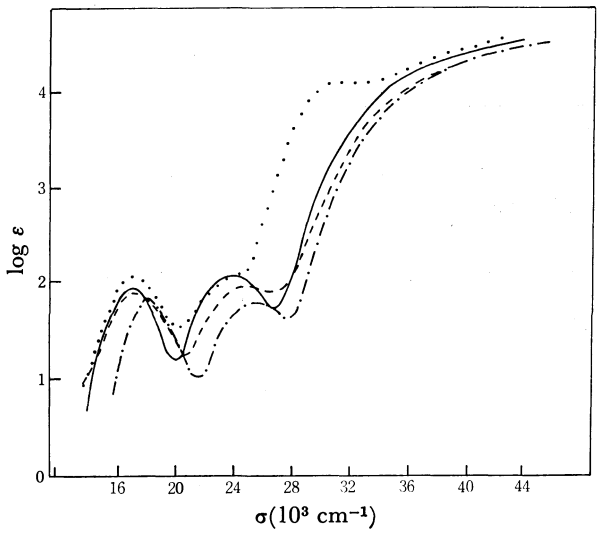

Fig. 3. Absorption spectra of $[Co(Nb_6O_{19})(ida)]^{7-}$ (——), $[Co(Nb_6O_{19})(gly)(NH_3)]^{6-}$ (----), $[Co(Nb_6O_{19})(dien)]^{5-}$ (-·-·-) and $[Co(Nb_6O_{19})(L\text{-methio})]^{6-}$ (·····).

absorption band. These spectral behaviors agree well with those which can be expected from the semi-empirical rule for d–d absorption bands.[6] The second absorption band of $[Co(Nb_6O_{19})(L\text{-methio})]^{6-}$ appears as a shoulder because of overlapping by the thioether charge transfer band,[7] which is located at 31300 cm^{-1} with log ε=4.07. For all the complexes studied, a strong absorption band due to the coordinated hexaniobate appears in a region of 38000—40000 cm^{-1}, and its position and intensity are independent of the pH change from 6.5 to 14, though a 41300 cm^{-1} band of the free $Nb_6O_{19}^{8-}$ ion depends strongly upon the pH. The two resembling complexes, $[Co(Nb_6O_{19})(L\text{-asp})]^{7-}$ and $[Co(Nb_6O_{19})(L\text{-asp})(OH_2)]^{7-}$, were distinguished from each other by the pmr spectra. The former complex shows an ABX pattern due to $-CHCH_2-$ protons of the tridentate L-aspartato ligand,[8] whereas the latter shows a more complicated pattern, which suggests the mixing of two ABX patterns resulted from the coexistene of two diastereomers.

The CD data of the present complexes are summarized in Table 2. The CD curve of $(+)^{CD}_{546}$-$[Co(Nb_6O_{19})(gly)(NH_3)]^{6-}$ obtained from the less soluble diastereomer with $(+)_{589}$-$[Co(en)_3]Br_3$ is shown in Fig. 5. As is seen in Fig. 4, the CD curves of two L-valinato isomers differ remarkably from that of $(+)^{CD}_{546}$-$[Co(Nb_6O_{19})(gly)(NH_3)]^{6-}$, and the difference may be attributed to the vicinal contribution due to the L-valinato ligand. When the additivity rule for the configurational and vicinal CD contributions is applied for the CD curves of L-valinato diastereomers,[9,10] the calculated configurational CD curve does not agree well with the observed CD curve of $(+)^{CD}_{546}$-$[Co(Nb_6O_{19})(gly)(NH_3)]^{6-}$ (Fig. 5). But the sign pattern suggests that the configuration of $(+)^{CD}_{546}$-$[Co(Nb_6O_{19})(gly)(NH_3)]^{6-}$ corresponds to

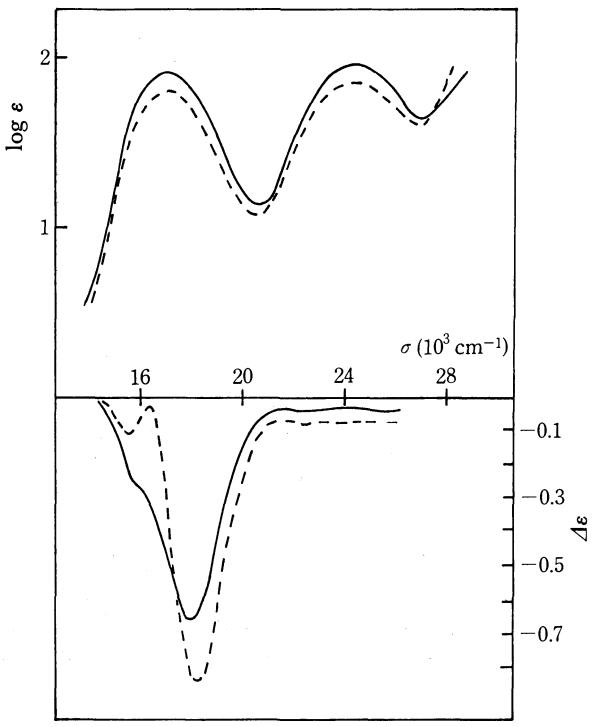

Fig. 4. Absorption and CD spectra of $[Co(Nb_6O_{19})(L\text{-val})(NH_3)]^{6-}$, F_1 (——) and F_2 (----).

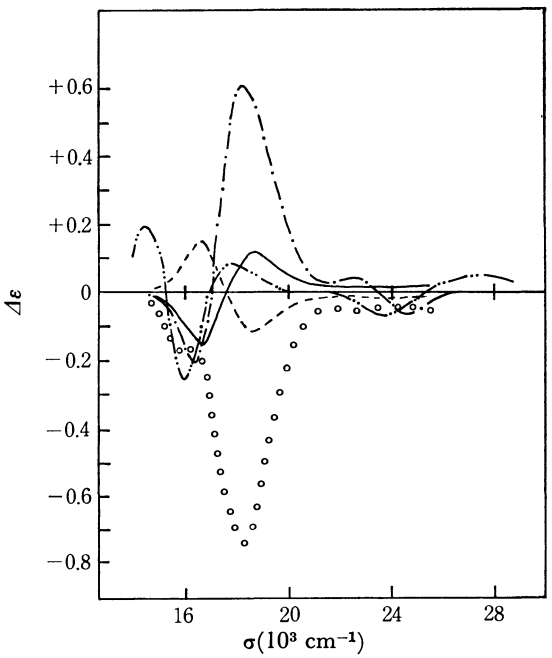

Fig. 5. Calculated configurational (F_1' ——, F_2' ----) and vicinal (oooo) CD curves of $[Co(Nb_6O_{19})(L\text{-val})(NH_3)]^{6-}$. Observed CD spectra of $(+)^{CD}_{546}$-$[Co(Nb_6O_{19})(gly)(NH_3)]^{6-}$ (-·-·-) and $(+)^{CD}_{546}$-$[Co(Nb_6O_{19})(gly)(OH_2)]^{6-}$ (-···-).

the L-valinato F_1 isomer. The formation ratio of F_1 to F_2 is about 2 as described in Experimental section. This fact suggests that the F_1 diastereomer is (A) in Fig. 2, since a less interaction is expected between the $-CH(CH_3)_2$ substituent and the coordinated hexaniobato ligand in the isomer (A) than in (B).

The configurational chirality in the present complexes is the same type as in the $[Co(am)NH_3(tame)]^{2+}$ complexes recently studied in this laboratory,[11] where the ligand tame is 1,1,1-tris(aminomethyl)ethane. In this $CoON_5$ type complexes the additivity of the configurational and vicinal CD contributions was reasonably well in contrast to the present hexaniobato complexes. The reason for such difference between the $CoON_5$ and the present CoO_4N_2 types still remaines unknown.

Studies of the Ruthenium Complexes. XI.[1] The Reaction Mechanism of the Base Hydrolysis of Halogenopentaammineruthenium(III) Complexes[2]

Akira OHYOSHI, Hiroyuki SAKAMOTO, Haruo MAKINO, and Keijiro HAMADA

Department of Industrial Chemistry, Faculty of Engineering, Kumamoto University, Kumamoto 860

(Received June 9, 1975)

The base hydrolysis of halogenopentaammineruthenium(III) complexes, $[RuX(NH_3)_5]X$, (X=Cl, Br, and I), has been studied in a solution with a 0.03—0.2 M hydroxide ion concentration in order to clarify the reaction mechanism. Some deviations from the first-order rate plots were observed early in the reaction. By the analysis of these results, it was proved that the concentration change with time for each species participating in the reaction was expressed by a linear combination of two exponential functions. The reaction can be well accounted for by a mechanism involving S_N2 CB and S_N2 processes:

$$[RuX(NH_3)_5]^{2+} + OH^- \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [RuX(NH_3)_4(NH_2)]^+ + H_2O$$

$$[RuX(NH_3)_4(NH_2)]^+ + OH^- \xrightarrow[H_2O]{k_2} [Ru(OH)(NH_3)_5]^{2+} + X^- + OH^-$$

$$[RuX(NH_3)_5]^{2+} + OH^- \xrightarrow{k_3} [Ru(OH)(NH_3)_5]^{2+} + X^-$$

The rate constants, k_1, k_{-1}, k_2, and k_3, at 15 °C were determined to be 9.29×10^{-2} M^{-1} s^{-1}, 2.65×10^{-2} s^{-1}, 6.78×10^{-1} M^{-1} s^{-1}, and 1.13×10^{-1} M^{-1} s^{-1} respectively for the chloropentaammine complex.

Among the several investigations[3-10] of the base hydrolysis of the metal-ammine complexes, Broomhead and his co-workers[9,10] have reported that the reaction of the halogenopentaammineruthenium(III) complex proceeds *via* the S_N1 conjugated-base (S_N1 CB) mechanism in a solution with a 3.78×10^{-4}—2.65×10^{-3} M hydroxide ion concentration. Certainly, this interpretation is reasonable. However, other mechanisms are possible considering the strong affinity of the ruthenium(III) ion for the oxygen atom. Thus, the base hydrolysis of halogenopentaammineruthenium(III) complexes, $[RuX(NH_3)_5]^{2+}$, X=Cl, Br, and I, has been studied at high concentrations of hydroxide ions (from 0.03 M to 0.2 M). On the basis of the experimental results, we assumed three types of elementary reactions for the mechanism and examined their validities by means of computer-simulation analysis.

Experimental

Preparation of Complexes. The complexes, $[RuX(NH_3)_5](ClO_4)_2$, were prepared by the method of the literature.[9] The complexes were confirmed by elemental analysis and by the visible and UV spectra. Found: H, 3.47; N, 16.32%. Calcd for $[RuCl(NH_3)_5](ClO_4)_2$: H, 3.60; N, 16.65%. Found: H, 3.40; N, 14.49%. Calcd for $[RuBr(NH_3)_5](ClO_4)_2$: H, 3.25; N, 15.06%. Found: H, 2.87; N, 13.58%. Calcd for $[RuI(NH_3)_5](ClO_4)_2$: H, 2.95; N, 13.68%.

Kinetic Run. The reaction solutions were adjusted to the ionic strength of 1.0 M and the hydroxide-ion concentration of 0.03—0.2 M with sodium hydroxide and sodium perchlorate. The reaction temperature was kept constant within ±0.1 °C by circulating water from a thermostated bath. A change in the concentration of $[RuX(NH_3)_5]^{2+}$ (or $[Ru(OH)(NH_3)_5]^{2+}$) as a function of time was followed by measuring the absorbance at λ_{max} of the spectra of the respective complexes, using a Hitachi 124 recording spectrophotometer.

Results and Discussion

The changes in the spectra during the base hydrolysis of bromopentaammine are shown in Fig. 1. The absorption band (398 nm) of the original complex rapidly decreases, with a slight shift to the low-wavelength region, and a new peak appears at about 300 nm. This peak grows with the shift to a constant wavelength (298 nm), a tendency which is in agreement with that of the hydroxo-complex.[9] Similar results were observed in the base hydrolysis of the other two complexes.

As is shown in Fig. 2, some deviations from the straight lines of the first-order plots are observed in the initial period of the reaction. This fact can be interpreted by assuming that the measured absorbance involves that of a short-lived intermediate in addition to that of the reactant. If the intermediate is an amido-

complex, which is a conjugated base of the reactant, it may be acceptable that the values of λ_{max} and the extinction coefficient of the intermediate are nearly equal to those of the reactant.

Thus, we assumed the following three types of elementary reactions:

Mechanism I (S_N1 CB):

$$[RuX(NH_3)_5]^{2+} + OH^- \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [RuX(NH_3)_4(NH_2)]^{+} + H_2O \quad (1)$$

$$[RuX(NH_3)_4(NH_2)]^{+} \xrightarrow{k_2} [Ru(NH_3)_4(NH_2)]^{2+} + X^- \quad (2)$$

$$[Ru(NH_3)_4(NH_2)]^{2+} + H_2O \xrightarrow{\text{fast}} [Ru(OH)(NH_3)_5]^{2+} \quad (3)$$

$$[A] = \{(\lambda_1-k_{-1}'-k_2)e^{-\lambda_1 t}-(\lambda_2-k_{-1}'-k_2)e^{-\lambda_2 t}\}[A]_0/(\lambda_1-\lambda_2) \quad (4)$$

$$[B] = (-e^{-\lambda_1 t}+e^{-\lambda_2 t})k_1'[A]_0/(\lambda_1-\lambda_2) \quad (5)$$

$$[A] + [B] = \{(\lambda_1-p)e^{-\lambda_1 t}-(\lambda_2-p)e^{-\lambda_2 t}\}[A]_0/(\lambda_1-\lambda_2) \quad (6)$$

where $[A] = [RuX(NH_3)_5]^{2+}$, $[B] = [RuX(NH_3)_4(NH_2)]^{+}$, $\lambda_1=(p+\sqrt{p^2-4q})/2$, $\lambda_2=(p-\sqrt{p^2-4q})/2$, $p=k_1'+k_{-1}'+k_2$, $q=k_1'k_2$, $k_1'=k_1[OH^-]$, and $k_{-1}'=k_{-1}[H_2O]$. The zero subscript indicates the initial concentration.

Mechanism II (CB and S_N2):

$$[RuX(NH_3)_5]^{2+} + OH^- \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [RuX(NH_3)_4(NH_2)]^{+} + H_2O \quad (7)$$

$$[RuX(NH_3)_5]^{2+} + OH^- \xrightarrow{k_2} [Ru(OH)(NH_3)_5]^{2+} + X^- \quad (8)$$

$$[A] = \{(\lambda_1-k_{-1}')e^{-\lambda_1 t}-(\lambda_2-k_{-1}')e^{-\lambda_2 t}\}[A]_0/(\lambda_1-\lambda_2) \quad (9)$$

$$[B] = (-e^{-\lambda_1 t}+e^{-\lambda_2 t})k_1'[A]_0/(\lambda_1-\lambda_2) \quad (10)$$

$$[A] + [B] = \{(\lambda_1-k_1'-k_{-1}')e^{-\lambda_1 t} - (\lambda_2-k_1'-k_{-1}')e^{-\lambda_2 t}\}[A]_0/(\lambda_1-\lambda_2) \quad (11)$$

where $p=k_1'+k_{-1}'+k_2'$, $q=k_{-1}'k_2'$, and $k_2'=k_2[OH^-]$. The other notations are the same as those for Mechanism I.

Mechanism III (S_N2 CB and S_N2):

$$[RuX(NH_3)_5]^{2+} + OH^- \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [RuX(NH_3)_4(NH_2)]^{+} + H_2O \quad (12)$$

$$[RuX(NH_3)_4(NH_2)]^{+} + OH^- \xrightarrow[H_2O]{k_2} [Ru(OH)(NH_3)_5]^{2+} + X^- + OH^- \quad (13)$$

$$[RuX(NH_3)_5]^{2+} + OH^- \xrightarrow{k_3} [Ru(OH)(NH_3)_5]^{2+} + X^- \quad (14)$$

$$[A] = \{(k_1'+k_3'-\lambda_2)e^{-\lambda_1 t}-(k_1'+k_3'-\lambda_1)e^{-\lambda_2 t}\}[A]_0/(\lambda-\lambda_2) \quad (15)$$

$$[B] = (-e^{-\lambda_1 t}+e^{-\lambda_2 t})k_1'[A]_0/(\lambda_1-\lambda_2) \quad (16)$$

$$[A] + [B] = \{(k_3'-\lambda_2)e^{-\lambda_1 t}-(k_3'-\lambda_1)e^{-\lambda_2 t}\}[A]_0/(\lambda_1-\lambda_2) \quad (17)$$

where $p=k_1'+k_{-1}'+k_2'+k_3'$, $q=k_1'k_2'+k_{-1}'k_3'+k_2'k_3'$, $k_2'=k_2[OH^-]$, and $k_3'=k_3[OH^-]$.

For all the mechanisms, [A]+[B] is expressed by Eq. 18:

$$[A] + [B] = C_1e^{-\lambda_1 t} + C_2e^{-\lambda_2 t} \quad (18)$$

Where C_1 and C_2 are the constants.

In the stationary-state period, the first term on the right-hand of Eq. 18 is nearly equal to zero. Therefore we can obtain the λ_2 value from the plots of ln{([A]+[B])} *vs.* the time. The values of λ_2 and λ_1 correspond to the respective slopes of the straight lines in Figs. 2 and 3. As $-\lambda_1$ and $-\lambda_2$ are roots of the quadratic equation, $\lambda_1+\lambda_2$ and $\lambda_1\cdot\lambda_2$ are equal to p and q respectively. Plots of $(\lambda_1+\lambda_2)$ (=p) and $\lambda_1\cdot\lambda_2$ (=q) *vs.* the concentration of hydroxide ions are shown in Fig. 4.

Let us examine the validity of the reaction mechanisms. For Mechanism I, k_1' has a linear dependence on the concentration of hydroxide ions, and the plot of p *vs.* the hydroxide-ion concentration should be a straight line, with an intercept corresponding to $(k_{-1}+$

k_2). Just as in the case of Mechanism I, a linear relationship can be expected to hold for Mechanisms II and III. Plots of q *vs.* the concentration of hydroxide ions should be straight lines for Mechanisms I and II, while a quadratic curve can be expected for Mechanism III; that is, the types of curves for Mechanisms II and III should be different. The former has the same double real roots, but the latter, two different real roots.

Judging from Fig. 4, the relation is not linear but quadratic, and the curve favors Mechanism III. Especially, if the reaction proceeds by means of Mechanism I, no irregularities should be allowed in the initial stage of the reaction.

k_{obsd}, $10^{-2}\cdot M^{-1}\cdot s^{-1}$	2.7 ±0.03 (3.0) 3.05±0.06 (6.0) 7.0 ±0.2 (10.0) 19.5 ±0.3 (15.0) 38 ±3 (19.0)	5.8×10^{18}	26	25	25

Now, let us estimate the rate constants based on Mechanism III. In Fig. 4, the slope and intercept of the straight line indicate $(k_1+k_2+k_3)$ and k_{-1} respectively. Since the variation in the concentration (=$\{[A]+[B]\}$) is almost linear in the initial stage of the reaction, as is shown in Fig. 5, the k_3 value can be obtained from the slope of the initial line. The values of k_1 and k_2 are calculated by the relation of p and q. Thus, all the rate constants were determined; they are given in Tables 1—3. It seems that the dissociation of hydrogen is very difficult in comparison with the hydrogen-exchange reaction of the hexaammineruthenium(III) complex.[10]

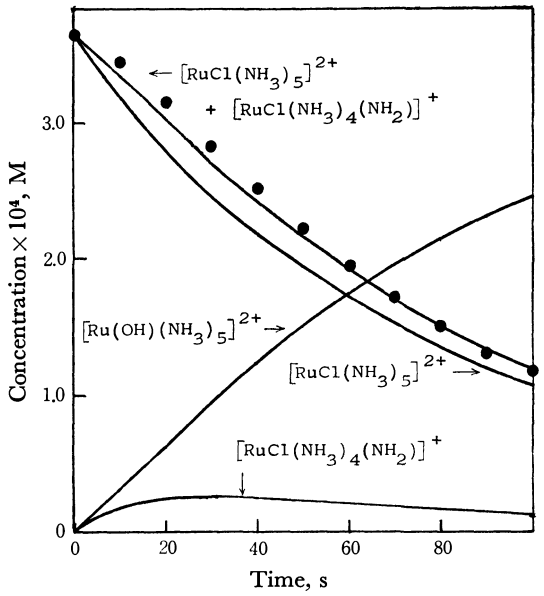

Fig. 6. Concentration variation of chemical species participating in the base hydrolysis of bromopentaammineruthenium(III).
$[RuBr(NH_3)_5]_0^{2+}=3.654\times10^{-4}$ M, $[OH^-]=0.11$ M, Temp.=10.0 °C, $\mu=1.0$ mol kg^{-1}, k_1, k_2, k_3, and k'_{-1} are 6.79×10^{-2} M^{-1} s^{-1}, 4.46×10^{-1} M^{-1} s^{-1}, 6.74×10^{-2} M^{-1} s^{-1} and 2.65×10^{-2} s^{-1} respectively.
● Experimental; —— Simulation.

Finally, we carried out a simulation analysis based on Eqs. 15—17 in order to check the validity of the estimated rate constants. The calculated results are shown in Figs. 5 and 6. The concentration of $[Ru(OH)(NH_3)_5]^{2+}$ was calculated by means of $([A]_0-[A]-[B])$. The curves showing the concentration change with the reaction time for the original and intermediate complexes obtained from the simulative calculation are in agreement with the experimental results.

As has already been pointed out[11] in connection with the influence of hydrogen peroxide on the reaction rate of the base hydrolysis of metal ammine complexes, the rate constant decreases upon the addition of hydrogen peroxide for the base hydrolysis with the S_N1 CB mechanism, while it increases for the reaction process of the S_N2 mechanism.

In the present experiment on the base hydrolysis, the rate constant in the solution of each 0.11 M hydroxide ion and hydrogen peroxide is about three times larger than that in the 0.11 M hydroxide ion solution. This fact indicates that the S_N2 mechanism favors the base hydrolysis reaction of halogenopentaammineruthenium(III).

The calculations were performed on a FACOM 230-25 computer at the Engineering Research Center of Kumamoto University.

The authors wish to thank the Ministry of Education for the financial support (No. 847009) granted to this research.

(Received July 21, 1975)

The kinetics of the thermal dehydration reactions of $MC_3H_2O_4 \cdot 2H_2O$(M=Mn(II), Fe(II), Co(II), Ni(II), and Zn(II)) were studied by the Freeman-Carroll and Coats-Redfern methods on the basis of the TG and DTG in nitrogen. The most reasonable reaction order for all the salts was found to be 2/3, indicating that the rate is controlled by the chemical process at a phase-boundary. This was also confirmed by the microscopic observations. The values of activation energy and frequency factor were 70—90 kJ mol^{-1} and 10^7—10^{10} s^{-1}, respectively. The enthalpy changes for all the salts were determined to be 60—80 kJ mol^{-1} by the DSC measurements. The X-ray powder diffractograms, infrared absorption and diffuse reflectance spectra of the hydrates and anhydrous salts were also examined to obtain informations on their crystal and bonding structures.

The thermal elimination reactions of the salts containing volatile ligands such as water, ammonia and pyridine have been extensively investigated both kinetically and calorimetrically in connection with the strengths of metal-volatile ligand bonds and with the structural changes caused by the eliminations.

Most metal dicarboxylates crystallize as hydrates. Oxalates of bivalent transition metals, in many cases, contain two water molecules, which were found by the X-ray analyses to be coordinated to the metals.[1] One of water molecules in copper succinate dihydrate was found by the X-ray analysis[2] to be coordinated to the metal and it was predicted that the water molecules in the succinates of other metals are also coordinated to the metals.[3] As for the malonates investigated in this study, each of them contains two water molecules, and some preliminary experiments indicate that both of them are coordinated to the metals, so that it may be possible to characterize their dehydration reactions by appropriate kinetic and calorimetric parameters related to the strength of metal–OH_2 bonds.

Several studies dealing with the thermal dehydration reactions of metal malonates have been reported in recent years: Yttrium and scandium malonate hydrates[4] lose all of their water almost continuously, while lanthanum,[4] europium[5] and uranyl[6] malonate hydrates lose water molecules into two steps. Sodium,[7] iron,[8] nickel,[9] cobalt[10] and barium[7] malonate hydrates lose their 1, 2, 2, 2, and 0.8 moles of water in one step, while potassium malonate hydrate[7] loses one mole of water at 323—363 K and another one mole at 423—463 K. Although thermal dehydration of copper malonate trihydrate or tetrahydrate has been investigated by several workers,[11] the results are divergent, since the dehydration is followed immediately by the decomposition of its anhydrous salt.

Experimental

Materials. To prepare each of the malonates investigated, the corresponding metal carbonate was dissolved into an aqueous solution of malonic acid (10% excess) at 343 K. Precipitation of the malonate crystals occurred immediately; after the solution was allowed to stand overnight at room temperature, the crystals were filtered, washed with water, ethanol and ether, dried in air, and sieved (Tyler mesh size: 170—200) before use. The results of the elemental analyses for C, H, and metal are given in Table 1.

Table 1. Analytical data for metal malonate dihydrates

M	C(%)		H(%)		Metal(%)	
	Found	Calcd[a]	Found	Calcd[a]	Found	Calcd[a]

Fe	18.81	18.58	3.19	3.12	28.70	28.46
Co	18.23	18.29	3.01	3.07	29.76	29.91
Ni	18.29	18.31	3.07	3.07	29.81	29.83
Zn	17.83	17.71	2.98	2.97	32.03	32.13

a) Calculated for $MC_3H_2O_4 \cdot 2H_2O$ (M=metal).

Measurements. The Mössbauer spectrum of the iron salt was measured with a constant acceleration spectrometer equipped with a 400 channel pulse-height analyzer (Elron, Oxford). The lines of the sample appeared at about 0.5 and 2.3 mm s^{-1}, offering the evidence for bivalent iron.

The crystal and bonding structures of the hydrates and anhydrous salts were examined by X-ray diffraction analysis and infrared and reflectance spectroscopy. The X-ray diffractograms were obtained with a Rigaku Denki diffractometer DS, using Cu$K\alpha$ or Fe$K\alpha$ radiations. The infrared measurements were made in a frequency region of 4000—250 cm^{-1} with a Hitachi 215 spectrophotometer by the KBr disk method. The diffuse reflectance spectra in the visible region were measured with a Hitachi EPS-3T spectrophotometer equipped with a standard integrating sphere attachment.

Non-isothermal kinetic measurements were made using a Shinku Riko TGD-3000 differential thermal microbalance. Samples of about 15 mg were heated at a scanning rate of 0.083 K s^{-1} (5 K min^{-1}) under nitrogen stream with a flow rate of 1 ml s^{-1}.

A Rigaku Denki DSC-8002 differential scanning calorimeter, calibrated by the heat of transition of KNO_3 (ΔH= 51.3 kJ mol^{-1} at 401 K), was used for the heat measurements. The details of experimental conditions were described previously.[12]

Kinetic Procedures. The values of reaction order (n) and activation energy (E_a) were found graphically using the Freeman-Carroll method[13]

$$\frac{-E_a \Delta\left(\frac{1}{T}\right)}{2.3R\,\Delta \log (W-W_c)} = -n + \frac{\Delta \log \frac{dW}{dt}}{\Delta \log (W-W_c)}$$

where W=sample weight at temperature T; W_c=sample weight at the completion of reaction; dW/dt=the rate of change in sample weight at temperature T. The values of $(W-W_c)$ and dW/dt were determined directly from TG and DTG curves, respectively, in terms of 15—20 divisions.

The frequency factor (A) was calculated using the basic relation:

$$\frac{d\alpha}{dt} = Ae^{-E_a/RT}(1-\alpha)^n$$

where α means the degree of reaction, $(W_0-W)/(W_0-W_c)$ (W_0=initial sample weight).

The values of E_a and n obtained using the Freeman-Carroll method were checked by the Coats-Redfern method[14] which allows a good linearization if the correct n value is assumed:

$$\log\left[\frac{1-(1-\alpha)^{1-n}}{T^2(1-n)}\right] = \log\frac{AR}{\phi E_a}\left[1-\frac{2RT}{E_a}\right] - \frac{E_a}{2.3RT}$$

where ϕ means heating rate.

Results and Discussion

Dihydrates. Recently, the diffraction and crystallographic data of several malonates have been reported;[8,10,15] according to them, the crystals of manganese and iron malonate dihydrates belong to the orthorhombic system, and those of cobalt, nickel and zinc to the monoclinic system. The authors have also obtained the X-ray diffractograms of all these salts, together with their infrared absorption spectra given in Fig. 1. The salts of the same crystal system give similar spectra, whereas there are apparant differences between the spectral pattern of the salts of the orthorhombic system and that of the salts of the monoclinic system. Most of absorptions can be assigned easily by applying the bands assignments made successfully with sodium malonate,[16] but two absorptions in the region of 900—850 cm^{-1}, observed only with the salts of Co, Ni and Zn (monoclinic system), could not be assigned. Sodium malonate, malonic acid and di- or tri-malonato complexes do not show any absorption in this region.[16] Some particular bonding manner may exist in these salts.

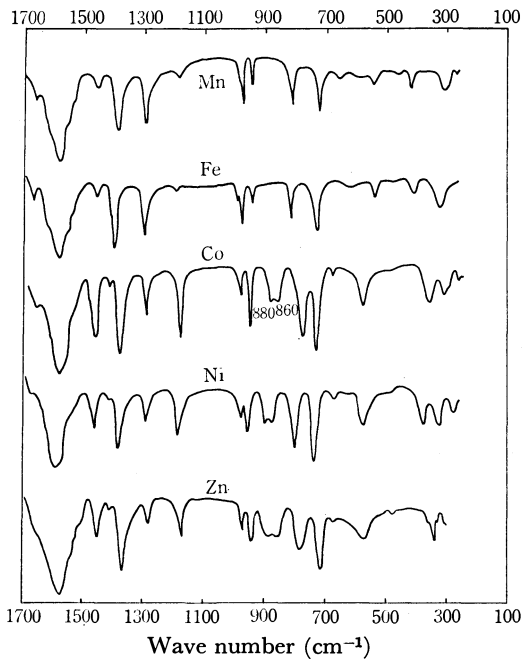

Fig. 1. Infrared absorption spectra of metal malonate dihydrates.

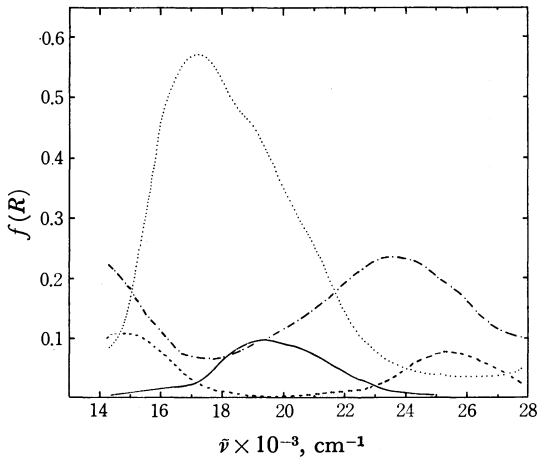

Fig. 2. Reflectance spectra of malonate dihydrates and anhydrous malonates. ——: $CoC_3H_2O_4\cdot 2H_2O$, ……: $CoC_3H_2O_4$, ----: $NiC_3H_2O_4\cdot 2H_2O$, -·-·-: $NiC_3H_2O_4$.

The diffuse reflectance spectra of the cobalt and nickel salts in Fig. 2 indicate that each metal is surrounded octahedrally by six oxygen atoms.[17] Since a malonate ion has four oxygen atoms, two water molecules of $MC_3H_2O_4\cdot 2H_2O$ (M=Co and Ni) seem to be coordinated to the metals.

Dehydration Reactions. The TG, DTA, DTG, and DSC curves were obtained in a nitrogen atmosphere for all the salts investigated. All the curves corresponding to the dehydration were smooth so that the dehydration reactions seems to take place in one step. The initial weight-loss temperatures (T_i), weight-loss values (W_0-W_c) and peak temperatures of DTG (T_m) are given in Table 2. The weight-loss data confirm the formura $MC_3H_2O_4\cdot 2H_2O$. Both T_i and T_m vary considerably with the metals and the variations are similar to those of metal oxalate dihydrates in which two water molecules are coordinated to the metals. Moreover, T_i, and T_m of the malonates are relatively higher than the ordinary values for the elimination of crystalline water. These facts support the view that

a) Freeman-Carroll method. b) Coats-Redfern method.

the water molecules in all the malonates are also coordinated.

The kinetic analyses of the traces of the TG and DTG curves lead to the plots shown in Fig. 3, yielding the values of activation energy and reaction order given in Table 3 (Freeman-Carroll method). For all the salts, a reaction order of 2/3 was found to fit best the experimental results, indicating that the dehydration begins on the surface of the crystals and propagates uniformly to their centers. Consequently it is probable that the overall reaction rate is controlled by the chemical process at the phase-boundary formed by the reactant and the product.

Figure 4 shows the microscopic photographs of partially dehydrated manganese malonate heated up to 434 K in nitrogen, indicating that the reaction proceeds from the outer surface of each particle inwards. The crystalline hydrate became finally amorphous on dehydration. As shown in Fig. 5, the change of the X-ray powder diffraction patterns for the manganese salt correspond well to the microscopic observations. Other anhydrous salts were also found to be amorphous to X-rays, supporting the former reports on iron[8] and cobalt[9] salts.

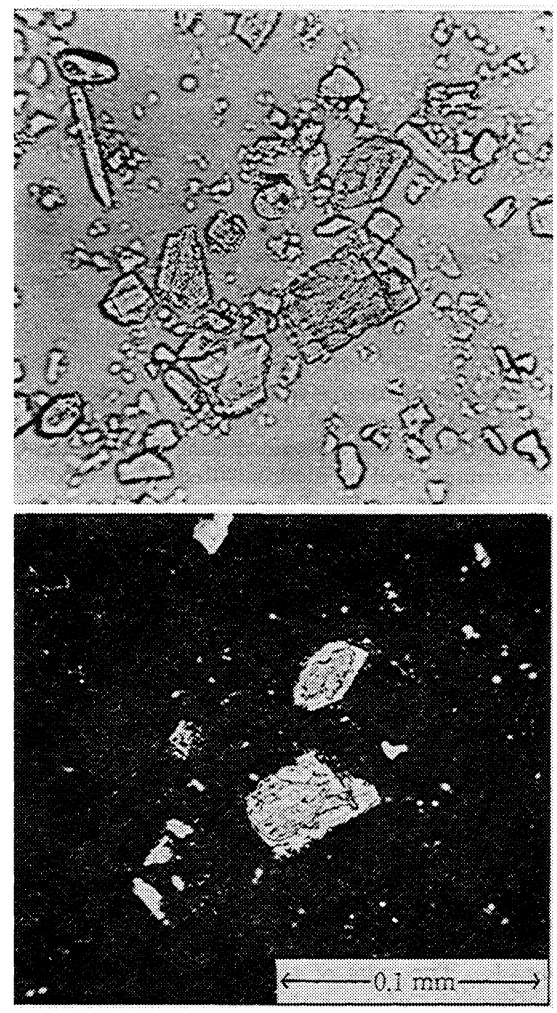

Fig. 4. Microscopic photographs of partially dehydrated manganese malonate; the lower one was taken between crossed polarizers.

When n is assumed to be 2/3, the plots by the Coats-Redfern method give good straight lines to yield E_a given in Table 3. The values agreed with those obtained by the Freeman-Carroll method, although the former values are somewhat lower. The bond strength of M–OH_2 is expected to be a function of the size of the metal ion if electrostatic attraction between it and the oxygen lone-pair is assumed, or to follow the well-known Irving-Williams order if ligand field effect is taken into consideration; but the variation of E_a in Table 3 with the metals are not as expected and the value for the manganese salt is apparently quite high. The bond strengths of M–OH_2 thus seem to be better reflected on T_i (or T_m) rather than on E_a.

The heat changes caused by the dehydration are given in Table 3. These values correspond to the average enthalpy changes per one mole of H_2O. Since the enthalpy changes obtained involve the amount corresponding to the change in the physical state of

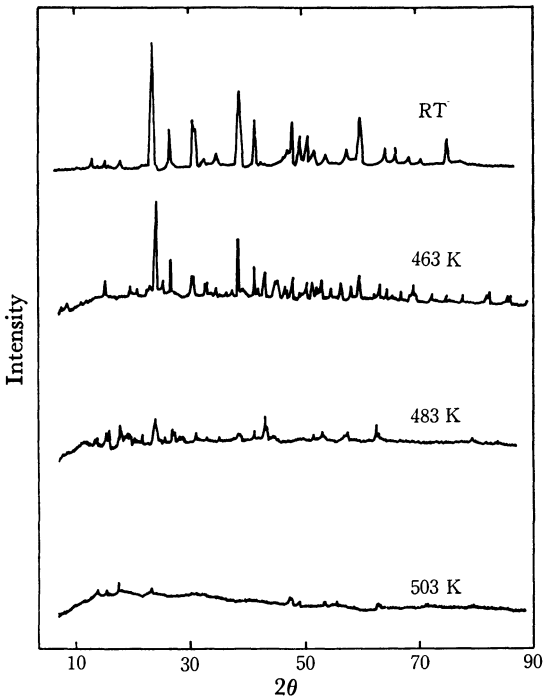

Fig. 5. X-Ray diffraction patterns of manganese malonate dihydrate and its dehydration products heated at various temperatures.

H_2O (ΔH_w), the net increases of enthalpy caused by dehydration may be 10—30 KJ mol^{-1} if ΔH_w is assumed to be in the vicinity of the heat of sublimation of ice (52 KJ mol^{-1}).

With a few exceptions, the ΔH of the malonates tends to increase with the increase of E_a, as shown in many elimination reactions. There are also remarkable differences in ΔH between the malonates and the oxalates.[18] The value for a malonate is always 10—20 KJ mol^{-1} larger than that for the corresponding oxalate. Since the values of T_i, which is seemingly a measure of the bond strengths of M–OH_2, are not so much different between the malonates and the oxalates, the differences in ΔH may be due to other factors. Other differences between these two carboxylates observed during dehydration are as follows: (1) all of the anhydrous malonates give broad infrared absorption bands, whereas anhydrous oxalates (as well as all the hydrates) give narrow bands; (2) the anhydrous malonates are poorer than the anhydrous oxalates in their crystallinity; (3) in the case of colored salts, the dehydration of the malonates are accompanied with more drastic color changes than that of the oxalates (*cf.* Table 4). These observations suggest that, compared with the anhydrous oxalates, the anhydrous malonates are composed of networks of more loosely linked polymers with higher potential energy.

Table 4. Color and spectral changes accompanying dehydration of malonate and oxalate dihydrates

Compound	Color	$\tilde{\nu}_{max}/cm^{-1}$
$Co(mal)\cdot 2H_2O$	pink→bluish violet	19400→17100
$Ni(mal)\cdot 2H_2O$	greenish blue→yellow	25400→23500
$Co(ox)\cdot 2H_2O$	pink→reddish violet	19200—20400→19900
$Ni(ox)\cdot 2H_2O$	blue→yellowish green	27100→25700

17) The fact that the Co^{2+} ion in anhydrous $CoC_3H_2O_4$ is 6-coordinated is, however, not quite certain, because bis(dipivaloylmethanato)cobalt(II), which is a tetrahedral CoO_4 type chelate, is known to show visible and near infrared spectra which are quite similar to those of the common octahedral chelates, although the band intensities in the former are considerably higher (F. A. Cotton, R. H. Soderberg, *Inorg. Chem.*, **3**, 1 (1964)). The same remarlk may be applicable to the spectrum of $K_2[Co(C_2O_4)_2]$ (K. Nagase, K. Sato, N. Tanaka, This Bulletin, **48**, 868 (1975)).

Adducts of Bis(hexafluoroacetylacetonato)metal(II) with Uni- and Bidentate Nitrogenous Bases

Fujio IZUMI,* Ryoko KUROSAWA, Hiroshi KAWAMOTO, and Hideo AKAIWA

**National Institute for Researches in Inorganic Materials, Sakura-mura, Niihari-gun, Ibaraki-ken 300-31*
Department of Chemistry, Faculty of Technology, Gunma University, Tenjin-cho, Kiryu-shi, Gunma-ken 376

(Received July 31, 1975)

Base adducts of the types: $M(hfa)_2(py)_2$, $M(hfa)_2phen$, and $M(hfa)_2bpy$ [M=Co(II), Ni(II), Cu(II), and Zn(II); Hhfa=hexafluoroacetylacetone; py=pyridine; phen=1,10-phenanthroline; bpy=2,2'-bipyridine] were prepared, and their infrared spectra were examined in detail. These adducts have a *cis*-octahedral configuration except for $Ni(hfa)_2(py)_2$. The metal-oxygen stretching frequencies of the adducts in the 405—370 cm^{-1} region decrease along the series: nickel(II)>cobalt(II)>copper(II)>zinc(II). Adduct formation leads to the marked weakening of Cu–O bonds in the copper(II) adducts, which is ascribable to the equatorial ligation of the neutral bases. The mass spectral studies of $M(hfa)_2phen$ and $M(hfa)_2bpy$ revealed that the addition of a neutral ligand affects the fragmentation of the complex remarkably. The exceptional behavior of $Cu(hfa)_2phen$ under electron impact is explained in terms of the tendency of copper(II) ion to undergo valency change.

Bis(β-diketonato)metal(II) complexes behave as Lewis acids and form five- or six-coordinate adducts with neutral donor molecules.[1] The stability of an adduct depends both on the basicity of a β-diketonate and on that of a neutral ligand. Introduction of an electron-withdrawing group such as CF_3- into β-diketone increases the affinity of a central metal ion for ligation.[2-6] For example, bis(trifluoroacetylacetonato)copper (II) and bis(hexafluoroacetylacetonato)copper(II) form isolable 1:2 adducts with pyridine,[2,5,7] whereas bis(acetylacetonato)copper(II) forms only an unstable 1:1 adduct that loses pyridine on exposure to air.[8] It is also known that the more basic a neutral ligand is, the more stable the resulting adduct tends to be.[9]

Most of the studies on base adducts have been concerned with the coordinatively saturated 1:2 ones containing unidentate ligands such as pyridine and its derivatives,[1] pyridine *N*-oxide,[10] aniline and its derivatives.[11] Single crystal X-ray studies revealed that these adducts are of *cis*- or *trans*-octahedral configuration. Bidentate neutral ligands also add to metal(II) β-diketonates to form *cis*-octahedral 1:1 adducts more stable than those of unidentate donors owing to the chelate effect.[12-14] Even bis(acetylacetonato)copper(II) was found to form a six-coordinate adduct with ethylenediamine, which is stable under dry conditions.[14] However, only copper(II) complexes have been referred to in these reports, and the structures as well as the properties of the adducts of other metal(II) β-diketonates should be investigated in some detail.

The present paper describes the mixed ligand complexes of the types: $M(hfa)_2(py)_2$, $M(hfa)_2phen$,[15] and $M(hfa)_2bpy$, where M=Co(II), Ni(II), Cu(II), and Zn(II); Hhfa=hexafluoroacetylacetone; py=pyridine; phen=1,10-phenanthroline; bpy=2,2'-bipyridine. The phen and bpy adducts are expected to be most stable because of both the presence of CF_3- groups and the chelate effect by the bidentate neutral ligands. Infrared spectroscopy was mainly used for estimation of the structures and the strength of metal-ligand bonds. Thus far few reports have been published on the infrared spectra of base adducts, while those of metal β-diketonate complexes have been studied extensively. The mass spectra of the phen and bpy adducts were also investigated in order to obtain information on the stabilities of the adducts against electron impact.

Experimental

Preparation of Complexes. $M(hfa)_2$[16]: A KOH solution was neutralized with Hhfa. This solution was mixed with a metal(II) acetate solution in a 2:1 molar ratio. The precipitate immediately formed was filtered, dried over P_2O_5, and recrystallized from methanol. $M(hfa)_2(py)_2$: $M(hfa)_2$ was dissolved in hot neat pyridine, and crystals formed on slow cooling were filtered and dried carefully. $M(hfa)_2phen$ and $M(hfa)_2bpy$: Methanol solutions of $M(hfa)_2$ and each nitrogenous base were mixed in a 1:1 molar ratio. After standing overnight, crystallized adduct was filtered and dried over P_2O_5. The analytical data for isolated complexes are given in Table 1.

Apparatus and Measurements. Infrared spectra were measured using a Hitachi EPI-G3 (4000—700 cm^{-1}) and a Nippon Bunko IR-F (700—200 cm^{-1}) infrared spectrophotometer. Samples were in the form of Nujol mulls between sodium chloride (4000—700 cm^{-1}) or KRS-5 (700—200 cm^{-1}) plates. X-Ray powder diffraction patterns were obtained using a Rigaku Denki 4051-5055 X-ray diffractometer with Cu$K\alpha$ radiation. Mass spectra were obtained on a Nihon Denshi JMS-07 mass spectrometer under the following conditions: ion source temperature 300 °C, ionization voltage 30 V, ion accelerating voltage 3 kV, ionization current 300 μA.

Results and Discussion

The infrared spectra of the adducts exhibited no band due to free carbonyl group or free nitrogenous base, which shows these complexes to be six-coordinate. Of course, the only reasonable structure for the phen or bpy adduct is *cis*-octahedral one, whereas either *cis* or *trans* isomer may be present in the case of the pyridine adduct.

Strong absorption bands due to the C–O stretching modes[1] were observedaround 1650 cm^{-1}. Published works have often referred to C–O stretching vibrations for the purpose of obtaining indirect information on the metal–oxygen bonds. However, it seems to us that no clear correlation exists between the perturbed C–O stretching vibration and the strength of M–O bond.[18,19]

a) Overlapped by the neighboring band.

Table 2 summarizes the metal-sensitive bands of the adducts in the far-infrared region. Above 700 cm^{-1}, almost all the bands observed are associated with vibrational modes of the ligands. The spectra in this region are very similar, and each band exhibited almost no sensitivity to a metal. Therefore, no further effort was devoted to examining the spectra above 700 cm^{-1}.

The pyridine ring vibrations located at 405 cm^{-1} (vibration 16b, out-of-plane ring deformation) and at 604 cm^{-1} (vibration 6a, in-plane ring deformation) in free pyridine are known to suffer marked shifts toward higher frequencies upon coordination to a metal.[20] In the pyridine adducts, the frequencies of the above bands showed the following order: cobalt(II)<nickel(II)<copper(II)>zinc(II). This is the same order as that reported in the literatures,[21,22] in which it is suggested that in a series of isostructural complexes, the frequencies of these two bands increase with a decrease in ionic radius of a metal. This conclusion is doubtful because the effective ionic radii of six-coordinate cobalt(II), nickel(II), copper(II), and zinc(II) ions are reported to be 0.73, 0.77, 0.81, and 0.83 Å, respectively.[23] Doublings of the 405 cm^{-1} band took place except for the case of the nickel(II) adduct, which is ascribed to the result of some interaction between different pyridine molecules.[22]

The assignments of phen and bpy vibrations in Table 2 are based on the work of Huchinson *et al.*[24] It is worth noting that the observed frequencies of the bidentate ligands vibrations showed the same order with the case of the pyridine ones. The frequencies of these vibrations may be reflection of some factors such as metal–nitrogen bond length, the strength of back-bonding, the polarizing power of metal ion.[21]

Metal-oxygen (M–O) stretching bands were assigned on the basis of the metal ion substitution technique applied extensively by Thornton *et al.*[25–27] It is generally recognized that in a series of isostructural complexes, substitution of a metal ion by another leads to a remarkable shift in a metal-ligand stretching frequency. The infrared spectra of the adducts showed five metal-sensitive bands in common in the 700—300 cm^{-1} region. These bands are considered to contain M–O stretching character to a varying degree bacause of the strong coupling between various vibrational modes. The bands observed at 405—370 cm^{-1} can be assigned to the least-coupled M–O stretching modes because they exhibit the maximum sensitivity to the metal ions. Since the transition metal(II) ions in the present study have similar masses, the variation in M–O stretching frequency may be considered to reflect the variation in the force constant of the M–O bond to a first approximation.

The M–O stretching frequencies of the adducts were found to decrease as follows: nickel(II)>cobalt(II)>copper(II)>zinc(II), which is inconsistent with the so-called Irving-Williams stability order: cobalt(II)<nickel(II)<copper(II)>zinc(II). The M–O stretching frequencies of metal(II) β-diketonates have been shown to follow this natural rule.[25,28] Hancock and Thornton[17] assigned the band at 427 cm^{-1} of $Cu(hfa)_2 \cdot H_2O$ to the copper-oxygen (Cu–O) stretching vibration, and the present study shows that M–O stretching frequencies of $Ni(hfa)_2$ and $Zn(hfa)_2$ are 404 and 385 cm^{-1}, respectively.

The above results revealed that adduct formation

causes a low-frequency shift of the M–O stretching band except for the case of $Ni(hfa)_2(py)_2$. The magnitudes of shifts were 11—13 cm^{-1} for nickel(II), zinc(II) complexes and about 50 cm^{-1} for copper(II), respectively. The shifts in the cobalt(II) complexes would be as large as those in the nickel(II) and zinc(II) complexes.[29]

These shifts can generally be explained in terms of the electrostatic repulsion between a neutral base and hfa. Anhydrous $M(hfa)_2$ are estimated to have a polynuclear octahedral geometry [M=Co(II), Ni(II), and Zn(II)] like acetylacetonate analogues of these metals.[1] A considerable "crowding" of donor ligands exists in the six-coordinate complex of a first-row transition metal(II). Thus, the coordination of more basic nitrogenous base in place of bridging oxygen atoms leads to the increased repulsion toward hfa, with the result that M–O distances are slightly lengthened. This interaction may be assumed to be caused by induced charges through the d orbital of the metal(II) ion.[7] Similar low-frequency shifts have been reported for bis-(nitrogenous base) adducts of nickel(II) acetylacetonate[11] and metal(II) thenoyltrifluoroacetonates.[29] The Lewis acidity of a metal(II) β-diketonate is enhanced by the introduction of an electron-withdrawing substituent to the β-diketone ligand. This fact may be ascribable to the reduction in the repulsion described above owing to a decrease in the electron density around the central metal(II) ion.

In the case of the copper(II) complexes, exceptionally large shifts of about 50 cm^{-1} were observed, which cannot be ascribed only to the repulsion effect. There are two possible interpretations for these results. One is that the coordination number of copper(II) changes from five in $Cu(hfa)_2 \cdot H_2O$ to six in the adducts. Increased coordination number generally causes a considerable low-frequency shift of metal-ligand stretching bands.[26] However, the shift as much as 50 cm^{-1} seems to be too large even if the change in coordination number is taken into consideration.

A more plausible explanation can be offered by considering a structure that has Jahn-Teller distortion arising from the d^9 electron configuration of copper(II) ion.[29] The *cis*-equatorial structure of $Cu(hfa)_2(py)_2$ and $Cu(hfa)_2$bpy has been established by single crystal X-ray studies.[7,12] In view of the fact that the Cu–O stretching bands of the three copper(II) adducts appeared at approximately the same frequency, $Cu(hfa)_2$-phen is thought to have a *cis*-equatorial structure as well (Fig. 1). The coordinating ability of phen is evidently higher than that of hfa which is the least basic in a series of β-diketonate ions.[30] The significant back-donation as well as the chelate effect will stabilize the bonds between copper(II) and phen. It is, therefore, reasonable to conclude that phen occupies the equatorial sites, forming a most stable chelate ring with copper(II) ion.

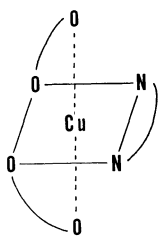

Fig. 1. The estimated structure of $Cu(hfa)_2$phen.

In each copper(II) adduct, one oxygen atom in hfa occupies the equatorial position. On the other hand, the other oxygen coordinates along the axial direction, which results in a longer and weaker Cu–O bond than the former. The observed Cu–O stretching bands of the adducts are considered to exhibit a character intermediate between the long and the short Cu–O bonds because of the vibrational coupling.[31] Consequently, the Cu–O stretching band of the copper(II) adduct appears at much lower frequency than that of $Cu(hfa)_2 \cdot H_2O$ in which the four equatorial sites are estimated to be occupied by hfa.

It should be noted that the nickel-oxygen (Ni–O) stretching band of $Ni(hfa)_2(py)_2$ showed a negligible low-frequency shift on adduct formation. This fact seems to exclude the possibility of $Ni(hfa)_2(py)_2$ having the *cis* arrangement of pyridine molecules because the Ni–O steretching bands of $Ni(hfa)_2$phen and $Ni(hfa)_2$-bpy, for which only a *cis*-octahedral structure is assumed. shifted toward the lower frequencies to the same extent as the other phen and bpy adducts. Single crystal X-ray studies[7] revealed that bis pyridine adducts of $Cu(hfa)_2$ and $Zn(hfa)_2$ are of *cis*-octahedral geometry, $Cu(hfa)_2(py)_2$: monoclinic, $P2_1/c$; $Zn(hfa)_2(py)_2$: monoclinic, C2/c. Figure 2 gives the X-ray powder patterns of the pyridine adducts. Since $Co(hfa)_2(py)_2$ was isomorphous with $Zn(hfa)_2(py)_2$, a *cis* structure is also implied. On the other hand, $Ni(hfa)_2(py)_2$ did not show any feature of isomorphism with the *cis* $Cu(hfa)_2$-$(py)_2$ and $Zn(hfa)_2(py)_2$ species. As Horrocks *et al.* suggested,[32] there is little energy difference between *cis* and *trans* forms of such adducts, and a *trans* isomer may well be present in the crystalline state. However,

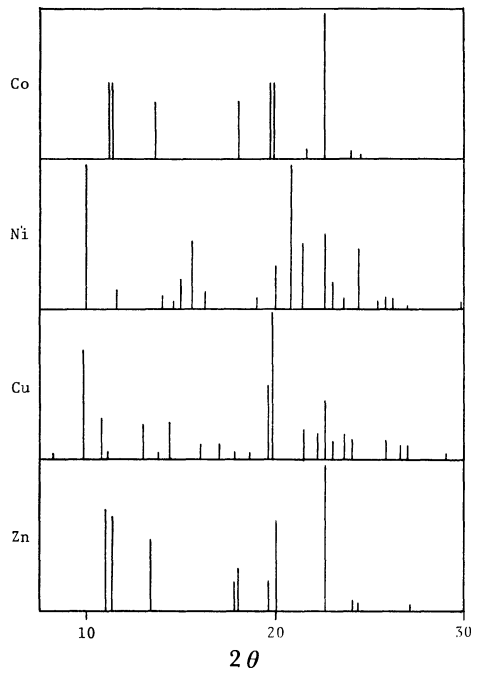

Fig. 2. X-ray powder patterns of $M(hfa)_2(py)_2$.

it is impossible at present to make a conclusive decision regarding a *trans* arrangement in $Ni(hfa)_2(py)_2$.

It has been established that the increased donor capacity of a nitrogenous base for a metal ion leads to a reduction in M–O stretching frequency.[11,29] However, the pyridine, phen, and bpy complexes showed no marked difference in M–O stretching frequencies. Incorporation of strongly electron-withdrawing CF_3-groups into β-diketone must result in weaker and longer M–O bonds. Thus, the interaction between hfa and a neutral ligand may be relatively weak, and the strength of M–O bonds is hardly affected by slight differences in the basicities of the three nitrogenous bases[33] (pK_a: py 5.22, phen 4.86, bpy 4.35).

The metal–nitrogen (M–N) stretching vibrations are expected to lie below 300 cm^{-1}. However, the assignment of metal pyridine stretching band has been subject to some confusion. In the infrared spectrum of $Ni(acac)_2(py)_2$ (Hacac=acetylacetone), the 249 cm^{-1} band was assigned to the nickel-nitrogen (Ni–N) stretching mode by Nakamoto *et al.*,[34] whereas Haigh *et al.*[11] indicated the absence of any band due to Ni–N stretching mode in the region above 200 cm^{-1}. To our knowledge, no reports have been published on the assignment of the M–N stretching vibration of six-coordinate mono phen or bpy complex. Therefore, we did not make any effort to assign the M–N stretching bands of the adducts although a few netal-sensitive bands were observed between 300 and 200 cm^{-1}.

The mass spectrometry of $M(hfa)_2$phen and $M(hfa)_2$bpy was investigated in order to examine the fragmentation of the adducts under electron impact. Though the mass spectra of metal β-diketonates have been studied extensively,[35–37] those of base adducts are still unknown. Table 3 lists the relative intensities of the main fragment peaks. The spectra in the *m/e* region greater than 500 where parent peaks might appear could not be measured because of the limitation of the apparatus used.

Table 3. Relative intensities of metal-containing ions in the mass spectra of $M(hfa)_2$phen and $M(hfa)_2$bpy L: hfa, B: phen or bpy

Ion	$M(hfa)_2$phen				$M(hfa)_2$bpy		
	Co	^{58}Ni	^{63}Cu	^{64}Zn	Co	^{58}Ni	^{64}Zn
LMB^+	100	100	100	100	100	100	74
$(L_2M-CF_3)^+$			37	45	8		100
$(L_2M-2CF_3)^+$			15				
$F\text{-}MB^+$	34	50		45	38	21	22
MB^+			78				
$(LM-CF_3)^+$			77				

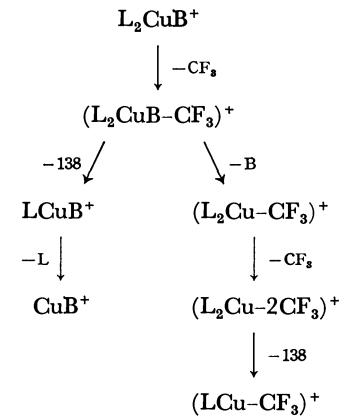
The previous study[38] on the thermal stability of the synergistic adducts of copper(II) β-diketonates has demonstrated that a unidentate pyridine base is readily released during thermal decomposition process. The thermal stability of phen or bpy adduct is expected to be enhanced far more exceedingly than that of pyridine adduct because of the chelate effect. In fact, no thermal decomposition of the adducts was observed during the mass spectral measurement except for the case of $Cu(hfa)_2$bpy.

It became evident that $Cu(hfa)_2$bpy decomposed into $Cu(hfa)_2$ and bpy prior to electron impact since the mass spectrum of $Cu(hfa)_2$bpy corresponded to just a superposition of that of $Cu(hfa)_2$ and bpy. The observed difference in the thermal stability between $Cu(hfa)_2$phen and $Cu(hfa)_2$bpy is mainly ascribable to the decreased rigidity of bpy molecule in comparison with that of phen. As the result of the above reaction, bpy molecule comes to rotate freely around the C–C bond between the two aromatic rings, which contributes positively to the entropy term of the free energy change in the decomposition reaction. A more reduced d_π–p_π interaction in the adduct of bpy having a shorter conjugated system may also play an important part.

(a) $M(hfa)_2$phen (M=Co and Ni) and $Ni(hfa)_2$bpy

$$L_2MB^+ \xrightarrow{-L} LMB^+ \xrightarrow{-188} F\text{-}MB^+$$

(b) $Cu(hfa)_2$phen



(c) $Zn(hfa)_2$phen and $M(hfa)_2$bpy (M=Co and Zn)

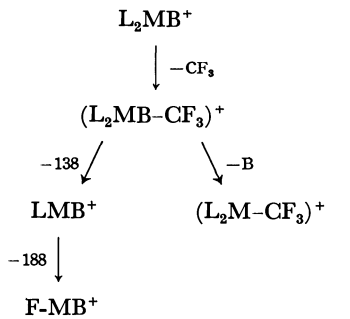


Chart 1. Mass fragmentations of $M(hfa)_2$phen and $M(hfa)_2$bpy.
L: hfa, B: phen or bpy

The fragmentation sequences assumed with regard to metalcontaining ions are shown in Chart 1. The fragmentation of L_2MB^+ to LMB^+ may occur *via* initial loss of CF_3 and subsequent loss of $CF_3COCHCO$ (mass 138). The nitrogenous beses in the group (a) adducts are bound more firmly to metal ions than those belonging to groups (b) and (c). In the latter complexes, the fragment ions containing no nitrogenous base, $(L_2M-CF_3)^+$ were detected. It is reported that

elimination of CF_2 occurs with migration of a fluorine atom to the metal in $Zn(hfa)_2$ and $Al(hfa)_3$.[36] The whole residual ligand $CF_3COCHCOCF_2$ (mass 188) was lost in the corresponding process of the phen and bpy adducts.

After loss of one hfa radical, $Cu(hfa)phen^+$ undergoes quite a unique fragmentation, *i.e.*, $Cu(hfa)phen^+ \longrightarrow Cu\text{-}phen^+ + \cdot hfa$. It is interesting to note that $Cu\text{-}phen^+$ formally involves Cu(I). Of the present four metals, only copper is relatively stable in the univalent state. A decrease in valency of a metal generally leads to increased covalent character of the metal-ligand bonds.[36] Thus, the copper-nitrogen bonds in $Cu\text{-}phen^+$ are fairly stabilized through the strong copper(I)-to-ligand back-donation.

An X-Ray Diffraction Study of the Structures of the Hexachloro- and Hexabromoplatinate(IV) Ions in Aqueous Solution

Masunobu MAEDA, Takeshi AKAISHI, and Hitoshi OHTAKI

Laboratory of Solution Chemistry, Tokyo Institute of Technology, O-okayama, Meguro, Tokyo 152

(Received August 6, 1975)

The structures of the $PtCl_6^{2-}$ and $PtBr_6^{2-}$ complexes in aqueous solution were determined by means of X-ray diffraction measurements of concentrated solutions of hexachloro- and hexabromoplatinic acids. Analysis of X-ray scattering data showed that the $PtCl_6^{2-}$ and $PtBr_6^{2-}$ complexes have a regular octahedral symmetry. The interatomic distances within the complexes are: Pt–Cl, 2.33 Å; *cis*-Cl–Cl, 3.30 Å; *trans*-Cl–Cl, 4.66 Å; Pt–Br, 2.47 Å; *cis*-Br–Br, 3.50 Å; *trans*-Br–Br, 4.94 Å. These distances are in good agreement with those reported in crystals of hexahalogenoplatinate(IV) compounds.

It is well known that platinum(IV) has a coordination number of six and forms stable hexahalogeno complexes with halide ions, which have an octahedral symmetry in the solid state.[1-3] Results from infrared and Raman spectroscopic measurements suggested that hexahalogenoplatinate(IV) complexes have a regular octahedral configuration in aqueous solutions.[4]

Vaughan *et al.*[5] carried out X-ray scattering measurements of solutions of hexachloro- and hexabromoplatinic acids, and they concluded that the observed data are in accord with the octahedral model of these complexes and that the platinum–halogen distances within the complexes are 2.39 Å for Pt–Cl and 2.43 Å for Pt–Br. The former is *ca.* 0.06 Å longer than that in crystals and the latter is shorter by 0.03 Å. Moreover, the peaks which corresponded to the *trans*–halogen–halogen distances were not seen in their radial distribution curves.

In a previous work,[6] we found that the $AuCl_4^-$ and $AuBr_4^-$ complexes have a square planar symmetry and the gold–halogen distances within the complexes are 2.29 Å for Au–Cl and 2.43 Å for Au–Br, which are very similar to those in crystals.

This paper describes X-ray scattering measurements on concentrated solutions of hexachloro- and hexabromoplatinic acids and compares the values of interatomic interactions within these complexes with the results reported by Vaughan *et al.* in aqueous solutions[5] and those in crystals.[1-3]

Experimental

Preparation and Analysis of Sample Solutions. Sample solutions of hexachloro- and hexabromoplatinic acids were prepared by dissolving metallic platinum of 99.99% purity in solutions of hydrochloric and hydrobromic acids, respectively, containing nitric acid and by removing the nitric acid by repeated evaporation with the corresponding hydrohalogenic acids.

The content of platinum in the sample solutions was determined gravimetrically both by reduction of platinum(IV) to metal with formic acid and by ignition of precipitates of ammonium hexahalogenoplatinate(IV) to platinum metal.[7] The results of analysis obtained by the two procedures agreed each other within the error of 0.2%. The chloride- and bromide-ion concentrations were determined gravimetrically as AgCl and AgBr, respectively, after reduction of the platinum(IV) with formic acid. The hydrogen-ion concentrations were calculated from the relation $[H^+]=[X^-]-4[Pt^{4+}]$.

The density of the solutions was determined with a pycnometer.

Table 1. Compositions of the solutions (in g-atom/l)

	Hexachloroplatinic acid solution	Hexabromoplatinic acid solution
Pt	2.882	2.739
Br	—	17.11
Cl	18.57	—
O	36.89	34.75
H	80.81	75.64

The compositions of the sample solutions are given in Table 1.

Measurements and Treatment of X-Ray Diffraction Intensities. X-Ray scattering measurements were carried out with an X-ray diffractometer (JEOL Co., Tokyo) in a room thermostated at 25±1 °C according to procedures described in previous papers.[8,9] Mo$K\alpha$ radiation ($\lambda=0.7107$ Å) was used for the irradiation of the sample solutions. The slit-openings were 1/12°, 1/4°, and 1° over the scattering angle ranges of 2° to 12°, 6° to 30°, and 12° to 140°, respectively. The scattered intensities were measured at discrete points between the scattering angle $2\theta=2°$ and 140°. The whole angle range was scanned twice in order to examine the reproducibility of the measured intensities. The intensities measured at the same angle usually agreed within 2%. The measured intensities $I(s)$, which were normalized to a common slit width, and then corrected for polarization in the solution and in the monochromator and scaled to electron units by means of the usual ways,[6,8,9] were used to calculate the reduced intensities $i(s)$ according to the following equation.

$$i(s) = I(s) - \sum_i n_i[(f_i(s)+\Delta f_i')^2 + (\Delta f_i'')^2 + \Phi(s)\cdot I_i^{\mathrm{inco}}(s)] \quad (1)$$

Here $s=4\pi\sin\theta/\lambda$, n_i represents the number of atom i, $f_i(s)$ the scattering factor of atom i at angle s, $\Delta f_i'$ and $\Delta f_i''$ the real and imaginary parts of the anomalous dispersion, respectively, $\Phi(s)$ the fraction of the incoherent radiation $I_i^{\mathrm{inco}}(s)$ reaching the counter.

All the calculations were referred to a stoichiometric volume of a solution containing one Pt atom.

The reduced intensities thus evaluated are shown in Fig. 1 in the form of $s\cdot i(s)$ *vs.* s.

The coherent and incoherent scattering factors for Pt were taken from Cromer and Waber[10] and from Cromer,[11] respectively. The values for anomalous dispersion of Pt were those given by Cromer and Lieberman,[12] which were corrected for the Breit-Dirac factors. The values for coherent, incoherent, and anomalous scatterings of other atoms were the same as those used in a previous paper.[6]

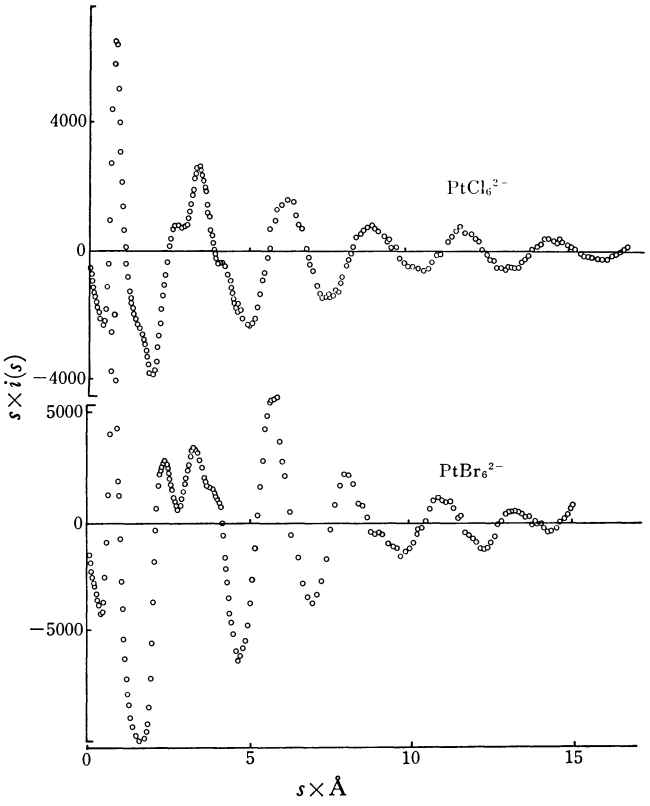

Fig. 1. Values $s\cdot i(s)$ for the chloride and bromide solutions as a function of s.

Results and Discussion

The radial distribution functions $D(r)$ were calculated from the reduced intensities $i(s)$ according to Eq. (2). The calculations were carried out with the aid of the computer program KURVLR.[13]

$$D(r) = 4\pi r^2\rho_0 + 2r\pi^{-1}\int_0^{s_{max}} s\cdot i(s)\cdot M(s)\cdot\sin(sr)ds \qquad (2)$$

Here ρ_0 denotes the average scattering density of the solution in electron units. The modification function $M(s)$ was chosen to be $(f_{Pt}^2(0)/f_{Pt}^2(s))\exp(-0.01\,s^2)$.

Spurious peaks below 1 Å in the distribution curves, which could not correspond to any interatomic distances, were used to correct the reduced intensities for low-frequency additions.

The radial distribution curves $D(r)$ for the two solutions thus calculated are shown in Fig. 2. Each distribution curve shows three peaks. The first dominant peak appeared at around 2.3 Å for the chloride solution and 2.5 Å for the bromide solution. These peaks can be identified as being due to Pt–Cl and Pt–Br distances within the complexes. The number of halide ions coordinated to a Pt(IV) ion was estimated to be about six both for the chloride and bromide solutions from the peak areas under the first peaks according to graphical procedures.[9] The second and third peaks appeared at around 3.3 Å ($\simeq$2.3 Å$\times\sqrt{2}$) and 4.6 Å ($\simeq$2.3 Å$\times$2) for the chloride solution, and at around 3.5 Å ($\simeq$2.5 Å$\times\sqrt{2}$) and 5 Å ($\simeq$2.5 Å$\times$2) for the bromide solution. These second and third peaks may be due to Cl–Cl and Br–Br contacts. The relation among the distances of

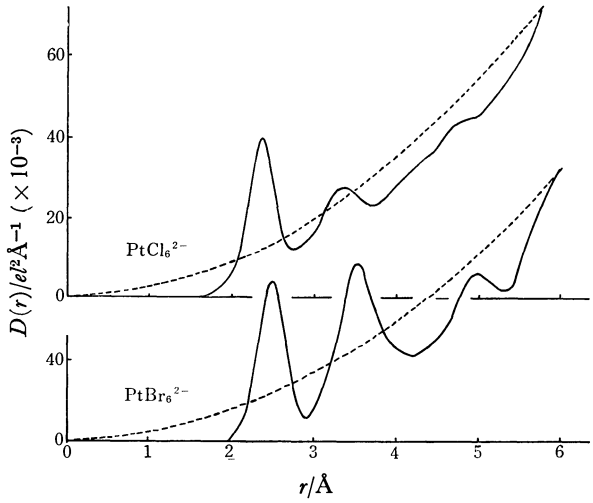

Fig. 2. Radial distribution curves for the chloride and bromide solutions. The brocken curves denote $4\pi r^2\rho_0$.

the three peaks in each $D(r)$ curve is that expected from a regular octahedral structure.

In order to refine the values for the structures of the complexes, analysis of the reduced intensity curve was carried out by means of a least squares method, in which a minimum was sought for the function $\sum s^2(i(s)-i_{calc}\cdot(s))^2$. Here, $i_{calc}(s)$ is the theoretical intensity due to interatomic interactions calculated from Eq. (3).

$$i_{calc}(s) = \sum_i\sum_j f_i(s)f_j(s)\frac{\sin(r_{ij}s)}{r_{ij}s}\exp(-b_{ij}s^2) \qquad (3)$$

where r_{ij} denotes the distance between two atoms i and j, $f_i(s)$ and $f_j(s)$ the scattering factor, and b_{ij} the temperature factor corresponding to the interaction between i and j atoms. For each interatomic interaction within the complexes the values of three parameters were refined: the distance r_{ij}, the temperature factor b_{ij}, and the frequency factor n_{ij}. For the refinement various subsets of the intensity data from different s ranges larger than 4 were used in order to detect errors in the refined parameters caused by a contribution to the intensity from the intermolecular interactions and experimental errors in the data. Two types of refinement (A and B) were carried out. In A type of refinement only the platinum–halogen bonds were included for $i_{calc}(s)$. The distance, the temperature factor, and the frequency factor were refined. In B type contacts for the platinum–halogen and the halogen–halogen at the *cis*-position were taken into account, and six parameters in all were changed simultaneously. The *trans*-halogen–halogen interactions were not included because of their small contributions to the intensities in the s ranges used for the calculations, as is seen from the theoretical intensities of interactions within the complexes in Fig. 3; the curves being calculated with the final parameter values in Table 3. Table 2 summarizes the results of the two types of refinement. As shown in Table 2 the number of the Pt–Cl and Pt–Br bonds per Pt atom does not differ from the value of 6 expected for the PtX_6^{2-} complex. The number of *cis*- Cl–Cl and Br–Br interactions (in B) was not definitely determined, but it is not so different from the expected value of 12 if the standard deviations are

(2) Comparison between observed $s \cdot i(s)$ values (circles) and calculated $s \cdot i(s)$ values (full line).

Table 2. Summary of the results of the least-squares refinements

	$PtCl_6^{2-}$	$PtBr_6^{2-}$
A	$r_{Pt-Cl}=2.332\,(5)$ Å	$r_{Pt-Br}=2.480\,(10)$ Å
	$b_{Pt-Cl}=0.0022\,(4)$ Å^2	$b_{Pt-Br}=0.0038\,(7)$ Å^2
	$n_{Pt-Cl}=6.0\,(4)$	$n_{Pt-Br}=6.1\,(4)$
B	$r_{Pt-Cl}=2.328\,(6)$ Å	$r_{Pt-Br}=2.474\,(7)$ Å
	$b_{Pt-Cl}=0.0015\,(4)$ Å^2	$b_{Pt-Br}=0.0033\,(5)$ Å^2
	$n_{Pt-Cl}=5.6\,(2)$	$n_{Pt-Br}=6.2\,(3)$
	$r_{cis\text{-}Cl\text{-}Cl}=3.30\,(4)$ Å	$r_{cis\text{-}Br\text{-}Br}=3.52\,(3)$ Å
	$b_{cis\text{-}Cl\text{-}Cl}=0.010\,(4)$ Å^2	$b_{cis\text{-}Br\text{-}Br}=0.0064\,(9)$ Å^2
	$n_{cis\text{-}Cl\text{-}Cl}=17\,(7)$	$n_{cis\text{-}Br\text{-}Br}=13\,(5)$

Numbers in the parentheses are least-squares standard deviations.

Table 3. Final parameter values for the hexachloro- and hexabromoplatinate (IV) ions

$PtCl_6^{2-}$	$PtBr_6^{2-}$
$r_{Pt-Cl}=2.33$ Å	$r_{Pt-Br}=2.47$ Å
$b_{Pt-Cl}=0.002$ Å^2	$b_{Ft-Br}=0.003$ Å^2
$n_{Pt-Cl}=6$	$n_{Pt-Br}=6$
$r_{cis\text{-}Cl\text{-}Cl}=3.30$ Å	$r_{cis\text{-}Br\text{-}Br}=3.49$ Å
$b_{cis\text{-}Cl\text{-}Cl}=0.010$ Å^2	$b_{cis\text{-}Br\text{-}Br}=0.006$ Å^2
$n_{cis\text{-}Cl\text{-}Cl}=12$	$n_{cis\text{-}Br\text{-}Br}=12$
$r_{trans\text{-}Cl\text{-}Cl}=4.66$ Å	$r_{trans\text{-}Br\text{-}Br}=4.94$ Å
$b_{trans\text{-}Cl\text{-}Cl}=0.015$ Å^2	$b_{trans\text{-}Br\text{-}Br}=0.015$ Å^2
$n_{trans\text{-}Cl\text{-}Cl}=3$	$n_{trans\text{-}Br\text{-}Br}=3$

taken into account. The ratio between the halogen–halogen and the platinum–halogen distances, which were refined independently in B, is about 1.42, which is close to the expected value of $\sqrt{2}$ for the regular octahedral configuration.

The final parameter values for the regular octahedral hexachloro- and hexabromoplatinate(IV) complexes are given in Table 3, in which the temperature factors for the halogen-halogen interactions at the *trans* position were roughly estimated from the corresponding peak shapes.

The intensities calculated by the use of the parameter values in Table 3 are compared with the observed ones in Fig. 3. It is seen that the agreement is satisfactory except at the low-angle part of the curves where the long range intermolecular interactions contribute significantly to the $s \cdot i(s)$ curves.

The theoretical peak shapes for intramolecular interactions were calculated by the use of the values in Table 3, and the peaks are compared with those of the radial distribution curves in Fig. 4. The residual curves obtained by subtraction of the calculated peaks from the radial distribution curves show two broad peaks at around 3.2 Å and 4.9 Å for the chloride solution and two distinct peaks at around 3.4 Å and 5 Å for the bromide solution. These peaks may be ascribed to the contacts between water molecules and halide ions unbonded and bonded to the platinum(IV) ions. In fact, the peak positions of 3.2 Å and 3.4 Å, respectively, are compatible with the distances of Cl–OH_2 and Br–OH_2 in the first hydration sphere so far reported.[14-15] The second peaks at 4.9 Å and 5 Å are in agreement with those found by

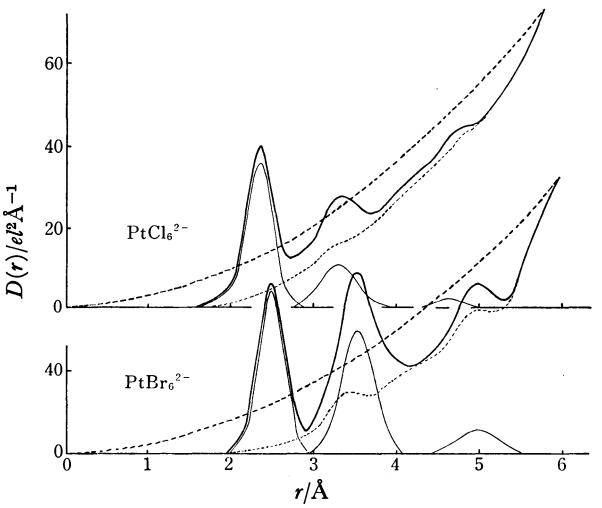

Fig. 4. Comparison between radial distribution curves and peak shapes calculated for the interactions within the PtX_6^{2-} ions using the parameter values given in Table 3. The difference between the distribution curve and the calculated peaks is shown by the dashed line.

Lawrence and Kruh in aqueous metal halide solutions.[14] They ascribed these peaks to the interactions of Cl–OH_2 and Br–OH_2 in the second hydration sphere. That the peaks for the chloride solutions are smaller than the corresponding ones for the bromide solutions is associated with the smaller scattering power of Cl than Br. No other marked peaks, which can be related to intramolecular interactions, are seen in the residual curves.

The Pt–Cl distance of 2.33 Å found in this work is shorter by 0.06 Å than that reported by Vaughan *et al.*[5] and is in good agreement with the average distance of 2.33 Å found in crystals of hexachloroplatinate (IV) compounds.[1,2] On the other hand, our Pt–Br distance of 2.47 Å is somewhat longer than that (2.43 Å) found by Vaughan *et al.* and our value agrees with the distance of 2.46 Å obtained in K_2PtBr_6 crystal.[3]

The work was supported by the Asahi Glass Foundation for the Contribution to Industrial Technology.

Photolysis of Methyl Benzenesulfonate in Methanol

Yasuji IZAWA and Naoki KUROMIYA

Department of Industrial Chemistry, Faculty of Engineering, Mie University, Tsu, Mie 514

(Received November 18, 1974)

The irradiation of methyl benzenesulfonate (**1**) in methanol undergoes a photolysis ($\Phi_{disapp}=0.07\pm0.005$) leading to benzene (5—34%), biphenyl (9—15%), and anisole (trace), in place of a photo-addition of methanol to give bicyclohexene derivatives. The rate of desulfonation of **1** is only slightly affected by triethylamine. Stern-Volmer quenching by piperylene occurs and the results suggest a significant singlet participation in this photolysis.

It has been reported that irradiation of benzene and alkylbenzenes in alcohols gives alkoxybicyclo[3.1.0]-hexenes by 1,3-addition of alcohols.[1-5] During the course of studies of the photochemical behavior of various monosubstituted benzenes, *e.g.*, anisole, *N,N*-dimethylaniline, benzoates, and phenylacetates, in protic solvents, it was discovered that, upon irradiation in methanol, methyl benzenesulfonate readily undergoes a photolysis to give benzene, biphenyl, and anisole, in place of a photo-addition of methanol; the results will be reported in this paper.

$$\underset{\mathbf{1}}{PhSO_3Me} \xrightarrow[MeOH]{h\nu} \begin{cases} -//\rightarrow \text{bicyclohexene derivatives} \\ \longrightarrow \underset{\mathbf{2}}{PhH} + \underset{\mathbf{3}}{Ph\text{-}Ph} + \underset{\mathbf{4}}{Ph\text{-}OMe} + \underset{\mathbf{5}}{\text{others}} \end{cases}$$

Although photochemical reactions beginning with an initial Ph-S bond cleavage have been reported for diaryl sulfone, sulfoxide, and sulfide in benzene,[6] little information is available on the photochemical reactions of benzenesulfonates.

Results and Discussion

A solution of **1** (1.7 g, 0.04 M) in methanol was irradiated with an unfiltered 300 W high pressure Hg lamp for 17 hr at about 10 °C, with N_2 gas being bubbled into the mixture during irradiation. After irradiation the photoproducts were separated by column chromatography on silica gel, giving colorless crystals (0.2 g), mp 69—70 °C, and other products (**5**) (44 mg) containing solid and polymeric materials. On the basis of mp and spectroscopic properties, the crystal was identified to be biphenyl (**3**). No bicyclohexene derivatives were detected in the other photoproducts. On the other hand, the formation of benzene and anisole was evident from glc on Carbowax 20 M of the reaction mixture. Thus, it has been shown that the benzene sulfonate (**1**) is photochemically desulfonated to give benzene, biphenyl, and anisole in methanol. Table 1 shows the relation between the yields of photoproducts and the initial concentration of **1**. As shown in Table 1, the relative yields of biphenyl to benzene decrease as the concentration of **1** is lowered. Furthermore, when a methanol solution of 0.7 mM of **1** was irradiated in a sealed quartz cell, after 30 min irradiation the spectrum of the solution became identical with that of benzene. That is, no biphenyl was detected in a dilute solution of **1**. These results suggest undoubtedly that benzene and biphenyl are derived from phenyl radicals produced by Ph-S bond cleavage. The quantum yield for disappearance of **1** was estimated to be 0.07 ± 0.005 at 254 nm at room temperature, using a ferrioxalate actinometer.

Table 1. PHOTOLYSIS OF METHYL BENZENESULFONATE (**1**) IN METHANOL USING 300W HIGH PRESSURE Hg LAMP

[**1**] M	Conv. (%)	Yield (%)[a]			Product ratio [**3**]/[**2**]
		2	**3**	**4**	
0.5	14	5.1	9.9	trace	1.9
0.1[b]	38	8.0	9.1	trace	1.1
0.2	30	21.9	15.3	trace	0.7
0.1	46	34.4	10.1	trace	0.3
0.05	43	24.0	12.0	trace	0.5

a) Determined by glpc after 20 hr, based on **1** consumed. b) 30W Low pressure Hg lamp.

Quenching by 1,3-pentadienes was carried out in order to obtain information about an excited state of **1**. The photolysis of **1** is quenched by 1,3-pentadienes to give a linear Stern-Volmer plot, whose slope ($k_q\tau$) is 18.6 M^{-1}. Assuming that the quenching is diffusion-controlled, the value of τ, the mean life time of an excited state of **1**, may be estimated. Hence, assuming again the bimolecular diffusion-controlled rate constant for neat methanol at 20 °C to be 1.06×10^{10} M^{-1} s^{-1} on the basis of the Debye expression, the value of τ is calculated to be 1.8×10^{-9} s. On the other hand, the fluorescence of **1** in methanol is quenched by 1,3-pentadienes[7] to give a linear Stern-Volmer plot, whose slope ($k_q\tau_f$, fluorescence quenching constant) is 14.0 M^{-1} at 30 °C. From the slope τ_f is estimated to be 1.1×10^{-9} s, which is in agreement with the value of τ. Thus, it seems that the photolysis proceeds *via* a singlet state rather than a triplet state of **1**.

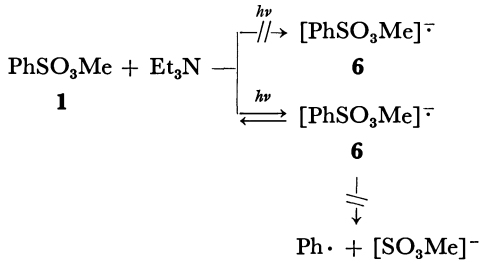
In order to examine whether the present desulfonation is induced by a photochemical electron transfer (ETR)[8] from methanol to **1**, the photolysis was carried out in the presence of triethylamine, which is an efficient electron domor.[9] If ETR takes place, the relative rates of disappearance of **1** would increase with addition of triethylamine. As shown in Table 2, however, the relative rates are about unity. These facts suggest that an electron transfer from amine to **1** to give a radical anion (**6**) does not occur and/or that the sulfonate group is less able to

Table 2. EFFECT OF NEt_3 ON THE PHOTO-DESULFONATION OF **1**

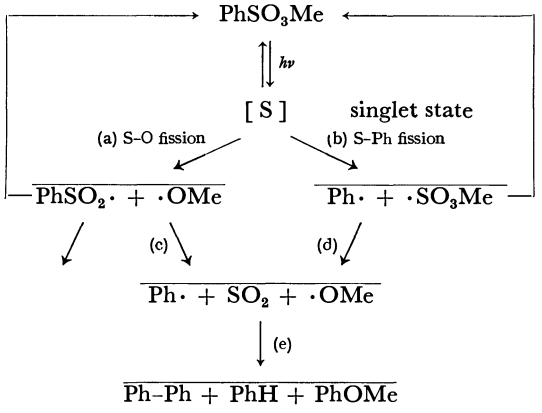
$[NEt_3]/[1]$ (Molar ratio)	0	0.5	1.0	2.0
Relative rate[a] (k/k_0)	1.00	1.00	0.98	1.07

a) Relative rates (k/k_0) of disappearance of **1** were determined by comparison with the rate (k_0) without triethylamine.

leave as an anion from **6**. This result implies that a similar ETR does not occur for methanol, since the I_p (10.85 eV[10]) of methanol is higher than that (7.50 eV[10a]) of the amine.



On the basis of these facts, the possible reaction pathways of photo-desulfonation of **1** to give benzene, biphenyl, and anisole can be postulated as follows:



Scheme 1.

Step (c), however, may be less probable, since a desulfonation of $PhSO_2\cdot$ radical to give Ph· radical may be significantly endothermic,[11] and it is known that two arylsulfonyl radicals react with each other to produce a sulfonic anhydride and thiosulfonate *via* a mixed sulfonic sulfinic anhydride.[12] Accordingly, the reaction pathway (b→d→e) beginning with the homolysis of Ph-S bond appears to play an important role in the photolysis of **1** leading to benzene, biphenyl, and anisole.

Experimental

The glpc analysis was carried out on a Yanagimoto GC-1800 apparatus equipped with hydrogen-flame detectors. The IR spectra were measured with a JASCO IR-G grating instrument and the UV spectra were recorded with a Shimadzu UV-200 spectrophotometer. The NMR data were obtained with a JEOL JNM MH-100 spectrometer. Monochromatic irradiation (254 nm) was performed with a monochrometer of the Hitachi MPF-2A type fluorescence spectrophotometer (150 W Xe lamp).

Materials. Methyl benzenesulfonate (**1**) was prepared from benzenesulfonyl chloride and methanol according to the known procedure,[13] bp 110—114 °C/1.5—3 mmHg, λ_{max}^{MeOH} (ε): 252.5 (390), 257.5 (680), 264.8 (980), and 272 (85) nm; δ (CCl_4): 3.70 (s, $-CH_3$) and 7.42—8.00 (m, -Ph); 1365 and 1189 cm^{-1} (liq. film, $-SO_2-$). Methanol was dried over Mg metal and distilled. Triethylamine was dried over Na metal and distilled. Silica gel Woelm containing an inorganic fluorescent indicator was used for column chromatography and silica gel PF_{254} containing $CaSO_4$ (Merk) was used for tlc. Piperylene (a mixture of isomers) of a g.r. grade supplied by the Nakarai Chemicals, Ltd. was distilled ,bp 41.8—42.0 °C. Other reagents were of the first grade commercial materials.

Preparative Scale Irradiation. The irradiation was carried out using an immersion type Halos 300W high pressure Hg lamp without filter. A solution of **1** (1.7 g) in methanol (250 ml) was placed in a reaction vessel, which was immersed in a water-bath, equipped with a N_2 gas inlet, thermometer, and a condensor. The solution was irradiated under N_2 at about 10 °C for 17 hr. After irradiation, the reaction mixture was carefully neutralized with aqueous sodium hydroxide solution and then evaporated under reduced pressure below 30 °C. Separation of photo-products was carried out by liquid chromatography with silica gel column (Nylon column, diameter: 3 cm, height: 35 cm), using a mixed solution of hexane and acetone (50: 1) as a eluent, to give **3** (0.2 g), brownish viscous liquid **5** (44 mg), and **1**. Furthermore, in order to detect the presence or absence of bicyclohexene derivatives, the viscous liquid (**5**) was then subjected to silica gel tlc using 50: 1 hexane-acetone solution as a developer. Three products were isolated and subjected to IR and NMR analyses. However, the existence of bicyclohexene derivatives could not be demonstrated.

Irradiation for Analtyical Purposes. The solutions (5 ml) of 0.05—0.5 M **1** in methanol were placed in 12-mm o.d. quartz tubes, and these were capped with polyethylene-stopples after flushing with N_2 gas at 0 °C for 5 min. A Halos 300 W high pressure Hg lamp with a water cooling quartz jacket was used without filter. The tubes and lamp were placed in a water-bath and irradiation was carried out at about 10 °C for 20 hr. After irradiation, the analysis of the reaction mixtures was done by means of glpc. The agreement of the retention times of the peaks with those of authentic samples established their identity. The conditions for glpc were as follows: 2 m×3 mm column of 13% Apiezon L on 60—80 mesh Diasolid L at 50 °C for benzene (**2**) and at 100 °C for anisole (**4**); 1 m×3 mm column of 5% PEG 20 M on 60—80 mesh Diasolid L at 130 °C for methyl benzenesulfonate (**1**) and biphenyl (**3**). The yields were estimated by glpc on the basis of **1** consumed.

Quantum Yield. These experiments were performed with 254 nm radiation from the monochrometer at room temperature and the quantum yields were determined by means of a liquid phase actinometer using potassium ferrioxalate. Cylindrical (ϕ=2 cm) fused-quartz cells with optically flat windows were used for the photolysis (path length 2 cm, 5 ml) and actinometer (path length 5 cm, 15 ml) cells. A solution of 0.4 mM **1** in methanol was placed in the photolysis cell; irradiation was started by opening a shutter and continued for 1 hr. The actinometer was photolyzed simultaneously. Photolysis was carried to 5% or less conversion and the number of molecules of consumed **1** in the cell was determined spectrophotometrically. The quantum yield was the average of the two analyses.

Effect of Added Triethylamine on the Photolysis. The solutions of 0.7 mM **1** and 0—1.4 mM triethylamine in methanol were flushed with N_2 gas at 0 °C for 5 min and sealed in 12 mm o.d. quartz tubes. The tubes were then irradiated on a merry-go-round apparatus using 30 W Halos low pressure Hg lamp without filter at room temperature for 10 min. The amount of consumed **1** in the tubes was determined spectrophotometrically. The relative rates (k/k_0) of disappearance of **1** were determined by comparison with the rate (k_0) without amine.

Quenching of Photolysis. The solutions of 7.1 mM **1** in

methanol with or without piperylenes were placed in closed 12 mm o.d. quartz tubes. The tubes were then irradiated on a merry-go-round apparatus using 300 W high pressure Hg lamp without filter at about 20 °C for 5 hr. Five concentrations (0.7—5.6 mM) of piperylenes, in addition to blanks containing no piperylenes, were used for the Stern-Volmer plot. The amount of consumed **1** in the tubes was determined spectrophotometrically.

Fluorescence Quenching of 1. A methanol solution of **1** showed a structureless fluorescence spectrum with a maximum at 289 nm. A stock solution of **1** in methanol (35.8 mM) was prepared and varying amounts of 1,3-pentadienes were added to aliquots of the stock; [dienes]=6.9—34.5 mM. Six solutions were used for the quenching experiment. The fluorescence spectra were recorded at room temperature (about 30 °C) and the relative intensities at 289 nm in the absence and presence of the dienes (I_0/I) were plotted with concentration of the dienes. A linear Stern-Volmer plot was obtained.

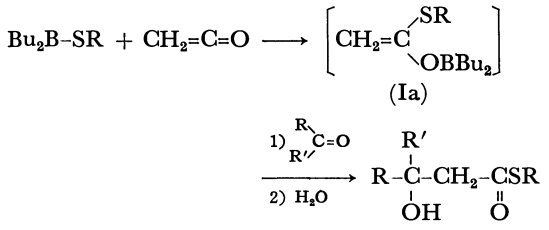
Reactions of Vinyloxyboranes with Carbonyl Compounds, Nitriles, and Formates[1]

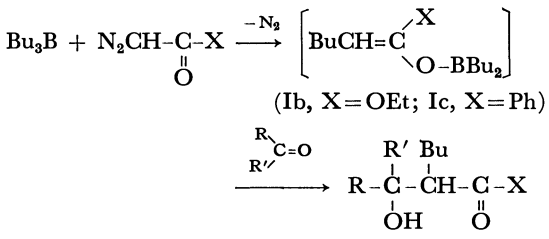
Masayoshi MURAKI,* Katsuhiko INOMATA, and Teruaki MUKAIYAMA
Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152
(Received February 25, 1975)

A new vinyloxyborane derivative, Id, was found to be formed in reaction of phenyl di-*n*-butylthioboronite (II) with methyl vinyl ketone. In order to explore its utilization in organic synthesis, the reactivity of Id and other known vinyloxyboranes was variously examined. Id and Ie gave β-hydroxyketones (IVa—c, Va—d) in fairly good yields when they were allowed to react with carbonyl compounds. The reaction of Ia′ and Ib with nitriles, followed by hydrolysis, afforded β-iminothioates (VIa—c) and β-ketoesters (VIIa—d) respectively. It was also found that the borane (Ib) reacted with formates or formamides at room temperature to give ethyl α-formylhexanoate.

In a previous paper,[2] it was reported that β-hydroxythioates are produced in high yields by the reaction[3] of thioboronites, ketene, and carbonyl compounds *via* the key intermediates, vinyloxyboranes (Ia). Similarly,

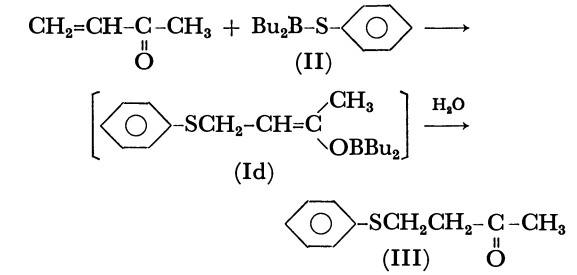


vinyloxyboranes[4] (Ib, Ic) prepared from tri-*n*-butylborane and ethyl diazoacetate or diazoacetophenone reacted with carbonyl compounds to afford β-hydroxyesters and β-hydroxyketones respectively.[1,3]



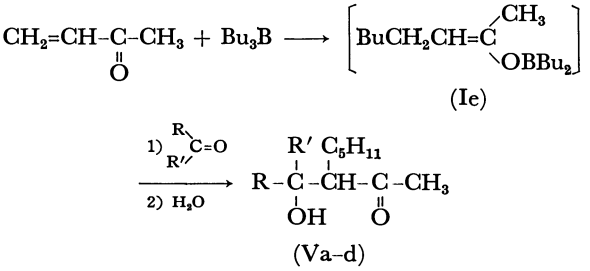
We have subsequently been studying the formation and reactivity of vinyloxyborane derivatives and now wish to report the formation of a new vinyloxyborane (Id), which was obtained from methyl vinyl ketone and thioboronite (II), and the reactivity of Id and Ie, which were prepared from tri-*n*-butylborane and methyl vinyl ketone,[5] with various carbonyl compounds. This paper will also describe the reactions of Ia′ and Ib with such electophiles as nitriles, acyl halides, and formates.

A new vinyloxyborane (Id) was formed by the reaction of methyl vinyl ketone with thioboronite according to the following procedure: an equimolar amount of *S*-phenyl di-*n*-butylthioboronite (II) was added to a solution of methyl vinyl ketone in CCl_4, and then the mixture was kept standing at room temperature for 30 min. The product was not isolated, but its structure was confirmed to be (1-methyl-3-phenylthio-1-propenyloxy)di-*n*-butylborane (Id) by PMR analysis. This assignment was also supported by the observation that the hydrolysis of Id in aqueous methanol afforded 4-phenylthiobuta-2-one (III) in an 86% yield. The reactivity of this intermediate (Id) to carbonyl compounds was then examined.



When Id was allowed to react with various carbonyl compounds in dry ether at room temperature, the corresponding β-hydroxy-α-(phenylthiomethyl)-ketones (IVa—c) were obtained in fairly good yields. The results are summarized in Table 1. This reaction proceeds in a mode similar to that with other vinyloxyboranes (Ia—c) described in a previous paper.[2]

Similarly, the vinyloxyborane (Ie), prepared from methyl vinyl ketone and tri-*n*-butylborane according to the method of Suzuki *et al.*,[5] was caused to react with carbonyl compounds to give β-hydroxy-α-*n*-pentyl ketones (Va—d) (Table 1). The reaction of Id, Id′, or Ie with aldehydes gave favorable results, whereas the yields of the products (IVc, Vc, d) were comparatively low when these boranes were treated with ketones.



(Va–d)

The addition of a solution of *S*-benzyl diazothioacetate in ether to tri-*n*-butylborane led to the liberation of the nitrogen. On the treatment of the resulting solution with a solution of benzaldehyde or propiophenone in ether, the corresponding α-butyl-β-hydroxyalkanethioates were obtained in 51% and 81% yields respectively. The structure of the intermediate was identified as If, in analogy with Ib:

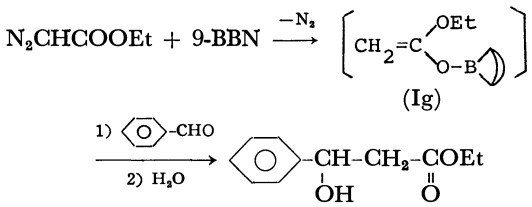
(If)

The reaction of ethyl diazoacetate, 9-borabicyclo-[3.3.1]nonane (9-BBN), and benzaldehyde were tried in order to know the migrating tendency of the substituents on the boron atom in 9-BBN.[6,7] Ethyl β-hydroxyhydrocinnamate was consequently obtained in a 43% yield by the same procedure as in the case of tri-n-butylborane. It was found that the preferential cleavage of the B–H bond in 9-BBN occurred to form the vinyloxyborane (Ig) as follows:



(Ig)

The experimental results in both the previous and

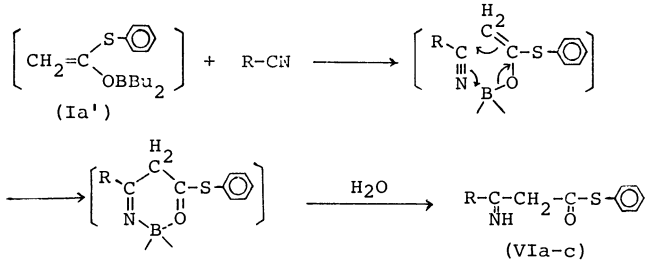
present papers show that vinyloxyboranes (Ia—h: R=H, alkyl, cyclohexyl, or thiomethyl; X=OR, SR, alkyl, or aryl) easily react with carbonyl compounds to afford the corresponding β-hydroxy- esters, thioates, or ketones in good yields. As an example, the reactions of these vinyloxyborane derivatives with benzaldehyde are listed in Table 2.

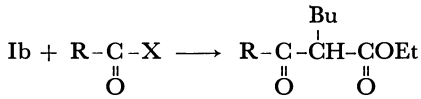
Next, the reaction of vinyloxyboranes with nitriles was attempted. When vinyloxyborane (Ia′; Ia, R=Ph), prepared from S-phenyl di-*n*-butylthioboronite (II) and ketene, was allowed to react with nitriles at room temperature for 1 day under argon, β-iminothioates (VIa—c) were obtained after hydrolysis (Table 3).



(Ia′) (VIa-c)

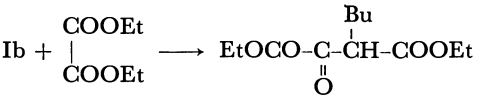
Similarly, Ib reacted with some nitriles to afford α-butyl-β-ketoesters in about 55—70% yields after hydrolysis, as is shown in Table 4.

Furthermore, the reactions of Ib with various carboxylic acid derivatives, such as acyl halides, esters, and amides, were examined. Benzoyl bromide and phenylacetyl chloride gave the corresponding β-ketoesters in 31% and 9% yields respectively when they were submitted to a reaction with Ib at room temperature under argon, followed by hydrolyses.



It was found that Ib hardly reacts at all with any esters or amides except for formic and oxalic acid derivatives. The borane (Ib) reacted with formic acid derivatives, such as ethyl or *p*-nitrophenyl formate and *N*,*N*-dimethylformamide, to afford ethyl α-formyl-*n*-hexanoate (Table 5). In general, such formyl compounds are prepared by the mixed Claisen condensation of esters and formate in the presence of strong bases. According to the present reaction, however, the formyl compounds are produced under almost neutral conditions.

Diethyl oxalate, which is often used in the mixed Claisen condensation, also reacted with Ib at room temperature to give ethyl α-ethoxalylhexanoate in a 46% yield.



There are two possible pathways for the reaction of vinyloxyborane with carboxylic acid derivatives: Path (a), similar to that of vinyloxyboranes with carbonyl compounds, and Path (b), accompanied by the initial fission of the C–OR′ or C–NR'_2 bond of formate or formamide, as is sketched below:

Table 4. Yields of α-butyl-β-keto esters[a]

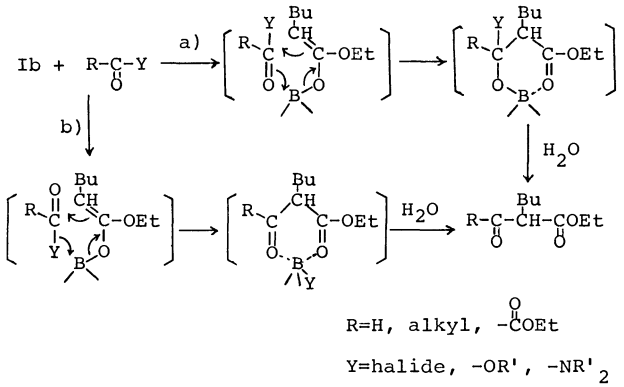
a) In ether at room temperature.



It should be noted that vinyloxyboranes, which react, under mild conditions, with carbonyl compounds, nitriles, or formates, may be useful as intermediates for the synthesis of a variety of β-hydroxy, β-keto- or α-formyl- ester, thioate, and ketone derivatives.

Experimental[9)]

Materials. Tri-*n*-butylborane was prepared from boron trifluoride diethyl etherate and *n*-butylmagnesium bromide in dry ether under argon. *S*-Phenyl di-*n*-butylthioboronite was prepared from tri-*n*-butylborane and thiophenol at 180 °C.[3)]

Reaction of S-*Phenyl Di*-n-*butylthioboronite and Methyl Vinyl Ketone.* To a solution of *S*-phenyl di-*n*-butylthioboronite (235 mg, 1.0 mmol) in CCl_4, we added methyl vinyl ketone (80 mg, 1.1 mmol) at room temperature under argon. After 30 min, the PMR spectrum of the solution was measured to show the formation of a vinyloxyborane (Id). PMR (CCl_4) δ 1.78 (s, 3H), 3.36 (d, J=8 Hz, 2H), 4.77 (t, J=8 Hz, 1H). The solution was then hydrolyzed with aqueous methanol and extracted with ether. The ethereal extracts were washed with water, dried over Na_2SO_4, and concentrated *in vacuo*. The residue was separated by preparative tlc to give 4-phenylthiobutan-2-one (III) in an 86% yield; bp 135—136 °C/8 mmHg. IR 1715, 1580, 1475, 740, 690 cm^{-1}. PMR ($CDCl_3$) δ 2.09 (s, 3H), 2.6—3.3 (m, 4H), 7.32 (s, 5H).

Reaction of Vinyloxyborane (Id) with n-*Butyraldehyde.* To a solution of (1-methyl-3-phenylthio-1-propenyloxy)di-*n*-butylborane (Id) prepared from *S*-phenyl di-*n*-butylthioboronite (319 mg, 1.4 mmol) and methyl vinyl ketone (100 mg, 1.4 mmol) in ether, we added a solution of butyraldehyde (94 mg, 1.3 mmol) in abs. ether (1 ml). The mixture was allowed to stand overnight and concentrated, and the residue was treated with water and bubbled air for 1 hr and then further extracted with ether. The ethereal layers were washed successively with 5% $NaHCO_3$ and H_2O, dried over Na_2SO_4, and evaporated. The residual oil was purified by preparative tlc (silica gel/$CHCl_3$) to give the pure oil of 4-hydroxy-3-phenylthiomethylheptan-2-one (IVb); 274 mg (83%); IR 3440, 1695 cm^{-1}. PMR ($CDCl_3$) δ 0.8—1.5 (m, 7H), 2.22 (s, 3H), 2.5 (broad s, 1H), 2.8—3.0 (m, 1H), 3.2 (d, 2H), 3.9 (d, 1H), 7.32 (m, 5H). Found: C, 66.48; H, 8.11; S, 12.79%. Calcd for $C_{14}H_{20}O_2S$: C, 66.62; H, 7.99; S, 12.71%.

The IR and PMR spectra and analysis of the other β-hydroxy-α-thiomethyl ketones (IVa, c, d) are consistent with the assigned structure. IVa; IR 3440, 1700 cm^{-1}. PMR ($CDCl_3$) δ 1.97 (s, 3H), 2.9—3.4 (m, 4H), 4.8—5.0 (m, 1H), 7.17 (s, 5H), 7.30 (s, 5H). Found: C, 70.85; H, 6.53; S, 11.28%. Calcd for $C_{17}H_{18}O_2S$: C, 71.28; H, 6.33; S, 11.19%. IVc; IR 3420, 1695 cm^{-1}. PMR ($CDCl_3$) δ 1.22 (s, 6H), 2.28 (s, 3H), 2.1—2.4 (broad s, 1H), 2.8—3.35 (m, 3H), 7.29 (s, 5H). Found: C, 65.28; H, 7.48; S, 13.32%. Calcd for $C_{13}H_{18}O_2S$: C, 65.51; H, 7.61; S, 13.45%. IVd; IR 3410, 1695 cm^{-1}. PMR ($CDCl_3$) δ 1.88 (s, 3H), 2.6—3.4 (m, 4H), 3.70 (s, 2H), 4.65—4.8 (m, 1H), 7.15 (s, 5H), 7.20 (s, 5H). Found: C, 71.70; H, 6.97; S, 10.88%. Calcd for $C_{18}H_{20}O_2S$: C, 71.97; H, 6.71; S, 10.68%.

Reaction of Vinyloxyborane (Ie) with Benzaldehyde. A solution of methyl vinyl ketone (150 mg, 2.1 mmol) and tri-*n*-butylborane (450 mg, 2.4 mmol) in abs. THF was stirred at room temperature under nitrogen containing a little oxygen overnight to give (1-methyl-1-heptenyloxy)di-*n*-butylborane (Ie). To the solution we then added a solution of benzaldehyde (160 mg, 1.5 mmol) in abs. THF. After 30 min, the solvent was removed. The residue was treated with a mixture of MeOH (20 ml) and 30% H_2O_2 (1 ml) for 1 hr, and further water was added. The mixture was concentrated *in vacuo* to remove the MeOH and extracted with ether. The extracts were washed with 5% $NaHCO_3$ and water, dried over Na_2SO_4, and evaporated. The oil was separated by preparative tlc to give 3-(α-hydroxybenzyl)octan-2-one (Va), both *threo* type (240 mg, 68%) and *erythro*-type (79 mg, 23%). Va of the *threo* type: IR 3420, 1700 cm^{-1}; PMR (CCl_4) δ 0.6—1.8 (m, 11H), 2.06 (s, 3H), 2.73 (m, 1H), 3.32 (s, 1H), 4.56 (d, 1H), 7.23 (s, 5H). Va of the *erythro* type: IR 3420, 1695 cm^{-1}: PMR (CCl_4) δ 0.6—1.8 (m, 11H), 1.83 (s, 3H), 2.70 (m, 1H), 3.15 (s, 1H), 4.70 (d, 1H), 7.23 (s, 5H).

The IR and PMR spectra of the other β-hydroxy-γ-pentylketones (Vb—d) are consistent with the assigned structure.

Vb; IR 3410, 1690 cm^{-1}: PMR (CCl_4) δ 0.7—1.9 (m, 18H), 2.13 (s, 3H), 2.3—2.7 (m, 1H), 3.17 (s, 1H), 3.5—3.9 (m, 1H). Vc; IR 3440, 1690 cm^{-1}: PMR (CCl_4) δ 0.6—1.8 (m, 11H), 1.10 (s, 3H), 1.15 (s, 3H), 2.13 (s, 3H), 2.3—2.9 (m, 2H). Vd; IR 3470, 1685 cm^{-1}: PMR (CCl_4) δ 0.6—2.0 (m, 21H), 2.15 (s, 3H), 2.53 (t, 1H), 2.65 (broad s, 1H).

Reaction of Vinyloxyborane (Ia') and Benzyl Cyanide. To a solution of *S*-phenyl di-*n*-butylthioboronite (419 mg, 1.8 mmol) in asb. ether (10 ml), we added 45 ml of gaseous ketene (prepared by the thermal cracking of acetone) at −78° under argon. After 10 min, we added benzyl cyanide (174 mg, 1.5 mmol) to the solution of vinyloxyborane (Ia') at room temperature. The reaction mixture was then allowed to stand for 21 hr and concentrated. MeOH was added to the residue and then, after 12 hr, removed *in vacuo*. The residual oil was separated by preparative tlc to give *S*-phenyl β-imino-γ-phenylbutyrothioate (VIb) 155 mg (39%). Recrystallization from cyclohexane: mp 74.0 °C. IR 3455, 3305, 1615, 1520 cm^{-1}. Found: C, 71.27; H, 5.75; N, 5.02; S, 11.88%. Calcd for $C_{16}H_{15}NOS$: C, 71.36; H, 5.61; N, 5.20; S, 12.14%.

The IR and analyses of the other β-iminothioates (VIa, c) are consistent with the assigned structure. VIa (mp 111—112 °C); IR 3380, 3290, 3200, 1610, 1520 cm^{-1}. Found: C, 70.70; H, 5.10; N, 5.68; S, 12.53%. Calcd for $C_{15}H_{13}NOS$: C, 70.58; H, 5.13; N, 5.49; S, 12.53%. VIc (oil); IR 3410, 3305, 3200, 1607, 1520 cm^{-1}. Found: C, 61.95; H, 6.04; N, 6.96; S, 16.56%. Mol wt, 193 (mass spectrometry). Calcd for $C_{10}H_{11}NOS$: C, 62.16; H, 5.74; N, 7.25; S, 16.51%. Mol wt, 193.2.

Reaction of Vinyloxyborane (Ib) with Benzonitrile. A solution of ethyl diazoacetate (242 mg, 2.1 mmol, dried over P_2O_5) in THF (1 ml) was stirred into a solution of tri-*n*-butylborane (398 mg, 2.1 mmol) in THF (3 ml) at room temperature under argon. N_2 was immediately evolved, and the yellow coloration characteristic of ethyl diazoacetate disappeared. After 5 min, a solution of benzonitrile (108 mg, 1.1 mmol) in THF was added to the solution. The reaction mixture was then allowed to stand at room temperature for 16 hr, after which the solution was treated with a mixture of 5% HCl (2 ml), MeOH (3 ml), and 30% H_2O_2 (1.5 ml) for 4 hr. Water was added to the solution, and the mixture was concentrated *in vacuo* to remove most of the THF and MeOH and extracted with ether. The ether layer was washed with 5% $NaHCO_3$ and satd. NaCl and dried over Na_2SO_4, and the solvent was removed. The crude oil was purified by preparative tlc (silica gel, benzene) to give the pure oil of ethyl α-benzoylhexanoate (VIIa); 184 mg, 71%. IR 1740, 1695 cm^{-1}. PMR (CCl_4) δ 0.65—2.4 (m, 13H), 4.10 (q, J=7 Hz, 2H), 7.4—7.6 (m, 3H), 7.8—8.05 (m, 2H). Found: C, 72.42; H, 8.18%. Calcd for $C_{15}H_{20}O_3$: C, 72.55; H, 8.12%.

The IR and PMR spectra of the other β-ketoesters (VIIb—d) are consistent with the assigned structure. VIIb; IR 1740, 1715 cm^{-1}; PMR (CCl_4) δ 0.7—2.0 (m, 12H), 3.47 (t, J=6 Hz, 1H), 3.73 (s, 2H), 4.10 (q, J=7 Hz, 2H), 7.17 (s, 5H). VIIc; IR 1740, 1720 cm^{-1}: PMR (CCl_4) δ 0.7—2.4 (m, 13H), 2.17 (s, 3H), 4.10 (q, J=7 Hz, 2H), VIId: IR 1745, 1715 cm^{-1}. PMR (CCl_4) δ 0.6—2.6 (m, 18H), *ca.* 3.2 (m, 2H), 4.08 (q, J=7 Hz, 2H).

Reaction of Vinyloxyborane (Ib) with Ethyl Formate. A solution of ethyl diazoacetate (2.74 g, 24 mmol) in asb. ether (5 ml) was stirred into a solution of tri-*n*-butylborane (3.65 g, 20 mmol) and ethyl formate (1.85 g, 25 mmol) in ether (20 ml) at room temperature under argon. The solution was then allowed to stand at room temperature for 16 hr, and ether was added. The solution was washed with a 5% solution of $NaHCO_3$ and water and then dried over anhydrous Na_2SO_4, after which the solvent was evaporated to give a crude oil. The oil was purified by silica-gel-column chromatography to give the pure oil of ethyl α-formylhexanoate (1.95 g, 60%); bp 88—91 °C/9 mmHg. (lit,[10] bp 94—96 °C/10 mmHg). IR 1740 (shoulder), 1720, 1660 cm^{-1}. Found: C, 62.57; H, 9.45%. Mol wt, 172 (mass spectrometry). Calcd for $C_9H_{16}O_3$: C, 62.76; H, 9.36%; Mol wt, 172.2.

The Reaction of Alkyl Halides with Mercuric Thiocyanate in Tetrahydrofuran. The Solvent Incorporation and the Intermediacy of *O*-Alkyltetrahydrofuranium Ions.

Nanao WATANABE,* Sakae UEMURA, and Masaya OKANO**
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611
(Received March 12, 1975)

The reaction of alkyl halides with mercuric thiocyanate in tetrahydrofuran (THF) affords mainly the THF-incorporated products, $R[O(CH_2)_4]_nNCS$ and $R[O(CH_2)_4]_nSCN$ (mostly $n=1$ and 2), where the isomer ratios (N/S ratios) are nearly 1. The reaction of $EtO(CH_2)_mBr$ ($m=2$—5) with mercuric thiocyanate in THF or *n*-Bu_2O proceeds rapidly only in the case of $m=4$ to give $EtO(CH_2)_4NCS$ and $EtO(CH_2)_4SCN$, the N/S ratio being also nearly 1, and gives EtNCS and EtSCN when $m=5$, while the reaction with potassium thiocyanate in DMF affords a good yield of $EtO(CH_2)_mSCN$ ($m=2$—5) as nearly the only product. It is suggested that the titled reaction involves the initial formation of a five-membered oxonium ion, *O*-alkyltetrahydrofuranium ion, and a subsequent attack by $XHg(SCN)_2^-$.

Previously, we reported that alkyl halides react with $Hg(SCN)_2$ in less polar solvents such as di-*n*-butyl ether and *n*-hexane to afford predominantly alkyl isothiocyanates (RNCS), in contrast to the reaction with the potassium salt in DMF, where alkyl thiocyanates (RSCN) are the main products.[1] When the former reaction was carried out in tetrahydrofuran (THF) as a solvent, it was found that the THF-incorporated products, $R[O(CH_2)_4]_nNCS(-SCN)$ ($n=1$ and 2), were mainly obtained instead of the expected substitution products, RNCS(–SCN). Here, the ratios of isothiocyanates to thiocyanates (hereinafter abbreviated as the N/S ratio) in the THF-incorporated products were nearly 1, regardless of the structure of the alkyl halides. In the present paper we wish to describe the results of the reaction and discuss its reaction mechanism.

Results and Discussion

When the reaction of various alkyl halides with $Hg(SCN)_2$ was carried out in THF at 65—70 °C (in the case of MeI, at 35—40 °C) for several hours, the THF-incorporated products (**1** and **2**) were mainly obtained, together with small amounts of the expected products (**3** and **4**), as shown in scheme 1. Typical results are summarized in Table 1. Besides the products listed in Table 1, small amounts of high-boiling substances which seemed to be **1** and **2** ($n=3$) were always detected in glc analysis. As can be seen from Table 1, the N/S ratios in **3** plus **4** increased upon changing from primary halides to secondary ones; this is in good agreement with the reported result of the reaction in *n*-Bu_2O.[1] On the other hand, the N/S ratios in **1** plus **2** were generally *ca.* 1, regardless of the structure of alkyl halides used. The reactions using $Cu(NCS)_2$ and AgSCN instead of Hg salt gave mainly 4-alkoxybutyl halide and a mixture of **3** and **4**, respectively, whereas the yields of **1** and **2** were very low even for a longer reaction time (see Experimental). Here the N/S ratio in **1** plus **2** was *ca.* 0.1, in sharp contrast to that in the Hg case. Therefore, the formation of nearly equal amounts of **1** and **2** as main products is a characteristic of the reaction with $Hg(SCN)_2$. Similar phenomena were also observed in reactions of EtI with metal bromides in THF, where the bromide analogue of **1** and **2** ($n=1$ and 2) was obtained in good yields by using $HgBr_2$, while the reaction occurred only slightly by using Cu(II) and Ag(I) bromides.[2]

$$RX + Hg(SCN)_2 + THF \longrightarrow \underset{\mathbf{1}}{R[O(CH_2)_4]_nNCS} + \underset{\mathbf{2}}{R[O(CH_2)_4]_nSCN} + \underset{\mathbf{3}}{RNCS} + \underset{\mathbf{4}}{RSCN} \quad (1)$$

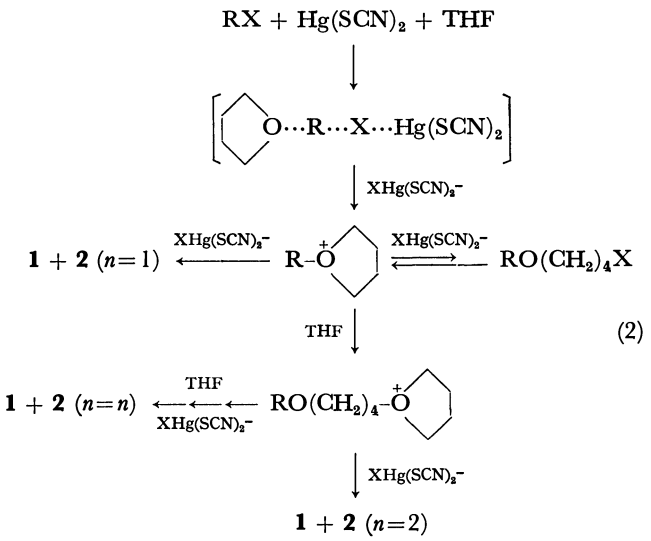
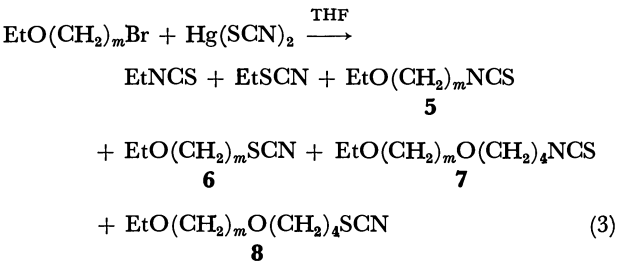
** To whom correspondence should be addressed.

Considering the well-clarified mechanism of the polymerization of THF under the influence of trialkyloxonium salts,[3] together with the finding that no reaction proceeded between THF and a mixture of ethyl thiocyanate and isothiocyanate by heating at 65—70 °C for 3 hr in the presence of $Hg(SCN)_2$, we propose a pathway for the formation of **1** and **2** such as that shown in scheme 2, where the *O*-alkyltetrahydofuranium ion is formed as an initial intermediate from RX and THF.



Since the yields of **1** plus **2** from primary alkyl iodides were generally comparable to that from *i*-PrI (see Table 1), it seems unlikely that free R^+ plays a part in the oxonium ion formation. When more polar 1,2-dichloroethane ($\varepsilon=10.36$) was used as a solvent instead of THF ($\varepsilon=7.58$) (a favorable condition for the S_N1 process), the conversion in the reaction of *i*-PrBr with $Hg(SCN)_2$ was only 0.5% at 65 °C for 7 hr. On the contrary, the reaction in THF showed a high conversion (see Table 1), suggesting a nucleophilic participation of the solvent. Therefore it seems to be reasonable to assume that both the push by THF and the pull by the Hg salt are involved in the formation of *O*-alkyltetrahydrofuranium ion. The resulting cation reacts with $XHg(SCN)_2^-$[1] to afford a mixture of **1** and **2** ($n=1$) and 4-alkoxybutyl halide, or with another THF molecule with ring opening to give a new tetrahydrofuranium ion, which in turn can react with $XHg(SCN)_2^-$ to afford **1** and **2** ($n=2$) or can add to another THF molecule. Although the formation of 4-alkoxybutyl halide was only slightly observed in this reaction, the halide became the main product in the reaction of EtI and $Hg(CN)_2$, instead of $Hg(SCN)_2$, in THF (see Experimental). Furthermore, we found that 4-butoxybutyl bromide reacted very rapidly with $Hg(SCN)_2$ in THF to afford **1** and **2** (*i.e.*, almost all of the bromide disappeared after 20 min at 65—70 °C), the N/S ratio in **1** plus **2** being *ca.* 1. Therefore it seems very likely that even if 4-alkoxybutyl halide is formed, the equilibrium is quite unfavorable to this halide in the presence of $Hg(SCN)_2$.

In the solvolysis of ω-methoxy-*n*-alkyl brosylates, $CH_3O(CH_2)_mOBs$, a considerable rate enhancement has been observed in the cases of $m=4$ and 5, as compared to those of $m=2$ and 3, and this has been attributed to the formation of a cyclic oxonium ion intermediate.[4] Furthermore, a favorable nucleophilic attack occurs at the O-methylene C atoms of the ring for a five-membered oxonium ion ($m=4$), while it occurs at the methyl C atom of the side chain for a six-membered one ($m=5$).[5] In order to obtain further evidence for scheme 2, namely the participation of *O*-alkyltetrahydrofuranium ion as an intermediate, we carried out the reaction of $EtO(CH_2)_m$-Br with $Hg(SCN)_2$ in THF and *n*-Bu_2O and obtained results similar to those described above. Thus the reaction proceeded rapidly when $m=4$, while ethyl thiocyanate and isothiocyanate were obtained only in the case of $m=5$ (Scheme 3, Table 2). The extent of rate



enhancement by the introduction of an alkoxy group at 4-position in *n*-BuBr is such that the reaction of 4-ethoxy-*n*-butyl bromide with $Hg(SCN)_2$ in *n*-Bu_2O gave a 77% yield of a mixture of **5** and **6** ($m=4$) at 65—70 °C for 1 hr (see Table 2), while only a 23% yield of *n*-BuN-

Table 2. Reaction of $EtO(CH_2)_mBr$ with $Hg(SCN)_2$ in THF and *n*-Bu_2O[a]

$EtO(CH_2)_mBr$ (20 mmol) *m*	Solvent (15 ml)	React. time (hr)	Products Yields (%),[b] (N/S ratios)[b] EtNCS+EtSCN	5 + 6	7 + 8

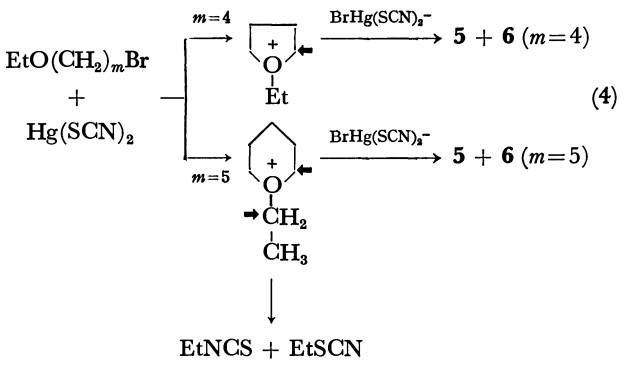
a) $Hg(SCN)_2$, 20 mmol. React. Temp., 65—70 °C. b) Determined by glc. c) Not characterized. d) Isolated yield. Here **5**+**6** and **7**+**8** correspond to **1**+**2** (R=Et, $n=1$) and **1**+**2** (R=Et, $n=2$), respectively. e) Other products: $EtO(CH_2)_4NCS(-SCN)$ 5.7%, N/S ratio=44/56. f) Not determined.

CS(–SCN) was obtained from the reaction with *n*-BuBr, even at 80—90 °C for 50 hr.[1] Considering these findings it is obvious that the reaction proceeds through a cyclic oxonium ion intermediate when $m=4$ and 5 (Scheme 4). It should be noted here that the N/S ratio



in **5** plus **6** ($m=4$) was nearly 1 in THF solvent, which is in good agreement with that in **1** plus **2** shown in Table 1. This fact clearly supports scheme 2, where the reaction of RX with $Hg(SCN)_2$ in THF is supposed to involve an *O*-alkyltetrahydrofuranium ion as an intermediate.

In separate experiments we confirmed that almost no isomerization occurs between the produced alkyl isothiocyanate and thiocyanate under the conditions shown in Tables 1 and 2. Therefore, it can be concluded that the N/S ratios in both Tables are kinetically controlled.

In contrast to the reaction of $RO(CH_2)_mBr$ with $Hg(SCN)_2$ described above, the reaction with KSCN in DMF proceeded smoothly with all kinds of $RO(CH_2)_mBr$; alkoxyalkyl thiocyanate was nearly the only product (Table 3). Here, the presence of alkoxy groups showed almost no significant effects on either the reaction rate or the yield of the products. In the reaction using THF as a solvent, where the rate was slow compared to that in DMF, none of the THF-incorporated products was formed and alkoxyalkyl thiocyanate was also nearly the only product. These results clearly indicate that the

Table 3. Reaction of $RO(CH_2)_mBr$ with KSCN in DMF and THF[a]

a) KSCN, 40 mmol. b) Isolated yield. Each product contained 0.6—0.8% of $RO(CH_2)_mNCS$ (by glc).

reaction of alkoxyalkyl bromide with KSCN is S_N2 type in either solvent, as expected.[1]

In a previous paper[1] we reported that the N/S ratios of the products in the reaction of alkyl halides with $Hg(SCN)_2$ are 21/79—34/66 for primary alkyl halides (S_N2 type) and 85/15—99/1 for secondary and tertiary ones (S_N1 type). A high selectivity for N attack was ascribed to the structure of $Hg(SCN)_2$, where Hg is S-bonded. As described above, the N/S ratio in **1** plus **2** was nearly 50/50 (more precisely 47/53—53/47) regardless of the structure of alkyl halides used; this ratio was thought to be determined by the step of the attack on the intermediate oxonium ion. In order to confirm this point we prepared $Et_3O^+BF_4^-$ separately and carried out the reaction of this oxonium ion with a mixture of KBr and $Hg(SCN)_2$ in 1,2-dichloroethane. As a result, although the yield was low, a mixture of EtNCS and EtSCN was obtained, with a N/S ratio of 66/34 (see Experimental). Here, neither THF nor n-Bu_2O could be used as a solvent because of the polymerization of the solvent or an alkyl exchange reaction. For comparison, when the reaction of $EtO(CH_2)_5Br$ with $Hg(SCN)_2$ was carried out in 1,2-dichloroethane at 65—70 °C for 4 hr, a mixture of EtNCS and EtSCN was obtained in 38% yield, with a N/S ratio of 61/39, together with **5** and **6** ($m=5$)

Table 4. Boiling points and analytical data of new compounds

Compounds[a]	Bp(°C/mmHg)	Found (Calcd) C (%)	H (%)	N (%)

n-$BuO(CH_2)_4SCN$[c]	120—121/6.5			

a) The N/S ratios in **1** plus **2** are shown in Table 1. $RO(CH_2)_mSCN$ contains 0.6—0.8% of $RO(CH_2)_mNCS$. b) Corresponds to **2** (R=Et, $n=1$). c) Corresponds to **2** (R=*n*-Bu, $n=1$).

(16% yield, N/S=55/45). The fact that the N/S ratios of the products, EtNCS and EtSCN, are nearly the same in both reactions shows that the latter reaction proceeds through an ethyloxonium ion, and also supports the reaction mechanism shown in schemes 2 and 4. The reason why the attack by N is more preferred in the reaction with the oxonium ion (N/S=47/53—53/47) than in that with primary halides (N/S=21/79—34/66) seems to be explained by the symbiotic effect in the HSAB principle proposed by Pearson,[6] since both reactions are supposed to be of the S_N2 type. This effect states that in an S_N2 reaction a grouping of either several hard ligands or several soft ligands on the central carbon atom should stabilize the transition state and cause an increased rate of reaction. Namely, the carbon bearing a harder ligand as the leaving group is apt to be attacked more preferably by a harder atom in an ambident ion. In our case, R_2O in R_3O^+ is harder than X^- in RX as the leaving group, and the N atom in the attacking species, $XHg(SCN)_2^-$, is harder than the S atom.[7]

Experimental

The N/S ratios in mixtures of alkyl thiocyanates and isothiocyanates were determined by gas chromatography (glc). Glc analyses were carried out on a Shimadzu 5APTF apparatus using EGSS-X (1 m), Apz-L (1 m), and PEG-6000 (3 m) columns (carrier gas, N_2). The retention time of RSCN was longer than that of RNCS in EGSS-X and PEG-6000 columns, while the reverse was observed by using Apz-L column. The NMR spectra were recorded with a Varian A-60 spectrometer in CCl_4, using TMS as an internal standard. The IR spectra were taken with a Hitachi EPI-S2 spectrometer.

Materials. All the organic substances, including the solvents, were used after distillation, while commercial inorganic salts were used without further purification. $Cu(NCS)_2$ was prepared from $CuSO_4 \cdot 5H_2O$ and KSCN by the reported method.[8] Alkoxyalkyl bromides, $RO(CH_2)_mBr$, were prepared by PBr_3 bromination of the corresponding alcohols which were synthesized from RBr and $NaO(CH_2)_mOH$:[9] R=Et and m=2, bp 126—127 °C (lit,[10] bp 126—127 °C); R=Et and m=3, bp 147—148 °C (lit,[9] bp 147—150 °C); R=Et and m=4, bp 78—80 °C/30 mmHg (lit,[11] bp 69 °C/15 mmHg); R=Et and m=5, bp 91—92 °C/20 mmHg (lit,[11] bp 185—192 °C/741 mmHg); R=*n*-Bu and m=4, bp 105—108 °C/25 mmHg (lit,[12] bp 57 °C/1.5 mmHg).

Reaction of Alkyl Halides with Mercuric Thiocyanate in THF. The following example shows a typical procedure. To a suspension of $Hg(SCN)_2$ (12.7 g, 40 mmol) in THF (30 ml) was added *i*-PrI (6.8 g, 40 mmol) drop by drop at 65—70 °C; the resulting yellowish-green homogeneous solution was kept for 2 hr under stirring while orange precipitates gradually came out. After being cooled down to room temperature, Et_2O (200 ml) was added and the precipitated inorganic salt was filtered off. The filtrate was washed several times with aqueous KI in order to remove a small amount of dissolved mercuric salt and then dried over $MgSO_4$. Distillation afforded the following products: **3**+**4** (R=*i*-Pr), bp 45—50 °C/40 mmHg, 0.2 g (5% yield); **1**+**2** (n=1, R=*i*-Pr), bp 91—102 °C/6 mmHg, 2.1 g (30% yield); **1**+**2** (n=2, R=*i*-Pr), bp 127—132 °C/2 mmHg, 1.7 g (17% yield).

Reaction of $RO(CH_2)_mBr$ with KSCN in DMF. The following example shows a typical procedure. To a homogeneous solution of KSCN (7.8 g, 80 mmol) in DMF (30 ml) was added $EtO(CH_2)_2Br$ (6.1 g, 40 mmol) at 65—70 °C. After being kept for 1 hr under stirring, the mixture was cooled down to room temperature, poured into water, and then extracted with Et_2O (200 ml). Distillation of the ether extract gave 4.1 g (78% yield) of $EtO(CH_2)_2SCN$, which contains a small amount of isothiocyanate (N/S=0.7/99.3); bp 99—101 °C/22 mmHg. IR 2150 (ν_{SCN}), 1120 (ν_{C-O}) cm^{-1}. NMR δ 1.21 (t. 3H, J=7 Hz, methyl), 3.1 (t. 2H, J=5.5 Hz, $-OCH_2-C\underline{H}_2S-$), 3.53 (q. 2H, J=7 Hz, $CH_3C\underline{H}_2O-$), 3.7 (t. 2H, J=5.5 Hz, $-OC\underline{H}_2CH_2S-$).

The boiling points and analytical data of all new compounds in Tables 1—3 are summarized in Table 4. All IR and NMR spectra were reasonably explained.

Reaction of Isopropyl Iodide with $Cu(NCS)_2$ or AgSCN in THF. When the heterogeneous mixture of $Cu(NCS)_2$ (7.2 g, 40 mmol) and *i*-PrI (6.8 g, 40 mmol) in THF (30 ml) was heated at 65—70 °C for 10 hr, the following compounds were obtained: *i*-PrNCS(-SCN) 0.24 g (6% yield, N/S=6/94), **1**+**2** (R=*i*-Pr, n=1) 0.52 g (7.5% yield, N/S=11/89), *i*-PrO-$(CH_2)_4I$ 1.65 g (17% yield), a small amount of unidentified product, and a residue (1.1 g). *i*-$PrO(CH_2)_4I$: bp 96—97 °C/20 mmHg, IR 1130 (ν_{C-O}) cm^{-1}. NMR δ 1.08 (d. 6H), 1.4—2.2 (m. 4H), 3.0—3.7 (m. 5H). Found: C, 34.93; H, 6.57%. Calcd for $C_7H_{15}OI$: C, 34.73; H, 6.25%.

A similar reaction using AgSCN at 65—70 °C for 24 hr afforded 0.6 g (14% yield) of *i*-PrNCS(-SCN) (N/S=24/76) and 0.35 g (5% yield) of **1**+**2** (N/S=14/86). Almost no reaction occurred at 65—70 °C for 1 hr in either case.

Reaction of Ethyl Iodide with $Hg(CN)_2$ in THF. A homogeneous solution of EtI (6.3 g, 40 mmol) and $Hg(CN)_2$ (10 g, 40 mmol) in THF (20 ml) was heated at 70 °C for 24 hr. The products were 4-ethoxybutyl iodide (1.1 g, 12% yield) and 0.86 g of an unidentified compound, probably $EtO-(CH_2)_4O(CH_2)_4I$. Almost no reaction occurred by heating for 1.5 hr. 4-Ethoxybutyl iodide: bp 87—89 °C/23 mmHg. IR 1130 (ν_{C-O}) cm^{-1}. NMR δ 1.15 (t. 3H), 1.4—2.25 (m. 4H), 3.1—3.6 (m. 6H).

Reaction of $Et_3O^+BF_4^-$ with $Hg(SCN)_2$ and KBr in 1,2-Dichloroethane. To 1,2-dichloroethane (5 ml) solution of $AgBF_4$ (1.0 g, 5 mmol) was added Et_2O (1 ml) and then EtBr (1 ml) at 15—20 °C under N_2 atmosphere.[13] After stirring for 1 hr the resulting AgBr was filtered off and washed with 1,2-dichloroethane (5 ml). A solid mixture of KBr (1.1 g, 5 mmol) and $Hg(SCN)_2$ (1.6 g, 5 mmol) was added to the combined 1,2-dichloroethane solution and the resulted heterogeneous mixture was stirred at 40 °C for 4 hr under N_2. Glc analysis of the mixture using *n*-BuNCS as an internal standard showed the presence of 5 mg (0.06 mmol, 1.2% yield based on $AgBF_4$) of a mixture of EtNCS and EtSCN (N/S=66/34). The reaction with KSCN was similarly carried out to give 11.6% yield of a mixture of EtNCS and EtSCN (N/S=2/98). Although it was conceivable that excess EtBr instead of $Et_3O^+BF_4^-$ reacted to give the product, we confirmed that EtBr did not react at all with $Hg(SCN)_2$ or KSCN under similar conditions.

Synthesis of D-Ribofuranosylpyrazolecarboxamides

Osamu MAKABE, Masakazu NAKAMURA, and Sumio UMEZAWA

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Kohoku-ku, Yokohama, Kanagawa 223

(Received March 13, 1975)

Several carbamoylpyrazole-nucleosides were synthesized by fusion of 1-*O*-acetyl derivatives of ribofuranoses with pyrazole derivatives in the presence of bis(*p*-nitrophenyl) hydrogen phosphate as an acidic catalyst. NMR and UV spectral studies revealed the orientation in *N*-glycosylation of the substituted pyrazoles.

The pyrazole-nucleoside antibiotic pyrazomycin[1] (3-(β-D-ribofuranosyl)-4-hydroxypyrazole-5-carboxamide) has been found to be an inhibitor of virus multiplication. On the other hand, 1-β-D-ribofuranosyl-1,2,3-triazole-4-carboxamide, previously synthesized in our laboratory,[2] was found to possess activity against vaccinia viruses, and, 1-β-D-ribofuranosyl-1,2,4-triazole-3-carboxamide (virazole), synthesized by Witkowski *et al.*,[3] was reported to possess activity against DNA and RNA viruses. These facts prompted us to investigate the structure-activity relationship of pyrazolecarboxamide nucleosides. This paper describes the synthesis of several carbamoylpyrazoles and related nucleosides.

In the present synthesis, blocked derivatives of pyrazoles were coupled with 1-*O*-acetyl derivatives of blocked ribofuranoses by the fusion procedure in the presence of bis(*p*-nitrophenyl)hydrogen phosphate (BNPP)[4] to give blocked nucleosides. Another purpose of the present investigation was to study the orientation in the *N*-glycosylation of pyrazole derivatives.

Fusion of ethyl pyrazole-3-carboxylate[5] (**1**) with 1-*O*-acetyl-2,3,5-tri-*O*-benzoyl-β-D-ribofuranose[6] (**4**) in the presence of BNPP gave a mixture of two major nucleosides, namely ethyl 1-(2,3,5-tri-*O*-benzoyl-β-D-ribofuranosyl)pyrazole-3-carboxylate (**6**) and -5-carboxylate (**7**), which were separated by chromatography to give **6** and **7** in a ratio of approximatly 8: 1. Treatment of **6** and **7** with methanolic ammonia gave 1-β-D-ribofuranosylpyrazole-3-carboxamide (**18β**) and 5-carboxamide (**19β**), respectively.

In an attempt to prepare the corresponding α-nucleosides, 1-*O*-acetyl-2,3,5-tri-*O*-benzyl-D-ribofuranose

(**5**), which has a benzyl group at *C*-2 as a non-participating group, was prepared and condensed with **1** by the fusion procedure to give ethyl 1-(2,3,5-tri-*O*-benzyl-α-D-ribofuranosyl)pyrazole-3-carboxylate (**10α**), its β-anomer (**10β**), and β-5-carboxylate (**11β**) in a ratio of approximately 2.6: 1.6: 1. Upon treatment with methanolic ammonia, these gave the carboxamide derivatives, (**14α**), (**14β**), and (**15β**), respectively. Catalytic hydrogenolysis of these products afforded 1-α-D-ribofuranosylpyrazole-3-carboxamide (**18α**), its β-isomer (**18β**), and β-5-carboxamide (**19β**), respectively.

Next, several pyrazole-3,5-dicarboxamide nucleosides, namely, 1-β-D-ribofuranosylpyrazole-3,5-dicarboxamide (**20β**), 4-nitro-1-(β-D-ribofuranosyl)pyrazole-3,5-dicarboxamide (**21β**), 4-amino-1-(β-D-ribofuranosyl)pyrazole-3,5-dicarboxamide (**22β**), and its α-anomer (**22α**) were synthesized. The fusion of ethyl pyrazole-3,5-dicarboxylate (**2**) with **4** gave ethyl 1-(2,3,5-tri-*O*-benzoyl-β-D-ribofuranosyl)pyrazole-3,5-dicarboxylate (**8**), which led to **20β** by the treatment with methanolic ammonia. Similar condensation of **2** with the benzyl sugar **5** also afforded a

Chart 2

β-nucleoside (**12β**) which led to **20β** through **16β**. In an attempt to prepare 4-amino nucleosides, ethyl 4-nitropyrazole-3,5-dicarboxylate (**3**) was prepared and coupled with **4** to give ethyl 1-(2,3,5-tri-*O*-benzoyl-β-D-ribofuranosyl)-4-nitropyrazole-3,5-dicarboxylate (**9**); subsequent amidation yielded the 4-nitro-3,5-dicarbamoyl derivative (**21β**), and catalytic reduction afforded the 4-amino derivative (**22β**). Similar fusion of **3** with the benzyl sugar **5** gave a mixture (approximately 1:1) of (**13α**) and (**13β**), which were separated by chromatography; subsequent amidation gave (**17α**) and (**17β**), respectively, and catalytic reduction yielded the 4-amino nucleosides (**22α**) and **22β**.

The structures of the above mentioned pyrazole-nucleosides were assigned on the basis of their NMR spectral data. An apparent difference in the chemical shift for the anomeric proton signals in the 3-carboxamides (**18α**, **18β**) and 5-carboxamide (**19β**) is consistently observed. The large downfield shift of the latter is attributable to the close location of the anisotropic carbamoyl group. The same effect has been observed in other nucleosides.[7-9] The proton of 3,5-dicarboxamide (**20β**) also showed a similar downfield shift. The ultraviolet spectra of the 3-carboxamides (**18α**, **18β**) and 5-carboxamide (**19β**) also showed a characteristic difference, as shown in Table 1.

Table 1. Ultraviolet absorption data for pyrazole-3- and 5-carboxamide derivatives

Compound No.	Solvents λ_{max} nm and ε					
	pH 7 H_2O		pH 1 HCl		pH 13 NaOH	
	λ_{max}	ε	λ_{max}	ε	λ_{max}	ε
18α	214	11500	215	12700	227	11000
18β	212	11100	213	11200	227	12200
19β	220	12500	221	12200	227	8400

Assignment of the anomeric configuration is also supported by the NMR spectral data. The *H*-1′ signal for 1′,2′-*trans*-nucleosides has been shown[10] to appear at higher field than the *H*-1′ signal of the corresponding 1′,2′-*cis*-nucleosides. No formation of α-anomers corresponding to **11β** and **12β** was detected in this procedure; however, their β-configurations were characterized by the small $J_{1'2'}$ values (2.0 Hz).

The data of the NMR spectra also shows that *N*-glycosylation causes a chemical shift: the proton at *C*-5 adjacent to glycosylated nitrogen is at a lower field than that of the proton at *C*-3 adjacemt to nitrogen which is not glycosylated. A similar trend has been observed in the case of the proton at *C*-5 of 1,2,3-triazoles glycosylated at *N*-1.[11]

Among the pyrazole-nucleosides prepared in this paper, the 3-carboxamide (**18β**), which is a carbon bioisostere of virazole, and 3,5-dicarbamoyl-4-nitro derivative (**21β**) were found to have antileuchemic and antitumor activities.[12]

Experimental

Melting points were determined on a micro hot stage and were uncorrected. Thin layer chromatography (tlc) was conducted by the use of a Wakogel B-5. Silica gel column chromatography was carried out by using a Wakogel G-200. UV-Spectra were taken with a Hitachi Perkin-Elmer UV-VIS spectrometer 139. The NMR spectra were measured with a Varian A-60D spectrometer (TMS as an internal standard).

Ethyl Pyrazole-3-carboxylate (1). Prepared by the method of K. V. Auewrs[5]; NMR ($CDCl_3$): δ 7.95 (d, 1H, H-5), 7.01 (d, 1H, H-4), 4.55 (q, 2H, CH_2-ester), 1.47 (t, 3H, CH_3-ester).

Ethyl Pyrazole-3,5-dicarboxylate (2). Pyrazole-3,5-dicarboxylic acid[13] (10.0 g, 64 mmol) was dissolved in a 70% hydrogen chloride ethanol solution (100 ml) and refluxed for 4 hr. After removal of the solvent, the residue was dissolved in ethyl acetate and chromatographed on a silica gel column (200 g) using benzene–ethyl acetate (3:1) as a solvent. The main fraction was evaporated to give colorless crystals of **2**, 9.8 g (72%); mp 49—51 °C. NMR ($CDCl_3$): δ 7.50 (s, 1H, H-4), 4.52 (q, 4H, CH_2-ester), 1.41 (q, 6H, CH_3-ester). Found: C, 50.80; H, 5.72; N, 13.14%. Calcd for $C_9H_{12}O_4N_2$: C, 50.94; H, 5.70; N, 13.20%.

Ethyl 4-Nitropyrazole-3,5-dicarboxylate (3). 3-Methyl-4-nitropyrazole-5-carboxylic acid[14] (10.0 g, 58.5 mmol) was dissolved in water (100 ml), to which powdered potassium permanganate (0.13 mol) was gradually added for 30 min under stirring. The solution was heated at 100 °C for 8 hr under stirring. After filtration, the solution was evaporated to dryness. 3 M Sulfulic acid (30 ml) was added and the precipitate was filtered. The dried crude precipitate was suspended in a 70% ethanolic hydrogen chloride solution (65 ml) and the solution was refluxed for 4 hr. After evaporation of the solvent, the residual syrup was dissolved in acetone (10 ml) and silica gel (6.5 g) was added; the mixture was evaporated and the crude product was purified by chromatography on a column (2.5×90 cm) of silica gel (130 g) using benzene–ethyl acetate (4:1) as a solvent, to give pale yellow crystals of **3**, 6.3 g (42%); mp 82—84 °C. Found: C, 41.96; H, 4.11; N, 16.18%. Calcd for $C_9H_{11}O_6N_3$: C, 42.03; H, 4.31; N, 16.34%.

1-O-Acetyl-2,3,5-tri-O-benzyl-D-ribofuranose (5). 2,3,5-Tri-*O*-benzyl-D-ribose[15] (10.0 g, 23.8 mmol) was dissolved in anhydrous pyridine (50 ml) and acetic anhydride (5 ml) was added. The mixture was stirred at room temperature for 12 hr. After evaporation of the solvent, the crude syrup was dissolved in ethyl acetate and chromatographed on a column of silica gel (400 g, 5×100 cm, packed with benzene) and eluted with benzene–ethyl acetate (20:1). The main fraction was evaporated to give a syrup of **5** (9.55 g, 87%); NMR ($CDCl_3$): δ 7.40 (s, 15H, Ar), 6.38 (s, 1H, H-1′), 4.8—3.9 (m, 9H, CH_2-Ar, H-2′, H-3′, H-4′), 3.71 (m, 2H, H-5′, 5″), 1.90 (s, 2.9H, CH_3), 1.87 (s, 0.1H, CH_3), α: β=1:29 (from acetyl peak). Found: C, 72.65; H, 6.50%. Calcd for $C_{28}H_{30}O_6$: C, 72.71; H, 6.54%.

Ethyl 1-(2,3,5-Tri-O-benzoyl-β-D-ribofuranosyl)pyrazole-3-carboxylate (6) and Ethyl 1-(2,3,5-Tri-O-benzoyl-β-D-ribofuranosyl)pyrazole-5-carboxylate (7). A mixture of ethyl pyrazole-3-carboxylate[5] (**1**) (0.62 g, 4.43 mmol) and 1-*O*-acetyl-2,3,5-tri-*O*-benzoyl-β-D-ribofuranose[6] (**4**) (2.0 g, 3.97 mmol) was heated to 140 °C. To the melt was added BNPP (4 mg) and the mixture was heated at 140 °C under reduced pressure about 20 min until the evolution of acetic acid ceased. The resulting mixture was dissolved in ethyl acetate and was placed on a column of silica gel (130 g, 2.5×90 cm, packed with benzene) and eluted succesively with benzene (150 ml) and benzene–ethyl acetate (20:1). The effluent was fractionized into 12 mls.

Fraction Nos 11—21 gave **7**, colorless syrup, 255 mg (11%); $[\alpha]_D^{25}$ −6.7° (*c* 1.73, chloroform). NMR ($CDCl_3$): δ 8.15

(m, 6H, Ar), 7.73 (d, 1H, H-3), 7.51 (m, 10H, Ar, H-1'), 7.02 (d, 1H, H-4), 6.50 (m, 2H, H-2', H-3'), 4.80 (m, 3H, H-4', H-5', 5''), 4.40 (q, 2H, CH_2-ester), 1.40 (t, 3H, CH_3-ester). Found: C, 65.49; H, 5.01; N, 4.58%. Calcd for $C_{32}H_{28}O_9N_2$: C, 65.75; H, 4.83; N, 4.79%.

Fraction Nos 31—49 gave **6**, colorless syrup, 1.92 g (83.5%); $[\alpha]_D^{25}$ −40.0° (*c* 3.2, chloroform). NMR ($CDCl_3$): δ 8.15 (m, 6H, Ar), 7.85 (d, 1H, H-5), 7.55 (m, 10H, Ar, H-1'), 6.95 (d, 1H, H-4), 6.30 (m, 2H, H-2', H-3'), 4.85 (m, 3H, H-4', H-5', 5''), 4.46 (q, 2H, CH_2-ester), 1.40 (t, 3H, CH_3-ester). Found: C, 65.49; H, 5.01; N, 4.58%. Calcd for $C_{32}H_{28}O_9N_2$: C, 65.75; H, 4.85; N, 4.79%.

Ethyl 1-(2,3,5-Tri-O-benzoyl-β-D-ribofuranosyl)pyrazole-3,5-dicarboxylate (8). A mixture of ethyl pyrazole-3,5-dicarboxylate (**2**) (630 mg, 2.97 mmol) and 1-*O*-acetyl-2,3,5-tri-*O*-benzoyl-β-D-ribofuranose (1.50 g, 2.97 mmol) was fused in the presence of BNPP (2 mg) in the same manner as described for the preparation of **7**. The resulting mixture was dissolved in hot acetone (50 ml) and 1.5 g charcoal was added. After heating the mixture on boiling water, the charcoal was filtered off and the filtrate was evaporated under reduced pressure. The syrup was crystallized from isopropylalcohol to give **8**, 1.66 g (85.1%); mp 106—107 °C. $[\alpha]_D^{25}$ −25.6° (*c* 0.96, chloroform). NMR ($CDCl_3$): δ 8.15 (m, 6H, Ar). 7.50 (m, 11H, Ar, H-4, H-1'), 6.45 (m, 2H, H-2', H-3'), 4.81 (m, 3H, H-4', H-5', 5''), 4.48 (q, 4H, CH_2-ester), 1.40 (t, 6H, CH_3-ester). Found: C, 64.24; H, 5.09; N, 4.06%. Calcd for $C_{35}H_{32}O_{11}N_2$: C, 64.02; H, 4.91; N, 4.27%.

Ethyl 1-(2,3,5-Tri-O-benzoyl-β-D-ribofuranosyl)-4-nitropyrazole-3,5-dicarboxylate (9). A mixture of ethyl 4-nitropyrazole-3,5-dicarboxylate (**3**) (765 mg, 2.98 mmol) and 1-*O*-acetyl-2,3,5-tri-*O*-benzoyl-β-D-ribofuranose (**4**) (1.5 g, 2.98 mmol) was fused at 138 °C in the presence of BNPP in the same manner as described for the preparation of **7**. The resulting mixture was dissolved in hot acetone (40 ml) and treated with charcoal. After removal of the charcoal, the acetone solution was evaporated under reduced pressure. The resulting syrup was crystallized from isopropylalcohol to give **9**, 1.38 g (66%); mp 92—93 °C. $[\alpha]_D^{25}$ −51.2° (*c* 1.0, chloroform). NMR ($CDCl_3$): δ 8.15 (m, 6H, Ar), 7.60 (m, 9H, Ar), 7.12 (d, 1H, $J_{1',2'}$=2.0 Hz, H-1'), 6.5—6.2 (m, 2H, H-2', H-3'), 4.80 (m, 3H, H-4', H-5', 5''), 4.49 (dq, 4H, CH_2-ester), 1.39 (t, 6H, CH_3-ester). Found: C, 60.01; H, 4.53; N, 5.83%. Calcd for $C_{35}H_{31}O_{13}N_3$: C, 59.91; H, 4.45; N, 5.99%.

Ethyl 1-(2, 3, 5-Tri-O-benzyl-β-D-ribofuranosyl)pyrazole-3-carboxylate (10β), Its α-anomer (10α) and Ethyl 1-(2,3,5-Tri-O-benzyl-β-D-ribofuranosyl)pyrazole-5-carboxylate (11β). A mixture of **1** (525 mg, 3.04 mmol) and **5** (1.40 g, 3.03 mmol) and a catalytic amount of BNPP were fused for 10 min in the same manner as described for the preparation of **7**. The resulting residue was dissolved in chloroform (5 ml) and silica gel (2 g) was added. The mixture was evaporated and then chromatographed on a column of silica gel (120 g) using *n*-hexane–isopropylether (2: 1) as a solvent. The effluent was fractionized into 13 mls.

Fraction Nos 31—43 gave **11β**, a colorless syrup, 282 mg (17.2%); $[\alpha]_D^{25}$ −1.4° (*c* 5.0, chloroform). NMR ($CDCl_3$): δ 7.65 (d, 1H, H-3), 7.41 (s, 15H, Ar), 7.15 (d, 1H, $J_{1',2'}$= 2.0 Hz, H-1'), 6.99 (d, 1H, H-4), 4.78—4.25 (m, 9H, CH_2-Ar, H-2', H-3', H-4'), 4.45 (q, 2H, CH_2-ester), 3.72 (m, 2H, H-5', 5''), 1.38 (t, 3H, CH_3-ester). Found: C, 70.53; H, 6.02; N, 4.64%. Calcd for $C_{32}H_{34}O_6N_2$: C, 70.83; H, 6.32; N, 5.16%.

Fraction Nos 49—53 gave **10β**, a colorless syrup, 455 mg (27.2%); $[\alpha]_D^{25}$ −30.1° (*c* 1.0, chloroform). NMR ($CDCl_3$): δ 7.88 (d, 1H, H-5), 7.40 (s, 15H, Ar), 6.83 (d, 1H, H-4), 6.17 (d, 1H, $J_{1',2'}$=2.4 Hz, H-1'), 4.80—4.20 (m, 11H, CH_2-Ar, H-2', H-3', H-4', CH_2-ester), 3.77 (t, 2H, H-5', 5''), 1.40 (t, 3H, CH_3-ester). Found: C, 70.51; H, 6.26; N, 4.97%. Calcd for $C_{32}H_{34}O_6N_2$: C, 70.83; H, 6.32; N, 5.16%.

Fraction Nos 56—67 gave **10α**, a colorless syrup, 727 mg (44.4%); $[\alpha]_D^{25}$ +35.8° (*c* 0.98, chloroform). NMR ($CDCl_3$): δ 8.17 (d, 1H, H-5), 7.40 (s, 15H, Ar), 6.95 (d, 1H, H-4), 6.44 (d, 1H, $J_{1',2'}$=4.9 Hz, H-1'), 4.70—4.15 (m, 11H, CH_2-ester, CH_2-Ar, H-2', H-3', H-4'), 3.62 (t, 2H, H-5', 5''), 1.38 (t, 3H, CH_3-ester). Found: C, 70.63; H, 6.37; N, 5.08%. Calcd for $C_{32}H_{34}O_6N_2$: C, 70.83; H, 6.32; N, 5.16%.

Ethyl 1-(2,3,5-Tri-O-benzyl-β-D-ribofuranosyl)pyrazole-3,5-dicarboxylate (12β). A mixture of ethyl pyrazole-3,5-dicarboxylate (**2**) (286 mg, 1.35 mmol) and 1-*O*-acetyl-2,3,5-tri-*O*-benzyl-D-ribofuranose (**5**) (622 mg, 1.35 mmol) was fused in the presence of BNPP (2 mg) in the same manner as described for the preparation of **7**. The resulting mixture was dissolved in ethyl aeetate and chromatographed on a column of silica gel (40 g, 2.5×30 cm) using *n*-hexane–isopropyl-ether (2: 1) as a solvent. The effluent was fractionized into 8 mls. Fractjon lNos 38—64 gave **12β**, a colorless syrup, 530 mg (63%); $[\alpha]_D^{25}$ −28.3° (*c* 1.0, chloroform). NMR ($CDCl_3$): δ 7.42 (t, 16H, H-4, Ar), 7.10 (d, 1H, $J_{1',2'}$=2.0 Hz, H-1'), 4.77—4.25 (m, 13H, CH_2-ester, CH_2-Ar, H-2', H-3', H-4'), 3.73 (m, 2H, H-5', 5''), 1.40 (t, 6H, CH_3-ester). Found: C, 68.08; H, 6.11; N, 4.36%. Calcd for $C_{35}H_{38}O_8N_2$: C, 68.39; H, 6.23; N, 4.57%.

Ethyl 1-(2,3,5-Tri-O-benzyl-β-D-ribofuranosyl)-4-nitropyrazole-3,5-dicarboxylate (13β) and Its α-Anomer (13α). A mixture of ethyl 4-nitropyrazole-3,5-dicarboxylate (**3**) (599 mg, 2.32 mmol) and the sugar component **5** (1.07 g, 2.32 mmol) was fused in the presence of BNPP (2 mg) and worked up in a similar manner to the above, using a silica gel column (80 g, 2.8×35 cm). The effluent was fractionized into 11 mls.

Fraction Nos 38—46 gave **13β**, a colorless syrup, 550 mg (36%); $[\alpha]_D^{25}$ −55.8° (*c* 2.0, chloroform), NMR ($CDCl_3$): δ 7.40 (t, 15H, Ar), 6.52 (d, 1H, $J_{1',2'}$=2.0 Hz, H-1'), 4.8—4.5 (m, 9H, H-2', H-3', H-4', CH_2-Ar), 4.42 (q, 4H, CH_2-ester), 3.52 (d, 2H, H-5', 5''), 1.35 (t, 6H, CH_3-ester). Found: C, 64.03; H, 5.56; N, 6.10%, Calcd for $C_{35}H_{37}O_{10}N_3$: C, 63.72; H, 5.65; N, 6.37%.

Fraction Nos 49—61 gave **13α**, a colorless syrup, 580 mg (38%); $[\alpha]_D^{25}$ −9.3° (*c* 3.0, chloroform). NMR ($CDCl_3$): δ 7.42 (t, 15H, Ar), 6.77 (d, 1H, $J_{1',2'}$=3.3 Hz, H-1'), 4.75—4.50 (m, 9H, H-2', H-3', H-4', CH_2-Ar), 4.42 (q, 4H, CH_2-ester), 3.65 (d, 2H, H-5', 5''), 1.35 (t, 6H, CH_3-ester). Found: C, 63.98; H, 5.46; N, 6.13%. Calcd for $C_{35}H_{37}O_{10}N_3$: C, 63.72; H, 5.65; N, 6.37%.

1-(2,3,5-Tri-O-benzyl-β-D-ribofuranosyl)pyrazole-3-carboxamide (14β). A sample of **10β** (400 mg, 0.785 mmol) in absolute methanol (40 ml) saturated with ammonia at 0°C was kept at room temperaturefor 12 hr, and evaporated under reduced pressure at 40 °C. The residual syrup was washed with *n*-hexane and dried at 80 °C for 10 hr to give a colorless oil of **14β**, 318 mg (84%); $[\alpha]_D^{25}$ −22.5° (*c* 1.0, chloroform). NMR ($CDCl_3$): δ 7.75 (d, 1H, H-5), 7.38 (d, 15H, Ar), 6.87 (d, 1H, H-4), 6.60 (br s, 2H, $CONH_2$), 6.03 (d, 1H, $J_{1',2'}$=3.2 Hz, H-1'), 4.70—4.20 (m, 9H, CH_2-Ar, H-2', H-3', H-4'), 3.70 (t, 2H, H-5', 5''). Found: C, 70.14; H, 6.14; N, 8.22%. Calcd for $C_{30}H_{31}O_5N_3$: C, 70.16; H, 6.08; N, 8.18%.

1-(2,3,5-Tri-O-benzyl-α-D-ribofuranosyl)pyrazole-3-carboxamide (14α). The same procedure as described above was applied to **10α** (700 mg, 1.29 mmo.) in absolute methanol saturated with ammonia (70 ml) to give a colorless oil of **14α**, 546 mg (82%); $[\alpha]_D^{25}$ +45.2° (*c* 0.92, chloroform). NMR

($CDCl_3$): δ 8.25 (d, 1H, H-5), 7.40 (m, 15H, Ar), 7.00 (d, 1H, H-4), 6.45 (br s, 2H, $CONH_2$), 6.31 (d, 1H, $J_{1'2'}$=5.2 Hz, H-1'), 4.80—4.13 (m, 9H, CH_2-Ar, H-2', H-3', H-4'), 3.67 (d, 2H, H-5', 5''). Found: C, 70.15; H, 6.12; N, 8.24%. Calcd for $C_{30}H_{31}O_5N_3$: C, 70.16; H, 6.08; N, 8.18%.

1-(2,3,5-Tri-O-benzyl-β-D-ribofuranosyl)pyrazole-5-carboxamide (15β). The same procedure as described above was applied to **11β** (260 mg, 0.48 mmol) in absolute methanol saturated with ammonia (26 m.) to give a colorless oil of **15β**, 196 mg (80%); $[\alpha]_D^{25}$ −2.5° (*c* 3.0, chloroform), NMR ($CDCl_3$): δ 7.60 (d, 1H, H-3), 7.40 (d, 15H, Ar), 7.18 (d, 1H, H-4), 6.60 (br d, 3H, $CONH_2$, $J_{1'2'}$=1.8 Hz, H-1'), 4.95—4.30 (m, 9H, CH_2-Ar, H-2', H-3', H-4'), 3.74 (m, 2H, H-5', 5''). Found: C, 70.47; H, 6.24; N, 8.27%, Calcd for $C_{30}H_{31}O_5N_3$: C, 70.16; H, 6.08; N, 8.18%.

1-(2,3,5-Tri-O-benzyl-β-D-ribofuranosyl)pyrazole-3,5-dicarboxamide (16β). The same procedure as described above was applied to **12β** (420 mg, 0.685 mmol) in absolute methanol (42 ml) saturated with ammonia. The residual syrup was chromatographed on a column of silica gel (30 g) using benzene–ethyl acetate (3: 1) as a solvent, to give a colorless glass of **16β**, 351 mg (92%); $[\alpha]_D^{25}$ −23.3° (*c* 1.0, dioxane). NMR (CD_3OD): δ 7.40 (t, 16H, Ar, H-4), 7.20 (d, 1H, $J_{1'2'}$=1.8 Hz, H-1'), 4.8—4.3 (m, 9H, CH_2-Ar, H-2', H-3', H-4'), 3.30 (d, 2H, H-5', 5''). Found: C, 66.66; H, 5.79; N, 9.96%. Calcd for $C_{31}H_{32}O_6N_4$: C, 66.89; H, 5.80; N, 10.07%.

4-Nitro-1-(2,3,5-tri-O-benzyl-β-D-ribofuranosyl)pyrazole-3,5-dicarboxamide (17β). A sample of **13β** (400 mg, 0.606 mmol) was led to its amide in a similar manner to that described above. The residual oil was washed with *n*-hexane and crystallized from benzene to give **17β**, 314 mg (81%); mp 82—83° C. $[\alpha]_D^{25}$ −27.5° (*c* 1.0, chloroform). NMR (CD_3OD): δ 7.42 (s, 15H, Ar), 6.27 (d, 1H, $J_{1'2'}$=3.1 Hz, H-1'), 4.8—4.4 (m, 9H, H-2', H-3', H-4', CH_2-Ar), 3.70 (m, 2H, H-5', 5''). Found: C, 61.78; H, 5.23; N, 11.58%. Calcd for $C_{31}H_{31}O_8N_5$: C, 61.89; H, 5.19; N, 11.64%.

4-Nitro-1-(2,3,5-tri-O-benzyl-α-D-ribofuranosyl)pyrazole-3,5-dicarboxamide (17α). By the same procedure as described above, **15α** gave **17α**, 296 mg (81%), crystallized from benzene–isopropylether; mp 161—162 °C. $[\alpha]_D^{25}$ −14.5° (*c* 1.0, chloroform). NMR (CD_3OD): δ 7.40 (d, 15H, Ar), 6.52 (d, 1H, $J_{1'2'}$=4.9 Hz, H-1'), 4.70—4.10 (m, 9H, H-2', H-3', H-4', CH_2-Ar), 3.68 (m, 2H, H-5', 5''). Found: C, 62.01; H, 5.22; N, 11.47%. Calcd for $C_{31}H_{31}O_8N_5$: C, 61.89; H, 5.19; N, 11.64%.

1-α-D-Ribofuranosylpyrazole-3-carboxamide (18α). A sample of **14α** (500 mg, 0.975 mmol) in 10 ml methanol was hydrogenated over a palladium black catalyst at 50 lb/sq inch for 24 hr. After removal of the catalyst, the methanol layer was evaporated and recrystallized from ethanol and benzene to give **18α**, 187 mg (79%); mp 175.5 °C. $[\alpha]_D^{25}$ +33.4° (*c* 1.0, water). NMR (DMSO-d_6): δ 8.15 (d, 1H, H-5), 7.44 (br d, 2H, $CONH_2$), 6.78 (d, 1H, H-4), 6.14 (d, 1H, $J_{1'2'}$=5.3 Hz, H-1'), 5.32 (t, 2H, OH), 4.47 (t, 1H, OH), 4.57—4.13 (m, 3H, H-2', H-3', H-4'), 3.60 (m, 2H, H-5', 5''). Found: C, 44.61; H, 5.41; N, 17.48%. Calcd for $C_9H_{13}O_5N_3$: C, 44.44; H, 5.39; N, 17.28%.

1-β-D-Ribofuranosylpyrazole-3-carboxamide (18β).

A. From 14β: A sample of **14β** (300 mg, 0.585 mmol) was hydrogenated and worked up in a similar manner to that described above. It was recrystallized from methanol to give **18β**, 111 mg (78%); mp 137 °C. $[\alpha]_D^{25}$ −41.6° (*c* 0.5, water). NMR (DMSO-d_6): δ 8.20 (d, 1H, H-5), 7.47 (br d, 2H, $CONH_2$), 6.83 (d, 1H, H-4), 5.85 (d, 1H, $J_{1'2'}$=4.0 Hz, H-1'), 5.50 (d, 1H, OH), 5.18 (d, 1H, OH), 4.95 (t, 1H, OH), 4.55—3.90 (m, 3H, H-2', H-3', H-4'), 3.71 (m, 2H, H-5', 5''). Found: C, 44.14; H, 5.37; N, 17.09%. Calcd for $C_9H_{13}O_5N_3$: C, 44.44; H, 5.39; N, 17.28%.

B. From 6: A sample of **6** (1.2 g, 2.06 mmol) in absolute methanol (120 ml) saturated with ammonia at 0 °C was kept at room temperature for 3 days and then evaporated under reduced pressure at 40 °C. The residual syrup was dissolved in water (30 ml) and washed with ether (5 ml × 10). The aqueous layer was evaporated to dryness to give 18β, 370 mg (72%).

1-β-D-Ribofuranosylpyrazole-5-carboxamide (19β).

A. From 15β: A sample of **15β** (180 mg, 0.351 mmol) was debenzylated by catalytic hydrogenation in a similar manner to that described above, in (A) of **18β**. After removal of methanol, the residual syrup was dissolved in aqueous ammonia and chromatographed on a column of silica gel (8 g, 1 × 10 cm) using butanol–ethanol–chloroform–17% aqueous ammonia (4: 4: 2: 3) as a solvent, to give **19β**, colorless crystals, 61.5 mg (72%); mp 150—151 °C. $[\alpha]_D^{25}$ −64.5° (*c* 1.91, water). NMR (DMSO-d_6): δ 7.85 (br d, 2H, $CONH_2$), 7.72 (d, 1H, H-3), 7.00 (d, 1H, H-4), 6.86 (d, 1H, $J_{1'2'}$=3.0 Hz, H-1'), 5.28 (d, 1H, OH), 5.02 (d, 1H, OH), 4.83—3.80 (m, 4H, OH, H-2', H-3', H-4'), 3.58 (m, 2H, H-5', 5''). Found: C, 44.73; H, 5.52; N, 17.43%. Calcd for $C_9H_{13}O_5N_3$: C, 44.44; H, 5.39; N, 17.28%.

B. From 7: A sample of **7** (230 mg, 0.394 mmol) in absolute methanol (50 m.) saturated with ammonia at 0 °C was kept at room temperature for 3 days. After removal of the methanol, water (10 ml) was added and the aqueous solution was extracted with ether (5 ml × 10). The aqueous layer was evaporated and the residual syrup was chromatographed in a similar manner as described above to give **19β**, 74 mg (75%).

1-β-D-Ribofuranosylpyrazole-3,5-dicarboxamide (20β).

A. From 8: A sample of **8** (600 mg, 0.91 mmol) was subjected to ammonolysis in a similar manner to that described for the preparation (*B*) of **19β**. The residual syrup was chromatographed on a column of silica gel (30 g), using butanol–ethanol–chloroform–17% aqueous ammonia (4: 4: 2: 3) as a solvent. The main fraction was evaporated to give a colorless glass of **20β**, 188 mg (72%); $[\alpha]_D^{25}$ −31.3° (*c* 1.0, water); NMR (DMSO-d_6): δ 7.80 (br d, 2H, $CONH_2$), 7.40 (s, 1H, H-4), 6.89 (d, 1H, $J_{1'2'}$=3.0 Hz, H-1'), 5.40 (d, 1H, OH), 5.00 (d, 1H, OH), 4.60 (m, 3H, OH, H-2', H-3'), 3.90 (m, 1H, H-4'), 3.60 (m, 2H, H-5', 5''). UV: λ_{max}^{water} 205 nm (ε 19700), λ_{max}^{pH1} 207 nm (ε 20600), λ_{max}^{pH13} 219 nm (ε 12500). Found C, 42.06; O, 5.00; N, 19.35%. Calcd for $C_{10}H_{14}O_6N_4$: C, 41.96; H, 4.93; N, 19.58%.

B. From 16β: A sample of **16β** (300 mg, 0.54 mmol) in 8 ml methanol was hydrogenated over a palladium black catalyst at 50 lb/sq inch for 70 hr. After filtration of the catalyst, the filtrate was evaporated and chromatographed on a column of silica gel with butanol–ethanol–chloroform–17% aqueous ammonia (4: 4: 2: 3) to give **20β**, 94.3 mg (61%).

4-Nitro-1-(β-D-ribofuranosyl)pyrazole-3,5-dicarboxamide (21β). A sample of 9 (800 mg, 1.14 mmol) was subjected to ammonolysis and worked up in a similar manner to that described for the preparation (*A*) of **20β** to give a colorless glass of **21β**, 272 mg (72%); $[\alpha]_D^{25}$ −23.5° (*c* 1.0, water); NMR (DMSO-d_6): δ 8.04 (br d, 4H, $CONH_2$), 5.82 (d, 1H, $J_{1'2'}$=3.7 Hz, H-1'), 5.55 (d, 1H, OH), 5.52 (d, 1H, OH), 4.80—3.90 (m, 4H, OH, H-2', H-3', H-4'), 3.60 (d, 2H, H-5', 5''). UV: λ_{max}^{water} 201 nm (ε 24500), 270 nm (ε 11200), λ_{max}^{pH1} 207 nm (ε 21200), 268 nm (ε 10600), λ_{max}^{pH13} 219 nm (ε 17300), 276 nm (ε 11100). Found: C, 35.98; H, 4.21; N, 20.90%. Calcd for $C_{10}H_{13}O_8N_5$: C, 36.26; H, 3.96; N, 21.14%.

4-Amino-1-(β-D-ribofuranosyl)pyrazole-3,5-dicarboxamide (22β).

A. From 17β: A sample of **17β** (200 mg, 0.332 mmol) in 6 ml methanol was hydrogenated over a palladium black

catalyst at 50 lb/sq inch for 24 hr. The catalyst was filtered off and the filtrate was evaporated. Recrystallization from water gave **22β**, 74 mg (74%); mp 227—229 °C. $[\alpha]_D^{25}$ −68.2° (*c* 1.0, water). NMR (DMSO-d_6): δ 7.50 (br s, 4H, $CONH_2$), 6.45 (d, 1H, $J_{1'2'}$=3.6 Hz, H-1′), 5.40 (br d, 3H, OH, NH_2), 5.00 (d, 1H, OH), 4.70 (m, 2H, H-2′, OH), 4.45—3.80 (m, 2H, H-3′, H-4′), 3.50 (m, 2H, H-5′, 5″). UV: λ_{max}^{water} 210 nm (ε 26000), 301 nm (ε 6330), $\lambda_{max}^{pH\ 1}$ 208 nm (ε 21200), 304 nm (ε 2470), $\lambda_{max}^{pH\ 13}$ 219 nm (ε 19300), 303 nm (ε 6620). Found: C, 39.50; H, 4.98; N, 23.10%. Calcd for $C_{10}H_{15}O_6N_5$: C, 39.37; H, 5.02; N, 23.25%.

B. From ***21β***: A sample of **21β** (200 mg, 0.604 mmol) was hydrogenated in the same way as above to give **22β**, 82 mg (82%).

*4-Amino-1-(α-*D*-ribofuranosyl)pyrazole-3,5-dicarboxamide (**22α**).* A sample of **17α** (250 mg, 0.415 mmol) was hydrogenated in the same manner as above. Recrystallization from methanol and benzene gave **22α**, 100 mg (80%); mp 206—207 °C. $[\alpha]_D^{25}$ +35.0° (*c* 0.5, water). NMR (DMSO-d_6): δ 7.55 (br d, 4H, $CONH_2$), 6.80 d, 1H, $J_{1'2'}$=5.7 Hz, H-1′), 5.25 (br s, 2H, NH_2), 5.2—4.8 (m, 3H, OH), 4.5—4.0 (m, 3H, H-2′, H-3′, H-4′), 3.60 (d, 2H, H-5′, 5″). UV: λ_{max}^{water} 211 nm (ε 27700), 300 nm (ε 6900), $\lambda_{max}^{pH\ 1}$ 208 nm (ε 22500), 300 nm (ε 28600), $\lambda_{max}^{pH\ 13}$ 219 nm (ε 20100), 302 nm (ε 6800). Found: C, 39.64; H, 5.03; N, 23.01%. Calcd for $C_{10}H_{15}O_6N_5$: C, 39.37; H, 5.02; N, 23.25%.

The authors wish to thank Mr. Saburo Nakada of our laboratory for the microanalysis and Mr. Takehiro Ogasa for his technical assistance. We are also thankful for a cancer research grant from the Ministry of Education.

Photochemistry in Micellar System. II. Photochemical Reduction of β-Arylquinonesulfonates in the Presence of Cationic Surfactants.[1]

Koji KANO, Yuzo TAKADA, and Taku MATSUO*

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received March 14, 1975)

The photochemical reduction of sodium 9,10-phenanthraquinone-3-sulfonate (PQ) and sodium 1,2-naphthoquinone-4-sulfonate (NQ) to the corresponding diols has been studied in water containing cationic surfactants. Photoreduction of PQ was markedly accelerated in the presence of cationic surfactants whereas that of NQ was highly retarded. Both the acceleration and retardation of the photoreaction of these quinonesulfonates in the presence of cationic surfactants are explained as due to the formation of association complexes betwen the quinones and the surfactants.

The chemistry in heterogeneous systems is important in relation to that of biological systems. The rates of many bimolecular reactions have been found to be considerably affected in the presence of surfactant micelles which provide a convenient heterogeneous model system.[2-4] These micellar effects are generally explained in terms of the solubilization of substrate into the micellar interior, where the electrostatic or hydrophobic interaction between substrate, reactant and micelles is so large that the rate of reaction is modified. In the case of photochemical reaction, the nature of photoexcited state of the substrate would also be modified when it is solubilized into apolar micellar interior. The micellar catalysis in photochemical reactions is expected to be large than that in thermal reactions. Hautala and Letsinger have found that the nucleophilic substitution of 4-methoxy-1-nitronaphthalene with cyanide ion is enhanced by a factor of about 6800 by the addition of cetyltrimethylammonium chloride (CTACl);[5] the enhancement factor is unexpectedly large in comparison with that of the micellar effects in thermal reactions.[2-4]

We reported that the photochemically generated radical anions of 9,10-anthraquinonesulfonates are remarkably stabilized in the presence of either anionic or non-ionic surfactant.[6] We have investigated the photochemistry of β-arylquinonesulfonates in water containing various surfactants and the results are given in this paper. In the case of sodium 9,10-phenanthraquinone-3-sulfonate (PQ), the photoreduction was enhanced by the cationic surfactants, neither anionic nor non-ionic ones having any effect at all. The photoreduction of sodium 1,2-naphthoquinone-4-sulfonate (NQ), on the other hand, was highly retarded by cationic surfactants in comparison with that in pure water.[7] These effects of surfactants were recognized even at a concentration far below the critical micelle concentrations (CMC) of the surfactants. The formation of association complexes between the β-arylquinonesulfonates and the cationic surfactants was suggested to account for the experimental observation.

Experimental

Spectroscopic measurements were made with a Shimadzu UV-200 recording spectrometer, a Bruker WH-90 FT NMR spectrometer (90 MHz) and a JEOL JES-ME-3X ESR spectrometer (X-band).

Materials. PQ was prepared according to the procedure given by Werner.[8] Reagent grade NQ (Tokyo Kasei Kogyo Co. Ltd.) was further purified by recrystallization from aqueous methanol. Cetyltrimethylammonium bromide (CTABr) and chloride (CTACl) were recrystallized from water and methanol, respectively. Water was distilled and deionized with a column of ion-exchange resin.

Irradiation. The solution in a pyrex tube (φ 15 mm) was irradiated with a Riko 100W high-pressure mercury lamp combined with a Riko rotary photolysis apparatus RH400-10W at room temperature. The photolysis was undertaken under the aerobic conditions unless otherwise stated.

Quantum Yield. Monochromatic light was isolated from a Ushio 500W super high-pressure mercury arc USH-500D either with a combination filter of a Toshiba UV-D25, an aqueous nickel sulfate solution, and a glass plate (313 nm) or with a combination filter of a Toshiba UV-D1C and a UV-35 (365 nm). The light intensity was determined with a potassium ferrioxalate actinometer.

Results

Photolysis of PQ and NQ. NQ in water is photoreduced to sodium 1,2-dihydroxynaphthalene-4-sulfonate (NQH_2).[7] The quantum yield for the disappearance of NQ was determined to be 0.118 ± 0.007 (pH 6.80). On the other hand, PQ in an aerobic phosphate buffer (pH 6.80) is considerably stable against irradiation. The quantum yield for the disappearance of PQ ($[PQ]_0 = 1.0 \times 10^{-3}$ M) at 313 nm is $(5.5 \pm 1.5) \times 10^{-4}$. Under the unaerobic conditions, the photolysis of PQ is accelerated about two-fold, no photoproducts being identified by UV spectra. The photolysis of PQ (5.0×10^{-4} M) is markedly accelerated, however, in the presence of CTABr (4.0×10^{-3} M). Upon irradiation, new absorption bands appear at 232, 254, 258, 275, and 318 nm, the intensities of the absorption due to PQ at 260, 264, 324, and 416 nm decreasing. The spectrum of the photoproduct is in complete agreement with that of the authentic sample of sodium 9,10-dihydroxyphenanthrene-3-sulfonate (PQH_2) prepared by the zinc dust-hydrochloric acid reduction. The isosbestic points are observed at 262, 283, and 327 nm up to the 70% conversion. The quantum yield for the disappearance of PQ ($[PQ]_0 = 1.0 \times 10^{-3}$ M) in the presence of CTABr (4.0×10^{-3} M) is $(1.3 \pm 0.1) \times 10^{-2}$. CTACl ($4.0 \times 10^{-3}$ M) catalyzes the photoreduction more effectively than CTABr ($\phi_{CTACl}/\phi_{CTABr} = 2.3$).

* To whom inquiries should be addressed.

Unlike the case of PQ, the photoreduction of NQ (5.0×10^{-4} M) in water is highly retarded in the presence of CTACl (5.0×10^{-3} M) ($\phi_{CTACl}/\phi_0=0.076$). Since the photoreduction of NQ in water is not affected by the addition of Cl^- (2.0×10^{-3} M) ($\phi_{NaCl}/\phi_0=0.99$) in contrast to the case of Br^- ($\phi_{KBr}/\phi_0=0.45$), the retarding effect of CTACl should be ascribed to the binding of NQ with the surfactant.

Photoreaction of either PQ or NQ is not affected by the addition of anionic (sodium lauryl sulfate) or nonionic (polysorbate 80) surfactant above the CMC.

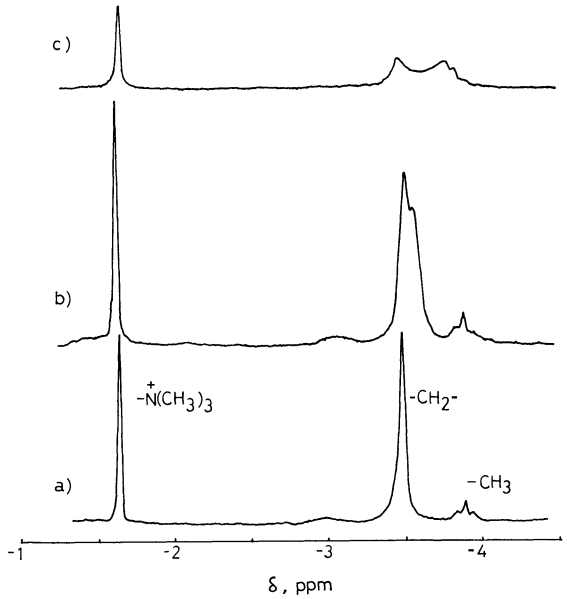

Fig. 1. NMR spectra of 2.0×10^{-2} M CTACl in D_2O: a) in the absence of PQ; b) with 4.0×10^{-3} M PQ; c) with 8.0×10^{-3} M PQ. The spectra were obtained by accumulation of 100-scans and the chemical shifts are expressed as measured downfield from HDO signal.

NMR of Quinone-CTACl System. The NMR spectra were examined in order to study the binding effect of the quinones with the CTACl-micelles. The variation of proton signals of CTACl in deuterium oxide with the concentration of PQ is shown in Fig. 1. The signals of $(CH_3)_3N^+$ and terminal $-CH_3$ protons are scarcely affected by the addition of PQ. As to the methylene protons, a part of the signal is shifted so that partially resolved two peaks are observed on the addition of PQ. At higher concentration of PQ, about a half of the methylene proton signals are shifted upfield, all the spectra showing considerable broadening due to the increased viscosity of the CTACl solution. Bunton studied the effects of added sodium alkylbenzenesulfonates on the proton signals of CTABr above the CMC and found appreciable broadening and upfield shift of the $(CH_3)_3N^+$ proton signals;[9] the methylene proton signals are separated into two groups, one shifted upfield and the other downfield. Bunton thus suggested that the phenyl group is inserted into the micelles so that the sulfonate group is in the aqueous environment (Fig. 2a). In the present experiment, the NMR spectra of the PQ-CTACl indicates that the $(CH_3)_3N^+$ protons are not affected by the magnetic anisotropy of the aromatic ring.

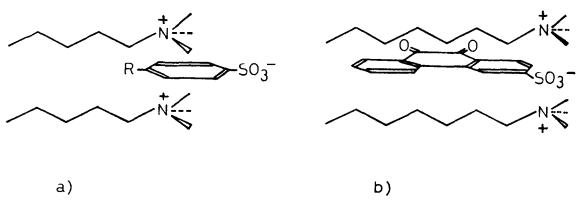

Fig. 2. Models of the binding of anionic substrates with cationic micelles: a) alkylbenzenesulfonate-CTABr; b) PQ-CTACl.

The SO_3^- group of PQ is considered to be associated with the $(CH_3)_3N^+$ of the surfactant so that the aromatic ring is incorporated into the hydrophobic micelle core (Fig. 2b).

Essentially the same results were obtained with the NQ–CTACl system.

Effect of Surfactant Concentration. If the effects of cationic surfactants on the photoreductions are due to the ordinary micellar effects, both the acceleration (PQ) and retardation (NQ) should become appreciable as the concentrations of the surfactants exceed the CMC. The effect of CTABr concentration on the photoreduction rate of PQ is shown in Fig. 3. Since the CMC generally

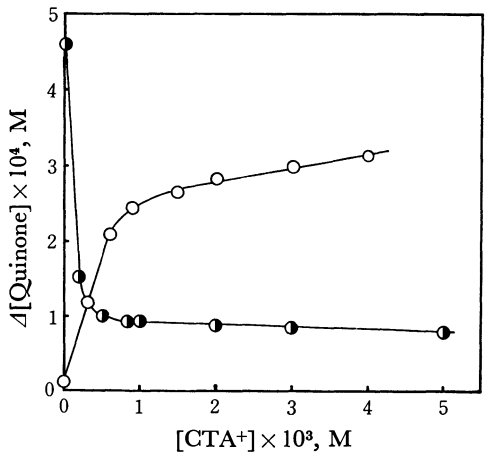

Fig. 3. The effect of cationic surfactant concentration on the β-arylquinones photochemistry. The aerobic aqueous solutions of PQ (—○—) and NQ (—◑—) (5.0×10^{-4} M) were irradiated for 15 and 2 min, respectively, at room temperature.

decreases on the addition of inorganic salts,[2-4] the experiments were carried out in non-buffered system (pH *ca.* 5.8). As shown in Fig. 3, the rate of photoreduction is significantly enhanced at the concentration of CTABr far below the CMC ($\sim10^{-3}$ M).[2] The onset of sharp decrease in the reaction rate of NQ was also located at CTACl concentration below the CMC (Fig. 3).[10] Further addition of surfactants above the CMC gave no effect on the photoreduction of either PQ or NQ. The results suggest that the effects of the cationic surfactants on the photoreactions of these β-arylquinonesulfonates are not attributed to the ordinary micellar effects. A similar effect of CTABr was observed in the fluorescent probe experiments with 8-toluidinyl-1-naphthalenesulfonate where the fluorescent yield is enhanced in the presence of CTABr below the CMC.[11]

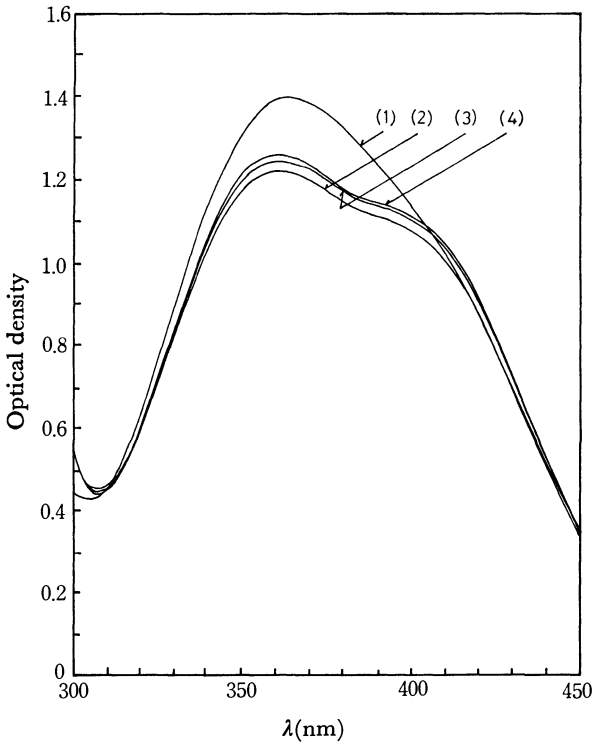

Fig. 4. Electronic absorption spectra of NQ in the presence of CTACl at various concentrations: none (1), 2.0×10^{-4} (2), 5.0×10^{-4} (3), $0.08-1.0\times10^{-2}$ M CTACl (4).

Association Complex of Quinonesulfonate and Cationic Surfactant. The NMR spectra indicate that the quinones with negatively charged group (SO_3^-) are associated with the positively charged nitrogen of the cationic surfactant. In fact, the association complex of PQ and CTABr gradually separated out of the freshly prepared equimolar solution of PQ and CTABr: mp 147—151 °C. IR (KBr disk) ν_{SO_2}, 1050, 1186; $\nu_{C=O}$, 1684; ν_{CH_2}, 2850, 2925; and δ_{CH_2}, 1465 cm^{-1}. The formation of the association complex was also verified by means of electronic absorption spectroscopy. The absorption spectra of NQ in the presence of various amounts of CTACl are shown in Fig. 4. When a small amount of CTACl is added to the aqueous NQ solution, the absorption band of NQ at 364 nm (ε_{max} 2.80×10^3) in water is split into two bands with λ_{max} at 361 (ε_{max} 2.50×10^3) and ~400 nm (ε_{max} $\sim2.0\times10^3$), respectively. The spectra of NQ in the presence of CTACl were in good agreement with those in organic solvents such as acetonitrile and alcohols. It is noteworthy that the absorption spectrum changes appreciably at the CTACl concentration far below the CMC. It may be suggested that the main body of NQ is in the hydrophobic environment which is provided by the long alkyl chain of the associated CTACl. The suggestion is supported by an examination of the absorption spectra of the equimolar solutions (5.0×10^{-4} M) of NQ and CTACl in water containing various amounts of acetonitrile. The π,π^* absorption band at 361 nm in water is shifted to 364 nm, and the one near 400 nm becomes obscure in 20—30% (v/v) acetonitrile–water solutions. The absorption spectrum observed in the 20—30% (v/v) acetonitrile–water agrees with that of NQ itself in water. At higher concentrations of acetonitrile (>40% (v/v)), the two absorption maxima at 361 and ~400 nm were restored. A possible explanation for the spectrophotometric behavior of the association complex in 20—30% (v/v) acetonitrile–water might be that the alkyl chain of the complex is elongated by the organic additive so that the water in the bulk phase become accessible to the main body of NQ.

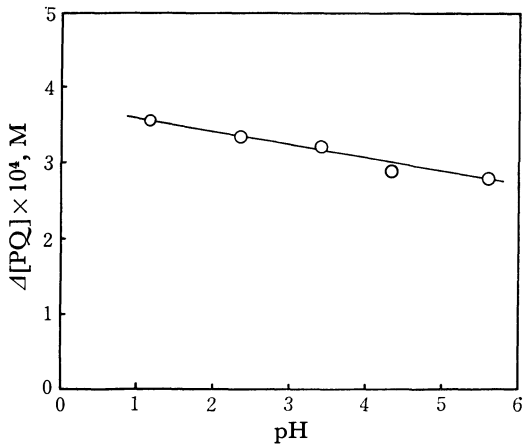

Fig. 5. Effect of pH on the disappearance of PQ in the presence of CTABr: $[PQ]_0=5.0\times10^{-4}$ M, $[SO_4^{2-}]=5.5\times10^{-2}$ M. The solutions were irradiated for 5 min at room temperature.

pH Effect. The pH effect on the photodecomposition of PQ in the presence of CTABr above the CMC is shown in Fig. 5. The pH (1.18—5.61) and the concentration of the sulfate ion ($[SO_4^{2-}]=0.055$ M) were adjusted with sulfuric acid and sodium sulfate, respectively. Disappearance of PQ is slightly depressed at higher pH. It appears that the photolysis of PQ is hardly affected by the hydroxide ions which are locally concentrated at the Stern layer of the cationic surfactant.

Deuterium Oxide Isotope Effect. The rate of formation of NQH_2 from NQ under irradiation in 99.8% D_2O is reduced in comparison with that in H_2O ($k_{H_2O}/k_{D_2O}=1.8$).[7] In the case of PQ (5.0×10^{-4} M), however, neither the disappearance of PQ nor the formation of

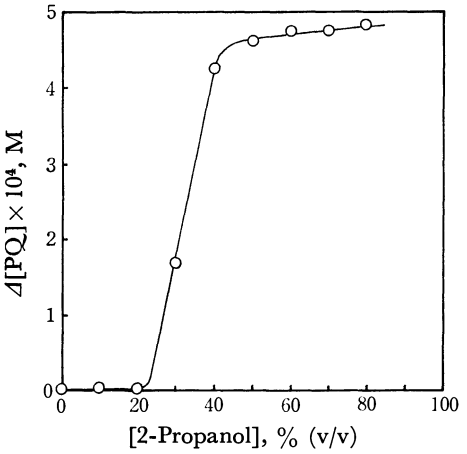

Fig. 6. Effect of 2-propanol concentration on the photoreduction of PQ in water. The solution of PQ (5.0×10^{-4} M) were irradiated for 2 min.

PQH_2 was affected by the use of deuterium oxide ($k_{H_2O}/k_{D_2O}=1.1$) in the presence of CTABr (4.0×10^{-3} M).

Photoreduction of PQ in 2-Propanol–water. In order to clarify the nature of the lowest photoexcited state of PQ in water, we examined the photochemical reduction of PQ in aqueous 2-propanol solutions. Figure 6 shows the effects of the concentration of 2-propanol on the photoreduction of PQ. Rapid photoreduction proceeds when the concentration of 2-propanol exceeds 20% (v/v), whereas PQ is scarcely photolyzed at low 2-propanol concentration. A linear relationship between the reciprocal of the quantum yields of the photoreduction and the reciprocal of the concentrations of 2-propanol is expected if the same chemical species is responsible for the reaction throughout the concentration range of 2-propanol investigated.[12] Contrary to expectation, a typical sigmoid profile was obtained (Fig. 6). The result suggests that the lowest excited state of PQ in water is an inactive π,π^* triplet, while that in 2-propanol is a n,π^* triplet. The critical concentration of 2-propanol for this disposition of the photoexcited species seems to be approximately 20% (v/v). The lowest photoexcited states of NQ are similarly suggested to be a π,π^* triplet in water and n,π^* triplet in organic media.[7]

Discussion

In the photoreduction of NQ in water to NQH_2,[7] it was found that:

1) The yield of NQH_2 is *ca.* 50%.

2) The quantum yield for the disappearance of NQ under irradiation at 365 nm is 0.118 ± 0.007 (pH5.00—6.80).

3) The radical anion of NQ ($NQ^{\cdot-}$) is detected by the ESR spectra when NQ is irradiated at pH 6.80, while no signal is observed at pH *ca.* 5.8.

4) The reactive species in this photoreduction is the π,π^* triplet of NQ.

5) The deuterium oxide isotope effect for the formation of NQH_2 (k_{H_2O}/k_{D_2O}) is 1.8.

Table 1. Effect of substrate concentration on quantum yields for the disappearance of NQ in water at 365 nm

$[NQ]\times10^3$, M	Quantum Yield
1.97	0.122
3.99	0.076
5.98	0.064
8.00	0.049
10.00	0.045

We have found in the present work that the quantum yields for the disappearance of NQ decrease with increase of the initial concentrations of NQ (Table 1). Therefore the D/D* scheme postulated in the photoreaction of 9,10-anthraquinone-2-sulfonate[13,14] should be excluded from the possible mechanisms.

$$NQ^* + NQ \longrightarrow NQ^{\cdot-} + NQ^{\cdot+} \quad (1)$$

We suggest the following sequence of reactions which lead to the photoreduction of NQ in water:[7]

$$NQ^* + OH^- \longrightarrow NQ^{\cdot-} + \cdot OH \quad (2)$$

$$NQ^{\cdot-} + H^+ \longrightarrow NQH\cdot \quad (3)$$

$$2NQH\cdot \longrightarrow NQH_2 + NQ \quad (4)$$

$$NQ + \cdot OH \longrightarrow NQ(OH)\cdot \quad (5)$$

The mechanism has not been confirmed, but it should be emphasized that water must be the reducing agent in the photoreduction of NQ.

The NMR spectra of the CTACl–micellar system containing NQ show that the SO_3^- group of NQ is associated with the positively charged nitrogen of CTACl so that the aromatic ring is incorporated into the hydrophobic micelle core. The electronic absorption spectra of NQ indicate that NQ is associated with CTACl so that the long alkyl chain surrounds the main body of NQ. Thus water can be excluded from the reaction site even at the concentrations of CTACl below the CMC. The photoreaction of NQ will be thus retarded in the presence of CTACl both above and below the CMC.

The photoreduction of PQ to PQH_2 was accelerated by the addition of the cationic surfactants (CTABr and CTACl). Neither ESR signal nor deuterium oxide isotope effect was observed in this case. Thus the mechanism of the photoreduction of PQ should differ from that of NQ in water. The surfactant concentration profile (Fig. 3) clearly indicates that the acceleration of the photolysis of PQ by cationic surfactants is not due to the ordinary micellar effects. As in the case of NQ–CTACl system, PQ and CTABr seem to form an association complex so that the main body of PQ would be surrounded by the long alkyl chain. The model might also be used to explain the fact that PQH_2 is completely stabilized toward oxidation with air in the presence of CTABr, whereas PQH_2 in pure water is rapidly oxidized to the original quinone. Under these circumstances, the photoexcited PQ would easily abstract hydrogen atom from the alkyl chain of the associated CTABr. If the hydrogen atom is abstracted from a free CTABr molecule, it is hardly expected for the reaction yield to reach an asymptotic value at such low CTABr concentration as in Fig. 3. The small deuterium oxide isotope effects is also explained by the same model. The photoreduction of PQ is influenced neither by the addition of sodium lauryl sulfate nor by polysorbate 80, inspite of the fact that they are expected to be better hydrogen donor than CTABr and CTACl due to the presence of $-OCH_2-$ group. All the data could be explained if the nature of the photoexcited state and its chemical reactivity vary with the change in environment surrounding PQ as summarised below.

1) The photoexcited PQ in water is considered to be the π,π^* triplet state. Since hydrogen abstraction is hardly induced by this particular species, no photoreduction takes place even in the presence of good hydrogen donors.

2) The lowest excited state of the association complex between PQ and CTABr is considered to be a n,π^* triplet so that hydrogen abstraction is easily induced in this case.

3) The hydrogen abstraction in the associated complex may be facilitated by the proximity effects of the alkyl chain (hydrogen donor) around the photoexcited PQ.

Table 2. The effects of solvents and organic additives on the photolysis of association complex between PQ and CTABr[a)]

Solvent	Additive	Irradiation time, min	$\Delta[PQ]\times10^4$, M
H_2O[b)]	—	15	2.09
CH_3CN	—	20	0.84
CH_3CN	CTABr(5.0×10^{-3}M)	20	0.15
CH_3CN	2-propanol (1 vol%)	1.25	4.30

a) $[\text{Association complex}]_0=5.0\times10^{-4}$ M. b) $[PQ]_0=5.0\times10^{-4}$ M, $[CTABr]=6.0\times10^{-4}$ M.

The effects of solvents and organic additives were examined in order to study the photochemical behavior of the association complex between PQ and CTABr (Table 2). The rate of reduction in acetonitrile was considerably less than that in water. The alkyl chain of CTABr surrounding the main body of associated PQ in water would be elongated in organic solvents. The rate of the hydrogen abstraction from the alkyl chain can be consequently reduced in acetonitrile. Addition of excessive CTABr quenches the photoreaction of the association complex in acetonitrile as expected from the heavy atom effects. It should be recalled, however, that the presence of CTABr in excess amounts did not quench the photolysis of PQ in water (Fig. 3). The difference in the effect of CTABr between these two solvents can be attributed to whether the reaction center of PQ is surrounded by the alkyl chain or not.

The same type of intramolecular hydrogen abstraction may also be expected to take place in the NQ-CTACl system as in the case of PQ-CTABr association complex. However, the photodecomposition of NQ in water was simply retarded on the addition of CTACl. It is suggested that the quantum efficiency for the hydrogen abstraction in the association complex between NQ and CTACl is much lower than that for the electron abstraction of NQ from the hydroxide ion.

The Photosensitized Oxygenation of Furanoeremophilanes. I. The Isomeric Hydroperoxides from Petasalbin and Their Transformations to Lactones

Keizo NAYA, Reizo KANAZAWA, and Michikazu SAWADA

Department of Chemistry, Faculty of Science, Kwansei Gakuin University, Uegahara, Nishinomiya, Hyogo 662

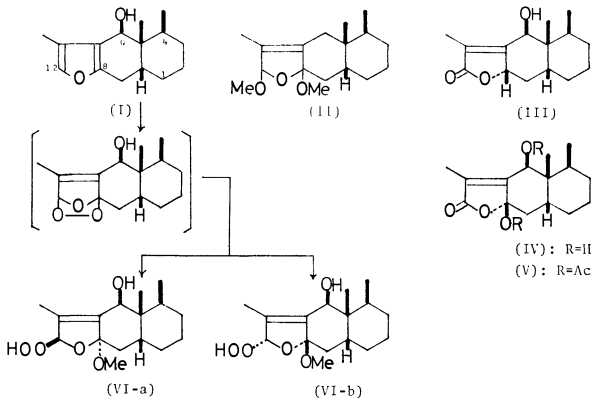
(Received April 3, 1975)

The photosensitized oxygenation of petasalbin I gave almost quantitatively a crystalline mixture of two isomeric hydroperoxides, V-a and V-b, both of which were then transformed to the corresponding lactones, VI-a and VI-b, respectively, in good yields. The stereochemistry of these hydroperoxides and lactones has been established by spectral and chemical methods. Furthermore, two natural lactones, III and IV, were prepared by the reduction of the hydroperoxides.

Petasalbin I has been isolated from *Petasites*[1] and *Ligularia*[2,3] species, and its absolute configuration has already been established. Then, from *Petasites officinalis* an interesting compound, II, was isolated by Šorm *et al.*, and for its formation it was postulated that the peroxides of methanol must play a role in a plant.[4,5] On the other hand, the dye-sensitized photooxygenation of furans has been extensively studied[6,7] and the oxygenation mode in methanol has been demonstrated, in that the reaction proceeds to give a cyclic peroxide by the 1,4-addition of oxygen to a furan ring, an addition which is often followed spontaneously by the addition of methanol, thus affording a 2-methoxy-2,5-dihydrofuran derivative.[6]

We have oureselves previously investigated the photosesnsitized oxygenation[8] of petasalbin I isolated from *Petasites japonicus* Maxim. as a biogenetic-type oxidation to the lactone homologues, such as the known 6β-hydroxyeremophilenolide, III,[2] and the newly isolated 6β,8β-dihydroxyeremophilenolide, IV, included in the same plant.

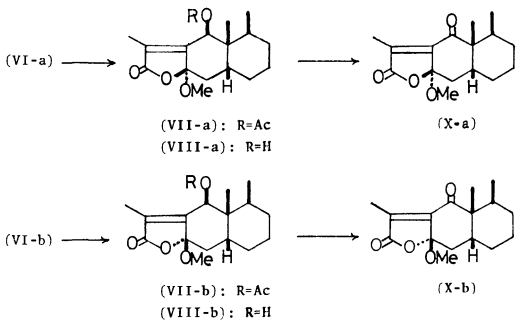
The present paper will report on the physical and chemical properties of the hydroperoxides, VI-a and VI-b, prepared from petasalbin I, and also on the stereochemistry of the hydroperoxides, VI-a,b, and their derivatives. Furthermore, the reduction products of VI-a,b were examined and found to include the same products as the natural lactones, III and IV.



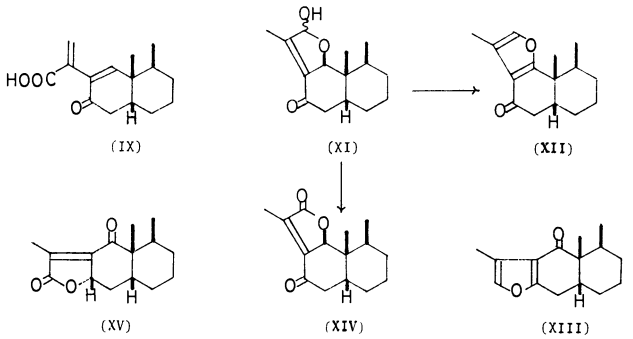
Scheme 1

Petasalbin I in methanol was photooxygenated, in the presence of Rose Bengal as a sensitizer, by irradiation with a circular fluorescent lamp (30 watt) under a bubbling of air. The reaction mixture was found on tlc to contain two compounds, which were separated by careful fractional crystallization to afford two hydroperoxides, (VI-a) (mp 119.3—119.5 °C (dec)) and (VI-b) (mp 116.0—116.5 °C (dec)). Both compounds have the same molecular formula, $C_{16}H_{26}O_5$, and both are positive to a peroxide test (KI–AcOH). Thus, there was no symptom of the exsistence of a cyclic ozonide-like intermediate, as in Scheme 1, and we could initially obtain the methanol adducts, VI-a,b, whose IR, UV, and NMR spectra were very similar to each other, suggesting that both are stereoisomers caused by a newly introduced 2-methoxy-5-hydroperoxy-2,5-dihydrofuran grouping. They showed these UV spectra: end absorption in both; IR bands at 3480 and 3350 (H-bonded OH), 1700 and 1630 cm^{-1} (C=C double bond) in VI-a, and at 3400 and 3330 (H-bonded OH), 1700 and 1630 cm^{-1} (C=C double bond) in VI-b; NMR signals (acetone-d_6): δ 11.13 (s, OO–H), 5.58 (s, OOCH), 3.08 (s, OCH_3) in VI-a, and 11.25 (s, OO–H), 5.70 (s, OOCH), 3.15 (s, OCH_3) in VI-b, besides the common signals with the original petasalbin I. The above results, therefore, led to the VI-a and VI-b structures for the hydroperoxides except for the configuration of the 8-methoxy and 12-hydroperoxy groups. These hydroperoxides, VI-a,b, were relatively stable in the crystalline state, but decomposed considerably in solution or upon chromatography on silica gel (Merck, grade II). Furethermore, the reduction of the hydroperoxides, VI-a,b, with sodium sulfite, sodium borohydride, and a platinum catalyst gave no principal or selective reduction product and rather complicated results, accompanied by decomposition, as will be described in detail later.

Finally, the hydroperoxides, VI-a,b, were quantita-



Scheme 2



Scheme 3

tively converted to two substances, epimeric 6β-acetoxy-8α-methoxylactone (VII-a) (mp 106.5—108.0 °C) and the corresponding 8β-methoxylactone (VII-b) (mp 174.5—175.5 °C) by acetylation with acetic anhydride–pyridine.

For the determination of the configuration, therefore, each hydroperoxide was transformed into a 6-oxo derivative, X-a,b, according to Scheme 1—that is, by acetylation followed by the partial hydrolysis of the 6β-acetoxy group and subsequently by oxidation with Jones' reagent. Both the first products, VII-a and VII-b, showed similar IR bands at 1760 (α,β-unsaturated lactone C=O), and 1740 cm^{-1} (C=C double bond) and similar NMR spectra (cf. Table 1 and Experimental section). By subsequent partial hydrolysis, compounds VII-a and VII-b gave 6β-hydroxy derivatives, (VIII-a) (mp 167.5—168.0 °C) and (VIII-b) (mp 129.5—130.2 °C), respectively, both of which showed NMR spectra closely similar to that of 6β-hydroxyeremophilenolide III except for the signals due to the 8-methoxy groups instead of the 8β-proton in III. On the other hand, a mixture of the 6β-acetoxy-8(α and β)-methoxylactones, VII-a,b, was treated with an excess of alkaline to afford quantitatively an acid (IX) as the sole product. The IX acid, $C_{15}H_{20}O_3$ (mp 96.0—97.0 °C), exhibited IR bands at 3400—2400 (OH in carboxyl group), 1695 (C=O in carboxyl group), 1680 (α,β-unsaturated ketone), 1615 (C=C double bond), 950 cm^{-1} (end-methylene in a conjugated diene system); NMR signals at δ 6.70 (s, 1H, 6-H), 6.28 and 5.69 (each d, J=1.5 Hz, 13-CH_2=), and its UV maximum at 239 nm. The above results led to the IX structure for the acid; hence, the 6β-acetoxy compounds, VII-a and VII-b, obviously became epimers with regard to the configuration of the 8-methoxy groups.

The configurational assignments of the 8-methoxy groups in the corresponding epimers (VI—VIII, and IX) were achieved by a comparison of the NMR spectra, ORD–CD curves, specific rotations, and adsorption properties (Table 1, Fig. 1, and Fig. 2).

The conformation of α,β-unsaturated keto-group in a pair of 6-oxolactones, (X-a) (mp 99.0—100.0 °C) and (X-b) (mp 160.5—161.5 °C), was defined by the ORD–CD curves. Similar effects[9] observed in the cisoid α,β-unsaturated ketones are to be expected for the 6-oxo compounds, X-a,b. The X-a,b epimers have opposite signs; those enantiomeric chiralities seemed to be dominated by the helicity of the α,β-unsaturated ketone moiety. Thus, on the basis of a consideration with the Dreiding model, a pair of 6-oxolactones, X-a,b, with intense negative and positive Cotton effects in the 250—

b*: broad singlet. a): measured with a methanol solution.

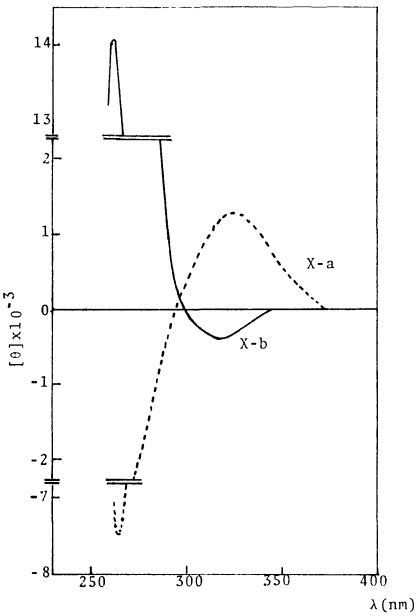

Fig. 2. Circular dichroism curves of 6-oxo-8-methoxylactone X-a and X-b.

400 nm region have been alloted the X-a and X-b formulas, those which have left- and right-handed helicities respectively.

In the NMR spectra, only the 8α-methoxy derivatives showed homoallylic couplings[10] (1.0—1.5 Hz) between 6–H and 13–CH_3. Upon the Dreiding model, the angles between the two bonds lie around 90° and 20° in the 8α- and 8β-methoxy derivatives respectively. The observed coupling, therefore, is consistent with the above assignment.

A further comparison between the corresponding 8-methoxy epimers also revealed the characteristics of this configurational correlation. The NMR spectra of the 8α-methoxy compounds exhibited chemical shifts due to 14-methyls at a lower field than those due to 15-methyls, and the chemical shifts were reversed in the 8β-epimers. The 8β-methoxy compounds have stronger positive rotations than the 8α-series except for the 6-oxo derivatives. The 8β-methoxy derivatives showed stronger adsorptive properties than the 8α-epimers, suggesting that the 8β- and 8α-series have *cis*- and *trans*-like geometries respectively, in agreement with the above configurational assignment.

Now the configuration of the hydroperoxides, VI-a and VI-b, can be explained in terms of the approved mechanism that the *cis*-1,4-addition of an oxygen molecule should occur from one side to the furan ring surface, followed by the attack of methoxide from another side to give hydroperoxides as in the stereoformulas, VI-a and VI-b.

Next we examined several reduction methods for the stabilization of the labile hydroperoxy group.

a) By Sodium Sulfite. After the photooxygenation of petasalbin I in methanol, the solution was immediately subjected to reduction with sodium sulfite without any isolation of hydroperoxides. The products were separated by repeated column chromatography on silica gel to afford 6β-hydroxyeremophilenolide (III, 7%) (mp 204.0—205.0 °C), 6β-hydroxy-8α-methoxyepieremophilenolide VIII-a (5%), and two other unknown products, (IV, 1.8%) and (XI, 36%).

The IV product, $C_{15}H_{22}O_4$ (mp 209.0—211.5 °C, $[\alpha]_D$ +172°), showed the presence of hydroxyl groups at 3500 and 3250 cm^{-1}, α,β-unsaturated γ-lactone groups at 1730 and 1695 cm^{-1}, and its UV maximum at 218 nm. The MS spectrum indicated the presence of two hydroxyl groups, *i. e.*, *m/e* 266 (M^+), *m/e* 248 (M−18), and *m/e* 230 (M−36). The structure was proved by a comparison of the NMR spectrum with those of 6β-hydroxyeremophilenolide III and the epimeric 6β-hydroxy-8-methoxylactones, VIII-a,b. The configuration of the 8-hydroxyl group was identified as β-substituent from the chemical shifts of the 14- and 15-methyls, and also from the absence of homoallylic coupling between 6–H and 13–CH_3, according to the generality mentioned above.

On the other hand, the crude extract from the rhizomes of *Petasites japonicus* Maxim. was reinvestigated in order to examine the lactone components by chromatography on silica gel; the natural 6β,8β-dihydroxyeremophilenolide (IV) (mp 211.0—212.0 °C, $[\alpha]_D$ +169°) was isolated from the polar part.

The XI product was a colorless oil and was positive to an Ehrlich test. XI showed IR bands at 3400 (OH), 1685, and 1650 cm^{-1} and its UV maximum at 250 nm (α,β-unsaturated ketone). The appearance of the above keto-group can be derived from the fission of the dihydrofuran ring, followed by the isomerization of the double bond and recyclization with the 6β-hydroxyl group. As the above color-test suggested that XI is closely connected with a furan derivative, XI was heated in acetic anhydride at 90 °C for 1 hr to afford quantitatively isoligularone (XII)[11] (mp 147.0—148.0 °C, $[\alpha]_D$ +39.0°), which was an isomer of ligularone (XIII)[1-b,c] (mp 66.0—67.5 °C), prepared from petasalbin I with chromium trioxide-pyridine. Jones' oxidation of XI gave 8-oxoisoeremophilenolide (XIV) (mp 76.5—77.5 °C, $[\alpha]_D$ +31.5°), which showed IR bands at 1760 (lactone C=O), 1695, and 1660 cm^{-1} and its UV maximum at 245 nm (α,β-unsaturated ketone). Its NMR spectrum showed signals at 5.42 (q, J=2.5 Hz, 6–H) and 1.92 (d, J=2.5 Hz, 13–CH_3) with homoallylic coupling. The XIV lactone distinctly differs from the isomeric ketolactone (XV)[1-a] (mp 124.0—126.0 °C, $[\alpha]_D$ −27.1°), prepared from 6β-hydroxyeremophilenolide III by Jones' oxidation. The configuration, therefore, can be assigned the XIV formula.

The former alcohol, XI, was indicated to be an epimeric mixture attributable to the orientation of the 12-hydroxyl group in its NMR spectrum—namely, pairs of signals centered at 5.32 and 5.12 (1H), 5.69 and 5.55 (1H), and 0.78 and 0.70 due to the 6–H, 12–H, and 15–CH_3 groups respectively. However, attempts to separate the mixture were unsuccessful.

b) By Sodium Borohydride. A crystalline mixture of hydroperoxides, VI-a,b, was treated with a methanol solution of sodium borohydride at room temperature, and the product was chromatographed on deactivated alumina (Merck, grade IV) to afford petasalbin I (30.2 %) and 6β-hydroxyeremophilenolide III (20%).

c) By a Platinum Catalyst. On hydrogenation with a platinum catalyst in acetic acid, the hydroperoxides,

VI-a,b, gave III (3.7%), 6β-hydroxy-8α-methoxyepieremophilenolide VIII-a (18.4%), and 6β,8β-dihydroxyeremophilenolide IV (24.5%).

When a mixture of the VI-a,b hydroperoxides was chromatographed on silica gel (Merck, grade II) in order to separate them, the eluate included recovered hydroperoxides (52%), IV (21%), and a mixture of lactones VIII-a,b (9%).

These reductions and silica gel chromatography invariably showed poor reproducibilities in the yield ratios of their products.

Experimental

The IR, UV, ORD-CD, and mass spectra were taken with Hitachi EPI-G3, Cary 14, JASCO ORD-5, and Hitachi RMU-6 spectrophotometers respectively. The NMR spectra were recorded with a Hitachi R-20B (60 MHz) spectrometer, and the chemical shifts are reported in δ-values (with TMS as the internal reference). The optical rotations were measured with a Perkin-Elmer 141 polarimeter. The tlc were run on Kieselgel G (Merck).

Isolation of Petasalbin (I), 6β-Hydroxyeremophilenolide (III), and 6β,8β-Dihydroxyeremophilenolide (IV). The dried rhizomes of *Petasites japonicus* Maxim. were extracted with ether at room temperature. The neutral oil (24 g) was chromatographed on neutral alumina (400 g, grade III). Elution with benzene and then benzene–ethyl acetate (20: 1) gave two fractions, including mainly petasalbin I and 6β-hydroxyeremophilenolide III respectively. Each fraction was purified by repeated chromatography on alumina or silica gel and by subsequent recrystallization to afford petasalbin I (2 g, tlc: R_f, 0.30, benzene) and 6β-hydroxyeremophilenolide III (1.9 g, tlc: R_f, 0.50, benzene–ethyl acetate, 5: 1).

The collected polar fraction (40 g), eluted with benzene–ethyl acetate (20: 1), was chromatographed on silica gel (400 g) with the same solvent to give crude III (1.4 g) and 6β,8β-dihydroxyeremophilenolide IV (2.2 g, R_f, 0.53, benzene–ethyl acetate, 2: 1).

Petasalbin (I):[1c] mp 79.0—81.0 °C, colorless needles (from ether or light petroleum), $[\alpha]_D^{22}$ −13.0° (*c*, 1.0, $CHCl_3$). (Found: C, 76.64; H, 9.40%).

6β-Hydroxyeremophilenolide (III):[2] mp 204.5—205.5 °C, colorless prisms (from ethyl acetate), $[\alpha]_D^{23}$ +203° (*c*, 1.01, $CHCl_3$). (Found: C, 72.05; H, 8.80%). The spectral data of the above compounds, I and III, are consistent with those reported in the lit. for 1-c and 2).

6β,8β-Dihydroxyeremophilenolide (IV): mp 211.0—212.0 °C, prisms (from methanol or ethyl acetate); $[\alpha]_D^{16}$ +169° (*c*, 0.985, $CHCl_3$); IR ($CHCl_3$): 3525, 3250, 1760, 1005, 990 cm^{-1}; NMR ($CDCl_3$): 4.60 (s, 6-H), 2.70 (br s, 2×OH), 2.07 (s, 9-CH_2), 1.87 (s, 13-CH_3), 1.11 (s, 15-CH_3), 0.78 (non-resolvable methyl signal, 14-CH_3).

Found: C, 67.46; H, 8.42%. Calcd for $C_{15}H_{22}O_4$: C, 67.64; H, 8.33%.

6β,8β-Diacetoxyeremophilenolide (V). 6β,8β-Dihydroxyeremophilenolide IV (241 mg) was dissolved in acetic anhydride (2.5 ml) and pyridine (1 ml), and the mixture was left at room temperature for 3 days. Subsequent working up in the usual manner gave quantitatively a crude diacetate, which was crystallized from isopropyl ether as prisms; mp 119.5—120.5 °C; $[\alpha]_D^{23}$ +64.7° (*c*, 1.00, $CHCl_3$); IR(KBr): 1780, 1760, 1740, 1250, 1170, 993 cm^{-1}, ($CHCl_3$): 1765, 1740sh, 1240, 993 cm^{-1}; NMR (CCl_4): 5.78 (s, 6-H), 1.95 (s, 13-CH_3), 1.90 (s, 2×OAc), 0.95 (s, 15-CH_3), 0.83 (non-resolvable methyl signal, 14-CH_3).

Found: C, 64.89; H, 7.36%. Calcd for $C_{19}H_{26}O_6$: C, 65.12; H, 7.48%.

The Photosensitized Oxygenation of Petasalbin (I) and Isolation of Hydroperoxides, (VI-a) and (VI-b). A stirred solution of petasalbin I (1.19 g) and Rose Bengal (47.5 mg) in methanol (60 ml) was irradiated with a circular fluorescent lamp (30 watt) for 3 hr under the bubbling of air. After the subsequent evaporation of the methanol *in vacuo*, the residue was extracted with benzene. The benzene extract was washed with water, and passed through a column filled with anhydrous sodium sulfate for drying and taking out the dye-stuff. On tlc, the benzene solution showed the existence of two products. The removal of the solvent *in vacuo* gave a colorless, crystalline mixture (1.4 g) of hydroperoxides, VI-a (R_f, 0.50, benzene–ethyl acetate, 3: 1) and VI-b (R_f, 0.40). The mixture was separated by fractional recrystallization from benzene. Thus, the evaporation of the solvent to some extent deposited a less-soluble compounds, VI-a; subsequently the mother liquor was fractionated by crystallization to collect VI-a and then VI-b.

Hydroperoxide (VI-a): mp 119.3—119.5 °C, colorless needles (from benzene), $[\alpha]_D^{24}$ +2.5° (*c*, 1.02, MeOH); positive to a peroxide test (KI–AcOH); IR(KBr): 3480, 3350, 1700, 1630, 1140, 1060, 930 cm^{-1}; MS: *m/e* 280 (M^+-18), *m/e* 109 (base peak); NMR (acetone-d_6): 11.13 (s, OO-H), 5.58 (s, OO-CH), 4.72 (split br s, 6-H), 4.13 (s, 6-OH), 3.08 (s, OCH_3), 1.99 (s, 9-CH_2), 1.73 (d, J=1.0 Hz, 13-CH_3), 0.94 (d, J=7.2 Hz, 14-CH_3), 0.78 (s, 15-CH_3).

Found: C, 64.37; H, 8.74%. Calcd for $C_{16}H_{26}O_5$: C, 64.40; H, 8.78%.

Hydroperoxide (VI-b): mp 116.0—116.5 °C, $[\alpha]_D^{24}$ +46.1° (*c*, 1.01, MeOH); positive to a peroxide test; IR(KBr): 3400, 3330, 1700, 1630, 1135, 1075, 980 cm^{-1}; MS: *m/e* 262 (M^+-36), *m/e* 78 (base peak); NMR (acetone-d_6): 11.25 (s, OO-H), 5.70 (s, OO-CH), 4.36 (s, 6-H), 4.22 (s, 6-OH), 3.15 (s, OCH_3), 1.73 (s, 13-CH_3), 1.00 (s, 15-CH_3), 0.72 (d, J=5.5 Hz, 14-CH_3).

Found: C, 64.75; H, 9.02%. Calcd for $C_{16}H_{26}O_5$: C, 64.40; H, 8.78%.

6β-Acetoxy-8α-methoxyepieremophilenolide (VII-a). Hydroperoxide VI-a (171.4 mg) was dissolved in pyridine (0.5 ml) and acetic anhydride (1 ml), and the mixture was left overnight at room temperature. Subsequent working up in the usual manner gave quantitatively the VII-a acetate, which was then crystallized from isopropyl ether as prisms: mp 106.5—108.0 °C, $[\alpha]_D^{24}$ −190.4° (*c*, 1.01, $CHCl_3$); UV: λ_{max}^{MeOH} 217 nm (ε, 10500); IR(KBr): 1760, 1740, 1700, 1230, 1060, 960 cm^{-1}; NMR ($CDCl_3$): 5.92 (d, J=1.4 Hz, 6-H), 3.20 (s, 8-OCH_3), 2.16 (s, 6-OAc), 1.85 (d, J=1.4 Hz, 13-CH_3), 0.97 (d, J=7.6 Hz, 14-CH_3), 0.85 (s, 15-CH_3).

Found: C, 67.10; H, 8.15%. Calcd for $C_{18}H_{26}O_5$: C, 67.06; H, 8.13%.

6β-Acetoxy-8β-methoxyeremophilenolide (VII-b). Hydroperoxide VI-b (125.5 mg) was acetylated in a similar manner to afford the acetate (VII-b, 118.2 mg), which was then crystallized from isopropyl ether as prisms: mp 174.5—175.5 °C, $[\alpha]_D^{23}$ +185.5° (*c*, 1.03, $CHCl_3$); IR(KBr): 1760, 1740, 1700, 1250, 1180, 1080, 925 cm^{-1}; NMR ($CDCl_3$): 5.62 (s, 6-H), 3.00 (s, 8-OCH_3), 2.05 (s, 6-OAc), 1.94 (s, 13-CH_3), 0.98 (s, 15-CH_3), 0.77 (d, J=5.5 Hz, 14-CH_3).

Found: C, 67.25; H, 8.13%. Calcd for $C_{18}H_{26}O_5$: C, 67.06; H, 8.13%.

Alkaline Hydrolysis of Acetates, (VII-a) and (VII-b). *a) 6β-Hydroxy-8α-methoxyepieremophilenolide (VIII-a).* The acetate VII-a (65.7 mg) was dissolved in an equimolecular potassium hydroxide–methanol solution (0.93 ml, 0.22 N), after which the mixture was left at room temperature for 1 hr. After the removal of the solvent and acidification with 1% sulfuric

acid, the reaction mixture was extracted with ether. The extract was washed with a saturated sodium hydrogen carbonate solution and water. The subsequent evaporation of the solvent gave 6β-hydroxy-8α-methoxyepieremophilenolide VIII-a (50 mg), which was then crystallized from light petroleum as needles: mp 167.5—168.0 °C, $[\alpha]_D^{23}$ −187.0° (*c*, 0.96, $CHCl_3$); IR(KBr): 3460, 1740, 1680, 1165, 1080, 1070, 940 cm^{-1}; UV: λ_{max}^{MeOH} 225 nm (ε, 7500); MS: *m/e* 280 (M^+), *m/e* 109 (base peak); NMR ($CDCl_3$): 4.95 (d, J=1.5 Hz, 6-H), 3.14 (s, 8-OCH_3), 2.62 (s, OH), 2.02 (d, J=1.5 Hz, 13-CH_3), 0.98 (d, J=7.0 Hz, 14-CH_3), 0.78 (s, 15-CH_3).

Found: C, 68.60; H, 8.68%. Calcd for $C_{16}H_{24}O_4$: C, 68.54; H, 8.63%.

b) 6β-Hydroxy-8β-methoxyeremophilenolide (VIII-b). The hydrolysis of the acetate VII-b (222 mg) was performed in a similar manner. The product was obtained quantitatively and was crystallized from ethyl acetate–light petroleum as prisms: mp 129.5—130.2 °C, $[\alpha]_D^{23}$ +205.1° (*c*, 1.01, $CHCl_3$); IR(KBr): 3450, 1730, 1690, 1210, 1190, 1130, 1090, 920 cm^{-1}, ($CHCl_3$): 3500, 1755, 1010, 1002, 992, 970, 930 cm^{-1}; NMR ($CDCl_3$): 4.49 (s, 6-H), 3.27 (s, 8-OCH_3), 2.71 (s, 6-OH), 2.00 (s, 9-CH_2), 1.87 (s, 13-CH_3), 1.08 (s, 15-CH_3), 0.75 (d, J=5.0 Hz, 14-CH_3).

Found: C, 68.87; H, 8.71%. Calcd for $C_{16}H_{24}O_4$: C, 68.54; H, 8.63%.

Alkaline Hydrolysis of the Mixture of 6β-Acetoxy-8(α and β)-Methoxylactones, (VII-a) and (VII-b). A mixture of 6β-acetoxy-8(α and β)-methoxylactones, VII-a, b was prepared from petasalbin I by photooxidation as has been described above, followed by acetylation. The crystalline mixture (6.138 g) was dissolved in a 1.84 N potassium hydroxide–methanol solution (80 ml) and then left at room temperature for 36 hr. After acidification with 2 N sulfuric acid, the mixture was extracted with ether. Subsequent working up in the usual manner gave a viscous oil (5.41 g), which crystallized on standing. The crystalline mass was recrystallized from isopropyl ether-light petroleum to afford the pure unsaturated acid IX (4.07 g) as needles: mp 96.0—97.0 °C, $[\alpha]_D^{22}$ +20.5° (*c*, 1.09, $CHCl_3$); IR (CCl_4): 3400—2300, 1695, 1680, 1615, 950, 928 cm^{-1}; UV: λ_{max}^{MeOH} 239 nm (ε, 5580); MS: *m/e* 248 (M^+), 133 (base peak); NMR (CCl_4): 10.5 (br s, COOH), 6.70 (s, 6-H), 6.28 and 5.69 (each d, J=1.5 Hz, 13-CH_2=), 1.13 (s, 15-CH_3), 0.92 (d, J=6.7 Hz, 14-CH_3).

Found: C, 72.24; H, 7.88%. Calcd for $C_{15}H_{20}O_3$: C, 72.55; H, 8.12%.

Jones' Oxidation. a) 6-Oxo-8α-methoxyepieremophilenolide (X-a). Jones' reagent (0.18 ml) was added to a stirred solution of 6β-hydroxy-8α-methoxylactone VIII-a (97.8 mg) in acetone (4 ml) over a period of 0.5 hr under cooling with ice-water. After stirring for a further 2.5 hr and after the decomposition of the excess reagent with methanol, the mixture was extracted with ether. Subsequent working up as usual gave, quantitatively, 6-oxo-8α-methoxyepieremophilenolide, X-a (mp 99.0—100.0 °C), as needles (from isopropyl ether), $[\alpha]_D^{23}$ −13.6° (*c*, 1.04, $CHCl_3$); IR (KBr): 1760, 1698, 1660, 1160, 1070, 915 cm^{-1}; UV: λ_{max}^{MeOH} 230 nm (ε, 8300); NMR ($CDCl_3$): 3.16 (s, 8-OCH_3), 2.35 (m, 3H), 1.98 (s, 13-CH_3), 1.04 (s, 15-CH_3), 0.90 (d, J=7.7 Hz, 14-CH_3); ORD (*c*, 0.116, MeOH): *cf.* Fig. 1; CD (*c*, 0.108, MeOH): Fig. 2.

Found: C, 69.04; H, 8.14%. Calcd for $C_{16}H_{22}O_4$: C, 69.04; H, 7.97%.

b) 6-Oxo-8β-methoxyeremophilenolide (X-b). Compound VIII-b (103.7 mg) was oxidized by a method similar to that described above to yield 6-oxo-8β-methoxyeremophilenolide, X-b (94.3 mg) (mp 160.5—161.5 °C), as prisms (from isopropyl ether); $[\alpha]_D^{23}$ −16.6° (*c*, 1.04, $CHCl_3$); negative to a Zimmermann test;[12] UV: λ_{max}^{MeOH} 230 nm (ε, 7630); IR (KBr): 1775, 1695, 1175, 995, 925 cm^{-1}, ($CHCl_3$): 1763, 1690, 1178, 998, 927 cm^{-1}; NMR ($CDCl_3$): 3.14 (s, 8-OCH_3), 2.26 (s, 3H), 1.96 (s, 13-CH_3), 1.15 (s, 15-CH_3), 0.66 (d, J=6.0 Hz, 14-CH_3); ORD (*c*, 0.118, MeOH): *cf.* Fig. 1; CD (*c*, 0.099, MeOH): Fig. 2.

Found: C, 69.02; H, 8.08%. Calcd for $C_{16}H_{22}O_4$: C, 69.04; H, 7.97%.

Chromatography of Hydroperoxides on Silica Gel. A crystalline mixture of hydroperoxides, VI-a, b (1.109 g), was chromatographed on silica gel (26.5 g, grade II). Elution with benzene–ethyl acetate (50: 1 and 20: 1) gave a mixture of 6β-hydroxy-8(α and β)-methoxylactones VII-a, b (94 mg), the recovered starting hydroperoxides, VI-a, b (576 mg), and 6β,8β-dihydroxyeremophilenolide IV (209 mg). The compounds, VII-a, b and VI-a, b, were identified by tlc analysis.

Compound IV was crystallized from ethyl acetate as prisms; mp 209.0—211.5 °C, $[\alpha]_D^{24}$ +172° (*c*, 0.97, $CHCl_3$).

Found: C, 67.52; H, 8.32%. Calcd for $C_{15}H_{22}O_4$: C, 67.64; H, 8.33%.

The acetate was prepared in a similar manner and crystallized from isopropyl ether as prisms; mp 119.5—120.5 °C.

Found: C, 65.31; H, 7.58%. Calcd for $C_{19}H_{26}O_6$: C, 65.12; H, 7.48%. Compound IV and its acetate were identified with the natural samples by a mixed-melting-point determination and by a comparison of their IR, UV, and NMR spectra.

Reduction of Hydroperoxides (VI-a, b). a) By Sodium Sulfite. A mixture of petasalbin I (500 mg) and Rose Bengal (30 mg) in methanol (50 ml) was photooxygenated as has been described above. A solution of sodium sulfite (700 mg) in water (10 ml) was added to the stirred mixture, and stirring was continued for 15 hr. After the removal of the methanol and the addition of water, the mixture was extracted with ether. The extract was worked up in the usual manner to give a crude product (427 mg), which was then chromatographed on silica gel (15 g, grade II). Elution with benzene–ethyl acetate (30: 1) gave 6β-hydroxy-8α-methoxyepieremophilenolide VIII-a (30 mg), hemiacetal XI (193 mg), 6β-hydroxyeremophilenolide III (38 mg), and 6β,8β-dihydroxyeremophilenolide IV (10.5 mg).

The above compounds, III (mp 204.0—205.0 °C: prisms from ethyl acetate; $[\alpha]_D^{23}$ +212° (*c*, 1.02, $CHCl_3$), was found to be identical with the natural specimen by a mixed-melting-point determination and by a comparison of their IR and NMR spectra.

Hemiacetal (XI): a colorless oil, positive to an Ehrlich test; IR (film): 3400, 1685, 1650, 1245, 1110, 995 cm^{-1}; UV: λ_{max}^{MeOH} 250 nm (ε, 4500); NMR (CCl_4): 5.7—5.5 (two signals centered at 5.69 and 5.55, 1H), 5.4—5.1 (two signals centered at 5.32 and 5.12, 1H), 4.18 (OH), 1.88 (s, 13-CH_3), 0.93 (d, J=7.0 Hz, 14-CH_3), 0.78 and 0.70 (each s, 15-CH_3). This compound was found to afford isoligularone (XII) on glc (SF-96, 2.6 m; column temperature, 200 °C; H_2-flow rate, 60 ml/min).

b) By Sodium Borohydride. A crystalline mixture of hydroperoxides, VI-a, b (224.8 mg), was treated with sodium borohydride (73.4 mg) in methanol (14 ml) at room temperature for 19 hr. Subsequent working up as usual gave a crude product (230 mg), which was chromatographed on alumina (6 g, grade IV). Elution with benzene and benzene–ethyl acetate (30: 1) afforded petasalbin I (68 mg) and 6β-hydroxyeremophilenolide III (48 mg). The products, I and III, were identified by a comparison of the tlc and the IR spectra and by a mixed-melting-point determination with natural samples.

c) By a Platinum Catalyst. Hydroperoxide VI-a (202 mg) in acetic acid (4 ml) was hydrogenated over platinum oxide (52.6 mg) at room temperature until the hydrogen-uptake

had ceased (0.91 mol). After working up as usual, the chromatography of the crude product (175 mg) on silica gel (4 g) with benzene–ethyl acetate (50: 1 and 20: 1) gave 6β-hydroxy-8α-methoxyepieremophilenolide, VIII-a (34.4 mg); 6β-hydroxyeremophilenolide, III (6.1 mg), and 6β,8β-dihydroxyeremophilenolide, IV (43.7 mg). All the products were found to be identical with the authentic samples by a comparison of the tlc and the IR spectra and by a mixed-melting-point determination.

Isoligularone (XII)[11] *from Hemiacetal (XI).* A solution of hemiacetal XI (70 mg) in acetic anhydride (1.5 ml) was warmed at 90 °C for 1 hr. The reaction mixture was then diluted with water (3 ml) and extracted with ether. The ethereal extract was washed with a saturated sodium hydrogen carbonate solution and then water, and dried. The removal of the solvent gave a crystalline product, isoligularone XII (68 mg), which was crystallized from methanol as needles: mp 147.0—148.0 °C, $[\alpha]_D^{23}$ +39.0° (*c*, 0.98, $CHCl_3$); positive to a Zimmermann test; IR (KBr): 3125, 3060, 1660, 1547, 1280 cm^{-1}; UV: λ_{max}^{MeOH} 269 nm (ε, 5100); MS: *m/e* 232 (M^+), 175 (base peak); NMR ($CDCl_3$): 7.02 (q, *J*=1.5 Hz, 6-H), 2.86 (dd, *J*=18, 13 Hz, 9α-H), 2.16 (d, *J*=1.5 Hz, 13-CH_3), 1.28 (s, 15-CH_3), 0.91 (d, *J*=7.5 Hz, 14-CH_3); tlc: R_f, 0.50 (benzene–ethyl acetate, 15: 1).

Found: C, 77.50; H, 8.73%. Calcd for $C_{15}H_{20}O_2$: C, 77.55; H, 8.68%.

Oxidation of Hemiacetal (XI). Jones' reagent (0.15 ml)[13] was added to a solution of hemiacetal XI (80 mg) in acetone (3 ml) over a period of 15 min under ice-cooling. After stirring for a further 45 min, the excess reagent was decomposed with methanol (5 drops), diluted with water, and extracted with ether. The extract was then worked up in the usual manner to give a crude oil (66 mg), which was subsequently chromatographed on silica gel (2 g). Elution with light petroleum–benzene (1: 1) gave 8-oxoisoeremophilenolide XIV (47 mg), which was crystallized from isopropyl ether as colorless needles; mp 76.5—77.5 °C, $[\alpha]_D^{23}$ +31.5° (*c*, 0.73, $CHCl_3$); positive to a Zimmermann test; IR(KBr): 1760, 1695, 1195 cm^{-1}; UV: λ_{max}^{MeOH} 245 nm (ε, 7700); NMR (CCl_4): 5.42 (q, *J*=2.5 Hz, W1/2=5 Hz, 6-H), 3.63 (dd, *J*=16.5, 6.5 Hz, 9α-H), 1.92 (d, *J*=2.5 Hz, 13-CH_3), 1.05 (d, *J*=7.5 Hz, 14-CH_3), 0.79 (s, 15-CH_3); tlc: R_f, 0.66 (benzene–ethyl acetate, 10: 1).

Found: C, 72.39; H, 8.13%. Calcd for $C_{15}H_{20}O_3$: C, 72.55; H, 8.12%.

Ligularone (XIII).[1b,c] Compound XIII was prepared from petasalbin I (100 mg) by chromium trioxide (80mg) in pyridine (6.8 ml). The crude product was chromatographed on alumina (800 mg) and then crystallized from light petroleum to afford ligularone XIII as prisms: mp 66.0—67.5 °C, $[\alpha]_D^{25}$ −50.0° (*c*, 1.03, $CHCl_3$); tlc: R_f, 0.90 (benzene); (Found: C, 77.48; H, 8.87%). This compound was found to be identical with natural specimen by a comparison of the IR and NMR spectra and by a mixed-melting-point determination.

6-Oxoeremophilenolide (XV).[1-a] Jones' reagent (0.26 ml) was stirred over a period of 30 min under ice-cooling into a solution of 6β-hydroxyeremophilenolide III (148 mg) in acetone (5 ml). After stirring for a further 2 hr, the reaction mixture was worked up as has been described above to afford 6-oxoeremophilenolide XV (136 mg), which was subsequently crystallized from isopropyl ether as prisms: mp 124.0—126.0 °C, $[\alpha]_D^{24}$ −27.1° (*c*, 1.07, $CHCl_3$); IR(KBr): 1740, 1690, 1190, 1150, 1090, 1050, 930 cm^{-1}; UV: λ_{max}^{MeOH} 240 nm (ε, 11100); NMR (CCl_4): 4.88 (m, W1/2=21 Hz, 8-H), 1.85 (d, *J*=2.2 Hz, 13-CH_3), 1.11 (s, 15-CH_3), 0.63 (d, *J*=6.0 Hz, 14-CH_3); tlc: R_f, 0.75 (benzene–ethyl acetate, 10: 1).

Found: C, 72.51; H, 8.21%. Calcd for $C_{15}H_{20}O_3$: C, 72.55; H, 8.12%.

The authors wish to thank the staff of the Shionogi Research Laboratory, Shionogi and Co., Ltd., for the microanalysis, and the Institute of Food Chemistry for the measurement of the MS and NMR spectra.

Autoxidation of Atactic Polypropylene and Related Alkanes. Rates and Reactivities toward Peroxy Radicals

Etsuo NIKI and Yoshio KAMIYA

Department of Reaction Chemistry, Faculty of Engineering, University of Tokyo, Hongo, Tokyo 113

(Received April 12, 1975)

Rates of autoxidations of atactic polypropylene, polystyrene, and several alkanes in solution initiated by azobiscyclohexanecarbonitrile were measured at 90 °C in the absence and presence of added hydroperoxide and the reactivities toward *tert*-butylperoxyl and tetralylperoxyl radicals were measured. Atactic polypropylene was found to be oxidized faster than expected from the related alkanes. On the other hand, polystyrene was quite resistant to autoxidation. The relative reactivities of secondary and tertiary hydrogens toward *t*-butylperoxyl radical were obtained as 1: 9.7 and that for primary hydrogen was estimated to be quite small. The observed reactivity of 2,2,4-trimethylpentane was much smaller than the calculated reactivity from the results of simple alkanes, whereas the observed reactivity of atactic polypropylene was higher than the calculated one. The high reactivity of atactic polypropylene for oxidation and toward peroxyl radicals was interpreted as being due to a fast intramolecular propagation. Tetralylperoxyl radical was 3.6 times as reactive as *t*-butylperoxyl radical toward both atactic polypropylene and 2,6,10,14-tetramethylpentadecane.

The oxidation of polymers by molecular oxygen is probably the most important reaction in the ageing, deterioration, and degradation of plastics, fiber, rubber, and food. This autoxidation proceeds by a radical chain mechanism, in which the chain carrying species are the peroxyl and alkoxyl radicals.[1] We have previously reported that the reactivities of atactic polypropylene and polystyrene toward *t*-butoxyl radical are considerably smaller than those of the corresponding simple model compounds.[2] The peroxyl radicals may be a more important chain carrier in the oxidation of polyolefins especially at ambient temperature. However, the relative reactivities of polyolefins and alkanes toward a specific peroxyl radical have not yet been reported. The objective of the present paper is to determine the relative reactivities of atactic polypropylene, polystyrene, and several simple low molecular weight model compounds toward *t*-butylperoxyl and 1-tetralylperoxyl radicals generated from corresponding hydroperoxide.

Experimental

Materials. Atactic polypropylene supplied by Mitsui Petrochemical Industries was first soaked in benzene at room temperature for several days and the insoluble fraction was separated by filtration. Then a soluble fraction was purified by the conventional method, using benzene and methanol as solvent and precipitant respectively. Finally it was dried to a constant weight under vacuum at room temperature. The glc analysis showed that the dried polypropylene contained little benzene or methanol. The average molecular weight of the purified polypropylene was obtained as 8400 from its intrinsic viscosity. The infrared spectrum of the purified polypropylene showed strong absorption at 975 cm^{-1}, but little absorption at 997 cm^{-1}, indicating that little isotactic polypropylene was present.[3] Polystyrene supplied by Asahi Dow Industries was purified as described previously.[2] The purified polystyrene had an intrinsic viscosity of 0.825 at 45 °C in benzene, and the number average molecular weight was 2×10^5. A monodisperse polystyrene was also used to examine the effect of the molecular weight. This polystyrene standard was obtained from Pressure Chemical Co. and was used without further purification. Decane, tridecane, 2,6,-10, 14-tetramethylpentadecane, and chlorobenzene were washed successively with acid, water, alkali and water, dried, and distilled. 2,4-Dimethylpentane, 2,2,4-trimethylpentane, and 3-methyloctane were percolated through an activated alumina column prior to use.

Commercial *t*-butyl hydroperoxide was purified by fractional distillation, 44 °C/27 mmHg, and stored over sodium carbonate. The purity determined by iodometric titration was always higher than 98%. Tetralyl hydroperoxide was prepared by air oxidation of tetralin at 50 °C and by repeated recrystallization from hexane. Azobiscyclohexanecarbonitrile (ACN) and 2,6-di-*t*-butyl-4-methylphenol (BMP) were recrystallized from methanol. Commercial oxygen and nitrogen were used as received.

Procedures. The polymer solutions were prepared by dissolving a weighed amount of polypropylene or polystyrene into chlorobenzene in a volumetric tube. All polymers dissolved completely both at room temperature and at 90 °C and the solutions were always homogeneous.

The oxidation was carried out in an ampoule immersed in a silicone oil bath carefully maintained at constant temperature (±0.02 °C). The rate of oxidation was measured either by following the pressure change using a pressure transducer or by measureing the initial and final amounts of oxygen in the reaction vessel by a Toepler pump and subsequent gas analysis by gas chromatography or Cu–CuO furnace.[4] Plots of pressure change as a function of time gave excellent straight lines without any noticeable autocatalytic or autoretarding effect at the initial stage of the oxidation. The rate of decomposition of ACN was measured from the rate of nitrogen evolution and the rate of initiation was determined from the induction period in the presence of inhibitor.[5] BMP was used as the inhibitor.

Results and Discussion

Rates of Oxidation of Atactic Polypropylene, Polystyrene, and Alkanes at 90 °C. The rates of oxidation of atactic polypropylene, polystyrene, and several alkanes initiated with ACN at 90 °C are summarized in Table 1. To obtain the rate of oxidation in the propagation step, the observed rate of oxidation was corrected for nitrogen evolution from ACN and oxygen absorption and evolution associated with initiation and termination by

$$R_{prop} = R_{obsd} + \frac{R_i}{2e} - \frac{7}{4}R_i \qquad (1)$$

where R_i is the rate of initiation and e is the efficiency of

initiation by ACN.[4] The ratio of the rate constants, $k_p/(2k_t)^{1/2}$, was calculated from the rate of oxidation by

$$k_p/(2k_t)^{1/2} = R_{prop}/[RH]R_i^{1/2} \quad (2)$$

where k_p and k_t are the rate constants for the propagation and termination reactions respectively.

Table 1 shows that $k_p/(2k_t)^{1/2}$ for tridecane is 1.25 times as large as that for decane, which corresponds well with the ratio of the number of secondary hydrogens in tridecane to that in decane, 22/16=1.38. This probably indicates that the rate constants for propagation (per active hydrogen) and termination reactions are similar for decane and tridecane. The high $k_p/(2k_t)^{1/2}$ for 2,6,10,14-tetramethylpentadecane must be ascribed to a relatively high k_p and low k_t due to the four tertiary hydrogen atoms. However, 2,2,4-trimethylpentane has an extraordinarily low $k_p/(2k_t)^{1/2}$, apparently due to the low reactivity of its tertiary hydrogen atom (see later text and Ref. 2). On the other hand, atactic polypropylene has a rather high $k_p/(2k_t)^{1/2}$. It is interesting that atactic polypropylene is as oxidizable as 2,6,10,14-tetramethylpentadecane. This may be because of a low k_t due to the tertiary alkylperoxyl radicals, but more probably because of a high k_p due to the fast intramolecular propagation. The rates of oxidation of polystyrenes were too small to permit the calculation of reliable $k_p/(2k_t)^{1/2}$. Considering that polystyrene has tertiary benzylic hydrogen, this extraordinarily low oxidizability is surprising. It may occur because of a very low reactivity of polystyrene toward oxy radicals[2] and high termination rate constants.

Oxidation with Added Hydroperoxide. Hydroperoxide is quite reactive toward peroxyl radical and therefore it is quite an efficient chain transfer agent in the autoxidation.[6] Accordingly, the addition of hydroperoxide changes the chain carrying peroxyl radical from substrate peroxyl radical to the peroxyl radical derived from the added hydroperoxide. When the added hydroperoxide (BOOH) gives a tertiary peroxyl radical ($BO_2\cdot$), the termination reactions proceed as follows:[7]

$$BO_2\cdot + BO_2\cdot \xrightarrow{\alpha} BOOB + O_2 \quad (3)$$

$$\xrightarrow{1-\alpha} 2\,BO\cdot + O_2 \quad (4)$$

$$BO\cdot + BOOH \longrightarrow BOH + BO_2\cdot \quad (5)$$

The alkoxyl radical generated from the non-terminating interactions of tertiary peroxyl radicals exclusively abstracts hydrogen from the hydroperoxide before it reacts with the substrate or cleaves. The rate of oxygen evolution in the termination step (R_{term}) is then given by[7]

$$R_{term} = R_i/2\alpha \quad (6)$$

where α is the fraction of the interactions of tertiary peroxyl radicals that are terminating.

The results of the oxidations of atactic polypropylene, polystyrene, and several alkanes at 90 °C in the presence of initially added *t*-butyl and 1-tetralyl hydroperoxides

a) b) See footnote of Table 1. c) Numbers in the parentheses are k_{BR} calculated with $k_{prim}=0$, $k_{sec}=0.0387$, and $k_{tert}=0.376\ M^{-1}\,s^{-1}$ (see text). d) The contribution of benzyl resonance is neglected (see Ref. 2).

are summarized in Table 2. In the presence of *t*-butyl hydroperoxide, the rate of oxidation in the propagation step was obtained by correcting the observed rate of gas absorption for nitrogen evolution from ACN and oxygen absorption and evolution associated with the initiation and termination steps by

$$R_{prop} = R_{obsd} + \frac{R_i}{2e} - R_i + \frac{R_i}{2\alpha} \quad (7)$$

The value of α for *t*-butylperoxyl radicals was determined from the rate of oxygen evolution in the induced decomposition of *t*-butyl hydroperoxide by ACN in chlorobenzene at 90 °C: the value of 0.059 was obtained. This shows that only 5.9% of the bimolecular interactions of *t*-butylperoxyl radicals are terminating and about 94% are non-terminating to give *t*-butoxyl radicals. It was assumed that the increase in the macroscopic viscosity due to atactic polypropylene and polystyrene had no effect on α.[8] For the oxidation with added tetralyl hydroperoxide, which gives a secondary peroxyl radical, the observed rate of gas absorption was corrected by Eq. (8) with the assumption that all the bimolecular interactions of tetralylperoxyl radicals are terminating.[9]

$$R_{prop} = R_{obsd} + \frac{R_i}{2e} - \frac{R_i}{2} \quad (8)$$

Tables 1 and 2 show that the addition of *t*-butyl hydroperoxide increased the rate of oxidation for every substrate except polystyrene. This is apparently due to a low termination rate constant for *t*-butylperoxyl radicals.[10]

The rate constant k_{BR} for the hydrogen atom abstraction from the substrate by *t*-butylperoxyl radical was calculated from Eq. (9)[6]

$$k_{BR} = R_{prop}/[RH](R_i/2k_{tBB})^{1/2} \quad (9)$$

where k_{tBB} is the rate constant for direct termination by *t*-butylperoxyl radical.[10] The absolute termination rate constant was calculated as $2k_{tBB}=1.2\times10^4$ M^{-1} s^{-1} at 90 °C from the literature value,[11]

$$\log(2k_{tBB}) = 9.2-8.5/2.303RT \quad (10)$$

This k_{BR} shows the reactivities of the substrate toward a *t*-butylperoxyl radical. The rate constants for hydrogen atom abstraction from primary, secondary, and tertiary carbon-hydrogen bonds by *t*-butylperoxyl radical were calculated from k_{BR} for decane, tridecane, 3-methyloctane, and 2,6,10,14-tetramethylpentadecane. The best results are $k_{prim}=0$, $k_{sec}=0.0387$, and $k_{tert}=0.376$ M^{-1} s^{-1} (per hydrogen). The rate constant for primary hydrogen was obtained as a negative value and so is estimated as zero, since this is obtained as a small difference between large quantities and a small experimental error would produce a large error in k_{prim}. The calculated k_{BR} from the above k_{prim}, k_{sec}, and k_{tert} is also shown in Table 2. The agreement between the observed and calculated k_{BR} values is satisfactory for decane, tridecane, 3-methyloctane, and 2,6,10,14-tetramethylpentadecane. However, the observed k_{BR} for 2,2,4-trimethylpentane is much lower than the calculated k_{BR}. This lower reactivity of 2,2,4-trimethylpentane toward *t*-butylperoxyl radical must be due to its preferred conformation as observed toward *t*-butoxyl radical.[2] The observed reactivity of atactic polypropylene was larger than the calculated one by a factor of more than 2. Since atactic polypropylene also has an alternate methyl group along the main chain, the tertiary hydrogens must be sterically protected from the attack of *t*-butylperoxyl radical. The high k_{BR} for atactic polypropylene must imply the contribution of intramolecular propagation even in the presence of a high concentration of *t*-butyl hydroperoxide. On the other hand, polystyrene was found to be quite stable toward a *t*-butylperoxyl radical. This may be ascribed to a profound steric protection by phenyl groups on the alternating carbon atoms.

The oxidation of alkanes has been studied by several investigators. Allara *et al.*[12] estimated the relative reactivities of primary, secondary, and tertiary hydrogens toward peroxyl radicals as 1: 10: 80 at 100 °C. In the oxidation of isobutane, primary hydrogen was found to be stable and only tertiary hydrogen was oxidized selectively.[13] Mill *et al.*[14] obtained the relative reactivities of primary and secondary hydrogens as 1: 45 in the oxidation of butane at 100 °C. On the other hand, Van Sickle *et al.*[15] reported that the ratio of attack by peroxyl radicals at primary and secondary hydrogens was 1: 38.5 in the oxidation of pentane at 100 °C. Bennett, Brown, and Mile[16] measured the relative reactivities of primary, secondary, and tertiary hydrogens by product analyses in the oxidation of 2-methylpentane and obtained the ratio of 1: 18: 133 at 20 °C. Some of these relative reactivities are not toward a specific peroxyl radical but toward composite peroxyl radicals and, in some cases, the contribution of an alkoxyl radical is also possible.

From Table 2, the relative reactivities of secondary and tertiary hydrogens toward *t*-butylperoxyl radical is obtained as $k_{sec}: k_{tert}=1: 9.7$. This is in satisfactory agreement with the literature value shown above. Since the relative reactivities of primary, secondary, and tertiary hydrogens toward *t*-butoxyl radical was 0.14: 1: 2.9 at 45 °C,[2] *t*-butylperoxyl radical is more selective than *t*-butoxyl radical, as was expected.

Bennett, Eyre, and Summers[17] measured the absolute termination rate constant in the oxidation of 2,6,10,14-tetramethylpentadecane and obtained $2k_t=3.0\times10^6$ M^{-1} s^{-1} at 88 °C. With this $2k_t$ and $k_p/(2k_t)^{1/2}$ in Table 1, we obtain $k_p=3.1$ M^{-1} s^{-1}, which is in fair agreement with k_{BR} in Table 2. The fact that k_p is about 30% higher than k_{BR} may be partly because of the contribution of the secondary peroxyl radicals, which are more reactive than the *t*-butylperoxyl radical.

In Table 2 is shown the effect of addition of 1-tetralyl hydroperoxide. The rate constants k_{TR} for the reactions of 1-tetralylperoxyl radical and 2,6,10,14-tetramethylpentadecane and atactic polypropylene were calculated from

$$k_{TR} = R_{prop}/[RH](R_i/2k_{tTT})^{1/2} \quad (11)$$

where k_{tTT} is the constant for the termination reaction of 1-tetralylperoxyl radicals, which was calculated from the literature value:[18]

$$k_{tTT} = 4.3\times10^9 \exp(-4300/RT) \quad (12)$$

The calculated k_{TR} are shown in Table 2. The reactivities of both atactic polypropylene and 2,6,10,14-tetramethylpentadecane toward 1-tetralylperoxyl radical are

higher than those toward *t*-butylperoxyl radical. 1-Tetralylperoxyl radical is more reactive than *t*-butylperoxyl radical by a factor of 3.6. Table 2 shows, however, that the rate of oxidation in the presence of 1-tetralyl hydroperoxide is considerably lower than that in the presence of *t*-butyl hydroperoxide. This is due to a higher termination rate constant for 1-tetralylperoxyl radical (1.1×10^7 M^{-1} s^{-1} at 90 °C) than that for *t*-butylperoxyl radical (6.0×10^3).

When the rate constans k_{BR} and k_{TR} are calculated from the rate of oxidation in the presence of initially added hydroperoxide as described above (Eqs. (9) and (11)), it is required that all the chain carriers are changed from the substrate peroxyl radical to the peroxyl radical derived from hydroperoxide.[19,20] In other words, if the contribution of the substrate peroxyl radical in either the propagation or the termination step is not negligiblly small, Eqs. (9) and (11) do not hold. This complication is especially important for reactive substrates at higher temperature. However, the substrates studied in this work are much less reactive than the hydroperoxide. Moreover, the contribution of the substrate peroxyl radical in the propagation or termination step should give less error, if any, in the relative k_{BR} and k_{TR} and therefore in the relative reactivities of primary, secondary, and tertiary hydrogens.

Another complication that must be considered is the reaction of *t*-butoxyl radical in the oxidation with added *t*-butyl hydroperoxide. For Eq. (7) to hold, a *t*-butoxyl radical generated from the non-terminating interactions of *t*-butylperoxyl radicals should exclusively abstract hydrogen from *t*-butyl hydroperoxide before it reacts with the substrate or cleaves to acetone and methyl radical. It may well be concluded that this condition is satisfied in this study from the experimental data that the observed α was independent of the concentration of *t*-butyl hydroperoxide when it was higher than 0.80 M.

Kinetics of the Thermal Decompositions of Diaryl and Dialkyl Disulfides

Tokuji MIYASHITA, Minoru MATSUDA,* and Masashi IINO
Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Sendai 980
(Received April 25, 1975)

A kinetic study of the thermal decomposition of diphenyl disulfide, its *p*-methoxy, *p*-methyl, and *p*-chloro derivatives, and di-*n*-butyl and di-*t*-butyl disulfides in tetralin was made. The rate of decomposition was followed by the decrease of disulfide and the spontaneous first-order rate constants for these disulfides at 196, 207, and 217 °C and the activation parameters were obtained. It was observed that the rates of the decompositions for diaryl disulfides are increased by *p*-substituents ($CH_3O > Cl \simeq CH_3 > H$) and that that of di-*t*-butyl disulfide is comparable to diaryl disulfides, whereas, di-*n*-butyl disulfide shows no decomposition under these conditions. A reaction scheme of the decomposition including induced decomposition is proposed from the kinetic results and product analysis. Moreover, the properties of a thiyl radical in relation to the above results are discussed from the electronic and ESR spectra of the aryl thiyl radicals generated from the photolysis of corresponding thiols in a glass of 2-methyltetrahydrofuran at −196 °C.

Although it is well known that the S—S bonds in organic disulfides are cleaved homolytically by heat or light yielding thiyl radicals,[1] there are few kinetic studies of the thermal decomposition of organic disulfides. The dissociation of tetramethylthiuram (TMTD) and 2,2'-dibenzothiazolyl (DBTD) disulfides into their thiyl radicals has been demonstrated from magnetic measurements[2] and these radicals initiate the radical polymerization of styrene and methyl methacrylate (MMA)[3,4] at temperatures above 60 °C. The first-order rate constants for the decomposition of TMTD at two temperatures (60 °C and 80 °C) have been estimated by Ferington and Tobolsky[3] from kinetic studies of styrene and MMA polymerizations initiated by the disulfide, and Davis and Perrin[5] have also determined the rate constants for both TMTD and DBTD at 56 °C and 100 °C using diphenylpicrylhydrazyl (DPPH) as a scavenger for radicals formed thermally. However, for both diaryl and dialkyl disulfides the first-order rate constants have so far not been reported, though the formation of thiyl radicals from the homolytic scission of disulfides has already been indicated from the fact that the reaction of diphenyl disulfide with benzyl alcohol gives both aldehyde and thiophenol[6] and that such a disulfide dehydrogenates from hydrocarbons.[7,8] Leandri and Tundo[9] have investigated the effects of substituents on the extent of the decomposition of diaryl disulfides at 170 °C from molecular weight measurements, but they have not determined the rate constants.

The purpose of this paper is to determine the first-order rate constants for the thermal decompositions of some symmetric diaryl and dialkyl disulfides in tetralin, and to obtain a relationship between the structure and the susceptibility to decomposition, as well as other information about the properties of thiyl radicals.

Experimental

Materials. Commercially available, diphenyl, di-*t*-butyl, and di-*n*-butyl disulfides were recrystallized three times from ethanol. Di-*p*-chlorophenyl and di-*p*-methylphenyl disulfides were prepared from the oxidations of the corresponding thiols and recrystallized from ethanol. Di-*p*-methoxyphenyl disulfide was prepared by the method of Tarbell and Fukushima[10] and recrystallized three times from ethanol. Tetralin was washed successively with concentrated sulfuric acid, water, 10% aqueous sodium carbonate, water, and then dried over anhydrous sodium sulfate and distilled from sodium metals. The distillate was refluxed over DPPH and redistilled before use.

Kinetics. A weighed sample of disulfide was dissolved in a known volume of tetralin. The solution was placed in a Pyrex glass-reaction tube, degassed many times (usually 6—9 times) by the freeze-thaw method, and finally the reaction tube was filled with nitrogen, sealed off and immersed in an oil bath which was maintained at the desired temperature to within ±0.1 °C. An aliquot of the solution was withdrawn after a definite time interval into a sample tube attached to the reaction tube, and evacuated by a high-vacuum pump through a stopcock. Then, the quantity of residual disulfide in the aliquot was determined by the following method:[11] the disulfide in the aliquot was reduced to the corresponding thiol with sodium borohydride and aluminum chloride and the quantity of the resulting thiol was determined by titration with silver nitrate using dithizone as an indicator.[12] Since the reaction mixture contained the thiol formed from the hydrogen abstraction of the thiyl radical, the disulfide content was determined by subtracting the amount of thiol in an unreduced aliquot from that obtained after reduction. It has been reported that the thiol and sulfide formed during the decomposition of disulfides (see the following section) are unchanged by the reduction and the presence of these compounds does not interfere with the reduction and titration.[11] The preliminary experiments show that the accuracy of the titration for diphenyl, di-*p*-methoxyphenyl, di-*p*-methylphenyl, di-*p*-chlorophenyl, and di-*n*-butyl disulfides is 99.0—99.5, 99.2—99.7, 93.0—93.5, and 98.5—99.0%, respectively.

The rate of decomposition is known to be represented generally by the following equations,[15]

$$-\mathrm{d[P]}/\mathrm{d}t = k_1[\mathrm{P}] + k_i[\mathrm{P}]^n = k_{obsd}[\mathrm{P}] \quad (1)$$

$$k_{obsd} = k_1 + k_i[\mathrm{P}]^{n-1} \quad (2)$$

where [P] is the concentration of the decomposed substance (disulfide, in this case) and k_1 and k_i are the first-order (spontaneous) rate constant and a constant including the rate constant for induced decomposition, respectively. The apparent first-order rate constants for various initial concentrations of disulfide were obtained from the slopes in the first-order plots (line (a) in Fig. 1) in a region of low conversion ($[\mathrm{P}] \simeq [\mathrm{P}]_0$), and then, these were treated according to Eq. (2) in order to obtain k_1 and n, as will be described in the section on the Results. In our experiments, first-order plots gave straight lines to at least a 20% conversion.

Analysis of Products for a Large Scale Experiment. A solution of 4.36 g (0.02 mol) of diphenyl disulfide in 70 ml of tetralin was deaerated with nitrogen gas and allowed to react at a reflux temperature (270.2 °C) for 90 hr. Most of the tetralin and thiophenol were distilled from the reaction mixture and then 1.32 g (0.012 mol) of thiophenol was isolated as a yellow crystal of lead salt (I) by the reaction of thiophenol with lead acetate.[13] This yield of thiophenol was almost equal to that obtained by titration with silver nitrate.

Found: C, 34.07; H, 2.16%. Calcd for $C_{12}H_{10}PbS_2$ (I): C, 33.86; H, 2.35%.

The residual mixture was analyzed by chromatography on a silica gel column in the usual way. Elution with petroleum ether gave tetralin, and then using a 90: 10 petroleum ether–benzene mixture, unreacted diphenyl disulfide (0.006 mol, 1.3 g). The oily product was eluted with a 80: 20 petroleum ether–benzene mixture and identified as 1,2,3,4-tetrahydro-1-phenylthionaphthalene (II) (0.006 mol, 1.4 g): NMR (δ, CCl_4): 4.45 (1H, t, CH), 1.6—2.0 (4H, m, CH_2), 2.4—2.8 (2H, m, $-CH_2-C_6H_4-$), 6.9—7.4 ppm (9H, m, arom).

Found: C, 80.76; H, 7.11; S, 14.00%. Calcd for $C_{16}H_{16}S$ (II): C, 79.95; H, 6.71; S, 13.34%. The yellow oily fraction (about 0.3 g) containing both sulfur (14.2%) and tetralin fragments was eluted with a 50: 50 petroleum ether–benzene mixture. Elution with diethyl ether produced a brown oily fraction (about 0.4 g) containing sulfur (6.9%) and tetralin fragments. The formation of a small amount of naphthalene was observed using glc.

Spectra of Thiyl Radicals. The electronic spectra of aryl thiyl radicals generated by the photolysis of the corresponding thiols in a rigid glass of 2-methyltetrahydrofuran (2-MTHF) at liquid nitrogen temperature have been obtained (matrix isolation technique[14]). The concentration of each thiol was 0.01 mol/l and a super-high-pressure mercury lamp was used for the photolysis.

Results

Kinetics. The thermal decompositions of various disulfides were studied in tetralin which is a good hydrogen-donating compound. In Fig. 2 (n=2 in Eqs. 1 and 2), the apparent first-order rate constants (k_{obsd}) for various initial concentrations are plotted against the initial concentrations of the disulfides. Nozaki and Bartlett[15] have indicated in their studies on the decomposition of the substituted benzoyl peroxides that the order n of the induced decomposition in Eq. (1) (and Eq. 2) can vary between 0.5 and 2.0, depending on which radicals attack the parent molecules and on the type of radicals participating in the termination step. In our experiments the

Table 1. First-order rate constants and activation parameters for the thermal decomposition of diaryl and dialkyl disulfides in tetralin.

Disulfide	Temp. °C	$k_1 \times 10^6$ s^{-1}	ΔS cal mol^{-1}	E_a kcal mol^{-1}
Diphenyl disulfide	196	0.47		
	207	1.1	1.5	43.0
	217	3.3		
Di-*p*-chlorophenyl disulfide	196	0.80		
	207	2.2	−4.0	40.0
	217	5.0		
Di-*p*-methoxyphenyl disulfide	196	3.3		
	207	9.0	0.5	40.6
Di-*p*-methylphenyl disulfide	207	2.0	−5.4	39.4
	217	4.6		
Di-*t*-butyl disulfide	207	1.9[a]		
Di-*n*-butyl disulfide	207	No decomposition[b]		

a) Value estimated from the amount of thiol formed. b) No decomposition occurs at 207°C for 20 hr.

trial and error method for determining n in Eq. (2) gives straight lines with different slopes for di-*p*-chlorophenyl and di-*p*-methylphenyl disulfides when n is equal to 2. Thus, it is suggested that a considerable amount of induced decomposition occurs in the decomposition of di-*p*-chlorophenyl disulfide and probably a small amount in that of di-*p*-methylphenyl disulfide, whereas, for the other disulfides no appreciable concentration effect was observed. The values of k_1 for both di-*p*-chlorophenyl and di-*p*-methylphenyl disulfides were estimated from an extrapolation of the straight lines to zero concentration; these values of k_1 were found to be 0.8×10^{-6}, 2.2×10^{-6}, and 5.0×10^{-6} s^{-1} at 196, 207, and 217 °C, respectively. The k_1 values for other disulfides at 196, 207, and 217 °C and the activation parameters are shown in Table 1. Since di-*t*-butyl disulfide was not reduced quantitatively with sodium borohydride, the k_1 value was estimated from the amount of the thiol formed and so this value may be considered to be the lower limit of the true value.

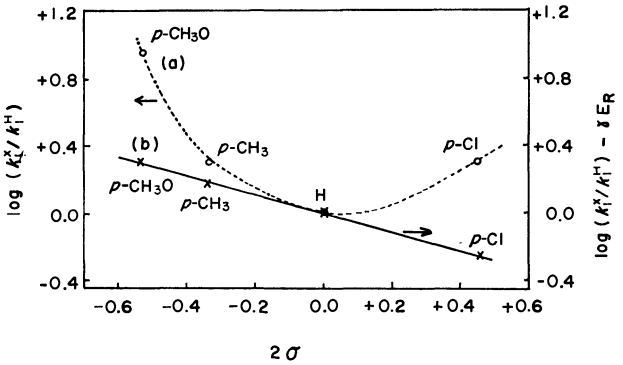

Fig. 3. Hammett plots of the first-order rate constants for the decompositions of di-*p*-substituted phenyl disulfides: (a) Log (k_1^X/k_1^H) *vs.* Hammett's σ values. (b) Log $(k_1^X/k_1^H)-\gamma E_R$ (Yamamoto-Otsu's equation) *vs.* Hammett's σ value ($\rho=-0.55$, $\gamma=3.0$).

The Effects of p-*Substituents on the Values of* k_1. Fig. 3(a) shows a plot of $\log k_1^X/k_1^H$ *vs.* 2σ, where k_1^H and k_1^X are the first-order rate constants for diphenyl and di-*p*-substituted phenyl disulfides, respectively, and σ is the usual Hammett substituents sigma-value. This plot does not give a straight line, but rather a curve which has a minimum value for diphenyl disulfide. The Yamamoto-Otsu equation,[16]

$$\log k_1^X/k_1^H = 2(\rho\sigma+\gamma E_R) \quad (3)$$

which is a modified Hammett equation including the resonance term, was applied to the present data of k_1 (Fig. 3(b)) in which σ and E_R are the polar and resonance substituent constants and ρ and γ are the reaction constants giving the susceptibilities for the polar and resonance effects of the substituents respectively. A constant 2 is used here, since symmetrically-substituted phenyl disulfide has two substituents. As shown in Fig. 3(b), the values of -0.55 and 3.0 for ρ and γ, respectively, are found to give a straight line.

Products Analyses. The rate of formation of the thiol obtained by titration with silver nitrate and that of "products" other than thiol are indicated by (b) and (c), respectively, in Fig. 1. This latter rate was obtained by the subtraction of the rate of the formation of thiol from that of the decomposition of the disulfide, and since these products are not reduced by sodium borohydride and aluminum chloride, they are, therefore, probably aryl sulfide (see Experimental). Fig. 1 indicates that the thermal decomposition of 1 mol of disulfide yielded about 1.5 mol of thiol and 0.5 mol of "other products". The analysis of products obtained from a large scale experiment for diphenyl disulfide at a reflux temperature of tetralin indicates the formation of thiophenol (0.90 mol), 1,2,3,4-tetrahydro-1-phenylthionaphthalene (0.41 mol) per 1 mol of diphenyl disulfide consumed, and unidentified oily products containing sulfur and tetralin fragments. Nakasaki[7] has reported that thiophenol and naphthalene were formed from the decomposition of diphenyl disulfide in tetralin at 260 °C. Ritter and Sharpe[8] have also found a similar dehydrogenation of tetralin by *iso*-amyl disulfide. Both authors have used disulfides as dehydrogenation reagents and thus the concentrations of disulfides in their experiments (11—18 mol/l) are much higher than that in those reported here (0.29 mol/l).

Discussion

Mechanism. The following reactions can be considered as the elementary steps in the thermal decomposition of disulfides in tetralin,

$$\mathrm{ArSSAr} \xrightarrow{k_1} 2\mathrm{ArS}\cdot \quad (4)$$

$$\mathrm{ArS}\cdot + \mathrm{RH} \xrightarrow{k_2} \mathrm{ArSH} + \mathrm{R}\cdot \quad (5)$$

$$\mathrm{ArS}\cdot + \mathrm{R}\cdot \xrightarrow{k_3} \mathrm{ArSR} \quad (6)$$

$$\mathrm{R}\cdot + \mathrm{R}\cdot \xrightarrow{k_4} \text{product} \quad (7)$$

$$\mathrm{ArS}\cdot + \mathrm{ArSSAr} \xrightarrow{k_5} \mathrm{ArS}\cdot + \text{product} \quad (8)$$

$$\mathrm{R}\cdot + \mathrm{ArSSAr} \xrightarrow{k_6} \mathrm{ArS}\cdot + \text{product} \quad (9)$$

where RH and R· are tetralin and its derived radical, respectively. A thiyl radical (ArS·) formed from step 4 abstracts α-hydrogen from tetralin (step 5) and the tetralinyl radical thus formed terminates with a thiyl radical or other tetralinyl radical. The step involving the addition of a thiyl radical to a phenyl ring is ignored since no such product was obtained.

Pryor, Gojon, and Stanley[17] have reported that the self-termination of the thinyl radicals is the only significant termination reaction in the reaction of the cyclohexyl thiyl radical with cumene at 80 °C. However, the reverse reaction of step 4 (self-termination) outside of the solvent-cage was ignored because of the situation described below. Probably due to the greater stability of the phenyl thiyl radical compared to that of the cyclohexyl thiyl radical, our preliminary experiment on the flash photolysis of *p*-chlorothiophenol in tetralin at room temperature[18] shows that the decay of the *p*-chlorophenyl thiyl radical obeyed first-order kinetics, that is, the thiyl radical reacts with tetralin and not with each other (the rate constant for this hydrogen abstraction reaction by the thiyl radical being found to be 1.5×10^2 $M^{-1}s^{-1}$), whereas, in a cyclohexane solution the thiyl radical decayed with second-order kinetics, indicating the self-termination of the thiyl radicals (the rate constant for the self-termination reaction was $2k_t=1.2\times10^9$

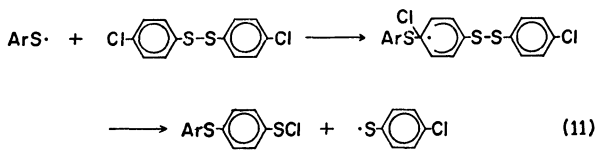
M^{-1} s^{-1}, this value being consistent with that of Thyrion[19]). Since the activation energy for hydrogen abstraction may be greater than that for a coupling reaction, these results can be used to consider our reaction scheme (our decomposition experiments were conducted at much higher temperatures than those on flash photolysis), and the rate constants obtained here are the values extrapolated to zero concentration of the disulfides, *i.e.*, they were obtained in extremely unfavorable conditions for the self-termination of thiyl radicals.

The k_{obsd} obtained in the decomposition of diphenyl and di-*p*-methoxyphenyl disulfides hardly varied with the initial concentrations of the disulfides, and these results are expected for the two following cases: (1) for $k_{obsd}=k_1$, and (2) for $k_{obsd}=k_1+k_i$, which is derived from $n=1.0$ in Eq. (1) (that is, in this case the decomposition proceeds by steps 4, 5, 6, and 9). The contribution of induced decomposition to k_{obsd}, such as in the second case, can be excluded experimentally by the presence of radical scavengers (a stable radical is used in these experiments), but this common method of using a stable free radical could not be applied at these high temperatures. For the following reasons, however, the process consisting of steps 4, 5, 6, and 9 leading to $n=1.0$ in Eq. (1) (and Eq. 2) can be neglected. First, as shown in Fig. 1, about 1.5 mol of the thiol (hydrogen abstraction product from tetralin by the thiyl radical) were obtained per mol of disulfide consumed. If a considerable amount of induced decomposition for $n=1$ occurs, the thiol yield should be less than 1 mol from steps 6 and 9. The yield (1.5 mol) greater than 1 mol indicates that all or a large portion of the thiyl radical was formed by step 4 (the maximum value being 2 mol when the termination occurs only due to step 7 which may not be the case from the fact that ArSR (product from step 6) was formed with a considerable yield). Second, step 9 is the attack of the disulfide by the tetralinyl radical. Tsuda and Otsu[20] have reported that a kinetic study of the induced decomposition of di-*p*-substituted phenyl disulfides with the polystyryl radical (the same benzyl-type radical as the tetralinyl radical) resulted in +0.23 for ρ in the Yamamoto-Otsu equation. Thus, if step 9 occurs at a high rate, the present ρ value should be a positive value, however, it is found to be −0.55. Moreover, the results reported by Nakasaki[7] and Ritter and Sharpe[8] suggest that the tetralinyl radical does not attack the disulfide, unlike the case of the reactive phenyl radical.[21] Therefore, the thermal decompositions of diphenyl and di-*p*-methoxyphenyl disulfides, for which the induced decomposition is found to be negligibly small, as shown in Fig. 2, seem to proceed *via* a process consisting of steps 4, 5, 6, and 7.

Steps 8 and 9 are considered to be induced decompositions by thiyl and tetralinyl radicals, respectively, which may occur in the thermal decomposition of both di-*p*-chlorophenyl and di-*p*-methylphenyl disulfides. The kinetic equation of the decomposition, assuming step 9 to be an induced decomposition, is not consistent with the present data, because the order *n* in Eq. (1) is not 2.0. However, if step 8 is assumed, the order *n* is 2.0, regardless of the type of termination step (step 6 or 7), in agreement with the present experimental results. From steps 4, 5, 6, and 8, the following equation can be derived:

$$-\frac{d[ArSSAr]}{dt} = k_1[ArSSAr] + \frac{k_1k_5[ArSSAr]^2}{k_2[RH]} \quad (10)$$

It appears reasonable that the thiyl radical induces the decomposition, while the tetralinyl radical does not, and thus, the latter radical may be more stable and less reactive than the thiyl radical. If induced decomposition by the tetralinyl radical under the present experimental conditions (high temperature and low disulfide concentration) occurs in a manner similar to that in the case of the polystyryl radical for the disulfide as previously described, di-*p*-methoxyphenyl disulfide should also be susceptible to induced decomposition. Benati and his coworkers[22] have reported interesting reactions of the thiyl radical with halogenobenzene; the phenyl thiyl radical formed from the homolytic scission of diphenyl disulfide in halogenobenzene attacks the carbon being substituting for the halogen atom and produces phenyl sulfide. From this result, reaction (11) is speculated to be the reaction of the thiyl radical with di-*p*-chlorophenyl disulfide.



(11)

Rate Constants and Activation Parameters. Table 1 shows that the homolytic scission of S—S bonds in disulfides is more difficult than of O–O bonds in peroxides for which the bond dissociation energy is 34—37 kcal/mol for diaryl peroxides and nearly 30 kcal/mol for dibenzoyl peroxide.[23] Although, from thermochemical studies, the bond energies of S–S bonds in dialkyl and diphenyl disulfides (in gas phase) are calculated to be 67—68[24] and 64 kcal/mol,[25] respectively, the bond dissociation energies of S–S bonds obtained experimentally for polysulfides (*e.g.*, dimethyltetrasulfide and S_8 ring), TMTD, DBTD, and benzhydrylhydro disulfide in solution are 36,[26] 31.6,[3] 26,[5] and 20 kcal/mol,[27] respectively, which are comparable to those of the O–O bonds in peroxides. Thus, the activation energies obtained (39.4—43.0 kcal/mol) for the decomposition of diaryl disulfides are reasonable values.

The Effects of Structure on the Decomposition. The following results suggest that the stability of thiyl radicals formed from decomposition is an important factor in the decomposition of the disulfide; the homolytic scission of S–S bonds in diaryl disulfides is easier than that of S–S bonds in dialkyl disulfides (for example, compare with di-*n*-butyl disulfide in Table 1). This can be explained from the greater stability (resonance stabilization) of aryl thiyl radicals in comparison with that of alkyl thiyl radicals.[28] The rates of the decompositions of the di-*p*-substituted phenyl disulfides are increased by a *p*-substituent, and the order of decreasing rates is $CH_3O > Cl \simeq CH_3 > H$. This order might be expected from the stability of thiyl radicals, which is increased by the resonance interaction of the *p*-substituent with the aromatic ring.[29] Similar curves for the Hammett plots have also been obtained for the decompositions of substituted benzoyl peroxides in acetophenone,[30] the dissociation of

hexaaryl ethane into triaryl methyl radicals,[31] and some substituent effects on the free-radical properties such as the λ_{max} shift in the electronic spectra of some nitrogen-centered radicals.[32]

It has been reported that, in the thermal decomposition of di-*p*-substituted benzoyl peroxides and of peresters, electron-donating substituents increase the rate of decomposition, since these substituents increase the difference in the electronegativity between the peroxide oxygens and the aromatic ring, and the repulsion between the negative charges located on the peroxide oxygen destabilizes the parent molecule in the ground state of the decomposition. Thus, the ρ value is negative in the Hammett equation, whereas, peroxides having electron-attracting substituents are subject to induced decomposition, with the ρ value being positive.[33] In the present study the ρ value (−0.55) in the Yamamoto-Otsu equation is also negative (the value of γ is 3.0), that is, electron-donating substituents destabilize the disulfide and increase the rate of thermal decomposition, probably for the same reason as that in the case of peroxides. It is interesting that the rate of decomposition of di-*t*-butyl disulfide is high and comparable to that of diaryl disulfides, whereas, di-*n*-butyl disulfide did not decompose under the same conditions. In the decomposition of dialkyl peroxides, however, it has been reported[34] that di-*t*-butyl and diethyl peroxides have the same dissociation energy. Therefore, the high reactivity of di-*t*-butyl disulfide, which is less strained than di-*t*-butyl peroxide, cannot be explained in terms of strain.

It may be concluded from the present study that *p*-substituents in di-*p*-substituted phenyl disulfides influence both the destabilization of the disulfide and the stabilization of the thiyl radical formed from thermal decomposition, and these two factors accelerate the rate of thermal decomposition of the disulfides.

Table 2. λ_{max} in the electronic spectra of aryl thiyl radicals in 2-MTHF at −196 °C and of benzyl-type radicals

Radical	λ_{max} (nm)		
p-Methoxyphenyl thiyl[a]		410 (418)[b]	530
p-Methylphenyl thiyl	312	397 (396)[b]	513
p-Chlorophenyl thiyl	318	386 (381)[b]	516
Phenyl thiyl	308	390 (387)[b]	
Benzyl[c]	318	452	
Phenoxy[d]	300	403	
Anilino[e]	307	400

Electronic Spectra of Aryl Thiyl Radicals. Electronic spectra of *p*-substituted phenyl thiyl radicals were observed by the photolysis of the thiols in a 77 K-matrix of 2-MTHF in order to obtain some information about the electronic states of aryl thiyl radicals and the interaction between the *p*-substituent and the odd electron of the radical. The absorption maxima of aryl thiyl radicals are summarized in Table 2 together with other benzyl-type radicals such as benzyl, phenoxy, and anilino radicals. Table 2 shows that the absorption maxima of phenyl thiyl radical at 310 and 390 nm are shifted by the *p*-substituents (the ESR spectrum of the phenyl thiyl radical being characterized by a large anisotropic *g* value ($g_{//}$=2.020 and $g_{\perp}$=2.019) under the same conditions). Similar absorption maxima around 300 and 400 nm being assigned to the π-electronic spectra of benzyl, phenoxy, and anilino radicals, the shift of the absorption maxima due to substituents have been observed by Porter and his co-workers,[35] and the molecular orbitals of the radicals have been calculated theoretically.[36] A comparison with the position of the absorption maxima of benzyl-type radicals and the considerable change in position due to *p*-substituents suggest that the thiyl radicals should be π-type radicals, which is supported by some theoretical and ESR studies,[37] and the present kinetic results, suggesting the importance of the conjugation among the sulfur atom, the phenyl ring, and the *p*-substituent.

Finally, it is found from a comparison of the first-order rate constants at 207 °C calculated from activation parameters taken from the literature[38] (Table 3), that the homolytic scission of S–S bonds in disulfides is most improbable in comparison with such related compounds as $ArS(=O)_2-SAr$, $ArS-S(=O)_2Ar$, $ArS(=O)-SAr$, $ArS(=O)_2-S(=O)_2Ar$, and $ArS(=O)-S(=O)Ar$, which differ in the oxidation state of the sulfur atom in the S–S bonds. Kice[39] has explained the change in the rate of the homolytic scission of these compounds by the difference in the stability of the radicals, stating that ArSO· is more stable than either ArS· or $ArSO_2$·.

We would like to thank Dr. K. Kikuchi and Dr. O. Ito for helpful discussions concerning the spectroscopic studies.

The Asymmetric (Enantioface Differentiating) Hydrogenation of the C=O Double Bond with Modified Raney Nickel. XXIX.

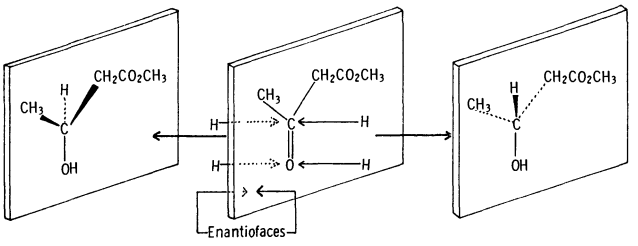
Tadao HARADA

Division of Organic Chemistry, Institute for Protein Research, Osaka University, Yamadakami, Suita, Osaka 565

(Received April 28, 1975)

In the asymmetric (enantioface differentiating) hydrogenation of methyl acetoacetate with modified Raney nickel catalysts, the effects of the modifying pH on the amounts of the modifying reagents adsorbed and the enantioface differentiating abilities of the catalysts were studied using glycolic acid, mandelic acid, and 2-hydroxy-3-phenylpropionic acid as the modifying reagents. The results indicate that the modifying pH governs the adsorption mode of the modifying reagent. Thus, the change in the adsorption mode of the modifying reagent with the change in the modifying pH results in changes in the amount of the modifying reagent adsorbed and in the enantioface differentiating ability of the catalyst.

The asymmetric hydrogenation of methyl acetoacetate to methyl 3-hydroxybutyrate has been previously studied by our research group[1,2] in the presence of Raney nickel catalysts modified with optically active 2-amino or 2-hydroxy acid (modifying reagent). This reaction can be classified as an enantioface differentiating reaction,[2,3] because in this reaction process the catalyst differentiates between the two sides of the enantiotopic plane (the enantiofaces) of methyl acetoacetate. The enantioface differentiating hydrogenation of methyl acetoacetate is shown in Fig. 1. In the course of our studies, it was found that the enantioface differentiating ability of the catalyst[4] and the amount of the modifying reagent adsorbed on the catalyst were both strongly affected by the pH of the aqueous solution of the modifying reagent (the modifying pH.)[5,6] In order to understand the change in the enantioface differentiating ability of the catalyst with the change in the modifying pH, it is essential to clarify the relationship between the enantioface differentiating ability of the catalyst and the amounts of the modifying reagent adsorbed at various modifying pH values.



(*S*)-Isomer Methyl acetoacetate (*R*)-Isomer

Fig. 1. Enantioface differentiating hydrogenation of methyl acetoacetate.

In the present work, the effects of the modifying pH on the amount of the modifying reagent adsorbed and on the enantioface differentiating ability of the catalyst were investigated by means of catalysts modified with 2-monohydroxy monocarboxylic acids, such as glycolic acid, mandelic acid, and 2-hydroxy-3-phenylpropionic acid.

Results and Discussion

The modified Raney nickel catalysts were prepared with glycolic acid, DL-mandelic acid, and L-2-hydroxy-3-phenylpropionic acid at various modifying pH values.

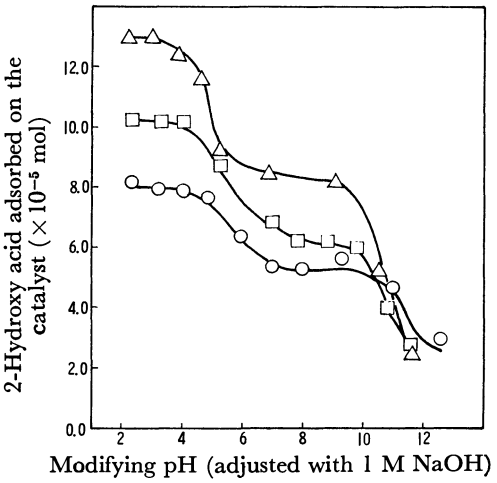


Fig. 2. Effects of the modifying pH on the amounts of the modifying reagents adsorbed.
△: glycolic acid
○: DL-mandelic acid
□: L-2-hydroxy-3-phenylpropionic acid
An amount of 1.5 g of Raney alloy (Ni: Al=42: 58) was used for each preparation of the catalyst.
Modifying solution: 100 ml of a 1% aqueous solution of the modifying reagent.

Plots of the amounts of the modifying reagent adsorbed against the modifying pH are shown in Fig. 2.

The amount of the modifying reagent (RCH(OH)-COOH) adsorbed at each modifying pH depends on the nature of the R group. However, on modification with these compounds, the changes in the amounts show a similar figure with the change in the midifying pH, regardless of the drastic changes in the R groups (*i.e.* H to phenyl). That is, the amounts of these compounds adsorbed are constant below pH 4 and at pH 6(7)—9, while they vary steeply at pH 4—6(7) and above pH 9. These observations indicate that the curve can be divided into four segments; that is, below pH 4(A), pH 4—6(7)(B), pH 6(7)—9(C), and above pH 9(D).

The enantioface differentiating abilities of the catslysts modified with L-2-hydroxy-3-phenylpropionic acid and L-mandelic acid were studied at various modifying pH values; the results are shown in Fig. 3. The enantioface differentiating abilities of the catalysts and the amounts of the modifying reagents adsorbed change in a fashion similar to each other with the change in the modifying

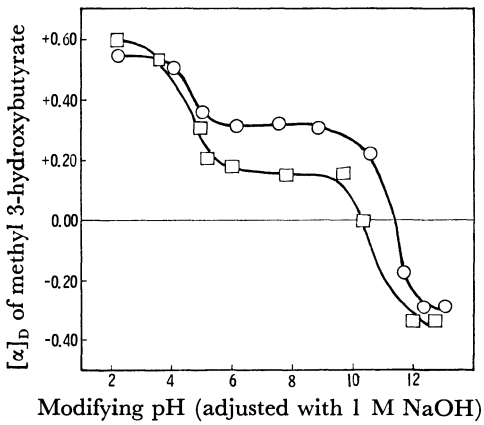

Fig. 3. Effects of the modifying pH on the enantioface differentiating abilities of the catalysts.
○: L-mandelic acid[a)]

pH. That is, the ability of the catalyst does not change in A and C, but does change drastically in B and D. However, the ratio of the enentioface differentiating ability in A to that in C is dependent on the nature of the R group, while the ratio of the amount of the modifying reagent adsorbed in A to that in C is independent of the nature of the R group, as is shown in Tables 1 and 2. From the data in Tables 1 and 2, it is clear that the ratio of the enantioface differentiating ability of the catalyst in A to that in C cannot be interpreted simply on the basis of the amount of the modifying reagent adsorbed. However, the similarity between the modifying pH dependence of the amount of the modifying reagent adsorbed and that of the enantioface differentiating ability of the catalyst suggests that there are some common factors which control both of them. The present author introduces the term of the adsorption mode to account for these common factors. Thus, the modifying pH governs the adsorption mode of the modifying reagent; the change in the adsorption mode results in the change in the amount of the modifying reagent adsorbed and that in the enentioface differentiating ability of the catalyst. The adsorption mode is determined by the adsorption species and the conditions of the catalyst surface.

Furthermore, on modifications with L-2-hydroxy-3-phenylpropionic acid and L-mandelic acid the direction of the optical rotation ($[\alpha]_D$) of the hydrogenation product is (−) above pH 12, while it is (+) below pH 10. These findings also support the dependence of the adsorption mode on the modifying pH.

The modifying pH dependence of the enentioface differentiating abilities observed with the catalysts modified with other 2-monohydroxy monocarboxylic acids can be explained in the same way, since our research group has obtained similar results with L-3,3-dimethyl-2-hydroxybutyric acid[7)] and L-2-hydroxy-3-methylbutyric acid.

Studies of the absorption modes of the modifying reagent in A, B, C, and D are in progress and will be reported soon.

Experimental

The preparation of the modified Raney nickel catalyst, the hydrogenation of methyl acetoacetate, and the measurement of the enantioface differentiating ability of the catalyst were carried out by the procedures described in the previous paper.[8)]

The modification of the catalyst was carried out at 0 °C for 90 min. During the modification, the mixture of the modifying solution and the catalyst was shaken every 15 min. After the midification, the catalyst was washed once with 10 ml of deionized water and then with three 50 ml portions of methanol.

Elution of the Modifying Reagent from the Catalyst Surface. A mixture of the modified Raney nickel and 10 ml of M sodium hydroxide was allowed to stand for 2 hr at 100 °C in a 50 ml, round-bottomed flask fitted with a condenser. The catalyst was removed by filtration and washed with deionized water. The filtrate and the washings were then combined and diluted accurately to 50 ml with deionized water. This solution was used for the determination of the modifying reagent adsorbed on the catalyst.

The Determination of L-2-Hydroxy-3-phenylpropionic Acid and

An Evaluation of the Effects of the Phosphorus Ligands on the Stereoselectivity of a Nickel-catalyzed Reaction. The Reaction of Norbornadiene with Acrylonitrile

Susumu YOSHIKAWA,* Kunihiro AOKI, Jitsuo KIJI, and Junji FURUKAWA
Department of Synthetic Chemistry, Kyoto University, Kyoto 606

(Received May 2, 1975)

The effects of nineteen phosphorus ligands on the nickel-catalyzed 4+2 cycloaddition reaction of norbornadiene to acrylonitrile have been studied. The cone angle and the ν_{CO} stretching frequency of $Ni(CO)_3L$ (where L is the phosphorus ligand) are used as measures of their steric and electronic parameters respectively. The steric factor of the phosphorus ligands is correlated with the ratio of the *exo*- and *endo*-isomers of the product. Consequently, this effect is important in determining the steric course of the reaction. The electronic property and the solvent effect are less influential.

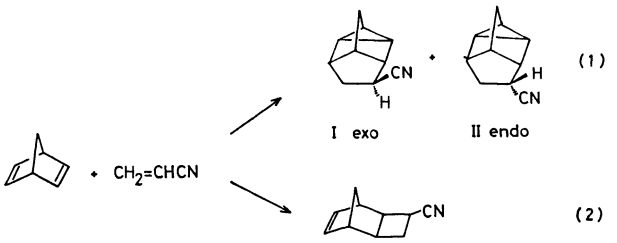
Many stereoselective reactions are catalyzed by transition metal complexes. In these catalytic reactions, the reaction participants are both electronically and sterically influenced by the effects of the ligands. Therefore, the transition metal-catalyzed homogeneous reactions have many advantages, *e.g.*, the available coordination sites for the reactions can be modified by adding some appropriate ligands, thus controlling a desired reaction. Such a modification has widely been used in synthetic and mechanistic studies of such transition metal-catalyzed reactions as the polymerization and oligomerization of olefins, hydrogenation, hydroformylation, and so on.[1] The electronic properties of phosphorus ligands have been evaluated from the infrared stretching frequencies of the ν_{CO} of $Ni(CO)_3L$ (where L is the phosphoru sligand).[2] On the other hand, the steric parameters of phosphorus ligands are somewhat complicated. Tolman has proposed the concept of a "cone angle", which encloses the van der Waals radii of the outermost atoms of the phosphorus ligand.[3-5] Until now, though, no satisfactory study of the electronic and steric effects of the phosphorus ligand on the transition metal-catalyzed homogeneous reaction has been made, because the reaction consists of many complicated steps. It seems that only a simple reaction can be discussed.

The reaction of norbornadiene with acrylonitrile is known to occur catalytically by means of nickel complexes.[6] This 4+2 cycloaddition is one of the most satisfactory model reactions for the evaluation of the stereochemical course of a transition metal-catalyzed reaction, because the *endo-exo* isomerization of the products is negligibly slow under the reaction conditions and the reaction can probably be explained by a simple intermediate which involves the coordination of two reactants and the phosphorus ligand.[7,8] In the past several years, the reactions of diolefins catalyzed by nickel complexes have been developed in our laboratory, and mechanistic studies have also been carried out.[9] The present study forms a part of this systematic investigation. This paper will deal with an evaluation of the effects of both the electronic and the steric factors of the phosphorus ligands on the reaction of norbornadiene with acrylonitrile as a model reaction.

* Present address: Government Industrial Research Institute, Osaka, Midorigaoka, Ikeda, Osaka 563.

Results and Discussion

The reaction of norbornadiene with acrylonitrile gives two products, I and II (Eq. 1). Around 100 °C no appreciable 2+2 reaction (Eq. 2) occurs. Some nickel catalysts are effective for the reaction (Eq. 1) at lower temperatures. Schrauzer and Eicheler have reported the bis(acrylonitrile)nickel-catalyzed reaction in the presence of a phosphorus ligand, but they did not discuss the stereoisomers in detail.[6] It has been found that the catalytic reaction, unlike the thermal reaction, affords the *exo* isomer predominantly, and that this stereoselectivity is influenced delicately by an added phosphorus ligand.[10] To gain insight into the effects of the ligands on the stereoselectivity of the reaction, various phosphorus compounds and triphenylarsine were prepared and used with bis(acrylonitrile)nickel, $Ni(AN)_2$. Bis(acrylonitrile)nickel itself, without a phosphorus ligand, had no catalytic activity under these conditions. Metal acetylacetonates, such as $Cr(C_5H_7O_2)_2$, $Mn(C_5H_7O_2)_3$, $Fe(C_5H_7O_2)_3$, $Co(C_5H_7O_2)_3$, $Ni(C_5H_7O_2)_2$, $Cu(C_5H_7O_2)_2$, and $V(C_5H_7O_2)_3$, combined with sodium borohydride were used in the presence of triphenylphosphine. None of these complexes except $Ni(C_5H_7O_2)_2$ catalyzed the reaction.



Before the systematic investigation, the optimum ratio of triphenylphosphine to the nickel complex was studied. The yields were increased with the amount of added triphenylphosphine, while the ratio of the *exo* to *endo* isomers was not influenced by its amounts (Fig. 1). Bis(acrylonitrile)nickel is slightly soluble under the present reaction conditions. The addition of triphenylphosphine seems to increase the solubility of $Ni(AN)_2$, thus increasing the yield. This observation reveals that the active species is specified only by the kind of the phosphorus ligand, not by its amount.

All the reactions were carried out between 70 and 130

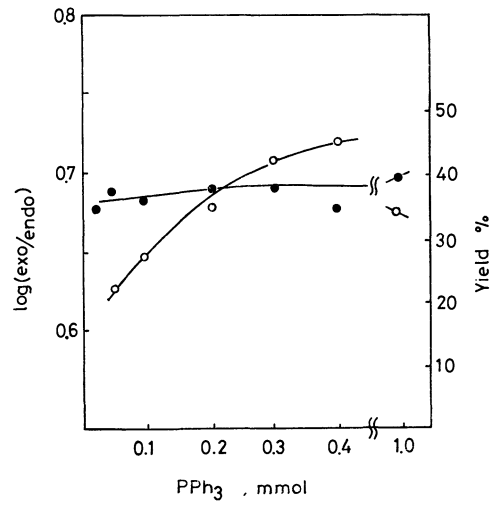


Fig. 1. Effect of added $(C_6H_5)_3P$ on the reaction at 80 °C. Conditions: $Ni(AN)_2$. 0.05 mmol; C_3H_3N, 6 mmol; C_7H_8, 6 mmol; reaction time, 10 hr.
(○): Yield (●): Isomer ratio

°C. Under these conditions, neither *retro*-reaction nor isomerization occurred. That is, the product (I or II) was separated by gas chromatography and heated in the presence of $Ni(AN)_2$–$(C_6H_5)_3P$ at 100 °C. After 20 hr, no isomerization occurred and I or II was recovered unchanged. Consequently, the isomeric ratio reflects the ratio of the rates of their formation; thus the reaction is kinetically controlled.

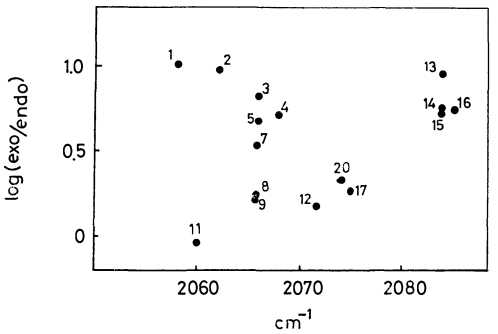

Fig. 2. Plot of *exo/endo* ratio at 80 °C against $\nu_{CO}(A_1)$ of $Ni(CO)_3L$ of phosphorus ligand (L) used with $Ni(AN)_2$. Ligand number refers to experimental section.

In general, ligand effects may be separated into electronic and steric factors. The electronic properties of the phosphorus ligands have been estimated by means of the ν_{CO} stretching frequency of $Ni(CO)_3L$ complex (where L is the phosphorus compound).[2] This spectrochemical estimation is applicable to some discussion of the catalytic process. Wilkinson and his co-workers[11] have employed this estimation for the explanation of the catalysis of tris(triarylphosphine)rhodium chloride. As is shown in Fig. 2, however, there is no correlation between the *exo/endo* ratio at 80 °C or 130 °C and the electronic properties of the added ligands. For example, there is a marked difference in the electronic properties between $(o\text{-}CH_3OC_6H_4)_3P$ and $(o\text{-}CH_3C_6H_4O)_3P$ (**1** and **13** in Fig. 2). The ratio of the isomers is nearly equal. All the phosphite ligands $P(OR)_3$ except $(o\text{-}CH_3C_6H_4O)_3P$ gave products in similar yields (see Experimental section). The electronic character of the phosphorus ligand has no appreiable influence on the reaction rate. This is a marked contrast to the dimerization of olefins or acetylenes. For example, the ratio of the stereoisomers (*exo-trans-exo* and *endo-trans-exo*) of the 2+2 cyclodimer of norbornadiene is strongly influenced by the electronic factor.[12]

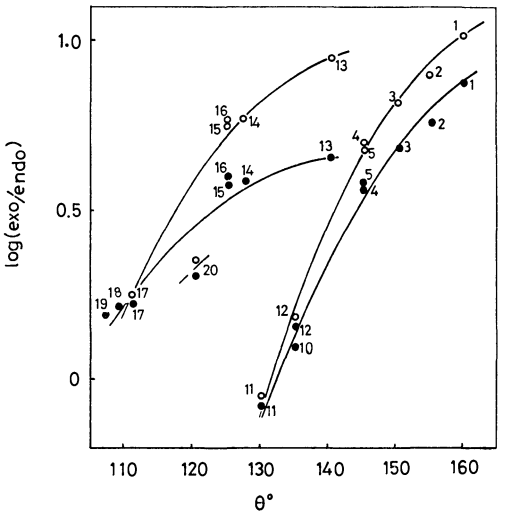

Fig. 3. Plot of *exo/endo* ratio against cone angle (θ) of the phosphorus ligands.
(○): 80 °C (●): 130 °C

Contrary to the electronic factor, an estimation of the steric factor of the phosphorus ligand is rather complicated. One measure of its bulkiness is the cone angle, θ, which is the maximum clearance angle for the rotation of the phosphorus ligand around its three-fold axis.[3] When this value is used as a measure of the steric parameter, it is shown in Fig. 3 that the steric factor is much more important than the electronic factor in determining the steric course of the reaction. The cone angles of the phosphorus ligand used and the ratio of *exo/endo* are correlated with each other. In Fig. 3 the phosphorus ligands are divided mainly into two groups; the first is a phosphite group, and the other, phosphine. The effect of $(C_6H_5)(C_2H_5O)_2P$ (**20**) is intermediate between those of the phosphites and phosphines. Within the phosphorus homologs, excellent correlations of log *exo/endo* with the cone angles are observed. The steric effect is more predominant at 80 °C than at 130 °C. These facts can reasonably be explained in terms of steric interaction between the coordinated acrylonitrile and the phosphorus ligand in the coordination sphere of the reaction intermediate.

Here it may be postulated that, among the four available coordination sites of the zero-valent nickel, two are occupied by diene and one by acrylonitrile,[8] and that their coordination takes place in the less-hindered tetrahedral configuration between the CN group and the phosphorus ligand (Fig. 4). Therefore, when a bulky phosphorus ligand is used, the less hindered coordination (Fig. 4 right) is favorable; thus the *exo* isomer is formed.

The steric effect of the phosphorus ligand on the reaction is further illustrated by the following facts. When

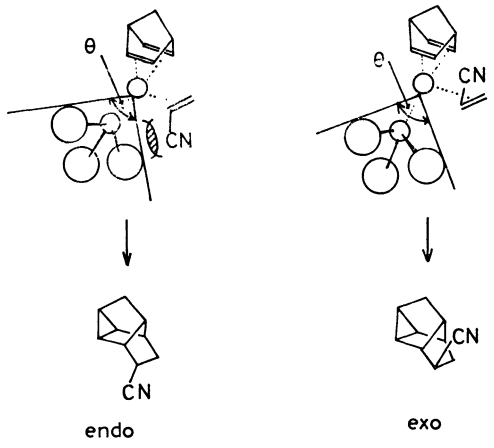

Fig. 4. Proposed structure of the intermediates.

the more bulky (o-$CH_3C_6H_4)_3P$ was used as the ligand, no appreciable reaction occurred between 80 and 130 °C. In the case of $(CH_3OC_6H_4)_3P$, the *ortho* isomer gave a lower yield than the other isomers. The fact that phosphites have a different steric effect on the reaction from that of the phosphine analogue cannot be explained by the present study. The effect of diphosphines (**7**—**9**) is too complicated to discuss, since diphosphines coordinate to the nickel competitively with norbornadiene and retard the reaction.

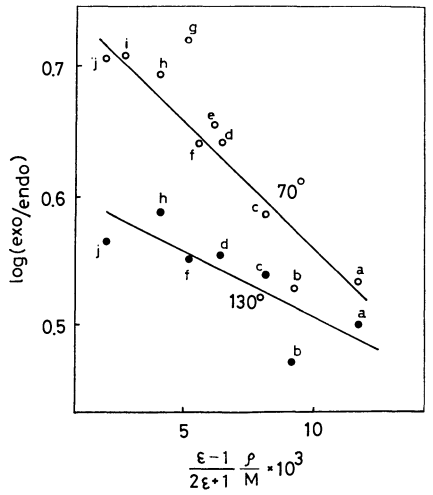

Fig. 5. Plot of *exo*/*endo* ratio against molar polarization of the solvent used.
(○): 70 °C (●): 130 °C
a, methanol; b, acetonitrile; c, ethanol; d, acetone; e, 2-propanol; f, pyridine; g, tetrahydrofuran; h, ethyl acetate; i, benzene; j, triethylamine.

The solvent effect was also investigated by using aprotic and protonic solvents, using triphenylphosphine as the auxiliary ligand. A linear free-energy relationship was observed for all the solvent. The polar solvent preferred the *endo* isomer. This can be explained by the dipolar interaction between the intermediate (Fig. 4) and the solvent. Thus, the intermediate (Fig. 4), which gives the *endo* isomer, is considered to have a larger total dipole moment than the other intermediate giving the the *exo* isomer and is stabilized by the polar solvent.[13] However, this effect on the reaction is smaller than that of the ligands.

Experimental

Commercially available phosphorus compounds were used without further purification. The other phosphorus compounds were prepared by the known methods. The products of the reaction of norbornadiene with acrylonitrile were identified by comparing their infrared and NMR spectra with those of the reported ones. Quantitative analyses were performed by gas chromatography on a column, Silicon DC 550 on Celite, 3 m at 150 °C, using tetralin as the internal standard. The *exo* isomer was eluted faster than the *endo* isomer. The cone angles and the stretching frequencies of $\nu_{CC}(A_1)$ were estimated by the reported methods. The Stewart molecular model was used for the estimation of the cone angle (θ). The values estimated in the present study are as follows:
$P(C_6H_5)(o\text{-}C_6H_4OCH_3)_2$ (**2**), 155; $P(C_6H_5)_2(o\text{-}C_6H_4OCH_3)$ (**3**), 150; $P(p\text{-}C_6H_4CH_3)_3$ (**5**), 145; $P(C_6H_5)(C_2H_5)_2$ (**10**), 135; $As(C_6H_5)_3$ (**12**), 135; $P(O\text{-}o\text{-}C_6H_4CH_3)_3$ (**13**), 140; $P(O\text{-}m\text{-}C_6H_4CH_3)_3$ (**14**), 127; $P(O\text{-}p\text{-}C_6H_4CH_3)_3$ (**15**), 125; $P(O\text{-}n\text{-}C_4H_9)_3$ (**17**), 111; $P(C_6H_5)(OC_2H_5)_2$ (**20**), 121.

Reaction. All the reactions were carried out in a glass tube (8 mm in diameter), as in the case of the dimerization of butadiene reported earlier.[14] In the glass tube, $Ni(AN)_2$ (0.05 mmol), the solvent (1 ml), norbornadiene (6 mmol), acrylonitrile (6 mmol), the phosphorus ligand (0.2 mmol), and tetralin (130 mg, as the internal standard for the gas chromatographic analysis) were placed under an atmosphere of argon. The tube was sealed with a flame and then heated without agitation. The total yields (*exo* and *endo* isomers) of the reactions in the presence of the various ligands shown in Figs. 2 and 3 are as follows (% at 80, 130 °C for 10 hr):
$P(o\text{-}C_6H_4OCH_3)_3$ (**1**) (26.9, 12.4), **2** (27.9, 11.2), **3** (27.4, 17.7), $P(C_6H_5)_3$ (**4**) (48.9, 28.1), **5** (42.5, 30.9), $NiBr_2[P(C_6H_5)_3]_2$ (**6**) (18.6, 15.7), $(C_6H_5)_2P(CH_2)_3P(C_6H_5)_2$ (**7**) (59.7, 28.4), $(C_6H_5)_2P(CH_2)_2P(C_6H_5)_2$ (**8**) (47.9, 25.0), $(C_6H_5)_2PCH_2P(C_6H_5)_2$ (**9**) (17.6, 19.1), $P(C_6H_5)(C_2H_5)_2$ (**10**) (42.1, 27.0), $P(n\text{-}C_4H_9)_3$ (**11**) (16.6, 8.4), **12** (17.6. 5.9), **13** (24.8, 12.9), **14** (49.9, 26.7), **15** (50.4, 29.5), $P(OC_6H_5)_3$ (**16**) (47.9, 26.7), **17** (58.7, 28.1), $P(OC_2H_5)_3$ (**18**) (58.2, 26.1), $P(OCH_3)_3$ (**19**) (57.2, 25.0), **20** (57.2, 27.5).

The authors are grateful to Drs. Yoshiaki Kobuke and Takuji Sugimoto for their helpful discussion.

Novel Synthesis of Anhydronucleosides *via* the 2′,3′-*O*-Sulfinate of Purine Nucleosides as Intermediates

Tsuneo Sowa and Kozo Tsunoda

Research Section, Foodstuff Plants, Asahi Chemical Ind. Co., Ltd., Nobeoka, Miyazaki 882

(Received May 6, 1975)

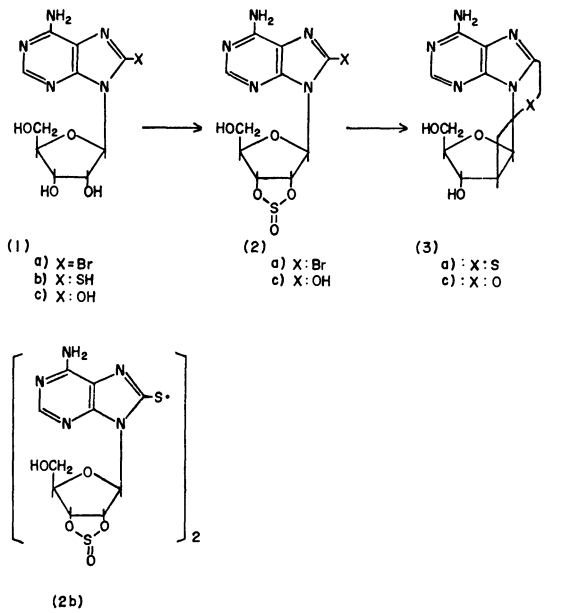
The synthesis of 8,2′-*O*-anhydro(9-β-D-arabinofuranosyl)-8-hydroxyadenine (**3c**) and 8,2′-*S*-anhydro(9-β-D-arabinofuranosyl)-8-mercaptoadenine (**3a**) is described. The active intermediates, 2′,3′-*O*-sulfinyl 8-bromoadenosine (**2a**), 2′,3′-*O*-sulfinyl-8-hydroxyadenosine (**2c**), and 2′,3′-*O*-sulfinyl-8-bromoguanosine (**2d**), were prepared from the corresponding nucleosides (**1a**, **1c** or **1d**) by successive treatment with thionyl chloride in the presence of pyridine in acetonitrile and with water. The anhydronucleosides, **3a** and **3c**, were formed in good yields by heating the intermediates (**2a** or **2c**) in *n*-butanol in the presence of thiourea or in *N*,*N*-dimethylformamide in the presence of sodium acetate. All attempts at the cyclization of Compound **2d** failed. The reaction product of 8-mercaptoadenosine (**1b**) with thionyl chloride was identified as the bis(2′,3′-*O*-sulfinyl adenosin-8-yl) disulfide (**2b**), which could not be transformed to Compound **3a**.

Anhydronucleosides are important analogues of natural nucleosides. 8,2′-Anhydronucleosides are key intermediates in the synthesis of many biologically active compounds and have provided new routes for the nucleotides.[1,2] Anhydronucleosides have been synthesized, by several procedures, from natural or unnatural nucleosides *via* the corresponding activated intermediates, such as tosyl,[3] triisopropylbenzene sulfonyl[4] or carbonyl derivatives,[5] but most of these methods are tedious.

The present authors[6] have previously reported that anhydropyrimidinenucleosides can be conveniently prepared in high yields *via* the corresponding 2′,3′-*O*-sulfinates as intermediates. In the present paper we wish to describe a simple and efficient method for the anhydropurine nucleosides.

Results and Discussion

Ogilvie[5] prepared 8,2′-thioanhydro(9-β-D-arabinofuranosyl)-8-mercaptoadenine by heating 2′,3′-*O*-carbonyl-8-bromoadenosine in the presence of thiourea in *n*-butanol. The essential step in the preparation of anhydronucleosides is the introduction of a good leaving group to the 2′ and 3′-positions in the ribose moiety of nucleosides, as is outlined in Scheme 1. In order to establish a convenient method applicable for large-scale preparation, a cyclic sulfinyl group[6] was used as the leaving froup; it was considered to be more active than the cyclic carbonyl group.



Scheme 1.

Thionyl chloride was allowed to react with 8-bromoadenosine (**1a**) in the presence of pyridine in acetonitrile at the temperature of 5 °C for 3 hr. Paper chromatography showed the presence of a single spot with an R_f-value of 0.91 other than that of the **1a** meterial (0.71). The reaction product was isolated in a 64% yield by pouring the reaction mixture into ice water and by then adjusting the pH of the resulting solution to pH 2.5 with sodium bicarbonate. The structure of the acylation product was identified as 2′,3′-*O*-sulfinyl-8-bromoadenosine (**2a**), which was negative to a periodate-benzidine test[7] and which gave ultraviolet spectra similar to those of **1a**. The alkaline hydrolysis of **2a** eliminated the cyclic sulfinyl group to give the **1a** material. The **2a** product had a broad band due to S=O stretching and three sharp bands associated with the five-membered cyclic sulfinyl group at 1201, 1205, and 1210 cm^{-1} in the infrared spectrum.[8] The elemental analysis of **2a** agreed with the proposed structure.

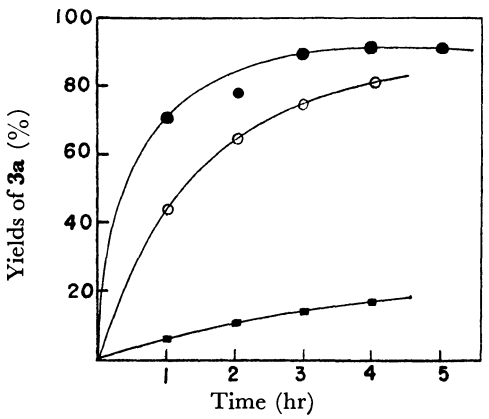


Fig. 1. Effect of reaction temperature of the preparation of **3a**.
Experimental conditions: 2′,3′-*O*-sulfinyl-8-bromoadenosine 1 mmol, thiourea 4 mmol, *n*-butanol 100 ml at 119 °C (●), 100 °C (○), 70 °C (■).

a) d: decompose.

In *n*-butanol, **2a** was stable at the temperature of 80 °C in the presence of thiourea but was transformed to **3a** at an elevated temperature (Fig. 1). When **2a** was refluxed in *n*-butanol in the presence of thiourea, the reaction went essentially to completion after 4 hr to form a 8,2′-thioanhydro-linkage. The reaction product was isolated in a 70% yield and was identified as 8,2′-*S*-anhydro(9-β-D-arabinofuranosyl)-8-mercaptoadenine (**3a**) by a comparison of the physical properties with those of an authentic sample.[5] Compound **3a** was easily converted to 2′-deoxyadenosine (**4a**) by reducing it with Raney-Ni.

The treatment of 8-mercaptoadenosine (**1b**) with thionyl chloride under the same conditions as **1a** gave a single product, with an R_f-value of 0.9, by paper chromatography. Compound **2b** had a λ-maximum at 281 nm in the aqueous solution at pH 2.0, and its ultraviolet spectrum differed from that of the **1b** material (307 nm). Though the **2b** product had a broad band due to S=O stretching at 1000—1050 cm^{-1} and three fairly sharp bands associated with a five-membered cyclic sulfinyl group at 1200, 1205, and 1210 cm^{-1}, the specific absorption peak due to the SH group could not be found at 2550 cm^{-1} in the infrared spectrum. These facts show that the structure of the **2b** product is the bis(2′,3′-*O*-sulfinyladenosin-8-yl) disulfide. The elemental analysis of **2b** agreed with the proposed structure. All attempts at the cyclization of **2b** failed.

8-hydroxyadenosine (**1c**) was allowed to react with thionyl chloride under the same conditions as **1a** to give 2′,3′-*O*-sulfinyl-8-hydroxyadenosine (**2c**) as the single product, as shown by paper chromatography. By heating **2c** in *N*,*N*-dimethylformamide at 115 °C for 1 hr in the presence of sodium acetate, 8,2′-*O*-anhydro(9-β-D-arabinofuranosyl)-8-hydroxyadenosine (**3c**) was obtained in a 44.3% yield. The physicochemical properties of **3c** were in good agreement with those of an authentic sample.[9] By treatment with hydrogen sulfide in pyridine, **3c** was easily converted to 9-β-D-arabinofuranosyl-8-mercaptoadenine (**4c**), which was then transformed to 9-β-D-arabinofuranosyladenine (**5c**) by treating it with Raney-Ni. The physical properties of **4c** and **5c** are listed in Table 1; they are identical with those of authentic samples. Though the 2′,3′-*O*-sulfinyl-8-bromoguanosine (**2d**), much like **2a**, was formed quantitatively by treating 8-bromoguanosine (**1d**) with thionyl chloride, Compound **2d** could not be transformed to the corresponding anhydronucleoside, presumably because Compound **2d** is conformationally the "Syn" form.

The above method of synthesizing the anhydropurine nucleosides is superior to those of Ikehara[9] and Ogilvie[5] with respect to the yield and the simplicity of the procedure.

Experimental

The ultraviolet spectra were recorded on a Hitachi EPS-3T spectrophotometer, and the infrared spectra, on a Hitachi EPI-G2. The paper chromatography of the reaction products was carried out by the ascending technique on Toyo-Roshi No. 51 paper (40 cm × 40 cm) using the following solvent system: Solv. A; *n*-butanol–acetic acid–water (4: 1: 5); Solv. B; 2-propanol–saturated ammonium sulfate–1 M-sodium acetate (2: 79: 19). The UV and chromatographic properties are shown in Table 1.

2′,3′-O-Sulfinyl-8-bromoadenosine (2a). Freshly distilled thionyl chloride (21.6 ml, 300 mmol) and pyridine (24 ml, 300 mmol) were placed in 100 ml of acetonitrile, after which the mixture was set aside at the temperature of 5 °C. To the solution we then added 8-bromoadenosine (34.7 g, 100 mmol), and the mixture was stirred at 5 °C for 3 hr. Then, 300 ml of water was mixed with the reaction mixture to destroy the reactant under vigorous stirring. Paper chromatography showed the presence of a single spot with an R_f value of 0.9 (solvent B); an aqueous extract of it showed an absorption maximum at 260 nm (pH 1.0). The resulting reaction mixture was adjusted to pH 2.5 with sodium bicarbonate and was then kept in the refrigerator overnight. The white precipitates thus obtained were collected by filtration, washed with water, and dried to yield 24.4 g (64%) of 2′,3′-*O*-sulfinyl-8-bromoadenosine; mp 146—148 °C (dec.).

Found: C, 31.6; H, 2.5; N, 18.0, Br, 19.5; S, 8.1%. Calcd for $C_{10}H_{10}N_5O_5S \cdot Br$: C, 30.6; N, 2.5, H, 17.8; Br, 20.4; S, 8.2%.

2′,3′-O-Sulfinyl-8-bromoguanosine (2d). Into a mixed solution of thionyl chloride (21.6 ml), pyridine (24 ml), and acetonitrile (100 ml), we vigorously stirred 8-bromoguanosine (100 mmol); the reaction solution was then maintained for

3 hr at 5 °C. A 300 ml portion of water was then added to the reaction mixture, and the pH of the resulting solution was adjusted to 2.5 with sodium bicarbonate. The white precipitates thus obtained were collected, washed with water, and then dried to yield 25.4 g (64.3%) of 2′,3′-*O*-sulfinyl-8-bromoguanosine. Mp 175—177 °C (dec.); R_f 0.85 (solv. B), λ_{max} 258 nm (pH 2.0).

Found: C, 30.8; N, 17.1; S, 7.89%. Calcd for $C_{10}H_{10}N_5O_6Br$: C, 29.4; N, 17.1; S, 7.8%.

*2′,3′-O-Sulfinyl-8-hydroxyadenosine (**2c**).* Into a mixed solution of thionyl chloride (3.6 ml, 50 mmol), pyridine (2.4 ml, 30 mmol), and acetonitrile (30 ml), we vigorously stirred 8-hydroxyadenosine (2.8 g, 10 mmol), after which the reaction solution was maintained for 2 hr at 0 °C. A 250 ml portion of acetonitrile was added to the resulting mixture, and the solid thus precipitated was collected by filtration, washed with acetonitrile and twice with ether, and then dried to yield 2.84 g (85.7%) of 2′,3′-*O*-sulfinyl-8-hydroxyadenosine hydrochloride. Mp 85—92 °C (dec.); R_f 0.82 (solv. B).

Found: C, 32.5; H, 3.2; N, 17.3; S, 7.87; Cl, 10.14%. Calcd for $C_{10}H_{11}O_6N_5S\cdot HCl$: C, 32.8; H, 3.3; N, 19.2; S, 8.74; Cl, 9.71%.

*Bis(2′,3′-O-sulfinyladenosin-8-yl) Disulfide (**2b**).* Into a mixed solution of thionyl chloride (10.8 ml, 150 mmol), pyridine (12 ml, 150 mmol), and acetonitrile (50 ml), we vigorously stirred 8-mercaptoadenosine (15 g, 50 mmol), after which the reaction solution was maintained for 3 hr at 0 °C. A 300 ml portion of water was added to the reaction mixture under vigorous stirring to destroy the reactant. The resulting aqueous solution was adjusted to pH 2.5 with sodium bicarbonate and was then kept in the refrigerator overnight. The precipitates were collected by the filtration and then washed with water and dried to yield 12.6 g of bis(2,3′-*O*-sulfinyladenosin-8-yl) disulfide. Mp 142 °C (dec.); R_f 0.9 (solv. B), λ_{max} 281 nm (pH 2.0).

*8,2′-S-Anhydro(9-β-D-arabinofuranosyl)-8-mercaptoadenine (**3a**).* 2′,3′-*O*-Sulfinyl-8-bromoadenosine (21 g, 50 mmol) and thiourea (14 g, 200 mmol) were dissolved in 5 l of *n*-butanol, and the solution was refluxed for 4 hr. After drying the reaction mixture *in vacuo*, the residual product was dissolved in hot water and then cooled. The solid thus precipitated was collected by filtration and then washed with cold water and dried to give 10.2 g (70%) of 8,2′-*S*-anhydro(9-β-D-arabinofuranosyl)-8-mercaptoadenine. Mp 212—214 °C (dec.); $[\alpha]_D^{20}$ −178.1° (*c*, 0.5, H_2O) λ_{max} 276 nm (pH 2.0), R_f 0.12 (solv. A), 0.61 (solv. B). Found: C, 41.0; H, 4.2; N, 23.2; S, 9.67%. Calcd for $C_{10}H_{11}N_5O_3S\cdot 1/2H_2O$: C, 41.4; H, 4.1; N, 24.1; S, 11.0%.

*8,2′-O-Anhydro(9-β-D-arabinofuranosyl)-8-hydroxyadenine (**3c**).* 2′,3′-*O*-sulfinyl-8-hydroxyadenosine hydrochloride (5.5 g, 15 mmol) and sodium acetate (2.8 g, 45 mmol) were heated in *N,N*-dimethylformamide (1500 ml) for 45 min at 115 °C. After the reaction mixture had been dried *in vacuo*, the residual product was dissolved in 1 l of water; then the aqueous solution was submitted to electrodialysis with an ion-exchange membrane. The resulting solution was evaporated *in vacuo*, and white precipitates were collected, washed with water, and dried to yield 1.32 g (44.3%) of 8,2′-*O*-anhydro(9-β-D-arabinofuranosyl)-8-hydroxyadenine monohydrate. Mp 202—202.5 °C (dec.); λ_{max} 260 nm (pH 2.0).

Found: C, 42.90; H, 4.38; N, 24.7%. Calcd for $C_{10}H_{11}O_4N_5\cdot H_2O$: C, 42.40; H, 4.59; N, 24.73%.

*2′-Deoxyadenosine (**4a**).* 8,2′-*S*-Anhydro(9-β-D-arabinofuranosyl)-8-mercaptoadenine (4.6 g, 16.9 mmol) and Raney-Ni (30 g, Ni-content 50%) were mixed with 400 ml of water. The mixture was then refluxed for 2 hr. The nickel was removed by filtration, and the filtrate and washings (hot water) were combined and evaporated *in vacuo* to about 40 ml. A 100 ml portion of methanol was added to the concentrated solution, and the solid thus precipitated was collected by filtration, washed with water, and dried to give 2.88 g (67%) of 2′-deoxyadenosine. Mp 184—188 °C (dec.); R_f 0.49 (solv. B), λ_{max} 257 nm (pH 2), λ_{min} 232 nm (pH 2).

Found: C, 47.83; H, 5.11; N, 26.73%. Calcd for $C_{10}H_{13}N_5O_3$: C, 47.81; H, 5.18; N, 26.89%.

*8-Mercapto-9-β-D-arabinofuranosyl Adenine (**4c**).* 8-Mercapto-9-β-D-arabinofuranosyl adenine was prepared by Ikehara's method.[9] 8,2′-*O*-Anhydro(9-β-D-arabinofuranosyl)-8-hydroxyadenine monohydrate (1.1 g, 4 mmol) was dissolved in pyridine (40 ml) and liquid H_2S (obtained by cooling with dry-ice–acetone, 40 g). The mixture was sealed in a steel tube and heated at 100 °C for 16 hr. The tube was then cooled with dry-ice and N_2 gas was bubbled through to remove the H_2S completely. The pyridine was removed by the distillation *in vacuo*, and the residual product was crystallized from water to yield 1.0 g (78.4%) of 8-mercapto-9-β-D-arabinofuranosyl adenine monohydrate. Mp 190—191 °C (dec.); λ_{max} 223, 248, 208 nm (pH 2).

Found: C, 37.81; H, 4.75; N, 21.98; S, 9.95%. Calcd for $C_{10}H_{13}N_5O_4S\cdot H_2O$: C, 37.85; H, 4.73; N, 22.08; S, 10.09%.

9-β-D-Arabinofuranosyl Adenine[9] *(**5c**).* 8-Mercapto-9-β-D-arabinofuranosyl adenine monohydrate (4.5 g, 15 mmol) dissolved in 750 ml of water, and Raney-Ni (7.5 g) was added. The mixture was refluxed for 3 hr. The nickel was removed by filtration, and the filtrate and washings (hot water) were combined and concentrated *in vacuo*. The solid thus precipitated was collected by filtration, washed with water, and dried to yield 4.05 g (90%) of 9-β-D-arabinofuranosyl adenine monohydrate. Mp 252 °C (dec.); λ_{max} 257 nm (pH 2.0), R_f 0.19 (solv. A), 0.45 (solv. B).

Found: C, 42.15; H, 5.33; N, 24.28%. Calcd for $C_{10}H_{13}N_5O_4\cdot H_2O$: C, 42.10; H, 5.23; N, 24.56%.

Ethanol and Lactic Acid Sensors Using Electrodes Coated with Dehydrogenase-Collagen Membranes

Shuichi SUZUKI, Fujio TAKAHASHI, Ikuo SATOH, and Nobuyuki SONOBE

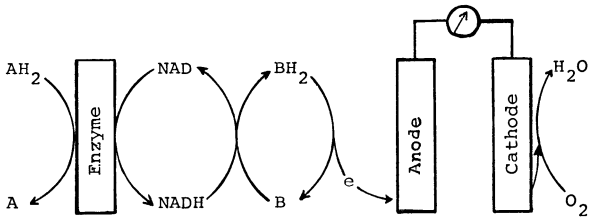
Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received May 7, 1975)

Electrochemical and enzymatic reactions were studied for the purpose of making sensors of ethanol and lactic acid. The dehydrogenase-collagen membrane coated onto a platinum plate was prepared by the electroshaping method. The substrates were dehydrogenated and nicotinamide adenine dinucleotide (NAD) was reduced to form the reduced NAD (NADH) by an enzymatic reaction on the collagen membrane. Flavin mononucleotide (FMN) was chosen as an electroactive substance which could oxidize NADH to return NAD. The reduced FMN ($FMNH_2$) was easily oxidized at the anode and a current was obtained. From the above reactions, the concentrations of ethanol and lactic acid in solutions were found to be determined by a current-substrate concentration relation. The accuracy was estimated to be within 10% error. The activity and stability of enzymes immobilized in the collagen membrane were investigated.

Since 1962, the characteristics of biochemical reaction cells have been studied in this laboratory.[1] These cells have been found not to generate a large quantity of power. However, these cells have a specificity that only one substrate in the mixture selectively reacts in the enzymatic reaction to form an electroactive substance which in turn reacts at the electrode to generate electricity. One of the present authors has already reported on the application of several sensors for the detection and analysis of hydrogen peroxide and uric acid using biochemical reaction cells.[2] It has been found that NAD can be utilized as one of electroactive substances in the biochemical reaction cells.[3] It has been found that NAD is involved in more than 200 kinds of enzymatic reactions as a coenzyme.[4] Therefore, it is expected that many kinds of substrates might be detected or determined by the measurement of the anodic reaction of NADH produced by the enzymatic reaction with each substrate.

The purpose of this study is to produce a sensor which combines the electrochemical reaction and the enzymatic reaction with NAD. The necessary conditions for the sensor are (1) to obtain the relative value of the potential or current corresponding to the substrate concentration, (2) to allow the electrochemical reaction to occur with a constant concentration of NAD, and (3) to be capable of using the enzyme repeatedly. It is already known that NADH is hardly oxidized at the anode electrochemically.[3] Therefore, it was proposed that another redox system, as an electroactive substance which can easily react with NADH, be introduced in the biochemical reaction cell as follows:



AH_2: Substrate, A: product, B,BH_2: electroactive substance

This paper reports on the studies of electrochemical and enzymatic reactions for making ethanol and lactic acid sensors.

Experimental

Materials and Preparation of Collagen Membrane. Alcohol dehydrogenase (ADH) and lactate dehydrogenase (LDH) were supplied by Oriental Yeast Co. All the other chemicals were of reagent grade or the best commercially available. ADH-collagen membranes were prepared, according to the method of Karube, as shown in Fig. 1, by an electrochemical method using collagen fibril suspensoid which was obtained from hide.[5]

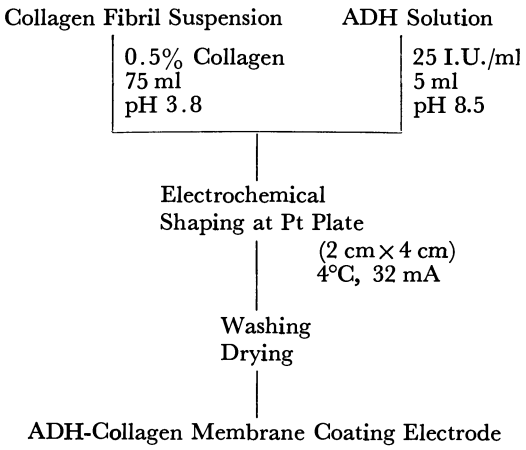


Fig. 1. Preparation of ADH-collagen membrane.

In the case of LDH-collagen membrane, the collagen fibril in the suspensoid was treated with pepsin to digest and to produce an almost transparent solution before adding LDH. The LDH-collagen membrane-coated anode was dipped in a glutaraldehyde solution and then washed with distilled water. NAD, NADH, and FMN were determined by UV spectrophotometry. The ADH was analyzed by measuring the zinc content in the enzyme by atomic absorption spectrophotometry. The ADH and LDH activities were determined by measuring NADH which was formed as a product of the enzymatic reaction.

Instruments. Absorption spectra and atomic absorption spectra were obtained using a Shimadzu spectrophotometer UV-200 and a Varian atomic absorption spectrophotometer A-A1000, respectively. A Toa Electric recorder EPR-2T and a Kikusui 114 Millivolt-ammeter were used for measuring the current. The potentials were determined with reference to a saturated calomel electrode.

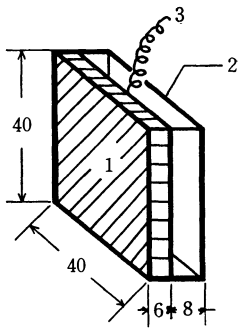

Fig. 2. The cathode.
1. Carbon, 2. plastic plate, 3. lead wire. unit: mm

Procedure and Measurement of Electrochemical Reaction. The electrochemical reaction was carried out with the following mounting: Anode: an intact or enzyme-collagen membrane-coated platinum plate (2 cm×4 cm). Cathode: a box-shaped cathode, as shown in Fig. 2. One surface of the carbon plate (4 cm×4 cm×0.6 cm) was soaked in the catholyte and the other side was exposed to air. The anolyte was 0.1 mol/l of a phosphate buffer solution (pH 7.7) containing substrates (ethanol or lactic acid), NAD and an electroactive substance. The enzyme was added to the anolyte when an intact platinum plate was used as the anode. The catholyte was 0.1 mol/l of a phosphate buffer solution (pH 7.7). The anolyte and catholyte in each beaker were connected *via* an agar bridge. When the circuit of the biochemical reaction cell was open, the anode potential went to less noble because of the enzymatic reaction in the anolyte, as shown in Fig. 3. Nearly 30 min after the enzymatic reaction were required to reach equilibrium in the anolyte. Then the discharge was started and the current was measured. During this procedure, nitrogen gas was bubbled into the anolyte.

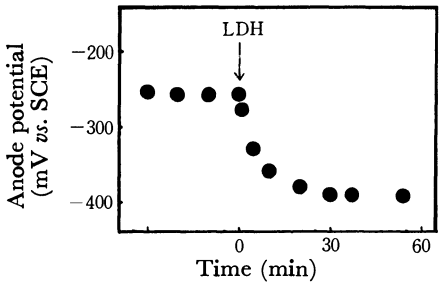

Fig. 3. Anode potential-time curve.

Results

The Electroactive Substances. FMN, thioglycolate, methyl viologen and phenazine methosulfate (PMS) were used as electroactive substances which reacted with NADH. In this biochemical reaction cell, 40 ml of an anolyte containing 1.5 mmol/l of the electroactive substance and 1 mmol/l of NADH, and an intact platinum anode were used. The values of current obtained from short-circuit discharging after the redox reaction between the NADH and the electroactive substance are summarized in Table 1. In the case when the anolyte contained only NADH, the current decreased to zero within 5 min after discharging. PMS oxidized NADH so rapidly that a high current was observed. But the PMS was unstable. It appears that the electrochemical reactions of thioglycolate and methylviologen are remarkably slow. It was found that an almost constant current was maintained after 1 minute in the case of FMN. From these results FMN was chosen as the electroactive substance for subsequent experiments.

Influence of Substrate, NAD, and FMN to the Current. The anode reaction process in process (1) includes 3 steps. For the purpose of the assignment of the rate-determining step in process (1), the current was measured in the ethanol-ADH system and in the lactic acid-LDH system in the anolyte containing various concentrations of the substrate, NAD and FMN. An intact platinum plate was used as the anode in the anolyte. The results are shown in Figs. 4, 5 and 6. The values of the current are thoughtsto be reliable to within 10%. The substrate concentration–current relation did not fall on a straight line.

Electrochemical Reaction Using an Enzyme-Collagen Mem-

brane-Coated Anode. The enzyme was immobilized in the collagen membrane, so that the enzyme might be used repeatedly. The anode reaction was studied using an anode coated with an enzyme-collagen membrane, which was prepared by means of the electrochemical process shown in Fig. 1. The enzyme content, activities and other properties of the enzyme-collagen membrane were determined (Table 2). The substrate-current relation was measured in the same way as in Fig. 4. The results (Fig. 7) showed a tendency similar to that in Fig. 4, but the current was lower. The same anode coated with an enzyme-collagen membrane was used repeatedly and its activity was determined with the hope of maintaining the same activity for each measurement. The anolyte contained 0.34 mol/l of ethanol, 1 mmol/l of NAD and 2 mmol/l of FMN.

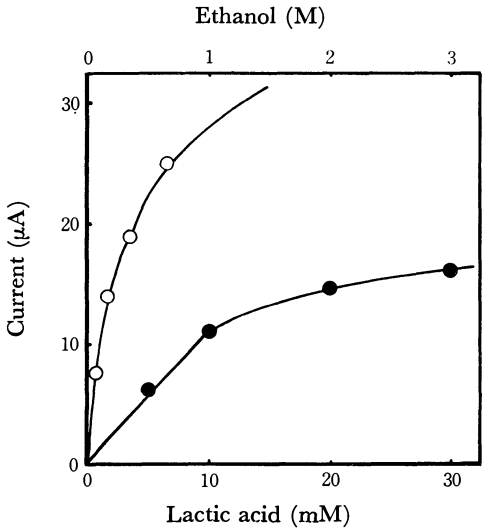

Fig. 7. Substrate-current relation (Enzyme-collagen membrane coating electrode).
—○—: Ethanol, —●— : lactic acid.

After each measurement of the current, the anolyte used was replaced by a new one and the same process was repeated. The enzyme activity was not found to decrease. The average value of current over 5 measurements was 33 ± 4 μA.

In the case of the LDH-collagen membrane, the enzyme activities were determined in a solution containing 12.5 mmol/l of lactic acid and 1 mmol/l of NAD and it was found that the activity remained constant over 8 measurements.

Discussion

It is clear that the reactions in process (1) can be utilized as a sensor. It was concluded, using the anode coated with ADH and LDH-collagen membranes, that (1) the value of the current increased non-linearly with the substrate concentration, (2) ethanol and lactic acid can be determined to within an accuracy of 10% error, (3) the enzyme activity remained constant over more than 5 measurements and (4) the necessary conditions for temperature, pH and concentrations of ethanol and lactic acid were lower than 30 °C, 6~8, 1 mol/l and 25 mmol/l, respectively.

Process (1) can be rearranged into 3 reactions as follows:

$$AH_2 + NAD^+ \longrightarrow A + NADH + H^+ \quad (2)$$

$$NADH + FMN + H^+ \longrightarrow NAD^+ + FMNH_2 \quad (3)$$

$$FMNH_2 \longrightarrow FMN + 2H^+ + 2e \quad (4)$$

If reaction (2) is the rate-determining step, the current

Reusability	5 times	8 times

a) In collagen membrane on platinum anode (2 cm×4 cm).

should be proportional to the substrate or total NAD concentration for a constant concentration of the NAD or substrate, respectively. However, Figs. 4 and 5 indicate that there is no linearity. If reaction (3) is the rate-determining step, the NADH concentration has to be constant during the reaction, and the concentration of $FMNH_2$ formed in the reaction could be negligible because of the rapid oxidation at the anode. The reaction velocity should be proportional to the product of the NADH concentration and the total FMN concentration. In turn, this velocity would be proportional to the current. If reaction (4) is the rate-determining step, the $FMNH_2$ concentration has to be constant in a steady state. Accordingly, the current remains constant during the electrochemical reaction, thus,

$$i \propto [FMNH_2] \quad (5)$$

From the result in Fig. 6, it can be said that reaction (4) should be the rate-determining step in lactic acid case, although it cannot be determined which step is the rate-determining one, reaction (3) or (4), in the ethanol case.

Favorable Conformations of 2-Amino-2-deoxy-D-hexopyranose Derivatives

Tooru TAGA and Kenji OSAKI

Faculty of Pharmaceutical Sciences, Kyoto University, Sakyo-ku, Kyoto 606

(Received May 12, 1975)

The conformational free energies of 2-amino-2-deoxy (hydrochloride) and 2-acetamido-D-deoxy derivatives of D-glucose, D-galactose, and D-mannose were calculated by using the empirical potential functions. The most stable conformations of these amino sugars were obtained for α- and β-anomers in the Cl and 1C chair forms through the procedure of searching for the energy minimum. The results of the energy calculations indicate that the increased anomeric effect in the protonated and *N*-acetylated amino derivatives in an aqueous solution is mainly due to the electrostatic interaction between the positive-charged amino group on C(2) and the hydroxyl group on the anomeric carbon atom, C(1).

This paper will present a theoretical calculation of the conformational free energies of the protonated, non-protonated, and *N*-acetylated amino derivatives of 2-amino-2-deoxy-D-glucose, -D-galactose, and -D-mannose. The anomeric equilibria of these amino sugars in an aqueous solution have been studied by many workers using the NMR[1] or optical rotatory methods.[2-9] The present work was undertaken in order to determine the most favored conformation of each of these amino sugars and to explain the increased proportion of the α-anomer in the protonated and *N*-acetylated amino derivatives of D-glucose and D-galactose, as pointed out by Neuberger and Fletcher.[8]

The theoretical prediction of the favored conformation of simple reducing sugars has been attempted by many workers by considering various factors, including the Hassel-Ottar effect,[9] the $\triangle_2$ effect[10,11] and the anomeric effect.[12-16] Angyal[14] has assigned the interaction energies for aldopyranoses by using the empirical rule. Rao *et al.*[17-19] have shown that the energy calculations taking the nonbonded and electrostatic interactions into account are consistent with the experimental data for aldopyranoses. In the present work, the potential energies for α- and β-anomers of each amino sugar in the Cl and 1C conformations have been calculated from the empirical potential functions, using a modification of the method of Rao *et al.*[18] The conformational entropies have also been estimated and added to the corresponding potential energies to obtain the total free energies.

Calculation of Free Energy

Potential Energy. The potential energy of a molecule can be expressed in terms of the nonbonded interaction, the electrostatic interaction, and the steric effect associated with the bond distortion.

The nonbonded interaction energy was evaluated by the use of the Lennard-Jones '6—12'-type potential function:

$$V_n = \frac{A}{R_{ij}^{12}} - \frac{B}{R_{ij}^{6}} \quad (1)$$

where R_{ij} is the distance between the interacting atoms, i and j. The A and B coefficients determined by Scott and Sheraga[20] were used in the present calculation.

The electrostatic interaction energy was calculated by using the following function:

$$V_e = \frac{Q_i \cdot Q_j}{\varepsilon \cdot R_{ij}} + \frac{Q_i \cdot \mu \cdot \cos\phi_i}{\varepsilon \cdot R_i^2} \quad (2)$$

where Q_i and Q_j are the charges of a pair of interacting atoms, i and j, where R_{ij} is the distance between them, ε is the effective dielectric constant of the medium, μ is the dipole moment of the lone pairs on the ring-oxygen atom, R_i is the distance between the i atom and the ring-oxygen atom, and Φ_i is the angle between the dipole vector on the ring-oxygen atom and the vector directed from the ring-oxygen atom to the i atom. The first term in Expression (2) is the Coulombic interaction between the partial charges localized at each atom. The values of Q used in the calculation are given in Table 3. They were obtained from the results of the molecular orbital calculations for aldopyranose and amino acid molecules by several workers.[19,21,23] The second term in Expression (2) is the charge-dipole interaction. The value of the dipole moment of the unshared electron pairs on the ring-oxygen atom is 0.37D, a value derived from the results of the theoretical calculation for 2-methoxytetrahydropyran by Zhadanov *et al.*[24] The effective dielectric constant, ε, is usually much smaller than the actual dielectric constant.[20] In the present calculation, the value of 4.5 was assigned, since the use of this value gave a good agreement between the calculated and observed free energies for aldopyranoses in an aqueous solution.

The energy caused by the steric effect of the covalent bonds was evaluated with the deviation of a single-bond angle, θ, from the normal tetrahedral angle, θ_t (109.5°), by using the following function:

$$V_b = \kappa \cdot (\cos\theta - \cos\theta_t)^2 \quad (3)$$

where κ is a constant dependent on the bonded atoms involved. The values of κ were assigned as 65 kcal/mol for C–C–C and C–C–O, 55 kcal/mol for O–C–O, and 45 kcal/mol for C–C–H and O–C–H.[25]

The energies associated with the internal rotation and the intramolecular hydrogen bond were neglected.

Entropy. The conformational entropy can be calculated by using the formula:

$$S = R \ln N \quad (4)$$

were R is the gas constant and where N is the total number of possible conformations of the molecule.[18]

Generally, the OH bond in the equatorial hydroxyl group has three favored orientations of the staggered form, while the OH bond in the axial hydroxyl group

has two favored orientations. Since, in an aqueous solution, the sugar molecules are extensively hydrated through hydrogen-bonding with the surrounding water molecules, the OH bond might be directed to the oxygen atom of the neighboring water molecule to form a strong hydrogen bond. Therefore, the orientations of the OH bonds are greatly restricted, not only by the intramolecular interactions, but also by the intermolecular hydrogen bonds. As a result, the possible orientations of the OH bond are dependent on the position of the hydroxyl group linked to the ring. For instance, the OH bond of the equatorial hydroxyl group linked to C(1) has only two favorable orientations. By taking account of all the possible orientations of OH bonds, together with the orientations of the CH_2OH and amino groups, the total number of possible conformations was calculated for each derivative.

Procedure of Calculation. The ring atoms and atoms linked directly to the ring were fixed in the Cl and 1C chair forms by using average values derived from 25 crystal structure analyses of pyranoses.[26-33] The CH_2OH side group was fixed in the *gauche-trans* conformation, which is one of the preferable orientations often found in the crystals.[34] The hydrogen atoms in the hydroxyl groups were fixed in one of the favorable staggered forms. The atoms in amino groups were fixed by using the bond lengths and angles given in Table 2. The NH_2 and *N*-acetyl groups were assumed to be planar. The positional parameters given for β-D-glucose are listed in Table 1. The bond lengths and angles calculated from these parameters are in good agreement with the values given by Arnott *et al.*[27]

The most stable conformation of each derivative was determined from the initial structure by the following procedure. As has been mentioned before, the OH bond in the equatorial hydroxyl group has three favored orientations, and the most favorable orientation of the three might be determined by taking the relative positions of the neighboring OH bonds into account. Thus, in the first step, the most preferable conformation was selected from the 81 possibilities which arose from the different orientations of OH bonds in the staggered form. The interaction energies were calculated for each conformation by using the (1) and (2) potential functions, and their values were compared. In the next step, the OH, CH_2OH, and amino groups were independently rotated around their free rotational bonds, and the minimum energy position of each substituent group was sought by the reiterative process. For example, the O(1)–H(O1) bond was rotated around the C(1)–O(1) bond at suitable angular intervals, and at each position the interaction energy between H(O1) and each fixed atom was calculated by using the (1) and (2) functions.

The minimum energy position for H(O1) was sought. After fixing the H(O1) atom in its minimum-energy position, the H(O2) atom was fixed in the same manner and the process was continued until all atoms were located. A similar reiterative procedure was applied to determine the distortion of the bond angles about the ring carbon atoms. In this process, each of the OH, CH_2OH, and amino groups and each of the hydrogen atoms linked to the ring were sequentially tilted by varying the bond angles about the ring atoms. For each bond angle, the steric energy was calculated using the (3) function, and the interaction energy, using the (1) and (2) functions, thus, the minimum-energy position was determined for each substituent group. The rotation and tilting procedures were repeated alternatively until, after four cycles, a convergence was observed. The potential energy of the molecule was found by the summation of the nonbonded and electrostatic interactions and the steric energies calculated in the last cycle.

The entropy of each derivative was calculated by using Formula (4), and the contribution of the entropy term, $-ST$, was added to the corresponding potential energy to obtain the total free energy at 300 K. The values of the entropies assigned for the amino derivatives are given in Table 4.

β-D-mannose	1.05	5.65	0.90	5.6

Results and Discussion

The conformational free energies calculated for D-glucose, D-galactose, and D-mannose in the Cl and 1C conformations are given in Columns 2 and 3 of Table 5. These values are in good agreement with Angyal's values,[14] given in Columns 4 and 5 of the same table. The results of the energy calculations for the amino derivatives are given in Table 6. The free energies given in Columns 2—5 of Table 6 show that the Cl conformation is more stable than the 1C conformation for all the derivatives and that the α-anomers in the Cl form are more stable than the β-anomers except in the cases of 2-amino-2-deoxy-D-glucose and -galactose and 2-amino-2-deoxy-D-mannose hydrochloride. The percentages, p, of the proportions of the α- and β-anomers in the Cl and 1C conformations in an equilibrium mixture of each derivative were calculated using the following formula:

$$p_i = \frac{\exp(-F_i/RT)}{\sum_i \exp(-F_i/RT)} \qquad (5)$$

where the summation includes all four conformations and where F_i is the free energy of the i component. Calculations by means of Expression (5) incorporating the free energy values given in Table 6 show that the proportions of both anomers existing in the 1C conformation in an equilibrium mixture are negligible for all amino derivatives except for α-D-glucosamine hydrochloride. The calculated anomeric ratios (α/β) in an equilibrium mixture of each derivative are given in Column 2 of Table 7, while the corresponding NMR and optical rotatory data observed from aqueous solutions are given in Columns 3 and 4 of the same table. The α/β ratios calculated here include both Cl and 1C conformations, whereas the NMR ratios are derived from the Cl peaks only. However, it is possible that the Cl peaks may include contributions from the 1C conformation, and, as the energy calculation indicates that the Cl conformation is much more stable than the 1C, a valid comparison can be made. In the case of D-glucosamine hydrochloride, the α/β ratio calculated from the Cl conformation is 52:48; this value is slightly different from the observed value.

As is well known, the anomeric effect makes an equatorial group on the anomeric carbon of D-glucose less stable than it would be in other positions on the ring. This effect has been explained in terms of the unfavorable parallel interaction between the anomeric carbon-oxygen dipole and the dipole formed by the unshared electron pairs on the ring-oxygen atom.[12,13] In the present case, such an anomeric effect seems likely to be increased further. However, we have no evidence that such dipole-dipole interaction would be enhanced by the amino group on C(2). Table 6 shows that the electrostatic interaction terms given in Columns 6—9 tend to reduce the free energy of the α-anomer significantly in the case of the protonated and *N*-acetylated amino derivatives. It may be, therefore, that the main factor responsible for the increased anomeric effect in these amino sugars is the charge-charge interaction between the positively charged amino group and the hydroxyl group on the anomeric carbon atom. The presence of an oxygen atom in the pyranose ring produces a significant deformation as compared with the cyclohexane ring, with the result

a) The NMR data was taken from Ref. 1.

that the amino group on C(2) is closer to the hydroxyl group on C(1) in the α-anomer than that in the β-anomer. This unequal distance in the two anomers might cause the increased anomeric effect.

The most stable conformations derived from several amino sugars by means of the potential energy calculations indicate the following structural features of the amino sugars. The hydroxyl group in an axial position has a tendency to be tilted toward the equatorial orientation as a result of the repulsive interaction between the axial substituents. The C–C–O angles outside of the ring for the axial hydroxyl group are larger than those for the equatorial group by 1° on the average. The CH_2OH side group in an axial position also has a similar tendency. It is more tilted when the hydroxyl groups occupy the axial positions of the C(1) and C(3) ring atoms. For example, the C(4)–C(5)–C(6) angles are calculated as 115° for α-D-glucose in the 1C form and as 117° for β-D-glucose in the 1C form, while the mean value of the corresponding angles in the equatorial epimers is 113°. However, the amino groups do not show such a tendency. In this case, the C–C–N angle is close to the tetrahedral angle in both the axial and the equatorial groups. This may be accounted for by the electrostatic attractive force due to the positive charge on the amino group. The stable conformation of the NH_3 group with respect to the pyranose ring is the staggered form, as observed in the β-D-galactosamine hydrochloride crystal.[28] The planar NH_2 and *N*-acetyl groups have two possible conformations when they link to the equatorial position of C(2) in a Cl-chair form. Each conformfftion is close to a *trans* form about C(2)–N, whith the N–H bond *trans*-antiparallel with respect to the hydrogen atom on C(2). The present calculations give the minimum energies at 90° and 145° for the C(1)–C(2)–N(2)–C(7) torsional angle. These calculated angles may be compared with the corresponding angles of 137°, 83°, 72°, and 113° observed in the crystal structures of the *N*-acetylated derivatives of α-D-glucose,[30] α-D-galactose,[31] α-D-muramic acid,[32] and 4-*N*-(α-D-glucopyranosyl)-L-asparagine[33] respectively.

The authors wish to thank Mr. Masanori Senma for his data collection of the crystal structures used in this work. All the computations were performed by using the FACOM 230-60 in the Data Processing Center, Kyoto University.

Azafulvenes. 2.[1] Formation of Iminium Salt from Pyrrole- and Indolecarbaldehyde and Its Reaction with Bases

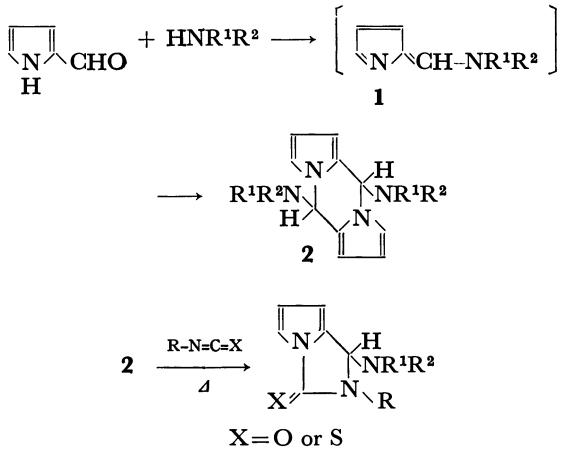
Takashi KOBAYASHI, Shoji KAJIGAESHI, and Shuji KANEMASA

Department of Industrial Chemistry, Faculty of Engineering, Yamaguchi University, Tokiwadai, Ube 755

(Received May 12, 1975)

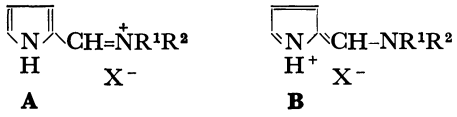
Pyrrole- and indolecarbaldehyde reacted with secondary ammonium perchlorate to produce the corresponding iminium perchlorate, which did not afford azafulvene, but instead its dimer, in good yield by deprotonation. These results indicate that the iminium perchlorate from pyrrole- and indolecarbaldehyde appears to be a convenient precursor of azafulvene.

In a preceding communication, the authors have reported that attempts to isolate 6-amino-1-azafulvene (**1**) from the reactions of pyrrole-2-carbaldehyde with secondary amines were unsuccessful because of a tendency to dimerize thermally. It has also been described that the thermal decomposition of dimer **2** regenerated **1** which was trapped as the corresponding [6+2] cycloadducts with isocyanates and isothiocyanate.[1]



X=O or S

It is well known that an enamine can be protonated to yield a stable iminium salt[2] which is also directly obtainable by the reaction of a carbonyl compound with the secondary ammonium salt.[3] Protonation of **1** containing an enamine system in its molecular structure would probably make itself stable enough to be isolated. Although two structures, iminium salt **A** and azafulvenium salt **B**, are possible as protonated products of **1**, both of them are possible as convenient precursors of 6-amino-1-azafulvene **1**.

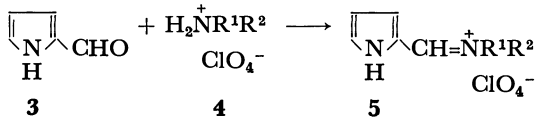


We have investigated which type of salt, iminium or azafulvenium salt, is formed from the reaction of pyrrole-2-, indole-2- and indole-3-carbaldehyde with secondary ammonium perchlorates and also examined whether these salts liberate the corresponding azafulvenes by deprotonation.

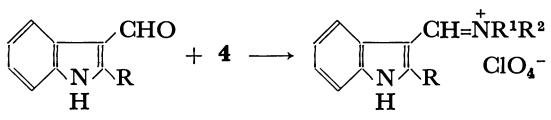
Results and Discussion

Preparation of Iminium Perchlorate. The reactions of pyrrole-2-carbaldehyde (**3**) with morpholinium (**4a**) and pyrrolodinium perchlorate (**4b**) in ethanol under refluxing conditions produced colorless prisms, **5a** and **5b**, in 57 and 40% yields, respectively. The molecular formulae of these products agree with those of the compounds derived from the 1:1 adduct with the elimination of water. The IR spectrum of **5a** showed the characteristic band of perchlorate salt at 1100 cm^{-1} and the band assignable to >NH and $-CH=\overset{+}{N}<$ absorption at 3220 and 1640 cm^{-1}, respectively. The compound **5a** exhibited an absorption maximum at 331 nm in its UV spectrum in ethanol and no absorption in the visible region, while it has been reported by Hafner and Pfeiffer[4] that 6,6-diphenyl-1-azafulvenium fluoroborate was of a deep yellow color (λ_{max} in CH_2Cl_2: 413, 363 and 267 nm). The corroborating evidence for the structure of **5a** was afforded by its NMR spectrum in trifluoroacetic acid, which revealed signals at τ 1.59 (1H, s, $-C\underline{H}=\overset{+}{N}<$), 2.38, 2.55 and 3.28 (each 1H, m, pyrrole ring protons) and 5.72 (8H, m, morpholino methylenes). The down field shift of the α-methylene protons of morpholino moiety are based on the electron affinity of the adjacent ammonium nitrogen atom.

From the above UV and NMR data, **5a** was deduced to be, not 6-morpholino-1-azafulvenium perchlorate **B** (X=ClO_4), but 2-pyrrolylmethylenemorpholinium perchlorate **A** (X=ClO_4). The compound **5b** has already been prepared by Sonnet[5] and identified to be *N*-(2-pyrrolylmethylene)pyrrolidinium perchlorate. No formation of azafulvenium salt **B** should occur due to

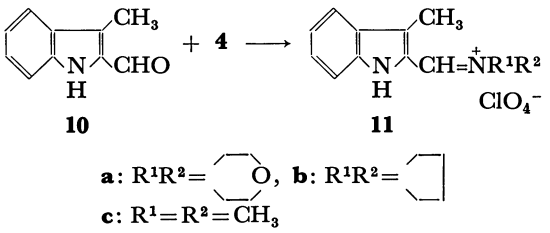


a: R^1R^2= **b**: R^1R^2=



6: R=H
8: R=CH_3

7a: R=H, R^1R^2=
7b: R=H, R^1R^2=
7c: R=H, R^1=R^2=CH_3
9a: R=CH_3, R^1R^2=
9b: R=CH_3, R^1R^2=



a lack of the stabilizing energy of the pyrrole ring, whereas iminium salt formation does not require any loss of energy.

The reactions of indole-3-carbaldehyde (**6**) with **4a**, **4b** and dimethylammonium perchlorate (**4c**) afforded the respective colorless crystals, **7a**, **7b** and **7c**, in excellent yield which were clearly identified to be 3-indolylmethyleneammonium perchlorates on the basis of their IR, NMR and UV spectra as well as elemental analyses.

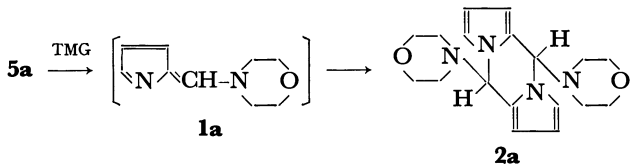
Similarly, the corresponding 3-(2-methylindolyl)-methyleneammonium perchlorates, **9a** and **9b**, were obtained on heating 2-methylindole-3-carbaldehyde (**8**) with **4a** and **4b** in ethanol.

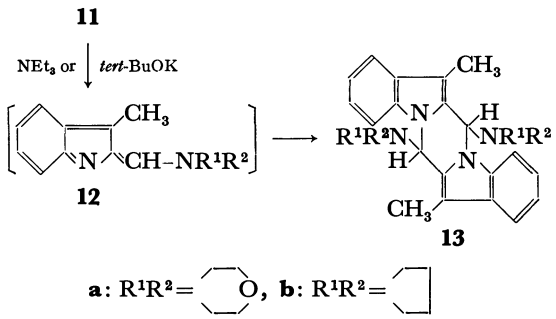
Although no reactions of 3-methylindole-2-carbaldehyde (**10**) with **4** took place during ethanol refluxing, **10** reacted with **4** to produce 2-(3-methylindolyl)-methyleneammonium perchlorate (**11**) when heated under reflux with continuous removal of the water formed in the reaction. The structures of **9** and **11** were also established by their spectroscopic results and elemental analyses.

Deprotonation of Iminium Perchlorate. For the purpose of the liberation of aminoazafulvenes, the deprotonation reactions of the iminium perchlorates, **5**, **7**, **9** and **11**, were investigated using bases such as triethylamine, tetramethylguanidine and potassium *tert*-butoxide.

The treatment of **5a** with tetramethylguanidine in ethanol gave pyrrole-2-carbaldehyde **3** which can be derived from the hydrolysis of the starting iminium perchlorate **5a** or 6-morpholino-1-azafulvene **1a** (NR^1R^2=N⟨O⟩). The fact that the iminium perchlorate **5a** considerably resists hydrolysis in ethanol indicates azafulvene **1a** is formed at first in this reaction, followed by hydrolysis into **3**. Therefore, the reaction under anhydrous conditions was carried out and afforded another product **2a** which was identical to the dimer of **1a**, 5,10-dimorpholinodipyrrolo[1,2-*a*: 1′,2′-*d*]pyrazine, obtained by heating **3** with morpholine in benzene.[1]

The new compound **13a**, mp 242—243 °C (decomp.), was yielded quantitatively by the reaction of **11a** with triethylamine in benzene. The molecular formula of **13a** corresponds to the dimer of azafulvene **12a**. The NMR spectrum of **13a** in deuteriochloroform showed two methyls- and two methines-protons at τ 7.64 (6H) and 4.10 (2H) as singlets, respectively. On the basis of the spectral data, **13a** was identified to be 6,13-dihydro-5,12-



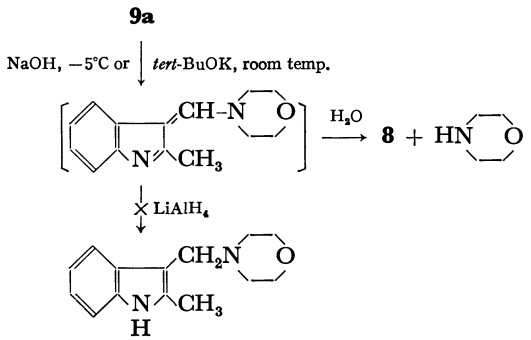


dimethyl-6,13-dimorpholinodiindolo[1,2-*a*: 1′,2′-*d*]-pyrazine.

Two isomers with the methine protons at the 6- and 13-positions of the pyrazine ring are possible for **13a**. Actually, both the *cis* and *trans* isomers have been isolated[1] in the case of the dimer of 6-(*N*-pyrrolidinyl)-1-azafulvene (**1b**), which is analogous to **13a**. The compound **13a** was determined to be the *trans* isomer because of the equivalence of the two methyls-protons and of the two methines-protons in the NMR spectrum.[1] Similarly, *trans*-6,13-dihydro-5,12-dimethyl-6,13-di(*N*-pyrrolidinyl)diindolo[1,2-*a*: 1′,2′-*d*]pyrazine (**13b**) was also obtained in excellent yield by treating **11b** with potassium *tert*-butoxide in benzene, while **11b** could not be deprotonated with triethylamine.

The above results show that 1-azafulvene is formed as an unstable intermediate[6] upon deprotonation of the corresponding iminium perchlorate and dimerized by [6+6] cycloaddition. This cyclodimerization reaction is considered to be reversible.[7] Therefore, the ease of the dimerization is attributable to the large difference between the stabilizing energies of 1-azafulvene and its dimer *via* a resonance. In particular, benzo[*b*]-1-azafulvene **12** has a tendency to change into the dimer **13** owing to the additional *o*-quinoid cyclic system in **12**.

On the other hand, benzo[*c*]-2-azafulvene, which is possible to be derived from the iminium salt **7** or **9**, is expected to be more thermally stable than benzo[*b*]-1-azafulvene. The reaction of **9a** with aqueous sodium hydroxide at −5 °C or with potassium *tert*-butoxide in benzene at room temperature gave a colorless product which was contaminated with 2-methylindole-3-carbaldehyde **8**. This moisture-sensitive product was not isolated in pure form and did not give reliable spectral data. Moreover, reduction with lithium aluminum hydride resulted in hydrolysis into **8**. The quantitative conversion of this product to **8** by the moisture in an atmosphere is explained by the guess that this water-



sensitive product is benzo[*c*]-2-azafulvene, which is thermally stable but subject to hydrolysis due to the nature of enamines.

Although similar deprotonation reactions of **7** gave products which did not include any halogen ions, the structures of these products have not yet been clarified.

Experimental

All melting points were determined using a Mitamura Riken micro melting point apparatus and are uncorrected. The IR spectra were taken in KBr disks with a Nihon Bunko IRA-1 spectrometer. The NMR spectra were obtained at 100 MHz using a Nihon Denshi JNM-MH-100 spectrometer with TMS as an internal reference. The mass spectra were determined with a Nihon Denshi JMS-06 mass spectrometer equipped with a direct inlet and at an ionization energy of 75 eV.

Materials. Pyrrole-2-(**3**); mp 44—47 °C, bp 128 °C/20 Torr (lit,[8] bp 78 °C/2 Torr), indole-3-(**6**); mp 193—195 °C (lit,[9] mp 194 °C) and 2-methylindole-3-carbaldehyde (**8**); mp 201—202 °C (lit,[10] mp 202—203 °C) were prepared by the Vilsmeier reaction of the corresponding pyrroles and indoles. 3-Methylindole-2-carbaldehyde (**10**) was obtained by oxidation of 2-(3-methylindolyl)methanol with activated manganese dioxide in a 58% yield; mp 139—141 °C (lit,[11] mp 138—140 °C).

N-*(2-Pyrrolylmethylene)morpholinium Perchlorate (**5a**).* The mixture of 0.95 g (0.01 mol) of **3** and 1.88 g (0.01 mol) of **4a** was heated under reflux in 20 ml of ethanol for 1 hr. On cooling, the precipitated product was filtered and washed with a benzene–ethanol (1:1 vol/vol) mixture giving 1.50 g (57%) of **7a**. Recrystallization from ethanol produced colorless prisms; mp 142—143 °C (decomp.). IR (KBr) cm^{-1}: 3220 (>NH), 1640 (–CH=$\overset{+}{N}$<) and 1100 (ClO_4). NMR (CF_3COOH) τ: 1.59 (1H, s, –C<u>H</u>=$\overset{+}{N}$<), 2.30, 2.47, 3.40 (each 1H, m, pyrrole ring protons) and 5.72 (8H, m, morpholino methylenes). UV (EtOH): 331 nm. Found: C, 40.75; H, 4.74; N, 10.43%. Calcd for $C_9H_{13}N_2O_5Cl$: C, 40.84; H, 4.95; N, 10.58%.

N-*(2-Pyrrolylmethylene)pyrrolidinium Perchlorate (**5b**).* Prepared in the same way as **5a**, starting with 0.95 g of **3** and 1.72 g of **4b** in 20 ml of ethanol. Colorless prisms from ethanol; mp 103—104 °C (decomp.). IR (KBr) cm^{-1}: 3220 (>NH), 1640 (–CH=$\overset{+}{N}$<) and 1100 (ClO_4). NMR (CF_3COOH) τ: 1.65 (1H, s, –C<u>H</u>=$\overset{+}{N}$<), 2.58, 2.82, 3.46 (each 1H, m, pyrrole ring protons), 6.01 and 7.77 (each 4H, m, pyrrolidinyl methylenes). UV (EtOH): 329 nm. Found: C, 43.40; H, 5.14; N, 11.19%. Calcd for $C_9H_{13}N_2O_4Cl$: C, 43.47; H, 5.27; N, 11.27%.

N-*(3-Indolylmethylene)morpholinium Perchlorate (**7a**).* A 1.45 g (0.01 mol) of **6** and 1.88 g (0.01 mol) of **4a** were refluxed in 20 ml of ethanol for 2 hr. After cooling, 2.80 g (89%) of **7a** were precipitated. Recrystallization from ethanol yielded colorless prisms; mp 242—244 °C (decomp.). IR (KBr) cm^{-1}: 3240 (>NH), 1640 (–CH=$\overset{+}{N}$<) and 1100 (ClO_4). NMR (CF_3COOH) τ: 1.31 (1H, s, –C<u>H</u>=$\overset{+}{N}$<), 1.64 (1H, d, 2-H of indole ring), 2.13—2.60 (4H, m, aromatic protons) and 5.66 (8H, m, morpholino methylenes). UV (EtOH): 288 nm. Found: C, 49.55; H, 4.79; N, 8.95%. Calcd for $C_{13}H_{15}N_2O_5Cl$: C, 49.61; H, 4.80; N, 8.90%.

N-*(3-Indolylmethylene)pyrrolidinium Perchlorate (**7b**).* The method used here is virtually identical with that used for **7a**: 1.45 g of **6** and 1.72 g of **4b** were refluxed for 2 hr. Colorless prisms from ethanol; mp 249—250 °C (decomp.). Yield: 2.43 g (81%). IR (KBr) cm^{-1}: 3280 (>NH), 1640 (–CH=$\overset{+}{N}$<) and 1100 (ClO_4). NMR (CF_3COOH) τ: 1.26 (1H, s, –C<u>H</u>=$\overset{+}{N}$<), 1.89 (1H, d, 2-H of indole ring), 2.08—2.68 (4H, m, aromatic protons), 5.95 and 7.64 (each 4H, m, pyrrolidinyl methylenes). UV (EtOH): 352 nm. Found: C, 52.07; H, 4.91; N, 9.40%. Calcd for $C_{13}H_{15}N_2O_4Cl$: C, 52.27; H, 5.06; N, 9.38%.

N-*(3-Indolylmethylene)*-N,N-*dimethylammonium Perchlorate (**7c**)* The same procedure as that for **7a** using 2.9 g of **6** and 2.92 g of **4c** in 40 ml of ethanol afforded 4.44 g (78%) of **7c**; colorless prisms from ethanol; mp 217—220 °C (decomp.). IR (KBr) cm^{-1}: 3260 (>NH), 1640 (–CH=$\overset{+}{N}$<) and 1100 (ClO_4). NMR (CF_3COOH) τ: 1.60 (1H, s, –C<u>H</u>=$\overset{+}{N}$<), 1.96 (1H, d, 2-H of indole ring), 2.24—2.73 (4H, m, aromatic protons), 6.28 and 6.50 (each 3H, s, =$\overset{+}{N}$(C<u>H</u>$_3$)$_2$). Found: C, 48.82; H, 4.82; N, 10.07%. Calcd for $C_{11}H_{13}N_2O_4Cl$: C, 48.63; H, 4.82; N, 10.31%.

N-*(2-Methyl-3-indolylmethylene)morpholinium Perchlorate (**9a**).* To the stirred suspension of **8** (3.2 g, 0.02 mol) in 40 ml of ethanol was added 3.76 g (0.02 mol) of **4a** and which were refluxed for 2 hr. On cooling, **9a** (6.34 g, 98%) was filtered and recrystallized from ethanol to give colorless prisms, mp 248—249 °C (decomp.). IR (KBr) cm^{-1}: 3280 (>NH), 1640 (–CH=$\overset{+}{N}$<) and 1100 (ClO_4). NMR (CF_3COOH) τ 1.48 (1H, s, –C<u>H</u>=$\overset{+}{N}$<), 2.36—2.67 (4H, m, aromatic protons), 5.65 (8H, m, morpholino methylenes) and 7.23 (3H, s, –C<u>H</u>$_3$). UV (EtOH): 289 nm. Found: C, 51.65; H, 5.05; N, 8.54%. Calcd for $C_{14}H_{17}N_2O_5Cl$: C, 51.15; H, 5.21; N, 8.52%.

N-*(2-Methyl-3-indolylmethylene)pyrrolidinium Perchlorate (**9b**).* The same method as that for **9a** starting from **8** (1.59 g) and **4b** (1.72 g) gave 2.31 g (74%) of **9b**; colorless prisms from ethanol; mp 238—239 °C (decomp.). IR (KBr) cm^{-1}: 3250 (>NH), 1640 (–CH=$\overset{+}{N}$<) and 1100 (ClO_4). NMR (CF_3COOH) τ: 1.67 (1H, s, –C<u>H</u>=$\overset{+}{N}$<), 2.21—2.78 (4H, m, aromatic protons), 5.84, 7.74 (each 4H, m, pyrrolidinyl methylenes) and 7.32 (3H, s, –C<u>H</u>$_3$). UV (EtOH): 344 nm. Found: C, 54.09; H, 5.46; N, 9.04%. Calcd for $C_{14}H_{17}N_2O_4Cl$: C, 53.77; H, 5.48; N, 8.96%.

N-*(3-Methyl-2-indolylmethylene)morpholinium Perchlorate (**11a**).* A heterogeneous mixture of **10** (1.1 g, 0.069 mol), **4a** (1.3 g, 0.069 mol) and 3 drops of morpholine in 100 ml of benzene was heated under reflux for 5 hr with stirring, while water was continuously removed by means of Dean-Stark trap. The separated solid was collected by filtration, washed with a small amount of ethanol. Colorless prisms from ethanol; mp 240—242 °C (decomp.). Yield: 1.82 g (80%). IR(KBr) cm^{-1}: 3320 (>NH), 1630 (–CH=$\overset{+}{N}$<) and 1100 (ClO_4). NMR (CF_3COOH) τ: 1.57 (1H, s, –C<u>H</u>=$\overset{+}{N}$<), 2.26—2.90 (4H, m, aromatic protons), 5.64 (8H, m, morpholino methylenes) and 7.36 (3H, s, –C<u>H</u>$_3$). Found: C, 51.20; H, 5.63; N, 8.74%. Calcd for $C_{14}H_{17}N_2O_5Cl$: C, 51.15; H, 5.21; N, 8.52%.

N-*(3-Methyl-2-indolylmethylene)pyrrolidinium Perchlorate (**11b**).* The similar procedure to that of **11a** using 1.2 g of **10**, 1.29 g of **4b** and 3 drops of pyrrolidine, but being refluxed for 10 hr, gave 2.13 g (91%) of **11b**. Recrystallization from ethanol afforded colorless prisms; mp 265—266 °C (decomp.). IR (KBr) cm^{-1}: 3320 (>NH), 1630 (–CH=$\overset{+}{N}$<) and 1100 (ClO_4). NMR (CF_3COOH) τ:1.43 (1H, s, –C<u>H</u>=$\overset{+}{N}$<), 2.18—2.81

(4H, m, aromatic protons), 5.72, 7.68 (each 4H, m, pyrrolidinyl methylenes) and 7.33 (3H, s, $-C\underline{H}_3$). Found: C, 53.51; H, 5.84; N, 8.87%. Calcd for $C_{14}H_{17}N_2O_4Cl$: C, 53.77; H, 5.48; N, 8.96%.

*N-(3-Methyl-2-indolylmethylene)-N,N-dimethylammonium Perchlorate (**11c**).* A mixture of **10** (0.31 g), **4c** (0.28 g) and a few drops of dimethylamine was refluxed in 70 ml of benzene for 17 hr to give 0.34 g (60%) of **11c**. Colorless prisms from ethanol; mp 257 °C (decomp.). IR (KBr) cm^{-1}: 3325 (>NH), 1640 ($-CH=\overset{+}{N}<$) and 1100 (ClO_4). NMR (CF_3COOH) τ: 1.55 (1H, s, $-C\underline{H}=\overset{+}{N}<$), 2.12—2.78 (4H, m, aromatic protons), 6.06, 6.14 (each 3H, s, $=\overset{+}{N}(C\underline{H}_3)_2$) and 7.28 (3H, s, $-C\underline{H}_3$).

*The Reaction of **5a** with Tetramethylguanidine.* To the suspension of **5a** (0.27 g) in 5 ml of dry tetrahydrofuran was added 0.12 g of tetramethylguanidine which was stirred at room temperature for 10 min. The resulting solution was dried *in vacuo*, and the residue was washed with water and then dried. Recrystallization from methanol gave 0.16 g (95%) of 5,10-dihydro-5,10-dimorpholinodipyrrolo[1,2-*a*: 1′,2′-*d*]-pyrazine (**2a**), mp 190—193 °C (decomp.) (lit,[1] mp 190—193 °C (decomp.)).

*The Reaction of **11a** with Triethylamine.* 1.0 g of **11a** was suspended in 6 ml of dry benzene added to an excess of triethylamine. After refluxing for 3 hr, benzene was evaporated to give a colorless powder which was washed with water. Recrystallization from ether gave colorless needles of 6,13-dihydro-5,12-dimethyl-6,13-dimorpholinodiindolo-[1,2-*a*: 1′,2′-*d*]pyrazine (**13a**), mp 242—243 °C (decomp.). Yield 0.7 g (100%). NMR ($CDCl_3$) τ: 2.44—2.96 (8H, m, aromatic protons), 4.10 (2H, s, $>C\underline{H}$–N<), 6.38, 7.16 (each 8H, m, morpholino methylenes) and 7.64 (6H, s, $-C\underline{H}_3$). Mass (*m/e*): 456 (M^+), 370 $\left(M^+-\text{N}\langle\rangle\text{O}\right)$, 284 $\left(370^+-\text{N}\langle\rangle\text{O}\right)$ and 228 (M^{2+}). Found: C, 74.23; H, 6.96; N, 11.99%. Calcd for $C_{24}H_{32}N_4O_2$: C, 73.66; H, 7.06; N, 12.27%.

*The Reaction of **11b** with Potassium* tert*-Butoxide.* The mixture of 0.9 g of **11b**, 0.35 g of potassium *tert*-butoxide in 30 ml of dry benzene was refluxed for 5 hr. The residue obtained by evaporation was washed with water to yield 0.43 g (70%) of 6,13-dihydro-5,12-dimethyl-6,13-(*N*-pyrrolidinyl)diindolo[1,2-*a*: 1′,2′-*d*]pyrazine (**13b**), mp 204—205 °C (decomp.). Colorless prisms from ether. NMR ($CDCl_3$) τ: 2.40—3.00 (8H, m, aromatic protons), 3.76 (2H, s, $>C\underline{H}$–N<), 7.13, 8.32 (each 8H, m, pyrrolidinyl methylenes) and 7.62 (6H, s, $-C\underline{H}_3$). Mass (*m/e*): 424 (M^+), 354 $\left(M^+-\text{N}\langle\rangle\right)$, 284 $\left(354^+-\text{N}\langle\rangle\right)$ and 212 (M^{2+}). Found: C, 79.81; H, 8.16; N, 12.97%. Calcd for $C_{24}H_{32}N_4$: C, 79.20; H, 7.60; N, 13.20%.

*The Reaction of **9a** with Aqueous Sodium Hydroxide.* The suspension of 0.62 g of **9a** in 10 ml of methylene dichloride was cooled to −5 °C with ice-salt and then 10 ml of a 10% sodium hydroxide solution was added dropwise under vigorous stirring. As soon as the addition was completed, the organic layer was separated and dried with anhydrous magnesium sulfate. Evaporation of the solvent below 20 °C gave 0.40 g of colorless crystals, which were tentatively assigned to be 3-morpholinomethylene-2-methyl-3*H*-indole.

Cycloaddition Reactions of *N*-Sulfinylsulfonamides with Ketenimines

Toru MINAMI, Futoshi TAKIMOTO, and Toshio AGAWA

Department of Petroleum Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received May 16, 1975)

N-Sulfinylsulfonamides, **1a, b**, reacted with ketenimines, **2**, in ether to give the unstable [2+2] cycloadducts, 3-ylidene-1,2,4-thiadiazetidin-1-oxides, **3**, which were then readily hydrolyzed to the *N,N'*-disubstituted amidine derivative, **4**, in good yields. The reaction of *N*-sulfinylmethanesulfonamide (**1b**) with diphenylketen-*N*-*p*-tolylimine (**2d**) at 130 °C gave the exchange product, *N*-sulfinyl-*p*-toluidine (**5**) in a 70% yield *via* the intermediate cycloadduct. In contrast to **2d**, the reaction of *N*-sulfinyl-*p*-toluenesulfonamide (**1a**) and phenylethylketen-*N*-phenylimine (**2f**), under the same conditions, led to the formation of a mixture of *N*-phenyl-*N'*-*p*-toluenesulfonyl-2-phenyl-*trans*- (**6a**) and *cis*-2-butenoamidine (**6b**) in an 81% yield.

We previously demonstrated that *N*-sulfinylamines react with heterocumulenes, such as isocyanate and isothiocyanate, to give exchange products *via* the intermediate [2+2] cycloadducts.[1,2]

However, recently we reported that, in contrast to the above heterocumulenes, carbodiimides afford the unstable [2+2] cycloadducts in reactions with *N*-sulfinylsulfonamides.[3] In the course of such studies of the chemical reactivities of *N*-sulfinylamines, we have observed that the reactions with ketenimines similarly yield the corresponding unstable cycloadducts. We wish to report here on the structures of the cycloadducts and their reactivities.

Results and Discussion

N-Sulfinyl-*p*-toluenesulfonamide (**1a**) was allowed to react with dimethylketen-*N*-phenylimine (**2a**) at the ambient temperature in ether to give, smoothly, a 1:1 cycloadduct, **3a**, which was precipitated on standing in a 79% yield. The infrared spectrum exhibits the characteristic absorption bands for the C=C group and the S=O group at 1580 and 1090 cm^{-1} respectively. The mass spectrum shows the molecular ion at *m/e* 362 and the fragment ions at 223 and 139 due to ($Me_2C{=}C{=}NTs^+$) and ($PhNSO^+$). The NMR spectrum ($CDCl_3$) indicates two singlet isopropylidene methyl (6H), *p*-methyl (3H), and phenyl protons (9H) at 1.94 and 2.00, 2.40, and 7.20—7.96 ppm respectively. Thus, the structure of **3a** was identified as 2-*p*-toluenesulfonyl-3-isopropylidene-4-phenyl-1,2,4-thiadiazetidin 1-oxide. Furthermore, this structure was confirmed by the hydrolysis of **3a** to *N*-phenyl-*N'*-*p*-toluenesulfonyl-isobutyramidine (**4a**) in a good yield.

The reaction of *N*-sulfinylmethanesulfonamide (**1b**) with **2a** similarly afforded the [2+2] cycloadduct **3b** in an 85% yield.

However, in the reactions of **1a** (or **1b**) with other ketenimines, **2b**—**e**, the expected cycloadducts, **3**, could not be isolated in pure forms since they are unstable and are readily hydrolyzed to the corresponding amidines, **4b**—**e**. The physical and analytical data and the yields of the cycloadducts and the amidines obtained above are shown in Table 1.

No 1:2-cycloadduct was obtained in any of the above reactions nor in the reactions between *N*-sulfinylsulfonamides and carbodiimides,[3] although the 1:2-cycloadducts are well known to be formed in the reactions of

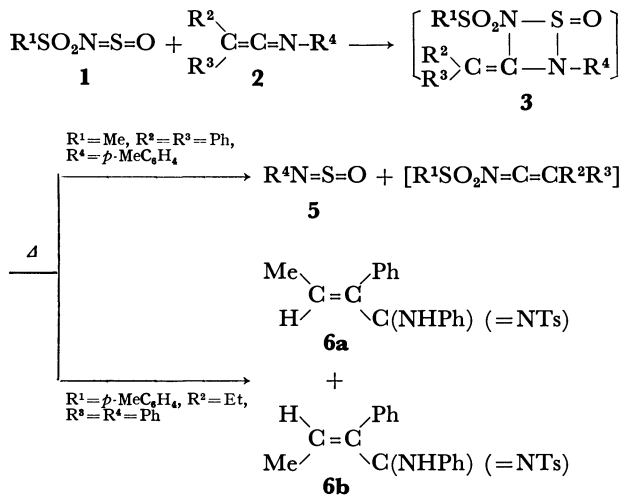
carbodiimides with isocyanates.[4] Therefore, in contrast to the reactions between carbodiimides and isocyanates, the cycloaddition reactions of *N*-sulfinylsulfonamides with heterocumulenes can be said probably to proceed *via* a concerted mechanism rather than *via* a step-by-step mechanism, although further kinetic evidence is necessary for the establishment of the mechanism.

A reaction using *N*-sulfinylarylamines or *N*-sulfinylalkylamines in place of reactive *N*-sulfinylsulfonamides afforded no cycloadduct.



Scheme 2.

On the other hand, the reaction of **1b** with diphenylketen-*N*-*p*-tolylimine (**2d**) at 130 °C for 1 hr under reduced pressure gave *N*-sulfinyl-*p*-toluidine (**5**) as a volatile liquid, which is an exchange product *via* the intermediate cycloadduct, in a 70% yield along with the residual polymeric product. However, the similar treatment of a mixture of **1a** and phenylethylketen-*N*-phenylimine (**2f**) containing hydrogen on the α carbon resulted in the formation of a mixture of *N*-phenyl-*N'*-*p*-toluenesulfonyl-2-phenyl-*trans*- (**6a**) and *cis*-2-butenoamidine (**6b**), the ratio of which was found by NMR to be approximately 5: 3, in an 81% yield. Their formations could be explained in terms of the elimination of sulfur monoxide from the [2+2] cycloadduct, **3**, which would be initially yielded from **1a** and **2f**, followed by a proton shift on the delocalized anionic nitrogen moiety. Such thermal decomposition is of interest since similar results have not been observed in the reactions of *N*-sulfinylamines with other heterocumulenes.

Experimental

All the melting points were determined with a Yanagimoto micro melting apparatus and are uncorrected. The NMR spectra were obtained on a JEOL LMM 3H-60 spectrometer, with tetramethylsilane as the internal standard. The IR spectra were recorded with a Jasco IR-E spectrometer. The mass spectra were taken with a Hitachi RMU-6E spectrometer.

Materials. The *N*-sulfinyl-*p*-toluenesulfonamide,[5] *N*-sulfinylmethanesulfonamide,[5] dimethylketen-*N*-phenyl-,[6] -*N*-*p*-tolyl-,[6] and -*N*-cyclohexyl-,[6] phenyl-*N*-cyclohexyl-,[6] and diphenyl-*N*-*p*-tolylketenimines[7] were prepared according to the established procedures.

2-p-Toluenesulfonyl-3-isopropylidene-4-phenyl-1,2,4-thiadiazetidin 1-Oxide (3a). Dimethylketen-*N*-phenylimine (**2a**, 1.02 g, 7 mmol) in 20 ml of dry ether was added, drop by drop, into a solution of 1.52 g (7 mmol) of *N*-sulfinyl-*p*-toluenesulfonamide (**1a**) in 30 ml of dry ether. After being stirred at the ambient temperature for 1 hr, the solution was allowed to stand overnight to give 2.0 g (79%) of a white solid, **3a**. Recrystallization from hexane–benzene afforded the analytical sample; mp 117—119 °C; IR (Nujol) ν 1600, 1580 (C=C), 1300 (SO_2), 1155 (SO_2), and 1090 cm^{-1} (SO); NMR ($CDCl_3$) δ 1.94 (s, 3H, $\underline{Me}>C=C<$), 2.00 (s, 3H, $\underline{Me}>C=C<$), 2.40 (s, 3H, $\underline{Me}Ar$), and 7.20—7.96 (m, 9H, phenyl protons); mass spectrum (70 eV) *m/e* 362 (M^+), 314 (M^+-SO), 223 (Me_2CCNTs^+), 145 (Me_2CCNPh^+), and 139 ($PhNSO^+$).

2-Methanesulfonyl-3-isopropylidene-4-phenyl-1, 2, 4-thiadiazetidin 1-Oxide (3b). This substance was prepared in the same way as **3a** by the reaction of **2a** (1.45 g, 0.01 mol) with *N*-sulfinylmethanesulfonamide (**1b**, 1.41 g, 0.01 mol). After the removal of the solvent, the resulting residue was recrystallized from hexane–benzene to give 2.45 g, (85%) of pure **3b**; mp 125—126 °C; IR (Nujol) ν 1600 (C=C), 1290 (SO_2), 1160 (SO_2), and 1130 cm^{-1} (SO); NMR ($CDCl_3$) δ 1.90 (s, 3H, $\underline{Me}>C=C<$), 1.95 (s, 3H, $\underline{Me}>C=C<$), 3.10 (s, 3H, $\underline{Me}SO_2$), and 7.25—7.75 (m, 5H, phenyl protons); mass spectrum (70 eV) *m/e* 286 (M^+), 238 (M^+-SO), 159 (M^+-MeSO_2), and 147 ($Me_2CCNSO_2Me^+$).

Base Catalyzed Hydrolysis of 3a. A solution of **3a** (1.09 g, 3 mmol) in 95% ethanol (20 ml) containing sodium hydroxide (0.12 g, 3 mmol) was refluxed for 1 hr. After the removal of the solvent, the residue was washed with water and then dried. The white solid thus obtained was recrystallized from ethanol to give pure *N*-phenyl-*N'*-*p*-toluenesulfonylisobutyramidine (**4a**, 0.74 g, 78%); mp 84—86 °C; IR (Nujol) ν 3240 (NH), 1560 (C=N), 1525 (NH), 1250 (SO_2), and 1135 cm^{-1} (SO_2); NMR ($CDCl_3$) δ 0.85—1.35 (m, 6H, methyl protons), 2.40 (s, 3H, $\underline{Me}Ar$), 3.60 (q, J=7 Hz, 1H, methine proton), 6.95—7.95 (m, 9H, phenyl protons), and 9.50—10.10 (broad, 1H, NH); mass spectrum (70 eV) *m/e* 316 (M^+), 247 ($TsNHPh^+$), and 224 (M^+-PhNH).

Reactions of N-Sulfinylsulfonamides, 1a—b, with Ketenimines, 2b—e. These reactions were carried out in a similar manner. After similar treatments, the cycloadducts corresponding to **3a** (or **3b**) could not be isolated in pure forms because of their easy hydrolysis. Therefore, the reaction products were chromatographed on alumina to give the amidine derivatives, **4b—e**, which are hydrolysis products, in good yields, as is shown in Table 1. The amidines, **4b—e**, had the following physical properties:

N-p-*Tolyl*-N'-p-*toluenesulfonyl-isobutyramidine (4b)*: IR (Nujol) ν 3280 (NH), 1560 (C=N), 1525 (NH), 1250 (SO_2), and 1135 cm^{-1} (SO_2); NMR ($CDCl_3$) δ 0.85—1.35 (broad d, 6H, methyl protons), 2.34 (s, 3H, $\underline{Me}Ar$), 2.40—2.90 (m, 4H, $\underline{Me}Ar$ and methine proton), 6.90—7.95 (m, 8H, phenyl protons), and 9.10—9.40 (broad, 1H, NH); mass spectrum (70 eV) *m/e* 330 (M^+), and 261 ($TsNHC_6H_4Me^+$).

N-*Cyclohexyl*-N'-p-*toluenesulfonyl-isobutyramidine (4c)*: IR (Nujol) ν 3290 (NH), 1570 (C=N), 1530 (NH), 1260 (SO_2), and 1130 cm^{-1} (SO_2); NMR ($CDCl_3$) δ 1.0—2.05 (m, 16H, two methyl and cyclohexyl protons), 2.40 (s, 3H, $\underline{Me}Ar$), 2.50—2.90 (m, 1H, methine proton), 3.50—3.90 (m, 1H, methine proton), 5.50—5.90 (broad, 1H, NH), and 7.05—7.85 (dd, 4H, phenyl protons); mass spectrum (70 eV) *m/e* 322 (M^+) and 241 ($TsNHC_6H_9^+$).

N-p-*Tolyl*-N'-p-*toluenesulfonyldiphenylacetamidine (4d)*: IR

(Nujol) ν 3200 (NH), 1570 (C=N), 1510 (NH), 1270 (SO_2), and 1130 cm^{-1} (SO_2); NMR ($CDCl_3$) δ 2.35 (s, 6H, methyl protons), 5.03 (s, 1H, methine proton), 6.80—7.70 (m, 18H, phenyl protons), and 9.55—9.85 (broad, 1H, NH); mass spectrum (70 eV) *m/e* 454 (M^+).

N-*Cyclohexyl*-N'-*methanesulfonyl-phenylacetamidine (4e)*: IR (Nujol) ν 3220 (NH), 1555 (C=N), 1540 (NH), 1270 (SO_2), and 1140 cm^{-1} (SO_2); NMR (DMSO-d_6) δ 1.0—2.15 (m, 12H), 2.80 (s, 3H, methyl protons), 3.25—3.40 (broad, 1H, methine proton), 3.65—4.10 (broad, 1H, NH), and 7.40—8.05 (m, 5H, phenyl protons); mass spectrum (70 eV) *m/e* 294 (M^+).

Exchange Reaction between ***1b*** *and Diphenylketen*-N-p-*tolylimine (2d)*. To 0.71 g (5 mmol) of **1b** in 20 ml of ether, we added, drop by drop, 1.42 g (5 mmol) of **2d** in 10 ml of ether. After the subsequent evaporation of the solvent under reduced pressure, the vacuum distillation of the residue at 130 °C for 1 hr under reduced pressure (15 mmHg) yielded 0.54 g (70%) of *N*-sulfinyl-*p*-tolylamine (**5**), whose structure was determined by a comparison of its IR spectrum and glpc behavior with those of an authentic sample.[8] No identification of the residue was attempted.

N-*Phenyl*-N'-p-*toluenesulfonyl-2-phenyl-2-butenoamidine (6)*.

The reaction mixture of **1a** (2.17 g, 0.01 mol) with phenylethylketen-*N*-phenylimine (**2f**, 2.21 g, 0.01 mol) was similarly thermolyzed. The crude product was recrystallized from ethanol to give a mixture (3.13 g, 81%) of *N*-phenyl-*N'*-*p*-toluenesulfonyl-2-phenyl-*trans*- (**6a**) and *cis*-2-butenoamidine (**6b**), whose ratio was determined by means of its NMR spectrum. The attempted isolation of pure samples of individual **6a** and **6b** was unsuccessful. The analytical and physical data of the product are as follows.

Mp 185—187 °C; IR (Nujol) ν 3260 (NH), 1565, 1510, 1275 (SO_2), and 1180 cm^{-1} (SO_2); NMR ($CDCl_3$) δ 1.70 (d, J=6 Hz, 3H, $\underline{Me}\rangle C{=}C\langle^{Ph}$), 1.82 (d, J=6 Hz, 3H, $\underline{Me}\rangle C{=}C\langle^{Ph}$), 2.32 (s, 3H, $\underline{Me}$Ar), 2.44 (s, 3H, $\underline{Me}$Ar), 5.80—6.25 (m, J=6 Hz, 1H, $^{\underline{H}}_{Me}\rangle C{=}C\langle_{Ph}$ and $^{Me}_{\underline{H}}\rangle C{=}C\langle_{Ph}$), 6.75—8.0 (m, 14H, phenyl protons), and 10.0—10.25 (broad, 1H, NH); mass spectrum (70 eV) *m/e* 390 (M^+), 247 ($PhNHTs^+$) and 235 (M^+-Ts).

Chemistry of Nitrosoimines. X.[1] Reactions of 3-Substituted 2-Nitrosoimino-2,3,-dihydrobenzothiazoles with Aryl and *t*-Butyl Grignard Reagents

Kin-ya AKIBA, Takayuki KAWAMURA, Motoyuki HISAOKA, and Naoki INAMOTO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received May 20, 1975)

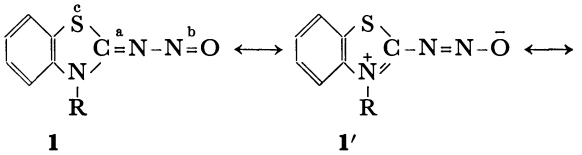
3-Substituted 2-nitrosoimino-2,3-dihydrobenzothiazoles (**1**) react with arylmagnesium bromide to give 3-substituted 2,2-diaryl-2,3-dihydrobenzothiazoles as the major product and 2-*N'*-arylhydrazono-2,3-dihydrobenzothiazoles as a minor product. **1** reacts also with *t*-butylmagnesium chloride to give 3-substituted 2-*t*-butyl- and 2-*N'*-*t*-butylhydrazono-2,3-dihydrobenzothiazoles and 2,3-dihydrobenzothiazol-2-one. Reaction of **1** with mesitylmagnesium bromide gave a similar result to that with *t*-butylmagnesium chloride.

Simple nitrosoimines are thermally unstable and apt to decompose unimolecularly to the corresponding carbonyl compounds and nitrogen. Sterically hindered nitrosoimines have been prepared as rather unstable compounds, some of their reactions being reported.[2] Resonance-stabilized nitrosoimines were found to be considerably unstable. 2-Nitroso-1,1,3,3-tetraphenyl guanidine is the only one compound which gave correct elemental analysis.[3]

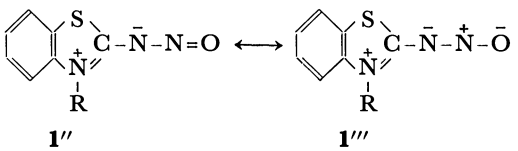
On the other hand, nitrosoimines are known to be stable when the nitrosoimino group is contained in heterocycles such as benzothiazole, 1,2,4-thiadiazole,[4] and 1,3,4-thiadiazole.[5]

We have chosen 3-substituted 2-nitrosoimino-2,3-dihydrobenzothiazole (**1**) as a model and investigated reactions of **1** with nucleophiles such as Grignard reagents,[6] lithium aluminum hydride,[1,7] organolithiums,[8] and Grignard type and lithium reagents of 3-substituted 2-imino-2,3-dihydrobenzothiazoles.[9] Preliminary results have been interpreted to be due to large contribution of an ambident character to **1**.

We recently obtained direct evidence for the contribution of ambident structures (**1'**, **1''** and **1'''**) to the ground state of **1** by UV[3] and ESCA study.[10a]



1 **1'**



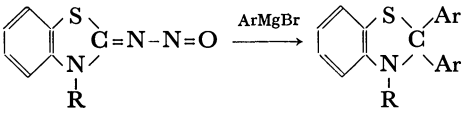
1'' **1'''**

a, R=Me, **b**, R=Ph, **c**, R=Et

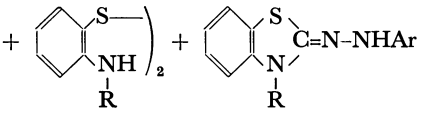
The result suggests that **1** has three possible reactive centers for nucleophiles, *i.e.*, the C-2 position of the ring (a), the nitrogen atom of the nitroso group (b), and the sulfur atom of the ring (c). We investigated the reactions of **1** with Grignard reagents and organolithiums.

From an investigation on the chemistry of nitrosoimines to prepare and investigate the nature of the nitrosoimino group, a new functionality, studies were turned to reactions of nucleophiles toward ambident cation (**1**). In this connection, it is necessary to mention the extensive studies on cyclic azosulfones by Hünig.[10b] He mainly studied the oxidative coupling of azosulfones with active methylenes and phenols, paying attention to the ambident nature of quaternary salts of azosulfones. A couple of reactions of 2-azido-3-ethylbenzothiazolium ions with nucleophiles have recently been interpreted by means of HSAB principle as the nucleophilic addition of bases to ambident aromatic cations.[10c] This paper describes the reactions of **1** with arylmagnesium and *t*-butylmagnesium halides.

Excess phenylmagnesium bromide reacted with 2-nitrosoimino-3-phenyl-2,3-dihydrobenzothiazole (**1b**) in ether at 0 °C under nitrogen to give 2,2,3-triphenyl-2,3-dihydrobenzothiazole (**2b**, 48%), a small amount of bis(*o*-anilinophenyl) disulfide (**3b**) and 3-phenyl-2-*N'*-phenylhydrazono-2,3-dihydrobenzothiazole (**4b**, 17%).



1 **2** Ar=Ph; **6** Ar=*p*-MeC$_6$H$_4$



a, R=Me; **b**, R=Ph — **3** — **4** Ar=Ph; **7** Ar=*p*-MeC$_6$H$_4$

The structures of **2b** and **4b** were confirmed by elemental analyses, NMR, IR and MS. The structure of **3b** was confirmed by comparing the spectral data with those of an authentic sample[11] prepared from 3-phenyl-2,3-dihydrobenzothiazol-2-one (**5b**) and potassium hydroxide.

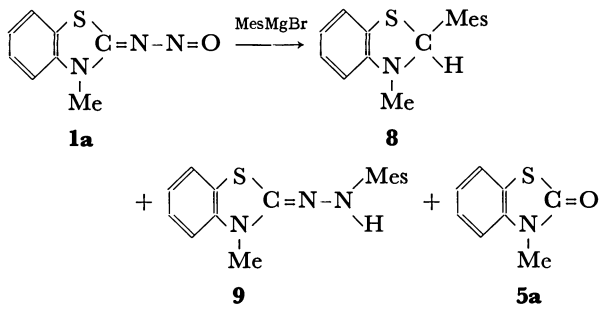
A similar reaction with 3-methyl derivative (**1a**) gave the corresponding **2a** (22%), **3a** (5%), and **4a** (*ca.* 15%), but **4a** could not be sufficiently purified for elemental analysis.

p-Tolylmagnesium bromide reacted with **1a** to afford 3-methyl-2,2-bis(*p*-tolyl)-2,3-dihydrobenzothiazole (**6a**, 66%) and 3-methyl-2-*N'*-*p*-tolylhydrazono-2,3-dihydrobenzothiazole (**7a**, 12%), and with **1b** to give the corresponding **6b** (50%) and **7b** (8%).

Reactions of **1a** were also carried out, but separation of the reaction products was unsuccessful. In particular,

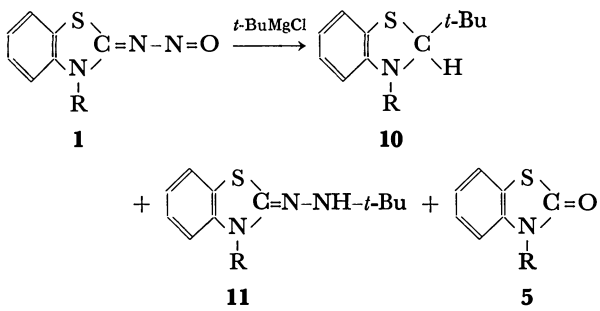
fractions containing mainly *N'*-arylhydrazono type compounds were unstable in the atmosphere, gradually producing a purple red tar.

Mesitylmagnesium bromide reacted with **1a** in a similar manner to give 2-mesityl- (**8**, 46%) and 2-*N'*-mesitylhydrazono-3-methyl-2,3-dihydrobenzothiazoles (**9**, 18%), and 3-methyl-2,3-dihydrobenzothiazol-2-one (**5a**, 10%).



1a **8** **9** **5a**

The formation of 2-monosubstituted compound (**8**) is in contrast to that of 2,2-disubstituted compounds (**2** and **6**) in the case of phenyl and *p*-tolyl Grignard reagents. The difference is attributable to the difference of the bulkiness of Grignard reagents. It was found that the reaction of **1** with *t*-butylmagnesium chloride gives the corresponding 3-substituted 2-*t*-butyl- (**10**), 2-*N'*-*t*-butylhydrazono-2,3-dihydrobenzothiazoles (**11**) and 3-substituted 2,3-dihydrobenzothiazol-2-one (**5**). The result is given below.



1 **10** **11** **5**

	10 (%)	**11** (%)	**5** (%)
1a	39	8	13
1b	50	15	22

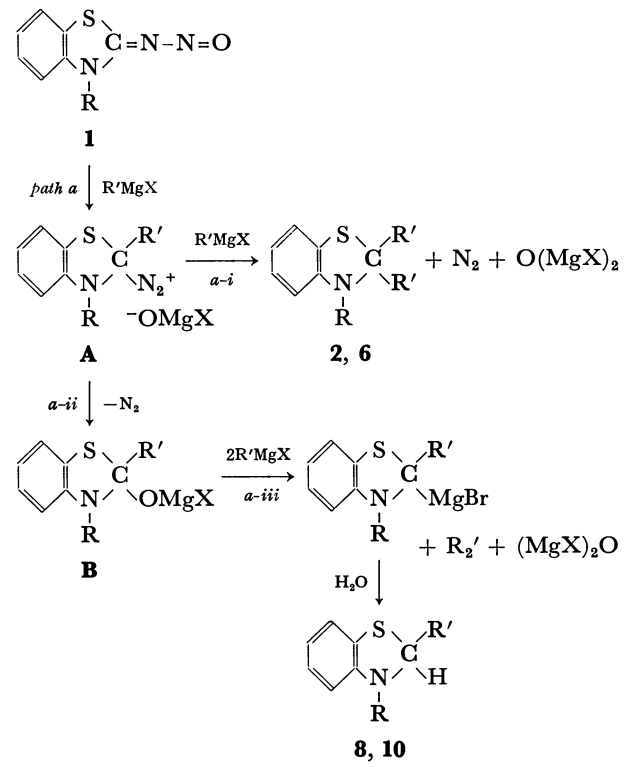
2,2-Diaryl (**2** and **6**), 2-mesityl (**8**) and 2-*t*-butyl (**10**) derivatives are considered to be formed *via* the common 1,4-addition intermediate between **1** and Grignard reagent, a diazonium salt (**A**), which reacts with Grignard reagent to give 2,2-disubstituted derivatives (*path a-i*) or loses nitrogen to give magnesium bromide 2-mesitly (or *t*-butyl)-2,3-dihydrobenzothiazol-2-yl oxide (**B**). The formation of **8** and **10** is explained below (*path a-ii*, *a-iii*).

The fate of **A** seems to depend on the bulkiness of Grignard reagents. Bulky Grignard reagents such as mesityl and *t*-butyl prefer the latter path (*path a-ii*).

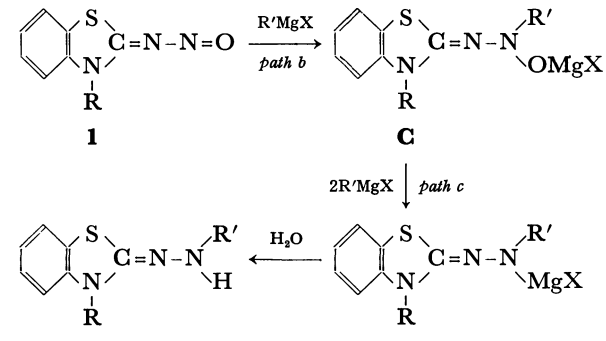
The *path a-ii* was supported by the fact that the evolved gas was only nitrogen in the reaction of **1b** with *t*-butylmagnesium chloride, the amount (76%) being nearly equal to the sum (72%) of the amounts of **10** and **5b**.

N'-Substituted hydrazono derivatives (**4**, **7**, **9**, and **11**) are considered to be produced as follows.

1 first reacts with Grignard reagent to give 1,2-addition intermediate (**C**), **C** then reacting with excess Grignard reagents to give **D**.



1 **A** **2, 6** **B** **8, 10**



1 **C** **4, 7, 9, 11** **D**

p-Cresol (4 mmol) was actually obtained in the reaction of **1b** (24 mmol) with *p*-tolylmagnesium bromide (100 ml). This seems to support OMgX-MgX exchange for *path c* producing R'OMgX as Wieland and Roseeu reported for the reaction of nitrosobenzene with phenylmagnesium bromide.[12]

However, their postulate was not substantiated by Gilman, who found that the following should be the case,[13] this being now accepted.

$$Ph_2NOMgBr + 2\,PhMgBr \longrightarrow Ph_2NMgBr + Ph_2 + (MgBr)_2O$$

This type of reaction is sensitive to the structure of both reagents. However, no systematic investigation has been carried out. We prefer Gilman's postulate. This can also be the case for *path a-iii*, although exact mechanism may be more complex.

The mechanism of formation of **3** will be discussed in a succeeding paper.[14]

Thiazolones (**5**) are formal products in the thermal decomposition of **1**, but **1** is completely stable under

the reaction conditions. The reason why **5** is produced in considerable amount in the reaction with bulky Grignard reagents is obscure.

We see that aryl and *t*-butyl Grignard reagents react at positions a (major) producing diazonium salt (**A**) as an intermediate and at b (minor) producing hydroxylamine type intermediate (**C**).

Experimental

All the melting and boiling points are uncorrected. NMR spectra were recorded with Hitachi R-20B and R-24 spectrometers (60 MHz) using TMS as an internal standard. IR spectra were taken with a Hitachi EPI-G2 spectrometer. MS were measured with a Hitachi RMU-6L mass spectrometer at 70 eV.

Materials. 3-Methyl- (**1a**, mp 143 °C (dec.))[15] and 3-phenyl-2-nitrosoimino-2,3-dihydrobenzothiazoles (**1b**, mp 140 °C (dec.))[16] were prepared by reported methods. Mesityl bromide was prepared by the bromination of mesitylene,[17] bp 80—85 °C/6 mmHg.

All the reactions were carried out under nitrogen except the one for the determination of evolved gas (argon).

*Reaction of 2-Nitrosoimino-3-phenyl-2,3-dihydrobenzothiazole (**1b**) with Phenylmagnesium Bromide.* To a stirred solution of Grignard reagent prepared from magnesium turnings (3.60 g, 0.15 mol) and bromobenzene (23.55 g, 0.15 mol) in anhydrous ether (150 ml), was added **1b** (7.61 g, 30 mmol) portionwise over a period of 1 hr at 0 °C. The reaction took place immediately with vigorous evolution of gas, stirring being continued for 3 hr. The reaction mixture was treated with saturated aqueous ammonium chloride and the resulting precipitates were filtered off. The precipitates were extracted with ether (100 ml×2) and benzene (100 ml). The extracts and ether layer of the filtrate were combined and dried over anhydrous magnesium sulfate. The solvent was evaporated in a vacuum and the residue was chromatographed on silica gel. 2,2,3-Triphenyl-2,3-dihydrobenzothiazole (**2b**, 5.25 g, 48%) was eluted with benzene and recrystallized from benzene–ethanol (1: 1) as yellowish crystals, mp 191.5—192.5 °C; MS: *m/e* 365 (M^+, 23%) and 288 (M^+—Ph, 100%).

Found: C, 82.35; H, 5.36; N, 3.79; S, 8.64%. Calcd for $C_{25}H_{19}NS$: C, 82.17; H, 5.24; N, 3.84; S, 8.76%.

A small amount of bis(*o*-anilinophenyl) disulfide (**3b**) was eluted with benzene as a yellow oil. The structure was confirmed by comparison with the spectral data of an authentic sample[11] prepared from 3-phenyl-2,3-dihydrobenzothiazol-2-one (**5b**) and potassium hydroxide in ethanol. 3-Phenyl-2-*N'*-phenylhydrazono-2,3-dihydrobenzothiazole (**4b**, 1.57 g, 17%) was eluted with dichloromethane–chloroform (1: 1) and recrystallized from benzene–ethanol (1: 1), mp 157—158 °C; IR (KBr): 3230 (NH), 1595, and 1585 cm^{-1}; NMR ($CDCl_3$): δ 3.45 (broad s, 1H, N–H) and 6.70—7.65 (m, 15H, Ar-H); MS: *m/e* 317 (M^+, 100%) and 225 (M^+—PhNH, 41%).

Found: C, 71.92; H, 4.77; N, 13.31; S, 9.80%. Calcd for $C_{19}H_{15}N_3S$: C, 71.91; H, 4.76; N, 13.24; S, 10.08%.

*Reaction of 3-Methyl-2-nitrosoimino-2,3-dihydrobenzothiazole (**1a**) with Phenylmagnesium Bromide.* To a stirred Grignard solution prepared from magnesium (3.63 g, 149 mmol) and bromobenzene (23.26 g, 148 mmol) in ether (100 ml) was added **1a** (4.80 g, 24.3 mmol) portionwise over a period of 2.5 hr at 0 °C and the mixture was stirred for 13.5 hr. After a similar work-up, 3-methyl-2,2-diphenyl-2,3-dihydrobenzothiazole (**2a**, 1.63 g, 22%) was eluted with *n*-hexane, mp 142—143 °C (from $CHCl_3$); NMR ($CDCl_3$): δ 2.59 (s, 3H, N-Me) and 6.12—7.63 (m, 14H, Ar-H); MS: *m/e* 303 (M^+, 16%) and 226 (M^+—Ph, 100%).

Found: C, 79.37; H, 5.37; N, 4.64; S, 10.43%. Calcd for $C_{20}H_{17}NS$: C, 79.17; H, 5.65; N, 4.62; S, 10.57%.

Bis(*o*-methylaminophenyl) disulfide (**3a**, 0.657 g, 5%) was eluted with *n*-hexane–benzene (1: 1) as yellow crystals, mp 66.5—67.0 °C (from chloroform–ethanol) (lit,[18] 64—68 °C).

A fraction corresponding to 3-methyl-2-*N'*-phenylhydrazono-2,3-dihydrobenzothiazole (**4a**, 1.0 g, 15%) was obtained, **4a** decomposing slowly during the course of isolation.

*Reaction of **1a** with* p-*Tolylmagnesium Bromide.* To a stirred Grignard solution prepared from magnesium (4.80 g, 0.20 mol) and *p*-bromotoluene (34.20 g, 0.20 mol) in ether (150 ml) was added **1a** (7.72 g, 40 mmol) portionwise at 0 °C and the mixture was stirred for 1 hr. After a similar work-up 3-methyl-2,2-bis(*p*-tolyl)-2,3-dihydrobenzothiazole (**6a**, 8.8 g, 66%) was eluted with benzene as yellowish crystals, mp 141.0—141.5 °C (from benzene–methanol (1: 1)); NMR ($CDCl_3$): δ 2.35 (s, 6H, 2 Me), 2.65 (s, 3H, Me), and 6.7—7.5 (m, 12H, Ar–H).

Found: C, 79.72; H, 6.16; N, 3.92; S, 9.59%. Calcd for $C_{22}H_{21}NS$: C, 79.73; H, 6.39; N, 4.23; S, 9.66%.

Red brown tarry material (2.45 g) was eluted with chloroform–ether (7: 1) and crystallized partly on standing, mp 155.0—156.5 °C. The compound was assigned as 2-*N'*-*p*-tolylhydrazono-3-methyl-2,3-dihydrobenzothiazole (**7a**) by comparison of its IR data with those of **4b** and **7b**. IR (KBr): 3350 (NH), 1610 (C=N), 1595, and 1590 cm^{-1}.

*Reaction of **1b** with* p-*Tolylmagnesium Bromide.* To a stirred Grignard solution prepared from magnesium (2.51 g, 0.10 mol) and *p*-bromotoluene (17.13 g, 0.10 mol) in ether (100 ml) was added **1b** (6.14 g, 24 mmol) portionwise at room temperature and the mixture was stirred for 2 hr. After a similar work-up, extraction with 20% aqueous sodium hydroxide gave *p*-cresol (0.43 g, 4 mmol), whose spectral data were in agreement with those of an authentic sample. The residue was chromatographed on silica gel. Elution with *n*-hexane–benzene (1: 1) gave a mixture of bi-*p*-tolyl and 3-phenyl-2,2-bis(*p*-tolyl)-2,3-dihydrobenzothiazole (**6b**), but separation of the mixture was very difficult. The yield of **6b** was estimated to be 4.7 g (50%) by its NMR spectrum, and the structure was determined by the following data; NMR ($CDCl_3$): δ 2.56 (s, 6H, 2 Me) and 6.15—7.20 (m, 19H, Ar-H).

Elution with benzene–dichloromethane (1: 1) gave a reddish purple tarry material (1.48 g), which was treated with dry column chromatography (silica gel) to give 3-phenyl-2-*N'*-*p*-tolylhydrazono-2,3-dihydrobenzothiazole (**7b**, 0.672 g, 8%), mp 186.5—187.5 °C (from chloroform–ethanol); IR (KBr): 3270 (NH), 1610, 1590, and 1580 cm^{-1}; NMR ($CDCl_3$): δ 2.23 (s, 3H, Me) and 6.30—7.53 (m, 13H, Ar-H) (N–H signal was obscure); MS: *m/e* 331 (M^+, 100%). Compound **7b** was unstable in solvents.

Found: C, 72.35; H, 5.18; N, 12.72%. Calcd for $C_{20}H_{17}N_3S$: C, 72.48; H, 5.14; N, 12.68%.

*Reaction of **1a** with Mesitylmagnesium Bromide.* To a stirred Grignard solution prepared from magnesium (4.8 g, 0.20 mol) and mesityl bromide (39.8 g, 0.20 mol) in ether (150 ml) was added **1a** (7.72 g, 40 mmol) portionwise and the mixture was treated and chromatographed in the usual way. Elution with benzene with 2-mesityl-3-methyl-2,3-dihydrobenzothiazole (**8**, 4.9 g, 46%) as yellowish crystals, mp 222.0—223.5 °C (from ethanol); NMR ($CDCl_3$): δ 2.1 (s, 3H, Me), 2.3 (s, 6H, 2 Me), 3.2 (s, 3H, Me), 5.0 (s, 1H, CH), and 6.7—7.4 (m, 6H, Ar-H).

Found: C, 75.62; H, 6.90; N, 5.18; S, 12.01%. Calcd for $C_{17}H_{19}NS$: C, 75.81; H, 7.11; N, 5.20; S, 11.88%.

Elution with dichloromethane gave 3-methyl-2,3-dihydrobenzothiazol-2-one (**5a**, 0.64 g, 10%), mp 74—75 °C (75—

76 °C,[11] 76 °C[15]). Elution with dichloromethane–chloroform (1: 1) gave 2-*N'*-mesitylhydrazono-3-methyl-2,3-dihydrobenzothiazole (**9**, 2.1 g, 18%), mp 152.0—154.5 °C; IR (KBr): 3310 (NH), 1610, and 1590 cm^{-1}. IR supports structure **9**.

Reaction of ***1b*** *with* t-*Butylmagnesium Chloride.* To a stirred solution of Grignard reagent prepared from magnesium (3.60 g, 0.15 mol) and *t*-butyl chloride (13.50 g, 0.146 mol) in ether (150 ml), was added **1b** (7.71 g, 30 mmol) portionwise over a period of 1 hr at 0 °C. Stirring was continued for 3 hr. 2-*t*-Butyl-3-phenyl-2,3-dihydrobenzothiazole (**10b**, 3.70 g, 50%) was eluted with benzene, mp 61—62 °C (from ethanol); NMR ($CDCl_3$): δ 1.00 (s, 9H, Me_3C), 5.10 (s, 1H, >C–H), and 6.85—7.25 (m, 9H, Ar-H); MS: *m/e* 279 (M^+, 8.9%) and 212 ($M^+ - t$-Bu, 100%).

Found: C, 75.81; H, 7.11; N, 5.20; S, 11.88%. Calcd for $C_{17}H_{19}NS$: C, 76.02; H, 7.15; N, 5.20; S, 11.60%.

3-Phenyl-2,3-dihydrobenzothiazol-2-one (**5b**, 1.48 g, 22%) was eluted with benzene–dichloromethane (1: 3), mp 78—79 °C (from *n*-hexane) (lit,[16] 75—76 °C). 2-*N'*-*t*-Butylhydrazono-3-phenyl-2,3-dihydrobenzothiazole (**11b**, 1.33 g, 15%) was eluted with dichloromethane, mp 161—162 °C (from ethanol); IR (KBr): 3230 (NH), 1615, 1590, and 1580 cm^{-1}; NMR ($CDCl_3$): δ 1.10 (s, 9H, Me_3C), 3.05 (broad s, 1H, N–H), and 6.7—7.6 (m, 9H, Ar-H); MS: *m/e* 297 (M^+, 88%) and 282 ($M^+ - Me$, 100%).

Found: C, 68.38; H, 6.22; N, 14.06; S, 10.99%. Calcd for $C_{17}H_{19}N_3S$: C, 68.66; H, 6.44; N, 14.13; S, 10.76%.

Reaction of ***1a*** *with* t-*Butylmagnesium Chloride (Reverse Addition Method).* *t*-Butylmagnesium chloride free of excess magnesium, prepared from magnesium (2.59 g, 0.106 mol) and *t*-butyl chloride (8.06 g, 87.1 mmol) in ether (100 ml), was added dropwise over a period of 1 hr at 0 °C with stirring to a suspension of **1a** (3.00 g, 15.5 mmol) in ether (50 ml). Stirring was continued for 1 hr. The reaction mixture was chromatographed on silica gel after the usual work-up. 2-*t*-Butyl-3-methyl-2,3-dihydrobenzothiazole (**10a**, 1.05 g, 39%) was eluted with *n*-hexane–benzene (1: 1) as an oil. The structure was confirmed by the following NMR data: NMR ($CDCl_3$): δ 0.93 (s, 9H, Me_3C), 2.99 (s, 3H, N–Me), 4.62 (s, 1H, >C–H), and 6.35—7.46 (m, 4H, Ar-H).

3-Methyl-2,3-dihydrobenzothiazol-2-one (**5a**, 0.346 g, 13%) was eluted with benzene, mp 76.0—76.5 °C (lit,[15] 76 °C). 2-*N'*-*t*-Butylhydrazono-3-methyl-2,3-dihydrobenzothiazole (**11a**, 0.307 g, 8%) was eluted with benzene–dichloromethane (1: 1) and chloroform as an oil. The structure was confirmed by the following spectral data: IR (KBr): 3220 (NH), 1630 and 1580 cm^{-1}: NMR ($CDCl_3$): δ 1.19 (s, 9H, Me_3C), 2.76 (broad s, 1H, N–H), 3.44 (s, 3H, N–Me), and 6.7—7.9 (m, 4H, Ar–H). By addition of D_2O, a broad singlet at δ 2.76 disappeared.

Determination of the Evolved Gas. *t*-Butylmagnesium chloride was prepared from magnesium (0.43 g, 18 mmol) and *t*-butyl chloride (1.67 g, 18 mmol) in ether (50 ml) under argon. In a closed system, **1b** (0.92 g, 3.6 mmol) was added to the above solution at 0 °C under stirring. The amount of evolved gas was 61.5 ml (76%). The gas was found to be pure nitrogen by MS. No dinitrogen oxide (*m/e* 44) was detected.

Chemistry of Nitrosoimines. XI.[1] Reactions of 3-Substituted 2-Nitrosoimino-2,3-dihydrobenzothiazoles with Benzyl and Allylic Grignard Reagents

Motoyuki HISAOKA, Kin-ya AKIBA, and Naoki INAMOTO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received May 20, 1975)

3-Substituted 2-nitrosoimino-2,3-dihydrobenzothiazoles (**1**) react with benzylmagnesium chloride to give 3-substituted 2,2-dibenzyl- (**2**), 2-*N'*-benzylidenehydrazono- (**3**) and 2-*N'*,*N'*-dibenzylhydrazono-2,3-dihydrobenzothiazoles (**4**). The main reaction (formation of **3** and **4**) occurrs on the nitroso group of **1**, which proceeds *via* 1,2-addition intermediate (**B**). Allylmagnesium bromide and cinnamylmagnesium chloride also react with 3-methyl derivative (**1a**) to afford 2-*N'*,*N'*-diallyl- and 2-*N'*-(1-phenyl-2-propenyl)hydrazono-3-methyl-2,3-dihydrobenzothiazoles, respectively.

In a previous paper,[1] it was shown that the major reaction of 3-substituted 2-nitrosoimino-2,3-dihydrobenzothiazoles (**1**) with aryl and *t*-butyl Grignard reagents occurs on the C-2 of the benzothiazoline ring (*path a*) and the minor one on the nitrogen of the nitroso group (*path b*). In order to clarify a correlation between structure of Grignard reagents and reaction center in **1** which has an ambident character,[2] reactions of **1** were carried out with benzyl, allyl and cinnamyl Grignard reagents, which are resonance-stabilized carbanions. Reactions of **1** with benzylmagnesium chloride, in particular, were investigated in detail.

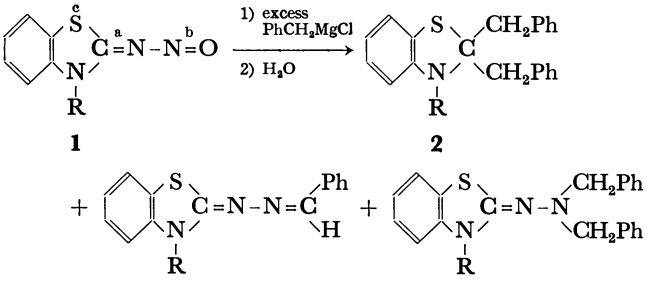
Table 1. Reaction products of **1** with excess (4 eqv.) benzylmagnesium chloride

Run	Reaction condition	Yield (%) 2	3	4
1[a]	**1a**, Et_2O, r.t. (4 hr)	8	44	19
2	**1a**, Et_2O, r.t. (4 hr) and then reflux (3 hr)	8	14	31
3	**1b**, Et_2O, r.t. (2.5 hr) and then reflux (1 hr)	4	9	25
4	**1c**, THF, r.t. (2.5 hr)	2	30	11
5[b]	**1a**, THF, r.t. (2.5 hr)	7	43	3

a) Neither $PhCH_2OH$ nor $PhCH_2Cl$ was detected by glc.
b) Reverse addition of Grignard reagent to a suspension of **1a** and $MgCl_2$. 2-*N'*-Benzylhydrazono-3-methyl-2,3-dihydrobenzothiazole (**5a**) was also isolated in 2% yield.

To an excess benzylmagnesium chloride in ether or tetrahydrofuran (THF) was added **1** under nitrogen. The reaction products were 2,2-dibenzyl- (**2**), 2-*N'*-benzylidenehydrazono- (**3**) and 2-*N'*,*N'*-dibenzylhydrazono-2,3-dihydrobenzothiazoles (**4**). The results are shown in Table 1.

From a comparison of the result of run 2 with that of run 1 (Table 1), it is seen that the yield of **2a** remains unchanged by reflux of the solvent, but that of **3a** decreases, accompanied by the increase of **4a**, the total



1 **2** **3** **4**

1 **B** **4** **A** **C** **2** **3** **5**

Scheme 1.

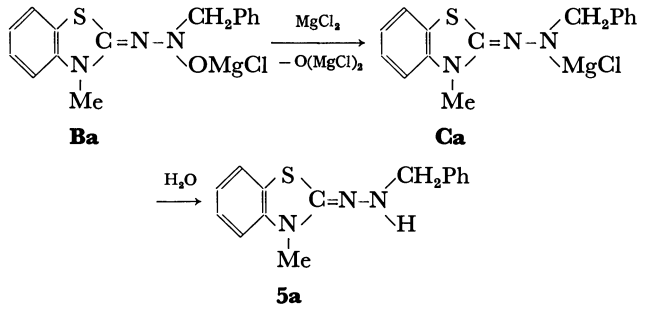
yield of **3a** and **4a** being almost the same as that of run 1. This suggests that **3a** and **4a** are produced through a common intermediate (**B**).

Similarly, 3-phenyl (**1b**, run 3) and 3-ethyl (**1c**, run 4) derivatives were allowed to react with excess benzylmagnesium chloride at room temperature. After 2.5 hr (run 3), the reaction mixture was refluxed to give a similar result to that of run 2. The result of run 4 was very similar to that of run 1.

From the results obtained in runs 1—4, paths of formation of **2**, **3** and **4** are proposed as shown in Scheme 1.

Nitrosoimines (**1**) react with benzylmagnesium chloride to produce initially 1,2- (**B**) and 1,4-addition intermediates (**A**).[1] Unsymmetric azines (**3**) and hydrazones (**4**) are formed *via* the common intermediates (**B**). Azines (**3**) are produced by the hydrolysis and dehydration of the intermediate (**B**). Two paths can be considered for the formation of **4** from **B**. One is the apparent exchange of the OMgCl group to give magnesium salt of hydrazones (**C**), which can proceed by Gilman's mechanism producing bibenzyl, Wieland's mechanism producing benzyl alcohol not being excluded *a priori*.[1] The other is the path along which a second Grignard reagent attacks directly on the nitrogen atom of the nitroso group to give **4** (*b-ii*). Two possibilities for the former path were ruled out since no benzyl alcohol could be detected in the reaction mixture by gas chromatography (glc) and no residual benzyl chloride was detected in the Grignard solution before use. The formation of **4** is accelerated by heating.

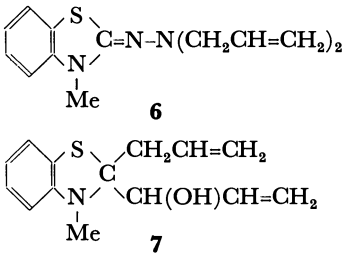
In the case of slow reverse addition of Grignard reagent to a suspension of **1a** and magnesium(II) chloride in THF (run 5), 2-*N'*-benzylhydrazono-3-methyl-2,3-dihydrobenzothiazole (**5a**) was also isolated in 2% yield together with **2a**, **3a** and **4a**. Thus, the path of formation of **5a** is explained as follows: the OMgCl-MgCl exchange between the 1,2-addition intermediate (**Ba**) and magnesium (II) chloride probably produces magnesium salt (**Ca**), which is hydrolyzed to produce **5a** (Scheme 2).



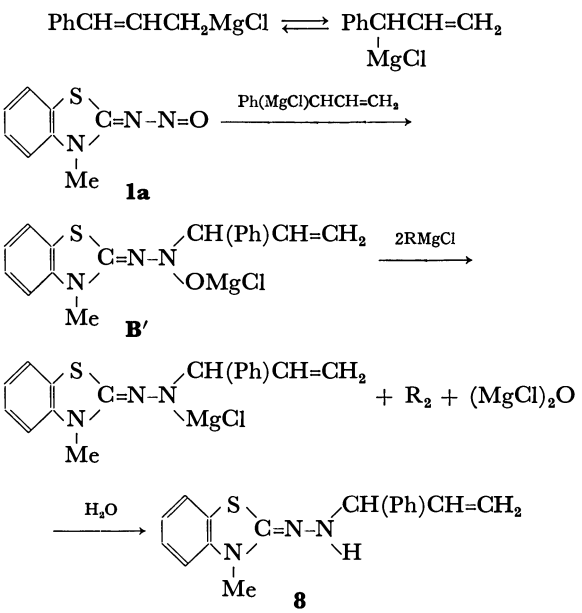
Scheme 2.

It is noteworthy that the benzyl protons of **2a** and **2c** appear as quartet whereas those of **2b** appear as singlet. The difference can be attributed to the presence of phenyl group in **2b**, although the exact reason is not clear.

Excess allylmagnesium bromide reacts with **1a** in ether at room temperature to give 2-*N'*,*N'*-diallylhydrazono-3-methyl-2,3-dihydrobenzothiazole (**6**) in 30% yield, together with an oily product, which is tentatively assigned as 2-allyl-2-(α-hydroxyallyl)-3-methyl-2,3-dihydrobenzothiazole (**7**, 27%) from spectral data. However, the mechanism of formation is obscure.



Excess cinnamylmagnesium chloride, which reacts easily with cinnamyl chloride to give a mixture of coupling products even without heating,[3] was allowed to react with **1a**, as soon as possible after the preparation. The isolated and identified products were found to be a mixture of 1,4-diphenyl- (main) and 1,6-diphenyl-1,5-hexadienes (minor) as coupling products and 3-methyl-2-*N'*-(1-phenyl-2-propenyl) hydrazono-2,3-dihydrobenzothiazole (**8**) in 8% yield. This result can be explained in terms of the equilibrium in the Grignard reagent and the apparent exchange between the OMgCl group of the addition product (**B**) and the MgCl group of Grignard reagent as shown in Scheme 3.



Scheme 3.

The main reaction of resonance-stabilized Grignard reagents such as benzyl, allyl, and cinnamylmagnesium halides with **1** occurs on the nitroso group (*path b*), accompanied by a minor reaction on the C-2 of the ring (*path a*). The results are in contrast with those reported for aryl- and *t*-butylmagnesium halides.[1] This can be explained as follows: resonance-stabilized Grignard reagents are not reactive enough to add on the C-2 and to cut off the entire conjugation between the benzothiazoline ring and the nitrosoimino group, whereas the latter type Grignard reagents are reactive enough. We should keep in mind the fact that C–C bond

formation is, in general, highly (or exclusively) favorable to C–N bond formation by Grignard reagents.[4]

Experimental

Materials. 3-Methyl (**1a**), 3-phenyl (**1b**) and 3-ethyl derivatives (**1c**) of 2-nitrosoimino-2,3-dihydrobenzothiazole were prepared by the reported methods: **1a**,[5] mp 143 °C (dec.); **1b**,[6] mp 140 °C (dec.); **1c**,[7] mp 143—144 °C (dec.). Cinnamyl chloride was prepared according to the method of Koch.[3]

In all cases, the reactions were carried out under nitrogen. MS spectra were measured at 70 eV.

Reaction of 3-Methyl-2-nitrosoimino-2,3-dihydrobenzothiazole (1a) with Benzylmagnesium Chloride in Ether at Room Temperature. To a stirred Grignard reagent prepared from magnesium (4.94 g, 0.20 mol) and benzyl chloride (12.99 g, 0.10 mol) in ether (100 ml) was added **1a** (4.83 g, 25.0 mmol) portionwise over a period of 1 hr at room temperature. Stirring was continued for 3 hr. The reaction mixture was treated with 20% aqueous solution of ammonium chloride, the resulting precipitates being filtered off and extracted with ether, benzene, and dichloromethane. The extracts and the ether layer of the filtrate were combined and washed with water and dried over anhydrous magnesium sulfate. After the solvents had been evaporated, the residue was chromatographed on silica gel. 2,2-Dibenzyl-3-methyl-2,3-dihydrobenzothiazole (**2a**, 0.63 g, 8%) was eluted with *n*-hexane–benzene (3: 2), mp 86.5—87.5 °C (from chloroform–ethanol). NMR ($CDCl_3$, 60 MHz): δ 2.90 (s, 3H, N–CH_3), 3.18 (AB q, J_{AB}=13 Hz, $\Delta\delta_{AB}$=20 Hz, 4H, 2PhCH_2), and 6.00—7.22 (m, 14H, Ar-H); MS: *m/e* (M^+, trace) and 240 (M^+-PhCH_2, 100%).

Found: C, 79.75; H, 6.44; N, 3.96%. Calcd for $C_{22}H_{21}NS$: C, 79.72; H, 6.39; N, 4.23%.

2-*N'*-Benzylidenehydrazono-3-methyl-2,3-dihydrobenzothiozole (**3a**, 3.06 g, 44%) was eluted with benzene and benzene–dichloromethane (1: 1) as pale yellow crystals, mp 162—163 °C (from benzene–ethanol).[5]

2-*N'*,*N'*-Dibenzylhydrazono-3-methyl-2,3-dihydrobenzothiazole (**4a**, 1.67 g, 19%) was eluted with benzene–dichloromethane (1: 1), mp 116.5—117.5 °C (from benzene–ethanol). IR (KBr): 1600 and 1580 cm^{-1}; NMR ($CDCl_3$): δ 3.31 (s, 3H, N–CH_3), 3.85 (s, 4H, 2PhCH_2), and 6.25—7.50 (m, 14H, Ar-H); MS: *m/e* 359 (M^+, 13%), 240 ($M^+-PhCH_2-N_2$, 50%), and 91 ($PhCH_2^+$, 100%).

Found: C, 73.61; H, 5.70; N, 11.95; S, 8.70%. Calcd for $C_{22}H_{21}N_3S$: C, 73.50; H, 5.88; N, 11.69; S, 8.92%.

Reaction of 1a with Benzylmagnesium Chloride in Ether at Room Temperature and Then with Reflux. To a stirred solution of Grignard reagent, prepared from magnesium (3.21 g, 0.13 mol) and benzyl chloride (8.60 g, 0.068 mol) in ether (80 ml), was added **1a** (3.24 g, 16.8 mmol) portionwise over a period of 1 hr at room temperature, stirring being continued for 3 hr. The reaction mixture was then refluxed for additional 3 hr. Compounds **2a**, **3a**, and **4a** were isolated in the amounts of 0.46 g (8%), 0.59 g (14%), and 1.90 g (31%), respectively.

Reaction of 2-Nitrosoimino-3-phenyl-2,3-dihydrobenzothiazole (1b) with Benzylmagnesium Chloride in Ether at Room Temperature and Then with Reflux. To a stirred Grignard solution prepared from magnesium (4.86 g, 0.20 mol) and benzyl chloride (12.71 g, 0.10 mol) in ether (100 ml) was added **1b** (5.20 g, 20.8 mmol) portionwise over a period of 0.5 hr at room temperature and stirring was continued for additional 2 hr. The reaction mixture was then refluxed for 1 hr. 2,2-Dibenzyl- (**2b**), 2-*N'*-benzylidenehydrazono- (**3b**), and 2-*N'*,*N'*-dibenzylhydrazono-3-phenyl-2,3-dihydrobenzothiazoles (**4b**) were eluted with *n*-hexane and *n*-hexane–benzene (1: 1), benzene–dichloromethane (1: 1), and benzene–dichloromethane (1: 1), respectively. All the products were recrystallized from chloroform–ethanol.

2b (0.33 g, 4%); mp 145.0—145.5 °C; NMR ($CDCl_3$): δ 3.20 (s, 4H, 2PhCH_2) and 6.25—7.50 (m, 19H, Ar-H); MS: *m/e* 393 (M^+, trace) and 302 (M^+-PhCH_2, 100%).

Found: C, 82.55; H, 5.77; N, 3.40; S, 8.18%. Calcd for $C_{27}H_{23}NS$: C, 82.40; H, 5.89; N, 3.56; S, 8.15%.

3b (0.64 g, 9%), pale yellow crystals; mp 124.5—125.0 °C; IR (KBr): 1605, 1575, and 1525 cm^{-1}; NMR ($CDCl_3$): δ 6.6—7.9 (m, 14H, Ar-H) and 8.25 (s, 1H, –N=CH–); MS: *m/e* 329 (M^+, 100%).

Found: C, 72.95; H, 4.58; N, 12.74; S, 9.73%. Calcd for $C_{20}H_{15}N_3S$: C, 72.92; H, 4.59; N, 12.76; S, 9.73%.

4b (2.18 g, 25%); mp 85.0—85.5 °C; IR (KBr): 1605, 1590, and 1575 cm^{-1}; NMR ($CDCl_3$): δ 3.81 (s, 4H, 2PhCH_2) and 6.32—7.60 (m, 19H, Ar-H); MS: *m/e* 421 (M^+, 13%), 302 (M^+-PhCH_2, 43%), and 91 ($PhCH_2^+$, 100%).

Found: C, 77.23; H, 5.78; N, 10.06; S, 7.71%. Calcd for $C_{27}H_{23}N_3S$: C, 76.93; H, 5.50; N, 9.97; S, 7.61%.

Reaction of 3-Ethyl-2-nitrosoimino-2,3-dihydrobenzothiazole (1c) with benzylmagnesium Chloride in Tetrahydrofuran (THF) at Room Temperature. To a stirred Grignard solution prepared from magnesium (4.84 g, 0.16 mol) and benzyl chloride (12.90 g, 0.10 mol) in THF (100 ml) was added **1c** (5.64 g, 27.2 mmol) portionwise over a period of 1 hr at room temperature, stirring being continued for 1.5 hr. 2,2-Dibenzyl-3-ethyl-2,3-dihydrobenzothiazole (**2c**, 0.37 g, 2%) was eluted with *n*-hexane–benzene (1: 1), mp 132—133 °C (from benzene–ethanol). NMR ($CDCl_3$): δ 1.20 (t, J=7 Hz, 3H, $C\underline{H}_3CH_2$), 3.24 (AB q, J_{AB}=14 Hz, $\Delta\delta_{AB}$=21 Hz, 4H, 2PhCH_2), 3.39 (q, J=7 Hz, 2H, $CH_3C\underline{H}_2$–N), and 5.95—7.45 (m, 14H, Ar-H); MS: *m/e* 345 (M^+, trace) and 254 (M^+-PhCH_2, 100%).

Found: C, 80.16; H, 6.69; N, 3.84; S, 9.21%. Calcd for $C_{23}H_{23}NS$: C, 79.96; H, 6.71; N, 4.05; S, 9.28%.

2-*N'*-Benzylidenehydrazono-3-ethyl-2,3-dihydrobenzothiazole (**3c**) was eluted with *n*-hexane–benzene (1: 1) and benzene as a yellow oil. The oil was rechromatographed on silica gel and eluted with *n*-hexane–benzene (2: 1 and 1: 1) and benzene to give an oil, 2.28 g (30%). The oil solidified to give yellow crystals (mp 51.0—52.2 °C (from *n*-hexane–benzene)) after being left to stand for several months. IR (KBr): 1610, 1570, and 1530 cm^{-1}; NMR ($CDCl_3$): δ 1.25 (t, J=7.5 Hz, 3H, $C\underline{H}_3CH_2$), 4.02 (q, J=7.5 Hz, 2H, $CH_3C\underline{H}_2$–N), 6.6—8.0 (m, 9H, Ar-H), and 8.39 (s, 1H, –N=CH–); MS: *m/e* 281 (M^+, 100%).

Found: C, 68.27; H, 5.09; N, 15.02%. Calcd for $C_{16}H_{15}N_3S$: C, 68.30; H, 5.37; N, 14.93%.

2-*N'*,*N'*-Dibenzylhydrazono-3-ethyl-2,3-dihydrobenzothiazole (**4c**) was eluted with benzene–dichloromethane (1: 1) as an oil. The oil was rechromatographed on silica gel and eluted with benzene and benzene–dichloromethane (1: 1) to give 1.19 g (11%) of **4c**, mp 108.5—109.0 °C (from chloroform–ethanol). IR (KBr): 1600 and 1580 cm^{-1}; NMR ($CDCl_3$): δ 1.10 (t, J=7 Hz, 3H, $C\underline{H}_3CH_2$), 3.86 (s, 4H, 2PhCH_2), 3.87 (q, J=7 Hz, 2H, $CH_3C\underline{H}_2$), and 6.57—7.58 (m, 14H, Ar-H); MS: *m/e* 373 (M^+, 12%), 254 ($M^+-PhCH_2-N_2$), and 91 ($PhCH_2^+$, 100%).

Found: C, 74.18; H, 6.18; N, 11.40; S, 8.60%. Calcd for $C_{23}H_{23}N_3S$: C, 73.96; H, 6.21; N, 11.25; S, 8.58%.

Reaction of 1a with Benzylmagnesium Chloride in THF at room Temperature in the Presence of Magnesium (II) Chloride (Reverse Addition of Grignard Reagent). A Grignard solution was prepared from magnesium (4.56 g, 0.19 mol) and benzyl chloride (11.93 g, 0.09 mol) in THF (100 ml) and transferred

to a dropping funnel through a Teflon tube fitted with glass wool in order to filter the unchanged magnesium under nitrogen. Seven-tenths of this solution, containing 66 mmol of benzylmagnesium chloride, was added dropwise to a suspension of **1a** (4.27 g, 22.1 mmol) and magnesium (II) chloride (0.25 g, 26 mmol) in THF (50 ml) over a period of 0.5 hr at room temperature with stirring, stirring being continued for 2 hr. Compounds **2a** (0.54 g, 7%), **3a** (2.53 g, 43%), and **4a** (0.22 g, 3%) were eluted with *n*-hexane–benzene (1: 1), benzene, and benzene–dichloromethane (1: 1), respectively. 2-*N'*-Benzylhydrazono-3-methyl-2,3-dihydrobenzothiazole (**5a**, 0.12 g, 2%) was also eluted with benzene–dichloromethane (1: 1), mp 143.5—144.5 °C (from chloroform–ethanol). IR (KBr): 3230 (NH), 1615 and 1580 cm^{-1}; NMR ($CDCl_3$): δ 3.07 (dd, $J_{vic}=7$ Hz, $J_{gem}=2.4$ Hz, 2H, $PhCH_2$), 3.30 (s, 3H, CH_3–N), 4.42 (t, $J_{vic}=7$ Hz, 1H, N–H), and 6.6—7.5 (m, 9H, Ar-H); MS: *m/e* 269 (M^+, 100%).

Reaction of ***1a*** *with Allylmagnesium Bromide.* To a stirred Grignard solution prepared from magnesium (11.00 g, 0.45 mol) and allyl bromide (18.43 g, 0.15 mol) in ether (150 ml) was added **1a** (4.38 g, 22.7 mmol) portionwise over a period of 1.5 hr at room temperature. Stirring was continued for 2.5 hr. 2-*N'*,*N'*-Diallylhydrazono-3-methyl-2,3-dihydrobenzothiazole (**6**) was eluted with benzene and recrystallized from *n*-hexane to give pure **6** (1.75 g, 30%), mp 50.5—51.5 °C. IR (KBr): 1610 and 1585 cm^{-1}; NMR ($CDCl_3$): δ 3.34 (d, $J_{CX}=6$ Hz, 4H, allylic-H_X), 3.38 (s, 3H, N–CH_3), 5.03 (dd, $J_{AC}=10$ Hz, $J_{AB}=2$ Hz, 2H, vinylic-H_A), 5.13 (dd, $J_{BC}=18$ Hz, $J_{AB}=2$ Hz, 2H, vinylic-H_B), 5.95 (dt, $J_{BC}=18$ Hz, $J_{AC}=10$ Hz, $J_{CX}=6$ Hz, 2H, vinylic-H_C), and 6.63—7.38 (m, 4H, Ar-H); MS: *m/e* 259 (M^+, 19%), 190 (M^+-CH_2CH-CH_2-N_2, 30%), and 41 ($CH_2=CHCH_2^+$, 100%).

Found: C, 64.79; H, 6.82; N, 16.16; S, 12.30%. Calcd for $C_{14}H_{17}N_3S$: C, 64.83; H, 6.61; N, 16.21; S, 12.36%.

Elution with dichloromethane gave crude 2-allyl-2-(α-hydroxyallyl)-3-methyl-2,3-dihydrobenzothiazole (**7**, 1.51 g, 27%) as an oil. Purification was difficult and no analytically pure sample was obtained. IR (neat): 3225 (OH), 1610, 1580, and 1470 cm^{-1}; NMR ($CDCl_3$): 2.33 (t, $J=6$ Hz, 2H, CH_2), 3.33 (s, 3H, N–Me), 3.62 (q, $J=6$ Hz, 1H, CH), 4.06 (s, 1H, OH), 4.86—5.37 (m, 4H, $2CH_2$–CH), 5.50—6.22 (m, 2H, $2CH_2=CH$), and 6.60—7.40 (m, 4H, Ar-H); MS: *m/e* 247 (M^+, 8.4%) and 218 ($M^+-HC=O$, 100%).

Reaction of ***1a*** *with Cinnamylmagnesium Chloride.* Cinnamylmagnesium chloride, prepared *in situ*, was allowed to react with **1a**. After a small amount of ethereal solution (100 ml) of cinnamyl chloride (15.10 g, 99 mmol) had been added to magnesium (7.67 g, 0.32 mol) covered with ether (15 ml) to start the reaction, **1a** (4.34 g, 22.4 mmol) was added with stirring. To this suspension, cooled with ice, was added the residual solution dropwise over a period of 8 hr. Stirring was continued for 0.5 hr after the addition. The reaction mixture was chromatographed on silica gel after usual work-up. A mixture (4.09 g, 21 mmol) of 1,4-diphenyl- (main) and 1,6-diphenyl-1,5-hexadienes (minor) was eluted with *n*-hexane and distilled to give an analytically pure sample, bp 160—162 °C/4 mmHg (lit,[3] 115 °C/0.005 mmHg).

Found: C, 92.46; H, 7.92%. Calcd for $C_{18}H_{18}$: C, 92.46; H, 7.84%.

3-Methyl-2-*N'*-(1-phenyl-2-propenyl) hydrazono-2,3-dihydrobenzothiazole (**8**), the only one identified product in this reaction, was eluted with dichloromethane–ether (1: 1) and ether, contaminated with a deep red oil, and recrystallized from ethanol to give 0.51 g (8%) of a pure sample, mp 103.5 °C. IR (KBr): 3225 (NH), 1620 and 1580 cm^{-1}: NMR ($CDCl_3$): δ 3.34 (s, 3H, CH_3–N), 4.2 (broad s, 1H, N–H), 4.9 (d, $J_{CX}=7$ Hz, 1H, allylic-H_X), 5.17 (dd, $J_{AC}=10$ Hz, $J_{AB}=2$ Hz, 1H, vinylic-H_A), 5.25 (dd, $J_{BC}=17$ Hz, $J_{AB}=2$ Hz, 1H, vinylic-H_B), 6.12 (sep, $J_{BC}=17$ Hz, $J_{AC}=10$ Hz, $J_{CX}=7$ Hz, 1H, vinylic-H_C), and 6.69—7.62 (m, 9H, Ar-H); MS: *m/e* 295 (M^+, 10%) and 178 ($M^+-CH_2CHCHPh$, 100%).

Found: C, 69.27; H, 5.67; N, 13.98; S, 10.87%. Calcd for $C_{17}H_{11}N_3S$: C, 69.12; H, 5.80; N, 14.22; S, 10.85%.

(Received May 20, 1975)

3-Substituted 2-nitrosoimino-2,3-dihydrobenzothiazole (**1**) reacts with primary or secondary alkyl Grignard reagents to afford bis[*o*-(*N*-substituted amino)phenyl] disulfide, 3-substituted 2-*N'*-alkyl- and 2-*N'*,*N'*-dialkylhydrazono-2,3-dihydrobenzothiazoles as major products. In the reactions with secondary alkyl Grignard reagents, 3-substituted 2-*N'*-alkylidenehydrazono-2,3-dihydrobenzothiazole was also produced. The general feature of the reaction of **1** with Grignard reagents has been summarized and is discussed.

In a previous paper,[2] it was reported that reactions of 3-substituted 2-nitrosoimino-2,3-dihydrobenzothiazole (**1**) with arylmagnesium or *t*-butylmagnesium halides give the corresponding 2,2-di- or 2-monosubstituted benzothiazolines in good yields (*path a*). Such Grignard reagents attack the nitrogen atom of the nitroso group of **1** to give 2-(*N'*-substituted hydrazono) derivatives (*path b*).

The reaction of **1** with benzylmagnesium chloride afforded 2,2-dibenzylbenzothiazolines as minor products (*path a*) and azines and 2-(*N'*,*N'*-dibenzylhydrazono) derivatives (*path b*) as major products.[1]

This paper describes the reactions of **1** with alkyl Grignard reagents in detail[3] and gives a summary of the general aspect of the reaction of **1** with Grignard reagents.

2-Nitrosoimino-3-phenyl-2,3-dihydrobenzothiazole (**1b**) reacts with excess *n*-butylmagnesium bromide in ether at 0 °C under nitrogen to afford 2,2-di-*n*-butyl- (**2b**, 6%), 2-*N'*,*N'*-di-*n*-butylhydrazono-3-phenyl-2,3-dihydrobenzothiazoles (**3b**, 26%), and bis(*o*-anilinophenyl) disulfide (**4b**, 23%).

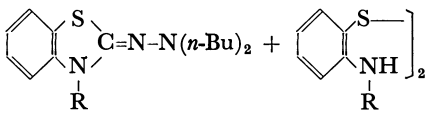
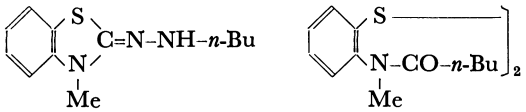
a, R=Me
b, R=Ph



3 **4**

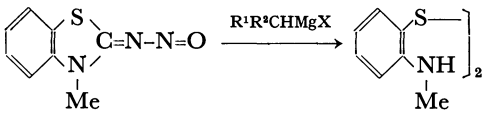
A similar reaction of **1a** with *n*-butylmagnesium bromide was found to give 2-*N'*-*n*-butylhydrazono-3-methyl-2,3-dihydrobenzothiazole (**5c**, 20%) and bis[*o*-(*N*-methyl-*N*-valeroylamino)phenyl] disulfide (**6**, 11%) together with **2a** (7%), **3a** (15%), and **4a** (12%).



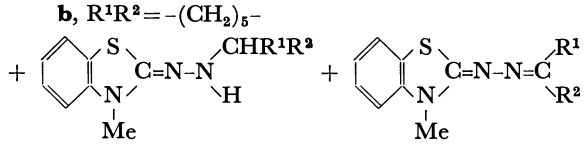
5c **6**

Reaction of **1a** with *sec*-butylmagnesium bromide gives **4a** (13%), 2-*N'*-*sec*-butylhydrazono- (**5a**, 18%), and 2-*N'*-*sec*-butylidenehydrazono-3-methyl-2,3-dihydrobenzothiazoles (**7a**, 22%).

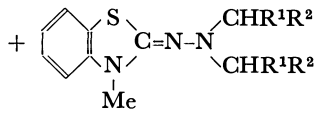
Reaction of **1a** with cyclohexylmagnesium chloride gives **4a** (8%), **5b** (20%), **7b** (14%), and 2-*N'*,*N'*-dicyclohexylhydrazono-2,3-dihydrobenzothiazole (**8b**, 6%). The reaction scheme is shown below.



1a **a**, R^1=Me, R^2=Et **4a**
b, R^1R^2=$-(CH_2)_5-$

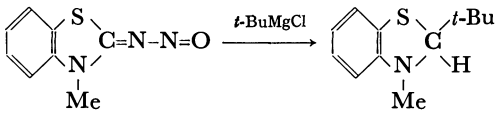


5 **7**

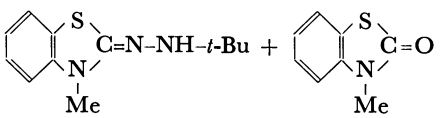


8

Reaction of **1a** with *t*-butylmagnesium chloride affords 2-*t*-butyl (**9**, 39%), 2-*N'*-*t*-butylhydrazono-3-methyl-2,3-dihydrobenzothiazoles (**10**, 8%), and 3-methyl-2,3-dihydrobenzothiazol-2-one (**11**, 13%).



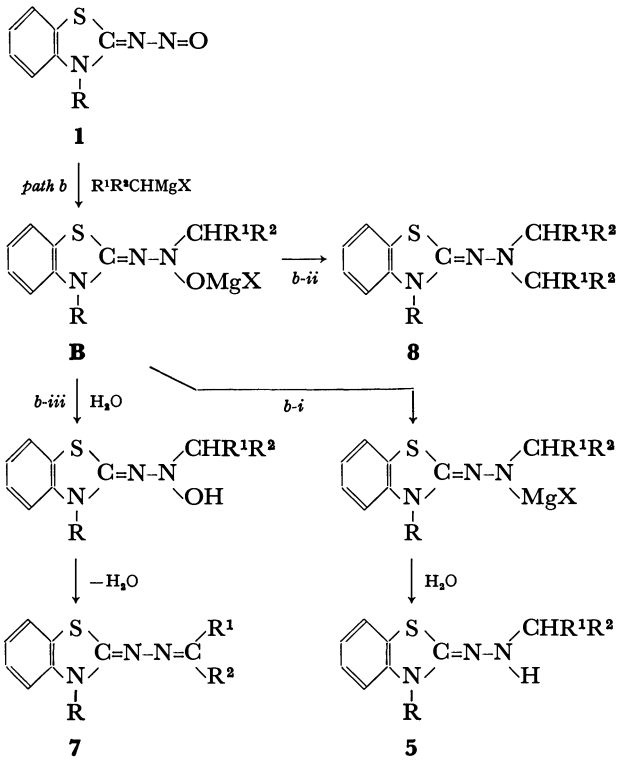
1a **9**



10 **11**

2,2-Disubstituted and 2-(*N'*-substituted hydrazono) derivatives are formed *via* the corresponding 1,4- (**A**) and 1,2-addition intermediates (**B**), respectively.[2]

2-*N'*-Alkylidenehydrazono derivatives in the case of secondary alkylmagnesium halides are produced by dehydration through the intermediate (**B**) because of the thermodynamic stability of the product. 2-*N'*,*N'*-Dialkylhydrazono derivatives can be formed through the intermediate (**B**) by direct attack with the second Grignard reagent (*path b-ii*) as was evidenced in the reactions with benzylmagnesium chloride in refluxing ether.[1]



Scheme 1.

The formation of disulfide (**4**) can be explained as follows. The direct attack of a Grignard reagent on the C-2 position of **1** gives the diazonium intermediate (**A**) (*path a-i*) and the corresponding ring-opened nitrosoimine (**C**) followed by loss of nitrogen to give the corresponding amide (**D**) (*path a-ii*). The magnesium salt (**D**) then reacts with the Grignard reagent to afford the corresponding *S,N*-dimagnesium salt, which, by hydrolysis followed by oxidation, gives disulfide (**4**).

The presence of the amide (**D**) was confirmed by the isolation of **6** in the case of the reaction of **1a** with *n*-butylmagnesium bromide. Nitrogen loss from the ring-opened nitrosoimine (**C**) should proceed rapidly, as seen from the decomposition of *N*-nitrosoketimines[4] and 1,1,3,3-tetrasubstituted 2-nitrosoguanidines.[5]

The yields of reaction products of **1a** with Grignard reagents are summarized in Table 1. The yields were estimated from the amount of isolated products by column chromatography followed by recrystallization, and not optimized. The apparent yield should thus be lower than that in the reaction mixture, cases where products did not crystallize easily being affected. This was especially the case for e) in Table 1. However, it sufficiently shows the general nature of the reaction.

Table 1. Yields[a] of reaction products of **1a** with RMgX

R	Reaction path[b]				Reaction path[c]			
	X	*a-i*	*a-ii*	*a*	*b-i*	*b-ii*	*b-iii*	*b*
a) $PhCH_2$	Cl	8	—	8	—	19	44	63
b) $Me(CH_2)_3$	Br	7	23	30	20	15	—	35
c) MeEtCH	Br	—	13	13	18	—	22	40
d) *cyclo*-C_6H_{11}	Cl	—	8	8	20	6	14	40
e) Me_3C	Cl	39	—	39	8	—	—	8
f) *p*-MeC_6H_4	Br	66	—	66	17	—	—	17
g) 2,4,6-$Me_3C_6H_2$	Br	46	—	46	18	—	—	18

a) Numerical values show the yield (mol %) of products based on **1a**. b) *a*, *a-i*, and *a-ii* correspond to the reaction paths shown in Scheme 2. c) *b*, *b-i*, *b-ii*, and *b-iii* correspond to the reaction paths shown in Scheme 1.

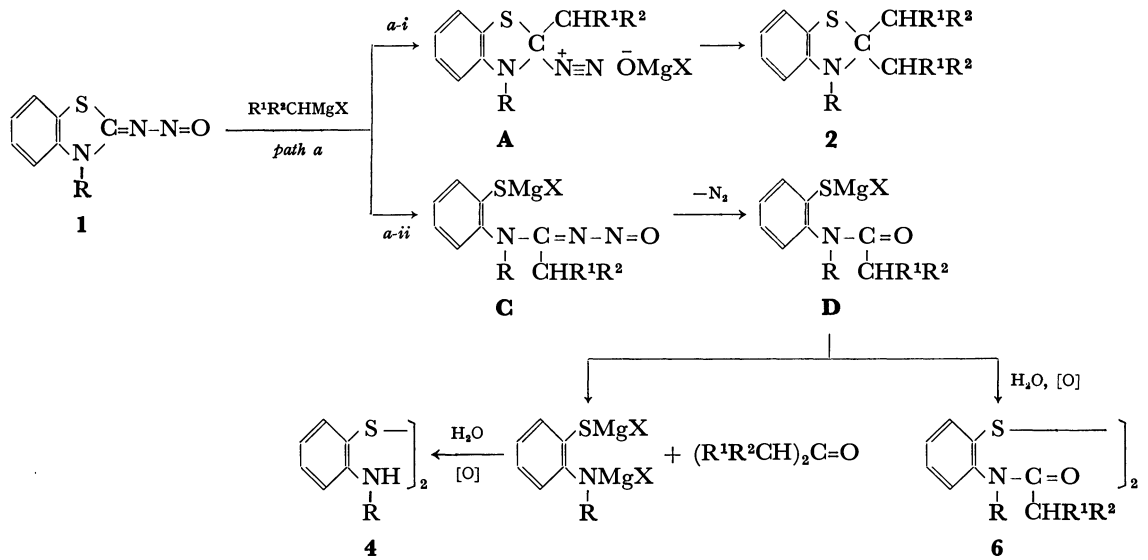
It is apparent from Table 1 that Grignard reagents can be classified into two groups:

group α (more reactive), consisting of aryl and *t*-butyl groups (e—g).

group β (less reactive), consisting of primary and secondary alkyl groups (a—d).

General features of the reaction are summarized and rationalized as follows:

1) The main path of group α is *path a* and that of group β *path b* (see Schemes 1 and 2). This is consistent with the nature of the ground state of **1**[6] and the



Scheme 2.

expected relative reactivity of Grignard reagents, since *path a* should be of a higher energy process than *path b*, the entire conjugation between the benzothiazoline ring and the nitrosoimino group being cut off in the former but conjugation between the ring and the imino group is retained in the latter. Here we must keep in mind that Grignard reagents add almost exclusively on the carbon of Schiff's base but not on the nitrogen.[7]

2) For *path a*, group α reacts exclusively through *path a-i*, whereas *path a-ii* is preferred by group β except benzylmagnesium chloride. This can be realized mainly by the electronic effect of the substituent (R), where R can stabilize positive charge on the C-2 more effectively, *path a-i* becomes predominant. It is noteworthy to mention that *path a-i* was not observed with secondary Grignard reagents, probably because of the balance between electronic and steric effects.

3) For *path b*, group α reacts exclusively through *path b-i*, whereas *paths b-i*, *b-ii*, and *b-iii* are competitive for group β. When the intermediate **B** is stabilized thermodynamically by dehydration, *path b-iii* is preferred as a typical one for benzylmagnesium chloride. *Path b-ii*, alkylation of Grignard type reagent of hydroxylamine by Grignard reagent, has not been observed so far. However, this was substantiated with benzylmagnesium chloride by refluxing the solvent.[1] The reason is not clear why group α does not follow *path b-ii* at all. However, it is understandable if we consider the nature of R-N-OMgX bond in the intermediate **B** (Ar-N-OMgX and *t*-Bu-N-OMgX compared with Alkyl-N-OMgX).

Experimental

Materials. 3-Methyl- (**1a**, mp 143 °C (dec.))[8] and 3-phenyl-2-nitrosoimino-2,3-dihydrobenzothiazoles (**1b**, mp 140 °C (dec.))[9] were prepared by the reported methods. All the reactions were carried out under nitrogen.

Reaction of 3-Methyl-2-nitrosoimino-2,3-dihydrobenzothiazole (1a) with n-*Butylmagnesium Bromide.* **1a** (4.78 g, 24.7 mmol) was added portionwise over a period of 0.5 hr at room temperature to a stirred Grignard solution prepared from magnesium turnings (2.76 g, 0.11 mol) and *n*-butyl bromide (13.82 g, 0.10 mol) in ether (100 ml). Stirring was continued for 3 hr. The reaction mixture was treated with saturated aqueous ammonium chloride and the resulting precipitates were filtered off. The precipitates were extracted with ether (100 ml×2) and benzene (100 ml). The extracts and ether layer of the filtrate were combined and dried over anhydrous magnesium sulfate. The solvent was evaporated *in vacuo* and the residue was chromatographed on silica gel. 2,2-Di-*n*-butyl-3-methyl-2,3-dihydrobenzothiazole (**2a**, 0.49 g, 7%) was eluted with *n*-hexane as an oil. The structure of **2a** was confirmed by the following spectral data: NMR ($CDCl_3$): δ 0.53—2.13 (m, 18H, $2CH_3CH_2CH_2CH_2$), 2.67 (s, 3H, N–CH_3), and 5.95—7.16 (m, 4H, Ar-H); Mass: *m/e* 263 (M^+, 7%) and 206 (M^+-n-Bu, 100%).

Bis(*o*-methylaminophenyl) disulfide (**4a**, 0.39 g, 12%) was eluted with *n*-hexane–benzene (1: 1) and recrystallized from chloroform–ethanol, mp 66.5—67.0 °C (lit,[10] 64—68 °C. Disulfide **4a** (0.13 g) was refluxed in acetic anhydride (8 ml) for 1 hr to give diacetylated compound (0.15 g, 87%), mp 173.0—173.8 °C (from chloroform–ethanol). IR (KBr): 1670 cm^{-1} (CO); NMR ($CDCl_3$): δ 1.85 (s, 6H, $2CH_3CO$), 3.26 (s, 6H, 2N–CH_3), and 7.05—7.72 (m, 8H, 2Ar–H); Mass: *m/e* 360 (M^+, 1.8%), 180 ($M^+/2$, 28%), and 148 ($M^+/2-S$, 100%).

Found: C, 59.76; H, 5.69; N, 7.60; S, 17.77%. Calcd for $C_{16}H_{20}N_2O_2S_2$: C, 59.97; H, 5.59; N, 7.77; S, 17.79%.

2-*N'*,*N'*-Di-*n*-butylhydrazono-3-methyl-2,3-dihydrobenzothiazole (**3a**, 1.44 g, 20%) was eluted as an oil and the structure was confirmed by the following results: IR (KBr): 1620 and 1580 cm^{-1}; NMR ($CDCl_3$): δ 0.66—1.92 (m, 14H, $2CH_3CH_2CH_2$), 2.15—2.80 (m, 4H, 2N–CH_2–*n*-Pr), 3.48 (s, 3H, N–CH_3), and 6.75—7.47 (m, 4H, Ar–H). 2-*N'*-*n*-Butylhydrazono-3-methyl-2,3-dihydrobenzothiazole (**5c**, 0.88 g, 15%) was eluted with dichloromethane, mp 66.0—66.5 °C (from chloroform–methanol). IR (KBr): 3200 (NH), 1620, and 1580 cm^{-1}; NMR ($CDCl_3$): δ 0.71—1.75 (m, 7H, $CH_3CH_2CH_2$), 3.03 (t, J=7.0 Hz, 2H, *n*-$PrCH_2$–N), 3.41 (s, 3H, N–CH_3), 4.02 (broad s, 1H, N–H, disappeared by addition of D_2O), and 6.73—7.45 (m, 4H, Ar–H); Mass: *m/e* 235 (M^+, 100%).

Found: C, 61.43; H, 7.44; N, 18.04%. Calcd for $C_{12}H_{17}N_3S$: C, 61.24; H, 7.28; N, 17.85%.

Bis[*o*-(*N*-methyl-*N*-valeroylamino)phenyl] disulfide (**6**, 0.65 g, 11%) was eluted with dichloromethane, mp 87.5—88.5 °C. The structure was confirmed by the following spectral data; IR (KBr): 1665 cm^{-1} (CO); NMR ($CDCl_3$); δ 0.58—2.20 (m, 18H, $2CH_3CH_2CH_2CH_2$), 3.23 (s, 6H, 2N–CH_3), and 7.0—7.7 (m, 8H, Ar-H); Mass: *m/e* 444 (M^+, trace) and 139 ($M^+/2$+H–*n*-PrCHCO, 100%).

Reaction of 2-Nitrosoimino-3-phenyl-2,3-dihydrobenzothiazole (1b) with n-*Butylmagnesium Bromide.* To a stirred Grignard solution prepared from magnesium (3.60 g, 0.15 mol) and *n*-butyl bromide (20.55 g, 0.15 mol) in ether (100 ml) was added **1b** (7.61 g, 29.8 mmol) portionwise at 0 °C, and the mixture was stirred for 1 hr. After the usual work-up, the reaction mixture was chromatographed on silica gel. Elution with benzene gave crude 2,2-di-*n*-butyl-3-phenyl-2,3-dihydrobenzothiazole (**2b**), which was purified by preparative thin layer chromatography with benzene–*n*-hexane (1: 3) to give pure **2b** (0.60 g, 6%) as colorless oil; NMR ($CDCl_3$): δ 0.90 (t, 6H, 2Me), 1.30—1.85 (m, 12H, $2(CH_2)_3$), and 6.75—7.40 (m, 9H, Ar–H). Elution with benzene gave tarry material (1.39 g, 23%). The IR spectrum was in agreement with that of bis(*o*-anilinophenyl) disulfide (**4b**).[11] Elution with dichloromethane–chloroform (2: 1—1: 5) and chloroform afforded red brown tarry material (3.34 g). The compound was purified twice by preparative thin layer chromatography with dichloromethane to give colorless viscous material (**3b**), which partly solidified on being left to stand for 2 weeks. **3b** (2.75 g, 26%); mp 40.0—41.5 °C; IR (KBr): 1610 (C=N) and 1580 cm^{-1}; NMR ($CDCl_3$): δ 0.85 (t, 6H, 2Me), 1.35 (m, 8H, $2(CH_2)_2$), 2.55 (t, 4H, $2CH_2$–N), and 6.7—7.4 (m, 9H, Ar–H); Mass: *m/e* 353 (M^+, 40%) and 310 ($M^+-C_3H_7$, 100%).

Reaction of 1a with sec-*Butylmagnesium Bromide.* **1a** (4.60 g, 23.8 mmol) was added portionwise over a period of 0.5 hr at room temperature to a stirred solution of Grignard reagent prepared from magnesium (2.77 g, 0.11 mol) and *sec*-butyl bromide (13.78 g, 0.10 mol) in ether (100 ml). Stirring was continued for 2 hr. The resulting reaction mixture was chromatographed on silica gel after the usual work-up. Bis(*o*-methylaminophenyl) disulfide (**4a**, 0.42 g, 13%) was eluted with *n*-hexane–benzene (1: 1) and the structure was confirmed by comparing its physical properties with those of an authentic sample.[2] 2-*N'*-*sec*-Butylidenehydrazono-3-methyl-2,3-dihydrobenzothiazole (**7a**, 1.47 g, 22%) was eluted with benzene, benzene–dichloromethane (3: 1 and 1: 1) and dichloromethane, mp 81.5—82.5 °C (from chloroform–ethanol). IR (KBr): 1635 and 1580 cm^{-1}; NMR ($CDCl_3$): δ 1.15 (t, J=7 Hz, 3H, =Ċ–$CH_2C\underline{H}_3$), 2.04 (s, 3H, =Ċ–CH_3), 2.34 (q, J=7 Hz, 2H, =Ċ–$C\underline{H}_2CH_3$), 3.44 (s, 3H, N–CH_3), and 6.65—7.39 (m, 4H, Ar-H); Mass: *m/e* 233 (M^+, 100%).

Found: C, 62.01; H, 6.53; N, 17.77; S, 13.72%. Calcd for $C_{12}H_{15}N_3S$: C, 61.77; H, 6.48; N, 18.01; S, 13.74%.

2-*N'*-*sec*-Butylhydrazono-3-methyl-2,3-dihydrobenzothiazole (**5a**, 1.05 g, 18%) was eluted with dichloromethane as an oil. The structure was confirmed by the following spectral data: IR (neat): 3200 cm^{-1} (NH); NMR ($CDCl_3$): δ 1.05 (t, J=7 Hz, 3H, $C\underline{H}_3$-CH_2), 1.10 (d, J=7 Hz, 3H, $C\underline{H}_3$-CHEt), 3.45 (s, 3H, N-CH_3), 3.82 (broad s, 1H, N-H), and 6.78—7.60 (m, 4H, Ar-H). Two multiplets, assignable to a methine proton and two methylene protons, overlapped each other.

Reaction of ***1a*** *with Cyclohexylmagnesium Chloride.* **1a** (4.47 g, 23.1 mmol) was added portionwise over a period of 0.5 hr at room temperature to a stirred solution of Grignard reagent prepared from magnesium (2.75 g, 0.11 mol) and cyclohexyl chloride (11.78 g, 99 mmol) in ether (100 ml). Stirring was continued for 4 hr. The reaction mixture was chromatographed after the usual work-up. 2-*N'*,*N'*-Dicyclohexylhydrazono-3-methyl-2,3-dihydrobenzothiazole (**8b**, 0.49 g, 6%) was eluted with *n*-hexane–benzene (1: 1), mp 121—122 °C (from ethanol). IR (KBr): 1615 and 1590 cm^{-1}; NMR ($CDCl_3$): δ 0.87—2.15 (m, 20H, $10CH_2$), 2.85 (broad s, 2H, 2CH), 3.47 (s, 3H, N-CH_3), and 6.67—7.36 (m, 4H, Ar-H); Mass: *m/e* 343 (M^+, 42%) and 150 ($M^+ - C_6H_{11}$-$C_6H_{10}N_2$, 100%).

Found: C, 70.11; H, 8.73; N, 12.24; S, 9.42%. Calcd for $C_{20}H_{29}N_3S$: C, 69.93; H, 8.51; N, 12.23; S, 9.33%.

Bis(*o*-methylaminophenyl) disulfide (**4a**, 0.27 g, 8%) was eluted with *n*-hexane–benzene (1: 1), mp 66.5—67.0 °C (from chloroform–ethanol) (lit,[10] 64—68 °C). 2-*N'*-Cyclohexylidenehydrazono-3-methyl-2,3-dihydrobenzothiazole (**7b**, 0.89 g, 14%) was eluted with benzene–dichloromethane (1: 3) as yellow crystals, mp 114.5 °C (from benzene–chloroform). IR (KBr): 1620, 1580, and 1575 cm^{-1}; NMR ($CDCl_3$): δ 1.4—2.9 (m, 10H, $5CH_2$), 3.50 (s, 3H, N-CH_3), and 6.74—7.46 (m, 4H, Ar-H); Mass: *m/e* 259 (M^+, 59%) and 121 ($C_7H_9N^+$, 100%).

Found: C, 65.02; H, 6.86; N, 16.32; S, 12.50%. Calcd for $C_{14}H_{17}N_3S$: C, 64.83; H, 6.61; N, 16.20; S, 12.36%.

2-*N'*-Cyclohexylhydrazono-3-methyl-2,3-dihydrobenzothiazole (**5b**, 1.21 g, 20%) was eluted with benzene–dichloromethane (1: 1) as pale yellow crystals, mp 112.5—114.0 °C (from chloroform–ethanol). IR (KBr): 3175 (NH), 1618, 1600, and 1580 cm^{-1}; NMR ($CDCl_3$): δ 0.85—2.18 (m, 10H, $5CH_2$), 2.95 (broad s, 1H, >CH), 3.41 (s, 3H, N-CH_3), 3.50 (broad s, 1H, N-H), and 6.65—7.44 (m, 4H, Ar-H). The singlet at δ 3.50 disappeared by addition of D_2O, a new singlet due to HDO appearing at δ 4.61. Mass: *m/e* 261 (M^+, 100%).

Found: C, 64.29; H, 7.23; N, 16.29; S, 12.37%. Calcd for $C_{14}H_{19}N_3S$: C, 64.33; H, 7.33; N, 16.08; S, 12.27%.

Chemistry of Nitrosoimines. XIII.[1] Reactions of 3-Substituted 2-Nitrosoimino-2,3-dihydrobenzothiazoles with Organolithiums

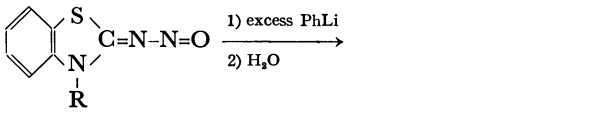
Motoyuki HISAOKA, Kin-ya AKIBA, and Naoki INAMOTO
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113
(Received May 20, 1975)

Reactions of 3-substituted 2-nitrosoimino-2,3-dihydrobenzothiazoles (**1**) with phenyl- and *n*-butyllithiums give the corresponding (*N*-substituted *o*-amino)phenyl sulfides as the major product due to direct attack on the sulfur atom of the benzothiazoline ring, while that with benzyllithium gives 2,2-dibenzyl derivatives and bis[*o*-(*N*-substituted amino)phenyl] disulfides. The difference between the reactions of **1** with Grignard reagents and those with organolithiums has been explained by the difference of the coordination site, thiophilicity and the ionic character of the reagents.

The reactions of 3-substituted 2-nitrosoimino-2,3-dihydrobenzothiazoles (**1**) with Grignard reagents give different types of main products depending on the structure of Grignard reagents.[1-3]

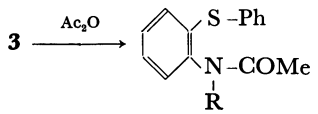
In this paper, the reaction of **1** with organolithiums,[4] which differ from those with Grignard reagents in their main reaction paths, are described in detail. The reason for the apparent difference in reactivity is also discussed.

3-Substituted 2-nitrosoimino-2,3-dihydrobenzothiazoles (**1**) were allowed to react with excess phenyllithium (about five molar equivalents) in ether for 1 hr at 0 °C under nitrogen. 3-Substituted 2,2-diphenyl-2,3-dihydrobenzothiazole (**2**), the main product in the corresponding Grignard reaction,[2] was obtained only in a very low yield. The major product was phenyl *N*-substituted *o*-aminophenyl sulfide (**3**) and benzophenone. Refluxing of **3** in acetic anhydride gave the corresponding acetylated derivative (**4**) in a high yield.



1 **2** **3**

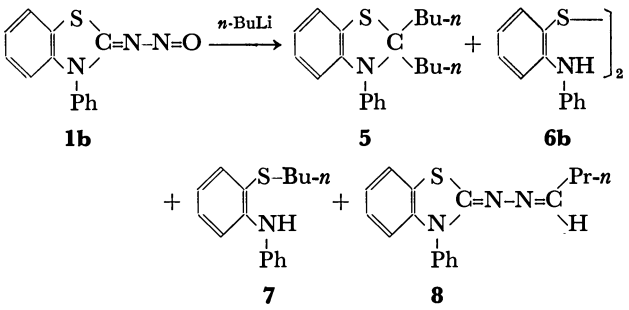
	R	2	3	Ph_2CO
a)	Me	trace	36%	52%
b)	Ph	trace	38%	58%



4

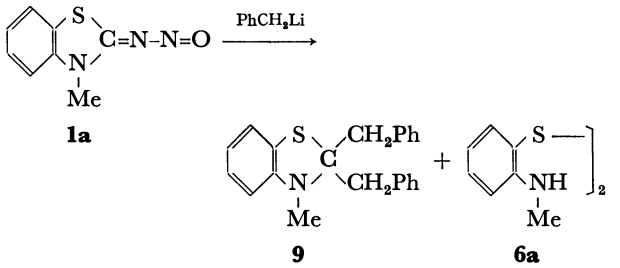
When excess *n*-butyllithium was added to a suspension of **1b** in ether under nitrogen at 0 °C, 2,2-di-*n*-butyl-3-phenyl-2,3-dihydrobenzothiazole (**5**, 10%), bis(*o*-anilinophenyl) disulfide (**6b**, 3%), *o*-anilinophenyl *n*-butyl sulfide (**7**, 43%), and 2-*N'*-*n*-butylidenehydrazono-3-phenyl-2,3-dihydrobenzothiazole (**8**, 10%) were obtained.

Attack on the C-2 position of the benzothiazoline ring became the main path, when **1a** and benzyllithium were allowed to react in tetrahydrofuran (THF) under almost the same conditions, giving **9** and **6a** in 16 and 38% yields, respectively.



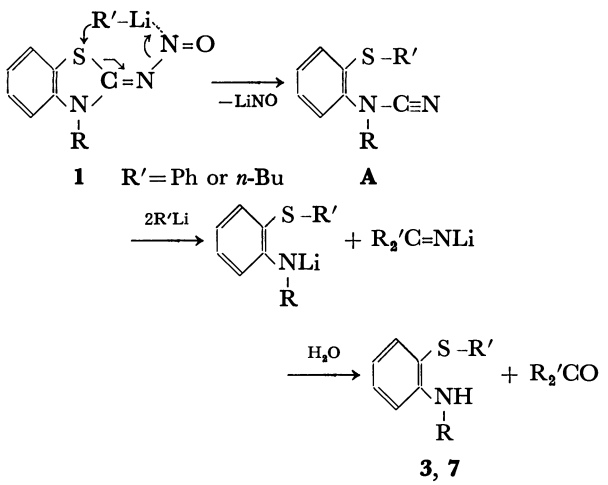
1b **5** **6b**

7 **8**



1a **9** **6a**

Mechanism of Formation. The formation of products other than **3** and **7** can be explained by a mechanism analogous to that for the reactions with Grignard reagents.[1-3] The path of formation of **3** and **7** is explained as shown in Scheme 1.



1 R'=Ph or *n*-Bu **A**

3, 7

Scheme 1.

Phenyl- and *n*-butyllithium directly attack the sulfur atom of the benzothiazoline ring *via* lithium–nitrogen coordination and cleavage of the carbon–sulfur linkage followed by loss of NO^- anion to give the corresponding phenyl and *n*-butyl *N*-substituted *o*-cyanaminophenyl sulfides (**A**) as a primary product. **A** reacts further with excess organolithium to produce **3** or **7** and benzophenone after hydrolysis.

The cyano group in **A** behaves as a pseudo-halogen, undergoing nucleophilic displacement or metal-cyanide exchange. In fact, the cyano group is transferred from *N,N*-diphenylcyanamide to phenylmagnesium bromide[5] and from *N*-methyl-*N*-phenylcyanamide to phenyllithium.[6] These results support the second step of Scheme 1.

The formation of **6** is ascribable to the intermediacy of ring-opened nitrosoimine (**C**) (Scheme 2), which is similar to that of Grignard reagent.[1]

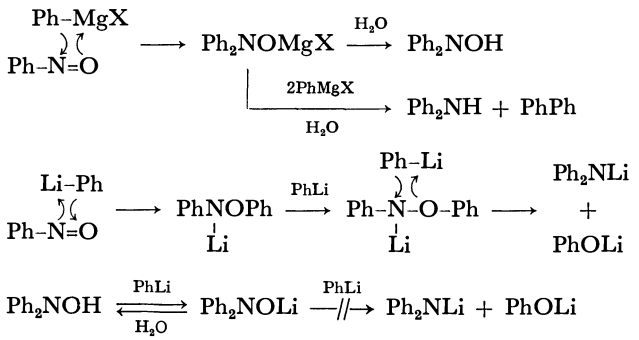
Path a-iii is assumed to be another route for **6**, due to the large ionic character of the –O–Li bond in contrast to the –O–MgX bond. The same kind of difference was observed in the reaction of **1** with lithium and Grignard reagents of the corresponding 2-iminobenzothiazolines.[7]

Direct attack on the sulfur atom of the benzothiazoline ring, which was the main path in the case of phenyl- and *n*-butyl–lithium, was observed neither in the case of benzyllithium nor in the reactions with Grignard reagents.

Discussion on the Difference between the Reactions with Grignard Reagents and Those with Organolithiums. Based on the results of the spectral study on **1**,[8] the reactions of **1** with nucleophiles are expected to take place on three possible reaction centers, *i.e.*, the C-2 position of the benzothiazoline ring (*a*), the nitrogen atom of the nitroso group (*b*) and the sulfur atom of the ring (*c*).

The difference between the reactions of **1** with Grignard reagents and those with organolithiums can primarily be attributed to the difference in the coordination position of organomagnesium and organolithium compounds to the nitrosoimino group of **1**.

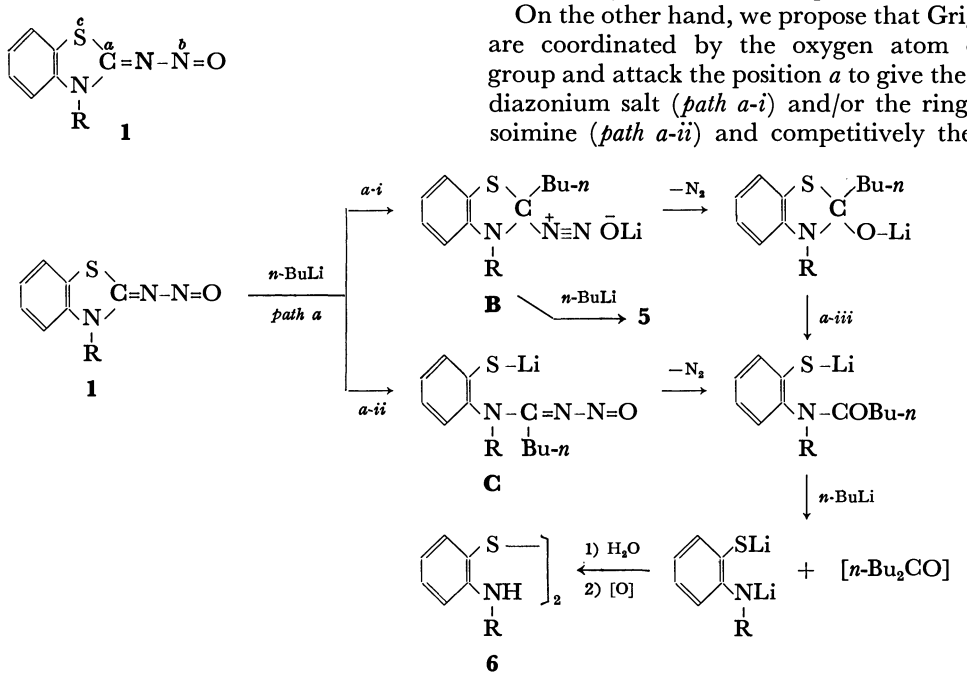
This postulate is supported by the reactions of nitrosobenzene with Grignard reagents[9–12] and phenyllithium.[13] The reaction with an equimolar amount of phenylmagnesium bromide has been shown to give the corresponding hydroxylamine,[9,11,12] which reacts successively with excess Grignard reagent to give diphenylamine and biphenyl.[11] On the other hand, nitrosobenzene reacts with excess phenyllithium to give diphenylamine and phenol, but the reaction of *N,N*-diphenylhydroxylamine with excess phenyllithium does not produce diphenylamine and phenol, recovering the hydroxylamine.[13]



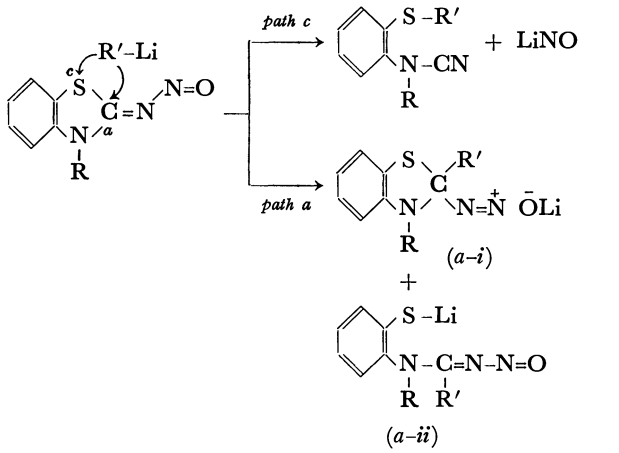
It was proposed from the results that the reaction of nitrosobenzene with phenyllithium initially gives not *O*-lithio compound but *N*-lithio compound, which is then attacked by another phenyllithium to give diphenylamine and phenol.[13]

Let us propose that organolithiums are coordinated by the nitrogen atom of the nitroso group and attack the sulfur atom of the benzothiazoline ring (*path c*) and competitively the C-2 position of the ring (*path a*). *Path c* may be a process of higher energy than *path a*, since benzyllithium follows *path a* exclusively.

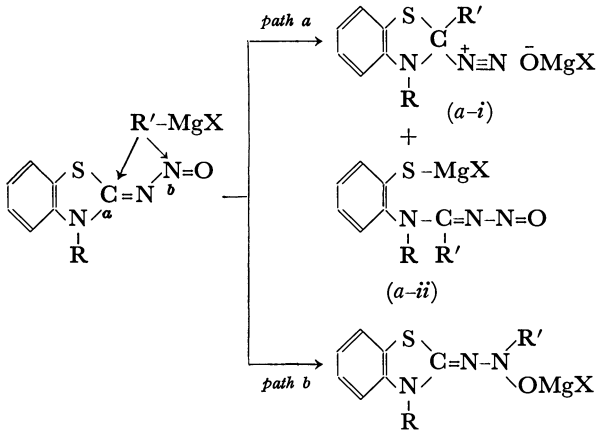
On the other hand, we propose that Grignard reagents are coordinated by the oxygen atom of the nitroso group and attack the position *a* to give the corresponding diazonium salt (*path a-i*) and/or the ring-opened nitrosoimine (*path a-ii*) and competitively the position *b* to



Scheme 2.



produce the magnesium salt of the corresponding hydrazono derivative (*path b*). Contribution of these paths to the reaction depends on the nature of Grignard reagents.[1]



It should be kept in mind that addition of Grignard reagents and organolithiums occurs exclusively on the carbon atom of Schiff's base[14] and that organolithiums are usually more reactive than Grignard reagents as shown by the addition of methyllithium to *N*-benzylidene-*t*-butylamine which is inert to methylmagnesium bromide.[15]

There may be another factor contributing to the difference in reactivity of Grignard reagents and organolithiums, *viz.*, thiophilicity.

Organometallics have been shown to attack the sulfur of thioketones[16] and thioketenes,[17] generating the corresponding carbanions. There is no definite comparison of thiophilicity of organolithiums and Grignard reagents. However, the fact that the yield of benzhydryl phenyl sulfide was 70% (isolated yield) and 37% (glc yield), respectively, when thiobenzophenone reacted with phenyllithium and phenylmagnesium bromide[17] shows greater thiophilicity of phenyllithium than that of phenylmagnesium bromide.

Thus, the difference in reactivity between organolithiums and Grignard reagents can be ascribed to three factors, *i.e.*, i) coordination site, ii) thiophilicity, and iii) ionic character of both reagents.[18]

Experimental

Materials. Benzyl methyl ether was prepared from benzyl chloride, methanol, and sodium hydroxide,[19] bp 48—49 °C/10 mmHg (lit,[19] 170.5 °C). Commercial *n*-butyllithium in *n*-hexane was used. Phenyllithium was prepared from lithium and bromobenzene in ether under nitrogen by the method of Jones and Gilman.[20] Excess lithium was filtered off before use. Benzyllithium was prepared from benzyl methyl ether and lithium in THF at −27——5 °C according to the method of Gilman and McNinch.[21] Excess lithium was filtered off before use. 3-Methyl- (**1a**, mp 143 °C (dec.))[22] and 3-phenyl-2-nitrosoimino-2,3-dihydrobenzothiazoles (**1b**, mp 140 °C (dec.))[23] were prepared by the reported methods.

All the reactions were carried out under nitrogen.

Reaction of 2-Nitrosoimino-3-phenyl-2,3-dihydrobenzothiazole (1b) with Phenyllithium. **1b** (4.91 g, 19.2 mmol) was added portionwise over a period of 0.5 hr at 0 °C to a stirred solution of phenyllithium prepared from lithium (1.71 g, 0.25 mol) and bromobenzene (15.87 g, 0.10 mol) in ether (100 ml). Stirring was continued for further 0.5 hr after the addition. The reaction mixture was treated with 100 ml of 17% aqueous ammonium chloride, and extracted with ether. The extracts were washed with water and dried over anhydrous magnesium sulfate. After evaporation of ether, the residue was chromatographed on silica gel. A trace amount of 2,2,3-triphenyl-2,3-dihydrobenzothiazole (**2b**) was eluted with *n*-hexane, mp 191.5—192.5 °C (from benzene–ethanol) (lit,[2] 191.5—192.5 °C). *o*-Anilinophenyl phenyl sulfide (**3b**) was eluted with *n*-hexane–benzene (1 : 1) and recrystallized from benzene–ethanol as pale yellow crystals, yield 1.83 g, (38%), mp 93.0—94.5 °C. IR (KBr): 3350 (NH) and 1585 cm^{-1}; NMR ($CDCl_3$): δ 6.35—7.65 (m, ArH). A signal due to N–H proton was obscure. Mass: *m/e* 277 (M^+, 100).

Found: C, 78.15; H, 5.22; N, 5.12; S, 11.53%. Calcd for $C_{18}H_{15}NS$: C, 77.94; H, 5.45; N, 5.05; S, 11.56%.

Compound **3b** (0.19 g, 0.7 mmol) was refluxed in acetic anhydride (5 ml) for 1.5 hr to give *N*-acetylated derivative (**4b**, 0.18 g, 80%), mp 107.0—107.5 °C (from ethanol). IR (KBr): 1670 cm^{-1} (CO); NMR ($CDCl_3$): δ 2.08 (s, 3H, CH_3) and 7.0—7.5 (m, 14H, ArH); Mass: *m/e* 319 (M^+, 8.9%), 277 (M^+–$H_2C{=}C{=}O$, 65), and 210 (M^+–PhS, 100).

Found: C, 75.37; H, 5.12; N, 4.30; S; 9.80%. Calcd for $C_{20}H_{17}NOS$: C, 75.21; H, 5.36; N, 4.39; S, 10.04%.

Benzophenone (1.81 g, 58%) was also eluted with *n*-hexane–benzene (1:1), benzene and benzene–dichloromethane (1:1), bp 123 °C/4 mmHg (lit,[24] 187—190 °C/15 mmHg). The spectral data (NMR and IR) were in agreement with those of an authentic sample.

Reaction of 3-Methyl-2-nitrosoimino-2,3-dihydrobenzothiazole (1a) with Phenyllithium. In a manner similar to run a), **1a** (4.91 g, 17.2 mmol) was allowed to react with phenyllithium (0.10 mol) in ether (100 ml). The reaction mixture was chromatographed on silica gel after the usual work-up. A trace amount of 2,2-diphenyl-3-methyl-2,3-dihydrobenzothiazole (**2a**, 0.11 g, 0.35 mmol) was eluted with *n*-hexane, mp 142—143 °C (from chloroform) (lit,[2] 142—143 °C). *o*-Methylaminophenyl phenyl sulfide (**3a**, 1.97 g, 36%) was eluted with *n*-hexane–benzene (1: 1) as an oil. The structure of **3a** was confirmed by the following spectral data: IR (neat): 3400 cm^{-1} (NH); NMR ($CDCl_3$): δ 2.75 (s, 3H, CH_3–N), 4.82 (broad s, 1H, N–H), and 6.5—7.6 (m, 9H, ArH); Mass: *m/e* 215 (M^+, 100%). Compound **3a** (0.57 g, 2.66 mmol) was refluxed in acetic anhydride (6 ml) for 1.5 hr to afford the *N*-acetyl derivative (**4a**, 0.47 g, 68%) as an oil, which was chromatographed on silica gel (dry column method) to give an analytically pure sample of **4a**. IR (neat): 1670 cm^{-1} (CO); NMR ($CDCl_3$): δ 1.85 (s, 3H, $COCH_3$), 3.23 (s, 3H CH_3–N), and 7.03—7.69 (m, 9H, ArH); Mass: *m/e* 257 (M^+, 4.1%), 215 (M^+–$CH_2{=}C{=}O$, 11), and 148 (M^+–PhS,

100).

Found: C, 69.72; H, 6.14; N, 5.24%. Calcd for $C_{15}H_{15}NOS$: C, 70.01; H, 5.87; N, 5.44%.

Benzophenone (1.624 g, 52%) was eluted with *n*-hexane–benzene (1: 1).

Reaction of ***1b*** *with* n-*Butyllithium.* *n*-Butyllithium (68 mmol) in *n*-hexane was added dropwise to a suspension of **1b** (4.90 g, 19.2 mmol) in ether (70 ml) over a period of 1 hr with stirring at 0 °C. Stirring was continued for 3 hr after the addition. After the usual work-up, the reaction mixture was chromatographed on silica gel. 2,3-Di-*n*-butyl-3-phenyl-2,3-dihydrobenzothiazole (**5**, 0.65 g, 10%) was eluted with *n*-hexane as an oil and the structure of **5** was confirmed by the following spectral data: NMR ($CDCl_3$): δ 0.5—2.2 (m, 18H, $2CH_3CH_2CH_2CH_2$) and 6.0—7.5 (m, 9H, ArH); Mass: *m/e* 325 (M^+, 12%) and 268 (M^+–*n*-Bu, 100). Bis(*o*-anilinophenyl) disulfide (**6b**, 0.13 g, 3%) was eluted with *n*-hexane–benzene (1: 1) as an oil. IR (neat): 3350 cm^{-1} (NH); MS: *m/e* 400 (M^+). The structure of **6b** was confirmed by comparing its spectral data (IR and NMR) with those of an authentic sample prepared from 3-phenyl-2,3-dihydrobenzothiazol-2-one and potassium hydroxide in ethanol.[25] *o*-Anilinophenyl *n*-butyl sulfide (**7**, 2.12 g, 43%) was eluted with *n*-hexane–benzene (1: 1) as an oil. The structure of **7** was confirmed by the following spectral data: IR (neat): 3350 cm^{-1} (NH); NMR ($CDCl_3$): δ 0.6—1.8 (m, 7H, $CH_3CH_2CH_2$), 2.7 (t, 2H, $-CH_2-S$), and 6.4—7.7 (m, 9H, ArH); Mass: *m/e* 257 (M^+, 97) and 201 ($M^+-CH_2=CHCH_2CH_3$, 100). 2-*N'*-*n*-Butylidenehydrazono-3-phenyl-2,3-dihydrobenzothiazole (**8**, 0.59 g, 10%) was eluted with benzene–dichloromethane (1: 1) as pale yellow crystals, mp 112—113 °C. The structure of **8** was confirmed by the following spectral data: IR (KBr): 1615, 1580, 1560, and 1550 cm^{-1}; Mass: *m/e* 295 (M^+, 55%) and 225 (M^+–*n*-PrCH=N, 100).

Reaction of ***1a*** *with Benzyllithium.* **1a** (3.44 g, 17.8 mmol) was added portionwise over a period of 0.5 hr at room temperature to a stirred solution of benzyllithium prepared from lithium (3.27 g, 0.47 mol) and benzyl methyl ether (14.07 g, 0.12 mol) in THF (320 ml). Stirring was continued for an additional 3 hr. After the usual work-up, the reaction mixture was chromatographed on silica gel. 2,2-Dibenzyl-3-methyl-2,3-dihydrobenzothiazole (**9**, 0.96 g, 16%) was eluted with *n*-hexane–benzene (1: 1), mp 86.5—87.5 °C (from chloroform–ethanol) (lit,[3] 86.5—87.5 °C). Bis(*o*-methylaminophenyl) disulfide (**6a**, 0.95 g, 38%) was eluted with *n*-hexane–benzene (1: 1) and benzene, mp 66.5—67.0 °C (from chloroform–ethanol) (lit,[2] 66.5—67.0 °C).

Syntheses of Tetracyclo[7.3.0.0^{3,7}.0^{4,10}]dodecane-2,8-dione ("[8]Diisotwistane-2,8-dione"[1]) and 8,9-Benzotricyclo[4.3.1.0^{3,7}]decane ("Benzoisotwistane")

Masao NAKAZAKI, Koichiro NAEMURA, and Hiroyuki YOSHIHARA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

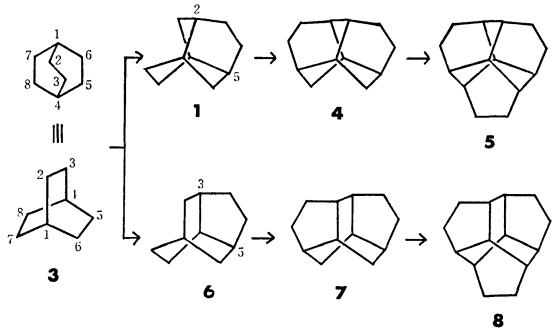
(Received May 21, 1975)

Tetracyclo[7.3.0.0^{3,7}.0^{4,10}]dodecane-2,8-dione ("[8]diisotwistane-2,8-dione") was synthesized from *trans-anti*-2,5-dioxo-7,8-diethoxycarbonylbicyclo[2.2.2]octane which was prepared by the Diels-Alder reaction of hydroquinone with diethyl fumarate. 8,9-Benzotricyclo[4.3.1.0^{3,7}]decane ("benzoisotwistane") was also synthesized from 2-oxo-5-*endo*-ethoxycarbonyl-7,8-benzotricyclo[2.2.2]octane which was obtained by the Diels-Alder reaction of β-naphthol with ethyl acrylate.

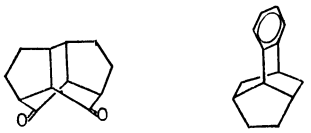
We have been interested in the preparation of "gyrochiral"[2] cage-shaped compounds such as twistane (D_2 point group) (**1**)[3] and twist-brendane (C_2 point group) (**2**)[4] as well as in the study of their chiroptical properties.

1 **2**

Although twistane (**1**) can be regarded as being constructed by the double 1–4 and 2–5 ethano-bridging over and below twist-cyclohexane (D_2 symmetry), one can also visualized it as being formed by the single diagonal ethano-bridging between 2 and 5 positions of bicyclo[2.2.2]octane (**3**). On continuance of this type of diagonal ethanol-bridging on twistane, there arise successively ditwistane (C_2 point group) (**4**)[5] and tritwistane (D_3 point group) (**5**). There remains another possible ethano-bridging, *i.e.* the collateral bridging between 3 and 5 positions this time, and this type of bridging on parent bicyclo[2.2.2]octane gives isotwistane (C_s point group) (**6**), "[8]diisotwistane"(C_2 point group) (**7**),[6] and the pentacyclic hydrocarbon (C_2 point group) (**8**)[8] successively.



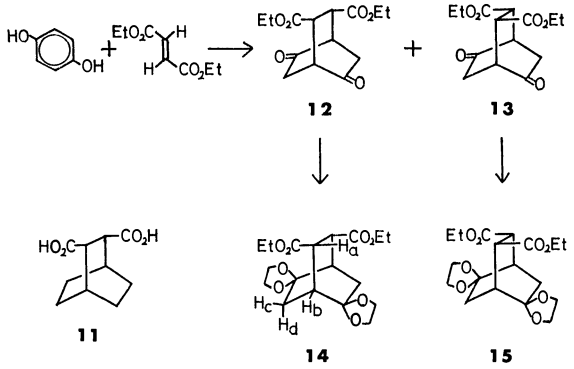
We have been making efforts to synthesize these "gyrochiral" tetra and pentacyclic compounds, and this paper reports the preparation of [8]diisotwistane-2,8-dione (**9**) as the first member of the tetracyclic compound with this unique structure. Although 8,9-benzotricyclo-[4.3.1.0^{3,7}]decane ("benzoisotwistane") (**10**) is achiral, since its preparation incidentlly follows an analogous scheme to the compound (**9**) in securing the starting material as well as in its final synthetic step, the synthesis of this compound will also be reported in the latter part of this paper.



9 **10**

[8]Diisotwistane-2,8-dione

Heating a mixture of hydroquinone and diethyl fumarate under a nitrogen atmosphere for 63 hr at 200—220 °C and chromatographic separation of the adduct gave two ketonic substances in a 3: 1 ratio; the major product melting at 88—89 °C and the minor product melting at 104.5—105.5 °C. The stereoisomeric nature of these compounds were demonstrated by their conversion to the same *trans*-2,3-dicarboxybicyclo[2.2.2]-octane (**11**) on Wolff-Kishner reduction. We resorted to the NMR spectra (Table 1) of their ketal derivatives (**14**) and (**15**) to securing the informations about their stereochemistry. A W-letter long-range coupling between proton H_a and proton H_d in ketalester (**14**) from the minor product which is clearly revealed on a spin decoupling experiment afforded the evidence to



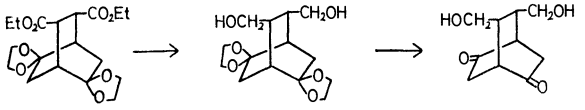
12 **13** **11** **14** **15**

TABLE 1. NMR SPECTRA (IN $CDCl_3$) OF **14** AND **15**

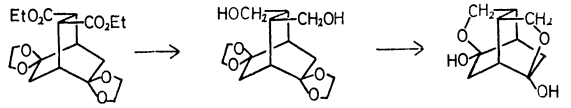
	14	**15**
Carboethoxy	δ 1.22 (t, 6H)	δ 1.21 (t, 6H)
	4.18 (q, 4H)	4.10 (q, 4H)
H_c	1.77 (q, 2H)	1.78 (q, 2H)
H_d	2.18 (q, 2H)	2.12 (q, 2H)
H_b	2.28 (m, 2H)	2.51 (m, 2H)
H_a	3.42 (d, 2H)	3.05 (d, 2H)
Ethylenedioxy	3.85—4.00 (m, 8H)	3.62—3.90 (m, 8H)

assign the *anti*-structure[9] (**12**) to the minor adduct whereas the *syn*-structure[9] (**13**) to the major adduct.

This assignment was further supported by their chemical behaviors as follows. Lithium aluminum hydride reduction converted these two ketals into two alcohols (**16**) and (**17**). Whereas treatment of *anti*-ketalalcohol (**16**) with 5% sulfuric acid led to the corresponding ketoalcohol (**18**), the same procedure led the *syn*-ketalalcohol (**17**) to the hemi-ketal (**19**) whose structure was confirmed by the IR spectrum.



14 **16** **18**



15 **17** **19**

Thus being convinced of the stereochemistry, we could carry on our syntheses. Tosylation of the *anti*-alcohol (**16**) provided the ketaltosylate (**20**) which was treated with sodium cyanide in DMF to give the *anti*-nitrile (**21**). Alkaline hydrolysis of the *anti*-nitrile (**21**) afforded the *anti*-carboxylic acid (**22**), which was reduced with lithium aluminum hydride to yield the *anti*-alcohol (**23**). After mesylation of the *anti*-alcohol (**23**), ketal functions were removed by treatment with 10% sulfuric acid. The resultant *anti*-ketomesylate (**25**) was treated with sodium hydride in DMF. Chromatography on silica gel followed by sublimation of the reaction product yielded a dione mp 88—89 °C, to which the structure (**26**) was assigned on the basis of the following spectral data. The NMR spectrum exhibited two multiplet signals centered at δ 2.53 due to protons H_b and at 2.83 due to protons H_c. The IR spectrum showed a carbonyl absorption at 1710 cm^{-1}. The UV spectrum showed absorption maxima at 258 (ε=40) and 289 (42) nm.

25 **26**

It seems in order here to divert attention from [8]diisotwistane series of compound to our sterile efforts to [8]ditwistane series of compound. The same procedure described for *anti*-form converted the *syn*-ketalalcohol (**17**) into *syn*-nitrile (**28**), *syn*-carboxylic acid (**29**), and *syn*-ketalalcohol (**30**) successively. On treatment with methanesulfonyl chloride and pyridine the *syn*-ketalalcohol (**30**) gave a corresponding ketal-mesylate (**31**) whose structure was confirmed on the basis of its NMR and IR spectra. But various fruitless attempts to remove the ketal functions at this stage forced us to abandon the hope to proceed further.

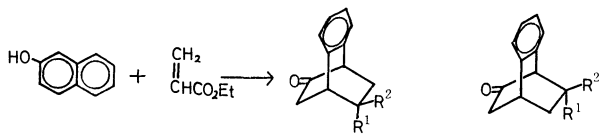
Benzoisotwistane

Diels-Alder reaction which was proved convenient to secure starting materials with functional groups suitable for the synthesis of the cage-shaped compound as described above, encouraged us to apply this reaction to β-naphthol and ethyl acrylate. Although formation of the four isomers (**32**)—(**35**) was theoretically expected, analysis of the adduct, bp 137—140 °C at 0.1 mmHg, by glc revealed a formation of only two components in a ratio of 2: 3. Reflection on steric and electric effects involved in the Diels-Alder reaction led to the conclusion that 2-oxo-5-ethoxycarbonyl-7,8-benzobicyclo[2.2.2]-octanes (**32**) and (**33**) should be formed preferentially over 2-oxo-6-ethoxycarbonyl-7,8-benzobicyclo[2.2.2]-octanes (**34**) and (**35**). Further structural information was accessible from the NMR spectrum which showed two three-protons triplets centered at 1.11 and 1.26 (relative ratio 4: 6 respectively). These signals were due to methyl protons of carboethoxy groups. The high field signal was assigned for *exo*-isomer (**33**)[10] and the low field one was due to *endo*-isomer (**32**).[10]



32 R^1=CO_2Et, R^2=H
33 R^1=H, R^2=CO_2Et
34 R^1=CO_2Et, R^2=H
35 R^1=H, R^2=CO_2Et

No attempt was made at this stage to separate these isomers because of difficulty encountered to accomplish the separation, and the product after ketalization with ethylene glycol was treated with lithium aluminum hydride to give a mixture of the ketalalcohols (**38**) and (**39**). Upon treatment with *p*-toluenesulfonyl chloride and pyridine the mixture of the ketalalcohols (**38**) and (**39**) was converted into the mixture of the tosylates (**40**) and (**41**). At this stage one isomer of the tosylates was separated as crystals and the other was liquid. The fact that this crystalline isomer was eventually led to benzoisotwistane implies the isomer has *endo*-structure (**40**) whereas the liquid one has *exo*-structure (**41**).

39 $R^1=H$, $R^2=CH_2OH$ **41** $R^1=H$, $R^2=CH_2OTs$

Upon treatment with sodium cyanide in DMF, the *endo*-tosylate (**40**) gave the *endo*-nitrile (**42**). Alkaline hydrolysis of the substance afforded the *endo*-carboxylic acid (**43**), which was reduced with lithium aluminum hydride to yield the *endo*-alcohol (**44**). After hydrolysis of the ketal function, the resultant ketoalcohol (**45**) was converted into the *endo*-ketomesylate (**46**), which was treated with sodium hydride in DMF. Sublimation of a solid product gave a tricyclic ketone mp 85—86 °C. We assigned benzoisotwistan-2-one (**47**) to the product on the basis of the NMR spectrum exhibiting double doublet signal centered at 3.38 for a proton H_a and this pattern ruled out twistane structure (**48**). The Wolff-Kishner reduction of the ketone (**47**) yielded benzoisotwistane (**10**) mp 56—57 °C.

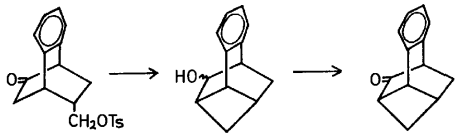
51 R=CH_2OH

Finally we made an effort to prepare the lower homolog of benzoisotwistane; 7,8-benzotricyclo[3.3.1.$0^{3,6}$]nonan-2-one (**56**). Upon treatment with acetone and *p*-toluenesulfonic acid, the *endo*-ketaltosylate (**40**) gave the *endo*-ketotosylate (**54**), which was heated with sodium hydride in DMF. Chromatographic separation of a product yielded a cyclized compound. It was not an expected ketone but an alcoholic compound. On oxidation with 8N Jones' reagent the substance gave a ketonic compound mp 90 °C, whose UV spectrum (Table 2) was very similar with that of benzoisotwistan-2-one (**47**). From the fact we assigned the structure (**56**) to the compound and its NMR and IR spectra were also consistent with the structure (**56**).

TABLE 2. UV SPECTRA (IN ISOOCTANE SOLUTION) OF **47** AND **56**

47		**56**	
nm	ε	nm	ε
259.5 (sh)	330	260 (sh)	320
265	409	265.5	368
271.5	361	272	327
291 (sh)	213	289 (sh)	268
299.5	261	296.5	309
309	254	305.5	297
319 (sh)	147	316 (sh)	177



54 **55** **56**

Experimental

All the melting points and the boiling points are not corrected. The IR spectra were measured with Hitachi EPI-S2 spectrophotometer. The NMR spectra were obtained on LNM-C-60HL and JNM-MH-100 spectrometer. The UV spectra were measured with Beckman DB spectrometer.

Diels-Alder Reaction of Hydroquinone with Diethyl Fumarate. A mixture of 160 g of hydroquinone and 320 g of diethyl fumarate was heated for 36 hr at 200—220 °C under a nitrogen atmosphere. After cooling, 105 g of hydroquinone was recovered by filtration and a liquid reaction mixture was distilled to recover 220 g of diethyl fumarate. A residue was chromatographed on neutral alumina (Woelm, activity III) and ealier fractions eluted with benzene gave an oily product, which was distilled to yield 14.6 g of **13**, bp 170—180 °C at 1.5 mmHg. This adduct was crystallized in a reciever, mp 88—89 °C. Followed fractions eluted with benzene gave a solid, which was recrystallized from benzene to yield 5.5 g of **12**, mp 104.5—105.5 °C.

13: IR (KBr): 1720 (s), 1260 (m), 1240 (m), 1190 (s), 1112 (m), and 1022 (m) cm^{-1}.

NMR ($CDCl_3$): δ 1.30 (t, 6H, J=7 Hz), 2.52—2.67 (m, 4H), 3.02—3.25 (m, 2H), 3.55 (s, 2H), and 4.20 (q, 4H, J= 7 Hz).

Found: C, 59.15; H, 6.54%. Calcd for $C_{14}H_{18}O_6$: C, 59.56; H, 6.43%.

12: IR (KBr): 1720 (s), 1253 (m), 1239 (m), 1190 (s), 1175 (m), and 1030 (m), cm^{-1}.

NMR ($CDCl_3$): δ 1.25 (t, 6H, J=7 Hz), 2.42—2.55 (m, 4H), 3.04—3.18 (m, 2H), 3.15 (s, 2H), and 4.18 (q, 4H, J= 7 Hz).

Found: C, 59.48; H, 6.42%. Calcd for $C_{14}H_{18}O_6$: C, 59.56; H, 6.43%.

trans-2,3-Dicarboxybicyclo[2.2.2]octane (11). *From* ***12***: A mixture of 1.37 ml of 80% hydrazine hydrate, 1.34 g of potassium hydroxide, 14 ml of triethylene glycol and 1.33 g of **12** was heated for 3 hr at 130—140 °C and then water was removed from the reaction mixture. A residual solution was heated for further 6 hr at 200 °C and then diluted with water.

After washing with ether, a water layer was acidified with hydrochloric acid and extracted with ether. The extract was washed with water and dried over magnesium sulfate. Removal of the solvent gave a solid which was recrystallized from ethanol to yield 692 mg of **11**, mp 232 °C (lit,[11] mp 234 °C).

Found: C, 60.74; H, 7.19%. Calcd for $C_{10}H_{14}O_4$: C, 60.59; H, 7.12%.

From ***13***: *trans*-2,3-Dicarboxybicyclo[2.2.2]octane (550 mg) was obtained from 1.25 g of **13** by the same method described above.

trans-anti-*2,5-Bisethylenedioxy-7,8-diethoxycarbonylbicyclo[2.2.2]octane (**14**).* A solution of 3.34 g of **12**, 24 mg of *p*-toluenesulfonic acid, and 40 ml of ethylene glycol in 176 ml of benzene was boiled for 25 hr during which time water generated was removed from the reaction mixture as the azeotrope with benzene. After cooling to room temperature, benzene layer was separated and washed with satd. aqueous sodium bicarbonate and water. Removal of the solvent gave a solid which was recrystallized from hexane to yield 4.22 g of **14**, mp 80—81 °C.

IR (KBr): 1728 (s), 1288 (m), 1220 (m), 1185 (s), 1110 (s), 1032 (s), and 1025 (s) cm^{-1}.

Found: C, 58.20; H, 7.27%. Calcd for $C_{18}H_{26}O_8$: C, 58.37; H, 7.08%.

trans-syn-*2,5-Bisethylenedioxy-7,8-diethoxycarbonylbicyclo[2.2.2]octane (**15**).* *syn*-Ketoester (**13**) (8.54 g) was converted into **15** (7.34 g), mp 98—98.5 °C, by the same method described above.

IR (KBr): 1740 (s), 1730 (s), 1312 (m), 1235 (m), 1185 (s), 1150 (m), 1105 (s), and 1020 (s) cm^{-1}.

Found: C, 58.38; H, 7.17%. Calcd for $C_{18}H_{26}O_8$: C, 58.37; H, 7.08%.

trans-anti-*2,5-Bisethylenedioxy-7,8-bis(hydroxymethyl)bicyclo[2.2.2]octane (**16**).* To a suspension of 1.15 g of lithium aluminum hydride in 50 ml of dry ether was added a solution of 6.30 g of **14** in 150 ml of dry ether at room temperature and then the mixture was refluxed for 2 hr. After cooling with ice, to the chilled reaction mixture was carefully added satd. aqueous ammonium chloride solution and then a solid was filtered off. A filtrate was washed with water and dried over magnesium sulfate. Removal of the solvent gave a solid which was recrystallized from acetone to yield 5.27 g of **16** mp 163—165 °C.

IR (KBr): 3350 (s), 1130 (m), 1098 (m), 1062 (s), 1038 (m), and 990 (m) cm^{-1}.

Found: C, 58.70; H, 7.80%. Calcd for $C_{14}H_{22}O_6$: C, 58.73; H, 7.75%.

trans-syn-*2,5-Bisethylenedioxy-7,8-bis(hydroxymethyl)bicyclo[2.2.2]octane (**17**).* Reduction of 14.0 g of **15** with 3.4 g of lithium aluminum hydride in dry ether afforded 9.65 g of **17**, mp 132 °C, by the same procedure described above.

IR (KBr): 3300 (s), 1155 (m), 1090 (s), 1045 (s), and 995 (s) cm^{-1}.

Found: C, 58.55; H, 7.81%. Calcd for $C_{14}H_{22}O_6$: C, 58.73; H, 7.75%.

trans-anti-*2,5-Dioxo-7,8-bis(hydroxymethyl)bicyclo[2.2.2]octane (**18**).* A solution of 500 mg of **16** in 10 ml of 5% sulfuric acid was kept for 3 days at room temperature. The reaction mixture was neutralized with solid sodium bicarbonate and concentrated under reduced pressure. Acetone was added to a residue and an insoluble solid was filtered off. A filtrate was concentrated to give a solid which was recrystallized from acetone to yield 210 mg of **18**, mp 126—127 °C.

IR (KBr): 3400 (s), 1725 (s), 1705 (s), 1080 (m), 1070 (m), and 1020 (s) cm^{-1}.

Found: C, 60.36; H, 7.17%. Calcd for $C_{10}H_{14}O_4$: C, 60.59; H, 7.12%.

Hydrolysis of trans-syn-*2,5-Bisethylenedioxy-7,8-bis(hydroxymethyl)bicyclo[2.2.2]octane (**17**).* A mixture of 10.3 g of **17** and 5% sulfuric acid was kept for 3 days at room temperature. After working up as the same manner described above, a solid product was recrystallized from acetone to give 3.83 g of **19**, mp 125 °C.

IR (KBr): 3300 (s), 1160 (m), 1090 (m), 1070 (m), and 980 (s) cm^{-1}.

Found: C, 60.46; H, 7.27%. Calcd for $C_{10}H_{14}O_4$: C, 60.59; H, 7.12%.

trans-anti-*2,5-Bisethylenedioxy-7,8-bis(cyanomethyl)bicyclo[2.2.2]octane (**21**).* To a solution of 5.05 g of **16** in 25 ml of dry pyridine was added 15.0 g of *p*-toluenesulfonyl chloride with ice cooling and then the mixture was stirred for 2 hr at this temperature. After standing overnight at room temperature, the mixture was poured onto ice water and acidified with hydrochloric acid. A solid was collected and washed with dilute hydrochloric acid, satd. aqueous sodium bicarbonate, and water. After drying over calcium chloride, 9.05 g of tosylate (**20**) was obtained, mp 156—157 °C. A mixture of 9.00 g of **20**, 4.7 g of sodium cyanide and 45 ml of *N,N*-dimethylformamide (DMF) was heated for 4 hr at 120—130 °C and then for further 8 hr at 140—150 °C. After cooling to room temperature, a solid was filtered off and a filtrate was concentrated under reduced pressure. A residue was poured into water and a solid was collected, which was washed with water. Recrystallization from benzene gave 4.10 g of **21**, mp 162—164 °C.

IR (KBr): 2260 (w), 1135 (s), 1110 (m), 1053 (s), 1025 (s), 983 (s), and 950 (m) cm^{-1}.

Found: C, 63.31; H, 6.69; N, 9.20%. Calcd for $C_{16}H_{20}O_4N_2$: C, 63.14; H, 6.62; N, 9.21%.

trans-syn-*2,5-Bisethylenedioxy-7,8-bis(cyanomethyl)bicyclo[2.2.2]octane (**28**).* Tosylation of 7.90 g of **17** with 15.7 g of *p*-toluenesulfonyl chloride and 42 ml of pyridine was carried out by the same procedure described above and 11.3 g of **27** was obtained. A mixture of 11.0 g of **27**, 5.8 g of sodium cyanide, and 55 ml of DMF was heated for 4 hr at 120—130 °C and then for further 10 hr at 140—150 °C. After working up as described above, a solid was collected and recrystallized from benzene to yield 2.09 g of **28**, mp 217—219 °C.

IR (KBr): 2260 (w), 1140 (s), 1100 (s), 1075 (s), 980 (m), and 960 (m) cm^{-1}.

Found: C, 63.25; H, 6.69; N, 9.06%. Calcd for $C_{16}H_{20}O_4N_2$: C, 63.14; H, 6.62; N, 9.21%.

trans-anti-*2,5-Bisethylenedioxy-7,8-bis(carboxymethyl)bicyclo[2.2.2]octane (**22**).* A mixture of 3.82 g of **21**, 4.23 g of potassium hydroxide and 35 ml of ethylene glycol was heated for 6 hr at 150—160 °C. After cooling to room temperature, the reaction mixture was diluted with water and acidified with hydrochloric acid. A solid was collected, washed with water, and dried over calcium chloride to yield 1.92 g of **22**, mp 208 °C dec.

IR (KBr): 2900 (broad), 1705 (s), 1295 (m), 1140 (m), 1120 (m), 1020 (m), and 998 (m) cm^{-1}.

Found: C, 55.65; H, 6.51%. Calcd for $C_{16}H_{22}O_8$: C, 56.13; H, 6.48%.

trans-syn-*2,5-Bisethylenedioxy-7,8-bis(carboxymethyl)bicyclo[2.2.2]octane (**29**).* Hydrolysis of 9.22 g of **28** with potassium hydroxide in ethylene glycol gave 3.95 g of **29**, mp 238 °C dec., by the same procedure described above.

IR (KBr): 2900 (broad), 1720 (s), 1205 (m), 1130 (m), 1090 (s), and 960 (m) cm^{-1}.

Found: C, 55.97; H, 6.44%. Calcd for $C_{16}H_{22}O_8$: C, 56.13; H, 6.48%.

trans-anti-*2,5-Bisethylenedioxy-7,8-bis(2-hydroxyethyl)bicyclo-*

[2.2.2]octane (23). To a suspension of 0.48 g of lithium aluminum hydride in 20 ml of dry tetrahydrofuran (THF) was added a solution of 1.82 g of **22** in 20 ml of dry THF at room temperature and then a mixture was heated under reflux for 2 hr. After cooling with ice, satd. aqueous ammonium chloride solution was carefully added to the chilled reaction mixture and a solid was filtered off. A filtrate was dried over magnesium sulfate and removal of the solvent gave a solid which was recrystallized from acetone to yield 1.39 g of **23**, mp 138—139 °C.

IR (KBr): 3300 (s), 1140 (m), 1118 (s), 1060 (m), 1012 (s), 995 (m), and 948 (m) cm^{-1}.

Found: C, 61.09; H, 8.52%. Calcd for $C_{16}H_{26}O_6$: C, 61.13; H, 8.34%.

trans-syn-*2,5-Bisethylenedioxy-7,8-bis(2-hydroxyethyl) bicyclo-[2.2.2]octane (30).* Reduction of **29** (3.95 g) with lithium aluminum hydride was carried out by the same procedure described above and recrystallization of a product gave 2.10 g of **30**, mp 183 °C.

IR (KBr): 3450 (m), 1110 (s), 1060 (m), 1045 (m), and 970 (m) cm^{-1}.

Found: C, 61.26; H, 8.28%. Calcd for $C_{16}H_{26}O_6$: C, 61.13; H, 8.34%.

[8]Diisotwistane-2,8-dione (26). To a solution of 1.6 g of **23** in 20 ml of dry pyridine was added 2.28 g of methanesulfonyl chloride at 0—5 °C and then a reaction mixture was stirred for 2 hr at this temperature. After standing for further 20 hr at room temperature, it was poured onto ice and extracted with ether. The extract was washed with dilute hydrochloric acid, satd. aqueous sodium bicarbonate, water, and dried over magnesium sulfate. Removal of the solvent gave 1.11 g of **24**, to which was added 30 ml of 10% sulfuric acid. After standing for 3 days at room temperature, it was extracted with ether. The extract was washed with satd. aqueous sodium bicarbonate, water, and dried over magnesium sulfate. Removal of the solvent afforded 0.78 g of **25** as an oily product.

IR (neat film): 1725 (s), 1350 (m), 1175 (m), and 945 (m) cm^{-1}.

The mesylate (**25**), without purification, was dissolved in 25 ml of dry DMF and a solution was added to a suspension of 1.0 g of sodium hydride in 10 ml of dry DMF. A reaction mixture was heated for 48 hr at 60—70 °C under a nitrogen atmosphere. After cooling to room temperature, a few drops of methanol was added to the mixture and then it was diluted with water and extracted with ether. The extract was washed with dilute hydrochloric acid, satd. aqueous sodium bicarbonate, water, and dried over magnesium sulfate. After evaporation of the solvent, a residue was chromatographed on neutral alumina (Woelm, activity III) and fractions eluted with ether–pentane (1:1 volume) gave a wax. The wax was sublimed to yield 85 mg of [8]diisotwistane-2,8-dione (**26**), mp 88—89 °C (in a sealed tube). A sample for elemental analysis was further purified by tlc (Kieselgel 60 PF_{254}, Merck) and sublimation.

IR (KBr): 1710 (s), 1222 (m), 1160 (m), and 1030 (m) cm^{-1}.

NMR ($CDCl_3$): δ 1.6—2.2 (m, 10H), 2.45—2.60 (m, 2H), and 2.68—2.88 (m, 2H).

UV: $\lambda_{max}^{ethanol}$ 258 nm (ε=40), 289 nm (42).

Found: C, 75.68; H, 7.49%. Calcd for $C_{12}H_{14}O_2$: C, 75.76; H, 7.42%.

Mesylation of 30. To a solution of 1.90 g of **30** in 20 ml of dry pyridine was added 2.70 g of methanesulfonyl chloride with ice cooling. After stirring for 5 hr at 0—5 °C, a mixture was stand overnight at room temperature and then poured onto ice. A solid was collected and washed with water to give 2.08 g of **31**, mp 169 °C dec.

IR (KBr): 1335 (s), 1170 (s), 985 (m), and 840 (m), cm^{-1}.

NMR ($CDCl_3$): δ 1.6—2.1 (m, 6H), 2.4—2.5 (m, 2H). 3.09 (s, 6H), 3.60—3.70 (m, 12H), and 4.22—4.31 (m, 4H),

Found: C, 45.78; H, 6.44; S, 13.56%. Calcd for $C_{18}H_{30}O_{12}S_2$: C, 45.95; H, 6.43; S, 13.60%.

Attempts to Hydrolyze Ethylenedioxy Group of 31. Mesylate (**31**) was quantitatively recovered unchanged from 10% sulfuric acid (for 2 days at room temperature), *p*-toluenesulfonic acid in acetone (for 4 days at room temperature), 1 N hydrochloric acid in THF (for 5 hr at room temperature), and 50% aqueous acetic acid (for 1 hr at 70 °C).

Diels-Alder Reaction of β-Naphthol with Ethyl Acrylate. A mixture of 90 g of β-naphthol and 120 g of ethyl acrylate was heated for 70 hr at 170—180 °C under a nitrogen atmosphere. From the reaction mixture, 75 g of ethyl acrylate was recovered by distillation. A residue was chromatographed on alumina (Sumitomo). Fractions eluted with benzene were distilled to give 22.1 g of a mixture of adducts, bp 137—140 °C at 0.1 mmHg. Analysis by glc on a 10% SE-30 column at 190 °C revealed the presence of two components having relative retention times 1.00: 1.24 (relative yield 39: 61 respectively). The structure (**33**) was assigned to a minor adduct and **32** to a major adduct.

IR (neat film): 1720 (s), 1625 (w), 1600 (w), 1170 (m), and 755 (m) cm^{-1}.

NMR ($CDCl_3$): δ 1.11 (t, J=7 Hz, 1.0*), 1.26 (t, J=7 Hz, 1.5), 1.8—3.0 (m, 4.5), 3.4—4.3 (m, 3.5), 7.13 (s, 1.5), and 7.16 (s, 2.0).

Found: C, 73.49; H, 6.63%. Calcd for $C_{15}H_{16}O_3$: C, 73.75; H, 6.60%.

*Ketalization of a mixture of 2-Oxo-5-*endo*-ethoxycarbonyl-7,8-benzobicyclo[2.2.2]octane (32) and 2-Oxo-5-*exo*-ethoxycarbonyl-7,8-benzobicyclo[2.2.2]octane (33).* A solution of 22.0 g of a mixture of **32** and **33**, 300 ml of ethylene glycol, 1.40 g of *p*-toluenesulfonic acid in 1400 ml of benzene was boiled for 30 hr. During this period, the water generated was separated as benzene azeotrope from the reaction mixture. After cooling to room temperature, a benzene layer was separated and washed with satd. aqueous sodium bicarbonate, water and dried over magnesium sulfate. After evaporation of the solvent, a residue was distilled to give 23.8 g of a mixture of **36** and **37**, bp 153—155 °C at 0.1 mmHg.

IR (neat film): 1725 (s), 1625 (w), 1600 (w), 1185 (m), 1120 (m), 1095 (m), 1030 (m), 1010 (m), and 755 (m) cm^{-1}.

Found: C, 69.51; H, 8.33%. Calcd for $C_{17}H_{24}O_4$: C, 69.83; H, 8.27%.

*A Mixture of 2-Ethylenedioxy-5-*endo*-hydroxymethyl-7,8-benzobicyclo[2.2.2]octane (38) and 2-Ethylenedioxy-5-*exo*-hydroxymethyl-7,8-bicyclo[2.2.2]octane (39).* A solution of 23.7 g of a mixture of **36** and **37** in 200 ml of dry ether was added to a suspension of 5.00 g of lithium aluminum hydride in 150 ml of dry ether at room temperature. It was refluxed for 2 hr and then cooled with ice. A chilled reaction mixture was added with satd. aqueous ammonium chloride solution and a solid was filtered off. A filtrate was washed with water and dried over magnesium sulfate. After evaporation of the solvent, a residue was distilled to yield 16.6 g of a mixture of **38** and **39**, bp 172—173 °C at 0.1 mmHg.

IR (neat film): 3400 (s), 1625 (w), 1600 (w), 1120 (m), 1080 (m), 1030 (m), and 750 (s) cm^{-1}.

Found: C, 72.98; H, 7.38%. Calcd for $C_{15}H_{18}O_3$: C, 73.14; H, 7.37%.

Tosylation of a Mixture of 38 and 39. To a solution of 16.5 g of a mixture of **38** and **39** in 40 ml of dry pyridine was

* Relative ratio of peak areas.

added 16.0 g of *p*-toluenesulfonyl chloride at 0—5 °C. The mixture was agitated at this temperature for 2 hr and then kept for further 24 hr at room temperature. After pouring onto ice, it was acidified with hydrochloric acid and extracted with benzene. The extract was washed with satd. aqueous sodium bicarbonate, water, and dried over magnesium sulfate. After evaporation of the solvent, a residue was added with ether and a solid precipitated was collected. The solid was recrystallized from benzene to yield 9.10 g of **40**, mp 139—140 °C.

IR (KBr): 1360 (s), 1175 (s), and 750 (m) cm^{-1}.

Found: C, 66.09; H, 6.11; S, 7.69%. Calcd for $C_{22}H_{24}O_5S$: C, 65.99; H, 6.04; S, 7.99%.

The solvent was removed from a filtrate to give 15.4 g of an oily substance (**41**), which was, without further purification, used for a subsequent reaction.

IR (neat film): 1360 (s), 1175 (s), and 755 (m) cm^{-1}.

*2-Ethylenedioxy-5-*endo*-cyanomethyl-7,8-benzobicyclo[2.2.2]octane (42).* A mixture of 11.5 g of **40**, 6.30 g of sodium cyanide, and 75 ml of DMF was heated for 1 hr at 120 °C and then for further 8 hr at 150—160 °C. After cooling to room temperature, a solid was filtered off and a filtrate was concentrated under reduced pressure. A residue was diluted with water and extracted with ether. The extract was washed with dilute hydrochloric acid, satd. aqueous sodium bicarbonate, water, and dried over magnesium sulfate. Removal of the solvent gave a solid, which was recrystallized from benzene–hexane to yield 6.10 g of **42**, mp 120—120.5 °C.

IR (KBr): 2250 (w), 1125 (m), 1090 (m), 1035 (m), 1010 (m), and 750 (m) cm^{-1}.

Found: C, 75.58; H, 6.78; N, 5.58%. Calcd for $C_{16}H_{17}O_2N$: C, 75.27; H, 6.71; N, 5.49%.

*2-Ethylenedioxy-5-*exo*-cyanomethyl-7,8-benzobicyclo[2.2.2]octane (49)* Treatment of 15.3 g of **41** with 8.20 g of sodium cyanide by the same manner described above yielded a solid which was recrystallized from benzene–hexane to give 5.20 g of **49**, mp 116.5—118 °C.

IR (KBr): 2250 (w), 1095 (s), 1075 (s), 1030 (m), 1015 (m), and 755 (m), cm^{-1}.

Found: C, 75.51; H, 6.78; N, 5.55%. Calcd for $C_{16}H_{17}O_2N$: C, 75.27; H, 6.71; N, 5.49%.

*2-Oxo-5-*endo*-(2-hydroxyethyl)-7,8-benzobicyclo[2.2.2]octane (45).* A mixture of 5.80 g of **42**, 10.0 g of potassium hydroxide, and 85 ml of ethylene glycol was heated for 2 hr at 120 °C and then for further 8 hr at 150—160 °C. After cooling to room temperature, a reaction mixture was diluted with water and acidified with hydrochloric acid. It was extracted with ether. The extract was washed with water and dried over magnesium sulfate. Removal of the solvent gave 6.53 g of an oily product (**43**), which was dissolved in 200 ml of dry ether. A solution was slowly added to a suspension of 2.00 g of lithium aluminum hydride in 50 ml of dry ether and a mixture was refluxed for 3 hr. After cooling with ice, to the chilled mixture was carefully added satd. aqueous ammonium chloride solution. A solid was filtered off and a filtrate was concentrated to give 5.92 g of a viscous oily product (**44**).

IR (neat film): 3450 (s), 1050 (m), 1110 (m), 1080 (m), 1030 (m), 1010 (m), and 755 (m) cm^{-1}.

To a solution of this substance in 400 ml of acetone was added 1.00 g of *p*-toluenesulfonic acid and the mixture was allowed to stand overnight at room temperature. After removal of acetone under reduced pressure, a residue was diluted with water and extracted with ether. The extract was washed with satd. aqueous sodium bicarbonate, water, and dried over magnesium sulfate. After evaporation of the solvent, a residue was distilled to yield 3.64 g of **45**, bp 180 °C at 0.5 mmHg.

IR (neat film): 3450 (s), 1725 (s), 1625 (w), 1600 (w), 1050 (m), and 755 (m) cm^{-1}.

Found: C, 76.99; H, 7.33%. Calcd for $C_{14}H_{16}O_2$: C, 77.75; H, 7.46%.

The substance was very hygroscopic.

*2-Ethylenedioxy-5-*exo*-carboxymethyl-7,8-benzobicyclo[2.2.2]octane (50).* Hydrolysis of 4.17 g of **49** with 8.00 g of potassium hydroxide in 70 ml of ethylene glycol was carried out by the same manner described above. A solid was obtained and recrystallized from benzene–hexane to yield 4.06 g of **50**, mp 119.5—120 °C.

IR (KBr): 3000 (broad), 1710 (s), and 755 (m) cm^{-1}.

Found: C, 70.27; H, 6.65%. Calcd for $C_{16}H_{18}O_4$: C, 70.05; H, 6.61%.

*2-Oxo-5-*exo*-(2-hydroxyethyl)-7,8-benzobicyclo[2.2.2]octane (52).* Reduction of 4.20 g of **50** with 2.10 g of lithium aluminum hydride in dry ether gave 3.66 g of an oily product (**51**).

IR (neat film): 3450 (s), 1050 (m), 1110 (m), 1080 (m), 1030 (m), 1010 (m), and 755 (m) cm^{-1}.

The substance was dissolved in 280 ml of acetone and to the solution was added 0.72 g of *p*-toluenesulfonic acid. The solution was stirred for 8 hr at room temperature and then worked up as described above to yield 2.30 g of **52**, bp 167—168 °C at 0.2 mmHg.

IR (neat film): 3450 (s), 1720 (s), 1050 (m), and 755 (m) cm^{-1}.

Found: C, 77.66; H, 7.50%. Calcd for $C_{14}H_{16}O_2$: C, 77.75; H, 7.46%.

8,9-Benzotricyclo[4.3.1.0^{3,7}]decan-2-one (47). To a solution of 3.32 g of **45** in 10 ml of dry pyridine was added 3.42 g of methanesulfonyl chloride with ice cooling and then a mixture was kept for 20 hr at room temperature. It was poured onto ice and acidified with hydrochloric acid. It was extracted with ether. The extract was washed with satd. aqueous sodium bicarbonate, water, and dried over magnesium sulfate. Removal of the solvent gave 4.40 g of **46**.

IR (neat film): 1720 (s), 1350 (s), 1170 (s), and 755 (m) cm^{-1}.

The methanesulfonate (**46**) was, without purification, dissolved in 45 ml of dry DMF and the solution was added to a suspension of 8.00 g of sodium hydride in 100 ml of dry DMF. It was stirred for 22 hr at 60 °C under a nitrogen atmosphere. After cooling with ice, to a chilled reaction mixture was added 3 ml of methanol and then poured onto ice. It was extracted with ether. The extract was washed with dilute hydrochloric acid, satd. aqueous sodium bicarbonate, water, and dried over magnesium sulfate. After evaporation of the solvent, to a residue was added pentane to give a solid which was collected and sublimed to yield 2.62 g of **47**, mp 85—86 °C (in a sealed tube).

IR (KBr): 1725 (s), 1630 (w), 1475 (m), 1455 (m), and 755 (s) cm^{-1}.

NMR (CCl_4): δ 1.4—1.6 (m, 2H), 1.6—2.3 (m, 4H), 3.17 (t, 2H), 3.38 (d,d, J=3.3 Hz, J=1.4 Hz, 2H), and 7.12 (s, 4H).

Mass spectrum: *m/e* 198 (parent peak).

Found: C, 84.60; H, 7.15%. Calcd for $C_{14}H_{14}O$: C, 84.81; H, 7.12%.

Tosylhydrazone; mp 182 °C dec.

Found: C, 69.11; H, 6.38; N, 7.32; S, 8.56%. Calcd for $C_{21}H_{22}O_2N_2S$: C, 68.83; H, 6.05; N, 7.65; S, 8.74%.

8,9-Benzotricyclo[4.3.1.0^{3,7}]decane (10). A mixture of 300 mg of **47**, 0.13 g of potassium hydroxide, 0.22 ml of 80% hydrazine hydrate, and 2 ml of triethylene glycol was heated for 90 min at 160 °C and then water was removed from the

reaction mixture. A residual solution was heated for further 3 hr at 200 °C and then diluted with water. It was extracted with pentane. The extract was washed with water and dried over magnesium sulfate. Removal of the solvent gave a solid which was sublimed to yield 131 mg of **10**, mp 56—57 °C (in a sealed tube).

IR (KBr): 2920 (m), 2870 (m), 1480 (m), 1450 (m), and 755 (s) cm^{-1}.

NMR (CCl_4): δ 1.3—2.1 (m, 10H), 2.81 (m, 2H), and 7.03 (s, 4H).

Mass spectrum: *m/e* 184 (parent peak).

Found: C, 90.98; H, 8.85%. Calcd for $C_{14}H_{16}$: C, 91.25; H, 8.75%.

Attempt to Cyclize exo-*Methanesulfonate (53).* Treatment of 2.30 g of **52** with 2.50 g of methanesulfonyl chloride and 7 ml of dry pyridine by the same manner described for *endo*-isomer gave 2.28 g of **53**, which was dissolved in 30 ml of dry DMF. This solution was added to a suspension of 4.80 g of sodium hydride in 60 ml of dry DMF. The mixture was agitated for 25 hr at 60 °C under a nitrogen atmosphere and 2 ml of methanol was added to the reaction mixture with ice cooling. It was then poured onto ice and extracted with ether. The extract was washed with dilute hydrochloric acid, satd. aqueous sodium bicarbonate, water, and dried over magnesium sulfate. Removal of the solvent gave an oily product which was chromatographed on neutral alumina (Woelm, activity III). But 8,9-benzotricyclo[4.3.1.$0^{3,7}$]-decan-2-one (**47**) was not obtained.

Hydrolysis of Ethylenedioxy Group of 40. A mixture of 8.21 g of **40**, 1.50 g of *p*-toluenesulfonic acid and 600 ml of acetone was stirred for 2 days at room temperature. The mixture was concentrated under reduced pressure and a residue was diluted with water. It was extracted with ether. The extract was washed with satd. aqueous sodium bicarbonate, water, and dried over magnesium sulfate. After evaporation of the solvent, a residue was added with benzene–hexane to yield 6.31 g of **54**, mp 121.5—123 °C.

IR (KBr): 1730 (s), 1595 (m), 1355 (s), 1175 (s), 970 (s), 845 (s), and 755 (m) cm^{-1}.

Found: C, 68.04; H, 6.01; S, 8.78%. Calcd for $C_{20}H_{20}O_4S$: C, 67.40; H, 5.66: S, 8.98%.

7,8-Benzotricyclo[*3.3.1.*$0^{3,6}$]*nonan-2-ol (55).* A solution of 4.50 g of **54** in 50 ml of dry DMF was added to a suspension of 8.00 g of sodium hydride in 100 ml of dry DMF and a mixture was agitated for 72 hr at 70 °C. After cooling to room temperature, the reaction mixture was diluted with water and extracted with ether. The extract was washed with dilute hydrochloric acid, satd. aqueous sodium bicarbonate, water, and dried over magnesium sulfate. After evaporation of the solvent, a residue was chromatographed on silica gel (Mallinckrodt) and fractions eluted with ether–pentane (1: 1 volume) gave 0.23 g of **55**, mp 95—98 °C.

IR (KBr): 3250 (s), 1030 (s), and 745 (s) cm^{-1}.

Mass spectrum: *m/e* 186 (parent peak).

Found: C, 83.78; H, 7.68%. Calcd for $C_{13}H_{14}O$: C, 83.83; H, 7.58%.

7,8-Benzotricyclo[*3.3.1.*$0^{3,6}$]*nonan-2-one (56).* To a solution of 150 mg of **55** was added 0.5 ml of 8N-Jones' reagent at 0—5 °C and a mixture was stirred for 30 min at the same temperature. After dilution with ether, it was washed with satd. aqueous sodium bicarbonate, water, and dried over magnesium sulfate. Removal of the solvent gave a solid which was sublimed to yield 61 mg of **56**, mp 90 °C (in a sealed tube).

IR (KBr): 1720 (s) and 750 (s) cm^{-1}.

NMR ($CDCl_3$): δ 1.4—1.7 (m, 2H), 2.30 (m, 1H), 2.70 (m, 3H), 3.82 (m, 2H), and 7.12 (s, 4H).

Mass spectrum: *m/e* 184 (parent peak).

Found: C, 84.80; H, 6.54%. Calcd for $C_{13}H_{12}O$: C, 84.75; H, 6.57%.

Peptides Containing Aminophosphonic Acids. III. The Synthesis of Tripeptide Analogs Containing Aminomethylphosphonic Acid

Kiyoshi YAMAUCHI, Yasuhiro MITSUDA, and Masayoshi KINOSHITA
Department of Applied Chemistry, Osaka City University, Sumiyoshi-ku, Osaka 558
(Received May 22, 1975)

A synthetic method for tripeptide analogs containing aminomethylphosphonic acid has been described.

Since β-aminoethylphosphonic acid was discovered from marine organisms,[1] human beings, *etc.*,[2] its potential biological roles have been investigated actively; the results have suggested the occurence of the compound in lipid[3] as well as in peptide.[4] These aspects of an aminophosphonic acid have stimulated the study of the synthesis of peptides containing aminophosphonic acid;[5] we ourselves reported previously the first attempt at the preparation of a tripeptide containing aminomethylphosphonic acid in the center.[6]

In the present paper, we wish to describe the synthesis of tripeptide analogs containing more than one aminomethylphosphonic acid unit. Unlike an amino acid, a phosphonic acid group of aminophosphonic acid must be converted to the phosphonochloridate group in order to couple with an amino group of amino acid or aminophosphonic acid.

Thus, diethyl phthalimidomethylphosphonate (I), which could be easily prepared by the reaction of *N*-bromomethylphthalimide with triethyl phosphite, was chlorinated with a slight excess of phosphorus pentachloride to the corresponding phosphomonochloridate (II). On the other hand, Compound (I) was treated with one equivalent of hydrazine in ethanol at room temperature to generate diethyl aminomethylphosphonate (III) in a 70% yield. The chloride (II) was then allowed to react with the amine (III), affording a phosphorus analog of the dipeptide (IV) in a fairly good yield. The further extension of IV by aminomethylphosphonic acid was performed by the dephthalylation of IV with hydrazine to the corresponding amine

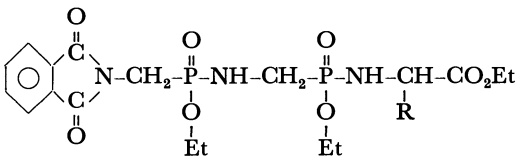
IX: R=CH_3



X: R=H
XI: R=CH_3

(V), followed by a reaction with II to provide a tripeptide analog (VI). Compound (V) was coupled also with phthalylglycine by means of dicyclohexylcarbodiimide to form VII. Similarly, dipeptides (VIII and IX) could each be elongated by one aminomethylphosphonic acid unit to tripeptide analogs (X and XI).

The above successive processes enable us to synthesize the higher analogs of peptides containing aminophosphonic acid; our studies in this direction are continuing.

Experimental

The infrared spectra (IR) were measured on a Jasco Model IR-G spectrometer. The nuclear magnetic resonance spectra (NMR) were recorded with a Hitachi-Perkin Elmer R-20 spectrometer, with a dilute solution in deuteriochloroform and tetramethylsilane as the internal standard.

Preparation of O-Ethyl Phthalimidomethylphosphonochloridate (II). Compound (I, 4.34 g, 0.0146 mol) was refluxed with phosphorus pentachloride (3.06 g, 0.0147 mol) in benzene (50 ml) for 15 hr. The light-boiling substances were distilled out from the reaction mixture under reduced pressure to give a slightly yellow liquid, which, upon standing at room temperature, solidified as crystals; 3.58 g (85%) (tetrahydrofuran-ether); mp 92—94 °C; IR ($CHCl_3$); 1780 (w), 1725 (s), 1600 (w), 1385 (s), 1300 (m), 1250 (m), and 720 (m) cm^{-1}; NMR: τ 1.8 (m, 4, phthalyl), 5.40 (d, 2, $C\underline{H}_2P$), 5.50 (m, 2, $POC\underline{H}_2$), and 8.55 (qua, 3, $C\underline{H}_3$).

Found: C, 46.21; H, 4.03; N, 5.10; Cl, 12.76%. Calcd for $C_{11}H_{11}ClNO_4P$: C, 45.93; H, 3.85; N, 4.87; Cl, 12.33%.

Preparation of Diethyl Aminomethylphosphonate (III). A mixture of diethyl phthalylimidomethylphosphonate (I, 4.34 g, 0.0146 mol)[6] in ethanol (30 ml) and hydrazine hydrate (100%, 1.2 ml) was kept at room temperature overnight and then refluxed for 2 hr. The resulting phthalyl hydrazide was removed by filtration, and the filtrate was concentrated to give diethyl aminomethylphosphonate as a light-yellow liquid; 1.7 g (70%); IR (neat): 3300 (s), 2820 (w), 1600 (s), 1505 (m), 1195 (s), and 1005 (s) cm^{-1}; NMR: τ 5.87 (qua, 4, $2OC\underline{H}_2$), 6.75 (s, 2, $N\underline{H}_2$), 7.02 (d, 2, $C\underline{H}_2P$) and 8.70 (t, 6, $2C\underline{H}_3$). A subsequent purification by distillation under reduced pressure resulted only in decomposition. Therefore, III was utilized for the next reaction without further purification.

Preparation of Peptide Analogs (IV.) A THF solution of II (50 ml) was added, drop by drop, to an ice-cooled chloroform solution (50 ml) of a mixture of the amine (III) and triethylamine (4 ml) over a 15-min period; the solution was then stirred at room temperature for 10 hr. After the subsequent removal of the triethylammonium chloride, the solution was concentrated. The residue was dissolved in chloroform (100 ml), and the solution was washed with saturated sodium hydrogen carbonate, and water and then dried with Drierite. The evaporation of the solvent and the recrystallization of the residue from THF-diethyl ether afforded white crystals of IV; 3.44 g (56%); 108—109 °C; IR (KBr): 3350 (w), 3100 (w), 1770 (w), 1720 (s), 1410 (m), 1200 (s), 1020 (s), 960 (m), and 720 (m) cm^{-1}; NMR: τ 2.15 (m, 4, phthalyl), 5.60—6.10 (m, 6, 3 $OC\underline{H}_2$), 5.90 (d, 2, PHT-$C\underline{H}_2$), 6.60 (s, 2, NH-$C\underline{H}_2$-P), 7i70 (t, 6, $2C\underline{H}_3$), and 8.72 (t, 3, $C\underline{H}_3$).

Found: C, 45.49; H, 5.58; N, 6.62%. Calcd for $C_{16}H_{24}N_2O_7P_2$: C, 45.93; H, 5.79; N, 6.70%.

VI. Dipeptide (IV, 1.25 g, 0.0030 mol) in ethanol (15 ml) was first treated with hydrazine hydrate (0.3 ml) to give its free amine (V) as a yellow viscous liquid; IR (neat): 3170 (m), 2930 (m), 1745 (s), 1655 (m), 1480 (w), 1200 (s), 1035 (s) and 680 (w); NMR: τ 5.90 (qua, 2, $COC\underline{H}_2$), 5.94 (qua, 2, $POC\underline{H}_2$), 6.5 (b, 2, $N\underline{H}_2$), 8.68 (t, 3, CH_3), 8.65 (t, 3, $C\underline{H}_3$). The amine (V) was subsequently allowed to react with II (0.89 g, 0.0031 mol) in the presence of triethylamine (1.5 ml) in a manner similar to that mentioned above, thus giving 0.53 g (32%) of VI; mp 136—138 °C (THF-diethyl ether); IR (KBr): 3350 (w), 3150 (w), 1770 (w), 1710 (s), 1410 (m), 1305 (w), 1220 (s), 1030 (s), 960 (s), 830 (m), and 720 (m) cm^{-1}; NMR: τ 2.18 (m, 4, phthalyl), 5.60—6.10 (m, 8, $4OC\underline{H}_2$), 5.90 (d, 2, PHT-$C\underline{H}_2$), 6.30—6.80 (m, 6, $2NC\underline{H}_2P$, and 2N$\underline{H}$), 8.70 (t, 6, $2C\underline{H}_3$), and 8.72 (t, 6, $2C\underline{H}_3$).

Found: C, 40.90; H, 5.69; N, 7.79%. Calcd for $C_{19}H_{32}N_3O_9P_3$: C, 41.44; H, 5.60; N, 7.71%.

VII. The amine (V), which was obtained *via* the dephthalylation of IV (1.34 g, 0.0032 mol), was stirred with phthalylglycine (0.65 g, 0.0032 mol) and DCC (0.68 g, 0.0033 mol) in THF (20 ml) at room temperature overnight. Aqueous acetic acid (40%, 1.5 ml) was then added to the reaction mixture, and the solution was kept at room temperature for 2 hr. The resulting dicyclohexylurea was filtered off, and the filtrate was concentrated. The residue was dissolved in chloroform, and the solution was washed with aqueous sodium hydrogen carbonate and water and dried with Drierite. The subsequent evaporation of the solvent afforded crystals of VII; 0.68 g (45 %); mp 149—150 °C (THF); IR (KBr): 3300 (w), 1770 (w), 1730 (s), 1660 (m), 1420 (s), 1200 (s), 1040 (s), 960 (s), and 710 (w) cm^{-1}; NMR: τ 1.65 (broad s, 1, CON$\underline{H}$), 2.15 (m, 4, phthalyl), 5.53 (s, 2, PHT-$C\underline{H}_2$), 5.5—6.10 (m, 8, $4OC\underline{H}_2$), 6.20—6.80 (m, 5, $2NC\underline{H}_2P$, and PN$\underline{H}$), 8.66 (t, 6, $2C\underline{H}_3$) and 8.69 (t, 3, $C\underline{H}_3$).

Found: C, 45.66; H, 5.73; N, 8.99%. Calcd for $C_{18}H_{27}N_3O_8P_2$: C, 45.48; H, 5.73; N, 8.84%.

X. A solution of the dipeptide (VIII, 1.95 g, 0.0055 mol) in ethanol (30 ml) was dephthalylated with hydrazine hydrate (0.4 ml) at room temperature overnight to give the corresponding amine through a procedure similar to that described in the preparation of III. The amine in THF (50 ml) was then added, drop by drop, to the chloride (II, 1.58 g, 0.0055 mol) in chloroform (50 ml), which had been precooled in an ice-water bath. After the mixture has been stirred further at room temperature overnight, it was processed in a manner essentially similar to that used in the preparation of IV, thus producing X; 0.56 g (22%); mp 159—160 °C (THF); IR (KBr): 3400 (w), 3150 (m), 2950 (w), 2900 (w), 1705 (s), 1410 (m), 1300 (m), 1060 (s), 960 (m), 900 (m), 830 (m), and 720 (m) cm^{-1}; NMR: τ 2.22 (m, 4, phthalyl), 5.60—6.10 (m, 9, $OC\underline{H}_2$, $2POC\underline{H}_2$, and PN$\underline{H}$,-$C\underline{H}_2$C) 5.90 (d, 2, PHT-$C\underline{H}_2$), 6.4—6.9 (m, 3, PN$\underline{H}C\underline{H}_2$P), 8.61 (t, 6, $2OC\underline{H}_3$), and 8.66 (t, 3, $C\underline{H}_3$).

Found: C, 45.55; H, 5.59; N, 8.96%. Calcd for $C_{18}H_{27}N_3O_8P_2$: C, 45.48; H, 5.73; N, 8.84%.

XI. The tripeptide analog (XI) was similarly synthesized from IX (1.19 g, 0.0032 mol) and II (0.92 g, 0.0032 mol), using triethylamine (0.7 ml); 0.185 g (12%); mp 140 °C; IR (KBr): 3300 (w), 1770 (w), 1740 (w), 1720 (s), 1405 (m), 1205 (s), 1160 (m), 1040 (s), 955 (m), 900 (w), and 720 (m) cm^{-1}; NMR: τ 2.20 (m, 4, phthalyl), 5.6—6.4 (m, 8, $3C\underline{H}_2$, and N$\underline{H}C\underline{H}C\underline{H}_3$), 6.4—6.7 (m, 3, N$\underline{H}C\underline{H}_2$P), 5.90 (d, 2, PHT-$C\underline{H}_2$), 8.56 (d, 3, $CHC\underline{H}_3$), 8.70 (t, 6, $2OC\underline{H}_3$), and 8.73 (t, 3, $OC\underline{H}_3$).

Found: C, 45.21; H, 5.93; N, 8.62%. Calcd for $C_{19}H_{29}N_3O_8P_2$: C, 45.63; H, 5.97; N, 8.59%.

Reactions between Nucleophiles and Sulfonium Ions Containing Electron-withdrawing Substituents

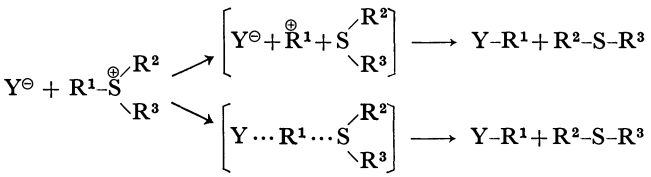
Haruo MATSUYAMA, Hiroshi MINATO, and Michio KOBAYASHI

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya, Tokyo 158

(Received May 27, 1975)

Sulfonium ions containing electron-withdrawing substituents are formed by the reactions between sulfonium ylides and suitable electrophiles. Reactivities of these sulfonium ions ($MeR\overset{+}{S}-CX(CO_2Me)_2$) with nucleophiles ($Y^-$) are investigated. The products found are those of 1) C-attack ($MeSR+YCX(CO_2Me)_2$), 2) Me-attack ($MeY+RSCX(CO_2Me)_2$) and 3) R-attack ($RY+MeSCX(CO_2Me)_2$). When R is (+)-2-octyl and Y^- is bromide ion, the RY found is (−)-2-octyl bromide with 59% optical purity. The mechanism of these reactions are discussed.

It has been shown that the reactions between trialkylsulfonium ions and nucleophiles yielding sulfides and alkylated nucleophiles have features different from ordinary S_N1, S_N2 or competitive S_N1-S_N2 reactions on carbon atoms.



In ordinary S_N2 reactions on carbon atoms (for instance, the leaving groups are halides), the relative reactivities of benzyl and methyl compounds are not much different from unity,[1] whereas benzylation predominates in the reaction of dimethyl-1-phenylethylsulfonium ion with nucleophiles.[2] When di-*t*-butylmethylsulfonium ion reacts with methyl sulfide, exclusive *t*-butylation takes place with no methylation accompanied.[3] Thus when sulfides are leaving groups, the behavior of the substitution are occasionally quite different from that with halides or ammonium ions as leaving groups. No comprehensive explanations have been proposed yet.

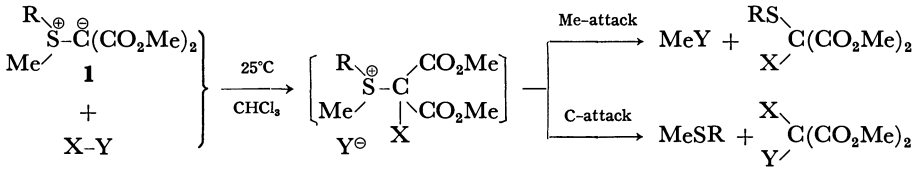
In an attempt to understand the reactions between sulfonium ions and nucleophiles, the reactivities of the sulfonium ions containing electron-withdrawing substituents have been investigated, and the results are described in this paper.

Results and Discussion

Sulfonium ions containing electron-withdrawing substituents were prepared by the reaction between sulfonium ylides and suitable electrophiles.

When sulfonium bis(methoxycarbonyl)methylide (**1**) was mixed in chloroform with Br–Br, Cl–Cl, PhS–Cl, PhS–Br, MeS–Br or H–Br, they reacted instantaneously at room temperature. Usually it was not possible to

Table 1. Reactions of sulfonium ions with nucleophiles



1	R	X	Y	Products (mol%) Me-attack MeY	Me-attack $(RS)XC(CO_2Me)_2$	C-attack MeSR	C-attack $XYC(CO_2Me)_2$
1a	Me	Br	Br	94	99	0	0
		Cl	Cl	95	84	0	0
		H	Br	100	100	0	0
		PhS	Cl	84	85	0	0
		PhS	Br[a]	92	64	0	0
		MeS	Br[b]	(25)	0	75	84

a) Determined from its methyl singlet absorption. b) The CO_2Me (δ 3.77—3.86, broad singlet) absorptions of (RS)XCQ$_2$, (MeS)XCQ$_2$ and XYCQ$_2$ usually could not be resolved. The amount of (MeS)XCQ$_2$ was determined from its MeS singlet, and that of XYCQ$_2$ was estimated by assuming the equimolar formation of MeSR and XYCQ$_2$. Then the amount of (RS)XCQ$_2$ could be calculated. c) Q=CO_2Me. d) The amounts of $PhCH_2Y$ (or $MeSCH_2Y$) were determined from its singlet near 4.50 ppm. The amounts of other RY's were estimated from the assumption of equimolar formation of RY and (MeS)XCQ$_2$ (determined from its MeS singlet).

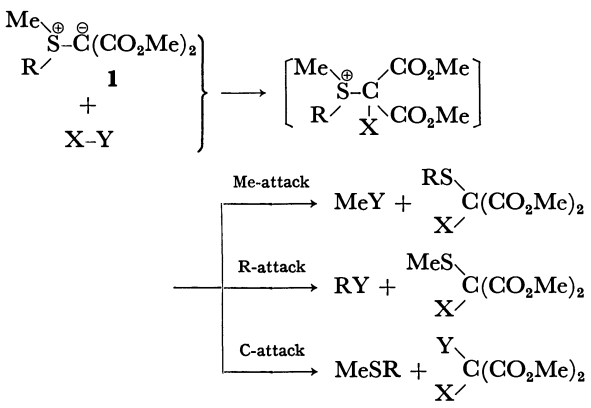
isolate the sulfonium salts. It was possible to isolate a white solid sulfonium salt from the reaction between **1a** (R=Me) and HBr; they decomposed when they were dissolved in chloroform and allowed to stand at room temperature for 5 hrs. The products of the reaction of **1a** (R=Me) and **1b** (R=Ph) with several electrophiles are listed in Table 1.

When R in **1** is an alkyl group, competitive S_N2 attacks on the methyl and alkyl groups are expected. Ylide **1** with various alkyl groups was allowed to react with X—Y, and the products are shown in Table 2.

The results shown in Tables 1 and 2 can be summarized as follows. The ylides and electrophiles react and form sulfonium ions and anions $Y^{\ominus}$, which further react in three different ways (namely, Me-attack, R-attack and C-attack).

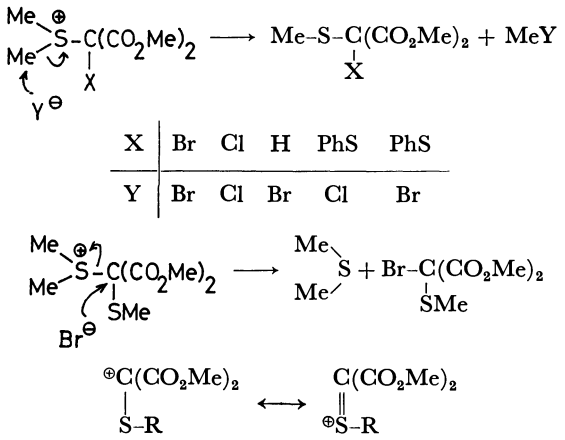
The course of the reaction depends upon the structure of the sulfonium ion (R and X) and the nucleophile $Y^{\ominus}$.

1) When R is Me, methyl attack of $Y^{\ominus}$ predominates



except one case, in which X is MeS.

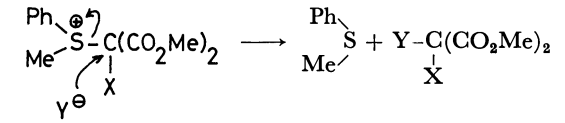
When X is MeS, Me_2S group easily leaves from $Me_2\overset{\oplus}{S}-C(SMe)(CO_2Me)_2$; it is known that R—S groups can stabilize the adjacent carbonium ion by resonance effect as shown below.[4]



X	Br	Cl	H	PhS	PhS
Y	Br	Cl	Br	Cl	Br

When X is PhS, such resonance effect is not great enough to help the elimination of Me_2S.

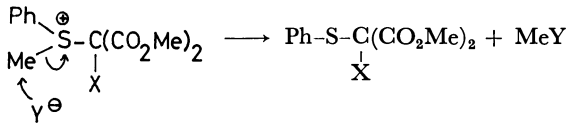
2) When R is Ph, and X is MeS or PhS, the elimination of PhSMe and the apparent C-attack of $Y^{\ominus}$ predominate.



X	PhS	PhS	MeS
Y	Cl	Br	Br

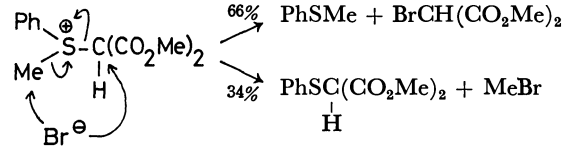
Apparently PhSMe is a better leaving group than Me_2S,[5] and even when X is PhS (a poorer resonance-stabilizing group), the elimination of PhSMe takes place readily.

3) When X is Br or Cl, the main reaction is methyl attack of $Y^{\ominus}$ and RSMe elimination is not observed.



It is reasonable that the carbon atom containing three electron-withdrawing groups (two CO_2Me's and one halogen) does not allow the RSMe elimination resulting in the formation of a carbonium ion.

4) When R=Ph and X=H, both the RSMe elimination and the methyl attack of $Y^{\ominus}$ take place.

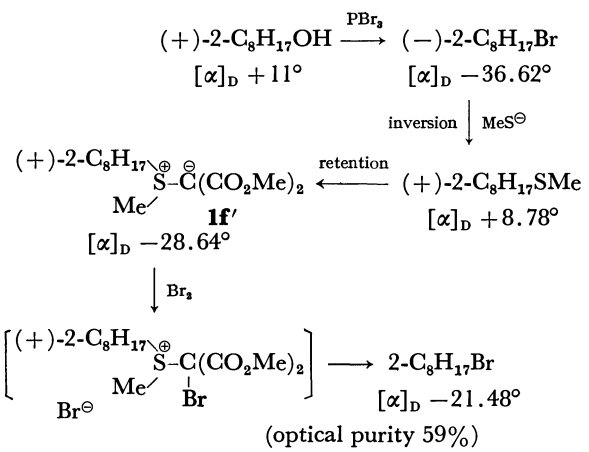


It is interesting to note that when one of the substituents is benzyl or methylthiomethyl group, the reaction is exclusive benzylation or methylthiomethylation of the nucleophile with no accompanying methylation. The ratio between the yields of methylated and alkylated products are calculated and summarized in Table 3. They are quite different from what are expected for ordinary S_N2 reactions on carbon. For instance, the relative reactivities of alkyl bromides with bromide anion in acetone at 25 °C are Me 1.0, Et 0.013, *i*-Pr 0.0086, and $PhCH_2$ 1.0.[6] The remarkable feature in the results shown in Table 3 is that the reactivity of methyl group is comparable to that of ethyl group, smaller than that of isopropyl group, and far smaller than that of benzyl group.

The relative reactivities of phenylmethylalkylsulfonium perchlorates with iodide anion in acetone at 50 °C are Me 1.0, Et 0.20, *n*-Pr 0.16, and *i*-Pr 0.05, and apparently these reactions involve S_N2 attack on the sulfonium alkyl groups.[7]

Table 3 shows that benzyl and methylthiomethyl are far more reactive than methyl group. These results suggest that these reactions may involve an S_N1-like process. In the reactions of **1** with hydrogen bromide, however, the reactivity of isopropyl group is smaller than that of methyl group. Thus, *sec*-alkyl groups are more reactive than methyl group only when the α atom in X is a hetero atom such as Br, Cl or S.

Reversible bond-formation between sulfonium sulfur atom and an anion is a possible process, since evidence for the formation of a tetracovalent sulfur intermediate from a sulfonium ion and chloride ion has been presented,[8] and many examples of tetracovalent sulfur intermediates were described in a recent review.[9] In an attempt to elucidate the mechanism of these reactions, a sulfonium ylide with optically active (+)-2-C_8H_{17}



Scheme.

Table 3. Relative reactivities of alkyl groups of sulfonium ions with nucleophiles[a]

Sulfonium ion	Nucleophile	Relative reactivity, k_R/k_{Me}						
		Me	Et	*n*-Bu	*i*-Pr	*sec*-C_8H_{17}	$PhCH_2$	$MeSCH_2$
$MeRS^{\oplus}$-$BrC(CO_2Me)_2$	$Br^{\ominus}$	(1.0)	0.61	0.23	3.79	3.76	∞	∞
$MeRS^{\oplus}$-$ClC(CO_2Me)_2$	$Cl^{\ominus}$	(1.0)	0.65	—	2.91	—	∞	∞
$MeRS^{\oplus}$-$(PhS)C(CO_2Me)_2$	$Cl^{\ominus}$	(1.0)	0.85	—	4.17	—	∞	∞
$MeRS^{\oplus}$-$HC(CO_2Me)_2$	$Br^{\ominus}$	(1.0)	0.15	0.18	0.21	—	∞	∞

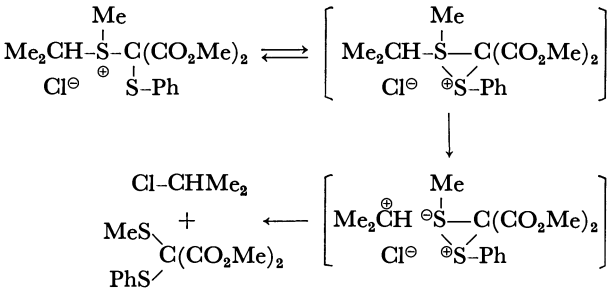
a) Relative reactivities are the ratio RY/MeY, calculated from Table 2.

group (**1f'**) was prepared and its reaction with bromine was examined according to the Scheme shown.

The reactivity of 2-C_8H_{17} group is about 4 times that of methyl group. The results of optical measurements show that the main course of the reaction is the inversion at the asymmetric carbon accompanied by some racemization.

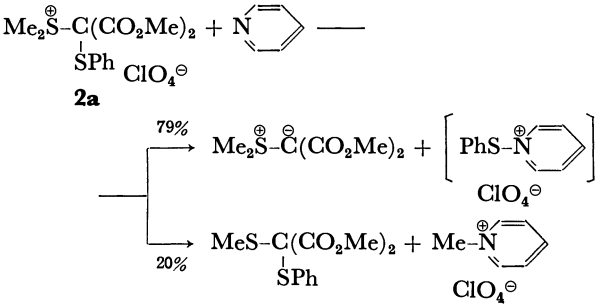
If a sulfurane intermediate is produced by the bond-formation between the sulfonium sulfur atom and bromide ion, the collapse of the sulfurane should yield (+)-2-C_8H_{17}–Br with retention of configuration. The optical data show that such sulfurane intermediates are probably not formed in the reaction between **1f'** and bromine.

It is of interest that $k_{i\text{-Pr}}$ is smaller than k_{Me} in the reactions between MeRS⊕—Ph $ClO_4^\ominus$ and $I^\ominus$,[7] and $k_{i\text{-Pr}}$ is greater than k_{Me} in the reactions between MeRS⊕—CX-$(CO_2Me)_2$ and $Y^\ominus$ only when the α atom in X is a hetero atom. One possible explanation is the formation of the following intramolecular sulfurane.



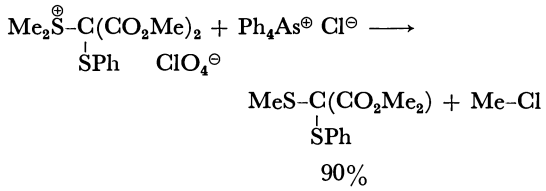
A similar intramolecular sulfurane has been proposed between a sulfonium ion and the neighboring nitro group.[10]

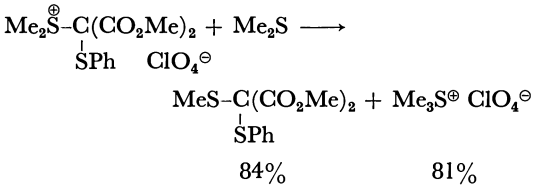
If the PhS group interacts with the solfonium sulfur atom, some positive charge is expected on the PhS sulfur atom. In order to check the possibility, sulfonium ion **2a** was prepared, and allowed to react with pyridine.



The product of the nucleophilic attack of pyridine on the PhS sulfur atom was found in 79% yield. These results suggest that the PhS sulfur atom has a partial positive charge in agreement with the above hypothesis.

Reactions of **2a** with $Cl^\ominus$ or Me_2S gave the results consistent with those shown in Table 1.





The results of the reaction between optically-active **1f'** and Br_2 may be rationallized by assuming some elongation of the R-S⊕ bond, development of positive charge on R, and the attack of $Br^\ominus$ taking place mainly from the backside.

Ōki and Kobayashi studied the reaction between (+)-α-phenylpropyl methyl sulfide and methanesulfenyl chloride, and found that $Cl^\ominus$ attacked the intermediate sulfonium ion, PhEtC*H—S⊕Me(SMe), forming (−)-PhEtCH—Cl with 70% inversion and 30% racemization.[11]

Experimental

Materials. Sulfonium bis(methoxycarbonyl)methylides **1a—h** were prepared by copper salts-catalyzed decomposition of dimethyl diazomalonate in large excess sulfides[12] and by transylidation.[13] Benzenesulfenyl chloride (bp 50 °C/2 mmHg) was synthesized by the methods described in the literature.[14] Benzenesulfenyl bromide (or methanesulfenyl bromide) was prepared by mixing equimolar amounts of phenyl disulfide (or methyl disulfide) and bromine in carbon tetrachloride. Sulfonium salt **2a** was prepared by dropwise addition of a CCl_4 solution of benzenesulfenyl chloride (1.45 g, 10 mmol) to a nitromethane solution of **1a** (1.94 g, 10 mmol) and silver perchlorate (2.07 g, 10 mmol) at 0 °C. Yield, 3.6 g (90%); recrystallized from ethanol; mp 105—106 °C; IR (KBr), 1740 cm^{-1} (ν_{CO}); NMR (DMSO-d_6), δ 7.60 (5H, s, PhS), 3.93 (6H, s, CO_2Me) and 3.20 (6H, s, $Me_2\overset{\oplus}{S}$–). Found: C, 38.26; H, 4.25%. Calcd for $C_{13}H_{17}O_8ClS_2$: C, 38.96; H, 4.27%. This salt partially decomposed when it was allowed to stand at room temperature for several days.

Reactions of Ylides 1a or 1b with Bromine. (a) When Br_2 (1.65 g, 10.3 mmol) was added to a chloroform (18 g) solution of **1a** (1.97 g, 10.0 mmol), they reacted instantaneously, and the solution turned from red to colorless. The ylide carbonyl absorptions (1630 and 1670 cm^{-1}) were replaced by the ester absorption (1730 cm^{-1}). The amounts of the products were determined by NMR spectroscopy with nitromethane as an internal standard. The low-boiling fractions from the mixture were trapped in liquid nitrogen, and the presence of MeBr was shown by NMR (δ 2.62, s). The high-boiling fractions were chromatographed (Florisil), and the oils obtained from the benzene eluate were found to be Br(MeS)$C(CO_2Me)_2$ (2.54 g, 9.9 mmol, 99%; IR (neat), 1740 cm^{-1} (ν_{CO}); NMR (CCl_4), δ 3.86 (6H, s, CO_2Me) and 2.22 (3H, s, MeS). Found: C, 27.76; H, 3.68%. Calcd for $C_6H_9O_4BrS$: C, 27.29; H, 3.44%). (b) A mixture of a $CHCl_3$ (10 g) solution of **1b** (1.25 g, 5.0 mmol) and Br_2 (0.80 g, 5.0 mmol) gave MeBr (δ 2.62, s) and Br(PhS)$C(CO_2Me)_2$ (liquid, 1.37 g, 0.43 mmol, 86%; IR (neat), 1740 cm^{-1} (ν_{CO}); NMR (CCl_4), δ 7.30—7.60 (5H, m, PhS) and 3.76 (6H, s, CO_2Me). Found: C, 41.26; H, 3.56%. Calcd for $C_{11}H_{11}O_4BrS$: C, 41.40; H, 3.47%).

Reactions of Ylides 1a or 1b with Chlorine. (a) The reaction between a $CHCl_3$ (10 g) solution of **1a** (1.0 g, 5.14 mmol) and a CCl_4 solution of Cl_2 (0.42 g, 6.0 mmol) was exothermic and instantaneous, and gave MeCl (δ 3.0, s) and Cl(MeS)C-$(CO_2Me)_2$ (liquid, 0.92 g, 4.34 mmol, 84%; IR (neat), 1740

cm^{-1} (ν_{CO}); NMR ($CDCl_3$), δ3.88 (6H, s, CO_2Me) and 2.25 (3H, s, MeS). Found: C, 32.75; H, 3.82%. Calcd for $C_6H_5O_4ClS$: C, 32.82; H, 4.13%).

(b) In a similar manner, a mixture of a $CHCl_3$ (19 g) solution of **1b** (2.61 g, 10.3 mmol) and a CCl_4 solution of Cl_2 (0.78 g, 11.0 mmol) gave MeCl (δ 2.97, s) and $Cl(PhS)C(CO_2Me)_2$ (liquid, 2.49 g, 9.09 mmol, 88%; IR (neat), 1740 cm^{-1} (ν_{CO}); NMR (CCl_4), δ 7.30—7.60 (5H, m, PhS) and 3.68 (6H, s, CO_2Me). Found: C, 48.17; H, 3.92%. Calcd for $C_{11}H_{11}O_4ClS$: C, 48.10; H, 4.04%). Methyl phenyl sulfide (PhSMe, δ 2.49, s) was not found.

Reactions of Ylides ***1a*** *or* ***1b*** *with Benzenesulfenyl Chloride.*

(a) When PhSCl (1.60 g, 11.1 mmol) was added to a chloroform (15 g) solution of **1a** (1.98 g, 10.3 mmol), they reacted instantaneously, and the solution turned from red to colorless. The amounts of the products were determined by NMR spectroscopy with nitromethane as an internal standard. From the low-boiling fraction trapped in liquid nitrogen, methyl chloride was identified by NMR (δ 2.97, s). The high-boiling fraction solidified at room temperature, and recrystallization from benzene yielded white crystals of $MeS(PhS)C(CO_2Me)_2$. 2.51 g (8.77 mmol, 85%): mp 71—72 °C; IR (KBr), 1730 cm^{-1} (ν_{CO}); NMR (CCl_4), δ 7.30 (5H, s, PhS), 3.64 (6H, s, CO_2Me) and 2.15 (3H, s, MeS). Found: C, 50.52; H, 4.93%. Calcd for $C_{12}H_{14}O_4S_2$: C, 50.33; H, 4.93%.

(b) In a similar manner, a mixture of a $CHCl_3$ (9 g) solution of **1b** (1.75 g, 6.87 mmol) and PhSCl (1.01 g, 7.0 mmol) gave PhSMe (from hexane eluates; 0.71 g, 5.75 mmol, 84%), $Cl(PhS)C(CO_2Me)_2$ (oil from benzene eluates; 1.66 g, 6.05 mmol, 88%).

Reactions of Ylides ***1a*** *or* ***1b*** *with Benzenesulfenyl Bromide.*

(a) A mixture of a $CHCl_3$ (14 g) solution of **1a** (1.95 g, 10.0 mmol) and a CCl_4 (6 g) solution of PhSSPh (1.1 g, 5.0 mmol) and bromine (0.8 g, 5.0 mmol) reacted instantaneously, and gave MeBr (δ 2.64, s) and MeS (PhS) C $(CO_2Me)_2$ (1.83 g, 6.4 mmol, 64%; mp 71—72 °C).

(b) A mixture of a $CHCl_3$ (10 g) solution of **1b** (2.54 g, 10.0 mmol) and a CCl_4 (10 g) solution of PhSSPh (1.1 g, 5.0 mmol) and bromine (0.8 g, 5.0 mmol) gave PhSMe (δ 2.49, from hexane eluates; 0.81 g, 6.50 mmol, 65%) and $Br(PhS)C(CO_2Me)_2$ (oil from benzene eluates; 3.09 g, 7.70 mmol, 97%).

Reactions of Ylides ***1a*** *or* ***1b*** *with Methanesulfenyl Bromide.*

(a) In a similar manner, a mixture of a $CHCl_3$ (10 g) solution of **1a** (1.92 g, 10 mmol) and a CCl_4 (9 g) solution of MeSSMe (0.42 g, 5.0 mmol) and bromine (0.8 g, 5.0 mmol) reacted instantaneously, and gave Me_2S (δ 2.10, s, 75%), MeBr (δ 2.64, s, 25%; produced from the reaction of free bromine) and $Br(MeS)C(CO_2Me)_2$ (oil from benzene eluates; 2.24 g, 8.40 mmol, 84%).

(b) A mixture of a $CHCl_3$ (10 g) solution of **1b** (1.90 g, 10 mmol) and a CCl_4 (8 g) solution of MeSSMe (0.42 g, 0.5 mmol) and bromine (0.8 g, 5.0 mmol) gave PhSMe (δ 2.49, s; from hexane eluates; 1.0 g, 8.0 mmol, 80%), MeBr (δ 2.64, s, 20%; produced from the reaction of free bromine) and $Br(MeS)C(CO_2Me)_2$ (oil from benzene eluates; 2.21 g, 8.30 mmol, 83%).

Reactions of Ylides ***1a*** *or* ***1b*** *with Hydrogene Bromide.* (a) When hydrogene bromide gas was bubbled through a $CHCl_3$ solution of **1a**, its NMR spectrum showed the formation of a sulfonium salt ($Me_2\overset{\oplus}{S}-$, δ 3.42, s). Evaporation of the solvent yielded white solids (NMR ($CHCl_3$), δ 4.01 (6H, s, CO_2Me) and 3.42 (6H, s, $Me_2\overset{\oplus}{S}-$)). When they were dissolved in $CHCl_3$ and allowed to stand for 5 hr at room temperature, the NMR spectrum showed the quantitative formation of MeBr (δ 2.63, s) and $MeSCH(CO_2Me)_2$ (δ 2.25, s).

(b) When a CCl_4 solution of hydrogen bromide was added to a $CHCl_3$ solution of **1b**, they reacted instantaneously, and it was not possible to isolate the sulfonium salt. The amounts of MeBr (δ 2.62, s, 34%) and PhSMe (δ 2.46, s, 66%) were determined by use of nitromethane as an internal standard.

Reactions of Ylides ***1c—h*** *with Halogens, PhSCl or HBr.*

The $CDCl_3$ solutions of Ylides **1c—h** (0.7—1.0 mmol) and X—Y (0.8—1.1 mmol) containing nitromethane (internal standard, 50 μl, 0.79 mmol) were let to react in NMR tubes at 25 °C, and the amounts of the reaction products were determined from their singlet methyl absorption by NMR spectroscopy (see Table 2); Me–Br (δ 2.62—2.64), Me–Cl (2.90—2.98), MeSEt (2.05—2.12), MeSBu-*n* (2.07), MeSPr-*i* (2.10), $MeSC_8H_{17}$-*sec* (1.99), $MeSCH_2Ph$ (1.92), $MeSCH_2$-SMe (2.10), $Br(MeS)C(CO_2Me)_2$ (2.23), $Cl(MeS)C(CO_2Me)_2$ (2.23), $MeS(PhS)C(CO_2Me)_2$ (2.19—2.20) and $MeSCH(CO_2Me)_2$ (2.25).

*Synthesis of (+)-2-Octylmethylsulfonium Bis(methoxycarbonyl)-methylide (***1f′***).* (−)-2-Octyl bromide was prepared from the reaction between (+)-2-octanol (purchased from Fluka, $[\alpha]_D$ +11°) (15 g) and PBr_3 (34.8 g) below +5 °C; yield, 13.8 g (62.6%); bp 55 °C/3 mmHg (lit,[15] 61 °C/3 mmHg); $[\alpha]_D^{26.6}$ −36.62° (*c* 8.36, 95% ethanol) (lit,[15] $[\alpha]_D^{25}$ −34.25°).

(+)-2-Octyl methyl sulfide was prepared from the reaction between (−)-2-octyl bromide (11.1 g) and sodium methylmercaptide (20% aq solution, 42 g) in ethanol; yield, 75.0%; bp 84—85.5 °C/10 mmHg; $[\alpha]_D^{26.5}$ +8.78° (*c* 11.8, $CHCl_3$).

Ylide **1f′** was not obtained by copper-catalyzed decomposition of methyl diazomalonate in the sulfide.[12] Therefore, it was prepared by transylidation.[13] A chloroform (11.5 g) solution of **1b** (3.04 g), (+)-2-octyl methyl sulfide (6.0 g) and dimethoxy disulfide (1.3 g; a catalyst) was kept at 40 °C. After 4 days, its NMR spectrum showed the complete disappearance of **1b**. Sulfides and the catalyst were distilled off under reduced pressure at 55 °C/3 mmHg, and the NMR spectrum of the residual oil showed that it is ylide **1f′**; yield, 2.5 g (72%); IR (neat), 1620 and 1670 cm^{-1} (ν_{CO}); NMR ($CDCl_3$), δ 3.74 (6H, s, CO_2Me), 2.88 (3H, s, $Me\overset{\oplus}{S}-$) and 0.88—1.44 (16H, m, 2-octyl group); $[\alpha]_D^{28.2}$ −28.64° (*c* 10.5, $CHCl_3$).

Reactions of Ylide ***1f′*** *with Bromine.* A CCl_4 (13.8 g) solution of Br_2 (1.38 g, 8.62 mmol) was added drop by drop to a $CHCl_3$ (21 g) solution of **1f′** (2.5 g, 8.62 mmol). The completion of the reaction was ascertained by the IR spectrum (ν_{CO}, 1730 cm^{-1}). The NMR spectrum showed the formation of 2-octyl bromide (79.3%) and methyl bromide (20.7%). After the reaction mixture was concentrated under reduced pressure, the residue was subjected to column chromatography (Florisil), and the *n*-hexane eluates yielded 2-octyl bromide. Its purity was checked by gas chromatography. $[\alpha]_D^{25.2}$ −21.48° (*c* 5.96, 95% ethanol).

Reactions of Sulfonium Ion ***2a*** *with Nucleophiles.* (a) A nitromethane solution of **2a** (1.0 mmol) and tetraphenylarsonium chloride (2.0 mmol) was heated at 50 °C for 5 min. After evaporation, the NMR spectrum of the residue (soluble in CCl_4) showed the presence of $MeS(PhS)C(CO_2Me)_2$ (δ 2.20, s, MeS; 90%).

(b) A DMSO-d_6 solution of **2a** (1.0 mmol) and methyl sulfide (1.5 mmol) was placed in an NMR tube at 25 °C. After 4 days, the amounts of trimethylsulfonium salt (δ 2.89, s, $Me_3\overset{\oplus}{S}$; 81%) and $MeS(PhS)C(CO_2Me)_2$ (δ 2.17, s, MeS; 84%) were determined by NMR spectroscopy.

(c) A DMSO-d_6 solution of **2a** (1.0 mmol) and pyridine (2.0 mmol) was placed in an NMR tube at 25 °C. After 2 hr, the amounts of **1a** (δ 2.88, s, $Me_2\overset{\oplus}{S}-$; 79%) and $MeS(PhS)C(CO_2Me)_2$ (δ 2.17, s, MeS; 20%) were determined by NMR spectroscopy.

Reaction of Ylide **1e** *with Methanesulfenyl Chloride.* In an NMR tube a $CDCl_3$ solusion of **1e** (1.0 mmol) and a CCl_4 solution of MeSCl were mixed. Rapid reaction took place, yielding MeSPr-*i* and $Cl(MeS)C(CO_2Me)_2$ quantitatively. The NMR spectrum showed the absence of isopropyl chloride.

Influence of Anhydrous Hydrogen Fluoride on Hen Egg-White Lysozyme. I. Effects on Native Hen Egg-White Lysozyme

Saburo AIMOTO and Yasutsugu SHIMONISHI

Institute for Protein Research, Osaka University, Yamada-kami, Suita, Osaka 565

(Received May 31, 1975)

The influences of anhydrous hydrogen fluoride on the native form of hen egg-white lysozyme under standard conditions of peptide synthesis were investigated by measuring the enzymatic activities of materials recovered from mixtures of anhydrous hydrogen fluoride and hen egg-white lysozyme. The enzymatic activity of hen egg-white lysozyme gradually decreased on incubation with anhydrous hydrogen fluoride at a given temperature. After incubation of the mixture at 0 °C for 60 min, at least three fractions could be separated by gel-filtration on Sephadex G-50. One of these was eluted in the same position as native lysozyme and was fully active enzymatically. Its ultra-violet, and circular dichroism absorptions were identical with those of native lysozyme, and the tetragonal crystals obtained from this fraction could not be distinguished from those of native lysozyme.

The authors are now studying the chemical synthesis of the native form of the well-characterized protein molecule, hen egg-white lysozyme (HEL). At present they are interested in establishing how much of the intact structure of this enzyme is retained after exposure to anhydrous liquid hydrogen fluoride (HF) under usual conditions for peptide synthesis and how much of the original enzyme can be recovered in an intact form after this treatment.

HF was first used in peptide synthesis by Sakakibara *et al.*[1,2] and since then it has been widely used for releasing free peptide, because it does not show any troublesome side reactions with simple protected peptides. However, in the synthesis of complicated polypeptides, it is uncertain whether it can be used to release free polypeptides from protected derivatives without causing side reactions. HF was originally used in studies on the chemistry of peptides and proteins by Katz[3] and Katz *et al.*[3,4] examined its effects on some natural polyepptide hormones, such as insulin and corticotropin, and also on enzymes such as ribonuclease and lysozyme. They reported that the biological activities of these compounds were not irreversibly affected by HF, provided that the temperature of exposure was low (−78 °C) and the exposure time was short (<2 hr). This suggests that a considerable amount of starting material might remain in an intact form during treatment with HF under these conditions. On the other hand, they found that considerable inactivation occurred on exposure to HF at a higher temperature (0—25 °C) and for a longer time (≥2 hr), particularly in the cases of ribonuclease and lysozyme. These findings indicate that highly oriented macromolecules may be considerably affected by prolonged exposure to HF at high temperature. However, unfortunately protecting groups can only be removed from protected complicated polypeptides under these conditions. Since the syntheses of complicated polypeptide hormones and enzymes have recently become of major interest, it will be very valuable to examine the influence of HF on complicated polypeptides or enzymes under conditions generally used for peptide synthesis.

In the present study, the influences of HF on the native form of HEL were investigated in the preliminary studies of the chemical synthesis of HEL. First, the effect of the conditions of HF-treatment on the enzymatic activity of HEL was examined. Second, the attempts were made to isolate intact HEL after treatments of native HEL with HF. The results show the possibility to recover intact HEL from native HEL treated with HF under the conditions generally used for peptide synthesis.

Materials and Methods

Substrates and Reagents. Spray-dried cells of *Micrococcus lysodeikticus* (Lot. No. 21—88—778) were purchased from Seikagaku Fine Biochemicals. Sephadex was purchased from Pharmacia Co. (Uppsala) and hydrogen fluoride was a product of Daikin Ind. Co. (Osaka). Urea of reagent grade was recrystallized from ethanol before use. All other chemicals used were of analytical grade.

Hen Egg-White Lysozyme (HEL). Hen egg-white lysozyme (6 x crystallized Lot. No. 7103) from Seikagaku Fine Biochemicals was used without further purification. It was dissolved in dilute acetic acid, lyophilized and then dried over P_2O_5 *in vacuo*. The freeze-dried powder was used in all experiments.

Treatments of Native HEL with HF. The freeze-dried powder (*ca.* 30 mg) of native HEL was weighed in a Daiflon cylinder of the HF-reaction apparatus.[2] HF (5 ml) was distilled into a cylinder containing HEL previously cooled to −78 °C in a dry-ice/methanol bath. The resulting solution was stirred at 0 °C or 25 °C for the required period. Under these conditions, the start of the reaction period was taken as 30 min after transferring the sample from the bath at −78 °C to that at 0 °C or 25 °C. After a given period, HF was completely removed from the reaction mixture by evaporation *in vacuo*, and the residue of the HF-solution of native HEL was dissolved in M/15 sodium phosphate buffer solution at pH 6.2 (30 ml), and stirred at room temperature for 20—24 hr. Then, its enzymatic activity was assayed.

Enzyme Assays. The specific activity of HEL after treatment with HF was determined by measuring the initial rate of lysis of *Micrococcus lysodeikticus* cells suspended in M/15 sodium phosphate buffer solution at pH 6.2 containing 0.1% sodium chloride at 37 °C using the method of Jolles,[5] with six times recrystallized native HEL as a standard. The extent of lysis was measured spectrophotometrically at 540 nm.

Desalting of Protein. Protein solutions containing various salts were charged on a column of Sephadex G-10 (3×60 cm), and eluted with 0.1M acetic acid. The fractions of eluate with absorption at 280 nm were collected and lyophilized.

Gel-filtration. The lyophilized powder of the material recovered after treatment of native HEL with HF was dis-

solved in a buffer containing 1M acetic acid and 5M urea and charged on a column of Sephadex G-50 (fine, 2.2×95 cm), equilibrated with the same buffer. The column was eluted with the same buffer and the absorption of each fraction at 280 nm was determined.

Ion-Exchange Chromatography. The lyophilized powder obtained after treatment of native HEL with HF was dissolved in a small volume of 0.2M sodium phosphate buffer solution at pH 7.15 and charged on a column of Bio-rex 70 (1.9×54 cm), equilibrated with the same buffer. The absorptions at 280 nm of the fractions eluted with the same buffer were measured and fractions in each peak were combined and lyophilized.

Ultra-violet and Circular Dichroism Absorption Spectra. Ultra-violet absorption spectra were measured using a Hitachi UV-spectrophotometer type-124, equipped with a recording attachment. Circular dichroism spectra were measured in a Jasco automatic spectropolarimeter J-20, equipped with a CD-attachment. $[\theta]_R$ represents the molecular ellipticity based on the mean residue weight. Protein concentration was calculated using the value, $E^{1\%}_{1cm}=23.7$ at 280 nm. The cell length was 1 mm for the range of wavelengths of 220 to 250 nm and 1 cm for those of 290 to 300 nm. The solvent was 0.1M sodium chloride, adjusted to pH 3.0 with hydrochloric acid. Spectra were measured at 25 °C.

Crystallization of HF-Treated HEL. Crystallization was carried out by the method of Berthou and Jolles[6] with some modifications. The lyophilized protein (35 mg) was dissolved in distilled water (0.50 ml), and then first 0.2M acetate buffer solution at pH 4.7 (0.063 ml) and distilled water (0.187 ml) and then 10% sodium chloride solution (0.75 ml) were added. The protein concentration was adjusted to 2.33% and the solution was allowed to stand in a refrigerator at 5 °C for 3 days. Crystals were deposited from solutions of biologically fully active materials.

Results

Treatment of Native HEL with HF. The freeze-dried native HEL was first treated with HF at 0 °C or 25 °C. After a given period of 60 to 240 min, the reaction was stopped by complete evaporation of the HF from the HF-solution of the freeze-dried native HEL. The residue was dissolved in M/15 sodium phosphate buffer solution at pH 6.2 containing 0.1% sodium chloride and after 20—24 hr its lytic activity on *Micrococcus lysodeikticus* was compared with that of standard HEL.

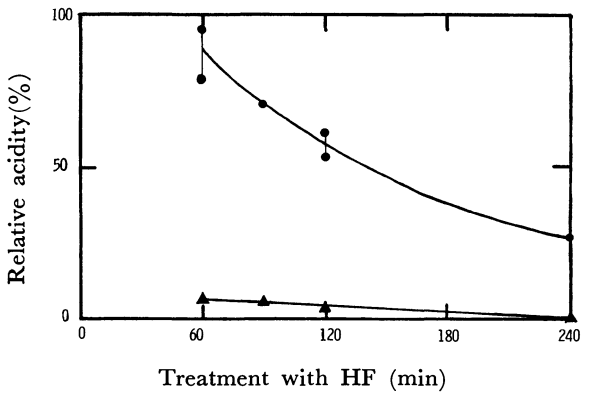

Fig. 1. Relative activity of HF-treated native HEL. The procedure used for treatment of HEL with HF and the method used of enzymatic assay of HF-treated HEL are given in the text.
—●—: treated at 0 °C, —▲—: treated at 25 °C.

The enzymatic activity of the solution of the freeze-dried native HEL treated with HF at 0 °C for 60 min was about 80% of that of standard HEL and decreased gradually on longer treatment. On the other hand, after treatment at 25 °C for 60 min its activity was only 10% of that of standard HEL and after 240 min-treatment it was almost inactive. These results are summarized in Fig. 1.

Gel-Filtration of HF-Treated Native HEL on Sephadex G-50. The material recovered from an HF-solution of the freeze-dried native HEL was desalted on Sephadex G-10 and subjected to chromatography on Sephadex G-50 using buffer solution containing 1M acetic acid and 5M urea. The chromatogram of the material recovered after treatment of the freeze-dried native HEL with HF at 0 °C for 60 min is shown in Fig. 2. These fractions (I, II and III) were separated. The first fraction (I) was eluted in the void voulme, and the

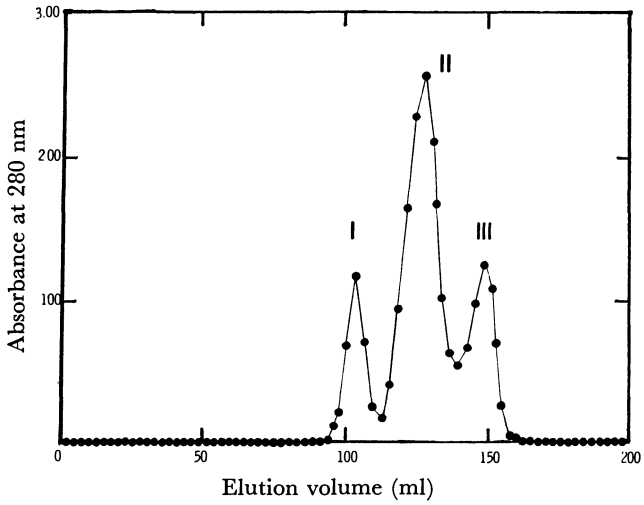

Fig. 2. Gel-filtration of native HEL treated with HF at 0 °C for 60 min on Sephadex G-50 (2.2×95 cm) using buffer containing 1 M acetic acid and 5 M urea. The flow rate was 10 ml per hr.

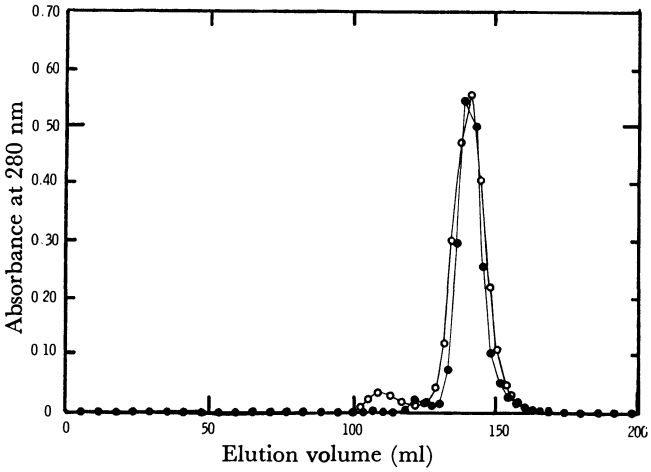

Fig. 3. Rechromatogram of fraction III of Fig. 2 on Sephadex G-50 (2.2×95 cm) using buffer containing 1 M acetic acid and 5 M urea. The flow rate was 10 ml per hr. —●—: fraction III of Fig. 2, —○—: native HEL.

third fraction (III) in the same position as standard native HEL under the same chromatographic conditions. Fraction III was rechromatographed on Sephadex G-50 using buffer containing 1M acetic and 5M urea as shown in Fig. 3. When the freeze-dried native HEL which had been treated with HF under various conditions was subjected to gel-filtration on Sephadex G-50 using buffer containing 1M acetic acid and 5M urea, different chromatograms were obtained depending on the conditions of HF-treatment. On prolongation of the reaction period at a given temperature the amount of fraction II increased and the amount of fraction III decreased. Furthermore, it was found that with a constant reaction period the amount of fraction III decreased on increasing the reaction temperature. Typical chromatograms are shown in Figs. 4 and 5.

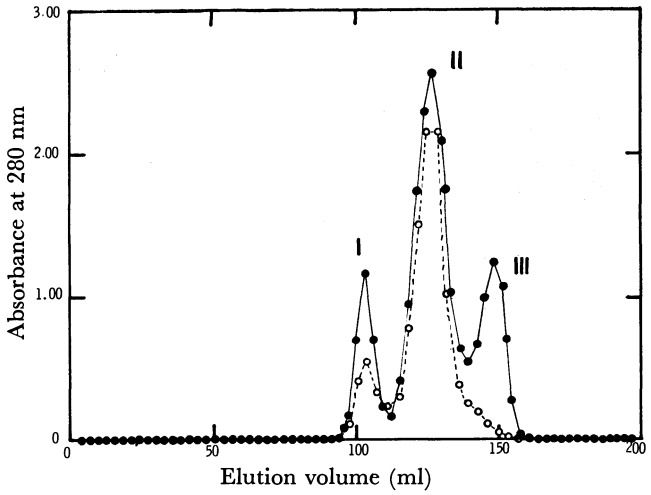

Fig. 4. Gel-filtration of native HEL treated with HF at 0 °C for 60 min (—●—) or 240 min (—○—) on Sephadex G-50 (2.2×95 cm) using buffer containing 1 M acetic acid and 5 M urea. The flow rate was 10 ml per hr.

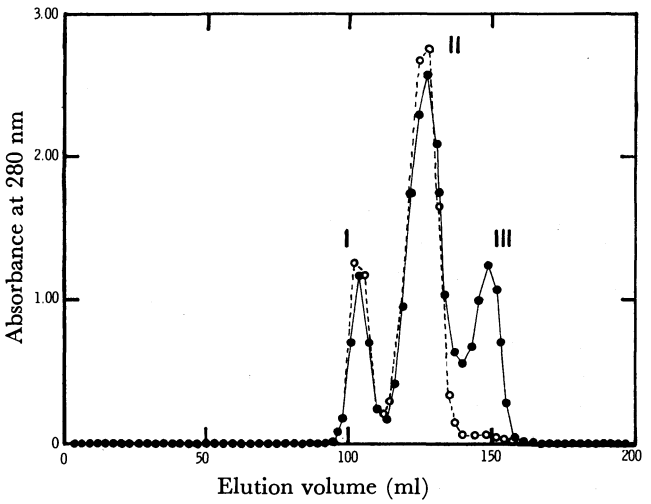

Fig. 5. Gel-filtration of native HFL treated with HF for 60 min at 0 °C (—●—) or 25 °C (—○—) on Sephadex G-50 (2.2×95 cm) using buffer containing 1 M acetic acid and 5 M urea. The flow rate was 10 ml per hr.

Effects of Various Buffers on the Recovery of Fraction III. The freeze-dried native HEL was treated with HF at 0 °C for 60 min and then stood in various buffers at room temperature for 20 hr. Then the solution was desalted and lyophilized and the residues were subjected to gel-filtration on Sephadex G-50. The recovery of fraction III corresponding to native HEL was calculated from its absorbance, as shown in Table 1.

Table 1. Effects of various buffers on the recovery of fraction III from HF-treated native HEL

Sodium phosphate buffer		Average recovery of fraction III
mol concn (M)	pH	(%)
0.067	3.5	46
0.067	6.2	47
0.067	8.0	54
0.1	6.2	49
0.1	8.0	55
0.2	6.2	40

Ion-Exchange Chromatography. The freeze-dried native HEL was treated with HF at 0 °C for 60 min and then chromatographed on Sephadex G-50. The fraction III obtained was subjected to chromatography on Biorex 70 using 0.2M sodium phosphate buffer solution at pH 7.15. This procedure is generally used for purification of crude HEL isolated from natural sources. It was found that fraction III was eluted in the same position as native HEL, as shown in Fig. 6.

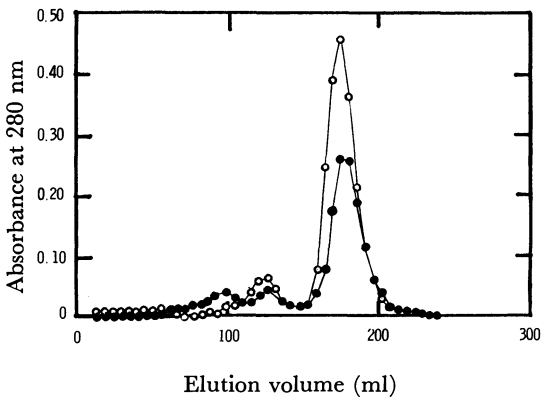

Fig. 6. Ion-exchange chromatogram of HEL on Biorex 70 (1.9×54 cm) using 0.2 M sodium phosphate buffer solution (pH 7.15). The flow rate was 16 ml per hr. —●—: fraction III of Fig. 2, —○—: native HEL.

Enzymatic Activity of the Fractions of HF-Treated Freeze-dried Native HEL. The lytic activities of various fractions of HF-treated freeze-dried native HEL, separated by gel- and ionexchange-chromatographes, were determined relative to that of standard HEL on *Micrococcus lysodeikticus* cell walls. Table 2 shows the

Table 2. Relative activities of fractions I, II, and III

HF-treatment	Fraction I	Fraction II	Fraction III
0 °C, 60 min	0%	45—66%	97—106%
25 °C, 60 min	0	10—15	—

specific activities of fractions I, II and III, separated by gel-filtration on Sephadex G-50. Fraction III consistently showed full specific activity after treatment with HF at 0 °C for 60, 90, 120 or 240 min. The main fraction separated by chromatography of fraction III on Bio-rex 70 (Fig. 6) was also fully active. However, the fraction II's, separated after treatment of the freeze-dried native HEL with HF under different conditions, showed different specific activities.

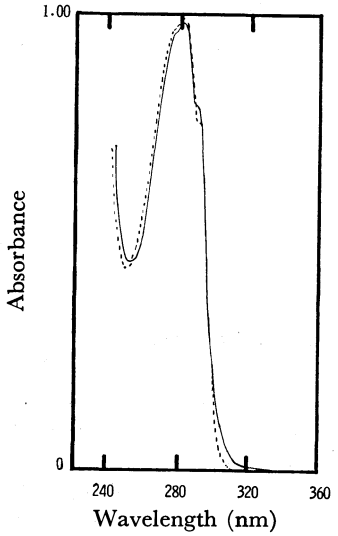

Fig. 7. Ultra-violet absorption spectra of fraction II of Fig. 2 (——) and native HEL (----). Solvent: Buffer containing 1 M acetic acid and 5 M urea.

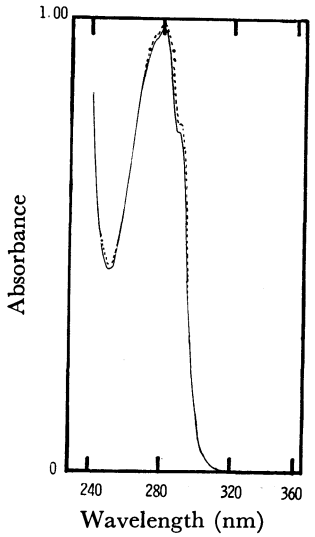

Fig. 8. Ultra-violet absorption spectra of fraction III of Fig. 2 (——) and native HEL (----). Solvent: Buffer containing 1 M acetic acid and 5 M urea.

Absorption Spectra. Figures 7 and 8 show the ultraviolet absorption spectra of fractions II and III, respectively in Fig. 2. The spectrum of fraction II was slightly different from that of the native HEL, while that of fraction III was the same as that of native HEL. In Fig. 9 the circular dichroism of fraction III of Fig. 2 is compared with that of native HEL. The two spectra are identical in the range of wavelengths measured.

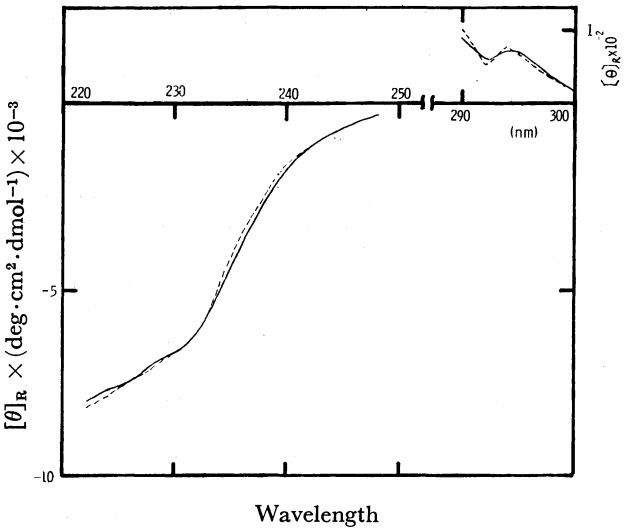

Fig. 9. Circular dichroism spectra of fraction III of Fig. 2 (——) and native HEL (----). Solvent: 0.1 M sodium chloride buffer solution adjusted to pH 3.0 with hydrochloric acid.

Crystallization of Fraction III. The material, recovered from fraction III in Fig. 2 was stood under conditions inducing crystallization. The tetragonal crystals obtained were like those of native HEL, as shown in Fig. 10.

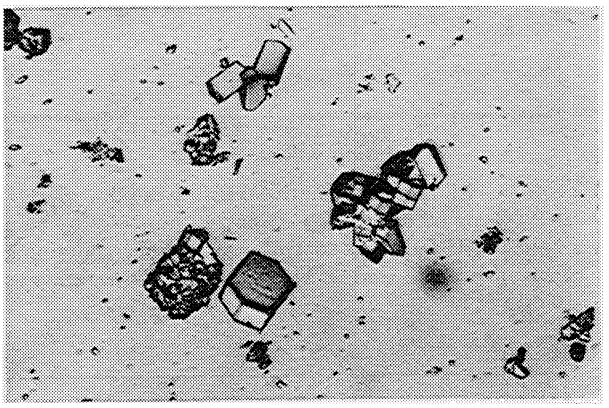

Fig. 10. Microphotograph of crystals of the material from fraction III obtained by the method of Berthou and Jolles.[7]

Discussion

The enzymatic activities of native HEL decreased during treatment with HF. This suggests that HF may affect structures which are essential for enzymatic activity. After treatment of native HEL with HF three fractions could be separated by gel-filtration in 1M acetic acid and 5M urea buffer. The first fraction eluted, fraction I, was inactive, the second, fraction II, was not fully active and the last, fraction III, was fully active. This suggests that molecules of native HEL were not affected uniformly by treatment with HF, some being only slightly affected and others greatly affected. This is supported by the finding that on prolongation of the period of treatment of native HEL with HF, the amount of fraction II increased while that of fraction III decreased.

The properties of fractions I, II and III were compared with those of native HEL. Fraction I seemed to contain polymeric material formed during treatment of native HEL with HF, because it was eluted in the void volume on gel-filtration, and because it was poorly soluble in a buffer and was enzymatically inactive. On gel-filtration fraction II was eluted before native HEL. The fraction II, separated after treatment of native HEL with HF at 0 °C for 60 min, had 45—66% of the activity of native HEL. However, preparations obtained after different conditions of treatment had different activities. Fraction II could be further separated into two fractions, IIa and IIb by gel-filtration in 5% NaCl and 5M urea buffer solution.[7] After treatment of native HEL with HF at 0 °C for 60 min, fraction II had 45—66% of the activity of native HEL, while fraction IIa had 2.5% and fraction IIb had about 85% of the activity of native HEL. Chromatograms of fractions IIa and IIb on Bio-rex 70 showed different patterns from that of native HEL.[7] Furthermore, when the material in fraction II was reduced and refolded under the method of Saxena and Wetlaufer,[8] the resultant material did not move in the position of fraction III on gel-filtration in 1M acetic acid and 5M urea buffer. Thus fraction II was a mixture of at least two components formed by modification of the structure of HEL during treatment with HF.

On gel-filtration fraction III was eluted in the same position as native HEL, and it also gave the same pattern on Bio-rex 70 as native HEL. These results suggest that fraction III has the similar properties to native HEL. In addition, the yield of fraction III was about 50% of the initial amount of native HEL. Accordingly, the properties of fraction III were further investigated. The ultra-violet and circular dichroism absorption spectra of fraction III were the same as those of native HEL over the range of wavelengths examined. Moreover, the crystals obtained from fraction III under the same conditions used to crystallize native HEL could not be distinguished from the latter.

The results described above indicate clearly that material which was indistinguishable in various properties from native HEL could be recovered in a crystalline state after treatment of native HEL with HF under usual conditions of peptide synthesis. The authors are now attempting to recover intact HEL from the reduced HEL treated with HF and refolded.[9] These studies should demonstrate the usefulness of HF in chemical synthesis of HEL.

Nucleophilic Displacement Catalyzed by Transition Metal. I. General Consideration of the Cyanation of Aryl Halides Catalyzed by Palladium(II)

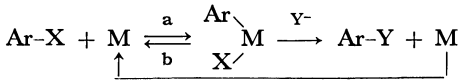
Kentaro TAKAGI, Tadashi OKAMOTO,* Yasumasa SAKAKIBARA,** Atsuyoshi OHNO,* Shinzaburo OKA,* and Naomi HAYAMA

College of Liberal Arts and Science, Okayama University, Tsushima, Okayama 700

(Received June 6, 1975)

The displacement reaction of various non-activated aryl halides with cyanide ions was investigated in the presence of palladium salts. Various aryl iodides and bromides were converted into the corresponding aryl cyanides in good yields under mild conditions. The addition of certain substances, such as potassium hydroxide and potassium carbonate, enhanced the catalytic activity. Hexamethylphosphoric triamide, in which potassium cyanide was scarcely soluble, was an outstanding solvent for the reaction. The reduced palladium species was supposed to be the active catalyst.

The inertness of aryl halides in the nucleophilic substitution reaction is generally recognized. The reaction with ordinary nucleophiles does not proceed unless the substrates are activated by electron-withdrawing groups.[1] Recently the great affinity of low-valent transition metal complexes for various halides has been reported.[2] Aryl halides, for example, exhibit a remarkable reactivity in oxidative addition to the complexes and sometimes produce isolable adducts in the presence of certain ligands, such as phosphines or isonitriles.[3] This fact suggests that the reversible oxidative addition of an aryl halide to a transition metal, when carried out in the presence of another nucleophile, may produce a product of a displacement reaction.



a: oxidative addition, b: reductive elimination, M: transition-metal catalyst, Ar-X: aryl halide, Y^-: nucleophile

Thus, a net nucleophilic aromatic substitution may take place with the aid of a transition-metal catalyst with otherwise inert substrates. From this point of view, the present authors intended to replace a halogen atom in aryl halide with a cyanide ion and found that palladium (II) salts in *N,N*-dimethylformamide (DMF) did indeed give satisfactory results. When the facile catalytic reaction at a moderate temperature was preliminarily communicated,[4] it was emphasized that the method is more useful for the syntheses of aryl cyanides than the conventional Rosenmund-von Braun reaction.[5] At almost the same time, a catalytic cyanation by a nickel catalyst was also reported.[6] In this paper the results of detailed studies of the reaction conditions will be presented.

Results and Discussion

Outline of the Reaction. Palladium salt, potassium cyanide, and iodobenzene were mixed in an appropriate solvent, and the reaction was carried out under nitrogen, Because of the poor solubility of potassium cyanide, the reaction mixture consisted of a heterogeneous system. The reaction mixture was colorless or pale yellow at the beginning and again at the end of the reaction, whereas it was deep yellow or reddish-brown during the reaction. Sometimes black precipitates appeared, presumably colloidal palladium metal. Benzonitrile, was almost the sole organic product.

$$C_6H_5I + KCN \xrightarrow[Pd(II)]{} C_6H_5CN + KI$$

Occasionally, small amounts of benzene and biphenyl were detected. Small amounts of water and air stopped the reaction before it reached completion. Under certain conditions, the presence of a co-catalyst such as potassium hydroxide was required to initiate the reaction (*vide infra*).

The Catalytic Cyanation of Various Aryl Halides. The results from catalytic cyanation with various aryl halides are listed in Table 1.

Aryl iodides, except for amino derivatives (Run 7), produce the corresponding aryl cyanides, in which a cyano group replaces the iodo atom. An *ortho* substituent in aryl iodide does not affect the reaction (Run 5), however, as may be seen in Table 1.

Catalytic cyanation with aryl bromides required more severe conditions than with aryl iodides. That is, a higher temperature (Run 9) or a larger amount of the catalyst and the addition of triphenylphosphine (Run 10) were necessary to complete the reaction. However, the presence of a small amount of potassium iodide promotes the reaction efficiently (Run 11).[7,8]

Chlorobenzene was the least reactive, and even the addition of potassium iodide was scarcelly effective in this case (Run 12). The marked difference in the reactivities of iodo and chloro atoms can also be observed from the experiment cited as Run 6 in Table 1.

The above difference in the reactivities of a series of aryl halides, I>Br>Cl, suggests that the bond dissociation is a crucial step in the catalytic reaction and that the formation of an activated aromatic system, *e.g.*, the π-complex, is not crucial. If such an intermediate should play an important role, the reactivity of aryl halides would decrease in the Cl>Br>I order as in the classical S_NAr reaction with activated aryl halides.[9,10]

The Catalyst System. The catalytic abilities of various palladium (II) salts for the reaction of iodobenzene in hexamethylphosphoric triamide (HMPA) were examined at various temperatures; the results are shown in Table 2. All the palladium salts, except for potassium tetracyanopalladate (II), are effective without the co-operation of any additives. In the presence of a small amount of potassium hydroxide, the reactivity of the catalyst system was greatly enhanced (Table 2). Other active co-catalysts are sodium ethoxide, potassium carbonate, and sodium phenoxide. The palladium complex in the zero oxidation state is also effective as a co-catalyst. The results are shown in Table 3.

Table 2. Activity of various catalyst system (correlation of catalytic activity and reaction temperature)

Catalyst system	Reaction temperature			
	120 °C	100 °C	80 °C	60 °C
$K_2Pd(CN)_4$	C	C	C	C

$Pd(CN)_2$+KOH	A	C	C	C
$K_2Pd(CN)_4$+KOH	C	C	C	C

Reaction condition: C_6H_5I 2 mmol, KCN 4 mmol, HMPA 3 ml, PdX_2 0.03 mmol, KOH (when used) 0.001 mmol.
A represents that the reaction proceeds to completion. B represents that the slower and unpractical reaction takes place or the reaction stops in the middles. C represents that the reaction dose not take place.

Since these co-catalysts have been widely used to reduce transition-metal ions of a higher valence to their corresponding lower-valent ones,[11] the above results seem to suggest the importance of zero-valent palladium. The inertness of cyanide salts ($Pd(CN)_2$, $K_2Pd(CN)_4$) and the solvent effect (*vide infra*) support this idea: since cyanide ion possesses a positive value as the oxidation potential of the next reaction, palladium cyanides may be hard to reduce, and the reduction of palladium cyanides can be achieved only at higher temperatures.[12]

$$Pd + 4X^- = PdX_4^{2-} + 2e^-$$
$$E^0(V) = -0.18\,(X=I),\ +0.4\,(X=CN)^{13}$$

Table 3. Effect of various co-catalysts

a) Recently $Pd(PPh_3)_4$ catalysed cyanation of aryl iodides in tetrahydrofuran was reported: A. Sekiya and N. Ishikawa, *Chem. Lett.*, **1975**, 278.

In fact, palladium acetate is spontaneously reduced to palladium metal on standing in HMPA at room temperature under nitrogen, whereas palladium cyanide resists the reduction.[14]

Solvent Effect. The catalytic cyanation of iodobenzene was examined in various solvents. The results are shown in Table 4. It is apparent that the solvent affects the catalytic reaction in a striking manner.

Table 4. Solvent effect

Run No.	Solvent	Reaction temp. °C	Other condition	Conversion %

31	DMF	100	D	100

a) reflux, b) convesion<5%
Reaction condition A: $Pd(OAc)_2$ 0.015 mmol, KCN 2 mmol, KOH 0.0005 mmol, C_6H_5I 1 mmol, Solvent 1 ml. Reaction condition B: $Pd(OAc)_2$ 0.033 mmol, KCN 0.5 mmol, C_6H_5I 0.2 mmol, DMF 1 ml. Reaction condition C: $Pd(OAc)_2$ 0.033 mmol, KCN 0.33 mmol, C_6H_5I 0.2 mmol, DMF 1 ml. Reaction condition D: $Pd(OAc)_2$ 0.033 mmol, KCN 0.33 mmol, $Ca(OH)_2$ 0.1 mmol, C_6H_5I 0.2 mmol, DMF 1 ml.

In such protic solvents as acetic acid and 1-butanol, the reaction did not occur under the conditions examined. Some dipolar aprotic solvents, such as acetonitrile, propionitrile, sulfolane, dimethyl sulfoxide (DMSO), and diethylene glycol dimethyl ether, also gave unfavorable results, while DMF, *N,N*-dimethylacetamide (DMAc), HMPA, tetramethylurea (TMU), propylene carbonate (PC), and *N*-methylpyrrolidone (NMP) gave satisfactory results. The favorable dipolar aprotic solvents may be further classified into two groups. The more favorable ones include HMPA and TMU, while the others consist of DMF, DMAc, PC, and NMP. That is, the catalytic reaction takes place at lower temperatures in solvents of the former group than in those of the latter (Runs 26, 27).

The advantage of dipolar aprotic solvents in organic reactions has generally been attributed to the stabilization of transition states by its high polarizability and to the formation of so-called naked anions by strong solvation to counter cations.[15] However, the solvent effect here observed could not be interpreted by the general concept alone. The difference in the concentrations of potassium cyanide in these solvents must be taken into account, because the present reaction system is heterogeneous. The solubilities of potassium cyanide in DMSO, DMF, or HMPA, as representatives of the three distinct groups mentioned above, were determined. The results suggest that the most favorable solvent is the one which dissolves potassium cyanide with most difficulty. This conclusion is supported by the fact that sodium cyanide could not be used in place of potassium cyanide as a source of cyanide ions, not even in HMPA: the former is more soluble in HMPA than the latter, which may mean that the cyanide anion itself inhibits the reaction, probably by forming an inert palladium-cyanide bond (*cf.* the discussion of the catalyst system above).[16]

Thus, the ratio of the concentrations of palladium to that of cyanide ions must be kept large for facile catalytic reactions. For example, the catalytic reaction took place at 60 °C in HMPA, whereas it did not occur below 120 °C in DMF (Runs 21, 28), into which potassium cyanide dissolves relatively well, with the same concentration of the catalyst. However, when the amount of the catalyst was increased greatly, the reaction in DMF took place at 100 °C (Runs 29—31).

Experimental

Materials. The palladium acetate,[17] potassium tetracyanopalladate,[18] palladium acetylacetonate,[19] tetrakis(triphenylphosphine)palladium,[20] and substituted iodobenzene[21] were prepared following the literature. The other materials were commercial products.

General Procedure and Analysis. All the reactions were performed in a test tube equipped with a magnetic stirrer and a three-way trap under a nitrogen stream following the procedures described in the previous section. Analytical glc were performed on a Hitachi Perkin-Elmer F 6D gas chromatograph: 35% silicon DC 200 on celite 545, 2 m for the analysis of iodobenzene, *p*-iodotoluene, *o*-iodotoluene, *m*-chloroiodobenzene, bromobenzene, and chlorobenzene at 140 °C (0.8 kg/cm² of a nitrogen carrier) and 20% silicon DC 200 on celite 545, 1 m for the analysis of *p*-iodoaniline and *p*-nitroiodobenzene at 160 °C (0.7 kg/cm² of a nitrogen carrier). The yields were determined by using internal standards.

A Typical Example of the Catalytic Reactions. Reaction of *p*-iodotoluene: To a mixture of 45.5 mg (0.7 mmol) of KCN (recrystallized from water), 109 mg (0.5 mmol) of *p*-iodotoluene, and 1.1 mg (0.005 mmol) of $Pd(OAc)_2$, a 3 ml portion of HMPA (NaOEt was dissolved) was added. The reaction system was then flushed with nitrogen under stirring and kept at 100 °C. After stirring for 2 hr, aqueous sodium chloride (5 ml) and benzonitrile (50 mg, internal standard) were added to the reaction mixture. The organic products were extracted with ether (5 ml), washed with aqueous sodium chloride (5 ml), and dried over sodium sulfate. The glc analysis showed the formation of 54 mg (0.47 mmol) of *p*-tolunitrile (yield, 93%).

Reaction of Bromobenzene with Potassium Iodide. A suspension of 200 mg (1.2 mmol) of KI, 78 mg (0.5 mmol) of bromobenzene, 3.4 mg (0.015 mmol) of $Pd(OAc)_2$, 6.7 mg (0.1 mmol) of NaOEt, and 1.5 ml of HMPA was heated at 100 °C for 4 hr under a nitrogen. Analysis showed the complete absence of iodobenzene in the solution.

Solubilities of Potassium Cyanide in HMPA, DMF, and DMSO. After a suspension of potassium cyanide in a solvent had been stirred overnight at room temperature under a nitrogen, the potassium metal in the solution was determined with an atomic

absorption spectrophotometer (Nippon Jarrell Ash, Type AA-I). One liter of HMPA, DMF, or DMSO dissolved about 0.1, 10, or 200 mmol of KCN respectively. (The solvents used contained, respectively, 10^{-4}, 10^{-5}, and 10^{-4} g of water per 1 ml of the solvent.)

Racemization of Amino Acid Residues Fused in Thiazoline, Oxazoline, and Imidazoline Rings

Ken YONETANI, Yoshihiro HIROTSU, and Tetsuo SHIBA

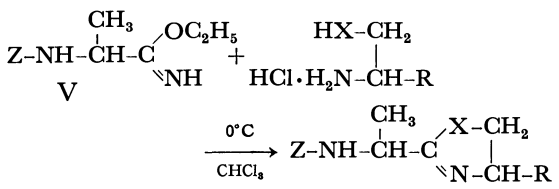
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received June 9, 1975)

For the purpose of study on racemization of *exo* methine carbon atom of thiazoline, oxazoline or imidazoline ring, the following four compounds were synthesized from amino acid imino ether: 2-(1-benzyloxycarbonylaminoethyl)-2-thiazoline (I), methyl 2-(1-benzyloxycarbonylaminoethyl)-2-thiazoline-4-carboxylate (II), methyl 2-(1-benzyloxycarbonylaminoethyl)-2-oxazoline-4-carboxylate (III), and 2-(1-benzyloxycarbonylaminoethyl)-2-imidazoline (IV). A racemization rate of the alanine residue was measured from an optical rotation of 2,4-dinitrophenyl derivative obtained from the acid hydrolyzate and from hydrogen-deuterium exchange reaction at α-carbon atom. All these compounds were found to be racemized very easily particularly in the presence of proton source. From the experimental results, a plausible mechanism for racemization peculiar to such heterocyclic compounds through protonation-deprotonation process was presented.

Bacitracin A is a peptide antibiotic which involves a unique structure of the thiazoline ring in its molecule. Among peculiar chemical characters of this antibiotic, the racemization at the *N*-terminal isoleucine residue seems to be significantly important, since it is directly related to decrease of the biological activity against microorganisms. Thus, Konigsberg *et al.*[1,2] recognized that a "high potency" form of bacitracin A was converted to a "low potency" form on standing under weak acidic condition and both forms became nearly equal in amounts after two days. This interconversion between the two forms took place even under nearly neutral condition. Meanwhile, it was observed that L-isoleucine of *N*-terminal residue linked to the thiazoline ring in the "high potency" form was isomerized to D-alloisoleucine in the "low potency" one without any change in the rest of the molecule. This epimerization proceeded according to the first-order kinetics in weak acidic media. As pointed out in our previous paper,[3] we postulated that the ease of the isomerization in this case could be attributed to the particular position of the asymmetric center at C-2 *exo* methine of the thiazoline ring.

In the present paper, optical properties of the amino acid components of the peptides containing imidazoline or oxazoline ring as well as the thiazoline ring were investigated in order to clarify the reaction mechanism in more detail. Four model peptides *i.e.*, 2-(1-benzyloxycarbonylaminoethyl)-2-thiazoline (I), methyl 2-(1-benzyloxycarbonylaminoethyl)-2-thiazoline-4-carboxylate (II), methyl 2-(1-benzyloxycarbonylaminoethyl)-2-oxazoline-4-carboxylate (III), and 2-(1-benzyloxycarbonylaminoethyl)-2-imidazoline (IV) were synthesized by iminoether method[4] according to the scheme as outlined in Fig. 1.



I X=S R=H
II X=S R=COOCH$_3$
III X=O R=COOCH$_3$
IV X=NH R=H

Fig. 1.

The thiazoline derivatives (I and II) were prepared by coupling of iminoether (V) derived from L-alanine with 2-aminoethanethiol hydrochloride and methyl L-cysteinate hydrochloride respectively in chloroform at 0 °C. Similarly, the oxazoline derivative (III) was synthesized by coupling of V with methyl L-serinate hydrochloride. The imidazoline derivative (IV) was also obtained by coupling of V with ethylenediamine in the same solvent at 0 °C.

An optical purity of the alanine residue in each compound was determined by means of the following two methods. First method was based on a measurement of an optical rotation of 2,4-dinitrophenyl (DNP)-alanine. Thus, acid hydrolyzate of the sample given was dinitrophenylated and DNP-alanine was isolated by preparative thin-layer chromatography (tlc). The optical rotation of DNP-alanine thus obtained was measured at 550 nm in aqueous sodium hydrogencarbonate solution and the concentration of the material in the same solution was calculated from UV absorbance at 360 nm compared with those of authentic DNP-L-alanine.[5]

The observed value of the optical purity of the alanine residue in thiazoline derivative (I) was found to be 48% by the DNP-method, whereas the same residue was completely racemized after standing of I at room temperature for a longer period than four weeks or even in the course of its purification procedure either by recrystallization or by silica gel column chromatography. When the oily thiazoline derivative (II) was purified by passing through silica gel column, the alanine residue in this compound was also perfectly racemized. In the case of oxazoline derivative (III), warming at 40 °C for 16 h caused complete racemization at the alanine residue, though the optical purity of this amino acid was maintained as L-form of 98% in the original compound III. When the oily oxazoline (III) was kept at around 20 °C for a couple of weeks, hydrolysis of III occurred by participation of moisture in air and crystals of optically pure benzyloxycarbonylalanylserine methyl ester corresponding to the open chain form of III was deposited. This finding may also mean that the racemization proceeded only in the

heterocyclic form. Although imidazoline derivative (IV) was obtained as crystals keeping an optical purity of 78% at the alanine residue, it was most easily racemized even during recrystallization. The racemization degrees in the above discussion were all obtained by the DNP method. However in the case of the compound I or IV where only one asymmetric center was involved, a racemization of the alanine residue can be determined simply by measurement of an optical rotation of the heterocyclic compound itself. Both methods can be applied to follow the progress of the racemization in the time course.

On the other hand, observation of NMR spectra of those compounds (I, II, III, and IV) in 0.5M CD_3OD solution indicated that the intensity of signal for methine proton on the alanine residue gradually decreased, and at the same time, the signal of methyl proton on the same residue changed to singlet from doublet. Hence, a rate of hydrogen-deuterium exchange on the α-carbon atom of the alanine residue could be calculated by comparison of integrated intensities of singlet and doublet signals due to methyl proton.

Discussion

The reaction times ($t_{1/2}$) of racemization and deuterium exchange reaction on the α-carbon atom of the *N*-terminal alanine residue of model peptides (I)—(IV) are summarized in Table 1. The reaction rates for those compounds at 30 °C are shown in Fig. 2.

Table 1. Reaction time ($t_{1/2}$, h) of racemization and deuterium exchange reaction

Compound	10 °C	30 °C	50 °C
I	1000[b]	140[a]	5[b]
		80[b]	
		22[c]	
II	550[b]	62[b]	8[b]
III	1300[b]	176	43
IV	3.2	0.5[a]	

a) Racemization (0.5 M CH_3OH solution). b) D-Exchange (0.5 M CD_3OD solution). c) D-Exchange (0.5 M solution in CD_3OD containing *ca.* 5% D_2O). The values with no mark represent the cases where both times for racemization and D-exchange reaction coincided each other.

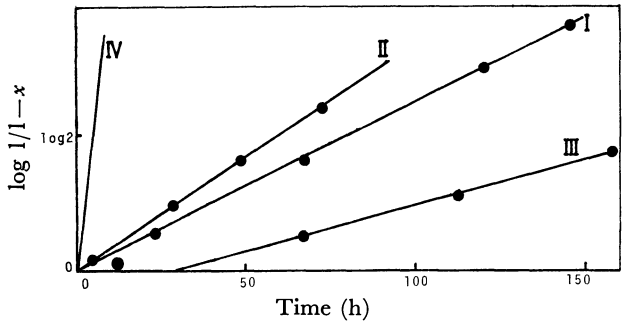


Fig. 2. The rates of racemization or D-exchange reaction at 30 °C.
For the Compound I, only the racemization rate is depicted.

Since an abscissa represents the time on a semilog scale, the straight lines in Fig. 2 indicate first-order kinetics either for racemization or deuterium exchang reaction. From the result in Table 1, it was shown that a higher temperature accelerates the reaction rate on each compound. The rates of racemization on oxazoline (III) and imidazoline (IV) are in agreement with those of deuterium exchange reaction with exception of the case of thiazoline derivative (I). The reaction rates on the compound I were further investigated as shown in Fig. 3. The reaction at 30 °C in CD_3OD

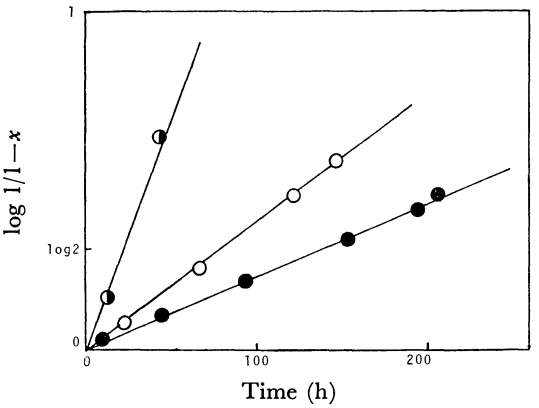

Fig. 3. The rate of racemization or D-exchange reaction in thiazoline compound (I) at 30 °C.
●: Racemization (0.5 M CH_3OH solution).

was shown to become faster in the presence of D_2O. This indicates that the reaction rate of thiazoline (I) is greately influenced by the presence of a trace amount of water or D_2O in the solvent. This effect may be a reason for discrepancy of reaction rates depending on the measurement condition in the case of the compound (I). Concerning a solvent effect for the racemization, the alanine residue of oxazoline (III) was partly racemized even at the stage of the coupling in methanol. On the other hand, no racemization occurred in chloroform in a preparation of III. This experimental fact suggests that the racemization depends on protic character of the solvent significantly. In this connection, an effect of the solvent was thoroughly investigated on imidazoline (IV) which was racemized most rapidly

Table 2. Racemization time ($t_{1/2}$) of imidazoline (IV) in 0.5 M solution at 30 °C

among four model peptides. The racemization time ($t_{1/2}$) obtained in various media is shown in Table 2. The reaction rate was much faster in methanol as protic solvent than in chloroform as aprotic one. In chloroform containing a little amount of acetic acid, the reaction rate was as fast as in methanol. However, the rate decreased as the acid concentration increased, and racemization did not proceed eventually in strong acid media. From these results, it was proved that a deprotonation at the α-carbon atom of alanine residue is inhibited in acidic solvent, though the racemization requires the presence of proton. Furthermore, it seems unlikely that the racemization proceeds through proton abstraction directly at the α-carbon atom since the reaction was not catalyzed on addition of triethylamine as base. Consequently, the most plausible mechanism through protonated intermediate can be now presented for this racemization as depicted in Fig. 4. It should be

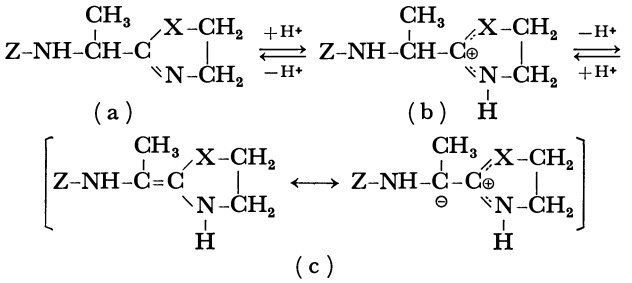

Fig. 4.

emphasized again that racemization and deuterium exchange reaction proceed in almost the same rates. From this fact it is assumed that protonation process from (c) to (b) is very rapid and the rate-determining step is deprotonation step from (b) to (c).[6,7] No effect of the base on racemization can be explained by assumption that either deprotonation from (b) to (a) proceeds predominantly or the protonation process from (a) to (b) might be inhibited. According to this mechanism, the reaction rate must be followed to first-order kinetics for the concentration of cation (b). This assumption is compatible with the results in model peptides I, II, and IV. Only exception is found in the rate of oxazoline (III) which showed the time lag for the reaction initiation. Although this phenomenon can not be elucidated unambiguously yet, an autocatalysis participated by some species formed in the process of deprotonation from (b) to (c) may be considered as one possibility since any protonation step should be rapid and seems to be improbable for explanation of such time lag.

Iminoether (V) used as starting material for the preparation of these model peptides was never racemized when it was treated under any coupling condition nor exchanged with deuterium at all even at 50 °C after 200 h. These results indicate that the racemization reaction is characteristic of heterocyclic structures such as thiazoline, oxazoline, and imidazoline rings. The cation protonated at N-3 of these heterocyclic compounds is stable owing to delocalization of the ring electron. The following deprotonation occurs concertedly with the shift of the inner double bond in the heterorings to the exocyclic position. Consequently, the racemization can take place in cases that the carbon atoms adjacent to C-2 of the heterorings are asymmetric. Therefore, it is useful to employ deuterium exchange as a detection method of racemization in these cases. It should be taken into consideration that racemization may occur always in the synthesis of such a heterocyclic compound, even when it is involved as an intermediate. At the same time, the possibility of electrophilic substitution on the carbanion adjacent to C-2 can be now suggested. For this purpose, the heterocyclic compound derived from glycine may be employed as substrate, and aldehyde or halide as electrophile. One can expect that the coupling product after hydrolysis is β-hydroxy-α-amino acid derivative or α-amino acid derivative respectively. A study along this line is in progress.

In conclusion, we not only clarified the racemization mechanism of heterocyclic compounds derived from amino acids but also pointed out the possibility for a new synthetic method of amino acid.

Experimental

All melting points are uncorrected. Nuclear magnetic resonances spectra were measured on a Varian T-60 spectrometer with tetramethylsilane as an internal standard. Optical rotations were observed with a JASCO ORD/UV-5 spectrophotometer. Ultraviolet spectra were obtained on a Hitachi 124 spectrophotometer. IR spectra were obtained on a JASCO IR-5 spectrophotometer.

Determination of Optical Purity of Alanine Residue. The sample (*ca.* 100 mg) was heated in 6M hydrochloric acid under reflux for 3 h. After evaporation *in vacuo*, the residue was dissolved in water (10 ml). Evaporation of the solvent was repeated. The hydrolyzate thus obtained was dissolved in 5% aqueous sodium hydrogencarbonate (12 ml). To the solution was added 1-fluoro-2,4-dinitrobenzene (*ca.* 200 mg) in 95% ethanol (24 ml). The reaction mixture was stirred at room temperature for 3 h and then concentrated *in vacuo*. The residue was dissolved in water (200 ml) and washed with ether. The aqueous layer was acidified with 6M hydrochloric acid to Congo red and extracted with ether. The ethereal extract was washed with water, dried over sodium sulfate and evaporated *in vacuo*. The residue was applied to preparative tlc on silica gel H to obtain DNP-alanine which was then dissolved in 1% aqueous sodium hydrogencarbonate (10 ml). The specific optical rotation of the solution was observed at 550 nm and the concentration of the same solution was calculated from the extinction coefficient at 360 nm: authentic DNP-L-alanine: $[\alpha]_{550}^{19}$ +197° (*c* 0.34, 1% $NaHCO_3$); $\lambda_{max}^{1\%\ NaHCO_3}$ 360 nm (ε 1.72×10^4).

2-(1-Benzyloxycarbonylaminoethyl)-2-thiazoline (I). To a solution of L-2-benzyloxycarbonylaminopropioimino ethyl ether[4] (3.00 g, 12 mmol) in chloroform (80 ml) was added 2-aminoethanethiol hydrochloride (1.8 g, 16 mmol) in anhydrous methanol (10 ml) with stirring at 0 °C under nitrogen atmosphere over a period of 2 h. The reaction mixture was stirred for additional 18 h and then concentrated *in vacuo* below 25 °C. The oily residue was dissolved in chloroform, washed with water and dried over magnesium sulfate. Evaporation of the solvent gave an oily material which was crystallized on addition of anhydrous *n*-hexane; yield, 2.06 g (64%); mp 51—53 °C; $[\alpha]_D^{28}$ −6.9° (*c* 1.5, CH_3OH); IR (Nujol): 1630 cm^{-1} (C=N), 1720, 1680 cm^{-1} (C=O); NMR (in $CDCl_3$): δ 7.4 (s, 5H), 5.8 (bd, 1H), 5.1 (s, 2H), 4.6 (q, 1H: J=7 Hz), 4.2 (t, 2H: J=8 Hz), 3.2 (t, 2H, J=8 Hz),

and 1.4 (d, 3H: J=7 Hz). The optical purity of the alanine residue in this material was found to be 84% by DNP method. When this sample was recrystallized from ethyl acetate–*n*-hexane, the obtained crystals were completely racemized: mp 93—95 °C; IR (Nujol): 1630 cm^{-1} (C=N), 1720 cm^{-1} (C=O); λ_{max}^{EtOH} 252 nm (ε 2.9×10³), $\lambda_{max}^{EtOH-12\ M\ HCl}$ 268 nm (ε 6.9×10³). Found: C, 59.08; H, 6.05; N, 10.43; S, 12.15%. Calcd for $C_{13}H_{16}O_2N_2S$: C, 59.06; H, 6.10; N, 10.60; S, 12.13%.

*Methyl 2-(1-Benzyloxycarbonylaminoethyl)-(*R*)-2-thiazoline-4-carboxylate (II).* To a solution of L-2-benzyloxycarbonylaminopropioimino ethyl ether (0.90 g, 3.6 mmol) in chloroform (40 ml) was added methyl L-cysteinate hydrochloride (0.70 g, 4.1 mmol) with stirring at 0 °C under nitrogen atmosphere. After the reaction mixture was stirred for 24 h, it was treated in a similar manner to that in preparation of I. The crude oily product (1.0 g) obtained was dissolved in anhydrous ether (10 ml) and subjected to silica gel (Merck silica gel 0.05—0.2 nm, 30 g) column. The column was eluted with anhydrous *n*-hexane–ether–acetone to give oily but pure II: yield, 0.80 g (69%); $[\alpha]_D^{23}$ +40.8° (*c* 2.7, CH_3OH); IR (Nujol): 1620 cm^{-1} (C=N); NMR (in $CDCl_3$): δ 7.4 (s, 5H), 5.6 (bd, 1H), 5.2 (s, 2H), 5.1 (t, 1H: J=9 Hz), 4.7 (q, 1H: J=7 Hz), 3.8 (s, 3H), 3.6 (d, 2H: J=9 Hz), and 1.5 (d, 3H: J=7 Hz). Found: C, 55.51; H, 5.51; N, 8.62; S, 9.78%. Calcd for $C_{15}H_{18}O_4N_2S$: C, 55.85; H, 5.63; N, 8.69; S, 9.95%. The alanine residue in II was found to be DL-form by DNP method.

*Methyl 2-(1-Benzyloxycarbonylaminoethyl)-(*S*)-2-oxazoline-4-carboxylate (III).* A solution of iminoether (V) (4.80 g, 19 mmol) and methyl L-serinate hydrochloride (3.80 g, 25 mmol) in chloroform (50 ml) was stirred at room temperature for 16 h. The reaction mixture was concentrated *in vacuo*. Purification by silica gel column chromatography, gave an oily product III: yield, 4.15 g (72%); $[\alpha]_D^{13}$ +30.0° (*c* 3.3, CH_3OH); IR (Nujol): 1670 cm^{-1} (C=N); NMR (in $CDCl_3$): δ 7.3 (s, 5H), 5.8 (bd, 1H), 5.1 (s, 2H), 4.1—4.9 (m, 4H), 3.7 (s, 3H), and 1.4 (d, 3H: J=7 Hz). Found: C, 58.79; H, 6.07; N, 9.08%. Calcd for $C_{15}H_{18}O_5N_2$: C, 58.81; H, 5.92; N, 9.15%.

An optical purity of the alanine residue in III was shown to be 98% by DNP method. When the oily product III (1.5 g) itself was allowed to stand at room temperature for a couple of weeks in an open vessel, crystals of benzyloxycarbonyl-L-alanyl-L-serine methyl ester were formed. This open chain peptide was recrystallized from ethyl acetate–*n*-hexane: yield, 1.2 g (76%); mp 133—134 °C; $[\alpha]_D^{28}$ −18.9° (*c* 1.1, CH_3OH). (lit,[8]: L-L form: mp 134.5—135.5 °C; $[\alpha]_D^{28}$ −17.7° (*c* 3.43, CH_3OH)). IR (Nujol): 3500 cm^{-1} (OH); NMR (in $CDCl_3$): δ 7.4 (s, 5H), 7.3 (b, 1H), 5.8 (bd, 1H), 5.1 (s, 2H), 4.2—4.8 (m, 2H), 3.9 (d, 2H, J=4 Hz), 3.8 (s, 3H), 3.3 (s, 1H), and 1.4 (d, 3H: J=6 Hz). Found: C, 55.49; H, 6.24; N, 8.59%. Calcd for $C_{15}H_{20}O_6N_2$: C, 55.55; H, 6.22; N, 8.64%.

When the oxazoline (III) was prepared in methanol, an optical purity of the alanine residue was found to be 70—90% by DNP method.

2-(1-Benzyloxycarbonylaminoethyl)-2-imidazoline (IV). To a solution of iminoether (V) (3.60 g, 14.4 mmol) in chloroform (30 ml) was added ethylenediamine (1.10 g, 20 mmol). The reaction mixture was stirred at 0 °C for 158 h and then evaporated *in vacuo* below 25 °C. The residue was readily crystallized on addition of anhydrous ether. The crystals were collected and washed with anhydrous ether: yield, 1.44 g (41%); mp 100—103 °C; $[\alpha]_D^{23}$ −24.9° (*c* 2.1, CH_3OH); IR (Nujol): 1620 cm^{-1} (C=N); NMR (in $CDCl_3$): δ 7.4 (s, 5H), 6.1 (bd, 1H), 5.1 (s, 2H), 4.4 (q, 1H: J=7 Hz), 3.6 (s, 4H), and 1.4 (d, 3H: J=7 Hz).

An optical purity of the alanine residue in VI was found to be 78% by DNP method. On recrystallization from acetone–ether, IV was changed to completely racemized form: mp 111—113 °C. Found: C, 63.11; H, 7.09; N, 16.68%. Calcd for $C_{13}H_{17}O_2N_3$: C, 63.14; H, 6.93; N, 16.99%.

Ethylation and Transethylation of Naphthalene[1]

Keizo SHIMADA and Shizuo NAGAHAMA

Central Research Institute, Teijin Limited, Asahigaoka, Hino, Tokyo 191

(Received June 9, 1975)

Transethylation of naphthalene by ethylxylenes and ethylbenzene in the presence of $AlCl_3$ as a catalyst was studied and compared with ethylation by ethyl bromide. When ethylxylenes were used, it was observed that the β-isomer of ethylnaphthalene initially formed (96.8%) was isomerized to the α-isomer. This was attributed to steric hindrance of the α-position in the transition state of reactions proceeding by the hydride abstraction mechanism. However, the formation of considerable proportion of the α-isomer (25%) was observed in the case of transethylation by ethylbenzene, as well as of ethylation with ethyl bromide (60% α-isomer). Thus, the S_N2 mechanism should be operative, at least partly, in the transethylation by ethylbenzene. The rates of transethylation by ethylxylenes were found to be in the order: 1,2-diMe-4-Et-≒1,3-diMe-4-Et-＞1,4-diMe-2-Et-≫1,3-diMe-5-5-Et-benzene. The equilibrium composition of ethylnaphthalene was found to contain 8.7—8.8% α-isomer.

Ethylation of naphthalene has been investigated a long time ago.[2] However, the nature of the isomer distribution of the ethylnaphthalene produced was obscure. Nickels and Kutz[3] described a product of 80% β- and 20% α-isomers by ethylation with ethylene using a silica-alumina catalyst.

Lien and McCaulay[4] reported that the β-isomer was formed exclusively by the transethylation of naphthalene with ethylbenzene in the presence of $HF-BF_3$. Karakureva *et al.*[5] also reported that the transethylation of naphthalene with ethylbenzene, diethylbenzene, and ethylxylene, prepared *in situ* from xylene and ethylene, in the presence of $AlCl_3$, all produced the β-isomer.

Here, the nature of the isomer distribution of the product obtained by ethylation and transethylation of naphthalene catalyzed by aluminium chloride is reported.

Experimental

1,3-Dimethyl-5-ethylbenzene. To a mixture of 244 g of *m*-xylene (95% pure) and 70 g of $AlCl_3$, 72.3 g of ethyl bromide was added with stirring. The reaction mixture was stirred for 24 h at 30 °C. The lower complex layer was separated and poured onto crushed ice, and the organic layer which appeared was washed with aqueous sodium hydroxide and water, and dried over potassium carbonate. *m*-Xylene was recovered and the residue was fractionated by a spinning band column. A fraction (bp 184 °C) of 97.3% purity was obtained.

1,3-Dimethyl-4-ethylbenzene. To a mixture of 650 g of *m*-xylene and 20 g of $AlCl_3$, 146 g of ethyl bromide was added and the reaction mixture was stirred for 2 h. The upper layer was separated by decantation and treated as above. A fraction (bp 188 °C) 85.7% pure and containing 14.2% 1,3-dimethyl-2-ethylbenzene and 0.1% 1,3-dimethyl-5-ethylbenzene was obtained.

1,4-Dimethyl-2-ethylbenzene was synthesized from *p*-xylene and ethyl bromide with $AlCl_3$ and was distilled. Bp 187 °C, purity 97.5%.

1,2-Dimethyl-4-ethylbenzene was synthesized from *o*-xylene and ethyl bromide as above and distilled by a spinning band column. Bp 190 °C, purity 97.5%.

Naphthalene was purified by sublimation, purity 99.7%.

Reactions. Ethylation was carried out using naphthalene (0.1 mol), ethyl bromide (0.025 mol) and $AlCl_3$ (0.01 mol) in 50 g of *n*-heptane at 30 °C. Transethylation by ethylxylenes was carried out using a mixture containing 0.1 mol each of naphthalene and ethylxylene, 0.02 mol of $AlCl_3$ in 30 g of *n*-heptane at 30 °C. In the case of transethylation by ethylbenzene, 0.2 mol of ethylbenzene was used without *n*-heptane at 20 °C.

Aliquots of the samples were taken at appropriate times, poured into ice water and ether to decompose the catalyst, washed and dried. The samples were analyzed by gas chromatography, using an MB MA Golay column (45 m) at 160 °C.

Results

Ethylation with Ethyl Bromide. The isomer distribution and the reaction time are shown in Table 1. The data clearly show the initial attack favorable to the α-position, followed by rapid isomerization to the β-position. By extrapolating to zero time, an initial isomer distribution of about 60% α-isomer was obtained.

Table 1. Isomer distribution in the ethylation of naphthalene with ethyl bromide

Time (min)	Ethylnaphthalenes (%) α	Ethylnaphthalenes (%) β	Conversion[a] (%)
5	45	55	1.1
10	30	70	2.2
15	16	84	3.5
30	14	86	6.8
90	12	88	9.7
210	10	90	12
24 (h)	8.8	91.2	

a) Calculated from the peak area of the gas chromatogram, (ethylnaphthalene+diethylnaphthalene)/(naphthalene+ethylnaphthalene+diethylnaphthalene).

Transalkylation with Ethylbenzene. The isomer distribution and the reaction time are shown in Table 2. The initial β-attack increased as compared with ethyl bromide ethylation. By extrapolation to zero time, an initial isomer distribution of about 25% α-isomer was obtained.

If transethylation proceeded by the hydride abstraction mechanism, the initial attack would be more probable at the β-position, and thus, isomerization from the β- to the α-isomer may be expected. However, isomerization from the α- to the β-isomer was none the less ob-

Table 2. Isomer distribution in the transethylation of naphthalene with ethylbenzene

Time (min)	Ethylnaphthalenes (%) α	Ethylnaphthalenes (%) β	Conversion (%)
2	20	80	1.5
5	15	85	5.5
15	9.7	90.3	14.5
30	8.9	91.1	19.5
60	8.8	91.2	28

served.

Transethylation with Ethylxylenes. The isomer distributions and the reaction times obtained from the reaction of individual ethylxylene isomers with naphthalene are shown in Tables 3—6.

It is observed, in all cases, that the initial products are rich in the β-isomer compared to the equilibrium composition. Thus, isomerization of the β-isomer to the α-isomer was observed.

Table 3. Isomer distribution in the transethylation of naphthalene with 1,4-dimethyl-2-ethylbenzene

Time (h)	Ethylpaththalenes (%) α	Ethylpaththalenes (%) β	Conversion (%)
1/4	4.2	95.8	3.5
1/2	5.3	94.7	8.7
1	5.3	94.7	17
2	5.7	94.3	32
3	6.0	94.0	40
5	6.2	93.8	46
7	6.4	93.6	48
24	7.8	92.2	57

Table 4. Isomer distribution in the transethylation of naphthalene with 1,3-dimethyl-5-ethylbenzene

Time (h)	Ethylnaphthalenes (%) α	Ethylnaphthalenes (%) β	Conversion (%)
3	3.2	96.8	1.5
5	3.2	96.8	3.4
7	3.9	96.1	10
15	5.1	94.9	38
24	5.9	94.1	54
26	6.3	93.7	57
32	7.3	92.7	62

Table 5. Isomer distribution in the transethylation of naphthalene with 1,3-dimethyl-4-ethylbenzene

Time (h)	Ethylnaphthalenes (%) α	Ethylnaphthalenes (%) β	Conversion (%)
1/12	3.5	96.5	9
1/4	3.5	96.5	23
1/2	3.8	96.2	36
1	4.2	95.8	47
2	5.0	95.0	57
3	5.8	94.2	60
24	8.7	91.3	61

Table 6. Isomer distribution in the ethylation of naphthalene with 1,2-dimethyl-4-ethylbenzene

Time (h)	Ethylbenzenes (%) α	Ethylbenzenes (%) β	Conversion (%)
1/2	3.2	96.8	8
1/4	3.3	96.7	34
1/2	3.3	96.7	50
1	4.3	95.7	59
2	6.7	93.3	59
3	7.0	93.0	60
24	8.7	91.3	61

As a result, the rates of transethylation with ethylxylene isomers decrease in the order 1,2-diMe-4-Et-≧1,3-diMe-4-Et>1,4-diMe-2-Et≫1,3-diMe-5-Et.

The equilibrium composition of ethylnaphthalene was found to contain 8.7—8.8% α-isomer.

Discussion

The mechanism of transethylation has received the attention of many researchers. McCaulay and Lien,[6] and later, Brown and Smoot[7] proposed an S_N2 mechanism without the formation of a free primary carbonium ion. On the other hand, Streitwieser and Reif[8] proposed a hydride abstraction mechanism, in which the formation of a secondary benzyl cation was characteristic, based on an experiment using $GaBr_3$ as the catalyst.

One of the present authors[9] (K.S.) reported on the transethylation of toluene to show that both mechanisms operate with an aluminum chloride catalyst and that the hydride abstraction mechanism is favored when an ethylalkylbenzene of stronger basicity is used. More precisely, ethyl-*m*-xylene produced *p*-ethyltoluene in greater prevalence over its *ortho*-isomer than did ethyl-*o*- and *p*-xylenes.

In the present work, it was found that there is virtually no difference in the initial isomer distribution among the ethylxylene isomers. Namely, 3.2—3.5% α- and 96.8—96.5% β-isomer was obtained. This may be due to the basicity of the reactants which is in the order, naphthalene>ethylxylenes>toluene.

However, the fact that the initial isomer distribution was richer in the β-isomer than at equilibrium, shows the strong steric hindrance of the α-position in the transition state. This means that the hydride abstraction mechanism was operated preferentially as discussed previously.[9]

On the other hand, the formation of considerable proportions of α-ethylnaphthalene was observed in the case of transethylation by ethylbenzene. Therefore, the transethylation of naphthalene with ethylbenzene should, at least partly, proceed by a mechanism, which shows lesser steric hindrance at the α-position as in the ethylation by ethyl bromide, namely, the S_N2-type mechanism.

The authors are indebted to Dr. Shoichi Sakajiri,

Director of the Central Research Institute, Teijin Limited, for his permission to publish this article.

Photochemical Reactions of Azido-1,3,5-triazines with Hydrocarbons and Ketones

Ryuichi KAYAMA, Haruo SHIZUKA, Shizen SEKIGUCHI, and Kohji MATSUI

Department of Synthetic Chemistry, Faculty of Engineering, Gunma University, Kiryu, Gunma 376

(Received June 12, 1975)

2-Azido-4,6-dimethoxy-1,3,5-triazine (**1**) produced 2-cyclohexylamino-4,6-dimethoxy-1,3,5-triazine as the sole major product upon irradiation at 254 nm in cyclohexane by the intermolecular insertion of the triazinyl nitrene into cyclohexane, while in the reaction with cyclohexene a derivative of the aziridine type was produced by the addition of triazinyl nitrene to the double bond of cyclohexene. In the photochemical reaction of **1** with ketones, 3,3-dialkyl derivatives of 5,7-dimethoxy-3*H*-[1,2,4]oxadiazolo[4.3-*a*]-*s*-triazine were obtained. The reaction is assumed to proceed *via* the electrophilic attack of the singlet nitrene on the carbonyl oxygen of the ketones followed by cyclization to give the final products. However, in the thermal reaction of **1** with ketones only 2-amino-4,6-dimethoxy-1,3,5-triazine was obtained.

In a previous paper,[1] the authors reported that the thermal reactions of azido-1,3,5-triazines with non-olefinic hydrocarbons proceed *via* a nitrene intermediate producing insertion and hydrogen abstraction products and that the reactions with olefinic hydrocarbons take place *via* a bimolecular mechanism involving the formation of an intermediate of the triazoline type to give alkenylamino- and amino-1,3,5-triazines as the final products.

Photolyses of a number of organic azides involving the formation of nitrene intermediates have been extensively investigated.[2] Although little is known about the photochemical reactions of azido nitrogenheteroaromatics, the reactions are considered to proceed *via* a nitrene intermediate producing amines,[3] azo-compounds,[3,4] insertion,[5] and ring contraction products,[6] *etc.* Recently, the formation of a nitrene intermediate was observed in the photolysis of azido-1,3,5-triazine;[7] amino-1,3,5-triazines were obtained upon irradiation of azido-1,3,5-triazines in methanol.[8] However, the details of the photochemical reactions of azido-1,3,5-triazines have not yet been determined. On the other hand, the photolysis of azido-1,3,5-triazines is of interest from the view point of the effect of the presence of three ring nitrogen atoms—the effect of an electron-attracting aryl nucleus on the photochemical reaction of arylazide. In addition, the photolysis of azido-1,3,5-triazines may provide useful and convenient methods for the preparation of a number of 1,3,5-triazine derivatives which would otherwise be difficult to prepare. This paper reports the photochemical reactions of azide-1,3,5-triazines with some hydrocarbons and ketones.

Results and Discussion

Photochemical Reactions of Azido-1,3,5-triazines with Hydrocarbons. When azido-1,3,5-triazines were irradiated in cyclohexane at 254 nm, a regular spectral change with isosbestic points was observed in every case, regardless of constituents of the 1,3,5-triazine nucleus, as is shown in Fig. 1.

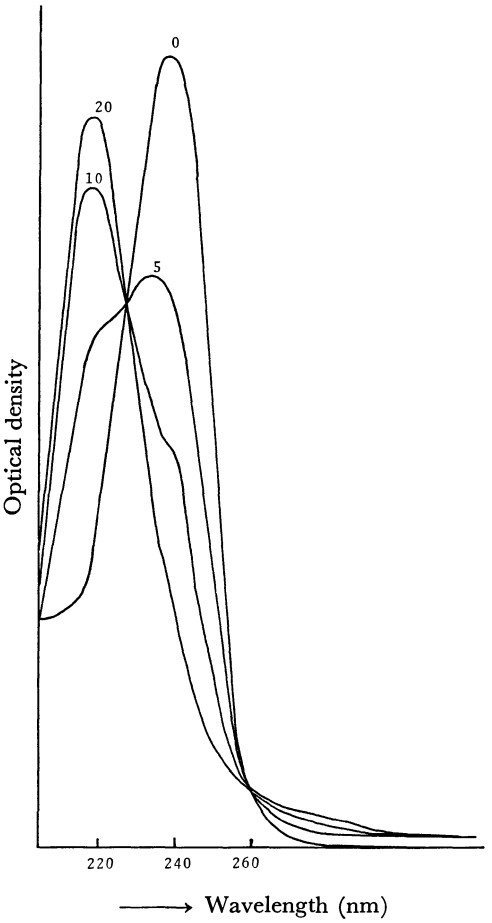

Fig. 1. Spectral change of cyclohexane solution of 2-azido-4,6-dimethoxy-1,3,5-triazine with lapse of time at 254 nm. Numbers refer to time at measurement in min.

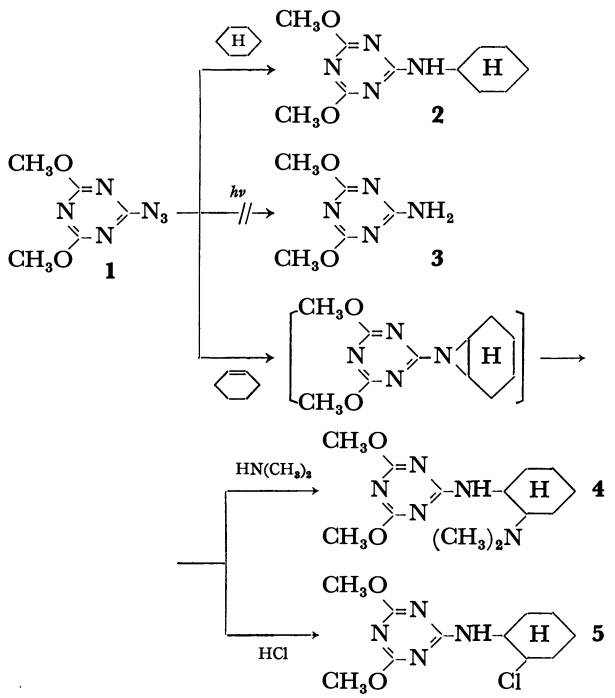
In the photochemical reaction of 2-azido-4,6-dimethoxy-1,3,5-triazine (**1**) in cyclohexane, 2-cyclohexylamino-4,6-dimethoxy-1,3,5-triazine (**2**) was obtained as the sole major photoproduct; in the reaction mixture, no amount of the corresponding amino-1,3,5-triazine (**3**) was observed.

On the other hand, when azido-1,3,5-triazines were irradiated at 254 nm in EPA at 77 K, a new spectrum involving vibrational structure assignable to the corresponding triplet nitrene appeared in the long-wavelength region[9] in all cases. These triplet nitrenes should result from an intersystem crossing of the singlet nitrenes produced by the photodecomposition of the azido-1,3,5-triazines. Ordinary monoazido-1,3,5-triazines are

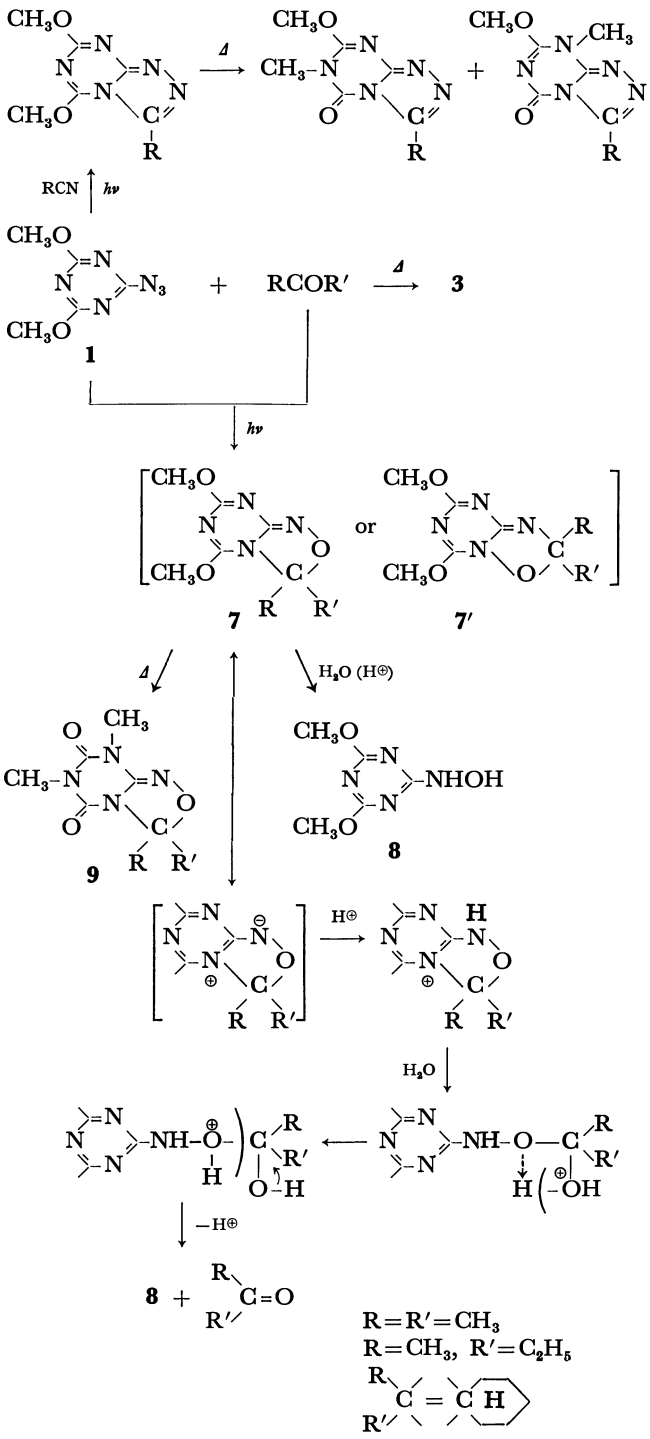
thermally very stable,[1] thus without irradiation they did not react with cyclohexane at room temperature. The photochemical reaction of azido-1,3,5-triazine with cyclohexane can be said to proceed *via* a singlet nitrene intermediate, judging from the formation of cyclohexylamino-1,3,5-triazine and the absence of the hydrogen abstraction product (amino-1,3,5-triazine) in the reaction mixture.

It has been pointed out that in the photochemical reactions of ordinary arylazides with hydrocarbons,[10,11] intermolecular nitrene insertion products are not obtained as the major product. However, in the case of azido-1,3,5-triazine, the reaction proceeded in a similar manner to those of acyl and sulfonyl azides to give the intermolecular insertion products. Thus, even though the 1,3,5-triazine nucleus is an aromatic group, the 1,3,5-triazinyl nitrene behaves as if it were acyl or sulfonyl nitrene rather than ordinary aryl nitrene; the peculiar situation of 1,3,5-triazinyl nitrenes correlates with the strong electron-withdrawing power of this heteroaromatic nucleus.

On the other hand, the photochemical reaction of compound **1** in cyclohexene yielded many kinds of by-products along with one major product. Since isolation and purification of the major product were found to be difficult, the reaction mixture was treated with dimethylamine and hydrochloric acid. The former treatment gave 2-(2-dimethylaminocyclohexylamino)-4,6-dimethoxy-1,3,5-triazine (**4**) while the latter gave 2-(2-chlorocyclohexylamino)-4,6-dimethoxy-1,3,5-triazine (**5**), suggesting that the major photoproduct of **1** with cyclohexene is a derivative of the aziridine type (**6**) resulting from the addition of 1,3,5-triazinyl nitrene to the double bond of cyclohexene. If 2-(cyclohexenylamino)-4,6-dimethoxy-1,3,5-triazine were produced during the photolysis as in the thermal reaction,[1] the final products **4** and **5** would not be produced by these treatments.



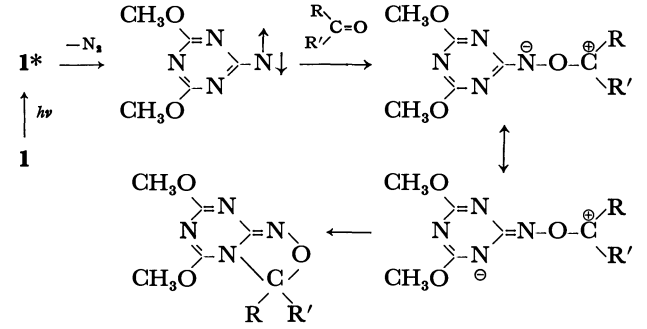
Photochemical Reactions of Azido-1,3,5-triazines with Ketones. Although there are many studies on the photochemical reactions of organic azides, little is known about the photochemical reactions of azides with ketones; only recently, it was reported that ethyl azidoformate reacts with acetone photochemically to give 2-ethoxy carbonyl-3,3-dimethoxyloxazirane, acetonyl carbamate, *etc.*[12] On the other hand, the present authors have recently reported that azido-1,3,5-triazine reacts photochemically with some nitriles to give the derivatives of *s*-triazolo[4.2-*a*]-1,3,5-triazine by the cycloaddition of triazinyl nitrene to nitriles.[9] When 2-azido-4,6-dimethoxy-1,3,5-triazine was irradiated at 254 nm



in acetone, an adduct consisting of the corresponding nitrene and acetone in a molar ratio of 1: 1 was obtained. The compound has two kinds of methoxyl groups and the lack of the characteristic IR band of the saturated aliphatic carbonyl group indicates that the compound has a bicyclic structure resulting from the cycloaddition of the nitrene to acetone, as is shown by **7** or **7'**. Similar photoproducts were obtained when **1** was irradiated at 254 nm in methylethyl ketone and cyclohexanone. On the other hand, it is known that the attempted intermolecular reaction of sulfonyl nitrene with cyclohexanone failed to give any products arising from the nitrene addition.[13] Therefore, even though 1,3,5-triazinyl nitrene behaves similarly to acyl and sulfonyl nitrenes, 1,3,5-triazinyl nitrene is not a mere adherent of acyl or sulfonyl nitrene. From the spectral data, it is difficult to distinguish between the two possible isomers **7** and **7'**. However, these photoproducts were readily hydrolyzed by dilute acid to give hydroxyamino-1,3,5-triazine (**8**) in a good yield indicating that **8** was derived from 7 (3,3-dialkyl derivatives of 5,7-dimethoxy-3*H*-[1,2,4]oxadiazolo[4.3-*a*]-*s*-triazine), because hydroxyamino-1,3,5-triazines do not result from **7'** by hydrolysis in the presence of an acid. The acidic hydrolysis of the photoproducts to give hydroxyamino-1,3,5-triazine (**8**) can be accounted for by the preceding scheme.

From these results, the photoproducts of **1** with ketones and nitriles are found to be very closely related to each other in chemical composition. In the photochemical reaction of **1** with nitriles, the cycloaddition of 1,3,5-triazinyl nitrene is known to proceed *via* a singlet nitrene. On the other hand, the photocycloadditions of carbethoxynitrene to acetone and nitriles[14,15] yielding 2-ethoxycarbonyl-3,3-dimethyloxazirane[12] and 2-alkyl-5-ethoxy-1,3,4-oxadiazoles also are known to proceed *via* a singlet nitrene.

In this case also, the photocycloaddition of triazinyl nitrene to ketones is assumed to proceed *via* a singlet nitrene; the singlet mechanism may be supported by the following data. The starting material (**1**) in aliphatic ketones absorbs more than 95% of the 254 nm incident light, although the solvent has a weak absorption band ($n\rightarrow\pi^*$) at 254 nm ($\varepsilon<4$),[16] and the singlet nitrene should be formed by the decomposition of the excited singlet azido-1,3,5-triazine, whose quantum yield is close to unity.[9] The solvents of ketones, themselves, are triplet quenchers of the starting material, and no effect of the quenchers or dissolved oxygen on the photocycloaddition would oppose the triplet pathway. It is known that the singlet nitrenes are electrophilic. Therefore, it seems likely that the initial step in the present reaction is



the electrophilic attack of the singlet nitrene on the carbonyl oxygen in the ketones followed by cyclization producing the final products, where **1*** is an excited singlet state of **1**. On the other hand, in the thermal reactions of azido-1,3,5-triazines with ketones no product arising from the nitrene addition was produced, for example, when **1** was heated at 180 °C in acetone, 2-amino-4,6-dimethoxy-1,3,5-triazine (**3**) was obtained as the sole major product in a 67% yield. The formation of **3** in this case can be understood in terms of the hydrogen abstraction reaction of the triplet 1,3,5-triazinyl nitrene. In the thermal reaction, there is another possibility that compound **7**, even if produced, decomposes owing to its thermal instability to give compound **3**. However, when compound **7** was heated at 180—190 °C in acetone, the main product obtained was found to be compound **9** resulting from the O→N migration of the methyl groups with a small amount (7%) of compound **3**. Thus, the formation of **7** as an intermediate in the thermal reaction can be neglected; it is apparent that the photochemical and thermal reactions of azido-1,3,5-triazine with ketones proceeded *via* different routes.

Experimental

All the melting points are uncorrected.

2-Azido-4,6-dimethoxy-1,3,5-triazone (**1**) was prepared by the condensation of 2-chloro-4,6-dimethoxy-1,3,5-triazine with sodium azide.[1] Irradiated solutions were concentrated and crystallized products were separated and purified by column chromatography and recrystallization. The assignments of the photoproducts were performed by means of NMR, IR, UV, and mass spectra, elemental analyses and by a mixed-melting-point test with an authentic sample. A low pressure mercury lamp was used as the 254 nm radiation source with a Vycor glass filter.

Photochemical Reaction of Compound 1 with Cyclohexane. A solution of 2.0 g of compound **1** in 300 ml of cyclohexane was irradiated for 10 days. From the irradiated solution 850 mg of the starting material was recovered. Crude 2-cyclohexylamino-4,6-dimethoxy-1,3,5-triazine obtained by purification using column chromatography (silica gel; benzene–acetone= 10: 1 by volume) was recrystallized from methanol to give 720 mg (yield 48%) of the pure product. Mp 125—127 °C (lit,[1] 127—128 °C).

Photochemical Reaction of Compound 1 with Cyclohexene. In this case the primary photoproduct formed in the beginning was found to decompose gradually upon further irradiation. Therefore, the irradiation was stopped at the point of 25% conversion of the starting material. After the solvent hat been evaporated *in vacuo*, the residue was dissolved in 30 ml of acetone and the solution was treated with 10 g of a 40% dimethylamine solution. After standing for 2 hr at room temperature, the solution was treated with an excess of a 2M hydrochloric acid solution to make the mixture acidic, and then, the solution was extreacted with benzene. The aqueous layer was neutralized with sodium carbonate and was extracted with ether to give 800 mg of a pasty substance from which 200 mg (yield 13%) of 2-(2-dimethylaminocyclohexylamino)-4,6-dimethoxy-1,3,5-triazine was obtained by recrystallization from methanol–water. Mp 119.5—120.5 °C. (Found: C, 55.25; H, 8.03; N, 25.11%. Calcd for $C_{13}H_{23}N_5O_2$: C, 55.48; H, 8.24; N, 25.28%) NMR ($CDCl_3$), δ 1.50 (m, 8H), 2.21 (s, 6H), 2.44 (m, 1H), 3.60 (m, 1H), 4.00 (s, 6H), 6.17 (broad, 1H). The benzene layer was evaporated and the residue was dissolved in

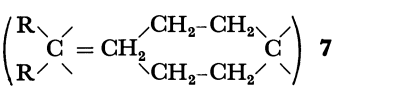
a small amount of ethanol. From the ethanolic solution the crystalline precipitate of 2-(2-chlorocyclohexylamino-4,6-dimethoxy-1,3,5-triazine was obtained by the addition of a small amount of water. Mp 170—171 °C (benzene–ligroin). Yield: 580 mg (39%). (Found: C, 48.71; H, 6.43; N, 20.78%. Calcd for $C_{11}H_{17}ClN_4O_2$: C, 48.44; H, 6.28; N, 20.54%) Mass: m/e=272. NMR ($CDCl_3$), δ 1.60 (m, 9H), 4.00 (s, 7H), 6.20 (broad, 1H). Thus, in the photochemical reaction of compound **1** with cyclohexene, the yield of the derivative of the aziridine type should exceed 50% of the decomposed azide.

Photochemical Reaction of Compound 1 with Ketones. A typical run is the case of the reaction of compound **1** with acetone. A solution of 1.0 g of compound **1** in 20 ml of acetone was irradiated for 24 hr. The solvent was evaporated *in vacuo* and the residue was purified by column chromatography (alumina: benzene–acetone= 10: 5 by volume) to give 300 mg of the starting material and 3,3-dimethyl-5,7-dimethoxy-3*H*-[1,2,4]oxadiazolo[4.3-*a*]-*s*-triazine in a 30% yield. Mp 144—145 °C (benzene–ligroin). (Found: C, 45.05; H, 5.43; N, 26.22%. Calcd for $C_8H_{12}N_4O_3$: C, 45.28; H, 5.70; N, 26.40%) Mass: m/e=212. NMR ($CDCl_3$), δ 1.70 (s, 6H), 3.92 (s, 3H), 4.07 (s, 3H). IR (KBr, cm^{-1}) (C=N), 1665.

Hydrolysis of Compound 7 in the Presence of Hydrochloric Acid. A mixture of 800 mg of compound **7** and 7 ml of a dilute hydrochloric acid solution (the pH of the solution was about 3.0) was warmed in a water bath for 3 min. After cooling, the solution was neutralized with sodium carbonate to give 550 mg (yield 85%) of hydroxyamino-4,6-dimethoxy-1,3,5-triazine as a crystalline precipitate. Mp 174—175 °C (under decomposition) (Methanol). (Found: C, 35.10; H, 4.82; N, 32.35 %. Calcd for $C_5H_8N_4O_3$: C, 34.88; H, 4.68; N, 32.55%). The compound was identified by a mixed-melting-point test with an authentic sample prepared by the condensation of 2-chloro-4,6-dimethoxy-1,3,5-triazine with hydroxylamine in the presence of sodium carbonate.

Similarly, in the reaction of compoun **1** with methyl ethyl ketone, compound **7** (R=CH_3, R′=C_2H_5) was obtained in a 52% yield. Mp 110—111 °C (benzene–ligroin). (Found: C, 47.83; H, 6.42; N, 24.92%. Calcd for $C_9H_{14}N_4O_3$: C, 47.78; H, 6.23; N, 24.76%). NMR ($CDCl_3$), δ 0.98 (t, 3H), 1.67 (s, 3H), 2.00 (m, 2H), 3.94 (s, 3H), 4.10 (s, 3H).

In the reaction of compound **1** with cyclohexanone, compound **7** was obtained in a 46% yield. Mp 137—138 °C (benzene–ligroin). (Found: C, 52.51; H, 6.44; N, 21.98%. Calcd for $C_{11}H_{16}N_4O_3$: C, 52.37; H, 6.39; N, 22.21%) NMR ($CDCl_3$), δ 1.80 (m, 10H), 3.94 (s, 3H), 4.08 (s, 3H).



7

Rearrangement of Compound 7 in Acetone. When a solution of 600 mg of compound **7** (R=R′=CH_3) in 50 ml of acetone was heated at 180—190 °C in an autoclave, 30 mg (7% yield) of crude 2-amino-4,6-dimethoxy-1,3,5-triazine [mp 210—214 °C (dioxane) (lit.,[17] 219 °C)] and 150 mg (yield 25%) of a product of mp 87—88 °C (methanol) were obtained. The latter compound was assigned to compound **9**, on the basis of the follwoing data. (Found: C, 45.45; H, 5.85; N, 26.31%. Calcd for $C_8H_{12}N_4O_3$: C, 45.28; H, 5.70; N, 26.40%). Mass: m/e=212. IR (KBr, cm^{-1}) (C=O), 1700, 1750: (C=N), 1650. NMR (CCl_4), δ 1.70 (s, 6H), 3.19 (s, 3H), 3.23 (s, 3H).

Thermal Reaction of Compound 1 with Acetone. When a solution of 3.0 g of compound **1** in 50 ml of acetone was heated at 180 °C for 12 hr in an autoclave, 2-amino-4,6-dimethoxy-1,3,5-triazine [mp 211—214 °C (dioxane)] was obtained in a 67% yield.

Low-temperature NMR Studies of the Conformations of 3-Aryl-1,2,3-oxathiazolidine 2-Oxides

Fukiko YAMADA, Tomihiro NISHIYAMA, and Hiroshi SAMUKAWA

Department of Applied Chemistry, Faculty of Engineering, Kansai University, Senriyama, Suita, Osaka 564

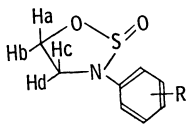
(Received June 12, 1975)

A complete iterative NMR spectral analysis has been carried out for twelve 3-aryl-1,2,3-oxathiazolidine 2-oxides at several low temperatures over a range of 111 °C. The magnitudes of the two vicinal coupling constants either increased or decreased markedly with a decrease in the temperature. On the basis of the resulting vicinal coupling constants, the correlations between the ratios of the vicinal coupling constants and the corresponding torsion angles were obtained and made it possible to assign their twist-envelope conformations. From the experimental data, the parameters of the Karplus equation could be given:

$$J\,\mathrm{vic} = 5.3 - \cos(135\pm\theta) + 4.3\cos 2(135\pm\theta)$$
$$+45^\circ \geq \theta \geq -45^\circ$$

In a previous paper of this series, the twist-envelope conformations have been assigned to the oxathiazolidine ring of 3-aryl-1,2,3-oxathiazolidine 2-oxides (**1**) on the basis of the vicinal coupling constants at room temperature.[1] These assignments are consistent with the results of the solvent-shift determinations.

The present study was initiated in order to examine the NMR spectral data at several low temperatures for the following compounds:



1

I, R=H	IIIc, R=*p*-OCH_3
IIa, R=*o*-CH_3	IV, R=*p*-Br
IIb, R=*m*-CH_3	Va, R=*o*-Cl
IIc, R=*p*-CH_3	Vb, R=*m*-Cl
IIIa, R=*o*-OCH_3	Vc, R=*p*-Cl
IIIb, R=*m*-OCH_3	VI, R=2,4,6-tri-Cl

Experimental

Compounds. A series of **1** compounds was prepared and was then purified by a previously reported method.[2,3] The reaction conditions and the physical properties of **1** were reported in our previous paper.[1]

NMR Spectral Determination. All the NMR spectra were recorded at 100 MHz on a Japan Electron Optics Model JNM-PS-100 spectrometer equipped with a Japan Electron Optics Model JNM-VT-3C variable-temperature controller, using acetone-d_6 as the solvent (0.5 mmol/ml). The probe temperature was measured both with a thermocouple and by the peak separation of a calibrated methyl alcohol sample; it is considered accurate to ±2 °C. The chemical shifts were reported in ppm downfield from the internal TMS. The details of the analyses and the stereochemical assignments were also provided in the previous paper.[1]

Results and Discussion

Spectra at Low Temperatures in an Acetone-d_6 Solution. Table 1 shows the NMR spectral data for the methylene protons of the **1** compounds at room temperature. Insignificant variations are observed in the NMR parameters in acetone-d_6 solutions relative to those in CCl_4 or $CDCl_3$–CCl_4 solutions at room temperature.[1] In this study, the shapes of all the NMR signals at several low temperatures over a range of 111 °C are quite similar. That is, cooling a sealed NMR tube containing one of the **1** compounds in acetone-d_6 at temperatures down to −85 °C (with the exception of the VI compound) produced no major change in the signals.

TABLE 1. CHEMICAL SHIFTS AND COUPLING CONSTANTS OF THE METHYLENE PROTONS OF THE **1** COMPOUNDS, IN ACETONE-d_6 AT 26 °C

Compd.	Chemical shifts, δ ppm				Geminal, Hz		Vicinal, Hz				r	θ

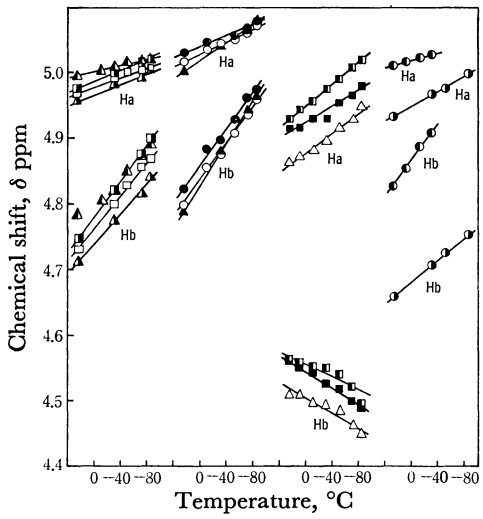
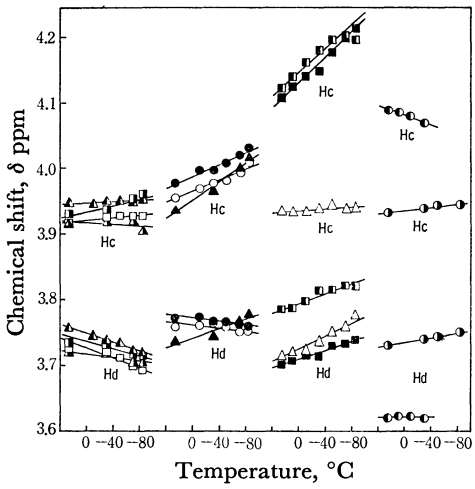
a) Values for J_{bc}/J_{ad}

Chemical Shifts. The chemical shifts for the methylene protons, H_a, H_b, H_c, and H_d, at several low temperatures are shown in Figs. 1-a and 1-b. From these observations, it is clear that the chemical shifts of the methylene protons of the **1** compounds are dependent on the temperatures, moving either to a lower or a higher field with a decrease in the temperature.





Figs. 1-a and 1-b. Temperature-dependence of the chemical shifts of the methylene protons of the **1** compounds.
Group 1a ▲, I; □, IIb; ◭, IIc; ◨, IIIb
Group 1b ▲, IV; ●, Vb; ○, Vc
Group 2 ■, IIa; △, IIIa; ◧, Va
Group 3, 4 ◑, IIIc; ◐, VI

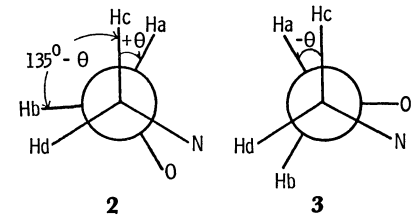
In the previous paper,[1] we proposed that the conformations of the **1** compounds could be divided roughly into several groups on the basis of their well-defined patterns of the appearance of the methylene-proton signals, the ratios (r values) of the vicinal coupling constants (that is, J_{ad}/J_{bc} or J_{bc}/J_{ad}), their torsion angles, and the data of the solvent-shift studies in benzene (Table 2). In this present study, the characteristic properties of these groups are reflected in the temperature-dependence of their methylene-proton chemical shifts. In particular, with a decrease in the temperature the H_b proton shifts of the IIa, IIIa, and Va compounds in Group 2 move markedly toward a higher field in comparison with those of other H_b protons. This interesting feature may be caused by the presence of an *o*-substituent.

Table 2. Classification of the conformations of the **1** compounds

Group	R	r value	θ°
1a	H, *m*-CH_3, *p*-CH_3, *m*-OCH_3	1.59—1.89[a] (1.8—2.2)[b]	9.0—13.1 (11—15)
1b	*p*-Br, *m*-Cl, *p*-Cl	2.00—2.20 (1.9—2.2)	13.5—15.2 (12—15)
2	*o*-CH_3, *o*-OCH_3, *o*-Cl	1.37—1.98 (1.3—1.8)	−6.2—−13.1 (−5—−11)
3	*o*-OCH_3, *p*-OCH_3	1.23—1.37 (1.2—1.3)	−6.2—+4.0 (−5—+4)
4	tri-Cl	4.48 (4.7)	28.6 (≥30)

a) The values in upper line are obtained in this study.
b) The values obtained in the previous paper[1] are shown in parentheses.

Geminal Coupling. Two geminal coupling constants of the **1** compounds have been determined in this study; they were found not to vary significantly in the temperature range of 111 °C. This phenomenon means that the angle of neither H_a–C_5–H_b nor H_c–C_4–H_d changes, not even at low temperatures.

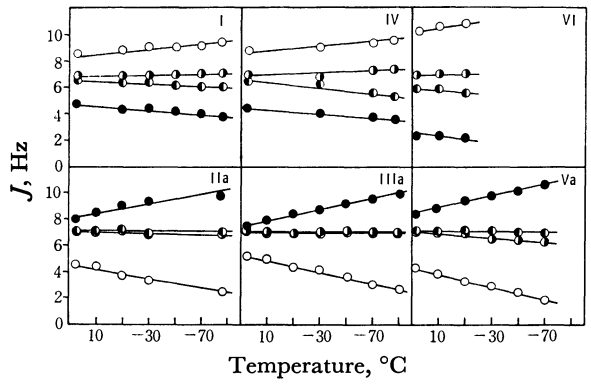


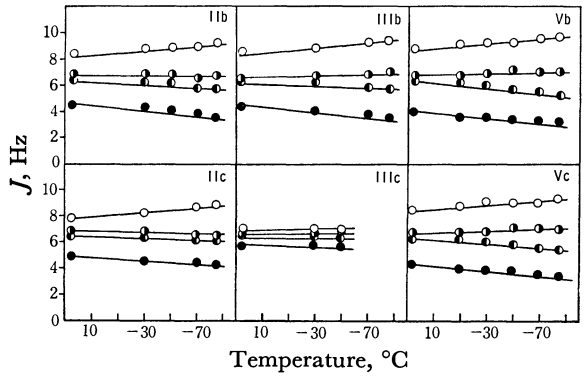
2 **3**

Fig. 2. Diagrams of **2** and **3** forms of the parts of methylene protons of **1**.
Dihedral angle (ϕ) = 135 °±Torsion angle (θ).

Vicinal Coupling. As has been discussed in our previous study,[1] the vicinal coupling data for the four methylene protons of the **1** compounds corroborate the explanations that the distortions of the compounds with an *m*- or *p*-substituent are in the direction of the **2** projection (in Fig. 2), while those with an *o*-substituent cause distortion toward the **3** projection. Furthermore, the r values, J_{ad}/J_{bc} for the **2** projection and J_{bc}/J_{ad} for the **3** projection, have been found to be nearly independent of the electronegativity of the substituent and of other factors, and to be dependent only on each dihedral angle. It was, therefore, possible to determine the conformational effects by means of the r value.

Figures 3-a and 3-b show the vicinal coupling constants, J_{ad}, J_{bd}, J_{ac}, and J_{bc}, of the **1** compounds at various low temperatures. The value of J_{ad} or J_{bc} increased with a decrease in the temperature, whereas J_{bc} or J_{ad} decreased with a decrease in the temperature. These figures clearly show that the values of J_{ad} and J_{bc} of the **1** compounds change almost linearly with the temperatures in the range from 26 to −85 °C. When the two straight lines for J_{ad} and J_{bc} are extended, the





Figs. 3-a and 3-b. Vicinal coupling constants of the **1** compounds at various temperatures.
○, J_{ad}; ◑, J_{bd}; ◐, J_{ac}; ●, J_{bc}

two lines intersect around 6.3, are symmetrical with respect to the line which is parallel with the x-axis, and pass through the point of 6.3 on the y-axis. That is, the average value of J_{ad} and J_{bc} obtained from the experimental data (118 pieces) of all the **1** compounds is 6.331. The results indicate that, at each intersection point, the values of both J_{ad} and J_{bc} are the same and are very close to 6.3 Hz; therefore, their r value becomes 1.000.

In the case of the well-known Karplus equation ($90 \leq \theta \leq 180°$), the curve passes through the inflection point at 135°.[4] From our results presented above that the increasing and decreasing straight lines are symmetrical and show the same gradient, it is possible to get a rough idea of the value of the projection angle of a CH_2 group—that is, the angles of H_a–C_5–H_b and H_c–C_4–H_d. (Fig. 2). We therefore suggest that, in the case of the oxathiazolidine ring, the projection angle is no longer 120°, but is close to the value of 135°, corresponding to the above inflection point.

On the other hand, the projection angle of a CH_2 group in the five-membered rings, must be larger than the 120° in the six-membered rings. At present, it is not possible to obtain an accurate value of the projection angle in the five-membered rings. However, it was necessary to estimate the size of this angle. Usually the value of 120° in the six-membered rings has been used for the calculation of Karplus-type equations of the five-membered rings.[1,5-7]

On the basis of the above observations and the results of the previous investigation,[1] we may set the following parameters of the Karplus equation by means of a "trial

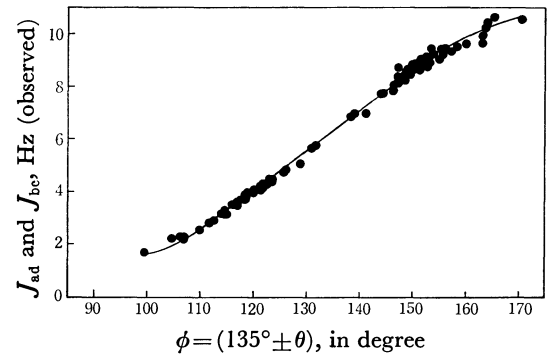


Fig. 4. Plots of the observed vicinal coupling constants, J_{ad} and J_{bc}, of all the **1** compounds at various temperatures *vs.* the dihedral angles.
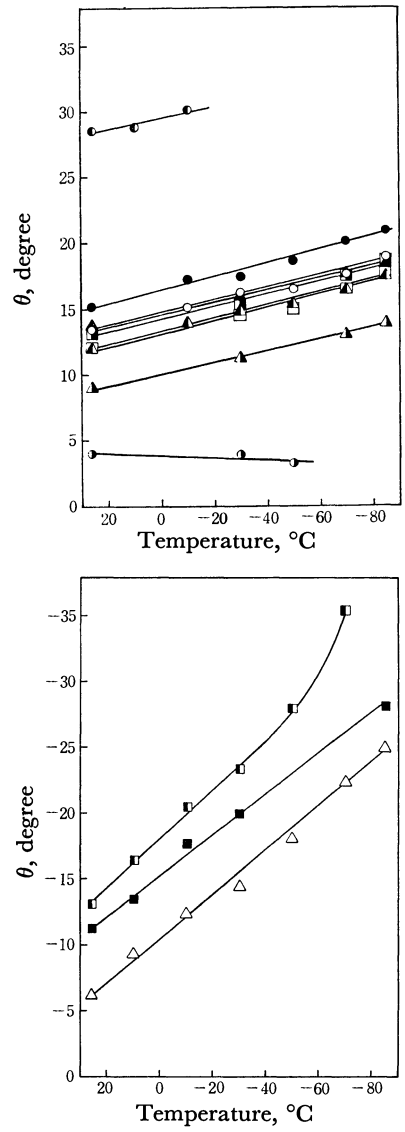
——, Calculated curves by Karplus eq.
●, J_{ad} or J_{bc}; number of dots in this figure is 118 pieces.



Figs. 5-a and 5-b. Temperature dependence of the torsion angles of the **1** compounds.
Group 1a: ◭, I; □, IIb; ▲, IIc; ◨, IIIb
Group 1b: ▲, IV; ●, Vb; ○, Vc
Group 2: ■, IIa; △, IIIa; ▮, Va
Group 3: ◑, IIIc
Group 4: ◐, VI

and error" procedure;

$$r = (J_{ad}/J_{bc}) \text{ or } (J_{bc}/J_{ad})$$
$$= \frac{5.3-\cos(135+\theta)+4.3\cos 2(135+\theta)}{5.3-\cos(135-\theta)+4.3\cos 2(135-\theta)}$$
$$+45° \geq \theta \geq -45°$$

After setting the above parameters, we evaluated the correlation among the θ, J, and r values. Then, the torsion angles can be obtained from the observed values of J_{ad} and J_{bc} by using this relation. Figure 4 shows the plots of the observed vicinal coupling constants, J_{ad} and J_{bc}, of all the **1** compounds at various low temperatures *vs.* the dihedral angles obtained by means of the above procedure. The experimental data clearly fall on the calculated Karplus curve for the above parameters.

Torsion Angles at Low Temperatures. The torsion angles of the **1** compounds at 26 °C are shown in Table 1. Figures 5-a and 5-b show the data at various low temperatures. The values of θ increased with the decrease in the temperature, except in the IIIc compound. As can be seen in these figures, the compounds belonging each group show a similar tendency toward increasing the torsion angle. These findings indicate that each group shows a sterically different feature.

Cyclic Dimerization of Ethyl 1-Arylethylidenecyanoacetates with Grignard Reagents

Shoji HAYASHI, Takami ANII, and Taizo TAMANO

Department of Chemistry, Faculty of Science, Kwansei Gakuin University, Uegahara, Nishinomiya, Hyogo 662

(Received June 24, 1975)

The treatment of ethyl 1-arylethylidenecyanoacetates (I) with Grignard reagents, especially mesitylmagnesium bromide, gave ethyl 2,4-diaryl-5-cyano-5-ethoxycarbonyl-6-imino-4-methyl-1-cyclohexenecarboxylates (II), a dimer of I.

The preparation of ethyl *t*-alkylcyanoacetate by the conjugate addition of Grignard reagents to ethyl 1-alkylethylidenecyanoacetate has been reported.[1] The treatment of ethyl 1-arylethylidenecyanoacetate (I)[2] with isopropylmagnesium bromide yielded ethyl 3-aryl-2-cyano-3-isopropylbutanoate and an unknown yellow compound II, which is a dimeric product. It was found that ester I reacted with mesitylmagnesium bromide (MesMgBr) to give only the same unknown dimeric product. Other Grignard reagents also yielded the dimeric product, as shown in Table 1. The structure of the dimeric product was assumed to be ethyl 2,4-diaryl-5-cyano-5-ethoxycarbonyl-6-imino-4-methyl-1-cyclohexenecarboxylate (II) on the basis of the mechanism of base-catalyzed dimerization shown in Chart 1.

TABLE 1. YIELD (%) OF DIMER II

Chart 1

The IR spectrum of compound IIa showed the presence of two ester groups (an α,β-unsaturated and a saturated ester), a cyano and an imino group (see Experimental). The NMR spectrum showed signals assigned to a tertiary methyl, a methylene group, and two ethoxy groups (see Experimental).

Compound IIa was stable for refluxing in conc. hydrochloric acid; however, the treatment of IIa with an acetic acid-concd hydrochloric acid solution under reflux gave white crystals (IIIa). The IR spectrum showed no absorption band due to the ester, cyano, and imino groups, but carbonyl bands due to α,β-unsaturated ketone and an amide group were observed. The UV spectrum showed an absorption maximum at 293 nm characteristic of 3-phenyl-2-cyclohexenone systems.[3] The above results, therefore, indicate that the imino group of compound IIa was hydrolyzed with the simultaneous hydrolytic decarboxylation of two ethoxycarbonyl groups.

The NMR spectrum of IIIa showed the presence of a vinyl, a tertiary methyl, a methylene (ABX-type), a methine (singlet), and an amide proton (see Experimental). The methine singlet due to H-6 indicates the presence of two groups (phenyl and methyl) on C-5. Therefore, the amide group is located on C-6.

From these data, compound IIIa was assigned to 6-carbamoyl-5-methyl-3,5-diphenyl-2-cyclohexenone.

The alkaline hydrolysis of IIa with potassium hydroxide in boiling ethylene glycol afforded pale yellow crystals (IVa). The IR spectrum showed the presence of an amino and a cyano group, and the NMR spectrum revealed signals due to the ABX system, in which the AB pattern of methylene appeared at δ 2.94 and the X part (a vinylic proton) at 6.02. From the results, IVa was assigned to 2-amino-6-methyl-4,6-diphenyl-1,3-cyclohexadienecarbonitrile.

The oxidation of IIa with alkaline hydrogen peroxide in acetone gave epoxide (Va). The epoxidation of the double bond caused the shift of the UV absorption band of a conjugated system to that of a simple aromatic system (see Experimental).

IIb was assigned to ethyl 5-cyano-5-ethoxycarbonyl-6-imino-4-methyl-2,4-di(*p*-tolyl)-1-cyclohexenecarboxylate from spectral analysis (see Experimental).

In contrast with the acid hydrolysis of IIa, IIb gave a product (IIIb) with the simultaneous loss of carbonyl groups. The analogy in the ring system was supported by the UV spectrum (λ_{max} 296 nm).[4]

IIb gave 2-amino-6-methyl-4,6-di(*p*-tolyl)-1,3-cyclohexadienecarbonitrile (IVb) by alkaline hydrolysis.

The epoxidation of IIb gave no crystalline products.

Experimental

All melting points are uncorrected. Unless otherwise noted, UV, IR, and NMR spectra were measured in 95% ethanol, chloroform, and deuteriochloroform (with TMS as an internal standard), and presented in λ_{max} nm (log ε), ν_{max} cm^{-1}, and δ ppm, respectively. The instruments used for the measurements are a Cary 14 recording spectrophotometer, a JASCO model DS-402G infrared spectrophotometer, and a JEOLCO model

C-60 spectrometer.

Materials. Ethyl 1-phenylethylidenecyanoacetate (Ia) was prepared according to the method of McElvain and Clemens,[5] bp 149.5—153 °C/3 Torr (lit,[5] 135—160 °C/0.35 Torr); Ethyl 1-(*p*-tolyl)ethylidenecyanoacetate (Ib) was prepared accoding to the methob of Cope,[6] bp 122—123 °C/ 3.5×10^{-3} Torr (lit,[6c] 160—170 °C/10 Torr).

Reaction of Ethyl 1-Arylethylidenecyanoacetate (I) with Grignard Reagent. To a Grignard solution, prepared from 2.92 g (0.12 mol) of magnesium, 0.12 mol of alkyl halide, and 22 ml of absolute ether, was added 0.1 mol of I in 30 ml of refluxing absolute ether over a period of 20 min. The mixture was refluxed under stirring for 1 hr and then left to stand overnight. An excess of the Grignard reagent was decomposed by the addition of aqueous ammonium chloride. The reaction mixture was extracted with ether and the ethereal extract was dried. After removal of the solvent, the residue dissolved in ethanol was treated with active carbon, and cooled with ice. The resulting yellow crystals were washed with cold ethanol, and recrystallized from ethanol to give II. The filtrate was concentrated *in vacuo* and analyzed by chromatography on silica gel. Elution with benzene-ethyl acetate (10: 1, v/v) gave yellow crystals (II). Combined II was recrystallized from 50% ethanol (the yield is indicated in the yield table). A pure sample was obtained after several recrystallizations.

a) IIa: Mp 134.5—135.0 °C. IR: 3400 (=NH), 2221 (C≡N), 1746, 1706 (C=O), and 1626 (C=C). UV: 240 (4.05) and 324 (3.97). NMR: 0.75 (t, 3H, J=7 Hz), 1.31 (t, 3H, J=7 Hz), 1.70 (s, 3H), 3.08 (ABq, 2H, J=18 Hz, $\nu_0\delta$=8.7 Hz), 3.88 (q, 2H, J=7 Hz), 4.27 (q, 2H, J=7 Hz), and 6.95—7.61 (m, 11H, 2 Ph and =NH). Found: C, 72.70; H, 6.01; N, 6.37%. Calcd for $(C_{13}H_{13}O_2N)_2$: C, 72.54; H, 6.09; N, 6.51%.

b) IIb: Mp 149.0—150.0 °C. IR: 3405 (=NH), 2219 (C≡N), 1741, 1702 (C=O), and 1617 (C=C). UV: 246 (4.07) and 336 (4.03). NMR: 0.80 (t, 3H, J=7 Hz), 1.29 (t, 3H, J=7 Hz), 1.65 (s, 3H), 2.30 (s, 6H), 3.01 (ABq, 2H, J=17 Hz, $\nu_0\delta$=10.5 Hz), 3.87 (q, 2H, J=7 Hz), 4.21 (q, 2H, J=7 Hz), and 6.80—7.37 (m, 9H). Found: C, 73.33; H, 6.57; N, 5.94%. Calcd for $(C_{14}H_{15}O_2N)_2$: C, 73.34; H, 6.59; N, 6.11 %.

Acid Hydrolysis of II. A mixture of 1 g of II, 10 ml of acetic acid and 5 ml of conc. hydrochloric acid was boiled under reflux for 13 hr. Carbon dioxide was evolved during the reaction. The reaction mixture was concentrated under reduced pressure. The residue dissolved in ether was washed with saturated aqueous sodium bicarbonate and the solvent was distilled off. The residue dissolved in benzene was analyzed by chromatography on silica gel and eluted with benzene. Elution with benzene gave white crystals, which, after recrystallization from ethanol, gave a pure sample (III).

a) IIIa: Yield 80 mg, mp 181.0—181.5 °C. IR (KBr disk): 3382, 3164 (NH_2), 1686 (amide I), 1632 (C=O), and 1600 (C=C). UV: 293 (4.22) and 255^{sh} (4.01). NMR (DMSO-d_6, JEOLCO PS-100 spectrometer): 1.51 (s, 3H), 3.38 (ABX, 2H, J_{AB}=18.5 Hz, J_{BX}=2 Hz, $\Delta\nu_{AB}$=12 Hz), 3.91 (s, 1H), 6.30 (d, 1H, J=2 Hz), 7.32 (s, 2H), 7.54 (m, 5H), and 7.77 (m, 5H). Found: C, 78.47; H, 6.28; N, 4.39%. Calcd for $C_{20}H_{19}O_2N$: C, 78.66; H, 6.27; N, 4.59%.

b) IIIb: Yield 450 mg, mp 105.0—106.5 °C. IR: 1655 (C=O) and 1607 (C=C). UV: 296 (4.29), 217^{sh} (4.22), and 231^{sh} (4.00). NMR (CCl_4): 1.41 (s, 3H), 2.28 (s, 3H), 2.36 (s, 3H), 2.59 (d, 2H, J=9 Hz), 2.89 (d, 2H, J=6 Hz), 6.21 (s, 1H), 7.06 (m, 4H), and 7.24 (m, 4H). Found: C, 87.12; H, 7.81%. Calcd for $C_{21}H_{22}O$: C, 86.85; H, 7.64%.

Alkaline Hydrolysis of II. A mixture of 1 g of II, 4.3 g (76.6 mmol) of potassium hydroxide and 280 ml of ethylene glycol was refluxed for 3 hr. The reaction mixture was poured into cold water, and extracted with ether. The ethereal extract was washed with saturated aqueous sodium chloride, drted and evaporated producing pale yellow crystals.

a) IVa: Yield 230 mg, mp 158.0—159.0 °C. Several recrystallizations from ethanol gave a pure sample, mp 158.5—159.0 °C. IR: 3399, 3490 (NH_2), 2193 (C≡N), 1645, and 1621 (C=C). UV: 271 (4.20) and 358 (4.06). NMR: 1.61 (s, 3H), 2.94 (ABX, 2H, J_{AB}=17 Hz, J_{AX}=1.8 Hz, $\Delta\nu_{AB}$= 14.4 Hz), 4.51 (s, 2H), 6.02 (d, 1H, J_{AX}=1.8 Hz), and 7.30 (m, 10H). Found: C, 83.95; H, 6.53; N, 9.95%. Calcd for $C_{20}H_{18}N_2$: C, 83.88; H, 6.34; N, 9.78%.

b) IVb: Yield 800 mg, mp 171.5—174.5 °C. Several recrystallizations from ethanol gave a pure sample, mp 174.0—175.0 °C. IR: 3490, 3399 (NH_2), 2190 (C≡N), 1642, and 1620 (C=C). UV: 275 (4.20) and 358 (4.05). NMR: 1.62 (s, 3H), 2.25 (s, 3H), 2.32 (s, 3H), 2.92 (ABX, 2H, J_{AB}=17 Hz, J_{AX}=1.8 Hz, $\Delta\nu_{AB}$=14.4 Hz), 4.44 (s, 2H), 6.02 (d, 1H, J_{AX}=1.8 Hz), and 7.00—7.40 (m, 8H). Found: C, 84.20; H, 7.24; N, 8.95%. Calcd for $C_{22}H_{22}N_2$: C, 84.04; H, 7.05; N, 8.91%.

Hydrogen Peroxide Oxidation of IIa. To a mixture of 1 g (2.33 mmol) of IIa, 25 ml of 30% hydrogen peroxide and 35 ml of acetone was added 3 ml of 10% aqueous sodium carbonate at room temperature over a period of 20 min. The mixture was heated in a water bath for 3 min and then left to stand for two days. The excess of hydrogen peroxide was decomposed by the addition of aqueous sodium thiosulfate. The reaction mixture was evaporated under reduced pressure, and then cooled with ice-water. The resulting white crystals were recrystallized several times from 50% aqueous ethanol to give a pure sample, mp 157.5—158.0 °C, yield 300 mg. IR: 3425 (=NH), 2227 (C≡N), 1751, and 1718 (C=O). UV: 266 (4.13). NMR: 0.72 (t, 3H, J=7 Hz), 1.31 (t, 3H, J=7 Hz), 1.70 (s, 3H), 2.59 (ABq, 2H, J=15 Hz, $\nu_0\delta$=21.3 Hz), 3.75 (q, 2H, J=7 Hz), 4.22 (q, 2H, J=7 Hz), 6.47 (m, 1H), and 7.07—7.44 (m, 10H). Found: C, 70.07; H, 5.89; N, 6.37%. Calcd for $C_{26}H_{26}O_5N_2$: C, 69.94; H, 5.87; N, 6.27%.

The authors are indebted to Professors Takeo Sakan and Toshio Miwa of Osaka City University, for fruitful discussions.

Anomeric Effect Involving Carboxyl and Ethynyl Group in Sulfur-Containing Heterocycles

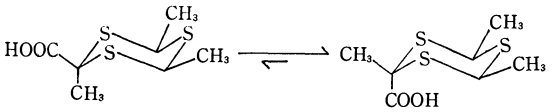
Kazutaka ARAI, Hiizu IWAMURA, and Michinori ŌKI

Department of Chemistry, Faculty of Science, The University of Tokyo, Tokyo 113

(Received June 24, 1975)

Normal anomeric effect is found in 1,3-dithiane-2-carboxylic acid, 1,3,5-trithiane-2-carboxylic acid, and their esters, in contrast to a report that oxane-2-carboxylic acid derivatives exhibit reverse anomeric effect. The results are interpreted from the difference in bond lengths between oxanes and polythianes which affects the extent of 1,3-diaxial interaction. The anomeric effect is found to be larger in 1,3-dithianes than in 1,3,5-trithianes. The differences is discussed on the ground of the energy levels of available electrons. Phenylethynyl derivatives also show small but definite anomeric effect.

During the course of other study, we needed a pair of 2,4,5-trimethyl-1,3,5-trithiane-2-carboxylic acids. Since the electrophilic reaction of 1,3,5-trithianide or 1,3-dithianide anion is known to proceed from the equatorial side,[1,2] it is no wonder to obtain 2,*c*-4,*c*-6-trimethyl-1,3,5-trithiane-*r*-2-carboxylic acid (**1e**) on treatment of 1,3,5-trithianide anion with carbon dioxide. We then tried to equilibrate **1e** with 2,*t*-4,*t*-6-trimethyl-1,3,5-trithiane-*r*-2-carboxylic acid (**1a**) with the aid of an acidic catalyst. The result was, however, almost a complete conversion to **1a**.



1e **1a**

The result indicates that the carboxyl-axial form is more stable than the carboxyl-equatorial form by *ca.* 2 kcal/mol or more and aroused our interest for the following reasons. The equilibration results may be explained by the stabilization of isomers governed by the anomeric effect,[3] since the carboxyl group is electronegative and provides a low-lying lowest unoccupied molecular orbital (LUMO). The anomeric effect in trithiane is known to be strong.[4] Contrary to these considerations, however, methyl oxanecarboxylate derivatives were found to be more stable in the methoxycarbonyl-equatorial conformation[5] and the phenomenon is referred to as reverse anomeric effect.

This sharp contrast of the trithiane case to the case of oxanes stimulated the further study on the reverse and/or normal anomeric effect and a series of studies of the polythiane cases have been undertaken. This paper is to describe the results of such studies, which conclude the presence of anomeric effect in the carboxypolythianes.

Syntheses and Structural Assignment

The monocarboxylic acids were prepared by carbonation of the corresponding lithio derivatives. Esters of the acids were prepared by the action of diazomethane on the free acids. Action of thionyl chloride to form acid chloride gave satisfactory results with the stable carboxylic acids but caused isomerization when applied to the less stable ones.

Phenylethynyl derivatives were prepared from chloropolythianes and phenylethynylmagnesium bromide.

9: X=CH_2

When a compound in question carries an α-proton to the carboxyl or methoxycarbonyl group, the structural assignment is straightforward. The proton gives a singlet signal and the paramagnetic shift is observed for the axial proton owing to the anisotropy of the C–S bonds.[6] Therefore the carboxyl-axial form gives a singlet signal at a higher field than the counterpart. In addition, the axial isomer gives a broad signal for the equatorial proton due to the presence of W-type long range coupling.[7] The difference in chemical shifts of methylene protons is also a clue for diagnosis of the conformation of 2-substituted 1,3,5-trithianes. The substituent-axial conformation gives larger difference in chemical shifts than the counterpart because of the anisotropy effect of the substituent.[4]

Those which possess a methyl group in α-position may be assigned in a similar manner. However, ambiguity may arise because of the long averaged distance of the methyl protons from the C–S bonds. Firm evidence for the configurations of **5a** and **5e** was obtained by measurement of the nuclear Overhauser effect. On irradiation of the methyl protons in position 2 of compound **5e**, the absorption intensity of the methine protons in positions 4 and 6 increased by 16%. In contrast, the same operation for the isomer **5a** caused no measurable enhancement. The results unambiguously show that 4- and 6-H's and 2-methyl are located closely in compound **5e** and consequently compound **5e** has the structure as shown.

5a

Results and Discussion

Equilibration of Polymethyltrithianecarboxylic Acids. Equilibration was carried out by using boron trifluoride etherate as a catalyst in various solvents and the results are summarized in Table 1.

Table 1. Conformational equilibrium data of polymethylpolythianecarboxylic acids and their derivatives at 23 °C

System	Solvent	ε	K	$\Delta G°$ (kcal/mol)
1a⇄**1e**	CCl_4	2.2	<0.02	>2.3
	CH_3CN	37.5	<0.02	>2.3
5a⇄**5e**	CCl_4	2.2	<0.005	>3.2
	$ClCH_2CH_2Cl$	10.7	<0.005	>3.2
	CH_3CN	37.5	~0.01	~2.7
2a⇄**2e**	CH_3CN	37.5	0.4	0.24

The results indicate that the axial form **1a** is one-sidedly more stable than the equatorial isomer **1e** in various solvents. The solvent effect on population is hardly seen because of the strong stabilization of the axial isomer: it is only acetonitrile that enabled us to measure the population of the less stable form of the ester and to calculate the difference in free energies at 23 °C which was obtained as 2.7 kcal/mol. In a series of cyclohexane derivatives, A values for methyl and methoxycarbonyl groups are known to be 1.7 and 1.2 kcal/mol, respectively.[8,9] Therefore the difference in conformational energies between cyclohexane analogs of **1a** and **1e** may amount to 0.5 kcal/mol: if we assume the same steric conditions in polythianes, the methyl-equatorial form is favored over the methyl-axial form and the ratio may be 1/3—1/2 with the former predominating. Since the ratio in reality is large in favor of the methyl-equatorial form, there must be reasons which stabilize that form and/or destabilize the other form. Anomeric effect can be present in these compounds because the carboxyl group has a low-lying LUMO. If the above-cited solvent effect is taken to be significant, it also supports the presence of anomeric effect because the magnitude of stabilization by the anomeric effect is suppressed in polar solvents.[3]

The equilibration of 4,6-dimethyl-1,3,5-trithiane-2-carboxylic acid (**2**) should provide data which are only affected by the conformational energy of the carboxyl group. As is seen in Table 1, $\Delta G°$ value becomes smaller because of the erasure of the effect of the methyl group, but the axial form (**2a**) is still favored in acetonitrile. Unfortunately, equilibration in other solvents failed because of extensive deterioration of the substrate.

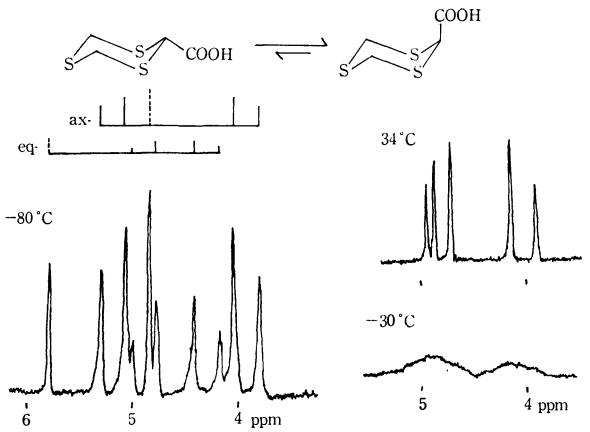

Fig. 1. ^1H NMR spectra of **3** in acetone-d_6 at three temperatures.

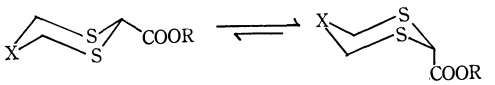
Low Temperature NMR Study of Polythianecarboxylic Acids. The difficulty seen in equilibration allured us to investigate the flexible polythianecarboxylic acids at low temperature. 1,3,5-Trithiane-2-carboxylic acid (**3**) and its methyl ester (**6**) showed only averaged signals at room temperature. The signal, however, broadened considerably at −40——50 °C,[10] and split into two sets of 2-H and 4,6-H's at −80 °C (Fig. 1). The results are shown in Table 2. It is interesting to note that the



3e **3a** R=H, X=S
4e **4a** R=H, X=CH_2
6e **6a** R=CH_3, X=S
7e **7a** R=CH_3, X=CH_2

Table 2. Data concerned with conformational equilibria of polythianecarboxylic acids and their derivatives at −80 °C

Compound	Solvent	Chemical shift of 2-H (δ) e-Form	Chemical shift of 2-H (δ) a-Form	a-Form/e-Form	$\Delta G°$ (kcal/mol)	A-Value
3	CD_3COCD_3	5.75	4.82	1.5	0.15	1.43
	CD_3COCD_3–$CDCl_3$ (3:1)	5.71	4.69	2.35	0.31	
4	CD_3COCD_3	5.42	4.48	5.5	0.66	
6	CD_3COCD_3	5.75	4.88	3.0	0.43	1.22
	CD_3COCD_3–$CDCl_3$ (3:1)	5.70	4.87	5.0	0.54	
7	CD_3COCD_3	5.44	4.53	8.5	0.83	
	CD_3COCD_3–$CDCl_3$ (3:1)	5.20	4.34	9.5	0.87	
	CS_2–$CDCl_3$ (1:1)	5.02	4.10	20	1.15	

difference in chemical shifts of the axial and equatorial protons in 2-position is almost constant at 0.9 ppm in these compounds.

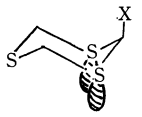
One can clearly see, from the data in Table 2, that the axial form is preferred in every case. The results are contrary to the case of 2,4,6-trimethyl-1,3,5-trithianes[11] in which the *cis* form is more stable because it has no axial methyl group. Anomeric effect is a probable cause again for the presence of the axial form. Solvent effects on the populations of the axial and the equatorial forms are in agreement with the anomeric effect: the less polar is the solvent, the more is the axial form preferred. We may now conclude that the anomeric effect is seen in polythianecarboxylic acids.

The magnitude of anomeric effect may be expressed by the following equation.[3]

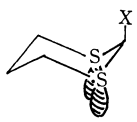
$$\Delta\Delta G^\circ = (\Delta G^\circ_{\text{substituent}})_{\text{hetero ring}} - (\Delta G^\circ_{\text{substituent}})_{\text{cyclohexane}}$$

Comparison of the results reveals that the magnitude of the anomeric effect is larger in 1,3-dithiane than in 1,3,5-trithiane.

The results seem to be explained by the delocalization of electrons. The UV spectra of 1,3-dithiane and 1,3,5-trithiane[12] indicate that the lone pair electrons in the latter are more delocalized than those in the former. Sweigart and Turner reported the results of photoelectron spectroscopy which reveal that the ionization potential of lone pair electrons in 1,3,5-trithiane is higher than those in 1,3-dithiane.[13] Thus transfer of lone pair electrons on sulfur to the antibonding orbital involving the axial substituent, as discussed by Hoffmann *et al.*,[14] must be smaller in its extent in trithianes (**10**) than in dithianes (**11**). By taking advantage of the above discussion, we may understand the weaker anomeric effect and consequently less population of the substituent-axial isomer of 1,3,5-trithiane derivatives than those of the 1,3-dithianes.



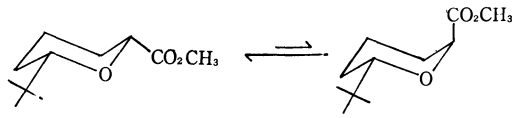
10



11

The anomeric effect is larger with the free carboxylic acids than the corresponding esters, both in trithiane series and in dithiane series. It is also known that the methoxycarbonyl group gives less preference in free energy than the carboxyl group in cyclohexane series, although the equatorial form is favored in this case.[9] The differences are almost constant at 0.2 kcal/mol. These results suggest that the difference is not of the electronic or electric origin but of the steric origin. Since the carboxyl group shows less preference of the axial form than the corresponding esters in polythianes, the latter may be taken as giving less steric effect. This is reasonable because the acid dimerizes under the conditions of the NMR measurement. Negligence of the electronic-electic effect will not give an important defect, since Hammett σ_m values of the carboxyl and methoxycarbonyl groups are 0.36 and 0.32, respectively.[15]

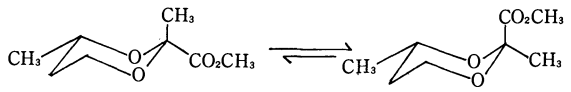
Comparison of the above results with those of oxane series is worthy of note. Methyl 5-*t*-butyloxane-2-carboxylate (**12**) was equilibrated with a base catalyst to show that the methoxycarbonyl-equatorial form (**12e**) is predominant in the equilibrium mixture. The phenomenon has been referred to as reverse anomeric effect.



12e **12a**

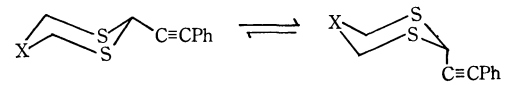
However, owing to the short distance of the C–O bond in oxanes, the 1,3-*syn*-diaxial interaction must be more severe in oxane series.[5] This disfavors the axial conformation. In trithianes and dithianes, the C–S bond is much longer than the C–O and the 1,3-diaxial interaction is surpressed to a great extent. Normal anomeric effect thus becomes detectable as conformational equilibrium constants.

Eliel *et al.* prepared ethyl 2,4-dimethyl-1,3-dioxane-2-carboxylate (**13**) under the conditions of thermodynamic control and found that the ethoxycarbonyl-axial conformation (**13a**) is disfavored in less polar solvents. The results are in line with the reverse anomeric effect,



13e **13a**

but the system may be too complicated to interprete in a straightforward manner, as suggested by the authors.[16]



8e **8a** X=S
9e **9a** X=CH_2

Finding the presence of anomeric effect in polythianecarboxylic acids, we were allured to investigate the case of phenylethynylpolythianes. The results are shown in Table 3.

Table 3. Data concerned with conformational equilibria of 2-phenylethynylpolythianes at −80 °C

Compd.	Solvent	Chemical Shift of 2-H (δ) e-Form	Chemical Shift of 2-H (δ) a-Form	a-Form / e-Form	ΔG° (kcal/mol)
8	CD_3COCD_3	6.00	5.68	1.18	0.07
	CS_2–$CDCl_3$ (1:1)	5.21	4.96	3.3	0.46
9	CD_3COCD_3	5.62	5.21	1.57	0.18
	CS_2–$CDCl_3$ (1:1)	5.16	4.73	3.1	0.44

The data suggest the presence of small but distinct anomeric effect in the phenylethynyl compounds: the axial forms (**8a** and **9a**) are preferred over the equatorial forms (**8e** and **9e**) in the solvents examined and the preference becomes less in more polar solvents. The 2-phenylethynyl group, providing a low-lying LUMO,

seems to be effective in accepting the electrons from the sulfur atoms in 1 and 3 positions.

Experimental

^1H NMR Measurement. The ^1H NMR spectra were recorded on a Hitachi R 20B spectrometer (60 MHz) equipped with a temperature variation accessory. Temperature was read by the difference in chemical shifts between protons of methanol.

Preparation of Carboxylic Acids and Their Esters. A general procedure of preparation of carboxylic acids will be described by taking the case of 1,3-dithiane-2-carboxylic acid (**4**) as an example. To a solution of 2.0 g (16.7 mmol) of 1,3-dithiane in 100 ml of tetrahydrofuran was added 18.5 mmol of butyllithium in 30 ml of ether at −20 °C and the mixture was stirred for 1 h at that temperature under a nitrogen atmosphere. Dried carbon dioxide was introduced into the solution for 3 h, during which time the temperature was allowed to rise to 0 °C, and the mixture was left to stand overnight. The solvent was evaporated and the residue was shaken with a mixture of dilute aqueous sodium hydroxide and ether. The aqueous layer was separated, acidified with hydrochloric acid, and extracted with ether. The ethereal solution was dried over magnesium sulfate and evaporated. 1,3-Dithiane-2-carboxylic acid (**4**), mp 112—113.5 °C, was obtained in 1.8 g (66%) yield. Found: C, 36.48; H, 4.69; S, 39.11%. Calcd for $C_5H_8O_2S_2$: C, 36.57; H, 4.91; S, 39.04%. IR: 1685—1690 cm^{-1} ($\nu_{C=O}$). ^1H NMR: (δ, $CDCl_3$): 2.1 (m, 2H), 2.4—3.7 (m, 4H), 4.17 (s, 1H), *ca.* 9 (s, 1H).

The methyl ester (**7**) was prepared almost quantitatively by treatment of the acid with diazomethane in ether. It was purified by chromatography on silica gel with benzene, oil (mp between 20 and 30 °C). Found: C, 40.53; H, 5.59; S, 35.81%. Calcd for $C_6H_{10}O_2S_2$: C, 40.43; H, 5.65; S, 35.97%. IR: 1730 cm^{-1} ($\nu_{C=O}$). ^1H NMR (δ, $CDCl_3$): 3.77 (s, 3H), 2.10 (m, 2H), 2.4—2.8 (m, 2H), 3.2—3.65 (m, 2H), 4.20 (s, 1H).

It could also be prepared by treating the corresponding acid with thionyl chloride in carbon tetrachloride–chloroform (9: 1) at reflux temperature for 5 to 7 h followed by treatment with methanol.

*1,3,5-Trithiane-2-carboxylic acid (**3**)*, mp 273 °C (decomp.), was prepared similarly from 1,3,5-trithiane. Found: C, 26.65; H, 3.35; S, 52.57%. Calcd for $C_4H_6O_2S_3$: C, 26.37; H, 3.32; S, 52.77%. IR: 1690 cm^{-1} ($\nu_{C=O}$). ^1H NMR (δ, acetone-d_6): 4.02 and 4.77 (q, J=14.5 Hz, 4H), 4.83 (s, 1H).

The methyl ester (**6**) melted at 96—97 °C. Found: C, 30.83; H, 4.34; S, 49.22%. Calcd for $C_5H_8O_2S_3$: C, 30.59; H, 4.11; S, 49.00%. IR: 1715 cm^{-1} ($\nu_{C=O}$). ^1H NMR (δ, CCl_4): 3.78 (s, 3H), 3.46 and 5.06 (q, J=15 Hz, 4H), 4.22 (s, 1H).

Treatment of *cis*-2,4,6-trimethyl-1,3,5-trithiane with butyllithium followed by carbonation gave 2,*c*-4,*c*-5-trimethyl-1,3,5-trithiane-*r*-2-carboxylic acid (**1e**), mp 137—138.5 °C, as a sole product. Found: C, 37.72; H, 5.14; S, 42.77%. Calcd for $C_7H_{12}O_2S_3$: C, 37.48; H, 5.39; S, 42.87%. IR: 1703 cm^{-1} ($\nu_{C=O}$). ^1H NMR (δ, $CDCl_3$): 1.59 (d, 6H), 2.07 (s, 3H), 4.39 (q, 2H), *ca.* 9 (s, 1H).

The methyl ester (**5e**) melted at 53—54 °C. Found: C, 40.25; H, 5.72; S, 40.35%. Calcd for $C_8H_{14}O_2S_3$: C, 40.31; H, 5.92; S, 40.35%. IR: 1737 cm^{-1} ($\nu_{C=O}$). ^1H NMR (δ, CCl_4): 1.54 (d, 6H), 1.95 (s, 3H), 3.82 (s, 3H), 4.29 (q, 2H).

Treatment of *cis*-2,4-dimethyl-1,3,5-trithiane with butyllithium followed by carbonation afforded *c*-4, *c*-6-dimethyl-1,3,5-trithiane-*r*-2-carboxylic acid (**2e**), mp 165—166 °C (decomp.), as a sole product. Found: C, 34.35; H, 5.03; S, 45.51%. Calcd for $C_6H_{10}O_2S_3$: C, 34.26; H, 4.79; S, 45.73%. IR: 1695 cm^{-1} ($\nu_{C=O}$). ^1H NMR (δ, acetone-d_6): 1.53 (d, 6H), 5.26 (s, 1H). The carboxyl proton was obscured because of the presence of water in the solvent.

*t-4,t-6-Dimethyl-1,3,5-trithiane-r-2-carboxylic Acid (**2a**).* *c*-4,*c*-6-Dimethyl-1,3,5-trithiane-*r*-2-carboxylic acid (**2e**) (0.2 g) was dissolved in 5 ml of dry acetonitrile and heated at 80 °C with 0.1 ml of boron trifluoride etherate for 3 h. The solvent was evaporated and the residue was shaken with a mixture of 20 ml of ether and 10 ml of 1 M hydrochloric acid. Evaporation of the ether layer afforded a mixture of *ca.* 3: 2 **2a** and **2e** which was extracted with carbon tetrachloride. Concentration of the carbon tetrachloride solution followed by standing afforded *ca.* 0.05 g (25%) of **2a**, mp 114—115 °C. Found: C, 33.99; H, 4.76%. Calcd for $C_6H_{10}O_2S_3$: C, 34.26; H, 4.79%. IR: 1685 cm^{-1} ($\nu_{C=O}$). ^1H NMR (δ, CCl_4): 1.50 (d, 6H), 4.76 (q, 2H), 4.58 (s, 1H), *ca.* 11.5 (s, 1H).

*2,c-4,c-6-Trimethyl-1,3,5-trithiane-r-2-carboxylic Acid (**1a**)*, mp 135.0—135.5 °C, was similarly prepared by heating 2.0 g of **1e** with 10 ml of boron trifluoride etherate at 60 °C in 75% yield. Found: C, 37.32; H, 5.12; S, 42.44%. Calcd for $C_7H_{12}O_2S_3$: C, 37.48; H, 5.39; S, 42.87%. IR: 1690 cm^{-1} ($\nu_{C=O}$). ^1H NMR (δ, $CDCl_3$): 1.55 (d, 6H), 1.78 (s, 3H), 4.69 (q, 2H), *ca.* 10 (s, 1H).

The methyl ester (**5a**) melted at 33.5—34.5 °C. Found: C, 40.52; H, 5.84; S, 40.41%. Calcd for $C_8H_{14}O_2S_3$: C, 40.31; H, 5.92; S, 40.35%. IR: 1728 cm^{-1} ($\nu_{C=O}$). ^1H NMR (δ, CCl_4): 1.51 (d, 6H), 1.70 (s, 3H), 3.70 (s, 3H), 4.66 (q, 2H).

Equilibration. Either of the equatorial or the axial form of the substrate (0.2 g) was dissolved in 2 ml of an appropriate solvent, mixed with 0.031 ml (*ca.* 1/3 equivalent) of boron trifluoride etherate, and allowed to stand at 23±2 °C. The progress of equilibration was followed by ^1H NMR spectra. It took *ca.* 60 days for equilibration of **1** in acetonitrile which required the longest time among the solvents used.

The analyses of the products were performed with integration of the ^1H NMR signals and the error is estimated to be ±2%. The esters were analyzed with vapor phase chromatography and the results are believed to be accurate within the error of ±0.5%.

*2-Phenylethynyl-1,3-dithiane (**9**).* To a solution of 2.2 g (18.5 mmol) of 1,3-dithiane in 20 ml of sodium-dried benzene was added 2.7 g (20.3 mmol) of *N*-chlorosuccinimide during a 15 min period at 20 °C under a nitrogen atmosphere. The mixture was stirred for 15 min under the same conditions and filtered. To this solution was added phenylethynylmagnesium bromide in ether which was prepared from 2.55 g (25 mmol) of phenylacetylene and isopropylmagnesium bromide (from 3.25 g of isopropyl bromide, 0.7 g of magnesium and 50 ml of ether) at 35 °C. The mixture was stirred for 2 h at room temperature and treated with dilute hydrochloric acid. Extraction of the mixture with chloroform afforded 2.6 g of crude 2-phenylethynyl-1,3-dithiane, which was purified by chromatography on silica gel. Elution with benzene–hexane (8: 2) gave a pure compound, mp 54—55.5 °C in 35% yield. Found: C, 65.40; H, 5.54%. Calcd for $C_{12}H_{12}S_2$: C, 65.41; H, 5.49%. IR: 2220 cm^{-1} ($\nu_{C\equiv C}$). ^1H NMR (δ, CCl_4): 1.8—2.3 (m, 2H), 2.5—3.5 (m, 4H), 4.63 (s, 1H), 7.3 (m, 5H).

*2-Phenylethynyl-1,3,5-trithiane (**8**)*, mp 66—67 °C, was similarly prepared from 1,3,5-trithiane. Found: C, 55.17; H, 4.03; S, 40.19%. Calcd for $C_{11}H_{10}S_3$: C, 55.42; H, 4.23; S, 40.35%. IR: 2205 cm^{-1} ($\nu_{C\equiv C}$). ^1H NMR (δ, $CDCl_3$): 3.91 and 4.83 (q, J=14.5Hz, 4H), 5.04 (s, 1H), 7.39 (m, 5H).

The Substituent Effect. VI. Inductive and π-Electronic Effects in the Phenol Hydroxyl Chemical Shifts in DMSO

Yuho Tsuno,[1] Mizue Fujio, and Yasuhide Yukawa*

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka 812
**Institute of Scientific and Industrial Research, Osaka University, Yamada-kami, Osaka 565*

(Received December 10, 1974)

Substituent effects on the NMR chemical shifts of the hydroxyl proton of *m*- and *p*-substituted phenols in DMSO have been studied by means of the LSFE equation. The effect of substituents was found to be considerably modified in the DMSO solution as compared with that in aqueous solution through strong substituent-solvent interactions. The LSFE equation was applied to the apparent substituent effects of such solvent-modified systems, and the practical set of parameters for the inductive and the π-electronic effects of the DMSO-modified substituents were estimated. The treatment was successful for $+R$ substituents but not for $-R$ substituents. This may be attributed to the much stronger solvent-substituent interactions. Characteristic features of LSFE treatment were discussed in comparison with Taft and Swain-Lupton treatments. It is suggested that the dual resonance reaction constants for $+R$ and $-R$ *para* substituents are required for Taft-type correlations.

Substituent effects on chemical and physical properties in a number of benzene derivatives have been treated by the following *Linear Aromatic Substituent Reactivity* (LArSR) *Relationship*:[2]

$$\log (k/k_0) \text{ or } P-P_0 = \rho\bar{\sigma} = \rho(\sigma^0+r^+\Delta\bar{\sigma}_R^+ + r^-\Delta\bar{\sigma}_R^-) \quad (1)$$

where $\Delta\bar{\sigma}_R^+$ and $\Delta\bar{\sigma}_R^-$ are the resonance substituent constants describing the capability of π-electron delocalization of conjugatively electron releasing ($-R$) and electron attracting ($+R$) *para* substituents, respectively. r^+ or r^- is the resonance reaction constant characteristic of given reaction giving a measure of the resonance exaltation. This equation gives a purely empirical description of the substituent effect on reactivities of substituted benzene derivatives in terms of the unexalted polar effect of substituted phenyl groups and aryl resonance exaltation effect. From the success of the treatment and particularly from the generality of the resonance parameters $\Delta\bar{\sigma}_R^+$ and $\Delta\bar{\sigma}_R^-$ for various types of reactions, we have extended Eq. (1) to an alternative theoretically simple expression, the *Linear Substituent Free Energy* (LSFE) *Relationship*:

$$\log (k/k_0)_p = \rho\bar{\sigma}_p = \rho(\sigma_i + q_r^+\sigma_\pi^+ + q_r^-\sigma_\pi^-) \quad (2)$$

$$\log (k/k_0)_m = \rho\bar{\sigma}_m = \rho(1.17\sigma_i + 0.50\sigma_\pi^\pm) \quad (2')$$

where the substituent effect is given as a first approximation by the combination of inductive and resonance effects of given substituents.[3] σ_i is the inductive substituent constant, which remains constant for a given substituent independent of its variable resonance contribution. σ_π^+ and σ_π^- are the parameters for the capabilities of $-R$ and $+R$ classes of substituents respectively to donate or withdraw electron through π-electronic delocalization, being constants characteristic only of substituents and not dependent upon the nature of reactivities, systems, and perhaps, detection variables. q_r^+ and q_r^- are the characteristic variables of a given reaction or system, indicating the degree of π-electronic interaction of $+R$ and $-R$ groups with detection center. Both q_r^+ and q_r^- are standardized by definition to be unity in the σ_p^0 scale; *i.e.*, $\sigma_p^0 = 1.00\,\sigma_i + 1.00\,\sigma_\pi^\pm$. σ_π^+ corresponds numerically to 0.42 $\Delta\bar{\sigma}_R^+$ and σ_π^- to 0.73 $\Delta\bar{\sigma}_R^-$.[4] The σ_i values are proportional to the relative inductive strength of substituents in the saturated system, and correspond to 0.74 σ'.

The applicability of Eqs. (1) and (2) to conjugatively electron attracting ($+R$) substituents in the nucleophilic exalted-resonance reactions has not yet been examined sufficiently, due to the lack of data on $+R$ substituents. In this series of studies, we have thus dealt with the effect of conjugatively electron attracting substituents, especially in various types of nucleophilic reactions, in order to ascertain the applicability and limitation of our treatment of the substituent effects in the benzene system.[4,5]

We reported a complete set of NMR chemical shift data of the hydrogen-bonding hydroxyl proton of *m*- and *p*-substituted phenols in DMSO,[5] and demonstrated a satisfactory fit of the substituent chemical shifts to Eq. (1), giving a ρ value of 1.53 and r^- 0.67. The apparent substituent constant for particular substituents differs significantly from the standard one. However, the effects remained essentially the same in the related series of the hydroxyl chemical shifts of 4-substituted 2- and 3-cresols and 2,6-xylenols in DMSO, as evidenced by excellent linear $\Delta\delta$—$\Delta\delta$ plots.

We have treated these series of chemical shift data in terms of Eq. (2), and attempted to estimate a practically useful set of the π-electronic and inductive substituent parameters, $(\sigma_\pi)_{DMSO}$ and $(\sigma_i)_{DMSO}$, for the DMSO-modified substituent groups. The present paper includes a comparison of the results with those of similar treatments based on Taft[6] and Swain-Lupton Equations.[7]

Results and Discussion

Table 1 gives the apparent substituent constants derived from the NMR chemical shifts of the hydroxyl proton of phenols in DMSO.[5] The constants obtained from 4-substituted phenols were identical with those derived from the corresponding 2- and 3-cresols[8] and 2,6-xylenols using appropriate ρ values.

According to Eq. (1), enhancement of the apparent $\bar{\sigma}_p$ values from corresponding σ^0 values are proportional to the resonance parameters, $\Delta\bar{\sigma}_R^-$ or $\Delta\bar{\sigma}_R^+$. Figure 1 gives a plot of apparent enhancement $\bar{\sigma}_p - \sigma_p^0$ for conjugatively electron attracting ($+R$) substituents in *p*-substituted phenols against standard $\Delta\bar{\sigma}_R^-$. Most substi-

tuents fall near the correlation line, but certain carbonyl and sulfonyl derivatives deviate from it. The deviation is large for the $CONH_2$ and SO_2NH_2 groups; that of the latter in particular suggests an unlikely electron releasing resonance contribution of this group. The scattered pattern is similar to that observed in DMF solution.[4] These deviations may arise from solvent-modification of the electronic nature of substituents in the DMSO solution. Since the standard $\sigma_p{}^0$ is the parameter referable to the substituents modified with water, the quantities $\bar{\sigma}_p-\sigma_p{}^0$ should include certain extraneous effects due to the change of solvents from H_2O to DMSO. The deviations in the above correlation are not merely due to the solvent-modification of π-electronic interaction of substituents but include changes in the inductive nature of substituents caused by solvation. It appears necessary to deal with the solvent-modified substituent effects in terms of both inductive and π-electronic effects.

From Eqs. (2) and (2′), we can eliminate the inductive contribution by using the unique *para*/*meta* inductive

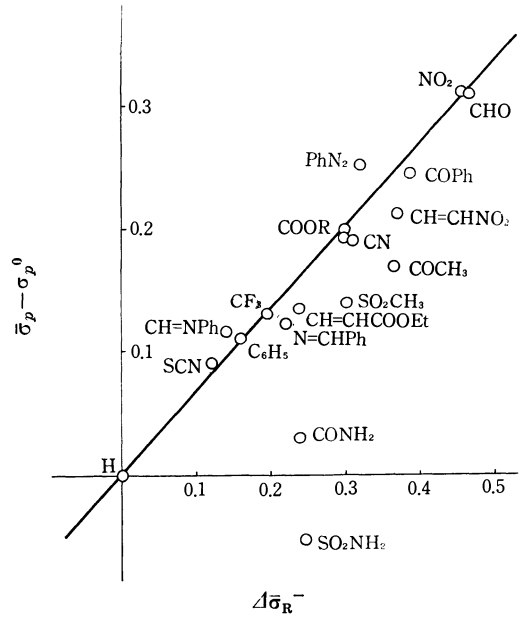

Fig. 1. Plot of the apparent resonance enhancements $\bar{\sigma}_p-\sigma_p{}^0$ against standard $\Delta\bar{\sigma}_R{}^-$ values for $+R$ substituents.

contribution ratio of 0.85 (=1/1.17) and obtain the following equation as the simplest linear resonance free energy relationship.

$$\log (k/k_0)_p - 0.85 \log (k/k_0)_m = \rho(\bar{\sigma}_p-0.85\bar{\sigma}_m) = \rho(q_r{}^{\pm}-0.425)\sigma_\pi{}^{\pm} \quad (3)$$

This relationship should also be valid for the solvent-modified substituent. $q_r{}^+$ is not generally identical with $q_r{}^-$ in nucleophilic or electrophilic resonance-exalted reactions. Accordingly, both $+R$ and $-R$ substituents can not be treated with a single q_r parameter. This paper deals with the effect of conjugatively electron attracting ($+R$ class) substituents, for which the results are successfully correlated.

The π-electronic effect of DMSO-modified +R substituents of interest can thus be given for the present system by the following equation since $\sigma_\pi{}^-=0.73\,\Delta\bar{\sigma}_R{}^-$ by definition.

$$(\Delta\delta_p-0.85\Delta\delta_m)/1.529 = C^-_{DMSO}(\sigma_\pi{}^-)_{DMSO} = 0.73C^-_{DMSO}(\Delta\bar{\sigma}_R{}^-)_{DMSO} \quad (4)$$

where C^-_{DMSO} is a coefficient giving the degree of effective resonance contributions from $+R$ substituents in the given system in DMSO and corresponds to $q_r{}^--0.425$ for the system. $(\sigma_\pi{}^-)_{DMSO}$ or $(\Delta\bar{\sigma}_R{}^-)_{DMSO}$ denotes the π-electronic (resonance) substituent parameters for the DMSO-modified $+R$ substituent. The correlation of the same type can be derived for $-R$ substituents, while the coefficient C^+_{DMSO} is not necessarily the same as the C^-_{DMSO} even in the same system.

The C^-_{DMSO} can be determined experimentally from the slope of the plots of $(\bar{\sigma}_p-0.85\bar{\sigma}_m)_{DMSO}$ against $(\Delta\bar{\sigma}_R{}^-)_{DMSO}$ or $(\bar{\sigma}_\pi{}^-)_{DMSO}$. We may utilize standard $\Delta\bar{\sigma}_R{}^-$ values for $(\Delta\bar{\sigma}_R{}^-)_{DMSO}$ since the effect of solvent modification is relatively small for most substituents. This process in turn can be used to determine a set of $(\Delta\bar{\sigma}_R{}^-)_{DMSO}$ and $(\sigma_\pi{}^-)_{DMSO}$. Figure 2 shows the plot for $+R$ substituents of the present phenol system against standard $\Delta\bar{\sigma}_R{}^-$,

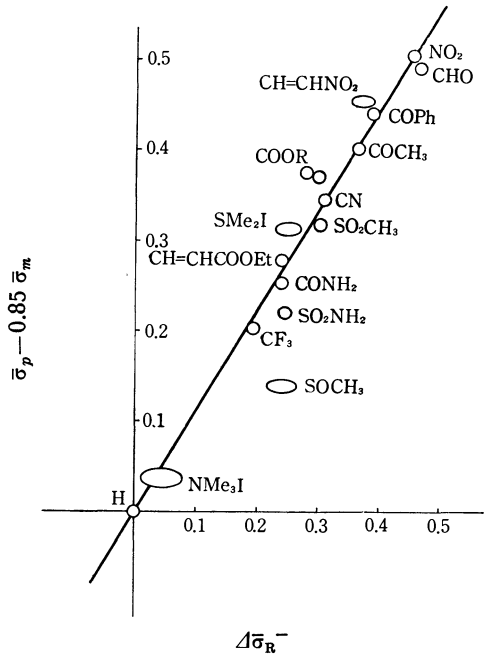

Fig. 2. Plot of the quantities $\bar{\sigma}_p-0.85\,\bar{\sigma}_m$ against standard $\Delta\bar{\sigma}_R^-$ values, for $+R$ substituents.

giving the slope of 1.12 with satisfactory linearity; correlation coefficient 0.987 and standard deviation ±0.028. A similar correlation has been obtained for the corresponding resonance quantities of the same series in DMF solution.[4] The modification of substituents with DMSO and DMF solvents is related more closely to each other than to those in aqueous solution, because of similarity in their aprotic and basic character. $(\Delta\bar{\sigma}_R^-)_{DMF}$ in fact give a much better correlation ($s=\pm0.010$ and $R=0.998$) than standard $\Delta\bar{\sigma}_R^-$. From the slope 1.12, $(\Delta\bar{\sigma}_R^-)_{DMSO}$ is obtained, and converted into $(\sigma_\pi^-)_{DMSO}$; *i.e.*, $(\sigma_\pi^-)_{DMSO}=0.818$ $(\bar{\sigma}_p-0.85\bar{\sigma}_m)$. The inductive substituent constants are given by

$$(\sigma_i)_{DMSO}=\bar{\sigma}_p-1.43(\Delta\bar{\sigma}_R^-)_{DMSO}.$$

$(\sigma_p^0)_{DMSO}$ can also be derived by combining $(\sigma_\pi^-)_{DMSO}$ and $(\sigma_i)_{DMSO}$. These sets of substituent constants are compared with corresponding standard parameters (Table 2).

Comparison of the DMSO-modified substituent parameters with standard σ^0 and σ^- parameters suggests that NO_2, CHO, CN, CF_3, COC_6H_5, and COOMe can be classified as well-behaving substituents even in the aprotic solvent since for these groups the effect of solvent-modification is negligible. Discrepancies are significant in $COCH_3$, $SOCH_3$, $CONH_2$, SO_2NH_2, Me_3N^+, and Me_2S^+ groups. In the first two loss of the hydrogen-bonding at the oxygen with aqueous solvents appears to be an important factor to lower the electron attracting power of these groups in aprotic DMSO.[4,5] For the amides the negative charge arising from the donating hydrogen-bonding to DMSO makes these groups less electron-attracting. The charged substituents are known to be highly sensitive to changes of solvents and reaction conditions, so that even the standard parameter values have not been definitely evaluated.[9] However, it is of interest to note that the Me_3N^+ group in the present system is effectively more electron attracting from *meta* than *para* position (Table 1). The trend $\bar{\sigma}_p<\bar{\sigma}_m$ is generally observed for this group as in the pK_a of benzoic acids and of phenols in various solvents.[10] According to Taft's assumption $\sigma_I^m=\sigma_I^p$, this group should be conjugatively electron releasing since $\bar{\sigma}_p-\bar{\sigma}_m<0$. In our treatment this group appears to be a weak $+R$ class or almost exclusively inductive class,[11] as indicated by the small positive value of $\bar{\sigma}_p-0.85\,\bar{\sigma}_m$. On the other hand, Me_2S^+ group is suggested from either treatment to be considerably strong $+R$ class substituent, not depending on solvent.

We see that the resonance parameters $(\Delta\bar{\sigma}_R^-)_{DMSO}$ as well as $(\sigma_\pi^-)_{DMSO}$ are generally in agreement with the standard values within uncertainty of average ±0.01 or so in σ unit except for $SOCH_3$ group (Table 2). The $(\sigma_i)_{DMSO}$ values are consistently less positive than the standard values for all substituents. The difference between the two values is significant for about a half of the entries, and particularly remarkable for SO_2NH_2 and $CONH_2$ and charged substituents Me_3N^+ and Me_2S^+. The substantial changes can be explained at least quali-

tatively in terms of the specific substituent-solvent interactions with DMSO, as discussed before.[4,5] The discrepancies of these DMSO values from ordinary σ_p^0 and σ_p^- appear to be caused largely by the modification of the inductive nature of substituents in DMSO, as far as $+R$ class substituents are concerned. Only the $SOCH_3$ group, with an exceptional behavior, shows a remarkable decrease in the π-electronic contribution without noticeable decrease in the inductive contribution in DMSO solution. This suggests that in hydroxylic solvents the contribution of the cannonical structure, O^-–S^+–CH_3, is particularly enhanced through hydrogen bonding, but in aprotic DMSO the decreased polarization due to loss of hydrogen-bonding makes the (p—d)π interaction far less effective giving no noticeable change in the inductive polarity.

It is possible that the specific magnetic term which does not correlate with any ordinary substituent parameters might fortuitously be cancelled out by process (4) to result in a set of parameters proportional to the resonance substituent constants. Such a non-electronic effect may be accommodated in the residual parameters, so that the resulting $(\sigma_i)_{DMSO}$ parameters are no longer proportional to the ordinary σ_i values. However, this does not seem reasonable from the fact that the deviation of $(\sigma_i)_{DMSO}$ from the standard σ_i value is remarkable in only carbamido and sulfonamide groups while negligible in other carbonyl and sulfonyl groups. Accordingly, any specific magnetic effect, if operative at all, is not so important that it does not overcome the solvent-modification of substituent inductive effects. This conclusion is further supported by the fact that the $(\sigma_i)_{DMSO}$ values essentially parallel the changes of ^{19}F NMR chemical shift of *m*-substituted fluorobenzenes in the same solvent.[6b]

When we consider the process of the derivation, $(\sigma_i)_{DMSO}$ and even $(\sigma^0)_{DMSO}$ and $(\sigma^-)_{DMSO}$ might be less reliable than $(\Delta\bar{\sigma}_R^-)_{DMSO}$ or $(\sigma_\pi^-)_{DMSO}$ parameters. However, the parameters, especially the resonance parameters, should serve as a useful measure to estimate the substituent effects in the aprotic DMSO. For the substituents whose standard parameter values are not yet known precisely, the present set of parameters should have practical value for estimation of the conjugative powers of the substituents. As an example, $CH{=}CHNO_2$ and $CH{=}CHCOOC_2H_5$ would have relatively strong electron-attracting resonance-ability. The set of DMSO-parameters can be applied to reactions in most anhydrous aprotic solvents, and to even those in aqueous organic solvent, more satisfactorily than the standard set of parameters.

For conjugatively electron releasing ($-R$) substituents, quantities $(\bar{\sigma}_p - 0.85\,\bar{\sigma}_m)$ give poor linear correlation with standard $\Delta\bar{\sigma}_R^+$ values. This is perhaps due to the deviation from the basic requirement that the solvent-modification of the nature of substituents should be of minor significance as compared with the electronic change of the detection site by substituents. The deviations of OH and NH_2 substituents are the most remarkable. The nature of the substituents is modified by DMSO to the same extent as the changes of the detection function OH or NH_2 caused by the hydrogen-bonding with DMSO. The interaction of such a substituent with DMSO should considerably differ at *meta* and *para* positions, to the same extent as the detection site being affected by a substituent from both positions. Thus the solvent-modification of a substituent could not be assumed to be the same for *meta* and *para* positions, which is especially important for a substituent capable of strong substituent-DMSO interaction. In view of the fit of the $+R$ substituents in the above treatment (4), however, it is reasonable that the quantities $(\bar{\sigma}_p - 0.85\,\bar{\sigma}_m)$ for most $-R$ groups in DMSO solution would be also, as a first approximation, proportional to the plausible $(\Delta\bar{\sigma}_R^+)_{DMSO}$ values. If the present set of apparent $\bar{\sigma}_p$ for $-R$ groups are assumed to be of the σ_p^0 class,[4] the C^+_{DMSO} value of 0.575 can be given for the $-R$ substituents, from the *meta*/*para* π-contribution ratio of 0.50 which is characteristic of the σ^0 scale. The resonance contribution scale of these substituents can be roughly approximated on this basis:

$$(\bar{\sigma}_p - 0.85\bar{\sigma}_m) = 0.242(\Delta\bar{\sigma}_R^+)_{DMSO} \qquad (5)$$

This leads also to a crude estimation of $(\sigma_i)_{DMSO}$ values for $-R$ substituents. The results are very close to those obtained in the treatment of the chemical shift in DMF solution. The uncertainty in the contribution scale of resonance for $-R$ substituents does not permit further discussion of these parameter values especially of $(\sigma_i)_{DMSO}$ values. It might be said that their general application can not yet be warranted for this class of substituents. However, we might conclude that the contribution scale of the $-R$ resonance in this system does not differ much from the scale in standard σ^0 constant; at most, less than that of the σ_p scale.[12]

Comparison with Related Treatment. From the above results, the hydroxyl chemical shifts of *para*-substituted derivatives in DMSO can be given by

$$\Delta\delta_p = 1.529[(\sigma_i)_{DMSO} + (\sigma_\pi^+)_{DMSO} + 1.96(\sigma_\pi^-)_{DMSO}] \qquad (6)$$

The second term applies to the $-R$ class and the third to $+R$ class substituents.[13] The use of the standard substituent constants in place of the DMSO values does not appear to affect the characteristics of the correlation at least for the $+R$ groups even though the precision of fit would be a little lowered. The higher q_r^- value evidently indicates the important contribution from only $+R$ class *para* substituents in this system, while the $q_r^- = 1.96$ is less than the q_r^- value $= 2.37$ for the pK_a of phenols in water, suggesting that the resonance contribution of *para* $+R$ substituents to the hydroxyl hydrogen-bonding is less important than that to the dissociation of the hydroxyl proton.

Fischer *et al.*[14] have applied the Taft equation

$$\log(k/k_0) = \rho_I\sigma_I + \rho_R\sigma_R^0 \qquad (7)$$

for sixteen *para* substituents in Traynham's data[15] to give the correlation

$$\Delta\delta_p = 1.53(\sigma_I + 1.54\sigma_R^0).$$

Although no detail of the treatment was given, it appears that the exaltation of resonance for $+R$ groups suggested by the $\rho_R/\rho_I = 1.54$ is significantly less than that expected from $q_r^- = 1.96$, since σ_R^0 values for the $+R$ groups are numerically of the order of 1/2 or less of the corresponding σ_π^- values.[16] It should be noted that this treatment

appears similar to but stands on a considerably different basis from ours. As the wide applicability of Eq. (1) indicates,[2] the general σ^+ class electrophilic reactivity is such that only the resonance effect of $-R$ but not of $+R$ class substituents is significantly exalted, and the reverse is held in the general σ^- class nucleophilic resonance reactivities. Such characteristics of exalted resonance for both classes are still retained in Eq. (2) with the introduction of dual parameters q_r^- and q_r^+ each for $+R$ and $-R$ class substituents. With this flexibility of π-electronic contributions, a full range of various types of reactivities from an extreme σ^+ class to the other extreme σ^- class can generally be treated by a single equation (2).[4,6a]

Apart from the question of fit, treatment with a single resonance reaction constant inevitably gives an indiscriminate change (parallel increase or decrease) in the resonance contributions from both $+R$ and $-R$ class *para* substituents in a given reaction. In the Taft treatment using a single ρ_R coefficient for both $-R$ and $+R$ groups, no combinations of σ_I and σ_R^0 can reproduce even Brown's σ^+ constants or σ^- constants where either the $-R$ or the $+R$ class substituents exerts the exalted resonance contribution. The results of Fischer *et al.*[14] do not offer any indication whether the system is of the σ^- or σ^+ type. The same criticism applies also to the Swain and Lupton equation,[7] $\log k/k_0=fF+rR$, which in principle does not differ from Eq. (7). From a slightly different view, Wiley and Miller[17] have questioned the significance of the Swain and Lupton f, r or % R values.

Although many correlations using Eq. (7) as well as the related equations with the single resonance coefficient have been reported for σ^+ or σ^- type reactivities, in most cases, the numbers of $-R$ and $+R$ substituents examined were not well balanced, so that the correlations obtained should be judged as those weighted more or less heavily on the effect of either $+R$ or $-R$ substituents. The correlations can be generally improved by excluding either $+R$ or $-R$ class substituents from the data set. Swain and Lupton gave[7] a satisfactory correlation for σ_p^- values with reasonable precision in terms of the F-R combination or the equation, $\log k/k_0=a\sigma_m+b\sigma_p$, while a few effective $-R$ groups were included in their calculation. For the same set of data, an excellent correlation can be obtained when the treatment is made only for $+R$ substituent groups; the latter treatment of the σ_p^- values for only $+R$ substituents gives a correlation, $\sigma_p^-=-0.13\sigma_m+3.44\sigma_p-0.011$, with remarkably improved precision of a correlation coefficient 0.996 and a standard deviation ±0.027.[18] The same is true for the correlation of σ_p^+ values for only the $-R$ substituents.[19] The results cast doubts upon the applicability of the single resonance coefficient treatments. It appears that the different ρ_R coefficients which are characteristic of reactions should be required for the effects of each $+R$ and $-R$ class substituents in exalted resonance type reactions as long as the resonance parameters σ_R^0 derived from the σ^0-reactivity are used. For such restrictions, Taft has noted[6c] that Eq. (7) with a single ρ_R (in terms of σ_I and σ_R^0) should be applied as a useful approximation to a limited class of substituted phenyl reactivities effectively insulated from the resonance interaction with the reaction site, and that apparent resonance parameters $\bar{\sigma}_R$ given by the difference between apparent $\bar{\sigma}_p$ and corresponding σ_I is applicable for most of substituents in only closely related types of reactions.[6] It is necessary for this treatment to utilize a most suitable set of apparent $\bar{\sigma}_R$ values for a given reaction, since any set of $\bar{\sigma}_R$ values does not cover evenly over a series of $+R$ and $-R$ substituents.[3,6,18] Consequently, the increase in the number of required sets of σ_R parameters is inevitable when a single ρ_R is employed.[20] Taft has demonstrated[6a] that at least four distinctive sets of $\bar{\sigma}_R$ parameters are required in practice for his treatment, depending on the σ^0, σ, σ^+, and $\bar{\sigma}^-$ type of reactivity. This is clearly not in line with Taft's original aim to accomplish an unified treatment of the aromatic substituent effect, retaining the simplicity of the linear free energy relationship. This very important deficiency is believed to arise primarily from an improper definition of the effective scale of the substituent inductive effect in the substituted benzene system. As relationship (2) shows, only with the assumption of the inductive scale for the *p*-substituted benzene system being $0.74\,\sigma_I$ instead of $1.00\,\sigma_I$, a universal set of π-electronic effect parameters can be obtained by $\bar{\sigma}-0.74\sigma_I$ from any class of reactivity.[3,4] Disagreement between both treatments appears to depend simply upon whether or not one might accept the continuum of the π-electronic contribution of respective substituents over a wide spectra of the reactivity changes from an extreme σ^+ to the other extreme σ^- classes, as well as the existence of a set of π-electronic parameters of substituents independent of reactivity classes.

Nevertheless, a separate determination of both q_r^+ and q_r^- parameters is not convenient, and the single q_r treatment has a practical advantage over the dual q_r treatment, especially when the number of substituents in a given data set is limited. From a practical point of view, the employment of a Taft-type equation only with a proper set of resonance parameters might be acceptable as a useful approximation. According to Eq. (2), any particular scale of the π-electronic effects over a range from extremely electron-releasing to -attracting substituents can reasonably be given for any class of $\bar{\sigma}_p$'s, by setting a proper ratio of q_r^- to q_r^+ values. Thus, the LSFE equation with dual q_r values can be easily reduced to the equation with a single q_r coefficient,[21] although the range of validity of such treatment with a fixed q_r^+/q_r^- ratio may be limited to a similar extent as that of the Taft equation.

20) However, see ref. 6c), p. 155.

21) The π-electronic effects involved in the representative substituent constants, σ_p^0, σ_p, σ_p^+, and σ_p^-, can be given for first three sets by $q_r^- = 1.00$ but $q_r^+ = 1.00$, 1.65, and 3.38, respectively, and for σ_p^-, $q_r^- = 2.37$ and $q_r^+ = 1.00$. The corresponding sets of π-electronic substituent parameters $\bar{\sigma}_\pi$ to the above sets of substituent constants can thus be obtained from these q_r values.

The Substituent Effect. VII. Substituent Chemical Shifts of NH Proton of Acetanilides[1a)]

NMR chemical shifts of the NH proton of fifty-three *m*- and *p*-substituted acetanilides were determined in dilute DMSO solutions. The substituent chemical shifts were correlated with σ^0 constants with considerable scatter. Deviations were particularly significant for $-R$ groups having α-hydrogen. Improved correlation was found for $-R$ substituents with $(\sigma^0)_{DMSO}$ values which had been derived from the phenol hydroxyl chemical shifts in DMSO. Application of the LArSR equation using the DMSO-modified substituent parameters gave a good linear correlation for all substituents; $\Delta\delta^{NHAc}=0.686\ [(\sigma^0)_{DMSO}+0.277\ (\Delta\bar{\sigma}_R^-)_{DMSO}]$. These results indicate that the deviations are caused primarily by solvent-modification of substituents, the modification being essentially the same for both the acetanilide and the phenol systems in DMSO. The lower r^- value 0.277 in the chemical shifts for the acetanilides than for the phenols suggests that the π-electronic contribution of $+R$ *para* substituents is less important in the acetanilide system than in the phenol one. The resonance substituent parameter for these solvent-modified substituents was found to be proportional to both $(\bar{\sigma}_p^{OH}-\bar{\sigma}_p^{NH})$, the difference between the apparent $\bar{\sigma}_p$ constants of the two systems, and to $\bar{\sigma}_p-0.85\,\bar{\sigma}_m$ of each series. Estimation of a practical set of inductive and resonance substituent parameters for DMSO-modified substituents is attempted.

Foregoing investigations[2-4)] have indicated the following: The hydroxyl chemical shift of *m*- and *p*-substituted phenols in DMF or DMSO is closely related to the chemical reactivities; the substituent effect can be described successfully in terms of the LArSR and LSFE relationships;[5)] the solvent-modification of substituents is of considerable importance in these aprotic solvents. The effect of solvent on the substituent effect in chemical reactivities and physical properties has received considerable attention.[6)] However, hardly any studies have been carried out to elucidate quantitatively such solvent effect on the basis of the linear free energy relationship. The solvent-modification of the nature of substituents can be measured by the deviations in the LArSR or LSFE correlation by means of the sets of substituent parameters which were determined from the reactivity data in aqueous media.

From our interest in the substituent effect in aromatic derivatives, we attempted to estimate the practical measure of inductive and π-electronic effects of "the solvent-modified substituents" in DMF and DMSO solutions.[2,3)] Evaluation of the resonance parameters $(\sigma_\pi)_M$ for the solvent-modified substituents in medium M was carried out by means of the following relation derived from the LSFE equation.[5)]

$$(\sigma_\pi)_M = (\bar{\sigma}_p-0.85\bar{\sigma}_m)_M/C_M \qquad (1)$$

where $\bar{\sigma}_p$ and $\bar{\sigma}_m$ are the apparent substituent constants obtained from the above system in medium M. The characteristic coefficient 0.85 corresponds to the ratio of inductive contributions of the substituent from *para* and *meta* positions in the LSFE relationship. C_M was determined by employing the standard σ_π in place of $(\sigma_\pi)_M$ parameters. The σ_i and σ_p^0 parmeters for solvent-modified substituents in DMF and DMSO were also derived.

This approach stands essentially upon the generality of the unique ratio 0.85 of *para*/*meta* inductive effects. It will be possible to establish significance of the inductive ratio by confirming its validity in chemical and physical properties whose requirements of resonance widely differ. For one of such systems, the substituent chemical shifts of the NH proton of *m*- and *p*- substituted acetanilides in DMSO have been chosen. The NH chemical shift in this system was found to follow the σ^0 parameters. The resonance exaltation for $+R$ class substituents does not appear to be so important as in the case of phenol hydroxyl chemical shift. Accordingly the comparison of the apparent $\bar{\sigma}_p$ values for both systems should provide interesting information on the resonance (π-electronic) and the inductive effects of the DMSO-modified substituent groups. Such a study would confirm generality of the LArSR and LSFE relationships.

Results and Discussion

The NH proton signal of acetanilides in DMSO is considerably more broadened than the hydroxyl proton signal of phenols in DMSO. However, the DMSO solution seems to give the sharpest and most stable signals of the NH proton, no significant dilution shift being observed. The experimental uncertainty appears to be slightly larger in the NH chemical shifts than the phenol OH chemical shift values. It is estimated that in most cases the error involved in the infinite dilution values does not exceed ±0.5 Hz, although in a few cases the uncertainty may be as high as ±1 Hz. The chemical shifts of NH proton of acetanilides are given in Table 1. Bennett *et al.*[7a)] and Rae *et al.*[7b)] have reported the chemical shift data of several acetanilides in the same solvent, their data being only of *p*-substituted derivatives. The chemical shift values reported were in good agreement with the present results.

Niwa reported the chemical shifts of NH protons of *meta* and *para* substituted formanilides in DMSO.[8)] His data can be compared with the present data to give a good linear relation; correlation coefficient 0.996 and standard deviation ±0.025.

$$\Delta\delta^{NHAc} = 1.003\Delta\delta^{NHCHO}$$

This suggests that there is no significant difference in the substituent effects on the shifts in both systems.

stituted phenylureas in DMSO.[9] Although no *meta* substituents were included, *para* substituents can be correlated linearly with our data by

$$\Delta\delta^{urea} = 1.282\Delta\delta^{NHAc}$$

with excellent precision, $R=0.998$ and $s=\pm0.023$, suggesting that essentially the same interaction mechanism is operating for both systems. The analysis we have made in the present study will be applied in the same way for these systems. The α-NH chemical shift in urea is significantly more susceptible to substituent changes than those in the other NH chemical shifts.

Relative NH chemical shifts of the substituted acetanilides (Table 1) are plotted against the standard σ^0 constants in Fig. 1. The general trends that electron attracting groups tend to shift the NH-resonance position toward low field and the chemical shifts appear to reflect the charge density at the NH-site are borne out, while substantial scatter does not permit us to draw any quantitative conclusion. However, following facts are obvious. No significant exaltation in the resonance contributions of conjugatively electron attracting ($+R$) substituents relative to σ_p^0 scale is observed, employment of σ^- values not improving the fit. This indicates that the present data belong to the so called σ^0 class reactivity. Deviations of higher halogens are attributed to the sub-

stituent anisotropy effect. Deviations of the $-R$ substituents with acidic α-hydrogens are all large but similar to the behavior observed in the phenol chemical shift in DMSO. It is most plausible to ascribe these deviations mainly to the substantial substituent-solvent interactions.

The substituent effect is appreciably modified by DMSO.[3] The solvent-modified substituents in DMSO may be assumed to be essentially the same in the acetanilide as in the phenol system. We could thus expect a good correlation between the present data and the $(\sigma^0)_{DMSO}$ derived from the phenol hydroxyl chemical shifts in DMSO.[3] The good correlation obtained is shown in Fig. 2. $-R$ *para* substituents fall on a straight line determined by *meta* substituents, whereas all the $+R$ *para* substituents deviate slightly but systematically to the direction of enhancing resonance. No improved correlation was observed for the anisotropic halogen groups.

Although the exaltation of resonance contribution of $+R$ class *para* substituents does not appear very significant, the effect may be described by

$$\Delta\delta = \rho(\sigma^0 + r^-\Delta\bar{\sigma}_R^-) \quad (2)$$

The following equation should be employed in place of Eq. (2) utilizing the modified substituent constants $(\sigma^0)_{DMSO}$ and $(\Delta\bar{\sigma}_R^-)_{DMSO}$.[5]

$$\Delta\delta^X = \rho[(\sigma^0)_{DMSO} + r^-(\Delta\bar{\sigma}_R^-)_{DMSO}] \quad (3)$$

The equation agreed excellently with the chemical shift data excluding halogen groups, giving ρ value of 0.686 and r^- of 0.277 with a correlation coefficient 0.994 and a standard deviation $\pm$0.030.[10] The ρ value obtained is, within experimental uncertainty, identical with the value derived from the correlation (Fig. 2). Using this ρ value, the apparent substituent constants $\bar{\sigma}^{NH}$ can be determined (Table 2). The small r^- value indicates that the through-conjugation interaction between conjugatively electron attracting ($+R$) *para* substituents and the NHAc site is not important in the present system in contrast to the phenol system. This can be explained by the deviation from coplanarity of the NHAc site with the benzene ring. Since an insignificant degree of through-conjugation operates for $+R$ *para* substituents, no significant exaltation of resonance with the $-R$ detection site would be expected for $-R$ *para* substituents. The substituent effect observed in the present system can be regarded as the effect of nearly unexalted σ^0 class. Hence, the excellent fit of $-R$ class substituents to the above correlation, to the first approximation, indicates the validity of $(\sigma_p^0)_{DMSO}$ values of $-R$ groups derived from the hydroxyl chemical shift of phenols.

On the basis of this correlation, we can determine a set of $(\sigma^0)_{DMSO}$. Because of the small r^- value of 0.277, possible errors involved in the $(\Delta\bar{\sigma}_R^-)_{DMSO}$ values do not significantly affect the resulting set of $(\sigma^0)_{DMSO}$ values. This suggests that the new set of $(\sigma^0)_{DMSO}$ values might be more reliable than the previous one at least for the $+R$ groups (*cf.* Table 3). The solvent-modified parameters $(\sigma^0)_{DMSO}$ as well as apparent substituent constants $\bar{\sigma}^{NH}$ are composed of the inductive and the π-electronic effects of the solvent-modified substituents in DMSO.

Solvent-Modified Substituent Parameters

The substituent effects in benzene systems are generally described by the LSFE relationship, to the first approximation, in terms of the combination of mutually independent inductive and π-electronic contributions:[5]

$$\log (k/k_0)_p = \rho(\sigma_i + q_r^+ \sigma_\pi^+ + q_r^- \sigma_\pi^-)$$
$$\log (k/k_0)_m = \rho(1.17\sigma_i + 0.50\sigma_\pi^\pm) \quad (4)$$

where σ_i is the inductive substituent constant, which is independent of q_r's, a measure of reaction-dependent contributions of its resonance effect. σ_π^+ and σ_π^- are the substituent constants measuring the capability of $-R$ and $+R$ class substituents respectively to donate and withdraw electron through π-electronic delocalization. σ_π^+ corresponds numerically to 0.42 $\Delta\bar{\sigma}_R^+$ and σ_π^- to 0.73 $\Delta\bar{\sigma}_R^-$. By the aid of the characteristic ratio 0.85 or 1/1.17 of the inductive contributions from *para* and *meta* substituents in Eq. (4), a linear π-electronic free energy relationship can be derived which should be free from any inductive contributions:

$$\log (k/k_0)_p - 0.85 \log (k/k_0)_m = \rho C^- \sigma_\pi^- \text{ or } = \rho C^+ \sigma_\pi^+ \quad (5)$$

where C^- and C^+ are parameters measuring the susceptibility to the π-electronic effects of $+R$ and $-R$ substituents respectively in a given reaction. A convenient modification to accommodate effects of the $+R$ groups in the present system gives Eq. (1).

We have demonstrated the utility of the quantities $\bar{\sigma}_p - 0.85\ \bar{\sigma}_m$ or $\Delta\delta_p - 0.85\ \Delta\delta_m$ for the hydroxyl chemical shifts of phenols in DMSO, as a measure of relative

resonance capabilities of the solvent-modified substituents.[2,4] The resonance substituent constants of the DMSO-modified substituents denoted by $(\sigma_\pi^{\pm})_{DMSO}$ or by $(\Delta\sigma_R^{\pm})_{DMSO}$ were determined by Eq. (1) providing 0.73 $C^-=1.12$ and $0.42C^+=0.24$.[4] The inductive and normal substituent constants denoted by $(\sigma_i)_{DMSO}$ and $(\sigma^0)_{DMSO}$ for the DMSO-modified substituents were subsequently determined from $(\sigma_\pi)_{DMSO}$. The same sort of treatment is expected to be applicable also to the present system. The most important feature of the LSFE treatment, Eq. (4), is the introduction of dual reaction constants for the π-electronic effect, q_r^+ and q_r^-, each for $-R$ and $+R$ substituents. The subsequent treatment has therefore to be applied separately for $+R$ and $-R$ substituent effects. Since our purpose has been to establish the general applicability of our treatment for conjugatively electron attracting ($+R$) groups, we have chosen the present acetanilide system where the effects of $+R$ *para* substituents significantly differ from those in the phenol chemical shifts.[3,4] Thus, Eq. (5) will be applied first to the analysis of $+R$ substituent effects.

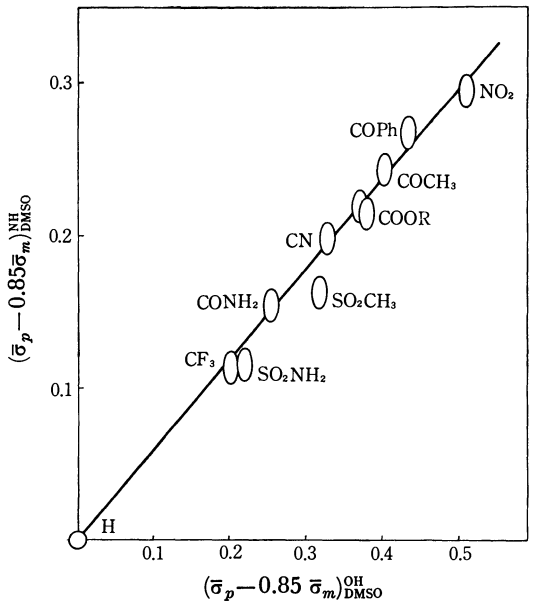

Fig. 3. The plot of $(\bar{\sigma}_p-0\bar{\sigma}.85_m)^{NH}_{DMSO}$ against $(\bar{\sigma}_p-0.85\,\bar{\sigma}_m)^{OH}_{DMSO}$ for $+R$ substituents.

Treatment of $+R$ Substituents. If the assumption of the solvent-modified substituent holds generally, Eq. (1) could be applied to the acetanilide system as well as to the phenol system in the same solvent. Equation (6) would hold provided that $(\Delta\bar{\sigma}_R^-)_{DMSO}$ for a series of $+R$ substituents are essentially independent of systems.

$$(\bar{\sigma}_p-0.85\bar{\sigma}_m)^{NH}=\alpha(\bar{\sigma}_p-0.85\bar{\sigma}_m)^{OH} \quad (6)$$

It follows that a plot of the quantities $(\bar{\sigma}_p-0.85\,\bar{\sigma}_m)^{NH}_{DMSO}$ against $(\bar{\sigma}_p-0.85\,\bar{\sigma}_m)^{OH}_{DMSO}$ for various $+R$ substituents should be a straight line of slope α. Figure 3 shows such a straight line with a correlation coefficient 0.997 and a standard deviation ±0.010. Using $\alpha=0.603$ in Eq.(6), $(\Delta\bar{\sigma}_R^-)_{DMSO}$ for $+R$ substituents can be derived from the apparent $\bar{\sigma}$ values from the acetanilides, and $(\sigma_\pi^-)_{DMSO}$ by $(\sigma_\pi^-)_{DMSO}=0.73\ (\Delta\bar{\sigma}_R^-)_{DMSO}$. The values are in precise agreement with those obtained from the phenol system, no serious corrections being required for the parameter values previously obtained. In this treatment, we have assumed that the *para/meta* inductive contribution ratio is a constant, 0.85, for all substituents irrespective of reactions. The good agreement thus may offer confirmation of the generality of 0.85 for the inductive contribution ratio.

We can apply the LArSR equation[5b] which is modified to (3) to accommodate the effect of DMSO-modified substituents on the chemical shift. If Eq. (3) is applicable to both the phenol and acetanilide systems, it follows that

$$(\Delta\bar{\sigma}_R^-)_{DMSO}=(\bar{\sigma}_p^{OH}-\bar{\sigma}_p^{NH})_{DMSO}/(r^{OH}-r^{NH})$$
$$=(1/\Delta r)(\bar{\sigma}_p^{OH}-\bar{\sigma}_p^{NH})_{DMSO} \quad (7)$$

The coefficient Δr can be determined from the slope of the correlation of $(\bar{\sigma}_p^{OH}-\bar{\sigma}_p^{NH})_{DMSO}$ against $(\Delta\bar{\sigma}_R^-)_{DMSO}$. Equation (7) is just the same expression as the basic one of the LArSR theory, indicating that the set of the differences between two sets of apparent $\bar{\sigma}_p$ in any two independent systems with different r's should be equivalent to the relative measure of resonance capabilities of the substituent.[5b] If Eqs. (3) and (4) are valid, the set of resonance quantities in Eq. (6) is proportional to another set of relative resonance capacities of substituents, namely,

$$(\bar{\sigma}_p-0.85\bar{\sigma}_m)^{OH}_{DMSO}=\beta(\bar{\sigma}_p^{OH}-\bar{\sigma}_p^{NH})_{DMSO} \quad (8)$$

A reasonably good linear correlation (Fig. 4) verifies the equivalency of these two sets of resonance measures.[11] An exceptionally large deviation indicated by the CN group is attributable to the anisotropy effect which appears to be considerably effective only in the acetanilide but not in the phenol chemical shifts.

The correlation could be applied for estimating the $(\Delta\bar{\sigma}_R^-)_{DMSO}$ parameter. However, because of the smallness of $(\bar{\sigma}_p^{OH}-\bar{\sigma}_p^{NH})$ quantities, the uncertainty would be larger for the parameter values derived from this set of quantities than those from the $(\bar{\sigma}_p^{NH}-0.85\,\bar{\sigma}_m^{NH})$ quantities. The former evaluation depends on the uncertainty of two independent ρ values, whereas in the latter based upon Eq. (6) any error involved in ρ values is practically unimportant for the evaluation of $(\Delta\bar{\sigma}_R^-)_{DMSO}$ parameters, since we can utilize directly two sets of experimental quantities $(\Delta\delta_p-0.85\,\Delta\delta_m)_{DMSO}$ instead of $(\bar{\sigma}_p-0.85\,\bar{\sigma}_m)_{DMSO}$. It is therefore more reasonable to evaluate a set of $(\Delta\bar{\sigma}_R^-)_{DMSO}$ parameters by Eq. (6), in comparison with the previous values derived from the phenol hydroxyl chemical shift (Table 3). $(\sigma_i)_{DMSO}$ and then $(\sigma^0)_{DMSO}$ parameters can be determined from $(\Delta\sigma_R^-)_{DMSO}$ or $(\sigma_\pi^-)_{DMSO}$ (Table 3). As anticipated, these sets of parameters derived from NH chemical shifts are identical within experimental uncertainty with the corresponding parameters derived from the phenol hydroxyl chemical shift. The identity between the corresponding sets from two independent sources with reasonable precision is a strong evidence for the generality of the LArSR and LSFE relationships. This proves also the validity of the assumption that the substituent effect in a given solvent can be treated as the effect of the solvent-modified substituents, independent of reactions or systems, at least for conjugatively electron

attracting substituents.

In order to rationalize the results, it is necessary to compare them with the results of the corresponding analysis of the present shift data according to Taft's equation.[12] Taft's treatment is based on the assumption of i) the equal inductive contributions from a given substituent at *meta* and *para* positions, and ii) the view that the σ_I parameters of any substituent essentially are invariant irrespective of the nature of reaction. Of course, the solvent-variation of these parameters may be imposed. From his theory, the apparent resonance parameters $\bar{\sigma}_R$ of the solvent-modified substituents in DMSO can be given by

$$(\bar{\sigma}_R)_{DMSO} = (\bar{\sigma}_p)_{DMSO} - (\bar{\sigma}_I)_{DMSO}$$

The equal inductive contribution from *meta* and *para* positions implies that the π-electronic effect (or resonance) parameters should be proportional to the difference between *meta* and *para* apparent substituent constants, $\bar{\sigma}_p-\bar{\sigma}_m$, in a given system, namely,

$$(\bar{\sigma}_R)_{DMSO} = \alpha'(\bar{\sigma}_p-\bar{\sigma}_m)_{DMSO} \quad (9)$$

where α' is a proportionality constant. If Eq. (9) were valid for various systems, $(\bar{\sigma}_p-\bar{\sigma}_m)_{DMSO}$ quantities for two systems may be expected to be linearly related. Figure 5 shows the correlation of the two sets of Taft's resonance quantities derived from phenol and acetanilide systems in DMSO solution. The correlation is less satisfactorily linear ($R=0.961$ and $s=\pm0.021$) than that given by Eq. (6). The plot appears to be better described by a smooth curve; otherwise, the deviation of the unsubstituted derivative is significant. Such non-linearity between any two sets of Taft's resonance parameters $\bar{\sigma}_R$ derived from various classes of $\bar{\sigma}$ values is generally observed even in chemical reactivities. For instance, similar resonance quantities $\bar{\sigma}_p-\bar{\sigma}_m$ for $+R$ substituents from the standard σ^- constants are not reasonably linear against the corresponding quantities from the other references σ^0 or σ parameters.[13] This is in contrast to the present results based on our LArSR and LSFE treatment. Taft has concluded that there are no general or universal parameters of resonance effects of substituents.[12] Generalized treatment of the same kind as we have employed could not be possible with Taft's equation based on the equal *meta* and *para* inductive contribution model.

Treatment of $-$R *Substituents.* In contrast to the remarkable success in correlating effects of conjugatively electron attracting substituents, the analysis of con-

jugatively electron releasing substituent effects does not appear to be so simple. The same sort of difficulty was observed in the analysis of phenol chemical shifts.[2,4] Neither σ_π nor σ_i parameters obtained were linear against the ordinary sets of corresponding parameters. Thus we can not attain ultimate accuracy in the evaluation of parameters of the solvent-modified substituents from the present data. Nevertheless, it appears of value to estimate somewhat rough but still useful measures of the apparent inductive and π-electronic effects of the so-called solvent-modified substituents.

Since the *para/meta* inductive contribution ratio of 0.85 is believed to be valid for $-R$ as well as $+R$ substituents, the quantities $(\bar{\sigma}_p - 0.85\,\bar{\sigma}_m)_{\mathrm{DMSO}}$ for $-R$ groups in either the phenol or the acetanilide system should give a relative measure of the resonance capability of DMSO-modified substituents. Thus, even though they might not be proportional to the standard σ_π^+ or $\Delta\bar{\sigma}_R^+$ parameters, it is anticipated that both sets of quantities are correlated linearly with each other; that is, Eq. (6) holds for $-R$ substituents. Since the apparent substituent constants $\bar{\sigma}_p$ for $-R$ *para* substituents in both systems are identical within their uncertainty and appear both to be of the σ^0 class, the slope α of the correlation should be close to unity. However, the result is not in line with anticipation. The fit does not appear to be satisfactory and the slope α corresponds to roughly 2/3. This implies that the C_M scale in Eq. (1) is not the same for the two apparent stes of $(\sigma_\pi)_{\mathrm{DMSO}}$. A similar treatment based upon Taft's assumption, Eq. (9) for $-R$ substituents, gives no reasonable correlation.

Assuming the effect of $-R$ groups to be of the σ^0 class, the conversion coefficient for $-R$ class substituents can be given as follows, provided that the ordinary resonance contribution scale $q_r^+ = 1.0$ for *para* $-R$ substituents and $q_r^m = 0.50$ for *meta* substituents by means of Eq. (4);

$$(\bar{\sigma}_p - 0.85\bar{\sigma}_m) = 0.575(\sigma_\pi^+)_{\mathrm{DMSO}} \qquad (10)$$

An apparent set of inductive parameters $(\sigma_i)_{\mathrm{DMSO}}$ can thus be given by

$$(\sigma_i)_{\mathrm{DMSO}} = \bar{\sigma}_p - (\sigma_\pi^+)_{\mathrm{DMSO}} = 1.48\bar{\sigma}_m - 0.74\bar{\sigma}_p \qquad (11)$$

The inadequacy of the scale of $(\sigma_\pi^+)_{\mathrm{DMSO}}$ parameters should reflect the consistency of the resulting set of $(\sigma_i)_{\mathrm{DMSO}}$ values. The reliability of the former parameters can be judged in turn from the consistency of the $(\sigma_i)_{\mathrm{DMSO}}$ values. The best practical way of critical examination of both parameters is to compare the $(\sigma_i)_{\mathrm{DMSO}}$ values with a certain reliable measure of the inductive effects of substituents obtained from a completely independent source in the same solvent. As such a reference measure, we have chosen the relative ^{19}F NMR chemical shifts of *m*-substituted fluorobenzenes, correlating with the inductive substituent constants alone.[14] We assume, to a first approximation, that the solvent-modified substituents remain essentially the same in the same solvent regardless of change of the system from acetanilides to *m*-substituted fluorobenzenes. In Fig. 6 the inductive quantities, $(\sigma_i)_{\mathrm{DMSO}}$ for $+R$ groups (Table 3) and those derived from Eq. (11) for $-R$ groups, are plotted against $\Delta\delta^{\mathrm{F}}_{m-\mathrm{X}}$ in DMSO. The $+R$ groups satisfy a linear correlation, while almost

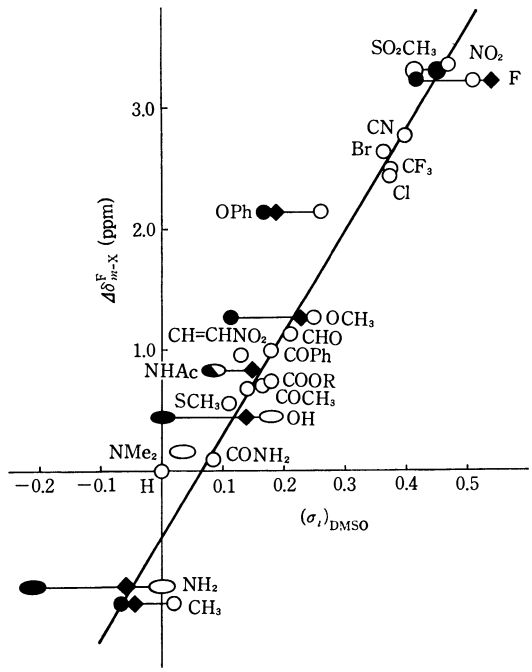

Fig. 6. The plot of ^{19}F substituent chemical shifts of *m*-substituted fluorobenzenes against DMSO-modified inductive substituent parameters, σ_i: open circles $(\sigma_i)^{\mathrm{OH}}_{\mathrm{DMSO}}$, closed circles $(\sigma_i)^{\mathrm{NH}}_{\mathrm{DMSO}}$, and squares $(\sigma_i)^{\mathrm{Corr}}_{\mathrm{DMSO}}$.

all $-R$ substituents deviate considerably from the correlation line. The fit of $+R$ substituents is excellent (correlation coefficient 0.986 and standard deviation ± 0.024) so that the correlation can give rise to a set of the inductive measure $(\sigma_i)^{\mathrm{F}}$, by

$$(\sigma_i)^{\mathrm{F}} = 0.118\Delta\delta^{\mathrm{F}}_{m\text{-}\mathrm{X}} + 0.066$$

As 0.85 for the *para/meta* inductive ratio is presumed to be valid for $-R$ groups in this system, the relative π-electronic contribution should be proportional to the quantities $(\bar{\sigma}_p - 0.85\,\bar{\sigma}_m)$. This gives the following equation concerning the π-electronic effect of $-R$ class substituent.

$$\bar{\sigma}_p{}^{\mathrm{NH}} - (\sigma_i)^{\mathrm{F}} = \gamma(\bar{\sigma}_p - 0.85\bar{\sigma}_m)^{\mathrm{NH}} \qquad (12)$$

The best-fit gave γ value of 2.36 for $-R$ groups in the acetanilide system. The $(\sigma_\pi^+)^{\mathrm{Corr}}_{\mathrm{DMSO}}$ values derived on this basis and $(\sigma_i)^{\mathrm{Corr}}_{\mathrm{DMSO}}$ values given by $\sigma_p - (\sigma_\pi^+)^{\mathrm{Corr}}_{\mathrm{DMSO}}$ are given in Table 4 in comparison with those from the phenol chemical shifts. $(\sigma_i)^{\mathrm{Corr}}_{\mathrm{DMSO}}$ for $-R$ substituents satisfy the correlation determined by $+R$ groups with an excellent precision (Fig. 6); especially, the sub-

Table 4. Modified substituent parameters in DMSO for $-R$ groups

No.	Subst.	Acetanilides		Phenols	
		$(\sigma_\pi^+)^{\mathrm{Corr}}_{\mathrm{DMSO}}$	$(\sigma_i)^{\mathrm{Corr}}_{\mathrm{DMSO}}$	$(\sigma_\pi^+)^{\mathrm{OH}}_{\mathrm{DMSO}}$	$(\sigma_i)^{\mathrm{OH}}_{\mathrm{DMSO}}$
1	F	−0.45	0.54	−0.49	0.51

7	NH_2	−0.56	−0.06	−0.64	0.00

stituents carrying acidic hydrogen at the α-position are brought closer to the line. The excellent fit of $-R$ substituents suggests that the quantity $(\bar{\sigma}_p - 0.85\,\bar{\sigma}_m)$ measures the relative capabilities of the π-electronic contributions of solvent-modified substituents, even though the γ value is not 1/0.575 expected for the system of the σ^0 class. On the other hand, the phenol system gives a correlation for $-R$ groups using $(\sigma_i)^F$ values;

$$\bar{\sigma}_p{}^{OH} - (\sigma_i)^F = (1.00+0.08)(\sigma_\pi{}^+)_{DMSO}.$$

The unit slope indicates that the scale of the π-electronic effect parameters estimated from the phenol system is reasonable, while deviations of $-R$ groups are considerably large.

The best correspondence to $\Delta\delta^F_{m-X}$ is observed with $(\sigma_i)^{Corr}_{DMSO}$ parameters (Fig. 6). Accordingly, $(\sigma_\pi{}^+)^{Corr}_{DMSO}$ derived from acetanilides seems to give a better measure of the π-electronic effect of solvent-modified substituents in DMSO than the other, while it is necessary to justify the higher γ value for the acetanilides before one may draw any conclusion. The identity of the apparent $\bar{\sigma}_p$ values of $-R$ groups in acetanilides and phenols indicates that the resonance contribution scale of $-R$ *para* groups, $q_r{}^+$ or r^+, should be essentially the same in both systems. The ambiguity of the contribution scale of π-electronic effect of *p*-substituents in either system, even if they differ from the σ^0-scale, does not theoretically cause any serious deviation in the γ-value. The contradiction has to be ascribed only an inadequate estimation of the contribution scale of resonance from *meta* substituents. The high γ-value requires the enhanced resonance contribution from *meta* substituents. The $-R$ *meta* groups exert more enhanced electron release in the NHAc than in the phenol chemical shifts. The apparent *meta* substituent constants $\bar{\sigma}_m^{NH}$ can be correlated with $\bar{\sigma}_m^{OH}$, taking into account the resonance exaltation in terms of modified LArSR equation:

$$\bar{\sigma}_m{}^{NH} = 1.03\bar{\sigma}_m{}^{OH} + 0.14(\sigma_\pi{}^+)$$

This means that the relative resonance effect of $-R$ *meta* substituents in the acetanilides is some 20% more effective than that in the phenol system. The resonance exaltation of *meta* substituents is unusual in general chemical reactivities in which the *meta* resonance remains constant $0.50\,\sigma_\pi{}^\pm$ regardless of the nature of substituents and independent of the type of reactions,[5] as evidenced by general reaction-independency of σ_m constants.

On the other hand, it has been pointed out that NMR chemical shifts of the proton attached to the *meta*-position relative to substituents do not precisely correlate with σ_m but rather with $\sigma_p{}^0$ values.[15] A plausible explanation for this behavior, based on the ring-current model, was proposed by Yukawa and co-workers:[16] The benzene ring current should be disrupted by the disturbance of π-electron distribution with the exo-delocalization with conjugative (either $-R$ or $+R$) substituents. Such an effect may be parallel to the capability of substituents to alter the π-electronic distribution; that is, parallel to $\sigma_\pi{}^\pm$ values. It would follow from this concept that the $-R$ substituents give the apparent resonance exaltation in the *meta* proton chemical shifts. The enhanced π-electronic contribution from *meta*-substituents in the present system can be explained if such an effect is effective in the chemical shifts of hydrogen-bonded NH proton of the acetanilides.

Experimental

Almost all *m*- and *p*-substituted acetanilides were prepared by the acetylation of substituted anilines with acetic anhydride sometimes with addition of pyridine. Anilines made available from other studies of substituent effects were used. The melting points and other physical constants agreed with established values.

The Substituent Effect. VIII. Solvolysis of *m*- and *p*-Substituted α-Methylbenzyl Chlorides

Yuho Tsuno,* Yoshiaki Kusuyama, Masami Sawada, Takahiro Fujii, and Yasuhide Yukawa

The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka 565

(Received December 10, 1974)

The rates of solvolysis of twenty-two *m*- and *p*-substituted α-methylbenzyl chlorides were determined in 80% aqueous acetone. The relative rates at 45 °C are not correlated linearly with σ^0 or σ. The use of Brown's σ^+ improves the fit but the resulting correlation is still concave. An excellent correlation, $\log k/k_0 = -4.950$ ($\sigma^0 + 1.147\,\Delta\bar{\sigma}_R^+$), was obtained by applying the LArSR equation. The r value 1.15 suggests that the π-electronic contribution relative to the inductive contribution of $-R$ *para* substituents at the transition states differs with reaction, and is more important in the present α-methylbenzyl than Brown's *t*-cumyl solvolysis ($r = 1.00$ by definition). A set of $\Delta\bar{\sigma}^+$ and σ^+ corresponding to the substituent constants for unit r were calculated. The calculated σ^+ values are in precise agreement with Brown's primary σ^+ values. The generality of the LArSR equation and some new substituent constants are illustrated.

Although Brown's $\rho\sigma^+$ treatment is successful for describing substituent effects in the solvolysis and aromatic substitutions,[1] there is substantial evidence that the actual blend of inductive and resonance effects varies with reaction.[2,3] Taking this into account, we proposed the equation,

$$\log (k/k_0) = \rho(\sigma^0 + r\Delta\bar{\sigma}_R^+) \quad (1)$$

and illustrated its applicability to various electrophilic reactions.[4-6] σ^0 is the normal substituent constant which does not involve any additional π-electronic interaction between substituents and the reaction center. $\Delta\bar{\sigma}_R^+$ is the resonance substituent constant measuring the capability for π-electron delocalization of conjugatively electron releasing ($-R$) substituents and is defined by $\sigma_p^+ - \sigma_p^0$. The r parameter is the resonance reaction constant describing the required resonance stabilization of the transition state of given reaction; $r = 1.00$ is referred to Brown's σ_p^+ scale and $r = 0.00$ to the unexalted σ_p^0 scale. Equation (1) has been employed for various reactivity data.[7,8] In order to confirm the applicability and the possible limitation of our treatment, it is necessary to reconfirm the validity of the required substituent parameters. Since the resonance substituent constant $\Delta\bar{\sigma}_R^+$ is based on two reference sets of substituent constants σ^0 and σ^+, our studies have been carried out along two principal lines of reconfirmation of both reference sets of the substituent parameters.[9] For the reexamination of σ^+ as well as $\Delta\bar{\sigma}_R^+$, we need data of the effects of a variety of substituents on the solvolytic system similar to Brown's reference reaction. Only a few data were available to test the applicability of Eq. (1). The system to be studied should be a simple reaction having a similar transition state to Brown's system. The solvolysis of *m*- and *p*-substituted α-methylbenzyl chlorides was chosen for study. The kinetic data of this series appear to be important in connection with the comparison of substituent effects in secondary and tertiary carbonium ion reactions. Results of several less extensive studies on this system are available,[10-12] but none are satisfactory.

We carried out kinetic studies of the solvolysis of various series of substituted arylmethylcarbinyl chlorides in various solvents. Parts of the results have been reported.[6,13,14] Several sets of interesting data of similar kinetic studies have also been reported.[14-16] A complete set of our data is presented with a discussion in comparison with the relevant data. Our studies include the solvolysis of substituted phenyl-, α-naphthyl,[17] 3′- and 4′-substituted biphenyl-,[18a] and 7-substituted 2-fluorenyl-[18b] derivatives.

The present paper is concerned with the substituent effects on the solvolysis of *m*- and *p*-substituted α-methylbenzyl chlorides in 80% aqueous acetone.

Results and Discussion

The rates of solvolysis of *m*- and *p*-substituted α-methylbenzyl chlorides were determined in 80% aqueous acetone at convenient temperatures to give moderate rates for respective derivatives. All the runs followed accurately the first order kinetic law, the rate constants being obtained with accuracy of 1%, except for *p*-methoxy derivative. Rate constants (Table 1) are in good agreement within the usual accuracy with the values in literature. Extrapolation of these data was made solely by means of the Arrhenius equation at 45 °C. The relative rate varies remarkably with substituent changes over a range of six powers of ten, and the reactivities for both the highest and lowest ends are not presumed to be less reliable. Especially for *p*-methoxy derivative a rather large uncertainty will be expected because of experimental difficulties in measuring the rapid reaction at extremely low temperatures and uncertainty in the extrapolation to 45 °C. *m*-Halogen derivatives may also involve somewhat large uncertainty because of extrapolation from measurements at temperatures higher than the boiling point of the solvent. From remarkable divergence of the reactivities, however, minor errors involved are not expected to affect the following discussion of the substituent effect. Logarithms of relative rates at 45 °C are linearly correlated in excellent precision ($s = \pm 0.030$, $R = 0.9999$) with those at 25 °C giving a slope of 0.9615. The same

a) Extrapolated from the rate constant at other temperatures by the Arrhenius equation. b) Estimated from the rate constant at 80°C on the basis of linear log k–log k relation between the rates at 80°C and those at 45°C. c) Average values of repeated determinations.

is true in the log-log plot of relative rates at 45 °C *vs.* those at 80 °C. Thus, an arbitrary choice of the reference temperature 45 °C also does not affect the present discussion, except for the minor temperature effect on the ρ-value.

As anticipated for the typical benzylic S_N1-solvolysis reactions, σ^0 or σ is unable to correlate linearly the present reactivity data as shown by the σ-plot in Fig. 1, in which *meta* substituents fall on a straight line to give a ρ_m value of -4.964 ± 0.025, but all $-R$ *para* substituents deviate upwards from the *meta* line. Brown's σ^+ provides a much better correlation (Fig. 2) with a ρ^+ value of

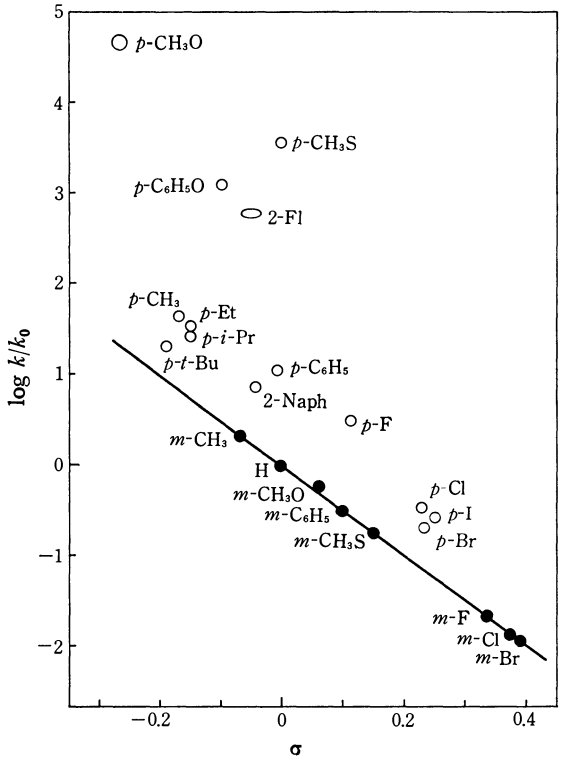

Fig. 1. Hammett plot of the solvolysis of α-methylbenzyl chlorides in 80% aq. acetone at 45 °C.

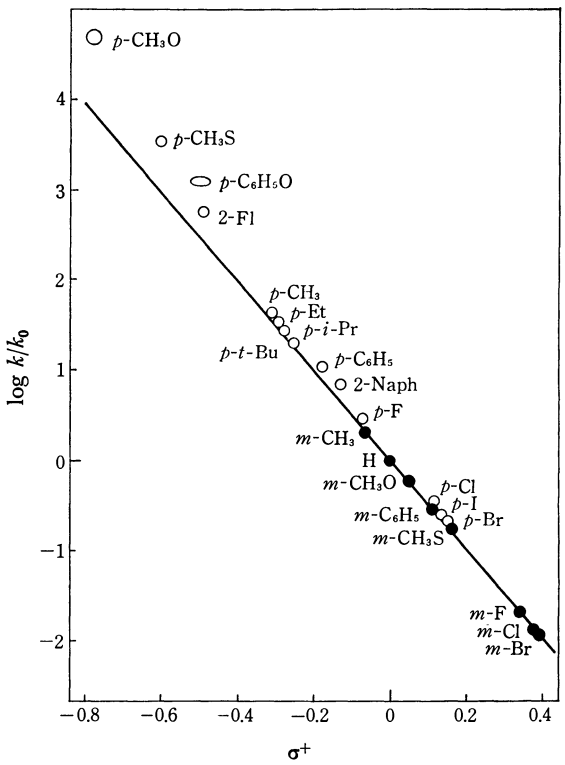

Fig. 2. Hammett-type plot against Brown's σ^+.

-5.51 (standard deviation ±0.17 and correlation coefficient 0.995). The line is not for the best fit correlation but is drawn through the points for *m*-substituents. The best-fit ρ^+ value is considerably higher (more negative) than the ρ_m value based on *meta* substituents. Points for weakly conjugative *para* groups appear to fall near the the ρ_m-line, whereas strongly electron-releasing ($-R$) groups, such as *p*-methoxy, *p*-phenoxy, 2-fluorenyl and *p*-methylthio groups, deviate significantly to the direction of enhanced reactivity from the ρ_m-line. Excluding four such faster reacting groups, an improved partial σ^+ correlation within a range of substituents from *p*-methyl

to *m*-bromo groups can be obtained with correlation coefficient 0.999 and standard deviation ±0.057, to give $\rho^+ = -4.980 \pm 0.060$, which is close to the ρ_m value. This indicates that Brown's $\rho\sigma^+$ treatment can practically be applied to the present reactivity set only within a limited range of weakly conjugative substituent groups. Even though the deviation of *p*-methoxy group might be ascribed to the error in its relative rate at 45 °C due to experimental difficulties, such serious errors are not expected for the rates of *p*-phenoxy and *p*-methylthio-derivatives. Deviation of these substituents should be due to difference in stabilization of the transition states between the present and cumyl system. The overall $\rho\sigma^+$ correlation is represented by a smooth upward curvature.[19] Brown's treatment can not describe adequately the effect of strongly electron-donating *para* substituents in the present reaction.

From the above ρ_m value, we can derive a set of apparent substituent constants ($\bar{\sigma}$) of the σ^+-type from the relative rates of the present solvolysis by

$$\bar{\sigma} = (\log k/k_0)/(-4.964)$$

As an operational definition, this set of apparent substituent constants are completely independent of and should be equivalent in nature to Brown's σ^+ parameters determined by the same procedure from the *t*-cumyl solvolysis rates. The apparent σ values for *m*-substituents, $\bar{\sigma}_m$, agree precisely with Brown's $\bar{\sigma}_m{}^+$, even better than with the standard σ_m values, while the σ values for all *—R para* substituents (Table 2) are consistently more negative than the corresponding Brown's σ^+ values. This suggests that the additional resonance contribution from *—R para* substituents is more important in the transition state of the secondary benzylic carbonium ion structure than in the latter tertiary carbonium ion transition state, and that there is no unique set of σ^+ constants applicable to electrophilic exalted resonance type reactivities. The blend of resonance and inductive effects represented by Brown's σ^+ constants appears to be only a sufficiently good average to fit most cases. The varied contribution of the resonance effect can be taken into account, as a precise approximation, by application of Eq. (1) from which it immediately follows that

$$(\log k/k_0)/\rho = \sigma^0 + r\Delta\bar{\sigma}_R{}^+ \qquad (2)$$

This indicates that the exaltation of apparent $\bar{\sigma}_p$ from σ^0,

a) Apparent $\bar{\sigma}$ values given by $\bar{\sigma} = \log k/k_0/(-4.964)$; use of $\rho = -4.950$ instead of $\rho_m = -4.964$ does not affect the results. b) Giving by $[\log k/k_0/(-4.950) - \sigma_p{}^0]/1.15$. c) $\sigma^+ = (\Delta\bar{\sigma}^+{}_R)_{calcd} + \sigma_p{}^0$. d) Brown's primary σ^+ values taken from Ref. 1.

the quantities $(\log k/k_0)/\rho-\sigma^0$, should be proportional to the resonance parameter $\Delta\bar{\sigma}_R^+$. Figure 3 illustrates such a plot. The slope should correspond to the r value. It is obvious that there is no trend of curvature in the plot but only the *p*-methoxy group clearly deviating from the line. The deviation can be attributed to the error in the relative rate of this group. The linear plot offers confirmation of the validity of our LArSR relationship. The ordinary LArSR plot for the present reaction is shown in Fig. 4. No trend of curvature except for the *p*-methoxy group is indicated. Least squares calculation gives a ρ-value −4.953 and r 1.147 excluding *p*-methoxy group (standard deviation ±0.040 and correlation coefficient 0.9997). Substituent constants utilized are given in

Table 3. The ρ-value is identical within experimental uncertainty to the ρ_m value based on *m*-substituents alone and appreciably less than that given by the σ^+-resorting. The high r-value is consistent with the view that the resonance contribution from $-R$ *para* substituents to the stabilization of the transition state is more important in the present series than in Brown's cumyl system. Putting $r=1.15$ and $\rho=-4.950$ in Eq. (1), we can obtain a calculated set of $\Delta\bar{\sigma}_R^+$ values and a secondary set of σ^+ values in Brown's scale ($r=1.00$). They are compared with Brown's primary values (Table 2). Both sets of σ^+ are in precise agreement within ±0.007 in σ unit for all *para* substituents except the *p*-methoxy group. The rates of solvolysis of several polynuclear arylmethylcarbinyl chlorides under the same conditions[12] have been treated on the basis of the above correlation in order to derive the σ^+ and $\Delta\bar{\sigma}_R^+$ constants for these aryl moieties as derivatives of the parent phenyl compound. The applicability of these parameters for other reactions was shown in a previous paper.[13] Kusuyama and Ikeda[14a] recently determined the rates of hydrolysis of *p*-cyclopropyl- and *p*-(β,β-dichloro-cyclopropyl)-α-methylbenzyl chlorides and obtained, on the basis of the above correlation, the σ^+ and $\Delta\bar{\sigma}_R^+$ constants for cyclopropyl and β,β-dichlorocyclopropyl groups.[14a] The results are given in Table 4. The σ_p^+ for *p*-cyclopropyl group is consistent with the estimation from the *t*-cumyl reactivity.[14] The particularly large $\Delta\bar{\sigma}_R^+$ value of −0.36 as compared with ordinary alkyl groups is striking, and suggests that the donating resonance power of this group is roughly close to that of

a) Apparent substituent constant given by $\bar{\sigma}=(\log k/k_0)/(-4.950)$. b) Taken from Ref. 13. c) Calculated by $(\bar{\sigma}-\sigma^0)/1.147$. d) $\sigma^+_{calcd}=\sigma^0+(\Delta\bar{\sigma}_R^+)_{calc}$. e) Ref. 12. f) Ref. 17. g) The parameter value does not appear to be practically applicable because of the reaction-dependent *peri*-effect. h) Ref. 14a. i) Shechter reported the same value of the primary σ^+ (Ref. 14b).

2-fluorenyl and much stronger than that of *p*-phenyl or ordinary alkyl groups.

The σ^+ values for *p*-methylthio, *p*-phenoxy, and 2-fluorenyl have seldom been applied to typical electrophilic reactions and have not yet been examined in detail. For the *p*-phenoxy group even the primary σ^+ value has not been determined. The present results will thus give some support for validity of σ^+ values for these groups. Clementi *et al.* studied the effect of *p*-CH_3S group on electrophilic aromatic substitutions in order to confirm the reliability of the σ^+ value and also illustrated far better results with LArSR treatment of the reactions whose r values differ from unity.[20a]

Equation (2) implies that, as a good approximation, the variation of apparent substituent constants of a given *para* substituent should be a linear function of r for varying reaction. The slope of the relation should correspond to the $\Delta\bar{\sigma}_R^+$ and the intercept to the σ^0 of the substituent.

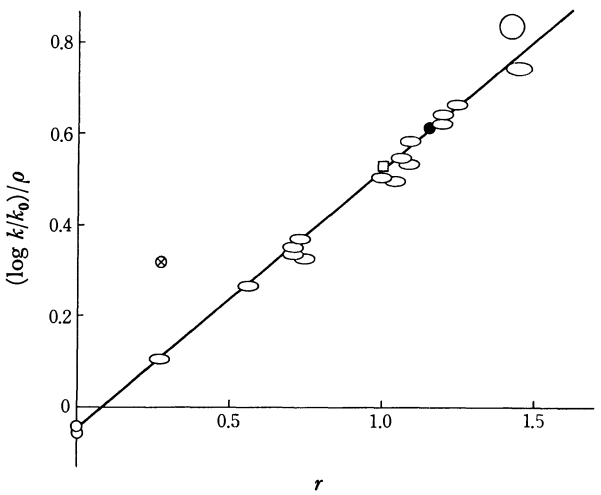

Fig. 5. Plot of the apparent substituent constants, $\bar{\sigma}=(\log k/k_0)/\rho$, for *p*-phenoxy group against r.
●: present study, □: σ^+_{calc}, ⊗: pK_a of benzoic acids.

Ordinary substituents satisfy this relation.[5] Figure 5[20c] shows the plot for *p*-phenoxy group. Both $\Delta\bar{\sigma}_R^+$ and σ^0 for this group estimated from this correlation are in good agreement with the above values, suggesting its applicability to various reactions. Similarly good correlations are obtained for *p*-phenyl and 2-fluorenyl derivatives.[5,13]

The *p*-methoxy group is in most cases the only substituent which has a particularly large $\Delta\bar{\sigma}_R^+$ value as compared with other ordinary substituents, such as alkyls and halogens. The best fit correlation should thus be determined most effectively by the *p*-methoxy group and might be constrained by the error involved in its reactivity. Since the above three groups, *p*-CH_3S, *p*-C_6H_5O, and 2-fluorenyl, are sufficiently stable under ordinary solvolytic conditions, use of these groups may be recommended as a good alternative of *p*-methoxy group for the correlational analysis of substituent effects and as auxiliary substituents for estimation of $-R$ resonance requirement of given reactions.

The point for the pK_a of benzoic acids in Fig. 5 deviates seriously from the correlation line, while the points for the saponification of benzoic esters and other σ-type reactivities having the comparable *r*-value (round 0.28) fall on the line. This suggests a limited applicability of the σ-value-0.32, recommended by Brown and McDaniel.[21] The σ value of -0.10 derived from the hydrolysis of substituted ethyl benzoates in aq. ethanol[22] is in accord with the calculated value from the above correlation (Fig. 5).

Another fact of interest is observed in the behavior of *p*-phenyl substituent. The lower $\Delta\bar{\sigma}_R^+$ value of *p*-phenyl group, or the smaller slope in the apparent $\bar{\sigma}$ *vs.* *r* plot, than that of 2-fluorenyl indicates a considerable decrease in the transition state resonance due to the deviation from the coplanarity of both benzene rings in the former. Stock and Brown suggested,[23] on the basis of their observation of a non-linear selectivity relation for *p*-phenyl but for fluorenyl derivatives in electrophilic aromatic substitutions, that the substituent phenyl-ring in the former should be forced to lie in a nearer coplanarity to get a maximum possible overlap of both π-systems as the demand of donative resonance of the reaction site becomes larger. On the other hand, Neuman pointed out that the log p_f for 2-fluorenyl was at least as good a linear function of log p_f for *p*-phenyl as that for *p*-methyl, and that the fluorenyl did not fit the selectivity relation much better than *p*-phenyl group.[24] Deviations in these relations were quite large in both plots and the failure of Brown's selectivity treatment is partly associated with variations of *r*-value. It may be expected that the twisting causes certain failure in the $(\log k/k_0)/\rho$ *vs.* *r* correlation for phenyl group. Since *r* can be regarded as a measure of the demand of resonance of the reaction site, the coplanarity of both phenyl rings may increase as the *r* increases, and cause a parallel increase in the resonance power ($\Delta\bar{\sigma}_R^+$) of phenyl group to approach the $\Delta\bar{\sigma}_R^+$ for 2-fluorenyl. No such effect is detectable in the present treatment, the plot for phenyl being as precisely linear against *r* as that for fluorenyl derivative. *p*-Phenyl group appears thus to be a well-behaving $-R$ substituent in the usual electrophilic reactions. As far as the ordinary solvolysis and aromatic electrophilic substitution reactions are concerned, the changes in the electron deficiency of reactions cause no significant changes in the twisting angle of the biphenyl at the transition states of varied reactions.

We see that the LArSR equation can describe the present reaction far more precisely than Brown's $\rho\sigma^+$ treatment. However, a sophisticated treatment with an additional term should give more satisfactory results than the simpler treatment. From a practical point of view the simpler $\rho\sigma^+$ treatment can provide satisfactory correlation for the present system within the limit of usual accuracy of linear free energy relationships. This is not inconsistent with the significance of the additional resonance parameter, because we have chosen the present reaction as the reference reaction mechanistically close to Brown's reference reaction. Essentially a small difference in the *r*-value between the present and Brown's reference reactions may not result in significant improvement of the correlation with the LArSR treatment.

Brown estimated the secondary σ^+ values for polynuclear aryl moieties from the solvolysis of α-arylethyl chlorides,[12] on the basis of a linear log *k*–log *k* relation of 4 common derivatives.[25] The σ^+ values compared in Table 4 are in good agreement with ours. The σ^+ treatment seems to be practically applicable to the solvolysis of α-arylethyl chlorides including these polynuclear aryl derivatives, even if the applicability might be limited in the choice of substituents as well as in accuracy. Streitwieser *et al.*[16] demonstrated the applicability of a set of σ^+ for these moieties to several benzylic carbonium ion reactions. The σ^+ was applied to the desilylation of aryltrimethylsilanes[26] and also to the pK_{BH}^+ of aryl methyl ketones.[13] The results support Brown's single σ^+ treatment, as a practical approximation of the simple linear free energy relationship, in a broad range

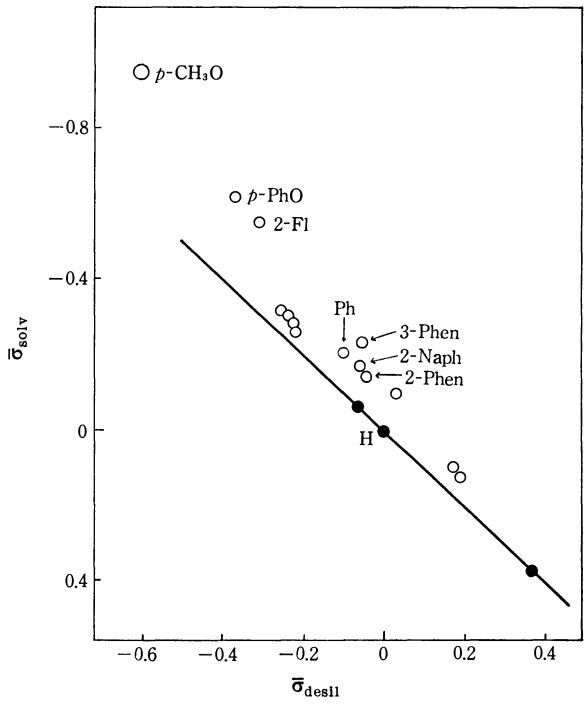

Fig. 6. Correlation of the apparent substituent constants between the present solvolysis and protodesilylation.

of electrophilic type conjugation reactions. We are not concerned here with the difference in the precision of fit with Eq. (1) and Brown's basis treatment, since introduction of more parameter should inevitably improve the precision of fit. Nevertheless, it must be pointed out that even through the σ^+ treatment is valid as a practical approximation both for the present solvolysis and the desilylation, the $\bar{\sigma}$ values from both reactions can not correlate linearly with each other (Fig. 6), giving a quite similar pattern to that in Fig. 1. —*R para* substituents as well as polynuclear aryls in Fig. 6 deviate more or less seriously from the *meta*-correlation line, apparently depending upon their resonance capabilities. The partial correlation with respect to polynuclear aryls is of poor quality. This arises from the significant difference in the r values of both reactions 0.7 and 1.15. The correlation between pK_{BH^+} of aryl methyl ketones and the present solvolysis is much the same as above.

σ^+ appears to be the best average to fit most cases and practically applicable within satisfactory precision to the electrophilic reactions having r value in the range 0.8—1.2, while a definite set of σ^+ can not describe the substituent effect in the reaction having the r value outside of this range. Examples are the acetolysis of neophyl brosylates[27] and β,β-diarylethyl tosylates[28] and the like which require r of about 0.5. The r-parameter has been verified to be a useful measure of the degree of resonance contribution from substituents in the rate determining transition state and is applicable to the estimation of the electronic structure of transition states. In a comparison of the solvolysis of benzyl, α-methylbenzyl, and *t*-cumyl chlorides, the r parameter appears to decrease in the order, 1.5 (approximate value), 1.15, and 1.00 as the number of α-methyl substitution increases.[6] The increased stabilization of the charged reaction center at the transition state by the α-methyl group should cause decreased demand of the electron releasing resonance contribution from *para* substituents. This predicts the above decreasing order of r-values. The distinctly low r-value for acetolysis of neophyl brosylates and the related derivatives might indicate the different mechanism of stabilization of the rate determining transition state from that of ordinary benzyl-type carbonium ion reactions.

As a possible factor affording a higher r value in the present reaction, we can not rule out the gradual change in the mechanism within respective series due to incursion of the S_N2-type solvent participation. This effect is observed in the case of substituted benzyl tosylates, for which our treatment fails.[5,6] The solvolysis of α-methylbenzyl chlorides is also a borderline case. The nucleophilic solvent participation might play an important role in the reaction of derivatives carrying stronger electron attracting substituents. The monotonic change in mechanism from limiting S_N1 to non-limiting solvolysis can be expected as the substituent becomes more electron attracting. If this is the case, the σ^+ plot might be monotonically concave upwards and subsequently a lower ρ value given by slow solvolyzing substituents may afford a higher r-value. For such a case, the LArSR equation provides a less precise correlation or none at all as an extreme case.[5,6] Evidently this is not the present case.

From the α-deuterium kinetic isotope effect on the solvolysis of substituted α-methylbenzyl chlorides, Shiner *et al.* suggested that derivatives faster solvolyzing than the unsubstituted were solvolyzed by the limiting mechanism but the reaction of *m*-bromo derivative which had a lower isotope effect should involve the S_N2 character to a certain extent.[15] In contrast, there is no consistent trend in LArSR correlation which might point to mechanistic change related to the substituent change. An excellent quality of the correlation leads to the conclusion that no serious change in mechanism is involved in the present solvolysis in this medium, at least down to *m*-halogen substituted derivatives. The constant isotope effect for faster reacting derivatives suggests that the deviation of *p*-methoxy derivative observed in Fig. 4 is not due to change in mechanism. The lower isotope effect value for *m*-bromo derivative of course does not indicate complete loss of the S_N1 character. Even though the incursion of S_N2 mechanism may be the case, we believe that the influence of concurrent S_N2 to the solvolysis rate is negligible in this group and throughout a series of substituents we examined. Determination of the reactivity should be extended further to the derivatives substituted by more strongly electron attracting groups than *m*-halogen.

Since the S_N2 process or the nucleophilic solvent participation depends on both the nucleophilicity and the ionizing power of the solvent, the effect of solvent changes on the correlation should provide important evidence for the above consideration. However, no noticeable effect was observed by changing solvents from 90% to 50% aqueous acetone, in the correlation of the substituent effects within the same range of substituents.[29] The data of Mechelynch-David and Fierens in less nucleophilic aqueous dioxane–formic acid[10] give a linear free energy correlation with the present data. The acetolysis rates also can be correlated by Eq. (1), giving an r higher than unity.[30] Thus, the high r value is characteristic of the transition state of this reaction. This is further supported by the fact that pyrolysis rates of α-methylbenzyl chlorides are correlated linearly to the present data. No irregularity was observed even in the behavior of strongly electron-attracting *p*-cyano derivative.[31] A strictly linear correlation by Eq. (1) may be taken as a criterion for the operation of a unique mechanism throughout the series of substituted members included.

Experimental

Acetophenones were obtained by the usual Friedel-Crafts acetylation of appropriate substituted benzenes. *m*-Bromoacetophenone was obtained by the bromination of acetophenone in the presence of anhydrous aluminum chloride. *m*-Methoxyacetophenone (bp 135—137 °C/20 mmHg) was obtained by treating *m*-hydroxyacetophenone with dimethyl sulfate in an alkaline solution. *m*-Methylthioacetophenone (bp 127—128 °C/2 mmHg) was prepared by converting *m*-aminoacetophenone with potassium ethylxanthate into the thiophenol, and treating with dimethyl sulfate.

α-Methylbenzyl Alcohols. Acetophenones were reduced with lithium aluminum hydride to the corresponding α-

a) Boiling point °C (uncorrected) under a given pressure, mmHg. Mp's are given in brackets. b) Used without purification.

arylethyl alcohols in 80—90% yields by the usual procedure. *m*-Methyl, *m*-phenyl, *m*-fluoro, and *m*-chloro-α-methylbenzyl alcohols were prepared by the Grignard reaction of the corresponding bromobenzenes with acetaldehyde in about 60% yields. They were purified before being converted into chlorides by distillation under reduced pressure or recrystallization from petroleum benzine. The physical constants of alcohols are summarized in Table 5.

α-Methylbenzyl Chlorides. Most *m*- and *p*-substituted α-methylbenzyl chlorides, α-(2-fluorenyl)ethyl chloride and α-(2-naphthyl)ethyl chloride were prepared by the following method. The alcohol in ether containing anhydrous calcium chloride was treated under cooling in an ice-bath with a stream of dry hydrogen chloride, through a concd. sulfuric acid trap, and the resulting solution was decanted and treated with hydrogen chloride in the presence of fresh anhydrous calcium chloride for *ca.* 3 h. The ether was removed under reduced pressure and the residue was purified by fractionation through a column or recrystallized from appropriate solvents. *p*-Methoxy and *p*-phenoxy-α-methylbenzyl chlorides were used without further purification for kinetic measurements immediately after evaporation of ether as completely as possible, since they were quite unstable. Unsubstituted and *m*- and *p*-halo-substituted and *m*-methoxy, *m*-phenyl and *m*-methylthio-α-methylbenzyl chlorides were obtained by the following procedure. Benzene solution of α-methylbenzyl alcohol (1 equivalent) was dropwise added with stirring into a benzene solution of thionyl chloride (2 equivalent). The mixture was kept overnight, and evaporated under reduced pressure. The residue was purified by distillation under nitrogen *in vacuo* (yield, 70—80%). Physical constants of the chlorides are summarized in Table 5. Chlorides were prepared in small portions each time before use. Some stable chlorides were stored in a refrigerator in sealed ampoules and were repurified before use.

Solvent. 80% aqueous acetone was prepared by mixing 8 volumes of purified acetone and 2 volumes of distilled water. Different batches of solvent were standardized each time by adding a small amount of water or acetone to give an identical solvolysis rate for the reference sample.

Kinetic Measurement. The procedure of the rate determination is essentially the same as that described by Brown and Okamoto.[1] The reaction temperature was controlled within ±0.01 °C in the range 15—18 °C, and ±0.02 °C or less at temperature outside of this range; very low temperature was estimated to be less accurate than ±0.1 °C. The rate studies were carried out by using freshly prepared or repurified samples before each run. Measurements at temperatures 10—30 °C were carried out in a long-necked flask with a ground joint stopper. A weighed amount of chloride was quickly dissolved in a small amount of the solvent and made up to the volume corresponding to 0.02 M with the solvent preheated to the reaction temperature in a volumetric flask, shaken vigorously and transferred to a reaction flask immersed in a thermostated bath. At appropriate time intervals, 10 ml aliquots were quenched by pouring into ice-cold acetone (50 ml) and the hydrochloric acid liberated was titrated with aqueous sodium hydroxide solution (*ca.* 0.03 M). Bromocresol purple was used as an indicator. The initial concentration was obtained from the infinity reading determined after 10 half-lives of the reaction. Measurements above 30 °C for slow reacting chlorides were carried out in sealed ampoules. Ten ml aliquot was used for each determination. Two of the sealed ampoules were allowed to

react for at least 10 half-lives, or for the corresponding period at higher temperature, in order to get the infinity reading. Reactions were followed to 75% completion or more, during which period generally more than ten determinations were made. The reaction followed first order kinetics in all cases for two half-lives and in optimum case for up to three half-lives, except the reaction of *p*-methyl derivative, in which a certain drop took place in the first order reaction rate with time. Lewis *et al.* reported a similar phenomenon but gave no clear reason.[11] The experimental errors in respective runs were generally less than 1.0% and correlation coefficients were better than 0.999. Rate constants from repeated runs were reproducible within an accuracy 1.5%. During the course of studies for several years, determinations were made repeatedly by different workers using different samples of the halide in different batches of the solvent. Nevertheless, the repeated runs gave mostly identical rate constants within the limit of our estimated accuracy. The rate constant 3.10×10^{-4} for *p*-methyl (obtained by Y. K. who carried out most measurements) was in agreement with average 3.18×10^{-4} of nine repeated runs by the others.

For the measurements below 10 °C for faster reacting chlorides aliquots were quenched with a large amount of dry ice cold acetone and titrated with aqueous ethanolic sodium hydroxide solution (*ca.* 0.03 M). Titration in a very cold (*ca.* −50 °C) less aqueous solution suffered from the slow response of indicator and the end point could hardly be determined. Rapid titration at an allowable high temperature and the use of a mixed indicator, bromocresol green—methyl red (3: 2), were more favorable. The rate constants for the most reactive *p*-methoxy derivative at low temperatures were less accurate. Respective runs gave good first order rate plots of the order of correlation coefficient not less than 0.99. The rate constants from 7 repeated runs at −30 °C agreed within a range of ±4%. The rate constant extrapolated to 45 °C is estimated for this derivative to be of ±10% uncertainty.

The Substituent Effect. X. Solvolysis of 3- and 4-Substituted 1-(1-Naphthylethyl) Chlorides

Yuho Tsuno,* Masami Sawada, Takahiro Fujii, and Yasuhide Yukawa
The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka 565
(Received December 18, 1974)

The rates of the solvolysis of eleven 3- and 4-substituted 1-(1-naphthylethyl) chlorides were determined in 80% (v/v) aqueous acetone solution at 45 °C. The effect of substituents in 3- and 4-positions of the naphthalene can be correlated with the LArSR relationship ($\log k/k_0)_{3\alpha,4\alpha} = -5.12\,(\sigma^0 + 1.04\,\Delta\bar{\sigma}_R^+) - 0.12$ (correlation coefficient, 0.999; standard deviation, ± 0.12). The ρ value in the naphthalene is slightly larger and the r value is slightly smaller than values in the corresponding benzene system under the same condition ($\rho = -4.95$, $r = 1.15$). The difference is reasonably interpreted in terms of the steric effect for the *peri*-hydrogen relative to the reaction center at the α-position of the naphthalene. The effect of substituents can be correlated with the LSFE relationship for conjugatively electron releasing groups with high precision ($R > 0.999$) in the series, 3α and 4α; ($\log k/k_0 = \rho_i\sigma_i + \rho_\pi{}^+\sigma_\pi{}^+$). In this solvolysis, the $3\alpha/4\alpha$ inductive ratio, $\rho_{i,3\alpha}/\rho_{i,4\alpha}$, was 1.37, only slightly larger than the *meta*/*para* inductive ratio of 1.17 for the corresponding reaction in the benzene series. The applicability of these equations to 3- and 4-substituted α-naphthyl system is also shown for some other reactivities.

In our studies of the substituent effect on chemical reactivities, we established that the following Linear Aromatic Substituent Reactivity (LArSR) relationship[1-3] is, in general, applicable to electrophilic and nucleophilic reactions of *meta*- and *para*-substituted benzene derivatives:

$$\log k/k_0 = \rho(\sigma^0 + r^+\Delta\bar{\sigma}_R{}^+ + r^-\Delta\bar{\sigma}_R{}^-) \quad (1)$$

This holds on the assumption of additive description of the substituent effect in terms of the unexalted polar effect of substituted phenyl groups and the aryl resonance exaltation effect.

It has been generally assumed that the electronic effect of substituents consists, to a first approximation, of inductive and π-electronic effects.[4-7] We have shown that the substituent effect on benzene reactivities can be successfully correlated with the Linear Substituent Free Energy (LSFE) relationship[3a-3d,8] based on the σ_i—$\sigma_\pi^\pm$ combination in place of the σ^0—$\Delta\bar{\sigma}_R^\pm$ combination in Eq. (1):

$$\log k/k_0 = \rho(C_i\sigma_i + q_r{}^+\sigma_\pi{}^+ + q_r{}^-\sigma_\pi{}^-) \quad (2)$$

The first term, $C_i\sigma_i$, represents the contribution of inductive effect and the last two, $q_r{}^+\sigma_\pi{}^+$ and $q_r{}^-\sigma_\pi{}^-$, the contributions of π-electronic effects for conjugatively electron releasing ($-R$) and attracting ($+R$) substituents, respectively. σ_i is the inductive substituent constant characteristic of given substituents and independent of the resonance requirement of their reactions. $\sigma_\pi{}^+$ or $\sigma_\pi{}^-$ is the π-electronic substituent constant characteristic of a given substituent describing the capability to donate or attract electron through π-electron delocalization. Both C_i and $q_r{}^+$ ($q_r{}^-$) are characteristic variables giving a measure of the inductive and π-electronic interactions with the reaction center, respectively.

From a statistical analysis of substituted benzene reactivities by means of Eq. (2), we arrived at two significant conclusions.[3a-3d,8] (i) The transmission coefficient of the inductive effect, C_i, depends only on the position of substituents and remains constant independent of reactions in the benzene system, that is, C_i is 1.00 for the *para* and 1.17 for the *meta* position. (ii) The contribution of the π-electronic effect, $q_r{}^+$ or $q_r{}^-$, effectively varies only for substituents that may conjugate with the reaction center and is a function of given reactions. Both $q_r{}^+$ and $q_r{}^-$ are standardized to be unity in $\sigma_p{}^0$ scale and $q_r{}^\pm$ is 0.50 in *meta* position. These are summarized in the following generalized forms.

$$\log (k/k_0)_p = \rho(1.00\sigma_i + q_r{}^+\sigma_\pi{}^+ + q_r{}^-\sigma_\pi{}^-)$$
$$\log (k/k_0)_m = \rho(1.17\sigma_i + 0.50\sigma_\pi{}^\pm) \quad (3)$$

In naphthalene derivatives, there are ten positional combinations between substituents and reaction centers, excluding *ortho* and *peri* combinations. It is expected that contributions of both the inductive and the π-electronic effects may differ from each other, depending upon the relative position of substituents in any single reaction. Since the substituent constants, σ_i and $\sigma_\pi{}^\pm$, are believed to be characteristic of substituents independent of the parent hydrocarbon, the application of Eq. (2) to the substituent effect on the naphthalene system offers important information on the positional transmittance of the inductive and π-electronic effects in naphthalene reactivities.

Very few substituent effect data have been reported on naphthalene, as compared with those on benzene reactivities. Three electrophilic reactions have been reported in which the effects of a wide range of substituents at almost all of the positions in the naphthalene system are systematically investigated: (1) dissociation of naphthoic acids in 50% aq. EtOH,[6,9] (2) alkaline hydrolysis of naphthoic acid esters in aq. organic solvents,[10,11] (3) detritiation of tritionaphthalenes in CF_3COOH.[12,13] The first two reactions are representative σ-type reactivities in the benzene system, having no large contribution of the π-electronic effect. Since an acidic solvent was utilized in the last reaction, there were some problems, *e.g.*, the methoxy substituent was evidently modified by direct solvent-substituent interaction; only methyl and halogens could be treated as ordinary substituents. In order to get more information on the substituent effect for naphthalene reactivities in which electron requirement of the reaction center a great

* To whom inquiries should be addressed. Present address; Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka 812

deal differs from the first two, we choose the solvolysis of substituted 1-(1-naphthylethyl) chlorides in an ordinary aqueous organic solvent. This reaction is representative of carbonium-ion type reactions and gives comparatively large π-electronic effects of $-R$ substituents at the conjugative positions in the naphthalene.

The present paper is mainly concerned with the treatment based on Eqs. (1) and (2) on the substituent effect of the solvolysis of 3- and 4-substituted 1-(1-naphthylethyl) chlorides in 80% aqueous acetone at 45 °C. These effects can be directly compared with those of *meta*- and *para*-substituted 1-phenylethyl chlorides which have been studied extensively under the same conditions.[3e]

Experimental

Materials. *3- and 4-Substituted 1-Acetylnaphthalenes*: Commercial 1-acetylnaphthalene was purified by recrystallization of the picrate (mp 119—120 °C),[14] followed by fractional distillation of the regenerated ketone. No impurities were detected by vpc. 4-Methyl-, 4-chloro-, 4-bromo-, and 4-methoxy-1-acetylnaphthalenes were prepared by the Friedel-Crafts acetylation of the corresponding 1-substituted naphthalenes and fractionated or recrystallized.[15-17] 1-Acetyl-4-cyanonaphthalene was synthesized from 1-acetyl-4-bromonaphthalene by the method of Friedmann and Shechter[18] (45% yield), using CuCN in DMF.

1-Acetyl-4-ethylnaphthalene: 1-Ethylnaphthalene was obtained by the Wolff-Kishner reduction[19] of 1-acetylnaphthalene in 84% yield. Friedel-Crafts acetylation of 1-ethylnaphthalene (32 g) with AcCl (19 g) and $AlCl_3$ (33 g) in CS_2 gave 1-acetyl-4-ethylnaphthalene in 63% yield; bp 159—159.5 °C/2.5 mmHg.[20]

1-Acetyl-3-chloronaphthalene: 1-Bromo-3-chloronaphthalene was prepared according to the prescription of Fischer *et al.*[21] Chlorination of *N*-acetyl-4-bromo-1-naphthylamine (mp 195—196 °C from MeOH or 95% aq. EtOH)[21,22] gave *N*-acetyl-4-bromo-2-chloro-1-naphthylamine; mp 233—233.5 °C from MeOH or 95% EtOH.[21] 1-Bromo-3-chloronaphthalene distilled at 141—145 °C/5 mmHg,[21,23] solidified on being left to stand (mp 45—50 °C), was obtained by deamination of crude 4-bromo-2-chloro-1-naphthylamine (mp 108—110 °C)[21] prepared by hydrolysis of the above naphthalide in EtOH–aq. H_2SO_4 solution.

A mixture of the bromochloronaphthalene and CuCN in DMF solution was refluxed for 4 hr.[18] The crude 3-chloro-1-naphthonitrile obtained (mp 88—94 °C) was hydrolyzed in AcOH–aq. H_2SO_4 solution. The resulting 3-chloro-1-naphthoic acid was purified by recrystallization from aq. EtOH and aq. AcOH; mp 229—232 °C.[21]

The acid was successfully converted into the 1-acetyl-3-chloronaphthalene by application of Browman's procedure[24] in 75% yield; *via* 3-chloro-1-naphthoyl chloride (mp 77—83 °C from hexane). The fractionated product was recrystallized from hexane.

1-Acetyl-3-bromonaphthalene: 3-Bromo-1-naphthoic acid (mp 234—237 °C from EtOH)[25] was prepared by a similar synthetic route by Dewar and Grisdale;[25] mercuration[26,27] of 3-bromonaphthalic acid anhydride (mp 243.5—244.5 °C)[25,28] and subsequent decomposition of the mercurated product.[26] The acid was converted into 3-bromo-1-naphthoyl chloride and subsequently to 1-acetyl-3-bromonaphthalene by the method described for the 3-chloro derivative.

1-Acetyl-3-cyanonaphthalene: This ketone (7 g) was obtained from 1-acetyl-3-bromonaphthalene (10 g) and purified by recrystallization from benzene–hexane.

1-Acetyl-3-methoxynaphthalene: 4-Bromo-2-naphthylamine (mp 71 °C)[29,30] was obtained, according to the prescription of Bergman,[29] from 1-bromo-3-nitronaphthalene (mp 128—130 °C)[29] derived from the deamination of the diazonium solution of 4-bromo-2-nitro-1-naphthylamine (mp 198—201 °C).[29] The 4-bromo-2-naphthylamine obtained was converted into 4-bromo-2-naphthol (bp 130—132 °C/1.5 mmHg, mp 117—120 °C)[31] by the usual diazonium method; the diazonium sulfate was decomposed by the dropwise addition to *ca.* 40% aq. H_2SO_4 solution at about 80 °C. Methylation of the 2-naphthol with Me_2SO_4 in an alkaline solution gave 1-bromo-3-methoxynaphthalene (mp 112—114 °C).

Reaction of the bromide and CuCN in DMF and working up by Friedmann's procedure[18] gave crude 3-methoxy-1-naphthonitrile (mp 102—104 °C). Direct hydrolysis of the

nitrile in AcOH–aq. H_2SO_4 gave 3-methoxy-1-naphthoic acid. This material was purified by recrystallization from MeOH; mp 220—223 °C. 1-Acetyl-3-methoxynaphthalene was prepared by the same method as described before.

3- and 4-Substituted 1-(1-Naphthylethanols). Alcohols were prepared by the $LiAlH_4$ reduction of the corresponding ketones in the ethereal solution,[3e,32] unless otherwise stated. The mixture was gently refluxed for about 1 hr and allowed to stand overnight at room temperature, and treated in the usual manner. The crude alcohols were purified by fractionation or recrystallization from appropriate solvents.

$NaBH_4$ in MeOH[33] was utilized for the reduction of bromo-, chloro-, and cyano-ketones. Gentle refluxing of the reaction mixture was continued until the ketone was consumed, which was confirmed by the disappearance of the 2,4-dinitrophenylhydrazone of the corresponding ketone. The methanol solution was decomposed by dil. HCl, neutralized, concentrated, and extracted with benzene.

The physical properties and the elemental analytical data for ketones and alcohols are listed in Tables 1 and 2, respectively.

3- and 4-Substituted 1-(1-Naphthylethyl) Chlorides. All the chlorides except for 3-chloro, and 3- and 4-cyano derivatives were obtained by passing a stream of dry HCl gas into the ethereal solution of purified alcohols at room temperature in the presence of $CaCl_2$.[3-,34] After prompt filtration, the ether was evaporated under reduced pressure. The crude product, dissolved in petroleum ether, was treated with excess K_2CO_3, filtered and evaporated. The same treatment was repeated twice. After final evaporation, the chloride was purified by fractionation or recrystallization from appropriate solvents (*e.g.*, petroleum ether). In the case of methoxy derivatives, the chlorinated products were directly employed for the rate measurements without further purification.

For 3- and 4-cyano- and 3-chloro-1-(1-naphthylethanols), chlorination with excess $SOCl_2$ in benzene was utilized. The solution was gently refluxed until the peaks of O–H vibration in IR spectra disappeared, and refluxing was further continued for 1 hr. Excess $SOCl_2$ was removed by azeotropic distillation, dry benzene being added twice. The chlorides obtained were purified by recrystallization from benzene–hexane or fractionation (Table 3).

Solvent. Acetone which had been refluxed with $KMnO_4$ for over 6 hr was distilled, dried over K_2CO_3 for several days. and fractionated. The stock solutions of 80% and 95% aqueous acetone were prepared by mixing the nominal volumes of acetone and freshly-boiled deionized water, both components being measured at 25 °C.

Kinetic Measurements. The rates of the solvolysis of 3- and 4-substituted chlorides were determined in 80% (v/v) or 95% (v/v) aqueous acetone solutions at appropriate temperatures by means of the usual titration method. The procedure employed for these measurements was essentially the same as that given in the literature.[3e,34] The bath temperature was controlled to ±0.02 °C. For reactions studied at below 0 °C, the runs were carried out in a thermo-

a) 4-Br-α derivative, bp 137—139 °C/1 mmHg; mp 58—60 °C. b) Lit, bp 128—129 °C/4 mmHg,[34] bp 125—126 °C/2 mmHg; Y. Okamoto and H. C. Brown, *J. Amer. Chem. Soc.*, **76**, 1903 (1957). *) All boiling and melting points were uncorrected.

stated bath maintained at ±0.05 °C or better with cooling by an external bath containing a dry ice–acetone solution.

All the runs at 45 °C and above were carried out at the initial concentration of the chloride, *ca.* 0.02 mol/l in aqueous acetone, in sealed tubes. After the ampoules (more than 10) had been brought to bath temperature, each ampoule was withdrawn at appropriate intervals and quickly immersed into an ice–water bath with vigorous shaking to stop the reaction. A 10 ml aliquot was pipetted, poured into *ca.* 50 ml ice-cooled distilled acetone, and titrated with standardized NaOH aqueous solution. Bromocresol purple or bromothymol blue was employed as an indicator. The two ampoules were allowed to react for at least 10 half-lives in a water bath at *ca.* 90 °C in order to get the infinity reading.

Kinetic runs below 45 °C were conducted in a stoppered Erlenmeyer flask. Ten ml sample solutions were pipetted out, at appropriate intervals, quenched with ice-cooled acetone (*ca.* 50 ml) except for 4-MeO-α derivative, and titrated immediately. For the 4-MeO-α one, about 100 ml acetone which had been cooled about −60 °C with dry ice–acetone was used to stop the reaction.

All the runs involving more than 10 measurements were covered up to 70—85% reaction. In the case of 4-CN-α derivative, calculated values of infinity titers were employed and runs were covered up to *ca.* 50% reaction. Rate constants were determined from the integrated form of the first-order rate equation by means of least squares calculation. The experimental uncertainty of a run was estimated to be less than ±1% and the rate constants from duplicated runs agreed within ±2%.

Results and Discussion

The rate constants of the solvolysis of 3- and 4-substituted 1-(1-naphthylethyl) chlorides (denoted by 3α and 4α, respectively) in 80% (v/v) aq. acetone at various temperatures are listed in Table 4. The solvolysis of 4-MeO-α derivative was too fast to follow by our method in 80% aq. acetone even at −35 °C, and an extrapolation from the rates in 95% (v/v) aq. acetone solution was employed. The reaction was retarded about 100-fold in the latter solvent, and could then be followed by titration in the temperature range from −10 °C to −30 °C. The rates of four derivatives, 4-Me-α, 5-MeO-α, 6-MeO-β, and 6-MeS-β derivatives in both 80% and 95% aq. acetone (Table 5) are correlated by

$$\log k_{80\%} = 0.847 \log k_{95\%} + 1.462 \quad (4)$$

with a correlation coefficient of 0.9991 and a standard deviation of ±0.031 (Fig. 1). From Eq. (4), the rate constant of the 4-MeO-α derivative in 80% aq. acetone can be estimated to be 1.22 s^{-1} at 45 °C. The extrapolation is supported by the substituent effect for substituted 1-phenylethyl chlorides;[3f] the solvent change from 80% to 90% aq. acetone mainly brings about a change in the ρ value but not in the *r* value of the LArSR Eq. (1). The relative rates in 80% aq. acetone at 45 °C, together with the activation parameters, are summarized in Table 5.

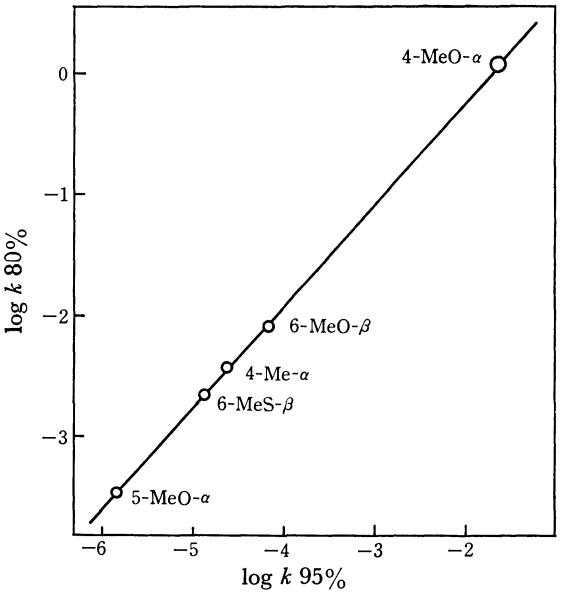

Fig. 1. Logarithmic plot of the present solvolysis rates between 80% and 95% aq. acetone at 45°C.

Comparison between Naphthalene and Benzene Systems. In 3- and 4-substituted 1-(1-naphthylethyl) chlorides, the reaction center and substituent groups are in the same relative positions as in *m*- and *p*- substituted 1-phenylethyl chlorides, respectively. Figure 2 shows the logarithmic plot of relative rates between the naphthalene and the benzene systems under the same conditions; in 80% aq. acetone at 45 °C. The correlation line suggests that the degree of the π-electronic effect of substituents is slightly less effective in the naphthalene system than in the corresponding benzene one.

a) Values of the present solvolysis of substituted 1-(1-naphthylethyl) chlorides. b) Values of the solvolysis of the corresponding *meta*- and *para*- substituted 1-phenylethyl chlorides in 80% (v/v) aq. acetone at 45 °C; data taken from Ref. 3e. c) Rate constants in 95% (v/v) aq. acetone at 45 °C are listed in parenthesis. d) Ref. 38. * Values were obtained by extrapolation from rates at other temperatures. ** See text.

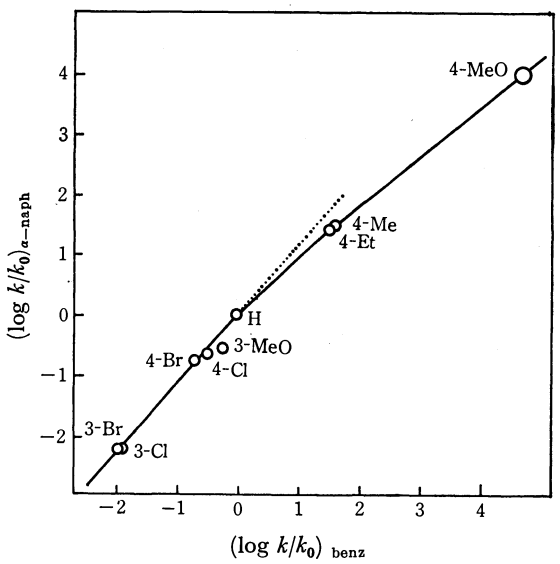

Fig. 2. Log-log plot of the solvolysis rates between α-naphthyl and benzene systems in 80% aq. acetone at 45 °C.

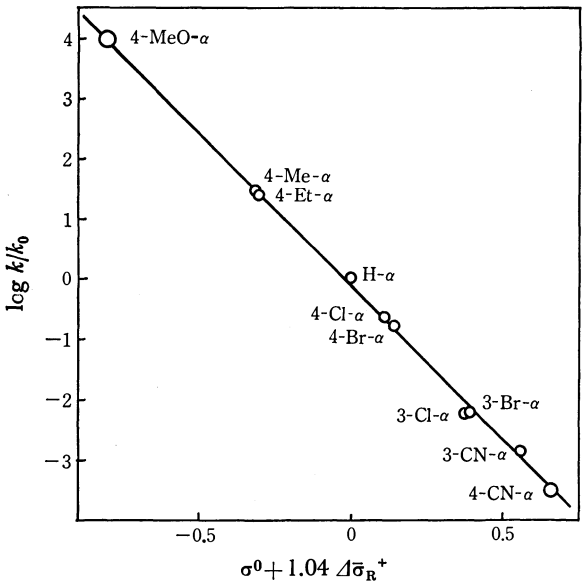

Fig. 3. LArSR plot for the solvolysis of 3- and 4-X-α-naphthylmethylcarbinyl chlorides in 80% aq. acetone at 45 °C.

Equation (1) is applied to the solvolysis rates in the naphthalene derivatives using the σ^0 parameters derived from benzene reactivities to give a correlation

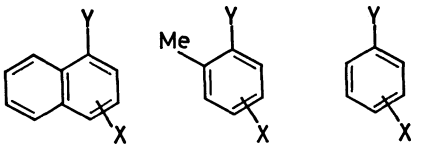
$$\log(k/k_0)_{3\alpha,4\alpha} = -5.12(\sigma^0+1.04\Delta\bar{\sigma}_R^+)-0.12$$

with a correlation coefficient of 0.9990 and a standard deviation of ±0.116 (n=10) (Fig. 3). The corresponding solvolysis rates in the benzene system under the same conditions satisfy Eq. (1) with high precision (R=0.9997).[3e,35]

$$\log(k/k_0)_{m,p} = -4.95(\sigma^0+1.15\Delta\bar{\sigma}_R^+)-0.023$$

The ρ value in the present naphthalene system is slightly larger but the r value is slightly smaller than that in the benzene system. The difference in the r value of the two systems results in the curvature in Fig. 2.

Even if the inductive effect of the substituents may be transmitted through space or carbon-carbon bond or both, it is reasonably assumed from the geometrical similarity that the contributions of the inductive effect from 3α and 4α positions are approximately equal to those from *meta* and *para* positions, respectively. If there are any differences, they would be the slight differences in bond length and/or bond order between the parent naphthalene and the benzene.



(I) (II) (III)

Chart 1

One model in which the steric requirement at the reaction center is analogous to the α-naphthyl derivative (I) is the benzene derivative with a methyl group *ortho* to the reaction site (II). In the dissociation of benzoic acids in 50% aq. EtOH, the ρ value is 1.77 with (II),[36a] and 1.51 without an *ortho* methyl group (III).[36b] In the substituent chemical shifts of the hydroxyl proton of substituted phenols in DMSO, ρ is 1.60 in (II)[3b] and 1.53 in (III),[3a] both values having high precision. The results indicate that, when a group is introduced into the proximity of the reaction site, the ρ value is not necessarily identical with that in the simple benzene system, possibly because of the difference in the solvation around the reaction center. In the analysis of the substituent effect on naphthalene reactivities, it was assumed that the ρ value in the α-naphthyl system (I) is identical with that in the benzene system (III).[6,9,10b] However, we consider that the assumption may not always be the case.

The *r* value for naphthalene solvolysis, 1.04, is smaller than 1.15 for the corresponding benzene solvolysis. In α-naphthyl derivatives, the *peri*-hydrogen prevents maximum overlap of the vacant orbital of the reaction site developed in the transition state with the ring π-orbitals. The *peri*-hydrogen steric effect causes a decrease in the bond order between the reacting carbon and the ring α-carbon. In the absence of the steric effect, it is suggested by the MO reactivity indices that the π-electronic effect in the conjugated 4α position in the naphthalene is more effective than in the *para* position in the benzene system.[6,12,13,37] Thus we may reasonably conclude that the increased contribution of the π-electronic effect in the 4α position is over-compensated by the decreased bond order due to the effective *peri*-hydrogen steric effect, resulting in a smaller *r* value in the present solvolysis.

The same type of approach is applicable to the data of alkaline hydrolysis of ethyl 3- and 4-substituted 1-naphthoates in 85% aq. EtOH at 50 °C.[10] Figure 4 shows the log-log plot of the relative rates between the naphthalene and the corresponding benzene systems. An excellent linear free energy correlation is obtained for all the substituents except 4-NO_2 and 4-NMe_2. The deviations are reasonably interpreted in terms of the non-coplanarity of these substituents with the ring due to the *peri*-hydrogen steric effect.[3b] The application of Eq. (1) to the hydrolysis of ethyl 1-naphthoates, except for the above two substituents, leads to an excellent linear correlation. The standard deviation from the regression line is ±0.03 and the correlation coefficient, 0.999(n= 10).

$$\log (k/k_0)_{3\alpha,4\alpha} = 2.19(\sigma^0+0.27\Delta\bar{\sigma}_R^+) + 0.02$$

On the other hand, the hydrolysis of ethyl benzoates (85% aq. EtOH, 25 °C)[38,39] is correlated by

$$\log (k/k_0)_{m,p} = 2.54(\sigma^0+0.27\Delta\bar{\sigma}_R^+) + 0.04$$
$$(R=0.997,\ s=\pm 0.08)$$

Nearly the same *r* value for both the naphthalene and benzene systems is evident.

In this hydrolysis, the increased contribution of the π-electronic effect in the 4α in the naphthalene is perhaps compensated by the decreased bond order between the ring α-carbon and the ethoxycarbonyl carbon, and consequently the overall contribution of the π-electronic effect becomes close to that in the *para* in the benzene system.

The present solvolysis is a typical carbonium-ion reaction and is known to show an exalted contribution of resonance (π-electronic) effect from the substituents at the conjugated position, whereas the ester hydrolysis is a typical σ-fit reaction having a small contribution of π-electronic effect. Thus it appears from the results in both reactions that the substituent effect on 3- and 4-substituted naphthalene α-reactivities can be treated successfully by means of Eq. (1) in the same way as on *m*-

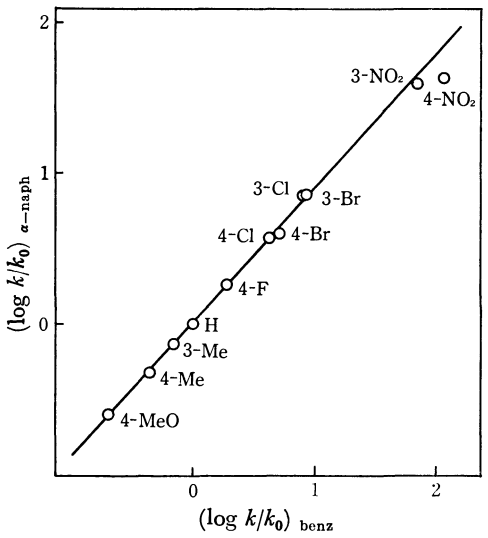


Fig. 4. Log-log plot of the alkaline hydrolysis rates between ethyl α-naphthoates (50 °C) and ethyl benzoates (25 °C).

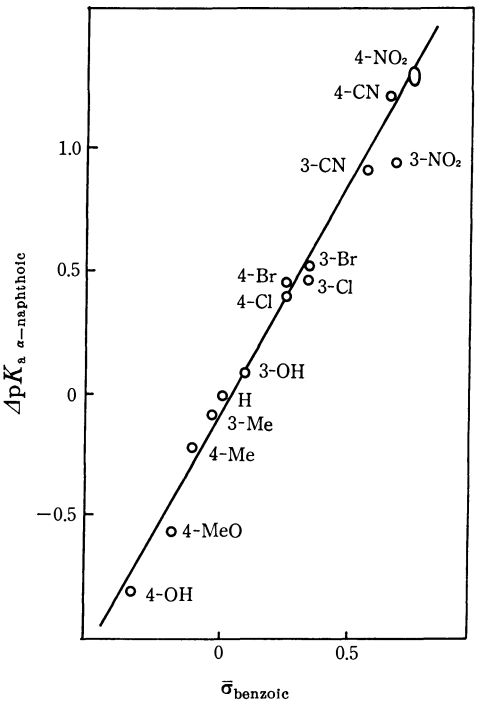

Fig. 5. The plot of ΔpK_a of α-naphthoic acids *vs.* the apparent $\bar{\sigma}$ values from ΔpK_a of benzoic acids in 50% aq. EtOH.

and *p*-substituted benzene reactivities, at least as far as electrophilic reactions are concerned.[40] Figure 5 shows the plot of ΔpK_a values of substituted 1-naphthoic acids in 50% aq. EtOH[6,9] against the apparent $\bar{\sigma}$ values calculated from the dissociation of benzoic acids in the same solvent.[36] In this case, however, considerable scattering is observed in the correlation.

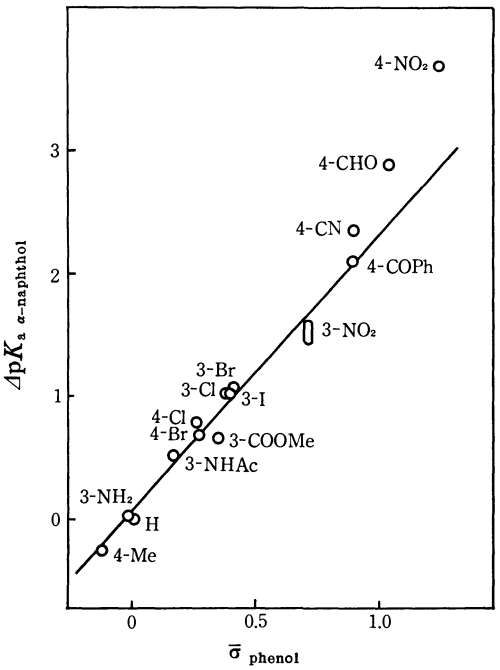

Fig. 6. Relation between ΔpK_a in α-naphthols and the apparent $\bar{\sigma}$ derived from ΔpK_a in phenols in H_2O.

The above argument may be consistent with the results of the application of Eq. (1) to nucleophilic reactivities of α-naphthyl system. An example is found in the substituent effect for dissociation of 3- and 4-substituted 1-naphthols in water at 25 °C.[41] Figure 6 shows the correlation of ΔpK_a in the 1-naphthols with the apparent $\bar{\sigma}$ derived from ΔpK_a in *m*- and *p*-substituted phenols in water. NO_2, CHO, and COC_6H_5 substituents in the 4-position may be forced out of coplanarity with the parent naphthalene ring by *peri*-hydrogen steric effect. Nevertheless the correlation line appears to be curved upward. The vertical deviations for these $+R$ substituents in 4-position from the line determined by 3α substituents and $-R$ 4α ones suggest a larger contribution of electron attracting π-electronic effect in the naphthols than that in the phenols. These findings of the direction of the change of *r* in both the naphthalene and the benzene systems are the same as the prediction based on the simple MO theory, presumably because of the less effective *peri*-hydrogen steric effect around the reaction site in this dissociation.

Application of LSFE Eq. (2) to α-Naphthyl Reactivities. According to Eq. (3), the contribution of inductive effect from substituents in *meta* position is transmitted 1.17 times more effectively to a reaction center than in *para* position. In the case of naphthalenes, the extent of the inductive contribution is also expected reasonably to depend upon the relative position of substituents to a reaction center, such as 4α, 5α, 6α, and so on. When substituents are attached to another ring of the naphthalene, *i.e.*, 5, 6, and 7-positions, the actual substituent effects may, in general, not be described successfully by any single set of substituent constants derived from the benzene system. The π-electronic contributions relative to inductive contributions from substituents at any positions of naphthalene system may differ from the relative π-electronic contributions in the benzene system.

In the pioneering studies of the substituent effect for dissociation of 1-naphthoic acids, Dewar and Grisdale proposed the *FM* equation[6]

$$\sigma_{ij} = 1/r_{ij}F + q_{ij}M$$

They considered simply that the field effect which corresponds to inductive effect in our sense was assumed to be transmitted with reciprocal of the simple distance between the ring carbons at which both substituents and COOH group were attached. Later, similar or revised treatments were employed by several authors in order to interpret other electrophilic reactivities in the naphthalene system.[42–46] However, these treatments are heavily based on the assumption of the transmission coefficients ($1/r_{ij}$ and q_{ij}) in the parent naphthalene ring.

On the other hand, Taft *et al.* adopted an alternative approach,[47] not based on any presumption of the transmission coefficients. They utilized the substituent parameters, σ_I and σ_R^0, derived from the benzene system, and analysed the substituent effect in the naphthalene system empirically; the transmission coefficients were determined by

$$\log k/k_0 = \rho_I\sigma_I + \rho_R\sigma_R^0 \qquad (5)$$

By means of statistical analysis, they examined the relative abilities of transmissions of both the inductive effect (ratio of ρ_I) and π-electronic effect (ratio of ρ_R) for a series of relative substituent positions. However, this treatment based on the substituent constant pair, σ_I and σ_R^0, must not be applied to general electrophilic reactivities such as the present solvolysis.

We have attempted a similar statistical approach by means of Eq. (2), where unique substituent constants, σ_i and $\sigma_\pi^\pm$, were employed instead of σ_I and σ_R^0. It would be expected that the relative transmission coefficients of inductive effect, C_i, can be derived from a given reaction. The expectation had been justified by the statistical analysis for both electrophilic and nucleophilic reactivities in the benzene system; C_i for *meta* relative to C_i for *para* is 1.17.

Conjugatively electron releasing ($-R$) substituents and conjugatively electron attracting ($+R$) substituents should be treated independently by Eq. (2)[1–3,8]; q_r^+ and q_r^- are substantially independent in any single reaction except for a σ^0-type reaction. Then, the present solvolysis rates for only $-R$ substituents were analysed by the least squares application of the equation

$$\log k/k_0 = \rho_i\sigma_i + \rho_\pi{}^+\sigma_\pi{}^+ \qquad (6)$$

The obtained statistical values are listed in Table 6, together with the results for other electrophilic reactivities available in 3α and 4α series. The substituent parameters utilized in this analysis are listed in Table 7.

It is evident from the results that all of the four reactivities are successfully described by Eq. (6) with high

Table 6. Statistical analysis of α-naphthyl reactivities for $-R$ substituents

a) Parameters taken from Ref. 8.

precision (R>0.99). The reliability of both ρ_i and $\rho_\pi{}^+$ values obtained in this approach is strongly dependent upon both the number of the substituents involved in the calculation and a wide variety of the electronic nature of the substituents. Although the numbers of substituents involved here are not sufficient in respective series of reactivities given in Table 6, typical $-R$ substituents such as alkoxy, alkyl, halogen, and hydrogen, are involved in the present solvolysis and in almost all of the remainder.

Since rate data for 3α series are limited in number by comparison with the *meta* series of the benzene system, the precision with which the parameters ρ_i and $\rho_\pi{}^+$ are determined is inevitably restricted, nevertheless the inductive contribution ratio, $\rho_{i,3\alpha}/\rho_{i,4\alpha}$, 1.37, appears to be slightly large as compared with 1.17 for the corresponding series in benzene systems. Similar ratios, 1.33, 1.19, and 1.38[48] are found in the detritiation, the ester hydrolysis, and the acid dissociation, respectively. The significance of these results might not be clear, but it is suggested that the transmission coefficient for 3α series relative to 4α in the naphthalene ring may differ slightly from that in the benzene ring. This might indicate that $\sigma_p{}^0$ and $\sigma_m{}^0$ are not exactly applicable to 4α and 3α series in the naphthalene reactivity. The LArSR treatment might be restricted for the application especially to the effects of substituents in another ring positions in the naphthalene. The LSFE treatment should be promising for these cases.

(Received December 18, 1974)

Fourteen 5-, 6-, and 7-substituted 1-(1-naphthylethyl) chlorides were prepared and the solvolysis rates were determined in 80% (v/v) aqueous acetone at 45 °C. The effects of $-R$ substituents at respective positions were treated on the basis of the equation, $\log k/k_0=\rho_i\sigma_i+\rho_\pi{}^+\sigma_\pi{}^+=\rho(C_{1j}\sigma_i+q_{r\,1j}^+\sigma_\pi{}^+)$. The position dependency of the inductive effect was given by $C_{1j}(=\rho_i/\rho_{i,4\alpha})$; $C_{3\alpha}=1.37$, $C_{4\alpha}=1.00$, $C_{5\alpha}=0.75$, $C_{6\alpha}=0.57$, and $C_{7\alpha}=0.72$. The C_{1j} values appear to be correlated with Dewar's simplified field function $1/r_{1j}$. The position dependency of *Pi*-electronic effect given by the ratio $\rho_\pi{}^+/\rho_{i,4\alpha}=q_{r\,1j}^+$ was consistent with the prediction from the MO indices, such as Forsyth's $\Delta q_{1j}(\mathrm{ArCH_2}^+)$ parameters. The same treatment was applied also to three other naphthalene reactivities, detritiation, pK_a of α-naphthoic acids and pK_a of naphthylammonium ions. The linear $\rho_i-\rho_i$ relation holds among these reactions, suggesting a reaction-independent scheme of the inductive transmission. The $q_{r\,1j}^+$ values vary at conjugate positions with reaction but not at non-conjugate positions irrespective of reactions. The results are discussed in comparison with those of relevant treatments.

We have found that the effects of substituents at the A ring positions of the α-naphthyl derivatives were successfully correlated with the following LArSR Eq. giving $\rho=-5.12$, $r=1.04$.[1]

$$\log k/k_0 = \rho(\sigma^0+r\Delta\bar{\sigma}_R{}^+) \quad (1)$$

This indicates that the substituent parameters, σ^0 and $\Delta\bar{\sigma}_R{}^+$, which were derived from the benzene system, are valid also for both 3α and 4α series in the naphthalene system. A more fundamental separation of the substituent effects into inductive and π-electronic effects was also examined by means of the equation

$$\log k/k_0 = \rho_i\sigma_i + \rho_\pi{}^+\sigma_\pi{}^+ \quad (2)$$

using inductive and π-electronic substituent parameters, σ_i and $\sigma_\pi{}^+$. Application to the 3α and 4α series gave excellent correlations, indicating that the parameters derived from the benzene system are valid again for the α-naphthyl A ring system. It seems that the substituent effects are given by a certain blend of unique substituent parameters, σ_i and σ_π, characteristic of only substituents and independent of parent hydrocarbons. The blend depends remarkably upon reactions and characteristically upon substituent positions as well as parent hydrocarbons. In this study a 3α/4α inductive ratio of 1.37 was observed, which is slightly larger than the 1.17 *meta*/*para* inductive ratio. The difference might not be unreasonable since the parent hydrocarbons differ.

Our interest in the analysis of substituent effects led us to carry out further studies on the naphthalene B ring positions. LSFE treatment of aromatic reactivities beyond the original benzene system enables us to accomplish the following objectives. The generality of the σ_i and especially $\sigma_\pi{}^+$ parameters can be tested most critically. If they are physically meaningful quantities characteristic of the substituent, they should be applied to any aromatic systems (naphthalene in the present case) as well as the benzene system, independent of different resonance requirement of the reactions. The study provides evidence to clarify the ambiguity in the scale of inductive parameters and subsequently in the definition of π-electronic parameters. The parametric analysis of the apparent substituent effect into the two basic components from different aromatic positions may shed light on the mode of operation of substituent effects.

The present paper is concerned with the treatment based on Eq. (2) of the substituent effects in the solvolysis of substituted 1-(1-naphthylethyl) chlorides in 80% aq. acetone, and also in other types of reactions of α-naphthyl derivatives; detritiation of α-tritionaphthalenes in CF_3COOH studied by Eaborn's group,[2-4] dissociation of α-naphthoic acids in 50% aq. EtOH,[5] and of α-naphthylammonium ions in H_2O.[6]

Experimental

Materials. Preparation of 5-, 6-, and 7-substituted 1-naphthoic acids was carried out by the standard method with slight modifications. The positions of substituents at substituted 1-acetylnaphthalenes were confirmed by the NMR splitting pattern of the *peri*-hydrogen relative to that of the acetyl group.

1-Acetyl-5-bromonaphthalene: 1-Naphthoic acid was prepared by the acid hydrolysis (H_2SO_4: AcOH: H_2O=1: 1: 1)[7] of 1-naphthonitrile (bp 123—126 °C/4 mmHg) obtained from 1-bromonaphthalene with CuCN in DMF.[8] The crude acid (mp 156—159 °C; lit, mp 160 °C[9]) was brominated according to the direction of Short.[9] Recrystallization from AcOH gave (average yields 60%) 5-bromo-1-naphthoic acid, mp 263—264 °C; lit, mp 262 °C,[10] 256—256.5 °C,[9,11] 258—259 °C.[12] Purification was carried out by further recrystallization from MeOH–AcOH, mp 264—265 °C.[13]

5-Bromo-1-naphthoic acid was converted into the corresponding methyl ketone by the application of Bowman's method.[14] 5-Bromo-1-naphthoic acid was chlorinated with $SOCl_2$ to give 5-bromo-1-naphthoyl chloride; mp 85—86 °C from hexane–benzene; lit,[11] mp 84—84.5 °C. A dry benzene solution (*ca.* 300 ml) of the above chloride (70 g) was added to an excess of diethylethoxymagnesio-malonate (0.6 mol) in benzene with cooling. The mixture was refluxed for 4 h, decomposed with dil. H_2SO_4, and extracted with benzene. The crude acylmalonate was refluxed for 2 h with propionic acid (180 g) and H_2SO_4 (50 drops). Dil. H_2SO_4 was then

* To whom inquiries should be addressed. Present address; Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka 812

added slowly, refluxing being continued for 22 hr. After addition of AcONa, 1-acetyl-5-bromonaphthalene was distilled to give pale yellow liquid, bp 179—182 °C/7 mmHg, which solidified soon on being left to stand (average yield, 73%); mp 55.5—56.5 °C from ligroin.

1-Acetyl-5-methoxynaphthalene: 5-Bromo-1-nitronaphthalene was prepared following the method of Newman,[15] by the bromination of 1-nitronaphthalene; mp 119—122 °C from EtOH–$CHCl_3$, (63% yield); lit, mp 118—122 °C,[15] 121 °C,[16] 122 °C.[10,17] 5-Bromo-1-nitronaphthalene was reduced with iron powder in aq. EtOH–HCl, 4 hr, giving 5-bromo-1-naphthylamine on distillation at 180—185 °C/7 mmHg (lit,[18] bp 156—158 °C/1.5 mmHg) which solidified on being left to stand, mp 69—71 °C (92% yield); lit, mp 69.5—71 °C[18] 69 °C,[10,17] 64—69 °C.[15] 5-Bromo-1-naphthylamine hydrochloride was diazotized in aq. AcOH solution of HCl, decomposed by dropwise addition to a boiling 40% aq. H_2SO_4, and extracted with benzene. The alkaline extract on acidification gave 5-bromo-1-naphthol in 40% yield, mp 142 °C from hexane–benzene, lit,[10,19] mp 137 °C. Alternate process, the conversion of 5-bromo-1-naphthylamine through 5-cyano-1-naphthylamine into 5-cyano-1-naphthol, appears to be more successful. 5-Bromo-1-naphthylamine (130 g) was converted with CuCN (53 g) and DMF (150 ml) into 5-cyano-1-naphthylamine in 70% yield; bp 205—210 °C/6 mmHg, mp 141.5—142 °C (from aq. EtOH); lit,[20] mp 140 °C. 5-Cyano-1-naphthol was prepared quantitatively by the diazonium method.[20] The diazotized mixture of 5-cyano-1-naphthylamine (39 g) in AcOH (300 ml) and 40% aq. H_2SO_4 (400 ml) with aq. $NaNO_2$ (16 g) solution was filtered and decomposed by dropwise addition to a boiling 40% aq. H_2SO_4 solution during a period of 1 h. After being boiled for further 1.5 hr, the solid product was collected, washed, and dried (38 g). Alkaline extract from the benzene solution gave on acidification practically pure 5-cyano-1-naphthol, mp 207—210 °C. Further recrystallization from MeOH gave mp 214—215 °C; lit,[20] mp 209.5 °C.

The 5-cyano-1-naphthol was hydrolyzed in aq. KOH solution. On acidification, 5-hydroxy-1-naphthoic acid was obtained. The aq. alkaline solution of the crude acid was methylated with Me_2SO_4 to give 5-methoxy-1-naphthoic acid (35 g); mp 234—235.5 °C from EtOH; lit, mp 232.5 °C,[20] 230—232 °C.[12] 5-Methoxy-1-naphthoic acid (28 g) was converted into 5-methoxy-1-naphthoyl chloride (24 g, mp 78—81 °C from ligroin; lit,[21] mp 80—81 °C) and then to 1-acetylmethoxynaphthalene (bp 160—175 °C/7 mmHg), in the same way as the preparation of 5-bromo-1-naphthyl derivative. The yellow distillate (15 g) solidified on standing; mp 88—89 °C from ligroin.

1-Acetyl-5-ethylnaphthalene: 1-Bromo-5-ethylnaphthalene (22 g) was prepared by the Wolff-Kishner reduction[22] of 1-acetyl-5-bromonaphthalene (35 g) by a method similar to that for 1-ethylnaphthalene;[1] bp 130—150 °C/5 mmHg; main fraction 144—145 °C/5 mmHg. The distillate was converted without purification into 1-cyano-5-ethylnaphthalene with CuCN in DMF and then into 5-ethyl-1-naphthoic acid, using alkaline and acid hydrolysis; recrystallized. from 70% aq. EtOH, mp 150—153 °C. 1-Acetyl-5-ethylnaphthalene was synthesized from the acid by the method described for 5-bromo-1-derivative in 75% yield from the corresponding naphthoyl chloride; bp 157—160 °C/5 mmHg, mp 35.5—36 °C from hexane.

1-Acetyl-5-chloronaphthalene: 1-Chloro-5-cyanonaphthalene was synthesized from the diazonium solution of 5-cyano-1-naphthylamine. The diazotized solution of 5-cyano-1-naphthylamine (40 g) in AcOH (400 ml) and aq. HCl (concd. HCl, 100 ml) was poured into the freshly-prepared CuCl[23] in concd. HCl (130 ml) with cooling, and allowed to stand two days at room temperature. The precipitates were dissolved in benzene, treated with alkaline solution and the solvent was evaporated. The crude 1-chloro-5-cyanonaphthalene (33 g) obtained was hydrolyzed by refluxing with AcOH (200 ml), H_2SO_4 (100 ml), and H_2O (100 ml) for 18 h. The acid obtained was purified by distillation of the methyl ester (27 g); bp 171—172 °C/10 mmHg (mp 63—64 °C); lit,[24] bp 130 °C/2 mmHg (mp 42 °C), mp 65—66 °C; and followed by recrystallization of the regenerated 5-chloro-1-naphthoic acid (from EtOH), mp 254—255 °C; lit, mp 246—247 °C,[11,12] 245 °C.[24] The acid (15 g) was similarly converted into the corresponding methyl ketone *via* the naphthoyl chloride; lit,[11] mp 68—69 °C. Recrystallization from hexane gave 1-acetyl-5-chloronaphthalene (9 g), mp 69.5—70 °C.

1-Acetyl-6-methoxynaphthalene: 6-Methoxy-1-naphthoic acid was prepared by the reaction of furoic acid and anisole with $AlCl_3$.[25] The acid obtained was purified by distillation of the methyl ester; methyl 6-methoxy-1-naphthoate (25 g), bp 180—186 °C/7—8 mmHg. After alkaline hydrolysis, 6-methoxy-1-naphthoic acid was recrystallized from benzene, mp 191.5—192 °C; lit, mp 180—180.5 °C,[25] 179—180 °C.[12] The acid (19 g) was converted into the corresponding methyl ketone (10 g), distilled at 156—159 °C/4 mmHg. Recrystallization from ligroin yielded 1-acetyl-6-methoxynaphthalene, mp 66—66.5 °C; lit,[26] mp 64—65 °C.

1-Acetyl-6-chloronaphthalene: 6-Chloro-1-naphthoic acid was prepared by the condensation of furoic acid and chlorobenzene with $AlCl_3$.[25] The product contaminated with 7-chloro-1-isomer[24] was recrystallized from benzene (67 g), mp 193—194 °C (lit,[25] mp 188—189 °C), and esterified with MeOH and concd. H_2SO_4. Vacuum distillation at 167—170 °C/4 mmHg (65 g) and repeated recrystallization from MeOH gave methyl 6-chloro-1-naphthoate (30 g) melting at 66.5—67 °C; lit, mp 66—66.5 °C,[24] 68—69 °C.[25] Alkaline hydrolysis yielded pure 6-chloro-1-naphthoic acid (28 g), mp 221—222 °C, lit,[12] mp 216—216.5 °C. The acid (20 g) was converted in the usual way into 1-acetyl-6-chloronaphthalene, being distilled at 155—156 °C/3 mmHg (14 g).

1-Acetyl-6-methylnaphthalene: 6-Methyl-1-naphthoic acid was derived by Price's method;[25] mp 182.5—183 °C from benzene; lit, mp 178—179 °C,[12] 176.5—177 °C.[25] 1-Acetyl-6-methylnaphthalene was derived from the corresponding acid and purified by repeated fractional distillation, bp 143—146 °C/4 mmHg.

1-Acetyl-7-methoxynaphthalene: 2-Acetylaminonaphthalene (mp 134.5—135 °C from benzene; lit,[27,28] mp 131—132 °C) was acetylated by the application of Brown's procedure,[28] with Ac_2O in CS_2 in the presence of $AlCl_3$, and the products were recrystallized twice from 50% aq. EtOH in average yield of 47%, mp 147.5—148 °C; lit, mp 149—150 °C,[27] 151 °C.[28] 1-Acetyl-7-acetylaminonaphthalene (40 g) was hydrolyzed in aq. EtOH in the presence of H_2SO_4 in average yield of 90%, and recrystallized from aq. MeOH, mp 111—112 °C; lit, mp 110—111 °C,[28] 108.5—110 °C.[27,29]

1-Acetyl-7-aminonaphthalene (25 g) was diazotized in the usual manner in a solution of H_2SO_4 (45 ml)–H_2O (200 ml) in AcOH (100 ml), and decomposed with aq. H_2SO_4. The product was dissolved into benzene, filtered, and evaporated to give practically pure 1-acetyl-7-hydroxynaphthalene (23 g), mp 150—152 °C. Recrystallization from benzene–ligroin raised the mp to 152.5—153.5 °C; lit,[27,30] mp 149—150 °C. The usual methylation with Me_2SO_4 gave 1-acetyl-7-methoxynaphthalene, bp 160—162 °C/5 mmHg, as a colorless liquid in 80% yield; mp 63.5—64 °C from hexane–benzene; lit,[27] mp 63 °C.

1-Acetyl-7-chloronaphthalene: Diazotization of 1-acetyl-7-

aminonaphthalene (22 g) in aq. HCl was carried out in the usual manner. The filtered diazonium chloride solution was poured into the ice-cooled freshly-prepared CuCl[23] in HCl (100 ml). Benzene was added to the mixture with vigorous stirring and left to stand at room temperature for 2 days. The benzene layer was separated, filtered, and washed with aq. alkali and water, and crude 1-acetyl-7-chloronaphthalene was distilled at 160—172 °C/5 mmHg, which was solidified soon (12 g) and recrystallized, mp 65—65.5 °C from hexane; lit,[28] mp 64—65 °C (bp 158—160 °C/4 mmHg).

1-Acetyl-7-cyanonaphthalene: The diazonium chloride solution of 1-acetyl-7-aminonaphthalene (50 g) was poured into an aq. solution of CuCN (40 g), NaCN (20 g), and KCN (50 g) with cooling and stirring. After being left to stand overnight, brown precipitates were collected, washed with aq. alkali and water, and dried. Yellow 1-acetyl-7-cyanonaphthalene was distilled at 197—205 °C/5—6 mmHg (23 g); mp 124—125 °C from 95% EtOH.

The cyanide (10 g) was hydrolyzed with the solution of AcOH (100 ml), H_2SO_4 (50 ml), and water (50 ml) for 27 hr to give 8-acetyl-2-naphthoic acid (10 g); mp 235.5—236 °C from 80% aq. EtOH. Found: C, 72.62; H, 4.58%. Calcd for $C_{13}H_{10}O_3$: C, 72.89; H, 4.71%.

1-Acetyl-7-methylthionaphthalene: The diazonium chloride solution of 1-acetyl-7-aminonaphthalene (16 g) was poured into the cooled solution of potassium ethoxyxanthate (30 g) in water (200 ml). After being left to stand overnight, solution was added to aq. KOH (30 g) solution. The mixture was hydrolyzed, made alkaline with 30 g KOH, and methylated with Me_2SO_4. Extraction with benzene, washing with aq. alkali and water, and evaporation of benzene gave crude 1-acetyl-7-methylthionaphthalene which was distilled at 180—205 °C/8 mmHg as yellow viscous liquid (9 g); the product solidified was recrystallized from 80% aq. EtOH, mp 63.5—64.5 °C.

1-Acetyl-7-bromonaphthalene: 2-Bromonaphthalene, bp 130—132 °C/8 mmHg, mp 56—57 °C (lit, bp 122—127 °C/4.5 mmHg, mp 54—56 °C,[31] 56—56.5 °C[28]) prepared from a commercial 2-naphthylamine-1-sulfonic acid,[31] was acetylated according to the method of Girdler *et al.*,[32] using AcCl and $AlCl_3$ in nitrobenzene. The acetylated product distilled at bp 183 °C/9 mmHg was extracted with hot petroleum ether to give a product of mp 62 °C(A). The remaining oily product was purified by column chromatography on Al_2O_3 using hexane–benzene as an eluent. The first and the second fractions gave impure product (mp 70—90 °C from ligroin or hexane), which was repeatedly recrystallized from hexane to give 2-acetyl-6-bromonaphthalene, mp 104.5—105 °C; lit, mp 104—105 °C,[20] 100.5 °C[32] The mother-liquor gave a substance melting at *ca.* 50 °C, which combined with the product (A) was purified by repeated recrystallization from ligroin to give 1-acetyl-7-bromonaphthalene, mp 60—63 °C; lit, mp 63—64 °C,[28] 62—63 °C.[32]

Alcohols and chlorides were prepared according to the reported method.[1] The physical properties and the elemental analytical data of the ketones, alcohols, and chlorides are

For respective series, a slightly different rate constant for the parent 1-(1-naphthylethyl) chloride was obtained; a) $k_1=12.7\times10^{-5}$, b) $k_1=12.1\times10^{-5}$, c) $k_1=11.1\times10^{-5}$. Relative rates (Table 5) were calculated by use of the corresponding k_1 value. d) slightly colored sample solutions were employed.

given in Tables 1, 2, and 3, respectively.

Solvent and Kinetics. The solvent 80% (v/v) aqueous acetone was prepared by mixing one volume of water with 4 of acetone. Different batches of aqueous acetone which gave only slightly differing rate constants (Table 4) were used without calibration for each series of rate measurements. Solvolysis was carried out at a concentration of *ca.* 0.02 mol/l.[1)] All the runs followed first order kinetics covering over 60—90% reaction within experimental error of *ca.* ±1%, and the rate constants from duplicated runs agreed within ±2% or better. The rate constants obtained at various temperatures are listed in Table 4. Almost all the rate data were based on least squares calculation with at least 10 points covering 2 half lives; those for 7-CN-α were based on initial 5 points (*ca.* 50% reaction) since the rate drifted down slightly with time.

Results and Discussion

The values of log k/k_0 for the solvolysis of substituted chlorides studied in 80% (v/v) aq. acetone at 45 °C are given in Table 5, which also includes the data for 3α and 4α derivatives.[1)] Log k/k_0 varies widely with respect to not only substituent changes but also changes of substituent position. The reactivities of MeO group at the conjugate positions are evidently higher than those at non-conjugate one, and those in the B ring positions are fairly lower than those in the A ring, the lowest being at 5α position; 4α>7α>5α>6α>3α. Schreiber and Byers found a similar sequence in the solvolysis of the methoxy-substituted 1-naphthylmethyl bromides in 80% aq. acetone and in acetic acid.[33)] The effects of Cl substituent at all positions are consistently negative and follow the sequence, 4α>7α>6α>5α>3α, which differs slightly from that of the MeO substituent. The different sequence between both substituents reflects delicately the different blends of the contribution of their *I* and *Pi* effects from respective positions.

The logarithmic relative rates for the present solvolysis at 45 °C are plotted in Fig. 1 against those for the detritiation of substituted 1-tritionaphthalenes in CF_3COOH at 70 °C.[2)] The linear relation suggests that the contributions of the *Pi* effect relative to the *I* effect from corresponding substituents at respective positions are very close to each other in both reactions. The deviations of MeO derivative from the correlation might result from the decreased rate of the detritiation due to the special interaction of the substituent with the acidic solvent.[34)] From the slope of the plot (0.80), the ρ value for the detritiation can be estimated to be −6.3 (least squares calculation, $R=0.998$, $n=11$). This value is consistent with the ρ value (−6.4) obtained from 3α and

*) Values were obtained by extrapolation from other temperatures. a) Ref. 1.

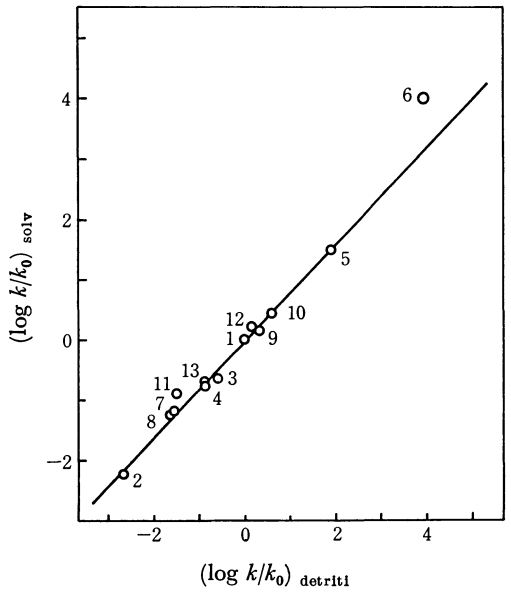

Fig. 1. LFER between the solvolysis and the detritiation rates (slope, 0.80). The points are identified as follows: (1) H-α, (2) 3-Cl-α, (3) 4-Cl-α, (4) 4-Br-α, (5) 4-Me-α, (6) 4-MeO-α, (7) 5-Cl-α, (8) 5-Br-α, (9) 5-Me-α, (10) 5-MeO-α, (11) 6-Cl-α, (12) 6-Me-α, (13) 7-Cl-α.

4α derivatives by the application of Eq. (1) (r=1.13, R=0.997, s=±0.14, n=7). Logarithms of relative rates of the present solvolysis are plotted in Fig. 2 against ΔpK_a of the corresponding substituted 1-naphthoic acids in 50% aq. EtOH.[5,35] In contrast with the plot

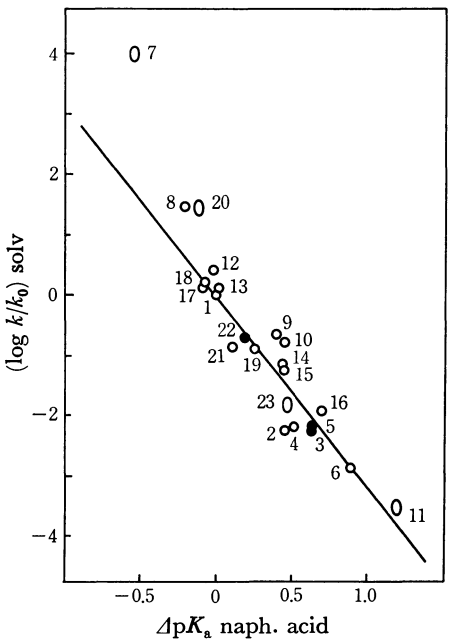

Fig. 2. Total plot of the solvolysis log k/k_0 against ΔpK_a for naphthoic acids (● corrected value for ΔpK_a was employed).
The points are identified as follows: (1) H-α, (2) 3-Cl-α, (3) corrected 3-Cl-α, (4) 3-Br-α (5) corrected 3-Br-α, (6) 3-CN-α, (7) 4-MeO-α, (8) 4-Me-α, (9) 4-Cl-α, (10) 4-Br-α, (11) 4-CN-α, (12) 5-MeO-α, (13) 5-Et-α, (14) 5-Cl-α, (15) 5-Br-α, (16) 5-CN-α, (17) 6-MeO-α, (18) 6-Me-α, (19) 6-Cl-α, (20) 7-MeO-α, (21) 7-Br-α, (22) corrected 7-Cl-α, (23) 7-CN-α.

in Fig. 1, the correlation is not linear, but appears to be quite analogous to that observed in the case of benzene derivatives against the σ-constants. This is reasonable since the pK_a's of naphthoic acids could be regarded as the essentially unexalted σ-type reactivity.

According to the LArSR assumption,[1] such a plot for an electrophilic resonance reaction against σ may be expected only for conjugatively electron releasing (−R) substituents at the conjugate position to give the substantial upward deviations, the extents of which depend upon their resonance contribution, as observed in the benzene reactivities. The correlation line may be drawn through the origin and the points for CN derivatives for which no exaltation of resonance might be expected. The weakly conjugating groups at the less effective conjugate position lie more closely to the correlation line. With respect to the σ^+ type reactivities, on the other hand, the theory predicts for any kinds of substituents to give no downward deviations from the correlation line. The figure seems to be satisfactory for most substituents except 3α- and 7α-halogen substituents. Unfavorable dispositions of 3α- and 7α-halogens may probably be due to the improper pK_a values for the corresponding naphthoic acids. This is suggested by the following facts. Such deviations of 3α- and 7α-halogen groups were not observed in similar logarithmic plots of the present data against pK_a's of naphthylamines[6] and also those against log k/k_0 of the hydrolysis of naphthoic esters.[36,37] The calibrated points on this basis (closed circles, Fig. 2) fall in fact near the correlation line determined by non- or

less conjugative derivatives. It is apparent that all the substituents at the non-conjugate 3 and 6 positions as well as the $+R$ substituents at any position fall on the correlation line for the unexalted substituent effect. The exalted contribution of substituents at any conjugate positions follows the usual order of $\Delta\bar{\sigma}_R^+$ values, MeO>Me> Cl, Br, as seen in the benzene reactivities, and that the enhancement of a $-R$ substituent, for example, the most effective MeO group, becomes less extensive by the positional change in the order, $4\alpha>7\alpha>5\alpha>3\alpha$, 6α. This is essentially valid also for the other $-R$ substituents. The exaltation of the substituent effects in the present electrophilic reactivities is observed only for the $-R$ class substituents at the conjugate position, but not for $+R$ class substituents even at the conjugate position.

The results are in line with the general features of the substituent effects observed in the Hammett-type treatment of the benzene reactivities, especially with those characteristic of the electrophilic σ^+-type reactivities in the benzene system.[38]

From a survey of the naphthalene reactivity data in the literature, including copious ones, the reaction dependence of the substituent effect can not be overlooked.

The Hammett-type description of the naphthalene reactivities requires several sets of substituents constants such as σ_{ij}, σ_{ij}^+, and σ_{ij}^-. As seen in the benzene case, however, each set of substituent constants should be applied within the limit of closely related classes of reactivities. This is clearly illustrated by a comparison of the plots in Figs. 1 and 2. The results suggest that the exalted-resonance type electrophilic naphthalene reactivities can be treated in the same way as that for benzene by means of the equation

$$\log k_{ij}/k_0 = \rho(\sigma_{ij}+r_{ij}^+\Delta\sigma_{R,ij}^+) \qquad (1')$$

where the subscripts i and j represent the respective naphthalene positions to which are attached substituents (i) and the reacting side-chain (j=α in the present case). The exalted resonance contribution of substituents at effectively conjugative positions (4α,5α,7α) can be given by the second term in Eq. (1'). For all $+R$ substituents and $-R$ ones at weak conjugate positions (3α, 6α), the second term should be zero. The values of $\Delta\sigma_{R,ij}^+$ may be defined by the differences of the apparent substituent constants between any two reference reactions in the same way as in the definition of $\Delta\bar{\sigma}_R^+$ in the benzene system. The treatment is applicable not only to the effect of substituents in the A ring,[1] but also might be applicable to that of substituents at all positions in the B ring, if the standard set of naphthalene σ values for respective substituents at respective positions, σ_{ij}, or more preferably the naphthalene σ_{ij}^0 parameters are determined. In this treatment, both σ_{ij} and $\Delta\sigma_{R,ij}^+$ are assumed to be the parameters characteristic of a substituent as well as constants of respective naphthalene positions. The r_{ij} should then be given as a constant of a given reaction and independent of substituent positions. This treatment will be most convenient for practical use. However, a fundamental set is not immediately available nor sufficient data to verify its general applicability.

For the present purpose, to determine the position dependency of inductive and π-electronic components of substituent effects, the LSFE treatment (2) using σ_i and σ_π^+ constants appears to be more reasonable. Accordingly, we employed Eq. (2) statistically for each naphthalene position with respect to only conjugatively electron releasing ($-R$) substituents. The correlational parameters obtained by the method of least squares are given in Table 6 and substituent constants, σ_i and σ_π^+, in Table 8. The reliability of statistical ρ_i and ρ_π^+ parameters is strongly dependent upon the number of substituents involved as well as the variation of electronic nature of substituents. Although the limited rate data in our study restrict the precision of fit with which the parameters ρ_i and ρ_π^+ are determined, respective series involves at least one of each representative type of $-R$ substituents, alkoxy, halogen, and hydrogen, and covers an extensive change of reactivity.

It is seen from Table 6 that most correlations are excellent (R>0.999) and the substituent effects of $-R$ substituents at each position in the present naphthalene system can be correlated quite successfully by means of Eq. (2). The same treatment can be applied also to the effects of $-R$ substituents in other naphthalene reactivities; detritiation of substituted α-tritionaphthalenes[2] and dissociation of substituted α-naphthylammonium ions[6] and of substituted α-naphthoic acids.[5,35] The results for these reactivities are given in Table 7. In the case of detritiation, the methoxy group was not included in the calculation because of the special interaction with the acidic solvent, CF_3COOH; only methyl and halogens can be treated as ordinary substituents. Eaborn stated that the kinetic data of halogen substituents at 70 °C are of probable 15% errors due to experimental difficulties.[3] One unpreferable feature resulting from the statistical application to less sufficient data appears as the positive ρ_π^+ value for 6α series, to which we can not give any physical significance; probably the ρ_i and ρ_π^+ values for 6α series in this reaction is not reliable (see Table 7). The correlations for the amine series (R> 0.997) appear to be more reliable than those for the acid series.

a) Values taken from Ref. 38.

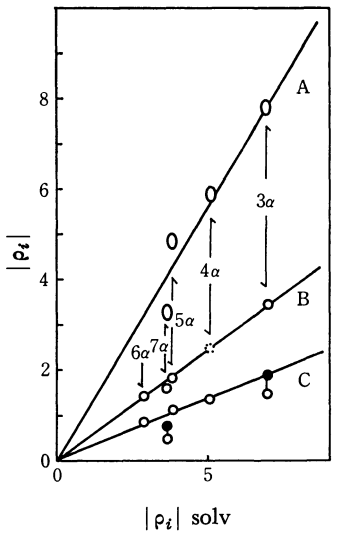

Fig. 3. $\rho_i-\rho_i$ plots.
A: the detritiation, B: the dissociation of naphthylammonium ions ($\rho_{i,4\alpha}$ can be interpolated from B line), C: the dissociation of naphthoic acids (● corrected value was employed).

Figure 3 shows the linear relations of the sets of ρ_i's for the detritiation (A), the dissociations of amines (B), and acids (C) with the corresponding ρ_i values obtained from the present solvolysis. The linear ρ_i—ρ_i relationship holds. The deviations of 6α and 7α in the plot A may arise from the inaccuracy of ρ_i values due to insufficient number of data in the detritiation. Deviations of 3α and 7α in C might be attributed to the unreasonable pK_a values.

The dissociation of naphthoic acids can reasonably be expected to be a representative σ class reactivity. The pK_a of substituted α-naphthylammonium ions should be a typical nucleophilic reactivity, that is, the resonance exaltation of $+R$ substituents at conjugate positions are significant, while the effect of the $-R$ substituents in this set could be regarded as the unexalted class even for those at conjugate positions. Both the present solvolysis and the detritiation should belong to the electrophilic reactivity. Evidently the linear ρ_i—ρ_i relationship is generally valid in various types of reactions (Fig. 3); between reactions not only of similar contributions but also of distinctly different contributions of the π-electronic effects.

In view of the positional consistency of the inductive components, it appears to be convenient to express Eq. (2) as follows.

$$\log k/k_0 = \rho(C_{ij}\sigma_i + q^+_{r,ij}\sigma_\pi^+) \qquad (3)$$

where i and j represent the naphthalene ring positions bearing a substituent and a reaction site, respectively. C_{ij} is the positional constant concerning the transmission of the inductive effects. The $q^+_{r,ij}$ is the characteristic variable of reactions as well as of substituted positions, giving a measure of the π-electronic interaction of substituents at respective positions with a reaction site. The

ρ value in Eq. (3) should be identical to $\rho_{i,4\alpha}$ (-5.09 for the solvolysis) by definition.

The reference set of C_{ij} can be determined from the ratios of the ρ_i values for the present solvolysis data, since they provide the relatively precise correlations and cover a more sufficient range of reactivity changes. The $\rho_{i,4\alpha}$ value is taken as a standard, as referred to the definition of σ_i scale for benzene derivatives. The values of C_{ij} obtained are as follows. $C_{3\alpha}=1.37$, $C_{4\alpha}\equiv 1.00$, $C_{5\alpha}=0.75$, $C_{6\alpha}=0.57$, and $C_{7\alpha}=0.72$.

In order to interpret the total substituent effects in the naphthalene reactivities, various correlational equations have been developed by various workers. Dewar and Grisdale have treated the dissociation of α-naphthoic acids in terms of the equation[5]

$$\sigma_{1j} = 1/r_{1j}F + q_{1j}M \quad (4)$$

The field effect is simply assumed to be proportionally transmitted with the reciprocal of the simplified distance between ring carbons, which is taken into account in the first term. The second term represents the mesomeric effect, whose position dependency is assumed to be proportional to the NBMO charge of each naphthalene position.

The same type of approach was developed to interpret the substituent effects on the detritiation of α- and β-tritionaphthalenes:[2,3,39]

$$\sigma_{1j}^{W} = 1/r_{1j}F + q_{1j}^{W}M^{+} \quad (5)$$

The main improvement lies in the employment of the other set of M^+ constants instead of M in Eq. (4). In these approaches, the transmission schemes of both *I* and *Pi* effects are restricted by *a priori* assumptions based upon simplified consideration. The transmission schemes were assumed to be reaction-independent. However, all these treatments were applied only to a single set of reactivities, and no definite evidence of the generality has yet been offered. Though a precise comparison may not be possible, it appears that these correlations are of considerably poorer quality than the present results. The present study does not lie on the same line of approach but aims at a purely empirical determination of the transmission schemes of *I* and *Pi* effects by means of Eq. (2). Taft and his co-workers developed the latter line of approach, not based on an *a priori* transmission scheme.[40] Their treatment is based on the assumption that the effects of substituents at respective positions can be given by the statistical blends of the terms proportional to their σ_I and σ_R^0 parameters, as represented by

$$\log k/k_0 = \rho_{I,ij}\sigma_I + \rho_{R,ij}\sigma_R^0 \quad (6)$$

The transmission schemes of the inductive and resonance effects were thus determined as the relative $\rho_{I,ij}$ and $\rho_{R,ij}$ values, by means of the statistical application of Eq. (6) for all the substituents, both $+R$ and $-R$ classes, at respective naphthalene positions. However, it should be noted that Eq. (6) can only be applied within the limited range of the unexalted σ^0- or at most σ-type reactivities, as noted by Taft. Otherwise the correlation of the reactivities at the conjugate position would not be so reliable. A similar treatment was also employed for the dissociation of naphthoic acids by Swain and Lupton, in terms of their F and R parameters.[41] The same limitation discussed above applies to this treatment.

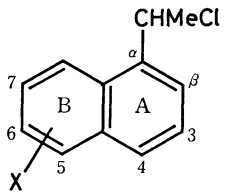
Dewar's treatment and its modifications assume that the so-called inductive polar effect of dipolar substituents is mainly controlled by the field effect. Such a field effect is ordinarily taken into account as a first approximation by certain functions of the distances, r_{ij}; $1/r_{ij}$ or $\cos\theta/r_{ij}^2$ for a special case.[5,35] It is of interest to compare the empirical C_{ij} values with familiar functions of distance accounting for the transmission of electrostatic interaction across space. The relevant parameter values are listed in Table 9. Most of the theoretical parameters

Table 9. Comparison between C_{1j} values and varisou functions of distance

Series	C_{1j}	Ratio of $1/r$[a]	Ratio of $1/R'$[b]	Ratio of $(\cos\theta/R^2)$[c]
3α	1.37	1.15	1.15	1.11
4α	1.00	1.00	1.00	1.00
5α	0.75	0.75	0.87	0.71
6α	0.57	0.67	0.85	0.72
7α	0.72	0.75	1.00	0.58

a) r is distance between ring carbons; Refs. 5 and 35. b) R' is distance between ring carbon and reaction center; Ref. 40 ($1/r_{rX}$ for $\gamma=1$). c) R is distance between center of substituent dipole and reaction center; Ref. 35.

indicate roughly the same trend and do not differ significantly from the characteristic order of the C_{ij} values, $C_{3\alpha}>C_{4\alpha}>C_{5\alpha},C_{7\alpha}>C_{6\alpha}$, in which the most striking feature is $C_{5\alpha}\simeq C_{7\alpha}$. As far as the α-naphthyl system is concerned, however, the simplest Dewar function, the dependence on $1/r_{ij}$, appears to be the best in various field-functions, explaining completely the characteristic order as well as the magnitude of C_{ij}'s. The more sophisticated one does not appear to provide any improvement in the parallelism with the empirical C_{ij}. It is apparent that any orientational factor (function of θ or angular dependence of the field effect of dipolar substituents) is of little practical consequence. The effect, if operative at all, is relatively unimportant at least in the α-naphthyl reactivities.



It might be concluded as follows. (1) The positional dependence of the inductive contribution can be given by the ratio of ρ_i parameters, *i.e.*, by $C_{ij}=\rho_i/\rho_{i,4\alpha}$, and remains generally a constant in the naphthalene system, independent of reactions, or more precisely, of the varied contributions of the *Pi* effects in any types of reactions. (2) Dewar's simplest field function $1/r_{ij}$ may be applicable, to a practically useful approximation, generally as the transmission factor of the *I* effects in the naphthalene reactivities. The results provide in part an evidence justifying the validity of the description of the substituent effects in the naphthalene system by means of Eq. (2).

Table 10. Comparison between the solvolysis ρ_π^+ and various theoretical values

a) Value in Eq. (3), $\rho_\pi^+/\rho_{i,4\alpha}$. b) Dewar's formal charge; Refs. 5and 43. c) Atom-atom polarizability; Refs. 5 and 35. d) Bond-atom polarizability, $\pi_{Rr,i}$ in Ref. 40. e) Eaborn's parameter; Ref. 3. f) Forsyth's regional charge difference; Ref. 44. g) Approximate value; Ref. 45.

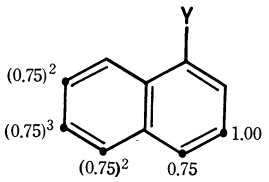

Chart 1. C_{ij} values are approximately represented as power dependence; bond fall off model.

Another instructive feature illustrated in Chart 1, where C_{ij} values are given as a power dependence upon numbers of intervening bonds to a good approximation, is of interest. It suggests that successive polarization of intervening bonds also plays an important role in the contribution of the σ-inductive effect, C_{ij}. A transmission factor per one carbon–carbon bond appears to be 0.75, when C_{ij} values are compared with each other in the naphthalene A or B ring. However, although the number of intervening C–C bond between the carbons i and j is equal for 4α, 5α, and 7α derivatives (through the most effective route), C_{ij} for 5α or 7α is 0.75 times smaller than that for 4α. This gap between rings A and B might reflect the effect of the branched ring-carbon at 9 or 10 position, at which the transmission route is separated into two ways. An explanation in terms of such branched carbons can also be applied to the fact that the ratio $C_{3\alpha}/C_{4\alpha}$ is slightly larger than C_{meta}/C_{para}, since two similar transmission routes are possible from *para* position to a reaction site in the benzene system.

Success in the separation of the contribution of the position-dependent *I* effects from the total electronic effects may provide sufficient reliability for a discussion on the remaining *Pi* effects, if the assumption of the additivity of the two effects is valid. The set of ρ_π^+ for the solvolysis (Table 6) shows that the contributions of the electron donative *Pi* effect of substituents at any conjugate position are evidently more effective than those from substituents at non-conjugate positions, just as the HMO theory predicts. The magnitude of ρ_π^+'s for the conjugate ones is appreciably different; the resulting order of the effectiveness is $3\alpha \simeq 6\alpha < 5\alpha < 7\alpha < 4\alpha$. Since the identical sequence is also found for other electrophilic reactivities such as the sets of ρ_π^+'s for the detritiation and the dissociation of amines (Table 7), it can be concluded that the sequence generally holds for $-R$ substituents in electrophilic reactivities and is inherent to the parent naphthalene π-electron system. This has been recently confirmed for $+R$ substituents in nucleophilic reactivities such as the substituent chemical shifts of OH protons of naphthols in a DMSO solution.[42]

The set of ρ_π^+'s empirically derived from the solvolysis could reasonably be compared with various sets of theoretical indices for the parent naphthalene or related hydrocarbons. The MO parameters of interest in connection with the transmission coefficient are listed in Table 10. As far as conjugate positions are concerned, the correspondence of ρ_π^+ with any HMO indices appears to be good to a rough approximation, but not necessarily complete, since small but definite electron donative *Pi* contributions are observed in the empirical set for non-conjugate 3 and 6 positions. Forsyth proposed a new set of theoretical index based on CNDO/2 approximations, $\Delta q_{ij}(ArH^+)$ or $\Delta q_{ij}(ArCH_2^+)$, in which the numerical values are derived from the difference of the regional charges at i'th carbon between a transition state and an initial state model.[44] The plot of the solvolysis ρ_π^+ *vs* $\Delta q_{ij}(ArCH_2^+)$[45] seems to be satisfactorily linear for all positions well within the limit of approximation (Fig. 4).

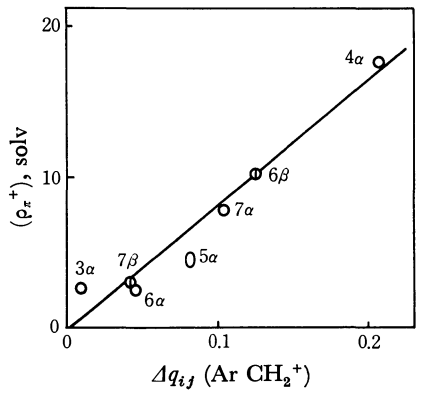

Fig. 4. The plot of solvolysis ρ_π^+ *vs.* $\Delta q_{1j}(ArCH_2^+)$.[45] (Data for 6β and 7β will be seen in a next paper).

This index can take account for not only the presence of electron donative contributions at non-conjugate positions, but also the relative magnitudes of ρ_π^+'s at conjugate ones. The good coincidence between the empirical and theoretical coefficients gives another evidence verifying the description of the substituent effects in the naphthalene system in terms of the *I* and *Pi* effects by means of Eq. (3).

The results of all four different reactions indicate that the π-electronic components are dependent not only upon the substituent positions but also upon reactions even at a given conjugate position. The most intuitive parameter illustrating such a reaction dependency of the *Pi* effects is the $q_{r,1j}^+$ value in Eq. (3), which is equivalent to the *r* value for the *para* position of benzene system in Eq. (1). The values are calculated as $\rho_\pi^+/\rho_{i,4\alpha}$ and summarized in Table 11.

Table 11. Comparison of $q_{r,ij}$ values for some electrophilic α-naphthyl reactivities

Series	Reaction[a]			
	Solv.	Detriti.	Acid	Amine
3α	0.5	0.2	0.4* (0.6)[b]	0.1[c]
4α	3.5	4.0	2.2	1.0[c,d]
5α	0.9	0.6	0.7	0.4[c]
6α	0.5		0.7	0.4[c]
7α	1.5	0.7*	0.5*(0.6*)[b]	0.7[c]

*) Value is less reliable since certain discrepancies are observed in the ρ_i—ρ_i plot in Fig. 3. a) See Table 7. b) Corrected ΔpK_a value was employed. c) Secondary value based on the estimated $\rho_{i,4\alpha}$ of 2.50. d) From ΔpK_a of 4-Br-α, $\rho_{\pi,4\alpha}^{+}$ was estimated as 2.41, using the parameter of Br in Table 8.

Although the crudeness of data does not permit a precise discussion, the results appear to suggest the following. The characteristic order of the $q_{r,ij}^{+}$ for the conjugate positions, 4α>7α>5α, obtained in the present solvolysis can be observed also in other reactivity sets. The $q_{r,ij}^{+}$ for any B ring position is much smaller and at most half as large as that for the 4α position. These are in qualitative agreement with the scheme of π-electronic transmission expected from MO indices mentioned above. However, the $q_{r,ij}^{+}$ is evidently reaction-dependent, in contrast to the reaction-independent C_{ij} value for the inductive contribution, and that for the conjugate position varies from reaction to reaction depending upon the reactivity classes or the amount of charge at the site delocalized through π-electronic interaction. It should be noted that the value for a given conjugate position, especially that for 4α position, shows practically the same dependency upon reactions as the q_r^{+} (and in the analogous way to the r value) for the same reactions of *para* substituted benzene derivatives. In the reaction of smaller electron demand such as the dissociation of naphthoic acids and naphthylamines, the $q_{r,ij}^{+}$ only for 4α is significant but those for 7 and 5 positions diminish to a value comparable to that for non-conjugate positions. Concerning the $q_{r,ij}^{+}$'s for non-conjugate positions (Table 11), although the number of substituents and of reactions examined are limited, it would be reasonable to consider that the $q_{r,ij}^{+}$ for the non-conjugate position remains practically constant in spite of the variation of reaction (*e.g.*, $q_{r,3\alpha}^{+}=0.4\pm0.3$ and $q_{r,6\alpha}^{+}=0.5\pm0.2$). This is in contrast to the behavior of the $q_{r,ij}^{+}$ for conjugate positions but in line with the general reaction-independency of σ_m values observed in benzene reactivities.[38]

Finally, the $q_{r,ij}^{+}$ values for the σ^0-class reactivity (*i.e.*, $q_{r,ij}^{0}$) may reasonably be expected to be close to the least exalted $q_{r,ij}^{+}$ values obtained for the pK_a of naphthylammonium ions and probably very close to 0.5 for all positions except 1.0 for 4α position, as far as the $-R$ substituents are concerned. A typical $+R$ cyano substituent at any position in Fig. 2 essentially satisfies the correlation determined by 3α and 6α substituents. This suggests that the exaltation of π-electronic effect of the $+R$ group even at strongly conjugative positions does not occur in the σ^+-type electrophilic reactivity of the naphthalene in the same way as in the benzene system.[38]

In fact, the apparent σ_{ij} values of the CN group in the present solvolysis can be calculated as a good approximation with the above $q_{r,ij}^{0}$ for σ^0-class reactivity (combined with C_{ij} values) but not with the set of $q_{r,ij}^{+}$ values for the solvolysis. It is apparent that the dual q_r values, $q_{r,ij}^{+}$ and $q_{r,ij}^{-}$, should generally be required each for $-R$ and $+R$ class substituents. The σ^0 class reactivity may thus be defined as the reactivity which shows minimal exaltation of both $-R$ and $+R$ resonance; *i.e.*,

$$q_{r,ij}^{+} = q_{r,ij}^{-} = q_{r,ij}^{0}.$$

From the results, we can figure out the general pattern of the transmission of the substituent effect in the naphthalene system. The substituent effect in the naphthalene system can be separable as a useful approximation into the reaction-independent inductive contribution and the reaction-dependent *pi*-electronic contributions from $+R$ and $-R$ substituents by means of the equation

$$\bar{\sigma}_{ij} = (\log k/k_0)/\rho = C_{ij}\sigma_i + q_{r,ij}^{+}\sigma_\pi^{+} + q_{r,ij}^{-}\sigma_\pi^{-} \qquad (3')$$

The last term applies to the effect of $-R$ substituents. The C_{ij} is generally independent of reactions. The $q_{r,ij}$ for non-conjugate positions also remains to be $q_{r,ij}^{0}$ regardless of reaction. The reaction dependency of the apparent substituent constants $\bar{\sigma}_{ij}$ is attributable to the changes of the $q_{r,ij}^{+}$ and/or $q_{r,ij}^{-}$ for the conjugate positions with reactions. The characteristic ratio $q_{r,ij}^{+}/q_{r,ij}^{-}$ reflects the nature of the reaction center at the transition state.[46]

Dewar's *FM* assumption is in line with the present statistical results at least with respect to the inductive transmission scheme. However, with respect to the *pi*-electronic transmission scheme it appears to be inconsistent with our conclusion, in two points. According to the present analysis there is no reaction-independent general-scheme of the *pi*-effect transmission, as Dewar assumed to be given by a fixed set of NBMO q_{ij} coefficients.[5] Even if it is valid as a first approximation, the application will be limited to some very narrow range of reactivity class. Use of Eaborn's q_{ij}^{w} scheme as in Eq. (5) for the electrophilic σ^+-type reaction gave better results.[2] The different reaction-dependency of the *pi*-effect transmission scheme for the $+R$ and $-R$ substituents was not taken into account in the *FM* treatment. The better fit for the σ^+-type reactivities by the use of q_{ij}^{w} in place of q_{ij} is consistent with our observation, since the values of q_{ij}^{w} are approximately 2-fold of q_{ij}, respectively for conjugate positions. However, in such highly electrophilic reactivities, the unexalted *pi*-effect transmission scheme (the $q_{r,ij}^{0}$ set) was evidently retained for the $+R$ substituents even at a strongly conjugative position. Incorporated application of the M^+ parameters which were derived from σ^+ constant in Eq. (5), instead of M from σ, is reasonably expected to improve the situation,[39] since the higher ratio of q_{ij}^{+}/q_{ij}^{-} required for electrophilic reactivities may partly be adjusted by the exalted $-R/+R$ resonance contribution ratio of the σ^+ constants.[47] The authors however do not agree to the use of multiple sets of resonance parameters.[46]

Taft suggested that there is no universal set of resonance parameters (providing the parameter $\bar{\sigma}_R$ is defined by $\bar{\sigma}_p-\sigma_I$) and that at least four fundamental sets of the resonance parameters, σ_R,[0] σ_R, σ_R^{+}, and σ_R^{-}, should be

required for different reactivity classes.[48] Consequently in the case of $-R$ exalted-resonance reactivities, such as the present solvolysis in the naphthalene system, the σ_R^+ should be employed instead of σ_R^0 in Eq. (6) as the most suitable set for the substituents at strongly conjugative position. However, σ_R^0 should be still utilized for the substituents at non-conjugative 3α and 6α positions. There appears however to be no definite rule for the choice of the most proper set of the parameters for the substituents at intermediate or moderately strong conjugate 5α and 7α positions. The best parameter could only be chosen as to give a best fit correlation. Presumably such $\bar{\rho}_I$ and $\bar{\rho}_R$ values could not be compared with each other within the same series or between different sets of reactivities.

The success in describing the substituent effects in the naphthalene beyond the benzene derivatives provides strong support for the possibility that a unique set of σ_i and σ_π^+ substituent constants can be utilized practically as universal substituent constants.

The Effects of the Properties of Trunk Polymers on the Flocculating Action of Graft Copolymers

Namiko MIYATA, Isao SAKATA* and Ryoichi SENJU*

Nakamura Gakuen College, Befu, Nishi-ku, Fukuoka 814

**Department of Forest Products, Faculty of Agriculture, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812*

(Received January 27, 1975)

Acryl amide (AM) was graft copolymerized onto hydroxy ethyl cellulose(HEC), polyvinyl alcohol (PVA), amylose (AL), and amylopectin (AP), whose molecular extensions in an aqueous solution are different. The graft copolymers were then purified by means of fractional precipitation. The effects of the properties of the trunk polymers of the graft copolymers on their flocculating action for kaolin suspensions were examined. It was found that: 1) when the molecular weights ($\overline{M}_n$) of the copolymers were equal, their flocculating action was much influenced by the kind of trunk polymer (HEC, AL, PVA, and AP) and decreased in that order; 2) the differences in their flocculating action are due to the differences in their molecular extensions in an aqueous solution; and 3) the flocculating action of the copolymers increased with an increase in the $\overline{M}_w$ of the branched poly AM (PAM), but was, however, scarcely affected by a small number of grafted PAM per trunk polymer molecule.

High-molecular polyacrylamide (PAM) is now used in large amounts as a flocculant for the treatment of waste water; however, it has some disadvantages, *e.g.*, the abscission of its molecular chains easily occures in a dissolution process because of its high molecular weight. Consequently, the development of flocculants whose molecular weight is relatively low and whose flocculating action is superior to that of high-molecular PAM has been attempted.

It seemed, therefore, that it would be interesting to study the graft copolymers of cellulose, starch, *etc.*, as flocculants. Up to now, in some studies[1] of water-soluble graft copolymers as flocculants, the flocculating action of a reaction mixture composed of graft copolymers, homopolymers, and unreacted trunk polymers has been examined, but that of pure graft copolymers has not yet been investigated. Previously, the present authors[2] proved that the flocculating action of the fractionated water-soluble hydroxyethyl cellulose (HEC)-AM graft copolymers was superior to that of PAM because of the rigid molecular chains and the large molecular extension of HEC.

In this paper, in order to make the relation clearer between the flocculating action of the copolymers and their molecular extensions in an aqueous solution, the flocculating action of the fractionated graft copolymers of the trunk polymers, polyvinyl alcohol (PVA, flexible), amylose (AL), amylopectin (AP, branched) and HEC (rigid), which have different molecular chains, was studied. Moreover, the effects of the molecular weight and the number of the grafted PAM on the flocculating action of the copolymers were examined. Graft copolymerization was carried out by means of the Ce (IV) salt method.[3]

Experimental

Materials. PVA, AL, AP, and HEC: Commercial PVA, AL, AP, and high-molecular HEC (*h*-HEC) were used without further purification. Their molecular weights ($\overline{M}_n$) were 8×10^4, 7×10^4, 1.9×10^5, and 1.8×10^5 respectively. The degree of the hydroxyethylation of HEC was 1.2 as the molar substitution (MS).[4] Low-molecular HEC ($\overline{M}_n$ of *l*-HEC: 7×10^4) was synthesized as has been described in a previous paper.[2] Ammonium cerium(IV) nitrate, AM, CCl_4, and kaolin: they were described in a previous paper.[2]

Graft Copolymerization and Fractionation of Graft Copolymers. Graft Copolymerization: Graft copolymerization was carried out by the Ce(IV) salt method[3] under a stream of N_2 at 40 °C for 30—220 min. In a polymerization apparatus, 0.4 g of the trunk polymers, 2.0—2.5 g of AM, the fixed Ce salt, and HNO_3, and 40 ml of water were added. The concentrations of Ce salt for grafting onto PVA, HEC, AL, and AP were 1.3×10^{-4}—4.0×10^{-4} mol/l, 8.0×10^{-4}—2.2×10^{-2} mol/l 1.8×10^{-3}—2.2×10^{-2} mol/l, and 3.7×10^{-3}—2.2×10^{-2} mol/l respectively, while those of HNO_3 were 0.05—0.07 mol/l (PVA) and 0.014—0.28 mol/l (others). For the preparation of the graft copolymers with low-molecular grafted PAM, a 2—4 ml portion of CCl_4 was added to serve as a regulator.

Fractionation of Graft Copolymers: In order to obtain the fractionated graft copolymers, the precipitation properties of the trunk polymers and PAM in an aqueous acetone sytem were examined, as is shown in Fig. 1. It can be seen from

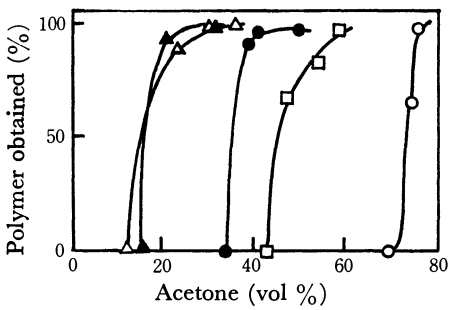

Fig. 1. The precipitation properties of the trunk polymers and PAM in an aqueous acetone system.
●: PAM, ○: HEC, □: PVA, △: Amylopectin, ▲: Amylose. 0.5% aqueous polymer solution at 30 °C.

Fig. 1 that the respective graft copolymers of HEC, PVA, AP, and AL are precipitated when the concentrations of acetone in a solution are 40—70%, 40—48%, 28—36%, and 23—36% respectively. The graft copolymers were precipitated fractionally at the above concentrations of acetone. These fractionated products were confirmed respectively by IR, turbidimetric titration in an aqueous acetone system, and the determination of the nitrogen by means of the Kjeldahl method.

Determination of the Molecular Weight and Intrinsic Viscosity ([η]). The molecular weight ($\overline{M}_n$) of the graft copolymers was measured with a 502-type high-speed membrane

osmometer manufactured by Hewlett Packard Co., while the molecular weights ($\bar{M}_w$ and $\bar{M}_n$) of the grafted PAM were determined from the following viscosity equations as has been described in a previous paper;[2] $[\eta]^{30°C}_{N\text{-}NaNO_3}=3.73\times10^{-4}\ \bar{M}_w^{0.66}$ and $[\eta]^{30°C}_{H_2O}=6.8\times10^{-4}\ \bar{M}_n^{0.66}$ [5]

Characterization of Graft Copolymers. This is shown in Table 1.

Flocculation Test. The flocculating action of the flocculants was measured by means of the sedimentation rate,[9] with a 25 ml graduated cylinder, and the transmittance of a supernatant solution, with a Shimadzu Bausch and Lomb Spectronic 20 colorimeter, which has been described in a previous paper.[2]

Results and Discussion

Effect of Difference in Kind of Trunk Polymers. Figures 2 and 3 show the effects of the difference in the kind of trunk polymers on the sedimentation rate and the transmittance respectively. Even though the $\bar{M}_n$ of the respective graft copolymers of *h*-HEC, *l*-HEC, AL, PVA, and AP are equal, the sedimentation rate and the transmittance decreased in that order, as is shown in Figs. 2 and 3.

It has been proposed[6,7] that the flocculation of kaolin suspensions with nonionic polymer flocculants is caused by a bridging of kaolin particles with the adsorbed poly-

mers. Consequently, their flocculating action must be determined by two factors. One is the molecular extension, which the molecular chains of the adsorbed polymers can bridge between particles; if the molecular extension of polymers in a solution is small, an interparticle bridging will be unfavorable. This is shown schematically in Fig. 4. The other is the adsorption properties of the flocculants on suspended particles. The adsorption properties of these graft copolymers on the kaolin particles used in this study were not determined. It seems, however, that the adsorption properties are almost identical because of the hydrophilic trunk polymers, which have only hydroxl groups. The difference in the flocculating action of these graft copolymers seems to arise from the difference in their molecular extensions caused by the properties of the trunk polymers. That is, the extension of the HEC graft copolymers seems to be the largest, because of the rigid molecular chains and the large extension of the trunk-polymer HEC. That of the AL graft copolymers appears to be the next largest, because AL has indeed bulky anhydrous glucose groups, just as HEC does, but it is not rigid. That of the PVA graft copolymers seems to be the third largest, because of the flexible and randomly coiled chains of PVA. The smallest one appears to be that of the AP graft copolymers, because of the small extension of AP on the ground of its branching chain structure.

Difference in Molecular Extension in an Aqueous Solution. The difference in the flocculating action of the graft copolymers seems to be due to the difference in their molecular extensions in an aqueous solution caused by the properties of the trunk polymers. In order to make sure of this, the molecular extensions of the graft copolymers were examined. No definitive theoretical equation of the molecular extensions of graft and block copolymers in an aqueous solution has yet been elucidated. It seemed that it would be interesting, however, to compare the extensions of the molecular chains by means of the dimensions (R_e: the radius) of Flory's non-draining equivalent sphere model.[8] The relation between R_e, the molecular weight ($\bar{M}$), and ($[\eta]$) is as follows: $[\eta]=KR_e^3/\bar{M}$[8] (K: constant). Consequently, $[\eta]\ \bar{M}_n$ was represented as the evaluation of the molecular extensions of the graft copolymers. When the $\bar{M}_n$ values of the copolymers are equal to each other, the molecular extensions ($\bar{M}_n[\eta]$) of the respective graft copolymers of HEC, AL, AP, and PVA decreased in that order, as is shown in Fig. 5. The order of the flocculating action of

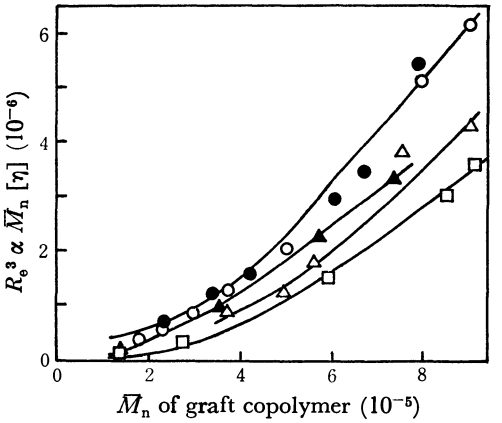

Fig. 5. Relation between the molecular extensions ($\bar{M}_n[\eta]$) and the $\bar{M}_n$ of the graft copolymers.
Symbols are the same as those in Fig. 2.

the graft copolymers was well in accord with that of their molecular extensions ($\bar{M}_n[\eta]$), except that the graft copolymers of PVA and AP were reversed. The plots of the extensions of the graft copolymers *vs.* the transmittance and the sedimentation rate gave an approximately linear relation regardless of the kind of the flocculants used in this study, as is shown in Fig. 6.

In conclusion, the difference in the flocculating action of the graft copolymers must be due to the difference in their molecular extensions in an aqueous solution, determined on the basis of the properties of the trunk poly-

mers.

Effects of the Molecular Weight and Number of the Branched PAM of Graft Copolymers. Figures 7 and 8 show the effects of the molecular weight ($\bar{M}_w$) of the branched PAM of the graft copolymers on the sedimentation rate and the transmittance of a supernatant solution respectively. As is shown in Fig. 7, the sedimentation rate increased with an increase in the $\bar{M}_w$ of the branched PAM in all the different trunk polymers. This result suggests that kaolin particles are sedimented by means of the bridging mechanism.[6] That is, the higher the $\bar{M}_w$ is, the more effective the bridging flocculation may be. The transmittance also increased with the increase in the $\bar{M}_w$ as well as the sedimentation rate, up to 3.5×10^6 of the $\bar{M}_w$ of the branched PAM. However, at the $\bar{M}_w$ values above that value, there was little effect of the $\bar{M}_w$ on the

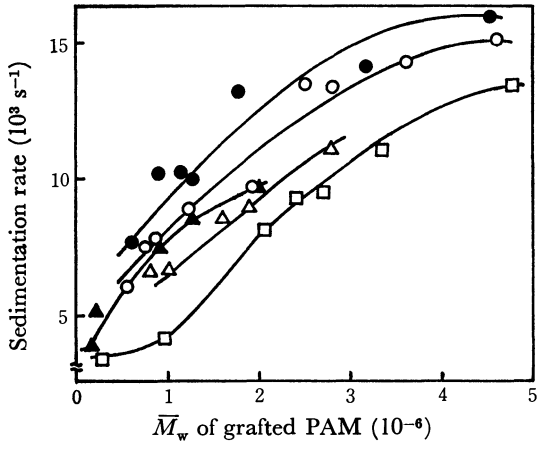

Fig. 7. Effect of the $\bar{M}_w$ of the grafted PAM of the graft copolymers on the sedimentation rate.

Dosage of flicculant: 1 mg/l suspension.

clarification. This may be because the clarification results from the reduction of the electrostatic repulsion between the colloidal fine particles, which could not be sedimented thoroughly by the bridging alone.

When the $\bar{M}_w$ values of the branched PAM were equal to each other, the flocculating action of the respective graft copolymers of HEC, AL, AP, and PVA decreased in that order. The difference in their flocculating action seems to be due to the difference in the molecular extensions caused by the properties of the trunk polymers. This was discussed before. The flocculating action of the *h*-HEC graft copolymers was superior to that of the *l*-HEC graft copolymers even if the $\bar{M}_w$ values of their branched PAM were equal. This must be due to the easier bridging with the former compared with the latter, because the molecular weight ($\bar{M}_n$) of the former was, as a whole, higher than that of the latter.

Figure 9 shows the effect of the number (1—3) of the

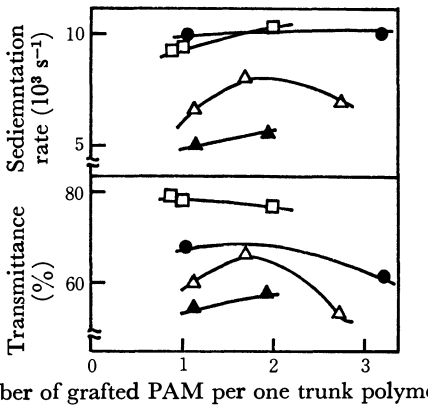

Fig. 9. Effect of the number of the grafted PAM per one trunk polymer molecule on the sedimentation rate and the transmittance of 3% kaolin suspensions.
$\bar{M}_n$ of grafted PAM:
●: *h*-HEC graft copolymer (4.0×10^5)

Dosage of flocculant: 1 mg/l suspension.

branched PAM on the sedimentation rate and the transmittance. The flocculating action of the graft copolymers which had two branched PAM was a little superior to that of others. However, on the whole, the flocculating action was scarcely affected by the number of the branched PAM, even if the kind of the trunk polymer was different.

Aromatic Substitution of Olefins. XXII. Unusual Reaction of *p*-Bromostyrene with Benzene in the Presence of Palladium(II) Acetate[1]

Hidetsugu TANAKA, Yuzo FUJIWARA, Ichiro MORITANI, and Shiichiro TERANISHI

Department of Chemistry, Faculty of Engineering Science, Osaka University, Machikaneyama, Toyonaka, Osaka 560

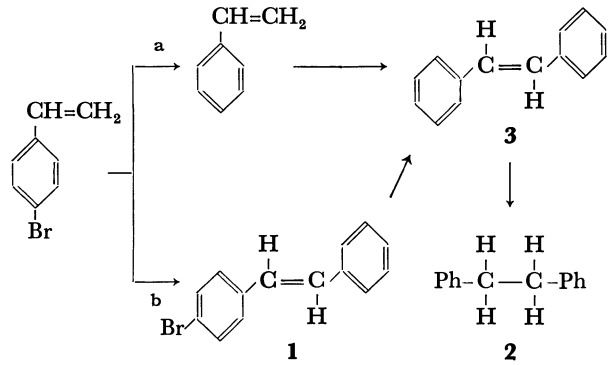
(Received June 19, 1975)

Synopsis. The reaction of *p*-bromostyrene with benzene in the presence of palladium(II) acetate gave unexpected bibenzyl (**2**) and *trans*-stilbene (**3**) in 12% and 5% yields respectively, in addition to the usual substitution product (**1**, 47%). This result shows that dehalogenation and subsequent hydrogenation accompany the aromatic substitution of olefins when both iodides and bromides are used.

We have reported a novel reaction of olefins with aromatic compounds to produce aromatic-substituted olefins *via* direct substitution in the presence of palladium (II) salts.[2]

In the course of our study on the aromatic substitution of olefins, we have performed the reaction of *p*-bromostyrene with benzene in the presence of $Pd(OAc)_2$ in the hope of obtaining *p*-bromo-*trans*-stilbene as the sole product. However, from this reaction, we obtained bibenzyl (**2**) and *trans*-stilbene (**3**) in yields of 12% and 5% respectively with a 47% yield of the usual substitution product, *p*-bromo-*trans*-stilbene (**1**).[3] This suggested that the bromine atom of bromostyrene was replaced with hydrogen by the action of $Pd(OAc)_2$. To chek this point, the dehalogenation and hydrogenation of halobenzenes with $Pd(OAc)_2$ were examined. Refluxing of bromobenzene with $Pd(OAc)_2$ gave the hydrogenolysis product (benzene) in 16% yield and, from iodobenzene, a 55% yield of benzene was obtained.[4]

These results show that $Pd(OAc)_2$ causes the dehalogenation-hydrogenation reaction and that the reactivity of halobenzenes is I>Br≫Cl. Thus it would be possible to describe two paths (a and b) for formation of **3**: one is the route *via* styrene which is derived from a debromination-hydrogenation of *p*-bromostyrene, and the other is the route involving a debromination-hydrogenation of **1**, which is the usual aromatic substitution product.[5] Compound **2** is formed *via* hydrogenation of **3**.[5] The reaction paths are shown in the following Scheme:



It has been reported that low-valent palladium reacts with halides (RX) to form organopalladium σ-complexes (R–Pd–X) *in situ*.[6] In the present case, an aryl-palladium σ-complex such as (H_2C=CH-  -PdBr) would also be formed, *via* the oxidative addition of Pd, but it would be decomposed by hydrogen to give hydrogenolysis products[5] without any further reaction with the olefins.

The results described here call for attention when halides, especially iodides and bromides, are employed in the aromatic substitution of olefins by palladium (II) salts.

Experimental

p-Bromostyrene was prepared from dehydration of 1-(*p*-bromophenyl)ethanol, bp_{16} 88—89 °C.

Reaction of p-*Bromostyrene with Benzene.* A solution of $Pd(OAc)_2$ (4.6 mmol), and *p*-bromostyrene (4.6 mmol) in a mixture of benzene (50 ml) and acetic acid (10 ml) was heated at 80 °C with stirring for 8 hr. The resulting mixture was worked up as described already.[7] The products were separated by preparative glc to give **1**, **2**, and **3**, which were all assigned by a comparison with authentic samples, mp of **1**, 138—139 °C (EtOH) (lit,[8] mp 139 °C).

Dehalogenation-hydrogenation of Aryl Halides. A solution of $Pd(OAc)_2$ (4.6 mmol) and bromobenzene (50 ml) was refluxed for 8 hr using octane as an internal standard. After work-up, glc analysis showed a 16% yield of benzene. Similarly, iodobenzene was refluxed using nonane as an internal standard to give a 55% yield of benzene. Under similar reaction conditions, chlorobenzene did not result in any formation of benzene.

Nuclear Magnetic Resonance Studies of Bicyclic Thiophene Derivatives. III. Through Space H-F Coupling over Seven Bonds

Toshiyuki HIROHASHI, Shigeho INABA, and Hisao YAMAMOTO

Institute for Biological Science, Sumitomo Chemical Co., Takatsukasa, Takarazuka, Hyogo 665

(Received October 18, 1974)

Synopsis. Bicyclic thiophene derivatives, 1,5-dimethyl-(**1**) and 3,5-dimethyl-4-(*o*-fluorophenyl)-1,2-dihydrothieno[2,3-*d*]-pyrimidin-2-ones (**3**), 2-acetylamino-3-(*o*-fluorobenzoyl)-4-methylthiophene (**5**), and some derivatives (**2**, **4**, **6**, **7**), have been prepared. ^{1}H, ^{19}F Spin couplings over seven bonds, $^7J_{HF}$, attributable to a through-space mechanism have been observed in the ^{1}H NMR spectra of these compounds.

In a previous paper,[1] we reported that long-range spin couplings over six bonds were observed between the fluorine and H_β of the thiophene rings in 4-(*o*-fluorophenyl)thienopyrimidines, 2-acetylamino-3-(*o*-fluorobenzoyl)thiophenes, 5-(*o*-fluorophenyl)-1,4-thienodiazepines, and 5-(*o*-fluorophenyl)-1,4-thienodiazepine-4-oxides, the synthesis of all of which are of interest biologically. The coupling was considered to arise from a through-space mechanism.[2] Thus, we have examined the ^{1}H NMR spectra of other kinds of bicyclic thiophene derivatives, **1**—**7**, and discovered that there are long-range spin couplings between methyl or dichloromethyl protons of the thiophene ring and the fluorine of the benzene ring over seven bonds, $^7J_{HF}$, which were also considered to be through-space couplings, as has hitherto been reported in a few papers.[3-6] In this paper, we will present our experimental results on the $^7J_{HF}$ found in these new compounds.

TABLE 1. NMR DATA ON BICYCLIC THIOPHENE DERIVATIVES

Compound	$^7J_{HF}$ (Hz)	δ (β-CH_3)	δ(H_α)	δ (NH)
1	1.0	1.85[a]	6.55	—
2	1.1	1.81	—	—
3	b)	1.50[c]	6.55	—
4	1.0	1.94[d]	6.86	—
5	0.5	1.73[e]	6.33	11.92
6	0.5	1.69	—	11.90
7	0.7	6.09[f]	—	—

a) $^4J(H_\alpha,5\text{-}CH_3)=1.1$ Hz. b) Not detectable. c) $^4J(H_\alpha,5\text{-}CH_3)=1.4$ Hz. d) $^4J(H_\alpha,5\text{-}CH_3)=1.1$ Hz. e) $^4J(H_\alpha,4\text{-}CH_3)=1.0$ Hz. f) Chemical shift of the dichloromethyl proton.

As is shown in Table 1, the β-methyl signals of the thiophene ring in **3** exhibited no detectable coupling with the fluorine. However, in **1** and **4**, which are isomers of **3**, $^7J_{HF}$ was observed (both 1.0 Hz). On the chlorination of the α-position of the thiophene ring, $^7J_{HF}$ was not practically influenced (in **2**, 1.1 Hz). The difference between the J_{HF} in **3** and those in **1**, **2**, and **4** should be due to the difference in steric hindrance; the torsional angle between the thiophene and the benzene planes should be greater for **3** than for **1**, **2**, and **4** as a result of the steric hindrance between the benzene and the *N*-methyl group in **3**. Accordingly, the internuclear distance between the fluorine and the methyl protons in **3** is so long that the through space coupling can not be detected. The dichloromethyl proton signal in **7** appears as a doublet (J=0.7 Hz), whose spacing is smaller than that of **2** (J=1.1 Hz). The difference might arise from the fact that, since the dichloromethyl group is bulkier than the methyl group, the torsional angle between the thiophene and the benzene planes should be greater for **7** than for **2**. Furthermore, $^7J_{HF}$ was also observed between the methyl protons of the thiophene ring and the fluorine in **5** and **6** (J=0.5 Hz). The difference between the $^7J_{HF}$ in **5** and **6** and those in **1** and **2** is probably due to the difference in the torsional angle between the thiophene and the benzene planes; the angle should be greater for **5** and **6** than for **1** and **2**, as has been reported in the case of $^6J_{HF}$ in the previous paper.[1]

Experimental

Measurements. The ^{1}H NMR spectra (δ, ppm) were recorded on a Hitachi R-20-B spectrometer at 60 MHz and at a probe temperature of 35 °C, using $CDCl_3$ solutions (about 10% w/v), with TMS as the internal reference. The chemical shifts are expressed in δ with a precision of $\pm$0.01. The coupling constants were measured by several sweepings at an expanded sweep width (60 or 120 Hz) with an accuracy of $\pm$0.1 Hz. The IR spectra (wave number, cm^{-1}) were recorded as Nujol mulls on a Hitachi EPI-G-3 spectrophotometer. The UV spectra (wavelength, nm) were determined in 95% ethanol with a Hitachi-323 spectrophotometer. The melting points were measured on a Thomas-Hoover melting-point apparatus and are uncorrected.

Materials. The Synthetic Procedures for 4-(o-Fluorophenyl)-1,5-dimethyl-1,2-dihydrothieno[2,3-d]-pyrimidin-2-one (1), 4-(o-

Fluorophenyl)-3, 5-dimethyl-2, 3-dihydrothieno[*2, 3*-d]-*pyrimidin-2-one (3), and 4-(*o-*Fluorophenyl)-2-methoxy-5-methylthieno*[*2,3*-d]-*pyrimidine (4)*: 2-Amino-3-(*o*-fluorobenzoyl)-4-methylthiophene was prepared from *ω*-cyano-*o*-fluoroacetophenone and mercaptoacetone as reported in a previous paper.[7] It was then heated with ethyl cabamate to give 4-(*o*-fluorophenyl)-5-methyl-1,2-dihydrothieno[2,3-*d*]-pyrimidin-2-one, which was methylated with methyl iodide to afford Compounds **1**, **3**, and **4**.

*2-Amino-3-(*o-*fluorobenzoyl)-4-methylthiophene.* Yield, 35.5%, mp 163—164 °C (from ethanol). IR: 3320, 3200, 3100, 1590, and 1560.

*4-(*o-*Fluorophenyl)-5-methyl-1,2-dihydrothieno*[*2,3*-d]-*pyrimidin-2-one.* Yield, 76.1%, it was used the next step without any further purification.

Compound 1. Yield, 18.0%, mp 275—277 °C (from $CHCl_3$–ethanol). IR: 3050, 1658, 1643, and 1608. NMR: 1.85 (3H, d-d, 5-CH_3), 3.75 (3H, s, *N*-CH_3) and 6.55 (1H, q, H_α). UV: 251 (26100) and 346 (5100). Found: C, 61.30; H, 4.17; N, 10.24%. Calcd for $C_{14}H_{11}N_2OSF$: C, 61.30; H, 4.04; N, 10.21%.

Compound 3. Yield, 10.0%, mp 178—181 °C (from $CHCl_3$–ethanol) IR: 3050 and 1655. NMR: 3.41 (3H, d, *N*-CH_3). UV: 220 (19700), 255 (23700), 295 (3000) and 373 (3900). Found: C, 61.33; H, 4.09; N, 10.10%. Calcd for $C_{14}H_{11}N_2OSF$: C, 61.30; H, 4.04; N, 10.21%.

Compound 4. Yield, 4.4%, mp 177—179 °C (from $CHCl_3$–ethanol). IR: 3065 and 1615. NMR: 1.94 (3H, d-d, 5-CH_3), 4.11 (3H, s, OCH_3) and 6.86 (1H, q, H_α). UV: 244 (34600) and 316 (3500). Found: C, 61.30; H, 4.17; N, 10.24%. Calcd for $C_{14}H_{11}N_2OSF$: C, 61.30; H, 4.04; N, 10.21%.

The other compounds were prepared according to the methods described previously.[7]

*2-Acetylamino-3-(*o-*fluorobenzoyl)-4-methylthiophene (5).* Yield, 74.0%, mp 96—96.5 °C (from ether). IR: 3200, 3080, 1690, and 1600. UV: 244.5 (10300), 282.5 (10700), and 351 (6400). Found: C, 60.84; H, 4.32; N, 5.14%. Calcd for $C_{14}H_{12}NO_2SF$: C, 60.64; H, 4.36; N, 5.05%.

*2-Acetylamino-5-chloro-3-(*o-*fluorobenzoyl)-4-methylthiophene (6).* Yield, 82.4%, mp 140—140.5 °C (from ether). IR: 3180, 1695 and 1605. UV: 250 (14400) and 358 (6700). Found: C, 53.86; H, 3.43; N, 4.29%. Calcd for $C_{14}H_{11}NO_2SClF$: C, 53.94%; H, 3.56; N, 4.49%.

*6-Chloro-1, 5-dimethyl-4-(*o-*fluorophenyl)-1, 2-dihydrothieno*[*2, 3*-d]-*pyrimidin-2-one (2).* Yield, 34.5%, mp 175—176 °C (from ethanol–ether). IR: 1660 and 1610. UV: 255 (26000) and 353 (5500). Found: C, 54.71; H, 3.44; N, 8.97%. Calcd for $C_{14}H_{10}N_2OSClF$: C, 54.46; H, 3.26; N, 9.07%.

*6-Chloro-5-dichloromethyl-4-(*o-*fluorophenyl)-1-methyl-1, 2-dihydrothieno*[*2,3*-d]-*pyrimidin-2-one (7).* This was prepared from **1** with an excess of sulfurylchloride. Yield, 28.2%, mp 215—216 °C. IR: 1675 and 1610. UV: 219 (19300), 251 (16900), 282 (8000), and 347 (6000). Found: C, 44.46; H, 2.19; N, 7.55%. Calcd for $C_{14}H_8N_2OSCl_3F$: C, 44.52; H, 2.13; N, 7.42%.

The authors wish to thank Professor Masamichi Tsuboi, The University of Tokyo, and Dr. Makoto Sunagawa of this Institute for valuable suggestions, and Mr. Hiromi Sato for his cooperation in the synthetic experiments.

ESR Studies of the Triplet-state Dimers of Michler's Ketone Metal Ketyls in Glassy Solutions

Hideo FUJITA, Saburo KAKO, Hiroaki OHYA-NISHIGUCHI,* and Yasuo DEGUCHI

Department of Chemistry, College of Liberal Arts and Sciences, Kyoto University, Kyoto 606

**Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606*

(Received February 15, 1975)

Synopsis. The ESR spectra (the $\Delta M_s = \pm 1$ and $\Delta M_s = \pm 2$ transitions) of the triplet-states of Michler's ketone metal ketyl dimers are observed in glassy solutions at 77 K. For these metal ketyl dimers, the correlation of the mean separation between spins to the radius of the counter cation was experimentally examined.

Several ESR studies have shown that the ESR spectra due to the magnetic dipole-dipole interactions of spins in glassy solutions can offer important information on the electronic and geometrical structures of the biradical-like dimeric species.[1-5]

In a previous paper,[6] it has been shown that, in the 4,4'-tetramethyldiaminobenzophenone (Michler's ketone) anion radical, the unpaired electron is mainly localized in the vicinity of its carbonyl group.[7]

In the present paper the authors will report their observations of the ESR spectra of the triplet-state in the system of Micher's ketone metal ketyls as produced by several alkali metals in ethereal solvents.

Experimental

A commercially obtained Michler's ketone was purified by recrystallization from ethyl alcohol (mp 179 °C). Its metal ketyls were prepared by the standard alkali metal reduction method, while both ketyls with lithium and calcium were prepared by the use of amalgams of both metals. The solvents used in the present study were 2-methyltetrahydrofuran (MeTHF), tetrahydrofuran (THF), 1,2-dimethoxyethane (DME), diethylene glycol dimethyl ether (diglyme), and triethylene glycol dimethyl ether (triglyme), each of which was treated by the standard purification method.

The ESR spectra were observed at 77 K by means of an X-band ESR spectrometer (JEOL ME-3) with 100 kHz field modulation. The zero-field splitting (ZFS) parameter, D, was determined by measuring the peak-to-peak separation of the $2F$ splitting, because no ZFS parameter, E, could be observed (see Fig. 1). The intensity of the weak signal for the half-field ($\Delta M_s = \pm 2$) transition was enhanced by the signal accumulation method of 32 or 64 scans by using a JEOL EC-6-type spectral computer. Thus, the ESR signals for the $\Delta M_s = \pm 2$ transitions could be observed in every case listed in Table 1. The magnetic field was calibrated by the hyperfine splittings of Mn^{2+} doped in MgO and of ^{14}N of the peroxylamine-disulfonate ion. The spectral simulations were carried out at the Computer Center of Kyoto University.

Results and Discussion

In Fig. 1 the observed and simulated ESR spectra of the triplet-state of Michler's ketone lithium ketyl dimer in MeTHF are shown as examples. In Fig. 1 (a), which depicts the spectrum for the full-field ($\Delta M_s =$

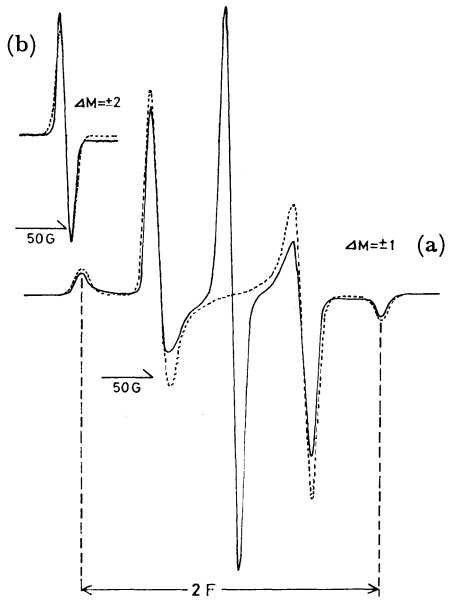

Fig. 1. The full line is the observed ESR spectrum of the triplet-state of Michler's ketone lithium metal ketyl dimer in MeTHF at 77 K, and the dotted line is its simulated one.

In the spectrum for the $\Delta M_s = \pm 1$ transition (a), the ZFS parameter D is 140.5 G. The spectrum for the $\Delta M_s = \pm 2$ transition (b) was enhanced by accumulation of 32 scans of the signal with the computer.

TABLE 1. THE ZERO-FIELD SPLITTING PARAMETERS FOR MICHLER'S KETONE METAL KETYL AT 77 K

Solvent and cation		$\lvert D \rvert$ (G)	$\lvert D \rvert / hc$ (cm^{-1})	$\bar{r}_{1,2}$ (Å)
MeTHF	Li^+	140.5	0.01312	5.83
	Na^+	113.8	0.01063	6.26
	K^+	97.6	0.00911	6.59
	Rb^+	84.4	0.00788	6.92
	Cs^+	75.2	0.00702	7.19
	Ca^{2+}	118.2	0.01104	6.19
THF	Li^+	119.4	0.01115	6.16
	Na^+	112.3	0.01049	6.29
	K^+	94.6	0.00883	6.66
	Rb^+	93.5	0.00873	6.68
	Cs^+	86.4	0.00807	6.86
	Ca^{2+}	102.9	0.00961	6.47

	Na^+	105.3	0.00983	6.42
	K^+	96.9	0.00905	6.61
	Rb^+	89.3	0.00834	6.79
	Cs^+	69.9	0.00653	7.37
	Ca^{2+}	101.9	0.00952	6.49

± 1) transitions, the sharp central absorption can be assigned to the paramagnetic monomer, its integrated intensity being about 10 per cent of the total absorption. Then, the residual part of the absorption (about 90 per cent) is attributable to the paramagnetic dimer.

In Fig. 1(a) the measured value of the ZFS parameter, D, is 140.5 G ($2F$=281.0 G), where the microwave frequency used is 9198.0 MHz and the g-value is 2.0036. The values of the ZFS parameter, D, as measured in different combinations of cations and solvents are summarized in Table 1.

The spectral simulations carried out under the assumption of the ZFS parameter, E, being zero are exhibited as dotted lines in Figs. 1(a) and (b). These simulated spectra fit well with those observed. From these results, we may safely conclude that $E=0$ in the ground-triplet-state spin Hamiltonian. Then, using the theoretical ZFS parameter, D ($D=-2/3g^2\beta^2\langle 1/r_{1-2}^3\rangle$),[1,2] the average distances ($\bar{r}_{1,2}$) between two unpaired electrons in every dimer for these metal ketyls are calculated and tabulated in Table 1, where the values of $\bar{r}_{1,2}$ measured in DME and triglyme are omitted since they are nearly equal to the corresponding values of diglyme.

In Fig. 2 the values of $\bar{r}_{1,2}$ for the system of MeTHF in

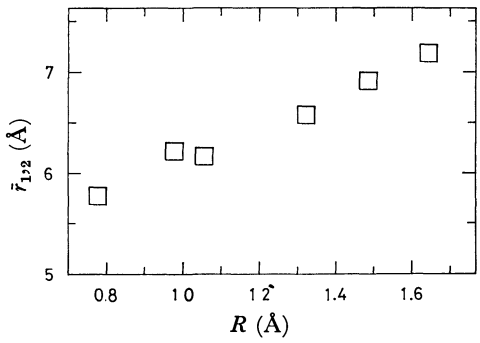

Fig. 2. The values of $\bar{r}_{1,2}$ in MeTHF are plotted against the values of R.

Table 1 are plotted against the radius (R) of the counter cations, for each of which the values of Goldschmidt's ionic radii (Li^+, 0.78; Na^+, 0.98; K^+, 1.33; Rb^+, 1.49; Cs^+, 1.65; and Ca^{2+}, 1.06 Å) were adopted.[8] The fact that $\bar{r}_{1,2}$ increases linearly with an increase in R may be understood if one considers each model as having either a triple-ion structure $(Me_2N\phi)_2CO^-M^+{}^-OC(\phi NMe_2)_2$ or an ion-quadruplet structure $(Me_2N\phi)_2CO^-{}^{M^+}_{M^+}{}^-OC(\phi NMe_2)_2$ with respect to two ketyls.[3,5,9] However, theoretical or quantitative explanation for this result is not yet available.

The authors are sincerely grateful to Professor Kohichi Itoh of Osaka University for offering the simulation program of the triplet-state ESR spectrum and also for his useful suggestions during the course of this work. They are also indebted to Dr. Jun Yamauchi and his collaborators for their helpful discussions.

The Dehydration and Dehydrogenation of Ethanol Catalyzed by TiO_2–ZrO_2

Kazushi ARATA and Hiromitsu SAWAMURA
Hokkaido University of Education, Hachiman-cho, Hakodate 040

(Received February 17, 1975)

Synopsis. Ethanol was converted into ether, ethylene, and butadiene over TiO_2–ZrO_2 with various contents of ZrO_2 in a flow system. Maximum acidity and activity were obtained at 50% ZrO_2. The butadiene formation was explained by both dehydration and dehydrogenation reactions on acidic and basic sites, implying that TiO_2–ZrO_2 is an acid-base bifunctional catalyst.

Binary metal oxides such as SiO_2–ZrO_2,[1] TiO_2–ZnO,[2] and SiO_2–TiO_2[3] have been found to show remarkable acidic properties and catalytic activity. Shibata and Kiyoura have recently found a new mixed oxide, TiO_2–ZrO_2, which exhibits a quite significant acidic property,[4] and Watanabe *et al.* have showed that its catalytic activity for the amination reaction of phenol to aniline was higher than that of SiO_2–Al_2O_3.[5]

The present study was undertaken to examine the correlation between the acidic property of TiO_2–ZrO_2 and its catalytic activity, as well as the selectivity for the reaction of ethanol.

Experimental

Catalyst. TiO_2–ZrO_2 of various compositions was prepared by two different methods reported by Shibata *et al.*[4] (1): a 1850 ml of 2.16 M ammonia water was added at the rate of 10 ml/min to a mixed aqueous solution (11 of 1 M) of titanium tetrachloride and zirconium oxychloride with stirring. (2): a mixed aqueous solution (5 l of 0.2 M) of titanium tetrachloride, zirconium oxychloride, and an excess amount of urea (300 g=5 M) was heated on a boiling water bath for 6—9 h.

The precipitates prepared by both methods were washed thoroughly with distilled water until no chloride ions were detected in the filtrate. They were dryed in air at 110 °C for 30 hr and finally calcined in air at 500 °C for 3 h.

Properties of Catalyst. The acidic properties of the catalysts were determined by the titration method with *n*-butylamine using a series of Hammett indicators. The differential thermal analyses were obtained in the range from room temperature to 720 °C.

Reaction Procedure and Analyses. The reaction was carried out by a conventional flow method using nitrogen as carrier gas at 300—360 °C. Ethanol, purified by distillation over anhydrous calcium oxide, and nitrogen were passed through the catalyst bed (2 g) at the flow rates of 7.5 ml/h and 1.0 l/h, respectively. The reaction products were analyzed by a gas chromatograph with FID using a column of PEG 1000 on Flusin T. The catalytic activity and selectivity were obtained from the product yields, given by the gas chromatograph peak areas (uncorrected), at 25 min after the reaction was initiated.

Results and Discussion

The catalytic activity of TiO_2–ZrO_2 (1: 1) precipitated by ammonia was 20% higher than that by urea.

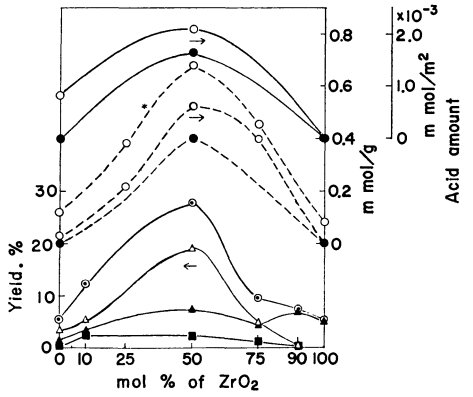

Fig. 1. Catalytic activity and acidity ($pK_a=-3.0$) of TiO_2–ZrO_2.
Reaction temperature: 300 °C, total conversion (—⊙—), yield of ether (—△—), ethylene (—▲—), butadiene (—■—).
Acidity: (○) and (●), for the samples precipitated by urea and ammonia, respectively; solid line, mmol/m²; broken line, mmol/g.
*$pK_a=6.8$.

Therefore, the TiO_2–ZrO_2 catalysts with various compositions prepared by the former method were mainly studied. The amount of acetaldehyde formed by the dehydrogenation of ethanol was almost negligible over all of the catalysts.

The catalytic activity, that is, the total conversion of ethanol, fairly well correlated with the acitidy*, as is shown in Fig. 1. TiO_2–ZrO_2 (1: 1) was most active, and the amount of ether formed was larger than that of ethylene. It is of interest that the total acidity of the sample prepared by urea was higher than that by ammonia, and the shapes of the curves were similar.

The catalytic conversion of ethanol to butadiene has been reported to proceed over solid acids such as Al_2O_3–ZnO,[6,7] though those to ethyl ether and ethylene are usually observed when catalyzed by ordinary solid acids. Therefore, this reaction was tested over the ZnO catalyst, which was prepared by the same procedure as TiO_2–ZrO_2, *i.e.*, the ammonia precipitation of $ZnCl_2$

* The acid amounts of TiO_2–ZrO_2 (1: 1) at various acid strengths were determined. The sample precipitated by ammonia showed 0.563 ($pK_a=6.8$), 0.440 (3.3), 0.363 (1.5), 0.400 (−3.0), 0.140 (−5.6), and 0.073 (−8.2), while the sample precipitated by urea exhibited 0.684 ($pK_a=6.8$), 0.460 (2.0), 0.520 (−3.0), 0.414 (−5.6), and 0.250 (−8.2). The acid amount of the sample prepared by urea was higher at each acid strength, in contrast to the observations with TiO_2–ZnO.[2] The amount at $pK_a=1.5$ or 2.0 was lower than that at $pK_a=-3.0$ in both samples, although the former value should be higher than the latter one. These unusual but interesting results seem to suggest an unusual surface property of TiO_2–ZrO_2.

aqueous solution. The products at 340 °C were 9.6% ethyl ether and 3.8% ethylene (13.4% in the total conversion). The butadiene yield increased at the higher reaction temperature, 330 °C, to 0.7, 2.3, 4.8, 12.4, 7.3, and 2.1% for ZrO_2, TiO_2–ZrO_2 (1: 9, 1: 3, 1: 1, 9: 1), and TiO_2, respectively. TiO_2–ZrO_2 (1: 1) also showed the highest activity for the formation of butadiene as well as that of ethylene and ethyl ether. Niiyama and coworkers have studied the butadiene formation from ethanol over SiO_2–MgO, which is an acid-base bifunctional catalyst, and concluded that the rate-controlling step is the acetaldehyde formation catalyzed by the basic sites.[8] Thus, it seems likely that the TiO_2–ZrO_2 catalyst also has basic sites which are effective for producing butadiene, and that the basicity increases by mixing TiO_2 and ZrO_2. In fact, TiO_2–ZrO_2 (1: 1) changed 2,4,6-trinitroaniline ($pK_a=12.2$) to its basic color, though B.T.B. ($pK_a=7.2$) did not change visibly to the basic color over TiO_2 and ZrO_2.

Table 1. Catalytic activity and selectivity of ZrO_2 for dehydration of ethanol at 360 °C

Temperature of calcination (°C)	Acidity[a] ($pK_a=6.8$) (mmol/g)	Conversion (%)	Products (%)

500	0.077	30.8	29.1	1.7
600	0.047	30.0	29.0	1.0

a) 0.230, 0.237 mmol/g at 200, 300 °C, respectively.

ZrO_2 produced no ether, resulting in a high selectivity for ethylene. A similar selectivity by ZrO_2 was also observed in the dehydration of *sec*-butanol, where 1-butene was formed in more than 90% selectivity.[9] The catalytic activity and selectivity of ZrO_2 at 360 °C are shown in Table 1. High selectivity for ethylene and also for butadiene implies that basic sites exist on this catalyst. Yamaguchi *et al.* also pointed out the basic character of ZrO_2 from its catalytic action in the isomerization of 1-butene.[9]

The strong exothermic peak at around 410 °C observed in DTA with ZrO_2, which is assigned to the crystallization of the amorphous state, moved to 510 to 640 °C as the ratio of TiO_2 mixed increased from 1: 9 to 1: 3. However, no peak was detected up to 720 °C with TiO_2–ZrO_2 (1: 1), probably being observed at above 720 °C. These discrepancies of peak might be related to acidity and catalytic activity.

We wish to express our thanks to Professor Kozo Tanabe (Faculty of Science, Hokkaido University) for his suggestions and interest in this work. Partial support of this work by Hokkaido Science Research Foundation is also gratefully acknowledged.

X-Ray Photoelectron Spectroscopy of 1,10-Phenanthroline Metal Chelates

Tooru YOSHIDA and Shigemasa SAWADA

Osaka Prefectural Industrial Research Institute, Enokojima, Nishi-ku, Osaka 550

(Received March 20, 1975)

Synopsis. Photoelectron spectra of several phenanthroline metal chelates were measured and the shifts of the N(1s) binding energy were plotted against the electronegativities of the metals. The plotted points appeared to fall into two groups, one for transition-metal chelates and the other for the other metal chelates.

The use of X-ray photoelectron spectrometry (XPS) to determine the effect of co-ordination on the electron density of a ligand is based on the fact that changes in the electron density about an atom are reflected in changes of the binding energies of the core electrons. The authors have previously reported results on the XPS of several metal chelate compounds.[1-3] It is well known that 1,10-phenanthroline (phen) and 2,2′-bipyridine (bipy), both having electron-donating and accepting capabilities, form very stable complexes with various cations, especially the Fe(II) ion.[4]

In this note, the results for several phen and bipy metal chelates using an XPS method will be presented.

Binding energies were measured employing an AEI ES200 photoelectron spectrometer under the control of a DS100/32 computer data-processing system using AlK_α radiation (E=1486.6 eV) as the photon source. All the metal complexes given in Table 1 were prepared according to the procedures of Schilt and Taylor.[5] The samples were ground to powder, dusted onto double-backed adhesive tape, and set inside the measuring chamber. The measurements were run at room temperature under a vacuum of about 10^{-7} Torr. However, a freezing technique was used for a few volatile samples.

The binding energy of the O(1s) peak was used as the energy standard throughout the present experiments; it was taken to be 532.0 eV, the O(1s) binding energies for all the samples being assumed to be constant. The C(1s) peak was, however, used for compounds having no perchlorate group as a constituent.

TABLE 1. N(1s) ELECTRON BINDING ENERGY VALUES

Samples	B.E. of N(1s)[a] (eV)	ΔE[b] (eV)	χ[c]	r[d] (Å)	pK[e]
phen	398.9				
phen(H_2O)	398.9				
phen($HClO_4$)	401.2; 398.9				
Mn(II)(phen)$_3$(ClO_4)$_2$	399.6	0.7	1.5	0.80	10.1
Fe(II)(phen)$_3$(ClO_4)$_2$	399.9	1.0	1.8	0.74	21.3
Co(II)(phen)$_3$(ClO_4)$_2$	399.7	0.8	1.8	0.72	19.9
Ni(II)(phen)$_3$(ClO_4)$_2$	399.7	0.8	1.8	0.69	24.8
Cu(II)(phen)$_2$(ClO_4)$_2$	399.9	1.0	1.9	0.72	11.0

Ni(II)(bipy)$_3$(ClO_4)$_2$	399.6	0.7			

a) Uncertainties are less than or equal to ±0.2 eV. b) Chemical shift of the N(1s) electron binding energy. c) Pauling electronegativity of the metal. d) Ionic radius of the metal. e) The logarithms of the overall stability constants of the chelates.[10] f) The value corrected according to Pauling.[12]

The measured values for the N(1s) electron binding energies are listed in Table 1 with other constants reported in the literature. Figure 1 shows the N(1s) electron spectra of phen($HClO_4$) and Fe(II)(phen)$_3$(ClO_4)$_2$. As can be seen from the figure, there are two kinds of nitrogen atoms in phen($HClO_4$), in addition to those observed in bipy($HClO_4$). The N(1s) spectrum of phen is a single peak with a full width at half height (FWHH) of 1.4 eV, and its binding energy value, 398.9 eV, agrees well with that of the peak with the lower binding energy of the two in phen($HClO_4$). Therefore, it can be concluded that the higher binding energy peak of the two in phen($HClO_4$) can be assigned to the protonated nitrogen atom and the lower to the unprotonated nitrogen atom.

The N(1s) binding energy value of phen(H_2O) is the same as that of phen, so the effect of the presence of a hydrogen bond in the molecule cannot be detected by XPS. The N(1s) spectrum of Fe(II)(phen)$_3$(ClO_4)$_2$ is a single peak with a FWHH of 1.4—1.5 eV, as are those of all other metal chelates. It can be concluded that all nitrogen atoms in the chelate molecule have equivalent charge densities.

The O(1s) electron spectra of all the compounds containing a perchlorate group are single peaks with a FWHH of 1.7—1.9 eV.

The chemical shifts ΔE are the differences between the N(1s) electron binding energies for the free phen and that for the chelates. Figures 2 and 3 show the chemical shifts which are plotted against the Pauling electronegativity of the metal and the ionic radius, respectively. In Fig. 2, the points appear to fall into two groups. The points for the transition-metal chelates (d^5, d^6, d^7, d^8, and d^9 complexes) Mn(II), Fe(II), Co(II), Ni(II), and Cu(II) fall near one straight line. On the other hand, the points for the Zn(II), Cd(II), Cu(I), Hg(II), and Ag(I) chelates (d^{10} complexes) fall near another straight line having a negative slope, the chemical shift in this case decreasing with increasing electronegativity of the metal. In Fig. 3, the points for all the chelates fall near one straight line, the chemical shift decreasing with increasing ionic radius.

In the charge-potential model,[6] the chemical shift can be expressed in terms of the charge on the atom and the Coulomb potential energy of an electron due to the other atoms in the molecule. In general, the neglect of the Coulomb potential energy may cause serious errors for ionic compounds, but for the covalent compounds as studied here, the chemical shift should be dominated by the charge on the atom concerned.

The difference just noted in Fig. 2 suggests that a fundamental difference of some sort may exist between the structures of the two groups of chelates. The most obvious difference between the transition-metal cations

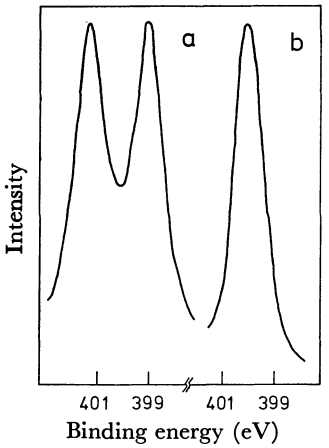

Fig. 1. N(1s) electron spectra of (a) phen($HClO_4$), and (b) Fe(II)$(phen)_3(ClO_4)_2$.

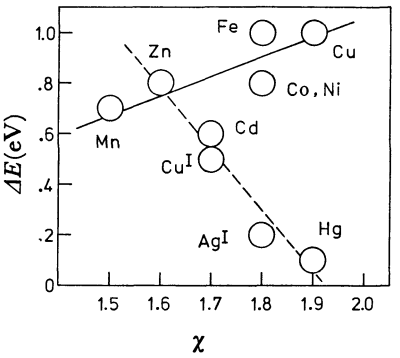

Fig. 2. Relation between electronegativity and chemical shift.

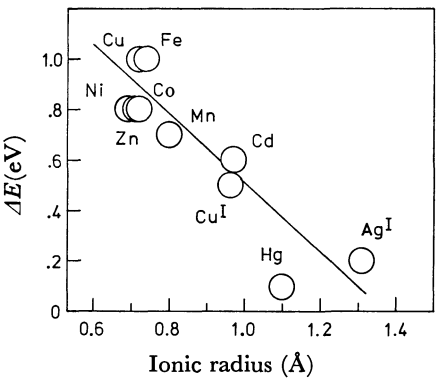

Fig. 3. Relation between ionic radius and chemical shift.

and the other metal cations mentioned is the presence of available 3d orbitals in the former. A possible explanation, then, for the difference noted is the participation of 3d orbitals in the metal–ligand bonding. However, Craig *et al.*[7] have reported on the basis of magnetic susceptibility measurements of $Ni(bipy)_3^{2+}$ that 3d-orbitals may not be involved in metal–ligand bonding for this chelate, and even if involved, not to the extent of forming a $3d^24s4p^3$ hybridized bond.

In general, the bond between a ligand and a metal for coordinate compounds is explained by a σ-bonding (the coordination of a lone pair electrons of a ligand to a metal) and a π-bonding (back-domation from filled metal ion orbitals to empty ligand orbitals) in many cases. These two effects work in opposite directions as for the electron density on the donor atom of the ligand.

If the σ-bonding is more important in the complex formation than the π-bonding, it can be said that the covalent character of the bonds between the metal ions and the ligand increases with the metal ion electronegativity, and that the degree of complex stability is affected by this character.[8] Furthermore, more covalent coordinate bonding is considered to decrease the electron density on the donor atoms, which appears in the increase of the electron binding energies.

When the π-bonding is important, there is no longer correlation between the metal ion electronegativity and the electron density of the donor atoms, as was stated above.

For EDTA, anthranilic acid and oxine chelates in which the double bond with the metal atom is not present or is weak, the plots of the N(1s) chemical shift as a function of the electronegativity of the metal actually showed that all the points for the transition and the other metal chelates appeared to fall near one straight line.[1,2,9]

It has been reported by Busch *et al.*[10] that the chemical behavior and properties of phen and bipy complexes are best described in terms of σ-bonds formed between the metal and the methine nitrogens, and of π-bonds resulting from interaction of the unhybridized d-electron pairs of the metal atom with the π-system of the ligand.

In this study, the fact that the N(1s) chemical shifts of the Hg(II) and the Ag(I) chelates are small compared to those of the Ni(II) and the Cu(II) chelates, as is seen in Fig. 2, which have stabilities similar to the former two chelates (the logarithms of the stability constants of the Hg(II) and the Ag(I) chelates are 23.3 and 12.0, respectively, while those of the Ni(II) and the Cu(II) chelates are 24.8 and 11.0, respectively)[11] may be attributed in part to the greater contribution of the dative π-bond in the metal-ligand bond of the Hg(II) and the Ag(I) chelates.

In the phen metal chelates, the ionic radii of metal ions may be one of the important factors that affect the electron density of the donor atom in view of the relation in Fig. 3. This may be correlated with the geometrical structure characteristic of the phen molecule that the distance between the two donor nitrogen atoms is invariable.

The authors wish to thank Mr. Taichiro Hirohara for the elemental analysis of all the samples.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 48 (11), 3381—3382 (1975)

Studies of the $\pi \rightarrow \pi^*$ Absorption Bands of α-Santonin

Akira KUBOYAMA, Yoshikuni SATO,* and Fumio KOBAYASHI
National Chemical Laboratory for Industry, Shibuya-ku, Tokyo 151

(Received March 29, 1975)

Synopsis. The $\pi \rightarrow \pi^*$ S–S absorption spectra of α-santonin in solutions up to the vacuum UV region were obtained. Based on the results of the MO calculations, the observed four $\pi \rightarrow \pi^*$ bands of α-santonin could be favorably assigned.

Heretofore, the electronic spectrum of α-santonin in the wavelength region shorter than 220 nm has never been reported.[1] We have measured the spectra of α-santonin in solutions up to the vacuum UV region. We have also carried out MO calculations on the π-electronic system of α-santonin, which is similar to that of 1,4-cyclohexadiene-3-one, in order to assign the observed $\pi \rightarrow \pi^*$ bands.

The electronic spectra were measured in the same manner as in the previous works.[2] The solvents—*n*-heptane, 1,1,1,3,3,3-hexafluoroisopropanol (HFIP), and ethanol—were the same as those used in the previous works. α-Santonin of the Japan pharmacopaeia was used without further purification (mp 171.5—172.5 °C).

In the P-P-P method calculations, the electronic integral values which were used in the calculations on *p*-benzoquinone, *etc.* in one[2a] of the previous works were used. All the singly-excited configurations were included. In this work, according to the results of the X-ray analysis of 2-bromo-α-santonin,[3] the π-electronic system of α-santonin was assumed to be planar and to be of the C_{2v} symmetry. The atomic distances of the conventional C=O, C–C, and C=C bonds were assumed to be 1.22, 1.47, and 1.35 Å respectively.[3,4] In the calculations, the intramolecular environmental effect on the π-electronic system of α-santonin was ignored.

The longest-wavelength singlet absorption band of α-santonin is the $n \rightarrow \pi^*$ band near 340 nm.[5] In Fig. 1, four $\pi \rightarrow \pi^*$ bands can be observed in an *n*-heptane solution near 255, 230, 200, and 180 nm. These $\pi \rightarrow \pi^*$ bands are denoted as Bands A, B, C, and D (Table 1).

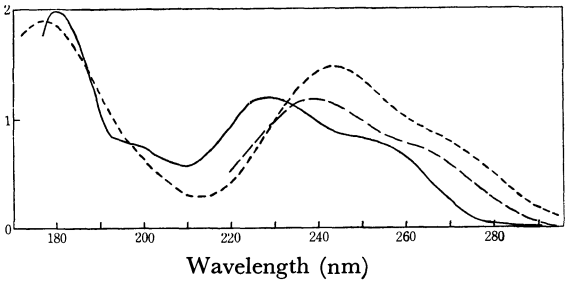

Fig. 1. Absorption spectra of α-santonin in various solvents. ——: *n*-heptane, — —: ethanol, ----: 1,1,1,3,3,3-hexafluoroisopropanol.
(In an *n*-heptane solution the scale of the ordinate is arbitrary.)

~200			C
180		177 (19000)	D

TABLE 2. CALCULATED EXCITATION ENERGIES, OSCILLATOR STRENGTHS, AND SYMMETRY SPECIES OF THE SINGLET π,π^* EXCITED STATES AND THE CORRESPONDING $\pi \rightarrow \pi^*$ BANDS IN AN *n*-HEPTANE SOLUTION

	Calcd			Obsd	
No.	Symmetry	E(eV)	f	Band name	E(eV)
1	B_2	5.139	0.042	A	~4.9
2	A_1	5.343	0.577	B	5.4
3	B_2	6.058	0.041	C	~6.2
4	A_1	7.156	0.033		
5	A_1	7.367	1.036	D	6.9

Bands A and C can be observed as shoulders. As for the solvent effects on the $\pi \rightarrow \pi^*$ bands in Fig. 1, Band D in a HFIP solution is far broader than that in an *n*-heptane solution. Furthermore, in a HFIP solution, Bands A and B shifts greatly toward longer wavelengths, while Band D shifts a little toward shorter wavelengths, in comparison with those in an *n*-heptane solution. In a HFIP solution, Band C can hardly be observed because of its blue-shift in comparison with that in an *n*-heptane solution. These solvent effects may be due to the strong hydrogen-bond formation between α-santonin and HFIP.[2b] Based on the calculated results, these four $\pi \rightarrow \pi^*$ bands can be reasonably assigned, as is shown in Table 2. The first column of this table denotes the numbering of the magnitude of the calculated excitation energies. In this table, the data on the higher excited states with small f-values have been omitted. Since the energy difference between the Nos. 4 and 5 states is small, the $\pi \rightarrow \pi^*$ band corresponding to the No. 4 state may be hidden by Band D. Based on the calculated results, it may be concluded that Bands B and D and Bands A and C are polarized parallel to, and perpendicular to, the C–O bond axis respectively. It is interesting that, according to the calculated results, the excited state of Band D is largely localized in two vinyl groups (*ca.* 66%). The above-mentioned fact that the excitation energies of Band D in an *n*-heptane and a HFIP solutions are relatively close to each other can be reasonably ex-

plained by this calculated result regarding Band D. The broadness of Band D in a HFIP solution may be due to an intensification of the $\pi \rightarrow \pi^*$ band corresponding to the No. 4 state, in addition to the above-mentioned blue-shift of Band C, comparison with those in an *n*-heptane solution.

The quinols have a π-electronic system similar to that of α-santonin. In the $\pi \rightarrow \pi^*$ absorption spectrum of 6-acetoxy-3-oxo-bicyclo-0,3,4-nonadiene-(1,4), which is classified as one of the quinols, in an ethanol solution, as reported by Wessely *et al.*,[6] two $\pi \rightarrow \pi^*$ bands, corresponding to Bands A and B, can be observed. On the other hand, in the absorption spectrum of spiro-5,5-undeca-1,4-dien-3-one, which also has a π-electronic system similar to that of α-santonin, in an *n*-hexane solution, up to the vaccum UV region, as reported by Boschi *et al.*,[7] $\pi \rightarrow \pi^*$ bands corresponding to Bands A and C can hardly be observed. The assignment of its two $\pi \rightarrow \pi^*$ bands, corresponding to Bands B and D, by Boschi *et al.*,[7] based on the P-P-P method calculation, agrees with that in Table 2.

We have also carried out similar MO calculations on other various planar conjugated dienones. According to the calculated results, in all the cross-conjugated dienones, among the singlet excited states and the lowest state does not have the largest *f*-value, unlike as in the cases of the linearly-conjugated dienones.

Structural Changes of Iron Oxides by Ball-Milling in Different Media

Yasuhiko UEHARA

Electron Tube Division, Hitachi Ltd., Hayano, Mobara, Chiba 297

(Received April 18, 1975)

Synopsis. γ-Fe_2O_3, Fe_3O_4, and α-Fe_2O_3 subjected to steel ball-milling in water changed into a spinel-type solid solution, while in polar organic media no remarkable changes occurred. In non-polar media, the γ-Fe_2O_3 and a part of the Fe_3O_4 were transformed into α-Fe_2O_3, although α-Fe_2O_3 remained unchanged. The diffraction lines of the resulting α-Fe_2O_3 broadened markedly.

γ-Fe_2O_3 is known to be transformed irreversibly into α-Fe_2O_3 by such treatments as applying high pressure and grinding mechanically.[1,2] The transformation proceeds *via* the reconstruction of close-packed oxygen ion layers together with the displacement of ferric ions located at the interstices between the oxygen ions.[3,4] The present paper describes the structural changes of γ-Fe_2O_3, Fe_3O_4, and α-Fe_2O_3 caused by the ball-milling in different liquid media in order to clarify the effect of the medium.

The structure of γ-Fe_2O_3 is an inverse spinel with a lattice parameter of 8.350 Å accompanied by a superstructure which has an ordered arrangement of cation vacancies and ferric ions in a ratio of 1 : 3 at the octahedral sites. Fe_3O_4 is crystallographically isomorphous with γ-Fe_2O_3, having a lattice parameter (8.396 Å) slightly larger than that of γ-Fe_2O_3 (8.350 Å). Fe_3O_4 and γ-Fe_2O_3 form a γ-Fe_2O_3–Fe_3O_4 solid solution; this can be expressed by $\square_{x/3}Fe_{3-x/3}O_4$, where $\square$ is the cation vacancy and x is the degree of oxidation. α-Fe_2O_3 has a corundum-type rhombohedral structure, its unit cell having the lattice parameters $a=5.427$ Å and $\alpha=55°17'$.

The γ-Fe_2O_3 used in this experiment showed a characteristic lattice parameter of 8.350 Å. The Fe_3O_4 used has the lattice parameter of 8.386 Å, indicating a slight oxidation of the stoichiometric Fe_3O_4. The particle shape of γ-Fe_2O_3 is rod-like approximately 0.8 μ in length and 0.2 μ in diameter. Both α-Fe_2O_3 and Fe_3O_4 are spherical particles about 0.3 μ in diameter. γ-Fe_2O_3, Fe_3O_4, and α-Fe_2O_3 powders were wet-milled in a steel ball mill having a capacity of 1.32 l. For each run, 30 g of the sample and 90 ml of the medium of extrapure grade were loaded into the ball mill. After milling at 90 rpm for 80 h, the resultant product was dried under reduced pressure and then examined by X-ray diffraction, using Mn-filtered FeK_α radiation. In order to compare the effect of different milling procedures, wet-milling in a porcelain ball mill and dry-grinding in an agate mortar were also carried out.

Table 1 shows the crystal structure, lattice parameter, and half-value width of each characteristic X-ray pattern of the products from γ-Fe_2O_3, Fe_3O_4, and α-Fe_2O_3 after 80 h of milling in the steel ball mill in the presence of different media. The structural changes occurred may be classified as follows:

1) In water, the spinel phase was stable and no significant line broadening of the X-ray diffraction lines was observed.

2) In polar organic media, neither structural changes nor line broadening was observed.

3) In a non-polar organic medium, the α-Fe_2O_3 phase was stable and nearly half of Fe_3O_4 was transformed into α-Fe_2O_3. However, a remarkable broadening of the diffraction patterns of both oxides was observed.

When γ-Fe_2O_3 was milled in the steel ball mill in the

TABLE 1. CHANGES IN CRYSTAL STRUCTURE, LATTICE PARAMETER, AND HALF-VALUE WIDTH OF EACH CHARACTERISTIC X-RAY PATTERN OF THE PRODUCTS FROM γ-Fe_2O_3, Fe_3O_4, AND α-Fe_2O_3 AFTER 80 hr OF MILLING IN THE STEEL BALL MILL IN DIFFERENT MEDIA

			Fe_3O_4	α-Fe_2O_3+Fe_3O_4	5.43	1.0
			α-Fe_2O_3	α-Fe_2O_3	5.43	1.0

a) Spinel: γ-Fe_2O_3–Fe_3O_4 solid solution. b) Lattice parameters of starting materials. γ-Fe_2O_3: 8.350 Å, Fe_3O_4: 8.386 Å, α-Fe_2O_3: 5.427 Å. c) Half-value widths for starting materials. γ-Fe_2O_3 (311): 0.27°, Fe_3O_4 (311): 0.20°, α-Fe_2O_3 (422): 0.22°.

presence of water, the lattice parameter changed from 8.350 Å to 8.371 Å, the superstructure lines such as (210), (211), and (300) disappeared completely and the color changed from brown to black. These facts indicate that γ-Fe_2O_3 was reduced during the milling to give a γ-Fe_2O_3–Fe_3O_4 solid solution. Fe_3O_4 was also reduced to some extent to give Fe_3O_4 containing less oxygen than the original Fe_3O_4, accompanied with a change in the lattice parameter from 8.386 Å to 8.393 Å. α-Fe_2O_3 showed a complete transformation from the rhombohedral into the spinel structure with a lattice parameter of 8.371 Å which coincides with that of the milled γ-Fe_2O_3. Meanwhile, the color of α-Fe_2O_3 changed from red to black. However, when γ-Fe_2O_3, Fe_3O_4, and α-Fe_2O_3 were milled in a porcelain ball mill, no changes in the structure, lattice parameter, and color occurred. Therefore, it is likely that a mechano-chemical reaction is characteristic of the milling in the steel ball mill.

When γ-Fe_2O_3, Fe_3O_4, and α-Fe_2O_3 were milled in such polar organic media as methyl alcohol, isopropyl alcohol, and acetone, their structures, lattice parameters, and colors remained unchanged. The diffraction lines were as sharp as they were in the case of milling in water.

When milled in non-polar cyclohexane, γ-Fe_2O_3 was completely transformed into α-Fe_2O_3. In the case of Fe_3O_4, nearly half of the sample was transformed into α-Fe_2O_3; the diffraction lines of the resultant α-Fe_2O_3 were found to be remarkably broadened. Nearly identical results were obtained from an experiment by dry-grinding in an agate mortar.

During the milling, a microstrain concentrates in the lattice increasing the lattice distortion and the strain energy.[5] The increase in the lattice distortion results in the X-ray line broadening.[6] At the same time, the fresh surface produced by the milling is reactive with respect to the adsorption of polar molecules decreasing the surface energy and the fracture stress.[7] The fact that the X-ray diffraction lines remained as sharp as before can be explained, if one accepts that the adsorption of polar molecules decreases the fracture stress avoiding a remarkable increase in the microstrain concentration in the lattice. In the case of milling in non-polar media, on the other hand, the microstrain concentration increases gradually in the lattice and the X-ray diffraction lines become broader. In the case of milling in water, the sample is reduced to give a spinel phase containing less oxygen. In this reduction reaction during the milling, the mechano-chemical reaction between the sample, the water, and the fresh iron surfaces should be taken into consideration.

Weak Fluorescence from [2.2]Metacyclophane

Haruo SHIZUKA, Toshio OGIWARA, and Toshifumi MORITA

Department of Chemistry, Faculty of Technology, Gunma University, Kiryu, Gunma 376

(Received April, 8, 1975)

Synopsis. Weak fluorescences from [2.2]metacyclophane (MCP) were observed: the normal and intramolecular excimer fluorescences were at 305 and 361 nm respectively. It has been shown that a rapid radiationless deactivation due to the interaction between the two benzene rings in MCP occurs preferentially and the excimer formation responsible for the photocyclization takes place to a small extent.

Recently, the transannular π-electronic interaction in [2.2]metacyclophane (MCP) has come to be of interest.[1-3] In contrast to that in [2.2]paracyclophane,[4] the assumption of the interaction in MCP was denied in both the ground[1] and the excited states.[2]

However, the transannular interaction between the two benzene rings in the excited state of MCP has been recently suggested from the abnormal photochemical behaviors: the small reaction quantum yields (less than 0.01), the large quantum yield for the radiationless deactivation process (0.99), and the lack of emission.[3]

The reason why the two central hydrogen atoms in the intermediate M resulting in the photocyclization should be *cis*-form[3] has not been given. In order to elucidate further the photochemical and photophysical behaviors in MCP, we have made measurements on the emission from MCP, using a highly sensitive single photon counter.

Experimental

The chemical reagents and procedures were essentially as previously described.[3] Samples were degassed by a freeze-pump-thaw method.

The fluorescence from MCP was measured by a single photon counter similar to that reported by Hikida *et al.*[5] It was possible to measure the fluorescence quantum yields up to $\sim 10^{-6}$. The yields for normal and excimer fluorescences of MCP at 270 nm were measured by comparison with quinine bisulfate 0.1 N H_2SO_4 at 366 nm. The absolute yield at 366 nm was determined to be 0.54 by Melhuish.[6] The light intensities at 270 and 366 nm were also measured using a quantum counter (an 8 g/l solution of rhodamine B).[7]

Results and Discussion

Figure 1 shows the fluorescence from MCP in degassed cyclohexane at room temperature. The fluorescence spectrum comprises two bands at 305 and 361 nm. From the mirror image in Fig. 1, the band at 305 nm was assigned to the normal fluorescence from MCP. The band at 361 nm was assigned to the intramolecular excimer fluorescence[8] judging from the broad and structureless fluorescence band which was shifted by 5100 cm^{-1} to lower frequencies relative to the normal fluorescence. The quantum yields for the normal and the excimer fluorescences in degassed cyclohexane at 270 nm

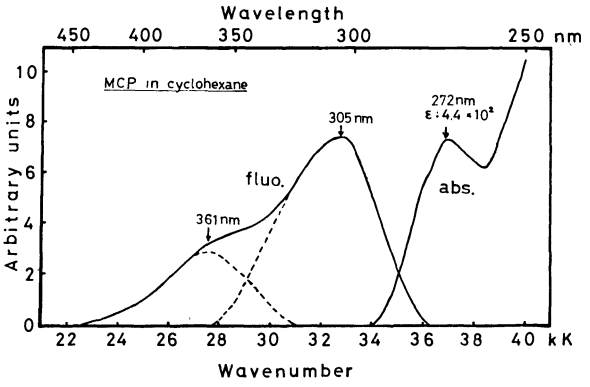

Fig. 1. Absorption and fluorescence spectra of 1.6×10^{-3} M cyclohexane solution of MCP.

and 15° were 2 $(\pm 0.1) \times 10^{-5}$ and $5._6(\pm 0.5) \times 10^{-6}$, respectively. The lifetime τ_{s1} of the lowest excited singlet state S_1, which corresponds to the $^1B_2$ state of the locally excited state of benzene, was estimated to be *ca.* 10 ps, from the values of the fluorescence quantum yield (2×10^{-5}) and the rate constant of k_f ($\sim 2.5 \times 10^6\ s^{-1}$) for the radiative transition from S_1 to S_0. No phosphorescence from MCP could be observed in MP at 77 K.

From these results, a rapid radiationless deactivation process k_d (see Fig. 2) should be involved in the S_1 state of MCP. A possible explanation for the large k_d is that rotational motions of the two benzene rings in S_1 may facilitate the internal conversion. It is well known that the deactivation process in the excited state of some dyes, such as auramine O and crystal violet, is enhanced by the rotational motion.[9-11]

Although the interacting chromophores in MCP are not separated by three carbon atoms ($n=3$ rule),[12] the sandwich configuration of MCP can be attained by rotating the benzene rings around the central carbon atoms. It is known that in the ground state this rotation with a large activation energy (>27 kcal/mol) is very difficult to take place.[13-15] This may be due to the fact that the transannular interaction[16] in the excited state gives an attractive force between them, resulting in the formation of MCP excimer. The excimer formation

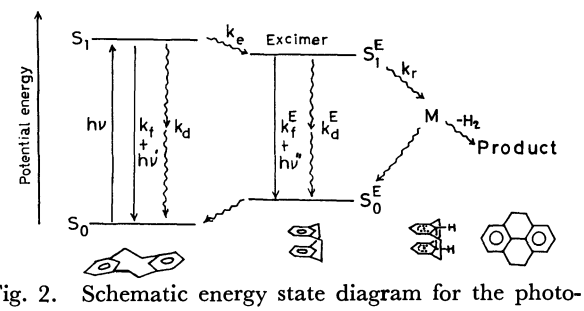

Fig. 2. Schematic energy state diagram for the photochemical processes in MCP.

of MCP has a very close relation with the intermediate M in the photochemical cyclization of MCP.[3] The "sandwich" excimer structure is responsible for the M formation, followed by the thermal reaction to give the products (4,5,9,10-tetrahydropyrene plus a hydrogen molecule) or the starting material.[3] The behavior in the excited state of MCP can be accounted for by the scheme shown in Fig. 2. Thus, the reason why the central hydrogen atoms in M should be in a *cis*-configuration can be well understood. The efficiency for the intramolecular excimer formation becomes small because of the rapid deactivation competing with the excimer formation.

In conclusion, it is obvious that the transannular interaction due to the proximity of two benzene rings exists in the excited MCP.

The authors wish to thank Dr. Takeo Sato, Tokyo Metropolitan University, for the supply of [2.2]metacyclophane.

Proton Transfer Reactions in Oxygen-Containing Molecules and Ammonia Mixtures

Akira MATSUMOTO, Satoshi OKADA,* Setsuo TANIGUCHI,* and Teruo HAYAKAWA

Department of Chemistry, Faculty of Liberal Arts and Sciences, University of Osaka Prefecture, Sakai, Osaka 593

**Radiation Center of Osaka Prefecture, Sakai, Osaka 593*

(Received April 19, 1975)

Synopsis. Ion-molecule reactions leading to the formation of NH_4^+ in a number of mixtures of oxygen-containing molecules and ammonia have been studied using pulsed-source mass spectrometry. Some unique features in the reactivities of $C_2H_4O^+$ and CHO^+ ions from ethylene oxide have been found.

The gas-phase ion chemistry of oxygen-containing molecules has been investigated by several investigators.[1-4] Blair and Harrison[1] have recently reported that the $C_2H_4O^+$ ion initially formed by electron impact of ethylene oxide is unreactive but undergoes a collisional modification to a more reactive species which shows a different reactivity from that of the $C_2H_4O^+$ ion from acetaldehyde. They have pointed out two possibilities: the difference arises from structural effects or from energy effects.

In this paper we report the rate constants of proton transfer reactions from the prominent ions in the mass spectra of oxygen-containing molecules including acetaldehyde and ethylene oxide to ammonia as a common neutral molecule. The results offer additional evidence for the unique features of ionic species from ethylene oxide. The rate constants of the hydrogen atom transfer reactions from oxygen-containing molecules to ammonia ion were also determined.

Experimental

The experiments were performed on a Hitachi-RMU5 mass spectrometer fitted with a pulsed ion source as described previously.[4]

Acetaldehyde prepared from paraldehyde, commercial dimethyl ether, and methanol were purified by vacuum distillation. The purities of these samples were more than 99%. Ethylene oxide and ammonia purchased from Takachiho Kagaku Co., Ltd., in research grade purity of 99.9% were used without further purification. The rate constants of the ion-molecule reactions studied were calibrated with reference to the reported rate constant, $k=1.22\times10^{-9}$ cm^3mol^{-1} s^{-1}, for the reaction $CH_4^+ + CH_4 \rightarrow CH_5^+ + CH_3$.[5]

Results and Discussion

As a preliminary to the study of the proton transfer reactions in mixtures containing ammonia, the reactions forming NH_4^+ ion in pure ammonia were investigated at 12—25 eV electron energies. NH_3^+, NH_2^+, and NH^+ were observed as the primary ions. However, as has been suggested by Derwish and co-workers,[6] NH^+ was not a reactant ion for forming NH_4^+ with ammonia. The rate constants of proton transfer reactions of NH_3^+ and NH_2^+ ions were determined from the analysis of $I_{NH_2^+}/I_{NH_3^+}$ *vs* delay time plots. The results obtained are given in Table 1 and are in agreement with those reported by Harrison and co-workers,[5] except for Reaction 2. It should be pointed out here that impact electron energies higher than 12 eV were employed for all the experiments, since k_1 varies with the energy of the impact electron below 12 eV.[7]

In the mixtures of an oxygen-containing molecule and ammonia, the significant primary ions, omitting the ions from ammonia, are as follows: $CH_3OCH_3^+$, $CH_3OCH_2^+$, $C_2H_3O^+$, and CHO^+ for dimethyl ether, $C_2H_4O^+$, $C_2H_3O^+$, and CHO^+ for acetaldehyde and ethylene oxide, and CH_4O^+, CH_3O^+, and CHO^+ for methanol. Table 1 shows the possible reactions leading to the formation of an NH_4^+ ion in each system.

The secondary ion current of NH_4^+ ($m/e=18$) can be generally described for the dimethyl ether–ammonia system by

$$I_{18} = \left\{k_1I_{17}+k_2I_{16}+k_3I_{46}+k_4I_{45}+k_5I_{43}+k_6I_{29} + k_7I_{17}\frac{[CH_3OCH_3]}{[NH_3]}\right\}[NH_3]t + C_1$$

Table 1. Rate constants of ion-molecule reactions in pure ammonia and oxygen-containing molecule-ammonia mixtures

	Reaction	Rate constant, $k\times10^{10}$ (cm^3 mol^{-1} s^{-1})
	NH_3	
1	$NH_3^+ + NH_3 \longrightarrow NH_4^+ + NH_2$	10.7(10.0[a])
2	$NH_2^+ + NH_3 \longrightarrow NH_4^+ + NH$	7.99(6.5[a])
	$CH_3OCH_3-NH_3$ mixture	
3	$C_2H_6O^+ + NH_3 \longrightarrow NH_4^+ + C_2H_5O$	8.43
4	$C_2H_5O^+ + NH_3 \longrightarrow NH_4^+ + C_2H_4O$	4.73
5	$C_2H_3O^+ + NH_3 \longrightarrow NH_4^+ + C_2H_2O$	<0.5
6	$CHO^+ + NH_3 \longrightarrow NH_4^+ + CO$	11.2
7	$NH_3^+ + C_2H_6O \longrightarrow NH_4^+ + C_2H_5O$	9.37
	$CH_3CHO-NH_3$ mixture	
8	$C_2H_4O^+ + NH_3 \longrightarrow NH_4^+ + C_2H_3O$	12.0
9	$C_2H_3O^+ + NH_3 \longrightarrow NH_4^+ + C_2H_2O$	<0.5
10	$CHO^+ + NH_3 \longrightarrow NH_4^+ + CO$	11.1
11	$NH_3^+ + C_2H_4O \longrightarrow NH_4^+ + C_2H_3O$	4.37
	$C_2H_4O-NH_3$ mixture	
12	$C_2H_4O^+ + NH_3 \longrightarrow NH_4^+ + C_2H_3O$	<0.1
13	$C_2H_3O^+ + NH_3 \longrightarrow NH_4^+ + C_2H_2O$	<0.1
14	$CHO^+ + NH_3 \longrightarrow NH_4^+ + CO$	1.8
15	$NH_3^+ + C_2H_4O \longrightarrow NH_4^+ + C_2H_3O$	5.46
	CH_3OH-NH_3 mixture	
16	$CH_4O^+ + NH_3 \longrightarrow NH_4^+ + CH_3O$	34.0
17	$CH_3O^+ + NH_3 \longrightarrow NH_4^+ + CH_2O$	8.57
18	$CHO^+ + NH_3 \longrightarrow NH_4^+ + CO$	10.4
19	$NH_3^+ + CH_4O \longrightarrow NH_4^+ + CH_3O$	9.00

a) From Ref. 5).

where k_i is the rate constant for reaction (i), I_M the intensity of ion (m/e=M), [NH_3] and [CH_3OCH_3] are the concentrations of the reactant molecules, t is the delay time, and C_1 is a constant. Similar relations consisting of several reactions shown in Table 1 can be applied to the other systems investigated. By analysis of the results obtained under various impact electron energies and mixing ratios of reactant molecules, the rate constants of the reactions leading to the formation of NH_4^+ were determined and are shown in Table 1.

The rate constants for a proton transfer reaction from the parent ions to ammonia are strongly dependent on ion species: highest for methanol, lowest ($<1\times10^{-11}$ $cm^3mol^{-1}s^{-1}$) for ethylene oxide. Taking into account our experimental conditions, in which the reaction time did not exceed 2 μs, the very low reactivity of the $C_2H_4O^+$ ion from ethylene oxide is in agreement with the result observed for initially formed $C_2H_4O^+$[1] prior to the collisional modification. Another interesting result is that the CHO^+ ions derived from dimethyl ether, acetaldehyde, and methanol show a high reactivity of about 11×10^{-10} $cm^3mol^{-1}s^{-1}$, while the CHO^+ ion from ethylene oxide is less reactive. Since the proton transfer processes of CHO^+ and $C_2H_4O^+$ ions from ethylene oxide and acetaldehyde to ammonia are all quite exothermic, a simple thermochemical consideration cannot explain the low reactivities of CHO^+ and $C_2H_4O^+$ ions derived from ethylene oxide.

The fragment ions $CH_3OCH_2^+$ and CH_3O^+ react with significant rates to give NH_4^+ ion, while the $C_2H_3O^+$ ions are unreactive.

The rate constants for the hydrogen atom transfer reaction from oxygen-containing molecules to ammonia ion are less specific compared with those of the proton transfer reactions.

Electronic Absorption Spectra of the Disulfone Radical Anion. Conjugative Effect of the Sulfone Group

Osamu Ito and Minoru Matsuda

Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Katahira-2, Sendai 980

(Received April 24, 1975)

Synopsis. Disulfone radical anions produced by γ-irradiation show a characteristic absorption band at a longer wavelength region (655—695 nm) than that of the mono-sulfone radical anion (*ca.* 400 nm). The former band is attributed to the charge-resonance originated from the delocalization of an unpaired electron between the linked two sulfone moieties.

The radical anions containing the sulfone group show a pronounced conjugative effect through the sulfone group.[1] The effect was studied by means of the electron spin resonance. We showed that the measurement of the absorption spectrum is useful for elucidating the effect from the absorption band appearing in a longer wavelength region.[2] In this note, we report on our findings that the radical anions of disulfones ($R–SO_2–SO_2–R$) show an absorption band in a longer wavelength region (655—695 nm) than that of the mono-sulfone radical anions such as phenyl methyl sulfone (*ca.* 400 nm). It is expected that the band appearing in a longer wavelength region is related to the effective conjugation of the disulfone moieties.

Experimental

Di-*n*-hexyl disulfone[3] and diaryl disulfones[4] were synthesized by the reported methods. Radical anions containing sulfone moieties were produced by the γ-irradiation (^{60}Co: *ca.* 1 Mrad) of degassed methyltetrahydrofuran (MTHF) glassy solution at 77 K, since the disulfone radical anions formed by the alkali metal reduction were not stable.

Results and Discussion

It is expected that the disulfone radical anion can be produced by γ-irradiation according to the electron (e^-)-capture as follows:

$$MTHF \overset{\gamma}{\rightsquigarrow} MTHF^+ + e^- \quad (1)$$

$$e^- + R–SO_2–SO_2–R \longrightarrow (R–SO_2–SO_2–R)^- \quad (2)$$

A glassy blue solution, obtained by γ-irradiation of diphenyl disulfone, exhibited a strong absorption band at 695 nm and a weak band at 368 nm (Fig. 1a). As a possible species in the blue solution other than the disulfone radical anion, the benzene sulfonyl radical ($Ph–\dot{S}O_2$) might be produced by the direct scission of $–SO_2–SO_2–$ bond or by the dissociative electron attachment process:

$$e^- + R–SO_2–SO_2–R \longrightarrow R–\dot{S}O_2 + R–SO_2^- \quad (3)$$

However, the benzene sulfonyl radical, which can be produced by the UV-irradiation of diphenyl disulfone or benzene sulfonyl halides at 77 K, shows an absorption band at 382 nm. Thus, the absorption spectrum of the blue species (Fig. 1a) can be assigned to the diphenyl disulfone radical anion.

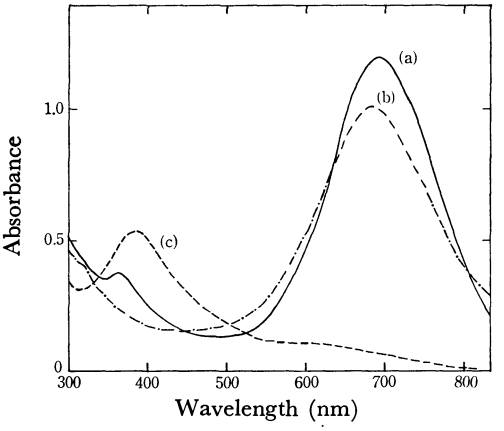

Fig. 1. Absorption spectra of the disulfone radical anions in MTHF at 77 K (5×10^{-3} mol/l in 2 mm cell); (a) diphenyl disulfone, (b) di-*n*-hexyl disulfone, and (c) phenyl methyl sulfone.

The radical anion of di-*n*-hexyl disulfone, an alkyl derivative of disulfone, was also produced by γ-irradiation. It shows a similar spectrum (Fig. 1b) to that of the diphenyl disulfone radical anion. This indicates that the electronic transitions of the disulfone radical anion appearing at *ca.* 690 nm are characteristic of two sulfone moieties and that the π-systems on the phenyl rings do not play an appreciable role in the transition. Moreover, the phenyl methyl sulfone ($Ph–SO_2–CH_3$) radical anion, a mono-sulfone, shows only one absorption band at 398 nm (Fig. 1c). An added electron to this mono-sulfone locates mainly on the sulfone moiety.[2] We see that, in the disulfone radical anion, the absorption band at *ca.* 690 nm results from the linked two sulfone moieties.

It is to be noted that the absorption spectra of the disulfone radical anions resemble those of the [2.2]paracyclophane radical anion (a strong band at 760 nm and a weak band at 360 nm) and biphenyl radical anion (two bands at 625 and 400 nm) as reported by Ishitani and Nagakura.[5] Their theoretical study of the [2,2]-paracyclophane and biphenyl radical anions indicates that the absorption bands appearing in a longer wavelength region than the benzene radical anion are assigned to the charge-resonance band originating from the delocalization of an unpaired electron between two phenyl rings. Thus, in the case of the disulfone radical anion, it can be suggested that the band appearing at *ca.* 690 nm has a charge-resonance character and that an added electron to disulfone is delocalized between the linked two sulfone moieties.

The absorption spectra of the disulfide radical anions

were reported by Shida.[6] Since the absorption band of the diphenyl disulfide radical anion appeared in the same region as that of the dialkyl disulfide radical anion (420—435 nm), he indicated that an unpaired electron added to disulfide is localized on the sulfur atoms. Although the diphenyl sulfide radical anion shows an absorption band in the same region as the diphenyl disulfide radical anion, the intensity of the band is reported to be very weak as compared with that of the disulfide.[7] Thus, there is a pronounced difference between the disulfide and disulfone radical anions; in the former the intensity of the band differs from that of mono-sulfide, and in the latter the position of the band differs from that of mono-sulfone. Since it is well established that the σ^*-orbital of the disulfide accepts an added electron, the different behavior in the spectra of the disulfone radical anion would be caused by the large π-character of O=S=O bond and/or large d-orbital participation on O=S=O bond.

Table 1. Absorption maxima of the diphenyl disulfone (X-C$_6$H$_4$-SO$_2$-SO$_2$-C$_6$H$_4$-X) radical anions

X	λ_1 (nm)	λ_2 (nm)
H–	695	368
CH_3–	665	366
CH_3O–	655	360

An abnormal shift by the substituents on the phenyl rings was observed in the absorption band appearing in a longer wavelength region (Table 1). When electron-donating substituents such as CH_3– and CH_3O– are introduced to *para*-positions, the absorption peaks shift towards shorter wavelength. In the case of the *para*-substituted diphenyl disulfide radical anions, however, an opposite tendency was observed by Miyashita, Iino and Matsuda (CH_3O–: 440 nm, CH_3–: 425 nm, and H–: 420 nm).[8] The red shift by the electron-donating substituents observed in the disulfide radical anions agrees with the well-known red shift of the substituted benzene molecules.[9] This is understandable if we assume that the transition energy of the charge-resonance band is approximately proportional to the electron density on each sulfone moiety, which might increase by the electron-donating substituents. Precise molecular orbital calculations might be necessary to elucidate the opposite substituent effect of the disulfone radical anions.

The authors are indebted to Mr. N. Tsuchihashi and Mr. K. Furukawa for their help in the γ-irradiation experiments.

Solvent Effect on the Dimerization of Tetracyanoquinodimethane Anion Radical

Tadayoshi SAKATA, Akihiro NAKANE,* and Hiroshi TSUBOMURA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received May 12, 1975)

Synopsis. The thermodynamic quantities of the dimerization of tetracyanoquinodimethane (TCNQ) anion radical in water–ethanol mixtures were determined. The free energy of dimerization $-\Delta G$ showed a monotone decrease with an increase in ethanol content, whereas the enthalpy and the entropy of dimerization, $-\Delta H$ and $-\Delta S$, showed a maximum. This unusual behavior is explained by proposing a solvation model in which the water molecules are attracted more strongly around the $TCNQ^-$ dimer than are the ethanol molecules. The entropy was found to play an important role in the dimerization.

Dimerizations of organic ion radicals in solutions have been extensively studied.[1-7] The dimerization is strikingly influenced by the solvents. For example, the anion radical of tetracyanoquinodimethane ($TCNQ^-$) dimerizes strongly in water at room temperature, whereas it does not in ethanol even at 77K. In order to clarify this remarkable solvent effect we determined the thermodynamic quantities of dimerization of $TCNQ^-$ in the water–ethanol system.

Li^+TCNQ^-, Na^+TCNQ^-, and K^+TCNQ^- used in this experiment were prepared by the method described in the literature.[8] Deionized water and distilled ethanol were used. Since $TCNQ^-$ is easily oxidized by oxygen, all solutions were prepared and transferred to an absorption cell by using the vacuum line technique.

The equilibrium constant K for the dimerization was determined spectroscopically using the molar extinction coefficients of the monomer and dimer anions obtained by Boyd and Phillips.[2] The changes of the extinction coefficients in the mixed solvents were neglected, since the anions were found to exhibit the same spectral features up to 50 volume % of ethanol. The concentrations at various temperatures were corrected by use of the expansion coefficients for water and ethanol, assuming that the volume of the mixture is equal to the sum of the components.[9] The plots of log K *vs.* T^{-1} gave good straight lines, from which the change in enthalpy ΔH and that in entropy ΔS of the dimerization ($2A^- \rightleftarrows (A^-)_2$) were obtained.

Figure 1 shows the dependency of the thermodynamic quantities on the volume ratio of ethanol to water. The change in free energy $-\Delta G$ at 25 °C decreases with an increase in ethanol content throughout the range studied, whereas both $-\Delta H$ and $-\Delta S$ increase at first, reach a maximum at 30~40% ethanol, and then decrease. In the region where the ethanol content exceeds 50%, the dimer formation was found to be so scanty even at low temperatures (−50 °C~−60 °C) that the thermodynamic constants could not be determined. In the region of small ethanol content (<20%), the change

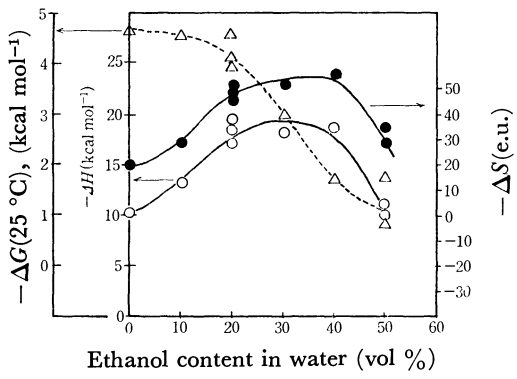

Fig. 1. Observed thermodynamic quantities for the dimerization of $TCNQ^-$ in the water–ethanol mixture.
△: $-\Delta G$(25 °C), ●: $-\Delta S$, ○: $-\Delta H$

in the enthalpy $-\Delta H$ with the ethanol concentration is opposite to that in the free energy $-\Delta G$. This behavior shows the important role of the entropy factor $T\Delta S$ in the free energy change $-\Delta G$ for the dimerization of $TCNQ^-$.

The presence of a maximum for $-\Delta H$ and $-\Delta S$ as seen in Fig. 1 is quite unusual,[10] and hard to explain by the usual understanding of the solvent polarization energy. By using Born's equation and dielectric constants for water and ethanol, the contributions of solvation in the $-\Delta H$ and $-\Delta S$ values can be calculated; the result shows a simple increase with an increase in ethanol content, and amounts to only 0.5 kcal mol^{-1} and 2.6 eu, respectively at 50% in ethanol content. Therefore, a model of a continuous and uniform medium cannot explain the experiment.

In order to understand this unusual behavior, we propose a simple model for the microscopic structure of the solvation sphere. The electrostatic field due to the dimer is considered to be must stronger than that of the monomer, because the charge of the dimer is twice as large as that of the monomer, and the effective radius is less than twice that of the monomer. Therefore, it attracts water molecules rather than ethanol ones into the solvation sphere more strongly than the monomer, since water is more polar than ethanol. Consequently, at small ethanol content, the ratio of the number of molecules in ethanol to that in water inside the solvation sphere may be lower than that in the bulk of the solution. The situation is illustrated schematically in Fig. 2. This will bring about more stabilization for the dimer anion than for the monomer anion, leading to larger $|\Delta H|$ values for the dimer formation. As the ethanol concentration becomes higher, this effect on ΔH and ΔS will diminish. Thus, the changes in enthalpies with the

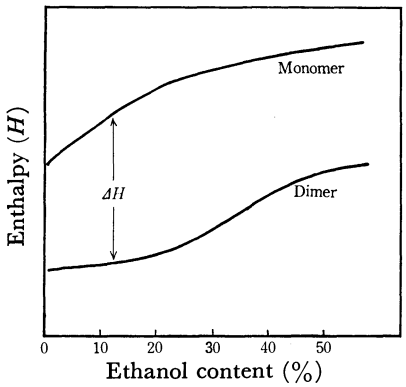

Fig. 3. Qualitative curves explain the behaviors of the enthalpies of the monomer and dimer in the water–ethanol mixture.

ethanol content for the dimer and monomer will be such as given qualitatively in Fig. 3, from which the appearance of a maximum for $-\Delta H$ in the monomer⇄dimer reaction can be understood. The appearance of a maxima in entropy $-\Delta S$ can be understood similarly.

The influence of counter cations on the thermodynamic quantities in the monomer⇄dimer reaction in water was also investigated. The result is that there is no essential difference in the thermodynamic quantities by changing the counter ions from Li^+ to Na^+ and K^+. No substantial change was detected for a solution containing LiCl 100 times more than the concentration of $TCNQ^-$. These results suggest that the counter ions exhibit a very small influence on the dimer-monomer equilibrium, and presumably they do not exist in a region very close to the anions in water.

Dipole Moments of the Iodine Compounds Complexed with Some Aliphatic Amines

Koichi TOYODA and Motoo IMAI*

Department of Chemistry, Faculty of Sciences, Kumamoto University, Kurokami-machi, Kumamoto 860

(Received May 13, 1975)

Synopsis. The dipole moments of some iodine compounds complexed with some aliphatic amines in benzene solution were obtained: 6.81D for EtH_2N–I_2; 6.78D for Et_2HN–I_2; 6.72D for Me_3N–ICl; 7.22D for Me_3N–IBr; 6.46D for Me_3N–ICN.

One of the present authors has recently reported the dipole moments of the electron-donor-acceptor (EDA) complexes between iodine and two aliphatic amines as follows: 12.4D in dioxane,[1] 6.78D in benzene,[2] 5.49D in cyclohexane,[2] for the triethylamine–iodine (Et_3N–I_2) complex, and 10.0D in dioxane,[1] 6.32D in benzene,[3] 5.25D in cyclohexane,[3] for the trimethylamine–iodine (Me_3N–I_2) complex. It was found that the experimental values of the dipole moments for these two complexes were strongly dependent on the solvents. The dipole moment of the Et_3N–I_2 complex was found to be time-dependent after mixing the two components. From the dipole moment of the Me_3N–I_2 complex in cyclohexane and the X-ray analysis data by Stroemme,[4] the contribution of the charge transfer (CT) structure in the ground state (b^2+abS) was evaluated to be about 0.30. Recently ESCA[5] and NQR[6] of pyridine–ICl (Py–ICl), for the gas phase and the solid state respectively, were measured. The charge distribution densities on each N, I, and Cl atoms has been directly evaluated from these data under certain assumptions. The dipole momemt measurement in solution at room temperature, however, is one of the most useful methods by which a direct measure for (b^2+abS) could be supplied. (b^2+abS) is one of the most basic constants of EDA complexes. The importance of the complex as a typical example is so great that extra efforts to obtain accurate data are justified.

Experimental

Cyclohexane, benzene, iodine, and Me_3N were purified by the method reported previously.[2,3] Ethylamine(EtH_2N) and diethylamine (Et_2HN) were purified by Nagakura's method.[7] ICl and IBr were prepared by the methods reported by Cornog and Karges,[8] and Popov and Skelly,[9] respectively. ICN, which was prepared by the method of Bak and Hillebert,[10] was colorless and melted at 145 °C in a sealed capillary. The apparatus for the measurements of dielectric constants, the picnometer for the measurements of densities, and the procedure of handling have been reported previously.[2] The temperature was kept constant at 25.00±0.05 °C or 20.00±0.05 °C throughout the series of measurements. The dipole moment of nitrobenzene obtained by means of this apparatus was 4.03D in a benzene solution at 25 °C. In each series of measurements, benzene solutions containing a fixed concentration of the amines and various concentrations of iodine, ICl, IBr, and ICN were used. The concentrations of the iodine compounds ranged from 0 to 1.8×10^{-3} mol/l in the benzene solution and did not exceed a tenth of that of amine in the solution. The dipole moments of the complexes were obtained by use of the Kobinata-Nagakura method.[11]

Results and Discussion

The experimentally observed dielectric constants (ε_{123}) and the densities (d_{123}) of the solutions were found to be linearly dependent upon the weight fractions (w_3) of the molecular complexes, as previously described.[2,3] The dipole moments of the complexes were evaluated from the slopes of these lines using only the first term of the Kobinata-Nagakura equation.[11] In spite of the low concentrations of the complexes, which were $(1.5-6)\times10^{-3}$ for EtH_2N–I_2 and $(1.8-7)\times10^{-3}$ for Et_2HN–I_2 in weight fraction and corresponded to about a tenth of the values in Nagakura's experiments,[11] the same results were obtained. As seen in Table 1, the dipole moments of the complexes increased with an increase in the amine concentration in a mixed solvent containing benzene and amine.

For the complexes between Me_3N and ICl, IBr, or ICN the dipole moments in benzene solution are presented in Table 1. The measurements in cyclohexane and hexane solution gave dispersed plots because the solubility in these solvents was a tenth of that in benzene. The geometries of the Et_2HN–I_2 and EtH_2N–I_2 complexes were assumed to be the same as that of Me_3N–I_2 by Nagakura *et al.*[11] Thus μ_1 was estimated to be 17.7D in the equation, $\mu_N=\mu_1(b^2+abS)$.[12] The X-ray diffraction study of Me_3N–ICl has been already reported

a) Assuming that a negative charge is located on the center of the I–X molecule. b) Assuming that a negative charge is located on the X-atom of the I–X molecule. c) C. Reid and R. S. Mulliken, *J. Amer. Chem. Soc.*, **76**, 3869 (1954).

by Hassel *et al*,[13] in which the bond lengths of I–Cl and N–I were 2.52Å and 2.30Å, respectively. Then the estimated values of (b^2+abS) are shown in Table 1. The assumption was made that μ_1 of Me_3N-IBr was equal to μ_1 of Me_3N-ICl. According to the NQR study on solid Py–ICl by Hanna *et al*,[6] negative charge concentrates upon the Cl atom. Assuming that the positive charge concentrates upon the N atom, the (b^2+abS) values are obtained; these are shown in II of Table 1.

Several authors[14,16] have recently pointed out the importance of the induced polarization in the observed dipole moments of the molecular complexes. The (b^2+abS) values in Table 1, however, are estimated by the conventional procedure without giving any allowance for the polarization effects. The amounts of charge transfer Δq at the Py–ICl complex were estimated to be 0.1 for the gas phase by the ESCA[5] and 0.16 for the solid state by the NQR.[6] The (b^2+abS) in the solid state, in general, gives larger values than in the gas phase.[15] Δq obtained by the ESCA and NQR for the Py–ICl complex are the same order to the ionic character, which was estimated by considering the dipole moments of the two components in the $Py-I_2$ complex. These experimental Δq's were quite large as compared with those calculated (Δq, 0.018) for the NH_3-I_2 complex[16] by the MINDO/2.

Mechanism of the Acceleration Effect of 1,10-Phenanthroline on the Rate of Color Change of Xylenol Orange in the Chelatometric Titration of Nickel(II)

Teisuke MURAYAMA and Michio TAKEMURA

Department of Industrial Chemistry, Faculty of Engineering, Shizuoka University, Johoku, Hamamatsu 432

(Received April 4, 1975)

Synopsis. The effect in the title was studied kinetically. Experimental results indicate that the color change reaction in the presence of 1,10-phenanthroline proceeds according to a mechanism proposed by Nakagawa and Wada.

It is essential for a metallochromic indicator to be released rapidly from the metal-indicator complex at the equivalence point in the chelatometric titration of the metal. The lack of this property causes a sluggish color change at the equivalence point, and introduces a titration error.

Because Xylenol Orange (XO) forms an inert complex with copper(II) or nickel(II), its color change is slow in direct titrations of these metals with EDTA. Pribil observed that the rate of the XO color change was markedly improved by addition of a small amount of 1,10-phenanthroline (phen) in the titration of copper.[1] He explained this effect by supposing a reaction scheme comprised of two rapid substitution reactions:

$$MI + X = MX + I \quad (1)$$

$$MX + Y = MY + X \quad (2)$$

where M is the metal ion, I the indicator, X an auxiliary complex-forming agent (namely, phen in this case), and Y a chelatometric titrant (namely, EDTA in this case).

Recently Nakagawa and Wada published results of an extensive study on effects of auxiliary complex-forming agents on the rate of color change of metallochromic indicators, and criticized Pribil's explanation on the ground of the smallness of the stability constant difference between copper-XO and copper-phen complexes.[2] They proposed another reaction scheme involving a mixed ligand complex.

$$MI + X = MIX \quad (3)$$

$$MIX + Y = MY + I + X \quad (4)$$

They, however, did not supply any kinetic data supporting this scheme.

The purpose of the present study is to examine the two schemes kinetically in the case of the titration of nickel(II).

Experimental

All chemicals used were of reagent grade, and all solutions were prepared with redistilled water. A standard solution of disodium salt of EDTA and stock solutions of XO and phen were prepared by dissolving weighed amounts. The concentration of nickel sulfate solution was determined by titration with the standard solution of EDTA, where murexide was used as indicator.[3] Acetate buffers of pH 4.54 to 5.33 were used for the control of hydrogen ion concentration of the reaction mixtures.

A solution of 50 ml was prepared by mixing nickel sulfate, XO, phen, an acetate buffer, and EDTA of insufficient amount to be equivalent to the amount of nickel sulfate, and by filling to the mark with water. The concentration of nickel sulfate was prepared to be 5.00_0 mM, and the ionic strength of the solution was controlled to 0.2. The solution, in a measuring flask, was placed in a thermostat kept at 25 °C. After equilibration a meaured volume (0.17 to 0.46 ml) of the EDTA solution was added to the solution to make the concentration of EDTA to be 1% excess of nickel sulfate. This was rapidly followed by thorough mixing and transfer of the solution into a quartz cell with light path of 10 mm. The change of transmittance of the solution with time was followed by a Hitachi Model 101 spectrophotometer, its cell compartment being kept at 25.0 °C. The transimittance was measured at 582 nm, where the nickel-XO complex showed an absorption peak and the free XO did not absorb to any appreciable degree.

Results and Discussion

The rate of the substitution reaction of the nickel-XO complex with EDTA follows the second-order rate law both in the presence and in the absence of phen, as shown in Fig. 1, where a and b are the initial concentrations of the nickel-XO complex and EDTA, respectively, and $(a-x)$ and $(b-x)$ are the concentrations of the respective species at time t.* Although the rate constant in the presence of phen, k_1, and that in the absence of phen, k_2, were both susceptible to the influence of con-

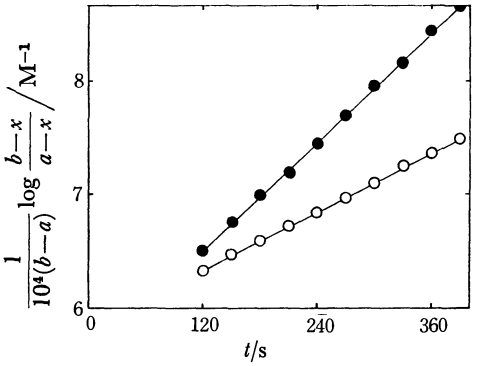

Fig. 1. Second-order rate plots of the substitution reaction of the nickel-XO complex with EDTA. pH of reaction mixtures, 4.92. Concentration of XO, 5.0 μM. Concentration of EDTA added just at the start, $20._0$ μM. Concentration of phen: ○, 0 μM; ●, 1.0 μM.

* XO, EDTA, and phen in solutions can exist in forms with different numbers of protons. Concentrations of these species were calculated, however, irrespective of the number of protons because the concentration of hydrogen ions had no influence on (k_1-k_2), about which we are concerned.

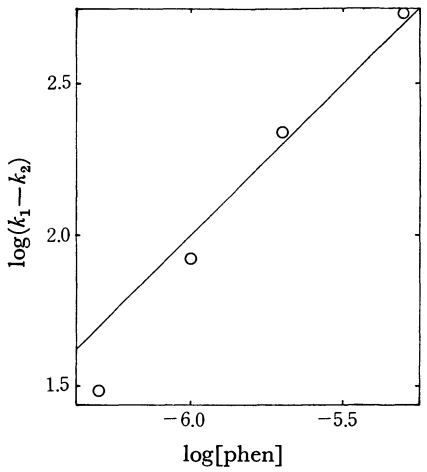

Fig. 2. Dependence of log (k_1-k_2) on log[phen]. The solid line is a straight line with a slope of 1. Units of [phen] and (k_1-k_2) are M and M^{-1} s^{-1}, respectively. pH of reaction mixtures, 4.92. Concentration of XO, 5.0 μM. Concentration of EDTA added just at the start, $30._0$ μM.

centrations of hydrogen ions and XO, the difference (k_1—k_2) was not. This difference, representing the acceleration effect of phen, varies with the first power of the concentration of phen, as shown in Fig. 2.

In Pribil's scheme the rate-determining step may be either Reaction (1) or (2). Neither case leads to the second-order rate law described above. Nakagawa-Wada's scheme, on the other hand, can satisfy this rate law if Reaction (6) is the rate-determing step as given by

$$MI + X \overset{K}{\rightleftharpoons} MIX \quad (5)$$

$$MIX + Y \overset{k}{\longrightarrow} MY + I + X \quad (6)$$

and if the equilibrium constant K is so small as to fulfill the relation $[X] \gg [MIX]$. Under these conditions the rate is written as

$$\text{rate} = kK[X][MI][Y] \quad (7)$$

which agrees with experimental observations. Hence Nakagawa-Wada's mechanism works in the case of titration of nickel(II).

The Phase Transition of Bismuth(III) Oxide Prepared by the Thermal Decomposition of Bismuth Sulfate

Ryoko MATSUZAKI, Hagio MASUMIZU, and Yuzo SAEKI

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received April 16, 1975)

Synopsis. The phase transitions of α-Bi_2O_3 prepared by the thermal decomposition of $Bi_2(SO_4)_3$ on heating and cooling are revealed. The phase transition on cooling is remarkably affected by the existence of a small amount of SO_4, such as 0.05%, in the Bi_2O_3.

The phase transition of α-Bi_2O_3 (monoclinic[1]), prepared by the thermal decomposition of $Bi_2(SO_4)_3$, has been examined with special attention paid to the effect of a small amount of SO_4 in the Bi_2O_3 on its phase transition.

The $Bi_2(SO_4)_3$ used as the starting material was prepared by dissolving high-purity commercial bismuth (Bi: 99.9999%) in HNO_3, followed by treatment with an excess of H_2SO_4.[2] Two samples of α-Bi_2O_3 were obtained as follows.

Sample A: According to a previous report of the present authors,[2] α-Bi_2O_3 was prepared by heating 15 g of $Bi_2(SO_4)_3$ placed in a platinum boat at 950 °C for about 130 hr in an argon stream. The SO_4 in the product was not detected by the indirect determination of a small amount of SO_4^{2-} using solid barium chromate.[3]

Sample B: Bi_2O_3 was prepared by heating $Bi_2(SO_4)_3$ at 950 °C for about 110 hr. The SO_4 content in the product was 0.05%. X-Ray analysis showed it to be α-Bi_2O_3.

The phase transitions of Bi_2O_3 on heating and cooling were examined by DTA. The heating and cooling rates of 5 °C/min were employed. Sample holders made of platinum were used, and α-Al_2O_3 was used as a reference. The accuracy of the temperature measurements was ±4 °C. The experimental results of DTA were followed by high-temperature X-ray diffractometry in order to examine the phase transition of Bi_2O_3. Ni-filtered Cu radiation was used, and the scanning speed of 2°/min was employed. The details of the techniques of DTA and high-temperature X-ray diffractometry were described in a preceding paper.[4]

The phase transitions of Samples A and B on heating were examined. The experimental results showed that both samples transformed to δ-Bi_2O_3 (cubic[5]) at 730 °C, which then melted at 827 °C. The phase transitions of Samples A and B on heating were the same as those of the α-Bi_2O_3 prepared by the thermal decompositions of $Bi(NO_3)_3 \cdot 5H_2O$, $(BiO)_2CO_3$, and bismuth nitrate oxide.[4]

The phase transitions of Samples A and B on cooling from temperatures of 740—890 °C were examined. The results for Sample A are shown in Table 1. The peak temperature of the DTA curve is shown as the transition temperature. When the DTA curve showed a supercooling effect and the peak temperature became higher than the temperature at which the exotherm started, the latter is shown as the transition temperature and is marked with an asterisk.

Table 1. Phase transition of sample A on cooling (Cooling rate: 5 °C/min)

Temperature before cooling (°C)	Phase transition
740	$\delta \xrightarrow{702°C} \alpha$
750	$\delta \xrightarrow{695°C} \alpha$
760	$\delta \xrightarrow{648°C*} \alpha$
770	$\delta \xrightarrow{650°C} \beta \xrightarrow{545°C*} \alpha$
800	$\delta \xrightarrow{648°C} \beta \xrightarrow{545°C*} \alpha$
810	$\delta \xrightarrow{650°C} \beta \xrightarrow{547°C*} \alpha$
840	melt $\longrightarrow \delta \xrightarrow{637°C} \beta \xrightarrow{503°C*} \alpha$
860	melt $\longrightarrow \delta \xrightarrow{635°C} \beta \xrightarrow{500°C*} \alpha$
880	melt $\longrightarrow \delta \xrightarrow{635°C} \beta \xrightarrow{500°C*} \alpha$
890	melt $\longrightarrow \delta \xrightarrow{625°C*} \alpha$

Note: Temperature accuracy, ±4 °C

The experimental results given in Table 1 show that the variation in the phase transition of Sample A with the temperature before cooling was similar to those of Bi_2O_3 prepared from $Bi(NO_3)_3 \cdot 5H_2O$, $(BiO)_2CO_3$, and bismuth nitrate oxide.[4,7]

The results for Sample B, which are shown in Table 2, were compared with those for Sample A shown in Table 1. The phase transitions of Sample B on cooling from

Table 2. Phase transition of sample B on cooling (Cooling rate: 5 °C/min)

Temperature before cooling (°C)	Phase transition
740	$\delta \xrightarrow{698°C} \alpha$
760	$\delta \xrightarrow{650°C*} \alpha$
770	$\delta \xrightarrow{640°C} \beta \xrightarrow{525°C*} \alpha$
780	$\delta \xrightarrow{640°C} \beta \xrightarrow{525°C*} \alpha$
800	$\delta \xrightarrow{642°C} \beta \xrightarrow{523°C*} \alpha$
810	$\delta \xrightarrow{645°C} \alpha$
840	melt $\longrightarrow \delta \xrightarrow{630°C} \alpha$
860	melt $\longrightarrow \delta \xrightarrow{632°C} \alpha$
890	melt $\longrightarrow \delta \xrightarrow{630°C} \alpha$

Note: Temperature accuracy, ±4°C

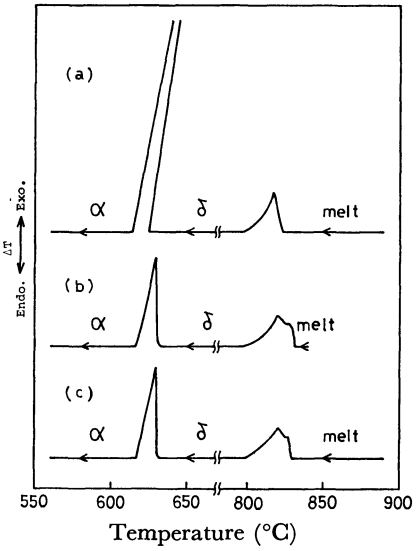

Fig. 1. DTA curves for the melt→δ→α transitions of Samples A and B
(a): Sample A on cooling from 890 °C
(b): Sample B on cooling from 840 °C
(c): Sample B on cooling from 890 °C

temperatures below 800 °C were the same as those of Sample A. However, the transition temperatures of δ→β and β→α for Sample B were lower than those for Sample A. When Sample B was allowed to cool from temperatures above 810 °C, δ-Bi_2O_3 transformed directly to α-Bi_2O_3 without passing through β-Bi_2O_3, regardless of the temperature before cooling. On the other hand, the phase transition of Sample A was dependent on the temperature before cooling, and the melt→δ→α transition occurred when Sample A was allowed to cool from 890 °C. This is the most remarkable difference between the phase transitions of Samples A and B.

The DTA curves observed when the melt→δ→α transitions occurred in Samples A and B are shown in Fig. 1.

By comparing the observations of Sample A (Fig. 1 (a)) with those of Sample B(Fig. 1(b), (c)), it was found that the DTA curve for the δ→α transition of Sample A showed a marked supercooling effect, which caused the sample temperature to increase remarkably. On the other hand, no such supercooling effect was observed in the DTA curve for the δ→α transition of Sample B. It was roughly estimated that the area of the exothermic peak due to the δ→α transition of Sample B was about one-fourth of that of Sample A. Also, the exothermic peak representing the solidification of Sample B had a shoulder. These differences may be due to the existence of SO_4 in Sample B.

The above-mentioned experimental results revealed that the phase transition of Bi_2O_3 on cooling was remarkably affected by the existence of a small amount of SO_4, such as 0.05%, in the Bi_2O_3.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 48 (11), 3399—3400 (1975)

A Kinetic Study on the Complex Formation of Iron(III) with *o*-Cresolsulfonphthalein: A Quinoidal Complex*

Hiroaki NAKAYAMA** and Masatoshi FUJIMOTO
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received May 22, 1975)

Synopsis. The kinetics of the 1: 1 complex formation of Fe(III) with *o*-Cresol Red is studied. The reaction scheme is quite different from that for the monophenolato complexes of Fe(III), and interpreted by the formation of a quinoidal complex.

A pH indicator *o*-Cresolsulfonphthalein, *o*-Cresol Red (abbr. CR), is a phenolic and quinoidal ligand with conjugated π-systems and hardly behaves as a chelating agent. It is interesting to note whether the given ligand forms a phenolato complex or a quinoidal complex with tervalent iron, and in what mechanism it reacts with the metal ion in comparison with monophenols.[1]

Experimental

Reagent grade *o*-Cresol Red (Wako), which gave only one spot on paper chromatogram,[2] was used. Other reagents and apparatus were described in detail in a previous report.[1]

Kinetic measurements were performed in aqueous perchlorate media of $\mu=0.1$ and at 25.0 ± 0.2 °C. Analytical concentration of the ligand, C_{CR}, was kept at 1.00×10^{-4} M. C_{Fe} was changed from 3.62 to 51.2×10^{-3} M. Hydrogen-ion concentration [H] was calculated from the observed pH value without correction of the activity coefficients. Absorbance change was followed at 580 nm, where the absorption of the ligand was weak.

Results and Discussion

Owing to the strong absorption band of the ligand chromophore in the visible region[3] it was rather difficult to obtain the absorption spectra of the unstable complex of Fe(III) with Cresol Red except for the distinct increase in absorbance at 550—600 nm in the tail region of the absorption band of the ligand. Observed difference spectra are shown in Fig. 1.

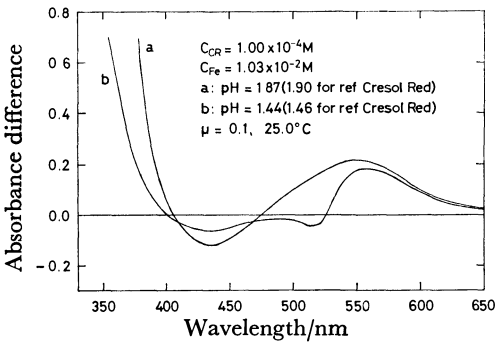

Fig. 1. Difference spectra between Fe(III)-Cresol Red and Cresol Red.

Formation constant of the complex could not be determined by the usual spectrophotometric method, since some slow side-reactions[5] involving the decomposition of the ligand ensued. At 580 nm, however, pseudo-first-order relaxation curves were obtained for the fast reaction process under the conditions of a large excess of Fe(III). Following discussions are concerned with this fast process regarded as the complex formation.

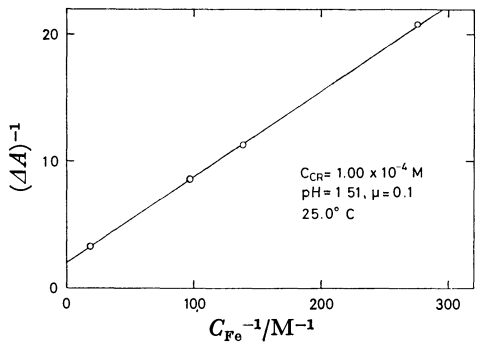

Fig. 2. Plot of $1/\Delta A$ at 580 nm *vs.* $1/C_{Fe}$.

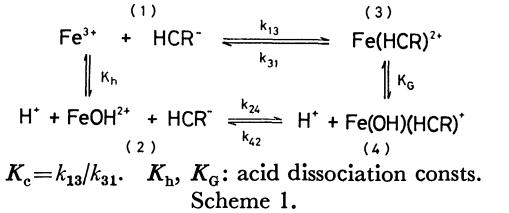
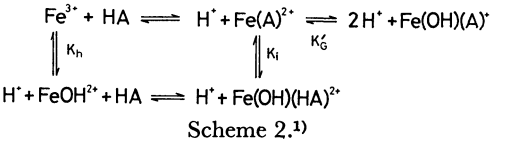
Apparent rate constant k_{obsd} decreased with increasing [H]. It showed no significant change through more than ten-fold change in C_{Fe}. Absorbance changes, ΔA, on the complex formation were obtained from the difference in absorbance in the stopped-flow signals.[6] The values of ΔA showed no significant dependence on [H], but depends on C_{Fe} (see Fig. 2). Scheme 1 is proposed to account for these results. It clearly contrasts with the Scheme 2 for the complex formation between Fe(III) and monophenols (HA).[1]



$K_c=k_{13}/k_{31}$. K_h, K_G: acid dissociation consts.

Scheme 1.



Scheme 2.[1]

The predominant species after the fast complex formation reached equilibrium may be Fe^{3+}, HCR^-, and $Fe(HCR)^{2+}$. The following approximate equation is derived:

$$1/\Delta A = (1+1/C_{Fe}\cdot K_c)/\Delta\varepsilon\cdot C_{CR},$$

$$\Delta\varepsilon = \varepsilon_{FeHCR} - \varepsilon_{HCR},$$

where ε_{FeHCR} and ε_{HCR} denote the apparent molar ex-

* Presented in part at the 1971 Winter Meeting in Hokkaido of the Chemical Society of Japan and the Japan Society for Analytical Chemistry, Sapporo, February, 1971.

** Present address: Kagawa Nutrition College, Sakado-machi, Saitama.

tinction coefficient at 580 nm, and $K_C=[Fe(HCR)^{2+}]/[Fe^{3+}][HCR^-]$. Thus ΔA becomes independent of [H]. The linear plot of $(\Delta A)^{-1}$ *versus* C_{Fe}^{-1} as shown in Fig. 2 confirms that only 1 : 1 complex formation is concerned. From the slope and the intercept,[7] $\Delta\varepsilon=5.05\times10^3$ $M^{-1}cm^{-1}$ and $K_C=29.3$ M^{-1}.

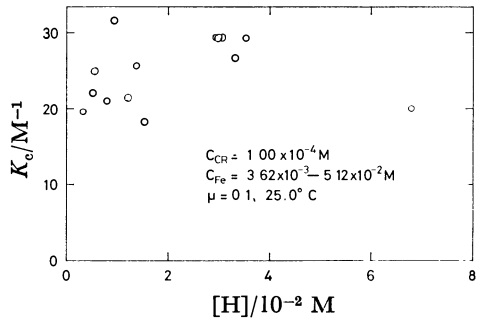


Fig. 3. Apparent stability constants K_c calculated from the absorbance change in the stopped-flow signals.

Spectrophotometric measurement gave $\varepsilon_{HCR}\leqq170$ so that ε_{FeHCR} is 5.2×10^3 $M^{-1}cm^{-1}$. Assuming the one-step mechanism[8] and the equilibrium for very fast proton transfer during the relaxation process, we obtained

$$k_{obsd}\simeq k_fC_{Fe}+k_r,$$

$$k_f=([H]k_{13}+K_hk_{24})/([H]+K_h)$$

and

$$k_r=([H]k_{31}+K_Gk_{42})/([H]+K_G).$$

Here, k_{obsd} was independent of C_{Fe}, so that $k_{obsd}=k_r$. Considering the Coulombic factor in the dissociative process, we assumed that $[H]k_{31}\ll K_Gk_{42}$, giving the approximation

$$k_{obsd}^{-1}\simeq[H]/K_G\cdot k_{42}+1/k_{42}.$$

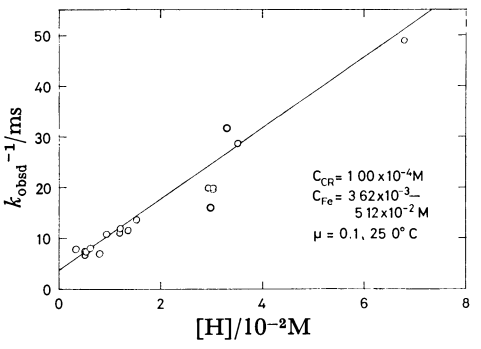

Fig. 4. Plot of $1/k_{obsd}$ *vs.* hydrogen-ion concentration.

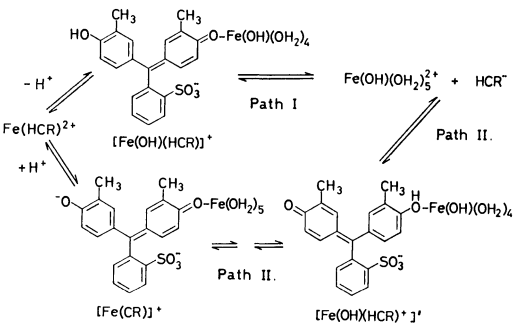
A plot of k_{obsd}^{-1} *versus* [H] gave a straight line (Fig. 4). From the slope and the intercept, $k_{42}=270$ s^{-1} and $K_G=5.6\times10^{-3}$ M. An anionic ligand HCR^- thus may be a comparably weak donor as H_2O, for the K_G is in the same order of magnitude as K_h (4.1×10^{-3} M).[9] The rate constant k_{24} was calculated from the given data to be $k_{24}=(K_GK_C/K_h)\cdot k_{42}=1.1\times10^4$ $M^{-1}s^{-1}$. This value is similar to the complex formation rate for Br^- and $Fe(OH)^{2+}$,[10] and significantly larger than that for monophenols and $Fe(OH)^{2+}$ (1×10^3 $M^{-1}s^{-1}$).[1,11] Thus, the experimental results are consistently interpreted on the basis of the Scheme 1, regarding k_{obsd} as k_r.

Though the following Path I is postulated in the Scheme 1, another intermediate $Fe(CR)^+$, which is isoprotonic to $Fe(OH)(HCR)^+$, can also be taken into



consideration (Path II). Going along the dissociative process, electronic configuration change of $Fe(CR)^+$ followed by intramolecular proton transfer results another isoprotonic intermediate $[Fe(OH)(HCR)^+]'$, which readily releases HCR^-. The observed K_G value is, however, only slightly larger than K_h and much larger than the acid dissociation constant of HCR^-. It is thus approved that the observed K_G concerns rather with the coordinated water than the phenolic hydroxyl group, though the coordination of quinoidal oxygen to Fe(III) may increase the dissociation of phenolic proton. Moreover, Path I is more favorable than Path II for the complex formation process when the charge densities on the two oxygen atoms of the ligand are considered.[12]

Temperature dependence of k_{obsd} was investigated at pH 1.81 and $C_{Fe}=1.65\times10^{-2}$ M. Apparent activation energy was found to be 68.81 $kJ\cdot mol^{-1}$.

3) Molar extinction coefficient of HCR^- at 435 nm (ε_{max}) was reported to be 1.80×10^4 M^{-1} cm^{-1}.[4]

4) M. Murakami, T. Yoshino, and S. Harasawa, *Talanta*, **14**, 1293 (1967).

5) At 435 nm the difference of the absorbance decreased monotonously, at 550 nm once increased and then decreased, and at 500 nm showed complicated feature.

6) Dead time of the stopped-flow apparatus was 1.7 ± 0.2 ms. In the present experiment absorbance may be estimated too small in the case of lower [H], with $k_{obsd}^{-1}=7$ ms.

7) Using the intercept value 1.98, each set of C_{Fe} and ΔA derives the value of K_c, which is plotted against [H] (Fig. 3).

8) Two-step mechanism involving a very stable intermediate gives k_{obsd} which is independent of C_{metal} and is concerned with the formation process. See Eq. (2) in Ref. 2.

10) P. Matthies and H. Wendt, *Z. Physik. Chem., N. F.*, **30**, 137 (1961).

11) According to the authors' mind the pre-equilibrium constants[2] for the ion-pair formation, which depend mainly on the charges and the radii of the solvated species involved, may characterize the complex formation rate constants of $Fe(OH)^{2+}$ with various ligands.

12) The possibility of the direct protolytic transformation between species $[Fe(OH)(HCR)]^+$ (A) and $[Fe(OH)(HCR)^+]'$ (B) is assumed to be quite small, since the contribution of the intervening resonance forms involving an intermediate protonated quinoid cation to the proton transfer between A and B is lowered because of the propeller-like distortion of the π-systems in the benzene and the quinoidal ring.

A Stoichiometric Investigation of the Reaction of Nitrosylpentaamminechromium(2+) with Ethylenediaminetetraacetatoaquachromate(II)

Hiroshi OGINO, Keiichi TSUKAHARA, and Nobuyuki TANAKA

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received June 9, 1975)

Synopsis. The reaction of $Cr(NH_3)_5NO^{2+}$ with $Cr^{II}(edta)(H_2O)^{2-}$ gives four chromium products: $Cr^{III}(edta)(H_2O)^-$, $Cr(NH_3)_6^{3+}$, a reddish-violet species which is considered to be a chromium dimer with a +2 charge, and a trace amount of $Cr(H_2O)(NH_3)_5^{3+}$.

Recently, Armor *et al.* studied the reaction of $Cr(NH_3)_5NO^{2+}$ with $Cr(H_2O)_6^{2+}$ (Cr^{2+}) and observed at least five different chromium(III) products.[1] In this work, the products of the reaction of $Cr(NH_3)_5NO^{2+}$ with ethylenediaminetetraacetatoaquachromate(II) ($Cr^{II}(edta)(H_2O)^{2-}$) are examined, and the results compared with those obtained by Armor *et al.*

Experimental

Materials. The $[Cr(NH_3)_5NO](ClO_4)_2$ complex was prepared by the method of Mori *et al.*[2] The solutions of Cr^{2+} and $Cr^{II}(edta)(H_2O)^{2-}$ were prepared as has been reported previously.[3]

Identification and Analyses of Products. The reaction of $Cr(NH_3)_5NO^{2+}$ with $Cr^{II}(edta)(H_2O)^{2-}$ was carried out in an acetate-buffer solution under a nitrogen atmosphere. The reaction was completed within 5 s under the present experimental conditions. The complex ions, $Cr(NH_3)_5NO^{2+}$, were always treated with more than four equivalents of $Cr^{II}(edta)(H_2O)^{2-}$. After the solution of the reaction mixture had been exposed to air, it was diluted with five times as much water and then poured into an SP-Sephadex C-25 column. The species which passed through the column without any affinity to the resin was identified as $Cr^{III}(edta)(H_2O)^-$ from the measurement of the visible and ultraviolet absorption spectra. After the column had then been washed with water, the adsorbed species on the column were eluted with an 0.2 M $NaClO_4$–0.1 M $HClO_4$ solution. Three distinct bands were observed—reddish-violet, reddish-orange (trace amount), and yellow from the bottom to the top of the column. The eluate from the lowest band was concentrated with a rotary evaporator below 40 °C. Reddish-violet crystals were thus deposited. However, the attempted isolation of crystals sufficiently pure to be subjected to elemental analyses has not yet been successful because of the highly hygroscopic nature of this compound. From the flow rate on the Sephadex column, this species was estimated to have a +2 charge. The visible absorption spectrum shows two maxima, at 566 nm ($\varepsilon=17$) and 406 nm ($\varepsilon=19$).[4] The reddish-orange and yellow bands were eluted out with an 0.5 M $NaClO_4$–0.1 M $HClO_4$ solution. The reddish-orange species was characterized as $Cr(H_2O)(NH_3)_5^{3+}$ from the measurement of the visible absorption spectra. When the yellow eluate was concentrated with a rotary evaporator, yellow crystals were deposited. They were identified as $[Cr(NH_3)_6](ClO_4)_3$ from the measurement of the infrared, visible, and ultraviolet absorption spectra. The chromium content of each fraction was determined spectrophotometrically as CrO_4^{2-} after oxidation with an alkaline hydrogen-peroxide solution. The visible and ultraviolet absorption spectra were recorded with a Hitachi EPS-3 spectrophotometer.

Results and Discussion

The quantitative product distribution was determined at 25 °C with a solution (total volume, 4.00 ml) with an ionic strength of 0.3 ($NaClO_4$) and a pH of 4.3 which had initially contained 3.68×10^{-3} M $Cr(NH_3)_5NO^{2+}$, 1.83×10^{-2} M $Cr^{II}(edta)(H_2O)^{2-}$, 6.7×10^{-3} M EDTA, and an acetate buffer with 0.125 M acetate. For the separation of the chromium products, a Sephadex column 1.4 cm in diameter and 5 cm in height was used; into it the reaction mixture was poured. From the chromium content of each product separated, the concentrations of $Cr(NH_3)_6^{3+}$, the reddish-violet species, and $Cr^{III}(edta)(H_2O)^-$ were determined to be 2.59×10^{-3} M, 2.21×10^{-3} M, and 1.64×10^{-2} M respectively. The following stoichiometry can be assigned to the formation of $Cr(NH_3)_6^{3+}$:

$$Cr(NH_3)_5NO^{2+} + 4Cr^{II}(edta)(H_2O)^{2-} + 5H^+ \longrightarrow Cr(NH_3)_6^{3+} + 4Cr^{III}(edta)(H_2O)^- + H_2O \quad (1)$$

The concentration of chromium in the reddish-violet species is equal to $2\times([Cr(NH_3)_5NO^{2+}]-[Cr(NH_3)_6^{3+}])$. Therefore, the reddish-violet species is considered to be a chromium dimer having a +2 charge:

$$Cr(NH_3)_5NO^{2+} + Cr^{II}(edta)(H_2O)^{2-} \longrightarrow \text{reddish-violet species}^{2+} \quad (2)$$

The product distribution revealed that 70% of the $Cr(NH_3)_5NO^{2+}$ was converted to $Cr(NH_3)_6^{3+}$ and the rest, to the reddish-violet species. The formation of $Cr(NH_3)_6^{3+}$ from $Cr(NH_3)_5NO^{2+}$ is chemical evidence that the nitrosyl group in $Cr(NH_3)_5NO^{2+}$ is a nitrogen-bonded ligand.

The chromium products of the reaction of $Cr(NH_3)_5NO^{2+}$ with Cr^{2+} were found to be $Cr(H_2O)_6^{3+}$, $Cr(H_2O)(NH_3)_5^{3+}$, $(H_2O)_4Cr(OH)_2Cr(H_2O)_4^{4+}$, and two polymeric products which may be represented by the formula $(NH_3)_5Cr\text{–}X\text{–}Cr(H_2O)_4Y^{n+}$, X=$OH^-$ or NH_2OH, Y=H_2O or NH_2OH.[1] These products are quite different from the products observed in the present reaction. According to the results obtained by Armor *et al.*[1], 1 mol of $Cr(NH_3)_5NO^{2+}$ reacts with 2 mol of Cr^{2+} to give 1 mol of NH_2OH. On the other hand, at least 70% of the nitrosyl group in $Cr(NH_3)_5NO^{2+}$ is reduced to NH_3 by $Cr^{II}(edta)(H_2O)^{2-}$ reduction. Therefore, the kind of ligand coordinated to the chromium(II)ions dramatically changes the products of the reactions of $Cr(NH_3)_5NO^{2+}$ with chromium(II). A similar observation was

also made of the reduction of NO_3^-. The reaction of NO_3^- with Cr^{2+} gives $Cr(H_2O)_5NO^{2+}$ [5], and the further reaction with Cr^{2+} yields NH_2OH.[6] The reaction of NO_3^- with $Cr^{II}(edta)(H_2O)^{2-}$ gives NH_4^+.[7,8] The difference between the reaction with Cr^{2+} and that with $Cr^{II}(edta)(H_2O)^{2-}$ may primarily come from the difference in their reduction potentials.[9] It is also apparent that the nature of the central metal ion inherently coordinated to the nitrosyl group controls the extent of the reduction of the nitrosyl group, because it is known that $Ru(NH_3)_5NO^{3+}$ reacts with Cr^{2+} to give $Ru(NH_3)_6^{2+}$.[10]

The absorption spectra of $Cr(NH_3)_5NO^{2+}$ change slowly in $NaClO_4$–$HClO_4$ media. It seems worthwhile to present some observations on these spectral changes (at 25 °C and at an ionic strength of 1.0 ($NaClO_4$–$HClO_4$)). When the hydrogen-ion concentration is higher than 0.2 M, absorbances over the whole range of the visible region decrease with the time. The rate of this change increases with an increase in the concentrations of hydrogen ions. For example, the rate constants of this process, as estimated by the Guggenheim method,[11] are 6.5×10^{-4} s^{-1} at $[H^+]=0.313$ M and 8.4×10^{-4} s^{-1} at $[H^+]=0.783$ M. When the hydrogen-ion concentration falls below 0.1 M, the reaction mentioned above can be neglected and another reaction occurs. The initial stage of the spectral changes shows isosbestic points at 351 nm and 430 nm. The rate constant of this process was determined to be 7.1×10^{-5} s^{-1} at $[H^+]=0.0940$ M. Then, the isosbestic points collapse and the spectra change in a complicated manner, suggesting the occurrence of some consecutive reactions. The spectrum which was obtained after heating the solution on a boiling water bath shows absorption bands at 390 nm (shoulder, $\varepsilon=94$), 447 nm ($\varepsilon=116$), and 566 nm ($\varepsilon=31$). This spectrum coincides satisfactorily with that of $Cr(H_2O)_5NO^{2+}$ reported by Griffith.[12] Therefore, the spectral changes at $[H^+]<0.1$ M may correspond to the following reaction:

$$Cr(NH_3)_5NO^{2+} + nH_3O^+ \longrightarrow Cr(H_2O)_n(NH_3)_{5-n}NO^{2+} + nNH_4^+ \quad (3)$$

where $1\leq n\leq 5$.

Solubility of Transition Metal Complexes in Aqueous Salt Solutions. II. Tris(1,10-phenanthroline)iron(II) Perchlorate in Hydrophobic Salt Solutions

Katsuhiko MIYOSHI, Chiyori SHIMADA, and Hayami YONEDA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received June 9, 1975)

Synopsis. Solubility of tris(1,10-phenanthroline)-iron(II) perchlorate in water was found to be much increased by the addition of hydrophobic ions. This was interpreted in terms of hydrophobic interaction of the complex cation with hydrophobic ions added.

It is generally accepted that ions in aqueous solutions are classified into three groups according to the nature of their interaction with water; structure-maker, structure-breaker, and hydrophobic structure-maker.[1-3] In our preceding paper of this series,[4] we proposed that $[Fe(phen)_3]^{2+}$ (phen=1,10-phenanthroline) belongs to the last group despite its relatively high charge. In order to ascertain our proposal, solubility of $[Fe(phen)_3](ClO_4)_2$ was measured at 25 °C in aqueous solutions of various hydrophobic salts as a function of total ionic strength.

$[Fe(phen)_3](ClO_4)_2 \cdot H_2O$ was prepared in the same manner as before.[4] Sodium alkane carboxylates (formate to octanoate) were prepared and purified in a similar manner to that described by Sakurai[5] and Tamaki *et al.*[6] Tetraalkylammonium bromides (methyl to *n*-butyl) were dried at 100 °C. Solubility measurements were carried out at 25±0.1 °C in the same manner as before.[4] Usually it took 7 to 8 h to attain solution equilibrium.

In Fig. 1 is plotted the solubility ratio S/S_0, *i.e.*, the ratio of solubility (mol/l) of the complex in aqueous salt solutions to that in pure water, against square root of total ionic strength I for sodium alkane carboxylate solutions. Also drawn are theoretical curves estimated by the Debye-Hückel approximation with $a=8$ and 9 Å.[4,7] It is seen that S/S_0 is more and more increased as the number of methylene groups in alkane carboxylates is increased,[8] *i.e.*, as the added anions bear more hydrophobic character,[9] and that higher carboxylates[10] (hexanoate to octanoate) show an increasingly positive curvature contrary to the prediction from the Debye-Hückel theory.

S_0 is so low (8.99×10^{-4} mol/l) as compared with the concentration of added salts that the co-sphere[2] of $[Fe(phen)_3]^{2+}$ overlaps predominantly with that of added anions rather than that of ClO_4^-. As a result, it follows that the increment in S/S_0 depends on whether the complex cation is cooperative or antagonistic with added

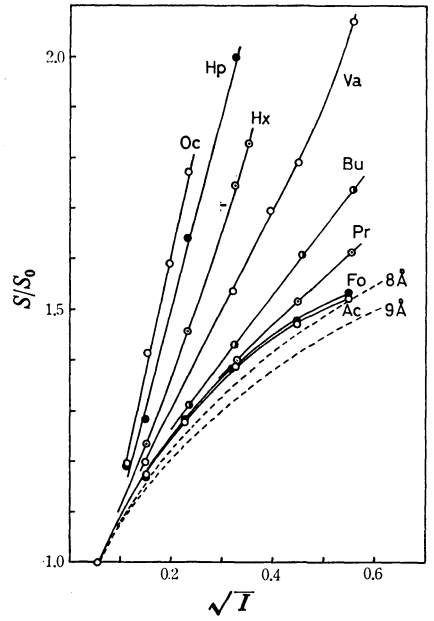

Fig. 1. Dependence of the solubility ratio S/S_0 on square root of ionic strength I for sodium alkane carboxylate solutions. Fo, Ac, Pr, Bu, Va, Hx, Hp, and Oc refer to sodium formate, acetate, propionate, butyrate, valerate, hexanoate, heptanoate, and octanoate solutions, respectively. Dotted lines represent theoretical values estimated by the Debye-Hückel approximation

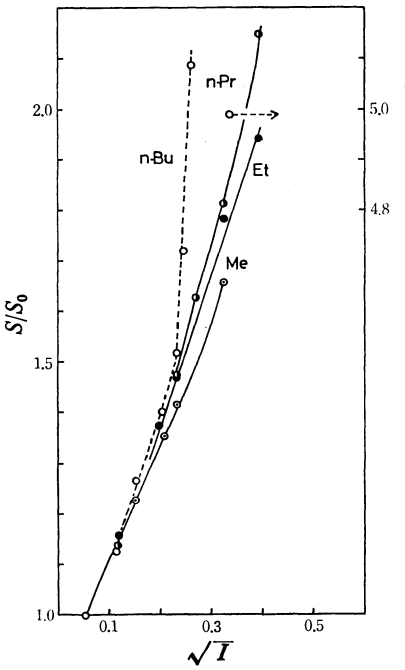

Fig. 2. Dependence of the solubility ratio S/S_0 on square root of ionic strength I for tetraalkylammonium bromide R_4NBr solutions. Me, Et, *n*-Pr, and *n*-Bu refer to Me_4NBr, Et_4NBr, *n*-Pr_4NBr, and *n*-Bu_4NBr solutions, respectively. Only one point in the most concentrated solution of *n*-Bu_4NBr corresponds to the right-hand scale.

anions with respect to their influence on the water structure, as pointed out by Steigman and Dobrow,[11] and Desnoyers *et al.*,[12] if ion association is negligible. Since added anions are all singly charged, their electrostatic association with the complex cation is not so extensive, at least at low salt concentrations.[4] Thus, it is confirmed from Fig. 1 that $[Fe(phen)_3]^{2+}$ is cooperative with hydrophobic anions.

Figure 2 shows similar plots for tetraalkylammonium bromide solutions and indicates that S/S_0 does not differ appreciably from salt to salt added when the salt concentration is relatively low. This is to be expected since the co-sphere of the complex cation firstly interacts with that of Br^- ion, which is common to all salt solutions. However, as the salt concentration is increased, S/S_0 begins to diverge; the more hydrophobic the added cation is,[13] the more S/S_0 increases (structural salting-in[3] or cation-cation interaction). In particular for tetra-*n*-butylammonium bromide (*n*-Bu_4NBr) solutions, S/S_0 suddenly increases greatly at *ca.* 0.05 mol/l. The critical micelle concentration (cmc) of *n*-Bu_4NBr is reported to be *ca.* 0.04 mol/l at 25 °C by Lindenbaum and Boyd.[14] Thus, this abnormal increase in S/S_0 is attributed to so-called solubilization of the complex cation into micelles composed of *n*-Bu_4N^+, though the electrostatic repulsion is expected between the complex and the micelles. Therefore, the complex cation is cooperative with hydrophobic cations, too.

In conclusion, $[Fe(phen)_3]^{2+}$ belongs to the hydrophobic structure-maker group and is stabilized by the hydrophobic interaction[15] with added hydrophobic ions in aqueous solutions.

The Preparation of 1- and 2-Aminophenazine Derivatives

Masao TADA

The Research Institute for Tuberculosis, Leprosy and Cancer, Tohoku University, Hirosemachi, Sendai 980

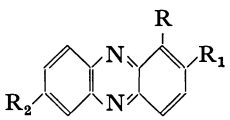
(Received February 3, 1975)

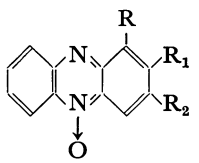
Synopsis. The reactions of chlorophenazines and their *N*-oxides with sodium azide in dimethyl sulfoxide or dimethylformamide yielded the corresponding aminophenazine derivatives.

In previous papers,[1,2] the reactions of halogenophenazines with piperidine, morpholine, sodium carboxymethyl mercaptide, and sodium methyl mercaptide were reported. During the study on the potential biological activities of phenazine derivatives, the preparation of aminophenazine derivatives was required. Pachter *et al.*[3] have reported that 2-aminophenazine (I) was prepared from 2-chlorophenazine (II) with aqueous ammonia by heating in an autoclave. This note describes the application of the transformation of a halogeno group into an amino group by the use of sodium azide.[4]

The reaction of 1-chlorophenazine (III) with sodium azide in dimethyl sulfoxide (DMSO) at 130 °C for 48 h gave 1-aminophenazine (IV).[5] The treatment of 1-chlorophenazine 5-oxide (V) with sodium azide in DMSO at 130 °C for 24 h gave 1-aminophenazine-5-oxide (VI), which was converted into IV by the reduction with zinc dust in acetic acid.

The reaction of II with sodium azide in DMSO or dimethylformamide (DMF) afforded a 2-amino compound (I). The reactions of 2-chloro- (VII) and 3-chlorophenazine 5-oxides (VIII) with sodium azide in DMSO gave the corresponding aminophenazine 5-oxides (IX and X). Both compounds IX and X were converted into I by reduction.





I: $R=R_2=H$; $R_1=NH_2$ V: $R=Cl$; $R_1=R_2=H$
II: $R=R_2=H$; $R_1=Cl$ VI: $R=NH_2$; $R_1=R_2=H$
III: $R=Cl$; $R_1=R_2=H$ VII: $R=R_2=H$; $R_1=Cl$
IV: $R=NH_2$; $R_1=R_2=H$ VIII: $R=R_1=H$; $R_2=Cl$
XI: $R=H$; $R_1=R_2=Cl$ IX: $R=R_2=H$; $R_1=NH_2$
XII: $R=H$; $R_1=NH_2$; $R_2=Cl$ X: $R=R_1=H$; $R_2=NH_2$

The heating of a mixture of VIII and sodium azide in DMF for 1 h under reflux afforded I, II, and X in yields of 3, 28, and 45%, respectively. Prolonged reflux (3 h), however, lead to the formation of I, II, and X in yields of 21, 19, and 20%, respectively. The results suggest that *N*-oxides are partially converted into the parent bases during the course of the displacement of a chlorine atom. This has been well confirmed by heating a solution of VIII in DMF, as shown in Table 1. Such a simple deoxygenation of *N*-oxide by DMF is hitherto unknown.[6]

A similar phenomenon was also observed in the heating of V and VII in DMF.

Table 1. Deoxygenation of 3-chlorophenazine 5-oxide (VIII)

Reflux time in DMF (h)	Deoxygenation product, II (%)	Recovery (%)
10	13	80
20	35	56
40	93	0

The amination of 2,7-dichlorophenazine (XI) gave 2-amino-7-chlorophenazine (XII) which also had been derived from VIII *via* nitration and reduction.[7]

Experimental

All the melting points are uncorrected. Absorption spectra were recorded with a Hitachi Model EPI-S_2 infrared spectrophotometer and a Hitachi Model 124 spectrophotometer.

1-Aminophenazine (IV). From 1-Chlorophenazine (III): To a hot solution of III (2.0 g) in DMSO (20 ml), sodium azide (1.0 g) was added. The mixture was then heated at 130 °C for 48 h, cooled, and poured into water. The crystals thereby separated were analyzed by chromatography on alumina, using benzene as the solvent, and then recrystallized from aqueous methanol to yield IV (520 mg, 29%), mp 176 °C, which showed no decrease in melting point on admixture with an authentic specimen.[5] Unchanged III (800 mg, 40%) was recovered.

From 1-Aminophenazine 5-Oxide (VI): Into a solution of VI (210 mg) in acetic acid (5 ml), zinc dust (1.5 g) was added. The mixture was then warmed in a water bath for 10 min, and filtered while hot. After usual treatment, recrystallization of the product from aqueous methanol afforded IV (150 mg, 77%), mp 176 °C.

1-Aminophenazine 5-Oxide (VI). A mixture of V (1.15 g) and sodium azide (450 mg) in DMSO (12 ml) was heated at 130 °C for 24 h, and treated as described above to afford crystals. Recrystallization from a mixture of chloroform and methanol (1: 1) gave VI (mp 226—227 °C (dec.), 400 mg) as reddish-violet micro-prisms in a 38% yield. Found: C, 67.98; H, 4.29; N, 19.98%. Calcd for $C_{12}H_9N_3O$: C, 68.23; H, 4.30; N, 19.90%. IR (KBr): 3440 and 3330 cm^{-1}. UV: λ_{max}^{MeOH} 252 (log ε=4.49), 289 (4.61), 367 (3.75), 384 (3.72), and 515 (3.60) nm.

2-Aminophenazine (I). In DMSO: A mixture of II (2.6 g) and sodium azide (1.1 g) in DMSO (30 ml) was heated at 130 °C for 10 h, and then diluted with water. The precipitate was dissolved in ethyl acetate. The solution was then passed through a column of alumina and eluted with ethyl acetate. From the effluent, reddish-orange crystals were obtained. Recrystallization from chloroform gave fine red crystals (900 mg, 38%), mp 267—268 °C (dec), which were identified with I[3] by a comparison of their infrared spectra.

In DMF: A suspension of II (1.2 g) and sodium azide (450 mg) in DMF (20 ml) was gently refluxed for 5 h, and then treated in a similar way to yield I (550 mg, 56%), mp 267—268 °C (dec).

2-Aminophenazine 5-Oxide (IX). A suspension of VII

(1.2 g) and sodium azide (450 mg) in DMSO (12 ml) was heated at 130 °C for 4 h, and then treated as in the procedure used in the preparation of I to give crystals, which were recrystallized from ethanol to afford IX (mp 260—261 °C (dec), 500 mg) as deep-violet micro-crystals in a 47% yield. Found: C, 68.34; H, 4.19; N, 19.72%. Calcd for $C_{12}H_9N_3O$: C, 68.23; H, 4.30; N, 19.90%. IR (KBr): 3400 and 3320 cm^{-1}. UV: λ_{max}^{MeOH} 279 (log ε=4.81), 333 (3.75), 350 (3.84), 371 (3.98), 391 (4.22), and 500 (3.82) nm.

IX (210 mg) was treated with zinc dust (0.5 g) in acetic acid (5 ml) to yield I (120 mg, 62%), mp 267—268 °C (dec).

3-Aminophenazine 5-Oxide (X). *In DMSO*: A mixture of VIII (1.16 g) and sodium azide (0.3 g) in DMSO (20 ml) was heated at 130 °C for 3 h, and then treated as in the above experiment to afford crystals. Recrystallization of the product from ethanol gave X (mp 253—254 °C (dec), 700 mg) as red micro-prisms in a 66% yield. Found: C, 68.45; H, 4.29; N, 20.10%. Calcd for $C_{12}H_9N_3O$: C, 68.23; H, 4.30; N, 19.90%. IR (KBr): 3400 and 3320 cm^{-1}. UV: λ_{max}^{MeOH} 241 (log ε= 4.22), 285 (4.75), 366 (3.79), 384 (4.08), and 500 (4.00) nm.

In DMF: A suspension of VIII (2.31 g) and sodium azide (0.6 g) in DMF (25 ml) was refluxed for 1 h to give I (50 mg, 3%), II (600 mg, 28%), and X (950 mg, 45%).

X (210 mg) was treated with zinc dust (0.5 g) in acetic acid (5 ml) to yield I (110 mg, 56%).

Deoxygenation of Chlorophenazine 5-Oxides. A solution of chlorophenazine 5-oxide (1.16 g) in DMF (20 ml) was refluxed, and then diluted with water. The crystals thereby separated were dissolved in benzene. The benzene solution was passed through a column of alumina, and eluted with benzene. From the first effluent, a deoxygenation product was obtained, and 5-oxide was recovered from the second effluent.

2-Amino-7-chlorophenazine (XII). A suspension of XI (1.25 g) and sodium azide (390 mg) in DMSO (30 ml) was heated at 130 °C for 4 h, and then treated as in the case of I to give red needles (450 mg, 39%), mp 252 °C, which showed no decrease in melting point on admixture with an authentic specimen.[7]

The author is grateful to Professor Yusaku Ikegami of Tohoku University for his encouragement, and to Miss Mieko Sasaki for her experimental cooperation.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 48 (11), 3407—3408 (1975)

Mechanism of the Formation of Phenyltolylmethane by the Reaction of Toluene with Phosphorus Trichloride and Oxygen

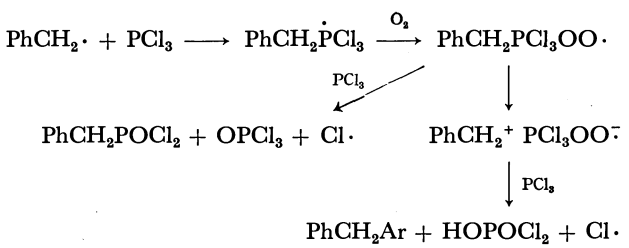
Yoshiki OKAMOTO and Hiroshi SAKURAI

The Institute of Scientific and Industrial Research, Osaka University, Yamada-kami, Suita, Osaka 565

(Received February 7, 1975)

Synopsis. The formation of phenyltolylmethane by the reaction of toluene with PCl_3 and oxygen was shown to proceed by electrophilic attack on toluene by the benzyl cation, resulting from the decomposition of the trichlorobenzyloxyphosphoranyl peroxy radical ($PhCH_2OPCl_3OO\cdot$).

The formation of phenyltolylmethane (I) by the reaction of toluene with PCl_3 and oxygen was reported in a previous paper,[1] in which the mechanism of the formation was explained by the electrophilic attack on toluene by benzyl cation, resulting from the electron transfer from the benzyl radical to PCl_3 with the participation of oxygen as shown in Scheme 1.



Scheme 1.

However, it has been found that when the initial ratio of PCl_3 to toluene was reduced under a constant flow rate of oxygen, or when the oxygen gas pressure was diminished by dilution with nitrogen with a constant initial ratio of PCl_3 to toluene, the ratio of I to benzylphosphonic dichloride (II) in the product decreased (Table 1).

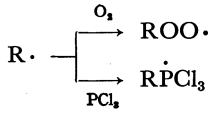
TABLE 1. THE PRODUCT RATIO (I/II) OBTAINED BY CHLOROPHOSPHONATION OF TOLUENE, CARRIED OUT UNDER SEVERAL CONDITIONS

Reactant ratio (Toluene/PCl_3)	Oxygen (%)	Time (h)	Yield (g)	Product ratio (I/II)
0.02	100	3	3.0	7
0.1	100	3	4.9	29
0.2	100	3	4.8	50
5	100	3	1.6	230
0.2	50	6	7.0	41
0.2	10	30	5.3	21

These results cannot be explained by Scheme 1, in which the benzyl radical reacts with PCl_3 exclusively to give a trichlorobenzylphosphranyl radical as an intermediate. It is well known that tervalent phosphorus compounds have high reactivities with free radicals, such as RO·, RS·, and methyl.[2] However, recently Dulog, Nielich, and Verhelst reported that resonance-stabilized radicals, such as $Ph_3C\cdot$, fail to react with PCl_3.[3] The reactivities of the free radical with PCl_3 decrease in the following order: $C_6H_5\cdot > t\text{-}C_5H_9\cdot > (CH_3)_2\dot{C}CN > (C_6H_5)_3C\cdot$. Bentrude also suggested that methyl and ethyl radicals react with $(C_6H_5)_2POR$, but that the more stable radicals, such as benzyl, do not appreciably react with $(C_6H_5)_2POR$,[4] because the ΔH_{PZ_4} for the reaction of $(C_6H_5)_2POR$ and benzyl radical (the enthalpy change of the formation of the phosphoranyl radical intermediate) is too small to form a phosphoranyl radical.[2,4] The ΔH_{PZ_4} is analyzed into three contributing terms: (1) the phosphorus orbital reorganization energy (ORE), (2) the strength of the bond to phosphorus being formed (ΔH_{PZ}), and (3) any resonance stability imparted to the phosphoranyl radical by the substituents on phosphorus (RE). Differences in the enthalpies of formation for strengths of the new bonds being formed and the resonance-stability difference (if ORE is assumed constant). The bond strength of benzyl is not known but is assumed to be considerably smaller than that for other free radicals, such as RO·, RS·, and methyl.[2] It is also supposed that PCl_3 may be less reactive than $(C_6H_5)_2POR$ because, in the former case, the effect of no resonance stability imparted to the phosphoranyl radical can be expected.

On the other hand, it is well known that the addition of oxygen to the radical is extremely fast and is probably diffusion controlled in many instances.[5] An extremely resonance-stabilized radical, such as $Ph_3C\cdot$, is very reactive with oxygen even though it is relatively inert with other species.[6]

Therefore, the benzyl radical may react preferentially with oxygen to form a benzyl peroxy radical (reaction 1) rather than with PCl_3 to form a trichlorobenzylphosphoranyl radical,



(1)

(2)

The benzyl peroxy radical is deoxygenated with PCl_3 to yield the benzyloxy radical (reaction 3),[3] which is trapped again with PCl_3 to form a trichlorobenzyloxyphosphoranyl radical (III),

$$ROO\cdot + PCl_3 \longrightarrow RO\cdot + POCl_3 \quad (3)$$

$$RO\cdot + PCl_3 \longrightarrow R\dot{O}PCl_3 \text{ (III)} \quad (4)$$

Radical III reacts with oxygen to give a trichlorobenzyloxyphosphoranyl peroxy radical (IV), thus

$$R\dot{O}PCl_3 + O_2 \longrightarrow ROPCl_3OO\cdot \text{ (IV)} \quad (5)$$

In the case of R≒benzyl, radical IV reacts with PCl_3 to give alkyl phosphorochloridate, $POCl_3$ and Cl.[7,8] However, when R has a lower ionization potential, such as for the benzyl radical (7.76 eV), the electron transfer from a benzyl group to an $OPCl_3OO$ group may occur to give an ionic structure such as IV′:

$$ROPCl_3OO\cdot \longrightarrow R^+(OPCl_3OO\cdot)^- \text{ (IV')} \quad (6)$$

The electrophilic attack of benzyl cation (IV') on toluene gives phenyltolylmethane (I) as a final product, thus

$$IV' + C_6H_5CH_3 \xrightarrow{PCl_3} I + HOPOCl_2 + POCl_3 + Cl\cdot \quad (7)$$

The formation of α-methylstyrene and its dimers by the chlorophosphonation of isopropylbenzene[1] can be explained in a similar manner.

But in this case, IV″ leads to α-methylstyrene by intramolecular proton-migration, thus

$$C_6H_5\overset{\overset{CH_3}{|}}{\underset{\underset{CH_3}{|}}{C^+}}\ OPCl_3OO^- \xrightarrow{PCl_3} \text{(IV'')}$$

$$C_6H_5\overset{\overset{CH_3}{|}}{C}=CH_2 + HOPOCl_2 + POCl_3 + Cl\cdot \quad (8)$$

The possibility of the direct formation of a benzyl cation from radical III (reaction 9) can be eliminated by the results that no α-methylstyrene and its dimers could be detected in the thermally-decomposed products of bis(α,α-dimethylbenzyl) peroxide in PCl_3 in a nitrogen atomsphere:

$$\dot{R}OPCl_3 \text{ (III)} \longrightarrow R^+ \dot{O}PCl_3^- \quad (9)$$

The remarkable formation of alkylphosphorodichloridate was observed in the chlorophosphonation of alkyl halide,[8] thus

$$ROPCl_3OO\cdot + PCl_3 \longrightarrow ROPOCl_2 + POCl_3 + Cl\cdot \quad (10)$$

Therefore, there is another possilibity of the formation of a benzyl cation: the reaction *via* the heterolytic dissociation of the C–O bond of benzylphosphorodichloridate (V), thus

$$ROPOCl_2 \text{ (V)} \longrightarrow R^+ OPOCl_2^- \quad (11)$$

However, the possibility of this reaction can also be eliminated, because a mixture of dibenzylphosphorochloridate, toluene, PCl_3 and $POCl_3$ did not gave I in the presence of a trace of HCl at 0—5 °C.

Experimental

The general and detailed procedure was described in a previous paper.[1]

Chlorophosphonation. A mixture (130 ml) of the prescribed ratio of toluene/PCl_3 was placed in a reaction vessel. Oxygen or a mixture of oxygen and nitrogen gas was bubbled into the reaction mixture at a flow rate of 300 ml/min at a temperature of −15—0 °C. After the removal of a large portion of the unreacted materials and $POCl_3$, the residue was distilled *in vacuo*.[9] The I/II ratios were determined by glc analysis after treating the distillate with ethanol–triethylamine.

Thermal Decomposition of Bis(α,α-dimethylbenzyl) Peroxide in PCl_3. Bis(α,α-dimethylbenzyl) peroxide (0.1 mol) in PCl_3 (50 ml) was heated (70—80 °C) in a nitrogen atmosphere for a period of approximatately 6 h. The reaction mixture was poured into ice water and an oily layer was extracted with ether. No α-methylstyrene or its dimers were detected but a small amount of phenol was found by glc.

Reaction of Toluene with Dibenzylphosphorochloridate in the Presence of PCl_3, $POCl_3$, and HCl. The mixture of toluene (9.2 g, 0.1 mol), dibenzylphosphorochloridate (29 g, 0.1 mol), PCl_3 (24 g, 0.2 mol), $POCl_3$ (15 g, 0.1 mol) and a trace of HCl was stirred for a period of approximately 12 h at 0—5 °C. The mixture was poured into ice water. And oily layer was analyzed by glc. No. I was detected.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 48 (11), 3409—3410 (1975)

Reactions of Diazomethyl-1,3,5-triazines with Cyclohexane

Akio KUMAGAI, Shizen SEKIGUCHI, and Kohji MATSUI
Department of Chemistry, Gunma University, Kiryu, Gunma 376

(Received March 28, 1975)

Synopsis. Diazomethyl-1,3,5-triazines reacted with cyclohexane thermally and photochemically to give cyclohexylmethyl-1,3,5-triazines as the major product. The reactions took place *via* a carbene intermediate; however, the hydrogen abstraction products (methyl-triazines) were not obtained in these cases.

There have been a number of studies of the reactions of aliphatic diazo compounds.[1] In recent years the reactions of diazoalkyl derivatives of heteroaromatics, such as triazole,[2] furan,[3-5] thiophene,[5,6] and pyridine,[6-8] have been investigated.

Diazomethyl-1,3,5-triazines have been known for a long time;[9-11] however, the thermal and photochemical reactions of diazomethyl-1,3,5-triazines have not yet been investigated.

On the other hand, the thermolysis and photolysis of diazomethyl-1,3,5-triazines may provide useful and convenient routes for the preparation of 1,3,5-triazine derivatives, which would otherwise be difficult to prepare.

This paper will report on the thermal and photochemical reactions of diazomethyl-triazines with cyclohexane.

Structure of Diazomethyl-1,3,5-triazines. 4,6-Dichloro-(1),[9,10] 4,6-dimethoxy- (2),[9] and 4,6-bis(dimethylamino)-2-diazomethyl-1,3,5-triazine (3)[10] are thermally stable; they can be purified by sublimation under reduced pressure. Generally, 2-diazomethyl nitrogen heteroaromatics are considered to exist in a diazomethyl-azomethine-triazole equilibrium. In the diazomethyl derivatives of pyridine, the equilibrium lies strongly on the side of triazole,[6-8,12] while in the derivatives of 1,3,5-triazine the triazole form is considered to be excluded on the basis of the mode of their reactions and the presence of the characteristic IR band of aliphatic diazo compound.[9]

The IR spectra of Compounds 1, 2, and 3 in KBr discs have a strong and sharp characteristic band near 2120 cm^{-1} assignable to the diazomethyl group, indicating that these compounds exist in the diazomethyl form in a solid state. In addition, the PMR spectra of Compounds 2 and 3 in CCl_4, $CDCl_3$, and DMSO-d_6 at 20 and 60 °C showed a signal assignable to $-OCH_3$ or $-N(CH_3)_2$ as a singlet in every case, in spite of the wide diversity in the nature of the solvent (see Table 1); this shows the absence of tautomeric triazole, which should possess two kinds of methoxyl or dimethylamino groups. Contrary to expectations, ordinary diazomethyl-1,3,5-triazines exist only in the diazomethyl form, not only in the solid state, but also in a solution, regardless of the solvent employed.

Table 1. PMR data of diazomethyl-triazines

Solvent	Chemical Shift (δ)[a]			
	Compound 2		Compound 3	
	$-CHN_2$	$-OCH_3$	$-CHN_2$	$-N(CH_3)_2$
DMSO-d_6	5.9	3.9	5.4	3.0
CCl_4	5.2	4.0	4.0	3.1
$CDCl_3$	5.1	3.9	4.7	3.1

a) Measured at 20 °C using TMS as the internal standard.

In diazomethyl-1,3,5-triazines, electrons poured into the aromatic nucleus from the side chain should spread over the 3-ring nitrogen atoms; therefore, interaction between one of these nitrogen atoms and the terminal nitrogen atom of the side chain would be weaker than in the cases of diazines and pyridine. Thus, it may generally be said that an increase in the number of ring nitrogen atom prevents the formation of a stable bicyclic tautomer in azido, diazoalkyl, and related derivatives of nitrogen heteroaromatic compounds.

Reactions of Diazomethyl-1,3,5-triazines with Cyclohexane. When compound 2 was heated in cyclohexane at 180 °C, 2-cyclohexylmethyl-4,6-dimethoxy-1,3,5-triazine (yield, 12%) was obtained as the sole isolable product;[13] however, the corresponding methyl-triazine was not detected in the reaction mixture by tlc.

On the other hand, when a cyclohexane solution of Compound 2 was irradiated at 254 nm, several photoproducts were produced, along with one major product. The major product was 2-cyclohexylmethyl-4,6-dimethoxy-1,3,5-triazine (yield, 14%); in this case also, the corresponding methyl-triazine was not obtained. The monodiazomethyl-triazines are thermally stable (the decomposition point of Compound 2 is 190 °C, and that of Compound 3 is 195 °C); therefore, without irradiation they did not react with cyclohexane at room temperature. Since most of the 254 nm incident light is absorbed by diazomethyl-triazine, the photochemical reaction with cyclohexane should take place *via* a carbene intermediate formed by the decomposition of the excited diazomethyl-triazine, even though the presence of the corresponding carbene could not be confirmed when diazomethyl-triazines were irradiated at 254 nm in EPA at 77 K.[14] The formation of cyclohexylmethyl-triazine in the photochemical and thermal reactions can be understood in terms of the intermolecular insertion of the singlet triazinyl carbene.

Similarly, 2-diazomethyl-4,6-bis(dimethylamino)-1,-3,5-triazine (3) reacted thermally and photochemically with cyclohexane to yield the corresponding cyclohexylmethyl-triazine as the sole isolable product (the yields were 10% and 16% respectively). The assumption that the thermal reaction of diazomethyl-triazines proceeds *via* a carbene intermediate may be supported by kinetic measurements of the reactions.

When diazomethyl-triazines were heated in hydrocarbons, an evolution of nitrogen was observed. There-

fore, for the kinetic measurements, an increase in the volume of nitrogen evolved in various substrates was followed after a lapse of time; however, in the reaction with cyclohexane the kinetic runs were carried out by measureing the decrease in the intensity of the $-CHN_2$ IR band after heating in small, sealed glass tubes.[16] The first-order rate constants for the decomposition of Compound 2 are listed in Table 2.

Table 2. Rate constants for the decomposition of 2-diazomethyl-4,6-dimethoxy-1,3,5-triazine in various substrates

Substrate	$k_1 \times 10^4$ (s^{-1})		
	180 °C	170 °C	160 °C
Cyclohexane	5.55	2.26	0.98
Decalin	3.25	1.43	0.41
Tetralin	2.57	—	—
Diphenyl ether	2.44	—	—

From Table 2 it is obvious that, in these reactions, there is little variation in the rate in spite of the wide diversity in the nature of the substrates, suggesting that the rate-determining step of these reactions is the loss of nitrogen to give a carbene species.

For a detailed discussion, the temperature dependence of the reaction constant was measured in decalin and cyclohexane; the activation parameters for the reactions are listed in Table 3.

Table 3. Activation parameters for the decomposition of 2-diazomethyl-4,6-dimethoxy-1,3,5-triazine

Substrate	$\Delta H^{\ddagger}$ (kcal·mol^{-1})	$\Delta S^{\ddagger}$(170 °C) (cal·deg^{-1}·mol^{-1})
Cyclohexane	33.5	−0.4
Decalin	39.7	+12.7

The entropies of the activation of −0.4 and +12.7, which were comparable in magnitude to those of the reactions of other diazomethyl derivatives with similar substrates,[15] support the idea that the reaction is of the first order, involving the carbene intermediate.

Experimental

All the melting points are uncorrected. The assignments of the reaction products were performed by means of NMR, IR spectra, and elemental analyses. A low-pressure mercury lamp with a Vycor glass filter was used as the 254 nm radiation source.

Materials. The diazomethyl-triazines were prepared by the condensation of cyanuric chloride with diazomethane,[9,10] followed by treatment with sodium methoxide[9] or dimethylamine,[10] (Compound 1, mp 112—113 °C) (lit,[9,10] 111.5—112.5 °C) (Compound 2, mp 103—104 °C) (lit,[9] 105—106 °C) (Compound 3, mp 93—94 °C) (lit,[10] 94 °C). The reaction mixtures were concentrated, purified by column chromatography (silica-gel; benzene: acetone = 10: 1 by volume), and dried *in vacuo*. 2-Cyclohexylmethyl-4,6-dimethoxy-1,3,5-triazine. Viscous oil. Found: C, 60.85; H, 8.10; N, 17.92%. Calcd for $C_{12}H_{19}N_3O_2$: C, 60.73; H, 8.07; N, 17.71%. NMR (CCl_4), δ 1.0 (m, 11H), 2.55 (d, 2H), 4.0 (s, 6H). 2-Cyclohexylmethyl-4,6-bis(dimethylamino)-1,3,5-triazine, mp 58—58.5 °C (Ligroin). Found: C, 64.20; H, 9.52; N, 26.73%. Calcd for $C_{14}H_{25}N_5$: C, 63.84; H, 9.57; N, 26.59%. NMR (CCl_4), δ 1.6 (m, 11), 2.3 (d, 2H), 3.1 (s, 12). The procedures of the kinetic measurements were almost the same as those previously described.[16]

On the Trimorphism of 7-Hydroxy-3-(*p*-methoxyphenyl)-4,6-dimethyl-1-indanone

Masayuki TAKATORI and Kazuko KANOMATA*

Department of Chemistry, Faculty of Education, Fukushima University, Hamadacho, Fukushima 960

(Received April 5, 1975)

Synopsis. The reaction of 2′-hydroxy-4-methoxy-3′,5′-dimethylchalcone with anhydrous $AlCl_3$ in benzene gave three kinds of crystals having different melting points. It is concluded that the crystals are three modifications of 7-hydroxy-3-(*p*-methoxyphenyl)-4,6-dimethyl-1-indanone on the basis of their mutal transformations, IR spectra and X-ray analysis.

Although the transformation of chalcone into indanone using $AlCl_3$ has already been reported,[1] the indanone obtained by the present authors showed an interesting behavior-polymorphism. Thus, a brief report on the study is presented here.

The attempt to obtain 4,2′-dihydroxy-3′,5′-dimethylchalcone (**1**)[2] from the corresponding 4-methoxychalcone (**2**)[2] by demethylation with the aid of anhydrous $AlCl_3$ in benzene gave colorless needles (**3a**), mp 81—82 °C, colorless plates (**3b**), mp 87—88 °C, and colorless needles (**4**), mp 211—212 °C, besides a small amount of expected **1**.

Compound **3b** ($C_{18}H_{18}O_3$; M^+=282) produced the following UV spectrum (in methanol): 222 (log ε, 4.47), 261.5 (4.03), 286.5 (3.63) and 334 nm (3.26), suggesting the presence of substituted aromatic carbonyl. The NMR spectrum (in CCl_4) of **3b** showed signals due to two methyls (δ=1.77s and 2.13s), one methoxyl (δ=3.66s), five aromatic hydrogens (δ=6.64d, 6.83d each J=9 Hz and δ=6.97 s) and one hydroxyl (δ=9.09 s). The signals (δ=2.36 dd, J=2 and 18 Hz, δ=3.04 dd, J=8 and 18 Hz, and δ=4.29 dd, J=2 and 8 Hz) could be assigned to the $-COCH_2CH=$ group. The IR spectral data are shown in Table 1. All of these results indicate that **3b** is 7-hydroxy-3-(*p*-methoxyphenyl)-4,6-dimethyl-1-indanone with an intramolecular hydrogen bonding between the hydroxyl and the carbonyl groups (Fig. 1).[3] Since dimethyl ether of **4** was identical with methyl ether of **3b**, **4** proved to be 7-hydroxy-3-(*p*-hydroxyphenyl)-4,6-dimethyl-1-indanone. This conclusion was also supported by the spectral data.

Both **3a** and **3b** transformed into colorless crystals (**3c**), mp 95—96 °C, upon heating near to their melting points followed by solidification. It was proved that the structures of **3a** ($C_{18}H_{18}O_3$) and **3c** ($C_{18}H_{18}O_3$) are

identical with that of **3b** by the comparison of their spectra. After crystallizing **3b** as well as **3c** from a small excess of methanol or 75% acetone, metastable **3a** was first separated out and then transformed into **3b**. The modifications **3b** and **3c** remained unchanged on standing at room temperature for five years, but **3a** transformed very slowly into **3b**.

The X-ray diffraction patterns of powdered samples of **3a**, **3b**, and **3c** were entirely different, as shown in Fig. 2. Analysis of the Weissenberg photographs indicated that crystals of both **3a** and **3b** belong to a monoclinic system, and that their lattice constants are a=11.2, b=

Table 2. Derivatives of indanones (**3** and **4**)

Compound	Color and crystals	Molecular formula	Mp (°C)	Elementary analysis Found (%)	Elementary analysis Calcd (%)	Yield (%)
Methyl ether of **3** (Dimethyl ether of **4**)	Colorless plates	$C_{19}H_{20}O_3$	75— 76	C 76.91 H 6.80	C 77.00 H 6.80	76[a] (79)
Benzoate of **3**	Colorless plates	$C_{25}H_{22}O_4$	183—184	C 77.77 H 5.88	C 77.70 H 5.74	73[a]
Oxime of **3**	Colorless needles	$C_{18}H_{19}NO_3$	151—152 (decomp)	N 4.75	N 4.71	80[a]
2,4-DNPH of **3**	Red needles	$C_{24}H_{22}N_4O_6$	282—284 (decomp)	N 11.83	N 12.12	83[a]
2,4-DNPH of **4**	Reddish orange needles	$C_{23}H_{20}N_4O_6$	285—287 (decomp)	N 12.61	N 12.50	85

a) These values show yields of the derivatives of **3b**. The yields of the derivatives of **3a** and **3c** are nearly the same as those of **3b**.

6.2, $c=10.2$ and $\beta=114°$ for **3a** and $a=10.7$, $b=15.6$, $c=9.3$ and $\beta=100°$ for **3b**. There is a small difference in the IR spectra of these three modifications in KBr and Nujol mull phases. The wave numbers of the absorption bands, ν(OH) and ν(CO), are shown in Table 1.

As mentioned above, it was found that the properties of **3a**, **3b**, and **3c** are different from each other in the solid state. However, the behavior of these modifications is identical in solution. They produced the same oxime, 2,4-DNPH, methyl ether and a benzoyl derivative; in two different solvent systems, their respective R_f values of tlc were the same and they produced identical UV and IR spectra (in CCl_4 and CS_2, Table 1).

Thus, it is concluded that **3a**, **3b**, and **3c** are three modifications of 7-hydroxy-3-(*p*-methoxyphenyl)-4,6-dimethyl-1-indanone.[4-6] The formation of these modifications might be due to differences in the packing mode of the molecule connected with hydrogen bonding in crystals.

Experimental

All melting points are uncorrected. The UV, IR and mass spectra were measured using Hitachi EPS-3T, JASCO IR-G (or DS-701G) and Hitachi RM-50GC spectrometers, respectively. The NMR spectra were recorded on a JEOL MH-100 spectrometer using TMS as an internal standard, and the X-ray analysis was carried out using a Rigakudenki Geigerflex D-2.

Indanone (3 and 4) and Chalcone (1). To a benzene solution of 5.0 g of **2**, 10 g of anhydrous $AlCl_3$ was added, and this suspension was kept at 50 °C for 2 h with stirring. The reaction mixture was hydrolyzed and then steam distilled. The black nonvolatile residue was dissolved in benzene, and to this solution, a 20% aqueous sodium hydroxide was added giving a yellow precipitate. a) From the precipitate; the precipitate was washed with benzene, then acetone and recrystallized from acetone with a small amount of methanol to give lemon yellow needles (**5**), mp about 240 °C (decomp). Compound **5** appeared to be a sodium salt of **3**, but was not further purified. A suspension of **5** in water was acidified, the precipitated white substance was collected and recrystallized from 75% acetone to give 0.61 g (12%) of **3b**. Modifications **3a** and **3c** were also obtained in the above manner. **3a**; Found: C, 76.53; H, 6.54%; mol wt (Rast), 282. **3b**; Found: C, 76.39; H, 6.24%; $M^+=282$. **3c**; Found: C, 76.63; H, 6.28%; $M^+=282$. Calcd for $C_{18}H_{18}O_3$ of **3a**, **3b**, and **3c**: C, 76.58; H, 6.43%; mol wt, 282.3. The R_f values of tlc on polyamide (Merck) were the same, 0.53 (Me_2CO: H_2O 3: 1) and 0.86 (*n*-BuOH: AcOH: H_2O 4: 1: 2) for **3a**, **3b** and **3c**. b) From the filtrate obtained by filtering off **5**; water was added to this filtrate, a benzene layer was taken off, and the precipitate which was produced by passing CO_2 into this sodium hydroxide solution was treated with acetic acid. The insoluble substance was recrystallized from ethanol to give 0.090 g (1.8%) of **4**. Found: C, 76.11; H, 6.08%; $M^+=268$. Calcd for $C_{17}H_{16}O_3$: C, 76.10; H, 6.01%; mol wt, 268.3. NMR (in $CDCl_3$): $\delta=1.87$s and 2.14s (2 CH_3), $\delta=2.55$dd, $J=3$ and 20 Hz, $\delta=3.29$dd, $J=8$ and 20 Hz, $\delta=4.47$dd, $J=3$ and 8 Hz ($-COCH_2CH=$), $\delta=4.87$s and 9.30s (2 OH), $\delta=6.77$d and 6.97d, each $J=8$ Hz and $\delta=7.19$s (aromatic 5H). IR: ν (KBr), 3460, 3330 (2OH) and 1667 cm^{-1} (CO). Compound **4** was also obtained in a 16% yield by refluxing **2** with anhydrous $AlCl_3$ in benzene for 2 hr. The acetic acid solution from which **4** was filtered off was diluted with water. A yellow precipitate was produced and recrystallized from a mixture of benzene and ethanol to give 0.10 g (2.2%) of **1** in the form of orange prisms, mp 190—191 °C. This compound had no mixed melting point decrease with authentic chalcone.[2]

Derivatives from 3a, 3b, and 3c (melthyl ethers, benzoates, oximes and 2,4-DNPH) and from 4 (dimethyl ether and 2,4-DNPH). They were prepared by the usual methods. No pairs of methyl ethers and dimethyl ether, of benzoates and of oximes produced mixed melting point depressions, and the IR spectra and melting points of each derivative from **3a**, **3b**, and **3c** were identical to each other. The NMR spectrum of the methyl ether of **3** showed the presence of two methoxyls ($\delta=3.73$s and 3.93s), and its MW was found to be 296 (Rast). Other properties of these derivatives are shown in Table 2.

The authors wish to thank Professor S. Sasaki of the Miyagi University of Education for reading the manuscript and Assistant Professor T. Ito of Hokkaido University for the lattice constant determinations.

Studies on Nitro Sugars. VI.[1] Synthesis of Methyl 2-Deoxy-2-nitro-α-D-glucopyranoside Derivatives

Tetsuyoshi TAKAMOTO and Rokuro SUDOH

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received April 28, 1975)

Synopsis. Oxidation of methyl 3-*O*-benzyl-4,6-*O*-benzylidene-2-oximino-α-D-*arabino*-hexopyranoside (**5**) with trifluoroperoxyacetic acid afforded in 76% yield the corresponding 2-nitro-glucopyranoside (**6**) which has a twist-boat conformation in chloroform.

During the course of our synthetic studies[2,3] on nitro sugars by oxidation[4] of sugar oximes with trifluoroperoxyacetic acid, we have presented[5] the synthesis of benzyl 2-deoxy-3,4-*O*-isopropylidene-2-nitro-β-D-arabino- and ribopyranoside from the corresponding 2-oximino derivative. On their PMR spectroscopic conformational discussion, a slightly twisted 1*C* and a twist-boat conformation were elucidated, respectively.

In continuation of this study on 2-deoxy-2-nitropyranosides, we now describe the synthesis and the conformational discussion of methyl 2-deoxy-2-nitro-α-D-glucopyranoside derivatives.

On preparation of 2-nitro sugars in this manner, starting materials should have a free hydroxyl group at the C-2 position. 3-*O*-Benzyl-5,6-di-*O*-acetyl-1,2-*O*-isopropylidene-α-D-glucofuranose[6] (**1**) was heated under reflux in methanol containing 3% hydrogen chloride[7] to afford syrupy methyl 3-*O*-benzyl-α-D-glucopyranoside (**2**) which was easily converted to methyl 3-*O*-benzyl-4,6-*O*-benzylidene-α-D-glucopyranoside (**3**) in 71% overall yield from **1** in the usual manner.

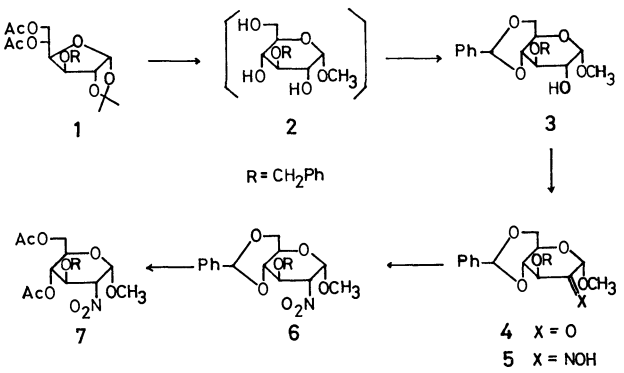
Assignment of α-D-glucopyranoside structure to **3** was based upon a specific rotation of +69.5° (acetone) and coupling constants, $J_{1,2}=3$ and $J_{2,3}=8$ Hz, on the PMR spectrum.

DMSO oxidation of **3** afforded in 54% yield amorphous powder of the corresponding 2-ulose (**4**), 1745 cm^{-1} ($\nu_{C=O}$), which was led to 2-oximino derivative (**5**) in 67% yield. Oxime **5** proved to be either single *syn*- or *anti*-form on the PMR spectrum (Table 1), although oxime is generally obtained as a mixture of them in such a reaction.

Oxidation of **5** with trifluoroperoxyacetic acid[8] at 42—43 °C gave selectively methyl 3-*O*-benzyl-4,6-*O*-benzylidene-2-deoxy-2-nitro-α-D-glucopyranoside (**6**), 1560 cm^{-1} (ν_{asNO_2}), in 76% yield.

On the structural discussion of **6**, the configuration at the C-2 only might be determined because it is unchangeable at the anomeric and the C-3 position in such a oxidation. As shown in Table 1, coupling constants, $J_{2,3}=0$, $J_{3,4}=9$, and $J_{4,5}=8$ Hz which were obtained by the use of decoupling technics for deutrated **6**,[9] indicate that dihedral angles, ϕ_{23}, ϕ_{34}, and ϕ_{45}, are ~100, ~160, and ~170 °, respectively.

All the data, consequently, are consistent with D-gluco form which has a twist-boat conformation. Moreover, for completion of the configurational assignment, **6** was treated with acetic anhydride in the presence of concentrated sulfuric acid to give methyl 3-*O*-benzyl-2-deoxy-4,6-di-*O*-acetyl-2-nitro-α-D-glucopyranoside (**7**). The coupling constants, $J_{2,3}=9$, $J_{3,4}=10$, and $J_{4,5}=11$ Hz, indicate that H^2, H^3, H^4, and H^5 have diaxial relationship each other. Therefore diacetate **7** has obviously a *C*1 conformation, being different from the case of **6**.



Experimental

General. Melting points were determined in capillaries and are uncorrected. Specific rotations were measured with a Carl Zeiss photoelectric polarimeter. PMR spectra were recorded at 100 MHz with a JEOL spectrometer (Type JNM-4H-100) and tetramethylsilane as an internal standard. IR spectra were obtained with a Hitachi EPI-S2 instrument.

TABLE 1. PMR DATA FOR RING PROTONS (H^1–H^4) AND OTHER SUBSTITUENTS OF METHYL 3-*O*-BENZYL-α-D-GLUCOPYRANOSIDE DERIVATIVES (in $CDCl_3$)

Compound	Chemical shift (ppm)				Coupling constant (Hz)				Chemical shift (ppm)

Methyl 3-O-benzyl-4,6-O-benzylidene-α-D-glucopyranoside (3). To a suspension of 3-*O*-benzyl-5,6-di-*O*-acetyl-1,2-*O*-isopropylidene-α-D-glucofuranose[6] (**1**) (20 g) and anhydrous methanol (125 ml), was added acetyl chloride (6 ml)[7] slowly. After refluxed for 6 h, the reaction mixture was cooled to room temperature and poured into saturated sodium bicarbonate solution with stirring. Removal of inorganic substances by using ethanol and evaporation of the solvent gave syrup (16.7 g, negative Fehling test) which was stirred vigorously with benzaldehyde (50 ml) in the presence of zinc chloride (10 g) for 14 h. Work up in the usual manner gave crude solid which was recrystallized from ethanol to give fine crystals (13.4 g, 71%): mp 180—180.5 °C, $[\alpha]_D^{20}$ +69.5° (*c* 1, acetone). Found: C, 67.90; H, 6.60%. Calcd for $C_{21}H_{24}O_6$: C, 67.73; H, 6.50%.

Methyl 3-O-benzyl-4,6-O-benzylidene-α-D-arabino-hexopyranosid-2-ulose (4). After a mixture of **3** (0.74 g), distilled dimethyl sulfoxide (6 ml), and distilled acetic anhydride (4 ml) was stirred for 24 h at room temperature, the mixture was evaporated *in vacuo* below 60 °C. The solution of the residue in ethyl acetate (30 ml) was washed with water and evaporated to give yellowish solid which was reprecipitated from ethanol: amorphous powder 0.4 g (54%), 1745 cm^{-1} ($\nu_{C=O}$). Found: C, 67.79; H, 5.99%. Calcd for $C_{21}H_{22}O_6$: C, 68.07; H, 5.99 %.

Methyl 3-O-benzyl-4,6-3-O-benzylidene-2-oximino-α-D-arabino-hexopyranoside (5). A solution of **4** (1.3 g) in a mixture of pyridine (7 ml) and ethanol (7 ml) was heated under reflux in the presence of hydroxylamine hydrochloride (1 g) for 2 h. The mixture was evaporated *in vacuo* to give syrupy residue which was washed with water several times and put on a column (7.0×3.5 cm) of silica gel. After elution of benzene (100 ml), oxime **5** was eluted with a solvent system 19 : 1 benzene–methanol. Removal of the solvent gave amorphous solid which was reprecipitated from ethanol to give **5** (0.9 g, 67%): mp 182—183 °C, $[\alpha]_D^{20}$ −54.3° (*c* 0.8, acetone), 3280 cm^{-1} (ν_{OH}). Found: C, 65.21; H, 6.02; N, 3.90%. Calcd for $C_{21}H_{23}O_6N$: C, 65.44; H, 6.02; N, 3.63%.

Methyl 3-O-benzyl-4,6-O-benzylidene-2-deoxy-2-nitro-α-D-glucopyranoside (6). To oxidizing reagent[8] prepared by mixing successively 90% hydrogen peroxide (0.25 ml), trifluoroacetic anhydride (1.5 ml), acetonitrile (5 ml), dibasic sodium phosphate (5.75 g), and urea (45 mg), was added a solution of **5** (1 g) in acetonitrile (40 ml) dropwisely with manual stirring. After the mixture was kept at 42—43 °C for 1 h, the solvent was removed *in vacuo* to give solid which was dissolved in chloroform and washed with water three times. Evaporation *in vacuo* gave crude product which chromatographed on a column of silica gel with benzene. The eluate that showed a single spot at R_f 0.71 on tlc in a solvent system 30 : 1 benzene–acetone, was evaporated *in vacuo* to give the product (0.9 g, 86%). Recrystallization from ethanol–petroleum ether gave **6** (0.79g, 76%): mp 121—122 °C, $[\alpha]_D^{20}$ +75.4° (*c* 1, acetone), 1560 cm^{-1} (ν_{asNO_2}). Found: C, 62.67; H, 6.04; N, 3.56%. Calcd for $C_{21}H_{23}O_7N$: C, 62.83; H, 5.78; N, 3.49%.

Methyl 3-O-benzyl-2-deoxy-4,6-di-O-acetyl-2-nitro-α-D-glucopyranoside (7). **6** (207 mg) was treated with acetic anhydride (500 mg) in the presence of concentrated sulfuric acid (6 mg) at room temperature. After 30 min, the red mixture was poured into sodium bicarbonate solution and extracted with dichloromethane. The extracts were washed with water and dried over sodium sulfate, and then was evaporated to give the product which was recrystallized from ethanol–petroleum ether: white needles (60 mg, 30%), mp 148—149 °C, $[\alpha]_D^{20}$ +96° (*c* 1, chloroform), 1555 cm^{-1} (ν_{asNO_2}). Found: C, 54.19; H, 5.65; N, 3.59%. Calcd for $C_{18}H_{23}O_9N$: C, 54.40; H, 5.83; N, 3.53%.

The authors are indebted to Mitsubishi Gas Chemical Co., Inc., for the gift of 90% hydrogen peroxide and to Mr. H. Matsumoto for recording the PMR spectra.

Oxidation of Isocyanides by Hg(II), Tl(III), and Pb(IV) Acetates

Sakuya TANAKA, Hiroshi KIDO, Sakae UEMURA, and Masaya OKANO*

Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

(Received May 2, 1975)

Synopsis. Isocyanides were oxidized to isocyanates in acetic acid in the presence of Hg(II), Tl(III), or Pb(IV) acetate through acetoxymetallation. The reaction of an isocyanide with Tl(III) acetate in various alcohols gave the corresponding carbamates in good yields.

Oxymetallations of isocyanides (α-addition) have recently been proposed in the carbamate formation from isocyanides by use of Tl(III) nitrate[1] and Hg(II) salts.[2] We now report the oxidation of isocyanides to the corresponding isocyanates by Hg(II), Tl(III), or Pb(IV) acetate in acetic acid which seems to proceed through acetoxymetallation. Various other reagents for such oxidation are cited in a review by Saegusa and Ito.[3]

Results and Discussion

When cyclohexyl isocyanide was treated with Hg(II), Tl(III), or Pb(IV) acetate in a mixture of benzene and acetic acid (9: 1 by volume) at 5—10 °C, cyclohexyl isocyanate was obtained as the product. The reaction also proceeded in acetic acid at 20 °C, but the yield of isocyanate was slightly lower. The metal acetates were reduced to Hg metal and Tl(I) and Pb(II) acetates, respectively. Some typical results are listed in Table 1. In the absence of metal acetates, no isocyanate was formed under any conditions shown in Table 1. An

elongation of the reaction time or an elevation of the temperature resulted in a decrease of the yield of isocyanate because of the formation of formamide from isocyanide and acetic acid and also of the secondary reaction of isocyanate with acetic acid. The reaction with Mn(III) and Co(III) acetates[4] instead of the above metal acetates gave only a trace amount of the isocyanate and almost all of the starting isocyanide was recovered. Moreover, although the oxidations of alkylbenzenes and olefins with Pb(IV), Mn(III), and Co(III) acetates are known to involve radical pathways,[5] no products which seemed to result from a radical reaction could be detected even at higher reaction temperatures.

Considering the well-known nature of Hg(II), Tl(III), and Pb(IV) acetates to afford oxymetallates of olefins and acetylenes and a proposal of oxymetallation of isocyanides,[1,2] it seems to be reasonable to assume that the reaction proceeded through acetoxymetallation as shown in Scheme 1. All attempts to isolate the intermediate acetoxymetallate of cyclohexyl and phenyl isocyanides were unsuccessful.

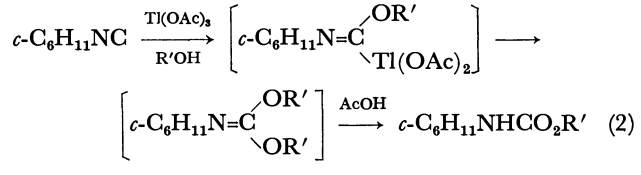
It has been reported that Tl(III) nitrate is a good reagent for synthesis of carbamates from isocyanides, but unfortunately only in methanol.[1] As we found that Tl(III) acetate could be used successfully in various alcohols for this purpose, we would like to add here the results obtained by using cyclohexyl isocyanide (Table 2). Carbamates may be formed mainly *via* alkoxythallation of the isocyanide, followed by redox decomposition to iminocarbonates which react with acetic acid (Scheme 2).



The protolysis of iminocarbonates to give carbamates has already been reported.[6] When ethylene glycol was used as an alcohol component, the expected carbamate, *c*-$C_6H_{11}NHCO_2CH_2CH_2OAc$, which may be derived from ethylene *N*-cyclohexyl iminocarbonate, was obtained as the only product.

Experimental

The IR spectra were taken with a Hitachi EPI-S2 spectrometer. Glc analyses were carried out with a Shimadzu 5APTF apparatus, using Apiezon L(30%)-Celite (1m) and EGSS-X(30%)-Chromosorb W (1m) columns (N_2 as the carrier gas).

Materials. Isocyanides (R–NC) were prepared by the method of Ugi *et al*:[7] R=*c*-C_6H_{11}, bp 65—69 °C/20 mmHg (lit,[7] bp 56—58 °C/11 mmHg); R=C_6H_5, bp 57.5 °C/19.5 mmHg (lit,[7] bp 50—51 °C/11 mmHg). Other organic materials including the solvents were purified before use by distillation. Commercial inorganic materials were used without further purification. $Tl(OAc)_3$ was prepared from Tl_2O_3 and acetic acid. Mn(III) and Co(III) acetates were prepared by the reported method.[4]

Reaction of Isocyanides with Metal Acetates in Acetic Acid. A typical experimental procedure is given below. To a stirred suspension of $Tl(OAc)_3$ (3.82 g, 10 mmol) in a mixture of benzene (18 ml)–AcOH (2 ml) was added slowly cyclohexyl isocyanide (1.09 g, 10 mmol) under cooling with an ice-bath and the resulting mixture was stirred for 3 h at 5 °C. After the precipitated TlOAc was filtered off from the reaction mixture, the filtrate was combined with benzene (50 ml) and washed with 50 ml of cold water and with aq. $NaHCO_3$ (50 ml). After being dried over Na_2SO_4, the benzene was evaporated to leave *ca.* 5 ml of a residue. Glc analysis of the residue by using iodobenzene as an internal standard revealed the presence of 5.4 mmol (54% yield based on $Tl(OAc)_3$ charged) of cyclohexyl isocyanate. Distillation gave 0.25 g of a pure compound: bp 52 °C/24 mmHg; IR, 2250 ($\nu_{N=C=O}$) cm^{-1}.

Reaction of Cyclohexyl Isocyanide with Tl(OAc)$_3$ in Alcohols. As an example, the reaction in ethanol is given below. To an orange suspension of $Tl(OAc)_3$ (3.82 g, 10 mmol) in ethanol (20 ml) was added cyclohexyl isocyanide (1.09 g, 10 mmol) at room temperature and the resulting mixture was heated for 1 h at 65—70 °C. After being cooled down to room temperature, the precipitated TlOAc (1.4 g, 5.3 mmol) was filtered off. The filtrate was treated as described above. Glc analysis of the residue by using ethyl benzoate as an internal standard showed the presence of 6.8 mmol (68% yield) of ethyl *N*-cyclohexyl carbamate. Distillation gave 0.5 g of crude product, which was recrystallized from *n*-hexane: mp 53.5—55 °C (lit,[8] mp 55—56 °C).

In a similar way, the following carbamates (*c*-$C_6H_{11}NHCO_2R'$) were obtained: R'=Me, mp 72—73.5 °C (lit,[8] mp 75 °C); R'=*n*-Pr, mp 40—41 °C from *n*-hexane; R'=*i*-Pr, mp 65—66.5 °C (lit,[9] mp 66.5—67 °C); R'=*t*-Bu, mp 65—68 °C (lit,[10] mp 68—69 °C); R'=CH_2CH_2OAc, mp 77—79 °C (lit,[11] mp 83.5 °C). The last compound was identified by comparison of IR and NMR spectra with an authentic sample prepared from the reaction of ethylene *N*-cyclohexyl iminocarbonate with acetic acid in ethylene glycol or benzene.[6]

Iron Carbonyl-catalyzed Reactions of Allyl Ethers and Amines Involving Claisen-type Rearrangement

Jitsuo KIJI, Satoshi NISHIMURA, Kazuyoshi YAMAMOTO, and Junji FURUKAWA
Department of Synthetic Chemistry, Kyoto University, Sakyo-ku, Kyoto 606

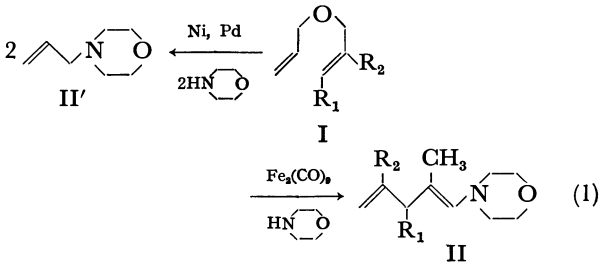
(Received May 2, 1975)

Synopsis. The iron carbonyl-catalyzed reaction of diallyl ether with morpholine gives 1,4-dienylamine. Diallylamine isomerizes to 4-aza-6-methyl-1,4-nonadiene.

Allylic compounds such as allyl alcohol or diallyl ether undergo a variety of reactions under the influence of transition metal complexes. Palladium-,[1] nickel-,[2] rhodium-,[3] and ion carbonyl-[4] catalyzed reactions have already been reported. These reactions attracted our attention from a view-point of synthetic application. Iron carbonyl reacts with cyclic compounds, which have a nitrogen or oxygen atom at the allylic position, resulting in interesting intermediates.[5,6] These reports prompted us to investigated the iron carbonyl-catalyzed reactions of some allylic compounds.

Results and Discussion

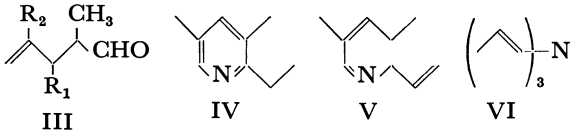
In the presence of $Fe_2(CO)_9$ diallyl ether (I) reacted with morpholine to give 1,4-dienylamine (II) in moderate yield, while nickel[2] and palladium[7]-catalyzed reactions give allyl amine (II'). A considerable amount of diallyl ether was recovered unchanged in each case.



II′ I II (1)

a: $R_1=R_2=H$, 40%.
b: $R_1=CH_3$, $R_2=H$, 27%.
c: $R_1=H$, $R_2=CH_3$, 17%.

The structure of II is indicated by spectroscopic data. This reaction can be explained reasonably by the isomerization of the double bond, followed by Claisen rearrangement and condensation of the substituted 4-pentanal (III) with morpholine. In fact, the diallyl ether isomerized to III in a very low yield without morpholine. Morpholine was superior to piperidine and benzylamine with regard to the yield of II.



III IV V VI

These facts show that the $Fe_2(CO)_9$–morpholine system plays a significant role in the isomerization of the double bond. Under these conditions, however, no reaction was observed with dimethallyl ether and allyl phenyl ether.

The reaction of the allylamines is interesting to note. The reaction of diallylamine catalyzed by $Fe(CO)_5$ or $Fe_2(CO)_9$ in a sealed tube at 160 °C gave 2,3,5-trisubstituted pyridine (IV). However, at *ca.* 112 °C (reflux) linear amine (V) was formed in moderate yield (see Table 1). Falbe *et al.*[8] have reported that the reaction of allylamine $C_3H_5NH_2$ catalyzed by $Fe(CO)_5$ at 250 °C at a high pressure of carbon monoxide forms IV through the formation of V in a 30% yield. The reaction of diallylamine takes place under more mild conditions than those of the latter. Therefore, it seems probable that the first step of the Falbe reaction is the formation of diallylamine, since the primary amine is converted to the secondary or tertiary amine under the influence of transition metal catalysts.[9]

This reaction is also explainable in terms of Claisen-"type" rearrangement. Triallylamine seems to be a key intermediate of this reaction. To gain insight into the reaction, triallylamine was allowed to react in the presence of $Fe_2(CO)_9$. In this case, however, rapid isomerization of the double bond occurred and VI was formed in high yield (>80%), *i.e.*, this isomerization is so fast that Claisen-"type" rearrangement does not take

Table 1. Reaction of allylamines

place. The use of morpholine as the solvent in this reaction resulted in the formation of *N*-(1-propenyl)morpholine (II'). The isomerization of the double bonds of triallylamine by $Fe_2(CO)_9$ proceeded more smoothly than the *t*-BuOK-catalyzed isomerization. Gas chromatographic analysis of the products of the latter reaction showed the presence of many isomers and the yields were in general low.

Experimental

Reactions. All the reactions were carried out in a sealed glass tube (8 mm in diameter).

Diallyl Ether with Morpholine: Iron enneacarbonyl (0.06 mmol) was placed in the tube. The tube was fitted with a three-way stopcock, through which the reagents were introduced by a syringe. Diallyl ether (0.5 ml, *ca.* 4 mmol) and morpholine (1 ml) were added in an atmosphere of argon. The tube was sealed with a flame and heated at 120 °C for 20 h.

Allylamines: All the reactions except run 2 (Table 1) were carried out in a manner similar to that described above. The reaction conditions are summarized in Table 1.

Analysis and Identification. Gas chromatographic analysis was performed on a column of Silicon DC 550 on Celite, 3 m in height, at 100—200 °C, using tetralin or *p*-xylene as an internal standard. The products were identified by analyzing the mass, IR and NMR spectra of the samples collected by gas chromatography.

Phenolysis of 1,1- and 3,3-Dimethylallyl Chlorides. Rates and Product Distributions

Ken'ichi TAKEUCHI, Yoshinobu FUJII, and Kunio OKAMOTO

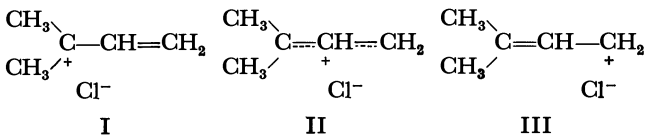
Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606

(Received May 29, 1975)

Synopsis. The phenolyses of 1,1- and 3,3-dimethylallyl chlorides were shown by kinetic studies to undergo S_N1 solvolysis. The distributions of the products, dimethylallyl phenyl ethers and (dimethylallyl)phenols, supported the mechanism that involves both localized ion-pairs and mesomeric ion-pairs.

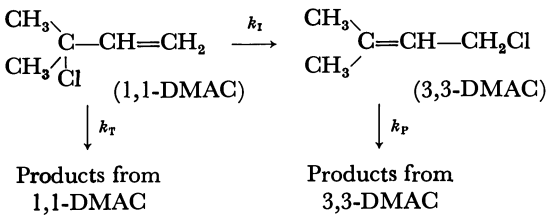
Since the finding of the significance of ion-pair intermediates by Young, Winstein and Goering[1] for the solvolysis of 1,1-dimethylallyl chloride, various efforts have been made to characterize the intermediates involved in the solvolysis of allylic compounds.[2,3] Recent works by Sneen and his coworkers[4] and by Wiberg and Nakahira[5] on the solvolyses of allylic compounds appear to have provided clear-cut evidence for the presence of discrete unsymmetrical ion-pairs preceding the formation of a symmetrical mesomeric ion-pair.

In the course of our study of solvolytic reactions in phenol,[6] the present authors have shown that phenol is characterized as a typical solvolytic solvent[7a] and that the phenolysis products provide useful information concerning the characteristics of the intermediates due to the ambident nature of the phenol molecule as a nucleophile.[7b] Consequently, the present study of the rates and products of the solvolysis of 1,1- and 3,3-dimethylallyl chlorides in binary mixtures of phenol with benzene was undertaken in the hope of distinguishing the intermediates I, II, and III which have occasionally been postulated in the solvolysis of the two isomeric chlorides.[1-4]



I II III

The rates of solvolysis were determined titrimetrically in phenol-benzene (1:9—3:7 by wt.) buffered with triethylamine. As expected from previous work,[1] the first-order plots for the solvolysis of 1,1-dimethylallyl chloride (1,1-DMAC) exhibited a downward drift as the reaction proceeded, showing concurrent rearrangement to 3,3-dimethylallyl chloride (3,3-DMAC). The



first-order rate constants (k_T, k_P, and k_I) were determined following the method of Young, Winstein and Goering[1] and are summarized in Table 1. The plots of the rate constants as a function of the Y-values[7a] provided

Table 1. Titrimetric phenolysis rates of 1,1- and 3,3-dimethylallyl chlorides in phenol–benzene at 25 °C[a]

Solvent[b]	Chloride M	Et_3N M	k_T	k_P $\times 10^5$ s^{-1}	k_I

30% PhOH	0.0482	0.0644	—	120	—

a) The temperature controlled at ±0.05°C. b) Percent by weight of phenol in phenol–benzene.

Grunwald-Winstein m-values[8] of 0.95, 0.96, and 0.91 for k_T, k_P, and k_I, respectively. The magnitude of the present m-values of approximately 1.0 provides an evidence for the S_N1 character of the phenolysis of 1,1- and 3,3-dimethylallyl chlorides.

The products, 1,1- and 3,3-dimethylallyl phenyl ethers and *o*- and *p*-(dimethylallyl)phenols, were isolated by tlc. Control experiments revealed that the phenyl ethers neither interchanged with each other, nor isomerized to alkenylphenols during the reaction and work-up. The isolated yields of the products were divided by the recovery percents which were determined from the control experiments. The corrected yields thus calculated are shown in the first column under the respective starting chlorides in Table 2. As pointed out above, 1,1-DMAC isomerizes to 3,3-DMAC during phenolysis. Therefore, the product in the solvolysis of 1,1-DMAC is actually a

blend of those from 1,1- and 3,3-DMAC. Thus the product distribution from 1,1-DMAC itself was estimated by utilizing the rate constants k_T, k_P, and k_I and the yields of the products from 3,3-DMAC alone. The results are shown in the fifth and sixth columns of Table 2. The ratio of the amount of tertiary alkenyl phenyl ether to that of the primary ether is 5.0 in the phenolysis of 1,1-DMAC, while it is 1.5 for 3,3-DMAC. Since kinetic studies showed that the phenolyses of the both chlorides are classified as S_N1-type solvolysis, the product spread[2a] in the ether formation will be explained most reasonably by postulating that the localized ion-pairs I and III are first formed from the corresponding chlorides.

The finding that 1,1-DMAC gives a larger *para*: *ortho* product ratio in (3,3-dimethylallyl)phenol than 3,3-DMAC appears to require the presence of another intermediate which attacks the phenol nucleus with higher *para* selectivity than the intermediate III. The postulation of a mesomeric intermediate II, which is present in equilibrium with III, gives a plausible explanation, since it is presumed that the intermediate II exhibits a larger steric requirement than the localized ion-pair III in *ortho* substitution, which leads to higher *para* selectivity.

It should be pointed out that no *p*-(1,1-dimethylallyl)-phenol could be detected in the product to within experimental error, with the corresponding *ortho*-isomer produced being less than 0.25%, if at all present. The absence of (1,1-dimethylallyl)phenol in the products is in accord with the absence of the same product in the reaction of isoprene with phenol catalyzed by phosphoric acid.[9] Presumably, the tertiary carbonium ion center is more sterically hindered to nucleophilic approach of the phenol nucleus than the primary carbonium ion center. A similar phenomenon has been observed in the trapping of intermediates with borohydride and in the *t*-butanolysis of 1,1- and 3,3-DMAC.[10]

The present results support the presence of two localized ion-pairs (I and III) and one mesomeric ion-pair (II).

Experimental

Materials. The isomeric chlorides were prepared by the method reported by Sneen and Kay[4b] and stored at −78 °C in the presence of small amounts of anhydrous potassium carbonate. The purity of each chloride was checked by glpc[10] just prior to use; 1,1-DMAC, bp 33.9—34.2 °C/150 Torr, n_D^{20} 1.4190; 3,3-DMAC, bp 59—66 °C/160 Torr, n_D^{20} 1.4489. Other organic reagents employed were of analytical grade and were fractionated before use.

Kinetic Measurement. The pipetting technique[7a] was employed and the first-order rate constants determined in the manner described in the literature.[1]

Isolation of the Phenolysis Product. To 1,1-DMAC (525.7 mg, 5.02 mmol) was added 100 ml of phenol–benzene (1:4 by wt.) containing 0.055 M of triethylamine which had been previously equilibrated at 25 °C. After 4 h at this temperature, the solution poured into 200 ml of chilled ether. The ether solution was washed with chilled water and then with a chilled 10% sodium hydroxide solution, and dried over magnesium sulfate. After evaporation of the ether, the products were separated by tlc (silica gel) into three fractions, alkenyl phenyl ethers, *o*- and *p*-alkenylphenols. The isomer distribution in each fraction was determined by NMR. The phenolysis of 3,3-DMAC was carried out in the same manner except that the reaction was conducted for 16 h.

The Synthesis of the Benzofuro[2,3-*b*]benzofuran Derivative

Mutsumu NANBU, Kaishû MOMONOI, Susumu OGURO, and Yoshiyuki KAWASE

Department of Chemistry, Faculty of Literature and Science, Toyama University, Gofuku, Toyama 930

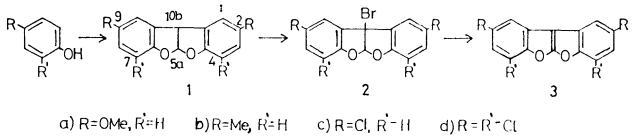
(Received May 15, 1975)

Synopsis. The synthesis of 2,9-dimethoxybenzofuro-[2,3-*b*]benzofuran from its 5a,10b-dihydro-compound was carried out by bromination with *N*-bromosuccinimide, followed by dehydrobromination. The attempted preparation of 2,9-dimethyl-, 2,9-dichloro-, and 2,4,7,9-tetrachloro-derivatives was unsuccessful.

The synthesis of the halo-derivatives of benzofuro-[2,3-*b*]benzofuran (**3**) has been carried out by Riemschneider and his co-workers[1-3] through the condensation of halo-phenols or their methyl ethers with chloral, followed by the cyclization of the products. On the other hand, the halo-[2,3] and methyl-derivatives[5] of 5a,10b-dihydrobenzofuro[2,3-*b*]benzofuran (**1**) have been prepared by the condensation of substituted-phenols or -anisoles with dichloroacetal, followed by the cyclization of the products. Also, the **1** compounds have been prepared in one step by the condensation of substituted-phenols with glyoxal.[4,5]

Now, in the present experiments, we have attempted the preparation of several derivatives of **3** from the corresponding dihydro-compounds (**1**) in order to investigate the electrophilic substitution of **3**.

The starting compounds (**1a**—**d**), among which the 2,9-dimethoxy-derivative (**1a**) was newly synthesized, were brominated with *N*-bromosuccinimide in carbon tetrachloride in the presence of benzoyl peroxide. The dehydrobromination of the brominated compounds was attempted by heating them with potassium acetate in ethanol to give the **3** compounds. The attempts succeeded only in the case of **1a**, and the structure of the product was determined to be **3a** from its elemental analysis and spectral data; the shape of the UV absorption curve was different from that of **1a** and was analogous to that of **3d**.[1] Moreover, the peaks due to 5a- and 10b-hydrogen of **1a** disappeared in the NMR spectrum in the case of **3a**. The intermediate brominated compound seems to be the 10b-bromo-compound (**2a**) by analogy to the case of **1c**. In the case of the 2,9-dimethyl-derivative (**1b**), the product was proved to be the 2-ethoxymethyl-9-methyl-derivative of **1** by its elemental analysis and by NMR spectroscopy; the formation of the compound seems to be due to bromination at the methyl group, followed by a reaction with ethanol. In the case of the 2,9-dichloro-derivative (**1c**), the brominated compound was obtained in a pure state and was considered to be the 10b-bromo-derivative (**2c**) from the absence of the doublet peaks due to the 10b-hydrogen in the NMR spectrum. However, the dehydrobromination of **2c** with potassium acetate was difficult. The brominated compound (**2d**) was also obtained from the 2,4,7,8-tetrachloro-derivative (**1d**), but the dehydrobromination was unsuccessful. Some attempts at the direct dehydrogenation as well as the hydroxylation of **2** were fruitless.



Experimental

The melting points are uncorrected. IR spectra; Hitachi Model EPI-S, UV spectra; Hitachi Model 124, NMR spectra; JEOL Model JNM-C-60H (60 MHz), Mass spectra; JEOL Model JMS-OIS.

*The Preparation of the 5a,10b-Dihydrobenzofuro[2,3-*b*]benzofurans (1).* 2,9-Dimethyl-[4,5] (**1b**), 2,9-dichloro-[3,5] (**1c**), and the 2,4,7,9-tetrachloro-derivative[2,3] (**1d**) of **1** were prepared by the reported methods. The 2,9-dimethoxy-derivative (**1a**) was prepared by an analogous method, which will be described below.

*2,9-Dimethoxy-5a,10b-dihydrobenzofuro[2,3-*b*]benzofuran (1a).* (a) Concentrated sulfuric acid (40 ml) was stirred, over a 1.5 h period and at 20—25 °C, into a mixture of *p*-methoxyphenol (24.8 g, 0.2 ml), a 40% aqueous glyoxal solution (28 g, 0.15 mol), and acetic acid (100 ml). After stirring for 40 min at that temperature, the mixture was poured into ice water; the precipitate thus formed was collected, washed with a dilute aqueous sodium hydroxide solution, and dried. Extraction by cyclohexane using a percolater and the recrystallization of the extract from ethanol gave 3 g (11% yield) of **1a**; mp 177—177.5 °C. UV: λ_{max}^{EtOH} nm (log ε) 210 (4.18), 220sh (4.12), 303 (3.93). NMR: $\delta(CDCl_3)$ 3.77 (6H, s, $-OCH_3$), 4.92 (1H, d, J=6 Hz, 10b-H), 6.75—6.95 (7H, m, arom-H and 5a-H). Mass: M^+ (*m/e*) 270. Anal. Found: C, 71.13; H, 5.26%. Calcd for $C_{16}H_{14}O_4$: C, 71.10; H, 5.22%. (b) Concentrated sulfuric acid (25 ml) was added, at 5—10 °C over a 2 h period, to a solution of *p*-methoxyphenol (12.4 g, 0.1 mol) and dichloroacetal (9 g, 0.05 mol) in acetic acid (25 ml); the mixture was stirred at room temperature for 20 h, and then concentrated sulfuric acid (25 ml) was added once more in a similar manner. The mixture was poured into ice water, extracted with ethyl acetate, and the crude 2,2-dichloro-1,1-bis(5-methoxy-2-hydroxyphenyl)-ethane obtained from the extract was refluxed for 2 h with methanol (100 ml) saturated with ammonia. The solvent was then distilled off, and the residue was crystallized from ethanol to give 0.4 g (6.5% yield) of **1a** (mp 177—177.5 °C, identical with that of the other sample).

*The Bromination of 1 and the Dehydrobromination of the Product to Give Benzofuro[2,3-*b*]benzofuran (3). In the Case of 1a*: A solution of **1a** (1.4 g ,0.005 mol) and *N*-bromosuccinimide (NBS) (1.8 g, 0.01 mol) in carbon tetrachloride (350 ml) was refluxed for 30 h with the addition of benzoyl peroxide (0.05 g). Most of the solvent was then distilled off, the residue was dissolved in chloroform, and the solution was washed with an aqueous sodium bicarbonate solution. The crude product obtained from the chloroform solution was dissolved in ethanol, and the solution was refluxed for 5 h with the addition of potassium acetate (2 g, 0.02 mol). The reaction mixture was then poured into ice water, extracted

with ether, and the ethereal solution was washed with the aqueous sodium bicarbonate solution. The residual product obtained from the ethereal solution was distilled (bp 150—250 °C/2 mmHg (bath-temperature)) and then crystallized from ethanol to give 0.7 g (50% yield) of 2,9-dimethoxybenzofuro[2,3-*b*]benzofuran (**3a**); mp 124.5—125 °C. UV: λ_{max}^{EtOH} nm (log ε) 204sh (4.37), 226 (4.57), 276 (4.28), 283 (4.27), 290 (4.26), 298 (4.14). NMR: δ (CCl_4) 3.84 (6H, s, $-OCH_3$), 6.70 (2H, dd, J=3 and 9 Hz, 3,8-H), 7.07 (2H, d, J=3 Hz, 1,10-H), 7.32 (2H, d, J=9 Hz, 4,7-H). Mass: M^+ (*m/e*) 268.

In the Case of ***1b***: The crude product obtained from **1b** (2.4 g, 0.01 mol) by a procedure similar to that described above was purified by chromatography, with alumina and benzene as the solvents. A fairly large amount of the **1b** was obtained at first, and then a small amount (*ca.* 50 mg) of 2-ethoxymethyl-9-methyl-5a,10b-dihydrobenzofuro[2,3-*b*]benzofuran (mp 95—96 °C (from ethanol)) was obtained. NMR: δ ($CDCl_3$) 1.24 (3H, t, J=7 Hz, $-CH_2-C\underline{H}_3$), 2.30 (3H, s, $-CH_3$), 3.53 (2H, q, J=7 Hz, $-C\underline{H}_2-CH_3$), 4.45 (2H, s, $-O-CH_2-$arom.), 4.96 (1H, d, J=6 Hz, 10b-H), 6.70—7.45 (7H, m, arom.-H and 5a-H). Found: C, 76.40; H, 6.29%. Calcd for $C_{18}H_{18}O_3$: C, 76.57; H, 6.43%.

In the Case of ***1c***: The bromination of **1c** (1.4 g, 0.005 mol) by the procedure described above gave a crude brominated compound which was easily purified by crystallization from acetic acid and then from ethanol to give 10b-bromo-2,9-dichloro-5a,10b-dihydrobenzofuro[2,3-*b*]benzofuran (**2c**); mp 188—188.5 °C; 0.8 g (45% yield). NMR: δ (CCl_4) 6.81 (2H, d, J=9 Hz, 4,7-H), 6.90 (1H, s, 5a-H), 7.15 (2H, dd, J=2 and 9 Hz, 3,8-H), 7.46 (2H, d, J=2 Hz, 1,10-H). Found: C, 46.82; H, 1.80%. Calcd for $C_{14}H_7BrCl_2O_2$: C, 46.94; H, 1.97%. The dehydrobromination of **2c** by the method described before was unsuccessful.

In the Case of ***1d***: A brominated compound, 10b-bromo-2,4,7,9-tetrachloro-5a,10b-dihydrobenzofuro[2,3-*b*]benzofuran (**2d**), was obtained by the crystallization of the crude brominated compound from **1d** (2.1 g, 0.006 mol); mp 195—195.5 °C (from acetone); 1.3 g (51% yield). The structure was determined on the basis of the results of the elemental analysis and by analogy to the case of **2c** (the NMR spectrum could not be measured, as it was insoluble in the apropriate solvent). Found: C, 39.22; H, 1.06%. Calcd for $C_{14}H_5BrCl_4O_2$: C, 39.38; H, 1.18%. The dehydrobromination of **2d** was also unsuccessful.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 48 (11), 3423—3424 (1975)

The Fries Rearrangement of Acetoxybenzofuran Derivatives and the Synthesis of Furochromenonecarboxylic Acids

Mutsumu NANBU, Seiji YAMAGUCHI, Yasuo SUGIMASA, Tatsuya MIYAURA, and Yoshiyuki KAWASE

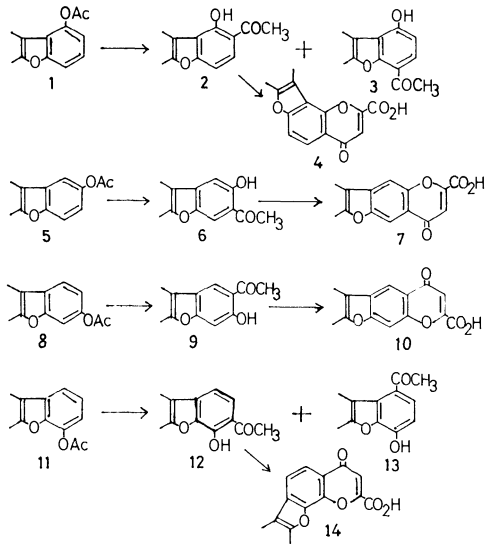
Department of Chemistry, Faculty of Literature and Science, Toyama University, Gofuku, Toyama 930

(Received June 4, 1975)

Synopsis. The Fries rearrangement of 4-, 5-, 6-, and 7-acetoxy-2,3-dimethylbenzofurans was studied and the *o*-hydroxy-ketones obtained were converted to dimethylfuro derivatives of 4*H*-chromen-4-one-2-carboxylic acid.

It has been reported that the Fries rearrangement of 6-acetoxy-3-methylbenzofuran gave a 2-acetyl compound[1] and that of 6-acetoxy-3-methylbenzofuran-2-carboxylic acid gave a 7-acetyl compound.[2] In the present experiments, the Fries rearrangement of *bz*-acetoxy-2,3-dimethylbenzofurans was studied, and the *o*-hydroxy-ketones obtained were converted to the corresponding furochromenonecarboxylic acid derivatives to test the pharmacological activity.

Four isomeric 4-, 5-, 6-, and 7-acetoxy-2,3-dimethylbenzofurans (**1**, **5**, **8**, and **11**) were heated with anhydrous aluminum chloride at 120 °C for 15 min and the reaction mixture was treated as usual to give the products, the structures of which were determined by comparing their melting points and IR spectra with those of authentic samples.[3,4] The products obtained from **5**, **8**, and **11** were the *o*-hydroxy-ketones **6**, **9**, and **12**, respectively, and a small amount of *p*-hydroxy-ketone (**13**) was also obtained in the case of **11**. But, in the case of **1**, the main product was *p*-hydroxy-ketone (**3**), as well as a small amount of the *o*-hydroxy-ketone (**2**). The same reaction in carbon disulfide at room temperature for 24 h gave some amounts of the *p*-hydroxy-ketone **3** or **13**, respectively, from **1** or **11**, while no reaction occured in the case of **5** and **8**. The *o*-hydroxy-ketones **2**, **6**, **9**, and **12** thus obtained were converted to furochromenonecarboxylic acid derivatives **4**, **7**, **10**, and **14**, respectively, by condensation with ethyl oxalate followed by hydrolysis and cyclization.[5,6]



Experimental

All the melting points and boiling points are uncorrected. IR spectra: Hitachi Model EPI-S. UV spectra: Hitachi Model 124. NMR spectra: JEOL Model JNM-MH-60 (60 MHz).

The Preparation of 4-, 5-, 6-, and 7-Acetoxy-2,3-dimethylbenzofurans (1, 5, 8, and 11). These compounds were prepared by heating the corresponding hydroxy-compounds[7] with acetic anhydride and sodium acetate. Compound **1**; bp 163—167 °C/22 Torr, ν_{CO} 1765 cm^{-1}. Found: C, 70.34; H, 6.05%. Calcd for $C_{12}H_{12}O_3$: C, 70.57; H, 5.92%. Compound **5**; mp 60 °C (from *n*-hexane), ν_{CO}^{KBr} 1760 cm^{-1}. Found: C, 70.79; H, 5.84%. Calcd for $C_{12}H_{12}O_3$: C, 70.57; H, 5.92%. Compound **8**; mp 54—55 °C (from *n*-hexane), ν_{CO}^{KBr} 1760 cm^{-1}. Found: C, 70.79; H, 5.84%. Calcd for $C_{12}H_{12}O_3$: C, 70.57; H, 5.92%. Compound **11**; bp 165—167 °C/20 Torr, ν_{CO} 1770 cm^{-1}. Found: C, 70.69; H, 6.13%. Calcd for $C_{12}H_{12}O_3$: C, 70.57; H, 5.92%.

The Fries Rearrangement of the Acetoxybenzofurans. *Method A*: A mixture of the acetoxybenzofuran (4.1 g) and powdered anhydrous aluminum chloride (3.2 g) was heated with stirring at 120 °C for 15 min. The cooled mixture was treated with diluted hydrochloric acid, extracted with ether, and the ethereal layer was extracted with dilute aqueous sodium hydroxide solution. The product obtained from the ethereal solution was *o*-hydroxy-ketone, and the precipitate obtained by the acidification of the alkaline extract was *p*-hydroxy-ketone. In the case of **1**, 0.04 g (1% yield) of 5-acetyl-2,3-dimethyl-4-hydroxybenzofuran (**2**), mp 47—50 °C (lit,[4] mp 58.5—60 °C), and 1.6 g (40% yield) of 7-acetyl isomer (**3**), mp 204—206 °C (lit,[4] mp 206—208 °C), were obtained. In the case of **5**, 1.8 g (45% yield) of 6-acetyl-2,3-dimethyl-5-hydroxybenzofuran (**6**), mp 139—142 °C (lit,[3] mp 141 °C) was obtained. In the case of **8**, 1 g (24% yield) of 5-acetyl-2,3-dimethyl-6-hydroxybenzofuran (**9**), mp 119—121 °C (lit,[3] mp 122 °C) was obtained. In the case of **11**, 2 g (49% yield) of 6-acetyl-2,3-dimethyl-7-hydroxybenzofuran (**12**), mp 129—130 °C (lit,[3] mp 130 °C) and 0.01 g (0.3% yield) of 4-acetyl-2,3-dimethyl-7-hydroxybenzofuran (**13**), mp 164—165 °C (lit,[3] mp 169 °C) were obtained.

Method B: A mixture of the acetoxybenzofuran (4.1 g), anhydrous aluminum chloride (3.2 g) and carbon disulfide (20 g) was stirred at room temperature for 24 h. The reaction mixture was treated similarly to the method described for method A. In the case of **1**, 0.6 g (15% yield) of **3** was obtained, and in the case of **11**, 0.4 g (10% yield) of **13** was obtained. In the cases of **5** and **8**, almost all of the starting compounds were recovered.

The Preparation of Furochromenonecarboxylic Acids. The *o*-hydroxy-ketone (1 g) and ethyl oxalate (2 g) were added to a suspension of powdered sodium metal (0.5 g) in xylene (75 ml) and the mixture was refluxed for 1 h. The cooled mixture was treated with ethanol to destroy the excessive

sodium metal and then with water. The alkaline aqueous layer was separated and acidified with dilute hydrochloric acid. The precipitate formed was crystallized from acetic acid to give the following furochromenone-carboxylic acids: 1,2-Dimethyl-6*H*-furo[2,3-*h*]chromen-6-one-8-carboxylic acid (**4**) was obtained from **2** in a 29% yield; mp 300—302 °C; ν_{CO}^{KBr} cm^{-1}: 1730 (COOH) and 1640 (γ-pyrone); λ_{max}^{EtOH} nm (log ε): 220 (4.54), 252 (4.41), and 322 (3.65); δ (DMSO-d_6): 2.18 (3H, s, 1-CH_3), 2.31 (3H, s, 2-CH_3), 6.70 (1H, s, 7-H), 7.27 (1H, d, J=9 Hz, 4-H), and 7.57 (1H, d, J=9 Hz, 5-H). Found: C, 65.30; H, 4.18%. Calcd for $C_{14}H_{10}O_5$: C, 65.12; H, 3.90%. 2,3-Dimethyl-8*H*-furo[2,3-*g*]chromen-8-one-6-carboxylic acid (**7**) was obtained from **6** in a 47% yield; mp 293—295 °C; ν_{CO}^{KBr} cm^{-1}: 1740 (COOH) and 1630 (γ-pyrone); λ_{max}^{EtOH} nm (log ε): 220 (4.39), 242 (4.22), and 325 (4.20); δ (DMSO-d_6): 2.15 (3H, s, 3-CH_3), 2.41 (3H, s, 2-CH_3), 6.83 (1H, s, 7-H), 7.65 (1H, s, 4-H), and 7.88 (1H, s, 9-H). Found: C, 64.84; H, 3.79%. Calcd for $C_{14}H_{10}O_5$: C, 65.12; H, 3.90%. 2,3-Dimethyl-5*H*-furo[3,2-*g*]chromen-5-one-7-carboxylic acid (**10**) was obtained from **9** in a 42% yield; mp 310—312 °C, ν_{CO}^{KBr} cm^{-1}: 1730 (COOH) and 1640 (γ-pyrone); λ_{max}^{EtOH} nm (log ε): 211 (4.57), 251 (4.54), and 343 (3.82); δ (DMSO-d_6): 2.15 (3H, s, 3-CH_3), 2.40 (3H, s, 2-CH_3), 6.80 (1H, s, 6-H), 7.70 (1H, s, 9-H), and 7.96 (1H, s, 4-H). Found: C, 64.88; H, 3.86%. Calcd for $C_{14}H_{10}O_5$: C, 65.12; H, 3.90%. 2,3-Dimethyl-6*H*-furo[3,2-*h*]chromen-6-one-8-carboxylic acid (**14**) was obtained from **12** in a 31% yield; mp 275—277 °C; ν_{CO}^{KBr} cm^{-1}: 1730 (COOH) and 1640 (γ-pyrone); λ_{max}^{EtOH} nm (log ε): 214 (4.30), 261 (4.36), and 327 (3.90); δ (DMSO-d_6): 2.21 (3H, s, 3-CH_3), 2.57 (3H, s, 2-CH_3), 6.97 (1H, s, 7-H), 7.57 (1H, d, J=8 Hz, 4-H), and 7.90 (1H, d, J=8 Hz, 5-H). Found: C, 64.35; H, 4.04%. Calcd for $C_{14}H_{10}O_5$: C, 65.12; H, 3.90%.

(Received June 5, 1975)

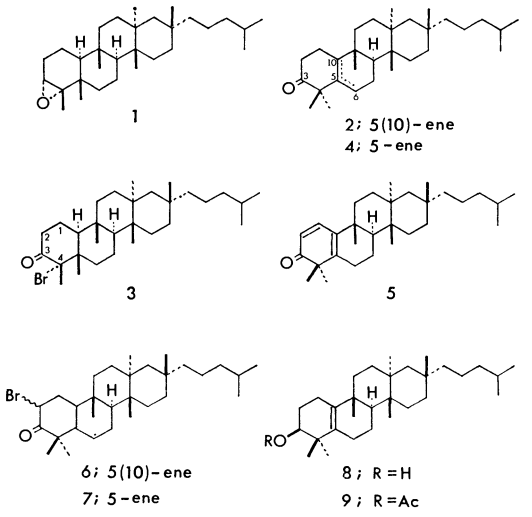
Synopsis. A mixture of D: B-friedo-bacchar-5(10)-en-3-one (**2**) and D: B-friedo-bacchar-5-en-3-one (**4**), prepared from 4α-bromoshionan-3-one (**3**) by the known procedures, was converted into a mixture of 2ξ-bromo-D: B-friedobacchar-5(10)-en-3-one (**6**) and 2ξ-bromo-D: B-friedo-bacchar-5-en-3-one (**7**) by bromination with pyridinium tribromide. The mixture (**6** and **7**) was subjected to dehydrobromination to give D: B-friedo-bacchara-1,5(10)-dien-3-one (**5**). Hydrogenation of the dienone (**5**) gave D: B-friedo-bacchar-5(10)-en-3-one (**2**).

In connection with studies on a backbone rearrangement of 3α,4α-epoxyshionane (**1**),[1] a pure sample of D: B-friedo-bacchar-5(10)-en-3-one (**2**) was required for identification of rearrangement products. It has been reported that 4α-bromoshionan-3-one (**3**) was treated with silver acetate to give a mixture[2] of D: B-friedo-bacchar-5(10)-en-3-one (**2**) and D: B-friedo-bacchar-5-en-3-one (**4**) and that a treatment of the mixture (**2** and **4**) in acetic acid with hydrochloric acid at 100 °C resulted in an isomerization of a double bond in **4** to give mainly **2** (mp 78—80 °C).[2] However, the 5(10)-en-3-one (**2**) thus prepared was found to be always contaminated with some amounts of **4**. An attempt to separate the the mixture (**2** and **4**) by chromatography under various conditions was hardly successful.

We now wish to report a synthesis of D: B-friedo-bacchara-1,5(10)-dien-3-one (**5**) and a preparation of pure D: B-friedo-bacchar-5(10)-en-3-one (**2**) from **5**.

Treatment of 4α-bromoshionan-3-one (**3**)[2] with silver acetate gave a mixture (mp 81—82 °C) of **2** and **4** in a ratio of about 1: 1. Signals due to an olefinic proton of **4** appeared at δ 5.70 as a broad multiplet with an integrated intensity due to about a half proton. Then the mixture (**2** and **4**) was brominated with pyridinium tribromide in acetic acid[3,4] to yield a mixture of 2ξ-bromo-D: B-friedo-bacchar-5(10)-en-3-one (**6**) and 2ξ-bromo-D: B-friedo-bacchar-5-en-3-one (**7**) as white crystals, mp 136—137 °C, which showed PMR signals at δ 4.57—5.00 (1H, m; $C_{(2)}$–H) and 5.75 (*ca.* 0.5H, br; $C_{(6)}$–H of **7**). In the mass spectrum the molecular ion peaks appeared at *m/e* 506 and *m/e* 504. The mixture (**6** and **7**) was dehydrobrominated with hexamethylphosphoric triamide[5] to give D: B-friedo-bacchara-1,5-(10)-dien-3-one (**5**). The conjugated dienone (**5**) was a yellow oil and showed a characteristic ultra violet absorption maximum at 324 nm (ε 5300) and PMR signals due to olefinic protons at δ 5.98 (1H, d, J=10 Hz) and 7.12 (1H, d, J=10 Hz).

Finally, the dienone (**5**) was hydrogenated in the presence of palladium-charcoal to afford pure D: B-friedo-bacchar-5(10)-en-3-one (**2**), mp 84—84.5 °C. No other enone such as the 5-en-3-one (**4**) was formed. D: B-Friedo-bacchar-5(10)-en-3β-ol (**8**)[2] free from its 5-en-3β-ol isomer was also prepared by reduction of pure **2** with lithium aluminium hydride.



Experimental

IR spectra were measured on a Hitachi EPI-G2 spectrometer. UV spectra were measured using a Hitachi EPS-2 spectrometer. Mass spectra were taken on a Hitachi RMU-6-Tokugata mass spectrometer operating at 70 eV with a direct inlet system. PMR spectra were measured using a JEOL JNM PS-100 (100 MHz), a Hitachi R-20 (60 MHz) or a Hitachi R-24 (60 MHz) spectrometer. Chemical shifts were expressed in ppm downfield from TMS as an internal standard (δ value) and coupling constants in Hz. Thin layer chromatography (tlc) was carried out on Kieselgel G or PF_{254} (E. Merck) in 0.25 mm thickness. Wakogel C-200 (Wako Pure Chemical Ind.) was used for column chromatography. All melting points were determined on a hot block and reported uncorrected.

Treatment of 4α-Bromoshionan-3-one (3) with Silver Acetate. 4α-Bromoshionan-3-one[2] (**3**; mp 122—123 °C; 2.62 g) in ether (600 ml) was added to a solution of silver acetate (2.63 g) in acetic acid (1 l) and water (60 ml). The mixture was heated, concentrated until the vapor temperature reached to 110 °C and then refluxed for 2 h. The reaction mixture, after removal of precipitates, was evaporated under reduced pressure and the residue was extracted with ether. The ethereal layer was washed with water, 10% aqueous sodium carbonate solution and then with brine, and dried over sodium sulfate. On evaporation, an oily residue (2.31 g) was obtained, which was subjected to separation by silica gel (150 g) column chromatography using benzene as an eluent to give an oil (1.23 g). This was crystallized from dichloro-

methane–methanol to afford a mixture (672 mg) of D: B-friedo-bacchar-5(10)-en-3-one (**2**) and D: B-friedo-bacchar-5-en-3-one (**4**), mp 81—82 °C (lit,[2] 81—81.5 °C); IR (KBr) 1710 and 825 cm^{-1}; PMR (60 MHz, $CDCl_3$) δ 5.70 (*ca.* 0.5H, br).

Bromination of the Mixture of D: B-Friedo-bacchar-5(10)-en-3-one (2) and D: B-Friedo-bacchar-5-en-3-one (4). A mixture (3.62 g) of the enones (**2** and **4**) in acetic acid (100 ml) was treated at 60 °C with pyridinium tribromide (4.53 g) for 15 min. The brownish solution, after removal of the solvent under reduced pressure, was extracted with ether. The ethereal extract was washed with water, 10% aqueous sodium carbonate solution, and with brine, and then dried over sodium sulfate. The solvent was removed and the residue was dissolved in petroleum ether. The solution was passed through a column of silica gel (450 g). Elution with a mixture of petroleum ether–benzene (2: 1 and then 1: 1) gave a mixture (1.75 g) of 2ξ-bromo-D: B-friedo-bacchar-5(10)-en-3-one (**6**) and 2ξ-bromo-D: B-friedo-bacchar-5-en-3-one (**7**) as an oil, which was crystallized from dichloromethane–methanol to give white crystals (1.22 g), mp 136—137 °C; IR (KBr) 1720, 760, 655, and 630 cm^{-1}; PMR (60 MHz, $CDCl_3$) δ 4.57—5.00 (1H, m) and 5.75 (*ca.* 0.5H, br); mass spectrum *m/e* 506, 504 (M^+; $C_{30}H_{49}OBr$), and 261 (base peak).

Dehydrobromination of the Mixture of 2ξ-Bromo-D: B-friedo-bacchar-5(10)-en-3-one (6) and 2ξ-Bromo-D: B-friedo-bacchar-5-en-3-one (7). A mixture (64 mg) of the bromo-derivatives (**6** and **7**) was dissolved in freshly distilled hexamethylphosphoric triamide (5 ml) and the solution was heated at 130—140 °C for 10 h under a nitrogen atmosphere. The reaction mixture, after cooling, was poured into ice water, extracted with petroleum ether. The organic layer was washed with water, 2M hydrochloric acid, 20% aqueous sodium carbonate solution, and with brine and then dried over sodium sulfate. The residue, after removal of the solvent, was dissolved in a mixture of chloroform and benzene (1: 1), passed through a column of silica gel (100 g) and eluted with the same solvent mixture to give D: B-friedo-bacchara-1,5(10)-dien-3-one (**5**; 11 mg), a yellow oil, IR (liquid) 1655 and 1620 cm^{-1}; UV λ_{max}^{EtOH} 324 nm (ε 5300); PMR (100 MHz, $CDCl_3$) δ 5.98 (1H, d, J=10 Hz) and 7.12 (1H, d, J=10 Hz); molecular weight (by high resolution mass spectrometry) Found: 424.3642. Calcd for $C_{30}H_{48}O$: 424.3705; mass spectrum *m/e* 424 (M^+) and 203 (base peak).

Hydrogenation of D: B-Friedo-bacchara-1,5(10)-dien-3-one (5). The dienone (**5**; 11 mg) in ethanol (5 ml) was hydrogenated in the presence of palladium–charcoal (10%, 2 mg) for 3 h. A yellow color of the solution faded and finally a colorless solution was obtained, which on filtration followed by evaporation, gave a colorless oil. The oil was subjected to separation by preparative tlc (SiO_2, 0.25 mm in thickness, developed with benzene) to give a colorless oil (5 mg), which was crystallized from methanol to give D: B-friedo-bacchar-5(10)-en-3-one (**2**) as fine needles, mp 84—84.5 °C (lit,[2] mp 78—80 °C); IR (KBr) 1715 cm^{-1}; PMR (60 MHz, $CDCl_3$) δ 2.40 (2H, m), no signal due to olefinic proton; mass spectrum *m/e* 426 (M^+; $C_{30}H_{50}O$) and 109 (base peak).

Reduction of D: B-Friedo-bacchar-5(10)-en-3-one (2) with Lithium Aluminium Hydride. To a solution of D: B-friedo-bacchar-5(10)-en-3-one (**2**; 37 mg), obtained by the above procedure, in ether (5 ml) was added lithium aluminium hydride (in excess), and the reaction mixture was allowed to stand overnight. After dilution with additional ether, the solution was washed with 1M hydrochloric acid, 5% aqueous sodium hydrogen carbonate solution and with brine, and then dried over sodium sulfate. On removal of the solvent, an oily residue was obtained, which gave a major spot with a smaller R_f value accompanied by a minor spot due to 3α-isomer on tlc developed with chloroform.

The major product was separated by preparative tlc developed with chloroform to afford D: B-friedo-bacchar-5(10)-en-3β-ol (**8**), mp 141.5—142 °C (lit,[2] mp 140.5—141 °C); IR (Nujol) 3350, 1065, 1040, 1025, and 975 cm^{-1}; PMR (60 MHz, $CDCl_3$) δ 3.42 (1H, dd, J=5 and 10 Hz), no signal due to olefinic proton; mass spectrum *m/e* 428 (M^+; $C_{30}H_{52}O$) and 135 (base peak).

Acetylation of D: B-Friedo-bacchar-5(10)-en-3β-ol (8). D: B-Friedo-bacchar-5(10)-en-3β-ol (**8**; 23 mg) in pyridine (0.2 ml) was treated with acetic anhydride (0.1 ml), and was kept at room temperature overnight. Usual work-up and crystallization from chloroform–methanol gave D: B-friedo-bacchar-5(10)-en-3β-yl acetate (**9**; 18 mg), mp 146.5—149 °C (lit,[2] mp 148.5—149.5 °C); IR (KBr) 1730, 1250, 1110, and 975 cm^{-1}; PMR (60 MHz, $CDCl_3$) δ 2.03 (3H, $-COCH_3$), 4.64 (1H, dd, J=5 and 10 Hz), no signal due to olefinic proton.

Antineoplastic Agents. The Preparation of 5-Fluorouracil-1-acetic Acid Derivatives

Masao TADA

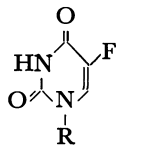
The Research Institute for Tuberculosis, Leprosy and Cancer, Tohoku University, Hirosemachi, Sendai 980

(Received June 23, 1975)

Synopsis. The condensations of 5-fluorouracil with α-halogenoacetic acid derivatives in the presence of alkali gave the 5-fluorouracil-1-acetic acid derivatives.

5-Fluorouracil (I)[1] and 1-(2-tetrahydrofuryl)-5-fluorouracil (II)[2] as antineoplastic agents have received much attention because of their antitumor activities. In a previous paper,[3] the preparations of various 1-acyl, 1-alkanesulfonyl-, and 1-arenesulfonyl-5-fluorouracils from I were reported. In an attempt to improve the antitumor activities, the introduction of the acetic acid group into the 1-position of I has been attempted. The preparations of 5-fluorouracil-1-acetic acid derivatives will be reported here.

The condensation of I with α-chloroacetic acid in the presence of potassium hydroxide in water afforded 5-fluorouracil-1-acetic acid (III) in a 66% yield; this acid formed ammonium salt (IV) upon subsequent treatment with ammonium hydroxide. The reaction of I with ethyl α-bromoacetate in the presence of anhydrous potassium carbonate in dimethylformamide gave both ethyl 5-fluorouracil-1-acetate (V) in a 57% yield and diethyl 5-fluorouracil-1,3-diacetate (VI) in a 22% yield.



I: R=H

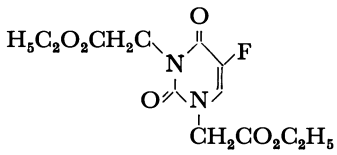
II: R=

III: R=CH_2CO_2H

IV: R=$CH_2CO_2NH_4$

V: R=$CH_2CO_2C_2H_5$

VII: R=$CH_2CO_2CH_3$



VI

The acid hydrolysis of V gave the corresponding carboxylic acid, III, in a quantitative yield; this acid was subsequently converted into V by esterification with ethanol in the presence of such catalysts as sulfuric acid and *p*-toluenesulfonic acid. Compound III was treated with methanol to afford the methyl ester (VII) in a good yield; this ester was then hydrolyzed with hydrochloric acid to give III. Compound VII was also obtained from I by the reaction of I with methyl α-bromoacetate.

TABLE 1. ULTRAVIOLET SPECTRAL DATA

Comp.	Solvent	λ nm max (log ε)	λ nm min (log ε)
III	0.1M HCl	269 (3.98)	234 (3.35)
	0.1M NaOH	271 (3.84)	247 (3.58)
V	0.1M HCl	268 (4.00)	233 (3.35)
	0.1M NaOH	272 (3.75)	248 (3.50)
VI	0.1M HCl	269 (3.96)	235 (3.30)
	0.1M NaOH	272 (3.92)	236 (3.43)
VII	0.1M HCl	268 (3.98)	233 (3.30)
	0.1M NaOH	272 (3.87)	247 (3.62)

1-Substitution on I has been established by a comparison of the absorption spectra (Table 1) of the products with those of authentic 5-fluorouracil derivatives.[4-6] The structures of the products have been further supported by their NMR spectra.

The above products are now being used for animal testing; the results will be reported elsewhere.

Experimental

All the melting points are uncorrected. The ultraviolet spectra were taken with a Hitachi Model 124 spectrophotometer. The NMR spectra were recorded in DMSO-d_6 (internal TMS standard) with a Varian Model 60T spectrophotometer.

5-Fluorouracil-1-acetic Acid (III). *From I*: Into a solution of I (1.3 g, 10 mmol) and potassium hydroxide (1.12 g, 20 mmol) in water (7.5 ml), a solution of α-chloroacetic acid (950 mg, 10 mmol) in water (4 ml) was stirred at room temperature. The pH of the reaction mixture was adjusted to, and kept at, 10 by the drop-by-drop addition of a potassium hydroxide aqueous solution. The mixture was then refluxed for 2 h, cooled, and acidified to pH 2 by the addition of concentrated hydrochloric acid. The crystals which separated were collected and washed with a little cold water to give III (1.24 g) in a 66% yield. The products were dissolved in saturated aqueous potassium bicarbonate and reprecipitated with concentrated hydrochloric acid to give colorless needles; mp 276—277 °C.

Found: C, 38.38; H, 2.72; N, 14.64%. Calcd for $C_6H_5FN_2O_4$: C, 38.31; H, 2.68; N, 14.89%.

NMR (DMSO-d_6): δ 4.40 (2H singlet, 1-CH_2-), 8.09 (1H doublet, J=7 Hz, H_6), 11.18 (1H broad singlet, 3-NH).

From V: A solution of V (430 mg, 2 mmol) in 12N hydrochloric acid (6 ml) was gently refluxed for 2.5 h and then diluted with water (6 ml). The crystals thereby separated were collected and washed with cold water to give III (240 mg). After the removal of the solvent, an additional 120 mg portion of III was obtained from the mother liquor. The total yield of III was 96%.

From VII: Compound VII was treated as in the case described above to give III (95%).

Ammonium 5-Fluorouracil-1-acetate (IV). To a suspension of III (940 mg, 5 mmol) in water (5 ml), concentrated ammonia water (0.6 ml) was added. The mixture was warmed on a water bath for 5 min. After the removal of the solvent under reduced pressure, the residue was recrystallized from diluted ethanol to give IV (0.5 g, 49%); mp 225—227 °C.

Found: C, 35.28; H, 4.12; N, 20.17%. Calcd for $C_6H_8FN_3O_4$: C, 35.13; H, 3.93; N, 20.48%.

The Reaction of 5-Fluorouracil (I) with Ethyl α-Bromoacetate. Into a suspension of powdered I (5.2 g, 40 mmol) and

anhydrous potassium carbonate (3.04 g, 44 mmol) in dimethylformamide (60 ml), ethyl α-bromoacetate (7.34 g, 44 mmol) was added. The reaction mixture was vigorously stirred at 100 °C for 10 h, cooled to room temperature, and then filtered off. The filtrate was evaporated to dryness under reduced pressure, and the residue was then extracted with absolute ethanol. The extract was concentrated by evaporation. After dilution with water, the crystals which separated were collected. Recrystallization from ethanol afforded needles (4.9 g) of ethyl 5-fluorouracil-1-acetate (V) in a 57% yield; mp 164—165 °C.

Found: C, 44.37; H, 4.39; N, 12.70%. Calcd for $C_8H_9FN_2O_4$: C, 44.45; H, 4.20; N, 12.96%.

From the mother liquor, the crystals were obtained after evaporation under reduced pressure. Recrystallization from diluted ethanol formed diethyl 5-fluorouracil-1,3-diacetate (VI), (2.60 g) as needles in a 22% yield; mp 84—85 °C.

Found: C, 47.66; H, 4.98; N, 9.58%. Calcd for $C_{12}H_{15}FN_2O_6$: C, 47.68; H, 5.00; N, 9.27%.

NMR (DMSO-d_6): δ 1.22 (6H triplet, J=7 Hz, $-OCH_2CH_3$), 4.18 (4H, quartet, J=7 Hz, $-OCH_2CH_3$), 4.60 (4H singlet, $1\text{-}CH_2-$), 8.30 (1H, doublet, J=7 Hz, H_6).

Ethyl 5-Fluorouracil-1-acetate (V). A solution of III (940 mg, 5 mmol) in absolute ethanol (30 ml) and concentrated sulfuric acid (0.2 ml) was refluxed for 8 h and then concentrated to one-third its original volume. After the addition of ice water, sodium bicarbonate was added to the reaction mixture. The crystals thereby separated were collected and washed with cold water to give V (750 mg, 69%). The mother liquor was then extracted with chloroform. The chloroform extract was washed with water and dried over anhydrous magnesium sulfate; an additional 50 mg portion of V was thus obtained; mp 164—165 °C. The total yield of V was 74%.

A solution of III (940 mg) and *p*-toluenesulfonic acid (0.5 g) in absolute ethanol (30 ml) was treated as in the above experiment to give V (425 mg, 40%).

Diethyl 5-Fluorouracil-1,3-diacetate (VI). Into a suspension of powdered I (2.6 g, 20 mmol) and anhydrous potassium carbonate (1.52 g, 11 mmol) in absolute ethanol (60 ml), ethyl α-bromoacetate (3.67 g, 22 mmol) was added. The mixture was refluxed with stirring for 10 h and then filtered off. The filtrate was concentrated under reduced pressure to give both I (350 mg, 14%) and V (300 mg, 7%). From the mother liquor, crystals (1.72 g, 29%, mp 84—85 °C) of VI were obtained after further concentration under reduced pressure.

Methyl 5-Fluorouracil-1-acetate (VII). *From I*: Into a suspension of powdered I (1.3 g, 10 mmol) and anhydrous potassium carbonate (1.52 g, 11 mmol) in dimethylformamide (30 ml), a solution of methyl α-bromoacetate (1.68 g, 11 mmol) in dimethylformamide (5 ml) was stirred. The reaction mixture was then further stirred at 100 °C for 10 h and treated as in the above experiment to give VII (960 mg, 48%). Recrystallization from methanol afforded needle; mp 185—186 °C.

Found: C, 41.63; H, 3.53; N, 13.65%. Calcd for $C_7H_7FN_2O_4$: C, 41.59; H, 3.49; N, 13.86%.

From III: A solution of III (1.88 g, 10 mmol) in absolute methanol (60 ml) and concentrated sulfuric acid (0.6 ml) was refluxed for 8 h, after which the reaction mixture was treated as in the procedure used in the preparation of the ethyl ester, V, to give VII (1.05 g, 52%).

The author is grateful to Professor Yusaku Ikegami and Dr. Masafumi Yasunami, Tohoku University, for their encouragement, and to Mitsui Pharmaceuticals, Inc., for supplying the 5-fluorouracil.

α-(3-Phenoxymethyl-7-oxo-4-thia-2,6-diazabicyclo[3.2.0]hept-2-ene-6-yl)-α-isopropenylacetates, Useful Intermediate from Penicillin to Cephalosporin

Hiroshi TANIDA, Ryonosuke MUNEYUKI, and Tadahiko TSUSHIMA
Shionogi Research Laboratory, Shionogi and Co., Ltd., Fukushima-ku, Osaka 553

(Received July 24, 1975)

Synopsis. Reaction of α-[2-(Benzothiazol-2-yl)-dithio-3-phenoxyacetamido-4-oxoazetidin-1-yl]-α-isopropenylacetates with phosphorus pentasulfide afforded the title compound. The first step in this reaction is suggested as an intramolecular nucleophilic attack of the thioamide function, initially resulted from the 3-acetamido groups, towards the disulfide-sulfur at the 2 position.

Warming of a penicillanic acid sulfoxide ester (**1**) with 2-mercaptobenzothiazol gave in an excellent yield the disulfide (**3**).[1,2] It has been evidenced that the formation of **3** is a result of intermolecular thiol trapping of the sulfenic acid intermediate (**2**) existing in a thermal equilibrium with **1**.[3,4] Since cleavage of the disulfide linkage and recyclization into new series of penicillin and cephalosporin is possible under mild conditions, the disulfide derived from 2-mercaptobenzothiazol may be a useful intermediate more than those from other thiols.[2] We have suggested that the side chain at C-6 might participate in reactions with the sulfenic acid (Formula **5**→**6**). Based on this hypothesis, we undertook an experiment to transform **3** into the thioamide **7**, because the thioamide function is known as a good nucleophile,[6] perhaps, better than the acetamide.

The reaction of **3** (R=$PhOCH_2$), derived from Penicillin V, with diphosphorus pentasulfide was tried. When a benzene solution of **3** containing 1.1 mol equivalents of phosphorus pentasulfide was refluxed for 30 min, there was found to form mainly the thiazoline-azetidinone **8** (the title compound) by liberating 2-mercaptobenzothiazol. The structure of **8** was established by comparing with an authentic sample prepared by the reported method.[7]

Reaction of **1** with trimethyl phosphite in refluxing benzene is known to give **8**.[7] This reaction has been considered as an initial formation of the sulfenic acid followed by reduction by the trivalent phosphorus reagent into a thiol which attacks at the amide-carbon as a nucleophile to give the cyclized **8**. Reduction of the disulfide **3** into a thiol by the pentavalent phosphorus reagent, diphosphorus pentasulfide, is improvable. Alternatively, it seems us doubtless that the thioamide-sulfur in **7**, initially formed by an action of diphosphorus pentasulfide on **3**, reacts as a nucleophile toward the sulfide-sulfur to give **6** (X=S) which does not unfortunately survive under the reaction conditions but, as a result of several steps of thermal rearrangements as shown in the last formulas, affords the stable **8** by eliminating sulfur.

Finally, it should be pointed out that the present reaction is a simple procedure to obtain **8**, which is known as an important intermediate for the conversion of penicillin derivatives into cephalosporin derivatives.[2,4]

Experimental

Reaction of 3 (R=$PhOCH_2$-) with P_2S_5. a) With the Methyl Ester (R'=CH_3): A solution of 329 mg (0.62 mmol) of **3** in 5 ml of benzene suspended with 35 mg (0.16 mmol) of P_2S_5 was refluxed for 30 min. The reaction mixture was filtered, evaporated under a reduced pressure and extracted with carbon tetrachloride.

After evaporation of the solvent, the residue (377 mg) was separated by thin-layer chromatography (benzene–ethyl acetate=4:1). The main fraction was the thiazolin derivative **8** (the title methyl ester) in 37.5% yield: IR ($CHCl_3$) 1780 and 1745 cm^{-1} (C=O), NMR ($CDCl_3$) δ 1.76 (s, 3, allylic CH_3), 3.77 (s, 3, $COOCH_3$), 4.93 (s, 2, $PhOCH_2$), 4.83 (s, 1, $-CHCOOCH_3$), 5.10 (broad, m, 1, vinyl H), 4.50 (d, 1, vinyl H, J=9.0 Hz), and 5.97 (m, 2, azetidinone H); CD (c=0.1467, in dioxane) 270 mμ ([θ]-1040), 245 (+13300), and 209.5 (−29300).

b) With the 2,2,2-Trichloroethyl Ester (R'=$-CH_2CCl_3$): The corresponding **8** (R'=$-CH_2CCl_3$), mp 139—141 °C, was similarly obtained by the above procedure.

The Calculations of Dipole Polarizabilities and Anisotropies by the CNDO Method: The Effect of an Extended-basis Set

Hiroyuki SHINODA and Tatsuo AKUTAGAWA

Department of Applied Chemistry, Faculty of Science and Engineering, Waseda University, Nishi-Ohkubo, Shinjuku-ku, Tokyo 160

(Received January 10, 1975)

The dipole polarizabilities and the anisotropies of several small molecules have been calculated according to a formula derived from the time-dependent perturbation theory. The wave functions and the energies were calculated by means of the CNDO-CI version, with an extended-basis set. The effects on the calculated results of the introduction of the atomic vacant orbitals into the basis set have been discussed.

Theoretical calculations of polarizabilities within the framework of the CNDO version have been performed by several investigators.[1-4] Miyazaki and one of the present authors[1] reported their theoretical calculations of polarizabilities according to the formula derived from the time-dependent perturbation theory. They calculated the polarizabilities by the use of the wave functions and the energies, which were evaluated by the CNDO-CI method using the valence-orbital-basis set. They discussed the effects of the parameters in the CNDO method on the calculated polarizabilities and concluded that the calculated polarizabilities were generally smaller than the experimental results and that the calculated anisotropies were larger than the observed results. Hush and Williams[2] used the finite perturbation theory with the valence-orbital-basis set in order to investigate the polarizabilities and the anisotropies of axial symmetric molecules. Their calculated values of polarizability-anisotropy, $\alpha_{\parallel}$-$\alpha_{\perp}$, were in good agreement with the experimental ones. However, the calculated values of the polarizabilities were small in comparison with the experimental ones, and the calculated vaules of the anisotropies were larger than the observed ones. They improved the calculated results by adding the correction terms to the diagonal elements of the molecular polarizability tensors.[3] Davies[4] calculated the polarizabilities of several small molecules by the use of the self-consistent perturbation method. From a comparison between the results of calculations in which the 2p-orbitals of the hydrogen atoms are considered and those in which they are not, he concluded that the valence-orbital-basis set is inadequate for the representation of the perturbed wave functions. At any rate, the polarizabilities calculated within the framework of the CNDO version with the valence-orbital-basis set were not in agreement with the experimental ones.

The purpose of this work is to investigate the effect on the calculated polarizabilities of the introduction of the atomic vacant orbitals into the basis set. The RCNDO method proposed by Salahub and Sandorfy[5] is a modified CNDO method with the extended-basis set. This method is, however, not always appropriate for the calculation of the polarizability, as will be shown later. Then the trial method, which differs from the RCNDO method, has been used to obtain the wave functions and the energies. Discussions have been based on a comparison of the results calculated by several approaches.

Methods of Calculations

Polarizability and Anisotropy: The polarizability, α, of a system in the electromagnetic field as a perturbation can be derived from the time-dependent perturbation theory.[1] By averaging the vector quantities over all the orientations of the system with respect to the field, α can be given as:

$$\alpha = \frac{2}{3h}\sum_b \frac{\nu_{ba}|\langle\Psi_a^\circ|e\sum_i \boldsymbol{r}_i|\Psi_b^\circ\rangle|^2}{\nu_{ba}^2-\nu^2}, \quad (1)$$

where $\boldsymbol{r}_i$ is the position vector of the i-th electron; ν is the frequency of the incident light, and $h\nu_{ba}=E_b-E_a$; here E_a is the energy of the unperturbed ground state described by the wave function, Ψ_a°, and E_b is the energy of the unperturbed excited state with the wave function of Ψ_b°. The anisotropy, k, is expressed by the components of the polarizability tensor as follows:

$$k^2 = \{(\alpha-\alpha_1)^2+(\alpha-\alpha_2)^2+(\alpha-\alpha_3)^2\}/6\alpha^2, \quad (2)$$

where α_1, α_2, and α_3 are the principal polarizabilities of the system.

Molecular Orbital Calculations: The molecular wave function, Ψ_a°, of an unperturbed ground state is described as the single Slater-determinant with a closed-shell structure, while those of unperturbed excited states, Ψ_b°'s, are described as linear combinations of all the singly-excited configurations obtained by the configuration-interaction (CI) treatment.

The atomic vacant orbitals considered in this work, in addition to the valence orbitals, have been restricted to those with a principal quantum number (p.q.n.) greater by 1 than that of the valence orbitals, and the effective nuclear charges for the atomic vacant orbitals are taken to be equal to those for the valence orbitals as determined by Slater's rule. Within the framework of the CNDO version, the diagonal element of the SCF energy matrix in the Roothaan LCAO-SCF equation[6] can be written as follows:[7]

$$F_{\mu\mu} = -I_\mu - (Z_A-1)\gamma_{AA}^{n\bar{m}} - \sum_{B\neq A} Z_B\gamma_{AB}^{n\bar{m}} + \left(P_{AA}^{nn}-\frac{1}{2}P_{\mu\mu}\right)\gamma_{AA}^{nn} + \sum_{m\neq n}^{A} P_{AA}^{mm}\gamma_{AA}^{nm} + \sum_{B\neq A}\sum_{m}^{B} P_{BB}^{mm}\gamma_{AB}^{nm}, \quad (3)$$

where n is the p.q.n. of the atomic orbital, φ_μ, which belongs to the A atom; I_μ, the average ionization potential of φ_μ; Z_A and Z_B, the core charges of the A and B atoms respectively; $P_{\mu\mu}$, the charge density of φ_μ; and P_{AA}^{mm}, the sum of the charge densities of

TABLE 1. AVERAGE IONIZATION POTENTIALS, I_μ, FOR ATOMIC VACANT ORBITALS (eV)

the atomic orbitals with the p.q.n. -m on the A atom; γ_{AB}^{nm} represents the repulsion between electrons in φ_μ and in the atomic orbital with the p.q.n. -m on the B atom, and $\bar{m}$ in $\gamma_{AB}^{n\bar{m}}$ is the p.q.n. of the valence orbital on the B atom. The electronic repulsion integral, γ_{AB}^{nm}, is calculated as a Coulomb integral including the ns and ms Slater orbitals. The values of the average ionization potentials for valence orbitals followed those of the CNDO/1 method,[7] while those of the vacant orbitals were evaluated from the table in Ref. 8 and are shown in Table 1. The off-diagonal element of the SCF energy matrix is described as follows:

$$F_{\mu\nu} = \beta_{AB}^{nm} S_{\mu\nu} - \frac{1}{2} P_{\mu\nu} \gamma_{AB}^{nm}, \tag{4}$$

where n is the p.q.n. of φ_μ on the A atom; m, the p.q.n. of φ_ν on the B atom; $S_{\mu\nu}$, the overlap integral between φ_μ and φ_ν, and $P_{\mu\nu}$, the bond order between φ_μ and φ_ν. The bonding parameter, β_{AB}^{nm}, is approximated by:

$$\beta_{AB}^{nm} = \frac{1}{2} \kappa (\beta_A^\circ + \beta_B^\circ), \tag{5}$$

where the values of the β_A° and β_B° are the same as those used in the CNDO/1 method[7] and where the κ parameter is determined as will be described below. The value of κ for the interaction between valence orbitals is taken to be unity, as in the CNDO/1 method. The average ionization potentials of the 2p-orbitals for the first-row elements are nearly equal to a half of the values of the β_A° and are roughly five times the average ionization potentials of 3p-orbitals. Therefore, the value of κ for the interaction between vacant orbitals is taken to be 0.2. The value of κ for the valence orbital-vacant orbital interaction is taken to be 0.6, the mean of 1.0 and 0.2. The geometries of the molecules followed the data listed in Ref. 9.

Results and Discussion

By the use of the molecular wave functions obtained from the CNDO/2-CI treatment including all the singly- and the doubly-excited configurations, Tatematsu[10] calculated the polarizabilities of several molecules according to the formula shown in Eq. (1). The calculated values were 0.504, 0.685, 0.721, and 1.128 Å^3 for N_2, CO, C_2H_2, and C_2H_4 respectively. These values are smaller than those obtained by the calculations considering only the singly-excited configurations in Ref. 1. However, the calculated anisotropies were slightly improved by considering the doubly-excited configurations, although they, as well as those in Ref. 1, are larger than the experimental ones. The electronic transition energies and the transition moments calculated by the CNDO/2-CI method are listed in Table 2 for N_2 as an example. The introduction of doubly-excited configurations reduces the transition moments in the calculation with only the singly-excited configurations and brings about new excited states which have large electronic excitation energies and small transition moments, so that the new ones contribute scarcely anything to the polarizability. The above discussions showed that the CI treatment including the doubly-excited configurations does not bring a drastic improvement in the calculation of polarizabilities, although the treatment is a powerful approach to an investigation of several lower electronic excited states.[11] In this study, therefore, calculations have been performed with the CI treatment including only the singly-excited configurations.

The polarizability and the anisotropy of C_2H_2 were calculated with various basis sets; the results are shown in Table 3. With the increase in the number of atomic orbitals in the basis set, the value of the polarizability increases and the value of the anisotropy decreases. In the investigation by Davies,[4] the 2p-orbitals of the hydrogen atom were used in the basis set for the perturbed wave functions, but the 2s-orbital was not considered. From the comparisons between the results of (D) and (F) and between those of (E) and (G) shown in Table 3, it is found that the introduction of the 2s-orbital of the hydrogen atom, in addition to the 2p-orbitals, into the basis set effectively improves the calculated results. The results in (F), (G), and (H) lead to the following discussion of the effects of the vacant orbitals of the carbon atom on the calculated results for the polarizability and the anisotropy. The value of the polarizability calculated by considering the 3s-, 3p-, and 3d-orbitals of the carbon atom, (H) in the table, is larger than the experimental one. On the other hand, the values of the polarizability in (F) and (G) are slightly smaller than the observed one. From a comparison between the results in (F) and (G), it is found that (F), including the 3s- and 3p-orbitals of the carbon arom, yields the good polarizability, while (G), including the 3d-orbitals, yields a good anisotropy.

On the basis of the above discussion of the results of C_2H_2, it is decided that two kinds of basis sets will be used in the following calculations. One of them contains the 1s-, 2s-, and 2p-orbitals of a hydrogen atom and the 2s-, 2p-, 3s-, and 3p-orbitals of first-row elements. The other one contains the 1s-, 2s-, and 2p-orbitals of a hydrogen atom and the 2s-, 2p-, and 3d-orbitals of first-row elements. The molecular orbital calculation with the former basis set will be

called EB/sp (Extended-basis Set containing 3s- and 3p-orbitals) method for short and the latter, the EB/d (Extended-basis Set containing 3d-orbitals) method. The calculated polarizabilities are listed in Table 4. In the table the values calculated by the use of the wave functions obtained from other molecular orbital calculations are also shown. The results calculated using the EB/sp and the EB/d methods are improved as compared with those from the CNDO method used in the previous work.[1] Also, the results from the RCNDO/v method are improved by the use of the RCNDO method; here, RCNDO/v means the RCNDO calculation without the vacant orbitals. However, the RCNDO method gives poor results for the polarizabilities in comparison with those of the EB/sp and the EB/d methods. There are differences between the orbital exponents of the vacant orbitals used in the RCNDO method and the method in this work and between the estimations of the molecular integrals in these methods. It is considered that the introduction of the different orbital exponents is not the direct cause of the inferiority of the RCNDO method, because the results from the EB/sp′ method, which is the EB/sp calculation with the same orbital exponents as those in the RCNDO method except for a hydrogen atom, are rather analogous to those calculated by the EB/sp method.

The calculated anisotropies are listed in Table 5. Most of the calculated results are larger than the experimental ones. The values calculated by the CNDO/2 method are much improved by the EB/sp and the EB/d methods. For the calculation of the anisotropies as well as the polarizabilities, the RCNDO method is inferior to both the EB/sp and the EB/d methods. The inferiority of the RCNDO method may be caused by the estimation of the bonding parameter for the valence orbital-vacant orbital interaction. In the RCNDO method, the bonding parameter, β_{AB}^{nm}, was given by the following expression:

as 0.4 for the valence orbital-valence orbital interaction and as 0.05 for all the others. By comparing the equation with Eq. (5), it is found that the values of the β_{AB}^{nm} for the valence orbital-vacant orbital interaction in the RCNDO method are smaller than those given by Eq. (5). The influence of the bonding parameters appears in the weights of the atomic vacant orbitals in the wave functions of the ground state. Some of the calculated results for the weights are shown in Table 6. The weights in the RCNDO method are very small in comparison with those in the other methods. The results obtained by the RCNDO method may be improved by the introduction of some other vacant orbitals, for example, 3d-orbitals of first-row elements, into the basis set, because the calcu lated values of the polarizabilities increase with the number of atomic orbitals, as has been shown in Table 3.

Finally, some results of the polarizabilities in the present work will be compared with those in the non-empirical calculations. The results are listed in Table 7. The values calculated by Liebmann and Moskowitz[13] by means of the uncoupled perturbed Hartree Fock (UPHF) method with the variation technique are larger than the experimental ones; this is the case even when the polynomial in the perturbing variable is restricted to only one term. The overestimation is not due to the zeroth-order wave function used in the calculation, because it appeared also in the results of the UPHF method using the other zeroth-order wave functions.[14] Arrighini *et al.*[15,16] used several basis sets for each molecule in the coupled perturbed Hartree Fock (CPHF) calculation in order to discuss the effect of the basis sets and concluded that their choice of the basis sets was improper for the polarizabilities because even their largest basis set yielded a small polarizability. The results obtained by the EB/sp and the EB/d methods seem to be good in comparison with those obtained by the non-empirical ones. Because of the results for C_2H_2 in Table 3, however, it can not be said that the basis sets used in the present work bring a convergence of the polarizabilities. The present work is not appropriate as the basis of a discussion of the convergence, which is rather an interesting subject for a non-empirical calculation.

From a consideration of the results in Tables 3—6, it may be said that the effect of the atomic vacant orbitals on the calculated polarizabilities is not independent of the parameter values in the molecular integrals and that good results for the polarizabilities can be obtained by the calculation with the basis set in the EB/sp or the EB/d methods if the parameter values are suitably determined. The influences of the introduction of the atomic vacant orbitals and of the parameter values on some other physical values will be investigated in future studies.

The authors would like to thank Professor Tomoo Miyazaki for his helpful advice and for his critical reading of the manuscript. They are also indebted to Mr. Hidenobu Tatematsu of the Railway Technical Research Institute, J. N. R., for permitting them to use his unpublished data in their discussion. In their calculations, they were helped by the "University Contribution" of UNIVAC Japan, Ltd.

An INDO Molecular-orbital Interpretation of the NMR of Several Protonated Heteroaliphatic Compounds

Katsutoshi OHKUBO, Kohji TSUCHIHASHI, Toshiaki YOSHIDA and Masahide OKADA

Department of Synthetic Chemistry, Faculty of Engineering, Kumamoto University, Kurokami, Kumamoto 860

(Received February 14, 1975)

Several protonated alcohols, acids, and esters were investigated by means of the INDO-MO theory and in connection with their proton and carbon-13 NMR results. The relative stability of the protonated conformers as detected by the NMR spectroscopy, had a good coincidence with the MO-theory and the experimental results. The proton or carbon-13 chemical shifts and coupling constants also showed satisfactory linear correlations between the theory and the experiment; the proton and isotropic (^{13}C) chemical shifts could be well explained by the linear correlation between the diamagnetic shielding constant and the electron density on the proton of the O–H bond and between the calculated paramagnetic shielding effect and the observed isotropic chemical shifts. The observed coupling constants of the proton and carbon-13 NMR had good overall parallelisms with those evaluated by means of the Fermi contact effect.

Considerable interest has recently centered on the elucidation of the structures of protonated heteroaliphatic compounds, with particular attention being paid to the NMR results of their protons or carbonium carbons.[1] Concerning protonated aliphatic alcohols, acids, and esters, which were investigated in the present work, Olah *et al.* [2-7] and others[8-10] have extensively studied their proton or carbon-13 NMR in a superacid system and have reported that all the keto-protonated conformers except for protonated alcohols are stable species.

The protonated compounds of the above oxygenated species, however, have been the object of only limited investigation in terms of their molecular orbital treatments. Only protonated formic acid has been studied in a few *ab initio* calculations;[11-13] the small Gaussian basis sets brought about some discrepancy between theory and experiment with respect to the relative stability of the protonated isomers.[12]

In connection with the NMR observations of several protonated species, an extensive investigation of the protonated compounds seems significant and of interest. In the present study we will focus on the PMR or ^{13}C NMR chemical shifts and coupling constants of the protonated conformers of alcohols, acids, and esters from the viewpoints of both the INDO-MO theory and experiments.

Method of Calculation

The following five homologue series were investigated in this work: (a) the protonated formates, $HC(OH)OR^+$ (R=H, CH_3, and CH_3CH_2); (b) the protonated acetates, $CH_3C(OH)OR^+$ (R=H, CH_3, and CH_3CH_2); (c) the protonated methyl esters, $RC(OH)OCH_3^+$ (R=H, CH_3, and CH_3CH_2); (d) the protonated acids, $RC(OH)_2^+$ (R=H, CH_3, and CH_3CH_2), and (e) the protonated alcohols, ROH_2^+ (R=CH_3, CH_3CH_2, and $CH_3CH_2CH_2$).

Since the geometric data for the above protonated compounds (except $HC(OH)_2^+$) are not available in the literature, the geometries of the protonated compounds were assumed to be the same as those of the parent molecules, which can be found in a standard compendium,[14] except for the bond lengths of C–O, R_{CO}, in $C-OH^+=R_{CO}$ in C–OH or C–OR, $R_{OH^+}=R_{OH}$, and $\angle COH^+=\angle COH$ or $\angle COR$; they are given in Table 1. The bond lengths of R_{CC} and R_{CH} were uniformly taken to be 1.54 Å and 1.09 Å respectively, while the bond angles of C–C–C and H–C–C were

Table 1. Assumed geometries of protonated compounds

Series	No.	Molecule	R_{CO}/Å	R_{OH}/Å	∠OCO	∠COC	∠COH
Protonated formates	1	$HC(OH)OH^+$ a)	1.312	0.95	124°18′		107°48′
	2	$HC(OH)OCH_3^+$	1.334	0.96	125°52′	114°47′	114°47′
	3	$HC(OH)OC_2H_5^+$	1.334	0.96	125°52′	114°47′	114°47′
Protonated acetates	4	$CH_3C(OH)OH^+$	1.430	0.95	130°		107°48′
	5	$CH_3C(OH)OCH_3^+$	1.360	0.96	124°	113°	116°
	6	$CH_3C(OH)OC_2H_5^+$	1.334	0.96	125°52′	114°47′	114°47′
Protonated methyl esters	2	$HC(OH)OCH_3^+$	1.334	0.96	125°52′	114°47′	114°47′
	5	$CH_3C(OH)OCH_3^+$	1.360	0.96	124°	113°	116°
	7	$C_2H_5C(OH)OCH_3^+$	1.360	0.96	124°	113°	114°47′
Protonated acids	1	$HC(OH)_2^+$	1.312	0.95	124°18′		107°48′
	4	$CH_3C(OH)_2^+$	1.430	0.95	130°		107°48′
	8	$C_2H_5C(OH)_2^+$	1.430	0.95	130°		107°48′
Protonated alcohols	9	$CH_3OH_2^+$	1.421	0.958			110°15′
	10	$C_2H_5OH_2^+$	1.480	0.958			110°15′
	11	$C_3H_7OH_2^+$	1.480	0.958			110°15′

a) All geometries of the protonated compounds were assumed on the basis of those for the parent molecules (see Ref. 14).

also uniformly settled to be 109°30′ for simplicity of computation.

Results and Discussion

Geometrical Aspects. We will first discuss briefly the geometries of the protonated compounds listed in Table 1; later we will consider the NMR of protonated species. It is noteworthy here with respect to the geometries of the protonated species that the C=O distance of the parent molecule is appreciably lengthened by the protonation so as to be near the single C–O bond-distance[11–13] and that the distance between the carbonyl oxygen and the proton is somewhat longer than the O–H bond length of formic acid or methyl alcohol.[12] In order to check the plausibility of the settled geometries, we compared the stretching-force constants, K_{AB}, for the C=O and O–H bonds of the parent molecules with those for the C–O and O–H bonds of the protonated compounds, using Badger's formula[18] with the parameters of Cossee and Schachtschneider[19]:

$$K_{CO} = 1.86/(R_e - 0.658)^3 \quad (1)$$

$$K_{OH} = 1.86/(R_e - 1.335)^3 \quad (2)$$

where the equilibrium distance, R_e, was based as the settled C–O or O–H bond-distance.

In regard to the parent molecules, the K_{CO} values of 9.19—11.68 mdyn/Å and the K_{OH} values of 7.69 (alcohols) —7.99 (acids) mdyn/Å seem plausible in view of the experimental values of K_{CO}=9.7—11.2 mdyn/Å[20] and of K_{OH}=7.2 (acids)—7.6 (alcohols) mdyn/Å.[20] It is also noticeable, with respect to the geometries of the parent molecules, that the dipole moments calculated by the INDO-MO method[15,16] are satisfactorily in accordance with the observed results.[17] On the other hand, the protonated compounds showed the K_{CO} values of 4.04—6.65 mdyn/Å and the K_{OH} value of 7.62 mdyn/Å. The force constants for both the protonated compounds seem somewhat too small in view of the fact that the *ab initio* calculation on the protonated formaldehyde[11] brought about the K_{CO} value of 8.11 mdyn/Å and a somewhat longer O–H bond (R_{OH}=0.985 Å) than that of methanol[21] or formic acid.[22] It is also of interest here, with respect to the property of the protonated compounds, that the calculated first-ionization potentials[23] for all the compounds in Table 1 were higher by 0.25—0.43 a.u. than those (about five-fourths of the experimental values[17]) for their parent molecules. This trend may be explained well by the decrease in the electron densities on the oxygen lone-pair orbitals by the protonation, which causes a lowering of the highest-occupied MO localized by the said lone-pairs.

With regard to the relative stability of the keto-protonated conformers (detected by the NMR spectroscopy) of the formates, acetates, methyl esters, and acids in Fig. 1, the present INDO calculations gave a good parallelism of the stability with the NMR observations:[1,4,9,10] that is, I>II>III in the protonated formates, I>II in the protonated methyl ester, and I>II in the protonated acids. It may be deduced, therefore, that the present assumed geometries for the

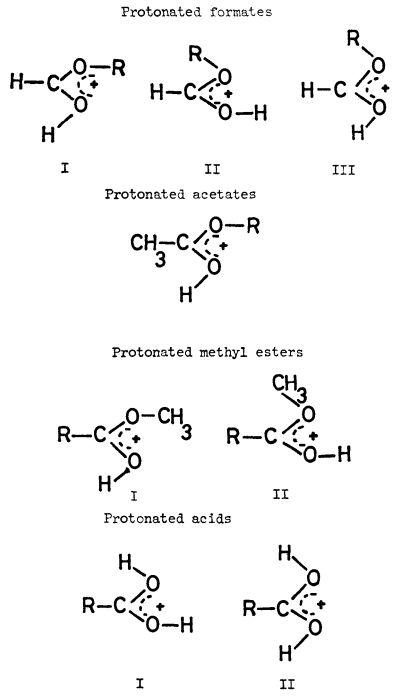

Fig. 1. Keto-protonated conformers used for the INDO calculation.

protonated compounds can be useful for discussing the NMR observations which will be developed below.

Proton Chemical Shifts and Coupling Constants. We will now investigate the correlation between the magnitude of the proton-chemical shift, δ ppm, of the protonated species and the electron density on their protons, q_H. As is shown in Fig. 2, there exist sufficient linear-correlations between the δ and q_H values for the proton of the O–H bond in all the homologue series investigated. Hence, in the proton-chemical shifts of the protonated compounds, the paramagnetic term, σ_p, and the magnetic anisotropy of the neighboring atom, σ', can be omitted from the total shielding constant, $\sigma(=\sigma_d+\sigma_p+\sigma')$, as is usual.[24] The above correlations can, then, be represented by:

$$\sigma_d(\text{ppm}) = -Aq_H \quad (A\text{: constant}) \quad (3)$$

where σ_d denotes the diamagnetic shielding constant. It is noteworthy here that the chemical shifts of the protons in the alkyl substituent, R, also have a good overall parallelism with their electron densities (q_H), as is shown in Fig. 3.

Next, let us notice the coupling constants of $J_{HH'}$, with a particular view to the correlation between the experimental and calculated constants (abbreviated as $J_{HH'}^{expt}$ and $J_{HH'}^{calcd}$ respectively). Since the proton-coupling constant depends predominantly on the Fermi-type contribution,[25] the $J_{HH'}^{calcd}$ values were evaluated by means of the following Fermi contact effect:[26]

$$J_{HH'}^{calcd} = (\hbar/2\pi)(64\pi^2/9)r_H r_{H'}\beta^2(s_H|\delta(r_H)|s_H) \times (s_{H'}|\delta(r_{H'})|(s_{H'}) \times \pi_{s_H's_H'} \quad (4a)$$

$$\pi_{s_H's_H} = 4\sum_i^{occ}\sum_j^{unocc}(\varepsilon_i-\varepsilon_j)^{-1}c_{is_H}c_{is_H'}c_{js_H}c_{js_H'} \quad (4b)$$

where the notations have the same meanings as in

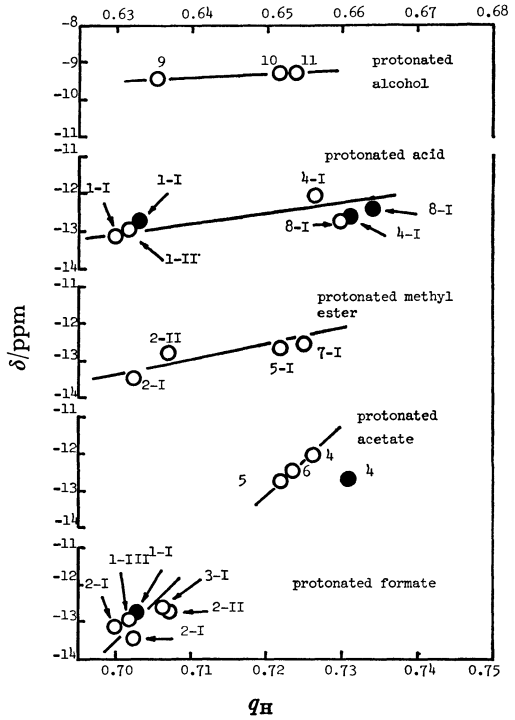

Fig. 2. Plots of δ *vs.* q_H values (remarked signs are specified in Table 1 and Fig. 1: empty circle for *cis*-proton against R; filled circle for *trans*-proton against R).

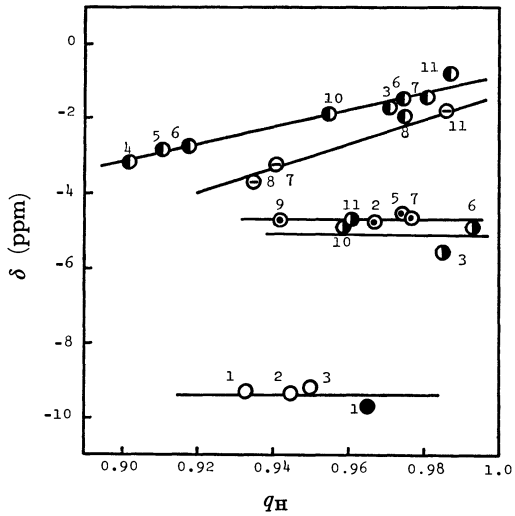

Fig. 3. The correlations between the δ values for the protons on the alkyl substituents and the q_H values (all compounds except the *cis-cis* isomer indicated by a filled circle, are the *cis-trans* protonated species specified by the compound number in Table 1).

◐: CH_3(-CH_2); ⊙: CH_3(-O).

Ref. 26; the atomic orbital constants and the nuclear magnetogyric ratio (r_H or $r_{H'}$) were taken to be 0.5500 a.u.[27] and 2.675×10^4 $G^{-1}s^{-1}$ respectively. The $J_{HH'}^{calcd}$ and $J_{HH'}^{exptl}$ values for the protonated formic acid and methyl formate are plotted against one another in Fig. 4 (the other protonated compounds in Table 1 were not found in the NMR data). The correlation

1: J_{13}(I) 2: J_{23}(I) 3: J_{13}(II)=J_{23}(II) 4: J_{13}(III) 5: J_{23}(III) 6: J_{13}(IV) 7: J_{23}(IV) 8: J_{13}(V) 9: J_{23}(V).

can be shown by a straight line with an intersect of zero, but the slope of the straight line was not 45°.

Carbon-13 Chemical Shifts and Coupling Constants. We will now investigate the correlations between the calculated and observed ^{13}C-chemical shifts and coupling constants, using the ^{13}C NMR (data found only for the protonated acids) and INDO calculation results. In the calculation, the total shielding tensor, σ, was approximated by the paramagnetic shielding effect, σ_p^{AA}, without the diamagnetic contribution and the effects of the circulation on all the other atoms and of ring currents:[28]

$$\sigma_p^{AA} = ((\sigma_p)_{xx} + (\sigma_p)_{yy} + (\sigma_p)_{zz})/3 \quad (5a)$$

$$(\sigma_p)_{zz} = -(e^2\hbar^2/2m^2c^2(\Delta E))\langle r^{-3}\rangle_{2p}[(Q_{AA})_{zz}+\sum_{AB}(Q_{AB})_{zz}] \quad (5b)$$

$$(Q_{AA})_{zz} = 2-2(P_{x_Ax_A}-1)(P_{y_Ay_A}-1) + 2P_{x_Ay_A}{}^2 \quad (5c)$$

$$(Q_{AB})_{zz} = -2P_{x_Ax_B}P_{y_Ay_B} + 2P_{x_Ay_B}P_{y_Ax_B} \quad (5d)$$

where $(\sigma_p)_{xx}$ and $(\sigma_p)_{yy}$ can be given by corresponding terms and where the notations have the same meanings as in Ref. 28. The calculated and observed ^{13}C -chemical shifts (δ_{calcd} and δ_{obsd} respectively) from the reference substance of carbon disulfide are listed in Table 2. In Table 2, the average excitation energy (ΔE) for the protonated species was taken to be a number (7.9 eV) higher than that for the parent molecules (ΔE=7.7 eV), because the energies of the ground states in the former were appreciably lower than those in the latter, and because the energies of the excited states in the former were slightly higher than those in the latter. As can be seen from Table 2, there is a good overall agreement of the δ_{calcd} values with the δ_{obsd} values, and the ^{13}C-chemical shifts of

Table 2. Calculated and observed isotoropic (^{13}C)-chemical shifts eor some protonated and parent molecules

Molecule	ΔE/eV	$-\sigma_p^{AA}$/ ppm	δ_{calcd}/ ppm	δ_{exptl}/ ppm

a) From Ref. 6. b) From Ref. 7. c) From J. B. Stothers and P. C. Lauterbur, *Can. J. Chem.*, **42**, 1563 (1964). d) From Ref. 29.

the protonated compounds appeared in a lower magnetic field than those of the parent molecules. It is of interest here to notice the changes in the local isotropic chemical shifts ($(\sigma_p)_{xx}$, $(\sigma_p)_{yy}$, and $(\sigma_p)_{zz}$) due to the protonation, taking the formic acid and its protonated species (all the atoms on the *x-y* cross section and the C=O and C$^+$–OH bonds on the *y* axis) as examples. The *yy* element, $(\sigma_p)_{yy}$, is deshielded predominantly by the protonation from −243 ppm to about −340 ppm; the *xx* element is shielded by about 32 ppm (from −459 ppm), while the *zz* element is deshielded slightly by about −2 ppm (from −378 ppm). In this case, all the elements (*xx*, *yy*, and *zz*) of the *cis-trans* isomer, I, are not markedly different from those of the *cis-cis* isomer, III. The negative *yy* element of the multiple-bond terms ($\sum_{B\neq A} Q_{AB}$) for the protonated molecule is appreciably diminished by the protonation to be less than one half of that for the parent compound.

Table 3. Calculated and observed C^{13}-NMR coupling constants and %s character for protonated and parent molecules

Molecule	$J^{exptl}_{^{13}CH}$/Hz	$J^{calcd}_{^{13}CH}$/Hz	%s	Hybridization
$HC^{13}OOH$	225.1[a]	75.91	29.74	$sp^{2.36}$
$HC^{13}(OH)_2^+\cdot$ (*cis-trans*)	244.8	83.98	31.68	$sp^{2.16}$
$HC^{13}(OH)_2^+\cdot$ (*cis-cis*)	235.8[a]	82.06	31.59	$sp^{2.17}$
$HC^{13}OOCH_3$	226.2[b]	76.03	29.65	$sp^{2.37}$
$HC^{13}OOCH_2CH_3$	225.6[b]	75.47	29.65	$sp^{2.37}$

a) From Ref. 6. b) From N. Muller and D. E. Pritchard, *J. Chem. Phys.*, **31**, 1471 (1959).

Finally, we will discuss the carbon-13 NMR coupling constants, J^{13}_{CH}, of the protonated compounds. The J^{13}_{CH} values were calculated by means of equations similar to Eqs. (4a—4b), with the r^{13}_C value of 0.6726×10^4 G^{-1}s^{-1} and the carbon atomic orbital constant of 2.767.[27] In Table 3 we list the calculated and experimental J^{13}_{CH} values (denoted as $J^{calcd}_{^{13}CH}$ and $J^{exptl}_{^{13}CH}$ respectively) and the %s characters for the protonated formic acid and a few parent molecules. Here, the %s character was evaluated from the INDO-MO calculation results, with the following relation:

$$\%s = 100N_{C_s}/(N_{C_s}+N_{C_p}) \quad (6)$$

where N_{C_s} and N_{C_p} stand for the AO densities of the carbon-13 s- and p-orbitals respectively.

There is a satisfactorily good linear correlation between the J^{13}_{CH} values and the %s characters; this correlation can be expressed by:

$$J^{exptl}_{^{13}CH} = 7.25\%s + 14.99 \quad \text{(in Hz unit)} \quad (7a)$$

$$J^{calcd}_{^{13}CH} = 3.66\%s - 32.03 \quad \text{(in Hz unit)} \quad (7b)$$

The contribution of the %s character to the isotropic chemical shifts is different between the calculated and the experimental results, so this is reflected in the slope (not unity) of the linear correlation between the $J^{exptl}_{C^{13}H}$ and $J^{calcd}_{C^{13}H}$ values:

$$J^{exptl}_{^{13}CH} = 2.16J^{calcd}_{^{13}CH} + 61.4 \quad \text{(in Hz unit)} \quad (8)$$

The trend shown in Eqs. (7a—b and 8) may be attributed mainly to the gap between the conditions in the present calculation and those in the NMR experiment; it seems that the %s character is not completely correct in view of the approximations involved in the INDO-MO theory.

The calculations were carried out on a FACOM 230-75 computer at the Data Procession Center of Kyushu University.

The Infrared Absorption Spectra of Nickel Metal Surfaces Modified with Optically Active α-Alanine from Its Aqueous Solution[1)]

Aritada HATTA, Yoshihiro MORIYA, and Wataru SUËTAKA

Laboratory of Interface Science of Metals, Faculty of Engineering, Tohoku University, Aramaki, Aoba, Sendai 980

(Received February 19, 1975)

The infrared absorption spectra of thin films of α-alanine formed on pure nickel and "Raney nickel" surfaces, modified with its aqueous solution, were measured by the high-sensitivity reflection method. From the infrared dichroism in the reflection spectra, the molecular orientations in the thin films were derived. In the thin film formed on pure nickel modified at 5 °C, the CO_2^- group of α-alanine is oriented nearly vertical to the metal surface and the O· · ·O axis is inclined to the surface. On the other hand, when the "Raney nickel" film is modified at 5 °C, the C_α–C_o(carboxylate) bond is oriented obliquely to the surface. When the "Raney nickel" film is modified at 100 °C, the Ni-alanine chelate is formed on the surface: the C_α–C_o bond and the NH_2 group are nearly parallel to the substrate surface, while the O· · ·O axis is vertical to that surface.

It is well recognized that infrared spectroscopy is one of the most powerful tools for investigating the adsorptions of a reactant or an intermediate on a catalyst. Adsorptions on metal supported on such carriers as silica and alumina are most often investigated by employing the transmission method.[2)] In this case, however, the metal particles give rise to background scattering, and the interaction of the supported metal with the carrier is also inevitable[3)]; hence, straightforward explanations of the observed spectrum are, in general, difficult to give. In addition, the transmission method can not give any direct information about the orientations. On the other hand, the high-sensitivity reflection method,[4)] which is relatively new, has been employed by a few investigators[5)] in studying the adsorptions of simple gaseous molecules to evaporated metals. In this method, the infrared radiation in the vicinity of the reflecting surface is markedly polarized normal to the mirror surface and the observed spectrum is closely correlated to the orientation of molecules existing on the metals. This technique may also be used in the investigation of the structure of thin crystal films formed on a metal substrate. In fact, it has been found that the crystal structures in thin films are often different from those in bulk materials.[6)] This result can be interpreted by taking account of the interaction of the metal substrate, which may determine the structure of the crystal nuclei on the substrate.

The asymmetric hydrogenation of the C=O double bond using Raney nickel modified with optically active amino acids or hydroxy acids has been systematically investigated by Izumi and his co-workers.[7)] In such an asymmetric synthesis, what we are interested in is the relationship between the absolute configuration of the modifying reagent and the asymmetric direction of the catalyst. In connection with this mechanism, it seemed that it might be interesting to observe the infrared dichroism arising from the preferred orientation of modifying molecules on the nickel metal surface.

Recently we have obtained results for the cases in which L-β-phenyllactic acid and L-β-phenyl-α-alanine were used as modifying reagents.[8)] In the latter case, the spectrum was in accord with an orientational model where the COO^- ion is asymmetric in alignment to the nickel surface. Recently, Groenewegen and Sachtler[9)] reported the spectrum of L-α-alanine adsorbed on silica-supported nickel; the spectrum they obtained was the same as that of a nickel chelate, but no details about the orientation were given. The objective of this paper is to obtain information about the orientation of α-alanine molecules in thin films formed on the nickel substrate. Although the direct determination of the orientation of species strongly adsorbed on the metal surface is quite desirable, the signal from the species was too weak to provide any available information, so the spectra of the thin films formed on modified nickel were observed in the present paper.

The thin films treated in this paper are probably a few hundred angstroms thick. Therefore, the reflection spectra of films with such a thickness cannot directly reveal the orientation of the species chemisorbed on the substrate. However, the orientation of the molecule in a thin film is very often determined by the orientation of the species which are adsorbed strongly on the substrate and which, consequently, act as the nuclei of the epitaxial overgrowth.[10,11)] The molecular orientation determined by the posture of the molecule at the interface is also known in liquid and liquid-crystal thin films on solid substrates.[12,13)] The orientation of the species strongly adsorbed on the substrate surface may, therefore, be deduced from the molecular orientation in the thin films.

α-Alanine was used in the present work because α-alanine is one of the simplest compounds which are practically used as modifying reagents in the asymmetric synthesis.[14)] It is, therefore, considered to be well-suited for the fundamental study of the mechanism of modification. In addition, the vibrational assignment[15)] for this molecule is almost completely established and, based on the available data, the reflection spectra can easily be analyzed.

Experimental

The infrared spectrum was obtained by means of a JASCO IR-G grating spectrophotometer with an assembly designed for use in single-beam reflection operation. Signal averaging and background-subtraction procedures were performed on a JEOL model JEC-5 spectrum computer. By using this technique, the absorptions of atmospheric water vapor was removed satisfactorily and the signal-to-noise ratios were greatly improved. The guaranteed-grade reagents of L- and D-α-alanine were obtained from the Wako Pure Chemicals Co. and were used without further purification. In

the present experiment, an electrolytical nickel (99.9% pure) plate and a thin "Raney nickel" film formed on a nickel plate were used as substrates and mirrors. The "Raney nickel" alloy was prepared, for convenience, by the vacuum deposition of aluminum onto nickel surfaces and by subsequent annealing at 550 °C for 3 hr under a nitrogen or hydrogen atmosphere.

Nickel metal plates with and without Al-Ni alloy layer were treated with a 20% aqueous sodium hydroxide solution at 80 °C and then rinsed in distilled water. The substrate, nickel or "Raney nickel," was modified with a 0.5% aqueous solution of L- or D-α-alanine at 5 °C and 100 °C. The pH-value of the solution was about 5.9 at room temperatures. The modified sample were then dried in air and subjected to the reflection measurement. Very fine crystals of the amino acids grew on the strongly adsorbed molecules, with the evaporation of water. The background spectra were obtained by using a pure nickel or thin "Raney nickel" plate just before modification.

Results and Discussion

Figure 1 shows the infrared absorption spectrum of L-α-alanine obtained as a KBr pellet in the frequency range from 1800 cm^{-1} to 900 cm^{-1}. The vibrational assignment of the infrared spectrum of DL-α-alanine was previously made on the basis of a normal coordinate treatment.[15] The high-sensitivity reflection spectra of bulk nickel plates, which were modified at

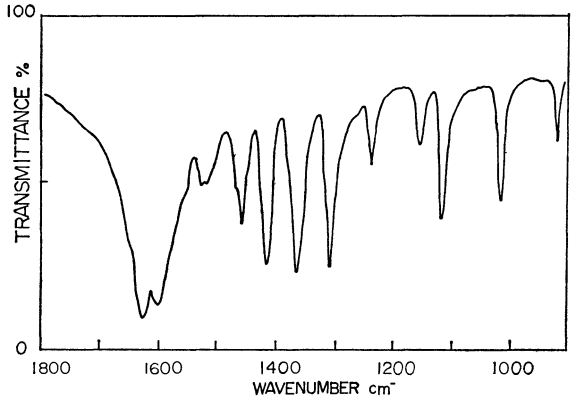

Fig. 1. Infrared transmission spectrum of L-α-alanine (KBr pellet).

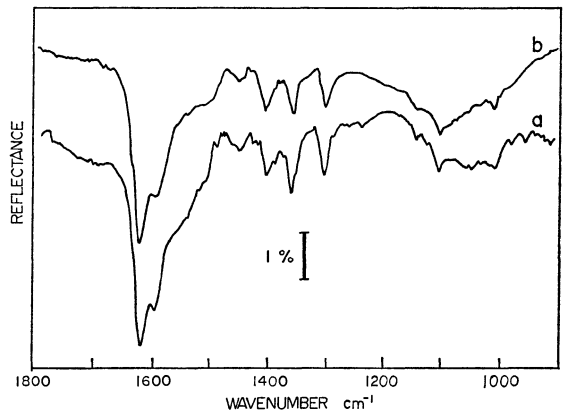

Fig. 2. High-sensitivity reflection spectra of bulk nickel plates modified at 5 °C with 0.5% aqueous solutions of L- and D-α-alanine. a: L-α-alanine; b: D-α-alanine.

5 °C over periods between a few hours and two weeks with 0.5% aqueous solutions of L-α-alanine (labeled a) and D-α-alanine (labeled b) and then covered by thin film crystals of these compounds, are shown in Fig. 2. No remarkable differences were detected in the spectra of different modifying times.

The most remarkable difference in the thin film spectra from bulk crystals, which can be clearly seen in Fig. 2, is the broad absorption with the maximum falling near 1070 cm^{-1}, probably due to the surface hydroxyl groups formed on the nickel substrate in the course of modification in an aqueous solution. Except for this band, however, the spectra of modified nickel plates with L-α-alanine and also D-α-alanine are in agreement with that of bulk L-α-alanine or D-α-alanine, except for band shifts to a slightly lower frequency, indicating that the α-alanine molecule in the film over the nickel surface is intact. Therefore, this allows us to compare the relative intensities of the bands of modified nickel with those of bulk crystals in order to determine the orientation of the α-alanine in the film on the nickel surface. As can be seen in Fig. 2, the most striking feature of the spectra of thin films on nickel is the enhanced intensity of the 1620 and 1600 cm^{-1} bands, which are assigned to NH_3^+ degenerate deformation and COO^- antisymmetric stretching respectively.[15] However, the band intensity of the COO^- antisymmetric stretching relative to that of the NH_3^+ degenerate deformation vibration somewhat decreases in comparison with the spectrum of the non-oriented sample (KBr pellet). The broad band centered at 1515 cm^{-1} in the thin film spectra, which is very weak in the spectra of Fig. 2 and which corresponds to the 1520 cm^{-1} band of bulk crystals, may be attributed to the NH_3^+ symmetric deformation. The same spectral feature was also obtained for thicker crystal films of α-alanine grown on nickel-metal surfaces during the evaporation of solvent water.

As has been mentioned above, the spectrum obtained by means of the high-sensitivity reflection method may be regarded as a polarized spectrum because it results from the interaction of molecular vibration with infrared radiation polarized normal to the reflection plane or the metal surface. Therefore, the relative intensities of the observed band in each vibrational mode depend on the orientation of the vibrational transition moments. On this basis, our attention is focused on the orientations of the CO_2^- and NH_3^+ ions, for which an approximate quantitative treatment is possible.

The transition moment of the antisymmetric CO_2^- stretching mode at 1600 cm^{-1} is parallel to the O–O direction, while that of the symmetric CO_2^- stretching mode at 1400 cm^{-1} is normal to the O–O direction. These moments are shown schematically in Fig. 3, where μ_a and μ_s refer the vibrational transition moments of antisymmetric and symmetric CO_2^- stretching vibrations respectively. The model is placed in a coordinate system where the C_α–C_0 axis lies on the yz plane, but the CO_2^- plane does not coincide with it. The rotation of the O–O axis about the C_2 axis is designated by the angle θ. The projection of μ_a on the yz plane is, therefore, given by $\mu_a \cos\theta$. Then,

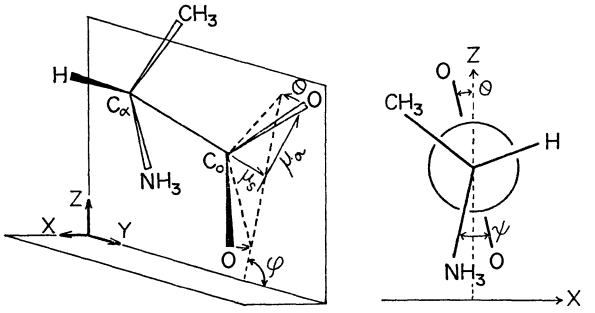

Fig. 3. Coordinates and angles for the oriented D-α-alanine. The conformation is shown as viewed along the C_α–C_o bond.

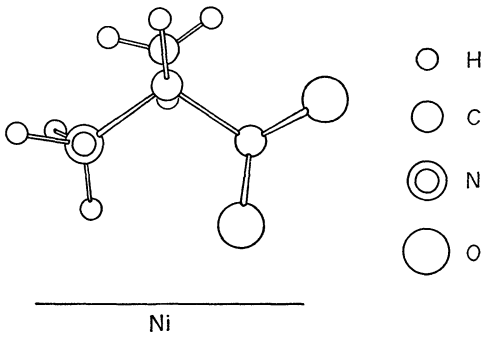

Fig. 4. Orientational model in thin D-α-alanine crystal formed on nickel metal surface at 5 °C.

the component of μ_a parallel to the radiation, polarized in the z direction, is equal to $\mu_a \cos\theta \sin\varphi$, where φ is the angle which the yz plane projection of μ_a makes with the xy plane (nickel surface). The transition moment of CO_2^- symmetric stretching, μ_s, lies along the C_α–C_o bond, regardless of the rotation of the CO_2^- group. The μ_s component parallel to the polarized radiation is, therefore, given by $\mu_s \cos\varphi$.

The electric vector of infrared radiation in the vicinity of the metal surface is practically vertical to that surface or parallel to the z axis. Accordingly, the band intensity to be observed in the high-sensitivity reflection spectra is proportional to the square of the transition moment in the z direction. Consequently, the band intensity of CO_2^- symmetric stretching relative to that of CO_2^- antisymmetric stretching can be expressed in the term: $R=(\mu_s^2/\mu_a^2)\sec^2\theta\cot^2\varphi$. The expression derived above is valid only when neither of the vibrational modes interacts with any other modes. In the present work, the coupling of the vibration is not important and so is neglected. Here, μ_s^2/μ_a^2 can be taken from the spectrum of randomly oriented α-alanine molecules. If the value is assumed to remain unchanged in the KBr matrix, the data from the spectrum shown in Fig. 1 can be used. The R value is, of course, obtained from the reflection spectrum exhibited in Fig. 2.

While the values of φ and θ can not be obtained separately, if θ is assumed, for simplicity, to be 0°, the values of φ may be calculated to be 57° and 60° for D- and L-α-alanine respectively. The difference obtained here is not significant in view of the uncertainties involved. When the θ value of 30° is used, $\varphi=61°$ is obtained from the spectrum of D-α-alanine.

The second point of special interest is the orientation of the C–NH_3^+ fragment. Information concerning the alignment of the C–N bond with respect to the CO_2^- group can be obtained from the NH_3^+ symmetric deformation band based on the assumption that the C–NH_3^+ group holds C_{3v} symmetry. The value of 110°, which is taken from the literature,[16] is used for the ∠C–C–N angle of L-α-alanine. Assuming $\theta=0°$ and $\varphi=57°$, the azimuthal angle, ψ, of the C–N bond measured from the CO_2^- plane is obtained to be 8°. If $\theta=7°$ and $\varphi=57°30'$ are chosen, the result of $\psi=16°$, which is near to the value 17° calculated by Hayashi *et al.*[17] from the X-ray data,[18] can be obtained. The orientational model of D-α-alanine is depicted in Fig. 4. The model agreed very closely with that previously obtained for L-β-phenyl-α-alanine.[8] Therefore, there seems to be no remarkable effect exerted on the molecular orientation in converting the methyl group of α-alanine to a phenyl group.

Recently Tanabe and Uyeda investigated the thin film of L-α-alanine, formed from an aqueous solution on nickel film, by electron microscopy and diffraction; they found that L-α-alanine overgrows epitaxially in a polymorphic form on the substrate surface. Different crystals were obtained according to whether or not the nickel film was treated with HCl, suggesting the occurrence of the original nucleation in a different form. However, it should be noted here that the orientation of the L-α-alanine molecule on the nickel film without HCl treatment agrees very well with that shown in Fig. 4.

The reflection spectrum of the nickel surface modified with D-α-alanine at 100 °C resembles that of the nickel surface modified at 5 °C, but several differences can be seen between them. The most noticeable are that the band intensity of the NH_3^+ degenerate deformation was much decreased on the 100 °C modified nickel surface, relative to that of the CO_2^- antisymmetric stretching band, and that the latter overcame the former, indicating a high orientation of the CO_2^- group normal to the nickel surface. In addition, the broad band centered at 1070 cm^{-1}, which was also observed with the 5 °C modified sample, was observed as a more intense band.

The reflection spectrum of the 100 °C modified nickel changed with time, showing that the thin film underwent a spontaneous change. The spectral change was complete after several hours, and the spectrum finally reached that of the 5 °C modified nickel. This fact shows that the crystal structure in the thin film, formed at 100 °C, is unstable, and that a rearrangement of the molecules to a more stable structure occurs. Although the reproducibility in band intensity was not very good, repeated experiments definitely showed that the bands due to the CO_2^- symmetric stretching as well as the NH_3^+ degenerate deformation increased in intensity with the change in the structure of thin films, whereas the CO_2^- antisymmetric stretching decreased. On the basis of the facts presented above, the orientation of the important part of the molecule

in the unstable film on the surface modified at 100 °C can be determined; the C_α–C_o bond lies approximately parallel to the nickel metal surface, with the remaining part randomly oriented. This results in an orientation which can be said to be near to that shown in Fig. 7 for the "Raney nickel" surfaces.

The reflection spectra of the unstable and the stable films can be elucidated without supposing the formation of a nickel–alanine chelate, which was found on the "Raney nickel" surface. This fact, however, does not exclude the presence of the chelate in a small amount at the interface, because the signal from the chelate must be very weak and may be masked by the bands of the molecules in the film.

The molecular orientation in the unstable film, which is similar to that in the film on the "Raney nickel" modified at 100 °C, may be determined by the orientation of chelates strongly adsorbed on nickel and acting as the nuclei of crystal growth. The chelate-nickel surface and/or chelate-alanine interaction may not be sufficiently strong, however, to maintain the unstable structure.

When a thin "Raney nickel" film was used as a substrate, the spectral behavior was different from that obtained using the bulk nickel plate mentioned above. It should be mentioned, however, that the "Raney nickel" used in this experiment contains aluminum oxide, undoubtedly developed while the vacuum-deposited aluminum film on a nickel plate was subjected to thermal treatment in order to prepare Ni–Al alloy layers on the nickel plate. The Al–O absorption band decreased upon treatment in an alkaline solution, the magnitude of the decrease depending upon the time-course of the treatment.

Figure 5 shows the high-sensitivity reflection spectrum of thin "Raney nickel" film modified with D-α-alanine at 5 °C. The most intense band, appearing at 940 cm^{-1}, is ascribed to the Al–O stretching; the intensity was unaltered despite prolonged modification at 100 °C. Except for the Al–O band, the spectrum is characterized by the strong absorption of the NH_3^+ degenerate deformation band at 1620 cm^{-1} and the weak absorption of the CO_2^- antisymmetric stretching band at 1595 cm^{-1}. Since the bands are essentially at the same frequencies as those of the bulk crystals shown in Fig. 1, the oxide layer at the substrate surface probably exerted an influence only upon the molecular orientation. The weak absorption of CO_2^- antisymmetric stretching can probably be ascribed to the molecular orientation in which the vibration has a small component of the transition moment normal to the substrate surface. The deduction regarding the orientation of the CO_2^- group can be supported by the fact that the band at 1400 cm^{-1} due to the CO_2^- symmetric stretching appears strong relative to the CO_2^- antisymmetric stretching, as is shown in Fig. 5. The orientation requires that the C_α–C_o bond should be largely tilted from the parallel direction with respect to the substrate surface. This orientation differs from that of molecules on pure nickel plates, shown in Fig. 4.

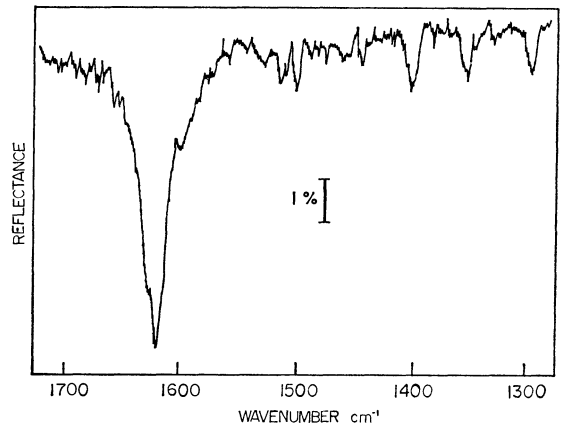

Fig. 5. High-sensitivity reflection spectrum of thin "Raney nickel" surface modified with D-α-alanine at 5 °C.

The modification of thin "Raney nickel" containing aluminum oxide with D-α-alanine at 100 °C resulted in the spectrum shown in Fig. 6. The spectrum obtained for L-β-phenyl-α-alanine is also shown in this figure for reference. The absorption at 1070 cm^{-1} is much stronger here than in the other cases mentioned above. The absorptions at 1070 and 3500 cm^{-1} (not shown in the figure) were intensified in a way parallel with each other by prolonged modification, implying that they belong to the same functional group, probably

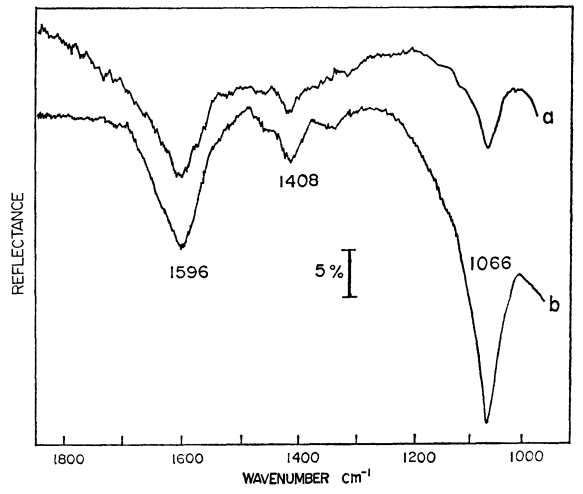

Fig. 6. High-sensitivity reflection spectra of thin "Raney nickel" surfaces modified with D-α-alanine and L-β-phenyl-α-alanine. a: D-α-alanine; b: L-β-phenyl-α-alanine.

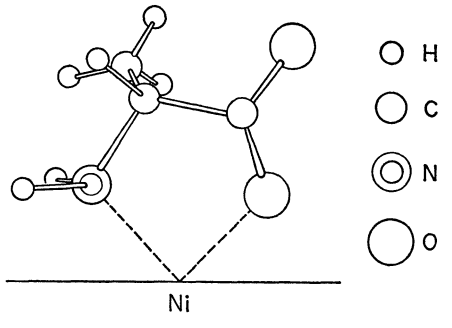

Fig. 7. Orientational model in thin D-α-alanine crystal formed on "Raney nickel" surface at 100 °C.

to the Ni–OH described above. Aside from the Ni–OH and Al–O bands, the spectrum consists of a strong CO_2^- antisymmetric stretching absorption and a weak CO_2^- symmetric stretching absorption. The absence of the NH_3^+ degenerate and symmetric deformation bands in Fig. 6 can be considered to be due to the formation of a nickel-alanine chelate on the substrate surface. It should be pointed out in this connection that this argument is valid also for the case of L-β-phenyl-α-alanine (see Fig. 6). The most probable model for molecular orientation in this case is shown in Fig. 7.

It is known that, on the chelate formation, the bands due to the NH_2 group appear instead of those of the NH_3^+ group.[19] The infrared spectrum of the nickel–alanine chelate, Ni(L-α-ala)$_2\cdot 5/2H_2O$, exhibits two intense bands, at 1600 and 1570 cm^{-1}, and two medium bands, at 1085 and 1050 cm^{-1}. Based on the band assignment given for Ni(DL-α-ala)$_2$, the former bands were assigned to the CO_2^- antisymmetric stretching and the NH_2 scissoring vibrations respectively, and one of the latter (1085 cm^{-1}), to the NH_2 wagging vibration.[19] Therefore, the orientational model shown in Fig. 7 is in accord with such a spectral feature that the NH_2 scissoring vibration is absent in Fig. 6, because its transition moment is parallel to the substrate surface and because the vibration is inactive in the reflection method employed in this experiment. On the other hand, the NH_2 wagging vibration should be observed, if the molecular orientation shown in Fig. 7 is the case, since the transition moment of the NH_2 wagging vibration lies along the direction normal to the substrate surface. However, no evidence of the NH_2 wagging band could be detected in the region where the band was expected to appear; it may be considered that the NH_2 wagging band was obscured by the overwhelming Ni–OH band, because these two bands are near in frequency. The nickel–alanine chelation observed with the "Raney nickel" modified at 100 °C is considered to be caused by its nature being more active than that of the bulk nickel plate.

Recently, Groenewegen and Sachtler[9] have examined the infrared spectra of L-α-alanine and a few amino butyric acids evaporated on Ni/SiO_2 and SiO_2. They reported that the chemisorption complex of L-α-alanine formed on Ni was very similar to the bulk complex Ni(ala)$_2$. Although it is difficult to compare the results of Groenewegen and Sachtler with ours because the experimental conditions are different, the suggestion can be made that the α-alanine reacts with the surface nickel to yield the α-alanine chelate complex at high temperatures and that this chelate formation would influence the catalytic properties of the Raney nickel.

A change in the modification temperature resulted in a change in the molecular orientation in the thin films on the bulk nickel surface as well as on the "Raney nickel" surface. This fact may correspond to the change in the optical activity of the compound obtained by the asymmetric synthesis with the modified catalyst.

The Adsorption of α- and β-Cyclodextrins on the Dropping Mercury Electrode in an Aqueous Solution

Yoshihisa MATSUI, Hiroshi SAWADA, Kazuo MOCHIDA, and Yoshio DATE
Department of Agricultural Chemistry, Shimane University, Nishikawazu, Matsue 690
(Received March 20, 1975)

The adsorption of α- and β-cyclodextrins on the surface of the dropping mercury electrode was examined in a phosphate buffer solution by means of voltammetry with a triangular potential sweep. The α- and β-cyclodextrins gave two capacitive peaks corresponding to the adsorption and desorption processes respectively. The α-cyclodextrin additionally gave two cathodic peaks and an anodic peak, probably due to reorientation processes. The effects on the peak heights were investigated in terms of the sweep rate, the cyclodextrin concentration, the temperature, the ionic strength, and the pH. The adsorption of both cyclodextrins followed the Langmuir isotherm, and the equilibrium constants for the adsorption were evaluated to be 1.2×10^4 M^{-1} for α-cyclodextrin and 1.0×10^5 M^{-1} for β-cyclodextrin at 25°C and pH 6.5.

The degradation of starch by the action of *Bacillus macerans* amylase yields cyclic dextrins composed of six (in α-cyclodextrin), seven (in β-cyclodextrin), or more α-D-glucopyranose units linked 1→4 as in amylose.[1] These molecules have void spaces and form 1 : 1 inclusion complexes with a variety of organic compounds in aqueous solutions.[2] In the course of a polarographic study of the inclusion complexes, we found that cyclodextrins are adsorbed on the surface of a dropping mercury electrode. This phenomenon is interesting in connection not only with the analysis, but also with the physicochemical properties of cyclodextrins. The present study was undertaken in order to examine the adsorption behavior of α- and β-cyclodextrins by means of voltammetry with a triangular potential sweep. This method is suitable for obtaining both the charging and discharging capacitive curves as functions of the applied potential,[3] although the method of differential capacity measurements with an impedance-type capacity bridge is in general use for the investigation of the electric double-layer structure and the adsorption of various organic substances.[4]

Experimental

The α- and β-cyclodextrins were prepared by the method of Lane and Pirt[5] and were purified according to the directions of Cramer and Henglein.[6]

The apparatus used for the measurement of the capacity patterns was of a Randles-Sevcik type with a triangular potential sweep (multi-sweep method). The details have been described previously.[7] A two-electrode system with a dropping mercury electrode and mercury pool electrode was used. In order to minimize the iR drop yielded across the cell, a fairly concentrated electrolyte solution (0.50 M of phosphate buffer) was used, except when the effect of the buffer concentration was examined. No test solution was degassed, since it had been found that dissolved oxygen gives no capacitive peak and has no influence on the current-potential curves of the α- and β-cyclodextrins. The dropping mercury electrode used in most experiments had the following characteristics in a 0.50 M phosphate buffer (pH 6.5): $m=0.587$ mg/s and $t=11.0$ s. The capacitive current increases with an increase in the surface area of the dropping mercury electrode. The influence of the growth of the mercury drop on the current was minimized by registering the current-potential curves immediately before the drop fell. The time interval from the moment the mercury begins to form to the time of exposure of the capacity pattern was measured by means of a stopwatch.

The DC and AC polarography were carried out with a Yanagimoto polarograph, model GA-103, which has an admittance-type capacity bridge. The superimposed sinusoidal voltage was 15 mV, 60 Hz.

Results

The adsorption of organic compounds on the mercury electrode surface causes, in general, a decrease in the surface tension of the mercury. Figure 1 shows the effects of α- and β-cyclodextrins on the electrocapillary curve of the 0.50 M phosphate buffer (pH 6.5)

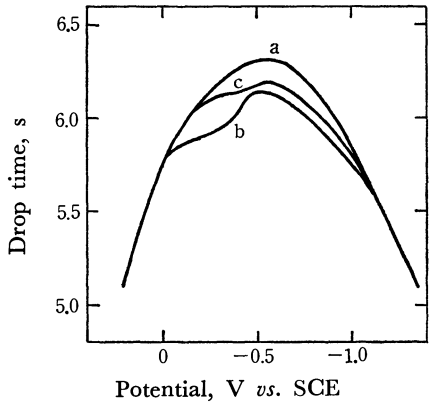

Fig. 1. Electrocapillary curves at 25 °C.
a: 0.50 M phosphate buffer (pH 6.5), b: a+5.0 mM α-cyclodextrin, c: a+5.0 mM β-cyclodextrin.

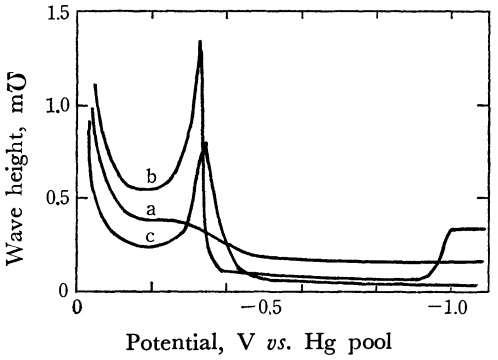

Fig. 2. AC polarograms of the cyclodextrins in 0.50 M phosphate buffer (pH 6.5) at 25 °C.
a: No cyclodextrin, b: 1.0 mM α-cyclodextrin, c: 1.0 mM β-cyclodextrin.

at 25 °C. The drop time of the mercury electrode did markedly decrease upon the addition of the cyclodextrins at potentials from 0.0 to −1.1 V *vs.* SCE for α-cyclodextrin and from −0.2 to −1.1 V *vs.* SCE for β-cyclodextrin.

Neither α- nor β-cyclodextrin gave any DC polarographic wave at these potential regions, but both did give a well-defined AC polarographic wave (Fig. 2).

Figures 3 and 4 are the current-potential curves of α- and β-cyclodextrins respectively, as determined by cyclic voltammetry. No other peaks due to the cyclodextrins were observed at any potential range not shown in these figures. A dilute solution (below 0.05 mM) of α-cyclodextrin gave two peaks (A and B) in the cathodic scan and two peaks (C and D) in the anodic scan, whereas a concentrated solution (above 0.10 mM) of the cyclodextrin gave another peak (A') on the right shoulder of the A peak. On the other hand, a solution of β-cyclodextrin gave only one cathodic peak (A) and one anodic peak (B) at all the concentrations studied (up to 1.00 mM). All the facts described above indicate that both α- and β-cyclodextrins are adsorbed on the surface of the mercury electrode and lower the differential capacity of the electrode, although the adsorption and desorption processes are not straightforward in the case of α-cyclodextrin. The potentials at which the capacitive peaks appeared are as follows (V *vs.* Hg pool): for 0.20 mM α-cyclodextrin; A, −0.44 V, A', −0.46 V, B, −1.19 V, C, −0.78 V, D, −0.36 V, for 0.01 mM β-cyclodextrin; A, −0.43 V, B, −0.37 V. The potentials of the A' and D peaks for α-cyclodextrin shifted slightly toward less negative potentials with an increase in the cyclodextrin concentration.

Since the capacitive current (i) varies in proportion to the surface area (A) of the dropping mercury electrode, the current density ($j=i/A$) was used instead of i in the following results. The value of A was calculated by means of this equation:[8]

$$A = (4\pi)^{1/3}(3mt/\rho)^{2/3} \quad (1)$$

where m is the average mass of mercury flowing per unit time; t, the time interval from the moment the mercury begins to form to the time of photographic exposure, and ρ, the density of mercury. According to Loveland and Elving,[3] the value of j should be proportional to the potential sweep rate (v). Figures 5 and 6 show the plots of j *vs.* v for the 0.10 mM α- and 0.010 mM β-cyclodextrin solutions respectively in the 0.50 M phosphate buffer (pH 6.5) at 25 °C. Virtually linear plots passing the point of origin were obtained for the A and C peaks of α-cyclodextrin and for the A and B peaks of β-cyclodextrin. However, the approximately linear plots for A', B, and D peaks of α-cyclodextrin did not pass the point of origin; this suggests that these peaks involve some complex processes other than the simple adsorption-desorption processes.

Figures 7 and 8 show the plots of j *vs.* the concentrations of α- and β-cyclodextrins respectively in the 0.50 M phosphate buffer (pH 6.5) at 25 °C. Again, the plots for the A and C peaks of α-cyclodextrin and for the A and B peaks for β-cyclodextrin showed the curves characteristic of the Langmuir isotherm, but the plots for the A', B, and D peaks of α-cyclodextrin did not. On the assumption that the value of $j-j_0$ (j_0 is the value of j at a zero concentration of the adsorbate) is proportional to the amount of material adsorbed,[9] the Langmuir isotherm can be written as:

$$(j-j_0)/(j_\infty-j_0) = Kc/(1+Kc) \qquad (2)$$

where j_∞ is the maximum value of j; c, the concentration of the adsorbate, and K, the equilibrium constant for the adsorption. Eq. (2) can be rewritten as:

$$j = j_\infty - (j-j_0)/Kc \qquad (3)$$

Figure 9 shows the plots of j *vs.* $(j-j_0)/c$ for the A peaks of α- and β-cyclodextrins. Both of the plots are approximately linear. The K values were determined from the slopes of the plots to be 1.2×10^4 M^{-1} for α-cyclodextrin and 1.0×10^5 M^{-1} for β-cyclodextrin.

The dependence of j on the temperature is shown in Table 1. The j values for the A and C peaks of α-cyclodextrin and for the A and B peaks of β-cyclodextrin increased slightly with an increase in the

temperature. On the other hand, the other peaks of α-cyclodextrin were significantly lowered with a temperature increase. When the concentration of the phosphate buffer at pH 6.5 increased from 0.025 M to 0.50 M, the heights of the A and C peaks for α-cyclodextrin increased slightly, whereas that of the A′ peak decreased slightly. The other peaks of α- and β-cyclodextrins showed virtually no change with an increase in the ionic strength. A similar change in the heights for the A and A′ peaks of α-cyclodextrin was observed when the pH of the phosphate buffer (0.50 M) was increased from 5.0 to 8.0.

Discussion

The adsorption of α- and β-cyclodextrins on the surface of the dropping mercury electrode is apparent on the basis of the following observations: (1) a solution of α- or β-cyclodextrin gives no DC polarographic wave, but does give an AC polarographic peak and some cyclic voltammetric peaks, and (2) the surface tension of the dropping mercury electrode in a phosphate buffer is markedly depressed by the addition of α- or β-cyclodextrin.

There is no dobut that the least negative capacitive peak in the cathodic scan for each cyclodextrin (Peak A) corresponds to the adsorption process of the cyclodextrin. The dependence of the peak height for this process on the rate of the potential scan agrees with the equation presented for the capacitive current. The peak height also follows the Langmuir isotherm. The equilibrium constant (K) for the adsorption of β-cyclodextrin ($1.0\times10^5\ M^{-1}$) is about 8 times larger than that of α-cyclodextrin ($1.2\times10^4\ M^{-1}$). This result may be related to the fact that β-cyclodextrin is about 8 times less soluble in water than α-cyclodextrin.[10] According to Blomgren, Bockris, and Jesch,[11] the adsorptivity of organic substances on the mercury surface increases with a decrease in the solubility in water. Similar results have also been reported by Kaganovich *et al.*[12] who showed that the adsorption of normal aliphatic acids, alcohols, or amines is enhanced by increasing the length of the hydrocarbon chains—that is, by a decrease in the solubility in water.

The anodic peak B of β-cyclodextrin is almost symmetrical with the cathodic peak A and may be due to the desorption of the cyclodextrin. In the case of α-cyclodextrin, the behavior of the peaks other than the cathodic peak A is very complex. The A′ peak does not appear until the concentration of α-cyclodextrin exceeds 0.10 mM, in which case, according to the plot of j for peak A *vs.* the cyclodextrin concentration in Fig. 7, about half of the adsorption sites of the mercury electrode are occupied by the adsorbate. The peak height decreases with an increase in the temperature, the pH, or the ionic strength. The peak can be attributed either to the multilayer adsorption of the cyclodextrin or, more probably, to the reorientation of the adsorbed molecules on the electrode surface. However, it is not clear why the behavior of α-cyclodextrin is so different from that of β-cyclodextrin. The behavior of the B peak of α-cyclodextrin is similar to that of the A′ peak, so it is reasonable to ascribe the peak to the reverse process of the A′ peak. The anodic peaks C and D of α-cyclodextrin may also involve the adsorption-desorption and/or reorientation processes, but the details remain still unclear.

The present cyclic-voltammetric method could be applied to the determination of microquantities of the cyclodextrins. By the use of calibration curves, it is possible to determine *ca.* 20—200 μg/ml of α-cyclodextrin or *ca.* 1—20 μg/ml of β-cyclodextrin at 25 °C.

Chemical Effects of $^{31}P(n,\gamma)^{32}P$ Reaction in Phosphate Glass—A Radiation Chemical Approach to Hot Atom Chemistry

Tsing-Ko Lin and Niro Matsuura*

Institute of Nuclear Energy Research, P.O. Box 3, Lung-Tan, Taiwan, Republic of China

**Department of Pure and Applied Sciences, College of General Education, University of Tokyo, Tokyo 153*

(Received March 25, 1975)

Sodium metaphosphate glass, with a polymerization degree of 50—100, was used as target material for the study of the chemical effects of (n, γ) reaction. Mean oxidation number of ^{32}P was introduced as a new parameter to elucidate the oxidation reaction brought on the recoil product. The mean oxidation number of ^{32}P from (n, γ) recoil in such glassy polyphosphate was about +4. More than 90% of the ^{32}P set free was reattached as an end group in the newly formed radioactive polyphosphate. The recoiled monoatomic ^{32}P species (less than 10% of the total ^{32}P) defficient in oxygen kept a low mean oxidation number *ca.* +3. Ionizing radiation produced color center (with λ_{max} at 510 nm) which seemed partially to oxidize the ^{32}P product. The effect was very weak, and could be suppressed by the hold scavengers. Thermal annealing showed that the mean oxidation number of ^{32}P rapidly attained +5 (the valence of target) by 300 °C; however, it seems very difficult to raise the mean oxidation number of ^{32}P to +5 by γ-ray annealing. The oxidation of ^{32}P through thermal annealing is considered to be a diffusion process, with an activation energy of *ca.* 7×10^3 cal/mol. Possible reaction between the hot-zone and the radiation spurs is discussed.

During the course of $^{31}P(n, \gamma)$ ^{32}P reaction in oxyphosphorus compounds, more than 90% of the recoil ^{32}P was set free from its bonding. However, most of the ^{32}P underwent recombination to form radiophosphates even in polymer skeletones.[1] Electrophoretic study of the reactor-irradiated oxyphosphates of ammonium and alkali metal salts at liquid nitrogen temperature indicates that fourteen different anions labelled with ^{32}P in the skeletones of polymer species were found.[2,3] Such ^{32}P-labelled polyphosphates were also observed in the aqueous target of varilous orthophosphate solutions.[4] Our experiments with polyphosphates as target clarified how the recoil ^{32}P was converted into the radiopolyphosphates.[5-7] Ionizing radiation seems to affect the distribution of radiophosphates. In a previous work we have thoroughly investigated the oxidation of ^{32}P species induced by γ-radiation in the tripolyphosphate solution, in which the recoil ^{32}P products were found almost in monomer forms.[9] In solid target, however, the separable ^{32}P-labelled polyphosphate products were so complicated that their chromatographic patterns provided no clue to clarify the redox reaction occurring on the recoil ^{32}P.[6,9,10] The radiopolyphosphate products can be classified into five kinds, each having one ^{32}P attached as an end group.[6,7] After acid hydrolysis they undergo the following changes quantitatively.[11,12] (Blazer's notation is used.[13])

$$\overset{3}{P}\text{-O-}\overset{3}{P}\text{-} \longrightarrow 2\overset{3}{P}, \qquad \overset{2}{P}\text{-}\overset{4}{P} \longrightarrow 2\overset{3}{P},$$

$$\overset{3}{P}\text{-O-}\overset{5}{P}\text{-} \longrightarrow \overset{3}{P} + \overset{5}{P}, \quad \overset{4}{P}\text{-}\overset{4}{P} \longrightarrow \overset{3}{P} + \overset{5}{P},$$

$$\overset{5}{P}\text{-O-}\overset{5}{P}\text{-} \longrightarrow 2\overset{5}{P}$$

The apparent oxidation unmber of ^{32}P is almost unchanged even after hydrolysis into monomers. The average of the oxidation number of the total recoil ^{32}P thus can be easily estimated from the hydrolyzed monomers. A mean oxidation number of the total ^{32}P is more available than the individual ^{32}P specimen for the study of the redox reaction occurring on the recoil ^{32}P.

In the present work, sodium metaphosphate glass, a glassy polyphosphate known as Graham's salt, was used as a target to investigate the reaction of ionizing radiation on the recoil ^{32}P, since such glass can firmly trap the reactive radicals produced by the γ-radiolysis at room temperature.[14-15] In order simplify the reaction system, all the ^{32}P precursors of low oxidation state can be represented by $\overset{3}{P}$ (phosphite species) since there are only $\overset{3}{P}$ and $\overset{5}{P}$ states after hydrolysis. The "mean oxidation number" (abbreviated as "MON") is also applied as a parameter to evaluate the effects of ionizing radiation on the chemical state of the recoil product.

Experimental

Preparation of Target Materials. Graham's salt, sodium metaphosphate glass having the chemical form $(NaPO_3)_n$ was prepared as follows:

Sodium dihydrogen phosphate dihydrate was dehydrated at 800 °C for three hours in an electric furnace. The fused salt was then quenched to give a clear glass sheet with thickness of about 2 ± 0.2 mm between two brass plates. The degree of polymerization, determined by pH titration[17] and viscosity measurement,[18] showed a value between 50 and 100. In the metal-doped Graham's slat, about 0.5—3 mol percent of MnO, Sb_2O_3, Sb_2O_5 or NiO was mixed thoroughly with sodium dihydrogen phosphate dihydrate and was then treated in the same way as in the preparation of a metal containing phosphate glass.

NaI doped Grabam's salt was prepared under nitrogen atmosphere in a specially designed quartz tube.[7] The content of iodide was determined colorimetrically after being extracted into chloroform.

Irradiation. Neutron activation was carried out with the Kyoto University Reactor (KUR), with a neutron flux of *ca.* 2×10^{13} n cm^{-2} s^{-1} and a gross γ-ray dose rate of about 4.5×10^{21} eV g^{-1} hr^{-1} in the pneumatic tube, or a neutron flux of *ca.* 4×10^{12} n cm^{-2} s^{-1} and a gross γ-ray dose rate of *ca.* 2×10^{21} eV g^{-1} hr^{-1} in a slant tube.

Gamma ray irradiation was carried out with a ^{60}Co source at the Institute for Solid State Physics of University of Tokyo.

Eight positions, with γ-ray dose rate of $(3.7\pm0.1)\times10^{18}$ eV·g^{-1} hr^{-1}, around the standard source were chosen.

Chemical Analysis. In order to prevent the redox reaction induced by dissolution, the irradiated solid sample was carefully dissolved in 6 M HCl under nitrogen atmosphere. The role of HCl is not only to hydrolyze polyphosphate into monomer forms, but also to suppress the oxidation reaction induced by the color center during the course of dissolution.[15,16]

All the samples except the isothermally annealed ones were separated by anion-exchange chromatography. A gradient elution of 0.1—0.6 M ammonium acetate solution through an acetate form Dowex 1×8 anion-exchange resin of the size of 1×15 cm ϕ was applied for the separation of the phosphoxy anions of different oxidation states.[6,8]

Separation of the annealed samples was carried out by the paper chromatographic method. Toyo Roshi No. 50 filter paper was used as paper strip, and a mixture of *n*-propanol, ammonia and water in the ratio 6 : 3 : 1 in volume was used as developer. The R_f-values of the radioactive $\overset{1}{P}$, $\overset{3}{P}$ and $\overset{5}{P}$ species, determined by automatic radioactive scanning method, were found to be 0, 0.30 and 0.66, respectively. Quantitative determination of the phosphorus species was carried out colorimetrically by the molybdenum blue method[19-22]; 1 ml from each of the separated fraction was taken prior to colorimetry for the determination of radioactivity.

Results

Distribution of Radioactive Species and the Mean Oxidation Number of ^{32}P in Pure Salt. Distribution of ^{32}P species in the forms of hypophosphite ($\overset{1}{P}$), phosphite ($\overset{3}{P}$) and phosphate ($\overset{5}{P}$), obtained from the Graham's salt after hydrolysis with 6 M HCl is given in Table 1 for two independent series of experiments, A and B. The result shows that all the ^{32}P is hydrolyzed into monomer forms. The MON ^{32}P calculated from the yields of $\overset{1}{P}$, $\overset{3}{P}$ and $\overset{5}{P}$, is given in the last column of Table 1.

The MON of ^{32}P depends predominantly upon the radioactivity ratio of $\overset{3}{P}$ and $\overset{5}{P}$ species. Since the yield of radioactive $\overset{1}{P}$ is negligibly small as compared with that of $\overset{3}{P}$ and $\overset{5}{P}$, it has little effect on the evaluation of MON. The estimated mean oxidation number of ^{32}P is *ca.* +4.0, when irradiation time is shorter than 60 s. (the absorbed energy, by referring to ^{60}Co γ-ray dose, was about 6×10^{19} eV/g).

A rise of mean oxidation number of ^{32}P was observed only when the exposure of target in the nuclear reactor is sufficiently long. For instance, the mean oxidation number of ^{32}P was found to be +4.2 by 120 s irradiation, in which the target absorbed an energy dose of about 1.2×10^{20} eV/g. Such an observation indicates that the ambient radiation in the reactor is partially effective in raising the oxidation state of ^{32}P.

A color center was formed in the glass during the course of exposure in the reactor. The absorbancy at 510 nm, which attributed to trapped hole by many workers[14,16,23] increased with the exposure time (Fig. 1).

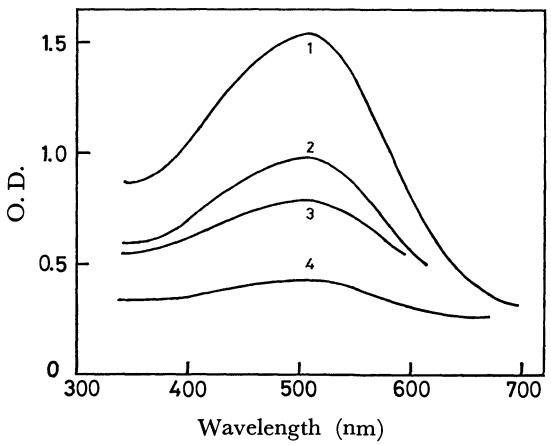

Fig. 1. Absorption spectra of reactor irradiated Graham's salts. Curves 1, 2, 3 and 4 denote irradiation times 120, 60, 30, 15 seconds in pneumatic tube.

Table 1. Distribution of radioactive hypophosphite ($\overset{1}{P}$), phosphite ($\overset{3}{P}$), and phosphate ($\overset{5}{P}$) species as well as the mean oxidation number of ^{32}P in reactor irradiated pure Graham's salt

Experiments of series A and B were carried out, independently.

a) Monitrored by phosphate glass. (*i. e.* by the optical densisy of Graham's salt)[7] b) Total recovery of radioactivity with average value of 98.9%. c) Mean oxidation number of ^{32}P. d) Irradiated in pneumatic tube.

A separate series of irradiation by ^{60}Co γ-ray shows that the optical density of the phosphate glass at 510 nm obeys Beer's law at least up to 10^{19} eV/g, which is in good agreement with Kobayashi's works[7,15,16] The optical absorbancy in a higher dose region does not seem to obey Beer's law but logarithmic one.[15,16,24] It should be emphasized that the mean oxidation number of ^{32}P increases beyond critical point, turning logarithmic.

Effect of Additives on MON of ^{32}P. In order to study the effect of ambient radiation in the reactor, hole scavengers such as Mn^{2+}, Sb^{3+} and I^- as well as electron scavengers such as Ni^{2+} and Sb^{5+} were doped individually from 0.5 to 3.0 mol% into Graham's salt. They were all irradiated in the slant tube together with a pure salt for about 6 min.

These glasses doped with hole scavenger always showed no absorption at 510 nm even after having absorbed a radiation energy *ca.* 10^{21} eV/g. The mean oxidation number of ^{32}P remained at 3.96—4.02, while that of ^{32}P in pure salt was found to be 4.25. The value on pure salt is also expected (Table 1), if we compare the energies absorbed. On the other hand the mean oxidation number of ^{32}P in these Ni^{2+}- and Sb^{5+}-doped salts were found to be +4.22 and 4.12, respectively. This value of MON for ^{32}P is very close to that observed in the pure salt which was irradiated under the same conditions. The detail of the experimental results are summarized in Table 2 (a) for both the distribution of ^{32}P species and its mean oxidation number. The results show that the oxidation of ^{32}P products might be due to the trapped hole. The reaction of electron is not clear, though electron may form oxygen center and reacts as an oxidant.[7,15,25,26]

The yields of the recoiled monoatomic ^{32}P species obtained merely by dissolving the irradiated glass into pure water without hydrolysis, are also given in the forms of $\overset{1}{P}$, $\overset{3}{P}$ and $\overset{5}{P}$ in Table 2 (b). The radioactivity involved in the monoatomic ^{32}P fractions was less than 10% except Sb^{3+}- and Sb^{5+}-doped glasses in which it was near 20%. As a matter of fact, more than 90% of the recoil ^{32}P was labelled into the polyphosphate.[6,7] The mean oxidation number of ^{32}P in such monoatomic ^{32}P product, however, kept a comparatively low value *ca.* +3.0, independent of the dopants. Both trapped hole and electron has little effect on such recoiled monoatomic ^{32}P species.

Table 2. Mean oxidation number of ^{32}P in doped Graham's salt

Irradiated samples were treated in two ways before chemical analysis:
(a) hydrolyzed with 6M HCl,
(b) dissolved in water without hydrolysis.

Ion doped (mol %)	$\overset{1}{P}$(%)	$\overset{3}{P}$(%)	$\overset{5}{P}$(%)	MON
(a) Hydrolyzed sample				
Mn^{2+} (2)	1.2	48.6	50.2	3.98
Sb^{3+} (2)	4.4	42.8	52.7	3.96
I^- (5)	0.8	47.2	52.0	4.02
Sb^{5+} (2)	—	44.0	56.0	4.12
Ni^{2+} (0.5)	1.9	37.4	61.7	4.22
pure salt	—	37.4	62.6	4.25
(b) Unhydrolyzed sample				
Mn^{2+}	0.4	4.4	1.0	3.2
Sb^{3+}	8.2	3.3	8.6	3.0
I^-	0.6	8.5	—	2.9
Sb^{5+}	5	4	5	2.9
pure salt	0.8	5.0	1.2	3.3

All samples were irradiated together in the slant tube for about 6 min. corresponding to a γ-energy of *ca.* 10^{20} eV/g.

Effects of γ-Ray Annealing on Recoil ^{32}P. Further studies of the radiation effect on ^{32}P were carried out by ^{60}Co source prior to neutron activation. After having absorbed an energy of about 10^{20} eV/g (approximately the order of energy which the target might absorb during its exposure in the reactor), the colored glasses were irradiated together with the untreated Graham's salts in the pneumatic tube. The results are illustrated in Figs. 2 (a) and (b) in terms of the radioactivity growth of $\overset{3}{P}$ and $\overset{5}{P}$ as a function of irradiated time. The yields of radioactive $\overset{1}{P}$ are always as low as 1% of the total activity, remaining virtually unchanged. The gamma ray treated samples always had higher $\overset{5}{P}$ activity and lower $\overset{3}{P}$ activity than the untreated ones. This indicates that the ionizing radiation may partially induce the oxidation of the recoil ^{32}P species and pre-neutron irradiation γ-ray treatment can enhance such a reaction. This evidence is more clearly confirmed in Fig. 3. The $\overset{5}{P}/\overset{3}{P}$ ratio and the mean oxidation number of ^{32}P for both series are shown as functions of the absorbed energy in Fig. 3 (a) and (b), respectively. The γ-ray treated sample always

kept higher $^5P/^3P$ ratio and the mean oxidation number of ^{32}P than those of the untreated sample, the difference increasing with energy. The oxidation induced by γ-radiation seems to have a threshold of energy. From the curves of untreated sample (Fig. 3), when energy absorbed was less than 6×10^{19} eV/g, the reaction does not seem able to occur. The oxidation would occur only after the target absorbed enough energy which might exceed 6×10^{19} eV/g.

The post-neutron irradiation γ-ray annealing was studied within the γ-ray dose ranging from 1.4×10^{20} to 1.9×10^{21} eV/g. The results are given in Fig. 4 in terms of the MON of ^{32}P and the yields of radioactive ^5P and ^3P. In contrast to the pre-neutron annealing curves (Fig. 3) the post-neutron annealing curves (Fig. 4) show an opposite trend in the oxidation of ^{32}P. The reaction is rapid in the beginning, but becomes slow with the increase in radiation dose. It seems very difficult for the mean oxidation number of ^{32}P to retain the valence state +5 of the target phosphorus by the gamma ray annealing.

Effects of Thermal Annealing on Recoil ^{32}P. Thermal annealing of the reactor irradiated glass was carried out at 50, 100, 200, 250, 300 and 400 °C. The results are summarized in Table 3.

The isothermal annealing curves at each temperature are given in Fig. 5. Paper chromatographic scanning was made for the two major components, ^3P and ^5P of ^{32}P products, from the hydrolyzed acidic solution (6M HCl) of the annealed sample. The detectable ^1P-activity was always less than one percent, almost completely disappearing at 300 °C. No matter what the annealing temperature was, within 2—5 min, the yield of ^{32}P components attained rapidly a fixed ratio between ^3P and ^5P. The higher the annealing

temperature, the more rapidly the isothermal curves reached its equilibrium. Such stationary composition of ^{32}P products at each annealing temperature maintained some 60 min.

In Fig. 6, the radioactive yields of both ^{3}P and ^{5}P, estimated at the stationary state of each isothermal curve, are plotted against the annealing temperature along with corresponding specific activity detected at the same temperature. A rapid increase (or decrease) of ^{5}P (or ^{3}P) yield was observed from 200 °C and finally the yield of ^{5}P (or ^{3}P) became closer to hundred (or null) percent by 300 °C. This range of temperature (200—300 °C) just covers the decomposition temperature of the low oxyphosphorus compounds such as phosphite.[11] In the case that decomposition occurs, a part of the ^{32}P would escape in the gaseous phosphine species,[27,28] and thus the detectable specific activity would decrease with the temperature from 200 °C. However, the specific activity curve (Fig. 7) showed no change even

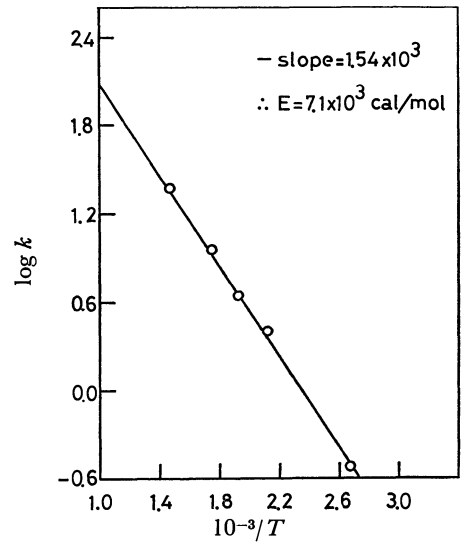

Fig. 7. An Arrhenins plot for estimation of the activation energy of the thermal annealing reaction.

when the sample was heated up to 400 °C. All the ^{32}P were converted into penta-valence by thermal annealing. The rate of conversion of ^{3}P into ^{5}P was estimated from the slope for each annealing curve (Fig. 5). This conversion rate was used for the Arrhenius plot to estimate the activation energy of this particular system. A straight line of such a plot is shown in Fig. 7, an activation energy of 7.1 kcal/mol being obtained.

A comparison was made between the fading in color and the change in mean oxidation number of ^{32}P in order to investigate the correlation between the trapped hole (the color center) and the oxidation of ^{32}P species (Fig. 8). The optical absorbancy at 510 nm attributed to the trapped hole[14,23] disappeared completely with the temperature range 100—200 °C. However, the rise of the mean oxidation number of ^{32}P between 100—200 °C was very gradual. It rose sharply from 200 °C and attained +5 by 300 °C (dotted line, Fig. 8).

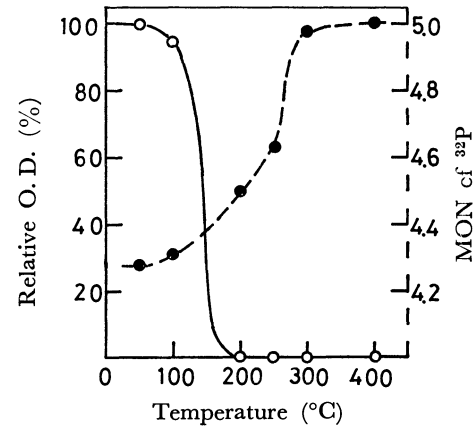

Fig. 8. Correlation between color center (trapped hole) and MON of ^{32}P at various temperature; solid line shows the fading of OD at 510 nm and dotted line denotes the variation of MON of ^{32}P.

The trapped hole might disappear through two ways; by recombination with the free electron located in the vicinity or by the reaction with the electron donor species such as ^{3}P.

The curves in Fig. 8 indicate that in glass matrix, though the oxidation of ^{32}P species by the trapped hole is not impossible, it is not a predominant reaction. Disappearance of the color center is mainly due to its recombination with electron or negative ion during thermal annealing.

Discussion

During $^{31}P(n,\gamma)$ ^{32}P recoil in polyphosphate, all the ^{32}P are freed from their bonding to become a monomer which is often deficient in oxygen.[7,29] However, in the spiral shape of polyphosphate molecule, about 90% of the recoil ^{32}P undergoes recombination to reform radioactive polyphosphate with one ^{32}P as end group which, compared with the monoatomic ^{32}P product, is fairly rich in oxygen[7]. Hence the mean oxidation number of ^{32}P in polymer forms is always higher than

that in monomer forms[30]. Ionizing radiation might cause the oxidation of the recoil ^{32}P product. Such oxidation seems to be an electronic process since it can be suppressed by the electron donor (Table 3 (a)). The γ-radiolysis of phosphate glass can be simplified as follows.

$$\underset{\text{(glass)}}{G} \rightsquigarrow \underset{\text{(trapped hole)}}{G^+} + \underset{\text{(electron)}}{e^-}$$

Subsequent reaction might occur between G^+ and hole scavenger(S):

$$G^+ + S \longrightarrow G + S^+$$

If there is no such electron donor as hole scavenger, G^+ may react with recoil ^{32}P species of lower chemical state; for instance:

$$G^+ + \overset{3}{P} \longrightarrow G + \overset{4}{P}$$

which apparently raises the mean oxidation number of ^{32}P. However, such an oxidation is partial and greatly depends on the concentrations of both the trapped holes and ^{32}P. Another possibility for raising the mean oxidation number by radiation is OH radical from water molecule[30]. In such a radiolytic achievement, phase effects play an important role. The post-neutron irradiation γ-ray annealing shows an entirely different behavior between solid and aqueous targets. The mean oxidation number of ^{32}P observed in solid target increases only from +4.1 to +4.6 by absorbing an energy even higher than 10^{21} eV/g.[7] Such discrepancy in oxidation reaction may be due to the different diffusion rates of the reactants in solid and liquid phases. The higher diffusion rate and concentration of OH radical in liquid state give rise to a more rapid and complete oxidation of the recoil ^{32}P product in aqueous target than in solid target.

The effect of diffusion phenomena on the oxidation of recoil product in the solid target can be elucidated by annealing. Isochronic curves (Fig. 6) indicate that within the temperature range 200—300 °C, all the recoil ^{32}P products are converted into $\overset{5}{P}$ state. The temperature range gives no definite correlation with the temperature for disappearance of the color center (positive defects) which disappeared completely by 100 °C (Fig. 8). The activation energy of the annealing is about 0.3 eV (7.1 kcal/mol). This value of activation energy seems to demonstrate that the thermal annealing reaction is not an electronic but a diffusion process. The potential well of the trapped hole (color center) produced by the γ-radiolysis in the glass is about 0.3 eV which is ten times as low as the optical activation energy 2.6 eV (510 nm). The following conclusion can be made for the annealing effects. In the reactor irradiation, two kinds of abnormal domains are produced and localized in the solid target, a) the recoil site (or hot zone) which involves radioactive product and many other reactive fragments, and b) the radiation spur which contains positively and negatively charged species (color centers). During the course of annealing, within the first domain, hot zone, the recoil product may react with its surrounding reactive fragments to raise the retention value.[31] Within the second domain, radiation spur, the interaction between the positive and negative defects also takes place.[32,33] Interactions between the recoil product and the color centers are possible. However, before the trapped species in the radiation spur diffuse to react with the recoil product which is considerably far away, they have already reacted one another within the domain (radiation spur). This is why the temperature of the complete disappearance of the color center and that of the oxidation of the recoil product do not coincide (Fig. 8).

Kinetics of Ion Exchange in the Chelating Resin Dowex A-1

Hideo MATSUZURU and Yoshiki WADACHI

Japan Atomic Energy Research Institute, Tokai-mura, Ibaraki-ken 319-11

(Received April 1, 1975)

The kinetics of ion exchanges of Ag^+, Zn^{2+} and Cr^{3+} at extremely low concentrations on the chelating resin Dowex A-1 has been studied by means of finite volume method. The rate of exchanges for both Ag^+ and Zn^{2+} is dependent on the ionic strength, particle size of the resin and reaction temperature. At higher ionic strength (0.1—0.05) the kinetics is controlled by particle diffusion, whereas at lower ionic one (0.01—0.001) film diffusion is predominant. The apparent activation energy obtained is 3.84 kcal/mol for Ag^+ and 3.91 kcal/mol for Zn^{2+}. The exchange rate of Cr^{3+} obeys a first-order rate equation independent of the ionic strength and particle size of the resin. The apparent activation energy is 15.5 kcal/mol. These results support the view that the rate-determining step of this reaction is chelate formation reaction.

It has long been established that the ion exchange reaction in the synthetic cation exchange resin is controlled either by film or by particle diffusion.[1] Since the chelating resin with iminodiacetic acid as the functional group was prepared by Moris *et al.*,[2] increasing interest has been paid to the kinetic behavior of the resin. Upon studying the exchange kinetics of a series of cations such as Na^+, Mg^{2+}, Ca^{2+}, Co^{2+}, Ni^{2+}, Mn^{2+}, Cd^{2+} and Cu^{2+} in Dowex A-1, Turse and Rieman[3] concluded that the rate-determining step is particle diffusion for cations which do not form chelate with the functional group, while in the case of cations which chelate with it the slowest step is a second-order chemical reaction. However, Schwartz *et al.*[4] reported that ion exchanges of Na^+, Co^{2+} and Zn^{2+} in this resin are controlled by particle diffusion. Varon and Rieman[5] reinvestigate this problem and concluded that the slowest step is particle diffusion. The authors found that exchanges of Ce^{3+} and Pu^{4+} in Dowex A-1 are controlled by a first-order chemical reaction.[6,7]

In this paper, an attempt was made to establish the kinetic behavior of this resin and to elucidate the possibility of the chemical reaction, *i.e.* chelate formation reaction between the metal ion and the functional group, being the rate-determining step with the use of Ag^+, Zn^{2+} and Cr^{3+} at extremely low concentrations.

Experimental

Materials. Dowex A-1 (crosslinked polystyrene matrix with iminodiacetic acid as the functional group, DVB content; *ca.* 1%, Dow Chemical) was used. The resin was treated with 2 M NaOH and 2 M HNO_3 three times in a column. After conversion into the sodium form, the resin was washed with distilled water until the effluent came to have the same composition as that of the influent. By subjecting the resin to the wet elutriation method, resin beads of a constant particle size were obtained. The mean particle radius was determined microscopically with a calibrated eye piece ocular. The quantity of iminodiacetic acid per unit weight of the resin was determinated by putting 300 mg of the resin (in the hydrogen form) into contact with 100 ml of 0.1 M NaOH in a 200 ml flask. When ion exchange equilibrium was reached, the supernatant solution was filtered, and free hydroxide was titrated with 0.1 M HCl. The capaicty obtained was 2.29 ± 0.24 mM/g resin. Radionuclides used were $^{51}CrCl_3$(8.8×10^4 mCi/g Cr), $^{65}ZnCl_2$ (7.4×10^2 mCi/g Zn), and $^{110m}AgNO_3$(1.2×10^3 mCi/g Ag) from the Radiochemical Centre, Amersham. The radiochemical purity of these nuclides was confirmed by γ-ray spectrometer using a Ge(Li) detector, no other peaks greater than 0.1% of the expected predominant peak being observed. Cr(III) was separately purified from Cr(VI) by adsorbing Cr(III) onto the cation exchanger(Dowex 50W×8), then desorbing it from the resin by eluting with 0.5 M HNO_3. The chemical form of Zn^{2+} was converted into the nitrate by the ion exchange method. Reagent grade chemicals were used without further purification.

Procedure. The batch method was used throughout the work. A three-necked flask containing 300 mg of the resin and 400 ml of the solution adjusted to pH 4.5 and to prescribed ionic strength ($NaNO_3$), was submerged in the thermostatically controlled water bath. From the requirement in the heterogeneous reaction system, the whole reaction system was vigorously stirred (400 rpm). This rotation speed was high enough to neglect the effect of agitation on the rate of exchange reaction. After thermal equilibrium was attained, a fixed volume of the solution containing a radionuclide was added to the reaction system to initiate the reaction. At each preset time interval, 100 μl of the solution was pipetted out for measurement of radioactivity. Even though the volume of reaction system decreased gradually owing to the fact that a definite volume of it has to be removed at preset time intervals, no correction was made for this decrease since the amount of the solution taken out was negligibly small as compared with that of the reaction system.

The radioactivity of the sample was determined with a conventional scintillation counter combined with NaI(Tl) detector.

The molar concentration of each metal ion was determined by the measured radioactivity obtained with a 2π-proportional counter and the specific activity of the corresponding radionuclide.

Results and Discussion

Kinetic Equation. Since the concentration of the adsorbing ion is extremely low, the changes in composition of the resin and the external solution remain insignificant. In such a system the conventional rate law for an isotope exchange reaction is valid.[8] The kinetic equation[9] for an exchange reaction controlled by film diffusion under the conditions of finite volume is

$$U(t) = 1 - \exp\left(\frac{-3Dt(\bar{C}\bar{V}+VC)}{r\delta\bar{C}\bar{V}}\right) \quad (1)$$

where $U(t)$ is the fractional attainment of equilibrium,

D the diffusion coefficient, r the radius of resin beads, δ the thickness of the film, C and $\bar{C}$ are the equilibrium concentrations in solution of volume V and in resin of volume $\bar{V}$, respectively.

Similarly for a particle diffusion controlled exchange with the finite volume condition, the kinetic equation is given by the Paterson' equation:[10]

$$U(t) = 1 - \frac{2}{3w}\sum_{n=1}^{\infty}\frac{\exp(-S_n^2\tau)}{1+S_n^2/9w(w+1)} \quad (2)$$

where $w=\bar{C}\bar{V}/CV$, $\tau=D\,t/r^2$, S_n are the roots of equation: $S_n \cot S_n = 1+S_n^2/3w$. Under the experimental conditions, the volume of the solution is significantly larger than that of the resin, hence this system may be taken as semi-finite. Equation (2) can be approximated by:[11,12]

$$U(t) = \frac{6Q_0\sqrt{Dt}}{r(Q_0-Q_\infty)\sqrt{\pi}} \quad (3)$$

where Q_0 is the amount of functional group in the reaction system, Q_∞ is the amount of exchange at equilibrium. The deviation from the linearity between $U(t)$ and $t^{1/2}$ is less than 2%, if $U(t)$ does not exceed *ca.* 0.5.

For an exchange reaction controlled by a chemical reaction, the rate is expressed by a conventional rate equation for a chemical reaction instead of such equation as Eqs. (1), (2) and (3) derived from the Fick diffusion law. Taking into consideration the fact that the amount of functional group in the reaction system is significantly larger than that of exchanging ion, this reaction can be regarded as first-order with respect to the exchanging ion.[13] The rate equation is

$$\log\left(\frac{Q_i}{Q_i-Q_t}\right) = kt/2.303 \quad (4)$$

where Q_i is the initial amount of the exchanging ion, Q_t the amount of exchange at time t, and k the rate constant. It was assumed that the reaction in the chelating resin was controlled either by diffusion (film or particle) or by a pseudo-first-order chemical reaction.

Diffusion Controlled Kinetics. Equation (1) predicts that if the rate-determining step is film diffusion, $-\log[1-U(t)]$ is directly proportional to the reaction time, and inversely to the particle radius and the film thickness. The film thickness decreases with an increase in the ionic strength. Thus the rate of exchange reaction increases with increasing ionic strength.[14] From Eq. (3), we see that $U(t)$ in the reaction controlled by particle diffusion is proportional to the square root of the time, and inversely to the particle radius.

The kinetics of exchanges of $Ag^+(1.5\times10^{-8}\,M)$ and $Zn^{2+}(1.6\times10^{-8}\,M)$ in the solution for Na^+ in the resin was studied as a function of the ionic strength. The results are given in Figs. 1 and 2 in which $U(t)$ is plotted against $t^{1/2}$. We see that at high ionic strength (0.1—0.05) a linear relationship is obtained for both ions, while at low ionic strength (0.01—0.001) no linearity is obtained in both cases. However, when the results are plotted in the form of $-\log[1-U(t)]$ *vs.* t, straight lines passing through the origin are obtained in both cases (Fig. 3). The rate of exchange increases with increasing ionic strength.

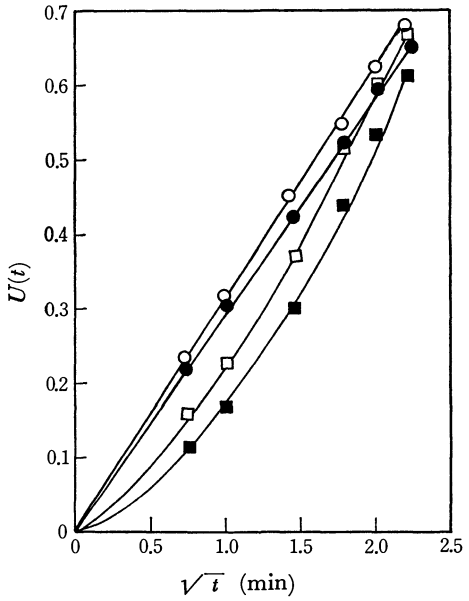

Fig. 1. Plots of $U(t)$ *vs.* $t^{1/2}$ for an ion exchange of Ag^+ on Dowex A-1 in the solutions of different ionic strength 25 °C (radius of the resin particle: 0.10 mm).
μ=○: 0.1, ●: 0.05, □: 0.01, ■: 0.001.

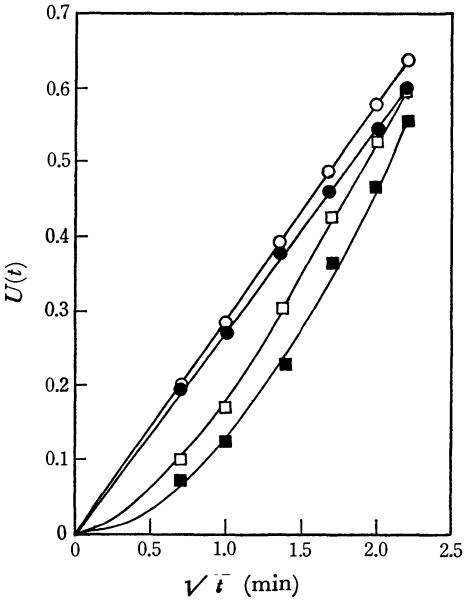

Fig. 2. Plots of $U(t)$ *vs.* $t^{1/2}$ for an ion exchange of Zn^{2+} on Dowex A-1 in the solutions of different ionic strength 25 °C (radius of the resin particle: 0.10 mm).
μ=○: 0.1, ●: 0.05, □: 0.01, ■: 0.001.

A small ionic strength effect can also be observed in the case of high ionic strength, *i.e.*, an increasing rate of exchange with an increase in the ionic strength (Figs. 1 and 2). The rate of exchange controlled by particle diffusion should also increase along with ionic strength, provided that the resin volume remains unchanged. According to Nikolaev's loose quasi-crystal model,[15,16] freely moving ions, cations and gegenions

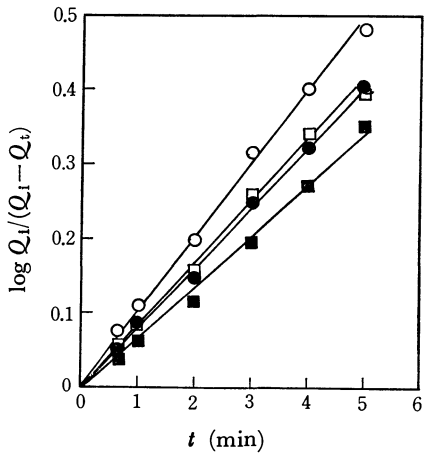

Fig. 3. Plots of $\log Q_i/(Q_i-Q_t)$ *vs.* t for ion exchanges of Ag^+ and Zn^{2+} on Dowex A-1 in the solutions of lower ionic strength, 25 °C (radius of the resin particle: 0.10 mm)

□: Zn^{2+}, $\mu=0.01$; ■: Zn^{2+} $\mu=0.001$.

present in the resin phase distort and diminish the depth of the potential well. The rate of diffusion of the ion which oscillates in a potential well a near the functional group, thus increases with an increase in ionic strength.

The rate-determining step of exchanges for both Ag^+ and Zn^{2+} changes from film to particle diffusion with increasing ionic strength. This may be explained as follows. In a range of lower ionic strength, the rate of diffusion through film is retarded by the Donnan exclusion, becoming significantly slow as compared with that of particle diffusion. With increasing ionic strength the Donnan potential and the film thickness might be sufficiently reduced to make the rate of diffusion through film by far greater than that of particle diffusion.

Table 1 shows the effect of the particle radius on the rate of exchange. In the cases of Ag^+ and Zn^{2+}, the half time of equilibrium increases with an increase in particle size. It seems that the effect of increasing particle radius on the exchange rate is nearly as large as that expected from Eq. (1) under the condition of low ionic strength, and from Eq. (3) under the condition of high ionic strength, within the over-all experimental error of *ca.* 10%.

Thus it could be concluded that the rates of exchange

Table 1. Effect of the radius of the resin particle (r) on the half time of equilibrium (τ)

Ion	$\mu(NaNO_3)$	r(mm)	τ(min)
Ag^+	0.1	0.10	2.6
Ag^+	0.1	0.13	4.2
Ag^+	0.001	0.10	3.3
Ag^+	0·001	0.13	4.3
Zn^{2+}	0.1	0.10	2.9
Zn^{2+}	0.1	0.13	4.7
Zn^{2+}	0.001	0.10	3.7
Zn^{2+}	0.001	0.13	4.7

for both Ag^+ and Zn^{2+} are governed by film diffusion at a low ionic strength, and by particle diffusion at a high ionic strength.

Chemical Reaction Controlled Kinetics. The kinetics of exchange of $Cr^{3+}(1.5\times10^{-8}$ M) in the solution for Na^+ in the resin was studied, and the results are given in Table 2. It can be seen that the relationship between $\log[Q_i/(Q_i-Q_t)]$ or $-\log[1-U(t)]$ and t is linear corresponding to Eq. (4) or to Eq. (1), no linearity being obtained in $U(t)$-t relation. Each value of $\log[Q_i/Q_i-Q_t)]$ at the corresponding time does not so much differ from that of $-\log[1-U(t)]$ (Table 2). This makes it difficult to determine which mechanism is operating as the rate-determining step.

Table 2. Rate of an ion exchange of Cr^{3+} on Dowex A-1 (25 °C, $\mu=0.1$, radius of the resin particle; 0.10 mm)

t(min)	$U(t)$	$\log Q_i/(Q_i-Q_t)$	$-\log[1-U(t)]$
1.00	0.109	0.049	0.050
2.00	0.193	0.091	0.093
3.00	0.306	0.155	0.159
4.00	0.370	0.196	0.201
5.00	0.433	0.238	0.246
6.00	0.505	0.297	0.305

For the sake of clarification, the effects of the ionic strength (0.1—0.0001) and the particle radius (0.10—0.13 mm) on the rate of exchange reaction were examined. The rate of exchange is independent of both the particle radius and the ionic strength over the ranges investigated. If the exchange reaction is controlled by film diffusion, the rate should depend on these factors. Thus it might be concluded that the rate of exchange of Cr^{3+} in the resin should be controlled by a pseudo-first-order chemical reaction.

The effect of temperature on the rate of exchange can also be expected to afford a criterion of mechanism, since the activation energy for an exchange controlled by diffusion is supposed to be distinctly lower than that for the chelate formation reaction. This is

Table 3. Influence of the reaction temperature on the diffusion coefficient for exchanges of Ag^+ and Zn^{2+} (particle diffusion) and the rate constants for an exchange of Cr^{3+}, $\mu=0.1$, radius of the resin particle; 0.10 mm.

Ion	Temperature (°C)	D(cm²/s)	k(s⁻¹)	E_a(kcal/mol)
Ag^+	15	1.13×10^{-8}		
	20	1.26×10^{-8}		
	25	1.41×10^{-8}		3.84
	30	1.56×10^{-8}

	20		1.21×10^{-3}	
	25		1.88×10^{-3}	15.5
	30		2.89×10^{-3}	

certainly the case with such metal ions as Ce^{3+} and Pu^{4+} adsorbed onto the Dowex A-1, where the apparent activation energy is about 14—20 kcal/mol, whereas that of most ions taking part in particle diffusion is about 4—6 kcal/mol. Table 3 shows the rate constant for an exchange of Cr^{3+} and the diffusion coefficient (particle diffusion) for exchanges of Ag^{+} and Zn^{2+}, depending on the temperature, and the apparent activation energy obtained from the Arrhenius plots. The apparent activation energy for an exchange of Cr^{3+} is higher than that for exchanges of both Ag^{+} and Zn^{2+} which are controlled by particle diffusion.

From the fact that Cr^{3+} is inert in the chelate formation reaction,[17] it is reasonable to suppose that the rate of chelate formation reaction between Cr^{3+} and iminodiacetate is sufficiently smaller than that of either film or particle diffusion.

The results also support the view that the rate-determining step of this reaction is chelate formation reaction.

Conclusion. The results of kinetic studies on Dowex A-1 given by various authours might be summarized as follows.

(1) The exchange reactions of univalent and divalent metal ions are controlled either by film or particle diffusion except for the cations which are inert in the chelate formation reaction such as Ni^{2+} and V^{2+}.

(2) The exchange reactions of multivalent and other ions which are inert in the chelate formation reaction are controlled by chemical reaction.

The kinetic behavior of Dowex A-1 is similar to that of Bio-Rex 63 (containing phosphonic acid as a functional group, Bio Rad Laboratories).[18]

The Mechanism of Amine Sensitization of the Emission of Tris(dibenzoylmethano)europium(III)

Tadashi FUKUZAWA,* Nozomu EBARA, Mikio KATAYAMA, and Hideaki KOIZUMI**

College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153

(Received April 14, 1975)

The mechanism of enhancement of emission quantum yield of the methanol solution of tris(dibenzoylmethano)europium(III) by triethylamine has been investigated. Lifetime of Eu^{3+} resonance emission of the chelate did not change remarkably when triethylamine was added. The aspect of temperature dependence of the emission intensity was similar for both the chelate itself and the chelate-amine adduct under direct excitation of the metal level, but differed under excitation of the ligand. It was suggested that the sensitization is mainly due to a suppression of nonradiative process in the ligand triplet state.

Intramolecular energy transfer process in rare earth metal chelate has been studied by many investigators since Crosby *et al.*[1] suggested that the transfer of energy from ligands to excited electronic levels of metal takes place *via* the lowest triplet state of ligands. Their assumption was supported by Matsuda *et al.*[2] who observed a sensitized emission of Eu chelate in the presence of La chelate, in which an energy transfer, if any, was allowed only from the ligand triplet of the latter to the ligand triplet of the former. The time constant of energy transfer from the triplet state to the rare earth level was determined by Tanaka *et al.* to be of the order of 10 ns.[3] Their observation proved to be in good coincidence with the cascade mechanism of Crosby *et al.*[1]

On the other hand, a number of mechanisms have been proposed for the sensitization and quenching effect of the emission of rare earth metal compound.[4–6] It is well-known that there are several rare earth metals, such as europium and terbium, which give narrow emission in solutions. Their quantum yields are generally low, varying with ligand, solvent, or temperature.

In order to study the energy loss due to the solvent or other added components, it is convenient to consider the three separate processes, (I) quenching in the ligand level, (II) quenching in the upper levels of the ions, and (III) quenching in the emitting levels of the metal. Weissman[7] assumed that process (I) is important but no experimental confirmation was given. Kropp and Dawson[8] showed that process (II) is effective in methanol solution of $Eu(NO_3)$. Contribution of quenching process (III) was investigated by Dawson *et al.*[9] who showed that for terbium chelate strong temperature dependence of the emission intensity can be explained in terms of quenching of the emitting level *via* thermal excitation to the lowest triplet state of the ligand.

Sato and Wada[10] also reported that the yield of the emission of europium chelate in several solutions depends upon the energy difference between the triplet level of ligand and the emitting level of europium ion, a maximum yield being observed at a certain value of the energy difference. They interpreted the change of the quantum yield as due to the thermal deactivation process from the emitting level of rare earth ions.

In a preceeding paper[11] the effect of several amines on the yield of the emission of tris(dibenzoylmethano) europium(III) (EuD_3) was reported with emphasis on the effect of triethylamine. It was shown that the yield of the emission of EuD_3 in methanol solution increased by a factor of 11 when triethylamine was added. It was suggested that the enhancement of the yield can be ascribed to the suppression of some deactivation process in which the solvent may take part. The present paper deals with the mechanism of the sensitization of the emission of EuD_3 by triethylamine molecule.

Experimental

Materials. Tris(dibenzoylmethano)europium(III) was prepared from europium oxide and dibenzoylmethane according to the method of Charles and Perroto.[12] Mp 231 °C. Elemental analysis; found: C, 65.73; H, 3.87%; calcd for C, 65.78; H, 3.87%. Triethylamine was used after fractional distillation. Commercial fluorescence spectrograde methanol was used as a solvent without further purification.

Method of Measurement. EuD_3-triethylamine were dissolved in methanol at a concentration of 10^{-4} mol/l. Emission and excitation spectra were observed with a Hitachi MPF II fluorescence spectrometer. The emission lifetimes of the EuD_3 and EuD_3-triethylamine complex in methanol were measured as follows. Fresh solutions of the sample were introduced into 3 mm diameter quartz tube and immersed in a liquid nitrogen or other coolants in a transparent quartz dewar. An exciting light pulse from Gellar coaxial nitrogen laser,[13] 10 kW peak power with 20 ns pulse width, was focussed on the sample through an aqueous $CuSO_4$ filter solution. The emission was focused on a Canon optical fiber guide (6 mm diameter, 1000 mm length) after transmission of Toshiba filters UV-39 and VR-60, and detected by HTV-R500 red sensitive and short transit time photomultiplier placed in an electric shield room. In order to minimize stray capacitance, an output resister of the photomultiplier was directly connected with the BNC receptacle of a vertical amplifier 7A11 plug-in-unit of Tektronix oscilloscope 7904. The apparatus had overall rise time of less than 10 ns. The measurement of the temperature dependence was carried out with the same sample tube and Dewar as was used in the lifetime measurement. After being cooled with liquid nitrogen, the sample was left standing to allow the temperature to rise gradually, and the emission intensity and the temperature were measured simultaneously. The tem-

** Present address: Naka Works, Hitachi Ltd. Katsuta, Ibaraki,

perature was measured with a Cu-constantan thermocouple placed in the sample solution just above the excitation volume.

First, the samples were excited by 365 nm radiation of a high pressure Hg-Xe lamp filtered through a $CuSO_4$ aqueous solution and a Toshiba UV-DIC filter, or by 465.8 nm line of an Ar ion laser Coherent Radiation model CR52G. The former radiation excited the ligand level efficiently. According to our observation of the excitation spectra of Eu^{3+} ion, 465.8 nm line of Ar laser coincides with one of the absorbing lines of Eu^{3+} ion ($^7F_0$-$^5D_2$). Since the ligand has no absorption at 465.8 nm, we can directly excite the ion which forms the chelate.

The temperature dependence of the emission intensity under 365 nm and 465.8 nm excitation was measured at 538 nm ($^5D_1$-$^7F_1$) and 612 nm ($^5D_0$-$^7F_2$), respectively. For the measurement of intensity, it is important to note that the magnetic field of Ar laser seriously affects the photomultiplier. In order to eliminate the effect, we used a long optical fiber between a monochrometer and HTV photomultiplier R 306 placed in a shield room. The output of photomultiplier and thermocouple was led into the x axis and y axis of a x-y recorder.

Results

Emission and Excitation Spectra. EuD_3 and triethylamine were mixed at 15 °C in methanol solution. The concentration of the former was kept constant (7.67×10^{-5} mol/l), and that of the latter was varied from 5.27×10^{-4} to 3.37×10^{-2} mol/l. The solutions were left standing more than 30 min, and the emission and excitation spectra were observed. At room temperature, there was no difference between the excitation and emission spectra of EuD_3 solution and those of EuD_3–amine complex solution. Even at 77 K the difference was slight.

The change of absorption spectrum of the EuD_3 solution by addition of the amine was also slight. Thus, the enhancement of emission intensity is not due to an increase in the photon uptake in the excitation process.

Lifetime of the Emission. The solution contains 4.72×10^{-4} mol/l EuD_3 and 4.25×10^{-1} mol/l triethylamine. Because of the weak intensities, lifetime measurements were made only for the strongest transition of $^5D_0$–$^7F_2$. The measured lifetimes of EuD_3 and EuD_3–triethylamine complex at several temperature are listed in Table I. Charles and Ohlman[4] showed that the lifetime of EuD_3–amine complex is 8 times as long as that of EuD_3. However, our measurement showed no remarkable difference between the lifetimes of EuD_3 and amine complex in methanol solutions.

The efficiency of the emission of the complex in methanol solution is 11 times as large as that of EuD_3. Such a striking enhancement can hardly be considered to be due to a decrease in the radiative lifetime. As the quantum yield of emission is low (0.005 in methanol)[9] it is also impossible that an increase in the radiationless lifetime of the emitting level causes the enhancement without affecting the overall lifetime. The effect should be attributed to the change in the radiationless process in the ligand levels.

Table 1. Emission lifetimes of EuD_3 and EuD_3–triethylamine complex

Materials	Lifetime		
	77 K	273 K	289 K
EuD_3 in MeOH	440 μs	384 μs	140 μs
EuD_3-TA in MeOH	439	394	136

Temperature Dependence of Emission Intensity. The solution contains 4.72×10^{14} mol/l EuD_3 and 4.25×10^{-1} mol/l triethylamine. Figure 1 shows the temperature dependence of the emission intensity at 538 nm ($^5D_1$–$^7E_1$) of EuD_3 and amine complex in methanol solution when only Eu^{3+} ions were excited by 465.8 nm of Ar ion laser. Both curves are normalized at the maximum intensities. With a rise in temperature they show sharp decrease at the temperature of phase change, presumably because of inhomogeneity of solid solution.

When the ligand was excited by 365 nm radiation, the emission intensities changed with temperature as shown in Fig. 2. In contrast to the 465.8 nm excitation, the intensity still decreased gradually with the rise of temperature in the liquid state, after a sharp decrease at melting point. This strongly suggests that the deactivation in the ligand level plays a dominant

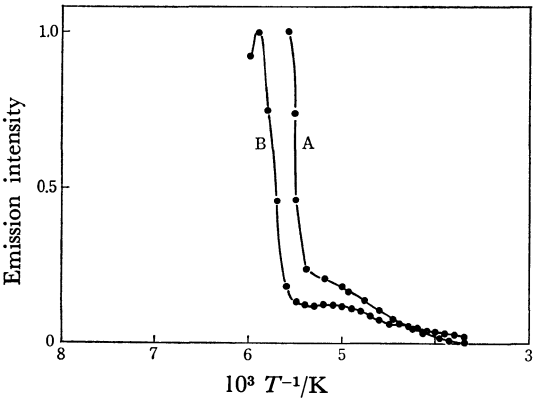

Fig. 2. Temperature dependence of the emission intensities excited by 365 nm radiation. A; EuD_3, B; EuD_2–amine complex. Wave length; 538 nm ($^5D_1-{}^7F_1$).

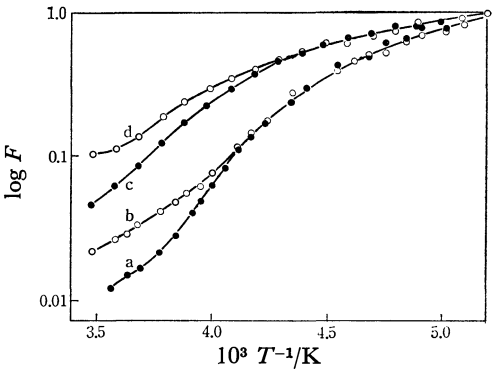

Fig. 3. Logarithm of the emission intensities measured at 612 nm and 538 nm versus $1/T$ in the case of excitation by 365 nm radiation. a; EuD_3, 612 nm, b; EuD_3, 538 nm, c; EuD_3-TA, 612 nm, d; EuD_3-TA, 538 nm.

role in the intensity change. Figure 3 shows the relation between $1/T$ and the emission intensities of 612 nm and 538 nm in logarithmic scale in the temperature range 192—294 K for both EuD_3 and the amine complex when the ligand was excited. All the curves are normalized at the value of 192 K.

The change of intensity of EuD_3 with temperature was larger than that of the complex. The intensity of 612 nm decreased much faster than that of the 538 nm radiation at temperatures above 240 K. Since the difference between a and b is similar to that between c and d (Fig. 3), the differences can be ascribed to the phonon process in $^5D_0$ level of EuD_3 in which triethylamine takes no part. The formation of EuD_3–amine complex causes the difference between a and c as well as that between b and d. It should be noted that these differences appeared only in the case of ligand excitation.

Mechanism of Thermal Quenching

Figure 4 shows the energy levels of EuD_3 and the processes involved in the excitation of emission from Eu^{3+} ion. Here, n_T, n_A and n_B denote deactivation rates from ligand triplet T and from metal levels A ($^5D_0$) and B ($^5D_1$), respectively, r_A and r_B the corresponding radiative rate constants and k_A, k_B, k_C, k_{TA}, k_{TB} and k_{BT} the internal transition rates from A to B, B to A, C to B, T to A, T to B and B to T, respectively.

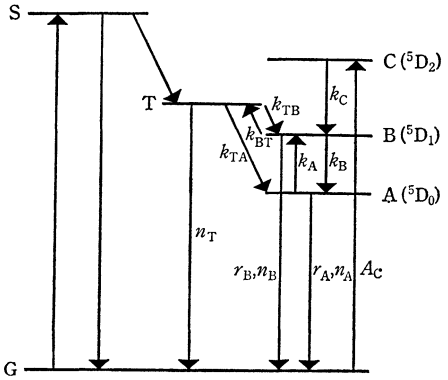

Fig. 4. Energy diagram of chelate. S and T are singlet and triplet of chelate, A, B and C are the excited states of europium ion.

To account for the thermal property of emission, the temperature dependence of radiationless process should be taken into consideration. Since the internal rates k_B, k_{TA} and k_{TB} can be regarded as temperature independent, we can assume that k_{BT}, k_A, n_A and n_T depend on temperature, because the former two are endothermic processes and the latter two are slow processes liable to external deactivation. n_A can be regarded as constant below 260 K, as the emission lifetime becomes constant. For k_{BT} and k_A, we assume that the transfer takes place *via* Boltzmann distribution, so that

$$k_{BT} = k_{TB}\exp(-E_{TB}/kT),$$

and

$$k_A = k_B\exp(-E_{BA}/kT),$$

where E_{TB} and E_{BA} are the energy differences between level T and level B and between level B and level A, respectively. Since both the values of E_{TB} and E_{BA} are nearly 1600 cm^{-1}, the Boltzmann factors amount to as 10^{-4} at room temperature.

As for the rate constant n_T, we assume that the deactivation of the triplet levels takes place by a thermalization which is established by the interaction between the vibronic levels of the triplet state of the ligand and the phonon levels of the solvent molecules; n_T is then expressed approximately as

$$n_T = k_n\exp(-E/kT),$$

where E is the average energy difference between the triplet state and some dissipative state which might be provided by weak bonded solvent molecules, and k_n is the density factor in the dissipative process in the triplet state.

The intensity of 538 nm emission ($^5D_1$-$^7F_1$) at temperature T under ligand excitation is expressed, after some manipulation, by

$$I = \frac{\alpha k_{TB}}{k_{TB}+k_{TA}+k_n\exp(-E/kT)},$$

where $\alpha = I_0 r_B/(r_B+n_B+k_B)$ and I_0 is the pumping intensity to the ligand triplet. This equation is rewritten as

$$\ln F = -E/kT + \ln(k_n/k_{TB}), \qquad (1)$$

where $F = 1/I - 1/I'$ and $I' = k_{TB}/(k_{TA}+k_{TB})$. Since I' can be assumed to be constant, we can plot in F *versus* T^{-1} by selecting an appropriate value of I' in order to obtain a straight line. The Arrhenius plots of 538 nm emissions of EuD_3 and amine complex are shown in Fig. 5, with best values of $1/I'$, 4.0 for the former and 4.5 for the latter (intensity scale is the same as in Fig. 2), from which the values of energy difference E are obtained: 2300 cm^{-1} for EuD_3 and 1400 cm^{-1} for the complex. It is to be noted that the energy values are not sensitive to the values of I'. Next, we define the radiative ratio R by

$$R = (k_{TB}+k_{TA})/k_n,$$

which can be obtained from the emission intensity ratio

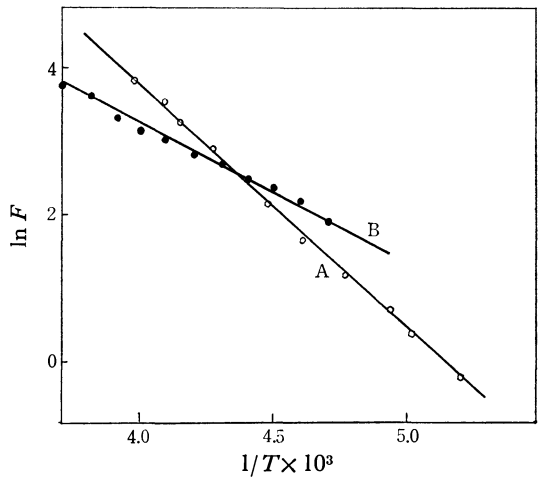

Fig. 5. Arrhenius plot of thermal quenching of emission measured at 538 nm. A; EuD_3, B; EuD_3-amine complex.

$$I_2/I_1 = \frac{k_{TB}+k_{TA}+k_n \exp(-E/kT_1)}{k_{TB}+k_{TA}+k_n \exp(-E/kT_2)} = \frac{R+\exp(-E/kT_1)}{R+\exp(-E/kT_2)}, \quad (2)$$

where I_1 and I_2 are the intensities observed at T_1 and T_2. The ratio R can be obtained from Eq. (2). Any pair of temperature T_1 and T_2 gives consistent R values, which indicates that the assumed mechanism is appropriate.

In the same way, the emission intensity of 612 nm ($^5D_0$-$^7F_2$) is represented by

$$I = \frac{(k_{TA}+\beta k_{TB})\gamma}{k_{TA}+k_{TB}+k_n \exp(-E/kT)} \quad (3)$$

where $\beta=k_B/(k_B+r_B+n_B)$ and $\gamma=I_0 r_A/(r_A+n_A)$, both of which can be assumed constant. Arrhenius plots are obtained from Eq. (3) in a similar way and we get energy difference E and the ratio R. The values of E and R for EuD_3 and amine complex calculated from both 538 and 612 nm emission are listed in Table 2.

Table 2. Energy difference between the ligand triplet level and quenching level and the ratio of the radiative to nonradiative processes

Materials	Emission Wave length	E		R
EuD_3	538 nm	2270 cm^{-1}		2×10^{-7}
			av. 2225 cm^{-1}	
EuD_3	612	2180		3×10^{-7}
EuD_3-TA complex	538	1390		8×10^{-4}
			av. 1507	
EuD_3-TA complex	612	1624		4×10^{-5}

Mechanism of Amine Sensitization

We have shown that the enhancement of emission intensity from Eu^{3+} ion is traceable to the change in the processes in the ligand levels. The values of I' for EuD_3 and the complex differ only by about 10%, which seems to circumscribe the range of the changes in k_{TB} and k_B (and possibly in k_{TA}). Table 2 shows that the ratio R of the complex is hundred to thousand times as large as that of EuD_3, although the value of E is somewhat smaller. The enhancement of the intensity in the amine complex seems to be entirely due to the large value of R, which is brought about by a marked decrease in the value of k_n. If we assume that the dissipative channel is provided by an interaction with solvent phonon state, weak bonds formed between the solvent molecules and chelate produce dense energy state near the vibronic band of the ligand to facilitate deactivation. Triethylamine forms a comparatively rigid bond with the chelate and replaces the solvent molecules, thus reducing the state density for deactivation.

It was found that at higher temperature the emission intensity of the amine complex decreased more rapidly than that of the chelate. This is presumably due to the fact that the amine molecule dissociates and is replaced by a solvent molecule. The lifetime of the 612 nm emission decrease abruptly above 273 K. This may be ascribed to the quenching in the $^5D_1$ and $^5D_0$ levels of EuD^{3+} ion.

We are grateful to Dr. A. Kuboyama of the National Chemical Laboratory for Industry of Tokyo for his stimulating discussion.

Infrared Band Shape of the C–I Stretching Vibration of Methyl Iodide in Solutions

Kenji FUJIWARA,* Kohji FUKUSHI, Shun-ichi IKAWA, and Masao KIMURA**

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received April 17, 1975)

The infrared band shapes of the fundamental and overtone C–I stretching vibrations of methyl iodide in solutions are well approximated by the superposition of Lorentzian functions. From a comparison of the band-widths of the $\nu_3(0\rightarrow1)$, $\nu_3(1\rightarrow2)$, and $\nu_3(0\rightarrow2)$ transitions, it is pointed out that the vibrational relaxation of the translational-diffusion type proposed by Bratos *et al.* contributes to the band-widths, in addition to reorientational relaxation. A slight deviation from the Lorentzian function was observed in the low-frequency region of the fundamental band.

The band shape of the infrared spectra of a liquid involves information about the molecular dynamics in the liquid. Shimizu[1] and Gordon[2] first showed that the band shape is given by the Fourier transformation of the time correlation function for the vibrational-transition dipole moment. They adopted a model of random reorientation of molecules in condensed phase. Since then, many studies have been carried out by means of the Fourier transformation of observed band shapes.[3–14] Meanwhile, it has been recognized that only the reorientational process is not always sufficient to provide a full account of an observed band shape. It is often necessary to take into account additional factors, such as the vibrational relaxation,[12,15] the vibration-rotation interaction,[13] the overlap of hot bands,[16] the overlap of bands of various isotopic species,[16] and the dielectric-field effect.[5,17–19]

In order to discuss band shape and molecular dynamics, it is necessary to extract the band assigned to a single transition from an observed band. Since methyl iodide is a representative of symmetric top molecules and has no isotopic species, extensive spectroscopic studies have been carried out on it. However, there are only a few studies on the band shape and on the reorientational process of this molecule in solutions.[20–22] Among the observed bands of methyl iodide, the ν_3 band of the C–I stretching vibration is appreciably deformed by the overlap of hot bands. Therefore, the half-width[23] of the ν_3 band reported in previous work must include some uncertainty. The present study has been undertaken in order to obtain the half-widths of the individual transitions, *i.e.*, the fundamental $\nu_3(0\rightarrow1)$, the hot band $\nu_3(1\rightarrow2)$, and the overtone $\nu_3(0\rightarrow2)$. For this purpose, the observed band at about 525 cm^{-1} was decomposed into the components, $\nu_3(0\rightarrow1)$ and $\nu_3(1\rightarrow2)$, by assuming a Lorentzian profile for each. A similar analysis was also applied to the overtone band, $\nu_3(0\rightarrow2)$, which appears at about 1030 cm^{-1} in the high-frequency wing of the intense ν_6 band.

Experimental

The infrared transmission was measured by a single beam method using two JASCO DS-701G Spectrophotometers at room temperature. The spectra were run at the rate of about 2.5 cm^{-1}/min. It was confirmed that no deformation of the observed band shape was induced at this scanning speed. For a band with a half-width of 10 cm^{-1} or narrower, it is very difficult to correct the observed half-width for deficiencies in the linearity of the wave number scale of the spectrophotometers. The reproducibility of the observed half-width on a spectrophotometer was good to within ±0.1 cm^{-1}, but the results from the two spectrophotometers differed from each other by about 0.3 cm^{-1}. Therefore, we estimated the error due to the uncertainty in the wave number scale to be ±0.2 cm^{-1}, although this estimate is rather arbitrary. The slit width was set to provide a resolution of about 1.5 cm^{-1}. Thus, the effect of the finite slit width on the band-width observed in the present study is insignificant.[24] Base lines were corrected for solvent absorption which exists more or less for all the solvents used. An error in the observed half-width due to uncertainties in drawing the base line and in reading the transmission on a chart was estimated to be 1%. Thus, the over-all error included in the observed half-width, ω_{obsd}, was estimated to be ±0.3 cm^{-1}.

Concentrations of methyl iodide in solutions were chosen in between 2.0 and 0.4 mol/l and the sample cells used were 0.2 to 1 mm thick. No concentration dependency of half-widths and solvent-induced frequency shifts, $\Delta\nu$, were observed for all the methyl iodide-solvent systems studied in the present work. The observed infrared absorption bands in some solutions are shown in Fig. 1.

Analysis of Bands and Results

The absorption bands of the solutions were measured at sample thicknesses of 0.2 mm or larger. For such weak bands, the deformation of the band shape by the dielectric field is negligible.[19)] The observed half-widths are shown in the fourth column of Table 1. The values reported previously[20–22)] are also entered in the last two columns. The present results agree fairly well with those of Higuchi *et al.*[22)] Except for the solutions in n-pentane and n-hexane which give rise to notably broader bands, the half-widths are identical to one another within the experimental errors. It appears to be difficult to determine a simple relation between the observed half-width and any physical quantity of the solvent, such as a relation associated with the viscosity of the solvent as proposed by Higuchi *et al.*[22)]

The band was decomposed into two components corresponding to the fundamental transition, $\nu_3(0\rightarrow1)$, and the hot-band transition, $\nu_3(1\rightarrow2)$, by the least-squares method based upon the following equation

$$I(\nu) = \frac{(\omega(0\rightarrow1)/2)^2 P(0\rightarrow1)}{(\nu-\nu^0(0\rightarrow1))^2+(\omega(0\rightarrow1)/2)^2} + \frac{(\omega(1\rightarrow2)/2)^2 P(1\rightarrow2)}{(\nu-\nu^0(1\rightarrow2))^2+(\omega(1\rightarrow2)/2)^2}$$

where $I(\nu)$ is the observed band intensity defined by $\ln(T_0/T)_\nu/\nu(1-\exp(-hc\nu/kT))$,[2)] and $\nu^0(m\rightarrow n)$, $\omega(m\rightarrow n)$, and $P(m\rightarrow n)$ are the wave number of the band center, the half-width, and the intensity of the band center for the m to n transition, respectively. The above equation contains six parameters to be adjusted. The second term is concerned with the hot band and accordingly, it makes only a small contribution to the total intensity. Since there must be a strong correlation between the parameters for the fundamental and hot bands, it was expected that the possible minor deviation of a single-transition band from a Lorentzian profile and small errors included in the observed intensity might obscure the resulting parameter values for the hot band. Indeed, it was found by a preliminary calculation that no plausible parameter values were obtained for the hot band. In such circumstances it is desirable to adjust the parameters under reasonable constraints.

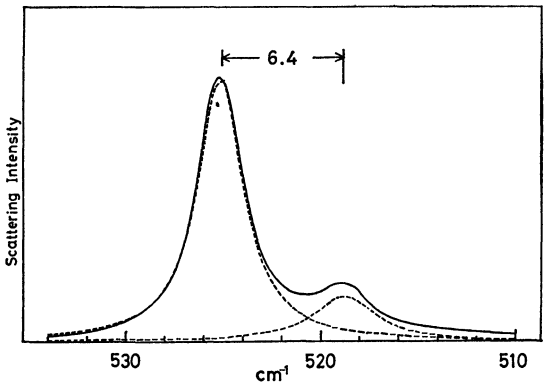

Fig. 2. The Raman ν_3 band of methyl iodide in carbon disulfide (1.8 mol/l). The band was decomposed into $\nu(0\rightarrow1)$ and $\nu(1\rightarrow2)$ using the Lorentzian functions shown by broken lines. The spectrum was recorded on a JASCO R300S Laser Raman Spectrophotometer.

The following two restrictions were then introduced into the calculations: (1) the ratio of the band areas, $[\omega(1\rightarrow2)\cdot P(1\rightarrow2)]/[\omega(0\rightarrow1)\cdot P(0\rightarrow1)]$, is equal to a theoretical value, $2\exp(-hc\nu/kT)$, which is 0.162 at $T=300$ K and $\nu=527\ cm^{-1}$, and (2), the separation between the fundamental and the first hot bands, $\nu^0(0\rightarrow1)-\nu^0(1\rightarrow2)$, is equal to the value in the gas phase, $6.6\ cm^{-1}$. This value was calculated from the fundamental and first overtone frequencies reported by Jones and Thompson[25)] by means of the relation $\nu^0(1\rightarrow2)-\nu^0(0\rightarrow1)=2x_{33}=\nu^0(0\rightarrow2)-2\nu^0(0\rightarrow1)$, where x_{33} is the anharmonicity constant for ν_3. This value is supported by the Raman spectrum of methyl iodide in carbon disulfide. As is shown in Fig. 2, the separation, $2x_{33}$, is almost the same as in the gas phase. The width of the highly-polarized Raman band is narrower than that of the infrared absorption band, so that the hot band is more conspicuous in the Raman spectrum.

The simulation was carried out over a range from 508 to $548\ cm^{-1}$ for the solutions in n-pentane, n-hexane, and carbontetrachloride, and a range from 504 to $544\ cm^{-1}$ for the solutions in carbon disulfide, chloroform, benzene, and bromobenzene. Figure 1 shows examples of the results. Good fits between the observed and calculated bands were obtained for

all the solutions except for slight discrepancies in the low-frequency wing. The higher hot-bands ignored in the above calculations are too weak to indicate this discrepancy. For the other a_1-type bands, ν_1 and ν_2, of methyl iodide, slight discrepancies were also found in the low-frequency wings,[4,21,26] although the general profile of each band was well reproduced by a Lorentzian function.[21] The deviation of the observed band from a Lorentzian function is a measure of the asymmetry of the band and will be discussed later.

The parameter values obtained are summarized in Table 1. If we take into account the fact that the values of $\omega(1\rightarrow2)$ involve more uncertainty than those of $\omega(0\rightarrow1)$, it may be said that the $\omega(0\rightarrow1)$ and $\omega(1\rightarrow2)$ values are nearly equal to each other in all the solutions studied and that they are about 10% smaller than the corresponding apparent half-widths, ω_{obsd}.

The band shape of the overtone, $\nu_3(0\rightarrow2)$, was determined from the spectrum of a solution in carbon disulfide. The overtone ν_3 band overlaps on the high-frequency wing of the strong degenerate vibrational band, ν_6. As may be seen in Fig. 3, the $\nu_3(0\rightarrow2)$ peak is well-resolved and the foot of the ν_6 band forms a strong background. Since the wing of the ν_6 band has been found to be well-reproduced by a Lorentzian function,[26] the spectrum ranging from 1010 to 1080 cm^{-1} was decomposed by means of the superposition of three Lorentzian functions. The analysis was carried out under the restriction, $\omega(0\rightarrow2)=\omega(1\rightarrow3)$, which was set referring to the results obtained for the fundamental band. The best fit parameters are as follows: $\nu^0(0\rightarrow2)=1046.7\ cm^{-1}$, $(\nu^0(1\rightarrow3)-\nu^0(0\rightarrow2))/2=-6.9\ cm^{-1}$ $(=2x_{33})$, $[\omega(1\rightarrow3)\cdot P(1\rightarrow3)]/[\omega(0\rightarrow2)\cdot P(0\rightarrow2)]=0.14$, and $\omega(0\rightarrow2)=\omega(1\rightarrow3)=13.2\ cm^{-1}$. The half-width of the hot band is larger than that of the fundamental band. The value of $2x_{33}$ obtained here agrees with the value of $-6.9\ cm^{-1}$, which is derived using the relation $2x_{33}=\nu^0(0\rightarrow2)-2\nu^0(0\rightarrow1)$. The value, $-6.6\ cm^{-1}$, assumed in the decomposition of the fundamental band is also satisfactorily close to $-6.9\ cm^{-1}$. The ratio of the band area, 0.14, is nearly the same as the ratio of 0.16, which was assumed in the analysis of the fundamental band.

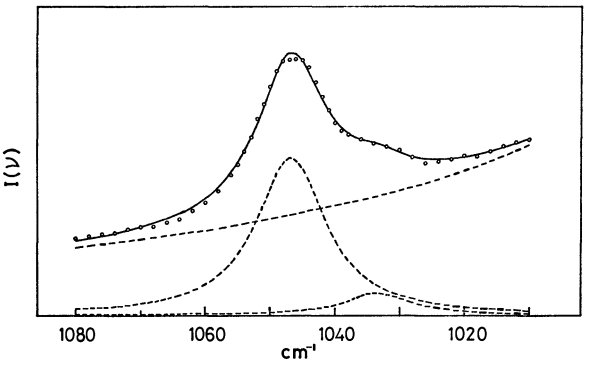

Fig. 3. The overtone $\nu_3(0\rightarrow2)$ band of methyl iodide in carbon disulfide solution (2 mol/l); ooo observed band, — calculated band, --- component bands; (1) $\nu_3(0\rightarrow2)$, (2) $\nu_3(1\rightarrow3)$, and (3) ν_6.

Discussion

An infrared band shape may be expressed by the convolution of spectral densities associated with the reorientational and vibrational relaxations of the transition dipole moment of a molecule.[15] If both of the relaxations are assumed to be characterized by exponential decays, the band width is given by the sum of the widths of the two spectral densities.[12]

The reorientational motion of a molecule should contribute equally to the band widths of the $\nu_3(0\rightarrow1)$, $\nu_3(1\rightarrow2)$, and $\nu_3(0\rightarrow2)$ transitions, for the vibration-rotation interaction, such as A_1-E type Coriolis interaction,[27] may be negligible in these transitions. Therefore, the observed difference in band-widths between the overtone and fundamental bands must be due to the difference in the vibrational relaxation for the two transitions.

According to Valiev,[28] the broadening of a quantum level due to the resonant exchange of vibrational energy between solute molecules is proportional to the square root of the product of its quantum number n and the concentration of the solution c. Then, the band broadening of the transition $n\rightarrow n'$ is given by the sum of the broadening of the n and n' vibrational levels as follows,

$$\omega_{res}(n\rightarrow n') = A\sqrt{c}(\sqrt{n}+\sqrt{n'}),$$

where A is a constant involving the dipole moment derivative with respect to the normal coordinate in question, the Stokes radius of the molecule, and the molecular weight. Accordingly, the half-widths for the $0\rightarrow1$, $1\rightarrow2$, and $0\rightarrow2$ transitions are given by $A\sqrt{c}$, $(1+\sqrt{2})A\sqrt{c}$, and $\sqrt{2}\,A\sqrt{c}$, respectively. However, the observed half-widths were independent of concentration, at least in the concentration range employed, and furthermore, $\omega(1\rightarrow2)$ and $\omega(0\rightarrow1)$ are nearly equal to each other and both are smaller than $\omega(0\rightarrow2)$. This means that the vibrational relaxation of the resonant exchange type does not contribute appreciably to the broadening of the C–I stretching band of methyl iodide in solution.

The vibrational relaxation of the translational diffusion type proposed by Bratos *et al.*[15] seems more favorable in order to interpret the present experimental results. According to their theory, the broadening of a band is related to the difference between the mean energies of the solute-solvent interaction in the two vibrational states involved in the transition. This difference is merely reflected in the solvent-induced frequency shift of the band center. The relationship between n and the frequency shift for a $0\rightarrow n$ transition, $\Delta\nu_{0n}$, was evaluated by Bratos *et al.*[15] As may be seen in Fig. 4 of Ref. 15, $\Delta\nu_{0n}$ is nearly proportional to n for a few lower vibrational states. This is obtained in the present study for the C–I stretching band of methyl iodide in carbon disulfide, *i.e.*, $\Delta\nu_{01}=6.4\ cm^{-1}$ and $\Delta\nu_{02}=13.2\ cm^{-1}$ [29]. Since $\Delta\nu_{12}=\Delta\nu_{02}-\Delta\nu_{01}$, $\Delta\nu_{12}$ is nearly equal to $\Delta\nu_{01}$. Bratos *et al.* also showed that the time scale in the decay of the vibrational relaxation function for the $n\rightarrow n'$ transition is inversely proportional to the frequency shift, $\Delta\nu_{nn'}$. Then, the

band broadening caused by vibrational relaxation of this type, $\omega_{tr}(n\rightarrow n')$, is roughly proportional to $\Delta\nu_{nn'}$. It follows that the values of $\omega_{tr}(0\rightarrow1)$ and $\omega_{tr}(1\rightarrow2)$ are nearly equal to each other and the value of $\omega_{tr}(0\rightarrow2)$ is about twice as large as those values. This is consistent with the information obtained about on the half-widths of $\omega(0\rightarrow1)$, $\omega(1\rightarrow2)$, and $\omega(0\rightarrow2)$. It has been pointed out that for a symmetric top molecule, the broadening of the isotropic component of an a_1-type Raman vibrational band arises exclusively from the vibrational relaxation of the molecules.[26,30-32] For the $\nu_3(0\rightarrow1)$ band of methyl iodide in carbon disulfide (concentration, 1.7 mol/l), the width of its isotropic component was measured to be 2.0 cm^{-1}.[33] The width due to vibrational relaxation may be the same for both the Raman and infrared absorption bands. If the observed value of 2.0 cm^{-1} is attributed to vibrational relaxation, then the contribution of the reorientational relaxation to $\omega(0\rightarrow1)$ is evaluated to be 6.3 cm^{-1} by subtracting the value of 2.0 cm^{-1} from the observed $\omega(0\rightarrow1)$ value. Moreover, if the vibrational relaxation is of the translational diffusion type, the $\omega(0\rightarrow2)$ value may be estimated by adding twice the vibrational contribution 2×2.0 cm^{-1}, to the reorientational one, 6.3 cm^{-1}. The resulting value of 10.3 cm^{-1} is smaller than the observed value of 13.2 cm^{-1} and is insufficient to interpret the observed width. Further explanation seems to be required to explain the broadening of the overtone band. Since the estimation of $\omega(0\rightarrow2)$ described above is very rough, it is inappropriate to draw any definite conclusion from the present results. However, for the time being, it appears that in addition to the reorientational relaxation, the vibrational relaxation of the translational diffusion type proposed by Bratos *et al.* contributes to the width of the ν_3 band.

A slight deviation from the Lorentzian function in the low-frequency wing was recognized in the observed band. In the band envelope of the ν_3 band of methyl iodide in the gas phase, the P branch has a longer tail than the R branch, as is shown in Fig. 4. This is due to the fact that the value of $B'-B''$ is not equal to zero because of the vibration-rotation interaction, where B is the rotational constant about the axis perpendicular to the three-fold symmetry axis, and the prime and double prime denote the excited and ground states respectively. This asymmetry of the band in the gas phase seems to correspond to that in the solution, although the latter is much less marked.[34]

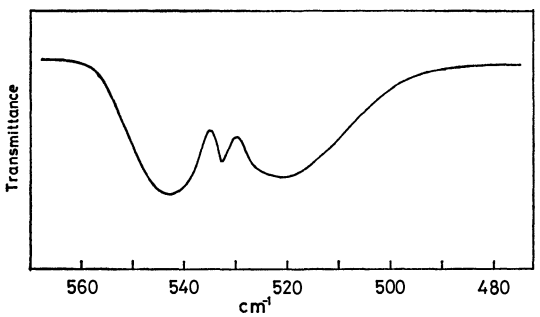

Fig. 4. The envelope of the infrared ν_3 band of methyl iodide in the gas phase.

The authors wish to thank Professors Kozo Tanabe and Osamu Yonemitsu of the Hokkaido University for permission to use the JASCO DS-701G infrared spectrophotometers. The numerical calculations were carried out on a FACOM 230—60 of the Hokkaido University Computing Center.

34) The value of $B'-B''$ for the $0\rightarrow2$ transition is about two times larger than that for the $0\rightarrow1$ transition. Thus, the overtone $\nu_3(0\rightarrow2)$ band should be more asymmetric than the fundamental $\nu_3(0\rightarrow1)$ band. However, such detailed character of the $\nu_3(0\rightarrow2)$ band cannot be discussed because of the uncertainty due to overlap with the intense ν_6 band.

The Triplet State of Acenaphthenequinone Crystals Studied by Means of Zeeman Spectroscopy

Mizuka SANO, Takatoshi NARISAWA, and Yasumasa J. I'HAYA

Department of Materials Science, The University of Electro-Communications, Chofu, Tokyo 182

(Received May 7, 1975)

The origin peak for the lowest singlet-triplet absorption transition of acenaphthenequinone crystals has been observed at 17981.7 cm^{-1} at 4.2 K. From the direction of the polarization and the Zeeman intensity pattern at 50 kOe, the lowest triplet-state configuration is identified as $^3B_1(n\pi^*)$. The transition to the state from the ground state gains its intensity from the z-polarized $^1A_1(\pi\pi^*)$—$^1A_1$ transition through the y-component in the spin-orbit interaction.

The phosphorescent emission of acenaphthenequinone has been reported to occur in various kinds of solvents[1,2] and in the vapor phase.[3] The spectral features, solvent effect, and lifetime are indicative of a triplet $n\pi^*$ emitting state. They, however, do not present information on the mechanism of spin-orbit coupling, through which the emission gains its intensity. If the emitting state were a pure triplet state, a radiative transition back to the ground singlet state would be forbidden by the spin-multiplicity rule. The phosphorescent emission indicates that the triplet state contains some singlet character through a spin-orbit interaction between the state and perturbing singlet states, and that the ground state contains a small admixture of a triplet character.

The transition from a ground state to a triplet state assumes a polarization of the transition to a perturbing singlet in the first-order approximation. Measurements of the polarized absorption spectra for single crystals will determine the polarization of the transition, and Zeeman spectroscopy will elucidate the mechanism of the spin-orbit interaction. In the presence of a sufficiently high, steady magnetic field, a triplet state splits into Zeeman levels which can be denoted by their magnetic quantum numbers. The relative probability for radiative transitions between the individual Zeeman levels and the ground state depends on a route effective in the spin-orbit coupling.

In this paper we will present sufficient experimental proof for the assignment of the lowest triplet-state configuration for acenaphthenequinone by determining both the polarization in absorption and an effective route in the interaction.

Experimental

Acenaphthenequinone (Tokyo Kasei Organic Chemicals) was purified by recrystallization three times from *o*-dichlorobenzene and then by repeated sublimation at 160 °C *in vacuo*. It could not be zone-refined, because it decomposed thermally upon prolonged heating at elevated temperatures. Single crystal platelets, *ca.* 30 μ thick with an area of *ca.* 6×3 mm^2, were obtained by sublimation. The platelets were found to be elongated along the c-axis, with the ac plane well developed, by X-ray diffractometry.

A crystal was mounted in an Oxford optical cryostat containing a 55 kOe superconducting magnet, and the absorption spectra were observed at 4.2 K. The spectra were analyzed with the aid of an NLM-E2M spectrometer with an Echelles grating in a 2-meter Czerny-Turner mount. The reciprocal dispersion at 550 nm was 0.068 nm mm^{-1} in the 10th order. They were photographed with Fuji spectroscopic plates and recorded with the aid of an HTV R189 photomultiplier tube and electrometer amplification. An Ushio 2 kW xenon arc was used as the light source, while a Polaroid HN-32 film placed between the crystal and the spectrometer acted as the polarizer.

The phosphorescence of a crystal immersed in liquid helium was excited by 365 nm radiation filtered from an ORC 1 kW superhigh pressure mercury arc through a $CuSO_4$ aqueous solution and Toshiba UV-DIC and UV-D25 filters.

Results and Discussion

The first peak was observed at 555.97 nm (17981.7 cm^{-1}) in the a-polarized absorption spectrum for a 30 μ thick crystal. The second peak, about 120 times stronger than the first one, was observed at 499.87 nm (19999.5 cm^{-1}). Under a magnetic field, the former was found to split into three lines, but the latter did not split, so the former could be assigned to the transition to a state of a triplet character, while the latter was assigned to a state of a singlet character. We could not find any prominent peak of a triplet character in the spectral region between these two peaks. Most of the intensity for the singlet-triplet transition lies in the first peak, which seems to show the feature of being orbitally allowed.

The phosphorescence spectrum observed at 2 K showed its first peak at 557.77 nm (17924 cm^{-1}). It is taken as the electronic origin of the phosphorescence. The spectral feature is also indicative of an orbitally allowed transition, the first peak being strongest in intensity in the spectrum. Another strong peak was found to be located at 1719 cm^{-1} from the origin. It is identified as the transition from the origin level to the ground-state vibrational level of the carbonyl stretching mode. The corresponding frequency in the Raman spectrum is 1724 cm^{-1}.[4] The good agreement between the values indicates that the phosphorescence originates not from an impurity but from crystalline acenaphthenequinone, probably from an X-trap level.

From these considerations, the first peak observed in the absorption spectrum is assigned to the origin for the lowest singlet-triplet transition. The second peak is assigned tentatively to the origin for the singlet-singlet transition.

The molecule is planar in a crystal, belonging to the C_{2v} point group. The z-axis is taken as the mole-

cular twofold axis, and the z, y-plane, as the plane of the molecule. The z-axis is approximately parallel with the crystallographic a-axis.[5] The polarization ratio for the triplet origin peak was found to be $I_a/I_c = 7.4+1.1$. The I_a/I_c ratios can be expected from the orientational data of the molecule to be 0.14, 0.24, and 6.4 for the x, y, and z polarizations respectively. The observed ratio indicates that the origin peak is predominantly z-polarized.

On the other hand, the singlet origin peak showed a polarization ratio of less than unity. This fact indicates that the peak is not z-polarized. More intense bands of a singlet character were observed around 22000 and 23000 cm^{-1} in the absorption spectrum for a crystal.

Figure 1 shows the Zeeman-absorption-intensity pattern for the triplet origin peak. The pattern was observed for a 30 μ thick crystal with the magnetic field directed along the b-axis, which is approximately perpendicular to the molecular z-axis. The single peak split into three sublines, the central line being found to be the most prominent in the magnetic-field direction mentioned above. The intensity ratio of the central line, I_0, to the wing lines, $I_{\pm 1}$, was found to be 13 at the field of 50 kOe.

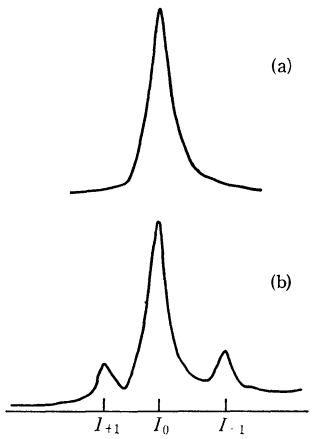

Fig. 1. Zeeman absorption pattern observed with the aid of a photomultiplier tube.
(a) $H=0$, (b) $H=50$ kOe, I_{+1}: 17985.8, I_0: 17981.7, I_{-1}: 17976.4 cm^{-1} (H//b, E//a).

If only one of the spin-orbit coupling routes is active in a spin-orbit interaction mechanism, the intensity ratio is expressed by:

$$\frac{I_0}{I_{\pm 1}} = \frac{2\rho}{1-\rho}, \tag{1}$$

where ρ is the squared direction cosine of the molecular axis with respect to the crystal axis along which a magnetic field is directed.[6] The calculated ratios are 0.29, 14.0, and 0 for the x, y, and z routes respectively, with the magnetic field directed along the b-axis of the crystal. Only when the y route is active, the central line is expected to be stronger than the wing lines. The experimental finding is consistent only with the route involved in the spin-orbit coupling being y (a B_1 representation in the C_{2v} point group).

A simple molecular orbital description of acenaphthenequinone leads to the prediction that the lowest triplet states are those corresponding to the lowest singlet $n\pi^*$ states, A_2 and B_1. Here we may conclude from the experimental results that the lowest triplet state belongs to $^3B_1(n\pi^*)$, and that the transition to this state gains its intensity mainly from the z-polarized $^1A_1(\pi\pi^*)-{}^1A_1$ transition through the y-route in the spin-orbit coupling mechanism. An intensity stealing from an allowed triplet-triplet transition is possible, but a large energy separation between a perturbing triplet and the ground state would reduce its contribution.

The Additions of Acetic Acid to Limonene over Solid Acid Catalysts

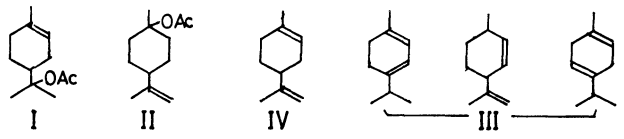
Tohr YAMANAKA

Central Research Laboratory of Takasago Perfumery Co., Ltd., Kamata, Ohta-ku, Tokyo 144

(Received May 13, 1975)

The addition of acetic acid (AcOH) to limonene (IV) over 111—333 g/l of solid acid catalysts, at 28—92 °C and in an excess of AcOH (19—100 times of IV in molarity), were studied in terms of the kinetic data, at a total conversion of IV less than 10 mol%, and in terms of acid strength distributions of the catalysts. In the reaction medium, a leveling of the acid strength on solids was observed. For the formation of α- and β-terpinyl acetates (I and II) and a mixture of the isomeric *p*-menthadienes (III) as by-products, (1) the rates are proportional to the square root of the initial concentrations of IV; (2) the apparent activation energies are 18.3 kcal/mol for all the catalysts, and (3) the pre-exponential factors are roughly proportional to the square root of the highest acidity ($h_{0,max}$) of the catalyst surface in the medium. The effects of the acid properties of the catalyst on the catalytic activity and the selectivity are different from those in a homogeneous liquid acid-catalyst system.

Recently,[1] we studied the addition of AcOH to limonene (IV), with H_2SO_4 as a catalyst, in a homogeneous system with a large excess of AcOH and without solvent. Considerable amounts of *p*-menthadienes (III) and β-terpinyl acetate (II) were formed besides the desired product, α-terpinyl acetate (I). It was regarded as very difficult to suppress the formation of III by the variation in the H_2SO_4 concentration.



Scheme 1.

In the present study, the kinetic data of the same additions over solid acids, such as metal sulfates and silica-alumina, in an AcOH solution were obtained and related to the acid properties of the solids in order to compare them with the previous results.[1] Those catalytic mechanisms were also discussed in connection with the catalytic activities and selectivities. In general, in the liquid phase, the extrapolations of the catalytic properties of homogeneous acids to heterogeneous solid acids are still uncertain,[2] although such extrapolations are desirable for both practical and theoretical reasons. Comparing the two catalytic systems experimentally will be helpful in establishing such extrapolations. The same reaction conditions as in the previous paper[1] were taken, except that solid catalysts were used instead of H_2SO_4.

Experimental

Solid Catalysts. $MgSO_4$, $Al_2(SO_4)_3$, $NiSO_4$, and $Fe_2(SO_4)_3$ of a guaranteed reagent grade and silica-alumina (Silica-alumina-L; Nikki Chemicals Co., Ltd.; termed Si-Al-L in this study) were ground and sieved to prepare powder of a 100—200 mesh. Some of them were calcined before grinding. $NiSO_4$ was calcined at 520 °C for 3 hr; $Fe_2(SO_4)_3$, at 100 °C for 3 hr, and $MgSO_4$, at 520 °C for 2 hr, all in a dry nitrogen stream. $Al_2(SO_4)_3$ and Si-Al-L were used without calcination.

Materials. Limonene (IV) was purified in the same way as before.[1] The content of IV was 96.7 wt%. AcOH was a guaranteed reagent and was not purified further.

Analysis. The composition of the products was determined by quantitative gas-chromatographic (glc) analysis with an internal standard, using a Shimadzu GC-3AH under the same conditions as before.[1]

Procedure. The reaction was the same as before,[1] except that a solid catalyst was suspended instead of H_2SO_4. A 24.3-g portion (which corresponds to a large excess over the stoichiometric requirement) of AcOH, 0.5—3.0 g of IV, and 3.0—9.0 g of the catalyst were used. At any reaction time, a 2—3 ml sample of the suspended solution of catalyst was taken out, diluted with 70 ml of NaCl-saturated water to stop the reaction, and extracted with *n*-hexane. The extract was then concentrated and used for the glc analysis.

During the reaction, sampling was repeated at arbitrary time intervals. The reaction temperature was 28—92 °C. The reference volume of the reaction mixture used to express the concentration of components or solids was taken at 28 °C. The concentration of IV was 0.151—0.782 mol/l, while that of the catalyst was 110.8—333 g/l.

Measurement of the Acid-base Strength Distribution. During the reaction, a drop of a basic indicator in benzene (0.1 wt%) was added to a portion of the suspended reaction medium in order to examine the existence of acid sites on the solid by means of the color change. The indicators used were Neutral red (+6.8), 1-phenylazo-4-naphthylamine (+4.0), Butter yellow (+3.3), *p*-(phenylazo)diphenylamine (+1.5), and dicinnamylideneacetone (−3.0); the values in parentheses are the pK_a values of the conjugate acids. On the other hand, a modified Johnson method[3] using a set of the same indicators was used to determine the acid-base strength distributions of fresh solids.

Results

Acidities of Catalysts. The acid-base strength distributions of the fresh catalysts are shown in Table 1, together with the qualitative data in the reaction medium, where H_0 denotes the acid strength on a solid defined by Benesi[5] employing the acidity function as defined by Hammett and Deyrup[4] in the liquid phase. The acidity and basicity in the reaction medium could not be titrated because of the existence of AcOH. Therefore, in Fig. 1, the extent of the color change to an acid one in the medium is indicated to decrease in this order: ++, +, −. As may be seen in Table 1, the stronger acid sites of most catalysts disappeared upon the addition of AcOH or IV. The range of the highest H_0 value of the remaining acid sites was estimated qualitatively from

TABLE 1. ACID-BASE STRENGTH DISTRIBUTIONS OF CATALYSTS

	Range of highest-H_0[a)]	Acid amount (meq/g) at different H_0				
		+6.8	+4.0	+3.3	+1.5	−3.0
$Fe_2(SO_4)_3$		0.969	0.848	0.751	0.175	0.071
	<−3.0	++	++	++	++	++
$NiSO_4$		9.502	0.393	0.278	0.127	0.070
	−3.0—+1.5	++	++	++	+	−
$Al_2(SO_4)_3$		0.097	0.083	0.075	0.037	B
	+1.5—+3.3	++	++	+	−	−
$MgSO_4$		0.191	0.101	0.0	B (0.035)[b)]	B
	+3.3—+4.0	++	+	−	−	−
Si-Al-L		1.67	1.47	0.570	0.169	0.089
	+1.5—+3.3	++	++	+	−	−

a) Remained range of highest-H_0 during reaction. b) Basic color of an indicator and the value in parenthesis shows the base amount.

the color change. Except for $Fe_2(SO_4)_3$, each catalyst lowered the highest H_0 value in the medium. In every reaction medium, the color in the liquid phase did not change, and the color change of a catalyst was not affected by the reaction time or by the amount of the catalyst.

Reaction Order. The components of the products were the same as in the homogeneous system —*i.e.*, I, II, and III. The concentration-time curve for each product, the acetates (I and II), and isomers (III) could be taken as a straight line when the total conversion of IV was less than 10 mol%. The formation rate (r_i) of I, II, and III was defined as $dC/d\theta$, where θ denotes the reaction time (hr). The C and i terms denote the concentration; the components I, II, and III, correspond to i=1, 2, and 3 respectively. Figure 1 shows the logarithmic plots of the initial rates (at $\theta=0$) *vs.* C_0 over Si-Al-L, where C_0 denotes the initial concentration of IV. The straight lines of the slope=0.5 indicate that every rate (r_i) at $\theta=0$ is proportional to the square root of C_0: $r_{i,\theta=0}=k_iC_0^{0.5}$. k_i was defined as a rate constant for each product.

Dependency on the Catalyst Amount. In Fig. 2,

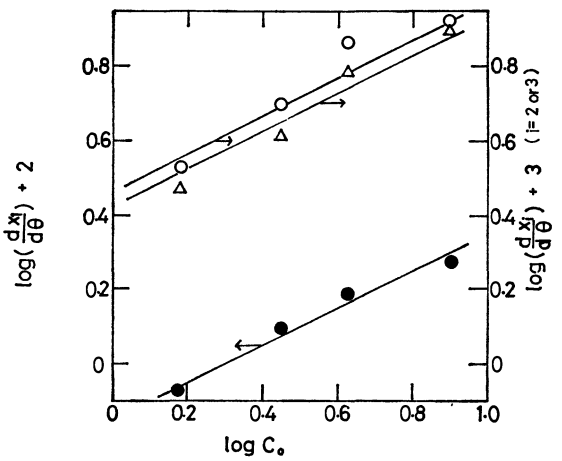


Fig. 1. Dependency of initial rates on initial concentrations of IV over Si-Al-L (166.5 g/l) at 78.5 °C. ●, I; ○, II; △, III.

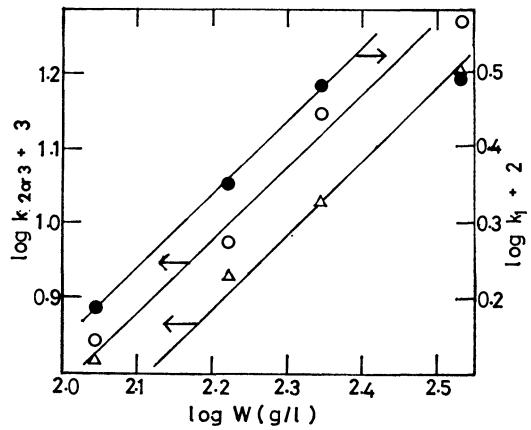

Fig. 2. Dependency of initial rates on amounts of Si-Al-L at $C_0=0.529$ mol/l and 78.5 °C. ●, I; ○, II; △, III.

the log k_i values are plotted against the log W of Si-Al-L. The linear correlation of the slope=1.0 for each product means that every k_i is proportional to W. It may be reasonable to consider that the catalytic action is restricted in the neighborhood of a solid surface in the heterogeneous catalyst system.

Temperature Dependency of k_i. In Fig. 3, the Arrhenius plots for k_i over every catalyst are shown. All the apparent activation energies (E_i) are the same in all cases, *i.e.*, 18,300 cal/mol. Therefore, the relative catalytic activity of the solids must be entirely due to the pre-exponential factors (A_i) of k_i in the equation: $k_i=A_i\exp(-E_i/RT)$. The constant activation energy in Fig. 3 suggests that all the reactions to form I, II, and III over each catalyst have equivalent rate-determinig steps and activated complexes with identical structures at the double bonds. A_i in every case was calculated to be as is shown in Table 2. In each catalyst, the A_i's are in almost the same order.

Effects of the Catalyst Acidity on the Activity and Selectivity. In Fig. 4, each log A_i is plotted against the highest H_0 value in the reaction medium. The correlations between log A_i and the highest H_0 seem to follow straight lines with a slope of ≈ 0.5. Therefore, the catalytic activities are roughly proportional

to the square root of the maximum h_0 (termed by $h_{0,max}$; highest $H_0=-\log(h_{0,max})$; $H_0=-\log h_0$) in the medium. When are compared A_i with the acid properties of catalyst (Tables 1 and 2), it must be noted that no significant correlation can be found between the highest H_0 or the acidity at a definite H_0 on the fresh catalyst and A_i.

The selectivities of the products depend entirely on the pre-exponential factors. They are presented in Table 2. The selectivity of I against II (A_1/A_2) lies in the range from 2.09 to 3.68. These values are different from those in the homogeneous system.[1] On the other hand, the selectivities of the isomers against the two acetates $A_3/(A_1+A_2)$ fall into two groups; one consists of $Fe_2(SO_4)_3$, $NiSO_4$, and $Al_2(SO_4)_3$ with 0.44—0.55, while the other consists of Si-Al-L and $MgSO_4$ with $\leq$0.27.

Discussion

Acid Sites in the Reaction Medium. In the medium, a positive shift of the highest H_0 from the original value was observed (Table 1). This must be due to a leveling effect[7] of the medium caused by a neutralization of the acid sites with AcO^-. Although IV may also neutralize acid sites, it has little effect because of its weak basicity. Therefore, the leveling effect must consist of the following steps:

$$2AcOH \rightleftharpoons AcOH_2^+ + AcO^- \quad (1)$$

$$AcO^- + HA_s \rightleftharpoons AcOH \cdot A_s^- \quad (2)$$

$$AcO^- + A_{sL} \rightleftharpoons AcO^- \cdot A_{sL} \quad (3)$$

where HA_s and A_{sL} denote a proton-acid site and a Lewis-acid site respectively. Steps (2) and (3) are possible with an acid site having $H_0 \leq 4.76$ (=pK_a of AcOH). A decrease in the AcO^- in Steps (2) and (3) will result in an increase of $AcOH_2^+$ *via* the autoprotolysis of Step (1). $AcOH_2^+$ also orients to sites where AcO^- has been adsorbed, there to supply the unbalanced negative charge of the surface by AcO^-. However, because of the low dielectric constant of the medium, the concentration of $AcOH_2^+$ can not be increased to finish the neutralization of acid sites, and the above steps will be settled into an equilibrium before the neutralization of the acid sites is complete. The case of $Fe_2(SO_4)_3$ seems to be the most obvious. After all, the leveling effect by Eqs. (1) to (3) will enrich the surface with AcOH.

The observed highest H_0 value in the reaction

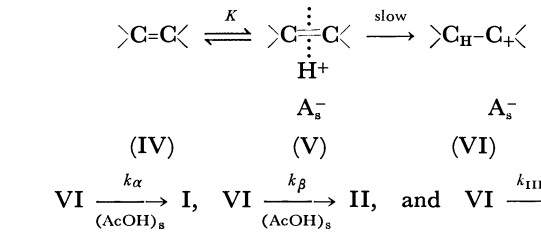
Table 2. Pre-exponential factors and selectivities

	Pre-exponential factors A_i ((mol/l)$^{0.5}\cdot$hr^{-1})			Selectivities	
	A_1	A_2	A_3	A_1/A_2	A_3/A_1+A_2
$Fe_2(SO_4)_3$	3.78×10^{12}	1.24×10^{12}	2.69×10^{12}	3.06	0.545
$NiSO_4$	1.27×10^{11}	3.44×10^{10}	7.13×10^{10}	3.68	0.443
$Al_2(SO_4)_3$	1.59×10^{10}	5.27×10^{9})	1.16×10^{10}	3.01	0.550
$MgSO_4$	6.62×10^{8}	3.16×10^{8}	—	2.09	—
Si-Al-L	6.33×10^{9}	2.60×10^{9}	2.38×10^{9}	2.44	0.266
H_2SO_4[a)]	8.90×10^{6}	6.91×10^{5}	5.24×10^{8}	12.9	0.6—1.7[b)]

a) Taken from the previous paper at $C_{H_2SO_4}$ 3.68×10^{-3} mol/l, and C_0 0.529 mol/l. In this case, A_i's are represented by hr^{-1}. b) The values in the range of 28 to 92 °C.

medium is considered to be the highest acid strength, among the remaining acid sites or some of the neutralized acid sites, capable of exchanging AcO^- with a weak base such as the indicators.

Catalytic Activity. It is clear that IV acts as a weak base to acid sites. Therefore, the following scheme can be postulated for the double bonds of IV with the remaining acid sites and AcOH on the surface:



In the above scheme, Step V→VI is considered to be the rate-determining step, because the diffusion of IV and the products (I, II, and III) in AcOH will be rapid enough; the activation energy is estimated to be 2—3 kcal/mol. Steps VI→I, VI→II, and VI→III can not be rate-determining steps because the same activation energies were observed.

The reaction rates are proportional to the concentration of the chemisorbed π-complex (C_v). C_v will be represented by $K\ C_{IV}^{1/n}$, where K denotes the apparent equilibrium constant in the chemisorption step (IV→V) and where n denotes a constant; $n=1$ in a chemisorption of the Langmuir type and $n>1$ in a chemisorption of the Freundlich type.[6] From the fact that each reaction rate (r_1) is proportional to $C_0^{0.5}$, within the low conversion range (Fig. 1), n can be estimated to be 2.0. This suggests a Freundlich-type adsorption and seems consistent with the concept of "surface heterogeneity,"[6] because a solid surface is considered heterogeneous in having sites of various acid strengths, or the surface, at least, behaves as a heterogeneous one the overall acid-strength, h_0, of which varies with the coverage of the sites. On the other hand, the fact that each pre-exponential factor (A_1) is proportional to $(h_{0,max})^{0.5}$ suggests that K is proportional to $(h_{0,max})^{0.5}$.

The apparent activation energy of overall reactions is the difference between the activation energy in Step V→VI and the apparent heat of the chemisorption. The equivalent activation energy over solids of various $h_{0,max}$ values suggests that the variation in the heats of chemisorption on different solid surfaces is negligibly small. Considering that the variation depends entirely on the variation in the energy of interaction between a protonated double bond and a conjugated anion (A_s^-), the interaction must be weak enough to result in a nearly constant heat of chemisorption.

The $K \propto (h_{0,max})^{0.5}$ relation explains the efficiency or the nature of the h_0 function on a solid surface. An h_0 is considered to be a parameter which indicates the overall ability of proton donation on the surface and its neighbor, supplied by various acid sites. Limonene (IV) will enter the vicinity of acid sites with the strength of h_0 and will be protonated at a double bond. The facility of the proton addititon will depend on h_0. The protonated IV will be immediately adsorbed to the anion (A_s^-), which itself came from an acid site upon the release of the proton. The adsorbed state, V, will be kept by an electrostatic interaction; the energy of the interaction seems neither to vary very much with the strength of the original acid site nor to be affected directly by h_0.

It must be noted that the catalytic mechanism in this study is quite different from that of the homogeneous catalyst system.[1]

Selectivity. According to the above scheme, the selectivities are represented:

$$A_1/A_2 = zK_\alpha/((1-z)k_\beta)$$

$$A_3/(A_1+A_2) = k_{III}/(C_{VII}[zK_\alpha+(1-z)k_\beta])$$

where z represents a fraction of C_8-position ion in C_{VI}; k_α, k_β, and k_{III} denote the rate constants in Step VI→I, VI→II, and VI→III respectively, of the above scheme; C_{VII} denotes the concentration of the AcOH adsorbed on the surface, $(AcOH)_s$.

The selectivity (A_1/A_2) will be determined by steric effects. The chemisorption (IV→V) at the double bond in the isopropenyl group is sterically more favored; $z>(1-z)$. On the contrary, in an adsorbed state, the carbonium ion at the β-position (C_1) might be less hindered from an attack of AcOH. Consequently, such a steric effect will settle the selectivity in a narrow range, compared with the case of the homogeneous system, where the α-position (C_8) is entirely predominant.[1]

The selectivity of III ($A_3/(A_1+A_2)$) will be due to the C_{VII} on the surface. The low selectivity of III over Si-Al-L may be interpreted in terms of the fact that a large number of acid sites are consumed, resulting in a large C_{VII} on the surface; the consumed acidity may be 0.169 meq/g, while it is 0.1 meq/g, at most, on the other solids. It must also be noted that, in a solid system, the formation of the isomeric *p*-menthadienes (III) can be suppressed by the selection and design of the catalyst, and that the effects of the steric factors and the catalyst acidity on the selectivity in a heterogeneous system are different from those in a homogeneous system.

We wish to thank the Takasago Perfumery Co., Ltd., for the permission to publish this article.

A Temperature-Jump Study of Electron-Transfer Reactions Involving Ion Radicals: Reactions of the Cation Radicals of Phenothiazine and Aromatic *p*-Diamines

Akihiko YAMAGISHI

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received May 16, 1975)

The reversible one-electron-transfer reactions of the following cation radicals were studied by temperature-jump and stopped-flow methods: phenothiazine (PhZ)/*N,N,N',N'*-tetramethyl-*p*-phenylenediamine cation (TMPD$^+$), PhZ/*N,N*-dimethyl-*p*-phenylenediamine cation (DMPD$^+$), DMPD/TMPD$^+$ and DMPD/*N,N,N',N'*-tetramethylbenzidine cation (TMBZ$^+$). The solvent used was either 1 : 3 ethanol–water or acetonitrile. For PhZ/TMPD$^+$, PhZ/DMPD$^+$ in ethanol–water and also for DMPD/TMPD$^+$ in acetonitrile, the backward reaction corresponding to the negative free energy change of reaction ($\Delta F^\circ < 0$) proceeds almost at the diffusion controlled rate. The backward rate constant for DMPD/TMPD$^+$ in ethanol–water, $(6\pm1)\times10^8$ M^{-1} s^{-1}, is slightly less than a diffusion controlled one even for $\Delta F^\circ < 0$. The results are discussed as compared with the previous study on 7,7,8,8-tetracyanoquinodimethane/substituted-*p*-benzoquinone anions.

In a previous paper, a study on the reversible one-electron-transfer reactions between 7,7,8,8-tetracyanoquinodimethane anion radical and substituted *p*-benzoquinones was given, attention being paid to the dependence of the rate constant on the free energy change of reaction.[1] It was revealed that the electron-transfer reaction proceeds with no activation free energy when the free energy change of reaction is negative. This result can not be interpreted by the application of the Marcus theory.[2]

The above results provide two possibilities for the mechanism of the electron-transfer; (i) there exists a non-equilibrium polarization of solvents at the activated state,[2] but the potential barrier due to it is much smaller than that expected by the theory, and (ii) the electronic interaction between electron donor and acceptor is so large as to cause an appreciable lowering of the potential surfaces. These two mechanisms could be discriminated, if it were possible to detect the relaxation process of solvent polarization before and after the electronic transition or to prove kinetically the existence of an intermediate complex as has been done in the innersphere electron-transfer reactions of metal ions.[3] At present, however, neither of these two approaches seems to be possible.

We have studied the reactions of cation radicals with the purpose of attacking the above problem from another approach. The reacting pairs studied differ from each other in molecular size, electronic structure and kind of substituent to varying extent. Accordingly the electronic interaction between an electron donor (neutral molecule) and an acceptor (cation radical) would vary a great deal from one extreme in which a stable intermediate (dimer cation) is possible, to the other extreme in which the overlap of electron clouds is hardly possible. By examining these effects on the reaction rates, we intended to see how far the electronic interaction between reactants dominates the electron-transfer rates.

Experimental

Phenothiazine (PhZ) was sublimed once. The dihydrochlorides of *N,N,N',N'*-tetramehyl-*p*-phenylenediamine (TMPD) and *N,N*-dimethyl-*p*-phenylenediamine (DMPD) were used without purification. The free base of DMPD was obtained by neutralizing it with NaOH and then extracting with diethylether. The obtained free base was sublimed once. *N,N,N',N'*-Tetramethylbenzidine(TMBZ) was used without purification.

Perchlorate salts of TMPD and DMPD (TMPD$^+$ClO$_4^-$ and DMPD$^+$ClO$_4^-$, respectively) were prepared according to the method of Michaelis and Granich.[4] Phenothiazine picrate (PhZ$^+$Pic$^-$) was supplied by Dr. Y. Iida. The cation radical of TMBZ was generated by electrolytic oxidation in acetonitrile, using a platinum electrode in 0.01 M tetra-*n*-propylammonium perchlrorate. The stability of these salts in various media was studied. Acetonitrile was distilled once using a distillating column of *ca.* 50 cm length (water content 0.5 mg/ml). Ethanol was distilled once. Water was deionized and distilled once.

The electronic spectra were measured with an EPS-3T spectrophotometer. pH was measured with a Radiometer equipped with G 200B glass electrode and K 100 reference calomel electrode. The concentration of proton in 1 : 3 ethanol–water solvent was calculated by means of the equation $p[H^+]=pH-\alpha$ ($\alpha=0.11$). This relation is obtained by measuring the pH of an ethanol–water mixture containing 10^{-2}—10^{-3} M of $HClO_4$. The variation of α with ionic strength (0—0.01 M) is neglected in calculating the proton concentration.

The rate of reaction was measured with a Union-Giken temperature-jump apparatus or a Union-Giken rapid-scan stopped-flow spectrophotometer. 0.01 M tetra-*n*-propylammonium perchlorate was added as a supporting electrolyte in measuring the rate in acetonitrile with a temperature-jump apparatus. Equilibrium and kinetic measurements were carried out at 10 °C. The effect of temperature at temperature-jump (2—5 °C) on the rate constants was considered to be negligible.

Results

A. Phenothiazine (PhZ) and N,N,N',N'-*Tetramethyl*-p-*Phenylenediamine (TMPD) Cation Radical System.* TMPD$^+$ClO$_4^-$ is stable in both water and ethanol at pH less than 8. Phenothiazine picrate (PhZ$^+$Pic$^-$) is stable in water at pH less than 3, but it decomposes rapidly in ethanol at any pH. The reaction between PhZ and TMPD$^+$ was, therefore, investigated in 1 : 3 ethanol–water solvent in the presence of more than 10^{-3} M HCl, since PhZ hardly dissolves in pure

TABLE 1. EQUILIBRIUM CONSTANT OF THE PhZ AND $TMPD^{+}$ SYSTEM

HCl/M	K_{ap}	$K_{ap}[H^+]^{-2}/M^{-2}$
4.5×10^{-3}	2.2×10^{-2}	1.1×10^{3}
9.1×10^{-3}	6.6×10^{-2}	0.80×10^{3}
18×10^{-3}	26×10^{-2}	0.80×10^{3}
35×10^{-3}	120×10^{-2}	1.0×10^{3}
67×10^{-3}	490×10^{-2}	1.1×10^{3}
		av. 0.96×10^{3}

water. The apparent equilibrium constant defined by

$$K_{ap} = [PhZ^{+}][TMPD]_t/[PhZ][TMPD^{+}]$$

is determined spectrophotometrically, adding a known amount of PhZ into a $TMPD^{+}ClO_4^{-}$ solution at a constant HCl concentration. Parenthesis $[\ ]_t$ represents the total concentration of TMPD, since TMPD is present as $TMPDH^{+}$ and $TMPDH_2^{++}$ in the pH region (1.3—2.5). $[PhZ^{+}]$ and $[TMPD^{+}]$ are determined, using the values ε_{437} (PhZ^{+}) 5.7×10^{3} and ε_{612} ($TMPD^{+}$) 1.1×10^{4}, respectively.[5,6] $[TMPD]_t$ is equated to the decrease of $TMPD^{+}$. The presence of the isosbestic point at 520 nm confirms the view that the one-electron-transfer reaction occurs between PhZ and $TMPD^{+}$.

$$PhZ + TMPD^{+} \rightleftharpoons PhZ^{+} + TMPD \quad (1)$$

K_{ap} is remarkably dependent on $[H^+]$ as seen in Table 1. The observed H^+ dependence of K_{ap} is ascribed to the protonation of TMPD in acidic media.

$$TMPD + H^+ \rightleftharpoons TMPDH^+;\ K_{a1} \quad (2)$$

$$TMPDH^+ + H^+ \rightleftharpoons TMPDH_2^{++};\ K_{a2} \quad (3)$$

Assuming that no protonation takes place on either PhZ or cation radicals, K_{ap} is expressed as

$$K_{ap} = (1+K_{a1}[H^+]+K_{a1}K_{a2}[H^+]^2)K$$

where K_{a1}, K_{a2} and K are the equilibrium constants of reactions (2), (3) and (1), respectively. K_{a1} and K_{a2} are determined by the pH titration of TMPD·2HCl with 0.02 M NaOH.

$K_{a1} = (3.3\pm1)\times10^{6}\ M^{-1}$

$K_{a2} = (3\pm2)\times10^{2}\ M^{-1}$ in 1 : 3 ethanol-water

The relations $1 \ll K_{a1}[H^+] \ll K_{a1}K_{a2}[H^+]^2$ hold in the pH range (1.3—2.5). Thus K_{ap} is reduced to

$$K_{ap} = K_{a1}K_{a2}K[H^+]^2$$

This expression agrees with the observed H^+ dependence of K_{ap} (the last column, Table 1). The true equilibrium constant K of reaction (1) is determined to be 0.96×10^{-6} at 10 °C, which leads to 7.8 kcal mol^{-1} for the free energy change of reaction (1).

The relaxation time observed by the temperature-jump experiments (*ca.* 1 s) exceeds the duration within which a raised temperature is maintained (*ca.* 0.5 s). The rate of this system is, therefore, followed with a stopped-flow apparatus. The backward rate of reaction (1) is obtained by mixing the $PhZ^{+}Pic^{-}$ solution with the TMPD·2HCl solution under the conditions of a large excess of TMPD·2HCl over $PhZ^{+}Pic^{-}$. The decrease of PhZ^{+} is exponential with time, leading to the following rate equation (Table 2),

TABLE 2. PSEUDO FIRST-ORDER RATE CONSTANT k_{obsd} OF THE REACTION BETWEEN PhZ^{+} AND TMPD

a) Dependence of k_{obsd} on [TMPD]. The initial concentrations of PhZ^{+} and HCl are $[PhZ^{+}]_0$ 3.0×10^{-6} M and $[HCl]_0$ 3.0×10^{-2} M, respectively.

HCl/M	k_{obsd}/s^{-1}	$k_{obsd}[H^+]^{-2}/M^{-2}\,s^{-1}$
9.4×10^{-2}	0.72	3.4×10^{-3}
5.6×10^{-2}	1.7	5.2×10^{-3}
3.8×10^{-2}	2.7	3.8×10^{-3}
1.9×10^{-2}	7.9	2.7×10^{-3}
		av. 3.8×10^{-3}

$$-d[PhZ^{+}]/dt = k_b[TMPD]_t[H^+]^{-2}[PhZ^{+}], \quad (4)$$

$$k_b = 12\pm2\ M\,s^{-1}$$

where the contribution of the forward rate is neglected, since the equilibrium concentration of PhZ^{+} is zero.

The forward rate is obtained by mixing the $TMPD^{+}ClO^{-}$ solution with the PhZ solution under the conditions of a large excess of $TMPD^{+}ClO_4^{-}$ over PhZ. The pseudo first order rate constant of the decrease of $TMPD^{+}$ is plotted against $[H^+]$ in Fig. 1. Although k_{obsd} increases slightly with the increase in $[H^+]$, it approaches a constant value k_f as $[H^+]$ decreases. Thus the rate equation in the low $[H^+]$ region is given by

$$-d[PhZ]/dt = k_f[PhZ][TMPD^{+}] \quad (5)$$

$$k_f = (8\pm2)\times10^{3}\ M^{-1}\,s^{-1}$$

The ratio k_f/k_b is equal to $(0.7\pm0.2)\times10^{3}\ M^{-2}$ which agrees with the equilibrium constant $K_{ap}[H^+]^{-2} = 0.96\times10^{3}\ M^{-2}$ (Table 1).

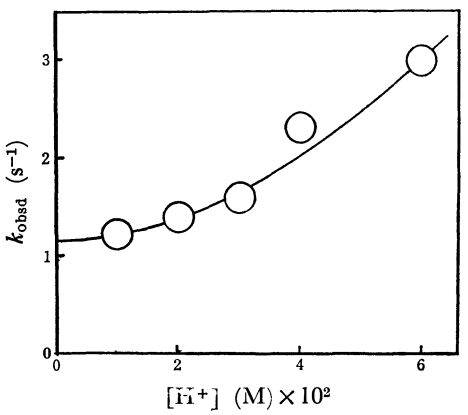

Fig. 1. The dependence of k_{obsd} on $[H^+]$ in the reaction between $TMPD^{+}$ and PhZ in 1 : 3 ethanol-water. $[TMPD^{+}]_0$ 1.7×10^{-4} M and [PhZ] 9.0×10^{-6} M.

The H^+ dependence of the backward rate could be interpreted by the assumption that the overall reaction proceeds only through the neutral form of TMPD, and through neither $TMPDH^+$ nor $TMPDH_2^{++}$. Under this assumption, k_f and k_b in Eqs. (5) and (4) are related to the forward and backward rate constants of Reaction (1), $\vec{k}$ and $\overleftarrow{k}$, respectively, as follows,

$$k_f = \vec{k} \text{ and } k_b = \overleftarrow{k}/K_{a1}K_{a2}$$

Thus

$$\vec{k} = (8\pm2) \times 10^3 \text{ M}^{-1} \text{ s}^{-1}$$

$$\overleftarrow{k} = (1.4\pm0.7) \times 10^{10} \text{ mol}^{-1} \text{ s}^{-1}.$$

The large uncertainty in $\overleftarrow{k}$ arises from the uncertainty of determining K_{a2}. The inertness of $TMPDH^+$ and $TMPDH_2^{++}$ in donating an electron was observed in both $TMPD^+$/DMPD and $TMPD^+$/TMPD systems.[7,8] The origin of the increase of k_f in the high $[H^+]$ region is uncertain.

B. Phenothiazine (PhZ) and N,N-*Dimethyl*-p-*Phenylenediamine (DMPD) Cation Radical System.* $DMPD^+ClO_4^-$ is less stable than $TMPD^+ClO_4$. It decomposes gradually in 1 : 3 ethanol–water solvents.

Table 3. Equilibrium constant of the PhZ and $DMPD^+$ system

HCl/M	K_{ap}	$K_{ap}[H^+]^{-1}/M^{-1}$
6.3×10^{-4}	6.4×10^{-2}	1.0×10^2
12×10^{-4}	12×10^{-2}	1.0×10^2
19×10^{-4}	21×10^{-2}	1.1×10^2
27×10^{-4}	54×10^{-2}	2.0×10^2
		av. 1.0×10^2

The decomposition is, however, depressed in the presence of excess TMPD. K_{ap} is determined by adding PhZ^+Pic^- to the DMPD solution (Table 3). $[DMPD^+]$ is calculated from the absorbance, using $\varepsilon_{555}=6.4\times10^3$.[6] In the $[H^+]$ range investigated, the monoprotonated form of DMPD is predominant.

$$DMPD + H^+ \rightleftharpoons DMPDH^+ ; K_{a1}$$

K_{ap} is related to K, the true equilibrium constant of the reaction, as follows.

$$PhZ + DMPD^+ \rightleftharpoons PhZ^+ + DMPD \quad (6)$$

$$K_{ap} = K K_{a1}[H^+]$$

where $K_{a1}[H^+] \gg 1$ is assumed. Using $K_{a1}=(3.3\pm0.3)\times10^6$ which is determined by the pH titration, K is calculated to be

$$K = (3\pm1) \times 10^{-5}$$

$$\Delta F^\circ = 5.9 \text{ kcal mol}^{-1}.$$

The rate of reaction (6) was studied with a temperature-jump apparatus. The pseudo first order rate constant defined by

$$d\Delta[DMPD^+]/dt = -k_{obsd}\Delta[DMPD^+]$$

is given as a function of $[H^+]$ (Fig. 2). Under the assumption that $DMPDH^+$ is inert in electron–transfer, k_{obsd} is expressed as

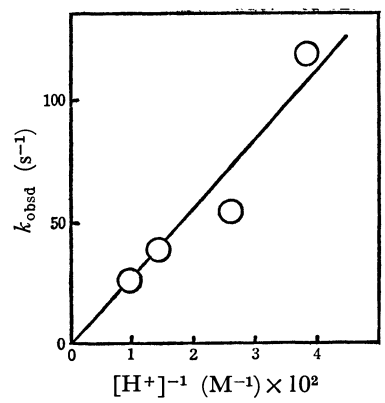

Fig. 2. The dependence of k_{obsd} on $[H^+]^{-1}$ in the reaction between PhZ and $DMPD^+$ in 1 : 3 ethanol–water. $[DMPDH^+]_e$ 2.5×10^{-4} M, $[PhZ]_e$ 3.1×10^{-5} M, $[DMPD^+]_e$ 8.9×10^{-5} M and $[PhZ^+]_e$ 8.9×10^{-5} M.

$$k_{obsd} = \vec{k}\{[PhZ]_e + [DMPD^+]_e\} + \overleftarrow{k}/(K_{a1}[H^+]) \times \{[DMPDH^+]_e + [PhZ^+]_e\}_c \quad (7)$$

where $\vec{k}$ and $\overleftarrow{k}$ are the forward and backward rate constants, respectively, of reaction (6) and $[\ ]_e$ denotes the equilibrium concentration of each species at the elevated temperature. Fig. 2 shows the linear dependence of k_{obsd} on $1/[H^+]$, the second term in Eq. (7) being taken to be predominant. From the results and the relation $K=\vec{k}/\overleftarrow{k}$, we get

$$\vec{k} = (1.0\pm0.5) \times 15^5 \text{ M}^{-1} \text{ s}^{-1}$$

$$\overleftarrow{k} = (2.8\pm1) \times 10^9 \text{ M}^{-1} \text{ s}^{-1}.$$

C. N,N-*Dimethyl*-p-*Phenylenediamine (DMPD) and* N,N,N′,N′,-*Tetramethyl*-p-*Phenylenediamine (TMPD) Cation Radical System.* A study of the TMPD/$DMPD^+$ system in water was reported previously.[7]

$$DMPD + TMPD^+ \rightleftharpoons DMPD^+ + TMPD \quad (8)$$

The forward and backward rate constants obtained are

$$\vec{k} = (4.2\pm2) \times 10^5 \text{ M}^{-1} \text{ s}^{-1},$$

$$\overleftarrow{k} = (1.5\pm0.2) \times 10^8 \text{ M}^{-1} \text{ s}^{-1}.$$

Since $\overleftarrow{k}$ which corresponds to the negative free energy change of reaction is apparently below a diffusion controlled limit in contrast to $\overleftarrow{k}$ in Reactions (1) and (6), the same system was studied in acetonitrile in order to clarify the role of solute-solvent interaction in electron-transfer.

$TMPD^+ClO_4^-$ is stable in acetonitrile. K for Reaction (8) in acetonitrile was, therefore, obtained spectrophotometrically by adding DMPD to the $TMPD^+ClO_4^-$ acetonitrile solution. The gradual decomposition of $DMPD^+$ causes about 40% error in K.

$$K = (3.8\pm1.5) \times 10^{-2}$$

$$\Delta F^\circ = 1.8 \text{ kcal mol}^{-1}$$

The rate was measured with a temperature-jump apparatus. k_{obsd} values at various concentrations are iven in Table 4. Here k_{obsd} is defined by the relation

TABLE 4. k_{obsd} OF THE TMPD AND DMPD$^+$ SYSTEM IN ACETONITRILE

C[a)]/M	k_{obsd}/s^{-1}	$k_{obsd}\,C^{-1}/M^{-1}\,s^{-1}$
1.2×10^{-5}	7.0×10^{4}	6.0×10^{9}
2.5×10^{-5}	12×10^{4}	5.0×10^{9}
6.4×10^{-5}	19×10^{4}	3.0×10^{9}
26×10^{-5}	35×10^{4}	1.3×10^{9}
		av. $4\pm2\times10^{9}$

a) C is defined as $K([TMPD^+]_e+[DMPD]_e)+[TMPD]_e+[DMPD^+]_e$. $[TMPD]_e$ $4.0-40\times10^{-5}$ M, $[DMPD]_e$ $8-25\times10^{-3}$ M, $[DMPD^+]_e$ $4.0-40\times10^{-5}$ M and $[TMPD^+]_e$ $9-25\times10^{-6}$.

$$-d\Delta[TMPD^+]/dt = k_{obsd}\Delta[TMPD^+],$$

and expressed by

$$k_{obsd} = \vec{k}\{[TMPD^+]_e+[DMPD]_e\} + \overleftarrow{k}\{[TMPD]_e+[DMPD^+]_e\},$$

or

$$= \overleftarrow{k}[K\{[TMPD^+]_e+[DMPD]_e\} + \{[TMPD]_e+[DMPD^+]_e\}],$$

where $K=\vec{k}/\overleftarrow{k}$. $\vec{k}$ and $\overleftarrow{k}$ are determined to be

$$\vec{k} = (1.5\pm1)\times10^{8}\ M^{-1}\,s^{-1},$$

$$\overleftarrow{k} = (4\pm2)\times10^{9}\ M^{-1}\,s^{-1}.$$

$\overleftarrow{k}$ is almost a diffusion controlled rate constant (*ca.* $10^{10}\ M^{-1}\,s^{-1}$) in acetonitrile. It is, therefore, concluded that the low value of $\overleftarrow{k}$ in water arises from the water-solute interaction, or most likely from the hydrogen-bonding of water on the nitrogen atoms of the amino groups in TMPD and DMPD.

D. N,N-Dimethyl-p-Phenylenediamine (DMPD) and N,N,N',N'-Tetramethylbenzidine (TMBZ) Cation Radical System. Electrolytically generated TMBZ$^+$ is stable in acetonitrile. Thus the equilibrium constant of reaction (9) is determined by adding DMPD to the solution containing TMBZ$^+$ and excess TMBZ (Fig. 3).

$$DMPD + TMBZ^+ \rightleftharpoons DMPD^+ + TMBZ \qquad (9)$$

The isosbestic point at 486 nm confirms the occurrence of the one-electron-transfer from DMPD to TMBZ$^+$. The equilibrium constant is determined to be

$$K = (3\pm1)\times10^{3}$$

and

$$\Delta F^\circ = -4.6\ \text{kcal mol}^{-1}$$

The molar extinction coefficient of TMBZ$^+$ $\varepsilon_{472}=2.5\times10^{4}$ is also obtained from the result in Fig. 3. At a large excess of DMPD over TMBZ$^+$, the isosbestic point at 472 nm disappears, showing the decomposition of cation radicals. When the temperature-jump measurements were performed, only an increase of the transmittance was observed in the time range of 50 μs at 470—550 nm, corresponding to the decrease of DMPD$^+$ at the temperature rise, no increase of TMBZ$^+$ being observed at 400—470 nm. It is not certain whether the signal obtained actually corresponds to the electron-transfer reaction (9).

We have tried to obtain the forward rate of reaction (9) with a stopped-flow apparatus, using a 1 : 3 : 0.4 ethanol–water–acetonitrile solvent. TMBZ$^+$ is stable in this solvent for $[H^+]<10^{-3}$ M. In more acidic media, the fine structure in the electronic spectra of TMBZ$^+$ in 430—480 nm is smoothed out, indicating the conversion of TMBZ$^+$ into another species. Thus the rate was measured by mixing the TMBZ$^+$ solution with the solution containing DMPD and HCl less than 10^{-3} M. The pseudo first-order rate constant of the decrease of TMBZ$^+$ depends linearly on $1/[H^+]$ (Fig. 4). Assuming that DMPDH$^+$ is inert in donating an electron, the forward rate constant of reaction (9), $\vec{k}$, is obtained from the relation

$$k_{obsd} = \vec{k}/(K_{a1}[H^+])\cdot[DMPDH^+].$$

This leads to

$$\vec{k} = (6\pm2)\times10^{8}\ M^{-1}\,s^{-1},$$

where K_{a1} is assumed to be equal to the one obtained

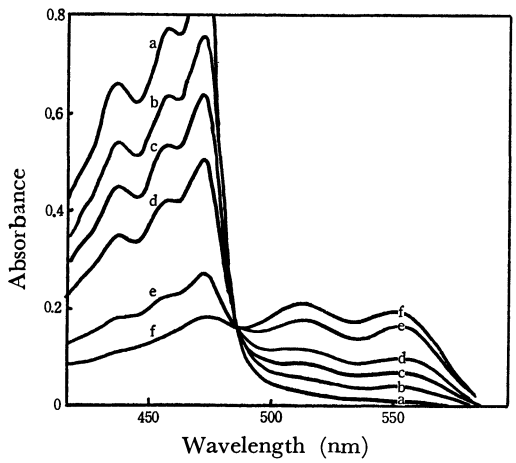

Fig. 3. The variation of the electronic spectrum of TMBZ$^+$ with the addition of DMPD in acetonitrile. a) TMBZ$^+$ only b)—e) DMPD added to the amount of 2.4×10^{-5} M f) no TMBZ$^+$ left when 3.3×10^{-5} M DMPD added.

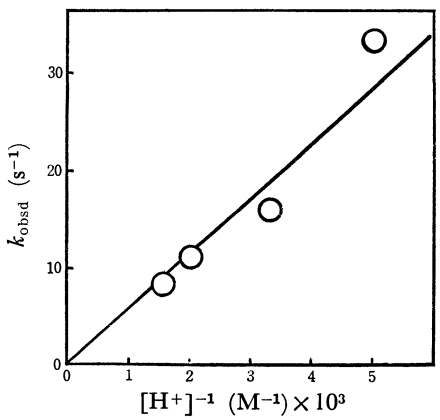

Fig. 4. The dependence of k_{obsd} on $[H^+]^{-1}$ in the reaction between TMBZ$^+$ and DMPD in 1 : 3 : 0.4 ethanol–water–acetonitrile. $[DMPD]=2.0\times10^{-5}$ M. $[TMBZ^+]_0=2.0\times10^{-6}$ M.

in 1 : 3 ethanol–water solvent. $\vec{k}$ is apparently below a diffusion controlled limit, which is analogous to the DMPD/TMPD^{+} system in water.

Discussion

The observed rate constants are plotted against the free energy change of reaction, $\Delta F°$ (Fig. 5). For the systems, PhZ/TMPD^{+}, PhZ/DMPD^{+} in ethanol–water, and DMPD/TMPD^{+} in acetonitrile, the rate constants for $\Delta F°<0$ are nearly equal to a diffusion controlled limit. The systems are quite analogous to the reactions between tetracyanoquinodimethane anion radical and substituted *p*-benzoquinones in acetonitrile.[1] In the latter systems, too, the rate constants for $\Delta F°<0$ are in the range 10^{9}—10^{10} M^{-1} s^{-1} at 25±2 °C. Thus, the results may lead us to the conclusion that the electron-transfer between a free organic ion radical and a neutral molecule takes place with no activation free energy, as long as $\Delta F°$ is less than zero, unless the rigid solvation structure or ion pairing is formed around reactants. This conclusion is consistent with the results accumulated for the electron exchanges between free organic ion radicals and their parent molecules.[8]

It should be noted that the electron-transfer from TMPD to PhZ^{+} proceeds at the same rate of magnitude as from DMPD to PhZ^{+} in spite of the increased steric hindrance of TMPD due to additional methyl groups on nitrogen atoms. As far as the dimerizations of TMPD^{+} and DMPD^{+} are concerned, the interaction between two cation fragments is appreciably diminished because of the presence of methyl groups.[9] It is concluded that the electronic interaction which operates in the electron-transfer of cation radicals is of a considerably different nature from the one operating in dimerization.

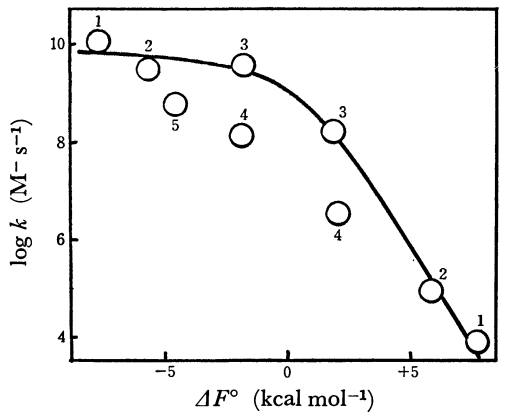

Fig. 5. The rate constants plotted against $\Delta F°$: (1) PhZ/TMPD^{+}, (2) PhZ/DMPD^{+}, (3) DMPD/TMPD^{+} (in acetonitrile) (4) DMPD/TMPD^{+} (in water), (5) DMPD/TMBZ^{+}.

In contrast to the above systems, the rate constants for the systems, DMPD/TMPD^{+} in water and DMPD/TMBZ^{+} in ethanol–water–acetonitrile, are about one order less than a diffusion controlled limit, even when $\Delta F°$ is negative. The origin for these slower rates is not certain. One possiblility is that the strong solvent-solute interaction causes an additional energy barrier to the electron-transfer as was reported for the electron exchange of nitrobenzene anion radical in acetonitrile/water.[10] In the systems showing slower rate constants, the nitrogen atoms on the amino groups of aromatic *p*-diamines seem to be hydrogen-bonded with water molecules. The difficulty in this interpretation lies in the fact that these hydrogen bonds do not slow down the rates of reactions between phenothiazine cation and TMPD or DMPD.

The author thanks Professor Masatoshi Fujimoto for his continuous encouragement, Dr. Mitsuyuki Soma for his valuable suggestions and Dr. Yoichi Iida for kindly supplying the materials. The work was supported by the Ministry of Education.

Nuclear Quadrupole Resonance of Tellurium Tetraiodide

Tsutomu OKUDA, Koji YAMADA, Yoshihiro FURUKAWA, and Hisao NEGITA
Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730
(Received May 22, 1975)

The nuclear quadrupole resonance (NQR) of ^{127}I in tellurium tetraiodide was observed, and the Zeeman effect on a single crystal was examined. Tellurium tetraiodide shows ten resonance lines in the frequency range from 195 to 260 MHz. From the analysis of the zero-splitting patterns, it has become apparent that tellurium tetraiodide crystals contain eight nonequivalent iodine atoms, two of which yield large asymmetry parameters (94.9% and 73.8%) and small quadrupole coupling constants (775.07 MHz and 929.55 MHz) at room temperature. These two may be assigned to the bridging iodine atoms, but they differ markedly from each other in the temperature dependences of e^2Qq/h and η. The other six iodine atoms have small η values and coupling constants of about 1600 MHz; they are assigned to the terminal atoms. From these results, it may be concluded that each tellurium atom has three terminal and two bridging iodine atoms.

The crystal structures of tellurium tetrachloride ($TeCl_4$)[1] and tellurium tetrabromide ($TeBr_4$)[2] are ionic and consist of tetramers $(TeX_3^+X^-)_4$ which have approximately the T_d symmetry. On the other hand, in the solid tellurium tetrafluoride (TeF_4)[3] each tellurium atom is surrounded by three terminal and two bridging atoms at the corners of a distorted square pyramid. These square pyramid units are linked by *cis* bridging into an endless chain. From the far-infrared spectrum of TeI_4,[4] it was concluded that TeI_4 has an ionic structure such as $TeI_3^+I^-$, because the spectrum is similar to those of SbI_3. According to the X-ray diffraction studies,[5] the crystal structure of TeI_4 belongs to an orthorhombic system with a space group P_{nma} or $Pn2_1a$, but its detailed structure has not been reported so far. In the NQR studies of $TeCl_4$ and $TeBr_4$,[6] six resonance lines were observed for both compounds; these lines were assigned to two species of TeX_3^+ (X=Cl, Br) ions. In this connection, we observed the ^{127}I NQR of TeI_4 and examined the Zeeman effect on a single crystal in order to determine the e^2Qq/h and η for each resonance line.

Experimental

The NQR spectrometer used in this experiment was a super-regenerative oscillator with frequency modulation, while the resonance frequencies were determined with a VHF signal generator and a frequency counter, TR-5578, from the Takeda Riken Co., Ltd. The Zeeman effect was examined by means of the zero-splitting cone method[7] on an oscilloscope at room temperature. The magnetic field of about 250 G was applied by means of a Helmholtz coil. The orientation of the magnetic field for the zero-splitting was determined by polar coordinates (Φ, Θ), where Φ and Θ are the azimuthal and polar angles respectively, in the coordinate system fixed to the sample. The single crystal of TeI_4 was grown by the Bridgman-Stockbarger method.

Results and Discussion

Zeeman Effect. As is shown in Table 1, ten resonance lines were observed in the frequency range from 195 to 260 MHz. As the nuclear spin of ^{127}I is equal to 5/2, a pair of NQR lines, ν_1 and ν_2, corresponding to the $\pm1/2\leftrightarrow\pm3/2$ and $\pm3/2\leftrightarrow\pm5/2$ transitions, are to be found for each kind of iodine atoms.[7] Therefore, the asymmetry parameter (η) and the quadrupole coupling constant (e^2Qq/h) can be derived from the frequency ratio, ν_1/ν_2. In the present compound, however, it is necessary to observe the Zeeman effect on each line in order to determine whether it is ν_1 or ν_2, and which ones form a pair, because the resonance lines distributed very widely.

In general, the zero-splitting cone can be expressed in the principal axis system of the efg tensor as follows:[7]

$$\sin^2\theta = \frac{A}{B+C\cos_2\phi} \qquad (1)$$

where θ and ϕ are, respectively the polar and azimuthal angles of the magnetic field which shows zero-splitting.

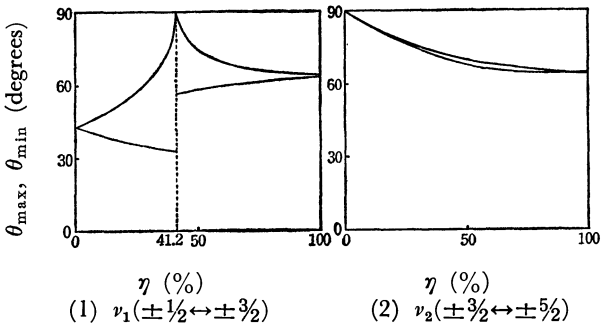

Fig. 1. Calculated maximum and minimum zero-splitting angles as a function of η for ν_1 and ν_2.

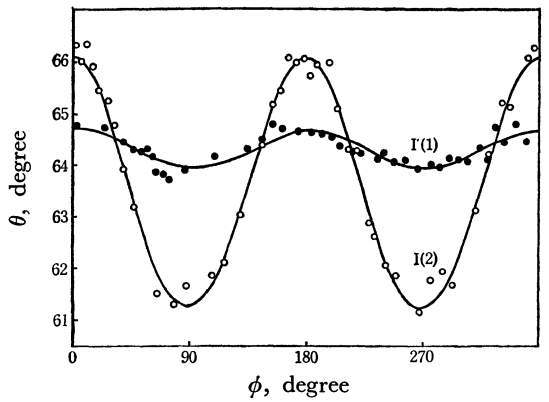

Fig. 2. Zeeman zero-splitting patterns of I'(1) and I(2) lines in the efg principal axis system.

Table 1. NQR parameters of TeI_4 (296 K and 77 K)

a) Obtained from the Zeeman effects. b) Obtained from the frequency ratio (ν_1/ν_2) using tabulated values of spin 5/2. c) The values in parentheses correspond to 77 K.

For the case of the 5/2 spin, A, B, and C can not be expressed in simple formulas when η is large. Hence, the maximum and minimum values of θ were calculated as a function of η for ν_1 and ν_2, as is shown in Fig. 1, according to the literature.[7,8] The zero-splitting patterns of I′(1) and I(2) lines are shown in Fig. 2 in the principal-axes system. The maximum and minimum values of θ for the zero-splitting patterns were obtained by the use of the least-squares method. These values were 66.1° and 61.3° for the I(2) pattern and 64.7° and 63.9° for that of I′(1). On the basis of these values, the I(2) line was assigned to ν_1, with $\eta=73.5\pm1.5\%$, and the corresponding ν_2 was observed at 256.79 MHz. On the other hand, the I′(1) pattern was assigned to ν_2, with $\eta=94.0\pm2.0\%$. The corresponding ν_1 was observed at 198.27 MHz, although this line was broad and weak compared with the others. The quadrupole coupling constants for these lines were calculated by the use of the tabulated eigenvalues of spin 5/2.

The I(3)~I(8) lines have approximately the same intensity for the powder sample, and from the zero-splitting patterns for the single crystal it becomes apparent that all these lines are ν_1 with small η values. For example, the zero-splitting patterns of the I(6) and I(7) lines are shown in Fig. 3. Therefore, η and e^2Qq/h can be calculated by means of the following equations:[7,9]

$$\eta = 17(\sin^2\theta_{max}-\sin^2\theta_{min})/24(\sin^2\theta_{max}+\sin^2\theta_{min}) \quad (2)$$

$$e^2Qq/h = 20\nu_1/3(1+1.0926\eta^2-0.6430\eta^4) \quad (3)$$

where θ_{max} and θ_{min} are the maximum and minimum zero-splitting angles. Table 1 shows the NQR parameters thus obtained. From these results it may be concluded that this crystal contains two nonequivalent TeI_4 molecules and that each tellurium atom is bonded to three terminal and two bridging iodine atoms. This configuration around the tellurium atom has a stronger resemblance to that of TeF_4 than to those of $TeCl_4$ and $TeBr_4$.

I(3) and I(6) yield two patterns of zero-splitting loci. On the other hand, for the I′(1), I(2), I(4), I(5), I(7), and I(8) lines only three patterns out of four were observed because one of the z-axis in each line was nearly parallel to the rf coil. From the symmetry of the observed patterns, three mutually perpendicular twofold axes were found within the limits

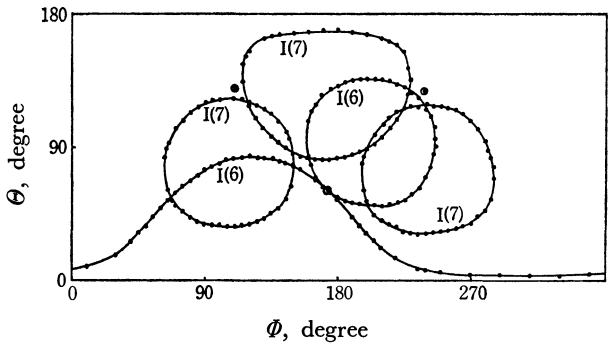

Fig. 3. Zero-splitting patterns of I(6) and I(7) lines in the coordinates fixed to the sample. Crystal axes of orthorhombic system are indicated by ⊙.

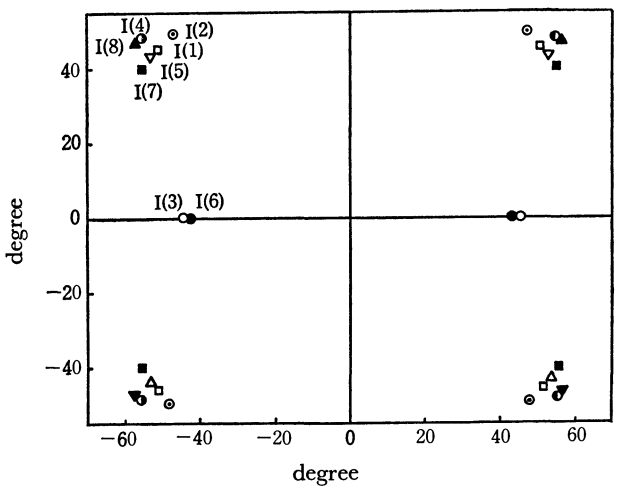

Fig. 4. Orientation of z-axes with respect to the crystal axes which are located at (0°, 0°), (90°, 0°), and (0°, 90°). In the case of I(2), y-axes are shown.

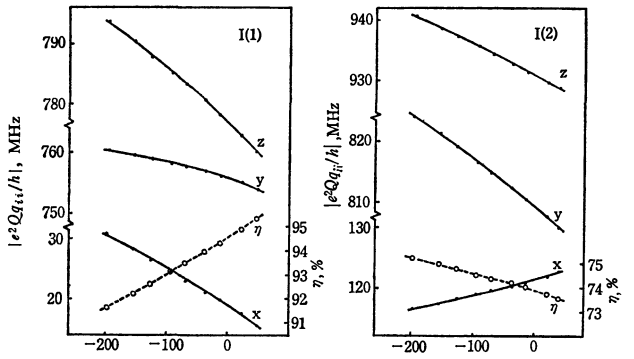

Fig. 5. Temperature dependence of quadrupole coupling constants for I(1) and I(2).

of experimental error. This finding suggests that the crystal is orthorhombic and that these three twofold axes correspond to the crystal axes.[10] Figure 4 shows the orientations of all the z-axes with respect to the crystal axes. In this figure, the three crystal axes are located at (0°, 0°), (90°, 0°), and (0°, 90°).

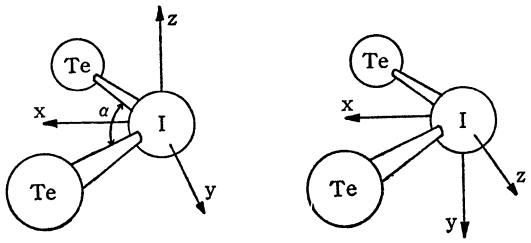
Temperature Dependences of the Quadrupole Coupling Constant for Bridging Iodines. Figure 5 shows the temperature dependences of $|e^2Qq_{zz}/h|$, $|e^2Qq_{yy}/h|$, and $|e^2Qq_{xx}/h|$ for I(1) and I(2). The principal values of the efg tensor can be expressed by:

$$\left.\begin{aligned} V_{zz} &= eq \\ V_{yy} &= -(1+\eta)eq/2 \\ V_{xx} &= -(1-\eta)eq/2 \end{aligned}\right\} \quad (4)$$

If the amplitudes of torsional oscillation about the x, y, and z axes are denoted by θ_x, θ_y, and θ_z respectively, the averaged principal values of the efg tensor can be expressed by the following equations:[11]

$$\left.\begin{aligned} V_{zz} &= eq_0\{1-\langle\theta_y^2\rangle(3-\eta_0)/2-\langle\theta_x^2\rangle(3+\eta_0)/2\} \\ V_{yy} &= eq_0\{-(1+\eta_0)/2+\langle\theta_z^2\rangle\eta_0+\langle\theta_x^2\rangle(3+\eta_0)/2\} \\ V_{xx} &= eq_0\{-(1-\eta_0)/2-\langle\theta_z^2\rangle\eta_0+\langle\theta_y^2\rangle(3-\eta_0)/2\} \end{aligned}\right\} \quad (5)$$

where q_0 and η_0 are the values in the static lattice and where $\langle\theta_i^2\rangle$ (i=x, y, and z) indicates the mean square amplitude of the oscillation about the i-axis. In the symmetrical bridging iodine, the principal axes of the efg tensor depend upon the bridging angle, as is shown in Fig. 6. It may be considered that the bridging iodine is more mobile in the direction perpendicular to the bridging plane than in that parallel to it. Therefore, we may assume that, in Model (a), the torsional oscillation about the y-axis contributes predominantly to the temperature dependence of the quadrupole coupling constant and the asymmetry parameter, whereas, in Model (b), the torsional oscillation about the z-axis contributes predominantly to the parameters. The temperature dependence of the I(1) atom can be interpreted satisfactorily by assuming $\langle\theta_x^2\rangle\approx\langle\theta_z^2\rangle<\langle\theta_y^2\rangle$ in Eq (5): this situation corresponds to Model (a). The positive temperature coefficient of η was also found



(a) $90°<\alpha<109.5°$ (b) $109.5°<\alpha<180°$

Fig. 6. Orientation of efg principal axis at a bridging iodine atom.

for the bridging iodine in Al_2I_6 and Ga_2I_6.[12] These bridging iodine atoms have been supposed to have the principal axes of Model (a) by analogy with Al_2Br_6.[13] Therefore, the temperature dependence of the I(1) atom is mainly due to the characteristic torsional oscillation of the bridging iodine atom, as in those of Al_2I_6 and Ga_2I_6. Furthermore, the I(1) atom is supposed to have bonds such as those in Model (a).

On the other hand, the tendency of the I(2) atom can be roughly interpreted on the basis of Model (b) by assuming $\langle\theta_x^2\rangle\approx\langle\theta_y^2\rangle<\langle\theta_z^2\rangle$. However, as the quadrupole coupling constant of I(2) is fairly larger than that of I(1), it may be considered that I(2) is not so symmetrical in its bridging as I(1). Therefore, the variation in the electronic structure of the bridging iodine atom may also contribute to the temperature dependence of the quadrupole coupling constant.

Proton Hyperfine Splittings in the ESR of Some Alkylphosphine Dimeric Radicals

Masamoto IWAIZUMI, Takashi KISHI, Fumio WATARI,* and Taro ISOBE

The Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Sendai 980

**Department of Applied Science, Faculty of Engineering, Tohoku University, Sendai 980*

(Received May 29, 1975)

The triplet splittings due to protons were observed for the ESR of the dimeric cation radicals of $P(CH_3)_3$, $P(CH_2CH_3)_3$, and $PH(CH_3)_2$; they were formed by the γ irradiation of the rigid CH_2Cl_2 solutions of these alkylphosphines at 77 K. The observed proton hyperfine splittings for the dimer-cation radicals, $[(CH_3)_3P\text{-}P(CH_3)_3]^+$ and $[(CH_3CH_2)_3P\text{-}P(CH_2CH_3)_3]^+$, were assigned to the hyperfine interaction with two of the methyl and with two of the methylene protons respectively, while those for the $[(CH_3)_2HP\text{-}PH(CH_3)_2]^+$ radical were assigned to the hyperfine interaction with the two P–H protons. In the former two radicals, the rotations of the methyl and the ethyl groups are restricted. The conformations of the methyl and the ethyl groups have been estimated on the basis of the observed proton hyperfine splittings. The P–H protons of the $[(CH_3)_2HP\text{-}PH(CH_3)_2]^+$ radical have an extremely large isotropic coupling constant of 58 G; it may be attributed to the direct interaction with the unpaired electron in the anti-bonding σ^* orbital of the P–P bond.

When γ-irradiated trialkylphosphines are examined by ESR at 77K, clear parallel and perpendicular features, separated by over 1000 G, are often observed. These hyperfine patterns have been assigned by Lyons *et al.*[1] to alkylphosphine dimer-cation radicals of the $(R_3P\text{-}PR_3)^+$ type. From the observed phosphorus hyperfine interaction, they concluded that these radicals are σ^* radicals which have their unpaired electrons in anti-bonding σ^* orbitals. In these investigations, the ESR of the dimer cation radicals showed only phosphorus splittings; no proton hyperfine splittings have not been resolved. During the course of our investigations of γ-irradiated phosphorus compounds, we found the ESR of dimer-cation radicals to show further splittings due to protons for the dichloromethane solutions of trimethylphosphine, triethylphosphine, and dimethylphosphine. In this paper we will report some information of the radical structure mainly obtained through these proton hyperfine splittings.

Experimental

The dimethylphosphine $[PH(CH_3)_2]$, trimethylphosphine $[P(CH_3)_3]$, and triethylphosphine$[P(CH_2CH_3)_3]$ were obtained as has been described elsewhere.[2] The deuterated compound of dimethylphosphine $[PD(CH_3)_2]$ was prepared by the reaction of $PH(CH_3)_2$ with D_2O in the presence of DBr, while $PH(CD_3)_2$ was prepared by using CD_3I instead of CH_3I in the course of the preparation of $PH(CH_3)_2$. $P(CD_3)_3$ was prepared by dissolving $(CD_3)_3PH^+I^-$, formed from $PH(CD_3)_2$ and CD_3I, into a KOH–dimethyl sulfoxide suspension; thereafter the product was separated from the solution by vacuum distillation. The CH_2Cl_2 solutions of these compounds were irradiated by ^{60}Co γ-rays in ESR sample tubes at 77 K after they has been degassed. The ESR spectra were measured with a Hitachi 771 ESR spectrometer with 100 kHz field modulation.

Results and Discussion

Figure 1 shows the ESR spectrum obtained from the γ-irradiated CH_2Cl_2 solution of $P(CH_3)_3$ at 77K. An ESR absorption similar to the outermost features in the figure (labelled I) is observed for all the compounds treated here; it is assigned to the dimer-cation radicals of the alkylphosphines by reference to Lyons and Symons' assignment for the triethyl- and tributylphosphine dimer-cation radicals.[1] The expected central component ($M_I^{31P}=0$) is considered to be hidden under the intense absorptions due to other radical species. Though Lyons *et al.*'s assignments of the dimer-cation radicals were made by the analogy between the reaction and that of trialkylarsines to form their dimer cations, conclusive evidence for the assignment of the spectra is given by the observation of the triplet splittings due to the two P–H protons in the radical $[(CH_3)_2HP\text{-}PH(CH_3)_2]^+$ (*vide infra*). It was also observed that the relative intensity of the dimer cation to the monomer-cation radical clearly changes in proportion to the concentration of the parent phosphine in the case of the $P(CH_2CH_3)_3$ solution.

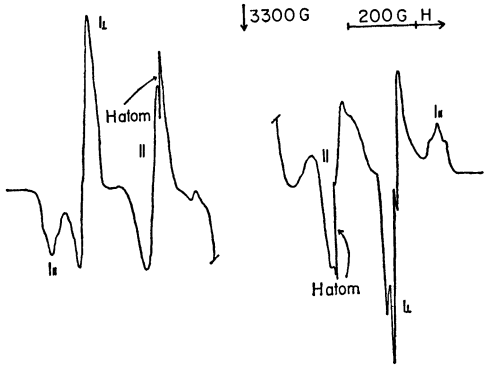

Fig. 1. ESR Spectrum of γ-irradiated $P(CH_3)_3$ at 77 K in CH_2Cl_2. ESR absorption I is assigned to $[(CH_3)_3P\text{-}P(CH_3)_3]^+$ and II to $P(CH_3)_3CH_2Cl$.[2]

The high-field-side signals for the dimer-cation radicals are shown in Figs. 2—4. The parallel and perpendicular features for the undeuterated compounds show triplet splittings. It is apparent that the triplet splittings for the $[(CH_3)_3P\text{-}P(CH_3)_3]^+$ radical arise from the hyperfine interaction with the methyl protons, since the dimer-cation radical of $P(CD_3)_3$ does not show such triplet splittings (Fig. 2). For the case

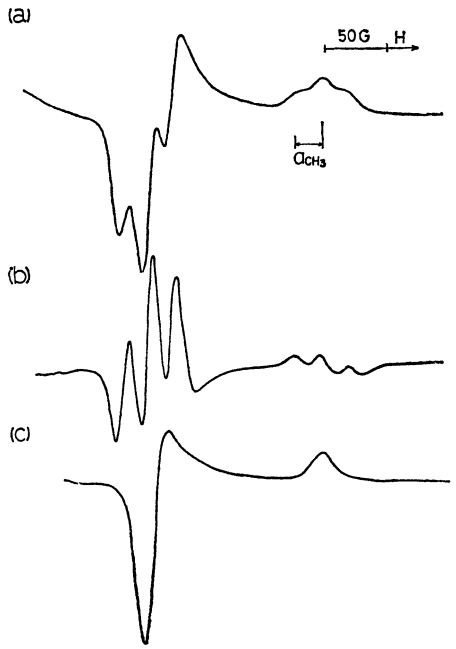

Fig. 2. High field components of ESR spectra for the radicals a) $[(CH_3)_3P\text{-}P(CH_3)_3]^+$ and c) $[(CD_3)_3P\text{-}P(CD_3)_3]^+$ at 77 K, and b) the derivative curve of (a) (2nd derivative ESR spectrum).

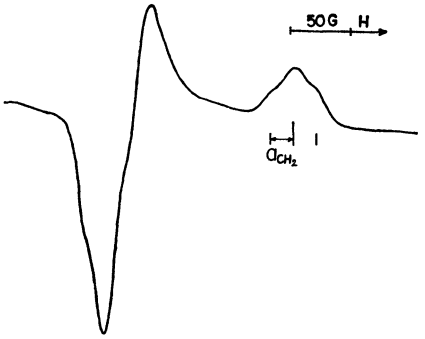

Fig. 4. High field component of the ESR spectrum for the $[(CH_3CH_2)_3P\text{-}P(CH_2CH_3)_3]^+$ radical.

of the $[(CH_3)_2HP\text{-}PH(CH_3)_2]^+$ radical, the triplet splittings were not observed when the P–H protons were deuterated, though the $[(CD_3)_2HP\text{-}PH(CD_3)_2]^+$ radical shows the same triplet splittings as the undeuterated dimer-cation radical. This apparently indicates that the triplet splittings in the $[(CH_3)_2HP\text{-}PH(CH_3)_2]^+$ radical arise from the hyperfine interaction with the P–H protons. The signals labelled "X" in Fig. 3 are probably due to the dimer-cation radical in which one of the P–H protons is replaced with the chlorine of the solvent. When diethylether was used as the solvent, the X signals were not observed. The ESR parameters obtained are summarized in Table 1, together with the orbital populations of the unpaired electron, which were determined by the use of the atomic parameters in the literature.[4]

As may be seen from the p/s ratios in Table 1, the phosphorus orbitals occupied by the unpaired electrons take the sp^3 hybridization. This indicates that Lyons *et al.*'s model[1] is reasonable for the present system also. An interesting result in the present system is the appearance of the proton hyperfine splittings. The triplet splittings due to the methyl protons in the $[(CH_3)_3P\text{-}P(CH_3)_3]^+$ radical indicate that only two among 18 methyl protons have an observable hyperfine interaction. This suggests that the rotation of the methyl groups is strongly restricted and that the radical takes a conformation where only two protons are at the positions of the maximum overlap with the anti-bonding σ^* orbital of the P–P bond containing the unpaired electron. That is, one of the three methyl groups on each phosphorus takes the Ia conformation, where one of the C–H bonds eclipses the lobe of the anti-bonding σ^* orbital, while the other two methyl groups take the Ib conformation, where the methyl group rotates about 60° from the conformation of Ia. In the latter conformation, though one of the C–H bonds is located at a position

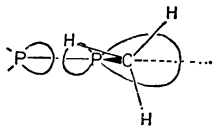
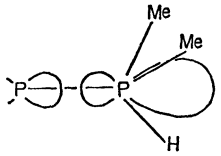
Ia



Ib

parallel to the σ^* orbital, it has no significant hyperfine interaction. It was observed that the triplet splittings smear as the temperature increases from 77 K, though the radical promptly decays above 150 K. The smearing of the proton hyperfine splittings may indicate the onset of the rotation of the methyl groups.

It may be noteworthy that the hyperfine interaction of the P–H protons in the $[(CH_3)_2HP–PH(CH_3)_2]^+$ radical has the large isotropic coupling constant of 58 G. In the case of the methyl radical, it has been shown by theoretical calculations[5] that the contribution of the direct interaction with the unpaired electron does not exceed the spin polarization effect on the isotropic hyperfine interaction, even when the radical deforms to a pyramidal structure, and that the hyperfine coupling constant of 23.04 G for the planar structure is the largest value which can be expected for the radical. In view of this fact, the hyperfine coupling constant observed in the present system is surprisingly large; it is probably due to the direct overlap of the unpaired electron orbital with the P–H protons, which are located on the same side as the big lobe of the unpaired electron orbital in the tetrahedral conformation of phosphorus (II).



II

The triplet splittings observed for the $[(CH_3CH_2)_3P–P(CH_2CH_3)_3]^+$ radical may be attributed to the two methylene protons of the radical by analogy with the case of the $[(CH_3)_3P–P(CH_3)_3]^+$ radical. The observation of the splittings also suggests that the rotation of the ethyl groups about the P–Et bond is restricted and that the ethyl groups take a conformation where two of the methylene protons are placed near the positions of the maximum overlap with the unpaired electron orbital, as in the case of the $[(CH_3)_3P–P(CH_3)_3]^+$ radical.

Photosolvation Reactions and Their Quantum Yields of Hexacyanocobaltate(III) in Non-aqueous Solvents

Katsumi NAKAMARU, Kazuo JIN, Atsuko TAZAWA, and Masaru KANNO

Department of Chemistry, Faculty of Science, Hirosaki University, Bunkyo, Hirosaki, Aomori 036

(Received May 31, 1975)

The photoreactions of hexacyanocobaltate(III) in non-aqueous solvents (methanol, ethanol, acetonitrile, DMF, pyridine) caused by irradiation at 365 nm or 313 nm are found to be the photosolvation

$$[Co(CN)_6]^{3-} + Solv. \xrightarrow{h\nu} [Co(CN)_5(Solv.)]^{2-} + CN^-$$

In pyridine, in addition to the photosolvation product, a fluorescent substance which is perhaps an aromatic compound is also formed by the irradiation at 365 nm. The quantum yields are almost the same as that in aqueous solution. In ethanol, the quantum yields irradiated at both 313 nm and 365 nm are the same, indicating that the quantum yield is independent of the exciting wavelength. The sensitized photosolvation using several donors failed to occur because of the solubility limitation. Interesting spectral results are also reported.

A large number of investigations have been performed on the photochemical[1,2] and photophysical[2,3] behaviors of transition metal complexes in the last decade. Most of these studies, however, have been done in aqueous solutions, except for the carbonyl complexes, and this seems to be due to the fact that most transition metal complexes have very low solubilities in non-aqueous organic solvents. It is mainly in aqueous solutions that many investigators have studied the photochemistry of transition metal complexes with great interest.

Recently several papers on the photochemistry and photophysics of transition metal complexes in non-aqueous solvents were reported. The photosolvation of tetrabutylammonium hexacyanochromate(III) in *N,N*-dimethylformamide (DMF) was studied and some evidence against the doublet hypothesis for the photoreactive state of the Cr(III) complex was obtained.[4] The same system was investigated from the standpoint of the sensitized photoaquation and photosolvation reaction and the photoreactive state was also identified as the lowest quartet excited state.[5] On the other hand, the intersystem crossing efficiency of hexacyanochromate(III) was reported from the results of the direct and $[Ru(bipy)_3]^{2+}$-sensitized phosphorescence intensities in DMF solutions.[6] Other papers dealt with the phosphorescence quenching of $[Ru(bipy)_3]^{2+}$ in ethanol–benzene,[7] and in DMF or methylformamide.[8] As for Co(III) complexes, however, neither photochemical nor photophysical studies have been made in non-aqueous solvents.

In the field of the photochemistry of transition metal complexes in aqueous solutions, it is well known that the Co(III) complexes show the photoredox reaction and/or the photoaquation and that the photoredox reaction is more likely to occur when irradiated at the shorter charge transfer band than at the longer ligand field band and that the phosphorescence cannot be seen except in a few cases even with the crystal at low temperature.[1] It is particular in the Co(III) complexes, however, that hexacyanocobaltate(III) shows only the photoaquation and does not exhibit any photoredox reaction even when the complex is irradiated at the charge transfer absorption band, 254 nm,[9] and that, moreover, it shows the phosphorescence with the crystal at low temperature (4.2 K or 77 K).[10] The reason for this unusual behavior of hexacyanocobaltate(III) has not been clarified yet. Therefore, taking account of the fact that the phosphorescence of hexacyanochromate(III) is observed in DMF but not in water,[4] photochemical and photophysical studies seem to be necessary for Co(III) complexes in non-aqueous solvents. First of all, hexacyanocobaltate(III), which shows the unusual behavior mentioned above, attracted our attention and we report in this paper the preliminary results obtained from the photochemical experiments of tetrabutylammonium hexacyanocobaltate(III) ($[Bu_4N]_3[Co(CN)_6]$) in several organic solvents.

Experimental

Materials. Tetrabutylammonium hexacyanocobaltate(III) ($[Bu_4N]_3[Co(CN)_6]$) was prepared from $K_3[Co(CN)_6]$ and tetrabutylammonium bromide.[11] The spectrum of $[Bu_4N]_3[Co(CN)_6]$ in water agreed with that of $K_3[Co(CN)_6]$.[9] Potassium pentacyanopyridinecobaltate(III) ($K_2[Co(CN)_5py]$) was prepared according to the literature.[12] Fluoranthene was purified by passing it through a column of silica gel. Michler's ketone was recrystallized twice from ethanol. Triacetylacetonatorhodium(III) ($Rh(acac)_3$) was recrystallized from chloroform. Reagent grade pyrazine and triphenylamine were used without further purification. Reagent grade methanol and ethanol were dried by the literature method.[13] Acetone, acetonitrile, and DMF were dried by the method reported.[14] Reagent grade pyridine was purified by distillation. Chloroform was of spectrograde and used without further purification. All these solvents were stocked in a desiccator in the dark.

Apparatus. The irradiation equipment was used in the usual way. The excitation wavelength 313 nm was isolated from a Toshiba SHL-100UV-2 mercury lamp by means of a combination of the chemical filter described by Murov[15] and the Toshiba UV-D25 glass filter. Light of 365 nm was isolated by using a Toshiba UV-D1C glass filter and a glass plate. Light of 436 nm was isolated by the method described.[16] The light intensity was measured by a ferrioxalate actinometer.[17] The absorption spectrum was measured with a Hitachi 124 double beam spectrophotometer and the emission spectrum was measured with a Aminco-Bowman spectrophotofluorometer.

Procedures. Although $[Co(CN)_6]^{3-}$ in organic solvents did not cause any thermal reactions, the sample solutions used for the irradiation were always prepared just before the measurements. When the organic sensitizers were added

to the solution of $[Co(CN)_6]^{3-}$, no change of the absorption of the complex was observed. The sensitization experiments were carried out under the condition that the donors absorbed most of the incident light. Degassed solutions were obtained by successive freeze-pump-thaw cycles. The quantum yields were determined spectrophotometrically using the molar extinction coefficients(ε) of the photoproducts, which were obtained by the complete photolysis of $[Co(CN)_6]^{3-}$. In the case of $[Co(CN)_5py]^{2-}$, the ε of the synthesized sample was used because the isosbestic points in the photolysis of $[Co(CN)_6]^{3-}$ in pyridine were not seen at later stages. In benzonitrile, the quantum yield could not be obtained because the reaction did not proceed with clean isosbestic points.

Results and Discussion

Absorption Spectra. $[Co(CN)_6]^{3-}$ shows three characteristic bands in the ultraviolet region which are assigned as follows, in the order of decreasing wavelength: $^1A_{1g}\rightarrow{}^1T_{1g}$ (the first absorption band), $^1A_{1g}\rightarrow{}^1T_{2g}$ (the second absorption band), and metal to ligand charge transfer(MLCT) band, respectively.[1,18,19] The first two bands are spin-allowed ligand field transitions and have rather low molar extinction coefficients (ε). The last one is an allowed $t_{2g}\rightarrow\pi^*$ transition and hence is a very intense band. The spin-forbidden, lowest energy ligand field transition, $^1A_{1g}\rightarrow{}^3T_{1g}$, is observed in the crystalline spectrum, but not in solution.[10]

The absorption data obtained in several organic solvents are summarized in Table 1, together with the values of the dielectric constants in the second column. At first sight, there seems to be no regularity in the position of the absorption maximum of $[Co(CN)_6]^{3-}$ in these solvents, but it may be seen that there are two groups of solvents: (a) one is water, methanol, ethanol, ethylenediamine, and chloroform; (b) the other is acetonitrile, benzonitrile, pyridine, and DMF. In the former group, as the values of dielectric constants decrease, the absorption maximum shifts to longer wavelengths (red shift). On the other hand, the behavior of the latter group is unusual: despite the values of the dielectric constants, they all show greater red shifts than the (a) group. For example, acetonitrile, which is next to water in the order of the dielectric constants of the solvents used, shows a longer maximum wavelength, 320 nm, than does chloroform, 318 nm, which has the smallest dielectric constant. The second absorption bands show a similar tendency to the first absorption bands. This phenomena cannot be explained only from the difference in the polarity of solvents. When we note that all the solvents in the (b) group have double or triple bonds, it can be said that the π-electrons of the solvents in the (b) group are responsible for the greater red shift in the spectra of $[Co(CN)_6]^{3-}$ in these solvents. It is known that the spectrochemical series should reflect the π-bonding properties of the various ligands and, in fact, strong π-acceptor ligands such as CN^- and NO_2^- cause larger Δ(the energy separation of the t_{2g} and e_g metal d orbitals in an octahedral complex) values. Hence, the π-electron interactions between the ligand CN^- of $[Co(CN)_6]^{3-}$ and the organic solvents in the (b) group may play an important role.

The various maximum wavelengths of the photoproducts can be reasonably explained from the standpoint of spectrochemical series. It may be noted that acetonitrile cannot coordinate at a position other than an N atom and that $[Co(CN)_5(CH_3CN)]^{2-}$ shows a peak at longer wavelengths than that of $[Co(CN)_6]^{3-}$. Thus a CN^- which coordinates at a C atom is at a higher position than CH_3CN in the spectrochemical series.

Photosolvation Reactions. The solutions of $[Co(CN)_6]^{3-}$ in ethanol, methanol, acetonitrile, DMF, pyridine, benzonitrile, acetone, chloroform, and ethylenediamine were irradiated at 365 nm (in ethanol, also at 313 nm) and the spectral changes are shown in Fig. 1 to Fig. 5.

In ethanol, upon irradiation at 365 nm, $[Co(CN)_6]^{3-}$

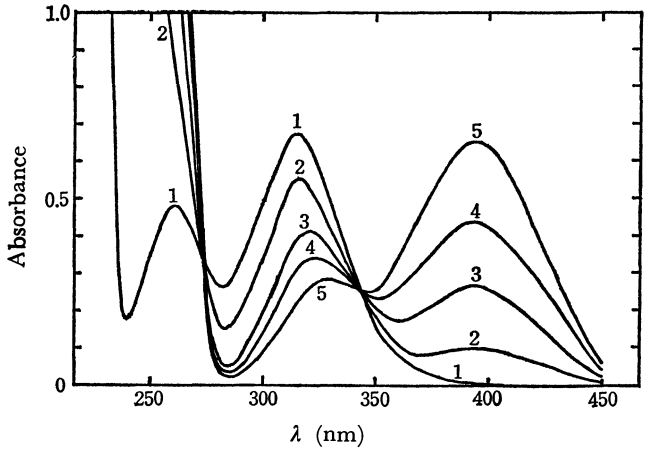

Fig. 1. Spectral change of $[Co(CN)_6]^{3-}$ in the aerated ethanol solution upon irradiation at 365 nm ([complex] 3.532×10^{-3} M, 25 °C). Time of irradiation, 1) 0, 2) 18 min, 3) 55 min, 4) 1 hr and 50 min, 5) 5 hr and 5 min.

undergoes a reaction and shows the spectral changes in Fig. 1, which are different from that in aqueous solution.[9] The peak at 314 nm decreases gradually and instead the peak at 392 nm increases. After sufficient irradiation time, this peak does not show any substantial increase. Two isosbestic points are seen at 280 nm and 342 nm, indicating that the primary photoproduct is photochemically stable. When the irradiated solution is left alone in the dark, the peak at 392 nm decreases and the peak at 314 nm recovers, but this back reaction is very slow and the recovery is not complete. Thus this thermal reaction is negligible during the irradiation. As for the photoproduct, it may be considered that ethanol has the ability to coordinate with the excited state transition metal complexes and, in fact, in the ethanol solution of $W(CO)_6$ which is studied in many coordinative organic solvents,[1] it is known that a solvent ethanol coordinates as a ligand by the irradiation.[20] Besides, we examined the effect of the addition of water to the ethanol solution. In this mixed solvent, $[Co(CN)_6]^{3-}$ undergoes a reaction also, but the isosbestic points cannot be seen cleanly. Moreover, the features of the spectral change upon irradiation become the same as that in aqueous solution[9] as the content of water increases, on the one hand, and it becomes the same as that in ethanol solution when the content of ethanol increases, on the other hand. Thus, we may consider from this preliminary result that in the dried ethanol solution, the following photosolvation reaction occurs:

$$[Co(CN)_6]^{3-} + EtOH \xrightarrow{h\nu} [Co(CN)_5(EtOH)]^{2-} + CN^- \quad (1)$$

The quantum yield of reaction (1) is 0.28 and almost the same as that in aqueous solution, 0.32 in our experimental conditions. When light of 313 nm is used for the excitation wavelength, the same reactions as described above occur and the quantum yield is also 0.28. Although, because of the solubility limitation, the photosolvation reaction irradiated at 436 nm could not be studied in ethanol as well as in other solvents, it seems that the same results obtained by the irradiation at both 313 nm and 365 nm show that the quantum yields are independent of the wavelengths and this agrees with the results in aqueous solution (we found that the quantum yield at the excitation wavelength of 436 nm was also 0.31 in aqueous solution). O_2 had no effect on the photosolvation quantum yield.

In methanol, as shown in Fig. 2, the reaction which occurs upon the irradiation at 365 nm can be regarded as a photosolvation similar to Eq. (1), for we found that when the photoproduct in methanol was redissolved in water, its spectrum had a peak at 388 nm which did not coincide with that of $[Co(CN)_5H_2O]^{2-}$ in aqueous solution, 382 nm. The quantum yield 0.32 is the same in aqueous and in ethanol solution. The back reaction is also slow and the degree of recovery is smaller than that in ethanol.

In acetonitrile and DMF, as shown in Fig. 3 and Fig. 4, respectively, the change of the spectra caused

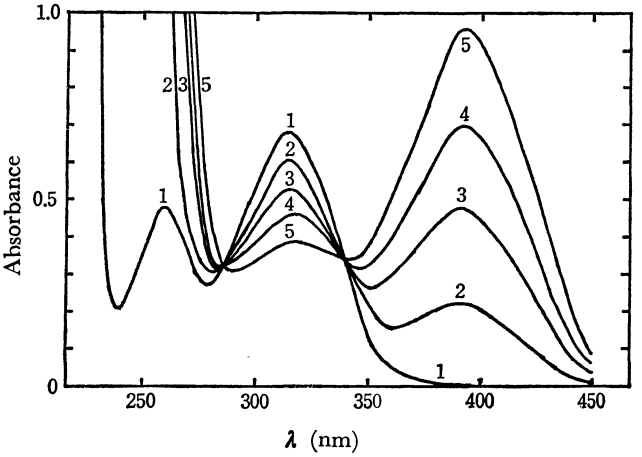

Fig. 2. Spectral change of $[Co(CN)_6]^{3-}$ in the aerated methanol solution upon irradiation at 365 nm ([complex] 3.524×10^{-3} M, 25 °C). Time of irradiation, 1) 0, 2) 35 min, 3) 1 hr and 35 min, 4) 3 hr, 5) 8 hr.

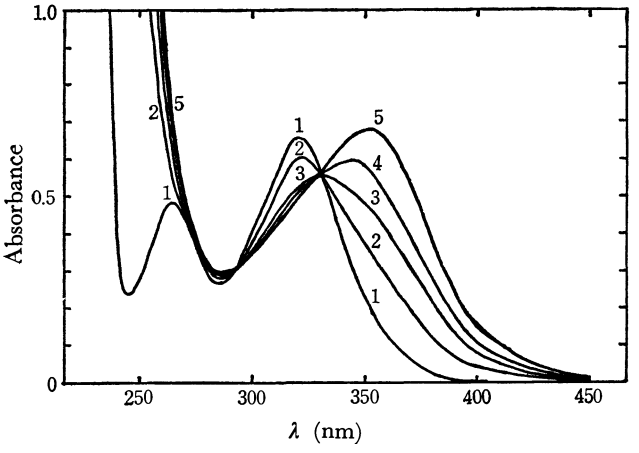

Fig. 3. Spectral change of $[Co(CN)_6]^{3-}$ in the aerated acetonitrile solution upon irradiation at 365 nm ([complex] 3.538×10^{-3} M, 25 °C). Time of irradiation, 1) 0, 2) 40 min, 3) 1 hr and 40 min, 4) 3 hr and 30 min, 5) 14 hr.

by the irradiation at 365 nm is also explained by the photosolvation

$$[Co(CN)_6]^{3-} + CH_3CN \text{ (or DMF)} \xrightarrow{h\nu} [Co(CN)_5(CH_3CN)(\text{or DMF})]^{2-} + CN^- \quad (2)$$

The quantum yield of the reaction in both solvents is 0.28. In DMF, O_2 had no effect on the quantum yield.

In pyridine solution (Fig. 5), the situation is greatly different from that in the above solvents; a fluorescent compound is formed by the irradiation at 365 nm. At the beginning, the fluorescence cannot be seen, but after about 30 minutes from the beginning of irradiation, the blue fluorescence becomes visible and the intensity increases with time. After about two hours, the intensity reaches a maximum. From this stage, however, the isosbestic points gradually disappear. The fluorescence and its excitation spectrum are given in Fig. 6. The absorption spectrum of the photoproduct shows a peak at 352 nm when

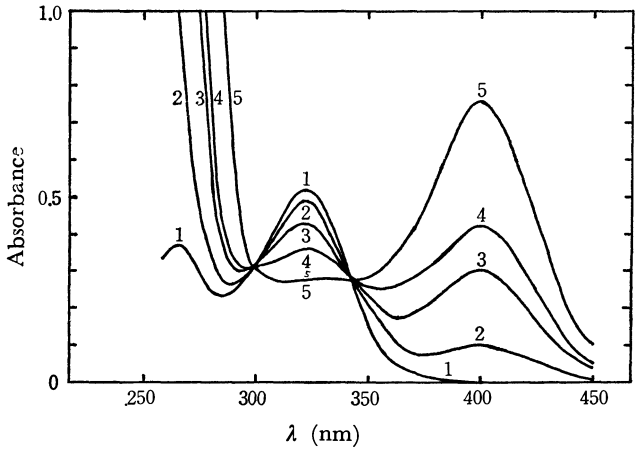

Fig. 4. Spectral change of $[Co(CN)_6]^{3-}$ in the aerated DMF solution upon irradiation at 365 nm ([complex] 2.746×10^{-3} M, 25 °C). Time of irradiation, 1) 0, 2) 10 min, 3) 40 min, 4) 1 hr, 5) 6 hr and 20 min.

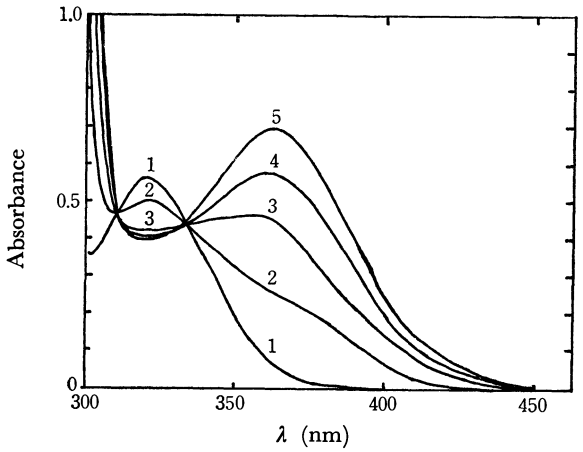

Fig. 5. Spectral change of $[Co(CN)_6]^{3-}$ in the aerated pyridine solution upon irradiation at 365 nm [(complex] 2.828×10^{-3} M, 25 °C). Time of irradiation, 1) 0, 2) 30 min, 3) 1 hr and 30 min, 4) 3 hr, 5) 6 hr.
